Sulfonation and Isomerization of some Halogenobenzenesulfonic Acids[1]

H. CERFONTAIN, MRS. A. KOEBERG-TELDER, AND W. A. ZWART VOORSPUY

Laboratory for Organic Chemistry, Nwe Achtergracht 129, University of Amsterdam, Amsterdam, The Netherlands

Received January 10, 1972

The behavior of the isomeric halogenobenzenesulfonic acids (halogen = F, Cl, and Br) in sulfuric acid was studied. In 115% H_2SO_4 at 25° only sulfonation takes place. Both the ortho- and para-isomers yield the 1-halogenobenzene-2,4-disulfonic acid, whereas the meta-isomers yield a mixture of mainly 3,4- and 3,5- with some 2,5-disulfonic acid.

In 98.1% H_2SO_4 at 150–170°, both sulfonation and isomerization occur. The ortho-isomers are sulfonated to the 2,4-disulfonic acid and isomerized to the para-isomer in competing reactions. The para-isomers are sulfonated to the 2,4-disulfonic acids much more slowly than the ortho-isomers. The least reactive are the meta-isomers which in competing reactions are sulfonated to a mixture of mainly 2,5- and 3,5- disulfonic acids, and isomerized to the para-isomers which eventually yield the 2,4-disulfonic acids.

It is suggested that the formation of the 3,4-disulfonic acids from the meta-isomers in 115% H_2SO_4 proceeds by an intramolecular rearrangement of the initially formed arenepyrosulfonic acids.

Le comportement des acides halogénobenzènesulfoniques isomères (halogène = F, Cl, Br) dans l'acide sulfurique a été étudié. A 25° dans l'acide sulfurique à 115%, seule la sulfonation a lieu. Les isomères ortho et para donnent tous deux l'acide halogéno-1 benzène disulfonique-2,4 tandis que les isomères méta conduisent à un mélange constitué principalement des acides disulfoniques-3,4 et -3,5 et un peu de -2,4.

Dans l'acide sulfurique à 98.1% à 150–170°, la sulfonation et l'isomérisation ont lieu toutes les deux. Les isomères ortho sont sulfonés en acide disulfonique-2,4 et isomérisés en para dans des réactions compétitives. Les isomères para donnent les acides disulfoniques-2,4 beaucoup plus lentement que pour les analogues ortho. Les moins réactifs sont les isomères méta qui, dans des réactions compétitives, sont sulfonés en un mélange d'acides disulfoniques-2,5 et -3,5 surtout et isomérisés en para pour donner éventuellement les acides disulfoniques-2,4.

On pense que la formation des acides disulfoniques-3,4 à partir des isomères méta dans H_2SO_4 115%, se fait selon un réarrangement intramoléculaire des acides arènepyrosulfoniques initialement formés.

Canadian Journal of Chemistry, **50**, 1574 (1972)

In connection with a study on the sulfonation of the halogenobenzenes (1, 2), an investigation was made of the sulfonation and isomerization of the fluoro-, chloro-, and bromobenzenesulfonic acids in sulfuric acid.[2] In 115% H_2SO_4 at 25°, only sulfonation occurs, whereas in 98.1% H_2SO_4 at 150–170° both sulfonation and isomerization occur. In 98.1% H_2SO_4 the halogenobenzenesulfonic acids are present in the un-ionized form ($ArSO_3H$) (4). In 115% H_2SO_4 they will be present mainly in the protonated form ($ArSO_3H_2^+$) and possibly partly in the pyrosulfonic acid form (ArS_2O_7H) (5, 6). The actual species undergoing sulfonation in fuming sulfuric acid is, however, the unionized sulfonic acid (5, 7).

Results and Discussion

Nuclear Magnetic Resonance Spectra

Information concerning the products formed with the halogenobenzenesulfonic acids in 98.1 and 115% H_2SO_4 was obtained from an analysis of the n.m.r. spectra. In order to make a comparison possible, the 115% H_2SO_4 mixtures were diluted to 98% H_2SO_4.

The assignments of the n.m.r. spectra of the three sets of reference compounds, *m*-, *p*-, and 2,4-disulfonic acid in 98.1% H_2SO_4 as solvent, are given in Table 1. The n.m.r. spectra of the sulfonation mixtures of the *m*-halogenobenzenesulfonic acids in 115% H_2SO_4 after dilution are given in Fig. 1. The formation of 2,3-disulfonic acid is considered highly improbable. In assigning the various absorptions we therefore took into account the possible presence of the three other disulfonic acid isomers. The results are listed in Table 1. The agreement between the assigned chemical shifts and those calculated on the basis of the principle of the additivity of substituent shifts is in general satisfactory.

Sulfonation in 115% H_2SO_4 at 25°

The n.m.r. spectra obtained on leaving both the *o*- and the *p*-halogenobenzenesulfonic acids in 115% H_2SO_4 at 25° for 7 days are identical

[1]Aromatic sulfonation, part 35. Preceding paper, ref. 27.

[2]The iodobenzenesulfonic acids behave differently. They suffer from deiodation in the Jacobsen reaction (2, 3).

*The data between brackets were calculated on the basis of the additivity principle of substituent effects, using the shift data for the halogens as given by Hayamizu and Yamamoto for C_6H_5Br and C_6H_5Cl (8) and by Suhr for C_6H_5F (9), and for the sulfonic acid substituent as determined recently by Ris for 85% H_2SO_4 (10) ($\Delta\delta_o = 0.44$, $\Delta\delta_m = 0.17$ and $\Delta\delta_p = 0.29$ p.p.m.).

†Chemical shifts are relative to external TMS in CCl_4 (50 vol. %).

‡The calculated chemical shifts are relative to the chemical shift of *p*-bromobenzenesulfonic acid, which was made the same as the shift of the experimentally observed singlet absorption.

§Assigned spectra.

‖Observed multiplet inbetween $\delta = 7.6$ and 8.1 p.p.m.

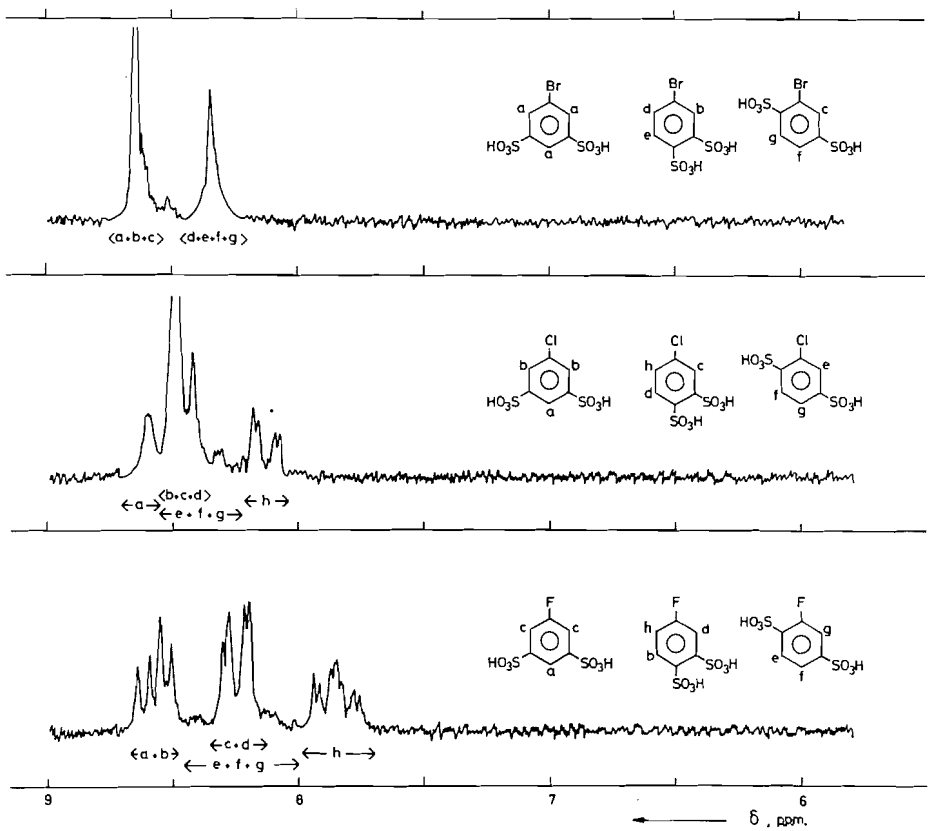

FIG. 1. The n.m.r. spectra with assignments of the sulfonation mixtures of *m*-$XC_6H_4SO_3H$ in 115% H_2SO_4 at 25°, after dilution to 98% H_2SO_4.

with those of the pure 2,4-disulfonic acid, indicating that this compound is the exclusive product.

The disulfonic acid isomer distribution in the sulfonation of the *m*-halogenobenzenesulfonic acids in 115% H_2SO_4 was determined by a three-component analysis of the n.m.r. spectra depicted in Fig. 1, each in terms of the three possible disulfonic acids. The results are given in Table 2 together with those for other meta-substituted benzenesulfonic acids. As is evident from the data for *m*-chlorobenzenesulfonic acid, the isomer distribution is kinetically controlled. Moreover Olivier has shown that the principal product under apparently thermodynamically controlled conditions is the chlorobenzene-3,5-disulfonic acid (13). The data of Table 2 illustrate that sulfonation ortho, meta, and para to the sulfonic acid group can be effected. The ratio of 3,4- to 3,5-disulfonic acid follows the order F > Cl > Me > *t*-Bu > H = 0. This order parallels the ability of the conjugative electron release of these substituents to the para-position. It therefore seems to emphasize the requirement of mesomeric electron release by the substituent at position 1 in order to effect sulfonation at position 4.

The degree of sulfonation at position 4 of the 3-halogenobenzenesulfonic acids is very much greater for the reaction in 115 than for that in 98% H_2SO_4 (*cf.* Tables 2 and 5). This may be explained in terms of a specific additional route for the introduction of a sulfo group ortho to the sulfonic substituent in the case of sulfonation in fuming sulfuric acid. In 115% H_2SO_4 the sulfonic acid substrate will be present mainly as the pyrosulfonic acid (6), and possibly in part as ArS_3O_9H.[3] Intramolecular rearrangement of the

[3]The presence of the entity $H_2S_3O_{10}$ in fuming sulfuric acid > 108% H_2SO_4 seems to be firmly established (14–17).

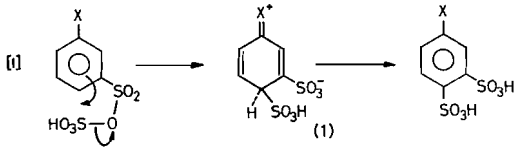
*In 104% H_2SO_4.
†The sulfonation of benzenesulfonic acid in 101–109% H_2SO_4 at 25° yields 2.8% *p*- and 97.2% *m*-disulfonic acid (12).

pyrosulfonic acid can then lead to the formation of the σ-complex **1** with eventual formation of the 3,4-disulfonic acid (reaction 1).[4] The assigned sulfonating entity in the normal sulfonation of arenesulfonic acids in highly concentrated fuming sulfuric acid is $H_2S_4O_{13}$ (7). Sulfonation of the *m*-halogenobenzene-



(pyro)sulfonic acids at position 4 by this bulky reagent seems on the other hand less probable for steric reasons.

Reaction in 98.1% H_2SO_4 at High Temperatures

The reactions of the halogenobenzenesulfonic acids occurring in 98.1% H_2SO_4 at 150° at low substrate concentration (0.7 mmol/l) were followed by means of u.v. absorption measurements. All reactions were found to be of the first order in the substrate.

With the *o*- and *p*-isomers as substrate, the composition of the reaction mixtures was analyzed by a three-component u.v. analysis using the *o*-, *p*-, and 2,4-disulfonic acid as reference compounds (19, 20). With the *o*-halogenobenzenesulfonic acids as substrate, the para-isomer and the 2,4-disulfonic acid are formed in a constant ratio. Apparently the two products are formed in competing reactions. On starting with the para-halogenobenzenesulfonic acids a very much slower reaction with formation of 2,4-disulfonic acid is observed. Typical experiments are given in Table 3. The kinetic results can be described in terms of reactions 2–4. The rate

[4]It may well be that the oxygen atom inbetween the two sulfur atoms of the pyrosulfonic acid has to be protonated first, or complexed by sulfur trioxide first, in order to allow the intramolecular ring sulfonation. In this connection the observation of the necessity of an additional molecule of sulfur trioxide in the aromatic sulfonylation by an arene-pyrosulfonic acid (18) seems of related interest.

*Data calculated on the assumption of the absence of the 2,5- and 3,4-disulfonic acid. This assumption does not affect the content of the 2,4-isomer, but only that of the 3,5-isomer. The assumption seems fair, as the total yield of the 2,5- + 3,4-isomers for the 546 h experiment amounts to only 10%.

†Data calculated on the assumption of the absence of the 3,4- and 3,5-disulfonic acid.

[2] $\text{ortho} \xrightarrow{{}_ik_{o,p}} \text{para}$

[3] $\text{ortho} \xrightarrow{{}_sk_o} \text{2,4-di}$

[4] $\text{para} \xrightarrow{{}_sk_p} \text{2,4-di}$

constants are listed in Table 4. The small variations in the isomerization rate constant ${}_ik_{o,p}$ and the sulfonation rate constant ${}_sk_p$ indicate the close balance between the mesomeric, inductive, and steric effects of the halogens. The constancy of ${}_sk_o$ indicates the balance between the mesomeric and the inductive effect (2).

The isomerization of arenesulfonic acids can be described as an intermolecular process, *i.e.* it proceeds via protiodesulfonation and subsequent sulfonation (21, 22). The amount of ortho- and meta-substitution in the sulfonation of the halogenobenzenes is only very small (1, 2). Therefore, in first approximation, the reported isomerization rate constants ${}_ik_{o,p}$ are equal to the desulfonation rate constants.

The reaction of a given *m*-halogenobenzenesulfonic acid (5 wt. %) in 98.1% H_2SO_4 at 170° was followed in time by recording the n.m.r. spectra of the withdrawn samples after cooling to ~32°. The compositions of the reaction mixtures, calculated by multicomponent analysis of the n.m.r. spectra, are given in Table 5. The *m*-halogenobenzenesulfonic acids in 98.1% H_2SO_4 at 170° undergo both sulfonation with formation of 2,5-, 3,5-, and possibly some 3,4-disulfonic acid, and isomerization with formation of the para-isomer, which is then sulfonated to yield the 2,4-disulfonic acid. At very high reaction times, when the starting compound is almost completely converted, the relative amount of the 3,5-disulfonic acid still increases and does so at the expense of the 2,4-isomer. The isomerization of chlorobenzene-2,4-disulfonic acid into the 3,5-isomer has been reported before as occurring in concentrated aqueous sulfuric acid at 300° (23). These isomerizations may proceed via the sequence 2,4-$(SO_3H)_2 \rightarrow$ 4-$SO_3H \rightarrow$ 3-$SO_3H \rightarrow$ 3,5-$(SO_3H)_2$, or via the sequence 2,4-$(SO_3H)_2 \rightarrow$ 2,5-$(SO_3H)_2 \rightarrow$ 3,5-$(SO_3H)_2$.

The ratio of isomerization to sulfonation of the *m*-halogenobenzenesulfonic acids was estimated from the low conversion ratio (4- + 2,4-)/(2,5- + 3,4- + 3,5-) to be 2.3 ± 0.5, 3.1 ± 0.6, and 4.0 ± 0.7 for the bromo-, chloro-, and fluoro-compound respectively.

The interconversion of the *m*- and *p*-chlorobenzenesulfonic acids in concentrated sulfuric acid at 185–220° was studied by Spryskov and Kachurin (24, 25), who reported equilibrium constants (24).

Experimental

The synthesis of the halogenobenzenesulfonates and the 2,4-disulfonates has been described previously (1, 2).

The u.v. absorption measurements were made with a Cary 14 recording spectrophotometer. The rate constants for the disappearance of a given halogenobenzenesulfonic acid in 98.1% H_2SO_4 were obtained from the u.v. spectra of the samples taken after appropriate reaction times, *viz.* from the slope of either log $|E_t - E_\infty|$ for a chosen wavelength or log |substrate| against reaction time. The former method was employed with the meta-isomers. The latter method was used with the ortho- and para-isomers; for these substrates the composition of the reaction mixtures was analyzed by a three-component, three-wavelengths u.v. analysis using *o*-, *p*-, and 2,4-disulfonic acid as reference compounds (19, 20).

The n.m.r. spectra were recorded with an A60 or HA100 Varian spectrometer using TMS in CCl_4 as an external standard. The substrate concentrations of the potassium or sodium halogenobenzenesulfonates for the reactions in 98.1% H_2SO_4 at 170° and in 115% H_2SO_4 at 25° were 5 and 10 wt. % respectively. The 115% H_2SO_4 mixtures were quenched with dilute sulfuric acid to yield 5 wt. % solutions in 98% H_2SO_4 as well; the n.m.r. spectra were recorded from these 98% H_2SO_4 solutions.

The composition of the reaction mixtures of the *m*-halogenobenzenesulfonic acids was determined by multicomponent n.m.r. analysis with the assignments of Table 1, using a method similar to that described extensively in connection with the analysis of the isomeric anthracenesulfonic acids (26).

Received November 19, 1971

The electrochemical reduction of *as*-triazines 3-one or -thione leads to a 1,4-dihydro derivative which rearranges into a 4,5-dihydro compound which is further reducible to an imidazolone or a tetrahydro *as*-triazine 3-one. In the case of simple *as*-triazine the 1,4-dihydro compound rearranges either to a 1,2- or to a 4,5-dihydro compound. This last derivative can be reduced to an imidazole or a tetrahydro *as*-triazine. The mechanisms are discussed.

La réduction électrochimique des *as*-triazine ones-3 ou thiones-3 conduit à un dérivé dihydro-1,4 qui se transpose en un dérivé dihydro-4,5 lui-même réductible en imidazolone ou en tétrahydro *as*-triazine one-3. Dans le cas des *as*-triazines simples, le dérivé dihydro-1,4 se réarrange en dihydro-1,2 ou 4,5 *as*-triazine. Ce dernier composé peut être réduit en imidazole ou en tétrahydro *as*-triazine. Les mécanismes sont discutés.

Canadian Journal of Chemistry, **50**, 1581 (1972)

Introduction

It has already been shown that the —N=C—C=N— group is electrochemically reduced at a mercury electrode according to eq. 1. The reaction is valid whether this group

[1] —N=C—C=N— + $2e^-$ + $2H^+$ ⇌ —HN—C=C—NH—

is included in an aromatic ring (quinoxalines (1)), in a non-aromatic ring (dihydro-5,6 pyrazines (2)), or in an open-chain compound (α-diimines (3)), and even if the substituents on the two carbons are different. It seemed interesting to study the electrochemical reduction of compounds with the same —N=C—C=N— group, but with different substituents on the two nitrogen atoms; this is the case of *as*-triazines. We have studied both *as*-triazine 3-one (or -thione) and simple *as*-triazines.

Results and Discussion

1. as-Triazines 3-One (or Thione)

We will first describe the polarography and the controlled potential reduction in hydro-organic medium of 5,6-diphenyl *as*-triazine 3-one (**1**), 5,6-diphenyl 2-methyl *as*-triazine 3-one (**2**), and 5,6-diphenyl *as*-triazine 3-thione (**3**). The polarography and the controlled potential electrolysis of the corresponding 4,5-dihydro compounds will then be described.

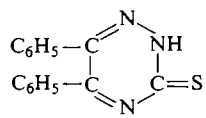
2



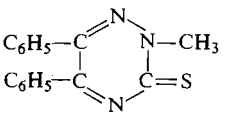
3

1.1 Reduction of as-Triazines 3-One (or-Thione)

1.1.1. Polarography and behavior in hydro organic medium

The stability of **1**, **2**, and **3** has been examined by u.v. spectroscopy in water–acetonitrile media at different p*H*. Compounds **1** and **2** are stable between p*H* 1 and 12, while **3** is only stable at p*H* > 7. The 5,6-diphenyl 2-methyl *as*-triazine 3-thione decomposes rapidly over the whole p*H* range.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



Compound **1** shows over the whole pH range studied ($c = 2.10^{-3}$ M, 20% CH_3CN) a single two-electron wave (3), the half-wave potential of which varies linearly with the pH as $E_{1/2} = -0.13 - 0.080$ pH (Fig. 1). In the case of **2** a single two-electron wave is observed in acidic medium, the $E_{1/2}$ of which varies linearly with the pH. At pH higher than 5 the wave height decreases while the height of a second wave, at more negative potential, increases. The $E_{1/2}$ of the second wave does not vary with the pH. This can be interpreted by supposing that the first wave corresponds to the reduction of protonated species and the second wave to the reduction of neutral species.

The sum of the heights of the first and the second wave remains constant and above pH 6 only the second wave is present.

The polarograms of **3** are strongly perturbed by adsorption phenomena. The half-wave potentials are given in Table 1.

1.1.2. Electrolyses in dilute solutions

We will describe the typical case of **1** at pH 1 (50% CH_3CN). The polarograms drawn in the course of electrolyses of dilute solutions under an argon atmosphere show that an anodic wave appears, the half-wave potential of which is close to that of the cathodic wave of **1**, followed by a cathodic wave at more negative potentials. (Fig. 2).

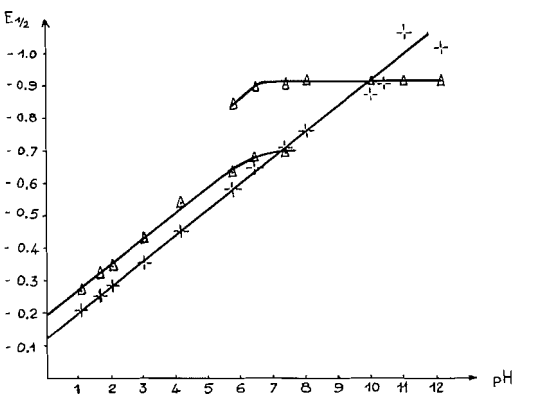


FIG. 1. The pH dependence of half-wave potentials $E_{\frac{1}{2}}$ (V/SCE) of **1** (-⊹-) and **2** (△).

TABLE 1. Half-wave potentials (V/SCE)

pH	1	3	5	7	9	11
1	−0.21	−0.37	−0.53	−0.69	−0.85	−1.01
2	−0.26	−0.44	−0.60	−0.69 −0.90	−0.92	−0.92
3				−0.6	−0.8	−1.0

As the electrolysis proceeds the height of the anodic wave increases until it reaches about a quarter of the height of the cathodic wave of **1** and then decreases.

At the end of the electrolysis (consumption of 2 F/mol) only a cathodic wave, the height of which is close to that of **1**, remains. If the electrolyse is interrupted before the second cathodic wave appears and if the flow of argon is stopped, the anodic wave decreases rapidly and the wave of **1** reappears at its original height.

At pH 6.30 (50% methanol) an anodic wave, the height of which remains constant, appears while a white compound precipitates; but no cathodic wave can be seen. At pH 11 (50%

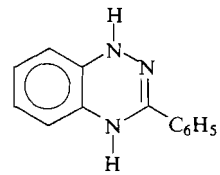
methanol) for **1** and **2** no anodic or cathodic wave appears; for **3** a cathodic wave is observed at potentials close to that of the background discharge. However, cyclic voltametry carried out on a hanging mercury drop shows that in basic medium the primary reduction compound of **1**, **2**, and **3** presents an anodic peak (*i.e.* for **1** pH 10.1, CH_3OH 50%, $v = 0.2\ V\ s^{-1}$, $E_c = -1.00$, $E_a = -0.66$ V, $i_a = 0.7\ i_c$).

Table 2 gives the half-wave potentials of **1**, **2**, and **3** ($E_{1/2c}$) and of the anodic waves of the primary reduction compounds ($E_{1/2a}$).

A similar phenomenon has already been observed in the electrochemical reduction of quinoxalines (1); it has been shown that the anodic wave corresponds to a 1,4-dihydro derivative of type —NH—C=C—NH— which rearranges into a derivative of type —N=C—CH—NH— which is reducible at the dropping mercury electrode at more negative potentials than the starting quinoxaline (Scheme 1). It will be shown that reaction Scheme 2 is proved by preparative electrolyses. This is in good agreement with the fact that the following compound shows an anodic wave and reoxidizes rapidly in the air as has been shown by Kwee and Lund (4).



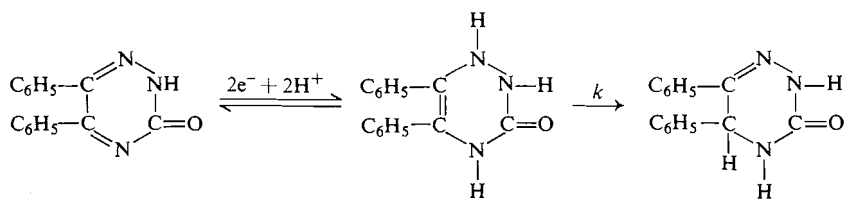
It must be noticed that as in the case of quinoxalines the rearrangement rate (which varies with the solvent, the pH, and the buffer composition) is under control of a general acidobasic catalysis.

Thus the electrochemical reduction in dilute solution of compounds **1**, **2**, and **3** yields a very oxidizable compound which shows an anodic wave and rearranges more or less rapidly, according to the pH, into a derivative evidencing a cathodic wave.[1]

1.1.3. Preparative electrolyses

Preparative electrolyses are carried out at 25° on a mercury pool, under argon. A saturated calomel electrode was used.

5,6-Diphenyl as-triazine 3-one (1). In acidic medium (pH 1, $E = -0.35$ V), a white compound precipitates in the course of the electrolysis. This compound is identified, by com-



SCHEME 2

[1]The electrochemical reduction of *as*-triazines into 1,4-dihydro compounds is electrochemically irreversible ($E_{\frac{1}{2}c} \neq E_{\frac{1}{2}a}$).

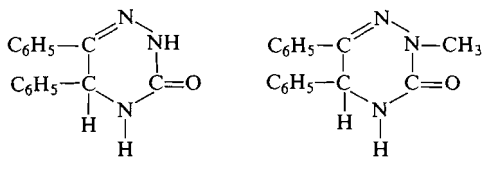
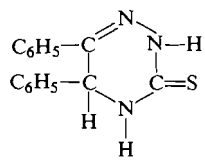
parison with an authentic sample (5), as the 4,5-dihydro 5,6-diphenyl *as*-triazine 3-one (**4**). In neutral medium (p*H* 6, $E = -0.95$ V) an easily reoxidizable white compound precipitates in the course of the electrolysis. It is the 1,4-dihydro 5,6-diphenyl *as*-triazine 3-one, as shown by its spectroscopic properties. In solution this compound shows the same anodic wave as that observed in the electrolysis of **1** in dilute solution. In basic medium (p*H* 11, $E = -1.10$ V) the same product as in acidic medium is obtained.

5,6-Diphenyl 2-methyl as-triazine 3-one (2). In acidic medium (p*H* 1, $E = -0.35$ V) an easily reoxidizable white compound precipitates in the course of the electrolysis. It is identified by its spectroscopic properties as the 1,4-dihydro 5,6-diphenyl 2-methyl *as*-triazine 3-one. It shows the same anodic wave as that observed in the course of the electrolysis of **2** in dilute solution. In basic medium (p*H* 11, $E = -1.05$ V) a white compound precipitates which is identified by comparison with an authentic sample (5) as the 4,5-dihydro 5,6-diphenyl 2-methyl *as*-triazine 3-one (**5**). This same compound can also be obtained in acidic medium, by leaving the solution under argon several hours after the end of the electrolysis.

5,6-Diphenyl as-triazine 3-thione (3). In neutral medium (p*H* 7.5, $E = -0.90$ V) a yellow compound precipitates in the course of the electrolysis. This easily oxidizable compound which shows in solution the same anodic wave as that observed in the electrolysis of **3** in dilute solutions is the 1,4-dihydro 5,6-diphenyl *as*-triazine 3-thione. In basic medium (p*H* 11, $E = -1.10$ V) the 4,5-dihydro 5,6-diphenyl *as*-triazine 3-thione (**6**) precipitates in the course of the electrolysis.



4 **5**



6

TABLE 3. Half-wave potentials (V/SCE)

p*H*	1.30	3.05	5.50	10.30
4	−0.97	−1.15	−1.33	
5	−1.00	−1.14	−1.33	
6			−1.60	−1.90

In conclusion, the preparative electrolysis supports Scheme 2. The primary reduction compound is a 1,4-dihydro triazine which presents an anodic wave at the dropping mercury electrode and is easily oxidizable. This 1,4-dihydro triazine rearranges into a 4,5-dihydro triazine with a rate depending on the medium.

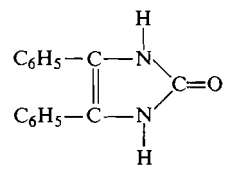
1.2. 4,5-Dihydro as-Triazines 3-One (or Thione)

1.2.1. Polarography of the 4,5-dihydro derivatives

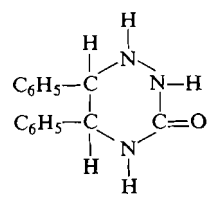
These compounds are reducible in certain p*H* ranges only and then show a single wave the height of which varies with the p*H*. The half-wave potentials are given in Table 3 ($c = 2.10^{-3}$ *M*, 40% CH_3CN).

1.2.2. Electrolysis of 4,5-dihydro derivatives

4,5-Dihydro 5,6-diphenyl as-triazine 3-one (4). In the course of the electrolysis of **4**, in acidic medium (p*H* 0.93, $E = -1.00$ V), a white compound precipitates which is identified by comparison with an authentic sample (5) as the 4,5-diphenyl imidazole 2-one (**7**). By making the filtrate alkaline (p*H* 11) a second compound precipitates: the *trans*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-one (**8***b*) (5). In neutral medium, only the *cis*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-one (**8***a*) is obtained.



7

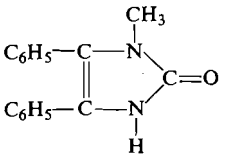


8

a cis
b trans

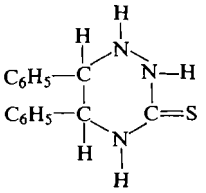
4,5-Dihydro 5,6-diphenyl 2-methyl as-triazine 3-one (5). The reduction in acidic medium gives the 4,5-diphenyl 1-methyl imidazole 2-one **9**.

4,5-Dihydro 5,6-diphenyl as-triazine 3-thione



9

(6). In the course of the reduction of **6** in basic medium (p*H* 10.67, $E = -2.00$ V) the *cis*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-thione **10** precipitates. Thus, the reduction of 4,5-dihydro compounds leads to two different kinds of



10

compounds: the 1,4,5,6-tetrahydro triazines and the 2-imidazolones. It has been shown that under the conditions of the electrolysis, the imidazolone does not come from the corresponding tetrahydrotriazine. No imidazolone can be detected in a solution of the tetrahydrotriazine which has been allowed to stand for a time equivalent to the length of an electrolysis. The reaction scheme can be rationalized as shown in Scheme 3.

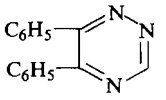
Scheme 3 is in good agreement with the reduction of phenylhydrazones in acidic medium (6) and with the scheme proposed by Kwee and Lund (4) for benzotriazines. The cleavage of the N_1—N_2 bond needs a preliminary protonation of the N_2 nitrogen, a quaternary ammonium then being a good leaving group. In the case of **5** only the imidazolone is obtained in acidic medium, this can be explained by the higher basicity of the N_2 nitrogen which carries a methyl group.

2. as-Triazines

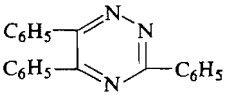
We will describe the case of 5,6-diphenyl *as*-triazine (**11**) and 3,5,6-triphenyl *as*-triazine (**12**).

2.1. Behavior in Hydroorganic Medium and Polarography

Compounds **11** and **12** are stable in hydroorganic medium over the whole p*H* range.



11

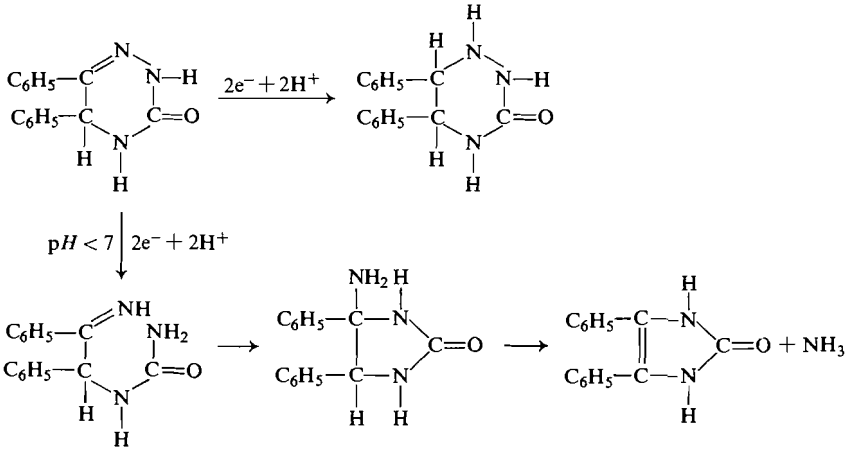


12

Compound **11** ($c = 10^{-3}$ *M*, 40% CH_3OH) shows two two-electron waves up to p*H* 7; at higher p*H* only the first wave remains; its half-wave potential (V/SCE) varies linearly with the p*H* as $E_{1/2} = -0.14 - 0.066$ p*H*. Compound **12** ($c = 10^{-4}$ *M*, 40% MeOH) behaves similarly; the second wave exists only up to p*H* 8. The half-wave potential of the first wave varies linearly with the p*H* as: $E_{1/2} = -0.23 - 0.062$ p*H*. The half-wave potentials are presented in Table 4.

2.2. Electrolysis in Dilute Solutions

An electrolysis of **11** under argon at a potential corresponding to the first plateau ($c = 2.10^{-3}$ *M*, p*H* 3.65, 50% CH_3OH, $E = -0.60$ V) gives



SCHEME 3

For personal use only.

TABLE 4. Half-wave potentials (V/SCE)

pH	1	3	5	7	9	11	
11	−0.21	−0.34	−0.47	−0.60	−0.74	−0.87	1st wave
	−0.88	−0.97	−1.15	−1.36			2nd wave
12	−0.29	−0.41	−0.54	−0.66	−0.79	−0.91	1st wave
	−0.77	−0.88	−1.05	−1.42			2nd wave

a compound which shows an anodic wave at a potential slightly more positive than the cathodic wave of the starting compound. The height of the anodic wave never exceeds about a tenth of the height of the cathodic wave of **11**. At the end of the electrolysis, after consumption of about 2 F/mol, only a cathodic wave, the half-wave potential of which is slightly different from that of the second wave of **11**, remains. The same phenomenon is observed at p*H* 6.20 ($E = -0.80$ V), while at p*H* 12.83 ($E = -1.20$ V) no anodic wave appears. Cyclic voltametry carried out on a hanging mercury drop shows that in alkaline medium the primary reduction compound also shows an anodic peak (p*H* 12.96, CH_3OH 50%, $v = 0.2$ V s^{-1}, $E_c = -1.00$, $E_a = -0.72$ V, $i_a = 0.9\, i_c$). The same behavior is observed for **12**. Table 5 gives the half-wave potentials of **11** and **12** ($E_{1/2c}$) and of the anodic waves of the primary reduction compounds ($E_{1/2a}$).

The similarity of the results obtained in the electrolysis in dilute solutions of **11** and **12** with those of compounds **1**, **2**, and **3** indicates that a 1,4-dihydro derivative is obtained as the primary reduction compound. This 1,4-dihydro compound then undergoes a rearrangement.

2.3. Preparative Electrolysis

*3,5,6-Triphenyl as-Triazine (**12**)*

Reduction on the first plateau. In the course of an electrolysis at p*H* 3.60 ($E = -0.70$ V) a white compound precipitates which is identified as the 1,2-dihydro 3,5,6-triphenyl *as*-triazine **13**. By extracting the filtrate with ether a second compound, the 4,5-dihydro 3,5,6-triphenyl *as*-triazine **14**, is obtained. A reduction at p*H* 13.5 ($E = -1.30$ V) leads only to the 4,5-dihydro 3,5,6-triphenyl *as*-triazine **14**. The spectroscopic properties of **14** do not allow a definite choice between a 4,5-dihydro structure and a 5,6-dihydro structure. However the analogy of polarographic behavior between **14** and **4**, **5**, and **6** points to a 4,5-dihydro compound. Besides, the 5,6-dihydro derivative would probably be irreducible at the dropping mercury electrode.

Reduction on the second plateau. By adding water to the electrolysis solution (p*H* 3.60, $E = -1.30$ V, 4 F/mol) the 2,4,5-triphenyl imidazole **15** is obtained and by neutralizing the filtrate with sodium bicarbonate the *cis*-1,4,5,6-tetrahydro 3,5,6-triphenyl *as*-triazine **16** precipitates. The reduction at p*H* 6.20 ($E = -1.40$ V) only leads to the 2,4,5-triphenyl imidazole **15**. The 5,6-diphenyl *as*-triazine **11** gives similar results.

2.4. Reduction of 4,5-Dihydro Compounds

The 1,2-dihydro derivatives are not reducible at the dropping mercury electrode, but the 4,5-dihydro *as*-triazine shows a two-electron wave ($E_{1/2}$ given in Table 6).

A preparative electrolysis of **14** at p*H* 3.60 ($E = -1.20$ V) yields the *cis*-1,4,5,6-tetrahydro 3,5,6-triphenyl *as*-triazine **16**.

2.5. Reduction Mechanism

The different steps of the electrochemical reduction of **12** are given in Scheme 4. The primary reduction compound for **11** and **12** is the 1,4-dihydro derivative characterized by its

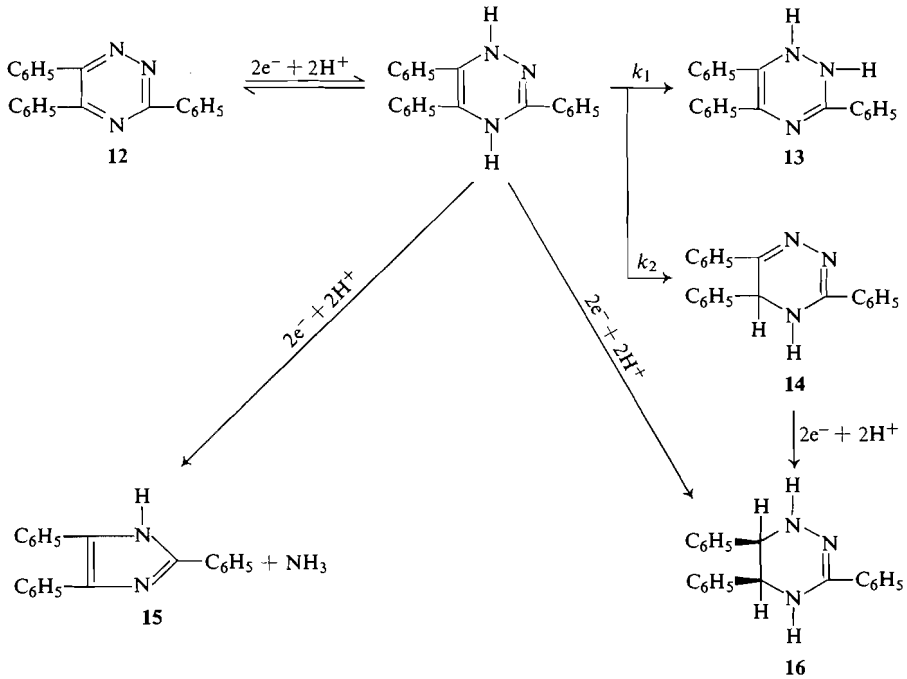
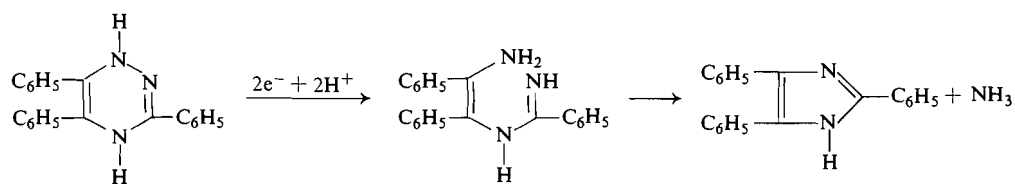


SCHEME 4

anodic wave, but it rearranges too quickly to be isolated. The 1,2- and 4,5-dihydro derivatives are obtained through two competitive reactions; it has been shown that under the conditions of the electrolysis these two compounds do not transform into each other; in the solution and during the time of the electrolysis the 1,2-dihydro compound does not give the 4,5-dihydro compound; in the same way the 4,5-dihydro compound does not give the 1,2-dihydro compound. The relative amount of these two compounds is strongly dependent on the p*H*. The 1,4-dihydro *as*-triazine shows two polarographic waves: an anodic wave (corresponding to the reoxidation into the starting compound) and a cathodic wave (the second wave observed on the polarograms of *as*-triazine). The reduction of the 1,4-dihydro *as*-triazine leads either to an imidazole or to a 1,4,5,6-tetrahydro triazine; here also the relative amount of the two compounds depends strongly on the p*H*. Scheme 5 could explain the formation of the imidazole. At last the 4,5-dihydro *as*-triazine is itself reducible, it corresponds to the cathodic wave observed at the end of the electrolysis of **11** and **12** in dilute solutions, and leads to a 1,4,5,6-tetrahydro *as*-triazine.

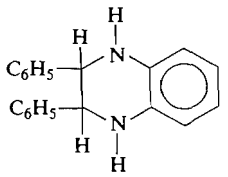
3. Remarks on the Stereochemistry of 1,4,5,6-tetrahydro as-Triazines

The n.m.r. spectra of **8**, **10**, and **16**, after addition of D_2O, show that either one or the other of the two possible isomers is obtained. The molecular models show that the ring takes a half chair conformation as cyclohexene and the two phenyl groups can be either *cis* or *trans* to each other. The coupling constants are: $J_{H_5-H_6} = 4.0$ for **10**, 8.2 for **8***b*, 4.0 for **8***a*, and 4.0 Hz for



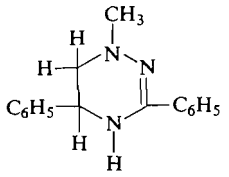
SCHEME 5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



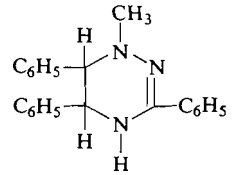
(Ref.7)

$J_{H_2-H_3}$ = 2.6–2.7 Hz (*cis*)
$J_{H_2-H_3}$ = 7.0–8.2 Hz (*trans*)



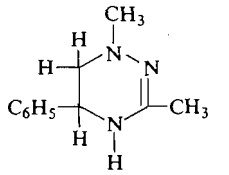
(Ref.8)

$J_{H_5-H_6}$ = 7.40 Hz (*trans*)



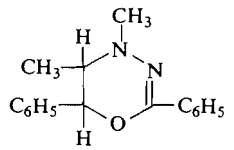
(Ref.8)

$J_{H_5-H_6}$ = 6.68 Hz (*trans*)



(Ref.8)

$J_{H_5-H_6}$ = 7.35 Hz (*trans*)



(Ref.9)

$J_{H_5-H_6}$ = 2.90 Hz (*cis*)
$J_{H_5-H_6}$ = 7.45 Hz (*trans*)

CHART 1

16. Chart 1 shows the values found in the literature. Therefore **8***b* is a *trans* derivative. The 5 and 6 protons are *trans* axial–axial with a dihedral angle of about 180°, and the two phenyl groups are in equatorial position. On the contrary **8***a*, **10**, and **16** are certainly *cis*-tetrahydro triazines. The coupling constant of 4.0 Hz obtained for **8***a*, **10**, and **16** is somewhat greater than the coupling constants given above. This may be due to a deformation of the ring which decreases the dihedral angle $C_5H—C_6H$ and thus increases the J_{H_5}–J_{H_6} coupling constant.

Thus, these results are different from that obtained in the electrochemical reduction of quinoxalines. These last compounds always yield *cis*-tetrahydro quinoxalines (1). These differences can be explained in the following way: the dihydroquinoxalines, **4** (in neutral medium), **6**, and **14** would be adsorbed when the last proton is fixed. On the contrary, the stereochemically determining step in the reduction of **4** in acidic medium, that is the fixation of the last proton, would take place in the bulk of the solution. The most stable isomer where the two phenyl groups are equatorial would then be obtained.

Conclusion

(*1*) Although the two substituents on the nitrogen atoms of the studied compounds are very different, the observed primary reduction mechanism is similar to that of the compounds with the —N=C—C=N— group previously studied (eq. 1).

(*2*) The electrochemical reduction of *as*-triazines allows selective preparation of some compounds which cannot be obtained by chemical reduction (5,10,11,16): the 1,4-dihydro *as*-triazines 3-one (or -thione), the 4,5-dihydro *as*-triazines, and the 1,4,5,6-tetrahydro *as*-triazines or *as*-triazinones. These last compounds are obtained stereoselectively.

Experimental

The apparatus and techniques used have been described previously (1). The cathodic compartment of the electrolytic cell is a glass cylinder of 85 mm diameter and the anodic compartment which fits in the cathodic compartment is a glass cylinder of 50 mm diameter closed at its lower end by a fine fritted glass. The organic cosolvents used in the elec-

For personal use only.

trolyses are either methanol or acetonitrile (for solubility reasons). It has been checked that the nature of the cosolvent does not change the results of the electrolyses. All the compounds gave correct elemental analysis.

1. Controlled Potential Electrolysis of as-Triazines 3-One (or -Thione)

1.1 Reduction of 5,6-Diphenyl as-Triazine 3-One (1)

Compound **1** is prepared according to Biltz and Stellbaum (12) by condensation of semicarbazide hydrochloride with benzile in boiling acetic acid. Yellow crystals, m.p. 224°, are obtained.

Reduction of 1 in acidic medium

A solution is prepared from 100 cm^3 CH_3CN, 40 cm^3 1 *N* H_2SO_4, 60 cm^3 of water. Three grams of **1** are dissolved in 150 cm^3 of this solution (p*H* 0.97). In the course of the electrolysis ($E = -0.35$ V, 2.0 F/mol) a white compound precipitates, m.p. 176°, 2 g (yield 67%) identified as **4** (4,5-dihydro 5,6-diphenyl *as*-triazine 3-one) by comparison (i.r., n.m.r.) with an authentic sample.

Reduction at pH 6.3

A solution (200 cm^3) is prepared from 100 cm^3 CH_3OH, 40 cm^3 1 *N* NaOH, 3.6 g of succinic acid, and water. Compound **1** (0.5 g) is dissolved in 150 cm^3 of this solution, the rest of it being used as anolyte. In the course of the electrolysis ($E = -0.95$ V, 2.0 F/mol) a white compound precipitates, recovered under nitrogen in a glove box. The product is identified as the 1,4-dihydro 5,6-diphenyl *as*-triazine 3-one (370 mg, yield 75%, m.p. 150°). The n.m.r. spectrum (DMSO-d_6): NH 1 proton(s) δ 6.30, 1 proton(s) 8.05, and 1 proton(s) 8.26 p.p.m. which can be displaced by D_2O; C_6H_5 10 protons(m) 7.00–7.60 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3280 (m), 3200 cm^{-1} (m), $\nu_{C=O}$ 1680 cm^{-1} (s). The product reoxidizes rapidly in the air.

1.2 Reduction of 5,6-Diphenyl 2-Methyl as-Triazine 3-One

Compound **2** is prepared according to Biltz and Stellbaum (12).

Reduction in acidic medium

Compound **2** (0.5 g) is dissolved in 150 cm^3 of a solution prepared from 100 cm^3 CH_3CN, 40 cm^3 1 *N* H_2SO_4, and 60 cm^3 H_2O. In the course of the electrolysis (p*H* 0.97; $E = -0.35$ V, 2.0 F/mol) a white compound precipitates, recovered under nitrogen in a glove box (350 mg, yield 70%, m.p. 153° (alcohol)). This compound is easily oxidized in the air. The n.m.r. spectrum (DMSO-d_6) N—CH_3 3 protons(s) δ 2.91, N_1—H 1 proton(s) 6.60, N_4H 1 proton(s) 8.46 p.p.m., both NH protons are displaced by addition of D_2O; C_6H_5 10 protons(m) 7.0–7.5 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3.200 (m), $\nu_{C=O}$ 1670 cm^{-1} (s). This allows assignment of the 1,4-dihydro 2-methyl *as*-triazine 3-one formula to this compound (in particular, there is no C—H protons in the n.m.r. spectrum).

Reduction in basic medium pH 11

A solution is prepared from 100 cm^3 CH_3OH, 1.7 g CO_3HNa, 4 cm^3 1 *N* NaOH, and 100 cm^3 of water. Compound **2** (0.5 g) is dissolved in 150 cm^3 of this solution. A white precipitate appears in the course of the electrolysis ($E = -1.05$ V, 2.1 F/mol); 350 mg, yield 70%, m.p. 195° (alcohol); n.m.r. spectrum (DMSO-d_6): N—CH_3 3 protons(s) δ 3.31, C_5—H 1 proton(d) 5.78, N_4H 1 proton(d) 8.13 p.p.m. $J_{C_5H-N_4H} = 4.0$ Hz; the addition of D_2O transforms the doublet of C_5H in a singlet and N_4H is displaced. The i.r. spectrum (KBr pellet) ν_{NH} 3200, $\nu_{C=O}$ 1680 cm^{-1}. This compound is identical (t.l.c., i.r., m.p., n.m.r.) to the compound obtained by hydrogenation of **2** in the presence of Raney nickel (5) and to that obtained by electrolysis of **2** in acidic medium when the solution is kept under argon several hours after the end of the electrolysis. Thus this compound is the 5,6-diphenyl 2-methyl 4,5-dihydro *as*-triazine 3-one **5**.

1.3. Reduction of 5,6-Diphenyl as-Triazine 3-Thione (3)

Compound **3** is prepared according to Klosa (13)

Reduction in neutral medium

A solution is prepared from 120 cm^3 CH_3OH, 50 cm^3 1 *N* NaOH, 30 cm^3 H_2O, and 3.9 g citric acid. Compound **3** (0.5 g) is dissolved in 150 cm^3 of this solution. In the course of the electrolysis (p*H* 7.42, $E = -0.90$ V, 1.8 F/mol) a yellow compound precipitates which is recovered in a glove box under nitrogen (350 mg, yield 70%), m.p. 210° (alcohol). The n.m.r. spectrum (DMSO-d_6): N_1H 1 proton(s) δ 6.5, N_4H 1 proton(s) 9.5, both NH are displaced by addition of D_2O, C_6H_5 10 protons(m) 7.0–7.6 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3150, $\nu_{N-C=S}$ 1530 (s), $\nu_{C=S}$ 1220 cm^{-1}. In solution this compound is easily oxidized by air to **3**. Thus, this compound is the 1,4-dihydro 5,6-diphenyl *as*-triazine 3-thione **6**.

Reduction in basic medium

A solution is prepared from 100 cm^3 CH_3OH, 100 cm^3 of water, 1.7 g CO_3HNa and 4 cm^3 1 *N* NaOH. Compound **3** (0.5 g) is dissolved in 150 cm^3 of this solution (p*H* 10.64). In the course of the electrolysis ($E = -1.00$ V, 1.9 F/mol) a white compound precipitates (350 mg, yield 70%) F = 222° (alcohol). The n.m.r. spectrum (DMSO-d_6): C_5H 1 proton (d) δ 5.71, N_4H 1 proton (d) 9.70, $J_{C_5H-N_4H} = 4.0$ Hz, N_2H 1 proton(s) 11.50 C_6H_5 10 protons(m) 7.0–8.0 p.p.m. The addition of D_2O displaces the peaks at 11.50 and 9.70 p.p.m. and transforms into a singlet the doublet at 5.71 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3150 and 3350 (m), $\nu_{N-C=S}$ 1550 (s) and $\nu_{C=S}$ 1180 cm^{-1} (s). The compound thus obtained is identical (n.m.r., i.r., t.l.c., and m.p.) to the compound obtained by hydrogenation of **3** by Raney nickel (11), this ascertains the structure of this compound: 4,5-dihydro 5,6-diphenyl *as*-triazine 3-thione (**6**).

2. Controlled Potential Electrolysis of 4,5-Dihydro as-Triazines

2.1 4,5-Dihydro 5,6-Diphenyl as-Triazine 3-One (4)

Reduction in acidic medium

A solution is prepared from 100 cm^3 CH_3CN, 60 cm^3 H_2O, and 40 cm^3 *N* H_2SO_4; 1.5 g of **4** are dissolved in 150 cm^3 of this solution. In the course of the electrolysis ($E = -1.00$ V, p*H* 0.93) white crystals precipitate (700 mg, yield 50%), m.p. 318° (alcohol) n.m.r. spectrum (DMSO-d_6): 2 NH 2 protons(s) δ 10.51 which are displaced by addition of D_2O, C_6H_5 10 protons (s) 7.33 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3200 (s), $\nu_{C=O}$ 1690 cm^{-1} (s). This compound is identical (n.m.r., t.l.c.) to the 4,5-diphenyl imidazole 2-one (5). When the filtrate is concentrated and made slowly alkaline to p*H* 11, a second white compound precipitates: the *trans*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-one **8***b* (700 mg, yield 45%), m.p. 220° (alcohol). The n.m.r. spectrum (DMSO-d_6 + D_2O) C_5H or C_6H 1 proton (d) δ 3.83, C_6H or C_5H 1 proton (d) 4.70 ($J_{H_5-H_6} = 8.2$ Hz),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

C_6H_5 10 protons (m), 7.1–7.4 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3400 (m) and 3200 (s), $\nu_{C=O}$ 1655 cm^{-1} (s).

Reduction in neutral medium

A solution is prepared from 125 cm^3 CH_3CN, 50 cm^3 1 *N* NaOH, 3.9 g citric acid, and 75 cm^3 H_2O; 0.5 g of **4** is dissolved in 200 cm^3 of this solution. The compound which precipitates during the electrolysis (p*H* 5.98, $E = -1.50$ V) is the *cis*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-one **8***a* (150 mg, yield 30%), m.p. 240° (alcohol). The n.m.r. spectrum (DMSO-d_6 + D_2O): C_5H or C_6H 1 proton (d) δ 4.50, C_6H or C_5H 1 proton (d) 4.93 ($J_{H_5-H_6}$ = 4.0 Hz), C_6H_5 10 protons (m) 6.8–7.3 p.p.m. The i.r. spectrum (KBr pellet): ν_{NH} 3200 (m) $\nu_{C=O}$ 1670 cm^{-1} (s).

2.2 4,5-Dihydro 5,6-Diphenyl 2-Methyl as-Triazine 3-One

Reduction in acidic medium

A solution is prepared from 100 cm^3 CH_3CN, 40 cm^3 1 *N* H_2SO_4, 60 cm^3 H_2O; 300 mg of **5** are dissolved in 150 cm^3 of this solution. In the course of the electrolysis (p*H* 0.93 $E = -1.00$ V, 2 F/mol) the 4,5-diphenyl 3-methyl imidazole 2-one precipitates (150 mg, yield 50%), m.p. 228° (alcohol). The n.m.r. spectrum (DMSO-d_6): N—CH_3, 3 protons (s) δ 2.95, N—H 1 proton(s) 10.71 displaced by addition of D_2O, C_6H_5 10 protons (m) 7.18 and 7.45 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3100 (s), $\nu_{C=O}$ 1730 cm^{-1} (s).

*2.3. 4,5-Dihydro 5,6-Diphenyl as-Triazine 3-Thione (**6**)*

Reduction in basic medium

A solution is prepared from 100 cm^3 CH_3OH, 100 cm^3 H_2O, 4 cm^3 1 *N* NaOH, and 1.7 g CO_3HNA; 0.5 g of **6** is dissolved in 150 cm^3 of this solution (p*H* 10.67). In the course of the electrolysis ($E = -2.00$ V) the *cis*-1,4,5,6-tetrahydro 5,6-diphenyl *as*-triazine 3-thione **10** precipitates (300 mg, yield 60%), m.p. 215° (alcohol). The n.m.r. spectrum (DMSO-d_6): C_5H and C_6H 2 protons (m) δ 4.20 and 4.90, N_1H 1 proton (d) 5.36 (J_{NH-CH} = 11 Hz), N_4H 1 proton (d) 8.73 ($J_{N_4H-C_5H}$ = 4.0 Hz), N_2H 1 proton(s) 9.56 p.p.m. By addition of D_2O the spectrum becomes more simple, the N—H are displaced, the C_5H and C_6H appear as doublets δ = 4.44 and 4.83 p.p.m., $J_{C_5H-C_6H}$ = 4.0 Hz. The i.r. spectrum (KBr pellet), ν_{NH} 3150 (s), $\nu_{N-C=S}$ 1560 (s), $\nu_{C=S}$ 1220 cm^{-1} (s).

3. Controlled Potential Electrolysis of as-Triazines

*3.1. 5,6-Diphenyl as-Triazine (**11**)*

Compound **11** is prepared according to ref. 14.

*3.2. 3,5,6-Triphenyl as-Triazine (**12**)*

Compound **12** is prepared according to Metze (15).

Electrolysis on the First Plateau

A solution is prepared from 5.3 g of citric acid, 15 cm^3 1 *N* NaOH, 110 cm^3 H_2O, 125 cm^3 CH_3CN, and 2 g $NaClO_4$. Compound **12** (700 mg) is dissolved in 200 cm^3 of this solution (p*H* 3.60). The temperature of the solution is maintained at about 10°. In the course of the electrolysis ($E = -0.70$ V) a white compound precipitates, m.p. 264.5° (washed with alcohol and ether) 163 mg (yield 23%). This compound is the 1,2-dihydro 3,5,6-triphenyl *as*-triazine **13**. The n.m.r. spectrum (DMSO-d_6): C_6H_5 (m) δ 7.40 p.p.m., no C—H proton appears on this spectrum. The i.r. spectrum (KBr pellet): ν_{NH} 3180 (m) and 3380 cm^{-1}. Water (200 cm^3) is added to the filtrate which is extracted with ether. A white compound is thus obtained, m.p. 249.5° (alcohol) 440 mg (yield 63%). This compound is the 4,5-dihydro 3,5,6-triphenyl *as*-triazine **14**. The n.m.r. spectrum (DMSO-d_6): C_5H 1 proton(s) δ 5.93, C_6H_5 15 protons (m) 7.2–8.2 p.p.m. The i.r. spectrum (KBr pellet) ν_{NH} 3260 cm^{-1} (m). Compound **14** is also obtained alone (98 mg) by reduction of **12** (124 mg) in basic medium (0.1 *N* NaOH, 50% CH_3CN, p*H* 13.47, $E = -1.30$ V) (yield 80%).

Electrolysis on the Second Plateau

Compound **12** (700 mg) is dissolved in the same solution as above (p*H* 3.60). At the end of the electrolysis ($E = -1.30$ V, 4.1 F/mol) 200 cm^3 of water are added and 300 mg (yield 80%) of a white compound m.p. 282° are filtered. This compound is identified (n.m.r., i.r., t.l.c.) by comparison with an authentic sample (16) as the 2,4,5-triphenyl imidazole **15**. The filtrate is neutralized with sodium bicarbonate and a second product precipitates (145 mg, yield 20%): the *cis*-1,4,5,6-tetrahydro 3,5,6-triphenyl *as*-triazine **16**. The n.m.r. spectrum (DMSO-d_6 + D_2O): C_5H or C_6H 1 proton (d) δ 4.31, C_6H or C_5H 1 proton (d) 4.81 ($J_{H_5-H_6}$ = 4.0 Hz), C_6H_5 15 protons (m) 6.7–8.0 p.p.m.

A reduction of **12** at p*H* 6.20 (700 mg of **12** in 200 cm^3 of a solution of 5.3 g citric acid, 6 ml 1 *N* NaOH, 125 cm^3 H_2O, and 125 cm^3 CH_3CN; $E = -1.40$ V, 4.2 F/mol) gives only the 2,4,5-triphenylimidazole **15** (yield 55%).

*3.2. Electrolysis of the 4,5-Dihydro 3,5,6-Triphenyl as-Triazine (**14**)*

The electrolysis of 300 mg of **14** at p*H* 3.60 (same solution as above) ($E = -1.20$ V, 2.2 F/mol) gives, after neutralization of the solution with sodium bicarbonate, 135 mg (yield 45%) of *cis*-1,4,5,6-tetrahydro 3,5,6-triphenyl *as*-triazine **16**.

Kinetics of Sulfonation of Phenylmethanesulfonic Acid[1]

MRS. Z. R. H. NIENHUIS, W. J. SPILLANE,[2] AND H. CERFONTAIN

Laboratory for Organic Chemistry, Nwe Achtergracht 129, University of Amsterdam, Amsterdam, The Netherlands

Received January 10, 1972

The kinetics of the sulfonation of phenylmethanesulfonic acid in 96.32–99.96% H_2SO_4 has been studied and partial rate factors for the $—CH_2SO_3H$ substituent are reported.

Les cinétiques de la sulfonation de l'acide phénylméthanesulfonique dans H_2SO_4 96.32–99.96% ont été étudiées et les facteurs partiels de vitesse pour le substituant $—CH_2SO_3H$ sont rapportés.

Canadian Journal of Chemistry, **50**, 1591 (1972)

With a view to elucidating the mechanism of sulfonation of phenylmethanesulfonic acid (α-toluenesulfonic acid) and comparing its reactivity with that of benzene (1) and of deactivated aromatic substrates, *e.g.* halogenobenzenes (2, 3) and polyfluorobenzenes (4), we have studied the homogeneous sulfonation of phenylmethanesulfonic acid in sulfuric acid ranging in concentration from 96.32 to 99.96%. The pseudo first order rate constants are given in Table 1.

In the sulfuric acid range of this study, phenylmethanesulfonic acid is present mainly in the unionized form.[3]

The relative reactivities of *p*-difluorobenzene, phenylmethanesulfonic acid, bromobenzene (3), and benzene (1) in 96.3% sulfuric acid at 25° are approximately 1:110:31 600:690 000 respectively.[4] Thus the reactivity of phenylmethanesulfonic acid lies somewhat closer to *p*-difluorobenzene than to bromobenzene.

For sulfonation in 99.7 ± 0.1% sulfuric acid the composition of the resulting disulfonic acid mixture was determined by n.m.r. to be 4 ± 1%, *o*-; 48 ± 10%, *m*-; and 48 ± 10% *p*-sulfophenylmethanesulfonic acid. For sulfonation in sulfuric acid decreasing in concentration from 99.8 to 96.5% H_2SO_4 during the sulfonation, the isomer distribution is the same within experimental error.

TABLE 1. Pseudo first order rate constant for the sulfonation of phenylmethanesulfonic acid at 25.0°

H_2SO_4 (wt. %)	${}_{ps}k_1 \times 10^4$ (s^{-1})
99.960 ± 0.002	155
99.915 ± 0.005	44.3
99.82 ± 0.02	9.7
99.63 ± 0.01	3.13
99.29 ± 0.02	1.18
98.75 ± 0.02	0.617
98.40 ± 0.05	0.385
,, ,,	1.82 (38.3°)
,, ,,	8.0 (50.4°)
96.32 ± 0.05	0.091

The correlation of the pseudo first order overall rate constant for sulfonation with the activity of $H_2S_2O_7$ [5] at the various sulfuric acid concentrations is similar for phenylmethanesulfonic acid and *p*-difluorobenzene (Fig. 1). Because of the similarity in isomer distribution at low and high sulfuric acid concentration this correlation does apply to the ortho-, meta-, and para-substitution of phenylmethanesulfonic acid. The present kinetic results may therefore be explained in terms of the mechanism proposed previously for *p*-difluorobenzene (4).

[1]Aromatic sulfonation, part 34. Preceding paper, see ref. 14.

[2]Present address: University College, Galway, Eire.

[3]Arenesulfonic acids (5, 6) and methanesulfonic acid (6) behave as weak bases in sulfuric acid more concentrated than 100% H_2SO_4, whereas they behave as weak acids in sulfuric acid less concentrated than 95% H_2SO_4 (half-deprotonation takes place at 82–84% H_2SO_4) (7, 8).

[4]${}_{ps}k_1$ for *p*-difluorobenzene in 96.3% sulfuric acid at 25° was obtained by extrapolation from the data of (4) to be 8.5×10^{-8} s^{-1}.

[5]The activities of $H_2S_2O_7$ were taken from refs. 4 and 9.

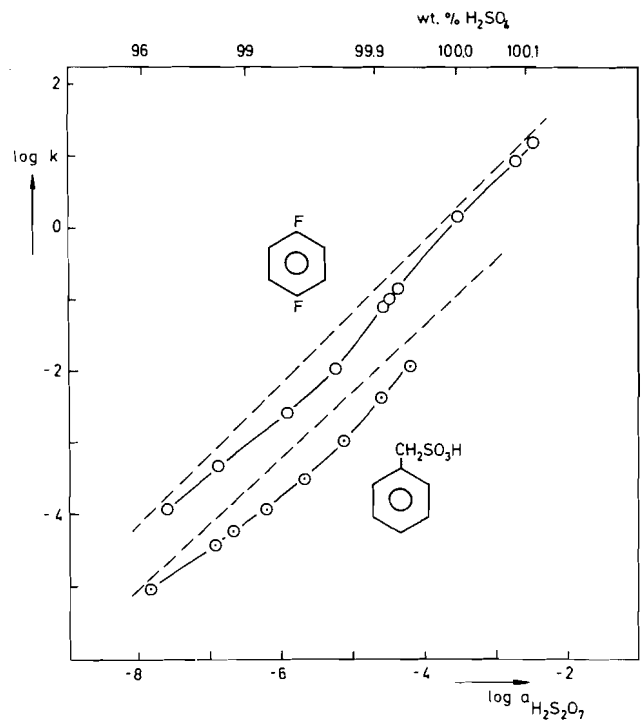

FIG. 1. Correlation of pseudo first order rate constant for sulfonation with the activity of $H_2S_2O_7$.

The temperature dependence of the overall rate of reaction was determined in 98.4% sulfuric acid, and corresponds with $E_a = 24.7$ kcal/mol. Since the sulfonation of phenylmethanesulfonic acid leads mainly to para- and meta-substitution which, by absence of steric hindrance will exhibit similar frequency factors, the activation energy value applies to both meta- and para-substitution. The present value of 24.7 kcal/mol is about 6 kcal/mol greater than observed for the sulfonation of benzene in 91–96% sulfuric acid (1).

The partial rate factors of phenylmethanesulfonic acid for sulfonation in 96.3% sulfuric acid at 25° were calculated from its reactivity relative to benzene (0.000160:1) and the sulfonation isomer distribution to be $f_o = (0.19 \pm 0.05) \times 10^{-4}$, $f_m = (23 \pm 5) \times 10^{-4}$, and $f_p = (46 \pm 10) \times 10^{-4}$. The substituent effect of the $-CH_2SO_3H$ group will be discussed and compared with the effects of the $-SO_3H$ and the $-CH_2C(CH_3)_3$ substituents in a forthcoming publication.

Whereas reaction of phenylmethanesulfonic acid in concentrated *aqueous* sulfuric acid leads to clean sulfonation, reaction with *fuming* sulfuric acid, *i.e.* >100% H_2SO_4, instead leads to decomposition with evolution of sulfur dioxide (smell).

Experimental

General

The u.v. measurements were made with a Zeiss PMQ2 spectrophotometer fitted with a thermostatically controlled cell holder. The n.m.r. spectra were recorded with a HA 100 Varian n.m.r. spectrometer equipped with a Time Averaging Computer, using TMS in CCl_4 (50 vol %) as external standard.

The potassium salt of phenylmethanesulfonic acid was prepared as described by Johnson and Ambler (10) by the action of potassium sulfite on benzyl chloride.

Anal. Calcd. for $C_7H_7O_3SK$: C, 39.98; H, 3.36; S, 15.25; K, 18.59. Found: C, 40.00; H, 3.48; S, 15.42; K, 18.60.

Rate Measurements

Rates were measured by following the u.v. extinction at an appropriate wavelength (*e.g.* 276 nm) with time. Pseudo first order rate constants were determined from plots of either log $|E_t - E_\infty|$ *vs.* time (1) or log $|E_{t+\Delta t} - E_t|$ *vs.* time (11). The latter method (the Guggenheim method) was used in most runs because some drift in the value of E_∞ was noticed. All rate runs were followed to at least 88% conversion and each run was repeated at least once. The rate constants obtained are accurate to within 5% with

For personal use only.

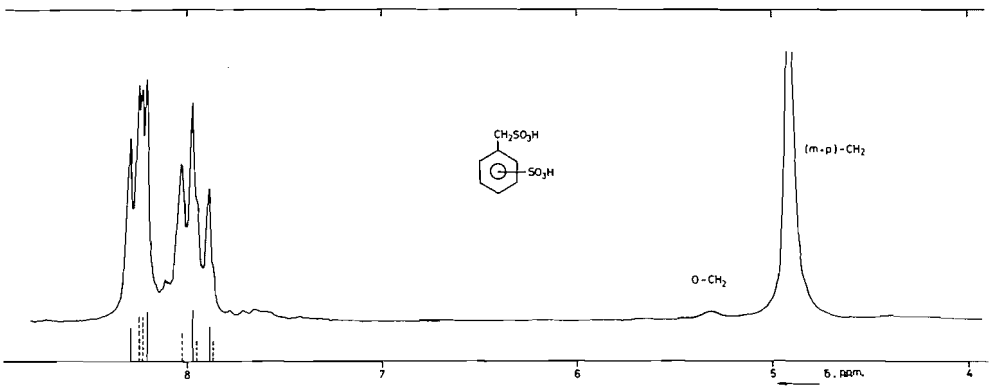

FIG. 2. Typical multiple scan (194 ×) n.m.r. spectrum of the sulfonation mixture of phenylmethanesulfonic acid in 96.5% H_2SO_4.

the exception of the rate constant obtained in 99.96% sulfuric acid which is accurate to within 10% (four determinations).

Isomer Distribution

Two samples of known amounts of substrate and 99.8% sulfuric acid (32 mg + 5.3 g and 101 mg + 1.7 g respectively) were placed in glass-stoppered flasks, and the mixtures were maintained at 25.0° for at least 2 days after which time the monosulfonation was complete. The final sulfuric acid concentration had then decreased to 99.5 and 96.5% H_2SO_4 respectively. The n.m.r. spectra of the sulfuric acid reaction mixtures exhibited two methylene singlets at δ 4.90 and 5.32 p.p.m. respectively and two slightly overlapping complex multiplets centered at δ 7.95 and 8.25 p.p.m. respectively for the aromatic hydrogens (Fig. 2). The ratio of the areas of the methylene to aromatic hydrogens was 0.50 ± 0.02. After the spectra had been compared with those of the three toluenesulfonic acids (12, 13) and with that of phenylmethanesulfonic acid (measured in 95% sulfuric acid), the singlet absorption at δ 5.32 p.p.m. was assigned to the benzylic hydrogens of *o*-sulfophenylmethanesulfonic acid and the singlet absorption at δ 4.90 p.p.m. to those of the *p*- and *m*-isomer. The ratio of *o*- *vs.* the sum of the *m*- and *p*-isomer was determined by measuring the ratio of the areas of the two benzylic hydrogen absorption peaks. The low field aromatic absorption comprises the absorption of the 2- and 4-hydrogens of 3- and of the 3- and 5-hydrogens of 4-sulfophenylmethanesulfonic acid, the high field absorption those of the other aromatic hydrogens. The AA′BB′ absorption pattern of the *p*-isomer is indicated schematically in Fig. 2. by full lines, the main absorption peaks of the *m*-isomer are indicated by dotted lines; these patterns are similar to those of *p*- and *m*-toluenesulfonic acid respectively (13). The ratio of the *p*- and *m*-isomer was estimated from the aromatic hydrogen pattern to be 1.0 ± 0.2.

Hindered Rotation in Carbamates: A Kinetic Anomaly

P. T. INGLEFIELD AND S. KAPLAN

Jeppson Laboratory, Chemistry Department, Clark University, Worcester, Massachusetts 01610

Received September 10, 1971

The energy barriers to hindered rotation in two carbamate structures have been measured by total line-shape analysis of the high resolution n.m.r. spectrum. Conclusions are presented concerning the influence of solvent on the nature of the transition state in such processes and the existence of frequency factors outside the normal expected range for a unimolecular transformation.

Les barrières d'énergie pour la rotation empêchée dans deux carbamates ont été mesurées au moyen d'une analyse complète raie-forme du spectre r.m.n. à haute résolution. Des conclusions sont présentées en ce qui concerne l'influence du solvant sur la nature de l'état de transition dans de tels processus et sur l'existence de facteurs de fréquence à l'extérieur du domaine normal attendu pour une transformation unimoléculaire.

Introduction

There has been considerable controversy in recent years concerning the energetics of the barrier to hindered rotation about the C—N bond in simple amide structures as determined by n.m.r. methods(1). It has become abundantly clear that in order to obtain reliable kinetic information a total line-shape analysis must be made of the steady state n.m.r. spectrum or a similar complete analysis made of the transient response of the nuclear spin system to a sequence of radio-frequency pulses (2, 3). The systematic errors inherent in these methods have been discussed at length (1–5) and it is concluded that in the high resolution method any instrumental line broadening will introduce a systematic error which will tend to increase the value obtained for the rate constant in the slow exchange region ($k < \delta$) and decrease its value in the fast exchange region ($k > \delta$). This is the most common type of error present in such studies and gives rise naturally to a low value for the Arrhenius activation energy, a low frequency factor, and consequently a large negative entropy of activation. This is readily apparent in a comparison between more recent determinations and those of an earlier vintage (3).

The above conclusions often lead the experimenter to suspect measured barriers which exhibit large negative entropies of activation for a unimolecular process. It should be pointed out, however, that although the frequency factors for most unimolecular reactions lie in the expected theoretical range of 10^{12} to 10^{14} s^{-1} (corresponding to $\Delta S^{\ddagger} \approx 0$), values are obtained outside this range if an entropy increase or decrease accompanies the formation of the transition state (6). In the case of a simple amide in solution in a polar solvent the possibility of differential solvation between the ground state and the transition state exists and caution should be used in disregarding reproducible negative entropies of activation when they may well be an indication of preferential solvation in the transition state. We will present some measurements made in this laboratory on systems which we believe fall into this category. We will comment on these measurements and those recently reported by Lemire and Thompson (7), on similar systems, with which we are in substantial agreement. We also report some conclusions concerning the nature of the transition state for the hindered rotation process in the amide structure when solvation is an important consideration.

Experimental

N:*N*-Dimethylmethylcarbamate and *N*:*N*-dimethylmethylthiocarbamate were prepared by reacting *N*:*N*-dimethylcarbamoyl and thiocarbamoyl chloride with methanol in pyridine solvent in a pressure capped bottle heated on a steam bath for 3 h. The resultant mixture was washed and extracted with ether and the compounds purified using a Hewlett Packard 776 Preparative Gas Chromatograph. Each sample was thoroughly degassed and sealed *in vacuo* in a 5 mm o.d. n.m.r. tube.

The n.m.r. measurements were made on a JEOLCO JNM-C-6OH spectrometer operating in the internal lock mode. The instrument is equipped with a variable temperature controller JES-VT-2 and the temperature monitored by means of a thermocouple placed near the sample and calibrated by

TABLE 1. Activation parameters

*No non-equivalence observed for the NMe_2 resonance.

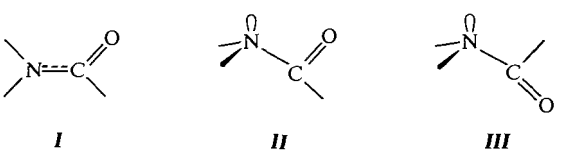
the method of Van Geet (8). The volumes used in the calibration and the samples were identical and the flow of heating air was kept constant thus minimizing any error due to temperature gradients within the sample. The sample temperatures are estimated to be accurate to $\pm 0.4°$.

The line-shape analysis of the high resolution p.m.r. spectra was accomplished by computer fitting as described previously (3). The value of the linewidth in the absence of exchange ($1/T_2^*$) was monitored at each temperature using the signal from a trace amount of $CHCl_3$ in the samples. The linewidth of $CHCl_3$ was identical to N—CH_3 at low temperatures indicating that inhomogeneity effects outweigh any quadrupolar broadening; it remained approximately constant at about 0.5 Hz. Both k (the rate constant) and $\delta\omega$ (the chemical shift between the methyl groups) were varied in order to obtain the best fit. $\delta\omega$ exhibited a small increase with temperature but did not vary appreciably over the temperature range studied. The errors quoted represent a 90% confidence interval in the least squares deviation calculations. An error propagation calculation assuming a rate constant precision of 2%, based on the criticalness of the computer fits, yields errors of approximately the same magnitude.

Results and Discussion

The results are given in Table 1 for *N*:*N*-dimethylmethylcarbamate and *N*:*N*-dimethylmethylthiocarbamate together with those of Lemire and Thompson (7). The results clearly demonstrate reproducible negative values of $\Delta S^{\ddagger}$ for the hindered rotation process. In the $Me_2NC(O)OMe$ case we observed no splitting of the —NMe_2 peak at low temperatures in the neat liquid in agreement with previous workers and in the 10 mol % solution in $CDCl_3$ a chemical shift of 1.8 Hz at 60 MHz was apparent at -23 °C, indicating considerable solvent interaction. Because of the small shift the precision on the activation parameters in this molecule is low. In the $Me_2NC(S)OMe$ molecule the chemical shift is much larger: $\delta = 11.9$ Hz in the neat liquid and $\delta = 15.0$ Hz in the 10 mol % solution in $CDCl_3$; again indicative of considerable solvation with the polar solvent. The activation parameters for this molecule are in good agreement with those obtained by Lemire and Thompson.

It is well known that the ground state structure in these molecules is planar or nearly planar due to the delocalization of the lone pair of electrons on nitrogen (**I** in Fig. 1) giving rise to the partial double bond character of the N—C bond. On rotation about the N—C bond breakdown of the conjugation between the N lone-pair π electrons and the carbonyl π-system would be expected with a corresponding change in hybridization at the N atom. The resulting trigonal pyramid configuration at the N atom leads to two possible transition states (**II** and **III** in Fig. 1). Support for the existence of these configurations has been recently reported from the results of a molecular orbital calculation in the CNDO/2 approximation (9) for possible configurations of the transition state for the hindered rotation in formamide. The CNDO study also confirms that $\mu_{II} > \mu_I > \mu_{III}$ and excellent agreement is obtained with the experimental dipole moment in the ground state configuration (**I**). The predicted energy difference between **II** and **III** is small and **II** could easily be the favored structure in a polar media due to mutual dipole–dipole interactions. Since $\mu_{II} > \mu_I$ preferential solvation in the transition state could easily account for the negative values obtained for



I *II* *III*

$\Delta S^{\ddagger}$. In the neat liquids the results are more difficult to rationalize unless a larger mutual dipole–dipole interaction leads to a decrease in entropy in transition state **II**. The large negative entropy of activation obtained for the cyclohexane solution of $Me_2NC(S)OMe$ by Lemire and Thompson is not in agreement with this explanation. However, we feel that the agreement between both laboratories in the results in polar media is the overriding consideration. The lower energy barriers obtained for these carbamates in comparison to many other amides (1, 3) is felt to be due to a slight decrease in C—N bond order caused by the inductive effect of the electronegative OCH_3 group.

In conclusion, we can say that considerable caution must be used in evaluating data on hindered rotations in amides since in view of our conclusions the possibility of having a negative $\Delta S^{\ddagger}$ for the process is not unreal. It is unfortunate that the precision of the frequency factor (or $\Delta S^{\ddagger}$) determination is so low in the n.m.r. method otherwise it would be possible to obtain detailed information on the exact nature of the transition state from a variable solvent study.

Canadian Journal of Chemistry, **50**, 1596 (1972)

Introduction

The platinum–ethylene bonding in Zeise's salt and the metal insertion into the double bond exhibits unusual features.

There have been conflicting reports concerning the platinum–olefin vibrations in the i.r. spectrum of Zeise's salt (1, 2) and similar platinum–olefin complexes (3, 4). The i.r. spec-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

trum of Zeise's salt has been investigated by many investigators (1–5). The platinum–olefin vibrations have been assigned in Zeise's monohydrate salt, but the presence of water of crystallization in the molecule obscured the 500 cm^{-1} region and resulted in a controversy over the Pt–olefin band assignments (2, 5).

The early work of Babuskin *et al.* (5*c*), which was the first attempt to interpret all the bands of the molecule, showed that the ethylene double bond, on complexation, becomes single and that the Pt—C bond strength was quite similar to a normal covalent bond. The recent vibrational studies of Hiraishi (2*b*), as well as the earlier work of Pradilla-Sorzano and Fackler (2*a*), are in agreement with the conclusions of the Russian workers.

Powell and Sheppard (5*b*) studied the n.m.r. spectra of a number of olefin complexes including Zeise's salt and came to the conclusion that the C—C bond is a weakly perturbed double bond and that the olefinic molecule is firmly bound to the platinum. This conclusion seems to be contradictory.

Earlier, Chatt and Duncanson (10), from a few features of the i.r. spectra of Zeise's salt, namely, a weak absorption in the region 1500–1525 cm^{-1}, concluded that this very weak band was due to the C=C double bond absorption lowered on complexation by 100–140 cm^{-1}. This interpretation implies a weakly perturbed double bond. However, the molecular model they proposed, based on Dewar's model of σ- and π-bonding, indicates a strong interaction of the metal with the double bond in agreement with the high stability of their complexes. This also is a contradictory conclusion.

Zeise's salt, anhydrous and monohydrate, has been prepared by a new method similar to the original method used by Zeise.

Results

Preparation of Zeise's Salt by a New Method

The slow reduction of ethanol by an acetylenic glycol (ac = $(C_4H_9)(C_2H_5)(OH)C—C\equiv C—C(OH)(C_2H_5)(C_4H_9)$ or $(CH_3)_3C—C\equiv C—C(C_2H_5)_3$) gave as main product Zeise's salt (yield: 50–60%). The acetylenic glycol is used as a reducing agent to transform ethanol into ethylene *in situ*. Potassium tetrachloroplatinate (II) reacts with ethanol in the presence of the acetylenic glycol as follows:

$$K_2PtCl_4 + C_2H_5OH + ac \xrightarrow{H_2O} K[Pt(C_2H_4)Cl_3] + KCl + ac.H_2O$$

The complex is recrystallized from acetone–ether or water–HCl solutions.

In the above reaction, the water seems to attack the triple bond and hydration with polymerization of the acetylenic glycol takes place. The acetylenic ligand could not be recovered after the reaction and a brown oil was always formed. The presence of the acetylenic glycol and of ethanol are essential for the preparation, since it was impossible to isolate the Zeise's salt without one of them. The reaction is similar to the method used by Zeise to prepare $K[Pt(C_2H_4)Cl_3].H_2O$

$$PtCl_2 + KCl + C_2H_5OH \xrightarrow{\Delta} K[Pt(C_2H_4)Cl].H_2O$$

Discussion

The i.r. and laser Raman spectra of the anhydrous Zeise's salt, the i.r. spectra of the deutero and the bromo analogs are reported in Table 1. Survey i.r. spectra of the anhydrous salts, $K[Pt(C_2H_4)Cl_3]$, $K[Pt(C_2D_4)Cl_3]$, and $K[Pt(C_2H_4)Br_3]$ and the hydrated salt $K[Pt(C_2H_4)Cl_3].H_2O$ are shown in Figs. 1 and 2. Laser Raman spectra are shown in Fig. 3.

The spectrum of the monohydrate salt is identical to that reported by Nakamoto and Grogan (1).

From the spectra, it is evident that the band at 490 cm^{-1} cannot be assigned to water of crystallization, since the band is present in the spectra of the hydrated salt, in the anhydrous salt and also in the bromo analog. It cannot be assigned to a combination band, since both complexes $K[Pt(C_2H_4)Cl_3]$ and $[Pt(C_2H_4)Cl_2]_2$ show an absorption band around 490 cm^{-1} and their far i.r. spectra are very different from each other. Similarly, this band is observed in the spectra of the complexes $[(Pt(C_2H_4)Cl_2)_2en]$, $[(Pt(C_2D_4)Cl_2)_2en]$, $[(Pt(C_2H_4)Br_2)_2en]$, and of $[(Pt(C_2H_4)ClBr)_2en]$ (6).

Both bands at 490 and 400 cm^{-1} are due to Pt—C stretchings. The assignment was carried out according to Hiraishi (2*b*). The bands at 400 cm^{-1} (ν_5) and at 490 cm^{-1} (ν_{12}) are respectively assigned to the symmetric and the anti-

symmetric Pt—C stretching vibrations. These bands are shifted on deuteration to 384 and 450 cm^{-1} and are found at 393 and 484 cm^{-1} for the bromo analog. The Raman band at 1253 cm^{-1} is assigned to C—C (ν_3) stretching (2*b*) from polarization data and the band at 299 cm^{-1} has been assigned to the Pt—Cl (*trans*) symmetric stretching. The 212 cm^{-1} band can be tentatively assigned to the PtC_2 rocking (2*b*) and the 180 cm^{-1} band to the Cl—Pt—Cl in-plane deformation (3*b*).

The recent X-ray study on the Zeise's salt monohydrate showed that the two types of platinum–chlorine bond (*i.e. cis* and *trans*) lengths are within one e.s.d. Therefore the difference in length cannot unambiguously be attributed to the *trans*-influence, since the surroundings of the chlorine atoms are different (7). An older neutron diffraction study (9) indicates that the four hydrogen atoms of the ethylene lie in a plane. The two carbon atoms are 0.18 Å above this plane toward the platinum atom. Thus the hydrogen atoms bend back significantly (9) and this should be consistent

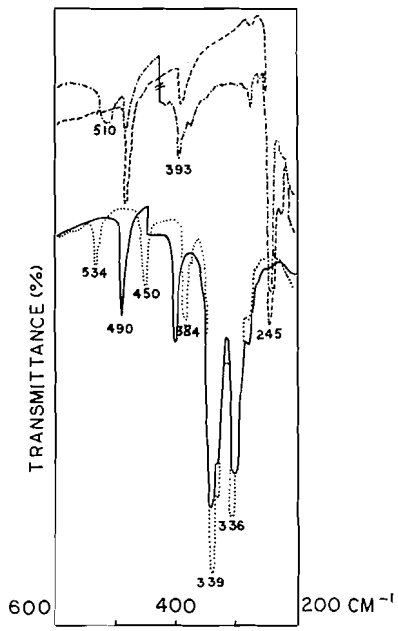

FIG. 2. Infrared spectra of Zeise's salt anhydrate (—); its deutero analog (...), the bromo analog monohydrate (-.-.-.), and the bromo analog anhydrate (---), in the region 600–200 cm^{-1} in Nujol mulls and between CsI plates.

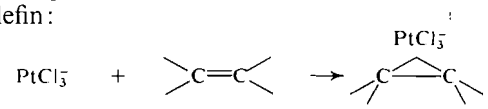
with a strongly perturbed C—C bond. However, the authors (9) reported a C—C length of 1.354 (15) Å compared to 1.37 (3) Å obtained by X-ray diffraction (7). These distances are fairly short, but the uncertainties on the bond lengths are relatively great and the values should be interpreted with great care.

The two platinum–carbon bond distances are not significantly different (2.121 (19) and 2.134 (19) Å). These values are not too far from a platinum–carbon σ-type bond (2.076) (15) Å (8).

A ring structure with two Pt—C— σ-type bonds and one C—C single bond with some double bond character as in the case of cyclopropane or ethylene oxide is considered for $(CH_2)_2Pt$ to interpret the vibrational spectra (2*a*, 5*c*). This model can be obtained by insertion of the platinum atom into the double bond of the olefin:



$PtCl_3^-$ seems to be similar in its chemical properties to CH_2 in cyclopropane, indicating that

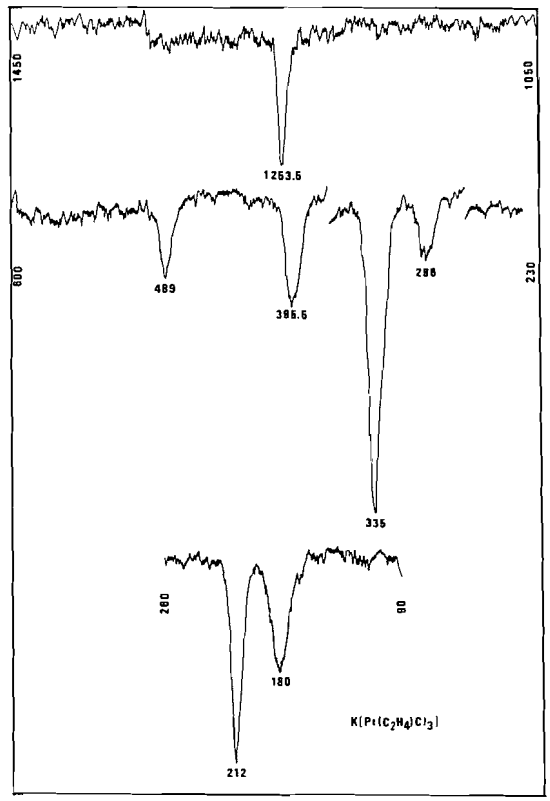


FIG. 3. Laser Raman spectra of the Zeise's salt anhydrate.

$PtCl_3^-$ has an electron affinity comparable to that of the group X in the series of molecules $X(CH_2)_2$, where X = CH_2, O, S, HN, *i.e.*, the molecules cyclopropane, ethylene oxide, ethylene sulfide, and ethylene amide. The angle $C\hat{X}C$ is decreasing as the atom X increases in size, cyclopropane (67°), ethylene oxide (60°), ethylene sulfide (48°), and Zeise's salt (39°) seems to fall well in the trend.

Experimental

The i.r. spectra between 4000 and 200 cm^{-1} were obtained with a Perkin–Elmer 621 i.r. spectrophotometer. Nujol or C_4Cl_6 mulls and KBr or CsI techniques were employed to record the spectra. Calibration of the frequencies was made with a polystyrene film and water vapor. Raman spectra were obtained with a Jarell Ash Raman spectrophotometer using He–Ne laser excitation at 6328 Å. The samples were examined as crystalline powders.

$K[Pt(C_2H_4)Cl_3].H_2O$ was prepared according to the method described by Chatt and Duncanson (10). The anhydrous salt $K[Pt(C_2H_4)Cl_3]$ was obtained by recrystallization

in 4 *N* hydrochloric acid. The water and HCl were evaporated in a desiccator under reduced pressure.

The salt was also prepared by the following method: potassium tetrachloroplatinite (0.002 *M*) was dissolved in 15 ml of water and the solution was filtered. A solution of 10 ml of 5,8-diethyl-6,6-dodecyne-5,8 diol or 2,2-dimethyl-5,5-diethyl-3-heptyne (0.005 *M*) in ethanol was added to the above solution. The mixture was stirred for a few minutes and left for a week. It was then filtered and the filtrate evaporated to dryness. The residue was washed with anhydrous ether and dissolved in 20 ml acetone. This was filtered and evaporated to dryness. Finally Zeise's salt was recrystallized slowly in a refrigerator in a mixture of acetone–anhydrous ether. Yield, 60%.

$K[Pt(C_2D_4)Cl_3]$ was prepared using ethylene-d_4 gas in D_2O and following the method described in ref. 10.

$K[Pt(C_2H_4)Br_3].H_2O$ was prepared by the above method (10) using a water solution of K_2PtBr_4. The red colored complex is extracted with acetone and recrystallized from acetone–ether. The i.r. spectrum of the complex was identical to the reported spectrum (2*a*).

$K[Pt(C_2H_4)Br_3]$ anhydrous was obtained by recrystallization in tetrahydrofuran or in 4 *N* hydrobromic acid and following the procedure as for $K[Pt(C_2H_4)Cl_3]$.

We wish to thank Johnson, Matthey and Mallory Ltd., for the loan of platinum chloroplatinite and the National Research Council of Canada for financial assistance. Many thanks also to Dr. I. S. Butler, McGill University for the use of the Jarell Ash Raman spectrophotometer.

Conductivity and Viscosity of the Tetrabutylammonium Bromide – Carbon Tetrachloride System

K. F. DENNING AND JAMES A. PLAMBECK

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 20, 1971[1]

Conductivity and viscosity measurements have been made on tetra-*n*-butylammonium bromide–carbon tetrachloride solutions for the mole ratio range 1:40 to 1:2 at temperatures from 25 to 40 °C. At any individual concentration, both conductivity and viscosity follow an Arrhenius type temperature dependence. Viscosity increases exponentially with tetrabutylammonium bromide concentration while conductivity has a maximum at approximately 1:5 mole ratio $R_4NBr-CCl_4$.

Des mesures de conductivité et de viscosité ont été effectuées sur des solutions constituées d'un mélange de bromure de tétra-*n*-butylammonium-tétrachlorure de carbone; les rapports molaires utilisés varient de 1:40 à 1:2 pour des températures allant de 25 à 40 °C. Pour chaque concentration individuelle, la conductivité ainsi que la viscosité dépendent de la température par une relation du type d'Arrhénius. La viscosité augmente d'une façon exponentielle avec la concentration en bromure de tétrabutylammonium, alors que la conductivité passe par un maximum pour un rapport molaire de 1:5 $R_4NBr-CCl_4$.

studying interesting electrochemical reactions, as will be reported elsewhere, and in this paper report the viscosity, conductivity, and density of the tetrabutylammonium bromide–carbon tetrachloride system. The concentrations considered correspond to a mole ratio range of 1:40 tetrabutylammonium bromide:carbon tetrachloride, where the solution was free-flowing, to 1:2 where the solution was extremely viscous. In this range the terms solute and solvent do not have any meaningful connotations and it is probably better to consider such mixtures as quasi-molten salts.

The literature of the dilute solutions dates back to the classic work of Walden (2) and Fuoss and Krauss (3). The latter measured the conductivity of tetraalkylammonium salts in benzene (dielectric constant 2.28 at 20 °C; that of carbon tetrachloride is very similar, 2.24) and, at concentrations far lower than those used in the present work, *i.e.* less than 0.2 *M*, observed a minimum in the equivalent conductivity *vs.* concentration curve. This was interpreted on the basis of ion association equilibria. Lind and Sageman (4) worked from the other end of the concentration scale. These authors measured the conductivities of fused tetraalkylammonium salts to which up to 0.06 mole fraction of nonelectrolytes had been added. They held that the observed increase in specific conductivity on these additions was due to the reduction in total friction on a given ion as the number of its ionic neighbors decreased. In the present study it was found that mole fractions of tetrabutylammonium bromide as high as those used by Lind and Sageman could be obtained only at high enough temperatures that decomposition of the halide became rapid. When cooled these highly viscous liquids became glassy solids. The highest concentration obtainable for a liquid at 30 °C was slightly over a 1:2 mole ratio of tetrabutylammonium bromide:carbon tetrachloride. The bromide salt was chosen as being the best compromise between high solubility and ease of solution preparation. The behavior of the other tetrabutylammonium halides is similar, insofar as our few studies have indicated, and that of some other tetraalkylammonium halides with smaller alkyl groups is somewhat similar although the solubilities in carbon tetrachloride are usually much lower.

Experimental

Chemicals

The tetra-*n*-butylammonium bromide (No. 7377, Eastman Organic Chemicals Ltd.) was dried under vacuum (5) or purified by dissolution in carbon tetrachloride and removal of solvent, followed by recrystallization from ethyl acetate and drying. The m.p. of material from either treatment was 117–119 °C, and no difference in conductivity due to treatment was observable. The carbon tetrachloride (Mallinckrodt Analytical Reagent) was used as supplied; use of redistilled material produced no observable change in solution conductivities.

Apparatus

Conductivities were measured at 1 kHz using a General Radio Company 1650-A Impedance Bridge. The Pyrex cell used platinized platinum electrodes 1 cm × 1 cm approximately 1 cm apart; the cell constant was determined with aqueous KCl before and after the series of determinations and found to be 0.717 cm. Viscosities were measured with a calibrated Cannon-type viscometer. Densities were obtained from the weight of an accurately measured volume of liquid and used to calculate the volume mole fractions given in Table 1.[2] All experiments were carried out in a water bath (Gebruder Haake, Type NBE) thermostated to ±0.05 °C and the temperature range for all data was 25 to 40 °C.

Procedure

Sets of measurements for both conductivity and viscosity were made with increasing and decreasing temperatures; no differences were noted, indicating no decomposition at 40 °C over the few minutes required for measurement. Decomposition was observed at higher temperatures. Six to ten temperatures were used in each set. These data, a summary at 30 °C, and the least-squares results for the Arrhenius form discussed below have been placed in the Depository of Unpublished Data. Least-squares calculations were carried out with the aid of the IBM 360/67 computer at the University of Alberta. Copies of the programs used are obtainable from the authors.

Results and Discussion

The viscosity at 30 °C increases exponentially with concentration over the range accessible in these experiments (Fig. 1). The analogous plot for specific conductivity, Fig. 2, is quite different, showing first an increase and then a decrease. The maximum appears in the region of approximately 1:5 mole ratio of tetrabutylammonium bromide to carbon tetrachloride.

The temperature dependence of conductivity (Λ) and viscosity (ν) at any individual concentration follows the expected Arrhenius form, *i.e.* $\Lambda = Ae^{-B/T}$ and $\nu = A'e^{B'/T}$, very well. The relationship between exponential terms and

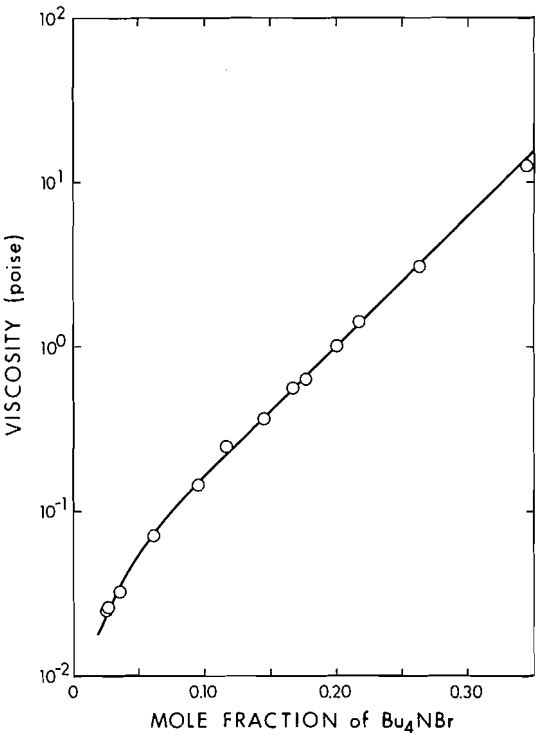

FIG. 1. Viscosity as a function of mole fraction of Bu_4NBr.

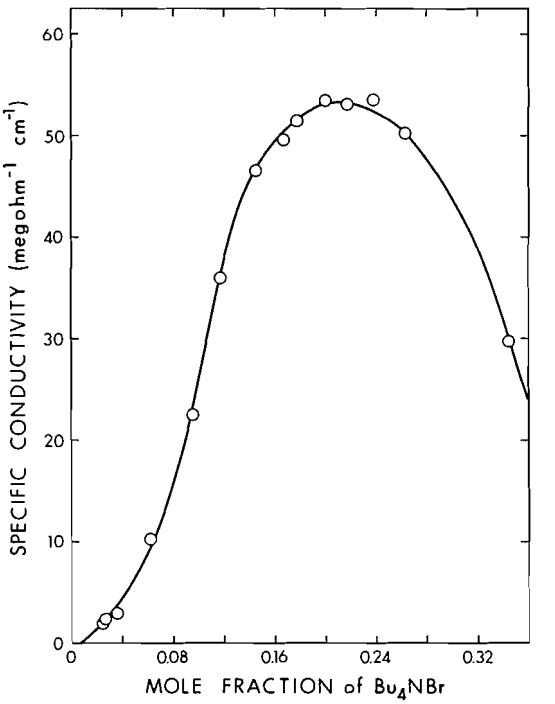

FIG. 2. Specific conductivity as a function of mole fraction of Bu_4NBr.

concentration is shown in Fig. 3, where the *B, B′* parameters are expressed as free energies of activation. The free energies of activation in the "dilute solutions" of the salt in carbon tetrachloride obtained from these conductivity measurements are in excellent agreement with the value of 1.96 kcal/mol calculated for the *pure fused tetrabutylammonium bromide* from the conductivity data of Lind *et al.* (5). It is not surprising that the free energy of activation from the viscosity data does not agree as the mechanisms for the two processes are different (6). In both cases the free energy of activation increases rapidly as the mole fraction of salt increases beyond 0.2, indicating that mass transport becomes much more difficult; on the basis of the data of Lind *et al.*, this should be followed by a subsequent decrease in the free energy of activation. Such a peaking behavior has previously been observed by Bloom (7) in ionic salt–ionic salt binary melts and by Boston, Grantham and Yosim (8) in $AlCl_3$–KCl mixtures, where it is ascribed to compound formation at the peak composition.

The formation of one or more complexes between the salt and carbon tetrachloride would be in general agreement with the observed change in conductivity with concentration shown in Fig. 2, although the rapid increase in viscosity with concentration alone should bring about some decrease in conductivity. The two are related, although not simply, since their product cannot be expected to be a constant in this concentration range. A complex at mole ratio 1:4.8 (and others at 1:1 and 2:1) was found by McDaniel and Deiters (9) through isothermal vapor pressure measurements on the tetrabutylammonium chloride–carbon tetrachloride system, and similar complexes are expected here.

The molar conductivity of these solutions in the peak region is approximately 0.03 cm^2 ohm^{-1} mol^{-1} at 25 °C, which is intermediate between that of highly conducting media, such as aqueous tetrabutylammonium bromide whose molar conductivity is 97.6 cm^2 ohm^{-1} mol^{-1} (10), and the virtually nonconducting carbon tetrachloride. It appears to be significantly greater than the molar conductivity of pure

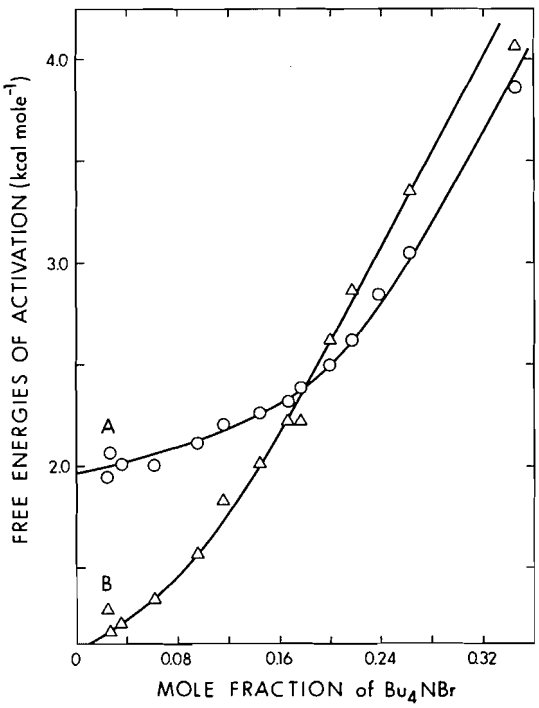

FIG. 3. Free energies of activation as a function of mole fraction of Bu_4NBr; Curve *A*, conductivity data; curve *B*, viscosity data.

fused tetrabutylammonium bromide, which we calculate as 0.012 cm^2 ohm^{-1} mol^{-1} by extrapolation of the data of Lind *et al.* (5) to 25 °C, but the extrapolation is well beyond the temperature range in which these authors' measurements were made.

The concentration–conductivity of the 1:5 mole ratio mixture permits cell resistances as low as 10 000 ohms at room temperature in reasonably practical electrolysis cells, and this mixture was therefore selected for further investigation.

The authors wish to thank the National Research Council of Canada for financial support.

Equilibrium Dissociation Pressures of $NbBr_5$ over $NbBr_4$

A. D. WESTLAND AND D. LAL
Department of Chemistry, University of Ottawa, Ottawa, Canada, K1N 6N5

Received December 9, 1971

Equilibrium pressures of the dissociation of niobium tetrabromide into pentabromide and tribromide:

$$(5-x)NbBr_4(s) \rightleftharpoons NbBr_x(s) + (4-x)NbBr_5(g)$$

where x lies in the range 2.67 to 3.03 have been measured over the temperature range 275–365 °C. The dissociation pressures were determined by measuring the dew points of $NbBr_5$ vapor in a closed system containing $NbBr_4$ and $NbBr_x$. The equilibrium decomposition pressure of $NbBr_4$ at a given temperature was found to be much lower than that of $NbCl_4$, thereby indicating that $NbBr_4$ is significantly more stable than $NbCl_4$.

Les pressions d'équilibre pour la dissociation du tétrabromure de niobium en pentabromure et tribromure:

$$(5-x)NbBr_4(s) \rightleftharpoons NbBr_x(s) + (4-x)NbBr_5(g)$$

où x appartient au domaine allant de 2.67 à 3.03, ont été mesurées sur l'échelle de température 275–365 °C. Les pressions de dissociation ont été déterminées par la mesure du point de rosée de la vapeur de $NbBr_5$ dans un récipient fermé, contenant $NbBr_4$ et $NbBr_x$. La pression d'équilibre à la décomposition de $NbBr_4$, pour une température donnée, est beaucoup plus basse que celle de $NbCl_4$; ceci indiquant que $NbBr_4$ est plus stable que $NbCl_4$.

Canadian Journal of Chemistry, **50**, 1604 (1972)

Introduction

There is a lack of thermochemical data for compounds of less familiar elements such as niobium and tantalum. For example, there is considerable disagreement in the literature regarding the melting point of $NbBr_5$. Whether this variation is due to impurities in the various samples or other experimental errors is not clear.

The tetrahalides of niobium undergo thermal disproportionation (1, 2) to the corresponding pentahalide and a lower halide at elevated temperatures according to the equation:

$$(5-x)NbBr_4(s) \rightleftharpoons NbBr_x(s) + (4-x)NbBr_5(g)$$

where x may vary between the limits 2.67 and 3.03 (2). Thus a knowledge of equilibrium pressures of NbX_5 is desirable for work with these compounds at elevated temperatures. In the preparation of NbX_4, it is necessary to maintain a high pressure of NbX_5 by having an excess of NbX_5 present as a liquid. Moreover, knowledge of the decomposition pressures of NbX_5 is extremely important in the difficult separation of the pure metals niobium and tantalum.

Schäfer, Bayer, and Lehmann (3) have measured the decomposition pressures of $NbCl_5$ over $NbCl_4 + NbCl_x$ by a dew point method. We have used their technique to measure the equilibrium dissociation pressures of $NbBr_5$ over $NbBr_4$ and $NbBr_x$. The dew point method permits the determination of pressure of the major component in a gaseous mixture of $NbBr_5$, $NbBr_4$, and $NbOBr_3$.

Experimental

The design of the apparatus and the experimental procedure employed have been described in detail by Schäfer *et al.* (3).

Apparatus

The apparatus was a Pyrex glass vessel, 20 mm in diameter and about 100 mm long, which contained the sample to be studied. A cold finger, for observing the $NbBr_5$ condensate, extended about 20–25 mm into the upper part of the vessel. The cold finger contained a constant boiling liquid, a heater, and a thermocouple. The temperature of the liquid in the cold finger was adjusted by means of a manostat which controlled the pressure over the liquid. A vapor mantle surrounded the upper part of the reaction vessel and its temperature was kept well above the dew point temperature so that condensate only appeared on the cold finger and not on the inner surface of the reaction vessel.

Measurement

The sample was transferred to the reaction vessel in a rigorously dry nitrogen atmosphere. The temperature of the solid sample was adjusted by an aluminum block, the temperature of which was measured close to the solid sample and kept constant to ± 0.2 °C. The temperature of the vapor mantle was kept about 20° higher than the dew point temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

To effect a measurement, the temperature in the cold finger was lowered from a point about 20° above the dew point until the condensate appeared on the upper part of the cold finger. A slight raising of the temperature caused the condensate to disappear.

Initially the dew point was approached from above by lowering the temperature in steps of 5°, followed by 2° steps, and finally in steps of 0.5°. This was repeated several times to get consistent readings.

The observation of the condensate at the cold finger was done with the aid of adequate lighting and a magnifying lens. Much care was taken to distinguish between liquid and crystalline condensate. A crystalline condensate of $NbBr_5$ was red-orange and its whisker-like growth on the cold finger was easily recognized. Appearance of liquid condensate, which was very deep orange, was somewhat more difficult to observe.

At high furnace temperatures, fine needles of $NbBr_4$ deposited on the cold finger but this deposition caused little interference in the observation of the dew point. Moreover, it was an easy matter to sublime the $NbBr_4$ crystals back to the bottom part of the reaction vessel by placing the vessel in a temperature gradient.

The unavoidable presence of $NbOBr_3$, in small amounts, caused problems in the initial stages of the measurements. Its appearance on the cold finger was similar to that of $NbBr_5$ crystals. However, with little experience it was possible to differentiate between the shiny orange-red crystals of $NbBr_5$ and the dull yellow-brown crystals of $NbOBr_3$. It should be mentioned that $NbOBr_3$ may dissolve in liquid $NbBr_5$. Schäfer and Pietruck (4) have shown that in the case of the chloride, the solubility was rather small and it did not markedly affect the saturation pressure of $NbCl_5$. We expect that the bromide system is similar in this respect.

The static method employed here for measuring the vapor pressure is superior to the dynamic method because the former method allows the equilibrium to be established over a period of time while the dynamic method requires the equilibrium to be established instantaneously. Schäfer and Dohmann (5) have shown that in the case of $NbCl_4$ decomposition, equilibrium is established only slowly. We would expect that the bromide system would show essentially the same behavior. To ensure that the equilibrium was established, we proceeded in the following way: The aluminum furnace was heated to a predetermined temperature. Readings were carried on for several days and the dew point remained unchanged. Then the temperature of the furnace was altered by ±3° and the dew point redetermined. A corresponding change of a few degrees in dew point was observed. Return to the original furnace temperature gave the original dew point. The changes in the vapor pressures with respect to temperature were too great to be accounted for by temporary Boyles' Law expansion. Therefore the changes in pressure are attributable to shifts in the equilibrium and the pressures are reproducible with respect to furnace temperature.

Results and Discussion

The dew point measurements are given in the curves of Fig. 1. The results of two different samples show excellent agreement. In Fig. 1 the two segments of the plot corresponding to solid and liquid condensed phases intersect at the melting point of $NbBr_5$. Table 1 gives melting points obtained by various workers.

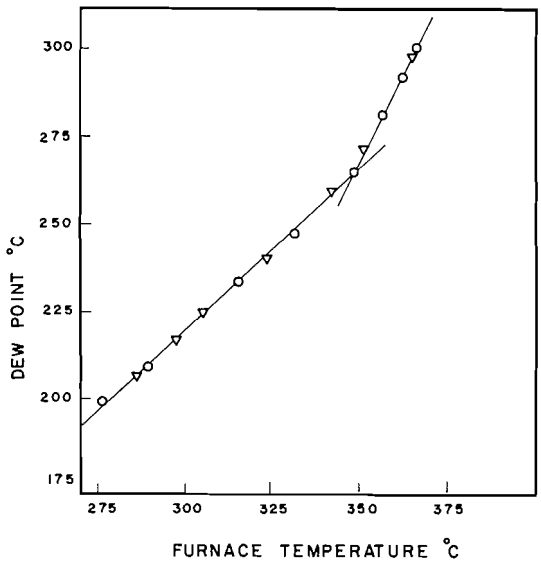

FIG. 1. The variation of dew point with furnace temperature: ○, sample No. 1; △, sample No. 2.

TABLE 1. Melting point data for $NbBr_5$

Melting point (°C)	Reference
254	6
255	7
267.5	8
265.2	9
264.5	This work

To utilize the dew point data, saturation pressures of $NbBr_5$ were needed. Two previous investigations of the vapor pressures of $NbBr_5$ have been reported. Alexander and Fairbrother (8) employed a static method using a Bourdon type gauge. We evaluated their data for temperatures above 239° by the method of least squares and obtained the following equations for the temperature dependence of vapor pressure:

$$\log_{10} p = 13.17 \pm 0.15 - (6.17 \pm 0.01)\frac{10^3}{T} \qquad (239\text{–}269\ ^\circ\text{C})$$

$$\log_{10} p = 9.30 \pm 0.06 - (4.08 \pm 0.01)\frac{10^3}{T} \qquad (270\text{–}360\ ^\circ\text{C})$$

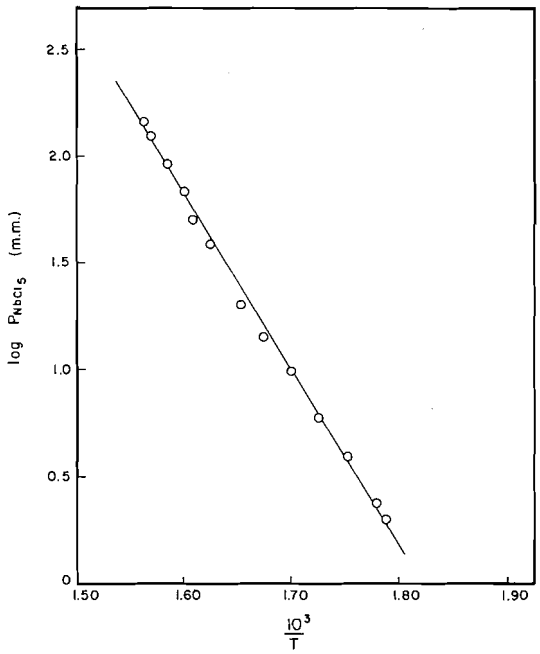

FIG. 2. Equilibrium decomposition pressures of $NbBr_5$ over $NbBr_4$.

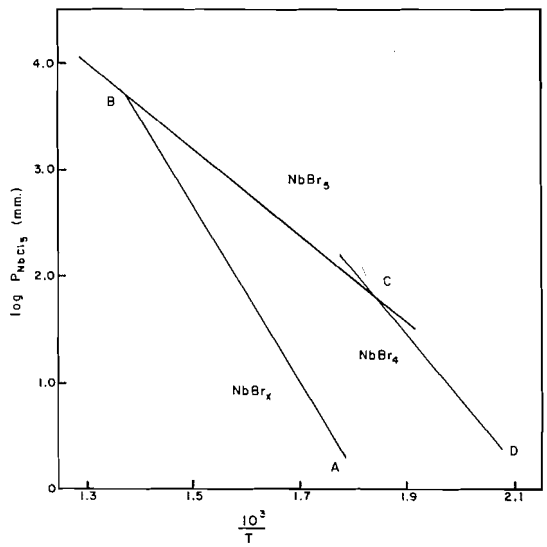

FIG. 3. Existence regions of various niobium bromide phases.

Berdonosov *et al.* (6) employed a radioactive tracer technique to a static method to obtain their data. They give the following equations for the dependence of vapor pressure on temperature

$$\log_{10} p = 12.52 \pm 0.33 - (5.782 \pm 0.158)\frac{10^3}{T}$$

(205–252 °C)

$$\log_{10} p = 9.784 \pm 0.260 - (4.347 \pm 0.147)\frac{10^3}{T}$$

(252–350 °C)

There is reasonably good agreement between the two sets of results only for the higher temperatures. Berdonosov *et al.* certainly show many more experimental points at low temperatures. However, our melting point value (Table 1) differs considerably from that given by Berdonosov *et al.* but agrees well with that of Alexander and Fairbrother. For this reason and also because Alexander and Fairbrother used direct pressure measurements, we have chosen to use their data.

Decomposition Pressures of $NbBr_4$

Saturation pressures of $NbBr_5$ at the dew point correspond to the decomposition pressures of $NbBr_4$. The decomposition pressures are given in Fig. 2. The following equation for the temperature dependence of decomposition pressures was obtained by the method of least squares

$$\log_{10} p\text{NbBr}_5 \text{ (over NbBr}_x \text{ and NbBr}_4) =$$

$$15.02 \pm 0.38 - (8.25 \pm 0.03)\frac{10^3}{T}$$

The straight line in Fig. 2 was obtained by the use of the above equation.

Figure 3 shows the existence region of solid $NbBr_4$. Line AB is the dissociation pressure curve obtained in this work. Below this line $NbBr_x$ and $NbBr_5$ vapor do not react to form $NbBr_4$. The line BCD is the vapor pressure curve for solid and liquid $NbBr_5$. Thus the tetrabromide phase is stable only within the conditions bounded by the figure ABCD. The maximum temperature region at which solid $NbBr_4$ can exist is found from Fig. 3 to be approximately 454°. It is assumed in the diagram that $NbBr_4$ is insoluble in liquid $NbBr_5$. One would expect as in the chloride system (10) that $NbBr_4$ is soluble in liquid $NbBr_5$. This would cause some reduction in the vapor pressure of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

liquid $NbBr_5$ and the line BC would be depressed. Consequently, the quadruple point would also be somewhat lower than the point indicated. That this is not too serious an error is seen from the melting point data for $NbBr_5$ in Table 1, which indicates that the solubility of $NbBr_4$ in liquid $NbBr_5$ is not substantial.

A comparison of the $NbBr_4$ and the $NbCl_4$ decompositions indicates that the bromide is much the more stable compound. At 300° we obtained a pressure of 4.3 Torr for the $NbBr_5$ pressure while Schäfer *et al.* (3) obtained 230 Torr for the pressure over $NbCl_4$ at 300°.

The coefficient of the temperature dependent term in the equation for $\log p$ leads to a value of 37.8 kcal for the heat of the decomposition reaction producing 1 mole of $NbBr_5$ vapor. This corresponds to the decomposition of $(5-x)/(4-x)$ moles of $NbBr_4$. The composition of the lower bromide should lie close to the upper limit of its homogeneity range, *i.e.* x should be about 3.03 (2). However, as x may vary somewhat with temperature, its value is uncertain and the reaction is not well defined. The above value for the heat of reaction should be understood accordingly.

A Convenient Synthesis of Monobromogermane

J. W. Anderson, G. K. Barker, J. E. Drake[1] and R. T. Hemmings
Department of Chemistry, University of Windsor, Windsor, Ontario

Received December 23, 1971

Monobromogermane, GeH_3Br, is conveniently prepared by the reaction of boron tribromide with germane.

Le monobromogermane, GeH_3Br, est aisément préparé par action du tribromure de bore sur le germane.

Canadian Journal of Chemistry, **50**, 1607 (1972)

The most common starting materials for studies of germyl compounds are the monohalogenogermanes, GeH_3X (X = F, Cl, Br, I). We wish to report a preparative method for monobromogermane which we believe has some advantages over the previously reported methods.

Monobromogermane was first prepared from germane and hydrogen bromide with an aluminum bromide catalyst (1) but the yields are as low as 10% (2). A particular disadvantage of this method is that the product tends to undergo decomposition possibly because of trace amounts of aluminum bromide carried over from the reaction vessel. A second method involves repeatedly passing germane over heated silver bromide (3) giving yields of 30%. A frequently used method is the reaction of bromine and germane (4). Although yields as high as 91% have been claimed for this reaction, it requires a large number of additions and separations and even with care the optimum yields are

seldom attained. Monobromogermane may also be prepared from germane and thionyl bromide in high yields (5) but there are difficulties involved in purifying and handling thionyl bromide.

We have found that monobromogermane is conveniently prepared from germane and boron tribromide according to reaction 1 in yields of over 70%.

$$[1] \qquad 6GeH_4 + 2BBr_3 \rightleftharpoons 6GeH_3Br + B_2H_6$$

After the two reactants are mixed and left at $-78°$ for 1–2 h, the pure GeH_3Br can be readily separated from the reactants or other products. Adherence to experimental conditions such as the starting ratio of reactants provides consistently high yields.

Experimental

The reactions were carried out on a conventional Pyrex–glass vacuum line. The typical reaction vessel (a flask with cold-finger for condensing in reactants and a ball-joint for connection to the vacuum line) had a capacity of *ca.* 250 ml. Germane (Mathieson) and boron tribromide (Alfa) were obtained commercially. They were degassed at -196 and $-78°$, respectively, and their purity checked by their i.r. spectra (6, 7) which were recorded on a Beckman IR 12 spectrometer. Boron tribromide (1.1 mmol) and germane (3.9 mmol) were condensed at $-196°$ into the reaction vessel.

The $-196°$ bath was replaced with a $-78°$ bath (Dry Ice–acetone) and the mixture left for 1–2 h. The volatile products were then distilled from the reaction vessel leaving traces of an unidentified yellow solid, and passed through a series of U-traps surrounded by baths at $-45°$ (fraction *A*), $-95°$ (fraction *B*), and $-196°$ (fraction *C*). The contents of the $-95°$ trap (fraction *B*) were again passed through traps at -63, -95, and $-196°$ when the $-95°$ fraction was pure monobromogermane (2.9 mmol). It was initially identified by its vapor pressure and i.r. spectrum (1, 4) and its purity further checked by its ^1H n.m.r. spectrum (8).

The unreacted germane could be recovered from fraction *C* which consisted of diborane and germane which were identified spectroscopically (9, 6). The mixture was condensed into a large excess of triethylamine and the products volatile at $-78°$ were distilled off. Further passage through a trap at $-126°$ gave germane (0.6 mmol) in a trap at $-196°$. The fraction *A* was shown spectroscopically (8, 10) to be small quantities of dibromogermane.

We wish to thank the National Research Council of Canada for financial support.

Formation Constants of Copper(II) and Zinc(II) with *N*-salicylideneanthranilic Acid in 50–50 Water–dioxane

R. K. MEHTA AND R. K. GUPTA
Department of Chemistry, University of Jodhpur, Jodhpur, India

Received June 29, 1971

Protonation constants of *N*-salicylideneanthranilic acid and formation constants of its Cu(II) and Zn(II) complexes have been studied potentiometrically in 50% dioxane (vol/vol) solutions ($\mu = 0.1$ sodium perchlorate) at 30 ± 0.2 °C. The color changes observed during titrations have been related to the formation of different complex species in solution. The formation constants are in fair agreement with the Irving and Williams rule.

On a étudié au moyen de méthodes potentiométriques les constantes de protonation de l'acide *N*-salicylidène anthranilique et les constantes de formation de ses complexes avec Cu(II) et Zn(II), dans des solutions (vol/vol) 50% dans le dioxanne ($\mu = 0.1$ perchlorate de sodium), à 30 ± 0.2 °C. Les changements de couleur observés pendant les titrages ont été associés à la formation des différents complexes dans la solution. Les constantes de formation sont en accord avec la règle de Irving et Williams.

Canadian Journal of Chemistry, **50**, 1609 (1972)

Introduction

N-salicylideneanthranilic acid (H_2SA) reacts with different metal ions to form colored compounds in aqueous solution. Although the magnetic data of some of its solid complexes including those of Cu(II) and Zn(II) have been reported, no work appears to have been done potentiometrically for the step-wise formation of these complexes in solution (1, 2). It was, therefore, considered interesting to investigate these complexes adopting the Calvin–Bjerrum p*H*-titration technique as used by Irving and Rossotti (3–5). The step-wise proton–ligand stability constants of the ligand and the metal–ligand stability constants of the metal complexes have been determined in 50% dioxane at 30 ± 0.2 °C as the ligand and its complexes are insoluble in water.

Experimental

Apparatus

A precision p*H*-meter (Type: OP-205 No. 837) with a wide range glass-calomel electrode assembly was calibrated at two p*H* values (4.0 and 7.0) with suitable buffers. An inert atmosphere of nitrogen was maintained in the potentiometric cell through the solution.

Stock Solutions

Aqueous solutions of the metal ions were prepared from $CuSO_4$ and $Zn(NO_3)_2$ (BDH-AnalaR) and standardized by usual procedures (6). Sodium perchlorate (BDH-AnalaR) solution in double distilled water was prepared (1.0 *M*) and estimated by the standard method (7). Standard carbonate free sodium hydroxide (E. Merck) was prepared and its solution in 50% dioxane was used as a titrant (5). Dioxane was refluxed with sodium for 24 h and freshly distilled before use. The H_2SA was prepared (2) spectroscopically pure, the required quantity was dissolved in dioxane and the solution standardized potentiometrically (7).

Calvin–Bjerrum pH-titration Technique (3–5)

Four mixtures (as shown in Fig. 1) were prepared, titrated with progressive addition of an alkali solution (*ca.* 0.1 *M*), and the titration curves were plotted (Fig. 1). The protonation constants of H_2SA were calculated from the titration curves I and II.

Results and Discussion

Proton–Ligand System

H_2SA is a weak acid due to the presence of a phenolic and a carboxylic group in its molecule. Its formation curve (Fig. 2) extends up to $\bar{n}_A = 2.0$ which indicates the formation of the species HSA^- and SA^{2-} in solution. H_2SA dissociates in two steps. The values of log K_1^H and log K_2^H were found by (*i*) interpolation at half $\bar{n}_A$ values and (*ii*) interpolation at various $\bar{n}_A$ values, as shown in Table 1 (8).

A change of color from colorless to orange takes place at p*H* 7.2, which corresponds to the $\bar{n}_A$ value of approximately 1.0. But at $\bar{n}_A \approx 1.0$, the species HSA^- is the predominant species. Since there is no marked change in the color of the species HSA^- and SA^{2-}, it appears that the species H_2SA (in 50% dioxane) is colorless, changing to orange species SA^{2-} at $\bar{n}_A > 1.0$.

Metal–Ligand System

Copper(II)–H_2SA System

The formation curve (Fig. 3) for this system

*Equals $\log K_1^H \log K_2^H$.

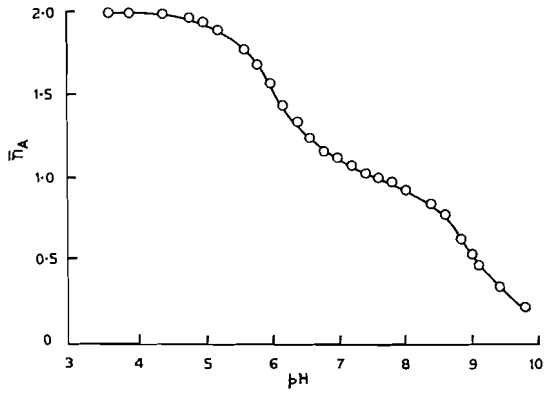

FIG. 2. Formation curve of proton–ligand system of H_2SA.

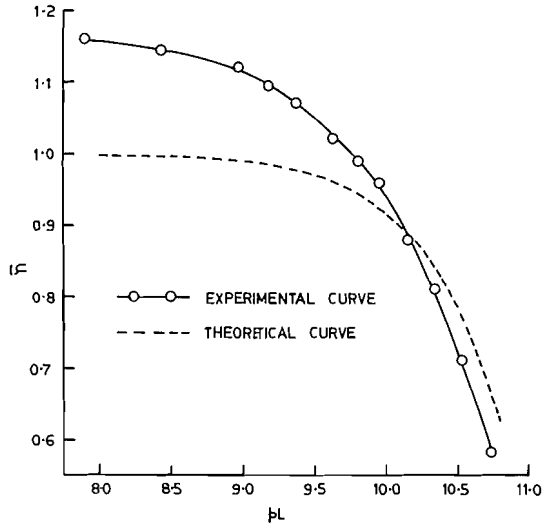

FIG. 3. Formation curve of Cu(II)-H_2SA system.

is incomplete at both ends and it is not symmetrical about its midpoint. Therefore, its formation constant, $\log K_1 = 11.05$, was calculated by interpolation at various $\bar{n}$ method. In Fig. 3 the deviation between the experimental (curve *A*) and theoretical (curve *B*) curves is observed only beyond $\bar{n} \approx 0.9$. From the nature of the experimental curve it appears that at $\bar{n} \approx 1.1$ the complex starts hydrolyzing with the result that 1:2 species does not exist.

In this system the formation of different species in solution is evident from the color change observed during the titration. A yellowish-green color appears in the p*H* range of 3.2–4.6. The p*H* 4.0 corresponds to $\bar{n} \simeq 1$ from which it may be concluded that the 1:1 species is yellowish-green in color.

Zinc(II)–H_2SA System

In this system the formation curve *A* (Fig. 4) attains maxima at $\bar{n} \approx 1.9$ which indicates that 1:1 and 1:2 complexes are formed. The values of $\log K_1$ and $\log K_2$ as obtained by Bjerrum's

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

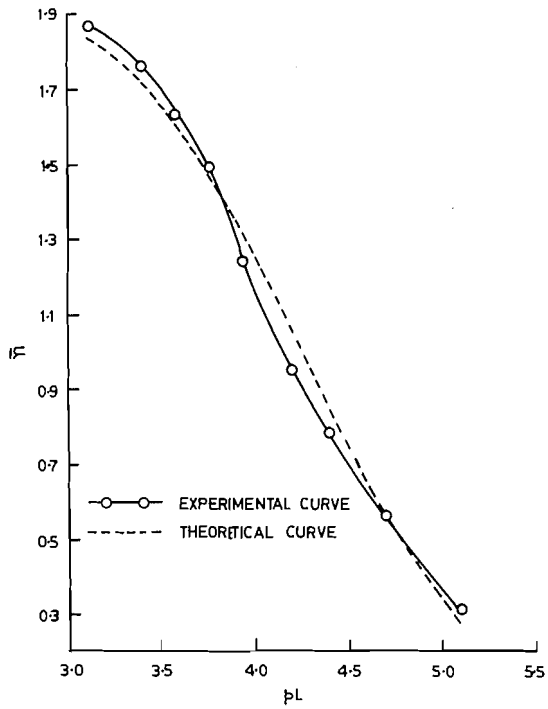

FIG. 4. Formation curve of Zn(II)–H_2SA system.

TABLE 2. Formation constants of zinc(II)–H_2SA Complex at 30 + 0.2 °C

Method	log K_1	log K_2	log β_2*
(*i*) Interpolation at half $\bar{n}$ values	4.69	3.84	8.53
(*ii*) Successive approximations	4.65	3.89	8.54
(*iii*) Correction term	4.62	3.80	8.42
Mean	4.65	3.84	8.49

*Equals log K_1K_2.

half $\bar{n}$ values method (3) were refined by interpolation at half $\bar{n}$ values method, correction term method and the method of "successive approximations" (8) as shown in Table 2. The theoretical formation curve *B* (Fig. 4) was thus derived by using log $K_1 = 4.65$ and log $K_2 = 3.84$. A perusal of the experimental and theoretical curves indicates negligible deviation.

In this system a lemon-yellow color appears in the p*H* range of 6.0–7.2. The p*H* 6.8 corresponds to $\bar{n} > 0.5$ and it may be concluded that the 1:1 species formed is lemon-yellow in color. The color becomes deep yellow in the p*H* range of 7.4–8.4 indicating the formation of 1:2 species. The p*H* 7.9 corresponds to $\bar{n} \approx 1.5$. Beyond p*H* 8.7, the complex starts decomposing which results in the hydrolysis of the metal ion.

The formation constants of Cu(II) and Zn(II) complexes with H_2SA are in fair agreement with the Irving and Williams rule (9).

The Wetting Properties of Aqueous Solutions of Valeric Acid on Solid Surfaces

A. B. PONTER

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

AND

A. P. BOYES

Department of Chemical Engineering, University of Birmingham, England

Received October 1, 1971

Contact angles are reported for aqueous solutions of valeric acid on copper, stainless steel and polytetrafluoroethylene surfaces in equilibrium with their own vapors at atmospheric pressure and 25 °C. It is demonstrated that the dependency on concentration for the polytetrafluoroethylene surface is in accord with theory.

Les angles de contact sont rapportés pour des solutions aqueuses d'acide valérique sur des surfaces en cuivre, en acier inoxydable et en polytétrafluoroéthylène, en équilibre avec leurs propres vapeurs sous pression atmosphérique et à 25 °C. Il a été démontré que la dépendance par rapport à la concentration pour une surface en polytétrafluoroéthylène est en accord avec la théorie.

Canadian Journal of Chemistry, **50**, 1613 (1972)

Introduction

The spreading coefficient, the wetting energy and the surface tension of a liquid spreading on a plane solid surface are related by the expression

$$[1] \qquad S_c = W_e - \gamma_{LV}$$

where S_c is the spreading coefficient, W_e is the wetting energy, and γ, interfacial free energy with subscript LV referring to liquid–vapor, SL to solid–liquid, and SV to solid–vapor, interfaces. The wetting energy may be expressed in terms of the surface energies at the solid–vapor and solid–liquid interface by the expression

$$[2] \qquad W_e = \gamma_{SV} - \gamma_{SL}$$

In the presence of a surfactant, the spreading coefficient increases partly by the lowering of the surface tension of the liquid and partly by an increase in the wetting energy, the wetting energy being increased by adsorption of the surfactant at the solid–liquid interface causing a decrease in γ_{SL} by an amount which is maximum when the solid–vapor interfacial free energy is unaffected by the surfactant. Such changes can be regarded as an interfacial surface pressure and may be used in conjunction with the Gibbs' equation to derive the excess of concentration at the solid–liquid interface which is equal to $RT\,\mathrm{d}\,\pi_{SL}/\mathrm{d}\,(\ln c)$, where π is surface pressure, R is gas constant, and T is temperature. Fowkes and Harkins (1) measured contact angles of aqueous solutions on paraffin wax and other low energy surfaces as a function of surfactant concentration. Assuming that adsorption at the solid–air interface was negligible, they used Young's equation to calculate the spreading pressure of the surfactant at the solid–liquid interface. Thus

$$[3] \qquad \gamma_{SL^o} - \gamma_{SL} = \gamma_{LV} \cos\theta - \gamma_{LV^o} \cos\theta$$

where the superscript zero refers to the system without surfactant and θ is the contact angle. They were then able to calculate adsorption by the use of Gibbs' equation. It was found that

adsorption at the paraffin–solution interface was very similar to that at the solution–air interface, surface excess and spreading pressures had approximately the same magnitude, and surface equations of state were similar at each interface.

Adsorption from solution at the solid–liquid interface is usually measured either by the depletion of the solute concentration, by using adsorbing molecules which have been rendered radioactive, by the effect on friction measurements or the effect on contact angles (Alexander (2)). Smolders (3) used contact angles to study adsorption at the mercury–solution interface, and Asahara and Goto (4), to observe the adsorption of surfactants at the paraffin wax–solution interface. Ruch and Bartell (5), Schulman and Leja (6), and Ténèbre (7) used various forms of the Young equation coupled with the Gibbs' equation to derive the adsorption from contact angle measurements. However, adsorption at the solid–vapor interface in their systems made it impossible to resolve adsorption at the solid–liquid interface. Padday (8) measured the spreading coefficient of solutions of sodium lauryl sulfate and Aerosol OT on a wax surface. The surface tensions of the spreading solutions were measured, then used to derive the wetting energy. From a plot of the wetting energy *vs.* the logarithm of the concentration of the surfactant he was able to derive the saturation adsorption. In the systems chosen the solid–vapor interfacial free energy was not in fact affected by surfactants, the whole change of wetting energy being derived from changes in γ_{LV}. Bernett and Zisman (9, 10) studied the wettability of low energy surfaces by aqueous solutions of non-fluorinated and fluorinated surfactants.

Using Fowkes and Harkins' original observations that adsorption is similar at the solid–liquid and liquid–air interface, then at constant T and P

$$[4] \qquad \frac{d\gamma_{SL}}{dc} = \frac{d\gamma_{SV}}{dc}$$

where c is the concentration of surfactant or

$$[5] \qquad \frac{d\gamma_{SL}}{d\gamma_{LV}} = 1$$

Differentiating Young's equation with respect to γ_{LV} gives

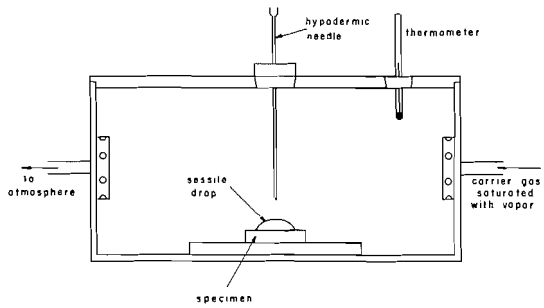

FIG. 1. Diagram of apparatus employed for contact angle measurement at equilibrium conditions at atmospheric pressure and 25 °C.

$$[6] \qquad \frac{d\cos\theta}{d\gamma_{LV}} = \frac{\dfrac{d\gamma_{SV}}{d\gamma_{LV}} - \dfrac{d\gamma_{SL}}{d\gamma_{LV}}}{\gamma_{LV}} - \frac{\cos\theta}{\gamma_{LV}}$$

Using eq. 4 and the assumption that $d\gamma_{SV}/d\gamma_{LV} = 0$

$$[7] \qquad \frac{d\cos\theta}{d\gamma_{LV}} = -\frac{1}{\gamma_{LV}}(1 + \cos\theta)$$

Integrating eq. 6 between the limits γ_c and γ_{LV} gives

$$[8] \qquad \cos\theta = \frac{(2\gamma_c - \gamma_{LV})}{\gamma_{LV}}$$

where γ_c is the critical surface tension. The experimental data of Bernett and Zisman (9) for the wettability of polyethylene by aqueous solutions of non-fluorinated surfactants showed good agreement with eq. 8; so their results are consistent with those of Fowkes and Harkins that adsorption is similar at the solid–liquid and liquid–air interfaces and that adsorption at the solid–air interface is negligible.

Experimental

For this investigation contact angles of a series of aqueous valeric acid solutions ranging from $6.68 \times 10^{-4} - 1 \times 10^{-1}$ M were measured on polytetrafluoroethylene ($R_A = 0.44$ μin.), stainless steel ($R_A = 1.02$ μin.), and copper ($R_A = 1.01$ μin.) surfaces in the apparatus shown in Fig. 1 (R_A is center-line average of surface roughness). Contact angles were measured using a travelling microscope fitted with a goniometer eyepiece and were reproducible to $\pm 1°$. The solid samples were prepared as outlined in Figs. 2 and 3 and the surface roughness measured, as the center-line average, on a Talysurf meter. The water used in the experiments was triply distilled, each stage incorporated a surface overflow device which continuously removed contaminants. Using a Du Noüy ring

balance the final product was shown to have a surface tension of 72.8 dyn/cm at 20 °C which is in excellent agreement with reported values.

Before each run the solid specimen was prepared as mentioned and left to soak in the test solution before use. The sample was then introduced into the observation box and tested to be horizontal using an optical method. Argon gas, 99.999% purity, was passed through four contacting cells, which were partially filled with solution of the same composition as the test solution, and then through the observation cell before finally being passed to a vent. After approximately 30 min a sample of the test solution was placed onto the solid surface by means of a syringe fitted with a hypodermic needle, care being taken to ensure that the drop was formed slowly until the equilibrium drop height had been achieved and that withdrawal of the needle did not disturb the drop. Contact angles were measured as a function of time using a travelling microscope fitted with a goniometer eyepiece. The reported values are an average of five readings and were reproducible to $\pm$ 1°. The results are presented in Tables 1–3.

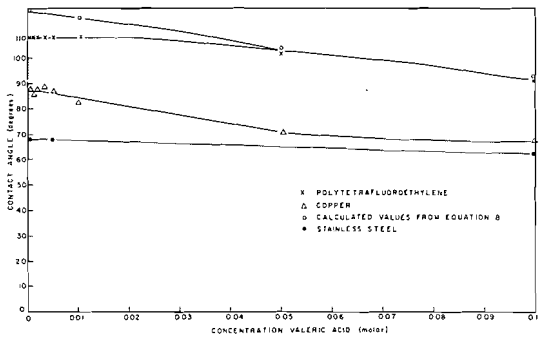

FIG. 4. Contact angles of aqueous valeric acid solutions on solid surfaces.

Discussion

It is evident from Fig. 4 that the contact angle remains constant up to a concentration of 1×10^{-2} M and then decreases with increasing valeric acid concentration. A comparison of results for contact angles obtained in these experiments, using the polytetrafluoroethylene surface ($\gamma_c = 18.5$ dyn/cm) with those predicted using eq. 8 are presented in Fig. 4. The polytetrafluoroethylene surface is chosen since eq. 8 is derived on the assumption that $d\gamma_{SV}/d\gamma_{LV} = 0$. The theory will not be expected to hold for the metal surface where adsorption at the solid–vapor interface will occur. Both results are in very good agreement except for concentrations below 0.05 M. A similar deviation in behavior is exhibited with the surface tension data of Meissner and Michaels (11) who showed for values below 0.1 M that the experimental and calculated values of surface tension of valeric acid solutions diverge in a similar manner. The effect of the valeric acid concentration on the surface tension is not great over the range 0–0.01 M (Meissner and Michaels (11)) since valeric acid is only a weak surfactant and thus no change in contact angle would be expected. No variation of contact angle with time occurs. However, with the copper and stainless steel results, the values of the contact angles varied slightly with time; this probably being partly due to adsorption of the valeric acid at the solid–vapor interface.

Effect of Electric Field Strength on the Free Ion Yields in the X-Radiolysis of Liquids: Influence of Molecular Structure and Temperature[1]

J.-P. DODELET, P. G. FUOCHI,[2] AND G. R. FREEMAN

Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received November 22, 1971

The relative increase in the free ion yield with increasing field strength E, expressed as G_{fi}^{E}/G_{fi}^{0}, is smaller when the following quantities are larger: (*1*) dielectric constant, (*2*) temperature, and (*3*) separation distance between the geminate ion–electron pairs. The field dependence $(dG_{fi}^{E}/dE)/G_{fi}^{0}$ equals $9.7/\varepsilon T^2$ cm/V at low E, but at higher fields it is affected by the above three factors and by E itself. Results obtained from the liquids propane (123–233 °K), 2-methylpropane (isobutane, 148–294 °K), 2,2-dimethylpropane (neopentane, 295 °K), argon (87 °K), oxygen (87 °K) and argon–oxygen solutions (87 °K) are presented and analyzed according to a theoretical model. Several types of ion–electron separation (y) distribution functions are tested. Within the framework of the model a power function $F(>y) = y_{min}\, y^{-x}$ with $x < 4$ provides a good interpretation of the results when $G_{fi}^{0} < 0.2$; a Gaussian distribution function provides the best interpretation of the field effects when $G_{fi}^{0} > 0.2$. Either the y distribution has a Gaussian core with a more gently sloping tail, or distributions are more Gaussian-like in liquids in which the electron ranges are greater. The electron range in pure argon ($b = 1300$ Å) is much smaller than had been expected and is only 2.6 times greater than that in liquid methane ($b = 500$ Å at 120 °K). Phonon emission by 10–0.01 eV electrons in liquid argon may be relatively efficient and might involve transient states of the type Ar_2^*.

L'accroissement relatif du rendement en ion libre avec le champ E, exprimé par G_{fi}^{E}/G_{fi}^{0}, est plus faible lorsque les grandeurs suivantes croissent: (*1*) la constante diélectrique, (*2*) la température, (*3*) la distance séparant les paires ion–électron géminées. La variation du champ $(dG_{fi}^{E}/dE)/G_{fi}^{0}$ est égale à $9.7/\varepsilon T^2$ cm/V pour E faible mais aux champs plus élevés elle est affectée par les trois facteurs cités ci-dessous et par E lui-même. Les résultats obtenus à partir des liquides propane (123–233 °K) méthyl-2 propane (isobutane, 148–294 °K) diméthyl-2,2 propane (néopentane, 295 °K), argon (87 °K), oxygène (87 °K), et argon–oxygène en mélange (87 °K), sont présentés et analysés selon un modèle théorique. Différents types de fonctions de distribution pour la séparation ion–électron sont essayés. Dans le cadre du modèle une fonction puissance $F(>y) = y_{min}\, y^{-x}$ avec $x < 4$ fournit une bonne interprétation des résultats pour $G_{fi}^{0} < 0.2$; une fonction de distribution gaussienne donne la meilleure interprétation des effets du champ pour $G_{fi}^{0} > 0.2$. La distribution y a soit une allure de type gaussien au centre finissant par une légère inclinaison soit une allure réellement gaussienne pour les liquides dans lesquels la distance parcouru par les électrons est plus grande. Le parcours de l'électron dans l'argon pur ($b = 1300$ Å) est beaucoup plus petit que celui attendu; il est seulement 2.6 fois plus grand que dans le méthane liquide ($b = 500$ Å à 120 °K). L'émission de phonons par les électrons de 10–0.01 eV dans l'argon liquide peut être relativement efficace et pourrait impliquer des états de transition du type Ar_2^*.

Canadian Journal of Chemistry, **50**, 1617 (1972)

Introduction

The free ion yield in an irradiated liquid increases with increasing applied electric field strength at field strengths greater than about 1 kV/cm (1–12). Jaffé (2) developed a theory to explain the effect of applied field strength on the escape of ions from the columnar tracks of high L.E.T. radiations such as α particles. He also noted that the experimentally observed field effects in β and γ (low L.E.T.) irradiated liquids were similar in form but smaller in magnitude to that for α irradiation (2, 3). However, the assumptions involved in the columnar ionization model were most questionable for low L.E.T. irradiations (2).

More recently (7) it seemed preferable to interpret electric field effects in γ irradiated liquids in terms of a model developed by Onsager (13) for high pressure gases irradiated by low L.E.T. radiations. Onsager assumed that ions and electrons were generated in isolated pairs and that the laws of Brownian motion apply to both types of charge. The Onsager model has been applied successfully to a limited number of systems such as *n*-hexane (7, 9, 11).

However, the discovery of the influence of molecular structure on the free ion yields in liquid hydrocarbons (10, 14, 15) makes it necessary to examine the Onsager model in liquid hydrocarbons with different molecular structures.

The free ion yield at low field strengths increases with increasing sphericity of the hydrocarbon molecule (15). A series of molecules with increasing sphericity is propane <2-methylpropane (isobutane) <2,2-dimethylpropane (neopentane). The free ion yields have been measured as functions of applied field strength in these liquids at different temperatures and the Onsager model has been applied to the data. The results are reported in this article.

Application of the model to the X-radiolysis of liquid argon, oxygen, and argon–oxygen solutions is also included.

Experimental

Materials

Phillips research grade propane, 2-methylpropane, and 2,2-dimethylpropane were purified by the method outlined earlier (15).

Matheson ultrahigh-purity argon was further purified as previously described (16), but using a more convenient quartz U-trap in which 150 g of activated coconut charcoal had been heated to 500 °C and evacuated to $<10^{-4}$ Torr over a period of two weeks.

Equipment and Technique

(a) Conductance Cell

The conductance cell was similar to that described earlier (16) except that a Kovar seal around the collector lead gave better electrostatic shielding against moving charges in the refrigerant baths and reduced the noise in the signals. The electrode spacing in a typical cell was $L = 0.49$ cm and the effective area of the collecting electrode was $A = 1.14\ \text{cm}^2$. The cell constant (L/A, cm^{-1}) was measured conductiometrically, using standard KCl solutions.

The refrigerants were liquid argon for 87 °K, isopentane slush for 123 °K, *n*-pentane slush for 148 °K, methanol slush for 183 °K and chlorobenzene slush for 233 °K.

(b) Sample Preparation

The conductance cells were filled by vacuum techniques. The argon–oxygen solutions were prepared by distilling pure oxygen into the cell containing part of the argon, followed by the rest of the argon. The solution was then distilled into a side-reservoir and back into the cell to hasten the mixing of the components. The amount of oxygen added was measured by a *PVT* technique, using a Pyrex spiral gauge connected to a mercury differential manometer.

(c) Measurement of the Free Ion Yield

The charge clearing method (14, 16, 17) was used with minor modification. A van de Graaff accelerator delivered 1 μs pulses of 1.7 MeV X-rays (absorbed dose/pulse = 2–5 $\times 10^{10}$ eV/cm^3). The current after a radiation pulse or blank (no pulse from the van de Graaff) was monitored with a Tektronix 549B oscilloscope containing a type 1A7 plug-in.

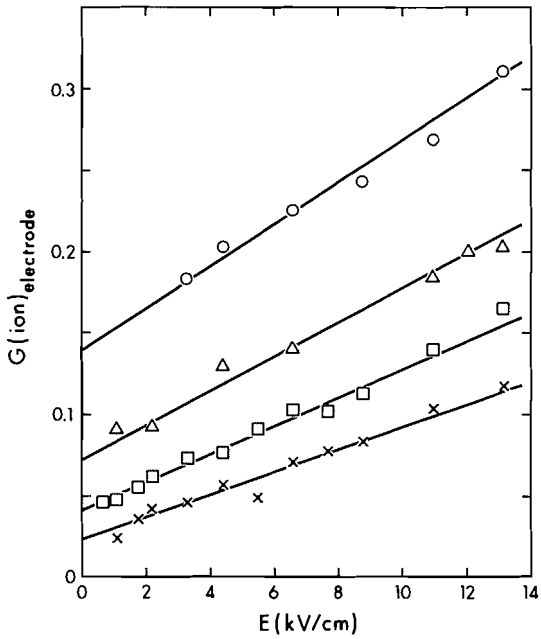

FIG. 1. Yield of ions collected at each electrode as a function of applied field strength in propane. Temperature: ○, 233; △, 183; □, 148; ×, 123 °K. The curves through the points were calculated using the *y* distribution function YP with $x = 2.5$ at all temperatures (see text).

For each measurement, sixteen alternate signals and blanks were fed into a low drift, high sensitivity integrator and averaged with a Fabritek 1062. The integration time for each signal and blank was 3 s. The averaged signals and blanks were then subtracted with the 1062. Sensitivities as high as 0.1 pC/cm were obtained.

Dosimetry

The dose in each pulse was monitored by measuring the charge collected on the gold target. The monitor was calibrated by thermoluminescent dosimetry, using doses of 10^{12}–10^{13} eV/cm^3 in the thermoluminescent crystals. The LiF crystals of the Harshaw model 2000 Thermoluminescent Analyser were calibrated against the Fricke dosimeter, using a ^{60}Co source. Conversion of dosimetry from one medium to another was done on the basis of their relative electron densities.

Physical Properties of the Liquids

The densities (18, 19), dielectric constants (19, 20), dipole moments (20), and viscosities (18, 21) of the liquids were obtained by extrapolation or calculation from data in the references indicated.

Results

Propane

The *G* value of ions collected at each electrode increased linearly with increasing field strength up to 13 kV/cm (Fig. 1). The yield extrapolated to zero-field strength may be taken as the free

ion yield in the absence of an applied field, G_{fi}^{0}. Measurements were made at four temperatures ranging from 123 to 233 °K. Both G_{fi}^{0} and the field dependence dG/dE increased with increasing temperature (Fig. 1). However, the relative rate of increase of G_{fi}^{0} was greater than that of dG/dE (Table 1).

A sample at 183 °K was studied up to 26 kV/cm to permit a more thorough test of the theoretical model. The points in Fig. 2 represent the averages of two experiments. The average precision of the measurements was ±3%. The ion yield increased linearly with field strength up to 26 kV/cm, within experimental error.

2-Methylpropane

The yield of ions collected at the electrodes in 2-methylpropane also increased linearly with field strength up to 13 kV/cm, within experimental error (Fig. 3). Although G_{fi}^{0} increased with increasing temperature the field dependence dG/dE was essentially independent of temperature between 148 and 294 °K (Table 1).

2,2-Dimethylpropane

The ion yield was measured at 294 °K at field strengths up to 24 kV/cm. The yield increased less than linearly with increasing field strength (Fig. 4), in agreement with an earlier report (12). It is difficult to estimate the initial slope of a curve, but from a plot with an expanded E axis it was estimated that $dG/dE = (7 \pm 2)10^{-6}$ ion cm/100 eV V, with $G_{fi}^{0} = 1.10 \pm 0.05$.

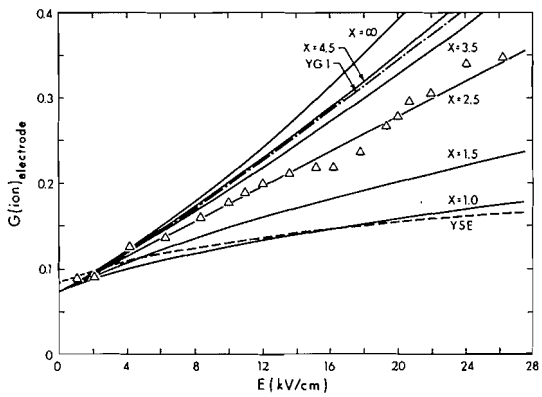

FIG. 2. Yield of ions collected in propane at 183 °K as a function of applied field strength. △, experimental. The curves were calculated with the following y distribution functions: —, YP with the x value indicated; -·-·-·, YG1; ---, YSE.

Theory

The model was developed by Onsager (13) to explain the effect of an applied electric field on the amount of "initial recombination" of ion–electron pairs that were generated in high pressure gases by β and γ radiations. It has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

extended to interpret the effect of an applied electric field on the yield of free ions in γ irradiated liquids (7). According to this model, the probability $\phi(y)^E$ that a thermalized electron–ion pair of initial separation distance y will escape geminate neutralization in the presence of an applied field E can be represented by an infinite series (7):

$$[1]\quad \phi(y)^E = e^{-r/y}\,[1 + \beta r + 0.375\beta^2 r^2 - 0.750\beta^2 ry + 0.0695\beta^3 r^3 - 0.417\beta^3 r^2 y + 0.417\beta^3 ry^2 + 0.0076\beta^4 r^4 - 0.091\beta^4 ry^3 + 0.274\beta^4 r^2 y^2 - 0.183\beta^4 ry^3 + \ldots\ldots]$$

where $\beta = \xi E/600\,kT$, $r = \xi^2/\varepsilon kT$, $\xi = 4.803 \times 10^{-10}$ e.s.u., E is expressed in V/cm, k is Boltzmann's constant, T is the absolute temperature, and ε is the dielectric constant of the medium.

The free ion yield in the presence of an applied field is then

$$[2]\quad G_{fi}^E = G_{tot}\int_0^\infty F(y)\,e^{-r/y}\,[1 + \beta r + 0.375\beta^2 r^2 - 0.750\beta^2 ry + \ldots]\,dy$$

where $F(y)dy$ is the fraction of thermalized electron–ion pairs with initial separation distances between y and $y + dy$, and G_{tot} is the total number of ion–electron pairs generated per 100 eV absorbed by the fluid.

By inserting the values of the appropriate constants one sees that $\beta r = 9.69E/\varepsilon T^2$. Similarly, the ratio of the free ion yield in the presence of an applied field E to that at zero applied field strength is

$$[3]\quad G_{fi}^E/G_{fi}^0 = \frac{\displaystyle\int_0^\infty F(y)\,e^{-r/y}\left[1 + \frac{9.690E}{\varepsilon T^2} + \frac{35.21E^2}{\varepsilon^2 T^4} - \frac{4.214\times 10^4 E^2}{\varepsilon T^3}\,y + \ldots\right]dy}{\displaystyle\int_0^\infty F(y)\,e^{-r/y}\,dy}$$

$$= 1 + \frac{9.690E}{\varepsilon T^2} + \frac{35.21E^2}{\varepsilon^2 T^4} - \frac{4.214\times 10^4 E^2}{\varepsilon T^3}\,\frac{\displaystyle\int_0^\infty F(y)\,e^{-r/y}\,y\,dy}{\displaystyle\int_0^\infty F(y)\,e^{-r/y}\,dy} + \ldots.$$

The initial slope of a plot of G_{fi}^E/G_{fi}^0 against E should equal $9.69/\varepsilon T^2$. This is equivalent to the ratio of the initial slope to the intercept of a plot of G_{fi}^E against E (eq. 2). These plots are linear at low E, then curve towards the E axis and asymptotically approach zero slope as G_{fi}^E approaches G_{tot} at very high fields. It can be seen from eqs. 2 and 3 that the field strength at which deviation from linearity becomes significant is smaller for larger values of y. This also implies that deviation from linearity will be observed at lower fields for liquids that have higher values of G_{fi}^0.

The preceding was given to facilitate understanding. However, the model is more conveniently programmed for a computer in the following way (7). For values of y greater than a certain value y_c eq. 4 applies.

$$[4]\quad \frac{\phi(y)^E}{\phi(y)^0} = e^{r/y}\left[1 - e^{-r/y}\,\frac{2r}{My}\sum_{i=1}^{M/2} e^{-2\beta y x_i^2}\sum_{n=0}^{\infty}\frac{(2\beta r)^n \gamma_n x_i^{2n}}{(n!)^2}\right] \qquad y \geqslant y_c$$

where

$$x_i = \cos\,[(2i-1)\pi/2M] \qquad \text{and} \qquad \gamma_n = \sum_{k=1}^{\infty}\frac{(r/y)^{k-1}}{(n+1)(n+2)\ldots(n+k)}$$

It was more than sufficient to take $M = 13$ and to vary n from 0 to 16. The computer ceased adding terms to the summation in γ_n when the $(k+1)$th term was less than 10^{-10} times as large as the sum of the first k terms.

To average eq. 4 over a distribution of y values the distribution function was broken into about

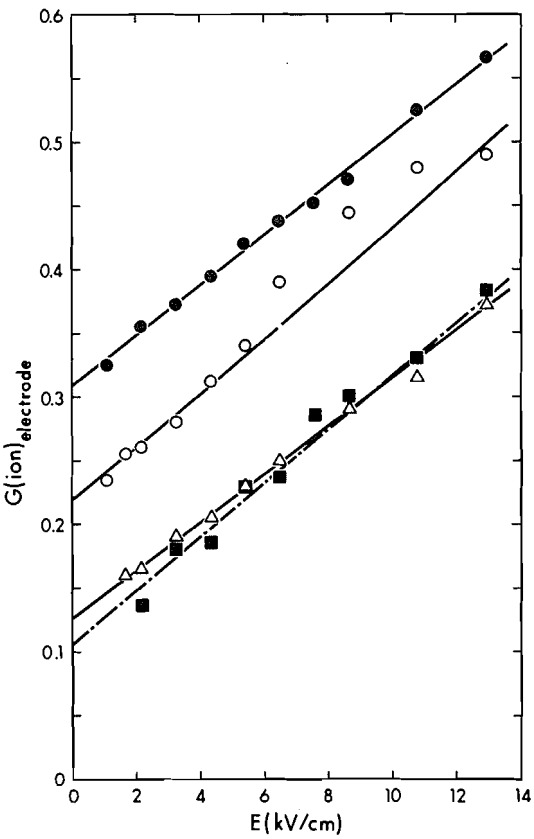

FIG. 3. Yield of ions collected at each electrode as a function of applied field strength in 2-methylpropane. Temperature: ●, 294; ○, 233; △, 183; ■, 148 °K. The curves through the points were calculated using the y distribution function YG1 at 294 and 233 °K, and the function YP with $x = 3.0$ at 183 °K and $x = 2.5$ at 148 °K.

twenty convenient steps, with $F(y_i)$ representing the fraction of ion–electron pairs in the i'th step, in which the average value of y is y_i. The free ion yield at field strength E is then

$$[5] \qquad G_{fi}^{E} = G_{tot} \sum_{i} F(y_i)\, e^{-r/y_i} \frac{\phi(y_i)^E}{\phi(y_i)^0}$$

Equation 4 becomes indeterminate for values of y less than y_c; the value of y_c increases with decreasing temperature and dielectric constant and is about 35 Å in liquid hydrocarbons at 300 K. However, eq. 6 can be derived from the Onsager model for the special case of $y = 0$ (7).

$$[6] \qquad \phi(0)^E/\phi(0)^0 = \sum_{j=0}^{\infty} (\beta r/2)^j (2j)!/(j!)^4$$

This series was summed up to $j = 17$.

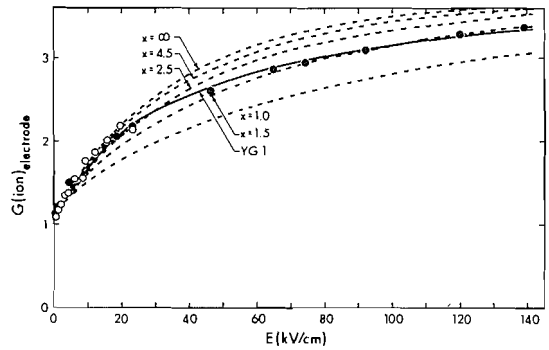

FIG. 4. Yield of ions collected at each electrode as a function of applied field strength in 2,2-dimethylpropane. ○, present results at 294 °K; ●, Schmidt's results (12) at 296 °K. The curves were calculated using the following y distribution functions: —, YG1; ---, YP with the value of x indicated.

The field effect expressed by $\phi(y)^E/\phi(y)^0$ is maximum for $y = 0$ and decreases continuously with increasing y (see later).

The negative term in the square brackets on the right hand side of eq. 4 equals zero at $y = \infty$ and approaches unity at small values of y. For practical purposes we allowed the value of the negative term to go as high as 0.99990, and the value of y that gave this value was taken as y_c. When the y distribution function contained y values less than y_c an interpolation was made between eqs. 4 and 6 using eq. 7.

$$[7] \qquad \frac{\phi(y)^E}{\phi(y)^0} = \frac{\phi(y_c)^E}{\phi(y_c)^0} + \frac{(y_c - y)}{y_c}\left[\frac{\phi(0)^E}{\phi(0)^0} - \frac{\phi(y_c)^E}{\phi(y_c)^0}\right] \qquad y < y_c$$

where $\phi(y_c)^E/\phi(y_c)^0$ is calculated from eq. 4.

In summary, values of G_{fi}^{E} were calculated from eq. 5, using eqs. 4 and 7 to determine $\phi(y)^E/\phi(y)^0$ over the appropriate ranges of y.

Discussion

Initial Slopes and Values of G_{fi}^{0}

The ratios of the initial slopes of the curves in Figs. 1–4 to their intercepts should equal $9.69/\varepsilon T^2$, according to eq. 3. Empirical values of the ratio $(dG/dE)/G_{fi}^{0}$ are given for the three hydrocarbons in Table 1. The empirical values agree satisfactorily with those of $9.69/\varepsilon T^2$ in all cases, at temperatures from 123 to 294 °K (Table 1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The values of G_{fi}^0 in the present work agree with the free ion yields measured by applying an electric field after the radiation pulse (22), within experimental error (Table 1).

Curvature in the ion yield plot for 2,2-dimethylpropane was detectable at about 5 kV/cm (Fig. 4), whereas the plot for propane was linear up to at least 26 kV/cm (Fig. 2). The free ion yield, and hence the mean value of y, is greater in 2,2-dimethylpropane than in propane. The curvature at lower field strength for fluids in which the y values are higher is predicted by eq. 3.

y Distributions

The true y distribution in a liquid is not known. Several types of distribution function have been assumed by different workers (a comprehensive list is given in ref. 23) and it is of interest to test four of them in eq. 5. The four functions are

(*a*) A power function designated YP (23–25)

$$[8a] \qquad \begin{aligned} F(>y) &= y_{min}^{x} y^{-x} && y \geqslant y_{min} \\ F(>y) &= 1 && y \leqslant y_{min} \end{aligned}$$

where

$$F(>y) = \int_{y}^{\infty} F(y)\, dy$$

and therefore

$$[8b] \qquad \begin{aligned} F(y) &= x y_{min}^{x} y^{-(x+1)} && y \geqslant y_{min} \\ F(y) &= 0 && y \leqslant y_{min} \end{aligned}$$

(*b*) A delta function YD (7, 23, 26, 27), which is simply eq. 8 with $x = \infty$, so $y = y_{min}$ for all ion electron pairs.

(*c*) A single parameter, three dimensional Gaussian function designated YG1 (23, 26, 27)

$$[9] \qquad F(y) = (4y^2/\pi^{\frac{1}{2}} b^3) \exp(-y^2/b^2)$$

where b is the dispersion parameter.

(*d*) The semi-empirical function YSE that has been used in charge scavenging calculations for liquids that contain distinctly non-spherelike molecules (23, 28–30).

Effects of y and E on $\phi(y)^E/\phi(y)^0$

Values of $\phi(y)^E$ in propane at 183 °K are plotted against y for $E = 0$, 10, and 100 kV/cm in Fig. 5. Although $\phi(y)^E$ increases with increasing y at any given field strength, the ratio $\phi(y)^E/\phi(y)^0$ decreases with increasing y (Table 2). The decrease in the ratio with y is more marked at higher field strengths.

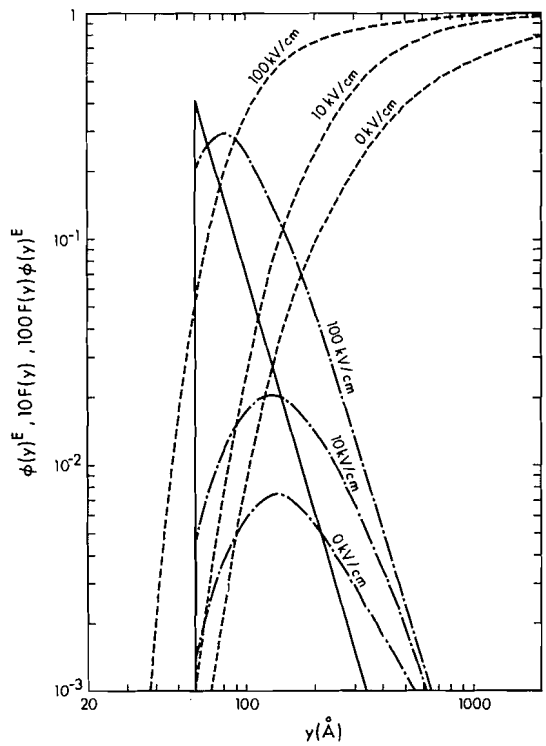

FIG. 5. Values of $\phi(y)^E$, $F(y)$, and $F(y)\phi(y)^E$ as functions of y in propane at 183 °K. $E = 0$, 10, and 100 kV/cm. ---, $\phi(y)^E$; —, $F(y) \propto y^{-3.5}$ (see text); -·-·-·, $F(y)\phi(y)^E$. The $F(y) \propto y^{-3.5}$ curve corresponds to the same function as the $F(>y) \propto y^{-2.5}$ curve shown in Fig. 6.

TABLE 2. Influence of y and E on $\phi(y)^E/\phi(y)^0$ in propane at 183 °K

y (Å)	$\phi(y)^0$	$\phi(y)^{10}/\phi(y)^{0*}$	$\phi(y)^{100}/\phi(y)^{0*}$
0†	0†	3.7†	1900†
70	0.001	3.2	100
200	0.090	2.6	8.2
600	0.45	1.7	2.1

*E is given in kV/cm.
†Hypothetical, eq. 6.

To illustrate the operation of $\phi(y)^E$ on a y distribution, a function $F(y) \propto y^{-3.5}$ (*i.e.* YP with $x = 2.5$) and the product $F(y)\phi(y)^E$ are also shown in Fig. 5. This $F(y)$ for propane at 183 °K gives values of G_{fi}^E that agree with experiment (see later). The product $F(y)\phi(y)^E$ passes through a maximum of 7.6×10^{-5} at $y = 140$ Å for $E = 0$. The value of the product increases and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the value of y at the maximum decreases with increasing E, reaching 2.9×10^{-3} and 80 Å, respectively, at 100 kV/cm.

Propane

Calculations using all four of the above mentioned types of y distribution were made for propane at 183 °K.

When YP was used, the values of the parameters x and y_{min} were varied to find the pair that gave the minimum mean difference between the calculated and the experimental ion yields over the field strength range studied. The best values for propane at 183 °K were $x = 2.5$ and $y_{min} = 60$ Å, corresponding to $G_{fi}^0 = 0.073$. The calculated ion yields are shown by the curve marked $x = 2.5$ in Fig. 2.

To illustrate the effect of the breath of the y distribution on the field effect, YP functions with $x = 1.0$–4.5 in steps of 0.5 and $x = \infty$ were chosen such that each gave $G_{fi}^0 = 0.073$. Some of the distributions are shown in Fig. 6. A lower value of x corresponds to a broader distribution. The field dependencies expected for several of the distributions are displayed by the curves in Fig. 2. Although the initial slopes of all the curves are the same, the magnitude of the field effect at higher fields increases with increasing x. It is the ion–electron pairs with the larger y values in a given distribution that have the greatest probability of becoming free ions (Fig. 5). The larger the value of x the lower is the average value of y of the pairs that become free ions (Fig. 6). The lower the value of y of these pairs, the greater the field effect (Table 2).

The YP distribution with $x = \infty$ corresponds to the delta function (23) mentioned in (*c*) above. It predicts the largest field effect of all the distributions, and is not suitable for the present system.

The Gaussian distribution also predicts too great a field dependence of the ion yield (Fig. 2). The value of b used was 90 Å. The excessively large predicted field dependence indicates that the tail of the Gaussian distribution towards high y values is too short.

The distribution YSE for propane at 183 °K was obtained by multiplying that for *n*-hexane at 293 °K (28) by the inverse ratio of the liquid densities; $d(\text{hexane})/d(\text{propane}) = 0.660/0.637 = 1.03$. The free ion yields calculated from eq. 5 using YSE are shown as the dashed line in Fig. 2.

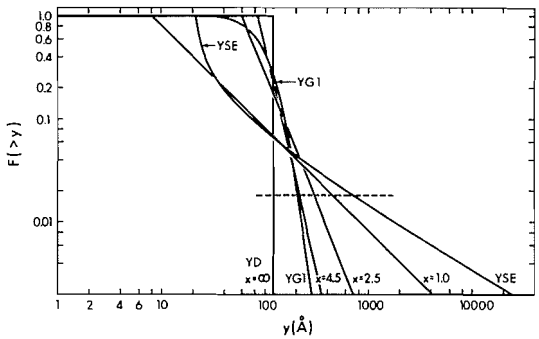

FIG. 6. Integrated y distributions for propane at 183 °K. $F(>y) = \int_y^\infty F(y)\,dy$. All these distributions except YSE give $G_{fi}^0 = 0.073$; YSE gives $G_{fi}^0 = 0.083$. Distributions YP are shown for $x = 1.0$, 2.5, and 4.5. The value of b in YG1 is 90 Å. The horizontal, dashed line marks the fraction that corresponds to $G_{fi}^0 = 0.073$.

The calculated field dependence of the ion yield is too low, which implies that the tail of the distribution YSE at high y values is too long.

The most suitable type of distribution for the treatment of field effects in propane at 183 °K is apparently YP. This function was therefore used in the analysis of the ion yields at the other temperatures. At each temperature the best value of x was found to be 2.5, with an estimated uncertainty of ± 0.5. The best-fit curves are drawn in Fig. 1 and the function parameters are listed in Table 3. The calculated values of G_{fi}^0 (Table 3) agree with the empirically extrapolated values within experimental error (Table 1).

Other things being equal, electron ranges are inversely proportional to the density of the medium (31). The product of the liquid density and the median y value in the best propane y distribution is independent of temperature (Table 3). This suggests that electron energy loss and localization processes are independent of temperature in propane at temperatures between 123 and 233 °K.

2-Methylpropane

Values of G_{fi}^E were calculated from eq. 5 using YP functions with several values of x. By contrast with propane where the best value of x was 2.5 at all temperatures, in 2-methylpropane the best value of x increased from 2.5 at 148 °K to 4.5 at 233 °K (Table 3). The behavior of the calculated curves at 148 and 294 °K is shown in Fig. 7. Increasing the temperature decreases the relative effect of E on G_{fi}.

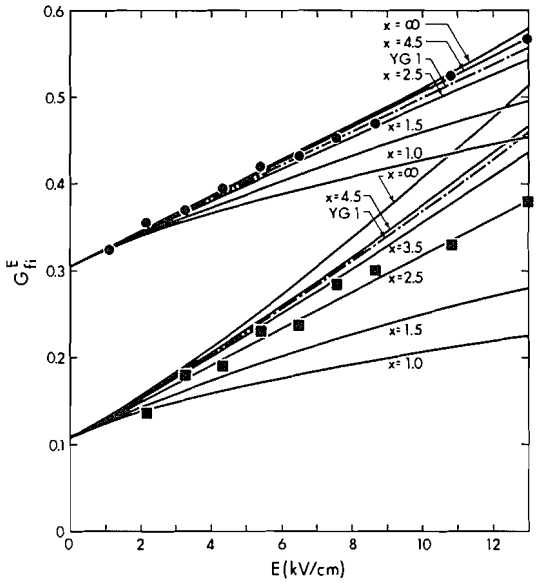

FIG. 7. Calculated values of G^E_{fi} for 2-methylpropane at 148 (●) and 294 °K (■), using different y distributions. —, YP with the value of x shown; -·-·-·, YG1.

The Gaussian distribution leads to too large a field effect at 148 and 183 °K, but gives reasonable agreement with experiment at 233 and 294 °K (Fig. 7). The Gaussian function was used to calculate the curves shown in Fig. 3 for the two higher temperatures.

The parameters for the best y distribution functions are listed in Table 3.

2,2-Dimethylpropane

Values of G^E_{fi} calculated from eq. 5 using a Gaussian y distribution agree with the present experimental results and those of Schmidt (12) over the range of field strength from zero to 140 kV/cm (Fig. 4). The YP distributions with values of $x \geqslant 3$ also gave satisfactory results at $E < 25$ kV/cm, but none of the YP functions was satisfactory over the entire range of E (Fig. 4).

Comparison of the Hydrocarbons

Within the framework of the present model it appears that the Gaussian distribution of y values provides the best interpretation of the field effects when $G^0_{fi} > 0.2$ and that a distribution YP with $x < 4$ is best when $G^0_{fi} < 0.2$ (Table 3). The Gaussian has a steeper slope at high y values than does YP with $x < 4$ (Fig. 6).

Perhaps a better description of all the distributions would be a Gaussian core with a more gently sloping tail.

An alternative interpretation is that the distribution is more Gaussian-like in liquids in which the electron range is greater.

Argon–Oxygen Systems

Ion yields reported elsewhere (22) for liquid argon, argon–oxygen solutions, and liquid oxygen have now been analyzed according to eq. 5. The best-fit calculated ion yields at different field strengths are displayed along with the experimental results in Fig. 8. The y distribution functions that gave the best calculated yields are listed in Table 4.

The results are consistent with those obtained with the different hydrocarbons. When the free

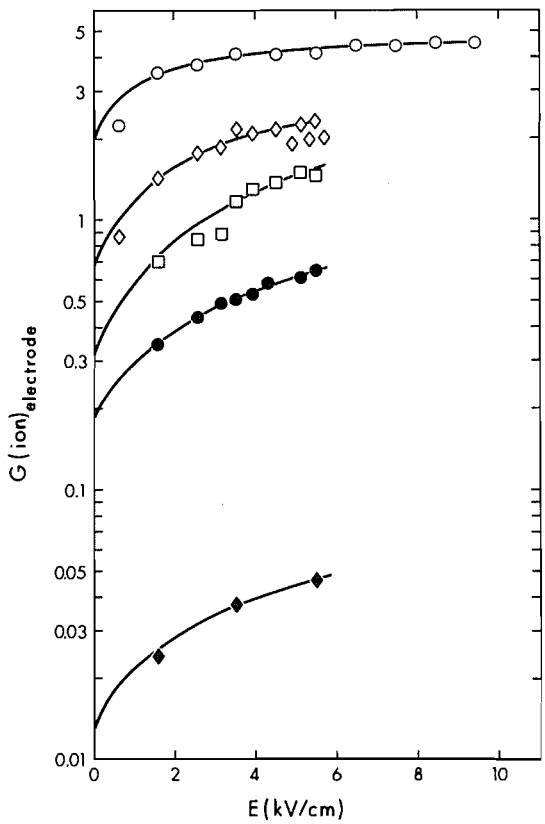

FIG. 8. Yield of ions collected at each electrode as a function of applied field strength at 87 °K in liquid Ar (○), Ar + 1.5 mol% O_2 (◇), Ar + 13 mol% O_2 (□), Ar + 28 mol% O_2 (●), and pure liquid O_2 (◆). The curves were calculated using the y distribution functions in Table 4.

ion yield is large the Gaussian y distribution gives the best results within the framework of the present model. However, when G_{fi} is small a distribution with a gentler slope, such as YP with $x < 3$, is required to fit the field dependence of the ion yield.

One may conclude that the tail of a relatively tight distribution, *i.e.* one for which G_{fi} is small, has a relatively gentle slope, and that the core of a relatively loose distribution has a Gaussian-like shape. The present experiments do not give information about the shape of the core of a tight distribution or the tail of a loose one. When the free ion yield is large the y values in the tail of the distribution may be so large that reaction 11 cannot compete with reaction 12 even in the absence of an applied field.

[10] $M \rightsquigarrow [M^+ + e^-]$

[11] $[M^+ + e^-] \rightarrow M^*$ (geminate neutralization)

[12] $[M^+ + e^-] \rightarrow M^+ + e^-$ (free ions)

The field effect on reaction 11 would then be only important for the ion pairs in the core of the y distribution, and the apparent shape determined from the field effect would apply only to the core. Conversely, information obtained about the shape of the tail in the systems with small free ion yields cannot be extrapolated to the core.

G_{fi} and Secondary Electron Ranges in Liquid Argon

The present analysis of the electric field effect has shown that, contrary to earlier belief (16, 32), not all the ion pairs in liquid argon become free ions. The facts that the monatomic molecules of argon do not possess internal energy levels between the ground state and the lowest excited electronic state at 11.6 eV, and that low energy electrons do not form a localized state in liquid argon (33) led one to expect that the ranges of the secondary electrons in argon would be so large that nearly all of the electrons would escape geminate neutralization. In reality only 37% of the electrons become free ions in X-irra-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

diated pure argon, and the most probable range of the secondary electrons is only $b = 1300$ Å (Table 4). This argon was sufficiently pure to permit the measurement of the rate constant $k(e^- + Ar_2^+)$ and the mobility of electrons in the liquid (22), so the low value of b is probably not due to the presence of impurities. The oxygen had been removed to $\ll 1$ p.p.m. and the nitrogen was < 5 p.p.m. One can estimate from Fig. 4 of ref. 22 that if b equalled infinity in pure argon the addition of 10 p.p.m. of oxygen or nitrogen would only reduce b to 40 000 Å. The observed $b = 1300$ Å therefore appears to be due to electron energy loss interactions with the liquid argon itself.

Methane molecules have excited electronic energy levels down to 8 eV above the ground state (34) and vibrational levels down to 0.2 eV (CH_2 bending). In spite of this gross difference from the internal energy levels of argon, the value of b in liquid methane is 500 Å (35), about 40% of the value in argon. The similarity of the secondary electron energy loss interactions in these two liquids is worthy of theoretical investigation. Phonon emission by the electrons in liquid argon may be much more efficient than had been expected and might involve transient states of the type Ar_2^*.

The authors are grateful to the staff of the Radiation Research Center for aid with the electronics.

Some Thermodynamic Properties of Lithium Chlorate in Water and Dioxane–Water mixtures

A. N. CAMPBELL AND O. N. BHATNAGAR

Department of Chemistry, University of Manitoba, Winnipeg R3T 2N2, Manitoba

Received November 4, 1971

Heats of solution and heats of dilution of lithium chlorate in water and dioxane–water mixtures have been determined experimentally. From these data apparent molal heat content, ϕ_L, and relative partial molal heat contents of solvent, $\bar{L}_1$, and of solute $\bar{L}_2$ have been calculated. The values of ΔG^0, ΔH^0, and ΔS^0 are also calculated.

Nous avons déterminé expérimentalement les chaleurs de solution et de dilution du chlorate de lithium dans l'eau et dans des mélanges eau-dioxanne. Nous avons calculé, à partir de ces résultats, la quantité de chaleur molale apparente, ϕ_L et les quantités de chaleur relatives molales partielles, $\bar{L}_1$ du solvant et du soluté $\bar{L}_2$. Nous avons aussi calculé les valeurs ΔG^0, ΔH^0, et ΔS^0.

Introduction

Lithium chlorate is one of the least studied inorganic compounds from the point of view of thermodynamic and electrochemical properties. Scatchard *et al.* (1) reported the activity coefficients ($\gamma_\pm$) of potassium, sodium, and lithium chlorates and perchlorate in water from freezing point measurements. Some earlier work on lithium chlorate from this laboratory comprehends phase equilibrium studies (2) and conductance density and viscosity measurements in dioxane–water mixtures (3, 4). Recently, Campbell and Oliver (5) reported the activity coefficients of sodium and lithium chlorates in water and dioxane–water mixtures, from vapor pressure measurements. In a recent paper (6) we have reported the thermodynamic properties of sodium chlorate in water and dioxane–water mixtures. The present paper is a similar study of lithium chlorate in water and dioxane–water mixtures.

Experimental

Lithium chlorate was prepared as described by Campbell and Griffiths (2). Our purification of dioxane is described elsewhere (5), where the methods of measuring heats of solution and heats of dilution are also given. Since lithium chlorate is extremely hygroscopic, all samples were measured out in a vacuum dry box under dry nitrogen atmosphere and sealed under vacuum. In order to determine the initial and final concentration for heat of dilution measurements, duplicate samples of lithium chlorate in water and dioxane–water mixtures were analyzed by both volumetric and gravimetric methods, but later on, a gravimetric method was adopted. All analyses of duplicate samples agreed within 0.2%. When determining the lithium chlorate in dioxane–water mixtures, special care was taken to see that the dioxane content was less than 10%, otherwise the lithium chlorate could decompose as observed by Campbell *et al.* (7).

Calculations and Results

The heats of solution, heats of dilution, and derived heats of solution in water, 44.5 wt.% dioxane–water and 64.5 wt.% dioxane are given in Tables 1–3. These data were utilized to calculate the apparent molal heat content, ϕ_L. From these values of ϕ_L the relative partial molal heat contents of solvent $\bar{L}_1$ and of solute $\bar{L}_2$ were calculated as follows:

$$[1] \qquad \bar{L}_1 = \frac{-M_1 m^{3/2}}{2000} \cdot \frac{d\phi_L}{dm^{1/2}}$$

$$[2] \qquad \bar{L}_2 = \phi_L + \frac{m^{1/2}}{2} \cdot \frac{d\phi_L}{dm^{1/2}}$$

where m is the molality of solution and M_1 is the molecular weight of the solvent.

In order to calculate the values of $\bar{L}_1$ and $\bar{L}_2$ the smoothed values of ϕ_L *vs.* $m^{1/2}$ were fitted to a least squares polynomial equation and the best curve fit was obtained on our IBM 360/65 computer. This equation, which is of the form

$$[3] \qquad \phi_L = Am^{1/2} + Bm + Cm^{3/2} + Dm^2 + \ldots$$

was differentiated with respect to $m^{1/2}$ to give the values of $d\phi_L/dm^{1/2}$. A second program was written to do this which also gave the values of ϕ_L, $\bar{L}_1$, and $\bar{L}_2$ at various concentrations. These data are given in Table 4.

The activity coefficients ($\gamma_\pm$) of lithium chlorate in the concentration range 1.0 m to satura-

tion have been reported by Campbell and Oliver (5). The $\gamma_\pm$ values of lithium chlorate in the concentration 0.1 to 1.0 m have been calculated by an empirical method proposed by the authors (8). According to this method, a reference electrolyte is chosen which is similar in molecular size and is of the same valence type as the unknown salt (in this case lithium chlorate), whose $\gamma_\pm$ values are known in the range 0.1–1.0 m as well as 1.0–2.0 m at various intervals. The ratios of $\gamma_\pm$ values of unknown and reference salt between 1.0 and 2.0 m are plotted against the concentrations. Since at $m = 0$ (infinite dilution) the $\gamma_\pm$ of all electrolytes becomes unity, this

curve is interpolated to unity at $m = 0$. From this curve the values of the ratio at various concentrations are chosen between 0.1 and 1.0 m. From the known values of $\gamma_\pm$ of the reference electrolyte we can obtain the activity coefficient of our unknown salt. In our case, we chose $NaClO_3$ as reference electrolyte for calculating the $\gamma_\pm$ values of lithium chlorate in water. Since the $\gamma_\pm$ values of hydrochloric acid are the only ones known in 45% dioxane–water and 65% dioxane–water mixtures (ref. 9, pp. 717, 718) we were obliged to use HCl as reference electrolyte for calculations of $\gamma_\pm$ for lithium chlorate in dioxane–water mixtures. We have assumed that the $\gamma_\pm$ values of HCl in 44.5 and 45.0% are essentially the same and similarly in 64.5 and 65% dioxane–water mixtures. These derived values of the $\gamma_\pm$ of lithium chlorate are given in Table 5. As mentioned above, for concentrations greater than 1 m, experimental activity coefficients were used. The $\gamma_\pm$ values were used to calculate the free energy of solution at various concentrations.

From the $\gamma_\pm$ of lithium chlorate at saturation concentrations, we can calculate the standard free energy, ΔG^0, of solutions

$$[4] \qquad \Delta G^0 = 2RT \ln m\gamma_\pm$$

knowing the value of ΔG^0 we can calculate ΔG values at various concentrations. The ΔG values, along with ΔH values, were used to calculate $T\Delta S$ values. The values of $\gamma_\pm$, ΔG, ΔH, and $T\Delta S$ are given in Table 5*a*. The values of ΔG^0, ΔH^0, and ΔS^0 for sodium and lithium chlorates are given in Table 6.

Discussion

The heats of solution and heats of dilution are negative in all three systems; the exothermicity increases in passing from 100% water to 44.5% dioxane–water to 64.5% dioxane–water mixtures. This could be explained on the assumption that, in water, some of the heat energy is consumed in breaking the hydrogen bonding. In 44.5% dioxane–water and 64.5% dioxane–water the hydrogen bonding decreases with increasing dioxane content and hence the heat effects are greater in mixtures. A similar trend was observed for sodium chlorate in dioxane–water mixtures, though the ΔH values were all positive there.

If we look at the rate of increase in ΔH^0 values from 100% water to 64.5% dioxane–water mixtures we find that there is little change in passing from pure water to 44.5% dioxane–water mixture, but from 44.5% dioxane to 64.5% dioxane–water mixtures, the change in ΔH^0 value is much greater; this is true for both $NaClO_3$ and $LiClO_3$. The reason for this may be that the addition of a small amount of dioxane to water initially increases the water structure, by making the hydrogen bonds stronger as compared to pure water, because dioxane is a better proton acceptor than water itself and consequently the increased structure breaking on addition of an electrolyte would result in a smaller change in ΔH^0 value. As more dioxane is added, a point will be reached when dioxane molecules can no longer be accommodated in the water structure and thus the solvent structure will break down again. Somewhat similar observations were made by Feakins *et al.* (10) when they compared the viscosity B coefficients of NaCl, KCl, and $MgCl_2$ in various dioxane–water mixtures, ranging from 10 to 50% dioxane. They found that the B coefficients increase with the increasing proportion of dioxane content. This kind of behavior is to be expected if the dioxane–water mixtures have less structure than water. The dioxane content, however, must be greater than 10%. Feakins' measurements of ΔH^0 for various alkali metal halides, in 20% dioxane–water mixtures, show that the heats of transfer, at infinite dilution, from 20% dioxane–water to 100% water, are negative, agreeing with our observations in 44.5 and 64.5% dioxane–water mixtures. Further support for this is given by the ΔS^0 values of $NaClO_3$ and $LiClO_3$ in 100% water, 44.5% dioxane, and 64.5% dioxane–water mixtures. In water, which has a three dimensional structure and is the most structurally complex solvent, the entropies are largest for both salts, and smallest in 64.5% dioxane–water mixtures.

The values of $\bar{L}_1$ and $\bar{L}_2$ given in Table 4 can be used to calculate $\gamma_\pm$ of lithium chlorate at any temperature, assuming $\bar{L}_2$ remains constant, because the $\gamma_\pm$ of lithium chlorate at 25 °C is known. Using the following equation

$$[5] \qquad \log \frac{\gamma_{25}}{\gamma'} = \frac{\bar{L}_2}{4.576v}\left[\frac{1}{T_{25}} - \frac{1}{T'}\right]$$

where γ_{25} and γ' are the mean ionic activity coefficients at T_{25} (*i.e.* 25 °C) and T' and v is the total number of ions resulting from a solute molecule, we attempted to calculate the γ' at

For personal use only.

0 °C in water, and compared the results with those obtained by Scatchard *et al.* (1). On the whole our calculated values of $\gamma_{\pm}$ at the freezing point are higher by almost 5–7% in the concentration range 0.1–1.0 *m*. However, when we considered hygroscopic electrolytes like LiBr, LiCl, NaOH, etc., and using the literature values (ref. 9, pp. 708–710) of $\gamma_{\pm}$ and $\bar{L}_2$ at 25 °C, calculated back $\gamma_{\pm}$ for these electrolytes at 0 °C, we found that in certain cases these calculated values were also higher by as much as 6% than those reported by Scatchard *et al.* (1). This implies that the results of Scatchard may be somewhat inaccurate even if we take into account the change in $\bar{L}_2$ with temperature. On the other hand, their results for non-hygroscopic salts are in good agreement with the calculated values (say within 2%). Tables of the $\bar{L}_1$ and $\bar{L}_2$ values have made possible the calculation of the relative partial molal entropy functions used by various authors (11, 12).

We have discovered some inconsistencies in the calculations of the Table 2 of our last paper (6) on $NaClO_3$. We give the corrected results in Table 5*b*.

We would like to thank Mr. B. Arya, M.Sc., of the Department of Mechanical Engineering for his help in computer programming.

Peptides de l'acide djenkolique. II. Une nouvelle méthode de synthèse du glutathion oxydé[1]

BERNARD MARINIER[2] ET MICHÈLE BÉRUBÉ[3]

Research Laboratories, Frank W. Horner Limited, Montréal, Québec

Reçu le 17 septembre 1971

Cette publication montre qu'il est possible de passer d'un peptide protégé contenant de l'acide djenkolique au peptide correspondant contenant de la cystine. Ainsi, le tripeptide **8** et le pentapeptide **9** ont été convertis aux peptides **10** et **11** respectivement par traitement avec le brome en milieu anhydre suivi d'une hydrolyse. Les pentapeptides **9** et **11** ont par la suite été débarrassés de leurs groupes protecteurs et purifiés par filtration sur Sephadex G-10 pour donner le pentapeptides bis-γ-L-glutamyl-L-djenkolyl-bis-glycine (**7**) et le glutathion oxydé (**2**) avec des rendements globaux respectifs de 57 et 38% à partir de l'acide djenkolique (**1**).

This paper shows that it is possible to convert a protected peptide containing djenkolic acid to the corresponding peptide containing cystine. Thus, the tripeptide **8** and the pentapeptide **9** were converted to peptides **10** and **11** respectively by treatment with bromine in anhydrous medium followed by an hydrolysis. The pentapeptides **9** and **11** were then deprotected and purified by filtration through Sephadex G-10 to give respectively the pentapeptide bis-γ-L-glutamyl-L-djenkolyl-bis-glycine (**7**) and oxidized glutathione (**2**) with overall respective yields of 57 and 38% from djenkolic acid (**1**).

Canadian Journal of Chemistry, **50**, 1633 (1972)

Dans la publication précédente (2), on a montré que l'acide djenkolique (**1**) est un acide aminé stable qui forme les dérivés usuels utilisés en synthèse peptidique. Comme cet acide est à la fois l'homologue supérieur de la cystine et le mercaptal de la cystéine avec la formaldéhyde, il sembla intéressant de voir si l'on pouvait passer directement des peptides de l'acide djenkolique à ceux de la cystine ou de la cystéine par élimination du CH_2 central. Cela impliquait tout d'abord la mise au point d'une méthode d'élimination du CH_2 central dans l'acide djenkolique ou ses dérivés, puis la synthèse d'un peptide simple de l'acide djenkolique que l'on transformerait au peptide correspondant de la cystine. On choisit de préparer par cette méthode le glutathion oxydé (**2**).

Il était évident, au départ, qu'une hydrolyse ne pourrait être utilisée pour éliminer le méthylène central car l'acide djenkolique est tellement stable que les conditions nécessaires à cette hydrolyse aurait provoqué rapidement un scission des liaisons peptidiques. Une réaction connue depuis 1887 (3) et étudiée plus récemment par Gauthier (4) retint notre attention: il s'agit de l'oxydation des mercaptals par le brome en milieu aqueux pour donner les disulfures correspondants (éq. 1). Cependant, le disulfure lui-même pouvant être oxydé en bromure de sulfonyle par un excès de brome selon l'éq. 2, la réaction générale se produit selon l'éq. 3 qui est l'addition des deux premières et elle utilise 6 équivalents de brome. L'équation 2 illustre la méthode de Siggia et Edsberg pour le titrage des disulfures (5).

$$[1]\quad (RS)_2CHR' + Br_2 + H_2O \rightarrow RSSR + R'CHO + 2HBr$$

$$[2]\quad RSSR + 5Br_2 + 4H_2O \rightarrow 2RSO_2Br + 8HBr$$

$$[3]\quad (RS)_2CHR' + 6Br_2 + 5H_2O \rightarrow 2RSO_2Br + R'CHO + 10HBr$$

On entreprit une étude de la réaction du brome sur les dérivés de l'acide djenkolique afin de déterminer les conditions conduisant exclusivement aux disulfures, c'est-à-dire aux dérivés correspondants de la cystine. On constata d'abord, qu'en présence d'eau, l'addition d'un seul équivalent de brome provoquait la formation de toute la gamme des produits d'oxydation, depuis le disulfure jusqu'à l'acide sulfonique, ce qui signifie que la première réaction (éq. 1) n'est pas plus rapide que les suivantes. On nota aussi que les sulfures (6) et même les bis-sulfures (7) peuvent donner des produits d'addition stables en milieu anhydre par réaction avec un seul équivalent de brome ou d'iodure de méthyle

[1]Ce travail a été présenté au 36° Congrès de l'ACFAS à Ottawa le 8 novembre 1968 et a également fait l'objet d'une communication (1).

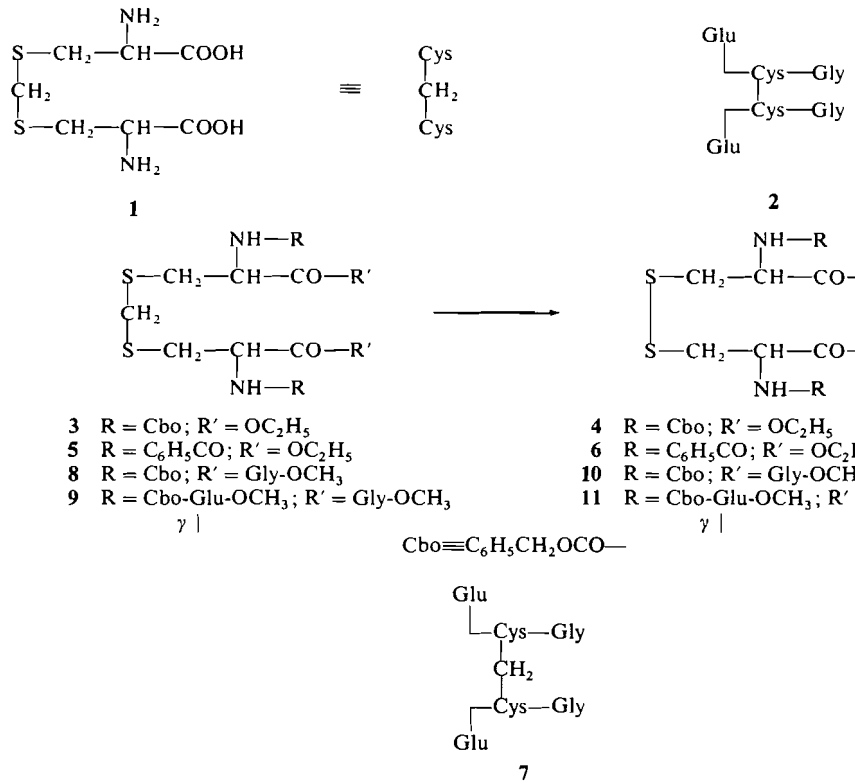
For personal use only.



par exemple. On imagina alors que l'addition d'une seule molécule de brome en milieu anhydre donnerait un produit d'addition sans qu'il y ait de brome en excès dans la solution. Par la suite, l'addition d'eau provoquerait la décomposition ou l'hydrolyse du produit d'addition en disulfure et la réaction s'arrêterait à ce stade. Ce serait, en fait, une façon d'assurer la réaction d'une seule molécule de brome avec une seule molécule de mercaptal.

En appliquant ce principe, on put transformer le dicarbobenzoxy-L-djenkolate de diéthyle (**3**) en dicarbobenzoxy-L-cystinate de diéthyle (4) avec un rendement de 76.3% tandis qu'en prolongeant le temps d'hydrolyse, le dibenzoyl-L-djenkolate de diéthyle (**5**) fut converti en dibenzoyl-L-cystinate de diéthyle (**6**) avec un rendement de 76.7%. Il restait à démontrer que la réaction pouvait s'appliquer aux peptides de l'acide djenkolique. La synthèse du peptide de l'acide djenkolique correspondant au glutathion oxydé, le bis-γ-L-glutamyl-L-djenkolyl-bis-glycine (7), fut alors entreprise.

L'acide dicarbobenzoxy-L-djenkolique (2) fut d'abord condensé avec 2 équivalents de glycinate de méthyle en utilisant le réactif de Woodward (8). On obtint une huile difficile à purifier et qui fournit le tripeptide dicarbobenzoxy-L-djenkolyl-bis-(glycinate de méthyle) (**8**) avec des rendements de 50 à 70%. Par contre, l'utilisation des anhydrides mixtes (9) donna très facilement un produit cristallisé avec un rendement de près de 95%. L'enlèvement des groupes carbobenzoxy par l'acide bromhydrique dans l'acide acétique sec (10) donna un dibromhydrate très hygroscopique qui fut condensé avec le carbobenzoxy-L-glutamate d'α-monométhyle préparé selon Nefkens et Nivard (11). Grâce à la méthode des anhydrides mixtes, le pentapeptide bis-γ-[*N*-carbobenzoxy-L-glutamyl-α-(*O*-méthyl)]-L-djenkolyl-bis-(glycinate de méthyle) (**9**) fut obtenu avec un rendement de 84%.

La synthèse de l'analogue 7 fut interrompue à ce point afin de transformer les peptides protégées **8** et **9** en leurs analogues contenant de la cystine. On effectua d'abord la conversion du

For personal use only.

tripeptide **8** en dicarbobenzoxy-L-cystinyl-bis-(glycinate de méthyle) (**10**) qui est un tripeptide connu (12). Après quelques essais peu encourageants, on prolongea le temps d'hydrolyse jusqu'à 24 h et réussit la conversion avec un rendement de 45%. En utilisant les mêmes conditions, il fut facile de transformer le pentapeptide **9** en son analogue contenant de la cystine, le bis-γ-[*N*-carbobenzoxy-L-glutamyl-α-(*O*-méthyl)]-L-cystinyl-bis-(glycinate de méthyle) (**11**) avec un rendement de 68.5%. Ce peptide, qui est le glutathion oxydé portant des groupes protecteurs, a le même point de fusion que le peptide **9** mais il donne un abaissement de point de fusion en mélange avec ce dernier, montre un R_f différent à la chromatographie sur couche mince, possède un indice de rotation plus négatif et donne un test positif pour les disulfures (13).

Les pentapeptides **9** et **11** furent débarrassés de leurs groupes protecteurs par une saponification d'une durée de 5 h suivie d'une scission des groupes carbobenzoxy par HBr dans l'acide acétique sec (10). Un filtration sur Sephadex G-10 de la solution aqueuse de chacun des bromhydrates permit d'obtenir le peptide **7** et le glutathion oxydé **2** avec des rendements respectifs de 76 et 68.5%, d'où des rendements globaux respectifs de 57 et 38% à partir de l'acide djenkolique.

L'analyse du peptide **7** selon Spackman *et al.* (14) donna lieu à certaines difficultés car, dans les conditions d'hydrolyse préalable, l'acide djenkolique est presque totalement détruit. En fait, un échantillon de cet acide aminé soumis à une hydrolyse identique montra quatre pics à l'analyse: le pic de l'acide djenkolique, celui de la cystine, un pic faible en position proline et un autre entre la thréonine et la sérine. On trouva que ce dernier pic est celui de la thioproline ou acide thiazolidine-carboxylique-4, résultat de la condensation d'une mole de cystéine avec une mole de formaldéhyde (15). Quant au pic en position proline, sa position et son faible facteur "C", calculé par différence, indiquèrent qu'il s'agissait probablement de cystéine (16). L'hydrolysat du peptide **7** donna évidemment ces quatre pics pour l'acide djenkolique en plus de ceux de la glycine et de l'acide glutamique mais l'addition de ces quatre pics permit d'obtenir le rapport théorique pour ces acides aminés. L'analyse du glutathion oxydé **2** ne donna évidemment que les trois pics Glu, Cys_2, et Gly dans le rapport attendu sans aucune trace d'acide djenkolique ou de ses produits d'hydrolyse.

L'indice de rotation du pentapeptide **7** dans l'eau est de $-34.2°$ à comparer à $-94°$ pour le glutathion oxydé. Ceci est conforme aux résultats obtenus tout au long de ce travail, à savoir que les indices de rotation des dérivés ou peptides de l'acide djenkolique sont toujours moins négatifs que les dérivés ou peptides correspondants de la cystine. Par contre, le peptide **7** est très soluble dans l'eau tout comme le glutathion oxydé et les deux peptides ont des R_f identiques dans tous les solvants utilisés en chromatographie sur papier.

Cette synthèse montre donc que l'on peut convertir un peptide de l'acide djenkolique au peptide correspondant de la cystine au moyen d'une réaction extrêmement simple et sans qu'il y ait racémisation. Il est évident qu'une telle méthode n'est pas toujours utile ou nécessaire mais elle peut rendre de très grands services dans certains cas particuliers.

Partie expérimentale

Les points de fusion ne sont pas corrigés et furent déterminés en tubes capillaires avec un appareil électrique de marque Gallenkamp. Les chromatographies sur couche mince furent effectuées sur silicagel (Eastman Chromagram Sheet, 5 × 20 cm) dans un des mélanges suivants: (A) chloroforme/acétone (8:2); (B) chloroforme/acétate d'éthyle (5:5); (C) cyclohexane/acétate d'éthyle (2:8). Les chromatographies sur papier Whatman No. 1 furent effectuées dans le mélange *n*-butanol/pyridine/acide acétique/eau (15:10:3:12). La révélation des taches fut faite par des vapeurs d'iode pour les peptides protégés et avec la ninhydrine pour les peptides libres.

Les analyses élémentaires furent effectuées par le Dr. C. Daesslé, Organic Microanalysis, 5757, rue Decelles, Montréal, Québec. Les échantillons furent d'abord séchés à 80–100° sous 0.1 mm de mercure durant au moins 18 h. Les analyses d'acides aminés furent effectuées dans un appareil Beckman-Spinco.

*Dicarbobenzoxy-L-djenkolyl-bis-(glycinate de méthyle) (**8**)*

On dissout 10.46 g (0.02 mol) d'acide dicarbobenzoxy-L-djenkolique dans 100 ml de chloroforme sec et on ajoute 4.46 ml (0.04 ml) de *N*-méthyl-morpholine à la solution. On refroidit à $-5°$, ajoute 5.22 ml (0.04 mol) de chloroformiate d'isobutyle et agite la solution durant 10 min. On ajoute alors 5.02 g (0.04 mol) de chlorhydrate du glycinate de méthyle presque complètement dissout dans 75 ml de chloroforme sec et froid (0°) contenant 5.55 ml (0.04 mol) de triéthylamine. Une autre portion de 75 ml de chloroforme sec est ajoutée et on agite la solution durant 4 h à tempéra-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ture ambiante, puis on la lave avec H_2O, $NaHCO_3$ 5%, H_2O, HCl dilué, et H_2O (trois fois). Après séchage sur Na_2SO_4 et évaporation sous vide, on obtient un solide p.f. 139–140° qui est recristallisé dans le nitrométhane après traitement au charbon actif: 11.95 g (90%), p.f. 139–140°, $[\alpha]_D^{25}$ −62.6°(*c*, 1 dans la diméthylformamide), R_f 0.53, 0.26 et 0.6 dans les mélanges A, B, et C respectivement. Les eaux-mères donnent une deuxième récolte, 0.64 g, p.f. 139–140°, d'où un rendement total de 94.7%.

Anal. calc. pour $C_{29}H_{36}N_4O_{10}S_2$: C, 52.39; H, 5.46; N, 8.43; S, 9.65. Trouvé: C, 52.47; H, 5.58; N, 8.49; S, 9.49.

Traitement du tripeptide **8** *par HBr/AcOH*

On met 6 g de peptide **8** en suspension dans 60 ml de HBr 4.2 *N* dans l'acide acétique sec. On agite de temps en temps jusqu'à dissolution complète ($\frac{1}{4}$ h) puis laisse au repos $\frac{1}{2}$ h. On ajoute 600 ml d'éther anhydre, filtre le solide sous vide, et le lave avec 600 ml d'éther anhydre. On le sèche durant une nuit sous vide dans un dessicateur en présence de NaOH solide et de P_2O_5. Ce produit est hygroscopique et doit être gardé sous vide dans un dessicateur.

*Bis-γ-[N-carbobenzoxy-*L*-glutamyl-α-(O-méthyl)]-*L*-djenkolyl-bis-(glycinate de méthyle) (***9***)*

On dissout 5.9 g (0.02 mol) de *N*-carbobenzoxy-L-glutamate d'α-monométhyle (11) dans 20 ml de diméthylformamide, ajoute 2.23 ml (0.02 mol) de *N*-méthyl-morpholine, et refroidit la solution à −5°. On ajoute 2.61 ml (0.02 mol) de chloroformiate d'isobutyle, agite 10 min puis ajoute 5.58 g (0.01 mol) du dibromhydrate du L-djenkolyl-bis-(glycinate de méthyle), et 2.23 ml (0.02 mol) de *N*-méthyl-morpholine dissoute dans 25 ml de diméthylformamide. On agite 4 h à température ambiante, puis verse cette solution dans 700 ml d'eau et laisse cristalliser durant $1\frac{1}{2}$ h. Le peptide est filtré sous vide, lavé sur le filtre avec de l'eau, et séché à l'air: il pèse 8.64 g (91%) et son p.f. est 177–180°. Par recristallisation dans l'éthanol absolu, on obtient 8 g (84%) de produit, p.f. 180–182°, $[\alpha]_D^{25}$ −52.7° (*c*, 1 dans la diméthylformamide), R_f 0.1 dans le mélange A. L'échantillon analytique obtenu après plusieurs cristallisations fond à 181–184°.

Anal. calc. pour $C_{41}H_{54}N_6O_{16}S_2$: C, 51.78; H, 5.72; N, 8.84; S, 6.74. Trouvé: C, 51.44; H, 5.48; N, 8.85; S, 6.81.

*Bis-γ-*L*-glutamyl-*L*-djenkolyl-bis-glycine (***7***)*

On dissout 0.237 g (0.00025 mol) de pentapeptide **9** dans 2 ml de diméthylformamide, on refroidit la solution à 0° et, sous agitation, on ajoute 1.1 ml de NaOH 1 *N* goutte à goutte sur une période de 10 min. On continue l'agitation durant 1 h à 0° puis à température ambiante durant 4 h. On acidifie jusqu'au virage du Congo rouge par addition de 1.2 ml de HCl 1 *N*, ajoute 15 ml d'eau et extrait le peptide par l'acétate d'éthyle. La solution organique est séchée sur Na_2SO_4, évaporée sous vide et le résidu est séché sous vide durant la nuit.

Ce résidu est dissout dans 2 ml d'acide acétique sec, puis on ajoute 2 ml d'une solution d'acide bromhydrique 5.4 *N* dans l'acide acétique et on agite durant 1 h: il y a un précipité à la fin. On ajoute 40 ml d'éther sec, filtre le précipité sous vide et le lave rapidement sur le filtre avec 40 ml d'éther sec. Ce dibromhydrate hydroscopique est séché dans un dessicateur en présence de P_2O_5 durant 3 h (poids 0.231 g), puis il est dissout dans 1.5 ml d'eau et la solution est ajustée au p*H* 2.85 avec NaOH 6 *N*. Cette solution est versée sur une colonne de Sephadex G-10 de 2.5 cm de diamètre par 90 cm de hauteur qui est ensuite éluée avec de l'eau. La vitesse d'élution est maintenue constante à 14 ml/h (2.85 ml/cm²/h) au moyen d'une pompe péristatique et des fractions de 2 ml sont recueillies. Les peptides présents sont détectés quantitativement par réaction avec la ninhydrine selon Moore et Stein (17) sur 0.1 ml de solution. La quantité de bromure de sodium est déterminée par titrage du brome selon la méthode de Volhard (18).

Les fractions 94 à 102 ne montrent qu'une seule tache R_f 0.06 à la chromatographie sur papier tandis que la fraction 104 est très légèrement impure. Les fractions 94 à 103 réunies et lyophilisées donnent 0.119 g (76%) de solide incolore, $[\alpha]_D^{25}$ −34.2° (*c*, 1 dans l'eau). Un échantillon hydrolysé dans HCl 6 *N* en tube scellé à 120° durant 24 h donne les acides aminés dans le rapport suivant: Glu, 2.06; Gly, 2.00; Dje (somme de quatre pics), 0.97.

*Dicarbobenzoxy-*L*-cystinate de diéthyle (***4***)*

*(a) A partir de la dicarbobenzoxy-*L*-cystine*

Préparé selon Baganz et Dransch (19), p.f. 86°, $[\alpha]_D^{22}$ −142° (*c*, 1 dans la diméthylformamide).

*(b) A partir du dicarbobenzoxy-*L*-djenkolate de diéthyle (***3***)*

On dissout 0.289 g (0.0005 mol) de dicarbobenzoxy-L-djenkolate de diéthyle (2) dans 3 ml de chloroforme et ajoute 1 ml d'une solution 0.5 *M* de brome dans le même solvant. Après 10 min d'agitation, on ajoute 2 ml de $NaHCO_3$ 10% et agite fortement: il y a décoloration partielle. On verse la solution dans une ampoule à décantation, ajoute quelques ml de chloroforme et agite fortement: la couleur disparaît. On sépare les couches, lave la couche chloroformique avec de l'eau, sèche, évapore le chloroforme sous vide, ajoute un peu d'éthanol 95%, et évapore à sec avec léger chauffage. Le résidu solide est cristallisé dans l'éthanol absolu: 0.176 g (62.2%) de cristaux p.f. 85°, sans abaissement avec le produit préparé en (*a*) et donnant un abaissement à environ 70° en mélange avec le produit de départ; $[\alpha]_D^{22}$ −139° (*c*, 1 dans la diméthylformamide). L'addition de quelques gouttes d'eau aux eaux-mères donne une autre récolte de 0.040 g, p.f. 82–82.5°, d'où un rendement total de 76.3%.

*Dibenzoyl-*L*-djenkolate de diéthyle (***5***)*

On dissout 3.22 g (0.007 mol) d'acide dibenzoyl-L-djenkolique (20) dans 40 ml d'éthanol absolu puis on sature avec HCl sec durant $\frac{1}{2}$ h. On chauffe à reflux 2 h puis évapore sous vide et recristallise le résidu dans l'éthanol absolu, d'où l'on tire 1.8 g (49.6%) de cristaux p.f. 156–158°, $[\alpha]_D^{22}$ −122° (*c*, 1 dans la diméthylformamide).

Anal. calc. pour $C_{25}H_{30}N_2O_6S_2$: C, 57.94; H, 5.83; N, 5.40; S, 12.36. Trouvé: C, 57.53; H, 5.88; N, 5.23; S, 12.11.

*Dibenzoyl-*L*-cystinate de diéthyle (***6***)*

*(a) A partir de la dibenzoyl-*L*-cystine*

On dissout 0.75 g de dibenzoyl-L-cystine (21) dans 10 ml d'éthanol absolu, sature la solution avec HCl sec durant $\frac{1}{2}$ h, chauffe à reflux durant 2 h puis laisse refroidir, et filtre. On obtient 0.61 g (72%) de produit p.f. 183°, $[\alpha]_D^{22}$ − 216° (*c*, dans la diméthylformamide). La littérature (22) rapporte p.f. 183–185.5°, $[\alpha]_D$ +13.3° (*c*, 0.5 dans EtOH 99%).

*(b) A partir du dibenzoyl-*L*-djenkolate de diéthyle (***5***)*

On dissout 0.259 g (0.0005 mol) de dibenzoyl-L-djenkolate de diéthyle dans 10 ml de chloroforme sec et ajoute 1 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

d'une solution 0.5 *M* de brome dans le même solvant. Après 10 min d'agitation, on ajoute à la solution jaune foncé 5 ml de $NaHCO_3$ 5% et quand la décoloration est complète, on ajoute 20 ml d'éther de pétrole 30–60° et agite le mélange durant $22\frac{1}{2}$ h. Les solvants sont évaporés partiellement, les couches sont séparées et la couche organique est lavée avec de l'eau, séchée, et évaporée. Le résidu recristallisé dans l'éthanol absolu donne 0.193 g (76.7%) de cristaux p.f. 181–183° sans dépression avec le produit préparé en (*a*) et $[\alpha]_D$ −217° (*c*, 1 dans la diméthylformamide).

*Dicarbobenzoxy-*L*-cystinyl-bis-(glycinate de méthyle) (**10**)*

*(a) A partir de la dicarbobenzoxy-*L*-cystine*

A une solution de 0.25 g (0.002 mol) du chlorhydrate du glycinate de méthyle et de 2.8 ml de triéthylamine dans 6 ml de $CHCl_3$, on ajoute 0.523 g (0.001 mol) de dicarbobenzoxy-L-cystine. On refroidit dans la glace et ajoute 0.412 g (0.002 mol) de dicyclohexylcarbodiimide sous bonne agitation. Après $\frac{1}{2}$ h, le bain de glace est enlevé et l'agitation à température ambiante est poursuivie durant 18 h. On ajoute quelques gouttes d'acide acétique 50%, filtre la dicyclohexylurée (0.418 g, 93.5%), lave le filtrat avec HCl dilué, $NaHCO_3$ 10%, et H_2O, sèche et évapore sous vide. Le résidu blanc fond à 164.5–165° mais après une cristallisation dans l'acétate d'éthyle, il fond à 156–156.5°. Une recristallisation dans le méthanol ramène le p.f. à 169–169.5° avec un rendement de 61%, un $[\alpha]_D^{25}$ −150° (*c*, 1 dans la diméthylformamide) et des R_f de 0.59, 0.29, et 0.63 dans les solvants A, B et C respectivement. La littérature (12) rapporte: p.f. 172–172.5° et $[\alpha]_D^{25}$ −146° (*c*, 1 dans la diméthylformamide).

*(b) A partir du dicarbobenzoxy-*L*-djenkolyl-bis-(glycinate de méthyle) (**8**)*

A une solution de 0.665 g (0.001 mol) du tripeptide **8** dans 20 ml de chloroforme, on ajoute 2 ml d'une solution 0.5 *M* de brome dans $CHCl_3$. Après 10 min d'agitation, on ajoute 20 ml de $NaHCO_3$ 5% et poursuit l'agitation durant toute la nuit. On sépare alors les couches, lave la couche aqueuse avec du chloroforme puis les couches organiques réunies avec de l'eau, sèche, et évapore le chloroforme sous vide. On obtient un solide un peu collant qu'on recristallise dans le méthanol pour obtenir 0.293 g (45%) de cristaux blancs, p.f. 168–169.5° sans abaissement avec le produit préparé en (*a*), $[\alpha]_D^{25}$ −145.5° (*c*, 1 dans la diméthylformamide) et donnant des R_f identiques à ceux obtenus en (*a*).

*Bis-γ-[N-carbobenzoxy-*L*-glutamyl-α-(O-méthyl)]-*L*-cystinyl-bis-(glycinate de méthyle) (**11**)*

Par chauffage, on dissout 0.475 g (0.0005 mol) du pentapeptide **9** dans 20 ml de chloroforme sec, puis on refroidit à température ambiante et ajoute 1 ml d'une solution 0.5 *M* de brome dans $CHCl_3$. Après 1 min d'agitation, on ajoute 10 ml de $NaHCO_3$ 5% et 10 ml d'eau et on agite violemment durant 2–3 min. On ajoute ensuite 60 ml d'acétate d'éthyle et poursuit l'agitation durant 24 h. Les solvants organiques sont alors évaporés et le solide qui précipite est filtré sous vide et lavé avec de l'eau. Après séchage sous vide, on obtient 0.370 g (79%) de solide blanc p.f. 176–178° donnant un abaissement de p.f. à 165–169° avec le produit de départ. Un cristallisation dans l'éthanol absolu donne 0.321 g (68.5%) de cristaux p.f. 178–181°. $[\alpha]_D^{25}$ −76.9° (*c*, 1 dans la diméthylformamide), R_f 0.23 dans le solvant A. L'échantillon analytique obtenu après plusieurs cristallisations fond à 182–183°.

Anal. calc. pour $C_{40}H_{52}N_6O_{16}S_2$: C, 51.27; H, 5.59; N, 8.97; S, 6.84. Trouvé: C, 51.06; H, 5.61; N, 8.95; S, 7.12.

*Glutathion oxydé (**2**)*

On dissout 0.234 g (0.00025 mol) de pentapeptide **11** dans 2 ml de diméthylformamide, on refroidit la solution à 0° et, sous agitation, on ajoute 1.1 ml de NaOH 1 *N* goutte à goutte sur une période de 15 min. On continue l'agitation durant 1 h à 0° et $2\frac{1}{2}$ h à température ambiante. On acidifie jusqu'au virage du Congo rouge, ajoute 15 ml d'eau, et extrait le peptide avec de l'acétate d'éthyle. La solution organique est séchée sur Na_2SO_4, évaporée sous vide, et le résidu est séché sous vide poussé durant la nuit.

Ce résidu est dissout dans 2 ml d'acide acétique sec, puis on ajoute 2 ml d'une solution d'acide bromhydrique 5.4 *N* dans l'acide acétique et on agite 1 h. On ajoute 40 ml d'éther sec et une gomme précipite. On décante la solution surnageante, lave la gomme plusieurs fois par trituration dans l'éther et sèche sous vide en présence de P_2O_5. Le résidu gommeux (0.259 g) est alors dissout dans 2 ml d'eau et la solution est ajustée au p*H* 2.85 avec NaOH 6 *N*. Cette solution est versée sur une colonne de Sephadex G-10 de 2.5 cm de diamètre par 90 cm de hauteur qui est éluée avec de l'eau tel que décrit précédemment. Les fractions 96 à 106 ne montrent qu'une seule tache R_f 0.07 à la chromatographie sur papier tandis que les fractions 107–108 sont légèrement impures. Les fractions 94 à 106 réunies et lyophilisées donnent 0.106 g (68.5%) de solide incolore, $[\alpha]_D$ −94° (*c*, 1 dans l'eau). Un échantillon hydrolysé dans HCl 6 *N* en tube scellé à 120° durant 24 h donne les acides aminés dans le rapport suivant: Glu, 1.03; Gly, 1.00; Cys, 0.9.

Nous remercions le Conseil National de Recherches du Canada qui a subventionné ce travail. Nos remerciements vont également au Dr. F. L. Chubb pour de nombreuses et utiles discussions, au Dr. L. Eric pour ses suggestions concernant la purification finale du peptide et au Dr. N. A. Attallah autrefois de l'Université McGill qui a effectué les analyses d'acides aminés.

The Alkaloids of *Ormosia semicastrata*: (−)-Ormosanine, (±)-Piptanthine, (−)-18-Epiormosanine, and (−)-Ormocastrine

STEWART MCLEAN AND MARIE LESSARD ROY
Department of Chemistry, University of Toronto, Toronto, Ontario
AND
H.-J. LIU AND D. T. CHU
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

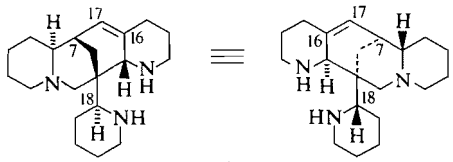
Received December 15, 1971

The alkaloids of *Ormosia semicastrata* have been shown to be (−)-ormosanine, (±)-piptanthine, (−)-18-epiormosanine, and (−)-ormocastrine. The structure and relative configuration shown in **1** have been assigned to ormocastrine on the basis of its 220 MHz n.m.r. spectrum and its conversion to ormosanine, among other products, on hydrogenation.

Les alcaloïdes de *Ormosia semicastrata* sont la (−)-ormosanine, la (±)-piptanthine, la (−)-18-épiormosanine, et la (−)-ormocastrine. La structure et la configuration relative représentées par **1** ont été attribuées à l'ormocastrine sur la base de son spectre r.m.n. à 220 MHz et par sa transformation en ormosanine, entre autre, par hydrogénation.

Canadian Journal of Chemistry, **50**, 1639 (1972)

We have recently reported (1) the isolation of four alkaloids from the seeds of *Ormosia semicastrata*: ormosanine, (±)-piptanthine, 18-epiormosanine, and one, $C_{20}H_{33}N_3$, which we will now call ormocastrine. Although our evidence indicated that ormocastrine was a stereoisomer of dihydroormojanine (2), it was not sufficiently conclusive to establish this unequivocally. We now present evidence that allows us to assign to ormocastrine the structure and stereochemistry (relative configuration) shown in **1**.[1]



1

The structural ambiguity was primarily concerned with the location of the double bond, which was tentatively assigned the position shown since at 100 MHz the n.m.r. spectrum of the alkaloid provided evidence for the presence of only one vinyl proton, and this was associated with a doublet, $J = 6$ Hz, (broadened by further weak coupling) at τ 4.35. The most probable explanation for this signal was that the vinyl proton had one neighboring proton and therefore should be placed at C-17, adjacent to the bridgehead proton at C-7. However, as Deslongchamps *et al.* (2) pointed out in the case of dihydroormojanine, the double bond could be in one of a small number of alternative locations in the molecule if the steric constraints caused the vinyl proton to couple relatively strongly ($J = 6$ Hz) with one proton of an adjacent methylene group and very weakly ($J \simeq 0$ Hz) with the other. We have now shown that the latter possibility can be excluded since a careful examination of the n.m.r. spectrum of ormocastrine at 220 MHz has allowed us to locate the signal arising from the proton to which the vinyl proton is coupled. This signal appears at τ 8.00 as an unresolved multiplet (its width at half-height is 16 Hz) with an area corresponding to one proton. This proton and the vinyl proton can be decoupled from one another; irradiation at τ 8.00 causes the vinyl signal at τ 4.35 to collapse to a slightly broadened singlet, while irradiation at τ 4.35 causes the signal at τ 8.00 to sharpen; although it is still a multiplet, its width indicates that the other

[1]In previous publications the Toronto and New Brunswick authors have differed in the manner in which they have represented structural formulae and, in order to assist the reader who may wish to compare formulae shown here with those in other papers, we have shown both conventions explicitly. In no case is an assignment of the absolute configuration implied by these representations.

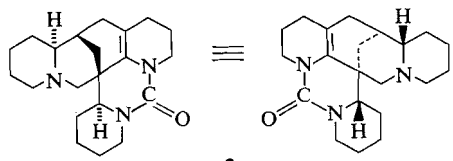
coupling constants associated with it are smaller in magnitude than that with the vinyl proton and it is highly improbable that a geminal coupling is present. It follows that **1** represents the true structure of ormocastrine.

The stereochemical question that remained was answered by first treating ormocastrine with phosgene and converting it to the urea, referred to as the homoxy derivative, in which the two secondary amine functions are joined by a carbonyl bridge. When homoxyormocastrine, which shows the vinyl proton as a doublet, $J = 6$ Hz, at τ 4.45 in its n.m.r. spectrum, was subjected to hydrogenation in the presence of platinum in glacial acetic acid, three products were isolated. Two were reduction products, one of which was identified as homoxyormosanine and the other was consequently deduced to be homoxy-16-epiormosanine. The third product resulted from isomerization of homoxyormocastrine and is assigned formula **2**; it is



2

identical with a synthetic product obtained by the group at the University of New Brunswick (3). Hydrogenation of ormocastrine itself afforded in good yield equal amounts of two products, the first identified as ormosanine and the second deduced to be 16-epiormosanine. The homoxy derivative of 16-epiormosanine produced in this way was identical with the material obtained by hydrogenation of homoxyormocastrine. Since ormosanine possesses all of the chiral centers present in ormocastrine, it follows that the relative configuration of ormocastrine is that shown in **1**, provided that no epimerization has occurred during the hydrogenation, and experience with the behavior of this class of compounds indicates that epimerization is unlikely in the present case (2, 3).

Ormocastrine proved to be laevorotatory, $[\alpha]_D$ $-29°$ in methanol, with a plain negative dispersion curve down to 250 mμ at least. This optical activity led us to examine more carefully the other alkaloids isolated from the plant since it might have been anticipated that either all would be active or all would be inactive. However, the piptanthine which we had previously described as racemic because of its melting point (1), did in fact prove to be optically inactive. On the other hand, we were surprised to find that our ormosanine is weakly laevorotatory, $[\alpha]_D$ $-9°$, with a plain negative dispersion curve. As we pointed out previously (1), we had expected the ormosanine to be inactive since it appeared that this alkaloid has always been isolated as a racemic modification, with the only exception being the early report of Lloyd and Horning (4) that their sample was very weakly dextrorotatory in chloroform. Our 18-epiormosanine is also weakly laevorotatory, $[\alpha]_D$ $-10°$, with a plain negative dispersion curve. In conclusion then, three of the four alkaloids are laevorotatory and one is racemic; the plant which provided the first natural (±)-piptanthine has also provided the first natural (−)-ormosanine.

Experimental

A Perkin–Elmer Infracord spectrophotometer and a Hitachi Perkin–Elmer RMU-6D mass spectrometer were used. The 220 MHz spectrum was recorded on a Varian HR-220 at the Canadian 220 MHz N.M.R. Center; decoupling experiments were carried out under track-field sweep decoupling conditions. Optical rotatory dispersion curves were recorded on a Jasco ORD/UV-5 instrument and $[\alpha]_D$ values were obtained on a Perkin–Elmer Model 141 Polarimeter with samples dissolved in methanol.

Hydrogenation of Homoxyormocastrine

Homoxyormocastrine (**1**) (12 mg) in glacial acetic acid (2 ml) was hydrogenated over Adams catalyst (10 mg) at room temperature under a hydrogen atmosphere overnight. The catalyst was filtered and washed thoroughly with glacial acetic acid and chloroform. The filtrate was basified with aqueous sodium hydroxide and extracted with chloroform. After it had been dried over magnesium sulfate, filtered, and evaporated, the extract gave an oil (10 mg) consisting of three products. Silica gel preparative t.l.c. using ether containing 15% methanol as eluent led to their separation and isolation as homoxy-16-epiormosanine (3 mg), homoxyormosanine (3 mg), and an isomer (1 mg) of ormocastrine, assigned structure **2**.

Homoxy-16-epiormosanine shows a molecular ion peak at *m/e* 343 in its mass spectrum and an urea absorption band at 6.21 μ (1610 cm^{-1}) in its i.r. spectrum. Homoxyormosanine and compound **2** thus obtained were found to be identical with authentic samples (3) by comparison of their i.r. and mass spectra and t.l.c. characteristics.

Hydrogenation of Ormocastrine

Ormocastrine (13 mg) was hydrogenated in the manner

described above. The reduction product (10 mg) obtained was shown to be a mixture of equal parts of ormosanine and 16-epiormosanine, which were isolated by preparative t.l.c. on alumina with elution by ether containing 10% methanol. The ormosanine obtained had i.r., t.l.c., and mass spectral characteristics identical with those of an authentic sample. The 16-epiormosanine showed a parent ion at *m/e* 317 in its mass spectrum and reacted with phosgene (5) to afford a quantitative yield of the homoxy derivative, identical with that obtained by the hydrogenation of homoxyormocastrine.

Discussions with Professor Z. Valenta during the course of this work have been of great value to us. Financial support from the National Research Council of Canada is gratefully acknowledged.

Adsorption of Co^{2+} by Oxides from Aqueous Solution

P. H. TEWARI, A. B. CAMPBELL, AND WOON LEE

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received November 22, 1971

The adsorption of Co(II) by Fe_3O_4, Al_2O_3, and MnO_2 has been studied as a function of Co(II) concentration, solution-pH, and temperature. It is observed that the adsorption of cobalt increases markedly with the solution pH between pH 5 and 7.5. Above pH 8 adsorption becomes increasingly masked by precipitation of $Co(OH)_2$ and no resolution of these two contributions to the loss of Co(II) from solution is possible. A $\log \theta/(1-\theta)$ *vs.* pH plot is found to be linear between pH 5 and 7.5, where θ is the fraction of occupied adsorption sites. The presence of 0.1 m Ba^{2+} and Mg^{2+} in the solution does not seem to affect the hydrogen ion dependence of the adsorption of Co(II) on alumina.

The adsorption results have been analyzed by the Langmuir adsorption isotherm over a wide range of Co(II) concentration (10^{-6}–10^{-3} m). The adsorption of Co(II) is found to be an endothermic process and increases markedly with temperature between 30 and 100 °C. The heat of adsorption decreases with increasing surface coverage of the oxides. At saturation coverage, the heats of adsorption for Co(II) on Al_2O_3, MnO_2, and Fe_3O_4 are −14.9, −14.3, and −6.3 kcal/mol, respectively. Hydrolysis of Co(II) is suggested as a possible mechanism for the marked dependence of adsorption on pH and temperature.

L'adsorption de Co(II) sur Fe_3O_4, Al_2O_3, et MnO_2 a été étudiée en fonction de la concentration en Co(II), du pH de la solution et de la température. On observe que l'adsorption du cobalt croît fortement avec le pH de la solution entre 5 et 7.5. Au delà de pH 8, l'adsorption est de plus en plus marquée par la précipitation de $Co(OH)_2$; il n'est plus possible alors d'estimer la perte de Co(II) de la solution à l'une de ces deux contributions. La courbe $\log \theta/(1-\theta)$ en fonction du pH est linéaire entre pH 5 et 7.5, θ étant la fraction de sites d'adsorption occupés. La présence de 0.1 M de Ba^{2+} et de Mg^{2+} dans la solution, ne semble pas affecter la relation existant entre l'adsorption de Co(II) sur l'alumine en fonction de l'ion hydrogène.

Les résultats de l'adsorption ont été analysés selon l'isotherme d'adsorption de Langmuir dans un grand intervalle de concentration en Co(II) (de 10^{-6} à 10^{-3} m). L'adsorption de Co(II) est un processus endothermique et croît fortement avec la température entre 30 et 100 °C. La chaleur d'adsorption décroît lorsque la surface recouverte en oxydes croît. Lorsque celle-ci atteint la saturation, les chaleurs d'adsorption de Co(II) sur Al_2O_3, MnO_2, et Fe_3O_4 sont respectivement de −14.9, −14.3, et −6.3 kcal/mol. On pense que l'hydrolyse de Co(II) est un mécanisme possible expliquant la dépendance marquée de l'adsorption en fonction du pH et de la température.

Canadian Journal of Chemistry, **50**, 1642 (1972)

Introduction

The adsorption of metal ions from aqueous solutions is of considerable practical importance in many areas. Our interest in the study of adsorption from solution lies in its possible role in the transport of radioactivity in water cooled nuclear reactors. In particular, the transport of cobalt adsorbed on corrosion product oxides seems to be an important factor in the growth of reactor radiation fields. The adsorption of Co(II) from solution by metal oxides is reported here as a function of solution pH, concentration and temperature.

Experimental

In this study small concentration changes due to adsorption were determined by counting γ-ray emissions from ^{60}Co tracer using a sodium iodide detector. A ^{60}Co solution of high specific activity, in the form of $Co(NO_3)_2$ was used as tracer. This was mixed with known amounts of inactive cobalt nitrate to give cobalt concentrations in the range of 10^{-7}–10^{-2} m. A count rate *vs.* concentration graph was found to be linear over a concentration range of four to five orders of magnitude. The concentrations of cobalt used for the calibration were also verified by atomic absorption spectroscopy. The precision of the cobalt determination in the concentration range $<10^{-5}$ m was ±10% and in concentrations $>10^{-5}$ m was ±5% (2σ).

Fe_3O_4 was synthesized by addition of ferrous sulfate to a solution of sodium hydroxide containing KNO_3 and was purified by repeated washing with conductivity water as described by Benton and Horsfall (1). Emission spectrographic analysis showed the following impurity concentrations in μg/g oxide: 17 Co, 19 Si, 5 Ni, and 100 Mn. Aluminum and magnesium were less than 1 μg/g. X-Ray diffraction data gave characteristic magnetite peaks.

The Al_2O_3 and MnO_2 used in the experiment were analytical grade reagents (Fisher Scientific Company) and were thoroughly washed with conductivity water to remove trace impurities. Analytical grade HNO_3, KNO_3, $BaCl_2$, and $Mg(NO_3)_2$ were used. The NaOH used was CO_2 free and was stored in plastic bottles.

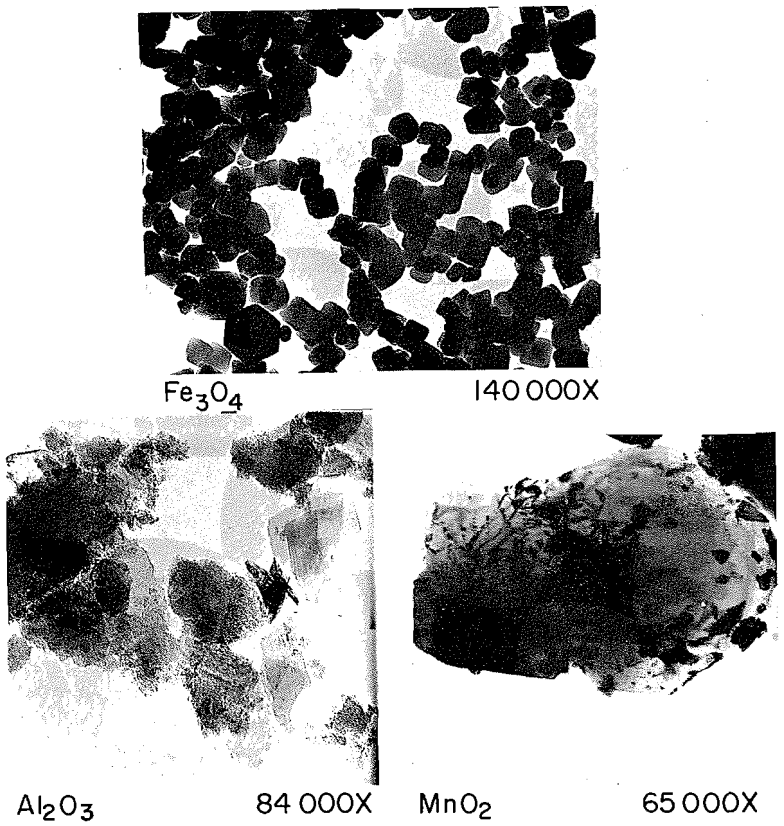

FIG. 1. Electron micrograph of: (*a*) Fe_3O_4, (*b*) Al_2O_3, (*c*) MnO_2.

Surface area measurements were obtained by the B.E.T. nitrogen adsorption method. The surface areas for Al_2O_3, Fe_3O_4, and MnO_2 were 247, 15, and 0.6 m^2/g, respectively.

Electron micrographs of the oxides were also obtained to further characterize the surfaces of the adsorbents. As evident from Fig. 1, the synthesized Fe_3O_4 was always a well formed crystalline material in contrast to Al_2O_3 and MnO_2 which showed ill-defined features.

When a known amount of the oxide was shaken with a Co^{2+} solution, the p*H* changed quite markedly due to the acidic or basic nature of the oxides. To avoid this, an automatic titrimeter (Fisher model 36) was used to maintain a constant p*H* during the adsorption experiments. HNO_3 was added to counteract basic reactions with Al_2O_3 and NaOH was added in acidic reactions for Fe_3O_4 and MnO_2. By these means the p*H* was maintained within ± 0.02 unit. Attempts to use chemical buffers to maintain the solution p*H* were not successful. In phosphate buffer, a significant portion of the activity was lost on centrifugation due to formation of highly insoluble cobalt phosphate and with borax buffer the capacity was exceeded.

A nitrogen atmosphere was maintained throughout the experiment. The temperature was controlled to ± 0.2 °C. Adsorption was continued for about 12 h for runs at temperatures up to 60 °C and for only about 6 h at 80 to 100 °C. Tests showed that these times were sufficient for equilibrium. The solution (including the oxide) was then centrifuged for half an hour at 15 000 r.p.m. The supernatant solution was analyzed for cobalt by determining the count rate for a 5 g sample.

In all adsorption experiments blank runs were performed to correct for any loss of activity due to adsorption on the reaction vessel or centrifugation tube. Glass vessels were found to adsorb a significant percentage of the Co^{2+} at lower concentrations. Polyethylene vessels were found to be satisfactory and were therefore used in all experiments.

Results

A marked increase in adsorption of cobalt on MnO_2 was observed with increasing p*H* as shown in Fig. 2. The percent of cobalt adsorbed on MnO_2 increased rapidly between p*H* 5 and 8. At p*H* values higher than 8 the percent of adsorption apparently levelled off. However, beyond this p*H*, activity losses due to $Co(OH)_2$ precipitation and adsorption could not be separated. A similar strong p*H* dependence for the adsorption of cobalt was exhibited by Fe_3O_4 and Al_2O_3.

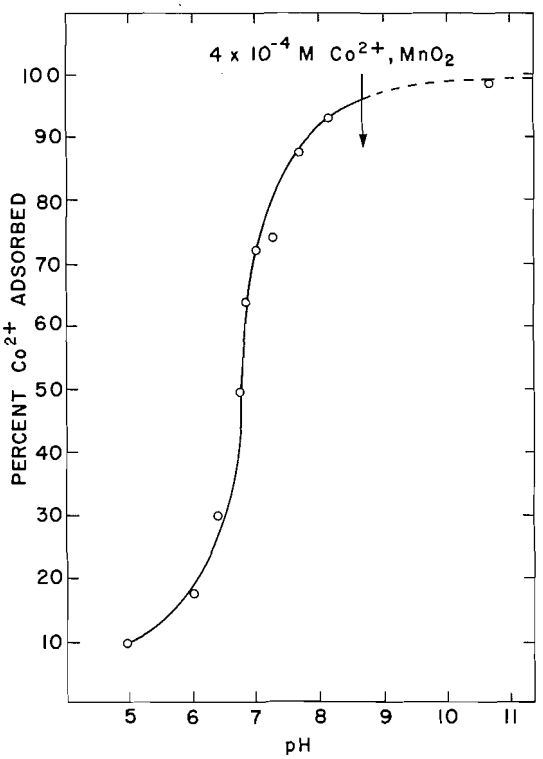

FIG. 2. Percentage of cobalt adsorbed on MnO_2 from solution (4×10^{-4} *m* Co^{2+}).

Experiments were also carried out to see the effect of ions such as Ba^{2+} and Mg^{2+} on the adsorption of cobalt. The presence of 0.1 *m* Ba^{2+} and Mg^{2+} in the solution did not have any significant effect on the hydrogen ion dependence of the adsorption of cobalt on alumina as shown in Fig. 3. The concentration of cobalt solutions in all the runs of this set was 4×10^{-4} *m* compared to 0.1 *m* of the competing Ba^{2+} and Mg^{2+} ions.

The adsorption results were analyzed by the Langmuir adsorption isotherm

$$[1] \qquad \theta = \frac{ac}{1 + ac}$$

where θ is the fraction of occupied adsorption sites, c is the equilibrium solution concentration and a is a constant related to the intensity of adsorption. For the case of adsorption in solutions eq. 1 may be represented as (2, 3)

$$[2] \qquad \frac{c}{w} = \frac{c}{M} + \frac{1}{aM}$$

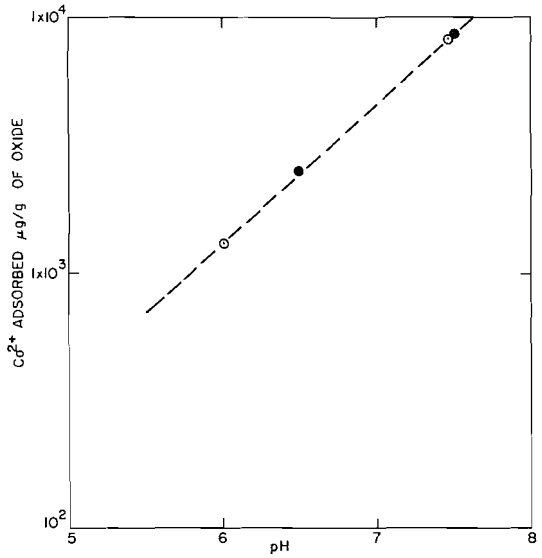

FIG. 3. Effect of competing Ba^{2+} and Mg^{2+} ions (0.1 *m*) on the hydrogen ion dependence of adsorption of cobalt on Al_2O_3 at 30 °C. Dashed line: adsorption of cobalt *vs.* p*H* without competing ions, Co(II) concentration 4×10^{-4} *m*. ○, Adsorption of cobalt in presence of 0.1 *m* Ba^{2+} ions; ●, adsorption of cobalt in presence of 0.1 *m* Mg^{2+}.

where c is the equilibrium concentration, w is the amount of absorbate per unit amount of adsorbent for a given concentration, M is the saturation amount of adsorbate per unit amount of the adsorbent and a is the same constant as in eq. 1. A Langmuir plot showing conformity of the data with eq. 2 is presented in Fig. 4.

From the slopes of the linear plots of c/w *vs.* c, the value of M, the capacity for adsorption for the oxides has been determined. The saturation values M for cobalt adsorption for Al_2O_3 and MnO_2 at p*H* 6 are 6.6×10^{-4} and 4.2×10^{-2} $\mu g/cm^2$, respectively. For Fe_3O_4 at p*H* 6.5 the M value is 3.7×10^{-2} $\mu g/cm^2$.

Discussion

Effect of Temperature

The adsorption process for cobalt on the oxides studied here is markedly endothermic. An endothermic adsorption of Co^{2+} on montmorillonite is also reported by Hodgson (4) between 25 and 55 °C. However, Chester (5) has found that while adsorption of Co^{2+} from sea water on illite increases with increasing temperature, the adsorption of Zn^{2+} decreases. Dyck (6) found no change in adsorption of

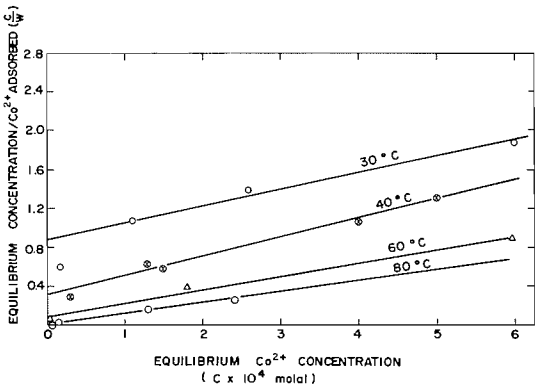

FIG. 4. Langmuir adsorption isotherm of Co on Al_2O_3 at pH 6.

silver ion on ferric oxide over the temperature range 25 to 50 °C. Endothermic adsorption of a colloidal dye on solid surfaces in aqueous solutions is reported by Giles *et al.* (7–9) and aggregation of the dye is thought to be responsible for the increased adsorption. An increase in adsorption with temperature has also been found for polymers on metal powders (10), and for some metal ions on glass, steel, and polyvinyl chloride (11).

Calculation of Heat of Adsorption

From the linear plots of c/w *vs.* c of eq. 2 M is derived from the slope. The ratio of slope/intercept determines the value of a. a is related to the heat of adsorption ΔH as follows (2, 3)

$$[3] \qquad a = a' \, e^{\Delta H/RT}$$

Thus from ln a *vs.* $1/T$ plots, the value of ΔH is calculated for saturation adsorption. Such a plot for Al_2O_3 is given in Fig. 5. The heats of adsorption calculated for Al_2O_3, MnO_2, and Fe_3O_4 from the above procedure are -14.9, -14.3, and -6.3 kcal/mol, respectively.

The heat of adsorption, ΔH_x, may also be calculated from the integrated form of the Clausius–Clapeyron relationship,

$$[4] \qquad \Delta H_x = R \left(\frac{\partial \ln c}{\partial (1/T)} \right)$$

The heat of adsorption calculated in this manner is always a function of surface coverage x. The value of ΔH_x may be obtained from the linear plot of log c *vs.* $1/T$ for a fixed coverage of the solid (Fig. 6). Table 1 gives the ΔH_x values for the oxides at different coverages.

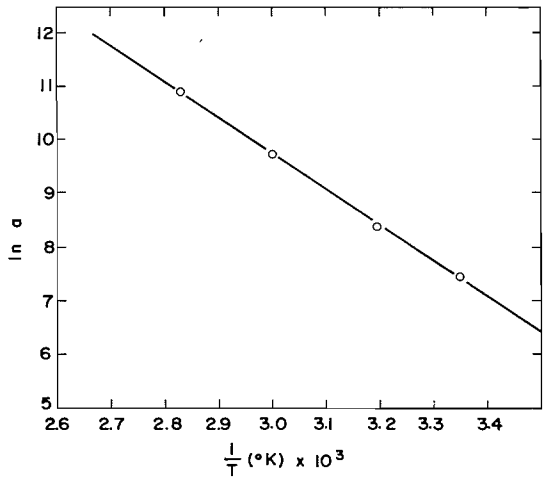

FIG. 5. Plot of ln a *vs.* $1/T$ for cobalt adsorption on Al_2O_3 at pH 6.

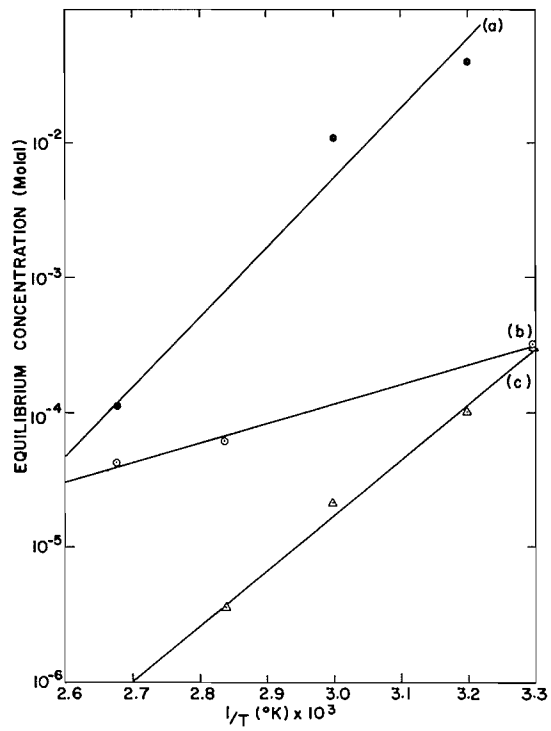

FIG. 6. Clausius–Clapeyron plot of log c *vs.* $1/T$: (a), MnO_2, surface coverage 1.67×10^{-2} μg/cm^2 at pH 6; (b), Fe_3O_4, surface coverage 3.3×10^{-2} μg/cm^2 at pH 6.5; (c), Al_2O_3, surface coverage 2×10^{-4} μg/cm^2 at pH 6.

It is seen from Table 1 that the value of ΔH_x decreases with surface coverage. A steady decrease of heat of adsorption with increasing

TABLE I. ΔH_x values for the oxides at different coverages

Oxide	pH	Coverage $\mu g/cm^2$	ΔH_x (kcal/mol)
MnO_2	6.0	1.0×10^{-2}	−22.2
		2.0×10^{-2}	−20.8
		*4.2×10^{-2}	−14.3
Al_2O_3	6.0	8.0×10^{-5}	−20.5
		2.0×10^{-4}	−18.7
		*6.6×10^{-4}	−14.9
Fe_3O_4	6.5	2.2×10^{-2}	−7.3
		3.3×10^{-2}	−6.6
		*3.7×10^{-2}	−6.3

*Saturation value.

amount of adsorption has been reported in the literature (12). The values of ΔH_x at saturation, for Al_2O_3 and MnO_2 are almost the same, −14.9 and −14.3 kcal/mol respectively. The above values compare favorably with the value of −16 kcal/mol for Co^{2+} adsorption on montmorillonite reported by Hodgson (4). The saturation ΔH_x value for Fe_3O_4 is only −6.3 kcal/mol. The reason for this low value of ΔH_x for Fe_3O_4 is not known. Fe_3O_4 was synthesized in the laboratory. It had well defined crystalline features (Fig. 1) and was probably much more hydrated because it had not been subjected to temperatures higher than 80 °C. Al_2O_3 and MnO_2, on the other hand, were commercial samples. The synthetic Fe_3O_4 might be easily hydroxylated which might facilitate the surface reaction.

Effect of pH

The adsorption of Co^{2+} on the oxides increases with increasing pH. A similar increased adsorption of metal ions by oxides with increasing pH has been reported by Kurbatov *et al.* (13), Von Grimme (14), Stryker and Matijevic (15 and references therein) and others (16–18). In general the hydrolysis of the adsorbing metal ions has been assumed to be responsible for the enhanced adsorption, although the use and the meaning of the term hydrolysis is not always consistent (15).

Hodgson *et al.* (16) point out that the enhanced adsorption of metal ions on clay mineral surfaces with increasing pH may be explained either by a mechanism involving prior hydrolysis of the metal ions in solution (reaction 5) to give a hydrolysis product which is more strongly adsorbed (reaction 6) or by a mechanism involving direct exchange of the unhydrolyzed ion (reaction 7) with a specific group on the adsorbing surface

$$[5] \qquad [M^{2+}] + [H_2O] \rightleftarrows [MOH^+] + [H^+]$$

$$[6] \qquad [MOH^+] + [X^-] \rightleftarrows [XMOH]$$

$$[7] \qquad [M^{2+}] + [HX] \rightleftarrows [M^+X] + [H^+]$$

where X represents the adsorbing surface and $[M^{2+}]$ and $[MOH^+]$ represent $[Co^{2+}]$ and $[CoOH^+]$, respectively.

Hodgson *et al.* (16) have shown that the two hypotheses cannot be distinguished on the basis of variations in θ with $[H^+]$, as both mechanisms exhibit the same type of pH dependence. However, the two mechanisms may be differentiated if a non-hydrolyzable bivalent competing ion is used. They have derived equations showing that θ for the adsorption process represented by reaction 7 will be independent of $[H^+]$ in the presence of a large concentration of nonhydrolyzable competing ions. Conversely, for the hydrolysis mechanism θ will still depend inversely on the hydrogen ion concentration.

In experiments, where Ba^{2+} and Mg^{2+} ions (0.1 m concentration) have been used, there seems to be no noticeable effect of the competing ions on the $[H^+]$ dependence of θ, *i.e.*, the slopes of the θ *vs.* pH plot for the adsorption of Co^{2+} on alumina both in the presence and absence of the competing ions are identical as shown in Fig. 3. This suggests hydrolysis as the dominant mechanism. It may be pointed out here that Ba^{2+} and Mg^{2+} ions have been shown (19) to remain unhydrolyzed above the pH values that have been used in this work.

To further test the hydrolysis mechanism eq. 1 may be rearranged on the consideration of the equilibria of the cobalt in solution (20). If C is the total concentration of cobalt in solution, then

$$C = [Co^{2+}] + [CoOH^+]$$

$$[Co^{2+}] = \frac{C[H^+]}{[H^+] + K}$$

and

$$[CoOH^+] = \frac{CK}{[H^+] + K}$$

where K is the hydrolysis constant of reaction 5. Substituting this value of $[CoOH^+]$ in eq. 1 the Langmuir adsorption isotherm reduces to

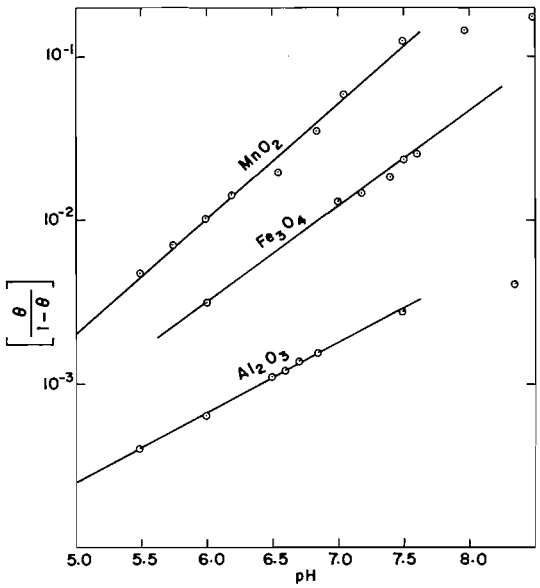

FIG. 7. Plot of log $\theta/(1-\theta)$ *vs.* p*H* plot at 30 °C for cobalt adsorption on Al_2O_3, MnO_2, and Fe_3O_4.

$$\theta = \frac{aKC}{[H^+] + K + aKC} \quad [8]$$

or

$$\frac{1}{\theta} = \frac{[H^+]}{aKC} + \frac{1}{aC} + 1 \quad [9]$$

The above equation predicts that a plot of $1/\theta$ *vs.* $[H^+]$ at a constant C will be linear. As the H^+ concentration used in the experiment varies many orders of magnitude, a more convenient plot will be log $\theta/(1-\theta)$ *vs.* p*H*. In a log form eq. 9 reduces to

$$\log \theta/(1-\theta) = \log aKC + pH - \log (1 + K/[H^+]) \quad [10]$$

Equation 10 predicts that under conditions of $K \ll [H^+]$ a plot of log $\theta/(1-\theta)$ *vs.* p*H* is linear. In the present case $K \ll [H^+]$. The plots as predicted are linear as shown in Fig. 7. The linearity is not obeyed above p*H* 7.5. Equation 10 predicts non-linearity at higher p*H*.

Equation 9 can be further rearranged to give

$$\frac{1}{\theta} = \frac{1}{C}\left[\frac{[H^+]}{aK} + \frac{1}{a}\right] + 1 \quad [11]$$

Equation 11 predicts that at constant $[H^+]$, a plot of $1/\theta$ *vs.* $1/C$ will be linear. For Al_2O_3 at p*H* 6, a plot of $1/\theta$ *vs.* $1/C$ is found to be linear over a wide range of concentration, as predicted, and is shown in Fig. 8. The results for Fe_3O_4 exhibit a similar plot. These results are consistent with the hydrolysis mechanism for the enhanced adsorption of Co^{2+} with increasing p*H*.

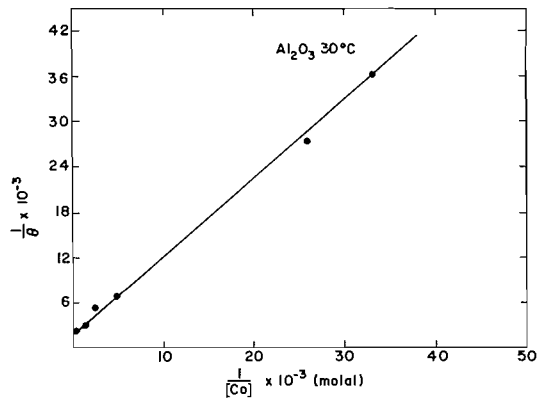

FIG. 8. Plot of $1/\theta$ *vs.* $1/C$ plot for Al_2O_3 at p*H* 6, temperature 30 °C.

The values of K were calculated from the slopes of the linear plots of eq. 11 and by substituting the values of a from the plots of eq. 2. The pK values thus calculated decreased with increasing temperature. (It decreased from 9.4 at 30 °C to 8.9 at 80 °C.) A decrease in pK or an increase in K with temperature was also reported by Bolzan and Arvia (21) (a decrease from 9.8 at 25 °C to 9.5 at 45 °C). However, the calculated pK values are lower than the reported values by 0.3 to 0.4 unit.

Matijevic *et al.* (22) found that the adsorption of thorium on AgI increased above p*H* 3.82, (equivalent to pK) where the ratio of hydrolyzed thorium to TH^{4+} also increased markedly. Between p*H* 5.5 and 7 the dominant species calculated from the pK is Co^{2+} and not $CoOH^+$. The adsorption increase thus does not correspond to the p*H* where the $[CoOH^+]/[Co^{2+}]$ ratio increases, based on the known pK (20). However, it is not necessary that the ratio $[Co(OH)^+]/[Co^{2+}]$ has to be greater than one for the adsorption of hydrolysis products on the surface. The hydrolysis products formed at p*H* values lower than pK may be adsorbed and the increased adsorption may be noticeable at p*H* values much lower than pK. A similar increase of Co^{2+} adsorption has been reported on silica (18) and for Cu^{2+}, Zn^{2+}, Mn^{2+}, and

Co^{2+} on goethite (14) at pH values much below the value of pK. Furthermore, at interfaces the pH for hydrolysis reactions may not correspond to the pH in the bulk solution. It has been reported (15) that hydrolysis products may be formed at solid–liquid interfaces at concentrations well below those for saturation or precipitation in the solution. The formation of a polymeric cobalt hydroxide has been reported (18) at a silica surface at concentrations below those for saturation or precipitation of cobalt. Ragland and Coleman (23) have also reported that hydrolysis of aluminum chloride can occur at pH values as low as 3.4 in presence of large interfacial surfaces, compared to a pK of 5.5.

Though quantitative agreement between the known hydrolysis constant of cobalt and the pH range over which the enhanced adsorption takes place is lacking, the hydrolysis mechanism satisfactorily explains the results of the adsorption studies and the increased adsorption of cobalt on the oxides with pH.

The assistance of our colleagues in the Analytical Science Branch for the surface area measurements of the oxides, for emission-spectrographic and atomic absorption analysis, and of Messrs. A. M. Duclos and E. E. Sexton for X-ray diffraction and electron-micrograph work is gratefully acknowledged. The authors thank Mr. G. W. A. Claus for the literature survey.

Equilibrium Constants for 2,3-Dihydroxypyridine and its Complex with Iron(III) in 1 *M* Hydrochloric Acid

K. E. CURTIS AND G. F. ATKINSON

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 4, 1971

Improved values for two acidity constants of 2,3-dihydroxypyridine have been computed using program PITMAP. The composition of the complex with iron(III) and its conditional and overall stability constants in 1 *M* hydrochloric acid have been evaluated.

On a calculé par ordinateur les valeurs améliorées des deux constantes d'acidité du 2,3-dihydroxypyridine en utilisant le programme PITMAP. On a évalué aussi la composition du complexe avec le fer(III) et ses constantes de stabilité globales dans l'acide chlorhydrique 1 *M*.

In a previous report from this laboratory (1), 2,3-dihydroxypyridine (DHP) was shown to react with iron(III) in mineral acid media 1.0 *M* in hydrogen ion to form blue complex species of metal-to-ligand ratios of 1:1. A spectrophotometric procedure for the analysis of iron(III) in 1.0 *M* hydrochloric acid has been developed (2). This work reinvestigates the acidity constants of DHP and reports on the complex composition and the conditional and overall stability constants of the complex with iron(III) in 1.0 *M* hydrochloric acid solution.

Experimental

Reagents

Iron(III) chloride solutions were prepared by dilution with 1.0 *M* hydrochloric acid solution from a 9.110×10^{-2} *M* stock solution prepared and standardized as before (1). Solutions of DHP were prepared by dissolving accurately weighed amounts of the sublimed reagent in a known volume of the appropriate solvent. Other chemicals were reagent grade and were tested as necessary for the absence of interfering impurities. Water used was deionized, distilled, and deaerated with nitrogen.

Apparatus

Absorbance measurements were made at 25 °C with a double beam Cary 14 recording spectrophotometer using fused quartz cells (10 mm) throughout. An Orion Model 801 p*H* meter with a glass and calomel electrode pair calibrated as a concentration probe was used to measure hydrogen ion concentration (3). All volumetric ware was Class A and all pipettes were calibrated.

Computations were performed on an IBM 360/75 computer with graphical output plotted by a Calcomp 763 digital incremental plotter.

Determination of the Acidity Constants of DHP

The p*H* of twenty-two solutions of DHP concentration 1.500×10^{-4} *M* was adjusted with standardized potassium hydroxide and/or hydrochloric acid solutions to give a range of $[H^+] = 9.50$ *M* to a p*H* of 13.12. The ionic strength of solutions between p*H* 0 and 14 was maintained at 1.0 by means of potassium chloride solution but constancy was sacrificed at higher acidities in order to determine the "approximate protonation constant" (4) of DHP. The spectrum of each of these solutions was recorded between 220 and 315 nm against a reference solution of a solvent blank, corrected for baseline, and absorbance values at every 5 nm tabulated. The p*H* of each solution between 0 and 14 was measured while the spectrum was being recorded, while those of the solutions of higher acidities were calculated from known hydrogen ion concentrations. These data were then submitted to the computer program PITMAP (5).

Investigations of the DHP–Iron(III) Complex

Two procedures were used:

(*a*) Following the method of Heller and Schwarzenbach (6) as modified by Budesinsky and Haas (7, 8) and the method of proportional absorbances of Budesinsky (9, 10), three sets of solutions were prepared so that while iron and DHP were kept equimolar in all cases, the iron and DHP, the chloride ion, and the hydrogen ion concentrations respectively were varied within each set. The hydrogen ion concentration was altered or kept constant at 1.0 *M* as required, with standardized perchloric acid solution, while the chloride ion concentration was similarly controlled by means of a standard sodium chloride solution. Details of all solutions are given in Table 1.

The spectrum of each solution was recorded from 700 to 500 nm against an appropriate solvent blank, corrected for baseline and absorbance values digitized every 50 nm.

(*b*) Eight spectra were recorded from 700 to 500 nm against the appropriate solvent blanks, for solutions of constant iron(III) concentration 7.916×10^{-4} *M* but with varying DHP concentrations. In this way, metal-to-ligand molar ratios of 0.5, 1.0, 2.5, 5.0, 10.0, 15.0, 20.0, and 25.0 in 1.0 *M* hydrochloric acid solution were obtained. After correction for baseline, the absorbance was digitized at 5 nm intervals. The p*H* of each solution was measured and these data, along with other known information, were submitted to PITMAP for computation of the overall stability constant of the complex.

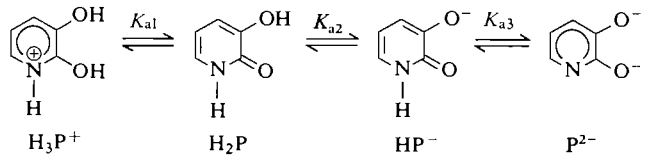
Results and Discussion

The Acidity Constants of DHP

The accepted mechanism for the stepwise deprotonation of DHP:



Evidence has been produced to support this order of proton removal, especially the tautomeric shift to the lactam structure for H_2P (11). Comparison with the known pK_a values for similar reagents also lends weight to the mechanism. In an extensive study of the spectral properties and ionization constants of substituted 2-hydroxypyridines, Spinner and White (11) have given values for pK_{a1} and pK_{a2} for DHP, with the third constant being reported as inaccessible. However, the value for pK_{a1}, of the order of 0.2, was reported with a rather large degree of uncertainty. The study of the reagent in media 1.0 *M* in hydrogen ion made it necessary to obtain a better value. Consequently, the computer program PITMAP, written by Metzler (12) and extensively modified in our laboratory (5) was used to compute a new set of pK_a values. The results are shown in Table 2, along with the wavelengths of maximum absorbance for each species. No evidence for the dissociation of the third proton was found up to a p*H* of 14.

PITMAP also supplies molar absorptivities of the individual species over the wavelength range, which may be plotted as shown in Fig. 1. When these values, along with the constants obtained, are submitted to program PLOT (5), spectra based on the optimized mathematical model are derived and compared graphically with the experimental input absorbances. Five such comparisons are shown in Fig. 2 and excellent agreements were also obtained with the other seventeen spectra.

The complex with iron(III) in 1.0 M hydrochloric acid solution

The general equation for the formation of the complex may be written as

[1] $$Fe_mCl_i + H_jP_n \rightleftharpoons Fe_mCl_iH_jP_n$$

It was already known from previous work (1) that the ratio of m:n was 1:1. The absolute values of m, i, j, and n were found and the overall stability constant determined by the method of Budesinsky and Haas (7–9), taking into account the side reactions of the ligand with hydrogen ion and of the metal with chloride ion. It was assumed that HP^- rather than P^{2-} was the most deprotonated species of the ligand, a valid assumption when working in acidities of 1.0 *M*. The overall stability constant was therefore represented by β^*_{mijn} to indicate this modification. The conditional stability constant was determined by the method of proportional absorbances (9, 10) supplemented by a table of computed values for log y and x_{mn} (13).

The mathematical treatment of the various relationships in these procedures gave the expression

[2] $$\log \beta^*_{mijn} = \log K_{mn} + m \log \alpha_{Fe(Cl)} + n \log \alpha_{HP(H)} + i\mathrm{p[Cl]} + (j-1)\mathrm{p[H]}$$

where

α represents the coefficient of a side reaction (14)

$$\beta^*_{mijn} = \frac{[Fe_mCl_iH_jP_n]}{[Fe]^m[Cl]^i[H]^{j-n}[HP]^n}$$

$$K_{mn} = \frac{[Fe_mCl_iH_jP_n]}{(C_{Fe} - m[Fe_mCl_iH_jP_n])^m(C_P - n[Fe_mCl_iH_jP_n])^n}$$

During the determination of K_{mn}, the absolute values of m and n were found to be unity, as shown in Table 3. Equation 2 then became

[3] $$\log \beta^*_{1ij1} = \log K_{11} + \log \alpha_{Fe(Cl)} + \log \alpha_{HP(H)} + i\mathrm{p[Cl]} + (j-1)\mathrm{p[H]}$$

TABLE 2. pK_a values for the deprotonation of DHP

Species	λ_{max} (nm)	pK_a	σ
H_3P^+	227, 291	0.107	0.007
H_2P	234, 297	8.694*	0.007
HP^-	255, 311		
P^{2-}	not observed		

*Value of $pK_a = 8.7$ found by potentiometric titration.

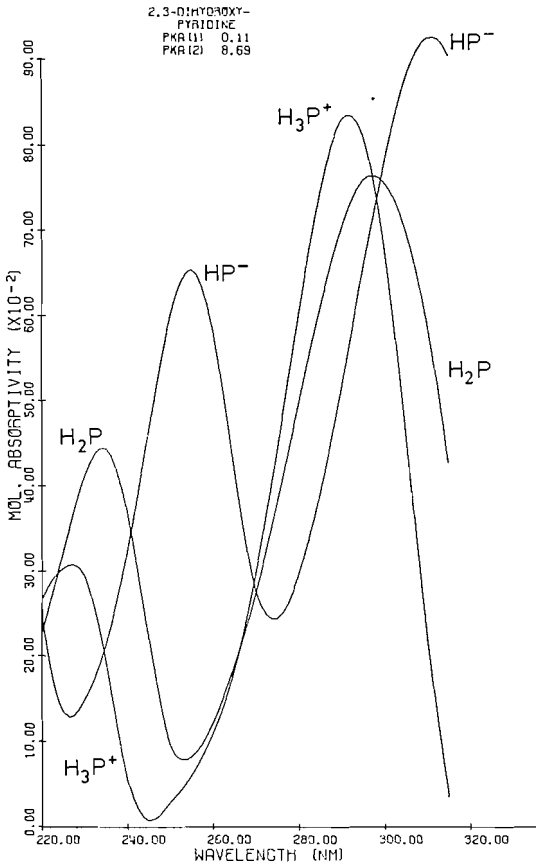


FIG. 1. Computed spectra of DHP species.

Then, at constant C_{Fe}, C_{DHP}, and $[H^+]$, eq. 3 reduced to

$$[4] \qquad \log K_{11}\alpha_{Fe(Cl)} = \text{constant} - i\text{p[Cl]}$$

The calculated dependence of $\log K_{11}\alpha_{Fe(Cl)}$ on p[Cl] was plotted in Fig. 3, in which the slope of the curve indicated a value of $-i = -1$, making the complex composition $FeClH_jP$. Similarly, at constant C_{Fe}, C_{DHP}, and $[Cl^-]$, eq. 3 became

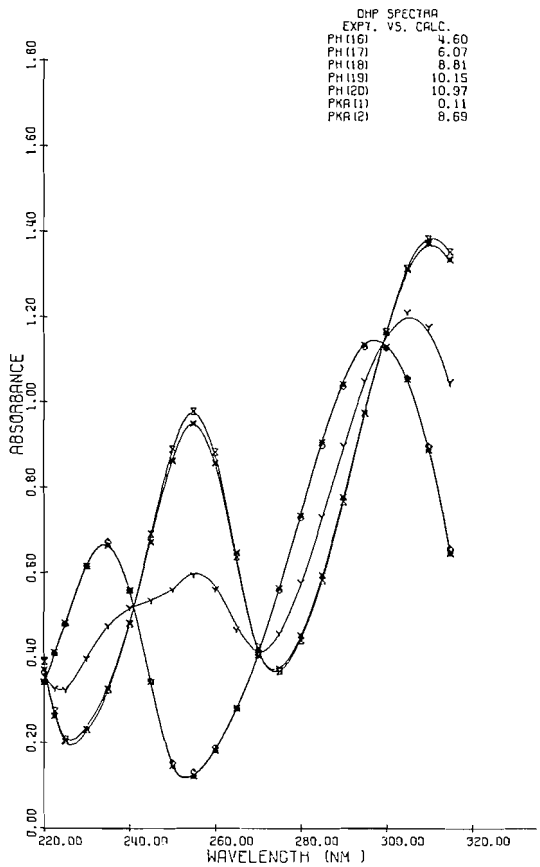

FIG. 2. Experimental (symbols) *vs.* calculated (solid lines) spectra of DHP solutions. Symbols for various p*H* values are ⁎, 4.60; ◇, 6.07; Y, 8.81; □, 10.15; ⧖, 10.97.

TABLE 3. Determination of m and n and the conditional stability constant

$-\log C_{Fe}$	x_{mn}*	$-\log y_{11}$	$\log K_{11}$†	$-\log y_{22}$	$\log K_{22}$†
2.38	1.539	−0.25	2.13	1.03	8.17
2.46	1.574	−0.33	2.13	0.97	8.35
2.56	1.621	−0.43	2.13	0.92	8.59
2.68	1.681	−0.56	2.12	0.79	8.83
2.86	1.749	−0.73	2.13	0.69	9.26

*$\lim_{y\to\infty} x_{11} = 2.00$ and $\lim_{y\to\infty} x_{22} = 8.00$ under the experimental conditions. The observed variation of x_{mn} therefore indicates $m = n = 1$.
†By inspection, $\log K_{11}$ values are more constant than those for $\log K_{22}$, confirming $m = n = 1$.

$$[5] \qquad \log K_{11}\alpha_{HP(H)} = \text{constant} - (j-1)\text{p[H]}$$

This plot is also shown in Fig. 3, a slope of $-(j-1) = 0$ being obtained. The final complex composition was thus FeClHP. Introducing this

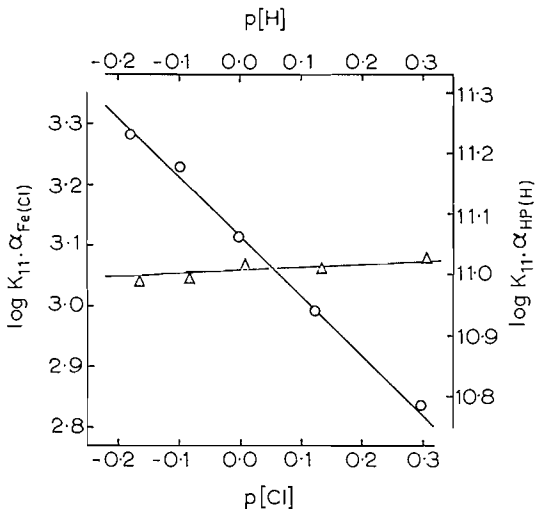

FIG. 3. Determination of the coefficients i and j in the complex $FeCl_iH_jP$. ○, left and lower scales show $i = 1$; △, right and upper scales show $(j - 1) = 0$.

information into eq. 3 gave

$$[6] \quad \log \beta^*_{1111} = \log K_{11} + \log \alpha_{Fe(Cl)} + \log \alpha_{HP(H)} + p[Cl]$$

Calculations then gave $\log \beta^*_{1111} = 12.13$ with a standard deviation of 0.06.

Using this value as an initial estimate of the true answer, program PITMAP was used to compute a value for the overall constant.[1] Subroutine EQUIL, which calculates concentrations of the individual species present, was rewritten for the proposed model FeClHP. Other input data for the program included molar absorptivities for all the metal and ligand species present (conveniently zero in all cases as neither absorbed in the wavelength region studied), the pK_a values computed above, $\log \beta$ values for the iron(III) chloride system (15), and for each solution, the pH, concentration of iron and DHP, and the digitized spectrum. An answer of $\log \beta^*_{1111} = 12.127$ with a standard deviation of 0.002 was obtained, in satisfactory agreement with the previous value found. Figure 4 shows the experimental *vs.* calculated spectra.

[1]More recent and convenient versions of the computer programs used may be obtained by requesting "Computer Programs for the Analysis of Electronic Absorption Spectra" from Dr. J. A. Thomson, Department of Biochemistry and Biophysics, Iowa State University, Ames, Iowa 50010, U.S.A.

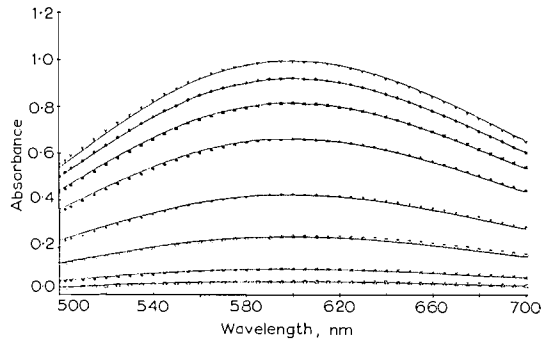

FIG. 4. Experimental (symbols) *vs.* calculated (solid lines) spectra of the complex FeClHP at various concentrations of DHP. Symbol for various [L]/[M] ratios are □, 0.5; ×, 1.0; ○, 2.5; +, 5.0; △, 10.0; ✳, 15.0; ◇, 20.0; Y, 25.0.

Summary

Improved values for two of the acidity constants of 2,3-dihydroxypyridine have been computed using program PITMAP.

Using these values, the overall stability constant of the complex with iron(III) in 1.0 *M* hydrochloric acid solution has been evaluated by two different procedures. One of these procedures also shows the composition of the complex to be FeClHP and gives a value of the conditional stability constant.

The values for the constants found are

$$pK_{a1} = 0.10_7 \quad \sigma = 0.007 \quad \text{for} \quad H_3P^+ \rightarrow H_2P + H^+$$

$$pK_{a2} = 8.69_4 \quad \sigma = 0.007 \quad \text{for} \quad H_2P \rightarrow HP^- + H^+$$

$$\log K_{11} = 2.13$$

$$\log \beta^*_{1111} = 12.12_7 \quad \sigma = 0.002$$

Evaluation of Unbonded O—H Groups for HDO in Liquid D_2O from Infrared Absorptivity Measurements[1]

E. C. W. CLARKE AND D. N. GLEW

Research Department, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received October 18, 1971

Wyss and Falk's infrared absorptivities between 10 and 85 °C for HDO in liquid D_2O in the fundamental O—H stretch region have been analyzed numerically and show a statistically significant weak band near 3600 cm^{-1} at each temperature. This band, the Raman analog of which was reported earlier, confirms the presence of HDO species with unbonded O—H groups in the liquid state. The percentage of HDO species with unbonded O—H groups is found to be 4.6, 6.1, 10.1, and 11.9, respectively, at 10, 35, 60, and 85 °C.

The four predominant HDO species in equilibrium at low temperatures are defined together with their equilibrium constant for the O—H---O bond-rupturing process. A standard enthalpy change of $\Delta H° = 6800 \pm 1100$ cal is found for the rupture of one mole of O—H---O bonds. This is in contrast with the apparent enthalpy change of 2900 ± 500 cal, as usually derived from the temperature dependence of the equilibrium quotient. Approximate mole fractions for each of twelve differently bonded HDO species are derived from a model for random H- and D-bond statistics. Results show that the four predominant HDO species give a full interpretation of the absorptivities at 10, 35, and 60 °C but that additional minor species contribute slightly to the absorptivity at 85 °C.

Nous avons analysé numériquement les absorbances infrarouges de Wyss et Falk entre 10 et 85 °C pour HDO dans D_2O liquide dans la région fondamentale d'élongation O—H; elles montrent une bande faible près de 3600 cm^{-1} à chaque température. Cette bande, dont l'analogue Raman a été rapportée précédemment, confirme la présence d'espèces HDO avec des groupes O—H non-liés à l'état liquide. On trouve que le pourcentage d'espèces HDO avec des groupes O—H nonliés est de 4.6, 6.1, 10.1, et 11.9, respectivement, à 10, 35, 60, et 85 °C.

Nous définissons les quatre espèces HDO prédominantes à l'équilibre à basses températures, de même que leur constante d'équilibre pour le procédé de rupture de la liaison O—H---O. Nous trouvons un changement d'enthalpie standard $\Delta H° = 6800 \pm 1100$ cal pour la rupture d'une mole deliens O—H---O. Cette valeur contraste avec le changement d'enthalpie apparen de 2900 ± 500 cal, tel que dérivé habituellement à partir de la dépendance de la température du quotient d'équilibre. Les fractions molaires approximatives pour chacune des douze espèces HDO différemment liées sont tirées d'un modèle pour les statistiques des liens H et D aléatoires. Les résultats montrent que les quatre espèces HDO prédominantes donnent une pleine interprétation des absorbances à 10, 35, et 60 °C, mais que d'autres espèces mineures contribuent légèrement à l'absorbance à 85 °C.

Canadian Journal of Chemistry, **50**, 1655 (1972)

Introduction

Wyss and Falk (1) recently published infrared molar absorptivities for HDO in liquid water and deuterium oxide between 10 and 85 °C. Strong, wide, single-peaked absorptions were shown for the O—H and O—D stretch modes, ν_3 and ν_1, respectively, with weak absorption for the angular deformation overtone mode, $2\nu_2$. In that work it was reasserted, as earlier (2), that the ν_3 and ν_1 absorptions were single bands, deriving from continuous distributions of H-bonded O—H and D-bonded O—D groups, and that these single ν_3 and ν_1 bands showed no evidence for unbonded O—H and O—D groups of HDO molecules with broken H- and D-bonds. This interpretation of the infrared measurements was inconsistent with Walrafen's Raman contours (3, 4, 30) which showed definite high-frequency shoulders on the O—H and O—D stretch bands of HDO. In this work we show a statistically significant decomposition of Wyss and Falk's O—H stretch absorption contours at each temperature into component bands which correspond with the observed Raman shoulders.

[1]Contribution No. 193.

Statement of Problem and Selection of Model

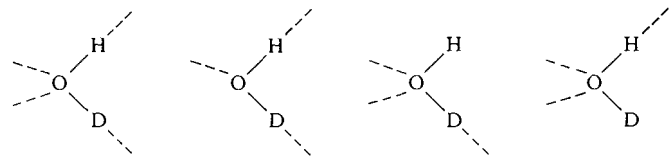
Predominant Species in Liquid Water

Many studies of the properties of liquid water and aqueous nonelectrolyte solutions indicate that at low temperature water is nearly completely H-bonded (1, 2, 5–14) and that the predominant and most stable molecular species

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is that in which the H_2O molecules maintain four, tetrahedrally oriented H-bonds with near water neighbors. These H-bonds are being ruptured continually in the liquid state and must have lifetimes of at least 10^{-12} s in order to show discrete quantized bands at 60 cm^{-1} (15, 16). Thus an H_2O molecular species with a given H-bond configuration may be reasonably assumed to exist for at least 10^{-12} s before its H-bond configuration changes, a time sufficient for 55 complete vibrations of the intramolecular O—H stretch modes at 3400 cm^{-1}. After the most probable H_2O species with four H-bonds, the next most probable species will be those maintaining three H-bonds with near neighbors, with progressively decreasing fractions of the less stable species forming two, one, and zero H-bonds with neighbors.

Similarly, if we consider a dilute solution of HDO in liquid deuterium oxide at low temperature, we anticipate that the predominant HDO species is the four-bonded species I, and that the next most common species are the three-bonded species II, III, and IV.



Species	I	II	III	IV
Mole fraction	[I]	[III] + [IV]	[III]	[IV]

Those HDO species forming two or less bonds occur at lower concentrations and will be disregarded until later discussion. If a mole fraction [III] of HDO is present as the three-bonded species III, a fraction [IV] must exist as the three-bonded species IV, then a fraction [III] + [IV] must be present as the three-bonded species II. In postulating the existence of species II, III, and IV we mean that these are equilibrium species which have life-times of at least 10^{-12} s. Thus if the O—H stretch absorption contour is not a single band due to a single species I, it must be a composite of at least four bands due to the four different major species I, II, III, and IV.

H-bond Dissociation Equilibria

Spectroscopic determination of the concentration of unbonded HDO species in the liquid state raises the problem of the proper definition of the HDO species present and of their appropriate equilibrium constant.

Earlier spectroscopic determinations (17–19) have used a concentration quotient, q, equivalent to [HDO, unbonded]/[HDO, bonded], to define the equilibrium between the bonded and unbonded HDO species. This implies that the bond-rupturing and bond-forming reactions are opposed first order processes. Such an equilibrium quotient ignores the fact that the formation of species with unbonded O—H or O—D groups leads to the concomitant formation of an equal concentration of independent species with unbonded lone-pair electrons.

It is more realistic to expect that successful H-bond formation occurs with the bimolecular encounter between an HDO molecule with an unbonded O—H group and one with an unbonded lone pair. Indirect support for a second order rate dependence of the H-bond-forming reaction is provided by the fact that the addition of polyvinylpyrrolidone to HDO solutions suppresses the concentration of unbonded O—H groups (17). Some part of the concentration reduction of unbonded O—H groups derives from the structure-making effect (17), as described elsewhere for aqueous nonelectrolyte solutions (20). However, the addition of the pyrrolidine groups, with lone-pair electrons on the ring nitrogen and carbonyl oxygen atoms, provides additional bonding sites for the unbonded O—H and O—D groups, the concentration of which is thereby diminished. Any bonding of HDO to the pyrrolidine groups leads to an attendant increase of concentration of HDO species with unbonded lone-pair electrons.

Additional evidence for a second order rate dependence of the H-bond-forming reaction is provided by the analogous ionization equilib-

Temperature (°C)	Degrees of freedom	Q	$\sigma(\varepsilon)$ (10^3 cm^2 mol^{-1})
10	32	12.34	0.62
35	32	15.40	0.69
60	32	24.18	0.87
85	32	18.43	0.76

rium of water. There the ionization reaction is pseudounimolecular giving OH^- and H_3O^+ and these two independent, three-bonded species exist in water for sufficient time that their recombination reaction rate is second order, proportional to their concentration product, $[OH^-][H_3O^+]$. In this case the independent lifetimes of given OH^- and H_3O^+ species are probably considerably shorter than those for the unbonded water species, due to their ionic charges promoting recombination.

The existence of species III and II as independent entities requires that the first H-bond dissociation constant, K_H, for liquid HDO be defined by the equation

$$[1] \qquad K_H = \frac{[III][II]}{[I]}$$

in which a pseudounimolecular bond-rupturing process for species I is opposed by a second order bond-forming reaction between species III and II. Similarly, the first D-bond dissociation equilibrium constant, K_D, is defined by

$$[2] \qquad K_D = \frac{[IV][II]}{[I]}$$

in which a unimolecular D-bond rupturing process for species I is opposed by a second order D-bond-forming reaction between IV and II.

Numerical Treatment of Absorptivities

Decomposition of Infrared Band Contours

As a necessary modification of earlier work (21) to allow for the possibility of band asymmetry (22), we represent the absorption contours of single bands by the Gauss–Cauchy (Lorentz) product function

$$[3] \qquad \varepsilon = \varepsilon_0 \frac{\exp[-G^2 Y^{-2}(\nu - \nu_0)^2 A]}{[1 + (1-G)^2 Y^{-2}(\nu - \nu_0)^2 A]}$$

with an asymmetry function defined by

$$[4] \qquad A = 1 + a(\nu - \nu_0) + a^2(\nu - \nu_0)^2/2,$$

where ε_0 is the peak extinction, ν_0 is the peak frequency, Y is proportional to the bandwidth w at half-extinction, G is the fraction Gaussian and $(1 - G)$ the fraction Cauchy (Lorentzian), and a is the asymmetry factor.

To decompose overlapped multiple-band contours into self-consistent sets of single bands we derive the band parameters using Pitha and Jones' non-linear least-squares method V (21). The errors on the parameters are evaluated by standard methods (23) from the inverse matrix elements of the linearized normal equations. The present work summarizes the final results from approximately 250 non-linear least-squares fits of absorptivity data using an IBM 360/40 computer. From Wyss and Falk's very accurate HDO absorptivities we represented their 37 values between 3720 and 3200 cm^{-1} at each temperature first by a single band, then by two bands, and finally by four bands.

Single-band Representation

Table 1 shows the five parameters together with their standard errors for the best single bands representing the measurements at each temperature. The residuals, plotted in Fig. 1 as the small dots joined by the fine lines, are seen to be conspicuously similar and non-random at all four temperatures. Significant positive resid-

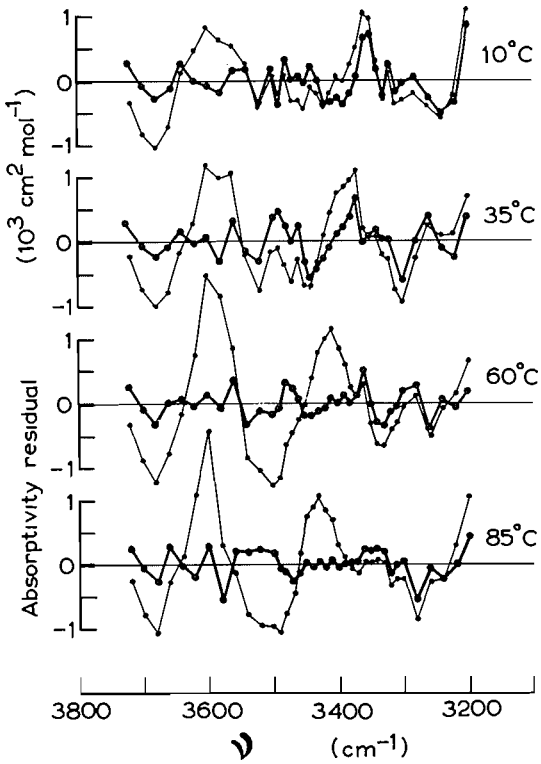

FIG. 1. Frequency distribution in the O—H stretch region of the absorptivity residuals at 10, 35, 60, and 85 °C. Small dots joined by fine lines show residuals from single-band representations. Large dots joined by heavy lines show residuals from four-band representations.

uals (absorptivity residual = absorptivity observed − absorptivity calculated) are invariably shown near 3600 cm^{-1} indicating the probable occurrence of a band. Consequently the sums of the squares of the residuals, Q, and the assessments of the standard error on a single absorptivity measurement, $\sigma(\varepsilon)$, shown in Table 1 are systematically too large. As the temperature increases the weakening of the H-bonds is indicated by the increase of the peak frequency, ν_0, and by the decrease of the integrated band area (24). Also with increasing temperature the single bands become wider and more Gaussian, and the representation of the measurements by a single band becomes poorer with larger Q values. The bands are never completely Gaussian and become more asymmetric with increasing low-frequency tails at higher temperatures.

Two-band Representation

Table 2 shows the parameters together with their standard errors for the two-band representation of the measurements at each temperature. In this approximation band I derives from all HDO species in which the O—H group is H-bonded, while band III near 3600 cm^{-1} derives from all species in which the O—H group is unbonded. Because it was impossible to obtain meaningful values for the percentage Gaussian and the asymmetry factor for band III, these parameters were made equal to those for the main band I. Preliminary fits of the data at 35, 60, and 85 °C showed that band III had widths at half-extinction of 119 ± 28, 93 ± 8, and 97 ± 14 cm^{-1}, respectively, which give a weighted mean value of 99 cm^{-1}. Since these half-widths were not well defined, even at the highest temperatures, we refitted the measurements taking a constant half-width of 100 cm^{-1} for band III at all temperatures. The two-band representations given in Table 2 are statistically unique in the sense that they are the only pairs of bands that properly fit the measurements.

The Q values for the two-band representations in Table 2 are considerably smaller than those for the single-band representations in Table 1. The variance ratio F-test (23) shows that the improvement of the seven-parameter, two-band representation over the five-parameter, single-band representation is statistically significant, occurring by chance alone at the 1×10^{-5}, 7×10^{-9}, 5×10^{-18}, and 2×10^{-11} probability levels at 10, 35, 60, and 85 °C, respectively. The overall probability that band III arises by chance alone is 10^{-41}. Thus the infrared absorptivity measurements of Wyss and Falk exhibit a real band near 3600 cm^{-1}.

We assign this HDO infrared band III near 3600 cm^{-1} mainly to the three-bonded species III, with the band area giving a direct measure of the species III concentration. The analogous HDO Raman band found at 3628 cm^{-1} (4, 30) was assigned earlier to the same three-bonded species (24). The existence of measurable concentrations of species III for liquid HDO chemically requires the simultaneous coexistence of equilibrium concentrations of species II and IV, as discussed above.

Four-band Representation

The use of four bands to represent the infrared

85	30	3.55	0.34

absorptivity measurements is dictated by the existence of the four instantaneously distinct species I to IV, each of which contributes its characteristic O—H absorption band. The introduction of the four bands is thus made subject to a number of constraints which are defined by information external to the infrared data. Subject to the systematic application of these constraints, which are described below, the four-band representations of the infrared measurements are statistically unique.

Table 3 shows the parameters and their standard errors for the four-band representations of the measurements. The residuals, plotted in Fig. 1 as the large dots joined by the heavy lines, are seen to be nearly randomly distributed and nearer to the zero ordinate than those for the single-band representations. Figure 2 illustrates the total absorptivity contour at 85 °C and its decomposition into four bands. To define the four-band representation the twenty undetermined parameters were reduced to nine by imposing reasonable constraints on the values of those parameters which were least well defined. The main band I for species I was represented by five undetermined parameters, while the smaller bands II–IV for species II–IV were represented by fewer undetermined parameters, the balance being constrained parameters.

Preliminary fits of the measurements at 10, 35, 60, and 85 °C showed that band III had half-widths of 105±36, 104±3, 86±8, and 97±7 cm^{-1}, respectively, which give a weighted mean of 102 cm^{-1}. Since these half-widths were not well defined we initially took a constant half-width of 100 cm^{-1} for band III at all temperatures. Band II was taken with a half-width of 150 cm^{-1} at all temperatures, the mean value from preliminary fits. Band IV was taken with a frequency 95 cm^{-1} lower than band I, with half-width equal to band I. The Gaussian and asymmetry parameters for bands II–IV were taken equal to those of band I. Two additional constraints were made so that the area of band IV gave a species IV concentration equal to that of species III, and the area of band II gave a species II concentration equal to the sum of the concentrations of species III and IV. Equal concentrations were taken for species III and IV because the Raman study of Walrafen (30) showed the same fraction of unbonded O—H and O—D groups in liquid deuterium oxide at 25 °C. Further, the best representations of the infrared absorptivities were invariably obtained when the concentrations of species III and IV were taken as equal.

Walrafen (30) has also shown it necessary to use four component bands to adequately represent his Raman O—H stretch band contours for HDO at 25 °C. In the near-infrared Luck

60	28	1.62	0.24
85	28	2.18	0.28

and Ditter (25) have used three component bands, one of which was anomalously wide compared with the other two.

The Q values for the four-band representations in Table 3 are considerably smaller than those for the single bands in Table 1, and are smaller than those for the two-band representations in Table 2. The variance ratio F-test (23) shows that the improvement of the nine-parameter, four-band representation over the seven-parameter, two-band representation is statistically significant, occurring by chance alone at the 3×10^{-3}, 7×10^{-3}, 5×10^{-1}, and 1×10^{-3} probability levels at 10, 35, 60, and 85 °C, respectively. The values for the assessment of the standard error $\sigma(\varepsilon)$ given in Table 3 are probably characteristic of the experimental reproducibility of the absorption measurements (1).

It is recognized that the constraints applied in the data treatment may lead to slight systematic bias in the values of the undetermined parameters, but such bias will be comparable for each temperature. The errors shown for the constrained parameters do not reflect the uncertainties of the assumed constraints.

However, the necessity for band III near 3600 cm^{-1} at each temperature was unaffected by any constraints which were applied to the parameters. For our final calculations Fig. 3(*a*) shows the dependence of the values for the sums of the squares of the residuals, Q, on the constrained value of the band III half-width. The minimum of Q defines the best value for the half-width at each temperature. The final best values for the band III half-widths and their standard errors are 106 ± 37, 105 ± 28, 88 ± 8, and 102 ± 7 cm^{-1}, respectively, at 10, 35, 60, and 85 °C. The smaller standard errors directly reflect the larger curvatures at the minima of Q. Figure 3(*b*) shows the aggregate sum of squares for all temperatures as a function of the band

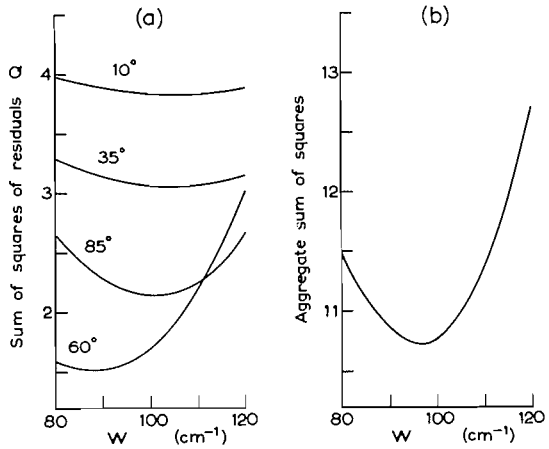

FIG. 3. The variation of (*a*) the sum of the squares of the residuals at each temperature and (*b*) the aggregate sum of squares for all temperatures with the constrained band III half-width.

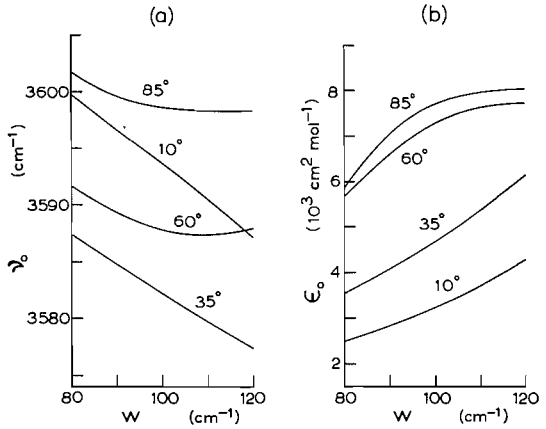

FIG. 4. The variation of (*a*) the band III frequency and (*b*) the band III peak extinction with the constrained band III half-width.

III half-width. This curve has a sharp minimum at 97 cm^{-1} and gives a best overall value of 97 $\pm$ 5 cm^{-1} for the band III half-width between 10 and 85 °C.

Figure 4 shows the variation of the band III frequency and peak extinction with the constrained band III half-width: a 1 cm^{-1} increase of half-width causes a 0.006% decrease of frequency and a 1.2% increase of extinction.

Results for final calculations in Table 3 show that the band III frequency is almost temperature invariant, as required for an O—H group which is not directly perturbed by any bonding neighbor. The band III half-width of 97 cm^{-1} is anomalously wide for an unbonded O—H group of HDO (24). This width for the three-bonded species III derives from the indirect inductive perturbations from the other bonds to the lone-pair electrons and to the O—D group (24). The most significant feature of band III is its monotonous increase of peak extinction, ε_0, with temperature.

Band II, with frequency about 3500 cm^{-1}, is assigned to the HDO species II since earlier work (24) indicates that the H-bond for species I should be stronger than that for species II, due to the increased induced charge polarization from the bonding of both lone pairs of electrons for species I. Band IV, with frequency lower than band I, is assigned to species IV because its H-bond is stronger than that for species I, due to the decreased repulsion from the unbonded O—D group of species IV. The monotonous

increases of ε_0 for bands II and IV result from the imposed constraints on the species II and IV concentrations.

Band I, with highest extinction, which decreases with temperature, moves between 3391 and 3437 cm^{-1} and is assigned to the predominant species I, for which the concentration must decrease with temperature. The half-width and Gaussian percentage for band I are significantly smaller than for the other representations, and these parameters agree well with the values found for dilute solutions of HDO in dimethyl sulfoxide and in the substituted pyridines (24, 26). Both of these parameters decrease at higher temperatures. Values for the asymmetry factor also agree with those found for HDO in dimethyl sulfoxide and in the substituted pyridines (26).

Band Frequencies and Half-widths

The infrared frequencies of band III, with a weighted mean value of 3593 cm^{-1}, and of band I, with a value of 3400 cm^{-1} at 25 °C, are both 35 cm^{-1} lower than the corresponding Raman bands at 3628 and 3435 cm^{-1} (4, 30). These differences are real and beyond the combined experimental errors. Half of this frequency difference can be explained by the H-bonding intensification of infrared bands at lower frequencies (24). Convolution of the intensity–frequency relationship [5] with symmetric 35% Gaussian bands at 3625 cm^{-1} of 100 cm^{-1} half-width and at 3435 cm^{-1} of 200 cm^{-1} half-width gives transformed asymmetric 45% Gaussian bands at 3608 cm^{-1} of 98 cm^{-1} half-width and at 3414 cm^{-1} of 198 cm^{-1} half-width, respectively. The half-widths are little changed by the convolution and we find good agreement between our 97 cm^{-1} half-width for band III and the 100 and 110 cm^{-1} values from Raman measurements (30).

Band III for HDO in liquid deuterium oxide has a lower frequency and larger half-width than the unbonded infrared O—H bands reported in polyelectrolyte salt membranes with low water contents (31), indicating a less extensively H-bonded environment (24) within the substituted polystyrene ion-exchange membranes.

Determination of Species Concentrations

Concentration of Predominant HDO Species

The recent infrared study of HDO in a wide range of basic solvents (24) has shown that the O—H stretch band area is directly proportional to the band frequency shift from the 3707 cm^{-1} value in the gas phase (27). Thus the band area A_0 for one mole of HDO in 1000 cm^3 is given by

$$[5] \qquad A_0 = D(3707 - \nu_0)$$

in which ν_0 is the peak frequency and D is a constant. In the earlier study D was found to be $66.3 \pm 1.7\ 10^3$ cm^2 mol^{-1} for all solvents, including deuterium oxide. When eq. 5 is applied to the four-band representations in Table 3 we find the D values of 65.1, 66.1, 67.9, and 67.8 10^3 cm^2 mol^{-1} at 10, 35, 60, and 85 °C, respectively. The small variation of these values with temperature and their good agreement among themselves and with the earlier value for all other solvents, provides an *a posteriori* justification for this treatment. An unknown concentration c mol 10^{-3} cm^{-3} of a species is evaluated from the species band area A using the equation

$$[6] \qquad c = \frac{A}{D(3707 - \nu_0)}$$

Table 4 presents the species III mole fractions $[III]_{obsd}$ derived from the final four-band repre-

sentations. The $K_{H\ obsd}$ values were evaluated from eq. 1 with [III] and with [IV] = [III], [II] = 2 [III], and [I] = 1 − 4 [III]. The best (28) weighted equation for the temperature dependence of K_H is

$$[7] \qquad \log_{10} K_H = 2.896 - 1478/T$$

which gives a standard error of 26% on a K_H determination of unit weight. The back-calculated $K_{H\ calc}$ values from eq. 7 together with their standard errors are shown in the final two columns of Table 4. The back-calculated $[III]_{calc}$ values and their standard errors were evaluated from the corresponding K_H values. The relative errors on the $[III]_{calc}$ values are two to three times smaller than on the $K_{H\ calc}$ values. The standard enthalpy and entropy changes together with their standard errors, determined from eq. 7, for the rupture of one mole of O—H---O bonds are $\Delta H^0 = 6800 \pm 1100$ cal and $\Delta S^0 = 13.2 \pm 3.3$ cal deg^{-1}. This ΔH^0 value for the H-bond dissociation equilibrium [1] is in good agreement with the 6800 ± 200 cal value derived for the low temperature bond-rupturing pre-equilibrium in the nuclear relaxation of D_2O (29). At low temperatures our species I is identified with the "lattice" water and the three-bonded species II, III, and IV with the "free" water of that work.

The temperature dependence of the concentration quotient, q, defined by

$$[8] \qquad q = \frac{[III]}{1 - [III]}$$

is represented by the weighted equation

$$[9] \qquad \log_{10} q = 0.912 - 632/T$$

which gives a standard error of 11% on a determination of q of unit weight (23). This yields an apparent enthalpy change of 2900 ± 500 cal for the process defined by eq. 8: the temperature dependence of q in eq. 9 agrees reasonably with earlier studies which give 2400 cal for H-bond rupture (17), and 2500 ± 600 (3) and 2300 ± 400 cal (19) for D-bond rupture.

The concentration of unbonded O—H groups derived from our treatment is some 60% lower than indicated by near-infrared measurements (25). However, recent Raman measurements (30) showed 5 and 7% unbonded O—H groups at 25 °C, which agree well with the 5.8 ± 0.6% given in Table 4 for HDO in liquid D_2O.

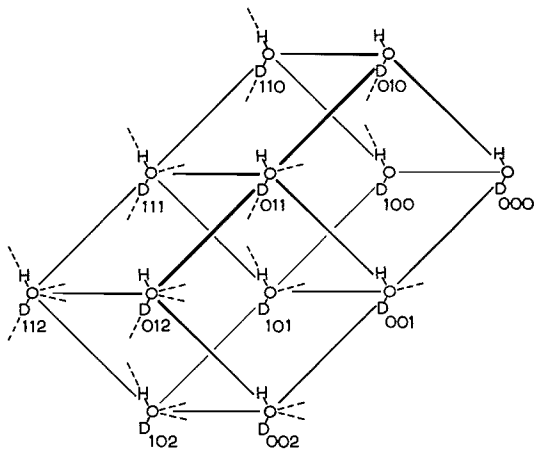

FIG. 5. Representation of the H-bonding interrelationship of the twelve HDO species, in which three dashes indicate H- or D-bonds, and the three-element array indicates the bonding configuration of the species.

Many and wide variations of the constraints have been investigated to determine their effect on the mole fraction $[III]_{obsd}$ and we found that $[III]_{obsd}$ was only slightly changed. Thus, we conclude that our values for $[III]_{obsd}$ in Table 4 represent realistic estimates for the unbonded O—H group mole fractions based on the infrared absorptivities of Wyss and Falk (1).

Estimation of the Concentrations of the Twelve HDO Species

In all earlier sections to maintain clarity of treatment we have disregarded the small concentrations of less stable HDO species which form two or less H- or D-bonds with near neighbors. We now present order of magnitude calculations for the concentrations of these minor species based on the gross assumptions that the H- and D-bonds of all species are equally likely to rupture and that there is no isotope effect. This reduces the statistical treatment for HDO to the case of simple random hydrogen-bond statistics which has been treated for water earlier by Levine and Perram (32).

For HDO in the liquid state there are twelve formally distinct bonding configurations which are indicated at the rhombic vertices in Fig. 5. Species with the same number of H- or D-bonds are shown in the same vertical column, while the species joined by a line differ from each other by the rupture of a single bond. Then, if H- or D-bond rupture is stepwise the fully or four-bonded species I at the leftmost vertex of the

TABLE 5. Temperature dependence of mole fractions of the twelve HDO species

Species	Mole fraction at 0 °C	25 °C	50 °C	100 °C
112	0.8634	0.7884	0.7055	0.5512
111	0.0646	0.0965	0.1285	0.1770
012	0.0323	0.0483	0.0643	0.0885
102	0.0323	0.0483	0.0643	0.0885
011	0.0024	0.0059	0.0117	0.0284
101	0.0024	0.0059	0.0117	0.0284
110	0.0012	0.0030	0.0059	0.0142
002	0.0012	0.0030	0.0059	0.0142
001	0.00009	0.00036	0.0011	0.0046
010	0.00005	0.00018	0.00053	0.0023
100	0.00005	0.00018	0.00053	0.0023
000	0.000002	0.00001	0.00005	0.0004

diagram must pass through the progressively less stable, three-bonded, two-bonded, and one-bonded configurations in order to form the fully unbonded HDO species at the rightmost vertex. We identify the bonding configuration of each species by a linear three-element array, *fgh*, in which *f* is 1 if the O—H group is bonded or 0 if unbonded, *g* is 1 if the O—D group is bonded or 0 if unbonded, and *h* is 2 if both lone pairs are bonded, 1 if a single lone pair is bonded, or 0 if no lone pair is bonded. Thus our major species I, II, III, and IV are shown in Fig. 5 represented by the arrays 112, 111, 012, and 102, respectively.

Table 5 presents the mole fractions for the twelve HDO species existing in liquid deuterium oxide at 0, 25, 50, and 100 °C, as evaluated from eq. 7 for random H-bond statistics (32) assuming that the fraction of unbonded species III is properly equal to the sum of the fractions for the species 012, 011, 002, 010, 001, and 000, each of which has an unbonded O—H group.

The completely unbonded species 000 comprises 0.0002% of the total HDO at 0 °C increasing to 0.04% at 100 °C, so that this species is spectroscopically negligible in the infrared over the temperature range. Species forming two and fewer H- or D-bonds comprise less than 1% of the total at 0 °C increasing to about 10% at 100 °C, so that these species are spectroscopically insignificant at 0 °C but just become significant near 100 °C. This *a posteriori* justifies our neglect of these minor species in treating the absorptivities at 10, 35, and 60 °C and shows that more than the four major species I–IV (112, 111, 012, and 102) make a small contribution to the absorptivity at 85 °C.

The species fractions in Table 5 clearly show that any two-state model (14, 29, 33, 34) for liquid HDO water is a gross oversimplification, even at low temperatures. If we consider a two-state water model, the completely H-bonded lower state of HDO "lattice" water must be comprised entirely of species 112, while the upper state of "free" water is comprised of a mixture of the three three-bonded species 111, 012, and 102 at low temperatures. At higher temperatures, near and above 100 °C, the upper state is comprised of a mixture of predominantly three-bonded species together with significant fractions of the two-bonded species 011, 101, 110, and 002. To what extent the pyramidally bound three-bonded species are orientationally free in the upper state is questionable on purely geometrical structural grounds: Hindman *et al.* (29) have indicated that in their "free" upper state the water molecules are not completely free at low temperatures. The fractions of the species in Table 5 appear to be generally consistent with the findings of Hindman *et al.* (29) and their proposed two-state relaxational model for $H_2^{17}O$ and D_2O, in which few "free" molecules exist at low temperatures and H-bond rupture precedes the relaxation process, while at higher temperatures above 100 °C many "free" molecules exist and the relaxation process can proceed without the necessity of prior H-bond rupture.

Heterogeneous Interactions of Methylamines on Porous Adsorbents. Part I. The Adsorption of Monomethylamine on Silica Gels and Silica–Alumina

W. G. Cook and R. A. Ross

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received December 29, 1971

The adsorption of monomethylamine has been studied near its boiling point, 266 °K, on silica–alumina and on a wide range of silica gels by measurement of adsorption–desorption isotherms and isothermal calorimetric heats of adsorption. In addition, surface areas and pore-size distributions have been determined by low-temperature nitrogen adsorption. Heats of adsorption on Davison "923" silica gel varied from around 33.0 kcal/mol at $\theta = 0.01$ to 6.2 kcal/mol at monolayer completion. Maxima were observed in this heat curve in the regions of $\theta = 0.15$, 0.28, and 0.40. These phenomena are believed to be related to interactions among the adsorbed species in pores of diameters approaching molecular dimensions. Heats of adsorption on silica–alumina fell smoothly from 39.5 kcal/mol at $\theta = 0.03$ to 13.0 kcal/mol at $\theta = 1.00$. Adsorption–desorption characteristics of methylamine were also examined on a series of silica gels with widely different pore structures. The variations in the heats of adsorption with surface coverage are discussed in terms of both the nature of the adsorbed surface species and lateral interactions among the adsorbed molecules.

L'adsorption de la monométhylamine a été étudiée au voisinage de son point d'ébullition, 266 °K, sur silice–alumine et sur plusieurs silica gels en mesurant les isothermes d'adsorption–désorption et les chaleurs d'adsorption isothermes calorimétriques. De plus les aires de la surface ainsi que les distributions dans la taille des pores ont été déterminées par adsorption de l'azote à basse température. Les chaleurs d'adsorption sur le silica gel Davison "923" varient de 33.0 kcal/mol à $\theta = 0.01$ à 6.2 kcal/mol à la saturation monocouche. Des maxima ont été observés sur la courbe de chaleur dans les régions $\theta = 0.15$, 0.28, et 0.40. On pense que ces phénomènes sont en relation avec les interactions entre les espèces adsorbées dans les pores dont les diamètres sont proches des dimensions de la molécule. Les chaleurs d'adsorption sur silica–alumine chutent lentement de 39.5 kcal/mol à $\theta = 0.03$ jusqu'à 13.0 kcal/mol pour $\theta = 1.00$. Les caractéristiques de l'adsorption–désorption de la méthylamine ont été également examinées sur une série de silica gels de structures de pore largement différentes. Les variations dans les chaleurs d'adsorption avec la surface recouverte sont discutées en tenant compte à la fois de la nature des espèces adsorbées sur la surface et des interactions latérales entre les molécules adsorbées.

Canadian Journal of Chemistry, **50**, 1666 (1972)

Introduction

Most adsorption studies of amines and basic vapors on siliceous adsorbents have been concerned with the estimation of the "acid strength" of the adsorbent (1–3). Such investigations are often activated by industrial interest in the properties of cracking catalysts, while certain other studies, using ammonia mainly, have provided fundamental data on surface complexes and gas/solid interactions through measurements of isosteric (4) and calorimetric (5, 6) heats of adsorption. Work in this general area has therefore both applied and basic connotations.

In previous papers (7, 8) the possible modes of the interaction of ethylamine on silica and silica xerogels have been deduced from studies of adsorption–desorption isotherms, rates of desorption, and isosteric heats of adsorption. However, many problems remain to be solved, particularly in regard to the general nature of the adsorption process up to 0.1 to 0.2 of a monolayer. With this aim and with the additional need to obtain comparative and comprehensive data on the adsorption of other amines, a study of the adsorption of monomethylamine vapor has been made from 246 to 286 °K, mainly through the measurement of isotherms and isothermal calorimetric heats of adsorption.

Experimental

Materials

The physical and chemical properties of the adsorbents other than silica–alumina have been specified (8) previously. The low temperature nitrogen adsorption–desorption isotherm for silica–alumina is shown in Fig. 1 with a B.E.T. plot inset. This material contained 13% w/w alumina, surface area 610 m^2/g and mercury "lump" density 0.445 g/cc after treatment at 240 °C for 3 h. Any other necessary data regarding these materials are included in the Results section.

Monomethylamine (Matheson) was vacuum distilled over three columns of sodium hydroxide into a cold trap. The

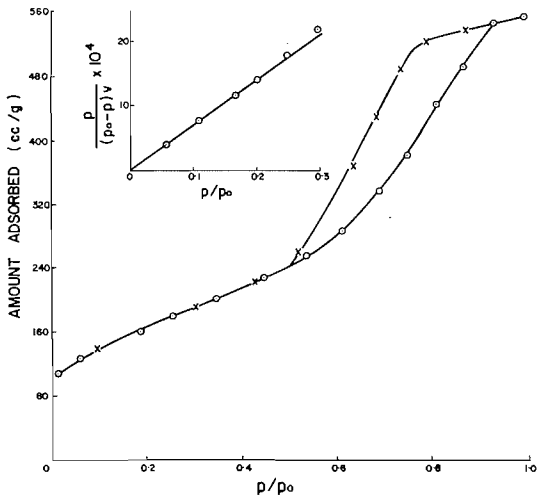

FIG. 1. Low temperature nitrogen adsorption–desorption isotherm for silica–alumina. Inset, B.E.T. plot.

first and last fractions were discarded while the acceptable fraction was outgassed thrice immediately prior to admission to the adsorbent. The final purity, determined by gas–liquid chromatography, was 99.6%, principal impurity was dimethylamine.

n-Butane (Matheson) and nitrogen (British Oxygen Co.) were both >99.90% pure.

Apparatus and Method

Details of the sorption balance have been described (7). The apparatus used to determine "lump" densities by mercury displacement was adapted from that used by Jepson (9). The calorimeter was operated isothermally (10) and was similar to that detailed earlier (10) with slight design modifications to the sample holder, calibration heater and thermistor assembly. Sample temperature control was $\pm 0.05°$ over the refrigeration bath range of -30 to $+60$ °C and the least detectable heat input from the internal heater was 0.2 cal.

Results

Monomethylamine Adsorption/Desorption Isotherms and Isosteric Heats of Adsorption

Figure 2 shows the complete adsorption–desorption isotherm of methylamine on Davison "923" silica gel at 266 °K, boiling point, after activation of the gel at 513 °K for 3 h. Adsorption equilibrium was achieved within 5–10 min up to about 160 mg/g methylamine adsorbed. The equilibrium time gradually increased to a maximum of 60 min at the highest relative pressures while the monolayer coverage value obtained from a B.E.T. plot, inset Fig. 2, was 157.5 mg/g. The reversibility of adsorption was

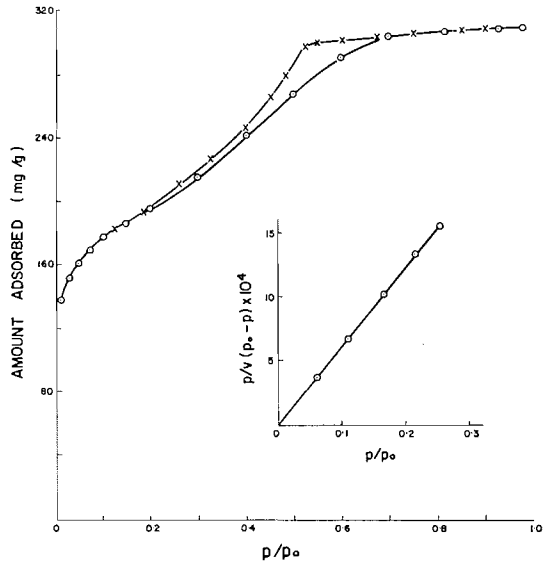

FIG. 2. Adsorption–desorption isotherm for monomethylamine at 266 °K on "923" gel. Inset, B.E.T. plot.

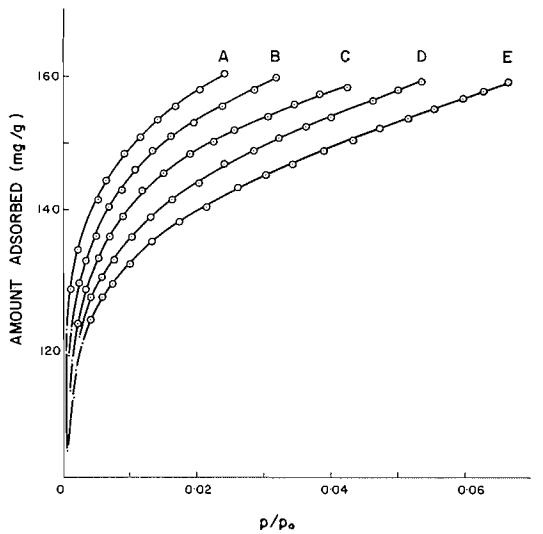

FIG. 3. Monolayer region isotherms for monomethylamine on "923" gel. Range 246–286 °K. *A*, 246 °K; *B*, 256 °K; *C*, 266 °K; *D*, 276 °K; *E*, 286 °K.

tested at four points along the isotherm in the usual fashion (7) for temperature switches between 266 and 338 °K. At each point complete reversibility of the system was found.

A series of monolayer isotherms was determined in the temperature region 246 to 286 °K at 10° intervals (Fig. 3). It can be seen from the proximity of the isotherms that the construction

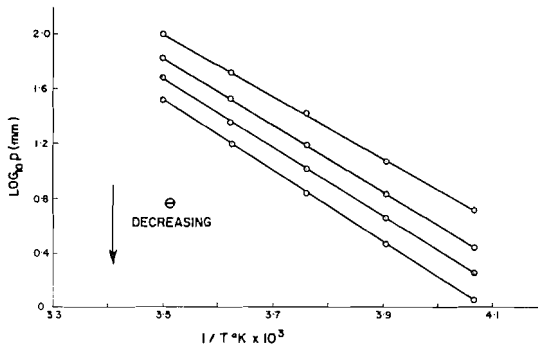

FIG. 4. Adsorption isosteres for monomethylamine on "923" gel. Surface coverage, 0.88 to 1.00 θ.

of adsorption isosteres was not possible below 140 mg/g. Figure 4 shows adsorption isosteres derived from isotherm data for the range $\theta =$ 0.88 to 1.00. For this range, isosteric heats calculated using the logarithmic form of the Clausius/Clapeyron equation (11) were of the order of 10 kcal/mol.

When the pressure of monomethylamine was increased after partial desorption in the region of the lower portion of the hysteresis loop, $p/p_0 = 0.42$ to 0.20, a new path was followed by the adsorption isotherm parallel to the original at a difference of about 4.5 mg/g above it. This new path coincided with the original at about $p/p_0 = 0.70$, the point of inception of the hysteresis loop (Fig. 5).

A series of partial adsorption/desorption isotherms was measured to ascertain the pressure at which hysteresis was initiated. Figure 6(*a*)–(*d*) shows the development of the lower part of the hysteresis loop as the isotherm was determined to increasingly higher relative pressures. The adsorption and desorption paths are coincident until p/p_0 exceeds 0.45 on adsorption and the hysteresis loop does not develop to its fullest extent until desorption from $p/p_0 = 0.60$, Fig. 6(*d*).

Monomethylamine isotherms were determined at 266 °K on a series of silica gels with different pore structures after pretreatment of these at 513 °K for 3 h. The measurements are shown in Fig. 7(*a*)–(*d*) with the B.E.T. plots inset. The adsorption characteristics of the materials are summarized in Table 1 along with the comparative information for Davison "923" gel.

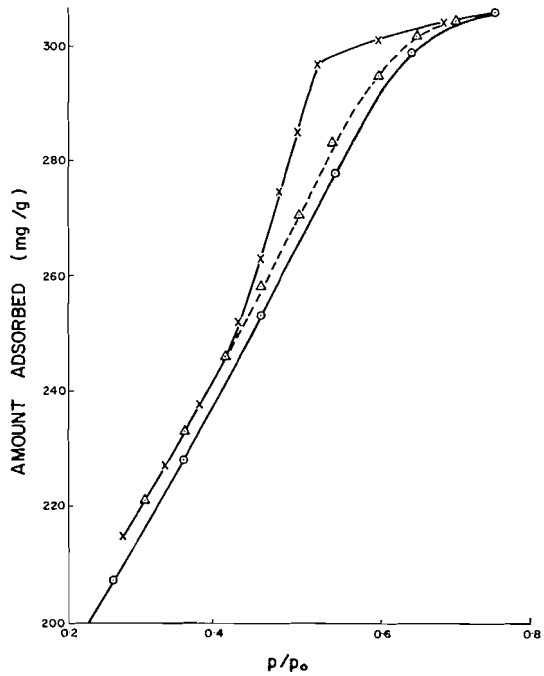

FIG. 5. Monomethylamine hysteresis loop on "923" gel. ○, Adsorption points; ×, desorption points; △, re-adsorption points.

Isothermal Calorimetric Heats of Adsorption

The heat curve from $\theta = 0.01$ to 1.00 at 266 °K for monomethylamine on "923" gel after activation at 513 °K for 3 h followed by outgassing the sample at 363 °K for 1 h at $> 10^{-5}$ mm is shown in Fig. 8, curve *A*. The three minima and maxima which occur between $\theta = 0.10$ to about 0.40 were particularly striking, they were repeated and carefully checked. To test further the validity of these results, a heat curve for *n*-butane was determined which would be expected to exclude any surface effects which might be due to acid site and/or polar interactions in the amine experiments, but would include any characteristics of the methylamine heat curve possibly related to instrumental functions. No maxima or minima were observed in the butane heat curve as shown in Fig. 8, curve *B*.

Since the "high surface area" silica gel gave a similar low temperature nitrogen adsorption/desorption isotherm to that of Davison "923" gel, calorimetric heats were determined on this material for comparative purposes. The results are shown in Fig. 9 along with the heat curve for

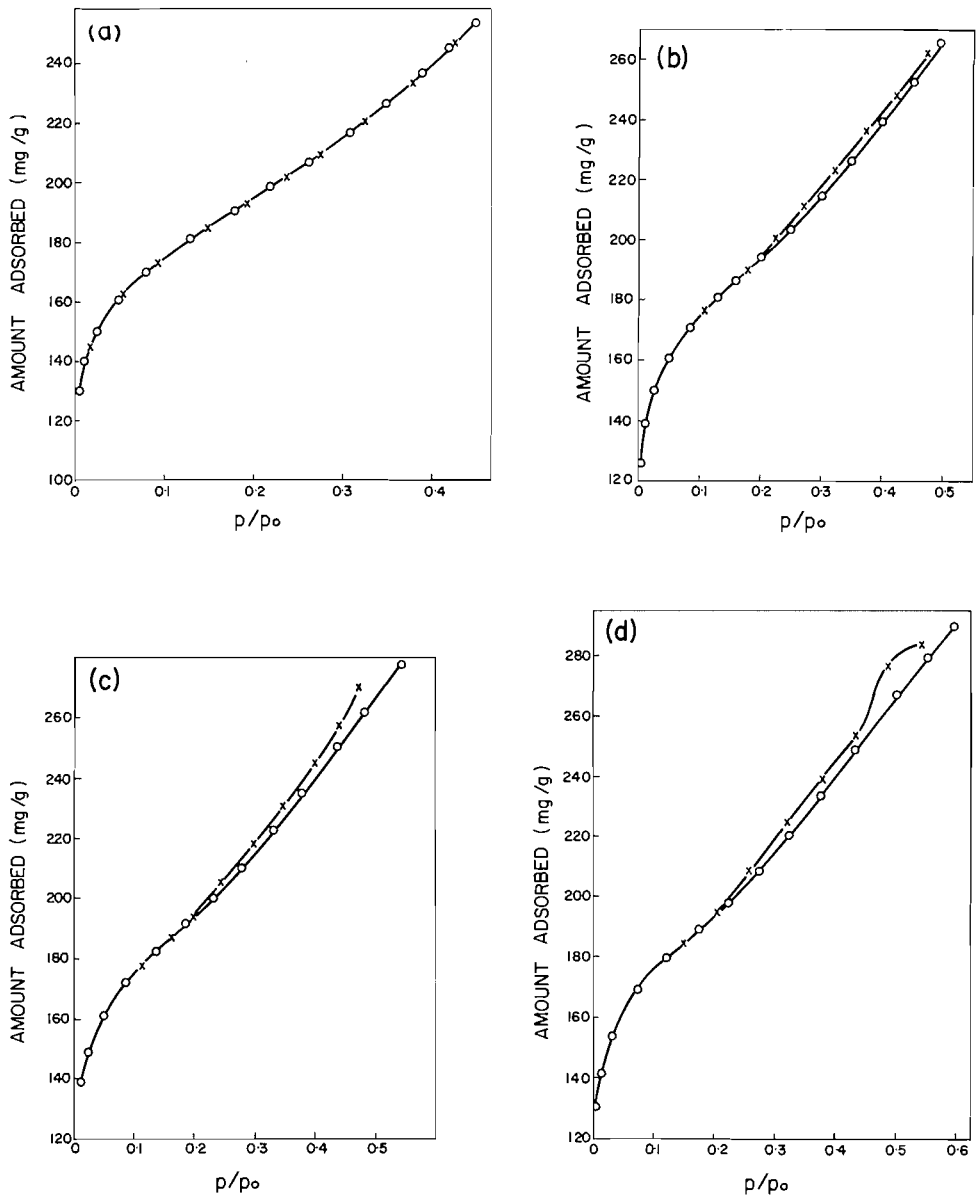

FIG. 6. Development of the lower portion of the hysteresis loop on adsorption to, and desorption from (*a*) $p/p_0 = 0.450$, (*b*) $p/p_0 = 0.500$, (*c*) $p/p_0 = 0.545$, and (*d*) $p/p_0 = 0.600$.

silica–alumina. Both of these materials were activated in the same fashion as the Davison "923" gel prior to the experiments.

A summary of the isothermal calorimetric heats for monomethylamine obtained with the various adsorbents for three standard values of surface coverage is presented in Table 2.

Discussion

Adsorption of methylamine on "923" gel was initially rapid with about one-third of the total adsorbed amount adsorbed below $p/p_0 \sim 0.001$. Equilibrium times were short and even after pumping to 10^{-5} mm at a temperature of 353 °K small amounts, ~4 mg/g, of the amine

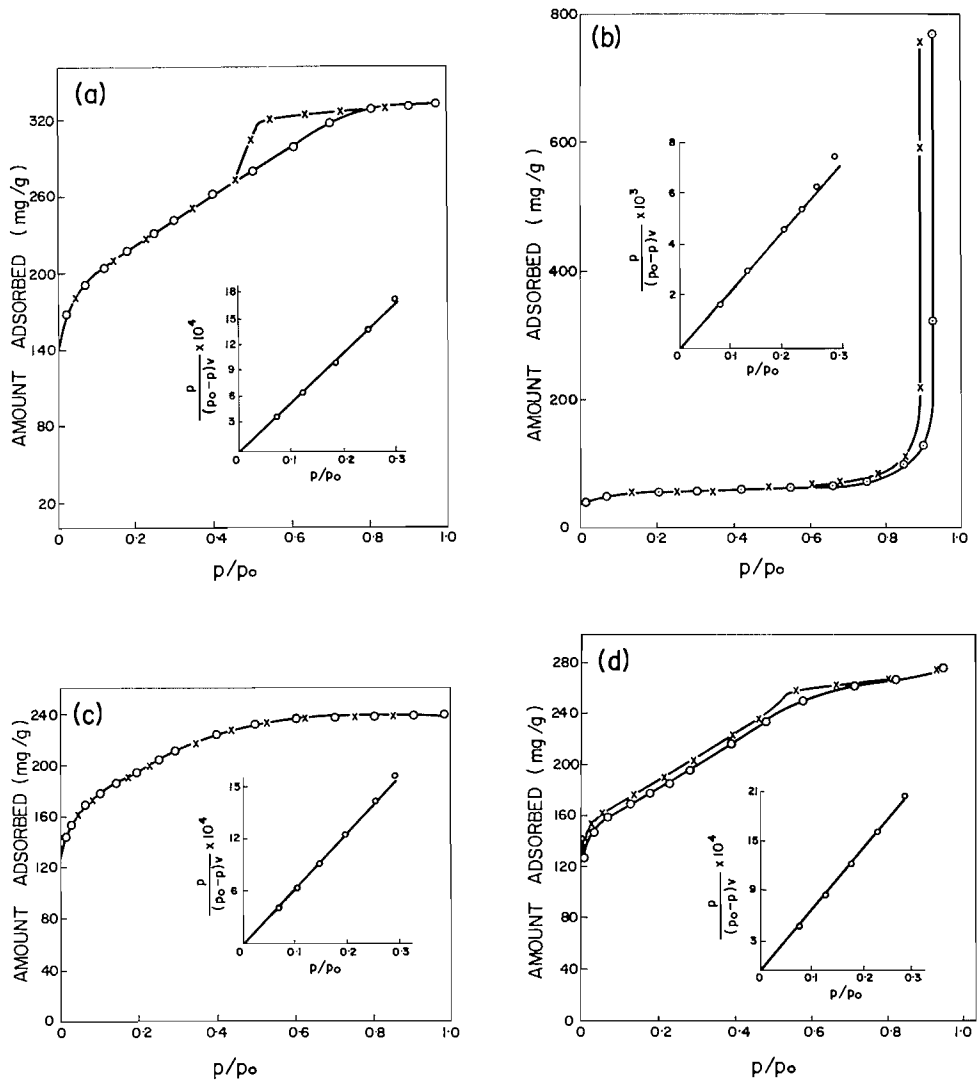

FIG. 7. Adsorption–desorption isotherms for methylamine on (*a*) "high surface area" gel, (*b*) "macroporous" gel, (*c*) "microporous" gel, (*d*) "neosyl F.X." silica. Inset B.E.T. plots.

were still retained by the gel on desorption from $p/p_0 = 0.90$. All of these factors (8) are indicative of strong adsorbate/adsorbent interactions in the initial steep adsorption region of the isotherm, which involve forces considered to be at least partly "chemical" in nature. Similar preliminary observations and conclusions have been made in previous studies concerning aliphatic amines (7, 12).

From the monolayer coverage amount of 157.5 mg/g on "923" gel and the B.E.T. surface area, 650 m^2/g, the average concentration of adsorbed methylamine molecules can be shown to be 47 per 1000 $Å^2$ of surface. This indicates that generally one methylamine molecule is adsorbed for every OH group on the gel surface since the hydroxyl group concentration, determined as previously described (7) was 49 per 1000 $Å^2$. Other workers (13) quote a concentration of 48 hydroxyl groups per 1000 $Å^2$ for similarly treated silica gels. From Livingstone's equation for cross-sectional areas of adsorbed molecules (14) and assuming two dimensional close packing, the cross-sectional area of an

adsorbed methylamine molecule was calculated as 19 to 20 Å^2. This alternative statistical approach yields an approximate figure of around 920 Å^2 for the total area occupied by 47 adsorbed molecules and adds evidence to the view

TABLE 2. Monomethylamine calorimetric isothermal heats of adsorption at various surface coverages on siliceous adsorbents

that the hydroxyl groups are directly involved in methylamine adsorption.

The general shape of the hysteresis loop given by methylamine on "923" gel falls between loop types "D" and "E" in de Boer's nomenclature (15). However, the tendency for the desorption branch to run nearly parallel with the adsorption branch at p/p_0 values from about 0.4 to 0.2 and also the path followed by the adsorption scanning-curve indicate that the pore shapes are largely of the "ink-bottle" type (16). Similar conclusions have been advanced previously for "923" gel from results obtained by electron microscopy and low-temperature nitrogen adsorption (17).

From the partial adsorption–desorption isotherms, Fig. 6, it can be observed that the partial hysteresis loop between $p/p_0 = 0.42$ to 0.20 is linked to adsorption which occurs between $p/p_0 = 0.45$ to 0.60. Pores filling in this region are from 37 to 53Å diameter (18). Molecules desorbing through the narrow passages in these "ink-bottle" pores where the cross-section approaches molecular dimensions would have a slow rate of outward diffusion, possibly involving a series of adsorption/desorption hops along the pore walls (7). This phenomenon is clearly linked to pore shape and structure since it was not observed with the other gels.

Figure 7(*a*)–(*d*) shows the isotherms for the other gels. The isotherm determined on "high surface area" material is best classified as type "E" (15). "Microporous" gel has a pore size distribution largely from 20 to 30Å diameter (11) and gave no hysteresis effects. The asymptotic rise in adsorption above $p/p_0 = 0.90$ with the "macroporous" gel is probably due to condensation of methylamine in macropores >200 Å diameter as the pore distribution of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

material ranges mainly from 200 to 240 Å diameter (11). The hysteresis loop obtained with "Neosyl F.X." remains open to below $p/p_0 = 0.01$. This material is finely divided silica with a lump density, 0.258 g cc^{-1}, much lower than that of "923" gel, 1.163 g cc^{-1}, but with a pore range comparable to that of "923" gel (11). The failure of the hysteresis loop to close is probably due to a small measure of irreversible adsorption within the interior pore matrix of this extremely porous material.

The calorimetric heat curve for methylamine on "923" gel, Fig. 8, indicates a high initial heat of 33 kcal/mol at $\theta = 0.01$. This compares with previously estimated values of 30 to 40 kcal/mol for the isosteric heat of adsorption of ethylamine on the same gel at surface coverages below $\theta = 0.10$ (8) and with a value of around 38 kcal/mol (19) for the isosteric heat of adsorption of ammonia on silica gel, heat-treated at 500 °C for 1 h under high vacuum, at a surface coverage of less than two adsorbed molecules per 1000 $Å^2$. Such heat values point to the formation of a linkage between the adsorbed molecule and surface silanol groups which is "chemical" in nature (8). The silanol groups may be expected to act as Brønsted acid sites (7) with the possibility of proton displacement to the adsorbed amine taking place such that, in the limit, a charge-transfer or ionic type of adsorbed complex may be formed on the surface. A similar possibility has been suggested previously to explain the adsorption of triethylamine on silica gel (20).

The initial heat falls rapidly to 17.0 kcal/mol at $\theta \sim 0.10$ on "923" gel, Fig. 8, and similarly to 15.0 kcal/mol with "high surface area" gel, Fig. 9, at the same surface coverage. Then, with both of these gels distinct heat rises amounting to about 2 kcal/mol were observed up to $\theta = 0.50$. This phenomenon has not been observed previously with such systems to the same extent, although single heat maxima beginning in similar surface coverage regions have been recorded in studies of the heats of adsorption of *n*-butylamine on kaolin (21), triethylamine on silica/alumina (4), and ammonia on silica/alumina and silica (5, 22). In the particular instance of ammonia adsorbed on silica (22) the heat rise of about 2 kcal/mol in the region of 5% coverage was not observed in later experiments (6). In view of the latter difference particular attention was given to the verification of the present results.

The explanation of the phenomenon seems most probably linked to the pore structure of the adsorbents. Thus the heat rises occur at similar coverages, $\theta = 0.15$, 0.28, and 0.40 with "923" gel and at $\theta = 0.18$, 0.27, and 0.36 with "high surface area" gel. These regions of surface coverage are most likely to correspond to adsorption in pores of monomolecular dimensions since monolayer coverages at about $p/p_0 = 0.04$ corresponds to the filling of pores of less than 20 Å diameter as determined by nitrogen adsorption methods (18). The interactions of adsorbing methylamine molecules at $\theta = 0.10$, with the previously formed ionic-type adsorbed species in molecular size capillaries could be expected to lead to a temporary rise in heat liberated. This possibility would be enhanced by the existence of some of the adsorbing hydroxyl groups in dense "islands" (23), thereby increasing the likelihood of the occurrence of lateral interactions among the adsorbed molecules.

The existence of three heat rises may indicate that molecular access to all such species does not occur at the same time but depends on increase of pressure allowing the occupation of slightly larger pores, thus bringing further adsorbing molecules into intimate contact with further charged species. It is especially noticeable that in the case of "923" gel the peaks are of approximately equal distance, 2 kcal/mol, above the base of the heat curve. As increasing numbers of methylamine molecules are adsorbed around the charged complexes their sphere of influence will decrease by virtue of the increase in distance, thereby causing a decrease in the heat liberated. This situation could cause the falls in the heat curve observed after the initial rise in each case.

From $\theta = 0.50$ to monolayer coverage with "923" gel the heat curve falls almost linearly from 13.5 to 6.2 kcal/mol, and for "high surface area" gel from 9.0 to 6.1 kcal/mol. These final heats are substantially higher than the latent heat of condensation for methylamine, 0.199 kcal/mol (24), and may indicate that the formation of bonds of the N---H—O type (8) is still likely even at monolayer completion.

The heat curve for methylamine adsorption on silica–alumina, Fig. 9, shows no irregulari-

ties and falls smoothly from 39.5 kcal/mol at $\theta = 0.03$ to 13.0 kcal/mol at $\theta = 1.00$. The general form of the curve is similar to that found previously for ammonia on silica–alumina (6, 19). The curve shows higher heat values at all points than either of the methylamine heat curves determined on "923" or "high surface area" silica gels. Thus at $\theta = 0.10$, 0.50, and 1.00 heats for silica–alumina were about 29.0, 19.6, and 13.0 kcal/mol while at these coverages the average values for the gels were 14.5, 11.3, and 6.2 kcal/mol, respectively. The higher heats may be explained by the adsorption of methylamine molecules through coordination of the lone-pair electrons of the nitrogen atoms to electron deficient aluminum atoms exposed on the gel surface as has been suggested previously to explain methylamine adsorption on alumina (25). The higher heat values over the entire range of coverage for silica–alumina are certainly indicative of the presence of a much greater number of strongly adsorbing sites than is present on the gels.

Réaction du sulfure de bore avec quelques composés difonctionnels

S. JERUMANIS, P. A. BEGIN, ET D. VU CONG
Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Reçu le 6 octobre 1971

Les auteurs ont étudié la réaction du sulfure de bore avec le catéchol, l'acide salicylique, l'acide succinique, l'acide maléique, et l'acide phtalique. La réaction du catéchol avec le sulfure de bore donne l'*o*-phénylènedioxy-2,2′ bis-(benzodioxa-1,3 borole-2) (**1**) tandis que l'acide salicylique réagit seulement par sa fonction hydroxyle pour donner le tris(*o*-carboxylphénoxy) borane (**3**). Les acides succinique et maléique ne réagissent pas, mais l'acide phtalique subit une déshydratation et se transforme quantitativement en anhydride.

Catechol reacts with boron sulfide to give 2,2′-*o*-phenylenedioxybis-(1,3,2-benzodioxaborole) (**1**) while only the hydroxyl function of salicylic acid reacts to give a quantitative yield of tris(*o*-carboxylphenoxy)borane (**3**). Phthalic acid is dehydrated to phthalic anhydride, but succinic acid and maleic acid have been found inert to the action of the boron sulfide.

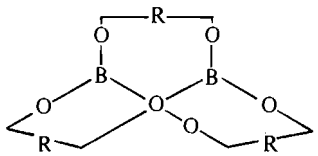
La réaction du sulfure de bore avec divers types de molécules monofonctionnelles possédant un hydrogène mobile, tels que les amines (1), les mercaptans (2), les alcools (3), et les acides (4) a été déjà étudiée. Par contre la réaction avec les molécules hydroxylées polyfonctionnelles n'a pas encore été rapportée. Nous avons étudié cette réaction avec l'acide salicylique, l'acide phtalique, l'acide maléique, l'acide succinique, et le catéchol.

Le catéchol réagit avec le sulfure de bore pour donner de l'*o*-phénylènedioxy-2,2′ bis-(benzodioxa-1,3 borole-2) (**1**), éq. 1.

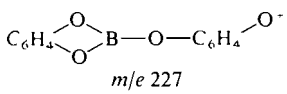
On admet que le biborate de tricatéchol **1** est linéaire, la forme bicyclique **2** proposée par



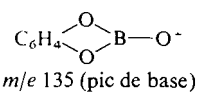
2

Dupire (5) pour les biborates des 1,2- et 1,3-diols étant considérés comme peu probable en raison de l'instabilité (6).

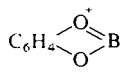
Même, si la formation de la liaison B—O est confirmée par une forte absorption à 1460 cm^{-1}, la spectroscopie i.r., la r.m.n., et l'analyse centésimale ne permettent pas une distinction très nette entre ces deux formes du biborate. Par contre, en analysant le spectre de masse de cette substance on peut établir plus clairement cette distinction. En effet, l'ion moléculaire à $m/e = 346$ indique que la réaction du sulfure de bore avec le catéchol donne un monomère et la présence des fragments:



m/e 227



m/e 135 (pic de base)



m/e 119

confirme que le biborate obtenu existe sous la forme linéaire.

L'acide salicylique réagit avec le sulfure de bore seulement par son groupement hydroxyle pour donner la naissance au tris(*o*-carboxylphénoxy)borane (**3**), éq. 2.

Les spectres d'absorption dans l'i.r. des com-

[1] 
1

[2] 
3

posés **1** et **3** montrent la présence de bore différemment hybridé (7) et sont compatibles avec leurs structures (voir partie expérimentale).

Avec l'acide phtalique on n'observe pas la formation de la liaison B—O mais une simple déshydratation. Même à la température ambiante l'acide phtalique en présence du sulfure de bore est quantitativement transformé en anhydride phtalique. Par contre, l'acide maléique ne se déshydrate pas. Dans le benzène à reflux l'acide maléique s'isomérise en acide fumarique et on n'observe aucune réaction avec le sulfure de bore. Egalement l'acide succinique reste inerte en présence du sulfure de bore.

Partie expérimentale

Les spectres i.r. ont été pris sur le spectrophotomètre Perkin–Elmer modèle 257.

Les spectres de r.m.n. ont été obtenus avec un appareil Varian A60, en se servant de tétraméthylsilane comme référence interne.

Les points de fusion (p.f.) ont été déterminés en tubes capillaires au moyen d'un appareil Büchi et ne sont pas corrigés. Les analyses élémentaires furent effectuées par "Schwarzkopf Microanalytical Laboratory" de New York.

Les spectres de masse ont été enregistrés sur un appareil Hitachi–Perkin–Elmer, modèle RMU-6D.

Le pourcentage de bore a été déterminé par la méthode de Thomas (8).

(1) Réaction du catéchol avec le sulfure de bore

Une solution de 18 g (0.16 mol) de catéchol dans 500 ml de benzène anhydre et 6.4 g (0.054 mol) de sulfure de bore est refluée sous atmosphère d'azote jusqu'à ce que cesse le dégagement du sulfure d'hydrogène. Durant cette réaction le sulfure de bore est maintenu en suspension par une agitation magnétique. Au terme de ce contact, le mélange réactionnel est filtré à chaud sur un filtre d'amiante et le filtrat concentré par évaporation sous pression réduite. On obtient ainsi une poudre légèrement jaunâtre, p.f. 71–104 °C. Ce produit brut est repris dans l'éther anhydre pour éliminer le soufre et la solution éthérée est évaporée sous vide. Le produit obtenu est traité par le sulfure de carbone pour séparer le catéchol qui n'a pas réagit. Après la filtration, le sulfure de carbone est évaporé sous vide. Cette opération est répétée plusieurs fois. On obtient ainsi une poudre blanche, p.f. 91–93 °C (litt. 99–104 (8); 104 (9); 71–73.5 (10); 72–74° (11)), représentant 50% du poids de substance mis en expérience. Spectre i.r. (KBr): bandes à 1460 et 1235 (fortes), 3050, 1600 (faibles), 735 cm^{-1} (large). Spectre de r.m.n. (dans l'acétone-d_6): absorption aromatique dans la région 2.6–3.3 τ.

Anal. calc. pour $C_{18}H_{12}O_6B_6$: C, 62.49; H, 3.47; B, 6.25. Trouvé: C, 62.44; H, 3.70; B, 6.40.

Spectre de masse, *m/e*: 346, 227, 135, 119, 109, 93, 65, 27.

(2) Réaction de l'acide salicylique avec le sulfure de bore

A une suspension de 6.62 g (0.05 mol) du sulfure de bore dans 500 ml de benzène anhydre 20 g (0.14 mol) d'acide salicylique est ajouté et la réaction est effectuée suivant le protocole donné pour le catéchol. Le produit obtenu après l'évaporation du solvant est lavé à l'éther sec. On obtient ainsi les cristaux blancs, p.f. 258–260 °C, avec un rendement quantitatif. Spectre i.r. (KBr): bandes à 3000 (large), 1700 (forte), 1615 et 1580 (moyennes), 1348 et 1225 (fortes), 775 cm^{-1} (épaulement). Spectre de r.m.n. (dans l'acétone-d_6): multiplet entre 1.90 et 3.00 τ.

Anal. calc. pour $C_{21}H_{15}O_9B$: C, 59.74; H, 3.58; B, 2.56. Trouvé: C, 59.47; H, 3.38; B, 2.35.

Spectre de masse, *m/e*: 285, 121, 120 (pic de base), 45.

(3) Réaction de l'acide succinique avec le sulfure de bore

A une suspension de 2 g (0.017 mol) du sulfure de bore dans 300 ml d'acétone, 6 g (0.051 mol) d'acide succinique est ajouté et le mélange chauffé et agité durant 6 jours sous atmosphère d'azote. Par la filtration on retrouve le sulfure de bore inchangé et un filtrat qui après décoloration et évaporation met en liberté la quantité initiale d'acide succinique, p.f. 144–146 °C.

(4) Réaction de l'acide maléique avec le sulfure de bore

Une solution de 20 g (0.17 mol) d'acide maléique dans 500 ml de dioxane anhydre est refluée pendant 6 jours en présence de 10 g (0.084 mol) du sulfure de bore en suspension. La solution chaude est ensuite filtrée et décolorée sur le charbon actif. Après évaporation sous vide le résidu est recristallisé dans le mélange de dioxane–éther. Le produit final est un solide blanc qui est identifié par les méthodes spectroscopiques (i.r. et r.m.n.) et d'après son p.f. (299–301 °C) comme étant l'acide fumarique.

(5) Réaction de l'acide maléique avec le sulfure de bore

Une solution de 20 g (0.12 mol) d'acide phtalique dans 500 ml de dioxane anhydre à 25 °C est agitée pendant 12 jours en présence de 5.64 g (0.046 mol) du sulfure de bore, sous atmosphère d'azote. La masse réactionnelle est filtrée. Le filtrat est évaporé sous vide et le produit solide lavé au sulfure de carbone, et puis repris dans l'éther anhydre. On obtient ainsi, après évaporation de l'éther, 17.5 g d'un produit incolore, sous formes d'aiguilles brillantes, p.f. 131 °C. Décrit pour l'anhydride phtalique, p.f. 130.8 °C. Les spectres i.r. d'un échantillon authentique de l'anhydride phtalique et de substance obtenue sont identiques.

Photolysis of 2,5- and 2,4-Dimethylpyrrole Vapors at Room Temperature[1]

E. CHUNG WU[2] AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pennsylvania 16802

Received December 6, 1971

Both 2,5- and 2,4-dimethylpyrrole vapors at pressures from 0.05 to 0.70 Torr were irradiated at 2139 and 2288 Å at room temperature. The products were H_2, CH_4, C_2H_6, and polymer. No ring cleavage products were found. $\Phi\{H_2\}$ and $\Phi\{CH_4\}$ were remarkably insensitive to which pyrrole was used, its pressure, I_a, or the wavelength of the incident radiation. They were ~0.10–0.15 and ~0.01–0.02, respectively. $\Phi\{C_2H_6\}$ was comparable to $\Phi\{CH_4\}$ and was also invariant to which substrate was used or the incident wavelength. However $\Phi\{C_2H_6\}$ did increase at low pressure or as I_a was reduced.

The effect of scavengers showed that the products were produced mainly from free radical precursors. The main primary steps are:

$$\begin{aligned} DMP + h\nu &\rightarrow DMP^* \\ DMP^* &\rightarrow H + F_a \\ &\rightarrow CH_3 + F_b \\ &\rightarrow DMP \end{aligned}$$

where DMP* is an electronically excited state of the dimethylpyrrole and F_a and F_b are radical fragments. Experiments with quenching gases showed that DMP* could be quenched, but that this reaction was less important than the first-order steps below 1 Torr.

Les vapeurs de diméthyl-2,5 et diméthyl-2,4 pyrrole ont été irradiées toutes deux à 2139 et 2288 Å à la température ambiante sous un vide de 0.05 à 0.70 Torr. Les produits obtenus sont H_2, CH_4, C_2H_6 et du polymère, à l'exclusion de produits d'ouverture de cycle. $\Phi\{H_2\}$ et $\Phi\{CH_4\}$ sont remarquablement indépendants du pyrrole utilisé, de sa pression, I_a, ou de la longueur d'onde de la radiation incidente; ils sont respectivement de ~0.10–0.15 et ~0.01–0.02. $\Phi\{C_2H_6\}$, comparable à $\Phi\{CH_4\}$ est aussi indépendant du substrat utilisé ou de la radiation incidente. Cependant $\Phi\{C_2H_6\}$ croît pour de basse pression ou lorsque I_a décroît.

L'effet des inhibiteurs montre que les produits découlent principalement de précurseurs radicalaires libres. Les étapes primaires principales sont:

$$\begin{aligned} DMP + h\nu &\rightarrow DMP^* \\ DMP^* &\rightarrow H + F_a \\ &\rightarrow CH_3 + F_b \\ &\rightarrow DMP \end{aligned}$$

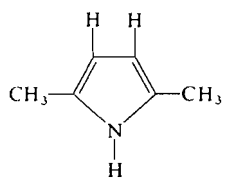
où le DMP* est un état électronique excité de diméthylpyrrole et F_a, F_b des fragments radicalaires. Les expériences en présence de gaz inhibiteurs montrent que le DMP* peut être capté mais que cette réaction est moins importante que les étapes du premier ordre en dessous de 1 Torr.

Canadian Journal of Chemistry, **50**, 1678 (1972)

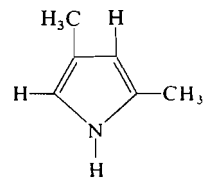
Introduction

Previously we have examined the photolysis of pyrrole vapor (1). We found that ring cleavage occurs, though the quantum yields were small. In this paper we extend our studies to the 2,5- and 2,4-dimethylpyrroles.

Earlier work in solution has shown that the substituted pyrroles undergo valence isomerization only. Thus the thermal (2) and photochemical (3) 1–2 and 1–3 valence isomerizations



2,5-dimethylpyrrole



2,4-dimethylpyrrole

of benzylpyrroles have been reported. However the 2-isomer is not the precursor to the 3-isomer in the photochemical reaction, because the 2-isomer does not photoisomerize to its 3-isomer, though it does so thermally. Hiraoka (4) showed that the irradiation of 2-cyanopyrrole in methanol yielded 3-cyanopyrrole as a major product, but that the reaction was not reversible, *i.e.* irradiation of 3-cyanopyrrole did not produce 2-cyanopyrrole.

We were interested to see if the ring cleavage reactions would occur in the vapor phase for the substituted pyrroles, or whether ring isomerization would dominate. To our surprise we found that other processes were important which produced H_2, CH_4, and C_2H_6, and this paper reports the production of these products.

Experimental

2,4-Dimethylpyrrole and 2,5-dimethylpyrrole from K & K Laboratories, Inc. showed no impurity peaks on the gas chromatograms from a 20-ft long column packed with 10% tricresyl phosphate on Chromosorb G. After degassing at −64 °C, these compounds were distilled *in vacuo* from trap to trap at room temperature to remove the dark color. All gases were from the Matheson Co. HBr was distilled *in vacuo* at −130° and NO was distilled *in vacuo* at −186° after degassing at −196°. Extra dry grade O_2 and C.P. grade C_2H_4 were introduced into the reaction cell directly. Both *i*-C_4H_{10} (Instrument Grade 99.5% pure) and C_2F_6 (99.6% pure) were used as received.

The experimental apparatus and procedure were the same as described in our previous report (1), except that one additional light source, a Phillips Type 93107E Cd lamp, was used. The photochemically effective emission of this lamp is the spectral line at 2288 Å, though weak lines at 2144 and 2265 Å are also present.

The reaction mixture was passed through a trap in an acetone slush (−90 °C) after irradiation. The gaseous products were collected in a Toepler pump and analyzed on the 10-ft Porapak Q gas chromatographic column as described previously (1).

Room temperature extinction coefficients (to base 10) were found on a Cary 14 spectrophotometer to be 0.370, 0.299, and 5.5×10^{-3} $Torr^{-1}$ cm^{-1} at 2139 Å and 0.152, 0.138, and 1.17×10^{-3} $Torr^{-1}$ cm^{-1} at 2288 Å for 2,4-dimethylpyrrole, 2,5-dimethylpyrrole, and HBr, respectively.

An attempt to investigate the photoisomerization of 2,5-dimethylpyrrole was also tried. Various lengths (1-ft to 10-ft long) of coiled copper columns (1/4-in. in diameter) with 10% by weight of tricresyl phosphate, dinonylphthalate, or 15% diethyleneglycol succinate on Chromosorb W were tried for this purpose. The column temperature was varied from 100 to 170 °C and the flow rate of He gas changed from 40 to 100 cm^3/min. A 6-ft long glass column (i.d. 1/8 in.) packed with 15% of diethyleneglycol succinate at 130 °C was also tried. A single peak with very broad tailing was observed with either 2,5- or 2,4-dimethylpyrrole, and the retention times of both compounds were similar on all the columns.

Results

The dimethylpyrrole (DMP) vapors were irradiated at room temperature with 2139 or 2288 Å radiation. The substrate pressures ranged from 0.05 to 0.70 Torr, the lower limit being imposed by experimental and analytical considerations, and the upper limit corresponding to the vapor pressure. The principal product of the reaction was H_2, though CH_4 and C_2H_6 were also produced. There was also evidence for polymeric material, since the transmission of the reaction cell to the incident radiation decreased after continued irradiation of the samples. Flaming and pumping the reaction cell would return the transmission to its original value.

Of special interest was the absence of the ring cleavage products. In particular no C_2H_2, CH_2CCH_2, or CH_3CCH were produced, except in trace amounts for very extended exposures of 2,5-DMP only. Four-carbon hydrocarbons were never produced. Consequently the presence of two methyl groups on the ring completely stabilizes pyrrole against ring decomposition. We have no evidence regarding the importance of CH_3 group migration during photolysis. Several attempts were made to study the isomerization, but the separation of the isomers was so poor on all of our chromatographic columns that we could not obtain meaningful results. Therefore we studied the photodecomposition only.

Initially the effect of irradiation time on the gaseous products was examined. Such studies are shown in Table 1 for conditions where a time effect should be most pronounced, *i.e.* at high intensities. With 2,5-DMP at 0.5–0.7 Torr, and the absorbed intensity, I_a, ~31–36 μ/min (μ/min can be converted to einstein/l min by dividing by 1.86×10^7) at either 2139 or 2288 Å, the quantum yields are constant for up to 20 min irradiation, but then fall off for longer exposures. As the absorbed light intensity decreased ~30% after a 2-h run, the fall-off at high conversions is attributed to the polymer build-up on the windows which reduces the incident intensity. With 2,4-DMP at 2139 Å, the time effect is unimportant. Also some runs were done for different exposure times with

*Average value from Table 2.

measure CH_4 and C_2H_6 production. The results for H_2 production alone, in the presence of O_2, and in the presence of other gases, are given respectively in Tables 2, 3, and 4. Likewise similar experiments for the CH_4 and C_2H_6 yields are given in Tables 5–7. All the results reported in these tables are for short irradiation times, and the quantum yields may be considered initial values.

Table 2 shows that in the absence of added gases $\Phi\{H_2\}$ is remarkably insensitive to which pyrrole is used, its pressure, I_a, or the wavelength of the incident radiation. There is some indication that $\Phi\{H_2\}$ may rise at very low substrate pressures, but this effect is not pronounced, if indeed it occurs at all. Average values are listed in Table 2 and $\Phi\{H_2\}$ is $\sim$0.10–0.15.

The effect of added O_2 on $\Phi\{H_2\}$ is shown in Table 3. The presence of O_2 markedly reduces $\Phi\{H_2\}$, and the amount of reduction depends on the DMP pressure. Thus about 1.6 Torr of O_2 drops $\Phi\{H_2\}$ from 0.113 to 0.030 with 0.50

Torr of 2,4-DMP at 2139 Å, but the drop is to 0.0090 for 0.10 Torr of 2,4-DMP. The addition of NO, C_2H_4, and C_2F_6 also reduces $\Phi\{H_2\}$, though all these gases were less efficient than O_2. The results are in Table 4.

With CH_4 and C_2H_6, the results are similar though somewhat more complex than for H_2. Table 5 shows the results in the absence of added gases. $\Phi\{CH_4\}$ is nearly invariant to changes in substrate, substrate pressure, I_a, or incident wavelength, being between 0.01 and 0.02 except at low pressures at 2288 Å, where it falls to about 0.006. $\Phi\{C_2H_6\}$ is comparable in magnitude to $\Phi\{CH_4\}$. It is reasonably invariant to substrate or incident wavelength. However it does increase at low pressure, the increase being more pronounced at 2139 than 2288 Å. The most remarkable result, though, is that $\Phi\{C_2H_6\}$ *increases* noticeably as I_a is reduced.

The effect of O_2 is shown in Table 6. Only small amounts of O_2 reduce $\Phi\{C_2H_6\}$ to zero showing that all the C_2H_6 comes from CH_3 radical combination. $\Phi\{CH_4\}$ is reduced less rapidly by the addition of O_2, but about 95% of the CH_4 is suppressed by the addition of one or more Torr of O_2.

Table 7 shows the results with added NO, i-C_4H_{10}, and C_2H_4. Both CH_4 and C_2H_6 are readily suppressed by NO, and both are reduced by i-C_4H_{10}, but considerably less efficiently. $\Phi\{CH_4\}$ is reduced by the addition of C_2H_4, but $\Phi\{C_2H_6\}$ is enhanced, thus demonstrating the presence of H atoms in the system. The peak increase in $\Phi\{C_2H_6\}$ corresponds roughly to the drop in $\Phi\{H_2\}$.

Discussion

The results clearly indicate the presence of both H atoms and CH_3 radicals. Thus the simplest scheme to explain the primary process is

[1] $$DMP + h\nu \rightarrow DMP^*$$

[2a] $$DMP^* \rightarrow H + F_a$$

[2b] $$\rightarrow CH_3 + F_b$$

[2c] $$\rightarrow DMP$$

The H atoms ultimately become H_2, but whether this occurs on the wall, by interaction with the fragments F_a and F_b, or by an abstraction reaction with DMP is not clear. For simplicity let us assume that the abstraction reaction with pyrrole predominates.

[3] $$H + DMP \rightarrow H_2 + F_a$$

In support of this hypothesis is the fact that the peak increase in $\Phi\{C_2H_6\}$ when C_2H_4 is added corresponds to the loss in $\Phi\{H_2\}$. This would be the case if each C_2H_5 radical produced by H addition to C_2H_4 produced a C_2H_6 molecule, whereas each H not scavenged produced an H_2 molecule.

The above simple reaction scheme leads to the rate law

[I] $$\Phi\{H_2\} = k_{2a}/k_2$$

which conforms with the results in the absence of added gases with $k_{2a}/k_2 \sim 0.10$–0.15. In the presence of a scavenger, such as O_2, the H atoms can be removed via

[4] $$H + S + M \rightarrow HS + M$$

where S is the scavenger. The reaction is written as third order since at the low pressures used here a chaperone is required, especially with O_2 or NO as scavengers. The rate law then becomes

[II] $$\Phi\{H_2\}^{-1} = \frac{k_2}{k_{2a}}\left(1 + \frac{k_4[S][M]}{k_3[DMP]}\right)$$

If $[M] \sim [DMP]$, then eq. II predicts that $\Phi\{H_2\}^{-1}$ should be linear with the scavenger pressure. Appropriate plots are shown in Figs. 1–5.

Figure 1 shows the scavenging by O_2 when 0.50 Torr of DMP is irradiated at 2288 Å, and good straight-line plots are obtained. In Fig. 2 the data are for 2,4-DMP with 2139 Å radiation. For 0.50 or 0.30 Torr the same results are obtained and the plot is linear as expected. However with 0.10 Torr of 2,4-DMP, the data points lie higher and the plot has curvature at

low O_2 pressures; 2,5-DMP shows the same behavior as seen in Fig. 3. Apparently at low DMP pressures other processes are occurring. Perhaps H_2 formation is from the interaction of H atoms with the fragments

[5] $$H + F_a, F_b \rightarrow H_2 +$$

Then [DMP] would disappear from the denominator of the last term in eq. II and the rise in $\Phi\{H_2\}^{-1}$ should be rapid with increasing O_2 pressure. Of course the rise might be quadratic since [M] is now $[O_2]$. On the other hand some H_2 could be produced molecularly

[2*d*] $$DMP^* \rightarrow H_2 + F_d$$

Then $\Phi\{H_2\}^{-1}$ would reach some upper limiting value. However this value is large and reaction 2*d* cannot account for more than 10% of the H_2 produced.

Figure 4 shows the scavenging effect of NO with 0.50 Torr of DMP. Again good straight line plots are obtained.

In addition to the scavenging of H atoms, an added gas might also quench DMP*

[6] $$DMP^* + M \rightarrow DMP + M$$

That this occurs is shown by the addition of C_2F_6 which cannot scavenge H atoms. For no scavenging of H atoms the mechanism predicts

[III] $$\Phi\{H_2\}^{-1} = \frac{k_2}{k_{2a}}\left(1 + \frac{k_6[M]}{k_2}\right)$$

Figure 5 shows that eq. III is followed for both

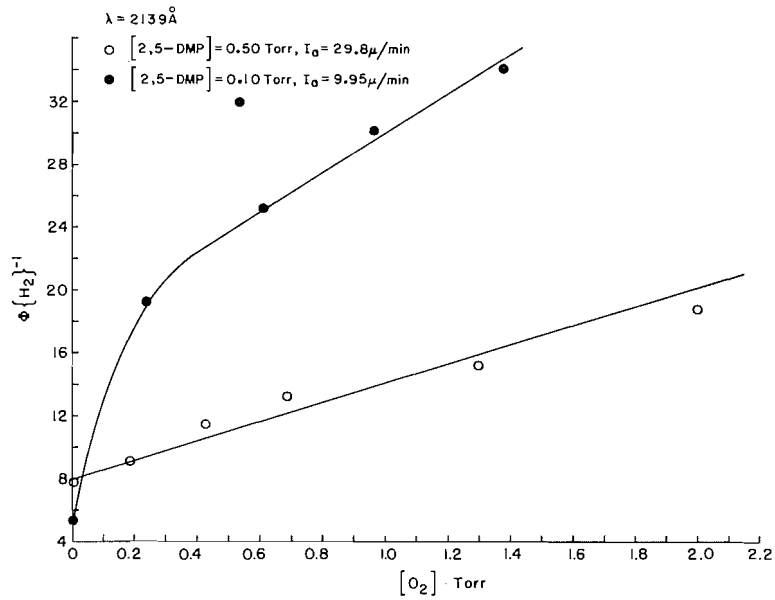

FIG. 3. Plot of $\Phi\{H_2\}^{-1}$ *vs.* O_2 pressure in the photolysis of 2,5-DMP at 2139 Å and room temperature in the presence of O_2.

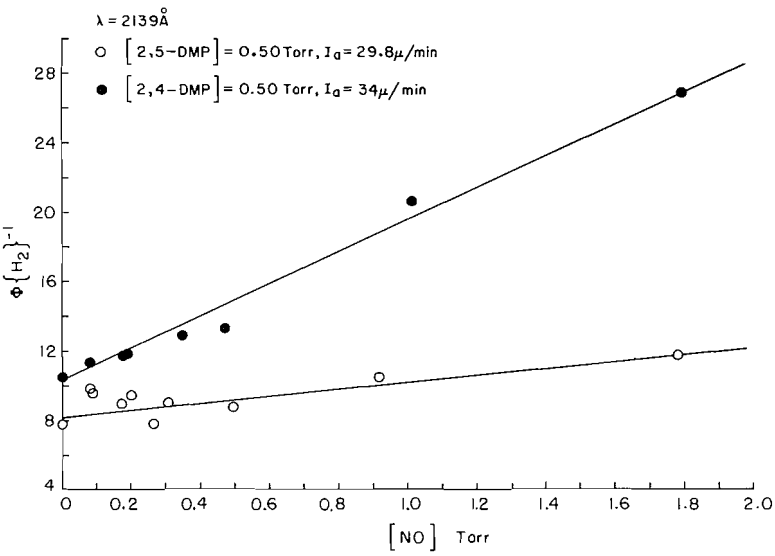

FIG. 4. Plot of $\Phi\{H_2\}^{-1}$ *vs.* NO pressure in the photolysis of dimethylpyrroles at 0.50 Torr pressure at 2139 Å and room temperature in the presence of NO.

C_2H_4 and C_2F_6. The ratio of slope to intercept gives $k_6/k_2 = 0.52$ and 1.45 $Torr^{-1}$, respectively, for C_2F_6 and C_2H_4. Of course in the case of C_2H_4, scavenging of H atoms is also occurring so that both effects may be important. However the C_2H_6 results (Table 7, X = C_2H_4) show that the scavenging of H atoms is essentially complete with 1 Torr of C_2H_4, so that the quenching effect is what is observed at higher pressures. Because of its greater molecular complexity,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

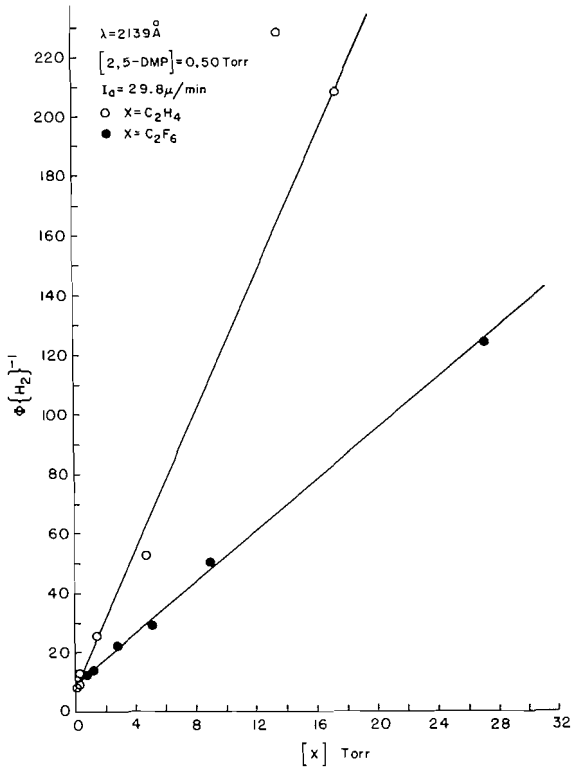

FIG. 5. Plot of $\Phi\{H_2\}^{-1}$ *vs.* the pressure of added gas in the photolysis of 2,5-DMP at 0.50 Torr at 2139 Å and room temperature in the presence of either C_2H_4 or C_2F_6.

C_2F_6 should be a more efficient quencher of DMP* than O_2 or NO (unless a triplet state is involved). Thus the quenching of DMP* by O_2 or NO at the pressures used is negligible.

The production of C_2H_6 comes from CH_3 radical recombination.

[7] $$2CH_3 \rightarrow C_2H_6$$

The CH_4 comes mainly from CH_3 radical abstraction reactions. If the sole process were

[8] $$CH_3 + DMP \rightarrow CH_4 + C_6H_8N$$

then

[IV] $$I_a^{1/2}\Phi\{CH_4\}/(\Phi\{C_2H_6\})^{1/2}[DMP] = k_8/k_7^{1/2}$$

Only a cursory examination of Table 5 will show that eq. IV is not obeyed, *i.e.* the quantity on the left hand side is not constant. Consequently the chief source of CH_4 is

[9] $$CH_3 + F_a, F_b \rightarrow CH_4 + ?$$

Some CH_4 might also come from the molecular process

[2e] $$DMP^* \rightarrow CH_4 + F_e$$

though the scavenging experiments in Tables 6 and 7 show that step 2*e* can account for no more than 5% of the CH_4.

The most unusual effect observed is that $\Phi\{C_2H_6\}$ *increases* as I_a drops. This can be explained if the fragments F_a and F_b are removed at the wall to form polymer. Then as the intensity is reduced, this wall removal reaction becomes more important relative to reaction 9, relatively fewer CH_3 radicals are removed in reaction 9, and $\Phi\{C_2H_6\}$ goes up. The pressure effect on $\Phi\{C_2H_6\}$ would be explained the same way, *i.e.* at lower pressures the wall removal reaction for F_a and F_b is enhanced, and $\Phi\{C_2H_6\}$ is reduced. Relatively little effect is seen on $\Phi\{CH_4\}$ since its production depends on the interaction of CH_3 and either F_a or F_b. As one reactant is reduced in

Microwave Spectrum of 1,3-Dioxane

R. KEWLEY[1]

Department of Chemistry, Queen's University, Kingston, Ontario

Received November 29, 1971

The microwave spectrum of 1,3-dioxane has been studied within the region 8 to 40 GHz. The rotational constants of the molecule in its ground vibrational state are, in MHz, $A = 4999.94(0.05)$, $B = 4807.61(0.05)$, and $C = 2757.12(0.05)$. The dipole moment components are, in Debye units, $\mu_b = 1.61(0.02)$, $\mu_c = 1.29(0.01)$, and $\mu = 2.06(0.03)$. The values of the above quantities are consistent with a chair form structure. Rotational spectra due to five excited vibrational states of 1,3-dioxane have been assigned.

Le spectre micro-onde du dioxane-1,3 a été étudié dans l'intervalle de 8 à 40 GHz. Les constantes de rotation de la molécule dans son état de vibration fondamental sont, en MHz, $A = 4999.94(0.05)$, $B = 4807.61(0.05)$, et $C = 2757.12(0.05)$. Les composantes du moment dipolaire sont, en unités Debye, $\mu_b = 1.61(0.02)$, $\mu_c = 1.29(0.01)$, et $\mu = 2.06(0.03)$. Les valeurs précédentes sont en accord avec une structure de forme chaise. Les spectres de rotation, dues à cinq états excités de vibration du dioxane-1,3, ont été attribués.

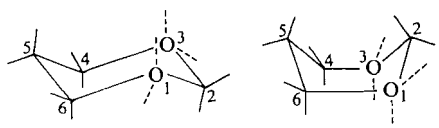
Introduction

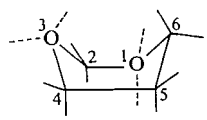
In earlier studies of the microwave spectra of the molecules piperidine (1), tetrahydropyran (2), morpholine (3), and *sym*-trioxane (4), the chair form structure of the ring atoms was in each case the only one for which a spectrum could be detected. This is expected for tetrahydropyran and morpholine on account of the boat form being energetically unfavorable because of repulsions between eclipsed hydrogen atoms attached to adjacent carbon atoms.

For 1,3-dioxane the possibility of hydrogen eclipsing is somewhat reduced. In the diagrams, the oxygen lone pair electrons are indicated by the dashed lines. In the form boat A a flagpole repulsive interaction between hydrogens on C-2 and -5 would be present together with C—H bond pair – oxygen lone pair repulsion for O_1—C_6 and O_3—C_4. In boat B the flagpole interaction between the O-3 lone pair and the C-6 hydrogen could be weakly attractive. An ordinary eclipsing of hydrogens would occur between C-4 and -5 hydrogens. Also possible are two twist forms. One of these, which relates two identical boat B forms, has C_2 symmetry and just one dipole moment component directed along the C_2 axis, which would also be a principal inertia axis. The other twist form relates the boat A form to either of the mirror image boat B forms, has no symmetry and would have sizeable dipole moment components along all three principal inertia axes. Each twist form has a mirror image form. The boat B form also lacks symmetry and would have three non-zero dipole components. The chair and boat A forms would each have just two dipole components and these would be directed in the molecular symmetry plane. It is expected that the chair form will be the lowest energy conformation, because of staggering of C—H bonding pairs and oxygen lone pairs and also by comparison with the results for *sym*-trioxane (4).



Chair

Boat A



Boat B

An additional point of interest for the chair form of 1,3-dioxane is the possibility that because of repulsion between the axial oxygen lone pair electrons the $O_1C_2O_3C_4C_6$ section of the molecule might be flattened towards a half chair structure.

The above considerations suggested that a

[1]On sabbatical leave September 1, 1971 to August 31, 1972 at Department of Chemistry, Rice University, Houston, Texas 77001.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

study of the microwave spectrum of 1,3-dioxane should be of interest. In addition, the quite large reported dipole moment of 2.134 (in benzene) and 2.145 D (in cyclohexane) (5) indicated that the spectrum would be intense, and favorable for the observation of satellite spectra from vibrationally excited states of the molecule.

Experimental

The sample of 1,3-dioxane was purchased from the Aldrich Chemical Company and used without further purification. All observations were taken at room temperature with sample pressures in the range 5 to 100 μ.

The spectrum was observed initially at Queen's University using the 100 kHz Stark modulation spectrometer described previously (2, 3). Direct monitoring of the variable 5 MHz output of the Micronow model 101D frequency standard was effected, using a Hewlett Packard model 5245M frequency counter. This counter was equipped with a model 5256A plug-in unit which was particularly useful when conducting survey frequency sweeps in the 13 to 18 GHz region. Almost all of the frequency measurements for the ground vibrational state of the molecule were taken with this spectrometer and are accurate to within 0.1 MHz. The majority of the Stark effect and vibrational satellite frequency and intensity measurements were made at Rice University using a Hewlett Packard model 8460A MRR spectrometer in the range 26.5 to 40 GHz. Such frequency measurements are accurate to 0.05 MHz or better.

Results

Rotational Spectrum

The rotational spectrum of only one conformer of the molecule could be detected. As in the molecules piperidine (1), tetrahydropyran (2), and morpholine (3) the dominant feature of the spectrum is a set of double Q-branch series. The branch heads occur at intervals of 4.29 GHz, see Table 1. For 1,3-dioxane the observed lines are due to transitions of the type ${}^{b}Q_{-1,J}$. The series to which the most attention was given was that with the branch head $J = 4$–4 very close to 15 GHz. In this case the sub-branch with $K_{-1} + K_{+1} = J$ proceeds continuously to lower frequency with increasing J but the $K_{-1} + K_{+1} = J + 1$ sub-branch decreases frequency for $J = 4$ to $J = 8$ and thereafter increases frequency starting at $J = 9$. A careful study of these lines was required to show that they are in fact due to b-type and not a-type transitions. The value of the asymmetry parameter κ of 0.82849 is very close to that of 0.82776 for tetrahydropyran (2). This facilitated further analysis. The R-branch assignment was obtained by identifying the superimposed transitions 3_{03}–4_{14} and 3_{13}–4_{04} by means of the expected first order Stark effect, due to oblate near degenerate asymmetry doublets. Thereafter other b-type and also c-type R-branch lines were observed. None of the c-type lines showed any evidence of splitting due to inversion of the molecule. The rotational constants were determined by a least squares fit to the 19 $J = 0$–1, 1–2, and 2–3 transitions given in Table 2. The standard deviation, σ, of the fit was 0.22 MHz. The resulting rotational con-

stants are given in Table 3. Centrifugal distortion was neglected. However this effect is probably the reason why the majority of the calculated Q-branch frequencies in Table 1 are above the observed ones.

Dipole Moment

Since first order Stark shifts are easily observed in this spectrum in addition to the usual second order shifts, the value of μ_c was determined independently of other dipole components from the splittings $\Delta\nu\pm$ between + and − M components of transitions involving asymmetry doublets, see Table 4.

Values for μ_a and μ_b were then obtained by least squares fitting to the observed second order Stark shifts. When this was done the value of μ_a was found to be close to zero. As a check on the value of μ_a two methods of calculation were used. In the first μ_c was calculated from the seven $\Delta\nu\pm/EM$ values by weighted averaging with weights proportional to (standard error in $\Delta\nu\pm/EM)^{-2}$ and a value $\mu_c = 1.29_0$ D obtained. Averaging with equal weights given to the values of $\Delta\nu\pm/EM$ yielded $\mu_c = 1.29_6$ D. After the least squares fitting the results were

	$\mu_a^2(D^2)$	$\mu_b^2(D^2)$
$\mu_c = 1.29_0(0.01)$ D	0.00305	2.59165
$\mu_c = 1.29_6(0.01)$ D	−0.00180	2.66073

A value of μ_c of about 1.29_4 D, which is entirely possible within the experimental error in μ_c, would bring μ_a to zero. It is thus considered highly probable that μ_a is in fact zero. The values of μ_a, μ_b, and μ_c quoted in Table 4 correspond to the weighted average procedure for μ_c. With such a low value of μ_a^2 no meaningful observations can be made concerning the definite presence or absence of *a*-type transitions in the rich spectrum of 1,3-dioxane. It is estimated that μ_a would have to be larger than about 0.25 D for *a*-type lines to be observable. Even then it would be difficult to distinguish the *a*-type lines from the many other small lines which are present.

Stark cell calibrations were made on the basis of $\mu_{ocs} = 0.71521(0.00020)$ D (6). The molecule methyl acetylene (7), with a dipole moment of 0.784(0.001) D, when corrected to the value of μ_{ocs} just quoted, was a very useful secondary standard for the 26.5 to 40 GHz region. Methyl acetylene has easily measurable first and second order Stark shifts for the $J = 1$–2 transition whereas for the ground vibrational state of OCS in the $J = 2$–3 transition the Stark lobes are not well separated from the line at low voltages.

The observed gas phase dipole moment of 2.06(0.03) D is in good agreement with the solution values of 2.134(0.03) (benzene) and 2.145(0.03) D (cyclohexane), quoted above (5).

Conformation

From the considerations given in the introduction it is expected that 1,3-dioxane exists very largely in the chair form. This has been stated to be the case in work in which the n.m.r. spectrum was recorded (8). No supporting evidence was given however. In the present work the observation of only μ_b and μ_c dipole components (taking μ_a to be zero) rules out the possibility that the spectrum is due to either the boat B or a twist form of the molecule. It

remains to decide between the chair and boat A forms. For tetrahydropyran a comparison of the observed and calculated angles between the total dipole moment and the principal a-axis was sufficient to identify the chair form (2). This was easily done because the chair form of tetrahydropyran was calculated to have only μ_a and μ_c dipole components over a reasonable range of variation in structural parameters, whereas the boat form was calculated to have μ_b and μ_c components. When the same approach is tried for 1,3-dioxane it is found that a clear decision cannot be reached on this basis alone. Calculations of the moments of inertia of chair and boat forms were made using the assumed parameters: C—H = 1.108, C—C = 1.533 Å, as quoted by Hendrickson (9), tetrahedral angles at carbon, C—O = 1.410 Å, and an angle C—O—C = 111°43′ as in dimethyl ether (10). The total dipole moment was assumed to be

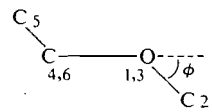
Boat, calcd.	94.183	88.946	17.694

given solely by the vector sum of the two COC group moments, each directed along a C—O—C angle bisector. These calculations predicted that both conformers should have μ_b and μ_c components. Also the calculated angle between μ and the b principal axis was 55°3′ for the chair form and 35°40′ for the boat form. The observed angle is 38°38′, seemingly favoring the boat form. However it is considered that the inherent errors in both the assumed structural parameters and the simple bond moment approach are such that the above angle comparison does not furnish any real evidence for the boat form.

More useful comparisons can be made between the calculated and observed moments of inertia and this is best done in terms of the quantities $\sum_i m_i a_i^2$, $\sum_i m_i b_i^2$ and $\sum_i m_i c_i^2$ where $\sum_i m_i a_i^2 = 1/2\ (I_b + I_c - I_a)$, for example. These quantities are given in Table 5. The corresponding values are given for tetrahydropyran which has been shown previously to be in chair form (2). It can be seen that for each molecule the observed value of $\sum_i m_i b_i^2$ is in very good agreement with that calculated for the chair but not for the boat form. More significant still is that for each molecule the observed $\sum_i m_i c_i^2$ is much closer to the chair, calculated than the boat, calculated value. It is therefore considered that these comparisons show that the observed conformer for 1,3-dioxane must be the chair form. Although the observed planar moments are also consistent with a flattened chair or even a half chair structure (see Table 5), these forms are ruled out by the dipole moment data (see below).

As a check on the assignment of the correct conformer and also to investigate the possibility of flattening of the molecule by oxygen lone pair repulsions, calculations were also made of the way in which the moments of inertia and dipole components would vary with the angle ϕ, between the $O_1C_2O_3$ and $O_1O_3C_4C_6$ planes.



$\phi = 57°18'$ (chair) and $-57°18'$ (boat) are the values obtained from the parameters assumed initially, see above. Figure 1 shows the variation of I_a and I_b and also the ratio μ_c/μ with ϕ. The observed moments of inertia are given in Table 3 and the observed value of μ_c/μ is 0.621. The most important result of these calculations is to show that for $-32° < \phi < 55°$ 1,3-dioxane is predicted to have only μ_a and μ_c dipole moments. The observation of just μ_b and μ_c components thus indicates that ϕ is outside the $-32°$ to 55° range. Taken together with the planar principal moment information of Table 5 this puts $\phi > 55°$ indicating little flattening of the molecule, if any. It should be borne in mind that these calculations are based on assumed parameters which almost certainly differ from the true values. Even so the conclusion reached is considered to be a firm one.

One further piece of empirical evidence for the chair conformation is that if the ratio $(A+B+C)_{\text{obsd.}}/(A+B+C)_{\text{chair,calcd.}}$ is evalu-

ated for each of 1,3-dioxane and tetrahydropyran the similar quantities 0.991322 and 0.990794 are obtained. The corresponding values for $(A+B+C)_{\text{obsd.}}/(A+B+C)_{\text{boat,calcd.}}$ are 0.979578 and 0.979523. Since these two molecules have similar structures and the same assumed parameters were used in each calculation it is probably not accidental that the two chair forms give closely similar ratios. It would be advisable to make a check on this procedure by carrying out the corresponding calculations for *sym*-trioxane. Unfortunately a value for the C rotational constant of this molecule has not yet been reported in the literature.

Excited Vibrational States

Each ground vibrational state Q-branch series was seen to have two vibrational satellite series towards higher frequencies. The $J = 6$–6 Q-branch heads for these satellites are at 23 788.88 and 23 849.68 MHz. The corresponding ground vibrational state line 6_{16}–6_{25} occurs at 23 582.82, see Table 1. These observations prompted a search for vibrational satellites of R-branch lines and a total of five vibrational states were identified. The assigned R-branch lines are given in Table 6 and the derived rotational constants in Table 7.

Table 7 also contains the vibrational frequencies estimated on the basis of relative intensities of the lines in the coincident transitions 4_{04}–5_{15} and 4_{14}–5_{05}, see Fig. 2. Additional lines at 29 607 and 29 640 MHz may be noticed which probably represent two other excited states. The corresponding lines in other transitions could not be positively identified, however. Calculating from the peak heights, good agreement is obtained with the observed Raman displacements in the 200 to 500 cm^{-1} region (11) provided that the displacements at 273 and 421 cm^{-1} each correspond to an unresolved

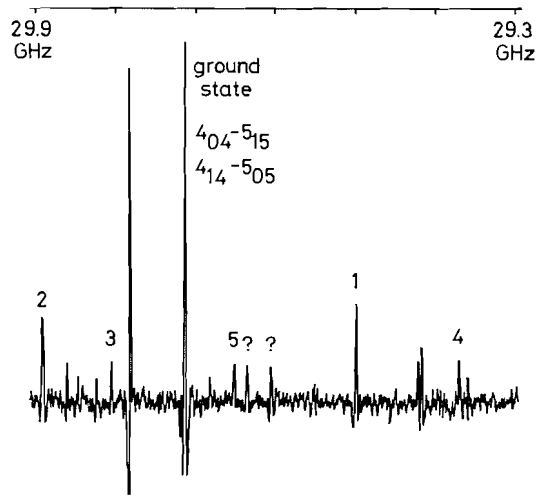

FIG. 2. Vibrational satellite pattern for an R-branch transition of 1,3-dioxane. The assigned satellites are labelled 1 through 5. The additional peaks at 29 607 and 29 640 MHz, denoted by ?, could also be due to excited vibrational states of the molecule. The diagram is a trace of a spectrum recorded with the Hewlett Packard 8460A spectrometer at a Stark voltage of 40 V cm^{-1} and a sample pressure of 15 μ.

doublet. The calculated frequencies of Voetler and Wollrab (12), 189, 221, 421, 450, and 468 cm^{-1} are in good agreement in the 400 to 500 cm^{-1} region. The present work shows conclusively that the lowest vibrational frequency of the molecule is the one corresponding to 273 cm^{-1} in the Raman work (11) and that calculated values of 189 and 221 (12) are in considerable error.

The fact that the lower vibrational frequencies of 1,3-dioxane are quite comparable to those of 242, 276, 402, 432, and 460 cm^{-1} for tetrahydropyran (13) and that 1,3-dioxane is found to be in the chair form indicates that repulsions between C—H bonding electron pairs and oxygen lone pair electrons do not allow any

marked increase in freedom of movement in this molecule compared to one which is restrained in the chair form by repulsions between C—H hydrogens only.

The author thanks Professor R. F. Curl and the Robert A. Welch Foundation for the use of computing and instrumental facilities at Rice University. Mrs. S. Leavell, C. D. Le Croix, Dr. H. Takeo, and Dr. H. Jones were all very helpful with spectroscopic equipment and computing. The support of this work by the National Research Council of Canada through operating grants is gratefully acknowledged.

Reactions of Ethylene with Rhodium(III) Chloride. Part III.[1] The Catalytic Oxidation of Ethylene to Acetaldehyde in Aqueous Hydrochloric Acid Solutions Containing Pentachloroaquorhodate(III)

B. R. JAMES AND M. KASTNER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received January 7, 1972

In the presence of iron(III) or other oxidants, aqueous acid chloride solutions of $RhCl_5(H_2O)^{2-}$ catalyze under mild conditions the oxidation of ethylene to acetaldehyde. The kinetics of the reaction measured by gas-uptake techniques indicate the presence of both ethylene dependent and independent paths. Besides fully protonated anions, hydroxy species such as $RhCl_5(OH)^{3-}$ and $RhCl_4(OH)(H_2O)^{2-}$, although present in very small concentrations, are significantly reactive towards ethylene. A mechanism, based on that postulated for a similar palladium(II) system in the well-known Wacker process, is presented. Under our reaction conditions the slow steps in the rhodium system involve formation of π-complexes in the ethylene dependent paths and the formation of tetrachlororhodate(III) complexes in the ethylene independent paths. Iron(III) regenerates the rhodium(III) catalyst by oxidation of the rhodium(I). Rate constants are estimated for the various reaction paths.

En présence de fer(III) ou d'autres oxydants, les solutions chlorhydriques aqueuses de $RhCl_5(H_2O)^{2-}$ catalysent dans des conditions douces, l'oxydation de l'éthylène en acétaldéhyde. Les cinétiques de la réaction, mesurées par des techniques d'absorption gazeuse, indiquent à la fois une certaine indépendance et dépendance vis-à-vis de l'éthylène. A côté des anions complètement protonés, des espèces hydroxylées telles que $RhCl_5(OH)^{3-}$ et $RhCl_4(OH)(H_2O)^{2-}$, bien que présentes en très faibles concentrations, réagissent de façon significative avec l'éthylène. Un mécanisme basé sur celui postulé pour le système voisin Pd(II) dans le processus bien connu de Wacker, a été présenté. Dans nos conditions de réaction, les étapes lentes dans le système rhodium dépendant de l'éthylène impliquent la formation de complexes π alors que c'est la formation de complexes tétrachlororhodate(III) qui expliquent l'indépendance vis-à-vis de l'éthylène. Le fer(III) regénère le catalyseur Rh(III) par oxydation du Rh(I). Les constantes de vitesse sont évaluées pour les diverses voies réactionnelles.

Canadian Journal of Chemistry, **50**, 1698 (1972)

Introduction

We have reported previously (1) on the reaction between ethylene and aqueous solutions containing rhodium(III) chloride trihydrate, $RhCl_3.3H_2O$, at 1 atm and ambient temperatures. The ethylene catalyzes the production of $RhCl_2(H_2O)_4^+$ species via a mechanism involving trace amounts of chlororhodate(I) species formed according to a reaction such as 1.

$$[1] \qquad Rh^{III} + C_2H_4 \xrightarrow{H_2O} Rh^{I} + CH_3CHO + 2H^+$$

Subsequent formation of a bridged Rh^{III}—Rh^{I} intermediate, followed by a 2 electron transfer and cleavage of a labile Rh^{I}—Cl bond, leads to rapid formation of $RhCl_2(H_2O)_4^+$ which is unreactive towards ethylene at the ambient conditions. At temperatures of *ca.* 50°, reaction 1 results in the production of metal via disproportionation of Rh^{I}, and the catalytic substitution is not observed.

Reaction between ethylene and $RhCl_3.3H_2O$ in *N,N'*-dimethylacetamide solution at 60–80° has also been shown (2) to give complete reduction to Rh^{I}, basically according to the stoichiometry of reaction 1, although 2 further moles of ethylene coordinate rapidly to stabilize Rh^{I} as the $RhCl_2(C_2H_4)_2^-$ complex.

It seemed highly likely that in the presence of an excess of a suitable oxidizing agent the Rh^{I} formed via reaction 1 could be rapidly reconverted to Rh^{III}, and an overall catalytic oxidation of ethylene to acetaldehyde achieved with consumption of the added oxidant. Such a system is closely akin to the well-known Wacker process (3) which employs a $Pd^{II} \rightarrow Pd^0 \rightarrow Pd^{II}$ cycle, the oxidant being a Cu^{II}/oxygen system.

The rhodium(III) chloride complexes $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ have been characterized in aqueous acid solutions (4), and hence we studied these systems for ethylene oxidation. This paper

reports on a detailed kinetic study under mild conditions using $RhCl_5(H_2O)^{2-}$ as catalyst and iron(III) to regenerate the rhodium(III), although a number of other oxidants, including molecular oxygen on its own, can be used.

Osipov and co-workers (5) have briefly mentioned the use of acid chloride solutions containing $RhCl_6^{3-}$ for the catalytic oxidation of ethylene to acetaldehyde, and noted that the activity was some 150 times less than that of $PdCl_4^{2-}$ solutions under the same conditions (90°, < 1 atm pressure and using Cu^{II}/oxygen to regenerate the catalyst).

Experimental

Rhodium(III) trichloride was obtained as the trihydrate $RhCl_3.3H_2O$ from Johnson Matthey Limited. Other materials used and the procedure used for following C_2H_4 uptake at constant pressure have been described earlier (6, 7). All uptake measurements were made on 2 ml of solution. Ferric solutions were standardized by reduction to the ferrous state using a Jones Reductor, and then reoxidized using standard dichromate solution.

Solutions of $RhCl_3.3H_2O$, in 0.1–3.0 *M* HCl and containing up to 3 *M* total chloride, equilibrated quite rapidly on heating, and showed absorption maxima at 400 nm ($\varepsilon \sim 85$) and 505 nm ($\varepsilon \sim 75$); the predominant species is $RhCl_5(H_2O)^{2-}$ (4).

Acetaldehyde from Eastman Organic Chemicals was distilled immediately before use. Liquid organic products were analyzed by use of a Beckman GC-2A chromatograph with a dinonyl phthalate column, and by a Varian T-60 NMR spectrometer.

Visible and ultraviolet absorption spectra were recorded in a Perkin–Elmer 202 spectrophotometer with matched silica cells of 1 mm path length.

Total pressures of 330–950 mm Hg were employed; the partial pressures of ethylene were obtained after correcting for the vapor pressures of the HCl solutions (8), and the ethylene solubilities were extrapolated values from those listed in ref. 7.

Results

Stoichiometry

When excess iron(III) was added to a solution of 0.1 *M* $RhCl_3.3H_2O$ in 3 *M* HCl and then the mixture exposed at 80° to ethylene at 1 atm, gas was absorbed at a linear rate. The reaction rate exhibited inverse chloride and acid dependences, and for kinetic convenience detailed studies were carried out mainly using solutions 0.1 *M* in HCl and 2.0 *M* in LiCl. Since protons are a product of the catalytic reaction (*cf.* reaction 1), some of the uptake plots (depending on the conditions) showed, after an initial linear region, a slightly decreasing rate presumably due to the inverse acid dependence. Eventually, all the uptake plots showed a sharp upward break at a point where metallic rhodium appeared. Just prior to metal production, the solutions gave absorption spectra almost identical to that of $RhCl_5(H_2O)^{2-}$; at this stage the spectrum shows none of the more intense absorption of iron(III) chloride (λ_{max} 422 nm) which has been consumed in the reaction. The iron(III) is converted entirely to iron(II), as shown by a potentiometric titration with standard dichromate (a solution initially 0.19 *M* in Fe^{III} analyzed finally for 0.18 *M* Fe^{II}). Ferrous chloride in the acid chloride media gave practically no absorption between 350 and 550 nm. In the absence of any added Fe^{III}, the $RhCl_5(H_2O)^{2-}$ solutions were immediately reduced to metal.

At the end of reactions when 0.19 *M* Fe^{III} had been consumed, the organic products were separated by distillation and analyzed by gas chromatography and n.m.r. Acetaldehyde corresponding to a 0.08 ± 0.01 *M* solution was the only product detected. Comparison with standard solutions showed no presence of acetic acid, ethylene glycol or paraldehyde. The distillate from a corresponding reaction using a 0.1 *M* DCl/2 *M* LiCl/D_2O solution yielded by n.m.r. a doublet at 8.1 τ showing that no deuterium is present in the acetaldehyde molecule.

The noted Fe:acetaldehyde stoichiometry (*ca.* 2:1) and the spectrophotometric data may be rationalized in terms of reaction 1 followed by reaction 2.

$$[2] \qquad Rh^{I} + 2Fe^{III} \rightarrow Rh^{III} + 2Fe^{II}$$

The net reaction is

$$[3] \qquad 2Fe^{III} + C_2H_4 \xrightarrow[H_2O]{Rh^{III}} 2Fe^{II} + CH_3CHO + 2H^+$$

However, the ethylene uptake plots using variable iron(III) concentrations and ethylene concentrations showed an apparent consumption of ethylene and iron(III) at the end of the reaction, when metal forms, in mole ratios of $1:3.7 \pm 0.5$ (approx. 1:4) instead of the anticipated 1:2. This apparent discrepancy arises from the fact that approximately one half of the acetaldehyde product appears in the gas phase, and hence the measured total uptake of ethylene is about one half the true uptake. This factor of

0.5 is for our particular apparatus (which has a dead-space volume of about 50 ml) using 2 ml of reactant solution, and is calculated using a literature value (9) of 380 mm Hg for the partial pressure of acetaldehyde over a 0.55 *M* aqueous acetaldehyde solution at 82°. It should be noted also that measured ethylene uptake rates at 82° would therefore be one half the true absorption rates. This factor is independent of the ethylene pressure but can become dependent on temperature. Using other data given in ref. 9, the factor is calculated to be 0.7 at 63° but is again 0.5 at 93.5°; a factor of 0.6 will be assumed for data at 75°. Under the conditions noted in Table 1, the acetaldehyde formed in the gas phase never contributes more than *ca.* 5% to the total pressure above the solution, *i.e.* the ethylene partial pressure is affected little during a kinetic uptake experiment in the constant pressure apparatus. That some of the observed rates are linear is consistent with this.

There was no sign of production of rhodium carbonyls via decarbonylation of acetaldehyde (*cf.* ref. 10) during the kinetic studies.

Kinetics

The kinetics of the catalyzed ethylene oxidation were readily determined from the linear plots or else the initially linear rates of the uptake plots. Tables 1 and 2 summarize the kinetic data for the $RhCl_5(H_2O)^{2-}$ system. The rates listed are the measured linear ones and are not corrected (see above). As anticipated from the linear uptake plots, no dependence of the rate on $[Fe^{III}]$ was found; there is a good first-order dependence on $[Rh^{III}]$ up to 0.15 *M*. The rate is linearly dependent on the ethylene concentration, but each plot at 3 different acidities at 80° and *ca.* 2 *M* chloride and at 3 different temperatures for 0.1 *M* HCl/2 *M* LiCl solutions

shows an intercept on the ordinate axis corresponding to zero ethylene (Fig. 1).

In order to establish the dependences of the rate on $[H^+]$ and on $[Cl^-]$, ethylene uptakes were studied at several acid and chloride concentrations. The results are summarized in Table 3. The [HCl] was varied in two sets of experiments in which the total chloride was kept essentially constant (3.0 and *ca.* 2 *M*) by addition of LiCl; plots of rate *vs.* $[H^+]^{-1}$ are reasonably linear (Fig. 2). A less pronounced inverse chloride dependence was noted for experiments performed using 0.1 *M* HCl solutions with different concentrations of added LiCl; these data refer to solutions with different

ionic strengths although such variations appear relatively unimportant considering the little effect addition of $LiClO_4$ has on the rates of reactions carried out at 0.1 *M* HCl and 1.0 *M* LiCl. There is no obvious relationship between the rate and the chloride concentration.

It should be noted that the total chloride concentration listed in Table 3 does not include consideration of equilibria involving the metal chloride complexes. Using the stability constants for ferric chloride complexes in 1 *M* $HClO_4$, $K_1 = 4.2$, $K_2 = 1.3$, $K_3 = 0.04\ M^{-1}$ at 27° (11), 0.19 *M* $FeCl_3$ in solution yields 0.24 *M* free chloride; 0.1 *M* $RhCl_3$ will require 0.2 *M* chloride to form the pentachloroaquo species.

The spectra of the various pre-equilibrated rhodium solutions used for the studies summarized in Tables 1–3 were essentially identical and all corresponded approximately to that for $RhCl_5(H_2O)^{2-}$.

Several other oxidants besides Fe^{III} were investigated for the catalyzed ethylene oxidation. The initially linear rates are given in Table 4 together with those for Fe^{III} for comparison. No rhodium metal was formed during these experiments, thus showing that the oxidants are efficient for removing Rh^I; as expected, the Cu^{II} system precipitated metallic copper.

Discussion

The Activity of the Pentachloro Species

The kinetic dependences on rhodium and ethylene may be expressed by eq. 4

$$[4] \quad -d[C_2H_4]/dt = k_a[Rh^{III}] + k_b[Rh^{III}][C_2H_4]$$

where k_a and k_b are pseudo first- and second-order rate constants containing all dependences except those of rhodium and ethylene, and $[Rh^{III}]$ refers to the total rhodium concentration. k_b refers to a rate determining step of the overall

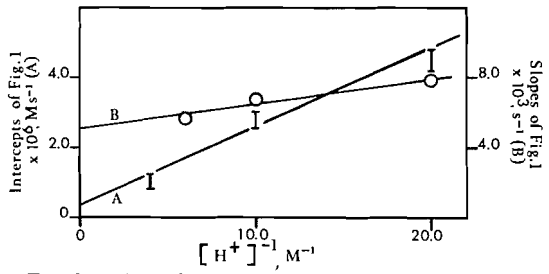

FIG. 3. Plots of the intercepts (*A*) and slopes (*B*) of the solid lines of Fig. 1 (the 80° data) *vs.* the inverse of the acid concentration.

reaction shown in reaction 3; the independence of the rate on $[Fe^{III}]$ is consistent with reaction 2 being fast. k_a for the ethylene independent step must refer to some relatively slow substitution reaction of the initial rhodium complex, which competes with the k_b process, to give a species which then reacts with ethylene in a more rapid step than the substitution; an aquation reaction would yield a tetrachloro complex while chloride substitution would give the hexachloro species. The small inverse effect of added chloride on the rate argues against formation of more active $RhCl_6^{3-}$ since the k_a path would then be expected to show a direct first-order dependence on chloride (13). Other studies using the series of $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ complexes have in fact shown that solutions containing $RhCl_4(H_2O)_2^-$ are generally more active than those containing $RhCl_5(H_2O)^-$ while $RhCl_6^{3-}$ is completely inactive (12), thus confirming that k_a refers to production of a tetrachloro complex.

The kinetic data give information only about the ways of forming the Rh^{III}–ethylene intermediates. The slow steps shown in reactions 5–8 are thought to be involved. The analysis given below was done to some extent on a trial and error basis to give internal consistency in the estimated rate constants; the lines plotted in Figs. 1–3 are drawn to give this consistency.

Figure 1 for $[H^+] = 0.1\ M$ gives $k_a = 2.8 \times 10^{-5}\ s^{-1}$ and $k_b = 6.7 \times 10^{-2}\ M^{-1}\ s^{-1}$ at 80°. The ethylene independent rate (k_a) is acid dependent since the intercepts of Fig. 1 for the 80° data are unequal; an inverse acid dependence is noted and a plot of these intercepts versus $[H^+]^{-1}$ goes close to the origin as shown in Fig. 3*A*. This shows that the major contribution to the k_a path is one involving hydroxy species:

$$[5] \quad RhCl_5(OH)^{3-} + H_2O \xrightarrow{k_1} RhCl_4(OH)(H_2O)^{2-} + Cl^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The possibility that a small contribution involves an aquo species (eq. 6) cannot be excluded completely, since this acid independent step requires that Fig. 3*A* shows a positive intercept on the ordinate axis.

[6] $RhCl_5(H_2O)^{2-} + H_2O \xrightarrow{k_2} RhCl_4(H_2O)_2^- + Cl^-$

The slopes of Fig. 1 for the data at 80° are not very different showing that the ethylene-dependent rate (k_b) is essentially acid independent. Figure 3*B* shows a plot of these slopes *vs.* $[H^+]^{-1}$; the intercept (*ca.* 5.2×10^{-3} s^{-1}) results from a contribution of the aquo species (eq. 7), while the slope (*ca.* 1.3×10^{-4} $M\ s^{-1}$) refers to a possible small contribution from hydroxy species (eq. 8).

[7] $RhCl_5(H_2O)^{2-} + C_2H_4 \xrightarrow{k_3} \text{products}$

[8] $RhCl_5(OH)^{3-} + C_2H_4 \xrightarrow{k_4} \text{products}$

Writing K_5 for the acid dissociation constant of $RhCl_5(H_2O)^{2-}$, eq. 4 can be expanded to include the acid dependence and the relevant rate constants k_1, k_2, k_3, and k_4.

$$[9]\quad \text{Rate} = \left\{\frac{k_1K_5}{[H^+]} + k_2\right\}[RhCl_5(H_2O)^{2-}] + \left\{k_3 + \frac{k_4K_5}{[H^+]}\right\}[RhCl_5(H_2O)^{2-}][C_2H_4]$$

At 80° and 0.1 M $[H^+]$, the k_a and k_b values estimated from Fig. 1 are thus identified with the constants involved in eq. 9:

$$[10]\quad k_a = k_1K_5[H^+]^{-1} + k_2 \qquad k_b = k_3 + k_4K_5[H^+]^{-1}$$

Equation 9 can also be rearranged to describe the plots of rate versus $[H^+]^{-1}$ shown in Fig. 2:

$$[11]\quad \text{Rate} = \{k_2 + k_3[C_2H_4]\}[RhCl_5(H_2O)^{2-}] + \frac{K_5\{k_1 + k_4[C_2H_4]\}[RhCl_5(H_2O)^{2-}]}{[H^+]}$$

For the line drawn for the 80° data at *ca.* 2 M chloride, the intercept gives for the reaction rate involving the aquo species,

$$[12]\quad 4.5 \times 10^{-6}\ M\ s^{-1} = \{k_2 + k_3[C_2H_4]\}[RhCl_5(H_2O)^{2-}]$$

As discussed above, the k_2 path is not important compared to the k_3 path and hence, on neglecting k_2 in eq. 12, k_3 is calculated to be $5.6 \times 10^{-2}\ M^{-1}\ s^{-1}$. Using the value for k_b defined by eq. 10, and the estimated k_3 value, k_4K_5 is calculated to be $1.1 \times 10^{-3}\ s^{-1}$. The intercept and slope of Fig. 3*B* noted above give the values $k_3 = 5.2 \times 10^{-2}\ M^{-1}\ s^{-1}$ and $k_4K_5 = 1.3 \times 10^{-3}\ s^{-1}$.

TABLE 5. Rate constant data at 80° in 2 M LiCl

k_1K_5 ($M\ s^{-1}$)	k_2 (s^{-1})	k_3 ($M^{-1}\ s^{-1}$)	k_4K_5 (s^{-1})
2.2×10^{-6}	0.6×10^{-5}	5.6×10^{-2}	1.1×10^{-3}

According to eq. 11 again, the slope of the line in Fig. 2 (80°, 2 M chloride) gives the reaction rate involving the hydroxy species, namely,

$$[13]\quad 3.1 \times 10^{-7}\ M^2\ s^{-1} = K_5\{k_1 + k_4[C_2H_4]\}[RhCl_5(H_2O)^{2-}]$$

Using the k_4K_5 value of $1.1 \times 10^{-3}\ s^{-1}$, eq. 13 gives $k_1K_5 = 2.2 \times 10^{-6}\ M\ s^{-1}$; the same value is also calculated directly by the slope of Fig. 3*A*. Lastly, using the k_a value defined by eq. 10 and the estimated k_1K_5 value, k_2 is calculated to be $0.6 \times 10^{-5}\ s^{-1}$ (this requires an intercept of $0.6 \times 10^{-6}\ M\ s^{-1}$ on Fig. 3*A*).

The above analysis of the kinetic data gives values for k_1K_5, k_2, k_3, and k_4K_5 for the system at 80° and 2 M LiCl; these are summarized in Table 5. The relative contribution to the total reaction rate at any acidity is readily estimated by use of eq. 9. At 0.1 M $[H^+]$, the relative contributions to the total rate of $8.1 \times 10^{-6}\ M\ s^{-1}$ for paths 5, 6, 7, and 8 are about 30, 7, 55, and 8%, respectively.

Robb and Steyn (13) have determined a value of k_2 directly to be $8 \times 10^{-5}\ s^{-1}$ at 30° in HCl–$HClO_4$ media at an acid concentration of 4 M. It is somewhat difficult to make too meaningful a comparison with the k_2 value estimated here. In our work the exact solubility of the ethylene is not known; we observed somewhat higher rates when using $HClO_4$ in place of HCl (Table 3) and this could be attributed to differences in ethylene solubility. Our estimation of k_2 from eq. 10 is subject to considerable error since it depends on the difference between two quite similar numbers 2.8×10^{-6} and 2.2×10^{-6}, and the latter is estimated through eqs. 12, 13 with some uncertainty; further, the k_2 value in Table 5

is uncorrected for the stoichiometry problem (see above), and should be multiplied by a factor of 2. The data of Robb and Steyn were measured at only one acidity and involved spectrophotometric studies; the possibility of an undetected contribution via a path involving reaction 5 cannot be excluded.

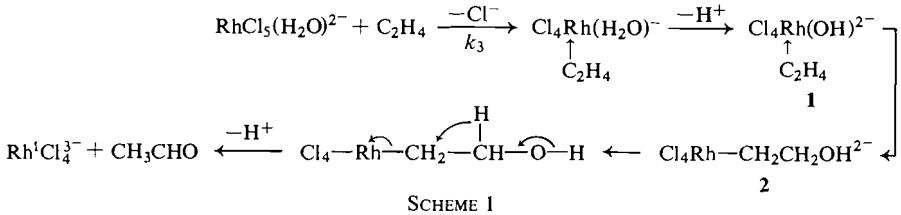
Acetaldehyde Production

The kinetic data show that both aquo and hydroxy complexes of rhodium(III) react with ethylene. $RhCl_5(H_2O)^{2-}$ and $RhCl_5(OH)^{3-}$ react with rates governed by k_3 and k_4 (reactions 7, 8), while reactivity with tetrachloro species can be represented by reactions 14 and 15 which are faster steps than reactions 5 and 6, respectively

[14] $RhCl_4(OH)(H_2O)^{2-} + C_2H_4 \xrightarrow{k_5}$ products

[15] $RhCl_4(H_2O)_2^- + C_2H_4 \xrightarrow{k_6}$ products

On analogy with the oxidation of ethylene by Pd^{II} (3), and Rh^{III} in non-aqueous solvents (2), reaction 7 probably involves the following steps, although the present kinetic data concern only the production of **1**:



SCHEME 1

Reaction 8 will produce the hydroxyl intermediate **1** directly. Migration of the hydroxy ligand would result in formation of the σ-bonded Rh^{III} hydroxyethyl intermediate **2**. Decomposition of **2** is unlikely to involve a carbonium ion since no ethylene glycol product was detected; the rhodium, after a 2-electron transfer, probably assists a 1,2 hydrogen shift which yields acetaldehyde and a proton (3). Reactions 14 and 15 presumably follow similar paths to those outlined in the scheme although it is not obvious whether ethylene will initially replace a coordinated water or chloride, *e.g.*,

[16] $RhCl_4(OH)(H_2O)^{2-} + C_2H_4 \rightarrow Cl_4Rh(C_2H_4)(OH)^{2-}$
or $Cl_3Rh(C_2H_4)(OH)(H_2O)^-$

Rhodium(I) complexes are labile (14), and $RhCl_n(H_2O)_{4-n}^{(n-1)-}$ seems the likely product from the various rhodium(III) complexes considered. The occurrence of some linear rates and spectrophotometric data indicate that the subsequent rapid redox reaction with ferric regenerates the rhodium(III) as $RhCl_5(H_2O)^{2-}$.

In a related study on the hydration of acetylene catalyzed by rhodium chloride complexes, the activity of $RhCl_5(H_2O)^{2-}$ was much greater than that of $RhCl_6^{3-}$ which was essentially inactive (15). The initial part of the reaction scheme follows that given above and it was concluded that a *ligand* water molecule was necessary for the hydration process. Similar reasoning seems likely for the ethylene reaction; in particular, the slight inverse chloride effect noted at higher chloride could be due to production of the relatively inactive $RhCl_6^{3-}$ complex (12).

The finding that no deuterium is incorporated into the acetaldehyde molecule on using DCl/D_2O solutions is consistent with the hydrogen shift shown in Scheme 1. The same result, that all the hydrogen atoms of the acetaldehyde come from the ethylene, has been observed for the Pd^{II} system (3). The small isotope effect shown in Table 1 (8.1:7.9) is probably significant. The corresponding isotope effect measured in the Pd^{II} system was 4.0; this was attributed to the difference in K_a values for the complex $PdCl_2(C_2H_4)(H_2O)$ in H_2O and D_2O, and showed that ionization to a hydroxy species was prior to the rate determining step which in this system is thought to be decomposition of the π-complex to the σ-complex (*cf.* **1** → **2**). In the present work, the low isotope effect indicates that ionization is subsequent to the rate determining step at the conditions of measurement (0.1 *M* HCl, 2 *M* LiCl); our analysis shows that this is true for about 62% of the reaction (reactions 6 and 7). Spectrophotometric and gas uptake measure-

(H_2O, H^+, and Cl^- as reactants and products are not shown)

SCHEME 2

ments showed no evidence for a rapid initial equilibrium process to form an ethylene π-complex via a reaction such as 17, as

$$[17]\quad RhCl_5(H_2O)^{2-} + C_2H_4 \overset{K}{\rightleftharpoons} RhCl_4(C_2H_4)(H_2O)^- + Cl^-$$

for the Pd^{II} system (3). If K is very small, such a process followed by ionization and slow decomposition of the π-complex would still give a linear dependence on ethylene. However, a direct inverse dependence on both proton and chloride would be anticipated for the ethylene dependent path. These were not observed and, considering also the measured isotope effect, the pre-equilibrium can be ruled out, at least at the conditions studied.[2]

We find that solutions of $PdCl_2$ at 0.1 M HCl and 2 M LiCl using ferric as oxidant are about twice as active as corresponding solutions of $RhCl_3$; it should be noted that the rate law reported for the Pd system shows an inverse second-order dependence on chloride (3) in contrast to the slight inverse dependence we observe for the Rh system, and undoubtedly conditions may be chosen in which the rhodium chlorides show higher activity than the palladium chlorides.

Further General Discussion

The rhodium in the 0.1 M HCl/2 M LiCl solutions seems to be present almost entirely as $RhCl_5(H_2O)^{2-}$. However, there are clearly kinetically significant quantities of other active catalysts. Assuming that all the various paths lead eventually to **1** shown in Scheme 1, the entire reaction may be outlined as shown in Scheme 2.

The acidity of $RhCl_5(H_2O)^{2-}$ will be much less than that of the $Rh(H_2O)_6^{3+}$ species (K_a *ca.* 10^{-3}, ref. 16) and somewhat greater than that of the $IrCl_5(H_2O)^{2-}$ complex (K_a *ca.* 10^{-10}, ref. 17). The concentration of hydroxy complexes in the acid solutions is clearly very low. A value of 10^{-8} M for K_5 gives $k_1 = 2.2 \times 10^2$ s^{-1} and $k_4 = 1.1 \times 10^5$ M^{-1} s^{-1}. Comparison of k_1 with k_2 shows that $RhCl_5(OH)^{3-}$ undergoes aquation with loss of a chloride some 10^7 times faster than $RhCl_5(H_2O)^{2-}$. The strong labilizing effect of the hydroxy group in octahedral coordination chemistry is well known (18). In the cobalt(III) system shown in eq. 18,

$$[18]\quad Co(en)_2LCl^+ + H_2O \rightarrow Co(en)_2L(H_2O)^{2+} + Cl^-$$

the rate constants for L = *cis*- or *trans*- OH are 10^3–10^4 times that for the corresponding aquo complexes (18). The data are rationalized in terms of the strong π-donor ability of OH^- to stabilize 5-coordinate intermediates formed by initial dissociation of the chloride in reaction 18. A similar conclusion could be drawn for the mechanism of the k_1 path. Swaminathan and Harris (16) have shown that the conjugate base cation of $Rh(H_2O)_6^{3+}$ is 6000 times more reactive towards chloride anation than the fully protonated cation. Comparison of k_4 with k_3 shows that C_2H_4 reacts *ca.* 10^6 times more rapidly with $RhCl_5(OH)^{3-}$ than with $RhCl_5(H_2O)^{2-}$. Assuming the same K_5 value, the hydroxy species is also some 10^8 times more reactive than the aquo complex towards carbon monoxide (19); after correcting for the stoichiometry problem, the k_3 value at 80° is *ca.* 0.1 M^{-1} s^{-1},

[2]As pointed out by a referee, the equilibrium concentration of an olefin complex commonly decreases with increasing temperature while the rate of its subsequent decomposition increases; also the palladium system (3) was studied at ambient temperatures at conditions when all of the metal was present as $PdCl_4^{2-}$.

*Corrected for the stoichiometry problem.

which is comparable to the value of 0.2 $M^{-1}\,s^{-1}$ for the corresponding reaction with carbon monoxide at 80°.

Values of k_a and k_b at 70, 80, and 85° can be estimated from the intercepts and slopes, respectively, of Fig. 1. The data are summarized in Table 6. The measured values have been converted to the true values by correcting for the stoichiometry problem as described above; a correction factor of 0.5 was used at 80–85°, and a factor of 0.6 at 75°. The k_b values (corrected or not) give a good Arrhenius plot, and an activation energy of 17.5 ± 1.0 kcal mol^{-1}; this ethylene dependent path occurs to the extent of *ca.* 85% via reaction 7, and the $\Delta H^{\ddagger}$ value must refer to the rate constant k_3. An activation energy of 22 kcal mol^{-1} was reported for the reaction between $RhCl_5(H_2O)^{2-}$ and acetylene (15). The k_a values cannot be determined with any accuracy but the data do show a smaller dependence on temperature, implying a lower activation energy; this $\Delta H^{\ddagger}$ value would refer to reaction 5 since this step contributes about 80% of the ethylene independent step under these conditions.

The present study gives no data on the fast reaction between Rh^{I} and Fe^{III}. In the reaction medium there are aquo, hydroxy, and chloride ligands, all of which are suitable for bridging so that an inner or outer sphere electron transfer process is possible (20). The mechanism may be similar to that suggested for Rh^{I}–Rh^{III} reactions involving chloro-bridged intermediates (1, 14, 19).

Table 4 shows that some variation in the reaction rate is observed on using different oxidants to regenerate the Rh^{III} catalyst. The variation on using Fe^{III}, Cu^{II}, and Cr^{VI} is less than a factor of 2 and is probably not significant. The rate using O_2 seems low; the measured uptake rate includes the half mole O_2 required for the oxidation of one mole per Rh^{I}, and so the ethylene uptake would in fact be 0.8×10^{-6} $M\,s^{-1}$, some 4 times lower than using Fe^{III} oxidant under corresponding conditions.

In conclusion, the kinetics of the Rh^{III} reaction with ethylene in acid chloride solutions proved to be much more complex than anticipated, since the overall reaction involved contributions from an ethylene independent path as well as the expected ethylene dependent one. Studies on the acid dependence of the contributing paths have shown that hydroxy species, although present in very small concentrations, are significant kinetically. The data also imply that solutions containing tetrachlororhodate(III) species are more active than those containing pentachlororhodate(III) species, at least at 0.1 *M* acidity.

The results are considered significant since they suggest that more efficient rates of conversion of C_2H_4 to CH_3CHO would be observed in less acid conditions where higher concentrations of Rh^{III} hydroxy complexes would be present; efficient oxidants would be required in these conditions to prevent accumulation of Rh^{I} and its disproportionation to metal. Oxygen is appealing since the process would then be somewhat simpler than the Wacker process where O_2 and Cu^{II} are needed to regenerate Pd^{II} from Pd metal; oxygen is probably not very efficient as an oxidant at ordinary pressures in aqueous solution because of its low solubility, and its oxidation power does decrease with decreasing acidity (21). However, the use of higher O_2 pressures and some other non-aqueous solvent system, where the O_2 solubility is higher and Rh^{I} is less likely to disproportionate (*e.g.* in *N*,*N*′-dimethylacetamide (22)), seems worthy of study.

Grateful acknowledgment is made to the National Research Council of Canada for financial support, and to Johnson Matthey Limited for loan of the rhodium.

Reactions of Ethylene with Rhodium(III) Chloride. Part IV.[1] Relative Activity of Tetra-, Penta-, and Hexa-chlororhodate(III) Complexes for the Oxidation of Ethylene to Acetaldehyde in Aqueous Acid Solutions

B. R. JAMES AND M. KASTNER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received January 7, 1972

The catalytic oxidation of ethylene to acetaldehyde using the rhodium(III) chloride complexes, $RhCl_n(H_2O)_{6-n}^{(n-3)-}$, in the presence of iron(III) has been studied kinetically in aqueous acid solutions under mild conditions. $RhCl_6^{3-}$ is inactive due to the absence of a coordinated water (hydroxide) ligand. Solutions containing tetrachloro species are generally more reactive than those containing pentachloro species because of the presence of a greater concentration of highly reactive hydroxy species. The neutral and cationic chloro-complexes are inactive due to their substitution inertness.

L'oxydation catalytique de l'éthylène en acétaldéhyde par un complexe chloré de rhodium(III), $RhCl_n(H_2O)_{6-n}^{(n-3)-}$, en présence de fer(III), a été étudiée cinétiquement en solution aqueuse et acide et sous des conditions douces. L'inactivité de $RhCl_6^{3-}$ est due à l'absence de ligand hydroxyle (eau) coordonné. Les solutions contenant des espèces tétrachloro sont, d'une façon générale, plus réactive que celles contenant des espèces pentachloro et ceci par suite d'une concentration plus élevée en espèces hydroxyles hautement réactives. Les complexes chloro, neutres et cationiques, sont inactifs par suite de leur inertie à la substitution.

Canadian Journal of Chemistry, **50**, 1708 (1972)

Introduction

We recently reported (1) on the use of aqueous hydrochloric acid solutions of pentachloro-aquorhodate(III) for the oxidation of ethylene to acetaldehyde; the rhodium(III) is reduced to rhodium(I). The reaction becomes catalytic with respect to rhodium in the presence of a suitable oxidant such as iron(III), which re-oxidizes rhodium(I) to the trivalent state.

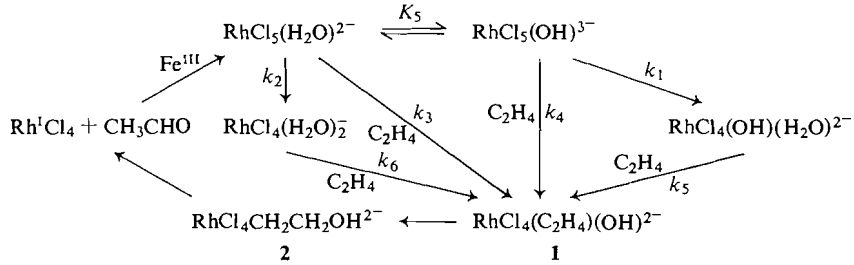
An observed 2 term rate-law showed the existence of an ethylene independent path, and this was rationalized in terms of a slow aquation to more reactive tetrachlororhodate(III) complexes. The reactions involved were summarized in Scheme 1.

Values of k_1K_5, k_2, k_3, and k_4K_5 at 80° were estimated from an analysis of the kinetic data; a small inverse chloride dependence was tentatively attributed to the formation of less active hexachlororhodate(III) species (1).

This paper describes studies to investigate the relative activities of the tetra-, penta-, and hexachloro complexes, in particular the estimation of the k_5 and k_6 rate constants of Scheme 1. The activities of the lower chloride complexes were studied also.

Experimental

The materials used and the procedure for following the C_2H_4 uptake at constant pressure have been described



(H_2O, H^+, and Cl^- as reactants and products are not shown)

$Rh(H_2O)_6^{3+}$	0.07	0.0	0.8

*Present initially as perchlorate.

(see ref. 1). Aqueous solutions containing the complexes $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ were made generally in HCl–$HClO_4$ mixtures from perchloric acid solutions of $Rh(H_2O)_6^{3+}$ (2), based on the methods of Wolsey and co-workers (3); the total acidity in these solutions was always 6.0 M, and the species were characterized by their absorption spectra (2, 3). We also found that equilibration (120° for 2 weeks) of 0.1–0.2 M perchloric acid solutions of 0.1 M $RhCl_3.3H_2O$ in the presence of 2 M LiCl and 0.2 M LiCl gave solutions containing predominantly $RhCl_5(H_2O)^{2-}$ and $RhCl_4(H_2O)_2^-$, respectively. In order to maintain more effective control over the chloride concentration in some of the experiments, the iron(III) reoxidant was added as the perchlorate rather than the chloride.

Other relevant experimental details are given in the previous paper (1).

The ethylene uptake rates reported are the measured "gas uptake" rates; no correction has been made for the presence of acetaldehyde product in the gas phase (see ref. 1).

Results and Discussion

Reactivity in 6 M Acid Solutions

The $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ complexes ($n = 0$ to 6) were characterized earlier by Wolsey and co-workers in perchloric acid – hydrochloric acid mixtures of 6 M acidity (3). We used such a series of solutions to investigate the relative activity of the complexes towards ethylene. The data at 80° are summarized in Table 1.

Solutions containing mainly cationic or neutral species absorbed ethylene extremely slowly at a linear rate which was followed for about 8 h. The visible spectra of the final solutions were identical with those of the respective starting solutions; no ferric had been reduced and the rhodium species were unchanged. That this slow rate (*ca.* $0.8 \times 10^{-6}\ M\ s^{-1}$) was a "blank" reaction was confirmed by a run in which no rhodium was present. This blank reaction was not studied further but is presumably a slow hydration reaction in the perchloric acid medium, since all the solutions showing this blank reaction are close to 6 M in $HClO_4$. No such reaction was observed in the aqueous hydrochloric acid – chloride media (1), and also in the present work, a 6 M HCl solution containing $RhCl_6^{3-}$ showed no reactivity whatsoever towards ethylene.

The inactivity of the hexachloro complex is significant since the complexes $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ show increasing lability with increasing number of coordinated chlorides (2–4). The conclusion drawn is that the presence of a coordinated water (hydroxide) is essential for the production of hydroxyethyl species (**2**) in the reaction scheme outlined above. In effect this means the reverse of reaction 1 competes effectively with any subsequent aquation reaction in this high chloride medium. Earlier studies (5) have reported a quite similar finding of inactivity for the hexachloro complex as a catalyst for the hydration of acetylenes. The slight inverse chloride effect measured for the rate of oxidation of ethylene by acid chloride solutions of $RhCl_5(H_2O)^{2-}$ (1) could therefore be explained qualitatively by the production of small amounts of the inactive $RhCl_6^{3-}$ complex.

$$[1] \qquad RhCl_6^{3-} + C_2H_4 \rightleftharpoons RhCl_5(C_2H_4)^{2-} + Cl^-$$

The solutions containing mainly $RhCl_5(H_2O)^{2-}$ or $RhCl_4(H_2O)_2^-$ were reactive towards ethylene but unfortunately metal was precipitated almost immediately, and it was impossible to make any quantitative measurements. The uptake plots were autocatalytic in nature and were most irreproducible, both these effects presumably due to production of metal. Semi-quantitatively, by measuring rates at corresponding reaction times, the system containing the tetrachloro complex appeared to be 2–4 times more active than that containing the pentachloro complex but no such definite conclusion can be drawn from the studies on these essentially heterogeneous systems. The studies on the activity of $RhCl_5(H_2O)^{2-}$ in HCl–LiCl solutions (1) show that at 6 M acid the k_3 path of the reaction scheme would predominate with a small contribution from the k_2 path, and an expected rate of *ca.* $4 \times 10^{-6}\ M\ s^{-1}$ can be estimated for the 0.07 M $RhCl_5(H_2O)^{2-}$ solution listed in Table 1; the measured rate in the presence of metal ranged from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

an initial value of *ca.* 0.6×10^{-6} M s^{-1} to the maximum measured of *ca.* 6.0×10^{-6} M s^{-1}.

Metal is almost certainly formed by disproportionation of rhodium(I)

$$[2] \quad Rh^{III} + C_2H_4 \xrightarrow{H_2O} Rh^{I} + CH_3CHO + 2H^+$$

$$[3] \quad 2Rh^{I} \rightleftharpoons Rh^{0} + Rh^{II}$$

In contrast to the system in HCl–LiCl (1), the rhodium(I) is apparently not oxidized rapidly enough to rhodium(III) by iron(III) to prevent the disproportionation reaction. We have not studied the possible reasons for the differences in the two media which could depend on a number of factors. The iron(III) was added as perchlorate in the present work and as trichloride in the other work (1), and the nature of the iron(III) species present could play an important role in the non-equivalent 2 electron transfer process. However, the difference in the acidities used in the two systems is certainly a more critical factor. Pertinent data for the HCl–LiCl systems were obtained at much lower acidities of 0.05–1.0 M; further, reoxidation of Rh^{I} by Fe^{III} was found to be effective in 0.1–0.2 M perchloric acid solutions (see below). Higher acidities could inhibit the Rh^{I}–Fe^{III} reaction by kinetic factors (*e.g.*, if some hydroxy species plays a significant role) or thermodynamic factors (*e.g.*, depending on the reduction potentials of the Fe^{III}/Fe^{II} and Rh^{III} (or Rh^{II})/Rh^{I} couples). There are no quantitative data on the disproportionation reaction (reaction 3). Some recent studies (6) on the oxidation of ethylene by rhodium(III) in acid chloride solutions, in the absence of any reoxidant, have shown that the rhodium is reduced to metal and a pale yellow filtrate, which gives an e.s.r. signal, possibly due to a monomeric paramagnetic rhodium(II) species.

In conclusion, the studies in the 6 M acid medium show that ethylene is unreactive towards the $RhCl_n(H_2O)_{6-n}^{(n-3)-}$ complexes with $n = 1$, 2, 3, and 6. The inactivity of the cationic and neutral species is consistent with their substitution inertness, while that of the hexachloro complex is attributed to lack of a ligand water molecule. The complexes with $n = 4$ and 5 are reactive towards ethylene, some semiquantitative data indicating possibly higher reactivity for the tetrachloro complex.

TABLE 2. Kinetic data at 80° for the reaction of ethylene with $RhCl_4(H_2O)_2^-$; 0.1 M $RhCl_3$, 0.2 M $Fe(ClO_4)_3$, 0.2 M LiCl

$[HClO_4]$ (M)	C_2H_4 (mm)	$[C_2H_4] \times 10^4$ (M)	Linear rate $\times 10^6$ (M s^{-1})
0.1	50	1.0	7.0
0.1	200	4.0	23.0
0.1	400	8.0	43.0*
0.2	53	1.1	4.2
0.2	203	4.1	15.0
0.2	403	8.1	23.0

*For a solution containing 0.1 M Rh as $RhCl_5(H_2O)^{2-}$ under corresponding conditions (but with 2.0 M LiCl), the linear rate was 12.8×10^{-6} M s^{-1}.

Reactivity in 0.1–0.2 M Acid Solutions

Conditions were found for the formation of perchloric acid solutions of lower acidities containing mainly $RhCl_5(H_2O)^{2-}$ or mainly $RhCl_4(H_2O)_2^-$ (see Experimental). These solutions now reacted at 80° with ethylene (up to 1 atm) in the presence of excess iron(III) in a manner quite analogous to that described for the pentachloro species in aqueous hydrochloric acid solutions (1). Catalytic oxidation of the ethylene to acetaldehyde occurs at the rhodium with the consumption of iron(III); the intermediate rhodium(I) is efficiently reoxidized by iron(III) and no metal production is apparent until the ferric concentration approaches zero. Spectrophotometric studies show that there is essentially no change in the equilibrium composition of the chlororhodate(III) complexes during the reaction; the $RhCl_5(H_2O)^{2-}$ solutions gave absorption maxima at 397 nm ($\varepsilon \sim 85$) and 500 nm ($\varepsilon \sim 85$), while the $RhCl_4(H_2O)_2^-$ solutions gave maxima at 375 nm ($\varepsilon \sim 70$) and 475 nm ($\varepsilon \sim 75$).

The initially linear rates of the uptake plots were readily measured; the rates were first order in rhodium to 0.1 M and were independent of the ferric concentration. Table 2 summarizes some kinetic data at 80° for the $RhCl_4(H_2O)_2^-$ system and shows the dependences on ethylene and proton concentrations.

Figure 1 demonstrates a reasonable first-order dependence on ethylene at 0.1 and 0.2 M $HClO_4$ for the reaction involving $RhCl_4(H_2O)_2^-$. In contrast to the previous studies (1) involving $RhCl_5(H_2O)^{2-}$, there is no *significant* contribution from an ethylene-independent path which

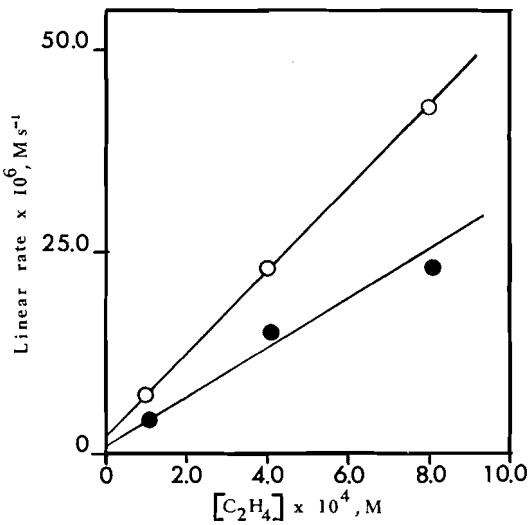

FIG. 1. Rate of ethylene absorption as a function of ethylene concentration with 0.1 *M* $RhCl_3$, 0.2 *M* $Fe(ClO_4)_3$, 0.2 *M* LiCl at 80°; ○ at 0.1 *M* $HClO_4$; ● at 0.2 *M* $HClO_4$.

would be evident as an intercept on the ordinate axis at zero ethylene concentration. However, there may be quite small such intercepts, and they could result from a contribution to the rate by some pentachloro species in the equilibrated and so-called $RhCl_4(H_2O)_2^-$ solutions. Some estimation of the probable magnitude of such intercepts can be made. The rate given in footnote * of Table 2 for the $RhCl_5(H_2O)^{2-}$ solution in 0.1 *M* $HClO_4$ (12.8×10^{-6} *M* s^{-1}) is some 50% higher than that observed previously for the analogous system in 0.1 *M* HCl (8.2×10^{-6} *M* s^{-1}, ref. 1), possibly attributable to differences in the solubility of ethylene in the two media; assuming 50% higher rates in the perchloric acid media, the intercepts of a plot such as shown in Fig. 1 for the system containing mainly $RhCl_5(H_2O)^{2-}$ would be about 6×10^{-6} *M* s^{-1} at 0.1 *M* acidity and about 2×10^{-6} at 0.2 *M* acidity (*cf.* Fig. 1 in ref. 1). Hence the intercepts in Fig. 1 would be some fraction of this depending on the fraction of the rhodium present as the pentachloro complex.

An important conclusion is that 0.1 and 0.2 *M* acid solutions containing $RhCl_4(H_2O)_2^-$ are about 3 times more reactive than corresponding solutions containing $RhCl_5(H_2O)^{2-}$.

The kinetic data in Fig. 1 will be analyzed neglecting possible intercepts on the ordinate axis. The data show an inverse acid dependence and thus, as previously (1), the ethylene reactions must involve both aquo and hydroxy species (see also Scheme 1):

$$[4]\quad RhCl_4(OH)(H_2O)^{2-} + C_2H_4 \xrightarrow{k_5} RhCl_4(C_2H_4)(OH)^{2-}$$

$$[5]\quad RhCl_4(H_2O)_2^- + C_2H_4 \xrightarrow{k_6} RhCl_4(C_2H_4)(OH)^{2-}$$

The rate-law can be written as

$$[6]\quad \frac{-d[C_2H_4]}{dt} = \left\{\frac{k_5K_4}{[H^+]} + k_6\right\}[RhCl_4(H_2O)_2^-][C_2H_4]$$

where K_4 is the acid dissociation constant of $RhCl_4(H_2O)_2^-$. Using eq. 6 the slopes of Fig. 1 (5.2×10^{-2} s^{-1} and 3.1×10^{-2} s^{-1}) may be used to calculate the value of k_5K_4 as 4.2×10^{-2} s^{-1}, and the value of k_6 as 0.1 M^{-1} s^{-1} at 80°. A value of *ca.* 10^{-8} *M* was assumed for the acid dissociation constant (K_5) for the $RhCl_5(H_2O)^{2-}$ complex (1). $RhCl_4(H_2O)_2^-$ will be a somewhat stronger acid, and K_4 is likely to be *ca.* 10^{-6}–10^{-7}. Thus, although present in very small concentrations, the hydroxy complex is kinetically very significant, *e.g.*, at 0.1 *M* acidity it contributes some 80% of the total reactivity and is some 10^5 times more reactive towards ethylene than the aquo complex. A similar conclusion was reached for the pentachlororhodate(III) complexes (1).

The rate constant data determined previously at 80° in HCl–LiCl solutions for the various reaction paths shown in Scheme 1 in the introduction are: $k_1K_5 = 2.2 \times 10^{-6}$ *M* s^{-1}, $k_2 = 6.0 \times 10^{-6}$ s^{-1}, $k_3 = 5.6 \times 10^{-2}$ M^{-1} s^{-1}, and $k_4K_5 = 1.1 \times 10^{-3}$ s^{-1} (1). There will be small differences in ethylene solubility in the somewhat different media, although the rate constants were estimated assuming the same solubility in each (8.0×10^{-4} *M* at 400 mm pressure). However, it seems clear from the rate constant data that rate paths showing no dependence on the ethylene concentration are indeed possible for the pentachloro complex. This requires that the aquation of $RhCl_5(H_2O)^{2-}$ to $RhCl_4(H_2O)_2^-$ is slower than the subsequent reaction of the latter with ethylene, and that aquation of $RhCl_5(OH)^{3-}$ to $RhCl_4(OH)(H_2O)^{2-}$ is slower

For personal use only.

than subsequent reaction of the latter with ethylene. These two requirements are met if $k_2 < k_6[C_2H_4]$ and $k_1K_5 < k_5K_4[C_2H_4]$, respectively, and the above data satisfy these conditions.

The finding of higher activity for acid solutions of $RhCl_4(H_2O)_2^-$ compared with corresponding solutions of $RhCl_5(H_2O)^{2-}$, which is initially surprising considering that lability increases with increasing number of coordinated chlorides, is readily rationalized on consideration of the various reaction paths involved. For example, at 0.1 *M* acidity and 1 atm pressure, the major contribution to the rate for the tetrachloro system is reaction 4 involving $RhCl_4(OH)(H_2O)^{2-}$ and C_2H_4 for which $k_5K_4 = 4.2 \times 10^{-2}\ s^{-1}$; the major contribution to the rate for the pentachloro system is the reaction involving $RhCl_5(H_2O)^{2-}$ and C_2H_4 for which $k_3 = 5.6 \times 10^{-2}\ M^{-1}\ s^{-1}$ (1). Thus, although hydroxy species are present in very small amounts in both systems, more kinetically significant amounts are present in the tetrachloro system and this is reasonable since $K_4 > K_5$. The rates of reaction between C_2H_4 and the hydroxy species are governed by k_5K_4 and k_4K_5, and the former is larger by a factor probably of about 25 to 40. The actual rate constants k_5 and k_4 are probably quite similar; on lability grounds, k_4 for $RhCl_5(OH)^{3-}$ is expected to be somewhat greater than k_5 for $RhCl_4(OH)(H_2O)^{2-}$ which requires that $K_4/K_5 > 25$–40, and this is quite reasonable.

At very high acidities, the ethylene-independent step for the pentachloro system becomes negligible (1), and the reaction rate will be governed purely by the rate constant k_3 for the reaction between $RhCl_5(H_2O)^{2-}$ and C_2H_4. Similarly, the rate for the tetrachloro system would be governed purely by the rate constant k_6 for the reaction between $RhCl_4(H_2O)_2^-$ and C_2H_4. As above, a somewhat greater value would be anticipated for k_3 and solutions of the pentachloro complex would be expected to have higher reactivity (k_3/k_6 for reactivity towards H_2 is reported elsewhere (2) as 1.5). The present data give k_3/k_6 *ca.* 0.6, and this will be somewhat higher if allowance is made for the higher rates measured in perchloric acid media (see above); within the errors of experiment and kinetic analysis, our data suggest very similar reactivity of the two aquo complexes towards ethylene.

The possible path for acetaldehyde production via faster steps following the rate determining formation of the rhodium(III)–ethylene intermediates (reactions 4, 5) was considered in the previous paper (1). The present work confirms the previous findings that the process is more efficient in less acid solutions where higher concentrations of the kinetically important hydroxy species are present, and shows that such solutions of the tetrachloro complex are more reactive than solutions of the pentachloro complex due to the higher acid dissociation constant of the tetrachlorobisaquorhodate(III) complex compared to that of the pentachloroaquorhodate(III) complex. These studies are being extended to other Group VIII metal systems.

Grateful acknowledgment is made to the National Research Council of Canada for financial support, and to Johnson Matthey Limited for loan of the rhodium.

High Resolution Nuclear Magnetic Resonance Investigation of the Structure of the Adducts Formed by the Interaction of Benzylidenemalononitriles with Trialkylphosphines[1]

C. A. FYFE AND M. ZBOZNY
Chemistry Department, University of Guelph, Guelph, Ontario

Received December 2, 1971

High resolution n.m.r. has been used to determine unambiguously the structure of the adducts formed by the action of trialkylphosphines on para-substituted benzylidenemalononitriles[2] as a zwitterionic species formed by attack of the phosphine on the α-carbon atom of the alkene. The relation of this result to possible mechanisms of nucleophilic alkene substitution reactions is discussed.

La r.m.n. à haute résolution a été utilisée pour déterminer sans ambiguité possible la structure des produits d'addition formés lors de l'action des trialkylphosphines sur les benzylidènemalononitriles substitués en para; il s'agit de zwitterions formés par l'attaque de la phosphine sur le carbone-α de l'alcène. Les résultats sont discutés en termes de mécanismes de réactions de substitution nucléophile sur l'alcène.

Canadian Journal of Chemistry, **50**, 1713 (1972)

Introduction

The initial product formed in nucleophilic attack on alkenes is postulated as an ionic intermediate of general formula **1**, eq. [1], (1).

[1] 
1

(X = electron withdrawing group)

Few attempts have been made to characterize intermediates of this general type formed by nucleophilic attack on alkenes until very recently (2–4). Stewart and Kroeger using u.v. spectroscopy and Fyfe, using high resolution n.m.r. have characterized the intermediates formed by the attack of methoxide ion (2–4) and other nucleophiles (2) on activated stilbene systems where further reaction was prevented by the use of aprotic solvents.

A special case occurs if the nucleophile is neutral, where a zwitterionic species will be formed. One case where 1:1 adducts of neutral nucleophiles with alkenes are known to be formed is the reaction of benzylidenemalononitriles with trialkylphosphines (11).

These adducts were originally described as zwitterions with structure **2**, but, as pointed out by Rappoport (5), since they dissociate in solution, 'chemical' tests of their structures are quite invalid. A variety of other structures have been considered, **3**–**5** (5). In addition, one should also consider structure **6**, produced by attack of the phosphine on the β-carbon atom and **7**, a phosphorane structure, analogous to the ylides proposed formed by the attack of triphenyl phosphine on maleic anhydride (6, 7), since

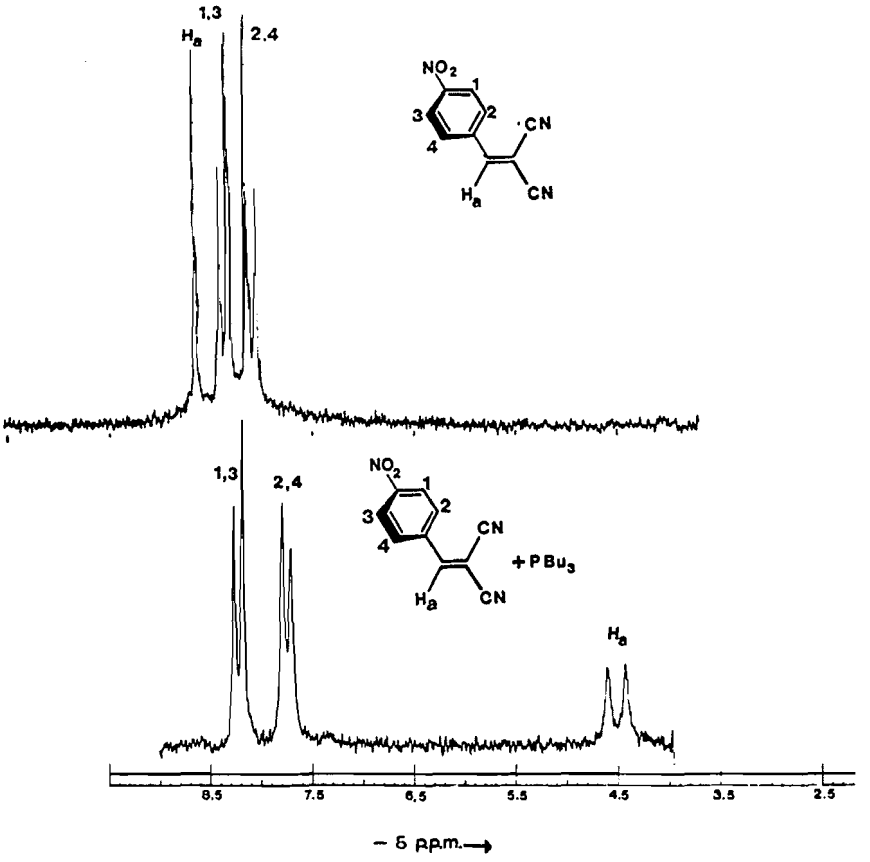

FIG. 1. The 100 MHz n.m.r. spectra in DMSO solution *p*-NO_2-BMN at probe temperature (31°) and the adduct formed from the attack of tri-*n*-butyl phosphine on *p*-NO_2-BMN (31°).

they too analyze as 1:1 adducts. There is indirect evidence in support of structure **2** in that the structures of closely related species formed by the action of trivalent phosphorous compounds on α,β unsaturated ketones (8, 9) have been recently established as being zwitterions.[3]

Because of their direct relevance to the postulated mechanism of nucleophilic substitution reactions of alkenes, an attempt has been made in the present work to define absolutely the structure of these adducts, with a view to ultimately determining the kinetic parameters for their formation and decomposition and the dependence of both these parameters on substituents and on solvents.

[3]The authors would like to acknowledge the help of a referee in bringing this work to their attention and pointing out its relevance to the present study.

Experimental

The ^{1}H n.m.r. spectra were recorded at 100 MHz on a Varian H.A. 100 spectrometer. Chemical shifts are reported in p.p.m. from an internal TMS reference. The ^{31}P n.m.r. spectra were recorded at 23.5 MHz and chemical shifts are quoted w.r.t. an external H_3PO_4 reference (see acknowledgments). The u.v. spectra were recorded on a Unicam S.P. 800 spectrophotometer using 1 cm matched cells.

All chemicals used were prepared by literature methods and were purified until their m.p.'s were in agreement with published values. The BMN's were prepared by the general method of Corson and Stoughton (10) and the tri-alkyl phosphine adducts as described by Horner and Klupfel (11).

Results and Discussion

The low field portion of the proton n.m.r. spectrum of *p*-NO_2-BMN in DMSO solution and that of the adduct formed from it by the addition of tri-*n*-butylphosphine are shown in Fig. 1. The spectrum of the alkene, (Fig. 1

upper), consists of a sharp resonance at $\delta = -8.69$ (relative intensity 1) due to the alkene hydrogen H_a, and an A_2X_2 pattern (relative intensity 4) centered at $\delta = -8.26$ assigned to the phenyl ring hydrogens. With the addition of tri-*n*-butylphosphine to form the adduct, we see a change in the spectrum: the singlet absorption due to H_a is no longer present at low field and the A_2X_2 pattern of the phenyl ring has shifted slightly upfield to $\delta = -8.0$ ($J_{1,2} = J_{3,4} \simeq 8.4$ Hz, $V_0\delta \simeq 45.1$ Hz). The spectrum of the adduct has a doublet absorption, ($J_{H-P} = 18.2$ Hz) (relative intensity 1), at higher field. (Although the room temperature spectra of several of the adducts show evidence of an exchange process (see below) this is not important in the present instance.)

From this spectrum one can eliminate possibilities **3**, **4**, and **6**. The charge-transfer structure can be eliminated since one would expect a singlet absorption due to the alkene hydrogen H_a; but such a low field singlet is absent. One would also expect a shift in the absorption due to changes in concentration but no concentration dependence is observed. Nor should a phosphorous–hydrogen coupling be observed, as such equilibria are usually fast (12). (The extreme case where a strong localized charge-transfer complex between phosphorous and carbon is formed, might show a slower exchange, but would in fact be the zwitterion **2**.)

Structure **4** can be eliminated since its spectrum should also show a singlet absorption for H_a. Structure **6** may be eliminated since one would expect a larger upfield shift for the phenyl ring protons because of the delocalization of the negative charge into the ring and onto the NO_2 group as is observed for the intermediates formed by nucleophilic attack on activated stilbenes (2). Further, compounds known to have similar electronic structures to structure **6** give rise to intense purple colors ($\lambda_{max} \sim 580$ mμ) on formation. Instead, the 1:1 adducts show absorptions <400 mμ and are orange–colorless. This eliminates all but possibilities **2**, **5**, and **7**.

A tabulation of chemical shifts and coupling constant data at room temperature in DMSO solution as well as in deuteroacetonitrile solution at -20 °C, for a series of BMN's and their PBu_3 adducts is given in Table 1. There is little variation in the chemical shift values of H_a in either solution, as would be expected if the structure is a zwitterion. Differences in P–H couplings and the non-observation of a P–H coupling for the unsubstituted BMN in DMSO-d_6 solution at room temperature and the presence of a P–H coupling in CD_3CN solution at -20 °C is attributed to an exchange process (see on). The data in Table 1 are in good agreement with the zwitterion structure, but, since information about compounds which are struc-

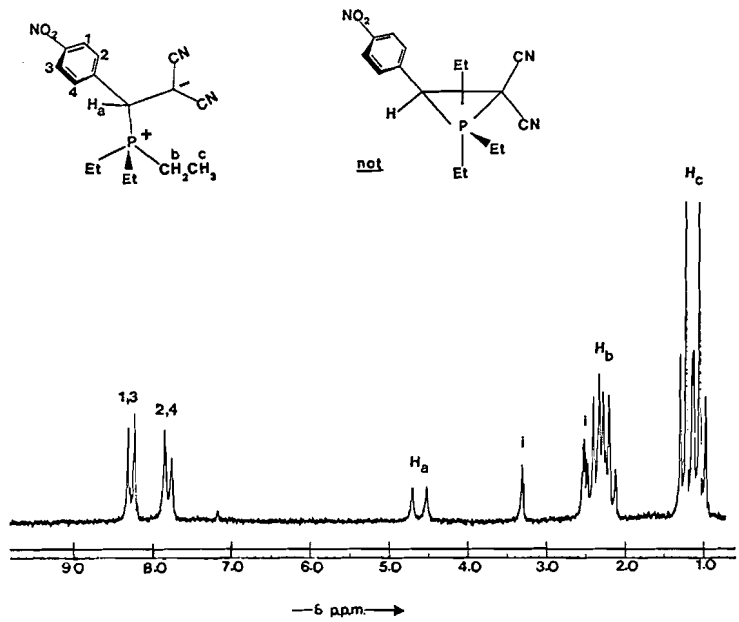

FIG. 2. The 100 MHz n.m.r. spectrum of the triethyl adduct of p-NO_2 at 34 °C in DMSO-d_6 solution.

turally related to **5** and **7** is lacking, they can not be dismissed on this basis.

However, when tri-ethylphosphine is used as the nucleophile, complete interpretation of the n.m.r. spectrum of the adduct formed is possible, resulting in the elimination of structure **5**. The spectrum in DMSO-d_6 of the adduct thus formed from p-NO_2-BMN is shown in Fig. 2. The A_2X_2 pattern centered at $\delta = -9.00$ p.p.m. ($J_{3,4} \simeq 8.8$ Hz, $V_0\delta \simeq 47$ Hz), can be assigned to the phenyl ring protons. H_a is a doublet centered at $\delta = -4.63$, $J_{P-H} = 18.3$ Hz (relative intensity 1) due to coupling with phosphorous and, as noted above, occurs at a field strength characteristic of protons attached to sp^3 hybridized carbons. Peaks marked i are impurities due to traces of H_2O ($\delta = -3.3$) and DMSO-d_5 impurity ($\delta = -2.54$ p.p.m.). The absorption of the methylene hydrogens of the ethyl groups, which are coupled both to the phosphorous and the methyl protons, appears as a multiplet; centered at $\delta = -2.3$ p.p.m. The absorption due to the methyl hydrogens is centered at $\delta = -1.1$ and appears as a multiplet due to coupling with the methylene hydrogens and the phosphorous. The coupling constants are ($J_{P-H_a} = 18.3$, $J_{P-CH_2} = 17.3$, $J_{CH_2-CH_3} = 8.0$ Hz). If structure **5** were correct, the proton n.m.r. spectrum should show an absorption due to the two types of ethyl groups as indicated in the stereo drawing, Fig. 2, which shows two "axial" ethyl groups and one "equatorial" ethyl group. As indicated above, the spectrum can be interpreted fully in terms of a single type of ethyl group, eliminating structure **5**, leaving only possibilities **2** and **7** to be considered. The spectrum is unchanged at $-30°$ in CD_3CN solution, ruling out the possibility that the equivalence of the ethyl groups is due to an exchange process.

The proton n.m.r. spectrum is thus compatible with either of structures **2** or **7**. However, ^{31}P n.m.r. should indicate which 1:1 adduct is actually formed, since ylides involving tri-phenylphosphine groups, analogous to structure **7**, have a phosphorous absorption at different field strengths from (approximately 15–20 p.p.m. upfield) the corresponding quadruply connected phosphorous compounds (13–15). One would expect a similar behavior pattern with tri-n-butylphosphine adducts.

The adducts show ^{31}P absorptions at -36.8 p.p.m. (p-Cl) and -37.2 p.p.m. (p-NO_2) from external phosphoric acid when the spectra are measured in DMSO solution. The proton spectra under these conditions indicate that there is no detectable exchange, and these shifts

9

$Bu_3P{=}CH_2$

10

are thought to be close to the true values for the complexes. The shifts are close to the value found for the closely related compound **9**, *known* to contain positively charged phosphorous, namely −31 p.p.m. (8).

Ylides, of similar structure, have a correspondingly higher chemical shift; in particular compound **10** absorbs at −16 p.p.m. (16). The general agreement between the ^{31}P chemical shifts of the adducts with that of the ion **9**, is taken as strong evidence for the zwitterionic structure **2** and against the proposed ylide structure **7**.

Thus it is thought that n.m.r. has allowed us to determine the structure of this adduct unambiguously as being the zwitterion in the solvents used, independent of any equilibrium processes in solution.

The u.v. spectra do not change appreciably when the solvent is varied, having λ_{max} values of 418, 405, and 428 mμ in acetone, acetonitrile, and DMSO respectively, indicating that the species is the same in *all* solvents studied, although substantial changes in the n.m.r. spectra may be observed.

The relatively sharp doublet obtained for the phosphorous—hydrogen coupling of **2** (p-NO_2) in DMSO solution (Figs. 1, 2) compared to the broad doublets in other less basic solvents prompted us to investigate the possibility of an exchange process involving the phosphines. Figure 3 shows the temperature dependence of the H_a resonance of **2** (p-NO_2) in CD_3COCD_3 solution, which at low temperature approximates to a simple two-site exchange process with equal population of the two sites, indicating that the equilibrium is well in favor of the adduct at these temperatures. However the spectra at higher temperatures are unsymmetrical, indicating an appreciable effect from the population of the third site, the parent alkene.

This aspect is currently under investigation, together with stopped flow measurements of the kinetics of the formation of the adducts, and it is hoped that both methods will give values for the activation energies of the forward and reverse steps in the equilibria. It is hoped that the theoretical interpretation of these parameters will eventually yield a model for calculations applicable to nucleophilic alkene substitutions in general.

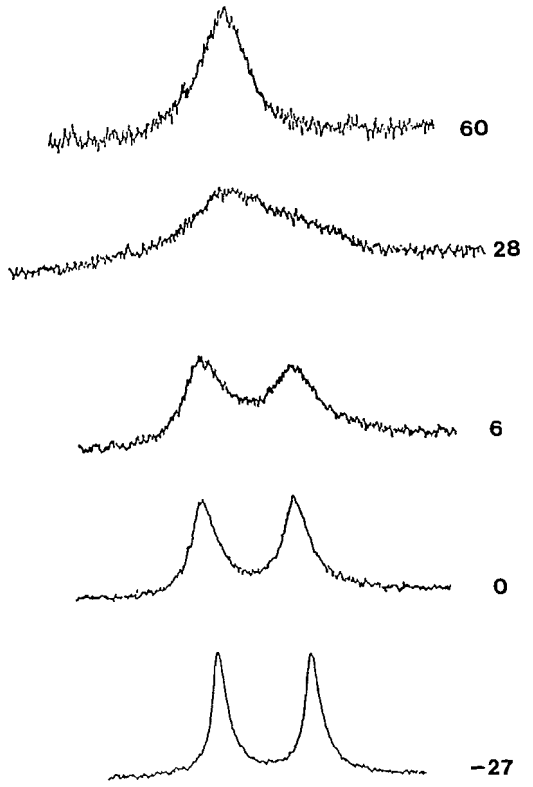

FIG. 3. The temperature dependence of the H_a resonance of the adduct **2**, (p-NO_2) in CD_3COCD_3 solution.

Circular Dichroism of Nitrate Esters: A Planar Symmetry Rule for the Nitrato Chromophore[1]

R. E. BARTON AND L. D. HAYWARD

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received December 9, 1971

Conformational analysis of nitrate esters based on X-ray and spectroscopic data showed the nitrato group to be coplanar with the α carbon atom and, in the preferred rotamer, the nitro moiety to be antiperiplanar to the β carbon atom. Three optically active absorption bands not apparent in the isotropic electronic spectra were resolved in the circular dichroism spectra. Band I (270 nm) reflected nitrato group libration changing sign and magnitude with changes in temperature and solvent polarity. Differences in rotatory strength of band III (210 nm) for *cis*- and *trans*-dinitrates indicated transition moment coupling. A planar symmetry rule for chromophores in the C_s point group correlated the molecular geometry and sign of band II for 42 nitrate esters: when the lowest-energy rotamer of the nitrate ester is viewed down the O—C bond with the nitro group uppermost rotatory contributions to band II (230 nm) are positive for perturbing atoms to the right and negative for those to the left of the nitrato symmetry plane.

L'analyse conformationnelle des esters nitriques, basée sur les données de la spectroscopie et des rayons-X, montre que le groupe nitrate est coplanaire avec l'atome de carbone en α et que, dans le rotamère privilégié, le fragment nitro est antipériplanaire à l'atome de carbone en β. Trois bandes d'absorption optiquement actives, non apparentes sur le spectre électronique isotrope, ont été résolues dans le spectre de dichroisme circulaire. La bande I (270 nm) reflète la vibration du groupe nitro et change de signe et d'amplitude lorsque la température et la polarité du solvant changent. Les différences dans le pouvoir rotatoire de la bande III (210 nm) pour les dinitrates *cis* et *trans* indiquent un couplage du moment de transition. Une règle de symétrie plane pour les chromophores du groupe C_s relie la géométrie moléculaire au signe de la bande II pour 42 esters nitriques: lorsque le rotamère de plus basse énergie de l'ester nitrique est regardé le long de la liaison O—C avec le groupe nitro, les contributions rotatoires décisives pour la bande II (230 nm) sont positives lorsque les atomes sont situés à droite du plan de symétrie du nitrate et négatives lorsqu'ils sont à gauche.

Introduction

A correlation of the absolute configuration (chirality) of nitrate esters with their accessible c.d. spectra was sought in the present work. Such a symmetry rule (1, 2) would permit assignment of unknown configurations and contribute to understanding of the bonding, electronic spectra, and conformational equilibria of these explosive and physiologically reactive compounds.

Early o.r.d. spectra of hexose nitrates (3–7) included background rotation due to other chromophores and only the transition of the nitrato group at 270 nm (band I) was identified with the aid of c.d. spectra (5, 6). The sign of band I was positive for nitrato groups in α- (or D) configuration and negative for those with β- (or L) configuration in α-glucosides, the signs being reversed for the corresponding β-anomers. Band I was reported to be red-shifted by steric crowding of the chromophore and to decrease in rotatory strength with location on the hexose chain in the order C-2 > C-3 > C-4 > C-5. It was also concluded from o.r.d. data that (*R*)- and (*S*)-α-nitrato-carboxylic acids showed positive and negative Cotton effects, respectively, at *ca.* 265 nm (5).

Our preliminary c.d. studies on a series of 1,4;3,6-dianhydrohexitol nitrates (8) revealed a new transition at 230 nm (band II) which was positive for *endo*-(*R*)- and negative for *exo*-(*S*)-nitrato groups at locations 4 and 8 on the *cis*-2,6-dioxabicyclo[3.3.0]octane skeleton. In this series of nitrates the sign of band I was positive throughout and was insensitive to changes in configuration at the α-carbon atom.

A third dichroitic band at 210 nm (band III) was detected in nitrato steroids (9). Exciton splitting as the source of band III was considered improbable since its rotatory strength varied independently of that of band II. Although the sign patterns of bands I–III were characteristic

[1]Taken in part from the thesis submitted by R. E. Barton in partial fulfilment of the requirements for the Ph.D. degree. This is Part III of a series on stereochemistry of nitrate esters. For part II, see ref. 24.

of location on the steroid skeleton, rotational mobility of the nitrato group precluded complete configurational analysis (9).

A fourth nitrato absorption band at 200 nm (band IV, ε 5800) was found in the isotropic spectrum of ethyl nitrate (10) but has not so far been reported in c.d. spectra. Band I has been identified with the $n \rightarrow \pi^*$ transition (11), and bands III and IV with the $\pi \rightarrow \pi^*$ transition (10) of the nitrato chromophore whereas the identity of the transition associated with band II is unknown.

The nitrato group, $-ONO_2$, with four coplanar atoms (12–16) belongs to the C_s point group with symmetry elements E and σ. The molecular orbitals of the nitro moiety probably resemble those of the nitroalkanes (17, 18); however, there is uncertainty concerning participation of the alkoxyl oxygen in π bonding (16). The scatter of the available values for the RO—NO_2 bond length (1.36 to 1.53 Å) (13–16) leaves open the question of electron delocalization over the entire $-ONO_2$ group.

From the C_s character table the pseudoscalar part of the $-ONO_2$ potential is the A'' representation and hence, according to Schellman's analysis (2), there should exist a planar symmetry rule for nitrate esters based on the symmetry plane. This approach specifies only the minimum number of spatial regions in which perturbing groups generate rotational strength (19); other nodal surfaces not determined by symmetry may lead to further spatial subdivisions. In view of the uncertainty in the bonding and orbitals in $-ONO_2$, however, only a planar rule was considered as a first approximation. The problem was then to establish the most probable position of σ in the molecular framework; once this was known examination of molecular models would reveal the distribution of polarizable groups with respect to the fiducial plane for comparison with c.d. spectra.

The investigation involved the following steps: (*a*) synthesis of model nitrate esters with known configurations and restricted molecular conformations, (*b*) measurement of isotropic and c.d. spectra to establish the preferred conformations, (*c*) analysis of the c.d. spectra in terms of the molecular geometry in an attempt to assign rotatory contributions from spatial regions of the intramolecular environment, and (*d*) generalization of the pictorial model through tests on nitrate esters with more varied patterns and degrees of substitution and greater degrees of molecular flexibility.

Experimental

Circular dichroism spectra were taken on JASCO J5 and J20 spectrophotometers calibrated for wavelength and dichroic absorption with 5α-cholestan-3-one in 1,4-dioxan ($\Delta\varepsilon + 1.13$ at 295 nm (20)). Low temperature measurements (21) were corrected for volume contraction from published solvent data (22). Ultraviolet spectra were run on a Cary 15 spectrophotometer with slit widths less than 1 mm and absorbance below 1.0. All solvents were of spectral grade or were purified by standard procedures to give satisfactory ultraviolet absorption spectra.

The nitrate esters were synthesized from the corresponding chiral alcohols (Table 3) (7, 24, 28–32) either with anhydrous nitric acid in acetic acid – acetic anhydride at 0° (23, 24) or via the corresponding chloroformate and silver nitrate (25) and were purified by distillation (*ca.* 0.5 Torr) or chromatography on columns of silica gel developed with chloroform (26). Purification was monitored by t.l.c. (26) and by the u.v., c.d., n.m.r., (27) and i.r. (24) spectra which agreed with the constitutional assignments. Elemental analyses of new nitrate esters are shown in Table 1.

Results and Discussion

The isotropic electronic absorption spectra of the nitrate esters in solvents of different polarity showed no maxima; however, the molar extinction coefficients of the band envelope were measured at wavelengths corresponding to bands I–IV (Table 2). These were generally larger in acetonitrile than in cyclohexane at 270 and 230 nm and the reverse was true at 210 and 200 nm. This trend of ε with solvent polarity was confirmed in the u.v. spectra of (−)-menthyl nitrate (**19**) in four additional solvents and suggested the presence of different unresolved transitions.

*Oxolanyl Nitrates (**1–11**)*

The restricted, approximately V-shaped conformation of the fused oxolane rings in the parent 4,8-dihydroxy-*cis*-2,6-dioxabicyclo-[3.3.0]octanes (**1–4, 8–10**) is known from X-ray data (14) and has been shown by n.m.r. measurements not to be significantly altered by intramolecular hydrogen bonding or esterification (28). The restricted nonplanar conformation of oxolan-2-one (**6, 7**) was established by microwave spectroscopy (29).

The barrier to rotation on the O—C bond in methyl nitrate is 2.3 kcal mol^{-1} and to rotation on the O—N bond, 9.1 kcal mol^{-1} (16), the

former value being comparable to the barriers restricting overall molecular rotation in various solvents (30). Our calculations from the atom coordinates of six nitrate ester groups in different chemical and crystal environments (12–15) showed that the carbon atom α to the nitrato group lies in or close to the symmetry plane of the group in every case as was also found for methyl nitrate by microwave spectroscopy (16).

The *endo*-nitrato groups at C-4 of the 2,6-dioxabicyclo[3.3.0]octane skeleton (14) was found to be also coplanar with the methylene β carbon atom, C-3, and to be antiperiplanar to it on the O—C bond (rotamer *anti*-C_β). This conformation brings the *endo*-nitrato group into proximity with the oxygen atom in the ad-

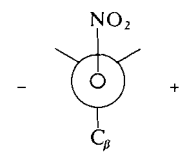
jacent ring (O....N 2.85 Å (14)) in compounds **1**, **3**, **9**, and **10** and causes an increase in the symmetric stretching frequency of the NO_2 group in acetonitrile solutions (24). The *exo*-nitrato group in compounds **2**, **4**, **8**, and **10**, on the other hand, does not show this frequency shift and cannot interact with the oxygen atom of the adjacent ring. Models show that rotamer *anti*-C_β, C_β=CH_2 is probably also preferred for the *exo*-nitrato group but with a somewhat greater degree of librational freedom. Rotamer *anti*-H is precluded by steric hindrance from the oxolane ring and rotamer *syn*-H may be ruled out on the basis of the microwave spectrum of methyl nitrate which showed the methyl hydrogens to be staggered with respect to the nearest oxygen of the NO_2 group (16). Models permitted selection of *anti*-C_β as the preferred rotamer in compounds **5**, **6**, **7**, and **11** (Table 4) with the choice of C_β being governed by steric crowding.

The sign of c.d. band I was found to be dependent on nitrato rotamer populations for other nitrate esters (*vide infra*) but did not change for compounds **6**–**11** on going from acetonitrile to cyclohexane as solvent (Table 3) thus confirming that rotamer *anti*-C_β persists in these solutions. The positive sign of band II for **7** distinguished it from the negative lactone band observed for the parent hydroxylactone (31). The rotatory strength of band II increased moderately ($I^{+5}_{-90} = -47\%$ (32)) and that of band I was drastically decreased ($I^{+5}_{-90} = +150\%$) on cooling a methanol solution of **7**. This result suggested that partial rotation (libration) of the nitrato group on the O—C bond alters an interaction of the lactone and nitrato chromophores.

Resolution of band II for the oxolanyl dinitrate, **11**, was achieved through variation of solvent and temperature. In nonpolar solvents it apparently was hidden under bands I and III but in polar solvents a negative peak appeared near 238 nm (Fig. 1). In methanol solution the intensity of both bands I and II decreased with temperature and in EPA solution band I passed through a minimum negative value between $-115°$ and $-145°$. These results are most readily understood as due to libration of nitrato rotamers leading to interaction of contiguous nitrato groups (13, 27) in the less polar solvents (24) and at the lower temperatures. In the absence of this attractive interaction in polar solvents the dihedral angle between the planes of the nitrato groups in **11** would increase to approximately 180° to give the rotamer conformation shown in Table 4.

The sign of band II was characteristic of the configuration of the nitrate esters **1**–**11** and was found to depend on the distribution of perturbing atoms with respect to the plane of the nitrato group according to the following rule

When the nitrate ester in the anti-C_β conformation is viewed down the O—C bond with the NO_2 group uppermost the rotatory contribution to band II is positive for atoms lying to the right of the plane of the nitrato group and is negative for atoms to the left of that plane.



In applying the rule only atoms other than hydrogen were counted and atoms lying in the

C_s plane were considered to make no rotatory contribution. For dinitrates the distribution of the perturbing atoms was examined for each nitrato group in turn and the algebraic sum of their contributions was used to predict the sign of band II. In Table 4 colums 2 and 3 show the *anti*-C_β rotamer conformations by means of the location numbers for the carbon atoms α and β to the nitrato groups. The distribution of perturbing atoms is shown in column 4 as left-of-plane, in-plane, and right-of-plane, respectively. For dinitrate **10** where the atom distributions for the *endo*- and *exo*-groups are equal and opposite a positive sign for band II was predicted from the greater magnitude of the positive band of the *endo*-group.

The agreement of predicted and observed signs is consistent with the known configurations and the conformational analysis, and permits extension of the symmetry rule to both vicinal and non-vicinal dinitrates.

*Alkylbicyclo[2.2.1]heptyl Nitrates (**12**–**18**)*

The rigid bridged bicyclic skeleton sterically hinders rotation of the nitrato group in this series. Models show that both *endo*- and *exo*-nitrato groups at C-2 are restricted to libration of about ±45° from the conformer *anti*-C_β with C_β = C-1. The C-3 nitrato group in the dinitrates also adopts rotamer *anti*-C_β with C_β = C-2 (Table 4). Nitrato group librational freedom decreases in the order **13** > **12** > **14** for the

mononitrates and **17** > **18** > **16** > **15** for the dinitrates.

The intensity of the isotropic absorption envelope at 230 nm (Table 2) increased with steric hindrance for the mononitrates, and, among the dinitrates, the most sterically hindered, **15**, had the largest ε value at this wavelength.

The sign of c.d. band I was reversed with change of solvent for nitrates **12** and **18** (Table 3). It was positive for compound **12** in four solvents and negative in seven. The rotatory

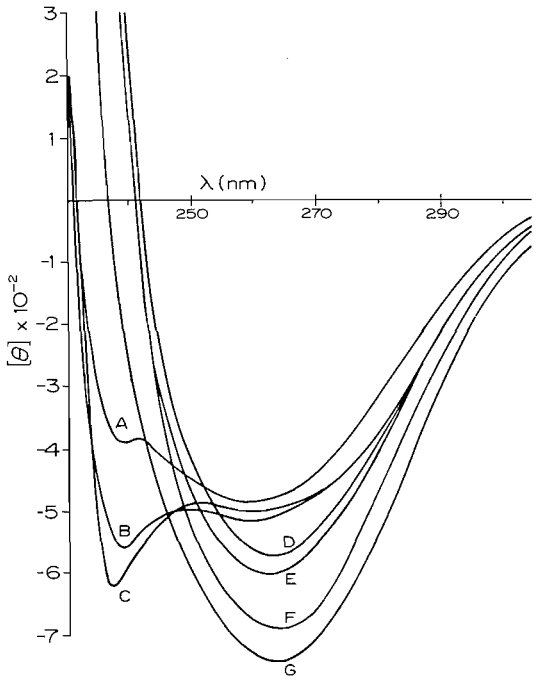

FIG. 1. Effect of solvent on the c.d. spectrum of L-threitan dinitrate (**11**). *A*, 2,2,2-trifluoroethanol; *B*, acetonitrile; *C*, methanol; *D*, pentane; *E*, heptane; *F*, cyclohexanes; *G*, tetrahydrofuran/cyclohexane (14:86, v/v).

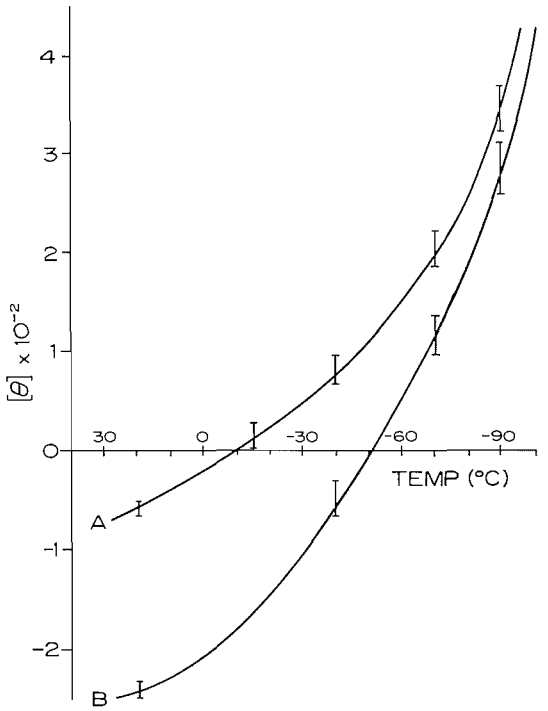

FIG. 2. Effect of temperature on band I (*A*) for isobornyl nitrate (**12**) and (*B*) for bornyl nitrate (**13**) in methanol.

strength of band I for compound **14** showed no correlation with the usual solvent parameters of refractive index, dipole moment, dielectric constant, *Z*-value, or the relation $K - 1/K + 2$ (33) of the eleven solvents. On cooling methanol solutions of **12–18**, band I showed no appreciable change in frequency but reversed sign for compounds **12**, **13**, (Fig. 2), **16**, and **17** and increased in intensity for **14**. Similar temperature effects were observed in other solvents, the smallest changes being observed for a chloroform solution of **13** and for a methanol solution of **15**. Varying the concentration of **12** from 0.036 to 0.1 *M* in methanol did not appreciably alter the molecular ellipticity *vs.* temperature plot for band I (Fig. 2).

The intensity of band III for the *trans*-dinitrates **16** and **18** was 5–8 times greater than for the *cis*-dinitrates **15** and **17** in acetonitrile solutions whereas the magnitudes of band II showed only 2-fold differences between the *cis*- and *trans*-isomers (Table 3). Since band III is a strong transition ($\varepsilon > 10^3$) and therefore probably allowed, electric dipole–electric dipole transition coupling could be expected (2, 34) which would lead to the observed lower rotatory strength for the approximately parallel *cis*-nitrato groups as compared to the more nearly orthogonal *trans*-nitrato groups (34, 35). The exciton splitting would not be evident because of overlap with band II.

The sign of band II was not altered by changes in solvent or temperature and, on application of the planar symmetry rule, was again found to be a reliable indicator of the molecular configuration (Table 4).

Alkylcyclohexyl Nitrates (19–25)

Conformational freedom in these nitrate esters includes the possibility of ring inversion as well as nitrato group rotation. The parent alcohols of **19** and **20** have *ca.* 100% and that of **21** *ca.* 70% population of the conformer with equatorial hydroxyl at 25° (36). Since cyclohexyl nitrate is 73% equatorial (37) and cyclohexanol 65% equatorial (38) at 25°, ring conformations with equatorial nitrato groups would be expected to predominate in compounds **19**, **20**, **22**,

and **24**. All substituents in compounds **21**, **23**, and **25** cannot be equatorial; however, estimates from conformational free energy differences for these groups (39) suggest that the nitrato group would be equatorial in **21** and axial in **23** and **25**. Similar estimates for the related methyl ethers correctly predicted axial and equatorial methoxyl groups (40). The n.m.r. spectrum of **23** indicated an axial nitrato group since the α-proton resonance, a distorted triplet, had a half-height band width of 10 Hz. This ring conformation of **23** also permitted maximum separation of the π orbitals of the exocyclic double bond and the nitrato group. The preferred ring conformations in this series are shown in formulae **19**–**25**.

The preferred nitrato rotamer was also *anti*-C_β in this series with C_β = C-2 for **19**–**21** and **23**, and C_β = C-6 for **22**, **24**, and **25** (Table 4). Ring inversion in **23** and **25** did not alter the rotamer preference.

The c.d. spectra of nitrates **19**–**25** showed bands I–III and, in addition, very weak new bands appeared in the region 292–320 nm (Table 3) which did not correspond to any previously reported nitrate ester transitions. Similar bands were found in the spectra of the acyclic nitrates **26** and **27** but not in those of more conformationally rigid nitrates. The new band was negative for compound **19** in 15 different solvents and as the neat liquid ($[\theta]_{max}$ −6.4 to −18 at 322 ± 2 nm). Its intensity rapidly approached zero as the temperature of a methanol solution was lowered to −90° while that of bands I and II increased more slowly. These results suggest that the new band may be a component of the n–π* transition, similar to the 350 nm band of nitro-compounds (17), or that it may be the resultant of partially-overlapped, oppositely-signed 270 nm bands from different conformers. In the latter case the conformers probably arise from nitrato group libration rather than from ring inversion since the energy barrier for the latter process is estimated to be *ca.* 4.4 kcal mol^{-1} for **19** and **20** and (+)-3-methyl-cyclohexyl nitrate (**24**), which could be expected to have a larger population of the axial conformer, had the weakest of these bands near 298 nm (Table 3).

Band I was even more sensitive to changes in temperature and solvent polarity for **19**–**25** than for the more conformationally rigid nitrate esters. It was positive in acetonitrile solution for all members of the series except **23** and changed sign for compounds **21** and **25** on going to cyclohexane solutions. It appeared at 270 ± 2 nm for compound **19** in 15 different solvents, as the vapor, and as the neat liquid, and was most intense in highly polar solvents such as hexafluoroisopropanol ($[\theta]_{max}$ + 1590) and weakest in cyclohexane (Table 3). There was no clear correlation of the molecular ellipticity of band I with the usual solvent parameters (33), and, as noted above, it increased linearly in magnitude with decreasing temperature.

Nitrates **22** and **23** showed greater intensity in band III than other members of the series and this might be attributed to transition moment coupling of the olefinic and nitrato chromophores.

Again in this series band II was relatively insensitive to changes in solvent and temperature showing no change in sign or wavelength and only ±3% differences in $[\theta]_{max}$ among eight solvents and an increase of only 13% in $[\theta]_{max}$ between +30° and −90° for compound **19**. Band II for compound **22** was partially obscured by band III but was clearly positive in sign. The agreement between the observed signs of band II and those predicted by the planar rule from

the preferred conformations was excellent (Table 4).

Steroid Nitrates

The planar rule was further tested on 20 nitrate esters of secondary steroid alcohols for which the nitrato c.d. bands have previously been reported (8, 9). The conformational analyses followed the procedure outlined above, the results, and the predicted and observed signs of band II are shown in Table 5. Agreement between observed and predicted signs for fourteen of these steroidal nitrates is very good. Six cholestane and androstane derivatives with 3α- or 3β-nitrato groups (compounds numbered **1**–**6** by Snatzke and co-workers (9)) could not be conformationally analyzed since molecular models showed no preference for one nitrato rotamer in the 3-position on ring A. Conformational lability is suggested by the absence of a detectable band I in the spectra of the 3-equatorial nitrates and the weakly negative band I found for the axial chromophores (7). The conformational preference of this nitrato group probably could be determined through variable temperature and solvent studies. The rule could not be applied to the c.d. spectra of hexose nitrates published by Tsuzuki *et al.* (5, 6) since only band I has been reported.

*Acyclic Nitrates (**26**–**28**)*

Since no skeletal constraint was apparent from models of these compounds, the planar symmetry rule was applied to predict molecular conformations.

Rotamer *anti*-C_β was assumed to predominate and selection of C_β as methyl, methylene, and methine carbons, respectively, in compounds **26**–**28** yielded agreement of predicted and observed signs for band II (Table 4). Nitrates **26** and **27** gave bands I–III and an additional, weak, long wavelength bands at 292 nm and 310 nm respectively which, as noted earlier, may be due to the presence of different rotamers in solution. The additional band did not appear

in the spectrum of the dinitrate of diethyl-L-tartrate (**28**). The o.r.d. data for **26–28** which suggested that nitrates of α-D-hydroxy acids have positive Cotton effects while those of α-L-hydroxy acids have negative Cotton effects (7) probably reflected the sign of band III only since the weaker bands I and II would have been obscured in the background rotation.

The acyclic nitrate esters of the primary steroid alcohols, 3β-acetoxy-5α-cholestane-19-ol and 3β-acetoxy-5β-cholestane-19-ol (9) when assigned *anti*-C_β conformations (C_α = C-19, C_β = C-10) showed a further degree of conformational freedom, namely rotation on the C_α—C_β bond. Assignment of the conformation with C-9 antiperiplanar to the nitrato group gave agreement of the predicted (+) and observed (+) signs for band II whereas similar assignments for C-1 or C-5 were less favored according to the molecular models of these compounds and predicted (+) and (−) signs for band II, respectively.

In general the application of the symmetry rule to the acyclic nitrate esters led to molecular conformations which appeared to be plausible from molecular models.

Meisenheimer Complex Formation Between 1,3,5-Trinitrobenzene and Hydroxide Ion. Equilibrium Constants for the Dimethylformamide–Water Solvent System

E. A. SYMONS AND E. BUNCEL

Department of Chemistry, Queen's University, Kingston, Ontario

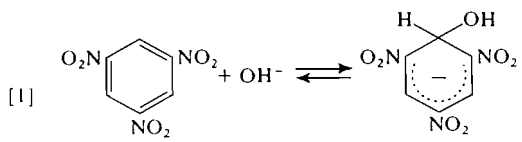
Received January 4, 1972

Sigma-complex formation between 1,3,5-trinitrobenzene (TNB) and hydroxide ion has been studied quantitatively as a function of medium composition for part of the dimethylformamide (DMF)–water solvent system by spectrophotometric methods. Only a 1 : 1 complex is detected under the conditions of measurement, with [TNB] ≥ [OH^-]. The equilibrium constant (K_{eq}) for complex formation in 22 mol % DMF has the value 3×10^3 l mol^{-1}, compared with 3 l mol^{-1} in purely aqueous medium. Further increases in K_{eq} occur as the DMF content of the medium is raised; in 50 mol % DMF $K_{eq} \approx 10^5$, but reliable K_{eq} values could not be obtained in this region of medium composition. The increase in K_{eq} with increasing DMF content is interpreted largely on the basis of hydroxide ion desolvation.

La formation d'un complexe-σ entre le trinitro-1,3,5 benzène (TNB) et l'ion hydroxyle a été étudiée quantitativement en fonction de la composition du milieu, constitué d'un mélange diméthylformamide (DMF)–eau, au moyen de méthodes spectrophotométriques. Dans les conditions des mesures, avec [TNB] ≥ [OH^-], seul un complexe 1:1 a été détecté. La constante d'équilibre (K_{eq}), pour la formation du complexe dans une solution à 22% en mol de DMF, a la valeur de 3×10^{-3} l mol^{-1}, comparée à 3 l mol^{-1} dans un milieu purement aqueux. La valeur de K_{eq} augmente si la teneur du milieu en DMF augmente; avec 50% en mol de DMF, $K_{eq} \approx 10^5$, mais dans ce cas, des valeurs fidèles de K_{eq} ne peuvent pas être obtenues dans cette zone de composition. L'augmentation de la valeur de K_{eq} avec la teneur du milieu en DMF est interprétée surtout sur la base d'une désolvatation des ions hydroxyles.

Canadian Journal of Chemistry, **50**, 1729 (1972)

The formation of Meisenheimer (σ) complexes between aromatic nitro compounds and bases is well documented (1–8). The present study was undertaken as part of a program aimed at elucidating the relationship between hydrogen–deuterium exchange (9, 10) and σ-complex formation in trinitrobenzene–base systems. Results of equilibrium measurements for reaction 1 as a function of medium composition for part of the dimethylformamide–water composition range are now reported.



[1]

1

Experimental

Reagents

1,3,5-Trinitrobenzene (Eastman) was purified by recrystallization; spectral absorption in 96% ethanol: λ_{max} 225 mμ, ε_{max} 25 700 l mol^{-1} cm^{-1}. The solvent DMF (Fisher Certified Reagent) was purified by the method of Ritchie and Megerle (11). Sodium hydroxide solutions (Fisher Scientific) and tetramethylammonium hydroxide solutions (Matheson, Coleman, and Bell) were stored in polyethylene bottles. The distilled water used was carbon dioxide-free.

Procedures

The main consideration with respect to the procedures employed was to avoid any serious complication arising from the reaction of hydroxide ion with the solvent, *i.e.* the basic hydrolysis of DMF (12). This problem was minimized by operating generally under the conditions [TNB] ≥ [OH^-], thus effectively reducing the concentration of free hydroxide ion as a result of complex formation. Extensive complexing of the hydroxide ion occurred in solvents even moderately rich in DMF ($K_{eq} \approx 10^3$ in *ca.* 20 mol % DMF). In the more aqueous media, where K_{eq} was considerably smaller, the irreversible loss of hydroxide ion (12) resulted in a decrease in absorbance with time, necessitating the observation of absorbance at a fixed wavelength and extrapolation back to the time of mixing. At 25° the typical decay in absorbance after 10 min was within 4% of the extrapolated zero time value for solvent mixtures containing more than 30 mol % DMF, but reached a maximum of about 40% in the region of 10 mol % DMF for the same period. Initial absorbance readings were taken about 1 min after mixing.

The possible problem of limited base solubility in media rich in DMF (12) did not arise since most of the hydroxide ion is present in complexed form in these TNB–OH^- systems.

Solutions for spectral examination were prepared by addition of standard hydroxide to a solution of TNB in DMF–water. Spectral measurements were made in quartz cells in

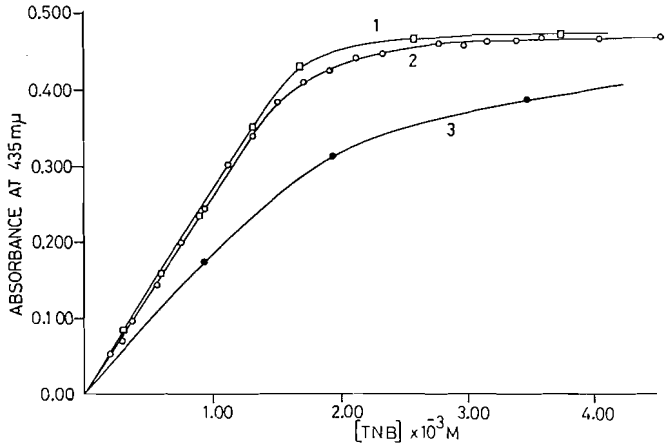

FIG. 1. Plot of absorbance *vs.* trinitrobenzene concentration at constant (1.92×10^{-3} *M*) NaOH concentration for various solvent compositions (0.1 mm cell, 25°). Curve 1, 45.3 mol % DMF; 2, 33.1 mol % DMF; 3, 18.2 mol % DMF.

the thermostatted ($25.0 \pm 0.1°$) cell compartment of a Unicam SP800 spectrophotometer or a Bausch and Lomb spectronic 600 spectrophotometer coupled to a Sargent SRL Recorder. The cuvettes used varied in pathlength between 0.1 and 10 mm, depending on the medium composition.

Results and Discussion

Spectral Characterization and Medium Dependence

The visible region spectrum of the colored solution formed between trinitrobenzene and hydroxide ion in aqueous DMF, consisting of a major peak at 435 nm and a minor, broader, peak centred near 500 nm, is ascribed to the σ-complex (Meisenheimer adduct) **1**. Under the conditions employed, with excess TNB and a moderately high DMF content, most of the hydroxide ion is present in complexed form. The molar extinction coefficient of the complex is thus readily obtained by measuring the absorbance at a given wavelength (λ_{max}) as a function of trinitrobenzene concentration, while keeping the base concentration constant (0.002 *M*). The application of this "overload" method to several solvent compositions is shown in Fig. 1. The curves level off at a progressively lower ratio of [TNB]:[NaOH] as the media become richer in DMF, indicating the trend in the magnitude of the equilibrium constant with changing solvent composition. However, this limiting absorbance method was not applicable to media containing less than *ca.* 20 mol % DMF because of the limited solubility of TNB in these more aqueous solutions, combined with the lower magnitude of the equilibrium constant.

The extinction coefficient data and the absorption maxima for media covering the range 18–80 mol % DMF, determined in the manner described above, are presented in Table 1. The usual relationship between the absorbance (A), molar extinction (ε), concentration (c), and cell pathlength (b), was used in the calculations ($A = \varepsilon cb$). It is apparent that there is a slight but definite increase in the extinction coefficients as the DMF content increases, though the ratio of the extinctions at the primary and secondary maxima remains constant. This relationship between the extinction coefficients at the two maxima and the medium composition, expressed as mol %, is approximately linear. Also, whereas the primary spectral maximum is independent of solvent composition, the secondary maximum exhibits a shift to longer wavelengths as the DMF content is increased.

The stoichiometry of the complex, determined by application of the method of continuous variations (13), was found to be 1:1 for 45 and 13 mol % DMF. Application of the slope-ratio method (13) also gave results indicating a 1:1 complex in these systems. The above methods do not distinguish whether or not there is more than a single 1:1 complex present. However, there have been numerous n.m.r. studies in recent years (1–5, 14–17), involving trinitrobenzene (albeit in other solvent systems and with other bases) which have given conclusive

*For DMF = 0.75, 1.2, and 2.5 mol %, [NaOH] was 1.00×10^{-3} *M*, otherwise 1.95×10^{-3} *M*.
†Saturated with trinitrobenzene.
‡K_{eq} was not large enough in this solvent region to allow direct measurement of ε.
§Measurements made with Me_4NOH.

evidence for formation of complexes such as **1**. It is reasonable then to conclude that there is only one such complex formed in the aqueous DMF system and that its structure is given by **1**.

Equilibrium Constants and Medium Dependence

Two methods were utilized to evaluate the equilibrium constants for σ-complex formation between trinitrobenzene and hydroxide ion as a function of DMF content. In the first, K_{eq} was calculated by means of eq. 2 which

$$[2] \quad K_{eq} = \frac{A}{\varepsilon b}([TNB]_{stoich} - A/\varepsilon b)^{-1} \times ([NaOH]_{stoich} - A/\varepsilon b)^{-1}$$

is obtained by substituting in the usual expression $K_{eq} = [TNB{\cdot}OH^-]/[TNB]_{eq}\,[NaOH]_{eq}$ for the equilibrium concentration of complex, *i.e.* $[TNB{\cdot}OH^-] = A/\varepsilon b$. The absorbances, A, corresponding to cell pathlengths, b, are given in Table 2. The results were determined as described in the previous section but equal concentrations of trinitrobenzene and sodium hydroxide (2×10^{-3} *M*) were used, in accord with recommended procedure (13). The extinction coefficient values, ε, for media containing less than 20 mol % DMF were obtained by extrapolation of the linear plot of ε *vs.* mol % DMF derived from Table 1. The error in K_{eq}, as estimated from eq. 2 based on an error of ± 3% in the measured absorbance value, is about ± 10% for $K_{eq} \leqslant 10^3$ but increases to about ± 100% for $K_{eq} \geqslant 10^4$. The limit of applicability of the method was hence taken as corresponding to $K_{eq} \approx 10^4$.

The second procedure, proposed by Foster and Matheson (18), is based on use of eq. 3.

$$[3] \quad \frac{b[TNB]_{stoich}}{A} = \frac{1}{\varepsilon} + \frac{1}{K_{eq}^{1/2}\varepsilon^{1/2}}\left(\frac{b}{A}\right)^{1/2}$$

The method involved measurement of the absorbance of solutions containing equal but variable concentrations of TNB and base (*ca.* 5×10^{-4} to 5×10^{-3} *M*). For this work Me_4NOH was the base used. In the graphical analysis of the data (18), plots of $b[TNB]_{stoich}/A$ *vs.* $(b/A)^{1/2}$ should be linear with slope $1/(K^{1/2}\varepsilon^{1/2})$ and intercept $1/\varepsilon$. In practise it was found that satisfactory plots could not be obtained for media containing more than *ca.* 30 mol % DMF; the reason was the appearance of a distinct upward curvature in these graphs at the lower concentrations of each set of data, combined with considerable scatter, arising at least in part from the great magnitude of K_{eq}.

10.9	—	—	1.53×10^2†
13.0	1.537 ± 0.020	0.100	3.15×10^2
18.2	0.279 ± 0.006	0.0104	1.16×10^3
22.1	—	—	3.30×10^3†
24.8	0.380 ± 0.008	0.0104	3.86×10^3
33.1	0.436 ± 0.006	0.0104	9.8×10^3
33.8	—	—	*ca.* 2×10^4†

*Stoichiometric [TNB] = 2.00×10^{-3} *M*, stoichiometric [NaOH] = 1.98×10^{-3} *M*; absorbance given is mean of triplicate runs.
†Determined by the method of Foster and Matheson (18), Me_4NOH was the base.

However, where acceptable plots were obtained, the K_{eq} calculated from the slope plus the appropriate ε value from Table 1 was in good agreement with the values obtained by the first method, as seen in Table 2. However, qualitatively, K_{eq} appears to be at least 10^5 by 50 mol % DMF.

The K_{eq} data in the region of low DMF composition may be extrapolated to the pure aqueous medium to yield the value $K_{eq} = 3.0 \pm 0.2$ l mol^{-1}. In a study of the trinitrobenzene–hydroxide ion system in aqueous solution, Abe (19) obtained the value $K_{eq} = 2.7$ l mol^{-1} by using a low (*ca.* 10^{-5} *M*) concentration of trinitrobenzene and excess of hydroxide. A revised value of 3.2 l mol^{-1} is obtained from the data of Gold and Rochester (20)[1]. (Both Abe (18) and Gold and Rochester (20) found evidence for a significant 2:1 OH^-:TNB interaction at very large ratios ($>10^3$) of hydroxide ion to trinitrobenzene.) Bernasconi (21) reports the value $K_{eq} = 3.7 \pm 0.4$ l mol^{-1} at 25°, as obtained from kinetic studies by fast reaction techniques of the forward and reverse reaction rates for eq. 1, with NaOH in excess over TNB and an ionic strength (NaCl) of 1.0 *M*.

The observed increase in K_{eq} with increasing DMF content is large indeed, covering over three powers of ten just over the range 0–25 mol (60 vol) % DMF. In previous studies (22, 23) of the effect of medium on Meisenheimer complex formation by trinitrobenzene (using other anions and different media) large increases in K_{eq} were also observed. It was concluded (23) that the dominant factor was desolvation of the small anionic reagent upon complex formation. In the present case, the increase in K_{eq} is thus ascribed to progressive desolvation of the small ("hard" in HSAB theory (24)) hydroxide ion, aided by some increased solvation of the large, polarizable ("soft") σ-complex as the aqueous component is replaced by the dipolar aprotic component (25, 26). This is in agreement with the conclusion drawn in an H_- study of proton abstraction equilibria by hydroxide ion in DMF–water mixtures (27), that DMF is a poor hydrogen-bond donor toward hydroxide ion but a strong hydrogen-bond acceptor from solvent water. In these properties DMF closely resembles DMSO and similar dipolar aprotic solvents (25–27).

[1]Gold and Rochester (20) quoted the value 2.7 l mol^{-1} using an approximate extinction coefficient of 30 000 for the complex. However, the current work yields, through extrapolation of the data in Table 1, a value of 24 700 for ε. A recalculation of the data of Gold and Rochester then leads to $K_{eq} = 3.2$.

Reactions of Thiyl Radicals. VIII. Photolysis of Methyl Ethyl Sulfide Vapor[1]

D. R. TYCHOLIZ AND A. R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received November 12, 1971

Methyl ethyl sulfide has been photolyzed in the vapor phase with wavelengths between 2000 and 2350 Å and the effects of pressure, temperature, and exposure time investigated. The vapor phase absorption spectrum of the sulfide has been determined and the variation in the nature and rates of formation of products in the presence of CO_2, CF_4, propylene, and 2-pentene measured. Quantum yields of products from the decomposition of the pure substrate were determined at 2288 Å.

The products of the reaction are, in order of decreasing importance, C_2H_6, $CH_3SSC_2H_5$, $C_2H_5SSC_2H_5$, CH_4, CH_3SCH_3, $C_2H_5SC_2H_5$, C_3H_8, C_2H_4, CH_3SSCH_3, C_4H_{10}, C_2H_5SH, and CH_3SH. A carbon/sulfur mass balance is obtained at all substrate pressures at 25 °C, and at the single substrate pressure examined at 120 °C. In the presence of propylene four additional products, n-C_5H_{12}, $CH_3S(CH_2)_2CH_3$, $(CH_3CH_2CH_2)_2S$, and $CH_2{=}CH{-}CH_2SC_2H_5$, were found.

Only a small fraction of photochemically excited methyl ethyl sulfide molecules undergoes chemical decomposition. The two primary processes

[3*a*] $$CH_3SC_2H_5 + h\nu \rightarrow CH_3 + C_2H_5S$$

[3*b*] $$CH_3SC_2H_5 + h\nu \rightarrow CH_3S + C_2H_5$$

and subsequent reactions of the radicals so formed account for the observed products. R_{3a}/R_{3b} has a value of 1.32 at 25 °C.

Le sulfure d'éthyle et de méthyle a été photolysé en phase vapeur avec des longueurs d'onde comprises entre 2000 et 2350 Å et les effets de la pression, température, et durée d'exposition ont été examinés. Le spectre d'absorption en phase gazeuse du sulfure a été déterminé et la variation, dans la nature et dans les vitesses de formation des produits en présence de CO_2, CF_4, propylène, et pentène-2, mesurée. Les rendements quantiques en produits, à partir de la décomposition du substrat pur, ont été déterminés à 2288 Å.

Les produits de la réaction sont, par ordre d'importance décroissante, C_2H_6, $CH_3SSC_2H_5$, $C_2H_5SSC_2H_5$, CH_4, CH_3SCH_3, $C_2H_5SC_2H_5$, C_3H_8, C_2H_4, CH_3SSCH_3, C_4H_{10}, C_2H_5SH, et CH_3SH. Une balance en masse carbone/soufre est obtenue pour toutes les pressions du substrat à 25 °C et pour une seule à 120 °C. En présence de propylène quatre produits supplémentaires ont été obtenus: n-C_5H_{12}, $CH_3S(CH_2)_2CH_3$, $(CH_3CH_2CH_2)_2S$, et $CH_2{=}CH{-}CH_2SC_2H_5$. Seule une petite fraction de sulfure d'éthyle et de méthyle photochimiquement excitée, subit une décomposition chimique. Les deux processus primaires

[3*a*] $$CH_3SC_2H_5 + h\nu \rightarrow CH_3 + C_2H_5S$$

[3*b*] $$CH_3SC_2H_5 + h\nu \rightarrow CH_3S + C_2H_5$$

et les réactions ultérieures des radicaux ainsi formés, rendent compte des produits observés. R_{3a}/R_{3b} a une valeur de 1.32 à 25 °C.

Canadian Journal of Chemistry, **50**, 1734 (1972)

Introduction

There has been only one reported investigation of the photochemistry of methyl ethyl sulfide. Milligan *et al.* (1) irradiated liquid $CH_3SC_2H_5$ at 2537 Å for 48 h. They reported CH_4, C_2H_6, and C_2H_4 in the ratio 60:35:5 along with CH_3SSCH_3, $C_2H_5SSC_2H_5$, $CH_3SSC_2H_5$, and trace amounts of CH_3SCH_3.

The photolysis of dimethyl sulfide vapor has recently been studied (2) and it was found that the main products of the reaction were CH_4, C_2H_6, CH_3SSCH_3, and CH_3SH. The thiol was a minor product indicating that disproportionation of RS radicals was relatively unimportant in that system. Evidence was also obtained that indicated the formation of hot CH_3 and CH_3S radicals in the primary process which involves scission of the S—C bond.

As part of a continuing series of investigations of the photochemical kinetics and mechanism of compounds that yield thiyl radicals on photolysis, we have examined in detail, and report on here, the vapor phase photolysis of methyl ethyl sulfide. This substrate has the advantage of

allowing the reactions of both methylthiyl and ethylthiyl radicals to be examined simultaneously.

Experimental

The photolyses were conducted in a conventional high vacuum system described previously (3). The light source was a Hanovia 30620 medium pressure mercury lamp filtered to remove wavelengths less than 2000 Å. The demountable reaction cell was a quartz cylinder, 5 cm o.d. and 10 cm in length with plane windows. The absorption spectrum of the substrate was determined using a Zeiss Model PMQ-II spectrophotometer fitted with a 1 m path length gas cell connected to the vacuum system.

Methyl ethyl sulfide (99.96 ± 0.04% purity American Petroleum Institute standard sample) was degassed and used without further purification after g.c. analysis indicated the absence of detectable impurities. Carbon dioxide (Canlab), carbon tetrafluoride (Matheson), and 2-pentene (Matheson, Coleman, and Bell) were degassed and purified by trap-to-trap distillation. Gas chromatographic analysis of samples of each of these addends confirmed the absence of detectable impurities.

Reaction products were identified initially by comparison of g.c. retention times and each identification was subsequently confirmed by mass spectrometric analysis of each product trapped from the g.c. effluent.

At the conclusion of reactions involving only the substrate, CH_4 was removed at −196 °C and determined in a gas burette, C_2H_6 and C_2H_4 were removed at −160 °C and analyzed on a 6 ft Poropak Q column, and the remaining fraction, including unreacted substrate, was analyzed using a 12 ft tricresyl phosphate column. When CO_2 was present, CH_4, C_2H_6, and C_2H_4 were removed first and then CO_2 was pumped off, along with C_3H_8, C_4H_{10}, and CH_3SH (products not analyzed in that series) at −130 °C and the remaining products analyzed as before. In experiments with added CF_4, the addend was pumped off at −183 °C along with CH_4 and C_2H_4 which were not determined, and the remainder of the analyses carried out as in pure substrate experiments. When propylene was added, it was removed at the end of the reaction, along with the undetermined products CH_4, C_2H_4, C_2H_6, C_3H_8, and C_4H_{10}, at −130 °C before the remaining products were analyzed on the g.c. The only products analyzed in the experiments with added 2-pentene were CH_4 in the gas burette and C_2H_4, C_2H_6, and C_3H_8, which were removed at −130 °C.

For the actinometry experiments, the light source was fitted with a Baird Atomic interference filter which had a 60 Å pass band centered at 2288 Å. The photolysis of diethyl ketone at 165 °C was used to determine the light intensity, taking Φ(CO) as unity at a ketone pressure of 29 Torr. The percent absorption by both substrate (100%) and actinometer (1.5%) was determined using the Zeiss spectrophotometer and the reaction cell employed in the actinometry experiments. The absorbed light intensity was found to be 6.7×10^{-6} μeinsteins/s and thus 40 h runs were required to obtain sufficient products for analysis.

Results

The absorption spectrum of methyl ethyl sulfide vapor is shown in Fig. 1. The band centered at 2225 Å would correspond to the principal photochemically effective absorption with the filtered light source used here. The absorption may be ascribed, by analogy with the interpretation of the dimethyl sulfide spectrum (4), to excitation of a non-bonding electron from the S-atom to an antibonding orbital of a C—S bond.

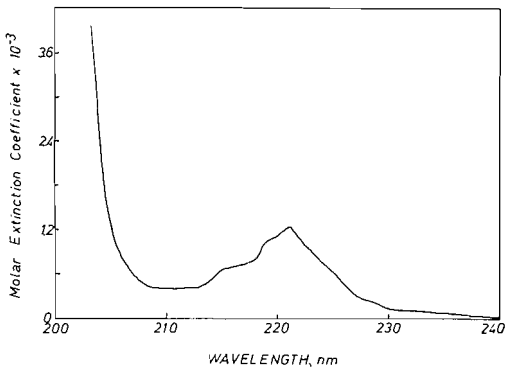

FIG. 1. The u.v. absorption spectrum of methyl ethyl sulfide vapor. The units of the molar extinction coefficient are l/mol cm.

It is apparent from Fig. 1 that although there is some suggestion of structure that might be observable at higher resolution, the spectrum does not exhibit the pronounced vibrational structure reported (5) and analyzed (4) for dimethyl sulfide and found in the present investigation when the CH_3SCH_3 spectrum was redetermined for comparison. The general similarity of the two spectra, however, would suggest that the same kind of bound state is involved in both compounds, but that the larger number of degrees of vibrational freedom in $CH_3SC_2H_5$ has the effect of increasing vibrational band overlap complexity to the extent that the fine structure could be discerned only under high resolution.

The room temperature photolysis of $CH_3SC_2H_5$ in the vapor phase yields the following detectable products, listed in order of decreasing rate of formation: C_2H_6, $CH_3SSC_2H_5$, $C_2H_5SSC_2H_5$, CH_4, CH_3SCH_3, $C_2H_5SC_2H_5$, C_3H_8, C_2H_4, CH_3SSCH_3, C_4H_{10}, C_2H_5SH, and CH_3SH. To test observed yields for a mass balance in carbon and sulfur, a rate for carbon containing products, R_C, may be evaluated on the basis of eq. 1, while a rate for sulfur con-

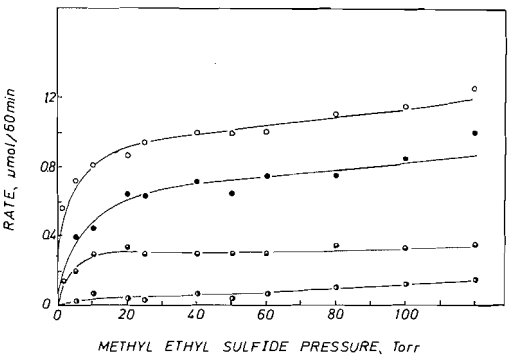

FIG. 2. Rate of formation of C_2H_6, ○; CH_4, ●; C_2H_4, ◒; and CH_3SH, ◑; in the photolysis of $CH_3SC_2H_5$ vapor at 25 °C for 60 min, as a function of substrate pressure.

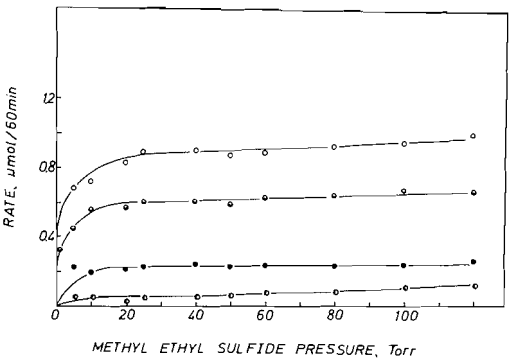

FIG. 3. Rate of formation of $CH_3SSC_2H_5$, ○; CH_3SCH_3, ◒; CH_3SSCH_3, ●; and C_2H_5SH, ◐; in the photolysis of $CH_3SC_2H_5$ vapor at 25 °C for 60 min as a function of substrate pressure.

$$[1]\quad R_C = 2R_{C_2H_6} + 3R_{CH_3SSC_2H_5} + 4R_{C_2H_5SSC_2H_5} + R_{CH_4} + 2R_{CH_3SCH_3} + 4R_{C_2H_5SC_2H_5} + 3R_{C_3H_8} + 2R_{C_2H_4} + 2R_{CH_3SSCH_3} + 4R_{C_4H_{10}} + 2R_{C_2H_5SH} + R_{CH_3SH}$$

taining products, R_S, may be calculated from eq. 2. For total rates defined in this way, the

$$[2]\quad R_S = 2R_{CH_3SSC_2H_5} + 2R_{C_2H_5SSC_2H_5} + R_{CH_3SCH_3} + R_{C_2H_5SC_2H_5} + 2R_{CH_3SSCH_3} + R_{C_2H_5SH} + R_{CH_3SH}$$

stoichiometry of $CH_3SC_2H_5$ decomposition requires that $R_C = 3\ R_S$. This test would, however, be insensitive to products in which the C:S ratio is 3:1, for example, the dimer of the substrate radical formed by H-atom abstraction, $C_2H_5SC_2H_4SC_2H_5$ and its isomers.

Figs. 2, 3, and 4 show the rates of formation of the 12 products from the photolysis at 25 °C as a function of methyl ethyl sulfide pressure. The most significant alteration in rates occurs in the 0–25 Torr range, and this may be ascribed to increasing absorption in the cell. The changes that occur in product rates at higher pressures are considerably less pronounced. Calculation of R_C and R_S at 25 Torr sulfide and at 100 Torr sulfide indicates that there is an acceptable mass balance among the analyzed products. Thus at $P(CH_3SC_2H_5) = 25$ Torr, $R_C = 13.9$ μmol/h while $3\ R_S = 14.3$ μmol/h; at $P(CH_3SC_2H_5) = 100$ Torr, $R_C = 16.5$ μmol/h, and $3\ R_S = 15.9$ μmol/h. Considering the experimental error in the determination of individual product yields,

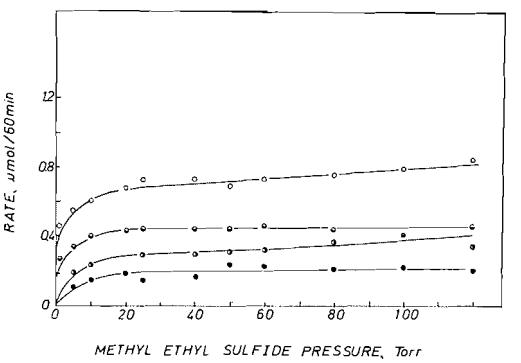

FIG. 4. Rate of formation of $C_2H_5SSC_2H_5$, ○; $C_2H_5SC_2H_5$, ◒; C_3H_8, ◑; and C_4H_{10}, ●; in the photolysis of $CH_3SC_2H_5$ vapor at 25 °C for 60 min as a function of substrate pressure.

inordinate significance should not be attached to the agreement in the carbon–sulfur balance, although the data do indicate that there are no additional major volatile products that were not detected and analyzed.

A series of experiments was carried out in which the yields of all products were determined as a function of exposure time. A representative graph giving the amount of $C_2H_5SSC_2H_5$, C_3H_8, C_4H_{10}, and C_2H_5SH formed at each exposure time studied is given in Fig. 5.[2] The yields of CH_3SCH_3, $C_2H_5SC_2H_5$, CH_3SSCH_3, and C_2H_4 were found to be linearly dependent on time. The products CH_4 and C_2H_6 appear to

[2]The yield curves for the other products have been placed in and may be obtained from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

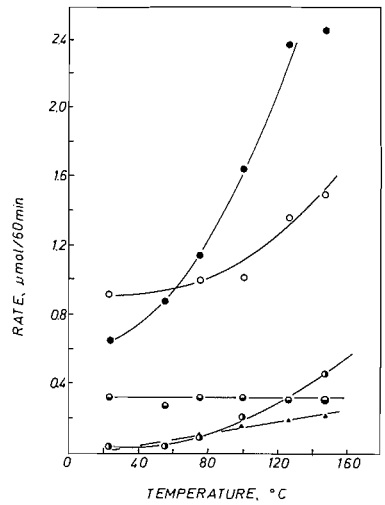

FIG. 6. Rate of formation of C_2H_6, ○; CH_4, ●; C_2H_4, ◒; CH_3SH, ◑; and $CH_3SCH(CH_3)_2$, ▲; as a function of temperature for the photolysis of 25 Torr methyl ethyl sulfide for 60 min.

be formed at a slightly increased rate after the first 30 min of reaction, while $CH_3SSC_2H_5$ shows a slight decrease in rate at longer exposure times. Ethanethiol exhibits the same behavior as CH_3SH, its rate increasing very slowly in the later stages of the reaction. This trend may result from H-atom abstraction reactions involving consumption of these products with labile hydrogen atoms by the various radicals in the system, which reactions would be expected to become more important at longer exposure times. The increase in C_3H_8 yield with time appears to drop off somewhat with time, to an extent comparable to the change in methane and ethane yields. The calculated percent decomposition in this run indicated that at 60 min, 2.03% of the substrate has reacted.

When the photolysis was studied as a function of temperature two additional products, $CH_3SCH(CH_3)_2$ and $CH_3SC_2H_4SCH_3$ were found in measurable quantities. Because of its relatively small yield it is not possible to determine definitely if methyl isopropyl sulfide is formed in the room temperature reaction. Although the yield of 2,5-dithiahexane is larger, its g.c. retention time is 2 h on the temperature programmed tricresyl phosphate column and accurate area determination is difficult. Therefore there was considerable scatter in the rate values obtained, but an extrapolation of an approximate rate *vs.* temperature plot for this product indicates that its rate at room temperature is finite.

The rates of product formation as a function of temperature were determined and a representative graph of these results is given in Fig. 6[3] for C_2H_6, CH_4, C_2H_4, CH_3SH, and $CH_3SCH(CH_3)_2$. The only other product that shows a significant increase in rate as the temperature is raised is C_2H_5SH. The stoichiometric calculations described by eqs. 1 and 2, modified to include the rate of $CH_3SCH(CH_3)_2$ formation, but not that of 2,5-dithiahexane, show that at 120 °C, $R_C = 12.9$ and $3R_S = 11.6$. The data for 2,5-dithiahexane were rather scattered; however, if a value of 0.32 μmol/60 min is taken for R(2,5-dithiahexane), the observed values being 0.21 at 99 °C and 0.39 at 147 °C, and eqs. 1 and 2 further modified to include that product, $R_C = 14.2$ and $3R_S = 13.5$.

The stoichiometric calculations show that the net effect of temperature is to alter product distribution without appreciably affecting the total rate of product formation. Thus at 25 °C and 25 Torr substrate the mean R_C, $3R_S$ value is 14.1 compared to the value of 13.8 at 25 Torr substrate and 120 °C. Again the uncertainty in these values must be considered, but the agreement obtained indicates the strong likelihood of a reasonable actual mass balance in the analyzed products.

[3]The rate *vs.* temperature plots for the other products have been placed in and may be obtained from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

*Exposure time, 60 min; temperature, 25 °C; methyl ethyl sulfide pressure, 25 Torr.

For the four products arising from primary radicals and whose rate increases with temperature the Arrhenius plots are linear[4] and apparent activation energies have been determined as follows: CH_4, 2.75; C_2H_6, 1.10; CH_3SH, 6.22 and C_2H_5SH, 3.55 kcal/mol.

To assess the possible participation in this system of excited species susceptible to collisional deactivation, two series of experiments were carried out with inert addends. Because of the wide range of vapor pressures among the products it was not possible to study the effect of a single addend on all products. In the first series for which the results are summarized in Table 1, the effect of CF_4 on the yields of all products except CH_4 and C_2H_4 was determined. Table 2 lists the results of a series of runs in which the sulfur containing products, and CH_4, were determined as a function of pressure of added CO_2. The data indicate that there is a pronounced dependence on addend pressure of CH_4 and C_2H_6 rates. The rates of formation of other products are affected as well but to a much smaller extent. Stoichiometric analysis of the data shows, however, that there is a relatively small decrease in the total detectable product yields. The experimental error in determining product yields is larger here than in other runs where the separation of a large amount of addend was not required. In applying eqs. 1 and 2, therefore, average values for product rates in the addend pressure range 500 to 900 Torr were employed. These data give $R_C = 11.6$ and 3 $R_S = 11.7$, compared to $R_C = 14.1$ for 25 Torr of substrate alone, and thus indicate that at the highest pressure examined the total amount of detectable decomposition might be decreased by up to about 20%.

Because of the evident production of both CH_3 and C_2H_5 radicals in this system, and the possibility of production of sulfur atoms in either the primary process or from the decomposition of excited sulfide molecules formed in radical recombination processes, the nature of products and, to a limited extent, rates of product forma-

[4]The value for $R(CH_4)$ at 147 °C would appear to be in error, since the other five values from Fig. 6 lie on a straight line in the Arrhenius plot.

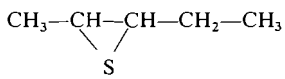
tion were studied in the presence of olefins. If sulfur atoms are formed in either the triplet or singlet state, their presence would be manifested by the production of episulfides via the well established S—atom–olefin addition raction (6).

The most detailed investigations were done with propylene where the rates for all sulfur containing products were determined. The formation of propylene episulfide was not observed. Four additional analyzable products, however, were found, n-C_5H_{12}, $CH_3S(CH_2)_2CH_3$, $(CH_3CH_2CH_2)_2S$, and a product tentatively identified as $CH_2{=}CH{-}CH_2SC_2H_5$. The latter product exhibited a mass spectrum that is also consistent with methyl ethyl ethylene episulfide. The identification of this product as the unsaturated sulfide is based on the relatively large yield of this material in the presence of propylene combined with the fact that a rather complex series of reactions, involving initially propylene episulfide formation (which should therefore have been detected), would be required to explain the formation of



The rates of formation of these new products are shown in Fig. 7, as a function of olefin pressure. Table 3 lists the rates of the other sulfur containing products.

To investigate the effect of olefin on the hydrocarbon products of the reaction, the rates of CH_4, C_2H_4, C_2H_6, and C_3H_8 formation were determined in the presence of 2-pentene. These results are listed in Table 4. No search was made for additional products with this olefin.

Finally, utilizing filtered light at 2288 ± 30 Å the quantum yields of formation of the products whose yields are sufficiently large for accurate

analysis in the small percent conversion runs involved in the low intensity actinometry runs, were determined at two substrate pressures. The results are listed in Table 5. The observed quantum yields follow the same general trend as the rates determined with the full lamp spectrum at appreciably higher effective intensity. Of the products determined, only ethane shows a significant increase in quantum yield as the substrate pressure is increased from 50 to 120 Torr.

Discussion

The low quantum yields observed in the decomposition, together with the observation of a mass balance among the products of the reaction and the spectroscopic indications of a bound state attained on absorption suggest that energy dissipation in the methyl ethyl sulfide molecule occurs primarily by routes other than photochemical decomposition. Elucidation of these processes will require further investigation of the photophysical aspects of the system.

The nature of the observed products is evidence for the occurrence of two primary processes (eqs. 3*a* and *b*) involving C—S bond cleavage. Assuming that no products involving RS radicals

[3*a*] $CH_3SC_2H_5 + h\nu \rightarrow CH_3 + C_2H_5S$

[3*b*] $CH_3SC_2H_5 + h\nu \rightarrow CH_3S + C_2H_5$

other than those detected in this study are formed, the observed rates for sulfur containing products can be utilized to estimate the relative importance of the two primary steps via eq. 4. The equation is set up on the assumption that the thiols, whose rates represent the maximum contribution from thiyl radical disproportionation, arise solely from H-atom abstraction. These rates are relatively minute, however, and even if both thiols were formed solely by disproportionation, the resulting error in calculated R_{3a}/R_{3b} values would be less than 1%. The two terms in eq. 4 that cannot be determined experimentally are the rates of the substrate reforming reactions, eqs. 5 and 6. In the absence of the

[5] $CH_3 + C_2H_5S \rightarrow CH_3SC_2H_5 \qquad R_{[5]} = R'_{CH_3SC_2H_5}$

[6] $CH_3S + C_2H_5 \rightarrow CH_3SC_2H_5 \qquad R_{[6]} = R''_{CH_3SC_2H_5}$

required data, it is assumed that R_5 and R_6 are the same, and are equal to the average of the rates of the combination of CH_3 and CH_3S radicals, $R_{CH_3SCH_3}$, and the combination of C_2H_5 and C_2H_5S radicals, $R_{C_2H_5SC_2H_5}$.

With these assumptions and calculating from the data presented in Figs. 2, 3, and 4 and the rate data determined at 120 °C the values obtained for R_{3a}/R_{3b} are 1.31 and 1.33 at substrate pressures of 25 and 100 Torr at 25 °C, and 1.10 for 25 Torr substrate at 120 °C. Thus at room temperature reaction 3*a* accounts for 57% of the primary decomposition, while 43% proceeds via 3*b*. Presumably the more equal rates for the two primary steps observed at 120 °C reflect a decrease in specificity associated with increased energy input to the system.

The four radicals produced in the primary processes all apparently undergo, in addition to other processes to be considered below, abstraction reactions involving the substrate and it is useful to consider these reactions separately. Representing CH_3, CH_3S, C_2H_5, and C_2H_5S as X, the three possible abstraction processes can be written as eqs. 7*a–c*. The observation that as

[7*a*] $X + CH_3SC_2H_5 \rightarrow \dot{C}H_2SC_2H_5 + XH$

[7*b*] $X + CH_3SC_2H_5 \rightarrow CH_3S\dot{C}HCH_3 + XH$

[7*c*] $X + CH_3SC_2H_5 \rightarrow CH_3SCH_2\dot{C}H_2 + XH$

[4] $$\frac{R_{3a}}{R_{3b}} = \frac{R_{C_2H_5SH} + R_{C_2H_5SC_2H_5} + 2R_{(C_2H_5S)_2} + R_{CH_3SSC_2H_5} + R'_{CH_3SC_2H_5}}{R_{CH_3SH} + R_{CH_3SCH_3} + 2R_{(CH_3S)_2} + R_{CH_3SSC_2H_5} + R''_{CH_3SC_2H_5}}$$

$$[8]\qquad \frac{R_{3a}}{R_{3b}} = \frac{R_{CH_4} + 2R^{c}_{C_2H_6} + R_{C_3H_8} + R_{CH_3SCH_3} + R'_{CH_3SC_2H_5}}{R^{ad}_{C_2H_6} + R_{C_2H_4} + 2R_{C_4H_{10}} + R_{C_3H_8} + R_{C_2H_5SC_2H_5} + R''_{CH_3SC_2H_5}}$$

reaction temperature is increased the product that appears in measureable quantities first is $CH_3SCH(CH_3)_2$ is evidence that reaction 7*b* may be the most important. This is consistent with the expectation that on energetic grounds the methylene H-atom would be most susceptible to abstractive attack.

Methyl isopropyl sulfide, however, is the only observed product formed by substrate radicals. Comparing its yield to the total yield of XH type products indicates that only a small fraction of CH_3SCHCH_3 and its isomers produced in reaction 7 are accounted for. As indicated in the discussion of the stoichiometric calculations, the recombination products would not affect the mass balance, nor would they likely be detected in the present system. In addition, there may be yields, below the detection limit, of the recombination or disproportionation of substrate radicals with other radicals in the system.

Some information about the relative contributions of the various processes, including reactions 7*a–c*, giving rise to the important products methane and ethane can be obtained from the stoichiometry and the values of R_{3a}/R_{3b} calculated from the yields of sulfur containing products. The primary process rate ratio may also be calculated from the rates for products consuming CH_3 and C_2H_5 radicals using eq. 8, where $R'_{CH_3SC_2H_5}$ and $R''_{CH_3SC_2H_5}$ are defined and estimated as outlined for eq. 4. The indicated rates of formation of ethane are related by eq. 9, which represents the observed rate of

$$[9]\qquad R^{t}_{C_2H_6} = R^{c}_{C_2H_6} + R^{ad}_{C_2H_6}$$

ethane formation, $R^{t}_{C_2H_6}$, as the sum of the rate of methyl recombination, $R^{c}_{C_2H_6}$, and the combined rates of ethane formation in reactions 7*a–c* and the disproportionation of C_2H_5 radicals with themselves and other radicals in the system, $R^{ad}_{C_2H_6}$. Again using the appropriate rate values along with the corresponding R_{3a}/R_{3b} values calculated above, eqs. 8 and 9 can be solved for $R^{ad}_{C_2H_6}$. The values calculated are 0.46 and 0.55 μmol/h for 25 and 100 Torr substrate at 25 °C. If the rate of disproportionation reactions involving ethyl radicals is independent of substrate pressure, the increase in $R^{ad}_{C_2H_6}$ would be consistent with the expected higher rate of H-atom abstraction as the concentration of substrate increases. From the data at 120 °C, the calculation indicates that $R^{c}_{C_2H_6}$ is zero within experimental error. The observed ethane yield at the higher temperature would thus apparently arise virtually in total from abstraction and disproportionation, consistent with the expected increase in abstraction with increasing temperature. The effect is of sufficient magnitude to be reflected in a decrease in the rate of C_4H_{10} as an increasing proportion of C_2H_5 radicals are involved in reactions 7*a–c*. The decline of $R^{c}_{C_2H_6}$ to zero within experimental error at 120 °C indicates that H-atom abstraction by CH_3 radicals is the most important source of methane at this temperature.

Production of C_3H_8 involves presumably CH_3 and C_2H_5 radicals and its decrease in rate from 0.30 μmol/h at 25 °C to 0.05 μmol/h at 120 °C is further evidence for an increase, in the case of both radicals, of the rate of abstractive processes compared to radical–radical reactions.

The observed deactivating effect of inert addends and the apparent activation energies determined from the temperature studies indicate the presence of excited species in this system. The average energy of incident quanta in the photolysis is *ca.* 125 kcal/mol, about 50 kcal/mol in excess of C—S bond energies in the methyl sulfide molecule. With the possible exception of E_a for CH_3SH formation, the apparent activation energies for XH type products formed in reactions 7*a–c* are appreciably less than would be expected for thermalized species. However, energy partitioning is evidently not on a simple mass basis since activation energies for the formation of C_2H_6 and C_2H_5SH are less than those for CH_4 and CH_3SH.

The approximately 20% decrease in total observable decomposition found at the highest addend pressures studied may be due to a limited contribution from a process in which the electronic excited state of the substrate attained in the absorption process is deactivated.

The formation of the observed reaction products can be explained on the basis of reactions 7*a–c* and radical–radical reactions, eqs. 10–20.

[10] $CH_3 + CH_3 \rightarrow C_2H_6$

[11] $CH_3 + C_2H_5 \rightarrow C_3H_8$

[12] $CH_3 + C_2H_5 \rightarrow CH_4 + C_2H_4$

[13] $CH_3 + CH_3S \rightarrow CH_3SCH_3$

[14] $C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$

[15] $C_2H_5 + C_2H_5 \rightarrow C_2H_6 + C_2H_4$

[16] $C_2H_5 + C_2H_5S \rightarrow C_2H_5SC_2H_5$

[17] $CH_3S + CH_3S \rightarrow CH_3SSCH_3$

[18] $CH_3S + C_2H_5S \rightarrow CH_3SSC_2H_5$

[19] $C_2H_5S + C_2H_5S \rightarrow C_2H_5SSC_2H_5$

[20] $CH_3 + CH_3SCHCH_3 \rightarrow CH_3SCH(CH_3)_2$

On the basis that a satisfactory mass balance is obtained among the reaction products, the disproportionation processes that would be alternatives to reactions 13 and 16, leading to the thioaldehyde and hydrocarbon, and to reactions 17, 18, and 19, leading to thioaldehyde and thiol, have not been included as significant reactions in the system. Although the small contribution that might be made by the former two reactions cannot be determined from the data available, the relative yields of RSH and RSSR products give an upper limit for the contribution from thiyl radical disproportionation. Thus comparing the total thiol yields with those of the three disulfides at 25 °C gives maximum R_d/R_c ratios of 0.067 at 25 Torr methyl ethyl sulfide and 0.12 at 100 Torr substrate pressure. In view of the evidence in favor of H-atom abstraction as an important source of RSH at room temperature, the actual extent of radical disproportionation is likely appreciably less than suggested by the calculated R_d/R_c ratios. This is in accord with evidence obtained in the photolysis of dimethyl sulfide (2) and methyl disulfide (3) for a minor role for thiyl radical disproportionation. At 120 °C, the thiol:disulfide rate ratio is 0.55, but this reflects the increased importance of RS abstraction since the disproportionation process will be temperature insensitive.

The additional products found in the presence of propylene may be explained in part on the basis of reactions 21–26, where X is any of the primary radicals in the system and RH is any H-atom source, including the substrate. The mechanism of dipropyl sulfide formation is not immediately apparent.

[21] $C_3H_6 + C_2H_5 \rightarrow C_5H_{11}$

[22] $C_5H_{11} + RH \rightarrow n\text{-}C_5H_{12}$

[23] $C_3H_6 + X \rightarrow C_3H_5 + XH$

[24] $C_3H_5 + C_2H_5S \rightarrow CH_2{=}CHCH_2SC_2H_5$

[25] $C_3H_6 + CH_3S \rightarrow CH_3SC_3H_6$

[26] $CH_3SC_3H_6 + RH \rightarrow CH_3S(CH)_2CH_3 + R$

Fig. 7 shows that the rates for the additional products are proportional to olefin pressure and that within experimental error, the rates extrapolate to zero in the absence of olefin, indicating that these products are not formed in the decomposition of the pure substrate. The data in Tables 3 and 4 illustrate that products for which formation via H-atom abstraction is important, CH_4, C_2H_6, CH_3SH, and C_2H_5SH, exhibit increases in rate as the olefin concentration, particularly in the case of 2-pentene, is increased, while other products that result from radical–radical reactions show diminished rates when the olefin is present.

The details of the reaction mechanism in the presence of olefin would require further study to elucidate the source of dipropyl sulfide and to rationalize the appearance of only a small number of the products that could possibly result from the interaction of the primary and secondary radicals with the addend. Stoichiometric calculations indicate that there are almost certainly other, higher molecular weight products that were not detected. However, the limited results with added olefin obtained here are of considerable value in providing definitive evidence against the formation of sulfur atoms in the decomposition of pure substrate.

The authors are grateful for the financial support of the research by the National Research Council of Canada. We are also indebted to Dr. P. J. Smith of this Department for assistance in the mass spectrometric analyses.

Cavitation-induced Reactions in Pure Substituted Benzenes[1]

G. K. Diedrich, P. Kruus, and L. M. Rachlis
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received January 5, 1972

The formation of polymers has been observed on exposure of pure substituted benzenes to ultrasound intense enough to cause cavitation. The products have some of the characteristics of the char obtained from low temperature pyrolysis of hydrocarbons. They are difficult to dissolve, melt above 300 °C, and give a large broad e.p.r. signal. A crude correlation between bond dissociation energy and the reaction rate suggests that the initiation reaction is a thermal decomposition in a cavitation bubble. The phenomenon is compared to radiolysis and thermal reactions.

La formation de polymères a été observée lorsque des composés purs, du type benzénique substitués, sont exposés à des ultrasons suffisamment intenses pour provoquer des cavités. Les produits obtenus ont certaines des caractéristiques des produits de carbonisation provenant de la pyrolyse à basse température d'hydrocarbures. Ils sont difficiles à solubiliser, fondent au-dessus de 300 °C, et donnent en r.p.e. un signal très large. Une corrélation grossière entre l'énergie de dissociation de liaison et la vitesse de réaction, suggère que la réaction d'initiation est une décomposition thermique dans une cafité en forme de bulle. Le phénomène est comparé aux réactions thermiques et de radiolyse.

Canadian Journal of Chemistry, **50**, 1743 (1972)

Introduction

There have been numerous studies of chemical reactions in liquids exposed to ultrasonic waves of high enough intensity to cause cavitation. El'piner (1) gives a comprehensive review of such work up to 1963. More recent reviews are given by LeBras (2) and Margulis (3). Nearly all the systems studied have been aqueous solutions. Reports of studies of cavitation-induced chemical reactions in pure organic liquids are few (4).

The mechanisms by which cavitation in a liquid could give rise to chemical reactions are reviewed by Flynn (5). When a liquid is subjected to an intense sound field, then at the rarefaction sites, holes or cavities can be formed, usually about some cavitation nucleus. The cavitation bubbles may then fill with the vapor of the liquid or dissolved gases.

The results of experiments examining variation of the chemical reaction rate with the thermal conductivity of gases saturating the liquid suggest that the chemical reactions are of a thermal origin (6, 7). On the collapse of cavitation bubbles, a high local temperature is developed, leading to chemical reactions and luminescence. An increase in the thermal conductivity in the bubble due to the presence of gas will lower the temperature which can be achieved (up to thousands of degrees (6)), and hence the rate of reaction. Other workers have only recently concluded, however, that electrical effects within the cavitation bubbles are of primary importance (8, 9).

Reactions can occur in places other than in the cavitation bubbles. Some reactions may occur due to the shock waves produced on collapse of the bubble, and products of any reaction in the cavitation bubble can cause further reactions in the bulk of the liquid. It has also been suggested that at higher frequencies, mechanisms other than cavitation may be partially responsible for chemical reactions (10).

Experimental

The following is a description of the experimental equipment and procedure used generally. Differences from this general experimental procedure will be described under the appropriate section in presentation of the results.

A Fisher–Blackstone Ultrasonic Generator (20 kc.p.s.) Model SS-2, together with a Probe, Model BP-2, were used in the cavitation experiments. The probe had a head on it which, in the case of most runs, was inserted into a glass cell as shown in Fig. 1. The whole assembly was set up in a darkened fume hood.

In most cases the runs were made with the oscillator power set on 70 (on a scale of 100) after a warm-up time of 20 min with tap water circulating through the cooling jacket. Argon gas which had passed through a P_2O_5 drying column was slowly bubbled through the cell in order to promote cavitation by providing nuclei for the formation of cavitation bubbles, and also to keep a positive pressure in the cell.

The rate of reaction was followed by withdrawing samples from the liquid at regular intervals with a syringe. Absorption

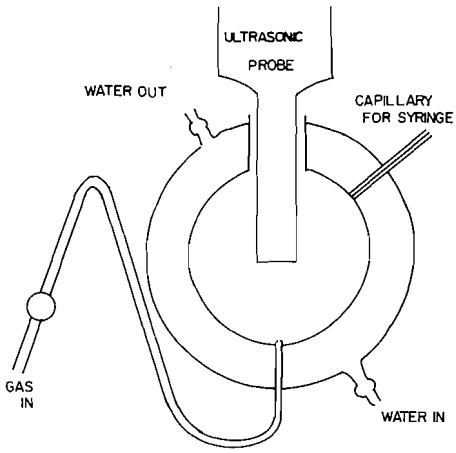

FIG. 1. Diagram of the cell.

was measured on a Perkin–Elmer 202 u.v.–visible spectrophotometer with the original liquid as both the diluent and the reference. Plots of the absorption of the wavelength of maximum absorption, corrected assuming a linear dilution relation, *vs.* the time usually showed a reasonable linear relationship. An example of such a plot is shown in Fig. 2. The scatter of the points from the straight-line relationship is typical of the runs made. Although up to 15 samples were taken for some systems to check the linearity, the rate of reaction in most cases was monitored by taking absorption measurements on only five samples. There seemed to be no change in the shape of the absorption bands as the absorption intensity increased. Plots of the area under the absorption curves *vs.* the time were also linear.

The liquids used were in most cases Fisher reagent grade which had been in storage over grade 4A molecular sieves.

Results

(a) Power Calibration

In order to estimate the acoustic power used in the experiments, measurements were made of the rate of formation of chlorine through cavitation in a saturated aqueous solution of carbon tetrachloride (11). The concentration of Cl_2 in water was determined spectrophotometrically using *o*-tolidine reagent (12).

When, for the above system, a value of 0.095 is used for the sonochemical G (11) (molecules produced per 100 eV energy absorbed), then the power level in the cavitation experiments was estimated to be about 6 acoustic W. This corresponds to an intensity level at the probe of the order of 5 W cm^{-2}.

Power levels of the same magnitude were also obtained using a far more simple technique. The temperature of a known amount of water in a dewar flask was followed for 10 min while cavitation was going on. A plot of temperature versus time was linear in all cases. The power delivered by the probe could then easily be calculated. As the temperature *vs.* time curve became sharply horizontal when the cavitation was stopped, then conduction of heat from the probe could be neglected.

Such power measurements were carried out regularly after every important run. This was necessary as the effectiveness of the probe decreased with use. After some use, the probe also did not always deliver constant power during the long periods (7 h) used for some runs. This, together with errors in dilution of the small (< 1 ml) samples withdrawn and in reading the spectrophotometer charts would seem to be the main causes of the scatter in the plots illustrated in Fig. 2.

The effect of the level of acoustic power on the rate of reaction was examined by making a series of runs with different power settings. The rate of darkening of nitrobenzene (dry, with dried argon bubbling through, at 23 ± 3 °C) was measured as well as the power delivered at the settings. The results of one series of runs indicate that there is a variation of less than 10% in the rate of reaction with power in the 5 to 8 W region, but that there is a decrease at lower power levels. Comparison with the other runs suggests, however, that unless runs are made in the same series, there may be an error of up to 20% introduced in making relative comparisons of rates. This error seemed to be due primarily to wearing out of the probe. All the runs discussed in the following sections were taken at power levels of 4.7 to 7 W with no corrections made for the differences in power levels.

(b) Effect of Water

Because it has been reported (1) that the presence of water is necessary to obtain cavitation-induced chemical reactions in most liquids, the effect of water on the rate of cavitation was examined.

Dry nitrobenzene was prepared by refluxing Fisher Reagent Grade material over barium oxide and then distilling it. The cell was filled in a dry box, and enclosed throughout the run in a plastic bag in which a considerable positive pressure of dry argon was kept. Water-saturated nitrobenzene was prepared by rapidly stirring

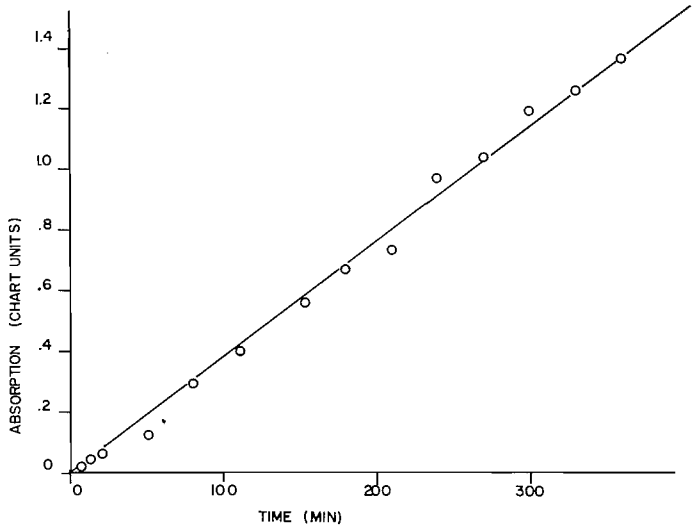

FIG. 2. Absorption at 430 mμ *vs.* time for nitrobenzene undergoing cavitation.

a water–nitrobenzene mixture overnight and then allowing a complete phase separation to take place. A solution of nitrobenzene half-saturated with water was prepared by mixing equal proportions of the dry and saturated.

The rate of darkening of dry nitrobenzene was measured to be 8.8 units, of half-saturated as 7.9 units, and of water-saturated as 6.5 units. Thus water is not essential to have a darkening occur. As the three runs were made consecutively, the decrease in the darkening with increasing water content is likely to be real and not just due to changes in experimental conditions.

(c) Effect of Temperature

A series of runs was made to test the sensitivity of the rate of reaction to the bulk temperature of the liquid under cavitation. Differences in temperature were obtained by adjusting the temperature of the water flowing through the cooling jacket of the cell.

Using nitrobenzene under the usual conditions, the following rates of darkening were obtained: at 12°, 8.8; at 27°, 6.2; at 43°, 5.1; at 75°, 2.0. Such a decrease in the rate of reaction with an increase in temperature occurs in other cavitation-induced reactions (12).

The temperature in the liquid undergoing cavitation in other series of runs was constant to within $\pm 3°$. However, depending upon the season, the average temperature in a series varied from 15 to 25 °C. As comparisons were made inside series of runs, and as the rate was relatively insensitive to the temperature (*cf.* 13), no improvements were made in the thermostatting.

(d) Effect of Solid Impurities

In some experiments, traces of metal powder were found in the solution arising from erosion of the probe due to cavitation. There may also have been some erosion of the reaction vessel. As solid impurities can act as nuclei for the formation of cavitation bubbles (14) and hence alter the rate of reaction, the effect of iron powder on the rate of reaction was investigated.

Two runs, one using nitrobenzene and the other nitrobenzene with iron powder added, were made under the usual conditions. The rate of darkening in the two runs differed only by 6%. This difference is within the experimental error. Thus the presence of iron powder has little if any effect on the rate of reaction.

(e) Effect of Bubbling Gas

Gas was bubbled through the cell in order to keep a positive pressure above the solution and thus to prevent entry of water vapor into the solution. It was also used in preliminary experiments in attempts to flush more volatile reaction products into a trap. A significant increase was noted in the reaction rate, however, when bubbling gas was present.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

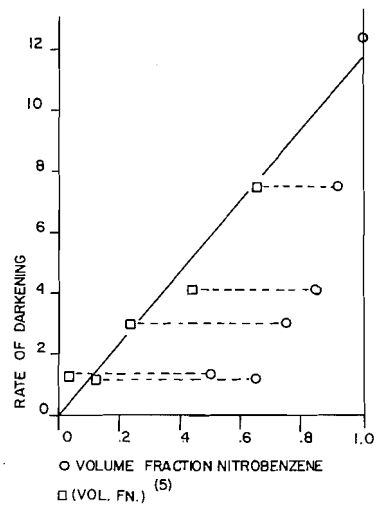

FIG. 3. Rate of darkening *vs.* volume fraction of nitrobenzene in benzene: ○ plotted *vs.* volume fraction to the first power; □ plotted *vs.* volume fraction to the fifth power.

With no bubbling gas present, the rate was measured as 2.6, as compared to 4.8 in the presence of dried nitrogen, 6.7 in the presence of dry air, and 9.4 in the presence of dry argon. Besides providing cavitation nuclei, the presence of gas also affects the cavitation phenomenon by changing the ionization potential and the thermal conductivity (6). The observations that the rate is greater with argon than with air than with nitrogen is in agreement with previous work (6, 7).

(f) Effect of Concentration

Figure 3 shows the effect of concentration on the reaction rate. The conditions for this series of runs were dry nitrobenzene, diluted by benzene, with argon bubbled through. The rate of darkening of benzene is negligible as compared to that of nitrobenzene (see section g).

The rate of darkening decreases rapidly as the nitrobenzene is diluted with benzene. In fact, the rate seems to vary as approximately the fifth power of the volume fraction, *i.e.* the concentration, of nitrobenzene. The absorption band shapes showed no change with the concentration of nitrobenzene.

(g) Effects of Substituents

A series of runs was made to observe the relative rates of reaction of different substituted benzenes. The results are shown in Table 1. Each run was for a 7 h period in order to make it possible to recover some of the product. The length of the runs and the difficulties in separating the product quantitatively introduce some measure of uncertainty into the results. The acetophenone was therefore run before, in the middle, and at the end of the series to test the reproducibility; this was found to be $\pm 10\%$.

The liquids used were all Fisher Reagent Grade except for benzene (Matheson, Coleman, and Bell Spectroquality Reagent), nitrobenzene (Baker and Adamson), and iodobenzene (Eastman Organic Chemicals). All were used as the commercially available product stored under 4A molecular sieves except iodobenzene, which was used directly, and aniline, which was distilled just prior to use.

The solutions resulting from the cavitation were concentrated to a small volume through vacuum distillation, transferred to a weighed clay dish, and dried at room temperature. All distillates had refractive indices within 0.0007 of the value of the initial reagent. The weight of the iodobenzene product is not very reliable, as some molecular iodine distilled over during the separation procedures. When the residue was heated, then crystals of iodine appeared on the cover. The presence of molecular iodine was not noted in the pure iodobenzene used, even when its temperature was raised above 85 °C for more than 5 min.

The plots of absorption of λ_{max}, the wavelength of maximum absorption, *vs.* time were generally all linear. However, the bromobenzene and the iodobenzene showed a more than linear increase in the intensity. The rates of darkening and λ_{max} are also given in Table 1. It was not possible to trap any volatile products with the apparatus and experimental methods used.

(h) Electron Paramagnetic Resonance Measurements

Some of the cavitation-induced reactions were run in a specially designed reaction vessel which fitted into the cavity of an e.p.r. machine (Varian V4502). Even though noise due to the presence of the ultrasonic generator made detection difficult, the growth of a broad signal was observed after some minutes. The solid product also gave a broad e.p.r. signal.

The e.p.r. signals from samples of the solid

TABLE 1. Rates of cavitation-induced reaction for substituted benzenes

Liquid	λ_{max} (mμ)	Absorption at λ_{max} after 2 h	Rate of reaction* (mol $h^{-1} \times 10^4$)	Dissociation energy (kcal mol^{-1})
Benzene	280	0.04	0.17	102.0
Toluene	285	0.12	0.15	78.0‖
Chlorobenzene	290	3.0	1.0‡	85.6
Bromobenzene	295	5.3	2.0	71.0
Iodobenzene	370	19.0	2.8§	57.0
Aniline	340†	11.0	3.8	75.0¶
Nitrobenzene	430	5.2	5.6	57.3¶
Acetophenone	390	1.0	1.8	75.0¶
Anisole	300	4.6	1.1	77.0¶

*Assuming an energy input of 5 W, the G value for the reactions is 5.4×10^{-3} times the values in the column.
†A weaker absorption maximum was noted at 460 mμ.
‡This is an estimate, as some of the product was lost on weighing. The results of two preliminary sets of runs are in good agreement with this figure.
§This figure may be somewhat low, as some of the iodine lost during distillation may not have been recovered.
‖This is for the formation of a benzyl radical. The dissociation energy for formation of a phenyl radical is 88.6 kcal mol^{-1}.
¶Figures for the CH_3—R bond (ref. 15). The extra resonance energy (~6 kcal mol^{-1}) in C_6H_5—R could make these bonds up to that much stronger. The corresponding differences for R = H, CH_3, Cl, Br, and I are 0, 4, 5, 4, and 4 kcal mol^{-1}, respectively.

products of benzene, iodobenzene, and nitrobenzene were examined. The mean G value was 2.0028 ± 0.0008 for the three samples, and the peak to peak width 3.3 ± 0.8 G. It was found impossible to find a solvent for the products, but a suspension could be formed which gave a weak decaying e.p.r. signal with the same spectrum as the solid.

(i) Other Properties of Products

The product of nitrobenzene cavitation was investigated by several methods. It was not found to be soluble in any solvent so that several physico-chemical measurements, *e.g.* n.m.r., were not possible.

No change is observed in the product when heated to above 350 °C in the absence of oxygen. A sample used for mass spectrometry at 250 °C also was unchanged. The only peaks showing in the mass spectrum were a strong nitrobenzene peak and fragments from nitrobenzene. These could be accounted for by residual nitrobenzene present in the sample after drying.

When heated in a Pyrex test tube over a Bunsen flame, some dense yellowish-white vapor is given off. Some dark-brown coloring appears on the sides of the test tube, but even after minutes at red heat, the greater part of the sample remains as a dark solid.

An elemental analysis of the sample gives 66.30% C, 3.88% H, 6.66% N, with 3% of the original material remaining as ash. Assuming the remaining 23.16% as O gives a formula of $C_6H_{4.1}N_{0.51}O_{1.56}$ for the product. It is thus deficient in H, N, and O relative to C. Volatile products containing primarily these three elements must thus have been produced. There is some possibility of material coming from erosion of the reaction vessel, the probe, and even from diffusion in against the positive pressure of argon.

(j) Cavitation in Other Liquids

A series of other liquids was exposed to cavitation under the same conditions as the substituted benzenes. No reaction was observed in the case of acetone, which decomposes on photolysis to give, among other things, biacetyl. There seemed also to be no acceleration of the rate of decomposition of di-*t*-butyl peroxide, which undergoes slow thermal decomposition even at room temperature. After hours of cavitation, its n.m.r. and v.p.c. (10% FFAD at 70 °C) was the same as that of a non-cavitated sample. The thermal decomposition of trimethylene oxide was also not accelerated by cavitation in a cyclohexane solution. No changes (v.p.c.) were observed in a sample of cyclohexane after 7 h exposure to cavitation.

A reaction similar to that for the aromatics was noted for acrylonitrile, however. The rate of formation of product was more than linear, varying as nearly the square of the time under cavitation. The acrylonitrile cavitation product

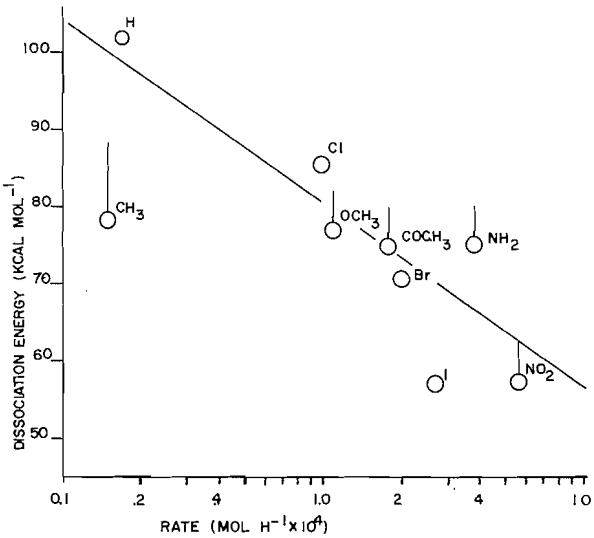

FIG. 4. Dissociation energy (from Table 1) *vs.* the logarithm of the rate of reaction (Table 1).

and a sample of polyacrylonitrile absorb at the same wavelength (275 mμ) in the u.v. While polyacrylonitrile is white, however, the cavitation product was yellowish-brown. The weight of product formed after 7 h was 0.03 g as compared to 0.08 g for anisole, for example.

Discussion

The effect of gas and temperature on the reaction indicate that the reactions must be due to cavitation. The reactions are also not critically dependent upon the presence of traces of water or solid impurities.

In the cavitation-induced reactions of most of the substituted benzenes, there is no indication that the reactions are autocatalytic, as the rate of darkening is constant with time. The nature of the products seem also independent of the degree of advancement of the reaction, as no change was observed in the shape of the absorption spectrum in the visible and u.v. region.

The non-linear changes in the intensity of iodobenzene and bromobenzene may well be due to the formation of highly colored charge-transfer complexes. The deviation from linearity became marked only after the reaction has proceeded for 1 h, and some molecular iodine or bromine may have been formed by that time. Molecular iodine was found in the distillate when reaction products from iodobenzene were recovered, but tests for molecular bromine or chlorine in the corresponding cases were negative.

An explanation for the concentration dependence of the reaction (Fig. 3) can be found by considering the vapor pressures of the compounds involved. Assuming that the primary reaction occurs in the cavitation bubble (6), then the composition of the vapor in the cavity is important. As benzene has a vapor pressure far greater than that of nitrobenzene (by a factor of 200 at 20 °C), then there would be greater amounts of benzene than nitrobenzene in the vapor even at mole fractions of nitrobenzene greater than 0.95 according to Raoult's law. The presence of the benzene would facilitate translational–vibrational energy transfer, and increase the instantaneous heat capacity in the cavitation bubble. This would moderate the final temperature which can be reached on compression of the bubble. The higher vapor pressure of benzene would also shorten the life-time of the bubble and slow the reaction.

Figure 4 shows a plot of the dissociation energy of the weakest bond (in most cases the C_6H_5–R bond) *vs.* the logarithm of the rate of formation of solid product. There is a crude correlation between these quantities. Some explanations can be suggested for the lack of better correlation in the data. Volatile products were not trapped, and may make up a variable and non-negligible part of the total product in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

the nine systems, especially in the case of iodobenzene. The inaccuracies in obtaining product recovery can be substantial, especially in cases such as toluene and benzene, where only 0.009 g of product were obtained after 7 h.

Even with completely accurate data, a better correlation may not be present. The thermal conductivity of the compounds does not vary much and would not be expected to be an important factor. However, the vapor pressure does vary significantly, and could be an important factor. The chemical nature of the substituent group and the ionization potential could also play an important part. Nevertheless, the correlation between the rate and the dissociation energy as shown in Fig. 4 is considerably better than other correlations tried.

Such a correlation suggests that it is reasonable to assume the primary process in the reaction to be a thermal decomposition in the cavitation bubble. When aromatic compounds are involved, such a decomposition would result in radicals, for benzene C_6H_5 and C_6H_7, formed by having H combine with C_6H_6 (16). Such radicals can then initiate polymerization in the bulk liquid (17, 18).

An estimate of the temperature present can be obtained from Fig. 4 if some questionable assumptions are made. The concept of temperature itself is not valid in such gross dis-equilibrium situations. Nevertheless, if a first order thermal decomposition is assumed, and if the concentration, pre-exponential factor, and temperature are taken to be the same in all cases, then from the slope of the line drawn in Fig. 4, the "temperature" can be calculated to be of the order of 5000 °C. This is at least of the order of magnitude suggested by Fitzgerald *et al.* (6).

The reason why cavitation-induced reactions occur in aromatic liquids and not in liquids such as di-*t*-butyl peroxide may lie in the relative stability of aromatic radicals (19). The radicals formed in the case of di-*t*-butyl peroxide would have a greater tendency to recombine as soon as formed, and would not produce any reactions in the bulk liquid. It may also be that no reaction was observed in the case of di-*t*-butyl peroxide, as without polymerization, the conversion to product is too small to be detected, especially if volatile products are not trapped.

The product of the reaction seems to be a high molecular weight polymer, as suggested by the insolubility and the high melting point. The e.p.r. spectrum is similar to the spectrum obtained in low temperature (500 °C) pyrolysis of carbohydrates (20), or in some natural substances such as coal.

The mechanism for the formation of the polymer would seem to be analogous to the mechanism for polymerization which occurs on the radiolysis of benzene (17, 18). The difference in the two radiolysis mechanisms suggested is that in the one, a hexatrienyl radical is postulated as an intermediate (17) forming a polymer $R(C_6H_6)_nR$, while in the other, it is a cyclohexadienyl (18), which may then react to form a phenylcyclohexadienyl.

In this case, the radical polymerization which occurs does not stop in many cases by combination with another radical. It may be that the concentration of radicals in this case is too low for such termination. Instead, some of the polymer molecules remain with an unpaired electron.

The element analysis of the nitrobenzene residue indicated a deficiency in H, in agreement with radiolysis work. A deficiency of N and O, and a deficiency of N with respect to O shows that volatile products from the substituent group must have been produced. The low N:O ratio may be due to a greater amount of N in the volatile products. However, even with a positive pressure of argon, there may be some diffusion of air into the reaction vessel to introduce some oxygen.

There are some interesting comparisons between the cavitation phenomena observed and radiolysis reactions. The *G* value for the formation of polymer for liquid benzene by radiolysis is 0.75 (19); the *G* value for cavitation-induced reactions is 0.001 (Table 1). The *G* value for cyclohexane by radiolysis is greater than for benzene, 1.7, while no reaction is observed in cavitation-induced reaction. For ultrasonic cavitation, a *G* value of 0.001 as for benzene is quite low; for nitrobenzene it is 0.03; 0.095 for $CCl_4 \rightarrow Cl_2$ (11); 0.0045 for $H_2O \rightarrow H_2O_2$ (11).

It would seem that in radiolysis the stability of excited aromatic molecules acts to make them "sponge-type protectors." In cavitation-induced reactions the stability of the radicals formed from decomposition of aromatics seems to make it possible for these to survive the collapse of the cavitation bubbles and initiate polymerization

in the liquid. The differences in such behavior are presumably due to the much greater energies concentrated in the case of radiolysis.

The thermal decomposition of benzoyl peroxide in aromatic solvents and the subsequent reactions would also seem to have some relation to this work. An analysis (21) indicates that phenylcyclohexadiene radicals form quickly when this reaction takes place in benzene, and that such radicals are fairly stable. High molecular weight residues are also found.

Conclusions

The formation of polymers in pure substituted benzenes has been observed on exposure to ultrasound intense enough to cause cavitation. The product has some of the characteristics of the char obtained from low temperature pyrolysis of carbohydrates.

A free-radical mechanism similar to that suggested for polymerization from radiolysis seems probable. A crude correlation between bond dissociation energy and the reaction rate suggests that the initiation reaction is a thermal decomposition in a cavitation bubble.

The mechanism for such reactions could quite certainly be clarified by extending the experiments to liquid mixtures and solutions. This may also lead to some practical applications. It would seem advisable to extend such work using a more sophisticated apparatus than that used in these experiments, so that reaction conditions can be better controlled. It also seems advisable to do the experiments both at high and at low frequencies.

The authors thank Mr. D. G. Fecchio and Mr. N. F. Feiner for technical assistance, Dr. P. M. Laughton and Dr. R. H. Wightman for helpful discussions, and Dr. J. R. Morton and Dr. A. H. Reddoch of the National Research Council of Canada for making e.p.r. examinations of the samples. Radiation-induced Oxidation of 2-Propanol by Nitrous Oxide in Alkaline Aqueous Solution

C. E. BURCHILL AND G. P. WOLLNER[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received December 30, 1971

The radiation-induced oxidation of 2-propanol to acetone by N_2O in alkaline aqueous solution proceeds via a free radical chain mechanism independent of p*H* above 12.5. The results are explained by abstraction of H from 2-propanol by O^- at both the α and β positions (85% α attack). Chain propagation is by reaction of the α radical anion, $(CH_3)_2\dot{C}O^-$, with N_2O with a rate constant of $(3.8 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$, and by reaction of the β radical, $\dot{C}H_2(CH_3)CHOH$, with 2-propanol to give the α radical with a rate constant of $430 \pm 30\ M^{-1}\ s^{-1}$.

The conclusions are supported by the demonstration of kinetic isotope effects for selectively deuterated alcohols.

La réaction d'oxydation, induite par les radiations, du propanol-2 en acétone par N_2O, en solution aqueuse et basique, se fait par un mécanisme radicalaire en chaîne qui est indépendant du p*H* au-dessus de 12.5. Les résultats sont expliqués par une abstraction d'H du propanol-2 par O^- et ceci sur les positions α et β (85% d'attaque α). La propagation de chaîne se fait par réaction du radical anion α, $(CH_3)_2\dot{C}O^-$, avec N_2O et ceci avec une constante de vitesse de $(3.8 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$, ainsi que par la réaction du radical β, $\dot{C}H_2(CH_3)CHOH$, avec le propanol-2 pour conduire au radical α selon une constante de vitesse de $430 \pm 30\ M^{-1}\ s^{-1}$.

Les conclusions s'appuient sur l'existence d'effets isotopiques cinétiques dans le cas d'alcools sélectivement deutérés.

Canadian Journal of Chemistry, **50**, 1751 (1972)

There have been several fragmentary reports of a radiation-induced chain oxidation of 2-propanol by N_2O in alkaline aqueous solution (1–3) but the only detailed study of this reaction has been for the case in which the solvent was the pure alcohol (4, 5). Few quantitative data are available for aqueous solutions.

Scholes *et al.* (1) reported only that the yields of acetone and N_2 were high, implicating a chain reaction. They suggested the sequence of reactions 1–3 to explain the chain yields.

[1] $$\dot{O}H + (CH_3)_2CHO^- \rightarrow H_2O + (CH_3)_2\dot{C}O^-$$

[2] $$(CH_3)_2\dot{C}O^- + N_2O + H_2O \rightarrow (CH_3)_2CO + OH^- + N_2 + \dot{O}H$$

[3] $$2\,(CH_3)_2\dot{C}O^- + H_2O \rightarrow (CH_3)_2CO + (CH_3)_2CHOH + OH^-$$

Allan and Beck (2) found that the N_2 yields, while showing an inverse dose rate effect did not fit the simple kinetic expression (eq. 4) which could be derived from this mechanism.

[4] $$G(N_2) = G_{e_{aq}^-} + k_2\left(\frac{G_R}{2k_3D}\right)^{1/2}[N_2O]$$

They suggested that this failure could be attributed to the incomplete acid dissociation of 2-propanol at p*H* 13 and the non-selective abstraction of H from 2-propanol by OH to give a finite yield of $\dot{C}H_2(CH_3)CHOH$. 2-Propanol was said to be 87% dissociated at p*H* 13 on the basis of an equilibrium constant proposed by Wells (6) from a change in the rate of photochemical autoxidation in this p*H* range. More recently Murto (7) has estimated pK_a for 2-propanol to be 17.1 so that it is unlikely that the anion plays any role in the reactions of 2-propanol in aqueous solution. However the radical $(CH_3)_2\dot{C}OH$ has been shown to undergo acid dissociation with $pK_a = 12.2$ (8) and it is probable that this is the controlling factor in both the radiation-induced reaction and the autoxidation. Non-selective abstraction of H from 2-propanol by OH has been demonstrated to be a significant factor in its free radical oxidation by H_2O_2 as a consequence of the differences in reactivity of the radicals formed (9–12).

Dainton *et al.* (3) observed that in the radiation-induced reaction of 2-propanol with N_2O in alkaline aqueous solution the yield of N_2 increased with increasing concentrations of both N_2O and alcohol. The latter effect is similar to that observed in the chain reaction of 2-propanol with H_2O_2 in neutral solution (9, 10) and suggests that reaction 5 may be significant.

[5] $$\dot{C}H_2(CH_3)CHOH + (CH_3)_2CHOH \rightarrow (CH_3)_2CHOH + (CH_3)_2\dot{C}OH$$

As part of a continuing study of radiation-

induced oxidations in aqueous solutions we have carried out an investigation of this particular reaction.

Experimental

Aqueous solutions were prepared with triply-distilled water. 2-Propanol and NaOH (Fisher, Certified Reagent) were used as received. Deuterium labelled alcohols ($(CD_3)_2$-CHOH and $(CH_3)_2CDOH$) were from Merck, Sharpe and Dohme and were used without further purification. N_2O (Matheson) was passed through a column of KOH pellets to remove CO_2 and was freed of permanent gases by repeated freeze–pump–thaw cycles on a vacuum line.

Samples, of 5 ml volume in Pyrex bulbs, were degassed by the freeze–pump–thaw method. An appropriate quantity of N_2O (measured manometrically in a side-bulb) was then condensed into the bulb using liquid nitrogen and the sample sealed off under vacuum. The samples were then thawed and equilibrated at 26 °C until immediately before irradiation. The N_2O concentration in the solution was calculated from the quantity of N_2O introduced and the volumes of the liquid and gas space. It was assumed that the solubility of N_2O in the alkaline solutions used was the same as for water containing the same concentrations of NaOH (13) (the concentration of 2-propanol was, for most experiments, $\leqslant 0.1$ *M*).

Irradiations were carried out in a ^{60}Co Gammacell 220 (AECL) at the ambient temperature of the unit. Because most of the irradiations were short (< 1 min) it was assumed that neither the temperature nor the N_2O concentration would change significantly during an irradiation. Dosimetry was based on $G(Fe^{3+}) = 15.6$ for the Fricke dosimeter (14) and the absorbed dose was assumed to be directly proportional to the electron density of the samples.

Acetone, the only product determined quantitatively, was measured spectrophotometrically using salicylaldehyde (15). The majority of *G* values reported were calculated from a minimum of four points on linear yield-dose plots. In a few cases, noted in Fig. 2, *G* values were calculated from single irradiations.

Results and Discussion

In irradiated alkaline aqueous solutions of 2-propanol containing N_2O the yield of acetone was found to depend upon the p*H* and the concentrations of N_2O and alcohol. Figure 1 shows the p*H* dependence of *G*(acetone) for solutions containing 2-propanol (0.105 *M*) and two different concentrations of N_2O. In both cases the yield showed a marked increase in the p*H* range 10.5–12.5. Further work on this system used solutions containing 0.3 *M* NaOH (p*H* 13.5).

In solutions containing N_2O, all e^-_{aq} will react with N_2O (reaction 6) and oxidation of 2-propanol is initiated by abstraction of H from 2-propanol by OH (or O^-). The α radical, $(CH_3)_2\dot{C}OH$, has been shown to undergo an acid dissociation at high p*H* (8, 16) and the

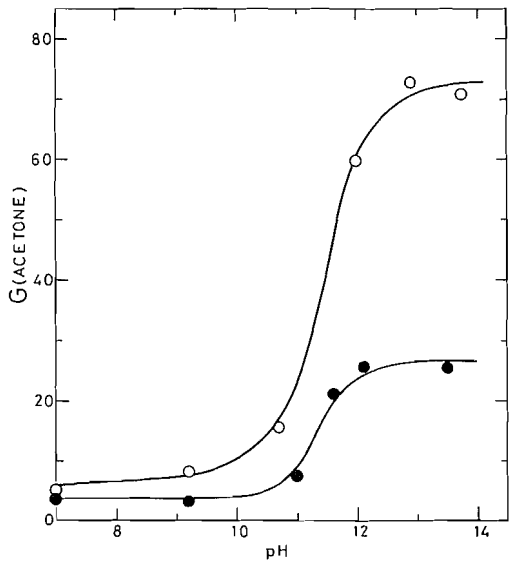

FIG. 1. Variation of *G*(acetone) with p*H*; [2-propanol] = 0.105 *M*, average dose rate = 1.13×10^{19} eV l^{-1} s^{-1}; ○, $[N_2O] = 1.04 \times 10^{-1}$ *M*; ●, $[N_2O] = 7.4 \times 10^{-3}$ *M*.

p*H* dependence of the yield may be understood on the basis of the equilibrium system represented by eq. 9 *if* only the anionic form of the radical undergoes the chain propagating reaction 10, as previously proposed (1–5). The mid-point of the rise in the yield curves of Fig. 1 (p*H* ~ 11.4) is significantly less than the pK_a estimated for the radical (~ 12.2) by Asmus *et al.* (8) but it may be that in both cases the points of inflection are determined by kinetic, rather than equilibrium, conditions.

[6] $e^-_{aq} + N_2O \rightarrow N_2 + \dot{O}^-$ $\quad (\dot{O}^- + H_2O \rightleftharpoons \dot{O}H + OH^-)$

[7] $\dot{O}H\ (\dot{O}^-) + (CH_3)_2CHOH \rightarrow H_2O\ (OH^-) + (CH_3)_2\dot{C}OH$

[8] $\dot{O}H\ (\dot{O}^-) + (CH_3)_2CHOH \rightarrow H_2O\ (OH^-) + \dot{C}H_2(CH_3)CHOH$

[9] $(CH_3)_2\dot{C}OH + OH^- \rightleftharpoons (CH_3)_2\dot{C}O^- + H_2O$

[10] $(CH_3)_2\dot{C}O^- + N_2O \rightarrow (CH_3)_2CO + N_2 + \dot{O}^-$

For fixed concentrations of base (0.3 *M*) and 2-propanol (0.105 *M*) the variation of *G*(acetone) with N_2O concentration is shown in Fig. 2. The yield approached a maximum limiting value at $[N_2O] > 9 \times 10^{-2}$ *M*. This effect is attributed to the formation of two different radicals, $(CH_3)_2\dot{C}OH$ and $\dot{C}H_2(CH_3)$-CHOH (reactions 7, 8), by abstraction of H from 2-propanol. Of these, only the α radical

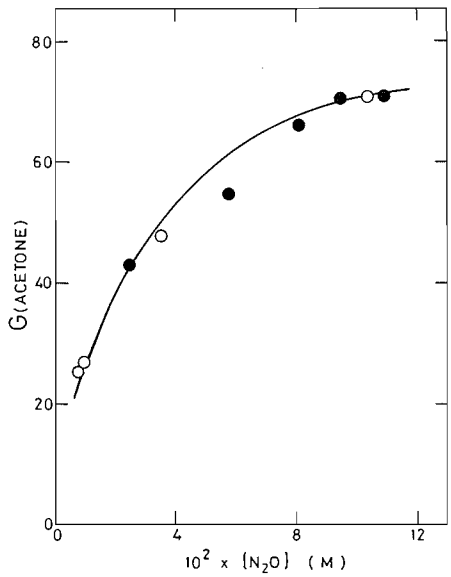

FIG. 2. Variation of G(acetone) with $[N_2O]$; [2-propanol] = 0.105 M, pH = 13.5, average dose rate = 1.13 × 10^{19} eV l^{-1} s^{-1}; ○, calculated from a yield–dose plot; ●, calculated from a single irradiation.

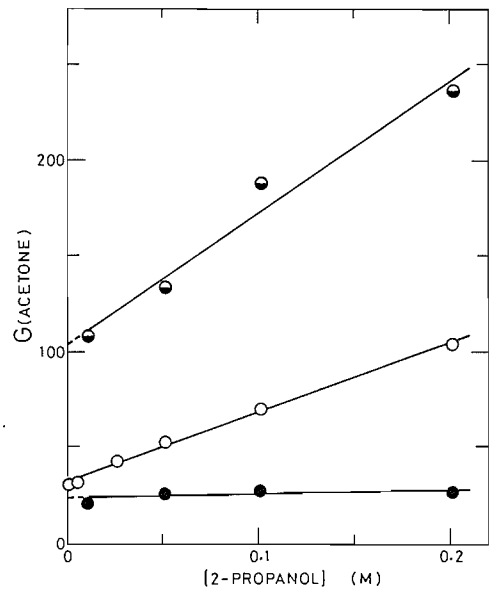

FIG. 3. Variation of G(acetone) with [2-propanol]; $[N_2O]$ = 0.104 M, pH = 13.5, average dose rate = 1.12 × 10^{19} eV l^{-1} s^{-1}; ○, $(CH_3)_2CHOH$; ◒, $(CD_3)_2CHOH$; ●, $(CH_3)_2CDOH$.

is assumed to ionize and undergo the chain propagating reaction with N_2O (eqs. 9, 10). (No acid dissociation of the radical from t-butyl alcohol, formally similar to the β radical above, was observed in pulse radiolysis studies (17).) However both radicals may undergo bimolecular termination, as in reactions 11–13. With increasing N_2O concentration the rate of reaction 10 would be increased and the steady state concentration of $(CH_3)_2\dot{C}O^-$ decreased until only reaction 13 would be a significant terminating process. At this point the yield of acetone would become independent of $[N_2O]$.

[11] $2\,(CH_3)_2\dot{C}O^- \rightarrow$ non-radical products

[12] $(CH_3)_2\dot{C}O^- + \dot{C}H_2(CH_3)CHOH \rightarrow$ non-radical products

[13] $2\,\dot{C}H_2(CH_3)CHOH \rightarrow$ non-radical products

At fixed concentrations of NaOH (0.3 M) and N_2O (0.104 M, corresponding to an equilibrium pressure of about 4.5 atm), where G(acetone) was essentially independent of their value, the yield was found to vary linearly with alcohol concentration, as shown in Fig. 3. This effect, similar to that observed in neutral solution for radiation-induced oxidation by H_2O_2, is ascribed to the reaction of the β radical with the alcohol as the rate-determining propagating step (eq. 5).

The overall mechanism proposed for high base and N_2O concentrations may be represented by eqs. 5–10, 13–16. It is assumed that

[14] $H_2O \rightsquigarrow e^-_{aq}, \dot{H}, \dot{O}H, H_2, H_2O_2, H_3O^+$

[15] $\dot{H} + OH^- \rightarrow e^-_{aq}$

[16] $\dot{O}H + OH^- \rightarrow H_2O + \dot{O}^-$

[6] $e^-_{aq} + N_2O \rightarrow N_2 + \dot{O}^-$

[7] $\dot{O}^- + (CH_3)_2CHOH \rightarrow OH^- + (CH_3)_2\dot{C}OH$

[8] $\dot{O}^- + (CH_3)_2CHOH \rightarrow OH^- + \dot{C}H_2(CH_3)CHOH$

[9] $(CH_3)_2\dot{C}OH + OH^- \rightarrow H_2O + (CH_3)_2\dot{C}O^-$

[10] $(CH_3)_2\dot{C}O^- + N_2O \rightarrow (CH_3)_2CO + N_2 + \dot{O}^-$

[5] $\dot{C}H_2(CH_3)CHOH + (CH_3)_2CHOH \rightarrow (CH_3)_2CHOH + (CH_3)_2\dot{C}OH$

[13] $2\,\dot{C}H_2(CH_3)CHOH \rightarrow$ non-radical products

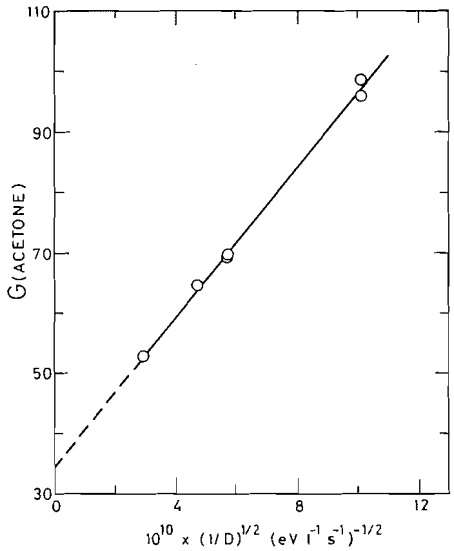

FIG. 4. Variation of G(acetone) with dose rate (D). [2-propanol] = 0.052 M, [N_2O] = 0.104 M, pH = 13.5.

at these high (0.3 M) base concentrations reactions 15, 16, and 9 are sufficiently rapid that all H atoms are converted to e^-_{aq}, all OH to O^-, and all $(CH_3)_2\dot{C}OH$ to $(CH_3)_2\dot{C}O^-$ before further reaction. It is also assumed that at the high concentration of N_2O (0.104 M) reaction 10 is the only reaction of $(CH_3)_2\dot{C}O^-$ (*i.e.* only reaction 13 is a significant termination step). Under these conditions a steady state kinetic analysis leads to eq. 17 ($G_R = G_{e^-_{aq}} + G_H + G_{OH}$, and D is the dose rate in units of 6.02×10^{25} eV l^{-1} s^{-1}).

$$[17] \quad G(\text{acetone}) = \frac{k_7}{k_8} G_R + \left(1 + \frac{k_7}{k_8}\right) k_5 \times \left(\frac{G_R}{2k_{13}D}\right)^{1/2} [\text{2-propanol}]$$

Equation 17 is in good agreement with the form of the experimental results shown in Fig. 3. The extrapolated non-zero intercept (32.0 ± 1.0) for G(acetone) at [2-propanol] = 0 corresponds to $k_7 G_R/k_8$ and, taking $G_R = 5.9$ (18), gives $k_7/k_8 = 5.4 \pm 0.2$. Equation 17 also predicts a linear dependence of the yield on $D^{-1/2}$, extrapolating to the same non-zero intercept at $D^{-1/2} = 0$. Figure 4 shows the dose rate dependence for fixed alcohol (0.052 M) and N_2O (0.104 M) concentrations. The extrapolated intercept (34.2 ± 1.2) is in good agreement with that found from the alcohol dependence and corresponds to $k_7/k_8 = 5.8 \pm 0.2$. Using these values of k_7/k_8, and assuming $2k_{13} = 2 \times 10^9$ M^{-1} s^{-1} (typical of bimolecular rate constants for termination of neutral alcohol radicals (17)), values of $k_5 = 445 \pm 20$ and 420 ± 20 M^{-1} s^{-1} may be calculated from the slopes of the lines in Figs. 3 and 4 respectively.

Strong support for this interpretation is obtained from the results for selectively deuterated alcohols, shown also in Fig. 3. If $(CD_3)_2$-CHOH is substituted for $(CH_3)_2CHOH$, reaction 8 would be expected to show a normal primary kinetic isotope effect ($k_{8(H)} > k_{8(D)}$). This would have the effect of increasing both the extrapolated intercept and the slope of the line in Fig. 3, which is the observed effect. From the ratio of the intercepts for the deuterated and undeuterated alcohols $k_{8(H)}/k_{8(D)} = 3.26 \pm 0.23$. Substitution of $(CH_3)_2CDOH$ for $(CH_3)_2CHOH$ would be expected to give $k_{7(H)} > k_{7(D)}$, and $k_{5(H)} > k_{5(D)}$, and to decrease both the intercept and the slope of the line in Fig. 3. The ratio of the intercepts gives $k_{7(H)}/k_{7(D)} = 1.35 \pm 0.10$ and, assuming no secondary isotope effects, the change in slope corresponds to $k_{5(H)}/k_{5(D)} = 11 \pm 6$.

The values for k_7/k_8, and the magnitudes of the kinetic isotope effects, are very similar to those obtained by Burchill and co-workers (9, 10) (and independently confirmed by Walling and Kato (11)) for reactions of OH with 2-propanol. The total rate constant for reaction of O^- with 2-propanol has been found to be very similar to that for reaction of OH (19). These results support the suggestion by Rabani (20) that O^- and OH are about equally efficient in hydrogen abstraction reactions.

The mean value for k_5 reported here (430 ± 30 M^{-1} s^{-1}) is much larger than that found by Burchill and co-workers (52 ± 3 M^{-1} s^{-1}) in neutral solution (9, 10). The latter value was suggested to be a lower limit (9) but it seems unlikely to be in error by such a large amount. A possible explanation for the higher value in alkaline solution is that reactions 5 and 9 represent a concerted or base-catalyzed reaction (eq. 18). This would, however, require a form

$$[18] \quad \dot{C}H_2(CH_3)CHOH + (CH_3)_2CHOH + OH^- \rightarrow (CH_3)_2CHOH + H_2O + (CH_3)_2\dot{C}O^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

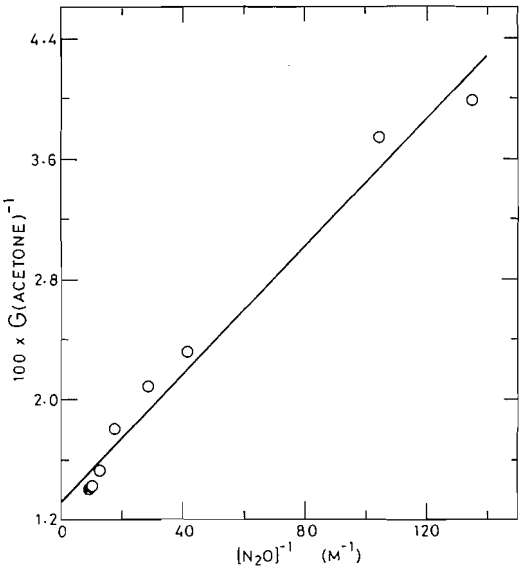

FIG. 5. Data of Fig. 2 replotted according to eq. 19.

of termolecular reaction which seems rather unlikely.

The kinetic analysis presented above was for high concentrations of N_2O, where the reaction of $(CH_3)_2\dot{C}O^-$ with N_2O was assumed to be stoichiometric and only reaction 13 was considered as a terminating step. If reactions 11–13 can be represented by a composite rate constant such that $k_t = 2k_{11} = k_{12} = 2k_{13}$ the results for lower N_2O concentrations may also be considered. A steady state solution leads to eq. 19.

$$[19]\quad G(\text{acetone})^{-1} = \left[\frac{k_7 G_R}{k_7 + k_8} + k_5\left(\frac{G_R}{k_t D}\right)^{1/2}[\text{2-propanol}]\right]^{-1} \times \left[\frac{k_8}{k_7 + k_8} + \frac{(G_R D k_t)^{1/2} + k_5[\text{2-propanol}]}{k_{10}[N_2O]}\right]$$

On the basis of the proposed mechanism, for a sufficiently high base concentration and a fixed concentration of alcohol, $G(\text{acetone})^{-1}$ should be a linear function of $[N_2O]^{-1}$. Figure 5 shows the data of Fig. 2 replotted in this way. The best straight line has been drawn but the experimental results suggest a systematic curvature. This probably arises from the fact that there is not a simple algebraic relationship among the three rate constants for the terminating reactions. However, using the values previously derived for k_7/k_8, k_5, and assuming $k_t = 2 \times 10^9\ M^{-1}\ s^{-1}$, an approximate value of $k_{10} = (3.8 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$ may be calculated from the slope and intercept of the line drawn. The results reported by Sherman (5) suggest that reaction 10 may be considerably faster in 2-propanol as solvent. If the chain is terminated by bimolecular radical reactions having rate constants *ca.* $10^9\ M^{-1}\ s^{-1}$ the very high yields reported by Sherman would require $k_{10} > 10^5\ M^{-1}\ s^{-1}$. The variation of acetone yields with N_2O concentration may be fitted to eq. 19, giving a value for k_{10} of $\simeq 8 \times 10^5\ M^{-1}\ s^{-1}$. There are, moreover, reasons to believe that this rate constant may increase in going from water to an alcohol as solvent. Experiments with water–methanol mixtures (21) indicated that the rate constant for reaction of $\dot{C}H_2O^-$ with N_2O increased with increasing methanol content. Moelwyn-Hughes (22) has proposed that for the reaction of an ion with an uncharged species a major portion of the activation energy is associated with the solvation energy of the ion. The decreased solvation energy of the anion, $(CH_3)_2\dot{C}O^-$, in going from aqueous to alcoholic solution could thus lead to a decrease in activation energy and an increase in the specific rate constant.

In his study of the radiation-induced oxidation of alkaline 2-propanol by N_2O Sherman (5) found a significant chain yield of methane and that the reaction was inhibited by small amounts of acetone added prior to irradiation. We have examined the gaseous products from our experiments in aqueous solution by mass spectrometry and were unable to detect methane. In our experiments the addition of $\simeq 10^{-3}$ M acetone (approximately the concentration formed during the longest irradiations) to the solutions before irradiation had no measurable effect on G(acetone).

Summary

A self-consistent mechanism has been proposed for the radiation-induced oxidation of 2-propanol by N_2O in alkaline aqueous solution. The mechanism is based on the acid dissociation of the α radical of 2-propanol followed by electron transfer from the anion to N_2O as the propagating step. This may be contrasted with the chain oxidation of 2-propanol by H_2O_2 in that only the α radical anion

TABLE 1. Rate constant data derived from oxidation of 2-propanol by N_2O in alkaline aqueous solution

k_7/k_8	5.6 ± 0.3
$k_{7(H)}/k_{7(D)}$	1.35 ± 0.10
$k_{8(H)}/k_{8(D)}$	3.26 ± 0.23
k_5	$430 \pm 30\ M^{-1}\ s^{-1}$
$k_{5(H)}/k_{5(D)}$	11 ± 6
k_{10}	$(3.8 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$

reacts with N_2O whereas the undissociated radical will react with H_2O_2 in neutral or acid solution (9, 12). The β radical is unreactive toward either N_2O or H_2O_2 but may react with the parent alcohol to give an α radical in a secondary propagating reaction. The ratio of $\alpha:\beta$ abstraction from 2-propanol by O^- in alkaline solution is very similar to that for OH in neutral solution. The principal numerical conclusions are summarized in Table 1.

Terpolymerization of Methacrylonitrile, Styrene, and α-Methylstyrene

ALFRED RUDIN, SCHUMANN S. M. CHIANG, H. KIRK JOHNSTON, AND PAUL D. PAULIN
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received January 31, 1972

The free radical copolymerization of methacrylonitrile, styrene, and α-methylstyrene was studied at 60 °C in toluene solution. Copolymer composition was calculated from the composition of the unreacted monomers, as measured by g.l.c. Reactivity ratios measured previously for the three monomer pairs involved were used with the simple terpolymerization equation to predict polymer composition. Agreement between predicted and experimental polymer compositions was satisfactory. The behavior of α-methylstyrene can be described by a simple model without reference to ceiling temperature or penultimate effects because sequence lengths of this monomer in the terpolymers are short.

A true azeotropic feed composition was not investigated, but several monomer mixtures produced copolymers with compositions which varied so little from that of the feed that the systems could be considered to be azeotropic for practical synthetic purposes. This behavior is in accord with expectations.

Analytical accuracy of the gas chromatographic techniques was examined and means are suggested to make the best use of this method in copolymerization studies.

La copolymérisation par radicaux libres de méthacrylonitrile, styrène, et α-méthylstyrène a été étudiée à 60 °C en solution dans le toluène. La composition du copolymère a été calculée à partir de celle des monomères restants par c.g.l. Les rapports de réactivité précédemment mesurés pour les trois monomères impliqués pris deux à deux, ont été utilisés dans la simple équation de terpolymérisation pour prévoir la composition du polymère. Un accord satisfaisant entre les compositions calculée et trouvée a été obtenu. Le comportement de l'α-méthylstyrène peut être décrit par un modèle simple sans faire référence à la température "de plafond" ou à des effets préterminaux car les longueurs des séquences de ce monomère dans les terpolymères sont courtes. La composition d'une alimentation azéotropique vraie n'a pas été recherchée car de nombreux mélanges de monomères ont donné des copolymères dont la composition diffère tellement peu de celle de l'alimentation, qu'il est possible de considérer ces systèmes comme étant azéotropiques, à des fins de synthèse pratique. Cette attitude est conforme aux prévisions.

La précision analytique des techniques de chromatographie en phase gazeuse a été examinée et des moyens ont été proposés afin de faire le meilleur usage de cette méthode à des études de copolymérisation.

Introduction

This paper reports the free radical copolymerization at 60 °C in toluene solution of methacrylonitrile, styrene, and α-methylstyrene. Previous communications from this laboratory have reported copolymerization behavior of the three binary pairs which can be chosen from this trio of monomers (1–4). Reactivity ratios were determined from loss of monomers measured by gas–liquid chromatographic analysis of the reaction mixtures. Values obtained differed somewhat from those reported by earlier workers, with the major difference being that α-methylstyrene copolymerizations were found to conform to simple copolymer behavior (5) even at reaction temperatures near or higher than the ceiling temperature of poly(α-methylstyrene). This result can be explained on the grounds that short sequence lengths of this monomer in the copolymer have greater enthalpies of polymerization and correspondingly higher ceiling temperatures than high molecular weight homopolymer (2, 3). Other discrepancies between the results reported and those found by other workers can be ascribed to use of more modern analytical procedures and data-handling methods (3, 4, 6).

The articles cited are not the first examples of use of gas chromatographic analyses in copolymerization studies, but the methods used to handle the raw data are novel. It was of interest to extend the investigation to simultaneous copolymerization of the three monomers involved to test the application of the analytical method to this more complicated system. This study also provided a test of the binary reactivity ratios which had been reported previously. Six reactivity ratios are required to determine the composition of the polymer formed from given concentrations of three monomers. Reactivity ratios cannot be measured at present directly in multicomponent systems, but values deter-

mined in two-component studies appear to be generally applicable in more complicated copolymerizations (7–10), although there have been reports in which the predicted and experimental copolymer compositions do not agree very well (11, 12).

Experimental

Materials

The middle third of the reduced pressure distillates of the monomers was retained and stored in the cold until polymerization. Toluene was dried over sodium and the middle third of the distillate at atmospheric pressure was used as a solvent. The azodiisobutyronitrile (AIBN) initiator was recrystallized from methanol. Hydroquinone used to terminate the free radical polymerizations was used as received.

Polymerization

Copolymerizations of styrene (S), methancrylonitrile (MAN), and α-methylstyrene (AMS) were carried out in toluene solution at 60 °C. Reaction mixtures contained 10 ml toluene and a total of 15 ml monomers. These quantities were pipetted into 75 ml capacity reaction bottles equipped with ground glass tapered necks. The same pipet was used for all liquid deliveries. Eight replicate mixtures were prepared for each polymerization. Two of these mixtures were retained as gas chromatographic standards and were not reacted. One standard solution was degassed with the six polymerization samples and one was used without degassing. The gas chromatographic analyses of the standards did not differ much, but preference was always given to the data from the degassed sample.

The solutions were degassed by freezing and thawing twice under "vacuum" and the reaction vessels were then flushed with nitrogen and sealed with rubber septum stoppers. Mixtures to be polymerized were warmed for 10 min in a 60 °C constant temperature bath before addition of 2 ml toluene solution containing 20 mg/ml AIBN initiator. The reaction bottles were then returned to the bath for times between 2 and 24 h. These polymerization schedules served to convert up to 15 weight percent of the monomer charge.

A syringe was used to bleed gas from the vapor spaces above the warmed mixtures and reduce the pressure in the reaction vessels to atmospheric or slightly less.

Samples were removed from the bath after the required reaction times and polymerization was terminated by addition of 15 ml toluene saturated with hydroquinone. Each vessel was then flushed with nitrogen, resealed and stored in the cold until analysis, which was always within 48 h.

The two standard solutions, which were not heated, were treated with 2 ml initiator solution followed immediately (or sometimes preceded) by 15 ml saturated inhibitor mixture. All solutions thus contained the same volume of solvent, within the limits of precision of pipet delivery.

Six different feed compositions were used. The volumes (totalling 15 ml) of monomers for these mixtures are given in Table 2.

Analysis

A Carle model 9000 gas chromatograph, with a hydrogen flame ionization detector and integrating recorder, was used to analyze for unreacted monomers and solvent. The column, which was packed with 8% dinonylphthalate on Anakron ABS, was operated at 93–96 °C with gas flow rates of 5 ml/15 s and 5 ml/7.2 s for helium and helium plus hydrogen, respectively.

A 1 μl syringe equipped with Chaney adaptor was used to inject 0.2–0.3 μl samples of the reaction mixtures directly into the column. A glass wool plug in the column inlet trapped the polymer and inhibitor. The only peaks observed with reacted samples were identical to those of the monomers and solvent in the standard samples. The pre-column unit was changed after analysis of the six reacted mixtures and two standards for each composition. This prevented excessive polymer build-up in the glass wool plug and consequent distortion of the gas chromatographic peaks.

The standard sample which had not been degassed was analyzed first. The degassed standard was analyzed immediately before and after the reacted mixtures. This checked that the detector sensitivity had remained constant over the course of the measurements. Reacted samples were analyzed in order of polymerization times, to minimize polymer loading on the pre-column plug. At least four replicate analyses were made for each reacted mixture and six for standard samples.

Analytical Accuracy

The accuracy of the analysis is determined by the limitations of the gas–liquid chromatographic technique. The accuracy with which the compositions of the standard solutions can be estimated from the make-up volumes is also a factor in the present application, because the solvent serves as an internal calibration standard (1). Systematic errors which have been troublesome in chemical analyses of nitrile-containing copolymers (10, 13) are unlikely in the present case because the monomers serve as calibration standards for detector sensitivity (4).

Five monomer mixtures were made to assess the accuracy of the gas chromatographic analysis and the metering of liquids in the initial feed compositions. All samples were analyzed in quadruplicate. One sample, containing 5 ml of each of the three monomers, was chosen as the standard and the ratios of its peak areas to those of the other mixtures were used to estimate the compositions of the other four solutions. All peak areas were normalized on the mean solvent peak area of the standard mixture, as described by Rudin and Yule (4).

The results of this experiment are shown in Table 1. It can be seen that the analytical technique used appears to be accurate to within 2% of the nominal make-up volumes of the monomer feeds. The coefficients of variation of peak areas of individual monomers appear to be independent of the concentration of the monomer. The reliability found here is generally as expected for gas chromatographic analyses and is probably at least as good as can be achieved by isolation and chemical analysis of polymer formed in the reaction mixture.

Analytical uncertainties of this order of magnitude make it impossible, however, to derive reliable reactivity ratios from measurements of a few polymer compositions at low conversions. This conclusion is probably valid for all analytical methods in current use, and is a factor in the lack of agreement which is often noted between results from different laboratories (6).

For this reason, gas chromatographic analysis of unreacted monomer concentrations is most reliable if a relatively large number of data points are obtained at various extents of reaction. These results are plotted against total percent conversion of monomers and the values for estimation of polymer composition are taken from the corresponding best-fit least squares line. The most accurate experimental points are those obtained at the highest conversions because the difference between the measured initial and final monomer concentrations is greatest under these conditions. The linear least squares fit gives these data the heaviest weighting. This procedure would appear to provide better estimates than those from the same number of analyses clustered at low conversions, because the uncertainty in the difference between two gas chromatographic analyses is independent of the magnitude of this difference. As pointed out below, this procedure does not prevent use of a differential form of the copolymer equation under some circumstances.

Calculations

The basic calculations used to obtain unreacted weight fractions of monomers from the raw data have been described previously, for copolymerization of styrene and methacrylonitrile (4). Figures 1–3 show plots of weight fraction monomer against reaction times for one of the feed compositions. The best-fit lines are obtained by a linear least squares fit to the mean values at each time.

The best-fit lines in such plots extrapolated to the feed composition at zero reaction time in previous studies of binary copolymerizations (2–4). This was not so, however, in the terpolymerizations reported here. The extrapolated value for initial weight fraction of MAN in Fig. 1 is lower than the value computed from the initial monomer volumes and densities. The converse situation is observed for AMS in Fig. 3. The deviations between make-up compositions and the corresponding extrapolated zero reaction time values are within the reliability limits indicated by the experiment summarized in Table 1. The differences could not be dismissed on these grounds, however, because they were systematic. The extrapolated initial values for methacrylonitrile tended to be lower than the figures estimated from volume make-up, styrene figures generally coincided, and the extrapolated α-methylstyrene values matched or exceeded the make-up counterparts.

These variations can be attributed to losses by volatilization from the reaction vessels and could have occurred when gases were removed by syringe to reduce pressure in the vapor phase at the beginning of the reaction or, less probably, when the septum cap was removed for addition of terminator solutions after the reaction

periods. The boiling points of the reaction mixture ingredients are: MAN 90, toluene 110.6, S 145, and AMS 163 °C. The deviations between initial feeds and zero-time extrapolation values can be accounted for if the vapor pressure of the liquids at 60° are in approximately the same ratios as their boiling points. No clear reason can be seen for the difference between the present work and previous experience with the same technique, although it is possible that it may be connected with a change of operators. The method used requires consistent manual technique; and even variations in the drainage of the pipet used to make the monomer feed mixtures can result in a noticeable increase in scatter of data. In retrospect, the estimates of initial feed compositions from relative volumes of monomers should have been verified by weighings.

For the reasons outlined above, the initial feed compositions were taken from the zero-time extrapolated values of the best-fit lines through the concentration reaction time plots (as

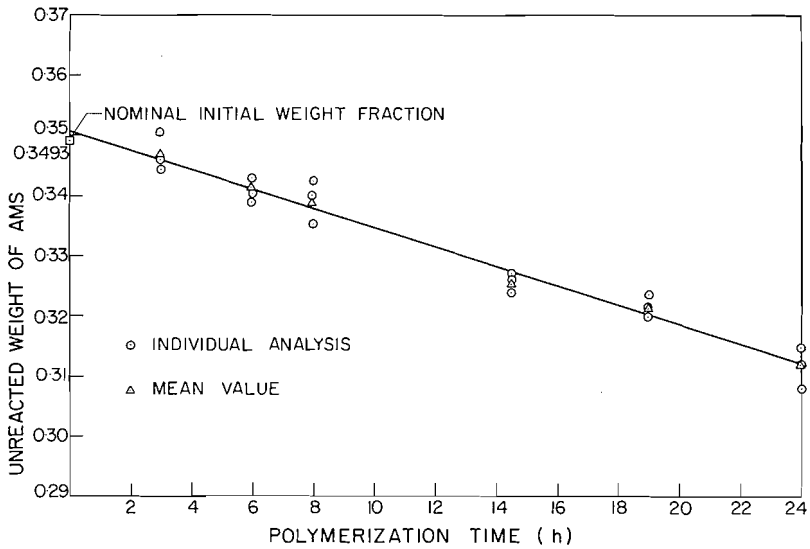

FIG. 3. Unreacted α-methylstyrene in 1 g initial total monomers as a function of reaction time. Feed composition: as in Fig. 1.

in Figs. 1–3) rather than from the make-up volumes. This procedure is consistent with the use of these lines to estimate relative monomer losses.

The experimental copolymer composition was compared to that calculated using the binary reactivity ratios reported previously for the three monomer pairs involved in these experiments (2–4). The instantaneous copolymer composition is given by the differential equation of Alfrey and Goldfinger (7): (eqs. 1 and 2) where the M_i are the molar concentrations of monomer i ($i = 1, 2, 3$) and r_{ij} ($i \neq j$) are the appropriate binary reactivity ratios. In the present case the monomer subscripts 1, 2, 3 refer to MAN, S, and AMS, respectively and the definitions of r_{ij} are the ones in standard use (14).

The terpolymer equation was integrated numerically, with a digital computer, using the method of Crescentini *et al.* (15) which assumes constant volume of reaction mixture. Integration was performed in increments of 0.001 mol change in M_3. The corresponding changes in M_1 and M_2 were calculated from eqs. 1 and 2 and the final monomer concentrations ($M_i - \mathrm{d}M_i$) were used as the initial values in the next iterative step. Fifty iterations accounted for about 15 weight percent conversion of monomers. The total weight percent conversion, conversion of each monomer and mean copolymer composition were calculated for each incremental change in M_3. The latter parameter is given by (15) eq. 3,

$$[3] \quad \bar{C}_{i\mu} = \frac{100 P_i \sum_{v=1}^{\mu} \delta M_{iv} \qquad i = 1, 2, 3}{\sum_{i=1}^{3} \sum_{v=1}^{\mu} P_i \delta M_{iv} \qquad P = 1, 2, \ldots}$$

where $\bar{C}_{i\mu}$ is the weight fraction of component i in the copolymer produced during μ iterative calculations, P_i is the formula weight of this monomer and δM_{iv} is the decrease in concentration of monomer i during the v'th iteration (from eqs. 1 and 2).

Reactivity Ratios

The binary ratios used in the foregoing calculations were reported previously (2–4). It should be noted in this connection that the reporting of a reactivity ratio as a single value with a standard deviation is not sound practice

$$[1] \quad \frac{\mathrm{d}M_1}{\mathrm{d}M_3} = \frac{M_1(M_1 r_{23} r_{32} + M_2 r_{31} r_{23} + M_3 r_{32} r_{21})(M_1 r_{12} r_{13} + M_2 r_{13} + M_3 r_{12})}{M_3(M_1 r_{12} r_{23} + M_2 r_{13} r_{21} + M_3 r_{12} r_{21})(M_3 r_{31} r_{32} + M_1 r_{32} + M_2 r_{31})}$$

$$[2] \quad \frac{\mathrm{d}M_2}{\mathrm{d}M_3} = \frac{M_2(M_1 r_{32} r_{13} + M_2 r_{13} r_{31} + M_3 r_{12} r_{31})(M_2 r_{21} r_{23} + M_1 r_{23} + M_3 r_{21})}{M_3(M_1 r_{12} r_{23} + M_2 r_{13} r_{21} + M_3 r_{12} r_{21})(M_3 r_{31} r_{32} + M_1 r_{32} + M_2 r_{31})}$$

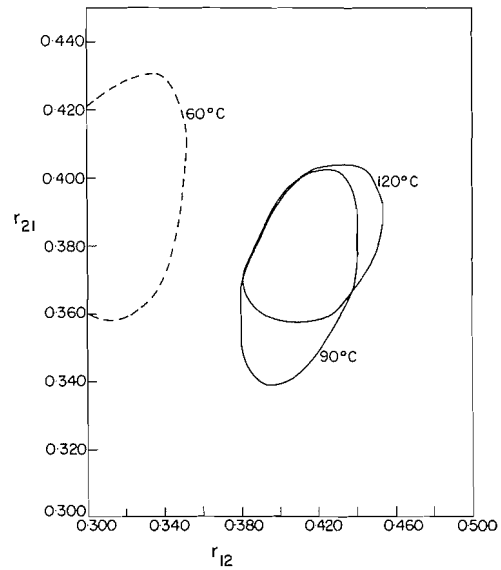

FIG. 5. Joint confidence limits for methacrylonitrile (monomer 1) and styrene (monomer 2) reactivity ratios.

because reactivity ratios are determined in pairs, and the corresponding experimental uncertainties are coupled. A better procedure involves calculation of joint confidence limits within which the correct values are believed to coexist with stated probability. Figure 4 shows the joint 95% confidence limits for MAN–AMS and S–AMS. These plots, which are combined from another report (3), were calculated by the method of Tidwell and Mortimer (16). Any point within the loops shown represents an equally likely ordered pair of reactivity ratios.

Joint confidence limit loops are shown in Fig. 5 for the methacrylonitrile–styrene pair. These calculations, which have not been reported before, are from the data of a previous study (4) of effects of temperature in this copolymerization. The data at 90 and 120 °C overlap and differ from those at 60 °C. It is expected theoretically that the temperature dependence of these reactivity ratios should be slight (17), and preliminary calculations did indeed show that calculated and experimental terpolymer compositions agreed better with r_{12} and r_{21} values from the overlapping elipses in Fig. 5 than from the 60 °C loop shown. This is further evidence, then, for the conclusion (4) that the reactivity ratios in this system are not significantly affected by reaction temperature in this range. The reasons for the deviation of the 60° copolymerization data are not clear.

Results

Table 2 compares the experimental and calculated mean terpolymer compositions at 5 weight percent total conversion of monomers. The reactivity ratios used were selected from the plots in Figs. 4 and 5 and are listed in Table 2. Other combinations of the six reactivity ratios could have been selected, of course, but a systematic study did not seem to be worthwhile, as a number of random selections of values from the joint confidence limit loops did not affect the agreement between experimental and calculated compositions very strongly.

The concordance between calculated and experimental copolymer compositions in Table 2 is about as close as those reported in studies of free radical terpolymerizations (8, 10, 15). The results indicate that the simple copolymerization model (7) is satisfactory, without allowance for penultimate effects or depropagation of sequences of α-methylstyrene units.

Prediction of copolymer composition is a

necessary, but not sufficient condition to show that a particular copolymerization model describes a system. The model should also be shown to give estimates which are independent of extent of reaction or feed composition (6). In this connection, Figs. 6–8 show the deviations between experimental and calculated copolymer compositions plotted against methacrylonitrile and styrene feed compositions, respectively. No particular trend is noticeable with varying feed composition in these figures. Similar plots against percent conversion of monomers would be trivial in the present case, for reasons discussed below.

Differential and Integrated Copolymer Equations

Analytical errors are reduced if the reaction is carried to as high a conversion as possible, since the content of a given monomer in the polymer equals the difference between its initial and final measured contents in the feed mixture. The uncertainty in the copolymer analysis is thus a smaller proportion of the estimated quantity, the greater the magnitude of the decrease in

9.50	9.17	0.255	0.339	0.406

monomer concentration in the feed (4). It seems appropriate under these circumstances to estimate reactivity ratios by fitting the data to an integrated form of the copolymer equation.

It should be noted, however, that straight-line representations, as in Figs. 1–3, imply that the copolymer composition does not vary significantly during the experiment. The ordinate in such a plot is the unreacted mass of a given polymer, with the intercept at zero reaction time being the mass of this monomer in unit total mass of monomers (weight fraction). The linear plot can then be expressed as:

$$[4] \qquad W_i = W_{0i} + S_i t$$

where W_i and W_{0i} are the mass of monomer i (in unit initial total mass of monomers) at reaction times equal to zero and t, respectively, and S_i is the slope of the line. The number of moles, P_i, of a given monomer in the polymer formed to time t is then:

$$[5] \qquad P_i = \frac{W_{0i} - W_i}{m_i} = \frac{S_i t}{m_i}$$

where m_i is the formula weight of monomer i. The corresponding mole fraction of this monomer in the polymer, f_i, is:

$$[6] \quad f_i = \left(\frac{S_i t}{m_i}\right) \Big/ \sum_i \left(\frac{S_i t}{m_i}\right) = \left(\frac{S_i}{m_i}\right) \Big/ \sum_i \left(\frac{S_i}{m_i}\right)$$

Thus f_i does not vary as long as the analytical data can be represented as shown in Figs. 1–3, by a line with constant slope, S. Conversely, a linear experimental relation shows that the copolymer composition does not vary significantly. Both the differential and integrated forms of the copolymer equation are then equally reliable in this range of monomer conversions. (The linearity observed cannot be expected to continue to complete conversion of monomers, except for azeotropic feed compositions (4).)

To illustrate this point, Table 3 lists integrated copolymer compositions calculated from the reactivity ratios listed in Table 2, for various conversions within our experimental range and at two of the more extreme feed compositions. The copolymer composition is seen to be almost invariant under these conditions if the simple copolymerization model describes the polymerization.

The predicted and experimental copolymer compositions could have been compared in the present case equally as well with a differential copolymer equation (eqs. 1 and 2) as with the integrated form which was actually used. Other factors must be taken into account, however, if the object of the experiments is the calculation of reactivity ratios from the analytical data. The best procedure then involves use of a non-linear least squares fit to a differential equation or use of an integrated form of the copolymer equation. A linear least squares fit of reactivity ratios to analytical data in a differential copolymer equation can lead to errors even when the polymer composition does not vary over the experimental range of monomer conversions (3, 4, 6, 16).

These considerations suggest that it might be possible to estimate reactivity ratios directly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

from gas chromatographic analyses of multicomponent polymerizations in some cases. If the plots of unreacted monomer against polymerization time are linear a sufficient number of analyses should be made to establish the slope of these lines accurately. A least-squares fit to eqs. 1 and 2 can then be made by computer iterations starting with approximate reactivity ratio values (as from Q–e calculations) to obtain the best values of the reactivity ratios. This procedure is being investigated and will be reported separately if it should prove to be mathematically tractable.

Azeotropy in Ternary Copolymerizations

The question of azeotropy in ternary copolymerization has been discussed extensively (18–22). Tarasov and coworkers (22) suggest that a necessary and sufficient condition for existence of an azeotrope is that S, Q, and R (eqs. 7*a–c*) have the same sign and are different from zero. The azeotropic feed composition is given by eq. 8. Substitution of the reactivity ratios listed in Table 2 into eq. 8 gives the azeotropic feed as 0.471, 0.320, and 0.209 in terms of mole fractions of MAN, S, and AMS, respectively.

$$[7a]\quad S=\left(1-\frac{1}{r_{13}}\right)\left(\frac{1}{r_{32}}-1\right)-\left(\frac{1}{r_{12}}-\frac{1}{r_{13}}\right)\left(\frac{1}{r_{31}}-1\right)$$

$$[7b]\quad Q=\left(\frac{1}{r_{21}}-\frac{1}{r_{23}}\right)\left(\frac{1}{r_{12}}-\frac{1}{r_{13}}\right)-\left(1-\frac{1}{r_{23}}\right)\left(1-\frac{1}{r_{13}}\right)$$

$$[7c]\quad R=\left(\frac{1}{r_{31}}-1\right)\left(1-\frac{1}{r_{23}}\right)-\left(\frac{1}{r_{32}}-1\right)\left(\frac{1}{r_{21}}-\frac{1}{r_{23}}\right)$$

$$[8]\quad M_1:M_2:M_3=R\left(\frac{Q}{r_{13}r_{32}}+\frac{S}{r_{12}r_{23}}+\frac{R}{r_{12}r_{13}}\right):S\left(\frac{S}{r_{21}r_{23}}+\frac{Q}{r_{23}r_{31}}+\frac{R}{r_{21}r_{13}}\right):Q\left(\frac{Q}{r_{31}r_{32}}+\frac{S}{r_{21}r_{32}}+\frac{R}{r_{12}r_{31}}\right)$$

None of the experimental feeds listed in Table 2 has exactly the same composition as that calculated for the azeotropic mixture. The listed mixtures which resemble the azeotrope to the extent that the mole fraction of MAN is greater than 0.4 do, however, yield polymers with compositions sufficiently close to that of the feed to qualify as azeotropic reactions, for practical synthetic purposes.

Slocombe (23) proposed an empirical rule for prediction of the occurrence of high clarity terpolymers. Termonomer systems which form two azeotropic copolymers were found to give clear products frequently when the ratio of monomers in the feed was taken from values on a line joining the azeotropic compositions in a triangular diagram. An example given was the acrylonitrile–styrene – α-methylstyrene system, which is formally similar to the monomer trio in this report. (It should be noted, however, that the reactivity ratios Slocombe used for the styrene – α-methylstyrene pair are quite different from those found in this laboratory (2).)

In binary systems, an azeotropic composition is defined by eq. 9. Both reactivity ratios must

$$[9]\quad \frac{M_i}{M_j}=\frac{1-r_{ji}}{1-r_{ij}}$$

be less than unity for occurrence of an azeotrope. In the present case, binary azeotropes can be formed by the styrene–methacrylonitrile and methacrylonitrile – α-methylstyrene monomer pairs. A plot of the data according to Slocombe's rule suggests that termonomer feeds containing about 0.5 mol fraction of methacrylonitrile and various corresponding combinations of styrene and α-methylstyrene concentrations would yield clear copolymers. This is consistent with the conclusions from the results in Table 2 that the experimental feeds with higher methacrylonitrile content gave copolymers with compositions quite close to that of the monomer mixture. The products of such reaction mixtures can evidently not vary much in composition as the monomer charge is depleted.

While no true azeotrope has been demonstrated in this work, it is clear nevertheless that a number of monomer mixtures gave products which are close enough to the azeotropic state to be so treated for all practical purposes. In this case, also, both the expression of Tarasov *et al.* (22) and Slocombe's rule (23) apparently predict

the azeotropic composition with an accuracy suitable for most purposes. (Slocombe's rule must be interpreted in this context as implying that optical clarity of the copolymer product indicates an invariant, azeotropic composition.)

Discussion

The results of this work support the conclusions of previous studies (2, 3) that free radical copolymerization behavior of α-methylstyrene is described by the conventional simple model in which the reactivity of a given polymer radical is determined only by the natures of the terminal unit in the radical and the adding monomer. The sequence lengths of this monomer in binary copolymers with styrene and methacrylonitrile are sufficiently short that their ceiling temperatures (24) are considerably higher than that of high molecular weight poly(α-methylstyrene). This difference stems from the inverse relation between enthalpy of polymerization and degree of polymerization, at low poly(α-methylstyrene) molecular weights (25). That is to say, the composition of binary copolymers was indicated to be controlled by kinetic rather than by possible thermodynamic (ceiling temperature) or steric (penultimate unit) effects.

Kinetic control would be expected to be even more pronounced in terpolymerizations than in binary copolymerizations. The average sequence length in high molecular weight terpolymers is smaller than in any one of the corresponding three binary copolymers made from the same feed ratio (26). It is not surprising, then, that the simple copolymer model which was found to apply in the binary cases also describes the terpolymerization.

Free radical polymerization of α-methylstyrene tends to be comparatively slow. This presumably reflects the existence of a normal bimolecular termination rate and slow propagation rate due to steric hindrances at the doubly substituted vinyl carbon atom. (Transfer of an allylic hydrogen from the α methyl could also be a factor.) Qualitatively, we note that polymerization rates are faster in a termonomer system than in binary polymerizations. Feeds (Table 2) with relatively low α-methylstyrene concentrations gave conversions of about 15% total monomers in 24 h at 60 °C. The conversion for higher α-methylstyrene contents was about 9%, but both polymerization rates are considerably faster than those noted previously in binary systems (2, 3). This would be expected to parallel the lower mean sequence lengths of terpolymers.

The authors thank the Defence Research Board of Canada for financial support.

Thermolysis of γ-Phenylazo-γ-valerolactone

H. LUI AND J. WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received January 20, 1972

γ-Phenylazo-γ-valerolactone decomposed at 230° to 4,5-dihydro-6-methyl-2-phenyl-3(2*H*)-pyridazinone and to 6-methyl-2-phenyl-3(2*H*)-pyridazinone.

La γ-phénylazo-γ-valérolactone se décompose à 230° pour donner la 4,5-dihydro-6-méthyl-2-phényl-3(2*H*)-pyridazinone et la 6-méthyl-2-phényl-3(2*H*)-pyridazinone.

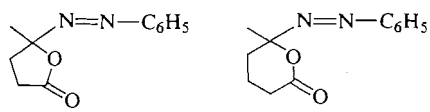
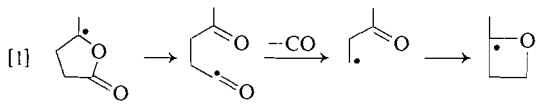
Introduction

A γ-phenylazo-γ-lactone (**1**) and a δ-phenylazo-δ-lactone (**2**) were synthesized recently by oxidation of appropriate phenylhydrazones with lead tetraacetate (1, 2). The chemistry of these



1 2

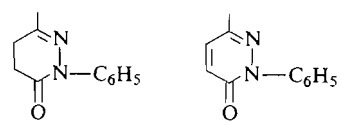
unsymmetrical azo compounds is of interest because they are potential sources of the corresponding γ- and δ-lactonyl radicals, the chemistry of which has not been explored. For example, the reactions of eq. 1 might occur; acyl radicals and α-alkoxyalkyl radicals being well known intermediates in other reactions. Accordingly we pyrolyzed **1**, both neat and as a solution in cumene.



Results and Discussion

The azo compound, **1**, was found to be surprisingly stable, with a half life at 230° (neat) near $3\frac{1}{2}$ h. For comparison, phenylazo-1,1-dimethylethane is reported (3) to be extensively decomposed on distillation at 56–58° (2.3 mm). Therefore substitution of ester oxygen for carbon, depicted below, appears to increase the stability of an azo compound substantially.

The products of thermolysis of **1** were also surprising. Analysis and molecular weight revealed that the major non-volatile products differ from starting material by one oxygen atom or by one oxygen and two hydrogen atoms. Their spectra suggested that appropriate structures might be **3** and **4**, respectively; an assignment that was confirmed by independent synthesis. The ratio (**3**:**4**) was 1.75:1, from pyrolysis of neat **1**, and the combined yield (estimated by n.m.r.) was greater than 80%. Gaseous products, which comprised about 0.5 mol per mol of **1** decomposed, consisted mainly of N_2 (and/or CO) and CO_2. Oxygen was also present but the amount of the latter varied from one run to another, presumably because it reacts at 230° with the organic materials present. Water and benzene were also detected.



3 4

It is fairly clear from the product composition that the major reaction pathway does not involve homolytic C—N bond-breaking characteristic of the high temperature chemistry of azo compounds. In view of this unexpected course, it became important to attempt rationalization of the reactions that do occur. An attractive first step is intramolecular nucleophilic addition to the carbonyl group, to form a bicyclo-[2.2.1]-system, which could open to a six-membered ring, eq. 2. If **6** were formed it might undergo an intramolecular addition of the Michael type, leading to **7** which in turn could open to the nitrone (**8**), eq. 3. Tautomerization of **8**, possibly by the action of the basic oxygen atom

[4] 
9 4

[5] 
of one molecule on the acidic ring protons of another (4), to hydroxylamine system **9**, is analogous to enolization (5). Finally, loss of water by 1,4-elimination (eq. 4) could lead to **4**.

It is more difficult to devise a reasonable route to the major product **3**, which differs from the substrate by one oxygen atom. Although organic reactions which liberate oxygen are rare, we considered the possibility that two molecules of **3**, and one of O_2, are formed in a bimolecular process from isomers of **1**. One such scheme is shown as eq. 5. We tentatively propose this mechanism because of the known tendency of nitrones to dimerize (5) and because, in invoking **8** as intermediate, it is consistent with the proposed mechanism for forming **4**.

In an attempt to change the reaction course through capture of an intermediate, **1** was heated at 230° in cumene. Again **3** and **4** were obtained, in approximately 1.3:1 ratio. A control experiment showed that **4** is not reduced to **3** by cumene under those conditions. The product ratio from pyrolysis of **1** in cumene is therefore about the same as that from pyrolysis of

neat **1** and provides no information about mechanism.

Experimental

γ-Phenylazo-γ-valerolactone (**1**, 1.9242 g, 0.0094 mol) was heated at 230° under nitrogen for 7 h. The crude product was placed on alumina (Fisher A950, 28 × 1.5 cm column) from which fractions were eluted with ether.

The first fraction (100 ml) contained a reddish-brown solid, m.p. 100–102°, which was recrystallized from a solution of alcohol in petroleum ether (1:1) to yield a white solid (0.97 g, 55%), m.p. 104–106°, identified as 4,5-dihydro-6-methyl-2-phenyl-3(2*H*)-pyridazinone (**3**) (lit.[1] (6) m.p. 107°), p.m.r. (CCl_4) δ 2.04 (s, 3, CH_3), 2.65 (s, 4, CH_2CH_2), 7.35 (m, 5, C_6H_5); i.r. ($CHCl_3$) 1670 cm^{-1} (C=O); u.v. (C_2H_5OH) λ_{max} 235 nm, log ε 4.02; mass spectrum (*m/e*, relative intensity in brackets) 189(14), 188(100), 186(12), 185(8), 160(8), 159(14), 119(62), 105(8), 93(12), 92(24), 91(30), 77(50), 65(8), 64(10), 53(8), 51(18).

The second 100 ml fraction from the column yielded a yellow semi-solid which was crystallized from ethanol in petroleum ether (1:1) to give 0.35 g (20%) of colorless plates identified as 6-methyl-2-phenyl-3(2*H*)-pyridazinone (**4**), m.p. 77.5–78° (lit. (6) m.p. 79–80°). Identity of this compound was confirmed by analysis, through its formation from **3** (see below), and from its spectra: p.m.r. (CCl_4) δ 2.28 (s, 3, CH_3); 6.88 (q, 2, vinyl); 7.48 (m, 5, C_6H_5); i.r. (CCl_4) 1675 cm^{-1} (C=O); u.v. (C_2H_5OH) λ_{max} 312 nm, log ε 3.64; mass spectrum (*m/e*, relative intensity in brackets) 188(20), 187(14), 186(100), 185(46), 158(22), 157(20), 119(12), 118(6), 117(8), 93(10), 92(12), 77(52), 53(30), 52(8), 51(20), 50(8).

Anal. Calcd. for $C_{11}H_{10}N_2O$ (mol. wt. 186): C, 70.96; H, 5.38; N, 15.05. Found (199 (vaporimetric)): C, 70.94; H, 5.32; N, 15.10.

Further fractions from the column gave small amounts of colored materials which were not identified.

4,5-Dihydro-6-methyl-2-phenyl-3(2H)-pyridazinone from Levulinic Acid Phenylhydrazone

Levulinic acid phenylhydrazone (31.5 g) was stirred for 24 h at room temperature with 150 ml of concentrated H_2SO_4 (6). The solution was diluted to 1600 ml with crushed ice and the white precipitate which settled was collected. It was washed several times with cold dilute bicarbonate solution and with water before it was dried. Crystallization from methanol gave the title compound (70%), m.p. 105–106°, with spectra identical to those of **3** obtained from **1** by pyrolysis. The mixture m.p. was 105–106°.

Thermolysis of 1 in Cumene

The lactone (**1**, 0.57 g, 2.8 mmol) and freshly-distilled cumene (1 ml), in an evacuated, sealed tube, were heated at 230° for 7 h. Cumene was then removed by vacuum distillation. The n.m.r. spectrum of a portion of the residue indicated roughly 50% of starting material still present, together with **3** and **4** in the ratio 1.3:1, respectively. Chromatography on neutral alumina (Fisher A950, 20 × 1.5 cm column) yielded **3** and **4** in the ratio 1.2:1 and unreacted **1**.

In a control experiment, **4** was heated with cumene at 230° for 7 h. The residue left after distillation showed only **4**, and no trace of **3**, by n.m.r.

Oxidation of 3 with DDQ

4,5-Dihydro-6-methyl-2-phenyl-3(2*H*)-pyridazinone (2.0 g, 0.01 mol) was treated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ, 2.4 g, 0.01 mol) in refluxing dioxane (80 ml). The color of the solution changed from green to brown during the sixth hour and crystals of the hydroquinone settled out. After 40 h had elapsed, the mixture was filtered and dioxane was removed from the filtrate by vacuum distillation. The residue was placed on a column (30 × 2.5 cm) of neutral (A 950) alumina. Elution with petroleum ether (2 l), followed by 50% ether in petroleum ether gave **4** which was obtained as colorless plates by recrystallization from CCl_4, m.p. 77.5–78°. Spectra of this material matched those of material, labelled **4**, originating from pyrolysis of **1**.

Gaseous Products

A sample of **1** (0.174 g, 0.85 mmol) was heated neat at 230° for 7 h in an evacuated tube fitted with a breakseal. The tube was fitted to a Hitachi RMU-6A mass spectrometer where the quantity of gas was found by expanding it from the cold tube into a calibrated section of the instrument. The volume was 141 cc at 52.5 mm and 293 °K; 0.41 mmol or 48%, based on one to one stoichiometry. Composition was estimated from the peak intensities at *m/e* 28, 32, and 44 to be $N_2:O_2:CO_2 = 1.7:1.9:1$; assuming that *m/e* 28 was primarily from N_2 and not from CO. The ratios varied greatly from run to run, with CO_2 apparently dominating in some cases, and with O_2 much less prominent. They have no quantitative significance.

The residue in the tube was dissolved in CCl_4 and the solution was filtered. A p.m.r. spectrum of the material showed primarily two products, **3** and **4**, in the ratio 1.75:1, and no trace of starting material.

[1]The authors (6) named **3** incorrectly as 2-phenyl-6-methyl-3-pyridazinone.

Mechanisms of S_Ni Reactions. The Kinetics of the Decomposition of Aralkyl Carbonates[1]

J. M. PROKIPCAK AND T. H. BRECKLES
Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 19, 1971[2]

Anisylic phenyl carbonates decomposed at elevated temperatures to give CO_2 and the corresponding anisylic phenyl esters. The decomposition follows first order kinetics very similar to those found for alkyl chloroformates. The decompositions involve the heterolysis of the aralkyl oxygen bond followed by the breakdown of the subsequent ion pair via a cyclic mechanism. The dependence of the decomposition rates on the nature of the solvent and structural changes of the starting carbonates is discussed.

Les carbonates d'anisyle et de phényle se décomposent à hautes températures pour donner du CO_2 et les oxydes correspondants d'anisyle et de phényle. La décomposition obéit à une loi cinétique du premier ordre, très semblable à celle trouvée dans le cas des chloroformates d'alkyle. La décomposition implique l'hétérolyse de la liaison aralkyle-oxygène, suivie d'une dissociation de la paire d'ions par un mécanisme cyclique. L'influence sur les vitesses de décomposition de la nature du solvant et de modifications structurales dans les carbonates de départ, est discutée.

Canadian Journal of Chemistry, **50**, 1770 (1972)

Introduction

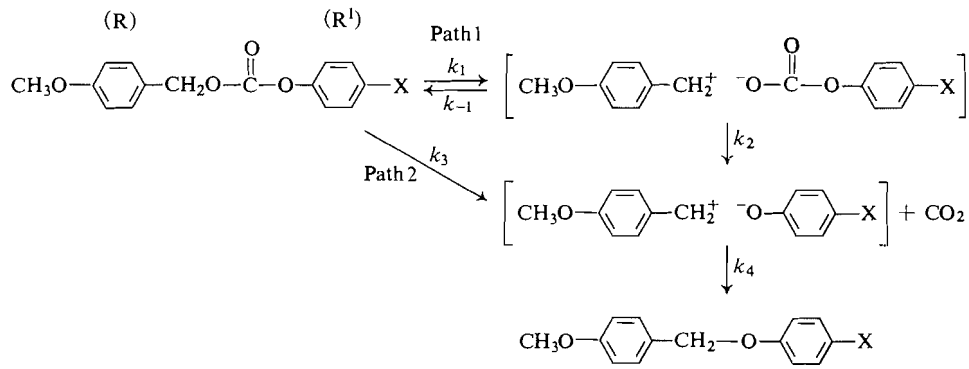
Previous work (1) indicated that the decomposition under investigation could follow one of the two paths as shown in Scheme 1. The overall reaction scheme applies to two analogous reactions. One is the thermal decomposition of thiocarbonates (2, 3) which involves a path 1 mechanism, whereas similar experiments on alkyl chloroformates (4, 5) show that the path 2 mechanism (or path 1 with $k_2 \gg k_{-1}$) may be operative. The basic difference in the two reaction paths is the timing of the various bond scissions.

All the carbonates studied decomposed reasonably fast at 150 °C to give excellent yields of the corresponding ethers. The variation in decomposition rates due to structural changes in R and R^1 as well as solvents of different dielectric constants was examined. This report gives the result of the investigation and a mechanism is proposed with particular attention being given to the question of timing of the various bond scissions.

Experimental

Synthesis and Decomposition of Carbonates

The synthesis, physical constants, etc. of the carbonates



SCHEME I

	p-Nitrophenyl	1.49×10^{-2}

*Decompositions carried out using hexamethylphosphoramide as solvent.

†General structure is R—O—C(=O)—O—R^1.

used in this study can be found in previous work (*1*). Similarly their decomposition temperatures, the identification of phenolic side products, the characterization of the major products (anisylic phenyl ethers) along with their physical constants and elemental analysis are reported.

Kinetics of the Decompositions

The decompositions of all the carbonates were followed by means of n.m.r. using a Varian A 60A instrument. A typical kinetic run will be outlined. A solution of the carbonate (5.0 g) in hexamethylphosphoramide (4 cc) was made and equal aliquots (0.5 ml) of this solution were put into a series of n.m.r. tubes. These tubes were placed in an equilibrated (constant temperature) oil bath at 150°. These tubes were then removed at proper time intervals and immediately quenched in a Dry Ice–acetone mixture. Equivalent amounts of diglyme (1.0 ml) were added to each tube to act as a standard and the carbonate methylene peak and the diglyme standard peak were measured. The relative integrated areas gave the carbonate concentration changes. Diglyme was used as a standard for three reasons: (*1*) diglyme did not have numerous peaks in the critical region of the n.m.r. spectrum which was being used; (*2*) diglyme had a singlet near the carbonate methylene peak which meant that only a small portion of the n.m.r. spectrum had to be integrated; (*3*) all reaction components were soluble in diglyme.

Results and Discussion

Using the aforementioned method, the decompositions were found to exhibit good first order kinetics over at least 90% of the reaction. The first order rate constants were obtained by plotting log concentration *vs.* time. Table 1 summarizes the results of the various kinetic runs for the anisyl *p*-substituted phenyl series. The method of least squares was used in order to determine the slopes of the lines and in all cases regression coefficients of at least 0.990 were obtained.

In order to get as complete a picture as possible, the influence of both R and R^1 on the decomposition rates was investigated. First the effect of structural changes of the aralkyl group (R) was examined. This group would form the carbonium ion in the reaction if indeed it formed and any variation in rate of decomposition would indicate just how dependent the reaction is on this carbonium ion formation. The results in Table 2 indicate that the mechanism involves at least in part the heterolysis of the aralkyl–oxygen bond with the formation of an aralkyl carbonium ion. The relative decomposition rates are very similar to what one would expect on the basis of carbonium ion stability. For example, the addition of a methoxy group which has the ability to stabilize an electron deficient center by its inductive effect causes an increase in decomposition rate. This is shown to be the case in going from the benzhydryl to the *p*-methoxybenhydryl as well as from the anisyl to the 3,4-dimethoxybenzyl compounds. Furthermore when one adds a benzene ring to the aralkyl group, one adds resonance stability to any carbonium ion that may be forming and an increase in rate should be observed. This occurred when a comparison of decomposition rates was made between the anisyl phenyl and *p*-methoxybenzhydryl phenyl carbonates. The variation in decomposition rates with the variation of the aralkyl group's ability to stabilize an electron deficient center by resonance or an inductive effect would seem to indicate at least partial carbonium ion formation is occurring.

Further support for the heterolysis of the aralkyl–oxygen bond is drawn from the influence of solvents of different ionizing powers. In order to make the solvent comparisons as valid as possible, all kinetic runs were carried out at 150°. At this temperature, the decomposition in diphenyl ether did not, practically speaking, occur. The decomposition reactions did occur more rapidly in solvents of high ionizing power. This very marked difference in rate upon going to solvents of the high ionizing power indicates that under the reaction conditions, the decomposition reaction does involve an ionization process (6). However, how complete this ionization actually is is not known at this time.

TABLE 2. Decomposition rates of aralkyl phenyl carbonates*

Aralkyl group (R)	Solvent (dielective constant)	k_1 (s^{-1})	Relative rate
	Hexamethylphosphoramide (HMP)	1.61×10^{-5}	0.05
	HMP	1.74×10^{-4}	0.57
	Dimethylformamide (38.9)	3.29×10^{-4}	1.09
	HMP (30.0)	3.02×10^{-4}	1.00
	Benzonitrile (25.2)	5.42×10^{-5}	0.18
	Diphenyl ether (3.65)	Too slow to measure	
	HMP	3.37×10^{-2}	112

*General structure is  .

The dependence of the decomposition rates on the nature of the substituted phenoxy group (R^1) was next investigated. Whether the actual mechanism involved path 1 or 2, there should be a correlation between the decomposition rate and the electron-withdrawing character of the phenoxy group. One should observe an enhancement in rate by an electron-withdrawing group since this should stabilize the negative charge of the carboxylate ion or the R^1O^- anion. This was in fact what was found when a plot of log k/k_0 *vs.* σn (7) was made for the two series. Figure 1 shows the plots for the anisyl and 3,4-dimethoxybenzyl series. Both series yielded a ρ value of +2.11. As in the case of the kinetic runs, the method of least squares was used to determine the slope of the two Hammett plots. The positive ρ values obtained would indicate that the decomposition of the transition state requires the dispersal of a negative charge which has accumulated adjacent to the benzene ring carrying the substituent, *i.e.* the phenoxy group. These results are in accord with results from studies of urethanes (8), thiocarbonates (2), and thiosulfonates (9). The fact that both series investigated have the same positive value is not surprising since the only difference between the anisyl phenyl and 3,4-dimethoxybenzyl phenyl carbonate is the additional methoxy group on the benzyl portion of the molecule. This could help to stabilize the positive charge when formed but would have no effect on the dispersal of the negative charge on the anion portion of the molecule.

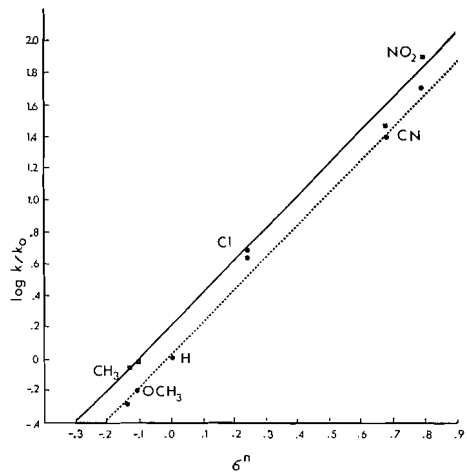

FIG. 1. Log k/k_0 for carbonates plotted against Hammett σ^n values, solid line for anisyl phenyl carbonates and dashed line for 3,4-dimethoxybenzyl phenyl carbonates. The ρ values for both plots were + 2.11

An interesting aspect of the decomposition was found when the rates of decomposition of the various anisyl phenyl carbonates were plotted against the pK_A values of the corresponding substituted phenols (Fig. 2). It can

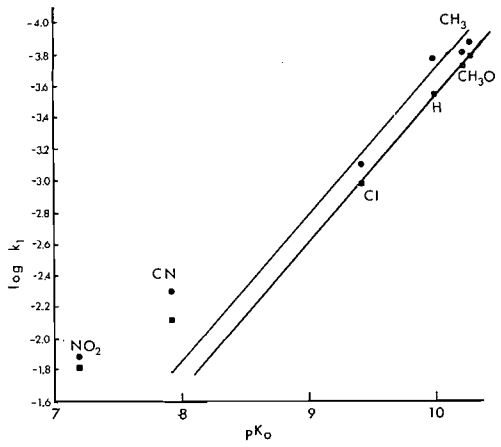

FIG. 2. First order rate constants for the anisyl (●) and 3,4-dimethoxybenzyl (■) phenyl carbonates *vs.* the pK_A values of *p*-substituted phenols H—O—C$_6$H$_4$—X.

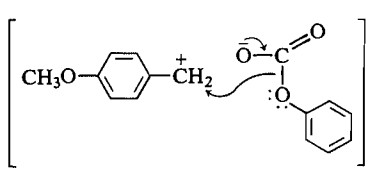
be seen from Fig. 2 that *p*-cyano and *p*-nitrophenol deviate from the straight line and these two rates are appreciably slower than would be expected on the basis of pK_A values. The observed deviation could be explained by a transition state of anionic character in which the *p*-CN and *p*-NO_2 groups can only interact partially with the full negative charge. Such would be the case if the anionic species in the transition state were the carboxylate anion. Here the negative charge is removed from the phenolic portion of the molecule and thus only a part of this charge can interact mesomerically with the *p*-CN or *p*-NO_2 group. If the negative charge which is to be dispersed in the transition state were on the phenolic oxygen, the *p*-CN and *p*-NO_2 groups would be able to exert their full influence and the relative decomposition rates should coincide with the pK_A values of the corresponding substituted phenols. This effect has been previously observed for thiocarbonate decompositions (2).

Another possible explanation would be to consider a transition state such as below where the initial ion pair intermediate resulting from the aralkyl–oxygen bond cleavage can break down via a cyclic mechanism.



The electrons on the phenolic oxygen are needed for the reaction to occur and any substituent such as cyano or nitro which could effectively remove these electrons by resonance would inhibit the decomposition to a certain extent. The chloro substituent, though electron-withdrawing, cannot remove electrons by resonance and so no appreciable deviation occurs. Cyclic intermediates have been proposed for chloroformate (10) and carboxylic thiolcarbonic anhydride (11) decompositions.

From the completed work, a path 1 mechanism seems to best explain the experimental results. The initial ion pair formed may then break down via a cyclic manner to give the products. The breakdown of the ion pair would seem to depend primarily on the ability of the phenoxy group to stabilize the negative charge on the anionic portion of the ion pair. It is doubtful if any appreciable separation of this ion pair occurs for if it did, electrophilic substitution of the phenolic portion by the anisylic carbonium ion should be substantial (12). This would result in a much lower yield of ethers than was actually obtained.

The experimental results obtained thus far do not permit us to distinguish whether in this path 1 mechanism $k_2 \gg k_{-1}$ or $k_2 < k_{-1}$. The data are consistent with either interpretation. Stereochemical work would indicate whether racemization (k_{-1}) of an optically active starting carbonate occurs faster or slower than its decomposition (k_2). This information along with activation parameters would do much to help in elucidating further on the mechanism of the decomposition and experiments in this line are now in progress.

The authors wish to thank the National Research Council of Canada for financial support of this research and the Department of University Affairs for the award of an Ontario Graduate Fellowship to T. H. Breckles. We also wish to thank Dow Chemical of Canada Ltd. for a generous supply of HMP.

NOTES

Triazine Intermediates in the Decomposition of 1-(*o*-Carbethoxyphenyl)-3-(*o*-cyanophenyl)-triazene in Aqueous Ethanol

KEITH VAUGHAN

Department of Chemistry, St. Mary's University, Halifax, Nova Scotia

Received December 14, 1971

The thermal decomposition of 1-(*o*-carbethoxyphenyl)-3-(*o*-cyanophenyl)-triazene (**4**) in aqueous ethanol has been found to give 2-phenylquinazolin-4(3*H*)-one (**8**); the formation of triazine intermediates in the reaction has been established.

La décomposition thermique du (*o*-carbéthoxyphényl)-1 (*o*-cyanophényl)-3 triazène (**4**) dans l'éthanol aqueux conduit à la 3 *H*-phényl-2 quinazolinone-4 (**8**); la formation intermédiaire de triazine dans la réaction a été établie.

Canadian Journal of Chemistry, **50**, 1775 (1972)

In a previous report (1), the thermal decomposition of 1,2,3-benzotriazin-4(3*H*)-one (**1**) was found to give quinazolino[3,2-*c*][1,2,3]benzotriazin-8-one (**2**). An extensive study by Stevens and his co-workers (2–4) has shown that the imino-analogue of **2** is an intermediate in the conversion of 1,3-di-*o*-cyanophenyltriazene (**3**) to 4-amino-2-phenylquinazoline in aqueous ethanol. It was thus of interest to study the reactions of 1-(*o*-carbethoxyphenyl)-3-(*o*-cyanophenyl)-triazene (**4**), which, by analogy, would be expected to provide an alternative route to the triazinoquinazolone (**2**).

The coupling reaction of aromatic diazonium salts with primary aromatic amines is a general method of synthesis of diaryltriazenes (diazoamino compounds) (5), but the triazene **4** required for this study had not previously been reported. Diazotization of ethyl anthranilate, followed by coupling of the cold diazonium salt solution with anthranilonitrile, gave a 50% yield of 1-(*o*-carbethoxyphenyl)-3-(*o*-cyanophenyl)-triazene (**4**); the spectroscopic properties of this product are in accord with either of the tautomeric structures **4***a* ⇌ **4***b*.

Prolonged refluxing (2–3 weeks) of the triazene **4** in 70% aqueous ethanol gave an 80% yield of 2-phenylquinazolin-4(3*H*)-one (**8**), which was identical with an authentic sample (6). Shorter reaction times in the same solvent medium gave mixtures of unchanged starting material (varying from 70% recovery after 2 h reflux to 10% after 100 h), the quinazolone **8**, and quinazolino[3,2-*c*][1,2,3]benzotriazin-8-one (**2**) (maximum yield 20% after 15 h reflux). The latter product, **2**, was identical with the product of thermolysis of 1,2,3-benzotriazin-4(3*H*)-one (**1**) (1). These results are summarized in Table 1.

The quinazolone **8** may arise from the triazene **4** by either route *i* or *ii*, as shown in Scheme 1. Nucleophilic addition at the nitrile group in tautomer **4***a*, a characteristic reaction of *o*-cyanophenyltriazenes (2), would lead to the formation of the 3-aryl-4-iminobenzotriazine **5**, which could cyclize directly to the quinazolino-[1,2-*c*][1,2,3]benzotriazine (**7**; route *ii*). Alternatively, the intermediate ester **5** could undergo Dimroth rearrangement to the isomeric 4-aryliminotriazine **6**, followed by cyclization at the ortho-ester group to give the triazinoquinazolone (**2**; route *i*). A less likely source of the triazinoquinazolone **2** is the isomerization **7** → **2**. Reductive loss of nitrogen from either of the isomeric triazinoquinazolones, **2** or **7**, would then yield the observed product, 2-phenylquinazolin-4(3*H*)-one (**8**).

The available evidence almost overwhelmingly supports route *i* as the more likely mechanism. The triazinoquinazolone **2** is a minor product when the triazene **4** is refluxed in aqueous ethanol for short periods, and has been shown in a previous report (1) to undergo conversion to the quinazolone **8** after 15 h refluxing in aqueous ethanol. Stevens has shown (2*b*) that

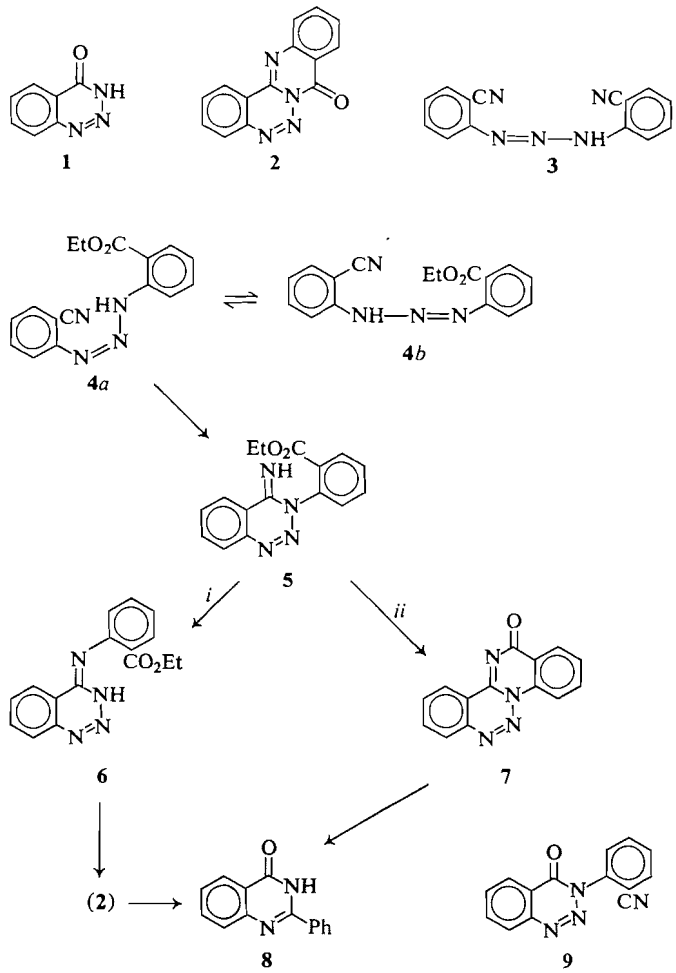

SCHEME I

3-aryl-4-imino-1,2,3-benzotriazines undergo facile Dimroth rearrangement to the isomeric 4-arylimino-1,2,3-benzotriazines (such as **5** → **6**), and that the rearrangement is accelerated in triazines bearing electron-attracting substituents (*e.g.* **5**). It has also been established that the conversion of 1,3-di-*o*-cyanophenyltriazene (**3**) to 4-amino-2-phenylquinazoline (**4**) most likely proceeds in a manner analogous to route *i*.

The long reflux time required for complete

decomposition of the triazene **4** indicates an unusually low reactivity compared with compounds of similar structure. The cyclizations of *o*-cyanophenyltriazenes (2) and *o*-carbalkoxyphenyltriazenes (7) to the corresponding 1,2,3-benzotriazines require only 1–2 h reflux in 70% aqueous ethanol, and the conversion of the dinitrile **3** to 4-amino-2-phenylquinazoline is quantitative in 95% ethanol at 20° after 48 h (3*a*). These cyclizations cannot take place unless the triazene is in the less stable *cis*-configuration about the N=N bond, and in all reactions of this type there is probably a *trans* → *cis* isomerization prior to cyclization (2*b*). Inspection of models of the *cis*-configurations of triazenes **3** and **4** shows that, in the nitrile-ester (tautomer **4***a*), there is considerable steric interaction between the nitrile and ester groups, whereas in the dinitrile **3**, there is no interaction at all between the nitrile groups. Thus the low reactivity of the nitrile-ester **4** is probably a result of the instability of the *cis*-isomer due to steric factors. The models do not reveal any difference in the stability of the tautomers **4***a* and *b*, and thus do not explain why the expected product of cyclization of tautomer **4***b*, 3-(*o*-cyanophenyl)-1,2,3-benzotriazin-4-one (**9**), is not found in any of the reaction mixtures. The latter observation may be interpreted as a difference in reactivity of nitrile and carbethoxy groups towards nucleophilic addition of amino nitrogen.

Stevens (3*a*) found that decomposition of 1,3-di-*o*-cyanophenyltriazene (**3**) on alumina afforded quickly the imino-analogue of the triazinoquinazolone **7**, and by analogy alumina-catalyzed decomposition of the triazene **4** would be expected to give rise to **7**. However, the triazene **4** was found to decompose very slowly in the presence of alumina and a low yield of the triazinoquinazolone **2** was obtained. Evidently, if isomer **7** is formed in this reaction, it must isomerize readily to **2**.

Experimental

Melting points were obtained on a Fisher–Johns apparatus and are corrected. The i.r. spectra were recorded with liquid paraffin mulls on a Perkin–Elmer Infracord spectrophotometer, and the n.m.r. spectrum with a Varian A-60A spectrometer using tetramethylsilane as the internal standard. Mass spectral data were obtained with a Dupont–C.E.C. model 21-491 spectrometer. Merck grade alumina was obtained from Brinkmann Instruments (Canada) Limited.

1-(o-Carbethoxyphenyl)-3-(o-cyanophenyl)-triazene (4)

Ethyl anthranilate (3.3 g) was dissolved in concentrated hydrochloric acid (5.0 ml) and the solution diluted with water (100 ml), cooled to 0 °C, and diazotized to starch-iodide end-point with aqueous sodium nitrite (1.4 g in 10 ml). After the cold diazonium salt solution had been stirred for 15 min, a solution of *o*-aminobenzonitrile (2.1 g) in 2 *M* hydrochloric acid (20 ml) was added dropwise with constant agitation. The mixture was then made alkaline with an excess of sodium acetate, stirred for 2.0 h, and then filtered to yield the triazene **4** (2.4 g, 50%), m.p. 156–157 °C (yellow needles from ethanol), ν_{max} 3220 (NH), 2220 (C≡N), 1675 (C=O), and 1410 (N=N) cm^{-1}; δ ($CDCl_3$) 6.90–8.10 (8H, m, aromatic), 4.42 (2H, q, methylene), and 1.42 (3H, t, methyl) p.p.m.; *m/e* 294 (P, $C_{16}H_{14}N_4O_2$), 266 ($C_{16}H_{14}N_2O_2$).

Decomposition of the Triazene 4 in Aqueous Ethanol

General Procedure

1-(*o*-Carbethoxyphenyl)-3-(*o*-cyanophenyl)-triazene (**4**) (0.001 mol) was refluxed in 70% aqueous ethanol (50 ml) for times varying from 2 h to 3 weeks. Unreacted starting material was recovered from the cooled reaction mixture by filtration. Evaporation of the filtrate gave a yellow solid residue, which upon recrystallization from absolute ethanol afforded quinazolino[3,2-*c*][1,2,3]benzotriazin-8-one (**2**), m.p. and mixed m.p. 215–216 °C, ν_{max} 1720, 1660, and 1605 cm^{-1}, identical with an authentic sample (1).

Evaporation of the mother liquor from the recrystallization afforded 2-phenylquinazolin-4(3*H*)-one (**8**), m.p. 238–239 °C (needles, from ethanol), ν_{max} 1665 cm^{-1}, identical with an authentic sample (6). Table 1 shows the yields of these products obtained after different durations of refluxing.

Alumina-catalyzed Decomposition of the Triazene 4 in Anhydrous Benzene

Basic alumina (Merck, activity I, untreated) (3.0 g) was added to a solution of the triazene **4** (0.2 g) in anhydrous benzene (50 ml), and the suspension was stirred at room temperature for 42 h. The alumina was separated by filtration and washed with 10 × 20 ml aliquots of anhydrous benzene. The combined benzene filtrate and washings afforded, on evaporation, a yellow gummy solid, which, after repeated recrystallization from benzene/petroleum ether and subsequently from benzene, yielded the quinazolinobenzotriazinone **2** (8 mg, 5%), identical with a sample from the previous reaction. Evaporation of the combined mother liquors from the recrystallizations gave unreacted starting material (0.13 g, 65%).

The financial support of the National Research Council of Canada is gratefully acknowledged. I am also grateful to Drs. W. D. Jamieson and A. W. McCulloch of the Atlantic Regional Laboratory, NRCC, for mass spectral and n.m.r. data respectively.

The Interception of *N*-Dibenzylaminonitrene Generated from *N*-Azido Dibenzylamine

RIAZ AHMED AND J.-P. ANSELME[1]

Department of Chemistry, University of Massachusetts, Boston, Massachusetts 02116

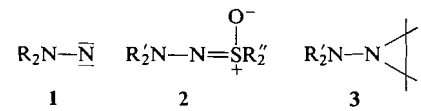
Received October 26, 1971

N-Dibenzylaminonitrene (**6**) has been shown to be generated from the decomposition of *N*-azido dibenzylamine (**9**) by its interception with 4-phenyl-1,2,4-triazoline-3,5-dione, as the azimine (**8**).

On a montré que le *N*-dibenzylaminonitrène (**6**) est issu de la décomposition de la *N*-azidodibenzylamine (**9**) par son interception avec la phényl-4 triazoline-1,2,4 dione-3,5, en tant qu'azimine (**8**).

Canadian Journal of Chemistry, **50**, 1778 (1972)

The concept of *N*-nitrenes (**1**) has gradually come of age (1) through a slow accumulation of results most conveniently rationalized via such intermediates, in particular, the formation of products resulting from nitrogen extrusion. Although the isolation of adducts such as **2** and **3** (2, 3) can be formally viewed as resulting from the trapping of *N*-nitrenes, it has not been established that such adducts did not arise from "prenitrene" precursors. Similarly, although the participation of **6** in the formation of **8**[2]



was suggested, it is also conceivable that **8** might have arisen via the oxidation of an initial tetrazane (**7**), without the intervention of **6** (4) (see eq. 1).

Earlier we had presented evidence for the

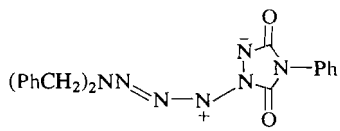
formation of *N*-azido dibenzylamine (**9**) from the *diazo transfer* of tosyl azide to 1,1-dibenzylhydrazine anion (**4***a*) and suggested that **9** was a precursor of **6** (5) (eq. 2). During the course of our investigation of some of the reaction of 4-phenyl-1,2,4-triazoline-3,5-dione (**5**), it was discovered that azides, in contrast to diazoalkanes (6, 8), do not react with **5** (PTD) at room temperature. This finding prompted us to attempt to demonstrate the formation of **6** from **9**. Indeed, if adduct **8** could be isolated from the reaction of **9** with PTD, this would constitute evidence for the direct interception of **6** with PTD since presumably, as with other azides (6), **9** would not react with PTD.

$$[2]\quad \underset{\mathbf{4}a}{(PhCH_2)_2N\bar{\underline{N}}H} \xrightarrow[-60^\circ]{TosN_3} \underset{\mathbf{9}}{[(PhCH_2)_2N{-}N_3]} \xrightarrow[-10^\circ]{-N_2} [\mathbf{6}] \rightarrow \text{Products}$$

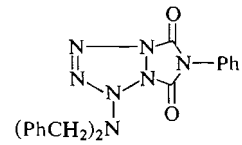
1,1-Dibenzylhydrazine monoanion (10 mmol) was prepared as previously described and then treated with a 1.2 equiv of tosyl azide at −60°. The reaction mixture was stirred for 15 min at that temperature. No apparent reaction took place when a solution of 2 equiv of **5** in tetrahydrofuran was added at −60°. The flask was removed from the cooling bath and allowed to warm up. The vigorous evolution of nitrogen which had begun slowly at about −20°, was accompanied by a slow fading of the red color above 0°. After 1 h at room temperature, the initial red color of the reaction mixture had completely disappeared and a yellow solid had precipitated. After addition of ether and water and work-up of the organic phase, **8** was isolated in 65% yield[3] as a yellow solid, m.p. 154–155° (dec.); it was identical to the product obtained from the reaction of 1,1-dibenzylhydrazine and **5** (4).

The interaction of **4***a* with **5** as the source of **8** was ruled out in control runs. When the above described experiment was repeated with less than an equivalent amount of tosyl azide, *immediate* reaction occurred upon addition of **5** as evidenced by the precipitation of **8** at −60°; as expected, *immediate* reaction was again evident when **5** was added to a solution of dibenzylhydrazine anion (**4***a*) at −60° *in the absence* of tosyl azide. These results are to be contrasted with the original experiment in which *no* reaction occurred until much higher temperatures (−10 to 10°) were reached. Both **8** and the triphenylphosphine adduct of tosyl azide (7) were isolated and characterized[4] by consecutive treatment of the mixture of **9** and tosyl azide (*freed from 1,1-dibenzylhydrazine*) (5) with **5** and triphenylphosphine. These results quite clearly indicate that in our reaction, **8** did *not* arise by the reaction of **4** or of **4***a* with **5**.

The alternative possibility that *N*-azido dibenzylamine reacted initially with **5** to give a primary adduct which decomposed to the azimine (**8**) was discussed above. Coupled with our finding that in contrast with diazoalkanes (6, 8), azides are completely inert toward **5**, the fact that the disappearance of the deep red color of **5** was concomitant with the evolution of nitrogen, did not support the formation of intermediates such as **10***a* or *b*. In order to establish this, the rate of the decomposition of **9** was measured in the absence of PTD and in the presence of 0.5 and 1 equiv of PTD. Within the limits of experimental error, there was no difference in the rate of nitrogen evolution between these three experiments.



10*a*



10*b*

In view of these results, the formation of **8** in our reaction can be most rationally regarded as the direct interception of *N*-dibenzylaminonitrene with **5** and further supports the validity of our original suggestion as depicted in eq. 2.

[3]In our initial experiment, only 1 equiv of **5** was used. Only a 28% yield of the adduct in addition to 4-phenyl urazole (0.7 mmol) and *p*-toluenesulfonamide (21%) were isolated. A 100% excess of **5** was used because we anticipated that **5** could be consumed via alternate reactions such as with *p*-toluenesulfonamide anion and with unreacted 1,1-dibenzylhydrazine anion.

[4]Bibenzyl and dibenzylbenzalhydrazone (5) were detected by t.l.c. from the filtrate of the reaction mixture.

Branched-chain Nitro Sugars. Methyl 4,6-*O*-Benzylidene-2,3-dideoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside

ALEX ROSENTHAL AND GÜNTER SCHÖLLNHAMMER

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received December 9, 1971

The preparations of methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside (**4**) and the *arabino*-epimer (**5**) are described. Schmidt–Rutz degradation of **4** and **5** afforded a *cis–trans* mixture of the branched-chain carbohydrate nitroolefins **6** which were stereoselectively reduced with sodium borohydride to yield methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside (7). The utility of circular dichroism studies in determining the configuration of nitro sugars is discussed.

Les préparations des méthyl 3-*O*-acétyl-4,6-*O*-benzylidène-2-déoxy-3-*C*-nitrométhyl-α-D-*ribo*-(**4**) (et *arabino* **5**) hexopyranosides sont décrites. La dégradation de Schmidt–Rutz sur **4** et **5** conduit à un mélange *cis–trans* de nitrooléfines ramifiées **6** qui par réduction par le borohydrure de sodium, conduisent stéréosélectivement au méthyl-4,6-*O*-benzylidène-2,3-didéoxy-3-*C*-nitrométhyl-α-D-*ribo*-hexopyranoside (7). L'utilisation du dichroisme circulaire dans la détermination des configurations des nitro sucres est discutée.

Canadian Journal of Chemistry, **50**, 1780 (1972)

In a previous communication (1) we have described the synthesis of methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-(and *arabino*-)hexopyranoside (**2** and **3**) by application of the nitromethane synthesis (2) to methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**1**). Acetylation of **2** with acetic anhydride and *p*-toluenesulfonic acid monohydrate gave an impure 3-*O*-acetate which underwent decomposition upon attempted purification on silica gel. Baer and co-workers (2) have warned about the difficulties encountered during acetylation and work-up of some nitro sugars.

In this communication we wish to report the successful preparation of the 3-acetates of **2** and **3** and their subsequent conversion via a Schmidt–Rutz degradation (3) followed by stereoselective sodium borohydride reduction of the nitroolefin to afford a 2,3-dideoxy branched-chain nitro sugar.

Acetylation of **2** and **3** was achieved with acetic anhydride and *p*-toluenesulfonic acid as catalyst under careful surveillance by t.l.c. monitoring. As soon as the reaction was complete the reaction was quenched by pouring the reaction mixture into a mixture of ice and water followed by immediate neutralization with sodium hydrogen carbonate. Extraction of the acetylation products of **2** and **3** with dichloromethane gave pure crystalline methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-(and *arabino*-)hexopyranoside (**4** and **5**) in good yields. Conversion of the latter compounds, via a Schmidt–Rutz reaction (3), into the expected carbohydrate nitroolefin **6** revealed

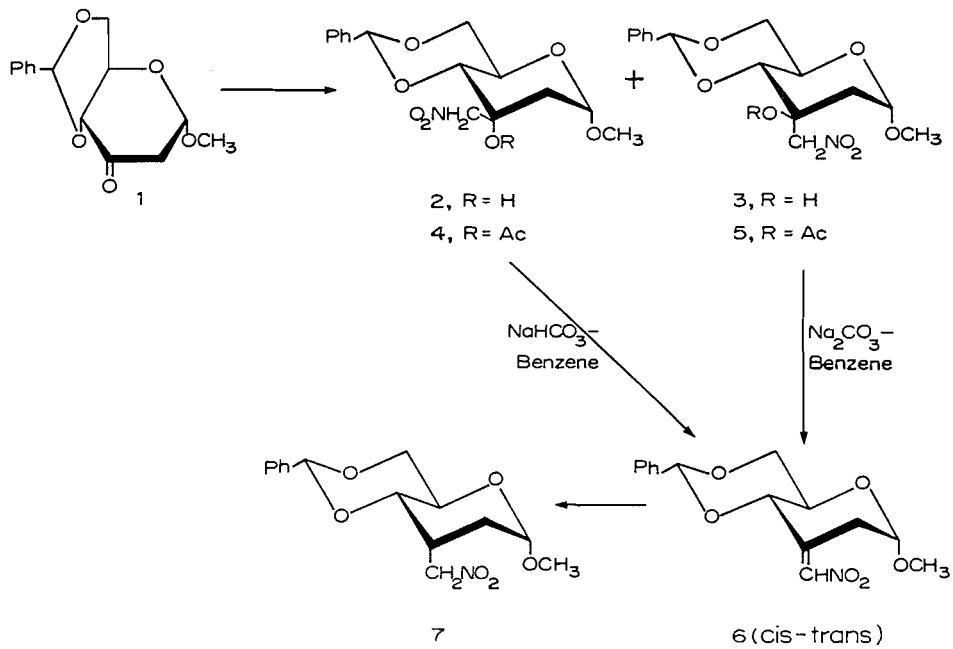
L'utilisation du dichroisme circulaire dans la détermination des configurations des nitro sucres est discutée.

Canadian Journal of Chemistry, **50**, 1780 (1972)

In a previous communication (1) we have described the synthesis of methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-(and *arabino*-)hexopyranoside (**2** and **3**) by application of the nitromethane synthesis (2) to methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**1**). Acetylation of **2** with acetic anhydride and *p*-toluenesulfonic acid monohydrate gave an impure 3-*O*-acetate which underwent decomposition upon attempted purification on silica gel. Baer and co-workers (2) have warned about the difficulties encountered during acetylation and work-up of some nitro sugars.

In this communication we wish to report the successful preparation of the 3-acetates of **2** and **3** and their subsequent conversion via a Schmidt–Rutz degradation (3) followed by stereoselective sodium borohydride reduction of the nitroolefin to afford a 2,3-dideoxy branched-chain nitro sugar.

Acetylation of **2** and **3** was achieved with acetic anhydride and *p*-toluenesulfonic acid as catalyst under careful surveillance by t.l.c. monitoring. As soon as the reaction was complete the reaction was quenched by pouring the reaction mixture into a mixture of ice and water followed by immediate neutralization with sodium hydrogen carbonate. Extraction of the acetylation products of **2** and **3** with dichloromethane gave pure crystalline methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-(and *arabino*-)hexopyranoside (**4** and **5**) in good yields. Conversion of the latter compounds, via a Schmidt–Rutz reaction (3), into the expected carbohydrate nitroolefin **6** revealed



a remarkable difference in chemical reactivity of **4** and **5** towards sodium hydrogen carbonate; the *ribo*-acetate **4** readily underwent dehydroacetylation, whereas the epimeric *arabino*-isomer **5** was inert under the same conditions. This difference in chemical reactivity might be attributed to conformational and steric factors. Although both epimers possess an axial anomeric methoxyl group, **4** has an equatorially oriented nitromethyl group and **5** contains an axially oriented nitromethyl group. Since it is presumed that dehydroacetylation is first initiated by an abstraction of an α-H from the carbon bearing the nitro group followed by β-elimination of the acetoxy group (4), it can be surmised that the approach of sodium hydrogen carbonate ion to the equatorially oriented nitromethyl group of **4** is not hindered by the axial methoxyl group and thus the formation of the nitromethine anion is easy whereas the access of the same nucleophile to the axially oriented nitromethyl group of **5** is restricted by the axially oriented methoxyl group. Other workers (4) have also reported that the ease of elimination of acetic acid from nitro sugar *O*-acetates can be expected to depend upon structural and steric factors. For example, the α-methyl glycoside of 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-D-glucoside exhibited much slower chemical reactivity to base than the corresponding anomeric β-methyl glycoside (5). On the basis of the n.m.r. spectrum of the carbohydrate nitroolefin **6** obtained from **4** it is suggested that a 1:4 mixture (*cis* and *trans* isomers) of **6** was formed since the ratio of the two low field ($\tau \sim 2.7$) multiplets was approximately 1:4. Although these geometrical isomers exhibited slightly different R_f's, attempts to separate them in pure form by preparative t.l.c. on silica gel were unsuccessful. Jones and coworkers (6) have successfully prepared and isolated both *cis* and *trans* nitroolefins during the course of their work on the synthesis of the carbohydrate moiety in lincomycin. Configurational assignments of the *cis* and *trans* unsaturated nitroolefins were made on the basis of their n.m.r. spectra. When the epimeric *arabino*-nitro compound **5** was subjected to a more rigorous treatment using sodium carbonate in refluxing benzene the same unsaturated nitro sugar **6** was produced, and in addition, an unstable carbohydrate nitroolefin which could not be separated from **6**. A possible similar rearrangement of a nitroolefin was encountered during studies of the dehydroacetylation of nitromethylcyclohexylacetate (7).

Reduction of methyl 4,6-*O*-benzylidene-3-*C*-nitromethylene-2,3-dideoxy-α-D-*erythro*-hexopyranoside (**6**) with sodium borohydride in

ethanol (8) proceeded stereoselectively to afford a 2,3-dideoxy branched-chain nitro sugar **7**. The structure of the latter compound was readily deduced from its n.m.r. spectrum (see Experimental). Although the resonance of H-4 (two doublets having $J = 4$ and 10 Hz) and H-6 overlapped at τ 6.25, irradiation of H-3 at τ 7.0 removed the coupling of H-4 and -3 leaving a doublet for H-4 and -5 having a value of 10 Hz. Thus the much narrower doublet having $J = 4$ Hz at approximately τ 6.25 is attributed to coupling of the axial H-4 with an equatorial hydrogen on C-3. Therefore the nitromethyl group is axially oriented and **7** must be methyl 2,3-dideoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside. This assignment, however, was not substantiated by circular dichroism (c.d.) studies (9). Possibly, Satoh's empirical rules (9) apply only to deoxy nitro carbohydrates having an asymmetric center adjacent to the carbon having the nitro or nitromethyl group and do not apply to dideoxy nitro carbohydrates. Indirect support for the assignment of structure is provided by the fact that reduction of an analogous unsaturated branched-chain ester obtained by a Wittig reaction on the same ketose **1** also proceeded stereoselectively to afford a 2,3-dideoxy *ribo* compound (10).

Experimental

General Consideration

The n.m.r. spectra were obtained in chloroform-*d* solution with tetramethylsilane as the internal standard (set at τ 10) by using a Varian HA-60 or 100 spectrometer (s, singlet, d, doublet, t, triplet, q, quartet, m, multiplet). The c.d. spectra were measured with a JASCO model ORD/UV-5 spectropolarimeter. The optical rotations were determined using a Perkin–Elmer model 141 automatic polarimeter. All melting points (micro hot stage) are corrected. Elemental analyses were performed by the microanalytical laboratory of the University of British Columbia, Vancouver, B.C.

*Methyl 3-O-Acetyl-4,6-O-benzylidene-2-deoxy-3-C-nitromethyl-α-D-ribo-hexopyranoside (**4**) and Methyl 3-O-Acetyl-4,6-O-benzylidene-2-deoxy-2-C-nitromethyl-α-D-arabino-hexopyranoside (**5**)*

Methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside (**2**) (0.57 g) (1) was acetylated with acetic anhydride (25 ml) and *p*-toluenesulfonic acid monohydrate (0.200 g) at room temperature. The progress of the reaction was monitored by t.l.c. on silica gel using 10:1 benzene–ethyl acetate as developer. When the reaction was complete the reaction mixture was poured into ice-water, neutralized with sodium hydrogen carbonate, and the product extracted with dichloromethane (5 × 50 ml). The dichloromethane extract was washed with aqueous sodium hydrogen carbonate, followed by water, then dried over sodium sulfate, filtered, and evaporated under reduced pressure to yield 0.465 g (74%) of crystalline **4** which was recrystallized from ethyl acetate–light petroleum ether (b.p. 30–60°); m.p. 138–148°; $[\alpha]_D^{23} + 90°$ (*c* 1, chloroform); c.d. (*c* 0.0004, methanol): $[\theta]_{285} -4170$; τ ($CDCl_3$) 2.5 (aromatic H), 4.4 (s, CHPh), 4.9 (d, CH_2NO_2), 5.2 (q, H-1, $J_{1,2e} = 1$, $J_{1,2a} = 4$ Hz), 5.4–6.4 (m), 6.60 (s, OCH_3), 7.70–8.1 (two m, H_{2e} and H_{2a}), 7.90 (Ac).

Anal. of **4** Calcd. for $C_{17}H_{21}NO_8$: C, 55.6; H, 5.8; N, 3.8. Found: C, 55.77; H, 5.76; N, 3.80.

The *arabino*-epimer **3** was acetylated by the same procedure used to prepare **4** to afford methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*arabino*-hexopyranoside (**5**); m.p. 145°; $[\alpha]_D^{22} + 38°$ (*c* 1, chloroform); c.d. (*c* 0.0004, methanol): $[\theta]_{285} + 4110$; τ ($CDCl_3$) 4.70 (d, CH_2NO_2), 5.2 (q, H-1, $J_{1,2e} = 1$, $J_{1,2a} = 4.5$ Hz), 5.35–6.32 (m), 6.65 (s, OCH_3), 7.12 (2-d, H_{2e}, $J_{2e,1} = 2$, $J_{2e,2a} = 13$ Hz), 7.60 (2-d, H_{2a}, $J_{2a,1} = 4$, $J_{2a,2e} = 13$ Hz), 7.95 (Ac).

Anal. of **5** Calcd. for $C_{17}H_{21}NO_8$: C, 55.8; H, 5.8; N, 3.8. Found: C, 55.35; H, 5.70; N, 4.0.

*Application of Schmidt–Rutz Reaction to **4** and to **5** to Yield cis–trans Methyl 4,6-O-Benzylidene-3-C-nitromethylene-2,3-dideoxy-α-D-erythro-hexopyranoside (**6**)*

To the acetate **4** (0.195 g) in anhydrous benzene (30 ml) was added finely powdered anhydrous sodium hydrogen carbonate (0.800 g) and the resulting mixture was refluxed for 15 h (or until all starting material was consumed as evidenced by t.l.c. on silica using 10:1 benzene–ethyl acetate). Both the *cis* and *trans* elimination products (1:4 ratio) having R_f's of 0.55 and 0.52 were formed. The solids were removed by filtration and washed with benzene. The combined benzene filtrate was evaporated under reduced pressure to yield 0.130 g of crystalline residue which was recrystallized from ethyl acetate–light petroleum ether: m.p. 134–136°; τ ($CDCl_3$) 2.60–2.68 (m, due to $C{=}CHNO_2$), 2.68–2.84 (m, due to $C{=}CHNO_2$ of other isomer; ratio 1:4), 4.40 (s, CHPh), 5.05 (d, H-1), 5.50–6.35 (m), 6.67 (s, OCH_3), 6.5–6.7 (m, overlapping OCH_3 peak), 7.4 and 7.63 (two q = 1 H).

Anal. Calcd. for $C_{15}H_{17}NO_6$: C, 58.7; H, 5.6; N, 4.6. Found: C, 58.74; H, 5.37; N, 4.40.

The acetate **5** was resistant to elimination of acetic acid using sodium hydrogen carbonate. Treatment of **5** with potassium carbonate in benzene under reflux for 12 h yielded compound **6** and another unstable unsaturated compound in about equal amounts. Attempts to isolate the second nitroolefin by preparative t.l.c. were unsuccessful.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-C-nitromethyl-α-D-ribo-hexopyranoside (**7**)*

Compound **6** (0.150 g) dissolved in ethanol (10 ml) was reduced with sodium borohydride (0.100 g) at room temperature for 1 h. The excess sodium borohydride was consumed by the addition of acetone. After addition of water (5 ml) the solution was acidified with acetic acid and then extracted with dichloromethane (3 × 20 ml). The dichloromethane extract was evaporated to dryness under reduced pressure to afford a product which was recrystallized from ethyl acetate–light petroleum ether to give pure **7** (0.084 g), m.p. 110–111°; $[\alpha]_D^{22} + 58°$ (*c* 1, chloroform); c.d. (*c* 0.0004, methanol): $[\theta]_{270} + 2740$; τ ($CDCl_3$) 2.7 (aromatic H), 4.5

(CHPh), 5.20 (CH_2NO_2), 5.36 (t, H-1), 5.8 (m, H-5), 6.25 (m, H-4, H-6, $J_{4,3} = 4$, $J_{4,5} = 10$ Hz), 6.70 (OCH_3), 6.83–7.05 (m, H-3), 7.96–8.10 (5 peaks, H-2a, H-2e). Irradiation at τ 8.0 (H-2) collapsed the H-1 signal to a singlet and altered the H-3 multiplet. Irradiation at τ 5.36 (H-1) collapsed the multiplet at τ 8.0 to three peaks. Irradiation at τ 7.0 (H-3) changed the multiplet at τ 8 to a broad singlet and altered the signals at τ 6.25 showing $J_{4,5} =$ 10 Hz.

Anal. Calcd. for $C_{15}H_{19}NO_6$: C, 58.2; H, 6.2; N, 4.5. Found: C, 58.18; H, 6.0; N, 4.35.

A Simple Synthesis of 2-Methoxy and 2-Ethoxytetrahydrofuran

Daniel Frehel and Pierre Deslongchamps[1]

Laboratoire de Synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received January 17, 1972

Ozonolysis of dihydropyran gives 4-formyloxybutyraldehyde which is then easily converted into 2-methoxy or 2-ethoxytetrahydrofuran.

L'ozonolyse du dihydropyranne conduit au formyloxy-4-butyraldehyde qui se transforme facilement en méthoxy-2- ou éthoxy-2-tétrahydrofuran.

Canadian Journal of Chemistry, **50**, 1783 (1972)

In connection with our recent investigation on the ozonolysis of acetals (1), we required a certain quantity of 2-methoxytetrahydrofuran (**1***a*). A search in the chemical literature revealed that the standard method to prepare 2-alkoxytetrahydrofuran is the addition of alcohols to 2,3-dihydrofuran in presence of mineral acid (2). However, 2,3-dihydrofuran is not very readily available (2–5). The alternative synthesis of 2-alkoxytetrahydrofuran (6) from tetrahydrofuran and *t*-butyl perbenzoate in the presence of alcohols is not more convenient (2).

We wish to report a new two-step synthesis of 2-methoxytetrahydrofuran from a readily available starting material while using simple experimental procedures.

Ozonolysis of dihydropyran in methanol at −78° followed by the addition of methyl sulfide (7) gave 4-formyloxybutyraldehyde (**2**) in 95% yield (see Scheme 1). The next operation was to convert **2** into 2-methoxytetrahydrofuran (**1***a*). One possible route for such a transformation was the hydrolysis of **2** to **3** and then the conversion **3** into **1***a*. We felt that such a two-step procedure should be avoided because we were expecting experimental difficulties in the isolation of the water-soluble 2-hydroxytetrahydrofuran (**3**) (8). Also, the use of methanol as solvent in the final step was not desirable since 2-methoxytetrahydrofuran (**1***a*) has a low boiling

A Simple Synthesis of 2-Methoxy and 2-Ethoxytetrahydrofuran

Daniel Frehel and Pierre Deslongchamps[1]

Laboratoire de Synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received January 17, 1972

Ozonolysis of dihydropyran gives 4-formyloxybutyraldehyde which is then easily converted into 2-methoxy or 2-ethoxytetrahydrofuran.

L'ozonolyse du dihydropyranne conduit au formyloxy-4-butyraldehyde qui se transforme facilement en méthoxy-2- ou éthoxy-2-tétrahydrofuran.

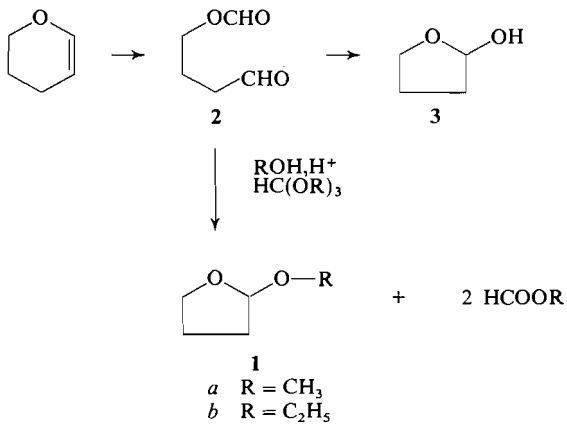
Canadian Journal of Chemistry, **50**, 1783 (1972)

In connection with our recent investigation on the ozonolysis of acetals (1), we required a certain quantity of 2-methoxytetrahydrofuran (**1***a*). A search in the chemical literature revealed that the standard method to prepare 2-alkoxytetrahydrofuran is the addition of alcohols to 2,3-dihydrofuran in presence of mineral acid (2). However, 2,3-dihydrofuran is not very readily available (2–5). The alternative synthesis of 2-alkoxytetrahydrofuran (6) from tetrahydrofuran and *t*-butyl perbenzoate in the presence of alcohols is not more convenient (2).

We wish to report a new two-step synthesis of 2-methoxytetrahydrofuran from a readily available starting material while using simple experimental procedures.

Ozonolysis of dihydropyran in methanol at −78° followed by the addition of methyl sulfide (7) gave 4-formyloxybutyraldehyde (**2**) in 95% yield (see Scheme 1). The next operation was to convert **2** into 2-methoxytetrahydrofuran (**1***a*). One possible route for such a transformation was the hydrolysis of **2** to **3** and then the conversion **3** into **1***a*. We felt that such a two-step procedure should be avoided because we were expecting experimental difficulties in the isolation of the water-soluble 2-hydroxytetrahydrofuran (**3**) (8). Also, the use of methanol as solvent in the final step was not desirable since 2-methoxytetrahydrofuran (**1***a*) has a low boiling

[1]A. P. Sloan Fellow, 1970–1972.



SCHEME 1

point. Consequently, we directed our effort in the development of a one-step procedure from **2**.

Treatment of **2** with 1 mol-equiv of trimethyl orthoformate containing a drop of methanol and a catalytic amount of *p*-toluenesulfonic acid at room temperature gave 2-methoxytetrahydrofuran (**1***a*) in 80% yield after distillation. During this reaction, 2 mol-equiv. of the low boiling methyl formate are formed. Using similar experimental conditions, and triethyl orthoformate, **2** was transformed into 2-ethoxytetrahydrofuran (**1***b*) in 84% yield after distillation.

Experimental

The i.r. spectra were taken on a Perkin–Elmer 257 Spectrophotometer. The n.m.r. spectra (τ value) were recorded on a Varian A-60 Spectrometer in solvent indicated and with TMS as internal standard. The ozonized oxygen was produced by a Welsbach T-816 Laboratory Ozonator. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y.

*4-Formyloxybutyraldehyde (**2**)*

Dihydropyran (63 g, 0.75 mol) was dissolved in reagent grade methanol (100 ml) and cooled at −78°. Ozonized oxygen (3.7%-O_3/O_2, 1.5 l/min) was passed through the solution and the end of the reaction was indicated by the appearance of the characteristic blue color of ozone. The excess ozone was swept away with a stream of nitrogen, methyl sulfide (80 ml) was added to the reaction mixture which was allowed to be warmed up at −10° (bath temperature) for 1 h, then at 0° for 1 h, and finally at room temperature for 3 h. The solvent was removed *in vacuo* and water (300 ml) was added. The aqueous phase was extracted with ether (4 × 50 ml) and with dichloromethane (4 × 50 ml). The combined organic phase was dried over magnesium sulfate, filtered, and evaporated to dryness yielding crude **2** (85.1 g, 97%). Distillation *in vacuo* (b.p. 55°, 2 mm) gave pure 4-formyloxybutyraldehyde (82.5 g, 95%). The i.r. ν (max) 1720 cm^{-1}; n.m.r.: τ ($CDCl_3$) 0.27 (1H, triplet, J = 1.0 Hz, CHO), 1.97 (1H, singlet, —OCHO), 5.82 (2H, triplet, J = 7.0 Hz, —CH_2—OCHO), 7.24–7.64 (2H, multiplet, —CH_2—CHO), and 7.79–8.27 (2H, multiplet, CH_2—CH_2—CHO).

Anal. Calcd. for $C_5H_8O_3$: C, 51.72; H, 6.94; O, 41.34. Found: C, 51.48; H, 7.20; O, 41.32.

*2-Methoxytetrahydrofuran (**1***a*)*

Trimethyl orthoformate (2.12 g, 0.02 mol) was slowly added (exothermic reaction) to a cooled mixture (0°) of 4-formyloxybutyraldehyde (2.32 g, 0.02 mol), *p*-toluenesulfonic acid (2 mg), and one drop of methanol. The reaction mixture was then left at room temperature for 36 h. Anhydrous sodium carbonate (100 mg) was added and the reaction mixture was magnetically stirred for 1 h. The inorganic salt was filtered and methyl formate was removed by distillation at normal pressure. Water (2 ml) was added to the reaction mixture which was extracted with ether (4 × 50 ml). Distillation of the dried (magnesium sulfate) organic phase gave pure 2-methoxytetrahydrofuran (1.63 g, 80%, b.p. 106–107°, lit. (8) b.p. 105–107°). The n.m.r.: τ ($CDCl_3$) 5.1 (1H, multiplet, C*H*OCH_2), 6.00–6.65 (2H, multiplet, CH_2O), 6.75 (3H, singlet, OCH_3), and 7.85–8.40 (4H, multiplet).

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.80; H, 9.87; O, 31.33. Found: C, 58.90; H, 9.81; O, 31.29.

*2-Ethoxytetrahydrofuran (**2***b*)*

2-Ethoxytetrahydrofuran (**2***b*, 1.95 g, 84%, b.p. 125°, lit. (9) b.p. 125°) was obtained by utilizing an identical experimental procedure as the one described above with the exception that trimethyl orthoformate was replaced by triethyl orthoformate (2.964 g, 0.02 mol) and methanol by ethanol (one drop). The n.m.r.: τ ($CDCl_3$) 4.92 (1H, multiplet, C*H*OC_2H_5), 5.95–6.80 (4H, multiplet, OCH_2 and OCH_2CH_3), 8.35–7.90 (4H, multiplet), and 8.85 (3H, triplet, J = 7.0 Hz, CH_3CH_2O).

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.04; H, 10.41; O, 27.55. Found: C, 61.86; H, 10.41; O, 27.73.

Anomalous Rate Laws in the Halogenation of Carbon Tetrahalides

B. K. DUNNING AND H. O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received January 7, 1972

The initial rate of bromination of carbon tetrachloride is independent of surface-to-volume ratio and can be fitted to a rate law which assumes that the rate-determining step is $Br + CCl_4 \rightarrow BrCl + CCl_3$; however, the overall temperature coefficient of the rate is inconsistent with the known thermochemistry of the system. The same anomaly has been reported recently in the fluorination of trichlorofluoromethane by Foon and Tait, and similar inconsistencies occur in the fluorination of carbon tetrachloride and the chlorination of bromotrichloromethane.

La vitesse initiale de bromation du tétrachlorure de carbone est indépendante du rapport surface-sur-volume et peut être exprimée par une loi de vitesse qui suppose que l'étape de vitesse déterminante est: $Br + CCl_4 \rightarrow BrCl + CCl_3$; cependant, le coefficient global de température de la vitesse est incompatible avec la thermochimie connue du système. La même anomalie a récemment été rapportée par Foon et Tait, lors de la fluoration du trichlorofluorométhane, et les mêmes contractions se retrouvent lors de la fluoration du tétrachlorure de carbone et de la chloration du bromotrichlorométhane.

To complement our recent investigation of the equilibria between carbon tetrachloride and bromotrichloromethane in the presence of bromine and chlorine (1) we undertook to study the kinetics of the bromination of carbon tetrachloride in the temperature range 500–540 °K and the chlorination of bromotrichloromethane in the range 370–430 °K. Experiments were carried out in 300 ml Pyrex flasks, which were thoroughly flamed under vacuum before filling and sealing off, to prevent the formation of spurious HCl or HBr: initial amounts of carbon tetrachloride and of halogen were each in the range $2–5 \times 10^{-5}$ mol, and reaction times (t) were such that 1–5% of the reactants were consumed; further details will be made available elsewhere (2). Since the reaction rate was unchanged when the reaction vessels were packed with short lengths of glass tubing, it is natural to assume that the reactions are homogeneous and that, for example, the bromination of carbon tetrachloride can be represented by Reactions 1–3, with other less important fates

$$[1] \qquad Br_2 \rightleftharpoons Br + Br$$

$$[2] \qquad Br + CCl_4 \rightarrow BrCl + CCl_3$$

$$[3] \qquad CCl_3 + Br_2 \rightarrow CCl_3Br + Br$$

of the CCl_3 radical being combination to C_2Cl_6, combination with Br atoms to form CCl_3Br and abstraction from BrCl to reform CCl_4. Similar reaction schemes have been proposed by Clark and Tedder (3) and by Foon and Tait (4) for the fluorination of carbon tetrachloride and trichlorofluoromethane respectively. In our experiment there was also some secondary bromination (about 10%) of the CCl_3Br to give CCl_2Br_2, but nevertheless plots of the total amount of product ($CCl_3Br + CCl_2Br_2$) against $[Br_2]^{1/2}[CCl_4]t$ were good straight lines, passing through the origin, as required by reactions 1–3.[1] The overall rates can be represented by the expression $2.0 \times 10^7 \exp(-24\,000/RT)$ $cc^{1/2}$ $mol^{-1/2}$ s^{-1}, whence, since $\frac{1}{2}D(Br_2) \approx 23$ kcal/mol, $E_2 \approx 1$ kcal/mol. However, despite uncertainties in the heat of formation of carbon tetrachloride (5), the known thermochemistry (6) implies that E_2 cannot be less than about 20 kcal/mol. Our results for the chlorination of bromotrichloromethane (which of course does not suffer from the complication of secondary halogenation) are less extensive, but equally unsatisfactory.

Foon and Tait (4) have recently performed extensive experiments on the fluorination of

[1]At 500 °K, the equilibrium constant for the reaction between Br_2 and CCl_4 is about 0.1, so that (for example) using equal quantities of reactant, 25% consumption of each would represent equilibrium (2); hence in the 1–5% reactant consumption range, the reverse reaction will not cause a severe perturbation in the rate law.

trichlorofluoromethane, reporting identical conclusions to those described above, and although it was not recognized at the time, the experiments of Clark and Tedder (3) on the fluorination of carbon tetrachloride appear to be equally inconsistent (4, 7) in that their proposed activation energy for the abstraction from CCl_4 by a fluorine atom is much too low. Foon and Tait suggest that these observations can be explained by assuming that both the chain initiation and termination are heterogeneous, in such a way that the overall rate is independent of surface-to-volume ratio, and it is our purpose here to note that the occurrence of such anomalous rate laws is common to many of the halogenations of carbon tetrahalides.

Nuclear Magnetic Resonance Spectra of Methyl Substituted 6-Aryl[1,2,4]triazolo[4,3-*d*]tetrazoles

R. N. BUTLER
Department of Chemistry, University College, Galway, Ireland

Received November 19, 1971

The n.m.r. spectral properties of a range of the title compounds are reported and discussed.

Les caractéristiques des spectres r.m.n. d'une série de 6-aryl[1,2,4]triazolo[4,3-*d*]tétrazoles sont rapportées et discutées.

Canadian Journal of Chemistry, **50**, 1786 (1972)

Of the six theoretically possible triazolotetrazole ring systems (1) only one such fused heterocyclic ring is known, namely the 1,2,4-triazolo[4,3-*d*]tetrazole systems **1** and **2** (2, 3). By classifying the azide–tetrazole ring closure as an electrocyclic 1,5-dipolar cyclization, which obeys the rules of orbital symmetry, Reimlinger (1) has explained the special stability of this system and has predicted that at least one of the other possible triazolotetrazole systems should have comparable stability. The isomeric materials **1** and **2** were obtained by cyclization of the corresponding hydrazones **3** and **4** (2, 3). The presence of the methyl group had an important stabilizing influence on the fused bicyclic system. With the unmethylated analog, cleavage of the tetrazole ring occurred and triazolyl azides were formed (2, 4). The influence of heterocyclic rings on the n.m.r. shifts of adjacent aryl protons has been used to advantage in elucidating the nature of electronic effects operating between the ring systems and studies of different isomeric modifications have led to the detection of resonance interactions in such systems (5). Hence the n.m.r. spectra of the different isomeric modifications **1** and **2** were studied with view to obtaining information on the properties of this new ring system.

The n.m.r. spectra of the materials **1** and **2** (Table 1) exhibit downfield shifts in the ortho and meta protons of the phenyl group. The ortho protons (H_A) are deshielded by an extra 0.7 p.p.m. relative to the meta protons (H_B). Columns 3 and 4 of Table 1 contain the shifts of the ortho and meta protons of the phenyl substituent in the materials. Columns 5 and 6 contain the difference between these shifts and those of the corresponding protons of the substituted benzene.

The deshielding nature and relative magnitudes of the shifts are of interest. Deshielding shifts have been observed for the ortho protons

in a number of other heterocyclic biaryls (6–9) and a very similar deshielding of the ortho protons relative to the meta protons has been observed for 5-aryltetrazoles by Fraser and Haque (5). The deshielding of the ortho protons has been attributed to (*a*) anisotropy of the heterocyclic ring (6, 8, 9); (*b*) a combination of ring anisotropy, nitrogen anisotropy, and a Van der Waals interaction with the nitrogen lone pair (7, 10); (*c*) the above factors combined with a resonance interaction of the heterocyclic ring system (5). Calculations of deshielding, based on the factors mentioned in (*b*), indicate that the ring anisotropic effect may account for less than half of the total effect (7, 10). Mayo and Goldstein (11) have reported the deshielding of the ortho protons in biphenyl to be 0.24 p.p.m.[1] Hence anisotropic effects alone may not account for an extra deshielding of 0.7 p.p.m. It is significant that the ortho protons of the hydrazones **3** are deshielded by only 0.29–0.37 p.p.m. relative to benzene. Furthermore, evidence has been cited that the contribution of the Van der Waals interaction to the deshielding is unimportant (12). A comparison of the shifts of the ortho ($\tau = 1.79 \pm 0.01$) and meta ($\tau = 2.485 \pm 0.00_5$) protons of compounds **1***b* and **2***b* with those of 5-phenyltetrazole (5) ($\tau_{ortho} = 1.90$ and $\tau_{meta} = 2.49$) shows a considerable similarity between the effects of both the tetrazole and triazolotetrazole ring systems on these protons.[1] Hence, from the present data it is concluded that effects, which result in an overall electron

[1]The deshielding of the ortho protons occurs only if coplanarity of the rings is not sterically forbidden. Information on the rotational barriers in these systems is not readily available. It is assumed here that energy differences between the conformations are small and comparable and that large population differences do not exist.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

withdrawing influence, are present in the triazolotetrazole ring system in addition to anisotropic effects. It is not possible, however, to quantify individual contributions from resonance and inductive effects because the balance of these, as detected by the n.m.r. of the phenyl protons, is not altered in the different isomeric modifications **1** and **2**. The available synthetic routes to the compounds **1** and **2** do not allow for the introduction of labile substituents such as OH and NH_2 which could be useful for this purpose. The rather small deshielding of the meta protons together with the relatively small discrepancy between the predicted and observed shifts (Table 1) for the ortho and meta protons may, however, be indicative of a weak electron donating resonance effect.

The net shielding experienced by the *N*-methyl substituents (Table 1) varies in the different isomers **1** and **2**, in contrast with that of the parent hydrazones (13), thus affording a means of distinguishing between such alkyl substituted isomeric triazolotetrazoles.[2] Differences in *N*-methyl resonances have been used previously as a useful basis for distinguishing between isomeric *N*-substituted tetrazoles (14–16).

[2]Professor Brian M. Lynch, Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia, has informed the author that methyl proton shifts in *N*-methylazoles often correlate very well with the calculated charge density at the pyrrole-type nitrogen as evaluated by HMO or SCF methods. Calculations, carried out by Professor Lynch, on the parent systems of **1** and **2** (*i.e.* lacking the phenyl group) indicate charge densities at the methyl-bearing nitrogen of 1.527 and 1.490 respectively in agreement with the observed chemical shifts for the methyl groups.

Experimental

The n.m.r. spectra were measured on a Varian Associates A60 n.m.r. spectrometer at 38° with deuteriochloroform as solvent and tetramethylsilane as internal reference. Concentrations were approximately 0.1 *m*. Because of insolubility the aromatic region of the *p*-bromo species could not be studied, even with saturated solutions.

The range of compounds **1**–**4** were prepared as previously described by us (2, 3, 13).

Aqueous Reactions of Sparingly Soluble Tellurites I. Silver Tellurite[1]

M. C. Mehra and S. M. Kahn

Department of Chemistry, University of Moncton, Moncton, New Brunswick

Received October 5, 1971

The aqueous interactions of the sparingly soluble silver tellurite show that in a controlled ionic medium and at a constant temperature, an aqueous complex, $Ag(TeO_3)_2^{3-}$ is formed in presence of free tellurite ions. The solubility product of silver tellurite and the stability constant of the complex species have been evaluated from the experimental data.

On a trouvé que le composé tellurite d'argent, forme un complexe $Ag(TeO_3)_2^{3-}$ dans un milieu aqueuse de force ionique constante en présence des ions tellurites libres. Le produit de solubilité de tellurite d'argent et la constante de formation du complexe ont été calculés à partir des données expérimentales.

withdrawing influence, are present in the triazolotetrazole ring system in addition to anisotropic effects. It is not possible, however, to quantify individual contributions from resonance and inductive effects because the balance of these, as detected by the n.m.r. of the phenyl protons, is not altered in the different isomeric modifications **1** and **2**. The available synthetic routes to the compounds **1** and **2** do not allow for the introduction of labile substituents such as OH and NH_2 which could be useful for this purpose. The rather small deshielding of the meta protons together with the relatively small discrepancy between the predicted and observed shifts (Table 1) for the ortho and meta protons may, however, be indicative of a weak electron donating resonance effect.

The net shielding experienced by the *N*-methyl substituents (Table 1) varies in the different isomers **1** and **2**, in contrast with that of the parent hydrazones (13), thus affording a means of distinguishing between such alkyl substituted isomeric triazolotetrazoles.[2] Differences in *N*-methyl resonances have been used previously as a useful basis for distinguishing between isomeric *N*-substituted tetrazoles (14–16).

Experimental

The n.m.r. spectra were measured on a Varian Associates A60 n.m.r. spectrometer at 38° with deuteriochloroform as solvent and tetramethylsilane as internal reference. Concentrations were approximately 0.1 *m*. Because of insolubility the aromatic region of the *p*-bromo species could not be studied, even with saturated solutions.

The range of compounds **1**–**4** were prepared as previously described by us (2, 3, 13).

[2]Professor Brian M. Lynch, Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia, has informed the author that methyl proton shifts in *N*-methylazoles often correlate very well with the calculated charge density at the pyrrole-type nitrogen as evaluated by HMO or SCF methods. Calculations, carried out by Professor Lynch, on the parent systems of **1** and **2** (*i.e.* lacking the phenyl group) indicate charge densities at the methyl-bearing nitrogen of 1.527 and 1.490 respectively in agreement with the observed chemical shifts for the methyl groups.

Introduction

The increasing number of potential applications of the heavy metal compounds of selenium and tellurium as semiconductors has resulted in a revived interest in the chemistry of metal chalcogens as a whole. The reactions of metal sulfur compounds appear to have been investigated in some detail in the past couple of decades, whereas very little seems to have been contributed to the solution chemistry of metal selenium or tellurium compounds (1).

In recent publications the authors have shown that sparingly soluble compounds of sulfur and selenium with heavy metal cations give rise to aqueous complexes of definite stoichiometries (2–6). This complexation behavior extends to the oxy-anions of sulfur and selenium as well (7–9). Although numerous metal tellurites have been prepared (10–13), the aqueous reactions of sparingly soluble compounds of tellurium or its oxygenated anions have been studied to a very limited extent. It was, therefore, thought worthwhile to explore the aqueous interactions of metallic tellurites and the present communication describes the aqueous reactions of silver tellurite.

Experimental

All the reagents employed were of analytical grade; doubly distilled deionized water was used throughout. Silver tellurite was produced *in situ* by mixing radioactive silver nitrate and sodium tellurite at the desired acidity, tellurite concentration, or ionic strength. The system was equilibrated for a period of 5 days before analyses. The radiotracer Ag-110 was obtained from AECL Chalk River, Ontario. Experimental details and the method of analysis were similar to one adopted in an earlier study on silver selenide (4). The radiometric solubility represents the total solubility of the system, while the potentiometric solubility represents the ionic solubility of silver tellurite. The measurements were made at unit molar ionic strength and 25 °C.

Results

Because of the limited solubility of sodium tellurite in water and also its decomposition to TeO_2 in slightly acid media, this study was restricted to the pH 8 to 12. Furthermore, it is only in alkaline condition that the system is composed of tellurite or bitellurite ions (13).

The experimental data of this system show that total solubility remains far superior to the ionic solubility, thereby indicating the formation of some complex species in the aqueous phase in equilibrium with the precipitated compound. Furthermore, the experimental solubility was also found to remain independent of pH of the medium, though it varied as a function of tellurite concentration. The average $[Ag]_{tot}$ for 19 experimental points in the pH range 8–12.5 was computed to be $10^{-6.2}$ M at ~ 0.02 M TeO_3^{2-} concentration, while the corresponding average $[Ag^+]$ was only $10^{-8.02}$ M. The data for another 16 experimental points at a higher ~ 0.125 M TeO_3^{2-} concentration were similarly $10^{-5.13}$ M and $10^{-8.49}$ M respectively.

The solubility pattern of Ag_2TeO_3 as a function of tellurite concentration has an interesting feature (Fig. 1); the solubility slope changes from 0 to 1.5 in the acidity region (p$H \simeq 9.5$) far removed from the second ionization constant of the so-called tellurous acid (H_2TeO_3). The experimental curve clearly indicates the formation of two complex species conformating to two distinct solubility slopes. Obviously one remains independent of pH or the tellurite concentration (slope 0) while the other, though independent of pH, increases its concentration progressively with increasing tellurite concentration. These species are identified by comparing the experimentally observed solubility slopes with the theoretical possibilities as discussed in detail earlier (4). Analysis of the experimental data indicates the presence of Ag^+, $Ag_2TeO_3(aq)$, and $Ag(TeO_3)_2^{3-}$ in the equilibrated supernatant phase.

Solubility Product of Silver Tellurite

The solubility product constant is derived from the potentiometric data utilising the following expressions

$$[1] \qquad [Ag^+]^2[TeO_3^{2-}] = K_{sp}$$

$$[2] \quad [TeO_3]_{tot} = [H_2TeO_3] + [HTeO_3^-] + [TeO_3^{2-}]$$

where $[TeO_3]_{tot}$ is the analytical concentration of tellurite in the medium.

Introduction of the two ionization constants K_1, K_2 of the acid H_2TeO_3 and rearrangement of eq. 2 above gives

$$[3] \qquad [TeO_3^{2-}] = \frac{[TeO_3]_{tot} K_1 K_2}{[H^+]^2 + K_1[H^+] + K_1 K_2}$$

The logarithmic numerical values of K_1 and K_2 have been reported as -2.52 and -7.70, respectively, which suggest that the species

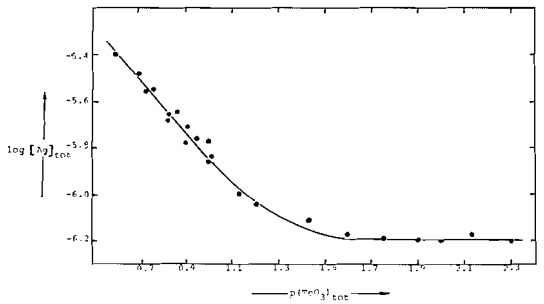

FIG. 1. Radiometric solubility curve of Ag_2TeO_3 as a function of $[TeO_3]_{tot}$, pH (9.4–9.8); $^{110}Ag_{tot}$ (original) = 0.001 M.

TeO_3^{2-} will become the predominant species in the medium only when pH is greater than 8, otherwise, the last two terms in the denominator in eq. 3 will remain significant (1). Hence the concentration of species TeO_3^{2-} at any required acidity is obtained by using the appropriate form of eq. 3 and the solubility product of the compound is obtained by inserting this in eq. 1. An average value of the solubility product of Ag_2TeO_3 from 26 experimental points was calculated to be

$$pK_{sp} = 17.85 \pm 0.11$$

The Formation Constant of Species $Ag(TeO_3)_2^{3-}$

As mentioned earlier, this species makes its appearance felt when the solubility of silver tellurite conforms to a distinct slope of 1.5 (*cf.* Fig. 1). However, one may still regard the experimentally observed $[Ag]_{tot}$ as the sum of all species in any appreciable concentration in solution *i.e.*

$$[4] \quad [Ag]_{tot} = [Ag^+] + [Ag_2TeO_3]_{aq} + [Ag(TeO_3)_2]^{3-}$$

It is assumed that the region of constant solubility (slope 0, Fig. 1) represents the inherent solubility of the compound or the average $[Ag]_{tot}$ here represents the concentration of the species $Ag_2TeO_3(aq)$. The species Ag^+, on the other hand, may even be neglected in eq. 4 since its concentration evaluated from the solubility product of Ag_2TeO_3 at the two different tellurite concentrations will remain inferior to concentration of $Ag_2TeO_3(aq)$. Hence, the concentration of the complex $Ag(TeO_3)_2^{3-}$ is derived by applying appropriate corrections to eq. 4 above and this may be expressed as

$$[5] \quad [Ag(TeO_3)_2^{3-}] = [Ag_{complex}] = [Ag]_{tot} - 10^{-6.19}$$

The stability constant of the complex is obtained from the expression below. The appropriate calculations are recorded in Table 1.

$$[6] \quad \beta_{12} = \frac{[Ag(TeO_3)_2^{3-}]}{[Ag^+][TeO_3^{2-}]^2} = \frac{[Ag_{complex}]}{K_{sp}^{1/2}[TeO_3]_{tot}^{3/2}}$$

$$[7] \quad p\beta_{12} = p[Ag_{complex}] - \tfrac{1}{2}pK_{sp} - \tfrac{3}{2}p[TeO_3]_{tot} = -4.34 \pm 0.05$$

Discussion

The low solubility product value of Ag_2TeO_3 as compared to values of the parallel Ag_2SO_3 and Ag_2SeO_3 under more or less similar experimental conditions reflects that in the series S, Se, and Te, the solubilities of the ionic compounds decrease as a function of atomic weight (1).

This is further borne out by the fact that the complexation reaction in the case of silver tellurite terminates with the formation of only one aqueous complex $Ag(TeO_3)_2^{3-}$ whereas the other two systems do form several aqueous species (7–9). Furthermore the tellurite complex is formed only at a higher ligand concentration, which confirms that the coordinating tendency of tellurite ligand is weaker than the corresponding sulfite and selenite ligands.

Lenher and Wolesensky (10) have reported by a gravimetric analysis that only the compound Ag_2TeO_3 is formed by the interaction of silver nitrate and sodium tellurite. In this study by pH titration of the inherently alkaline sodium tellurite with silver nitrate, the stoichiometry of 2:1 for Ag^+ and TeO_3^{2-} ions has been reconfirmed for the precipitated compound. It has been further shown that up to pH 12, the alkalinity of the medium does not influence the composition of the precipitate. It may, thus, be inferred confidently from the experimental data that OH^- ions do not participate in the complexation reaction or in other words mixed complex formation with OH^- as ligand is totally absent under the controlled experimental conditions described earlier in the text.

It is tacitly assumed in the present work that the tellurite system stems from a diprotic acid the same way as sulfite or selenite systems origi-

nate from sulfurous or selenous acids. However, there is a general lack of agreement in the literature on the existence of the species H_2TeO_3 (1, 14). On the other hand, formation of two series of salts, bitellurites and tellurites has been generally accepted (13). Although it is beyond the scope of this note to comment on the formation of tellurous acid, this study does lend support to the argument that sodium tellurite may be treated in much the same manner as sodium sulfite or sodium selenite. This is very important since eq. 3 and the argument leading to the identification of complex species depend on such a behavior. Assuming that the two reported ionization constants of the so called tellurous acid, K_1 ($10^{-2.52}$) and K_2 ($10^{-7.70}$) are true, then the compound Na_2TeO_3 will dissociate in such a manner that in pH region beyond the value of K_2 it will essentially be ionized as Na^+ and TeO_3^{2-} ions. If sodium tellurite under a condition $pH > pK_2$ is reacted with a cation forming a sparingly soluble compound with tellurite ions, the ionic solubility of the compound formed will theoretically remain independent of pH. This aspect has actually been discussed in detail in an earlier publication for a system involving a diprotic acid (4). The experimental results for the system silver tellurite do show such a behavior, where one observes that the potentiometric and radiometric solubilities remain independent of pH, though these vary as a function of tellurite concentration. Therefore, the mathematical equations derived for a diprotic acid system for the identification of aqueous complex species originating through heterogeneous system remain valid for the tellurite system as well. The formation of the complex species $Ag(TeO_3)_2^{3-}$ thus appears justified both on theoretical and experimental grounds. There is, however, no report available in the literature on the complexation of reactions of tellurite ion.

The Hydrogenation of Allene. IV. The Reaction of Allene with Hydrogen Catalyzed by Palladium, Platinum, Iridium, Rhodium, Ruthenium, and Osmium Catalysts

R. S. MANN AND A. M. SHAH

Department of Chemical Engineering, University of Ottawa, Ottawa K1N 6N5, Canada

Received July 9, 1971[1]

The reaction between allene and hydrogen over unsupported palladium, platinum, iridium, rhodium, ruthenium, and osmium catalysts has been investigated in a static constant volume system between 70 and 149 °C for a wide range of reactant ratios. The orders of reaction with respect to hydrogen and allene were one and zero, respectively, and temperature independent. The overall apparent activation energies for unsupported platinum, iridium, palladium and rhodium were 17.7, 9.1, 6.4, and 17.4 kcal/mol, respectively. The catalytic activities of the unsupported metals were in the sequence Pd > Ir > Rh > Pt > Ru, Os. Selectivity was highest with palladium and rhodium, and least with iridium. The polymerization was highest with platinum and least with iridium.

Nous avons étudié la réaction entre l'allène et l'hydrogène sur des catalyseurs non-supportés de palladium, platine, iridium, rhodium, ruthénium, et osmium, dans un système de volume statique constant entre 70 et 149 °C et dans un large domaine de rapports des réactifs. Les ordres de réaction par rapport à l'hydrogène et à l'allène étaient respectivement un et zéro et indépendants de la température. Les énergies totales d'activation apparentes pour le platine, l'iridium, le palladium et le rhodium sans support sont respectivement de 17.7, 9.1, 6.4, et 17.4 kcal/mole. Les activités catalytiques des métaux sans support étaient dans l'ordre: Pd > Ir > Rh > Pt > Ru, Os. La sélectivité était plus élevée pour le palladium et le rhodium et plus faible avec l'iridium. La polymérisation était plus élevée avec le platine et plus faible avec l'iridium.

Canadian Journal of Chemistry, **50**, 1793 (1972)

Introduction

In Parts I, II, and III of this series, the kinetics and products obtained from the reaction of allene with hydrogen catalyzed by pumice supported metals of the eighth group (1), unsupported nickel, iron, and cobalt (2), and nickel, copper, and their alloys (3) were reported. In this concluding paper of the series, we report the kinetics of allene hydrogenation over palladium, platinum, iridium, rhodium, ruthenium, and osmium.

Experimental

The apparatus, experimental procedure and method of product analysis were the same as described earlier (3, 4). The unsupported palladium, platinum, iridium, rhodium, ruthenium, and osmium catalysts were prepared by evaporating the solutions containing $(NH_4)_2PdCl_6$, $(NH_4)_2PtCl_2$, $(NH_4)_2IrCl_6$, $(NH_4)_2RhCl_6$, $(NH_4)_2RuCl_6$, and $(NH_4)_2OsCl_6$, respectively. The catalysts were reduced in a hydrogen stream for 24 h at 400 °C. The amount of polymers formed (allene lost) was calculated as the difference between the initial allene pressure and the pressure of hydrocarbons in the products. The pressure of hydrocarbons was the sum of the unreacted allene, propylene, and propane in the products.

Results

Unsupported platinum, palladium, iridium, and rhodium catalysts were found to be quite active and did not get poisoned when allene or hydrogen was admitted first into the reactor. The activity remained fairly constant for several days. Though ruthenium and osmium were found to be active at the beginning, they lost their activity after a few hours, and no measur-

[1]Revision received March 1, 1972.

TABLE 1. Order of reaction and activation energies

Catalyst	Weight of metal (g)	Temperature range (°C)	Order with respect to Hydrogen (±0.005)	Order with respect to Allene (±0.04)	k, specific rate at 60 °C (min^{-1} g $metal^{-1}$)	E, activation energy (kcal/mol)
Platinum	0.03054	120–149	1.00	0.00	0.0034	17.7
Iridium	0.02940	93–141	1.00	0.02	0.0981	9.1
Palladium	0.01933	70–142	0.996	0.00	0.3853	6.4

Ruthenium	0.21810	20–140	Catalyst deactivated after few runs			
Osmium	0.32560	20–194				

able rates were observed at high temperatures. The loss of activity of ruthenium and osmium was not due to mercury poisoning. While studying the reaction over palladium, a few drops of silicone oil were placed over the mercury in the manometer connected to the reactor to avoid the poisoning of the palladium catalyst, and the catalyst was isolated by closing the valve connected to the manometer when the reaction was not being studied.

A. Kinetics

The pressure–time curves observed during the study of allene hydrogenation over unsupported platinum, palladium, iridium, and rhodium catalysts were of Type III (4), regardless of (*i*) the initial reactant ratio, (*ii*) the order of admission of the reactants, and (*iii*) the temperature.

The orders of reaction were determined by the method of initial rates, the partial pressure of allene or hydrogen being varied while the other was kept constant at 50 mm. The orders of reaction with respect to hydrogen and allene were one and zero respectively and were temperature independent (Table 1).

Plots of $\log_{10}$ specific reaction rate against the reciprocal of absolute temperatures were good straight lines over a wide range of temperatures for unsupported platinum, palladium, iridium, and rhodium catalysts, satisfying the Arrhenius equation. The derived apparent activation energies are given in Table 1.

B. Selectivity

The course of the reaction and the dependence of the selectivity upon pressure fall was studied for hydrogen/allene ratios of 1 and 2, by analyzing the reaction products at different pressure falls. The selectivity (S) has been defined as the ratio of propylene to propylene plus propane.

The dependence of the selectivity upon pressure fall for hydrogen/allene ratio of 1 is shown in Fig. 1. Selectivity was independent of pressure fall for palladium and rhodium. While the selectivity increased with pressure fall for platinum, it decreased with the progress of the reaction in the case of iridium. The amount of allene polymerized increased with pressure fall, irrespective of the reactant ratio or the catalyst.

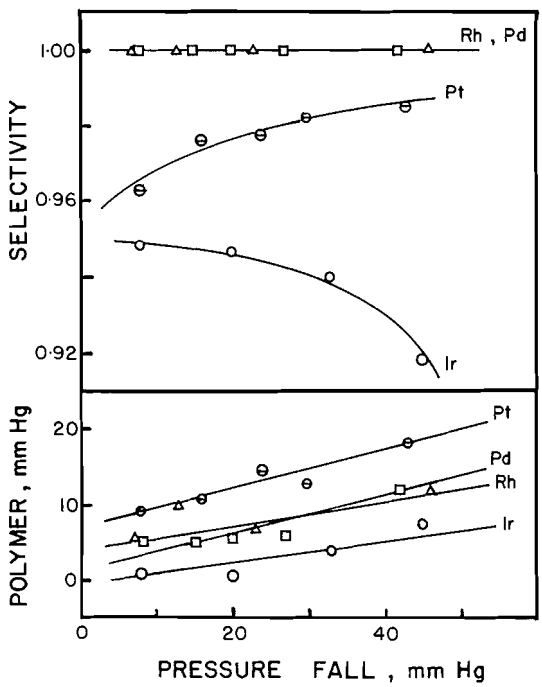

FIG. 1. Dependence of selectivity upon pressure fall, $P_{H_2} = 50$ mm Hg, $P_{C_3H_4} = 50$ mm Hg. Ir powder, ○, $T =$ 132.5 °C; Rh powder, Δ, $T = 107.0$ °C; Pd powder, □, $T = 128.5$ °C; Pt powder, 0, $T = 143.0$ °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

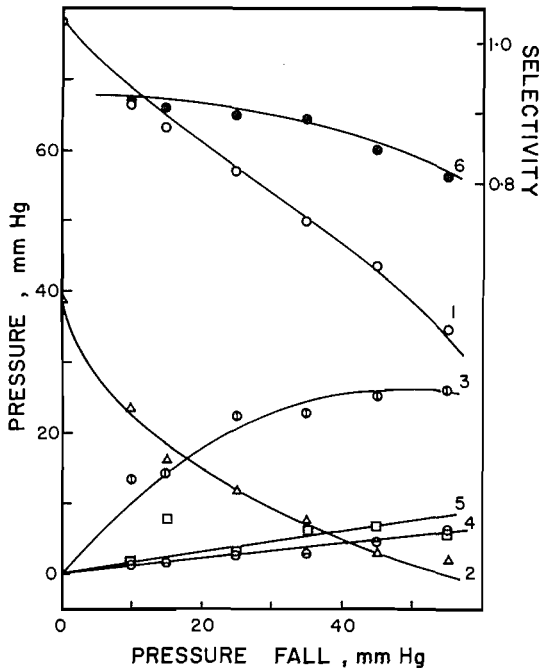

FIG. 2. Distribution of products during the course of reaction over Ir-powder catalyst at 132.5 °C. $P_{H_2} = 100$ mm Hg, $P_{C_3H_4} = 50$ mm Hg, Curve *1*, hydrogen; curve *2*, allene; curve *3*, propylene; curve *4*, propane; curve *5*, polymer; curve *6*, selectivity.

The product distribution during the course of the reaction for iridium catalyst is shown in Fig. 2. Similar results were obtained for platinum, palladium, and rhodium catalysts.

Measurements were made of the selectivity of the catalysts as a function of initial hydrogen pressure at several temperatures by using a fixed allene pressure (50 mm) and varying the hydrogen pressure (40–170 mm). The products were analyzed when the total pressure fall was equal to 30 mm. While the selectivity was independent of initial hydrogen pressure for rhodium and palladium, it decreased with increased hydrogen pressure for platinum and iridium catalysts. The extent of allene polymerization was nearly independent of hydrogen pressure for all catalysts.

The dependence of selectivity upon initial allene pressure was studied by using a fixed hydrogen pressure and varying the allene pressure (40–150 mm). The products were analyzed at a fixed pressure fall (20 mm for Ir, Pd, and Rh, and 30 mm for Pt). The selectivity was independent of allene pressure for palladium, rhodium, and iridium catalysts. However, the selectivity of platinum increased with increased allene pressure up to 80 mm, and thereafter remained constant. While the amount of allene polymerized increased with allene pressure for platinum, iridium, and rhodium catalysts, it was independent of allene pressure for palladium catalysts.

The temperature dependence of the selectivity for hydrogen/allene ratio of 2 was studied by analyzing the products at several temperatures at a pressure fall of 20 mm in the case of iridium, rhodium, and palladium, and 30 mm for platinum catalyst. While the selectivity was independent of the temperature for rhodium and palladium catalysts, it decreased with increasing temperatures for platinum and iridium catalysts. While the extent of polymerization was independent of temperature for platinum and rhodium catalysts, it increased with increased temperatures for palladium and iridium.

Discussion

The pressure–time curves (Type III) observed in the present study were similar to those observed earlier in the study of allene hydrogenation over nickel–copper alloys (3). The pressure–time curves of Type III were also observed in the study of allene hydrogenation over pumice supported transition metals of the eighth group (1) and unsupported iron, cobalt, and nickel catalysts (2).

The orders of the reaction with respect to hydrogen and allene were one and zero, respectively. Similar orders were observed for allene hydrogenation by other investigators (1–3, 5). Mann and Khulbe (6) in the study of methylacetylene hydrogenation over unsupported palladium, platinum, iridium, rhodium, and osmium catalysts observed that order with respect to hydrogen was one, and zero to slightly negative with respect to methylacetylene.

The order of relative activities of the various unsupported metals observed for the hydrogenation of allene (Table 1) in the present investigation is

(*a*) Pd > Ir > Rh > Pt ≫ Ru, Os

as compared to

(*b*) Pd > Ir > Pt > Rh > Ru > Os

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

observed by Mann and Khulbe (6) for methylacetylene hydrogenation over unsupported metal catalysts. Since no studies have been made of the catalytic activities of various unsupported metals for allene hydrogenation, by any other investigator, no direct comparison of the present work can be made with any published work. The catalytic activities of pumice supported metals for allene hydrogenation were reported by Mann and To (1) to be in the sequence

(*c*) $$Pt > Pd > Rh > Ir > Ru > Os$$

The results of the present investigations show close similarity in the catalytic activities of unsupported metals to those obtained by Mann and Khulbe (6) for methylacetylene hydrogenation over the same metals. Palladium was found to be the most active catalyst for allene and methylacetylene hydrogenation. Comparing (*a*) and (*c*), the relative activities of the unsupported and supported metals, it is seen that the activity of the catalyst depends on the form (supported or unsupported) of the catalyst. Thus pumice supported platinum (*c*) was more active than supported palladium, as compared to unsupported palladium being more active than unsupported platinum (*a*). It has been found that irrespective of the fact whether the catalysts were supported or unsupported, the metals having the face centered cubic structure (Pd, Pt, Ir, and Rh) were found to be active catalysts, whereas those having close packed hexagonal structure (Ru, Os) were not active at all.

The unsupported metals can be placed in the following sequence of decreasing selectivity for allene hydrogenation:

(*d*) $$Pd \approx Rh > Pt > Ir$$

The order of the sequence found in this investigation compares well with the order of the selectivities derived for methylacetylene (6). It is important to note that the selectivity exhibited is primarily a function of the particular metal and is substantially independent of the hydrocarbon undergoing reaction and of the conditions under which the reaction is carried out.

The results of the present investigation largely confirm the expected resemblance between the hydrogenation of allene and acetylenes. Since the dependence of the selectivity on temperature and pressures of the reactants and the kinetics of the reaction of hydrogen with allene and acetylene are very similar, it can be assumed that the reaction mechanism for these may be similar, and that the allene hydrogenation reaction is the one in which gaseous allene and hydrogen are adsorbed on the surface to form the half hydrogenated state

Studies of β-Diketone Complexes of Rhenium. Part II. Physical Studies of Dihalobis(pentane-2,4-dionato)rhenium(IV) Compounds

W. D. COURRIER, C. J. L. LOCK,[1] AND G. TURNER

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received October 1, 1971

Studies on *trans*-$Re(acac)_2Cl_2$ in the solid state, solution, and gas phases by spectroscopic and classical physical methods show that the compound is a monomer and not a dimer as previously claimed (2). *cis*-$Re(acac)_2Cl_2$, $Re(acac)_2Br_2$, $Re(acac)_2I_2$, and $Re(dbm)_2Cl_2$ have been prepared for the first time and corresponding physical measurements are reported.

Les études effectuées sur le *trans*-$Re(acac)_2Cl_2$, en phase solide, en solution et en phase gazeuse au moyen des méthodes spectroscopiques et physiques classiques, montrent que ce composé est un monomère et non un dimère comme cela avait été annoncé (2). Les composés nouveaux, *cis*-$Re(acac)_2Cl_2$, $Re(acac)_2Br_2$, $Re(acac)_2I_2$, et $Re(dbm)_2Cl_2$, ont été préparés et les mesures physiques correspondantes sont rapportées.

Canadian Journal of Chemistry, **50**, 1797 (1972)

Introduction

Several β-diketone complexes of rhenium have been described (1, 2). One of the compounds prepared was described as $Re_2(acac)_4Cl_4$ in which two acetylacetonate ions, bonding through the oxygen atoms bridged two rhenium atoms.[2] The structure was suggested on the basis of analysis, molecular weight determinations, and spectroscopic results. It has been shown (3) that in the solid state the compound is a monomer, *trans*-dichlorobis(pentane-2,4-dionato)rhenium(IV). It seemed appropriate, therefore, to reexamine spectroscopic results for this compound, and for the corresponding bromide and iodide complexes which had not been prepared previously.

Experiments

Analyses were performed by Galbraith Laboratories, Inc., Knoxville Tennessee, A. B. Gygli, Toronto, Canada and Meade Microchemical Laboratories, Amherst, Mass. Infrared spectra were recorded on Perkin–Elmer 337, 521, and 301 machines. Samples were ground into a mull with Nujol and mounted between potassium bromide or polyethylene plates. Raman spectra were excited by the 6328 Å line of a helium–neon laser and were recorded on a Czerny–Turner-type Spex laser Raman recording spectrograph. Samples were powders contained in Pyrex melting-point tubes. Ultraviolet and visible spectra were recorded on a Cary 14 instrument. Samples were solutions of the compound in benzene contained in 1 cm quartz cells. Measurements of the magnetic susceptibilities of powdered, solid samples were made by the Gouy method on an apparatus described previously (4). To minimize packing errors, the samples, in 3 mm o.d. quartz tubes, were placed in the vibrator of a Hoover (Philadelphia, Pa.) Unimelt apparatus and shaken to a constant 10 cm length. Calibration of the magnetic apparatus was accomplished using mercury thiocyanatocobaltate(II), obtained from Eastman Organic Chemicals, Rochester, New York. Magnetic susceptibilities were measured at four different field strengths to check for ferromagnetic behavior of either the sample or any impurities present. Corrections for diamagnetism of ligands and metal ions were taken from Selwood (5) and Föex (6). Mass spectra[3] were recorded on a Consolidated Electrodynamics Corporation mass spectrometer Model 21-110B. The samples were injected directly at 200 °C. X-Ray diffraction photographs of powdered samples were recorded on a Debye–Scherrer camera using nickel-filtered CuKα radiation. The samples were sealed inside quartz tubes. Line intensities were measured from the photographs with a Joyce–Loebl microdensitometer.

Dielectric constants and refractive indices of dilute benzene solutions of the dihalobis(pentane-2,4-dionato)-rhenium(IV) isomers were measured at 25.0 ± 0.1 °C. Dielectric constants were measured using a Wissenschaftlich-Technische Werkstätten dipolemeter Type DMO1, and a measuring cell Type DFL1. The measuring condenser was calibrated with air, *n*-hexane, carbon tetrachloride, benzene, carbon disulfide, and diethyl carbonate. The calibrating liquids were all Fisher Scientific A.R. grade, and were dried over Lindeman molecular sieve type 4A. Refractive indices were determined at the sodium D line with a Bausch and Lomb dipping refractometer which was calibrated with benzene. The dipole moments were calculated using the Guggenheim method (7). The results are presented in Table 4.

Calculations

Dipole moments were determined by the equation

$$\mu^2 = \frac{9kT}{4\pi N}\left[\frac{3}{(\varepsilon_1 + 2)(n_1^2 + 2)}\right] \times (a_\varepsilon - a_n) \times \frac{M_2}{d_1}$$

d_1, ε_1, n_1 are density, dielectric constant, and refractive index of solvent; M_2 is molecular weight of solute; a_ε is the slope of

the line obtained by plotting $e_{solution} - e_{solvent}$ *vs.* w_2; a_n is the slope of the line $n^2_{solution} - n^2_{solvent}$ *vs.* w_2; w_2 is the "weight in" quantity of solute = weight of solute/weight of solution. Conductivities were determined on an Industrial Instruments, N. J. Model RC1632 conductivity bridge as distributed by Fisher Scientific. The molar conductance of *cis*-$Re(acac)_2Cl_2$ in acetonitrile at 25 °C was 0.767 ohm^{-1} cm^2 at 5.25×10^{-3} *M* and 0.456 ohm^{-1} cm^2 at 2.1×10^{-3} *M*. The molar conductance of *trans*-$Re(acac)_2Cl_2$ in acetonitrile at 25 °C was 0.241 ohm^{-1} cm^2 at 1.8×10^{-4} *M* and 0.218 ohm^{-1} cm^2 at 1.1×10^{-4} *M*.

The Measurement of Molecular Weight

Molecular weight measurements in solution were made on a Hitachi–Perkin–Elmer 113 molecular weight apparatus. The apparatus was calibrated using benzil as a solute in benzene and dichloromethane solvents. It was established that to obtain reproducible results carefully purified and dried chemicals had to be used. The calibration curve for benzene solvent was obtained using benzil (mol. wt. 210) recrystallized from benzene to a m.p. of 95 °C, and A.C.S. Standard benzene which had been sodium dried (density 0.8787 g ml^{-1} at 22 °C). Measurements were made with a main oven temperature 40.8 °C, a sub oven temperature of 35.2 °C, and room temperature of 22.2 °C. Calibration was made over a range 0.02–0.0034 mol solute/kg of solvent. The time to reach equilibrium was 2 min. Repeat calibrations showed that the extreme error which could exist was ±7%. The instrument specification claims ±15% in the range $1 \times 10^{-4} - 5 \times 10^{-2}$ mol/kg and ±3% for $3 \times 10^{-2} - 2 \times 10^{-2}$ mol/kg for a benzene solvent. The calibration was checked with recrystallized triphenylphosphine (mol. wt. 262) and the results are shown in Table 3. The calibration for dichloromethane used benzil in dichloromethane (A.C.S. AR reagent, molecular sieve dried, density 1.327 g ml^{-1} at 22 °C). The main oven temperature was 25.2 °C and both the sub oven and room temperatures were 22.2 °C. Greater variation was observed in calibration (±10–15%) and equilibrium time was taken at 4 min, the maximum allowable according to the manual. Calibration was made over a range $2.43 \times 10^{-2} - 2 \times 10^{-3}$ mol/kg. A check was made using triphenylphosphine and the results are presented in Table 3. Measurements of the molecular weight of *cis*-$Re(acac)_2Cl_2$ were then made in both dichloromethane and benzene and of *trans*-$Re(acac)_2Cl_2$ in dichloromethane. The results are presented in Table 3.

Subsequently, the molecular weight of *trans*-$Re(acac)_2Cl_2$ was determined by Meade Microchemical Laboratories,

*Determined by Meade Microchemical Laboratories, Amherst, Mass. using a Mechrolab osmometer.

Amherst, Mass. using a Mechrolab Osmometer, in both dichloromethane and *o*-dichlorobenzene as solvents. These results are also shown in Table 3.

Rhenium metal was obtained from the Rhenium Division, Chase Brass and Copper Co. Inc., Solon, Ohio. Perrhenic acid was obtained as an aqueous solution from S. W. Shattuck Chemical Co., Denver, Colorado. All solvents and reagents used were reagent grade. Solvents were dried, when necessary, by treatment with freshly regenerated molecular sieves (Linde Type 4A) and were deoxygenated by bubbling dry nitrogen through them using a dispersion bubbler.

Preparation of Compounds

trans-Dichlorobis(pentane-2,4-dionato)rhenium(IV), $ReCl_2(acac)_2$

This compound was made by a number of methods. The products from the various reactions were identical. (*a*) The compound was prepared by the method of Grove *et al.* (2) for tetrachlorobis(pentane-2,4-dionato)-μ_2-bis(pentane-2,4-dionato)dirhenium(IV). (*b*) $ReOCl_2(acac)P(C_6H_5)_3$ (0.6 g) (2) was refluxed in acetylacetone (5 ml) for 4 h under an atmosphere of nitrogen. The solution was cooled and the orange crystals collected by filtering the solution; yield 0.25 g (58%). (*c*) $ReCl_2(acac)(P(C_6H_5)_3)_2$ (2) or $ReCl_2(acac)(OP(C_6H_5)_3)P(C_6H_5)_3$ (9) when refluxed with acetylacetone in air overnight gave fair yields of $ReCl_2(acac)_2$ on cooling (39 and 69%, respectively).

cis-Dichlorobis(pentane-2,4-dionato)rhenium(IV), $ReCl_2(acac)_2$

The filtrates of several preparations of *trans*-$ReCl_2(acac)_2$ were combined and evaporated slowly. A small amount of a reddish-brown crystalline compound was isolated.

Dibromobis(pentane-2,4-dionato)rhenium(IV), $ReBr_2(acac)_2$

$ReO(OCH_3)Br_2\{P(C_6H_5)_3\}_2$ (1 g) (8) was refluxed with 50 ml of acetylacetone for 48 h in air. The solution was cooled and the red crystals collected by filtering the solution. Yield, 0.69 g(33%).

Diiodobis(pentane-2,4-dionato)rhenium(IV), $ReI_2(acac)_2$

The dark red compound was prepared in ~29% yield from $ReOI_2(OCH_3)\{P(C_6H_5)_3\}_2$ (8) in a way similar to the bromo-compound.

Dichlorobis(1,3-diphenylpropane-1,3-dionato)rhenium-(IV), $ReCl_2(dbm)_2$

$ReO(OCH_3)Cl_2\{P(C_6H_5)_3\}_2$ (2 g) was fused with dibenzoylmethane (10 g), at a minimum temperature necessary to keep the mixture molten, for 48 h in a nitrogen atmosphere. Dark red needles of the compound were isolated by dissolving excess ligand in acetone. Yield 0.8 g (47%). Analyses and properties for all compounds are summarized in Table 1. None of the compounds was soluble in methanol, diethyl ether, or 30–60° petroleum ether, nor did they show any sign of halogen exchange when boiled in dichloromethane.

Results and Discussion

Previous work (3) has shown that $ReCl_2(acac)_2$ is not dimeric in the solid state. In order to see whether any dimerization occurred in the gas phase we have made mass spectral measurements on four of the compounds described in

this work: it was not possible to obtain a mass spectrum of $ReCl_2(dbm)_2$ because of its low volatility. The results are presented in Table 2. In all cases the fragment with the highest *m/e* value was $ReX_2(acac)_2^+$ and there was no evidence of $Re_2X_4(acac)_4^+$ or any derived dimeric fragments.

A comparison of the relative intensities of the $ReX_2(acac)_2^+$ and $ReX(acac)_2^+$ fragments suggests that the difficulty of removal of the halogen group is Cl > Br > I, in line with the expected rhenium–halogen bond strengths. It is not clear, however, why the proportion of $ReBr(acac)_2^+$ is so low when compared to the iodide. The pattern of break up of the compounds is very similar to that observed for $Re(acac)_3$ (12). There is some tendency to form oxo- and hydroxo-containing species, but little tendency to form ions con-

For personal use only.

taining other fragments of the acetylacetone group. Indeed, the most characteristic feature of the breakup of *cis*-$ReCl_2(acac)_2$ is the formation of the ion $ReCl(acac)(C_3H_4O)^+$. Otherwise the differences between the *cis*- and *trans*-isomers are very slight, which is to be expected since after the first chlorine atom is lost, the remaining ions will have the same structure. This makes us suggest that $ReCl_2(acac)(C_3H_4O)^+$ must have been formed directly from the parent ion $ReCl_2(acac)_2^+$.

Although it proved easy to establish that $Re(acac)_2Cl_2$ was monomeric in the solid state (3) and gas phases, it was far more difficult to test the claims that the material was dimeric in solution (2, 10). We were unable to get high enough solubilities to check the molecular weight of *trans*-$Re(acac)_2Cl_2$ using either ebullioscopic methods or a Mechrolab osmometer. Two commercial analysts also found the same problem with the osmotic method. Recently, however, using the Hitachi–Perkin–Elmer isopiestic molecular weight apparatus we have obtained results (Table 3), which although varying considerably because we were working close to the concentration limit of the instrument, are consistent only with the monomeric formulation for *trans*-$Re(acac)_2Cl_2$. Subsequently Meade Microchemical Laboratories determined the molecular weight of two different samples of *trans*-$Re(acac)_2Cl_2$ using an osmometer and have confirmed our results. Thus previous reports (2, 10) that *trans*-$Re(acac)_2Cl_2$ is dimeric in solution are clearly in error.

The isolation of a second form of $Re(acac)_2Cl_2$ suggested that this material might have been responsible for previous reports of a dimeric species. It was possible that this second form of $Re(acac)_2Cl_2$ was (*a*) an ionic compound such as $[Re(acac)_3]_2ReCl_6$ or $[Re(acac)_2Cl]Cl$; (*b*) a dimer, trimer, or polymer; (*c*) a different crystal form of the *trans*-isomer; (*d*) the *cis*-isomer. Clearly our results are only consistent with (*d*). The negligible conductivity eliminates (*a*) and the molecular weight eliminates (*b*). The dipole moment of 5.5(5) D (Table 4) is somewhat smaller than 6.3 D for *cis*-$Sn(acac)_2Cl_2$ (11) but clearly eliminates (*c*). Again there is no evidence of a dimeric form of $Re(acac)_2Cl_2$ in solution (Table 3).

The interconversion of the *trans*- and *cis*-isomers of $Re(acac)_2Cl_2$ must occur extremely slowly. Once we had separated the materials, in all subsequent operations there was no evidence of formation of the opposite isomer. In particular the *trans*-isomer is much less soluble and the *cis*-isomer was prepared by collecting the supernatant solutions and concentrating them. After the *trans*-isomer had been removed, subsequent concentration of the solutions yielded negligible amounts of *trans*-isomer, but ultimately good crystals of the *cis*-isomer could be obtained. The two forms are extremely easy to distinguish by color (*trans*, orange; *cis*, orange-brown) and crystal habit (*trans*, needles or plates; *cis*, truncated spheres). We have made detailed studies of the physical properties of both compounds in order to compare them.

TABLE 5. Electronic spectral data for $ReX_2(dik)_2$ compounds

Compound	Wavenumber (cm^{-1})	$\varepsilon_{max} \times 10^{-3}$
trans-$ReCl_2(acac)_2$	36 230	4.8
	30 100	1.6
	23 600	0.81
	19 900	0.26
cis-$ReCl_2(acac)_2$	39 050	7.8
	30 300	3.1
	25 000	1.6
$ReBr_2(acac)_2$	36 350	5.1
	27 800	3.2
	22 750	1.4
	20 000	0.68
$ReI_2(acac)_2$	34 000	7.2
	28 100	2.8
	24 050	4.2
	18 200	2.5
$ReCl_2(dbm)_2$	35 450	2.6
	29 400	8.6
	20 750	3.0
	19 600	3.1

The electronic spectra for the compounds are presented in Table 5. The electronic spectra in no way resemble those of the best-studied Re(IV) compound, K_2ReCl_6. The absorption coefficients are high enough to correspond to charge transfer or ligand bands. It is possible, because of the low solubility of the materials, that lower energy weaker bands were not observed. There are some superficial resemblances to the spectrum of $Re(acac)_3$ (12) and the observed bands do not vary regularly with the halogen suggesting that the transitions are associated with the β-diketone ring. The transition at 34 000–39 000

*Obtained by fit of data to $\chi = c/(T + \theta) + \alpha$.
†Obtained by linear extrapolation of $1/\chi$ against T after 100 × 10^{-6} c.g.s.u. subtracted from each value of χ.
‡Value obtained by linear extrapolation of magnetometer data (CI) or fit to Kamimura *et al.* (18) plot. These are the preferred values.

cm^{-1} is in the region assigned by Cotton *et al.* to a ligand $\pi \rightarrow \pi^*$ transition (13), although ε_{max} is low for such a transition.

The magnetic data for the compounds are presented in Table 6. No data were obtained for *cis*-$ReCl_2(acac)_2$ because of the small amount of sample available. We have attempted to fit the magnetic data for our complexes to an expression of the type

$$\chi = \frac{C}{T + \theta} + \alpha$$

used by Eisenstein (14) to explain the magnetic susceptibility of K_2ReCl_6 and K_2ReBr_6. It is possible using the constants listed as constants 1 in Table 7 to get an excellent fit for the data with the r.m.s. deviation of ~1% being of the order of the experimental error. It is clear, however, that despite the excellent fit, the derived constants are nonsense, since as Griffith (15) has shown, one would expect α to be ~100 × 10^{-6} c.g.s.u. In addition our magnetic susceptibility data are very similar to those for $M^I_2ReX_6$ compounds (16, 17) where an excellent treatment of the data has been made by Eisenstein (14) using a value of $\alpha \approx 100 \times 10^{-6}$ c.g.s.u.

TABLE 8. Plot of μ_{eff} vs. I

Compound	μ_{eff} at 0° K (extrapolated)	100 °K	300 °K
$Re(acac)_2Cl_2$	2.87	2.99	3.32
$Re(acac)_2Br_2$	2.55	2.87	3.21
$Re(acac)_2I_2$	2.05	2.50	3.11

Our first consideration was to show that the data were reliable. Re^{III} compounds such as $Re(acac)X_2(PPh_3)_2$ (9) from which our compounds were made and $Re(acac)_3$ (12) show large ($\sim$1000–1400 $\times 10^{-6}$ c.g.s.u.), essentially temperature-independent paramagnetism (t.i.p.), and if present as impurities might appear to give rise to t.i.p. in our compounds. We find no evidence of any impurity in our samples using such techniques as analysis and infrared spectroscopy, and susceptibility data from different samples agree within experimental error.

The second point was to show that antiferromagnetic interactions were small. If our data are corrected by about 100×10^{-6} c.g.s.u. to allow for a reasonable value of α, plots of $1/\chi$ against T are curved and extrapolation of $1/\chi$ to 0 is not good; nevertheless, the maximum possible values for θ for the Cl, Br, and I compounds are 18, 25, and 60°, respectively. As a check we have measured the susceptibility of $Re(acac)_2Cl_2$ to 10 °K using a vibrating magnetometer and see no point of a Néel point; furthermore a plot of $1/\chi$ extrapolates to give $\theta = 3°$.

An attempt was made to correlate the data using the method of Kamimura *et al.* (18)[4] by plotting μ_{eff} $(2.84\sqrt{\chi T})$ against T. The values of μ_{eff} are shown in Table 8.

The curves were of the form calculated by Kamimura *et al.* but the variation with halide should not be present. A much better plot was obtained using the alternative plot suggested by Kamimura *et al.*, namely, $\mu_{eff} = (2.84\sqrt{\chi(T+\theta)})$ against T. Using values for θ of 3, 13, and 43° for Cl, Br, and I, respectively, which are consistent with extrapolations of our $1/\chi$ against T plots, the values of μ_{eff} at given T for all halides are very similar (2.88 at 0 °K, 3.04 at 100 °K, and $\sim$3.35 at 300 °K). The spin–orbit coupling parameter, ζd, can be obtained from these plots; unfortunately the values obtained lie outside the range calculated by Kamimura *et al.* Attempts have been made to estimate the values of $\eta = \zeta d/(3B + c)$ and the slope of μ_{eff} against T (since Kamimura *et al.* plot μ_{eff} against $KT/\zeta d$) by extrapolation of the published curves. Because our data lie well outside the range of values calculated by Kamimura *et al.* our extrapolated values for η and ζd, which were obtained graphically, are very rough indeed. Values of η of 1.6–2.0 are obtained depending on the extrapolation, and assuming $3B + C \sim 2000$ cm^{-1}, ζd is $\sim$3200–4000 cm^{-1}. A fit of the slope of the curve gives $\zeta d \sim 1000$ cm^{-1}. We feel that the true value of ζd probably lies closer to the higher value since we have more faith in our extrapolation to find η. Clearly, however, the value of η is greater than 1.3, the value found previously for K_2ReCl_6. Thus, despite the excellent fit of our original calculations we feel that our compounds are behaving much like K_2ReCl_6 (14). The values of θ obtained for our compounds are smaller than those obtained for K_2ReX_6 (see Table 7) and are consistent with superexchange being smaller. For *trans*-$Re(acac)_2Cl_2$ (3) superexchange through chlorine atoms can take place in one direction rather than three for K_2ReCl_6 (14). In addition the increase in θ from chloride to iodide is consistent with the observation that the superexchange is increased as the electronegativity of the anion decreases (19).

The vibrational spectra for $Re(acac)_2X_2$ compounds are presented in Table 9. It was only possible to obtain a Raman spectrum for *trans*-$Re(acac)_2Cl_2$ as the other compounds absorbed the laser beam and decomposed. The vibrational transitions were assigned by comparison with the work of Fay *et al.* (20) and following the arguments we have used previously (12).

The spectra bear considerable resemblance to those of $Zr(acac)_2X_2$ and $Hf(acac)_2X_2$(X = Cl, Br) (20) except in the region above 1450 cm^{-1} where there are some small differences. The spectra of *cis*- and *trans*-$Re(acac)_2Cl_2$ are also quite similar, although there are small but significant variations in intensity and band wave number. The most important differences occur in the Re—Cl stretching region where, as expected the *cis*-compound has two strong bands in the infrared spectrum at 336 and 346 cm^{-1}, whereas only one band is observed in the infrared spectrum of *trans*-$Re(acac)_2Cl_2$ at 309 cm^{-1}.

Fay *et al.* (20) have argued that the coinci-

dences in the infrared and Raman spectra of $Zr(acac)_2X_2$ and $Hf(acac)_2X_2$ show that these compounds had *cis*-conformations (other evidence is presented elsewhere (21)). Examination of the infrared and Raman data for *trans*-$Re(acac)_2Cl_2$ shows at least as many coincidences. The explanation is that while *trans*-$Re(acac)_2Cl_2$ does have a center of symmetry (3), the

vibrations under consideration are ligand modes and the ligands do not have a center of symmetry. The arguments about coincidence and the center of symmetry apply only to the coupled vibrations of the ligands. If this coupling is very weak the coupled symmetric and asymmetric modes will be shifted very little, if at all, from the uncoupled modes and we shall get apparent coincidence. Thus, the presence of coincidences of ligand vibrations in the spectra of compounds of the type $M(acac)_2X_2$ does not allow one to decide whether the compound has the *cis*- or *trans*-conformation; the coincidence test should only be applied to modes which should be strongly coupled such as ν(M—O) and ν(M—Cl).

The infrared spectrum of $Re(acac)_2Br_2$ shows two bonds assigned to Re—Br stretches suggesting this is the *cis*-form and $Re(acac)_2I_2$ shows one bond in the Re—I region suggesting a *trans*-isomer. The X-ray data are also consistent with this interpretation.

The X-ray data were recorded for powdered samples of $Re(acac)_2X_2$ compounds, primarily for identification purposes, and the results are presented in Table 10. It has not proved possible to index the powder films, but this is hardly surprising since we know that *trans*-$Re(acac)_2Cl_2$ is triclinic (3). A comparison of our X-ray data with that of Fay *et al.* (21–23) for the series $M(acac)_2X_2$ (M = Ti, Zr, Hf; X = Cl, Br, I)[5] shows that data for *trans*-$Re(acac)_2Cl_2$ bear little resemblance to those for $M(acac)_2Cl_2$. However, there are some similarities in both *d*

[5]M is used to mean Ti, Zr, and Hf unless a metal is mentioned specifically.

value and intensity for *cis*-$Re(acac)_2Cl_2$ and $M(acac)_2Cl_2$.

There is an even higher correspondence between the data for $Re(acac)_2Br_2$ and $M(acac)_2Br_2$, the major difference being extra lines in the powder pattern of the rhenium compound. Since $M(acac)_2Br_2$ compounds are claimed to be *cis*-isomers we suggest that our material is principally *cis*-isomer with some small amount of *trans*-isomer. This result is consistent with the infrared data and the dipole moment which is somewhat lower than would be expected for the pure *cis*-isomer. The value obtained corresponds to about 70% *cis*-isomer.

Similarities in the X-ray data for $Re(acac)_2I_2$ and $Ti(acac)_2I_2$ which is postulated to be the *trans*-isomer suggest that $Re(acac)_2I_2$ was isolated as the *trans*-isomer and again this is borne out by the infrared data and the dipole moment.

We conclude that we have prepared and characterized what we have shown unambiguously to be *monomeric trans*-$Re(acac)_2Cl_2$, *cis*-$Re(acac)_2Cl_2$, a mixture of isomers of $Re(acac)_2Br_2$ which is primarily the *cis*-isomer, and *trans*-$Re(acac)_2I_2$. However, at this point we are unable to say what factors are important in deciding which isomer is formed.

We thank the National Research Council of Canada and the International Nickel Company for support of this work and the grant of scholarships to two of us (W.D.C. and G.T.).

Received October 27, 1971

We have been unable to prepare $TcCl_6$ by the method published previously even though our reaction between Tc and Cl_2 gave products which appeared the same. TcO_3Cl and $TcOCl_4$ have been prepared and fully characterized for the first time.

Il a été impossible de préparer $TcCl_6$ par la méthode précédemment publiée, même si la réaction entre Tc et Cl_2 conduit à des produits qui semblent les mêmes. Les composés TcO_3Cl et $TcOCl_4$ ont été préparés et caractérisés sans ambiguïté pour la première fois.

Canadian Journal of Chemistry, **50**, 1807 (1972)

Introduction

Rhenium hexachloride and technetium hexachloride were reported in notes published in 1962 (1, 2) but almost no further data were published on these compounds. Recently there has been a report of $ReCl_6$ prepared by a different method and with significantly different magnetic properties (3). In addition we have published our investigations of the original method for preparing $ReCl_6$ in which we show that the product we obtained in all cases was impure $ReOCl_4$ (4).

Because $ReCl_6$ and $TcCl_6$ were originally prepared by essentially the same method it became of interest to reinvestigate the Tc–Cl system. In this paper we report our studies.

Experimental

Precautions used in handling air-sensitive materials have been described previously (4). All operations involving handling more than 50 mg of technetium were performed in a "hot-lab". ^{99}Tc was purchased from Oak Ridge National Laboratories as powdered metal and was not purified further except for certain experiments indicated below where the metal was vacuum dried and heated in hydrogen to reduce surface oxides. All other reagents were purified by methods described previously (4).

Analyses were performed on hydrolyzed samples of compounds. Chloride was determined gravimetrically as silver chloride. Technetium was determined by counting. A diluted sample solution was evaporated on a planchet (about 1 μg ^{99}Tc per analysis) and the β-activity compared with that of a standard sample. The standard solution was prepared by dissolving an accurately weighed amount of ^{99}Tc metal in concentrated nitric acid and diluting. Counting was performed on a Nuclear Chicago windowless proportional flow counter. Oxidation number of the technetium was determined by hydrolysis with dilute ammonia solution. The precipitate was dissolved in nitric acid, and samples of this solution and of the filtrate were evaporated and counted to give the Tc^{IV}: Tc^{VII} ratio (1).

Infrared spectra were recorded on a Perkin–Elmer 521 grating spectrometer as Nujol mulls between KBr plates or in the vapor phase in a cell described previously (5). Ultraviolet–visible spectra were recorded on a Cary 14 recording spectrometer in the vapor phase in a 10 cm path length quartz cell.

The Chlorination of Technetium Metal

All reactions were carried out in the same type of apparatus. This consisted of a Pyrex tube about 50 cm long and 2 cm i.d. One end was fitted with a three way stopcock to allow gas to be admitted and the other end was connected to a train of U-traps made of Pyrex glass (8 mm i.d.). The traps were generally 20 cm in depth and the arms were about 5 cm apart. Each U-trap was fitted with a breakseal. The 2 cm tube could be heated with a tube furnace.

Reaction Scheme (a)

A sample of technetium metal was placed in the 2 cm tube. The tube was flushed with a dried deoxygenated nitrogen stream while the metal was heated to about 150 °C for 2 h to remove water. The metal was cooled in the nitrogen stream, the flow stopped and then chlorine was passed through the tube while the metal was heated to temperatures from 300–550 °C depending on the experiment. In all cases reaction occurred and at the beginning of the reaction a volatile material distilled off and was condensed as a blue solid in a trap cooled in an ice–salt mixture. Subsequent reaction produced red-brown technetium tetrachloride (confirmed by X-ray diffraction), which condensed in the tube at the point it emerged from the tube furnace. It was found that the blue material was very sensitive to light, but could be separated by trap-to-trap distillation under vacuum in the dark using slush baths in the -30 to -60 °C range, into purple $TcOCl_4$ and very pale yellow TcO_3Cl (see below).

Reaction Scheme (b)

Reaction (*a*) was repeated, but the technetium metal was vacuum dried, and reduced in hydrogen for 3 h at 200 °C and

then 3–4 h at 550 °C before chlorination. Chlorination was carried out as in (*a*) but the chlorine was purified as in ref. 4. The amount of volatile blue material produced was very small and the major product was $TcCl_4$.

Reaction Scheme (c)

Technetium metal was converted to pertechnic acid in cold concentrated nitric acid. The solution was then evaporated to near dryness and neutralized with 2 *M* ammonia solution. The solution was diluted to about 10 ml with water, and pieces of broken porous pot were dropped into the solution and the mixture slowly evaporated to dryness. The bits of pot were transferred to the reaction tube and heated (24 h at 200 °C/24 h at 550 °C) in a hydrogen stream. The pot was then cooled, and chlorination was carried out at 300–500 °C (depending on the run) as in method (*b*). The major product of chlorination was a volatile material which condensed in a U-trap cooled in ice-water as a green solid (>90%). The other material produced was $TcCl_4$ which condensed in the reaction tube at the point where it left the furnace. The green material was easily decomposed by light, but could be separated by trap-to-trap distillation under vacuum in the dark at −30 to −60 °C into $TcOCl_4$ and TcO_3Cl (see below).

Chlorotrioxotechnetium(VII), Pertechnyl Chloride, TcO_3Cl

This was prepared by (*a*) vacuum distillation from the mixture of oxochlorides produced on chlorination of technetium metal. (*b*) placing technetium tetrachloride in a Carius tube fitted with a breakseal which was then filled with oxygen and sealed. The tube was heated to 450 °C for a few hours. On cooling the tube was connected to a vacuum line via the breakseal and the product distilled out. A quantitative yield of TcO_3Cl was obtained. TcO_3Cl is a very pale yellow liquid boiling at 25 °C.

Anal. Calcd. for ClO_3Tc: Cl, 19.5; Tc, 54.2. Found: Cl, 19.4; Tc, 54.1.

Tetrachloroxotechnetium(VI), $TcOCl_4$

This was separated from the mixture of oxochlorides produced on chlorination of technetium metal by trap-to-trap distillation *in vacuo*, in the dark. The pure product is a purple crystalline solid (m.p. ~ 35 °C), which is photodecomposed.

Anal. Calcd. for Cl_4OTc: Cl, 52.3; Tc, 38.5. Found: Cl, 52.6; Tc, 38.2.

Trichloroxotechnetium(V), $TcOCl_3$

This was prepared by decomposition of $TcOCl_4$. The $TcOCl_4$ was allowed to decompose to involatile $TcOCl_3$ and chlorine in sunlight and the chlorine removed under vacuum. It was not even necessary to purify the $TcOCl_4$ before use, if it was distilled off the mixture obtained on chlorinating technetium, since the other volatile oxochloride TcO_3Cl was removed with the chlorine. $TcOCl_3$ is a brown solid indentical to the physical and spectral properties to the compound described previously (6).

Technetium Tetrachloride, $TcCl_4$

This was the major product of the chlorination of technetium metal and was identical to the product described previously (7).

Discussion

Direct chlorination of powdered technetium metal at 550 °C did not produce the green compound described previously (1) but gave initially a bright blue "compound", the other product being technetium tetrachloride. By taking great care to reduce oxygen contamination of the reactants it was possible to reduce the amount of blue material to a very minor product, but never to eliminate it entirely. However, if the chlorination was of a metal film on porous pot, a reaction almost entirely like Colton's was observed. A green "compound" was formed in much higher yield than the blue product described above and in this case technetium tetrachloride was the minor product. Vacuum distillation in the dark of the blue and green "compounds" has shown that both are mixtures of a very pale yellow volatile liquid and a volatile purple crystalline solid.

The liquid has been shown to be pertechnyl chloride (TcO_3Cl). TcO_3Cl was hydrolyzed by dilute ammonia to give a colorless pertechnate solution thus proving the oxidation number of seven and chlorine and technetium elemental analyses confirm our formulation. The vapor-phase infrared spectrum, the liquid phase Raman spectrum and the vapor phase ultraviolet–visible spectrum have been recorded and are very similar to those of perrhenyl chloride. (Infrared Tc=O stretch at 955 cm^{-1} (broad), u.v.–visible bands at 1920, 2280, and 3150 Å (band has vibrational structure)). Detailed analyses of the spectra will be reported elsewhere (8, 9). We note, however, that the previously reported spectrum (12) for "TcO_3Cl" is incorrect. Strong bands at 3450, 3900, and 5950 Å are not consistent with a pale yellow compound and differ markedly from our results.

Colton and Tomkins (7) have speculated that the volatile blue compound formed on chlorination of TcO_2 was technetium oxotetrachloride, but reported that the compound was too thermally unstable to isolate. We have found that $TcOCl_4$ appears to be blue when some impurity TcO_3Cl is present but when pure is a purple color and forms large crystals similar in all but color to $ReOCl_4$. Contrary to previous reports $TcOCl_4$ is stable at room temperature for months (we have a sample over a year old) if kept out of the light but decomposes rapidly even at −78 °C if left in sunlight or artificial fluorescent light. Hydrolysis by dilute ammonia solution gave a TcO_2/TcO_4^- ratio of 1:2 proving an oxidation number of VI and chloride and technetium analysis results are consistent with the $TcOCl_4$ formulation. An infrared spectrum, taken as rapidly as possible of a cell of vapor which had

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

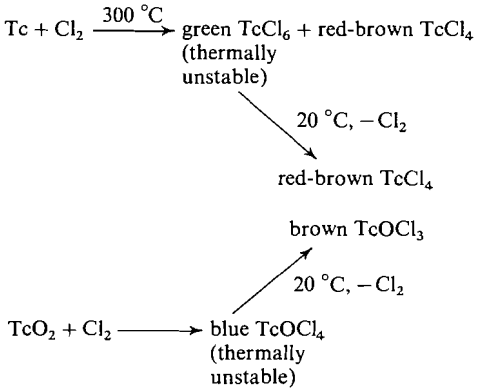
been filled in the dark, showed only a peak at 998 cm^{-1}. This is considerably lower than the metal–oxygen stretching frequency of gaseous $ReOCl_4$ which occurs at 1040 cm^{-1}. The lowering of frequency may be caused by a lowering of force constant associated with a weakening of the Tc=O bond when compared to Re=O. This is not unexpected since the Tc 4d orbitals are less extended than the Re 5d orbitals and there will be less $p\pi$–$d\pi$ overlap. A similar lowering of Tc=O stretch frequencies is seen in TcO_3Cl (955 cm^{-1}) compared to those for ReO_3Cl (1003, 971 cm^{-1}).

After exposure to the globar source a brown compound deposited on the cell windows, the peak at 998 cm^{-1} disappeared and a peak at 1016 cm^{-1} appeared. The new peak arises from the Tc=O stretching vibration in $TcOCl_3$ which has a reported value of 1017 cm^{-1} (10). The chlorine produced in the photochemical reaction

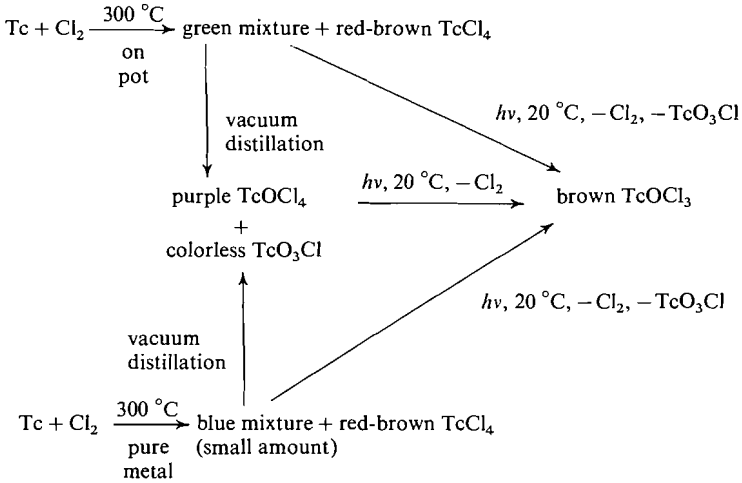
$$2TcOCl_4 \xrightarrow{h\nu} 2TcOCl_3 + Cl_2$$

was identified by its ultraviolet spectrum.

Below we summarize previous work on the Tc–Cl system and compare it with our results. Previous results have suggested



Our results are



We show that we have not prepared $TcCl_6$ by the action of chlorine on technetium metal, but we have isolated and fully characterized TcO_3Cl and $TcOCl_4$ for the first time. We note that there is a great similarity between our experimental observations and those of previous workers although our interpretation is quite different. Because of the small amount of previously published data useful for identification we cannot show that the two reaction schemes are the

same. However, our scheme is more satisfactory than one which postulates the preparation at 300 °C in a chlorine stream of a compound which is thermally unstable at room temperature *even in a chlorine atmosphere* and which decomposes rapidly "even on very gentle warming" (1, 11). Indeed, the only positive evidence for $TcCl_6$ is the Tc:Cl ratio of 1:6 (1) and an oxidation state of VI, but it has been noted elsewhere (11) that "chlorine is quite soluble in $TcCl_6$" and is difficult to remove. In the light of this and our previous results on the rhenium system we suggest that the existence of technetium hexachloride has not been proved.

The Preparation, Physical Properties, and Structure of Oxotetrachloroaquorhenium(VI), $ReOCl_4(OH_2)$

P. W. FRAIS AND C. J. L. LOCK[1]

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received January 5, 1972

Oxotetrachloroaquorhenium(VI), $ReOCl_4 \cdot H_2O$, has been prepared and characterized for the first time by analysis, infrared spectroscopy and single crystal X-ray diffraction. The crystals were orthorhombic, $a = 10.834(8)$, $b = 11.089(8)$, $c = 5.517(4)$ Å, $Pn2_1a$, $Z = 4$. Intensity data were recorded by integrating film methods and measured with a Joyce–Loebl microdensitometer, and 624 observable of the 704 measured independent reflections were given non-zero weight in the final cycle of full matrix least-squares refinement where $R_1 = 0.0572$ and $R_2 = 0.0687$.[2] The molecular structure is based on a very distorted octahedron with a strongly bonded oxo-group (Re—O, 1.63(2) Å) *trans* (177(2)°) to a weakly bonded aquo-group (Re—O, 2.27 (2) Å). The Re—Cl distances do not differ significantly (2.29(1) Å av). The chlorine atoms are bent away from the oxo-group (angles vary from (94–102°(1)).

L'oxotétrachloroaquorhénium(VI), $ReClO_4 \cdot H_2O$, a été préparé et caractérisé pour la première fois par analyse, spectroscopie infra-rouge et diffraction des rayons-X. Les cristaux sont orthorhombiques, $a = 10.834(8)$, $b = 11.089(8)$, $c = 5.517(4)$ Å, $Pn2_1a$, $Z = 4$. Les intensités des tâches de diffraction ont été enregistrées sur film (intégration) et évaluées avec un microdensimètre Joyce–Loebl. Des 704 réflections indépendantes mesurées, 624 furent considérées comme observées au cours du dernier cycle d'affinement par moindres carrés (matrice complète). L'accord final est indiqué par $R_1 = 0.0572$ et $R_2 = 0.0687$.[2] La structure moléculaire est basée sur un octaèdre très déformé avec un groupe oxo fortement lié (Re—O = 1.63(2) Å) en *trans* (177(2)°) d'un groupe *aquo* faiblement lié (Re—O = 2.27(2) Å). Les distances Re—Cl ne diffèrent pas d'une manière significative (moyenne 2.29(1) Å). Les atomes de chlore tendent à s'éloigner du groupe oxo (angles variant entre 94 et 102(1)°).

Canadian Journal of Chemistry, **50**, 1811 (1972)

Introduction

We have reported previously some of the products obtained from the reaction of $ReO_3 + ReCl_5$ (1). One product, which was observed on several occasions but isolated only once, was a red crystalline material. Although the crystals were stable in an evacuated tube, the compound was unstable even in a good dry box. Nevertheless, it was possible to isolate several single crystals and do a single crystal X-ray structure analysis. The only other chemical experiment done on these crystals was neutron activation analysis (2). The combined results showed a molecular compound containing a rhenium atom, four chlorine atoms, and two other light atoms, probably oxygen atoms. The results suggested a compound of the type $ReOCl_4 \cdot OH$ or $ReOCl_4(OH_2)$ but we were unable to determine which was correct because of lack of material.

The formulations did suggest alternative methods of preparation and we subsequently prepared the compound by the reaction of water and $ReOCl_4$. We have shown that the two products are identical and that the stoichiometry is $ReOCl_4 \cdot OH_2$. The crystal and molecular structure of $ReOCl_4(OH_2)$ as well as some physical and chemical properties are described in this paper.

Experiments

Analyses for rhenium and chlorine, as well as determination of the oxidation state of rhenium by the alkaline hydrolysis method were performed using the neutron activation method described previously (2). Infrared spectra were recorded on Perkin–Elmer 337 and 521 spectrometers. Solid samples were either the solid powder ground between two potassium bromide discs or were solid ground into a mull with dry Nujol and mounted between potassium bromide plates. The Nujol was dried by refluxing over phosphorus pentoxide and vacuum distilled. Gas samples were contained in a heated gas cell with silver chloride windows (3). Solution samples were prepared in the manner described previously (4) and were contained in standard solution cells with potassium bromide windows. Raman spectra were excited by the 6328 Å line of a helium–neon laser and were recorded on a Czerny–Turner-type Spex laser Raman recording spectrograph, which contained a double monochromator. Solid samples were mounted in melting point tubes and maintained at a temperature of −100 °C. X-Ray diffraction photographs of powdered samples were recorded on a Debye–Scherrer

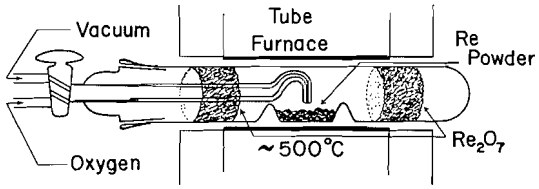

FIG. 1. Apparatus for the preparation of Re_2O_7.

camera using nickel-filtered CuKα radiation. Samples were sealed inside quartz tubes. All X-ray film intensities were measured using a Joyce–Loebl microdensitometer.

Preparation and Purification of Starting Materials

Powdered rhenium metal, rhenium trioxide, rhenium oxotetrachloride, oxygen, and chlorine were obtained and purified as described previously (4). Rhenium heptoxide was prepared from vacuum dried rhenium metal and dry oxygen using a method similar to that of Melaven *et al.* (5), but using a modified apparatus (Fig. 1) that greatly increases the rate of reaction. In the modified apparatus, the excess pressure of oxygen gas is forced directly onto the surface of the metal and this displaces the very dense vapors of Re_2O_7 which provide a blanket in the conventional apparatus and slow the reaction.

Rhenium pentachloride was prepared in a similar apparatus using a modification of normal methods (6, 7) and purified by the method we have described previously (4).

Preparation of Oxotetrachloroaquorhenium (VI)

(*a*) Rhenium pentachloride (91 mg) and rhenium trioxide (65 mg) were heated in an evacuated Pyrex reaction vessel, fitted with a breakseal, at 445 °C for 3 days. The vessel was cooled slowly and sealed to a vacuum line, which was evacuated and allowed to degas for some hours. The breakseal was broken and volatile products of the reaction were allowed to sublime into a U-trap cooled in liquid nitrogen, while the reaction vessel was submerged in an oil bath at 80 °C. After 24 h, the evacuated reaction vessel and U-trap system were separated by sealing under vacuum, and the involatile black residue in the reaction vessel was analyzed by X-ray powder photography. It was the orthorhombic phase of rhenium dioxide with small amounts of an impurity which was not rhenium metal, Re_3Cl_9, $ReCl_4$, or $ReCl_5$.

The bright red sublimate was kept at room temperature, while an adjacent U-trap was cooled in ice–water. After a week the evacuated traps were separated by sealing the neck between them. The ice–water trap contained small amounts of a yellow liquid, probably impure ReO_3Cl. The room-temperature U-trap contained a very fine red coating, which after standing at room temperature for several weeks developed plates of dark red crystals, usually away from the bulk of the starting material. The U-trap was opened in a dry box cooled to 10 °C, and several crystals were isolated and sealed in quartz capillary tubes. The bulk of the material changed to a black residue within hours. Neutron activation analysis of one of the crystals gave a Cl:Re atom ratio of 4.07 (calculated value 4.00), but because of surface decomposition and the size of the sample, an oxidation state analysis was not attempted. The preparation (but not purification) described above was not reproducible and in many experiments, other products were obtained (see ref. 1). This is hardly surprising since it is evident that the formation of the compound is dependent on water impurity being present.

(*b*) A known amount of $ReOCl_4$ (estimated from the volume of the melt) was distilled into a tube fitted with a breakseal and which was cooled in liquid nitrogen. An equimolar amount of water vapor was then distilled into the reaction tube. (The amount of water was obtained by connecting an evacuated calibrated vessel to a source of water and varying the vapor pressure of the water by varying the temperature.) The reaction vessel was isolated by sealing and placed in a tube furnace at 350 °C for 24 h, care being taken to avoid a temperature gradient. The furnace was cooled very slowly to room temperature. The reaction vessel contained bright red crystals in the form of long rectangular plates. The tube was transferred to a dry box before opening and subsequent experiments on the crystals. Three independent analyses gave an average chlorine to rhenium atom ratio of 3.92(9) (calculated value 4.00) and a ReO_4^-/ReO_2 ratio on hydrolysis of 2.2(1) (calculated value 2.0).

Crystallography

Single crystal X-ray studies were done on a crystal prepared by method *a*. The crystal was sealed in a fused silica capillary tube. All crystal data were obtained from a triangular plate crystal with sides 0.4, 0.5, 0.5 mm and thickness 0.11 mm.

Weissenberg photographs of the crystal showed that it was orthorhombic with systematic absences $0kl, k + l =$ odd, and $hk0, h =$ odd suggesting the space groups $Pnma$, or $Pn2_1a$. Precession photographs of the ($hk0$) and ($0kl$) layers taken with CuKα radiation were calibrated with a crystal of TiO_2 (rutile) and accurate cell parameters were obtained using the parameters for TiO_2, $a = 4.5929(5)$, $c = 2.9591(3)$ Å (8). Crystal data were

$H_2Cl_4O_2Re$ f.w. = 362.1

Orthorhombic, $a = 10.834(8)$, $b = 11.089(8)$, $c = 5.517(4)$ Å, $V = 662.8$ Å^3, $Pn2_1a$, ρ_o not determined, see text, $Z = 4$, $\rho_c = 3.62$ (22 °C; CuKα, $\lambda = 1.5418$ Å). Because of the instability of $ReOCl_4(OH_2)$ it was not possible to obtain an experimental value for the density.

Intensity data were obtained from films recorded on a precession camera using MoKα radiation. The (nkl), $n =$ 0–4 and (hkm), $m = 0, 1, 2$ layers were recorded. The intensities were measured using a Joyce–Loebl microdensitometer and then corrected for Lorentz and polarization effects. No absorption corrections were made because of the irregular shape of the crystal.

Standard errors, σ, were assigned to each intensity measured and weights $w = 1/\sigma^2$ were used throughout the refinement. For each reciprocal lattice layer measured, a minimum value of σ was estimated from the accumulated relative errors of the factors used to scale different films and different wedges on the densitometer. To this minimum value of σ was added an additional value which took account of the intensity of the spot, the intensity profile of each spot, irregular background, intensity of the background, edges of the beam stop or layer screen, and average reproducibility of each measured intensity. Smallest values of σ were therefore assigned to well-defined spots of uniform integrated intensity, whose intensity could be measured on three or more films. For unobserved reflections, weights calculated from $\sigma = 0.5\ F_{min}$ were used only when the calculated structure factor $|F_c| > 0.8\ F_{min}$, where F_{min} was the local minimum of

the observed structure factor; otherwise they were given zero weights.

Atomic scattering factors used for rhenium, oxygen, and chlorine were obtained from Cromer and Waber (9) and anomalous dispersion corrections for rhenium and chlorine were obtained from Cromer (10).

Solution of the Structure

The systematic absences indicated the space groups *Pnma* or $Pn2_1a$. The two dimensional Patterson maps for the $(h0l)$ and $(0kl)$ layers were readily soluble for the x and y coordinates of the single rhenium atom in the asymmetric unit. Assuming the centrosymmetric space group *Pnma*, the y coordinate was fixed at 0.25. The large reduction in value of the R factor, as well as the reasonable value of U_{iso} indicated that the chosen coordinates for rhenium were approximately correct. The large interatomic Re–Re distances excluded the possibility of any oxygen or chlorine bridging, so an octahedral arrangement around each Re atom was assumed. The position of the remaining atoms were found from electron density and difference synthesis maps phased on the heavy atom positions.

Since only a few crystals of the material were available at this stage, and a neutron activation analysis had not yet been done, the compound was assumed to be $ReOCl_5$ from the similarity of the unit cell parameters with $OsOF_5$ (11) and from the stoichiometry of the reaction; *i.e.*

$$ReO_3 + ReCl_5 \rightarrow ReO_2 + ReOCl_5$$

With an unweighted R value of 0.09, four chlorine atoms were stable at Re—Cl distances of ~2.3 Å, and one oxygen at Re=O of ~1.6 Å, with reasonable isotropic temperature factors. The fifth chlorine, *trans* to the terminal oxygen was found at a distance of ~2.2 Å from the rhenium atom, a distance much shorter than that expected for a terminal chlorine opposite a double bonded oxygen (12). In addition the temperature factor for this atom was much larger than expected, and chlorine–chlorine non-bonded distances to the other four chlorine atoms were unreasonably short.

If the atom *trans* to the terminal oxygen was assumed to be oxygen, the Re-atom distance was now reasonable, and a much more satisfactory value for U_{iso} was obtained. At this point, neutron activation was carried out on another crystal of the same batch, and the rhenium to chlorine ratio of 1:4 was confirmed. Unfortunately the small size of the crystal, and the surface decomposition made a meaningful oxidation state analysis impractical, and it was not attempted.

Refinement was continued assuming both *Pnma* and $Pn2_1a$ space groups, and of the 704 independent reflections used, 624 were given non-zero weights in the last cycle of the least squares refinement, where convergence occurred at $R_2 = 0.0687$ for $Pn2_1a$ and $R_2 = 0.0716$ for *Pnma*. The Hamilton significance test (22) was applied to these refinements, and the conclusion was reached that to a 90% confidence level, the noncentrosymmetric space group $Pn2_1a$ fits the data better than the centrosymmetric space group *Pnma*. The choice of $Pn2_1a$ as the space group for $ReOCl_4(OH_2)$ was based on the Hamilton test alone, since the geometry of the molecules or the presence of hydrogen bonding (see Discussion) did not provide any basis for choosing either space group.

The observed structure factors are compared with those calculated in Table 4.[3] In the final cycle of refinement no parameter changed by more than 1/3 of its estimated standard deviation. A difference synthesis obtained had no peaks higher than 1.2 e/Å^3 or lower than 0.8 e/Å^3.

Observations and Discussion

The Structure of $ReOCl_4(OH_2)$

The final atomic parameters, including the estimated standard deviations, are listed in Table 1. Bond distances and bond angles are shown in Table 2, and intra- and intermolecular non-bonded distances less than 3.50 Å are listed in Table 3.

It is not possible to attribute any real chemical significance to the nonisotropic temperature factors listed in Table 1 because of absorption and the highly irregular shape of the crystal. Attempts were indeed made to approximate the shape of the crystal by cylinders of appropriate thicknesses for each of the two orientations of the crystal on the precession camera used to gather the data. On this basis, the data were corrected, and subsequent refinement yielded atomic parameters that were, within error, unchanged from those obtained from the uncorrected data, with the exception of the temperature factors, which were uniformly larger. In

*Distances > 3.50 Å are not included.
†Atoms indicated with a prime mark are related to the atoms listed in Table 1 (x, y, z) by the symmetry relationships listed in column 2.

addition, the R factor was found to be ~2% larger than in the case of uncorrected data. Using the uncorrected data, plots were made of $|F_o - F_c|$ *vs.* $\sin\theta/\lambda$ as well as F_o/F_c *vs.* $\sin\theta/\lambda$ for each layer measured, and no systematic trend was found in these graphs that could be attributed directly to absorption.

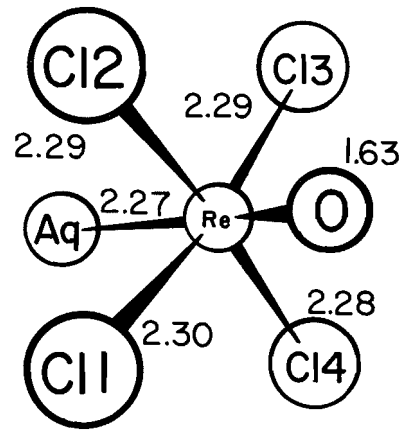

FIG. 2. Geometry of a single molecule of $ReOCl_4(OH_2)$ with bond distances in Å.

Because of these facts, the data were left uncorrected for absorption. Since the thin part of the crystal lies along the x axis, one would expect that the values obtained for U_{11} should be smaller than expected if no adsorption had taken place, and those for U_{22} and U_{33} should be larger than expected. This effect is indeed observed for the rhenium atoms.

The geometry of a single molecule of $ReOCl_4(OH_2)$ viewed along the c axis is shown in Fig. 2. As expected, the rhenium atom has a distorted octahedral environment with the four chlorine atoms bent away from the terminal oxygen atom, and toward the loosely bound aquo group.

A careful examination of the aquo groups (shown in Fig. 3 as double circles) reveals that the intermolecular environment of this group includes one terminal oxygen and four chlorine atoms, to which the possibility of hydrogen bonding exists. Examination of Table 3 shows that the terminal oxygen is 3.31(3) Å from the oxygen of the aquo group, while two of the four chlorines are 3.32(4) and 3.36(4) Å away and the remaining two more than 3.50 Å away (actually 3.55(4) and 3.58(4) Å). These distances are very large for even very weak hydrogen bonding (13). The acceptor angles for the three combinations of the terminal oxygen and two chlorines at 3.32 and 3.36 Å are 129° (O—Aq—Cl1), 61.4° (O—Aq—Cl4), and 67.8° (Cl1—Aq—Cl4). These values are on the upper and lower extremes of the acceptor angle variation found in hydrates (13).

It seems probable that any hydrogen bonding

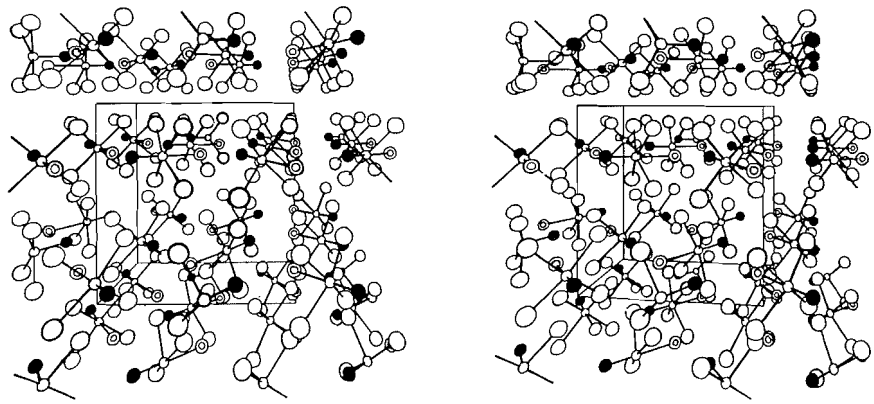

FIG. 3. Stereogram (stereoscopic pair of perspective projections) of $ReOCl_4(OH_2)$ viewed down the *c* axis, with the origin at the upper right hand corner, and the *a* and *b* axes parallel to the horizontal and vertical directions of the page. Open circles are chlorine or rhenium atoms, double circles are aquo groups and filled circles are terminal oxygen atoms.

is weak. Nevertheless, hydrogen bonding to neighboring groups probably occurs, and such bonding would cause changes in the structure. It seems probable that these small changes are concealed by disorder and the present parameters represent an average position. Such an effect may explain the difficulty in determining the correct space group. Unfortunately, because of the errors in the temperature factors caused by the absorption problem mentioned above, the disorder cannot be detected from anomalies in the temperature factors.

Although $ReOCl_4(OH_2)$ represents the first molecular species of the type $MOX_4(OH_2)$ (M = transition metal, X = halogen), several salts containing the species $MOX_4(OH_2)^{n-}$ have been studied by X-ray diffraction techniques. A comparison of the bond distances, bond angles, and non-bonded distances of $ReOCl_4(OH_2)$ (Tables 2 and 3) with those of $MoOBr_4(OH_2)^-$ (14), $ReOBr_4(OH_2)^-$ (15), and $VOCl_4(OH_2)^{2-}$ (16) shows that the intramolecular parameters for these compounds are comparable.

Figure 3 gives a three-dimensional view of how the molecules of $ReOCl_4(OH_2)$ are packed in the structure relative to the unit cell. An approximate depth of three unit cell distances along the *c* axis as well as two unit cell distances in the *a* and *b* directions are shown in the diagram. The structure is made up of chains of molecules stacked in the *c* direction, and these chains are arranged to give clearly defined layers parallel to the *ac* plane. Contact between molecules in the *c* direction is between the aquo and two chloro groups of each molecule and the oxo and two chloro groups of the next. In the *a* direction the oxo and two chloro groups of one molecule in a chain interleave with the aquo and two chloro groups of two molecules (one higher, one lower along *c*) in the adjacent chain. Thus all the oxo groups are on one side of each chain. In the next layer of chains in the *b* direction the oxo groups are on the other side of the chains. In the *b* direction contact between layers of chains is only between chlorine atoms.

To ensure that the crystals isolated from the reaction of ReO_3 and $ReCl_5$ were the same as those prepared subsequently by the aquation of $ReOCl_4$, single crystals of the latter product were mounted and precession photographs compared with those obtained from the former. In addition, a powder photograph was taken on a sample of powder, prepared by grinding some crystals (method *b*) in the dry box at 10 °C, sealed in a fused silica capillary tube. The unit cell parameters, space group, and atom parameters listed in Table 1 were used to calculate *d* spacings as well as theoretical intensities. The agreement between observed and calculated powder data (Table 5) is moderately good.

Physical and Chemical Properties of $ReOCl_4(OH_2)$

$ReOCl_4(OH_2)$ is a bright red volatile solid, which forms rectangular plate crystals. It is completely soluble in $ReOCl_4$, and a mixture of the two compounds is very similar in appearance to pure $ReOCl_4$ itself. If a solution of the two com-

pounds is allowed to sit at room temperature under vacuum (for a period of weeks), crystals of $ReOCl_4(OH_2)$ slowly form at the far extremes of the vessel, away from the bulk of the material. When heated under nitrogen, pure $ReOCl_4(OH_2)$ begins to decompose to a yellow-green liquid at $\sim 120\,^{\circ}C$, and appears to melt at $\sim 160\,^{\circ}C$.

The oxygen atom *trans* to the terminal oxygen was characterized as belonging to an aquo group rather than a hydroxo group by the oxidation state analysis as well as the i.r. spectrum. Table 6 summarizes the i.r. data, and some of the spectra obtained are illustrated in Fig. 4.

Solid $ReOCl_4(OH_2)$ is characterized in its i.r. spectrum by a broad peak in the 3600–3300 cm^{-1} region, corresponding to the stretching modes of water, a sharp peak at 1580 ($\pm$ 5) cm^{-1}, arising from a bending mode of water, and a strong peak at 1016.5 ($\pm$ 1.0) cm^{-1}, corresponding to an Re=O stretching mode. The bending mode at 1580 cm^{-1} is slightly lower than the corresponding vibrational mode in $[Et_4N][ReOBr_4(OH_2)]$ which was found at 1605 cm^{-1} (15), but comparable to that found in $[RuCl_5(OH_2)]^{2-}$ at 1570 cm^{-1} (17). The occurrence of the terminal oxygen stretching frequency at 1016.5 cm^{-1} compared to that in $ReOCl_4$ at 1033 cm^{-1} is similar to that observed in $ReOCl_4 \cdot OPCl_3$, recently reported by Guest and Lock (4) at 1020 cm^{-1}. The far i.r. spectrum shows only one broad peak centered at $\sim 350\ cm^{-1}$, a little lower than the 372 cm^{-1} reported for $ReOCl_4$ (4). Since some attack on polyethylene occurred, the assignment of this peak as νRe—Cl for $ReOCl_4(OH_2)$ may be invalid.

The gas phase i.r. spectrum of $ReOCl_4 \cdot OPCl_3$ showed that decomposition into $ReOCl_4$ and $POCl_3$ had occurred, but this is not the case with $ReOCl_4(OH_2)$. As shown in Fig. 4 and Table 5, $ReOCl_4$ does appear to be one of the products (1033 cm^{-1}), but the liberated water quickly hydrolyzes the rest of the material to yield ReO_3Cl (1003, 971 cm^{-1}), and at least one other

material characterized by the peak at 936 cm^{-1}. It is possible that this peak arises from the formation of the adduct $ReOCl_4 \cdot ReO_3Cl$ (21). This could account for the splitting observed in the 1033 cm^{-1} peak.

In Nujol, as well as for the pure powder ground between KBr plates, a weak, very sharp peak of very variable intensity relative to that of the 1016.5 cm^{-1} peak was always observed at ~1025 cm^{-1}. One would expect only one Re=O stretch for $ReOCl_4 \cdot OH_2$, and the variability suggests it is caused by an impurity. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

may arise from the surface coating which always forms when handling $ReOCl_4 \cdot OH_2$. We have been unable to characterize this impurity at this stage of our investigations.

An attempt was made to measure the Raman spectrum of $ReOCl_4(OH_2)$ at room temperature, but decomposition occurred immediately. At $-120\,^{\circ}C$, several absorptions were observed, but as the sample had at least partially decomposed, no attempt was made to assign these peaks.

Several authors (18–21) have reported absorptions at ~ 1033 and $\sim 1016\ cm^{-1}$ in the i.r. spectrum of $ReOCl_4$ in Nujol. We have observed only a single strong peak at $1033\ cm^{-1}$ for $ReOCl_4$ in Nujol consistent with our previous observations of $ReOCl_4$ in the gas phase and in $TiCl_4$ and CCl_4 solutions (4). Since $ReOCl_4(OH_2)$ is completely soluble in $ReOCl_4$, and the solution of these compounds has properties very similar to those of $ReOCl_4$ itself, we suggest that the peak at $\sim 1016\ cm^{-1}$ arises from $ReOCl_4(OH_2)$ impurity formed by the reaction of $ReOCl_4$ with traces of water.

$ReOCl_4(OH_2)$ is stable in vacuum in the absence of a temperature gradient. The compound could be distilled under vacuum, but partial decomposition always occurred. The decomposition products include $ReOCl_4$, ReO_3Cl, and an involatile black residue. $ReOCl_4(OH_2)$ is insoluble in CCl_4 and $TiCl_4$, but slowly decomposes to form a green solution of $ReOCl_4$. When $ReOCl_4(OH_2)$ is handled in a dry box at $10\,^{\circ}C$, a black surface coating forms within hours. The powder photograph shows these decomposition products as impurity lines at $d = 7.39$ and 6.65 Å. The exact nature of the various decomposition reactions of $ReOCl_4(OH_2)$ is being studied further.

The total synthesis of (±) ochrobirine is described.

La synthèse totale de la (±) ochrobirine est décrite.

Canadian Journal of Chemistry, **50**, 1819 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Ochrobirine was first isolated by Manske (1) in 1936 from *Corydalis sibirica* (L.) Pers. and has since been found in other species of Corydalis (2, 3). Recently (4), the spirobenzylisoquinoline structure **1** was assigned to the alkaloid almost entirely on the basis of its p.m.r. spectrum.

Since no rational degradations of ochrobirine could be found it was decided to attempt a synthesis of the alkaloid in order to confirm its structure. Many syntheses of spirobenzylisoquinoline alkaloids have been successfully achieved (5) by Pictet–Spengler condensation of suitable β-phenethylamines with various 1,2-indanediones. Consequently, it was decided to attempt the synthesis of ochrobirine by an extension of this method using 4,5-methylenedioxyindanetrione in a similar Pictet–Spengler condensation. Preliminary experiments, carried out in this laboratory, demonstrated that such a condensation between homopiperonylamine (**2**) and ninhydrin (**3**) produced a spirodione **4** in excellent yield (6) thus verifying the applicability of this route to ochrobirine. In the latter case the synthesis would entail the elaboration of the methylenedioxy ninhydrin **5**, a similar Pictet–Spengler condensation, *N*-methylation, and reduction of the resulting spirodione **6** to produce a mixture of diastereomers which should contain (±) ochrobirine.

The synthesis of **5** thus becomes the major task of this undertaking and predictably enough, was tedious, time-consuming, and beset with poor yields. Two approaches were explored. The first, illustrated in Scheme 1, was based on the

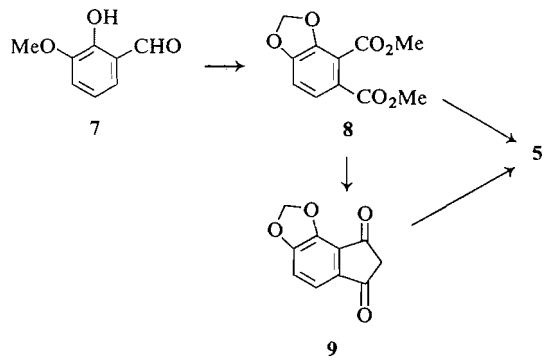


SCHEME 1

use of *o*-vanillin (7) as the starting material and on the demonstration that diethyl phthalate is readily converted into ninhydrin in high yield by condensation with dimethyl sulfoxide under basic catalysis (7). The dimethyl phthalate **8** was prepared by standard methods in an overall yield of 6% from *o*-vanillin. However, the condensation of **8** with dimethyl sulfoxide produced a red gum lacking methylenedioxy resonance in its p.m.r. spectrum but possessing a broad peak at δ 9.0 (exchangeable with D_2O) and providing a deep blue–black color with neutral ferric chloride. Use of irreversibly formed methylsulfinyl carbanion (8) gave similar results. An alternative method for effecting the required conversion of **8** to **5** was also investigated. This involved the sodium hydride condensation of **8** with ethyl acetate (9) to the 1,3-indanedione **9** which could be oxidized with selenium dioxide (10) to **5**. Again, a red gum was obtained in the ester condensation and only a very small amount of **9** could be isolated. It therefore appears that the methylenedioxy group is unstable under the strongly basic conditions, probably undergoing nucleophilic displacement in the course of the reaction.

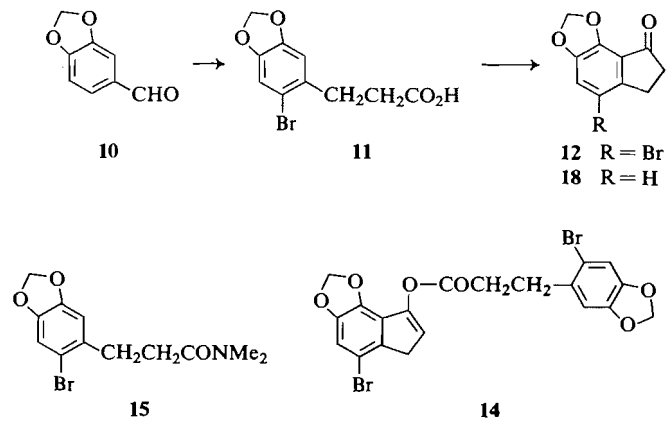
An alternative starting material, piperonal (**10**), has the advantage of possessing the required methylenedioxy group, and the problem of the unsuitable meta situation of the aldehyde group could be overcome by modifying the synthetic target to the bromoindanetrione **13** so as to accommodate a blocking bromine atom. Piperonal was converted by standard procedures to the bromoacid **11** which was cyclized with phosphorus pentoxide (11) to the bromoindanone **12** (Scheme 2). This cyclization was found to be a most temperamental reaction and the yield at the best of times was only about 20%. Moreover the product was accompanied by a significant impurity, which could only be removed by several crystallizations or repeated chromatography. The nature of this impurity was investigated and it was shown to be the enol ester **14**. This structure was supported by the i.r. and p.m.r. spectra (see Experimental) and also by the fact that alkaline hydrolysis of it afforded **11** and **12**. A similar product has been identified in the PPE cyclization of a substituted phenylpropionic acid (20). In subsequent runs of this experiment the crude solid product was therefore saponified with aqueous methanolic potassium carbonate before isolation of the indanone. In this manner a purer product was obtained.

Several other methods of cyclization of this acid were also attempted. Concentrated sulfuric acid, fluorosulfonic acid, and hydrofluoric acid caused charring; the sulfur trioxide dimethylformamide complex (12) gave an excellent yield of the *N*,*N*-dimethylamide **15**, probably by amide exchange. The structure of **15** was evident from its i.r. and p.m.r. spectra and from the fact that it could be obtained by reaction between the acid chloride of **11** and dimethylamine. Attempts were made to cyclize the acid chloride. It was treated with aluminum chloride at temperatures ranging from -15 to $+20°$ but only traces of the desired indanone were obtained. Results were similar with stannic chloride as the catalyst.

Nonetheless, the indanone **12** was available and now had to be converted to the indanetrione **13** and here there was a choice of two methods. The first which was Ruhemann's classical synthesis of ninhydrin (13) was known to give a poor yield. The second method (14), more recent, consisted of oxidation of 1-indanone with selenium dioxide directly to ninhydrin in 79% yield, but in our case it furnished the trione **13** in only 15% yield.

The Pictet–Spengler reaction of **13** with homopiperonylamine (**2**) was now carried out to afford the spirodione **16**. It was decided to *N*-methylate this compound via the urethane **17** in view of a recent report (15) that stereospecific reduction of a carbonyl group in a closely related

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 2

spiro compound was achieved in a like manner. The urethane thus obtained from the reaction of **16** with ethylchloroformate was then reduced with lithium aluminum hydride to a product which was a mixture of two compounds, presumably diastereomers, of which the preponderant component was identical with natural ochrobirine (i.r., p.m.r., and t.l.c.). The hydrogenolysis of the bromide was not entirely unexpected (18) and could be regarded as a nucleophilic substitution favored by the presence of the ortho carbonyl group. Alternatively, if this carbonyl group was reduced initially, an intramolecular hydride transfer via a cyclic alkoxide intermediate may be envisaged by analogy with the earlier work (18).

A short while after the completion of this synthesis a communication claiming the total synthesis of (±) ochrobirine by a similar route appeared (16). The sodium borohydride reduction of the dione **6**, contrary to previous reports with similar systems (*5b*, *5c*, 6) and to our own experience with **17**, was claimed to take place stereospecifically to give (±) ochrobirine exclusively. Furthermore, the melting point of the product as reported was 23° lower than that of our synthetic compound. This synthesis was therefore repeated in our laboratory starting from the bromoindanone **12** which was catalytically hydrogenated (palladium–charcoal) to **18**, oxidized with selenium dioxide to **5**, and condensed with homopiperonylamine to give **6**, which was *N*-methylated with formic acid and formalin to the *N*-methyl dione **19**. Reduction of this compound by sodium borohydride in methanol yielded a mixture of two compounds of very similar R_f (t.l.c.) which were separable by preparative thick-layer chromatography. The preponderant product was (±) ochrobirine identical with our previous synthetic sample. An independent synthesis of (±) ochrobirine (17) via a Pomeranz–Fritsch cyclization involved, in its penultimate stages, intermediates **6** and **19** which were identical with ours. A mixture similar to ours resulted in the final borohydride reduction of **19**.

TABLE 1. Melting points recorded for ochrobirine and some synthetic intermediates

Compound	Melting point (°C)		
	Present synthesis	Reference 16	Reference 17
5	222	208–210	—
6	198–200	167–171	198–199
19	194–196	118–122	195–196
1	210	185–187	210–212

Furthermore, there were surprising discrepancies in the reported melting points of these intermediates (Table 1).

We have also observed that the melting point of synthetic (±) ochrobirine increased on standing to about 225° after *ca.* 4 months. In later preparations, the product obtained melted at 235°. As all these products were structurally identical (i.r. in chloroform solution, t.l.c.) the differences in melting point can only be attributed to the existence of two crystalline modifications of (±) ochrobirine.

Experimental

Melting points were determined using a Fisher Meltemp unit and are uncorrected. The p.m.r. spectra, unless otherwise specified, were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Spectra at 60 MHz were recorded on a Varian T-60 instrument. Samples were dissolved in $CDCl_3$, unless otherwise specified, using TMS as the internal locking signal. Chemical shifts were measured relative to TMS. The i.r. spectra were recorded on a Perkin–Elmer 457 spectrometer and a Coleman–Hitachi EPS-3T spectrophotometer was used for the u.v. spectra.

*Dimethyl-3,4-methylenedioxyphthalate (**8**)*

3,4-Methylenedioxyphthalic acid (19) (0.7 g) in methanol (25 ml) was treated with excess ethereal diazomethane and the mixture allowed to stand overnight. The brownish gum obtained after removal of the solvents was purified by column chromatography (alumina, Brockman Activity I, 80–200 mesh) in methylene chloride. The colorless thick oil crystallized upon standing and was washed with ligroin (40–60°) (0.6 g) and the solid recrystallized from methylene chloride – ligroin m.p. 57–59°.

The i.r. spectrum: ν_{max} ($CHCl_3$) 1720 cm^{-1}. The 60 MHz p.m.r. spectrum (δ): 3.83 (3H, s); 3.87 (3H, s); 6.40 (2H, s); 6.83 (1H, d); 7.47 (1H, d) (J_{AB} = 8 Hz).

Anal. Calcd. for $C_{11}H_{10}O_6$: C, 55.47; H, 4.23. Found: C, 55.70; H, 4.26.

*3,4-Methylenedioxyindan-1,3-dione (**9**)*

A solution of **8** (0.5 g) in dry ethyl acetate (1 ml) was added to sodium hydride (0.148 g, 50% dispersion in mineral oil) contained in 5 ml round-bottomed flask fitted with a condenser and calcium chloride guard tube. The mixture was refluxed on a steam bath for 4 h, after which the dark red gum was washed with ether and filtered. It was treated with 3 *N* hydrochloric acid (8 ml) and heated on a water bath at 80–85° for 1 h. The mixture was extracted with methylene chloride, washed, and dried ($MgSO_4$). After removal of the solvent the resulting red product was chromatographed (silica gel) in ethyl acetate, and a small amount of **9** obtained and recrystallized from benzene, m.p. 198–200°.

The i.r. spectrum: ν_{max} ($CHCl_3$) 1710 and 1740 cm^{-1}. The 60 MHz p.m.r. spectrum (δ): 3.23 (2H, s); 6.31 (2H, s); 7.27 (1H, d); 7.57 (1H, d); (J_{AB} = 8 Hz).

*4-Bromo-6,7-methylenedioxyindan-1-one, (**12**) and 1-(4′,5′-Methylenedioxy-2′-bromo)hydrocinnamoyloxy-4-bromo-6,7-methylenedioxyindene (**14**)*

Compound **12** was prepared by the method of Haworth *et al.* (11). The crude solid obtained consisted of two compounds (t.l.c. silica, benzene–acetone 4:1). The faster moving component **14** was separated from the slower **12** by column chromatography using the same system and crystallized from methanol m.p. 163°.

The i.r. spectrum of **14**: ν_{max} ($CHCl_3$) 1762 cm^{-1}. The 60 Hz p.m.r. spectrum (δ): 3.00 (4H, m); 3.33 (2H, d); 6.27 (1H, t) (J_{AX} = 2 Hz); 6.00 (2H, s); 6.03 (2H, s); 6.90 (1H, s); 6.93 (1H, s); 7.07 (1H, s).

Anal. Calcd. for $C_{20}H_{14}Br_2O_6$: C, 47.16; H, 2.77. Found: C, 47.65; H, 2.85.

*Hydrolysis of **14***

Compound **14** (200 mg), potassium carbonate (100 mg), methanol (15 ml), and water (2 ml) were heated on a steam bath for 2 h. The mixture was diluted with water and extracted with ether. The ethereal extract was washed with water and dried (Na_2SO_4) to leave a residue which was crystallized from benzene (80 mg). The product was identical with **12** (p.m.r., i.r., and m.p.).

The aqueous extract on acidifying with concentrated HCl deposited a precipitate which was dissolved in ether, dried (Na_2SO_4), and evaporated to dryness to leave a residue which crystallized from chloroform (94 mg). This product was identical with 6-bromo-3,4-methylenedioxy hydrocinnamic acid (p.m.r., i.r., and m.p.).

*N,N-Dimethyl-3,4-methylenedioxy-6-bromohydrocinnamamide (**15**)*

3,4-Methylenedioxy-6-bromohydrocinnamic acid (1 g) was heated with sulfur trioxide – dimethylformamide complex (12) (20 ml) at 160° for 30 min. The solution was poured into crushed ice and the white precipitate which separated extracted with chloroform. The chloroform extract was washed (10% aqueous sodium carbonate), dried ($MgSO_4$), evaporated to dryness, and the residue crystallized from benzene (780 mg), m.p. 77°.

The u.v. spectrum: λ_{max} (MeOH) 238 and 294 nm (log ε 3.63 and 3.63). The i.r. spectrum: ν_{max} ($CHCl_3$) 1630 cm^{-1}. The 60 MHz p.m.r. spectrum (δ): 7.0 (1H, s); 6.8 (1H, s); 5.97 (2H, s); 2.97 (6H, s); 2.9–3.2 (2H, m).

Anal. Calcd. for $C_{12}H_{14}BrNO_3 \cdot \frac{1}{2}H_2O$: C, 46.60; H, 4.54; N, 4.54. Found: C, 46.43; H, 4.89; N, 4.53.

*4-Bromo-6,7-methylenedioxyindan-1,3-dione-2,2-diol (**13**)*

Compound **12** (5.3 g) was added to a solution of selenium dioxide (4.4 g) in peroxide free dioxane (60 ml) and water (0.5 ml). The mixture was heated at 95–100° for 6 h. The black precipitate of selenium was filtered. The red filtrate was concentrated under reduced pressure to half its volume. Water (50 ml) was added, and the solution was brought to boiling and filtered. The hot filtrate was decolorized (charcoal), and on cooling deposited pale yellow prisms (800 mg), recrystallized from water, m.p. 230–233°.

The u.v. spectrum: λ_{max} (MeOH) 253, 315, and 358 nm (log ε 4.37, 3.70, and 3.63). The i.r. spectrum: ν_{max} ($CHCl_3$) 1728, 1753 cm^{-1}. The p.m.r. spectrum (acetone-d_6, δ): 6.37 (2H, s); 7.47 (1H, s).

Anal. Calcd. for $C_{10}H_5BrO_6 \cdot \frac{1}{2}H_2O$: C, 39.35; H, 1.97. Found: C, 39.43; H, 2.03.

*6,7-Methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(4′bromo-6′,7′-methylenedioxy-1′,3′-indanedione) (**16**)*

A solution of homopiperonylamine (**2**) (200 mg), in absolute ethanol (5 ml) was placed in a 100 ml two-necked flask equipped with a magnetic stirrer, pressure-equalizing dropping funnel, and a calcium chloride guard tube. The flask was cooled in an ice bath and a solution of **13** (200 mg) in absolute ethanol (20 ml) was added dropwise over a period of 15 min. The solution was stirred for another 25 min. The solution on further cooling (Dry Ice – acetone) deposited a white precipitate which dissolved to an orange solution when dry hydrogen chloride was bubbled through the mixture (15 min). The temperature was now raised to 25° and the solution poured into crushed ice, basified with concentrated ammonia solution, and extracted with ether. The ether was removed to yield a yellow residue which crystallized from acetone–methanol (180 mg), m.p. 219–221°.

*2-Carbethoxy-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(4′-bromo-6′,7′-methylenedioxy-1′,3′-indanedione) (**17**)*

A solution of ethyl chloroformate (200 mg) in chloroform (10 ml) was added to a stirred suspension of **16** (150 mg) in 20% aqueous sodium carbonate solution (20 ml) maintained between 0 and 10°. The mixture was stirred for 1 h, the chloroform layer was separated and washed with 1 *M* hydrochloric acid, dried (Na_2SO_4), and the chloroform removed under reduced pressure. The residue was crystallized from methanol (120 mg), m.p. 225–226°.

The u.v. spectrum: λ_{max} (MeOH) 251, 303, and 362 nm (log ε 4.51, 3.93, 3.80). The i.r. spectrum: ν_{max} ($CHCl_3$) 1681, 1726, 1758 cm^{-1}. The p.m.r. spectrum (δ): 1.26 (3H, t); 4.10 (2H, q) ($J_{AX} = 8$ Hz); 3.0 (2H, t); 3.90 (2H, t) ($J_{A'X'} = 5$ Hz); 5.88 (2H, s); 6.18 (1H, s); 6.30 (2H, d) (2′,3′-O—CH_2—O); 6.68 (1H, s); 7.36 (1H, s).

*(±) Ochrobirine (**1**)*

A solution of the urethane, **17** (200 mg) and lithium aluminum hydride (150 mg) in dry tetrahydrofuran (40 ml) was refluxed for 13 h. The excess reagent was decomposed with water and the mixture extracted with ether. The ethereal extract was washed with water, dried ($MgSO_4$), and evaporated to dryness. The residue on t.l.c. (silica gel) showed two spots of similar R_f, from which (±) ochrobirine the major component, was isolated by column chromatography (silica gel; benzene, acetone, methanol (65:15:20)) and crystallized from methanol (52 mg), m.p. 210°. In subsequent preparations the product melted at 235°.

All these samples had identical i.r., p.m.r. spectra with natural ochrobirine and on t.l.c. (silica gel) had similar R_f values in the following solvent systems: benzene, acetone, methanol (65, 15, 20); benzene, ethyl acetate, methanol (30, 10, 10); benzene, ether, methanol (30, 10, 10).

*4,5-Methylenedioxyindan-1,3-dione-2,2-diol (**5**)*

6,7-Methylenedioxyindan-1-one (5*c*) (3.5 g) was added to a solution of selenium dioxide (4.4 g) in peroxide free dioxane (50 ml) and water (0.5 ml). The mixture was heated at 95–100° for 6 h. The black precipitate of selenium was filtered. The red filtrate was concentrated under reduced pressure to 20 ml, water (50 ml) was added, and the solution was brought to boiling and filtered. The hot filtrate was decolorized (charcoal), and on cooling deposited pale yellow prisms (850 mg), crystallized from water, m.p. 221–222°.

The u.v. spectrum: λ_{max} (MeOH) 247, 295, and 347 nm (log ε 4.48, 3.73, 3.64). The i.r. spectrum: ν_{max} ($CHCl_3$) 1710 and 1740 cm^{-1}. The 60 MHz p.m.r. spectrum in MeOH (δ): 6.01 (2H, s); 7.07 (1H, d); 7.27 (1H, d) ($J_{AX} = 8$ Hz).

Anal. Calcd. for $C_{10}H_6O_6$: C, 54.05; H, 2.70. Found: C, 54.00; H, 2.97.

*6,7-Methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(4′,5′-methylenedioxy-1′,3′-indanedione) (**6**)*

A solution of homopiperonylamine (**2**) (200 mg), in absolute ethanol (5 ml) was placed in a 100 ml, two-necked flask equipped with a magnetic stirrer, pressure-equalizing dropping funnel, and a calcium chloride guard tube. The flask was cooled in an ice bath and a solution of **5** (200 mg) in absolute ethanol (35 ml) was added dropwise over a period of 15 min and the solution stirred for another 45 min. The solution on cooling (Dry Ice – acetone) deposited a white precipitate which dissolved to an orange solution when dry hydrogen chloride was bubbled through the mixture (15 min). The temperature was raised to 40°, the solution was poured into crushed ice, basified with concentrated ammonia solution, and extracted with ether. The yellow residue obtained on removal of the ether crystallized from methanol–chloroform (230 mg), m.p. 199–201°.

The u.v. spectrum: λ_{max} (MeOH) 245, 297, and 348 nm (log ε 4.55, 3.97, and 3.80). The i.r. spectrum: ν_{max} ($CHCl_3$) 1711 and 1743 cm^{-1}. The p.m.r. spectrum (δ): 1.95 (1H, s); 2.81 (2Ht); 3.42 (2Ht); ($J_{AX} = 6$ Hz); 5.83 (2H, s); 6.03 (1H, s); 6.31 (2H, s); 6.63 (1H, s); 7.27 (1H, d) 7.67 (1H, d) ($J_{AB} = 8$ Hz).

*2-Methyl-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(4′,5′-methylenedioxy-1′,3′-indanedione) (**19**)*

A solution of the amine **6**, (100 mg), in 90% formic acid (1.5 ml) and 37% formaldehyde (1.5 ml) was heated on a steam bath for 6 h. The solution was poured into crushed ice and basified with concentrated ammonia solution. The mixture was extracted with ether, dried ($MgSO_4$), and evaporated to dryness. The yellow residue crystallized from methanol (60 mg), m.p. 194–196°.

The u.v. spectrum: λ_{max} (MeOH) 245, 297, and 348 nm (log ε 4.57, 3.96, and 3.80). The i.r. spectrum: ν_{max} ($CHCl_3$) 1710 and 1741 cm^{-1}. The p.m.r. spectrum (δ): 2.39 (3H, s); 2.99 (2H, m); 3.31 (2H, m); 5.81 (2H, s); 5.96 (1H, s); 6.32 (2H, s); 6.63 (1H, s); 7.30 (1H, d); 7.64 (1H, d) ($J_{AB} = 8$ Hz).

Anal. Calcd. for $C_{20}H_{15}NO_6$: C, 65.75; H, 4.11. Found: C, 65.81; H, 4.28.

*(+) Ochrobirine (**1**)*

Sodium borohydride (150 mg) was added to a solution of **19** (60 mg) in methanol (20 ml). The solution was stirred for 24 h. The solution was acidified with acetic acid and solvent was removed under reduced pressure. The residue was basified with concentrated ammonia solution and was extracted with ether. The ether extract was dried ($MgSO_4$) and evaporated to dryness. The residue on t.l.c. (silica gel) showed two spots of similar R_f, from which (±) ochrobirine the major component, was isolated by preparative t.l.c. (silica gel; benzene, acetone, methanol (65:15:20)) and crystallized from methanol (31 mg), m.p. 235°.

The i.r. and p.m.r. spectra were identical with that of the natural ochrobirine and on t.l.c. (silica gel) had similar R_f values in the same solvent systems as before.

We wish to thank Prof. D. B. MacLean for the high resolution mass spectra of **16** and **17**. Generous support from the National Research Council of Canada is gratefully acknowledged.

An Electron Spin Resonance Examination of Ferrocenylalkyl- and Aryl Ketyls

G. BIGAM, JOHN HOOZ,[1] SIEGFRIED LINKE,[2] R. E. D. MCCLUNG,[1]
MELVYN W. MOSHER,[3] AND DENNIS D. TANNER[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received October 25, 1971

Several ferrocenylalkyl- and aryl ketyls were generated and their e.s.r. spectra were recorded. Pentadeuteriobenzoylferrocene and benzoyl perdeuterioferrocene were synthesized. Analysis of the e.s.r. spectra of their corresponding ketyls enabled the determination of the hyperfine splitting constants of benzoylferrocene ketyl, and allowed an assignment of the electron densities at various positions in the molecule.

A comparison of the magnitudes of the *g*-values for the ketyls derived from benzophenone (2.0034), benzoylferrocene (2.0062), and 2,2-dimethylpropanoylferrocene (2.0126), combined with the proton hyperfine splittings, gave some insight into the nature of the interaction of the free electron with the ferrocene system.

Plusieurs ferrocenylalkyl- et arylcétyles ont été engendrés et leurs spectres r.p.e. enregistrés. Le benzoylferrocène pentadeutérié et le benzoylferrocène perdeutérié ont été synthétisés. L'analyse des spectres r.p.e. de leurs cétyles correspondants rend possible la détermination des constantes de multiplicité hyperfine du benzoylferrocène cétyle et permet une attribution des densités électroniques sur les différentes positions de la molécule.

Une comparaison des grandeurs des valeurs *g* pour les cétyles dérivés de la benzophénone (2.0034), du benzoylferrocène (2.0062) et du diméthyl-2,2 propanoylferrocène (2.0126), combinée avec les multiplicités hyperfines du proton, a permis de pénétrer la nature de l'interaction de l'électron libre avec le système ferrocène.

Canadian Journal of Chemistry, **50**, 1825 (1972)

Introduction

The nature of the bonding in α-ferrocenyl carbonium ions (1–11) and radicals (12–15) has been the subject of conjecture by a number of workers. The bonding interactions in these intermediates have been interpreted in a variety of ways. One view is that π-bonding between the cyclopentadienyl ring and the α-carbon atom confers extra stability; the new π-bond being formed at the expense of a carbon–iron bond. Another view is one in which there is significant d–p bonding due to the interaction of doubly occupied iron d-orbitals with the unoccupied p-orbital on the α-carbon atom.

In order to study the interactions of the atomic orbitals which impart stability to these α-ferrocenyl intermediates, we have investigated the ketyls derived from some ferrocenyl ketones. In going from the carbonium ion to the ketyl, the character of the iron–carbon bonding, hopefully, would not be drastically different and consequently any information which we could obtain about bonding in the ketyls would likewise be useful in the description of the bonding in the carbonium ion.

Results

The ketyls derived from benzoylferrocene (**1**), pentadeuteriobenzoylferrocene (**2**), benzoylperdeuterioferrocene (**3**), and 2,2-dimethylpropanoylferrocene (**4**) were generated by reduction of the parent ketones with potassium metal, using tetrahydrofuran (THF) as the solvent.

The e.s.r. spectrum of **1** consists of 15 incompletely resolved lines as shown in Fig. 1. A computer simulation of this spectrum, using the proton hyperfine splittings given in Table 1, is also shown in Fig. 1. These proton splittings agree reasonably well with those previously reported (12) although, as discussed later, we have assigned unequal splittings to the ortho-protons in the phenyl group. An unambiguous assignment of the hyperfine splittings to the protons in the ketyl could not be made without further information. A study of the e.s.r. spectra of the ketyls **2** and **3** was therefore undertaken.[4]

The e.s.r. spectrum of **2** consists of a single line with a peak-to-peak derivative width of 2.4 G.

[1]Authors to whom inquiries should be directed.

[3]University of Alberta Postdoctoral Research Fellow, 1967–1969.

[4]Since the completion of our work, but prior to its submission, some of the deuteration experiments which we describe have been reported by other workers (15), although no experimental or computational details were given. The values of the hyperfine splittings which they report are sufficiently different from ours that the spectrum simulated with their splittings does not agree with the observed spectrum.

TABLE 1. Hyperfine splitting constants of ferrocenyl ketyls

Ketyl	Proton hyperfine splitting constants (G)
Benzoylferrocene  **1**	a_1,a_5* = 3.30, 2.91 a_2,a_4 = 0.89 a_3 = 4.34 a_{10},a_{13} = 0.89
Pentadeuteriobenzoylferrocene  **2**	No splittings observed in a single line of width 2.4 G
Benzoylperdeuterioferrocene  **3**	a_1a_5* = 3.30, 2.91 a_2,a_4 = 0.89 a_3 = 4.34
2,2-Dimethylpropanoylferrocene  **4**	No splittings observed in a single line of width 5.8 G

*The specific assignment of the different proton splittings to positions 1,5 has not been attempted.

No hyperfine splitting due to the protons in the ferrocenyl group was discernible.

The ketyl **3** has the e.s.r. spectrum shown in Fig. 2. The computer simulation of this spectrum, using the proton hyperfine splittings given in Table 1, is also presented in Fig. 2. The assignment of the proton hyperfine splittings to the *o*-, *p*-, and *m*-positions on the benzene ring was made by analogy to the assignments in benzophenone (16, 17) ketyl and was in agreement with the spin density calculations described in the Discussion. The deuteration of **3** was incomplete (85.3% as indicated from the mass spectrum). Since the ketyl molecules which have protons at the 10 or 13 positions in the cyclopentadiene ring will give a different e.s.r. spectrum from that due to ketyl molecules with deuteriums at these positions, a computer simulation of a mixture of 75% dideuterated and 25% monodeuterated (at the 10 and 13 positions) was performed. This simulation is shown as the dashed curve in Fig. 2. This

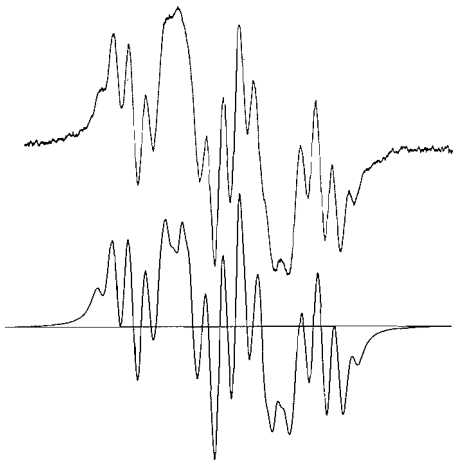

FIG. 1. Comparison of experimental (upper) and computed (lower) e.s.r. spectra for benzoylferrocene ketyl (**1**) in THF solution. Hyperfine splittings used in the computed spectra are given in Table 1.

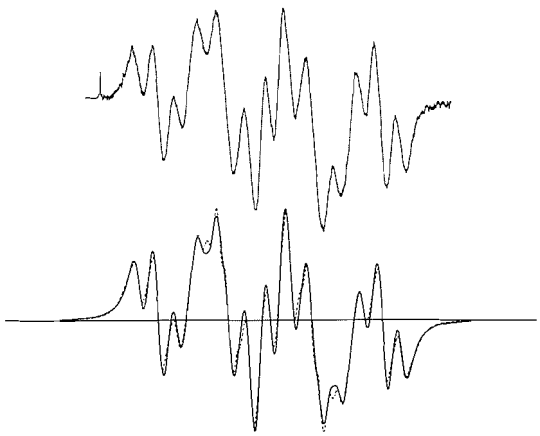

FIG. 2. Comparison of experimental (upper) and computed (lower) e.s.r. spectra for benzoylperdeuterioferrocene ketyl (**3**) in THF solution. Hyperfine splittings used in the computed spectra are given in Table 1. The dotted curve in the computed spectrum corresponds to a mixture of ketyls, 75% dideuterated and 25% monodeuterated at the 10 and 13 positions.

simulated spectrum resembles very closely the spectrum calculated assuming 100% dideuteration at the 10 and 13 positions.

The ketyl **4** exhibited an e.s.r. spectrum consisting of a single line of width 5.8 G. No experimental conditions were found which permitted resolution of the hyperfine structure to be expected from the interaction of the unpaired electron with the ferrocenyl protons.

The g-values of the ketyls **1** and **4** and those of related ketyls, nitroxides, and nitroanions are given in Table 2.

Discussion

The g-values of the ketyls studied in this work, together with those for related systems, form a basis for the discussion of the participation of iron orbitals in the π-electron molecular orbitals of substituted ferrocenes. It is apparent, from a comparison of the g-values of benzophenone (18) and benzoylferrocene (**1**), that the replacement of a phenyl group by a ferrocenyl moiety causes a substantial increase in the g-value which can be directly attributed to the participation of iron orbitals in the π-system. A further increase in g-value occurs when the phenyl group (**1**) is replaced by a t-butyl group (**4**) because the iron orbitals are even more important in this ketyl since the π-system is less delocalized than in benzoylferrocene. These increases in g-value are very good evidence for a significant degree of participation of the iron orbitals in the π-system, in particular for the orbital containing the unpaired electron. Significant contributions of iron orbitals to the π-electron systems in the nitroferrocene anion (12) and t-butyl ferrocenyl nitroxide (13) are also evident from the comparison of their g-values with those of the analogous phenyl compounds (19, 20).

It has been pointed out (15) that the g-value of the benzoylruthenocene ketyl (2.0035) is close to that for the benzophenone ketyl (2.0036), which could be interpreted as evidence against significant metal orbital participation in the π-system of benzoyl ruthenocene. The evidence presented in Table 2 for the ferrocene systems unequivocally indicates significant iron participation in those systems.

However, the interplanar distances in ruthenocene and ferrocene differ by 0.36 Å (22), and the nature of the interactions between the benzoyl and metallocene are undoubtedly quite different. The observation that the proton hyperfine splittings in the benzoylferrocene and benzoylruthenocene are identical is most unexpected and more detailed work on the ruthenocenes is required before the e.s.r. parameters in that system can be interpreted correctly.

In order to gain a better understanding of the π-electron system in the ketyls **1** and **4**, we performed McLachlan semiempirical calculations

*See Table 1 for numbering of centers.
†No specific assignment of the different spin densities was attempted.
‡The value of $Q = 23.7$ G is that found to give best results for aromatic ketones (19).
§This choice of integrals is consistent with those used for benzophenone, see ref. 16.

(23) of the spin densities in the benzoylcyclopentadienide (**5**) and 2,2-dimethylpropanoylcyclopentadienide (**6**) ketyls using the values of the resonance and coulomb integrals given in Table 3. These integrals were used by previous investigators (16) for benzophenone ketyl. The calculated spin densities for **5** and **6** are compared with the observed spin densities of **1** and **4** in Table 3. In both cases, the calculated spin densities at the ortho carbon atoms in the cyclopentadienide ring are much larger than those observed in the corresponding ferrocenyl ketyl. This is what one would expect if there were participation of the iron atom in the π-system.

We have assigned different values to the hyperfine splittings of the two ortho-protons in the phenyl group of the benzoyl ferrocenyl ketyl because much closer agreement between computed and observed e.s.r. spectra was obtained than in attempts to fit the observed spectra with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

equal ortho-proton splittings. Rieger and Fraenkel (17) investigated several ketyls including benzophenone ketyl (where no difference in ortho splittings is observed), but were not able to explain satisfactorily the occurrence of "locked" planar structures or "unlocked" structures on theoretical grounds. The calculated bond order between the ring carbon atom and the carbonyl carbon is larger in benzoylcyclopentadienide ketyl (**5**) than in benzophenone but not so large that one could state conclusively that one should expect a "locked" planar structure for **1** on this basis.

The results of our e.s.r. investigation of the ferrocenyl ketyls and those of other workers (12–15) clearly indicate that the iron orbitals contribute significantly to the occupied molecular orbitals of highest energy, which are the orbitals of greatest importance in the chemistry of the ferrocenes.

Experimental

Melting points were determined with a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded with a Perkin–Elmer grating spectrophotometer Model 421. Mass spectra were measured by Dr. A. M. Hogg and his associates using an A.E.I. MS-9 spectrometer at an ionization potential of 70 eV; n.m.r. spectra were recorded on a Varian A-60 spectrometer using tetramethylsilane as internal reference and $CDCl_3$ as solvent.

Materials

Benzoylferrocene (24), m.p. 107–108°; n.m.r. τ 1.9–2.8 (5H, phenyl protons), 5.08 (2H, t), 5.41 (2H, t), 5.79 (5H, s, unsubstituted cyclopentadienyl ring protons); i.r. ($CHCl_3$) 1632, 1102, 995 cm^{-1}.

Ferrocene-d_{10} was prepared by a modification of the method of Little and co-workers (25), m.p. 170–173°, from ferrous chloride and cyclopentadiene-d_6 (obtained by repeated exchanges of cyclopentadiene with NaOD–CH_3OD (26)).

Benzoylperdeuterioferrocene was prepared from ferrocene-d_{10} and benzoyl chloride by the method of Weliky and Gould (24), m.p. 107–108°; n.m.r. 2.0–2.7 τ (phenyl protons); the sample contained approximately 13% protons in the ferrocenyl moiety; i.r. ($CHCl_3$) 1632, 995 cm^{-1}, and the "9μ" band corresponding to the "9,10μ Rule" of monosubstituted ferrocenes (27) was missing; *m/e* 299.0950 (calcd. for $C_{17}D_9H_5FeO$: 299.0959), and also indicated 14.7% of undeuterated ferrocene moieties, in excellent accord with the n.m.r. results.

Pentadeuteriobenzoylferrocene was prepared by a Friedel–Crafts reaction between ferrocene and benzoyl-d_5-chloride (Merck, Sharp and Dohme of Canada, Ltd.) according to the method of Weliky and Gould (24), m.p. 107–108°; n.m.r. τ 5.13 (2H, t), 5.47 (2H, t), 5.84 (5H, s, unsubstituted cyclopentadienyl ring protons); i.r. ($CHCl_3$) 1628, 1098, 995 cm^{-1}; *m/e* 295.0699 (calcd. for $C_{17}D_5H_9FeO$: 295.0708), and a maximum of 3% of d_4 species.

2,2-Dimethylpropanoylferrocene, m.p. 90–92°; n.m.r. τ 5.19 (2H, t), 5.59 (2H, t), 5.86 (5H, s, unsubstituted cyclopentadienyl ring protons), 8.69 (9H, s, CH_3); i.r. ($CHCl_3$) 1650, 1375, 1362, 1102, 999; *m/e* 270.0707 (calcd. for $C_{15}H_{18}FeO$: 270.0709).

Tetrahydrofuran was purified by successive reflux periods over potassium hydroxide pellets, sodium metal, and lithium aluminum hydride, prior to being distilled from lithium aluminum hydride under a dry nitrogen atmosphere. The purified tetrahydrofuran was stored in degassed sealed ampoules containing clean slivers of potassium metal, and distilled into the tube containing the appropriate ketone immediately prior to ketyl formation.

The Electron Spin Resonance Sample Preparation and Measurements

The ferrocenyl ketyls were generated by reduction of the corresponding ketones in tetrahydrofuran solution. The procedure used to prepare samples for e.s.r. studies involved double distillation of freshly cut potassium under vacuum into a clean glass bulb separated from a tube containing a degassed solution of the ketone (10^{-3} *M*) by a break-seal. Just prior to spectral examination, the break-seal was broken and the ketone solution was shaken with the potassium metal. The formation of the ketyl was accompanied by a change in the color of the solution.

The e.s.r. spectra were recorded with a Varian V-4502 spectrometer system. The magnetic field was calibrated using a Harvey–Wells Magnion model G-502 proton gaussmeter and the microwave frequency was measured with a Hewlett–Packard model X532 wavemeter. *g*-Value measurements were made relative to an aqueous solution of potassium peroxylamine disulfonate, which has $g = 2.00550$ (28), using a Varian V-4532 dual cavity accessory. We estimate the precision of our *g*-value measurements to be ± 0.0005. In order to obtain optimum spectral resolution, the temperature of the sample was varied using a Varian V-4557 variable temperature accessory.

The Structure of Nupharolutine, an Alkaloid of *Nuphar luteum*

J. T. WROBEL AND A. IWANOW
Department of Chemistry, University of Warsaw, Warsaw, Poland
AND
C. BRAEKMAN-DANHEUX, T. I. MARTIN, AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario

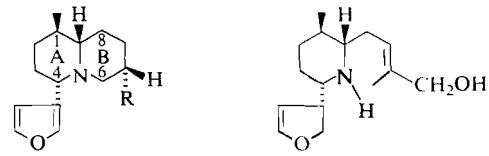
Received January 5, 1972

A new alkaloid, nupharolutine, ($C_{15}H_{23}NO_2$) has been isolated from the basic extract of the rhizomes of *Nuphar luteum*. By spectroscopic and chemical methods it is shown to be a hydroxy derivative of deoxynupharidine. The mass spectra of the new base and several isomers are reported.

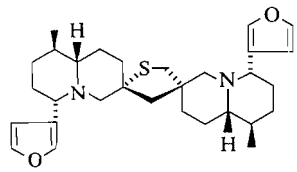
Un nouvel alcaloïde, la nupharolutine ($C_{15}H_{23}NO_2$) a été isolé à partir des extraits basiques de rhizomes du *Nuphar luteum*. Au moyen de méthodes spectroscopiques et chimiques il a été montré qu'il s'agit d'un dérivé hydroxylé de la désoxynupharidine. Les spectres de masse de cette nouvelle bas et de plusieurs isomères sont rapportés.

Canadian Journal of Chemistry, **50**, 1831 (1972)

Several structural types have so far been identified among the alkaloids of *Nuphar* species (1, and references cited therein) exemplified by deoxynupharidine (**1**), nuphamine (**2**), and neothiobinupharidine (**3**). Whereas deoxynupharidine and its relatives have a quinolizidine system, nuphamine and its structural analogues are piperidine derivatives formally derived by fission of the N—C_6 bond of **1**. Neothiobinupharidine and other C_{30} alkaloids have two deoxynupharidine units joined through carbon and sulfur linkages as illustrated. All of the *Nuphar* alkaloids are characterized by the presence of one or more furan rings in their structure and are apparently terpenoid in origin.



1 Deoxynupharidine, R = CH_3 **2** Nuphamine
5 Nupharidine = *N*-oxide of **1**
6 Castoramine, R = CH_2OH



3 Neothiobinupharidine

During the examination of the alkaloids of *N. luteum* a new base (**4**) was isolated to which the trivial name, nupharolutine, has been assigned. Its composition ($C_{15}H_{23}NO_2$), determined by elemental analysis and high resolution mass spectrometry, is identical with that of nupharidine (**5**) (1) and castoramine (**6**) (2, 3). On comparison of the properties of **4** with those of **5** and **6** it is evident that nupharolutine is isomeric with both of the known alkaloids. Only small quantities of **4** were isolated and therefore it was necessary to rely mainly on physical methods in the study of its structure.

The i.r. spectrum of **4** in carbon tetrachloride shows the presence of bonded and non-bonded hydroxyl absorption. The former shifts upon dilution indicating that the hydrogen bonding is intermolecular. The i.r. spectrum also shows the presence of Bohlmann bands (4) suggesting the presence of a *trans*-quinolizidine system similar to that known to be present in deoxynupharidine. Attempts to acetylate the new alkaloid with acetic anhydride–pyridine at 20° for 24 h or at 100° for 2 h led only to the recovery of starting material indicating that the hydroxyl function was tertiary.

The 100 MHz p.m.r. spectrum of **4** was similar to that of deoxynupharidine (5) but there was one major difference. Deoxynupharidine shows two doublets attributed to $>CHCH_3$ groups centered at 0.89 and 1.01 δ while the new alkaloid has a doublet centered at 0.92 and a singlet (3H)

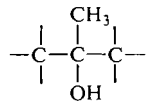
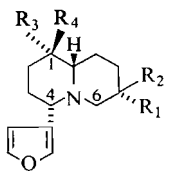
SCHEME 1

at 1.21 δ. The singlet nature of this peak and its chemical shift are compatible with the grouping



in the molecule. The presence of a tertiary hydroxyl function was deduced also from the acetylation studies. Like deoxynupharidine the spectrum of **4** has signals attributed to three protons in a furan ring at 7.22 (2H, α-protons) and 6.34 δ (1H, β-protons). A poorly resolved quartet of area one centered at 3.03 δ ($J = 8.3$ and 6.0 Hz) resembles a similar signal in the spectrum of deoxynupharidine attributed to C_4H (axial), the proton α to nitrogen and α to the furan ring, which is reported to appear at 2.88 δ ($J = 8.0$ and 6.2 Hz). A doublet of doublets (1H) centered at 2.67 δ ($J = 11.0$ and 2.0 Hz) is assigned by analogy with the spectrum of deoxynupharidine to C_6H_α (equatorial). In **1** this signal appeared as a quartet centered at 2.70 δ ($J = 12.5$ and 2.5 Hz). The remaining protons are present as a complex multiplet between 1.0 and 2.0 δ.

These data suggested that nupharolutine has one of the following structures:



4(*i*) $R_1 + R_2 = CH_3 + OH$
$R_3 + R_4 = CH_3 + H$
4(*ii*) $R_1 + R_2 = CH_3 + H$
$R_3 + R_4 = CH_3 + OH$

To resolve the structural problem we resorted to mass spectrometry. The spectrum of **4** was recorded and compared with that of deoxynupharidine, nupharidine, and castoramine. From the spectra shown in Fig. 1, it is obvious that the spectrum of **4** resembles those of **1** and **6** but is distinctly different from that of **5**. An interpretation of the spectra follows.

The mass spectrum of deoxynupharidine was first reported in 1964 (6). Our spectrum is identical with that reported earlier showing intense peaks at *m/e* 233 (M^+) and at *m/e* 136, 98, and 94. High resolution studies have enabled us to confirm the composition assigned to the intense ions in the original work and to determine the composition of less intense ions, thereby gaining further insight into the fragmentation process. In all cases measured masses agreed with the calculated values within ± 3 milli mass units.

There are four positions β to nitrogen in **1** that may undergo fission to yield the molecular ions designated A, B, C, and D in Scheme 1. Of these C and D should be more stable than the others and they are used to explain the subsequent fragmentation of the molecule. Thus the homologous ions shown in Scheme 2 at *m/e* 204 (*a*), 190 (*b*), and 176 (*c*) are considered to form from **1**C by the loss of the hydrocarbon fragments, C_2H_5, C_3H_7, and C_4H_9, respectively, processes accompanied by hydrogen rearrangement and the ions *m/e* 162 (*d*) and 148 (*e*) through retro Diels–Alder loss of propylene from *m/e* 204 and 190, respectively. The ion at *m/e* 178 (*f* or *g*) may arise from **1**D or **1**C, respectively, by the processes shown in Scheme

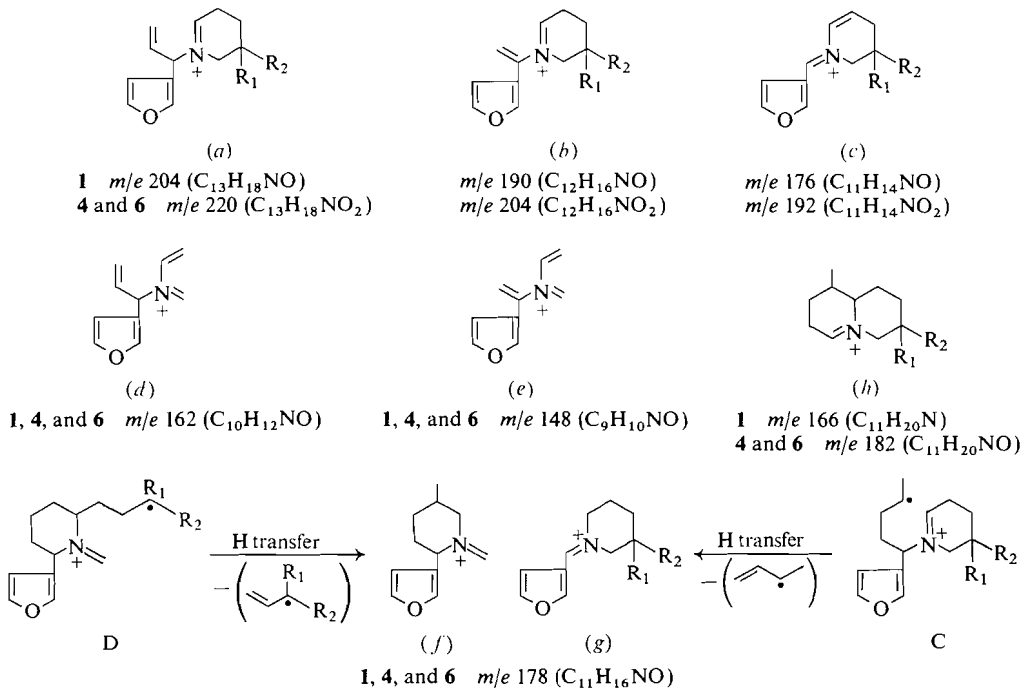

SCHEME 2

2 but the former is favored (compare with the spectrum of castoramine below). An ion at *m/e* 166 (*h*) has the composition $C_{11}H_{20}N$ and must be formed by cleavage of the furan ring as illustrated in Scheme 2.

The major ions in the spectrum of **1** appear at *m/e* 136 (*j*), 98 (*k*), 97 (*l*), 94 (*m*) and 55 (*n*) and a less intense but significant ion at *m/e* 107 (*o*). In Scheme 3 a proposal for their derivation is outlined. Their compositions have been established and all may be considered to arise from the molecular ion **1**C. Recent labelling studies are in harmony with the structure proposed for *m/e* 98 (7). In fragmentation by route 3*a* the charge is retained on the furan-containing fragment to give the ion at *m/e* 136 (*j*), and in route 3*b* on the nitrogen-containing fragment to give *m/e* 97 (*l*), which by a retro Diels–Alder process (route 3*c*) leads to *m/e* 55 (*n*). When fragmentation proceeds with hydrogen transfer as in route 3*d* the ion at *m/e* 98 (*k*) results. (Hydrogen transfer from C-2 is shown but there is no evidence that the hydrogen actually arises from this site.) The further fragmentation of *m/e* 136 via processes 3*e* and 3*f*, leads to the ions at *m/e* 107 (*o*) and 94 (*m*), respectively.

Analysis of the spectrum of castoramine shows that it fragments in a manner analogous to deoxynupharidine. Thus ions *a*, *b*, *c*, and *h* of Scheme 2 contain one oxygen more than those derived from **1** but are deemed to have the same carbon framework. The ions *d* and *e* are the same in **6** as in **1** and the ion at *m/e* 178 has the composition $C_{11}H_{16}NO$ and can be represented as *f*. Of the ions of Scheme 3, *j*, (*m/e* 136) *m*, (*m/e* 94) *n*, (*m/e* 55), and *o* (*m/e* 107) are identical in composition in both **1** and **6** but *k* and *l* appearing at *m/e* 114 and 113, respectively are shifted upwards by 16 mass units in **6** from their position in **1** reflecting the presence of the OH group.

Recent work of ours (8) on the spectra of neothiobinupharidine (**3**) and related systems shows that the dimeric compounds have many ions in their spectra whose formation may be interpreted through the schemes suggested here. The fact that the fragmentation of **1** and **6** and many of the fragmentations of **3** may be interpreted through Schemes 2 and 3 lends credibility to them.

The hydroxyl group present in **6** leads to new ions in its spectrum not present in the spectrum

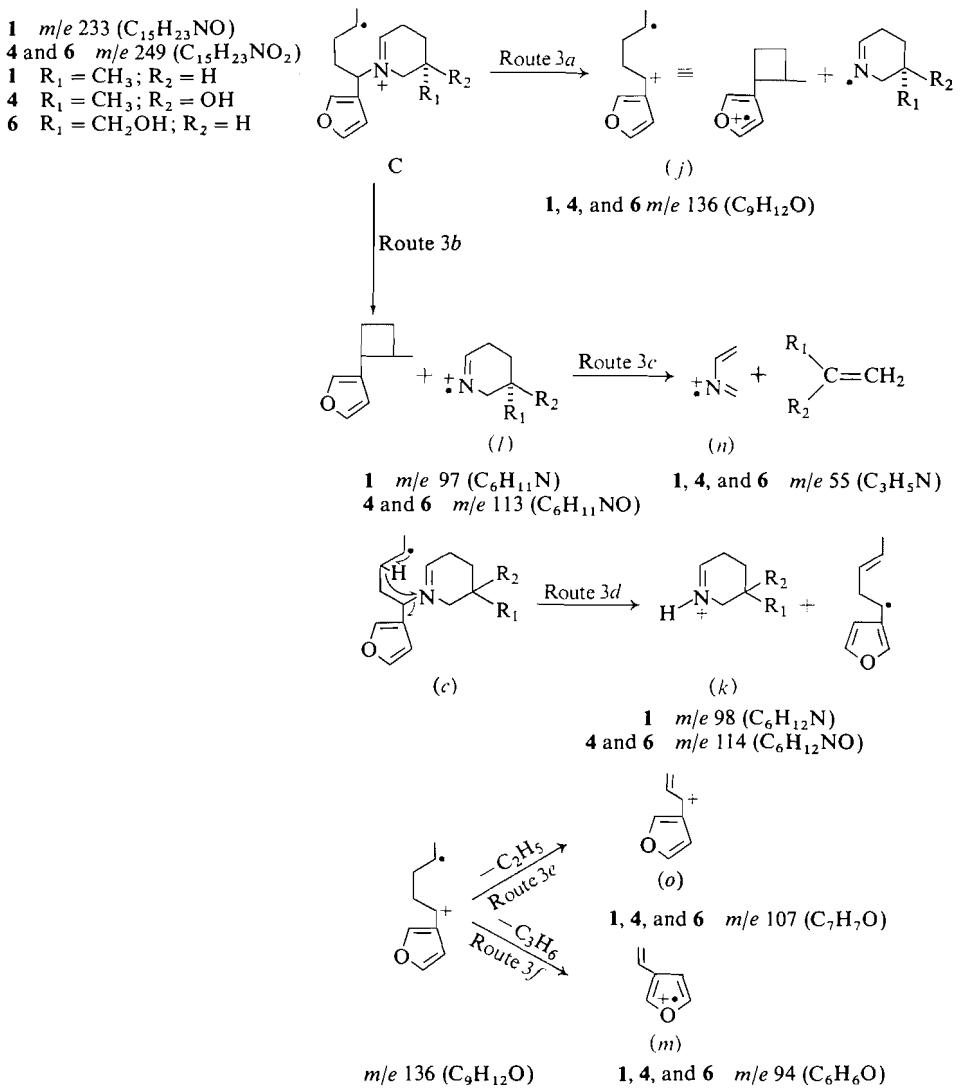
For personal use only.



SCHEME 3

of **1**. Thus a strong ion at *m/e* 96 can be ascribed to **6***k*—H_2O and an ion at *m/e* 164 to **6***h*—H_2O and the ions at *m/e* 218 and 219 to loss of CH_2O and CH_2OH from the molecule as shown in Scheme 4. The spectrum of nupharolutine **4** has many features in common with that of castoramine but it is distinctly different from that of nupharidine. There seems little doubt, therefore, that nupharolutine must have an OH group in ring B and may be represented as **4**(*i*).

The differences between the spectra of **4** and **6** are compatible with the structural differences. Thus the loss of CH_3 and OH would be predicted to be favored more in **4** than in **6** as would the formation of ion *f*. The spectra bear this out. It is interesting to note that the loss of H_2O from *m/e* 114 to form *m/e* 96 is more pronounced in **4**, the tertiary alcohol, than it is in **6**, the primary alcohol.

The spectrum of nupharidine (**5**) is discussed briefly below. Like other *N*-oxides it suffers loss of oxygen and OH with peaks at *m/e* 232 and 231 (9). The peak at *m/e* 220 results not from loss of an ethyl fragment but from loss of CHO, a frag-

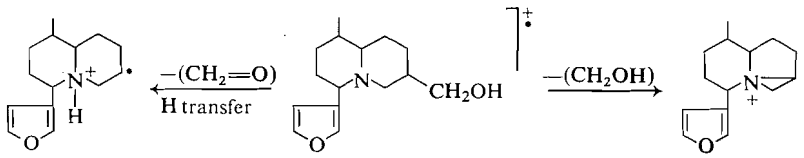
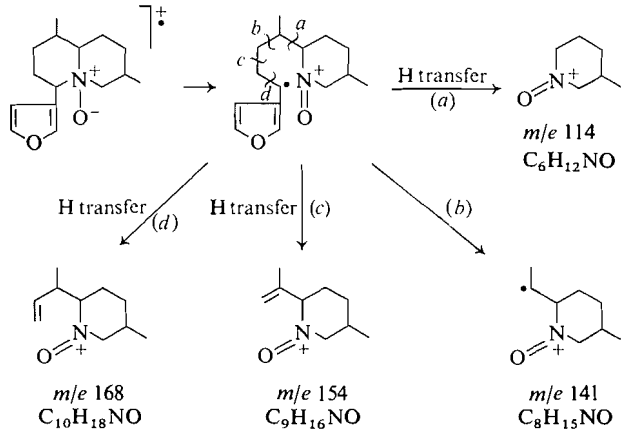


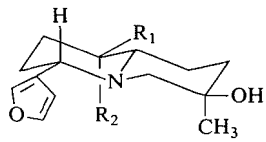
SCHEME 4



SCHEME 5

mentation characteristic of furans (10). In Scheme 5 proposals are put forward for the derivation of the major ion at *m/e* 114 and related fragments, based upon a determination of their compositions by high resolution studies.

The spectroscopic and other evidence presented points to structure **4**(*iii*) $R_1 + R_2 = CH_3 + H$ below for nupharolutine. The Bohlmann bands in the i.r. point to a *trans*-quinolizidine system and since the tertiary hydroxyl is not internally hydrogen bonded it must occupy the equatorial position at C-7. The p.m.r. evidence discussed earlier points to an equatorial position for the furan ring. The coupling of C_6H_α in **4** requires comment since it is almost identical with the corresponding proton in **1** where the two couplings were explained on the basis of a large geminal coupling and a smaller coupling to C_7H_β. A geminal coupling is still possible and present in **4** but the smaller coupling must be a "w" type (11) coupling with the equatorial proton at C-8 since C-7 is quaternary. The only structural feature remaining unsolved is the configuration of methyl at C-1 and although the p.m.r. evidence suggests that it is the same as in **1** it is not convincing. Accordingly we set out to convert **4** to **1**. Treatment of **4** with $POCl_3$–pyridine gave a chloro compound **7**,



4(iii)

separated from the reaction mixture by t.l.c., which was reduced over Pt to a substance identical with **1** by t.l.c. and on two g.l.c. columns. Thus nupharolutine must be **4**(*iii*), $R_1 = CH_3$, $R_2 = H$. A spectroscopic comparison was not possible because of a lack of material.

The mass spectrum of **7**, determined at low resolution is worthy of comment. It shows the intense ions observed at *m/e* 136, 107, and 94 in **1**, **4**, and **6**. Ion *k*, Scheme 3, appears as an isotopic doublet at *m/e* 132 and 134 which, through loss of HCl, leads to an ion at *m/e* 96 also observed in the spectra of **4** and **6**. Aside from the isotopic molecular ions at *m/e* 267 and 269 the only intense ion in the high mass region appears at *m/e* 232 (M^+—Cl).

Experimental

Apparatus, Methods and Materials

Mass spectra were determined on a C.E.C. 21-110B double-focusing mass spectrometer. Samples were intro-

duced through a direct inlet system. Spectra are plotted in terms of relative abundance, with the most intense peak (base peak) taken as 100%. Only those peaks with an intensity equal to or greater than 3% of the most intense peak have been recorded.

The high resolution mass spectra (h.r.m.s.) were recorded on Ilford Q-2 photographic plates, which were developed in the usual manner. The spectra were then recorded on magnetic tape, using a Gaertner comparator-densitometer linked to a Datex system. They were processed on a CDC-6400 computer using a modified version of the HIRES program of Tunnicliff and Wadsworth (12).

The 100 MHz spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency.

A Perkin–Elmer 337 grating i.r. spectrometer was used to record i.r. spectra.

Melting points were determined on a Kofler hot stage and are uncorrected.

Isolation of Nupharolutine

The crude bases derived from the rhizomes of *N. luteum* harvested in Poland were adsorbed on a column of alumina (activity III) and eluted successively with benzene, ether, chloroform, and methanol.[1] The methanol fraction was subjected to a 50 transfer counter current distribution using 1-butanol and a citrate–phosphate buffer (p*H* 4). Fractions 20–35 were combined, the basic fraction recovered, and subjected to chromatography on silica gel with $CHCl_3$: acetone = 1:1. The middle fractions were collected and combined. The crystalline residue obtained on removal of solvent was recrystallized from methanol–acetone, m.p. 96–98°; $[\alpha]_D^{22°}$ ($CHCl_3$) −105°.

Anal. Calcd. for $C_{15}H_{23}NO_2$ (mol. wt. 249.173): C, 72.3; H, 9.3; N, 5.6. Found (249.173 (h.r.m.s.)): C, 72.4; H, 9.5; N, 5.9.

Preparation of 7-Chlorodeoxynupharidine

Nupharolutine (10 mg) was treated with 1 ml of a solution of $POCl_3$ in dry pyridine (1:4) and the mixture allowed to stand at 0° for 24 h with occasional shaking. The resultant light brown solution was added to ice water (5 ml), basified by addition of 1 *M* NaOH, and extracted with CH_2Cl_2 (4 × 10 ml). The extract was dried over anhydrous sodium sulfate and then taken to dryness under reduced pressure. The residue was separated into two components (R_f = 0.60 and 0.45) on a t.l.c. plate (0.5 mm, silica gel) using benzene–acetone = 3:1 as developer. The major component (R_f = 0.60) was recovered by extraction of the silica gel with methylene chloride; yield 3.7 mg. The mass spectrum of this product showed isotopic molecular ions at 267 and 269 in approximate ratio, 3:1.

Reduction of 7-Chlorodeoxynupharidine

The chloro compound prepared above (3.4 mg) was dissolved in absolute ethanol (10 ml) and to the solution 50 mg of solid KOH and 25 mg of 30% Pd on $CaCO_3$ were added and the whole was shaken with hydrogen at 45 p.s.i.g. for 30 min. The reduction mixture was neutralized with ethanolic HCl, the catalyst separated by filtration, and washed with CH_2Cl_2. The ethanolic and methylene chloride solutions were combined and evaporated to dryness under reduced pressure. The residue was separated by t.l.c. (silica gel, 0.5 mm) into a major component (R_f = 0.25) and a minor component (R_f = 0.45) with $CHCl_3$–acetone = 5:4. The band, R_f = 0.25, was removed from the plate and extracted with CH_2Cl_2 yielding 2 mg of colorless product which had the same R_f value on t.l.c. as an authentic sample of deoxynupharidine. The mass spectrum was identical with that of deoxynupharidine and this product had the same retention time on g.l.c. on two different columns as authentic deoxynupharidine. The g.l.c. columns used were (*a*) 5% SE 30 on 60/80 Chromosorb W (5 ft × 1/8 in. column, 175°, 35 p.s.i.g. He), and (*b*) 20% DEGS on 60/80 Chromosorb W (5 ft × 1/8 in. column, 180°, 35 p.s.i.g. He).

This work was supported at McMaster University through a grant from the National Research Council of Canada. We thank Professor Z. Valenta for a sample of castoramine hydrochloride. One of us, C. Braekman-Danheux, wishes to thank the Canada Council for the award of a fellowship.

Relative Rate of Reaction of $O(^1D_2)$ with N_2O [1]

G. PARASKEVOPOULOS, V. B. SYMONDS,[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

The rate of reaction of $O(^1D_2)$ with N_2O relative to the rate of its reaction with neopentane has been determined by a competitive method. The value obtained, $k_{N_2O}/k_{neop.} = 0.145 \pm 0.010$, is in good agreement with several values in the literature. It is also found that N_2O does not deactivate $O(^1D_2)$ to $O(^3P)$ but reacts with it to form products.

La vitesse de réaction de $O(^1D_2)$ avec N_2O par rapport à la vitesse de sa réaction avec le néopentane a été déterminée par une méthode compétitive. La valeur obtenue, $k_{N_2O}/k_{neop.} = 0.145 \pm 0.010$, est en bon accord avec plusieurs valeurs de la littérature. Il a également été trouvé que N_2O ne désactive pas $O(^1D_2)$ en $O(^3P)$ mais qu'il réagit avec $O(^1D_2)$ pour former des produits.

Introduction

The photolysis of N_2O at 1850–2300 Å gives electronically excited oxygen atoms, mainly in the $O(^1D_2)$ state (1). At 2139 Å, in particular, reaction 1 is the only primary process (1, 2).

[1] $$N_2O + h\nu \rightarrow N_2 + O(^1D)$$

The $O(^1D)$ atoms can react further with N_2O to give O_2, N_2, and NO

[2a] $$O(^1D) + N_2O \rightarrow N_2 + O_2$$

[2b] $$\rightarrow 2NO$$

Although the value of the ratio k_{2a}/k_{2b} has been subject to some controversy (3, 4) (discordant values of 0.6 and 1.0 have been reported), Preston and co-workers (4) have recently established by three different experimental techniques that $k_{2a}/k_{2b} = 1.0$.

The photolysis of N_2O has been used extensively in this and other laboratories for the production of $O(^1D)$ atoms. Moreover, the yield of N_2 from reaction 2*a* has also been used for the measurement of relative rates of $O(^1D)$ reactions in experiments in which various added gases compete with N_2O for $O(^1D)$ (5, 6). However, the published values of the rate of reaction of $O(^1D)$ with N_2O (5–13), usually expressed relative to the rate of the $O(^1D)$ reaction with CO_2, differ by a factor of about 2. As a result of this large uncertainty, comparison of the relative values obtained by the N_2O technique with other measurements of relative rates of $O(^1D)$ atoms is difficult and uncertain. Further determinations of k_{N_2O}, using independent techniques, are therefore necessary.

In the present work a relative rate of the N_2O reaction was obtained in competitive experiments with neopentane. This technique is based on the measurements of the decrease in the yield of neopentanol, the main product of the reaction of $O(^1D)$ with neopentane, when other gases compete with neopentane for $O(^1D)$. The technique, described in detail elsewhere (2), has been used successfully in this laboratory to measure relative rates for a number of $O(^1D)$ reactions (2, 6, 14). The relative value of k_{N_2O} now obtained permits interconversion and thus direct comparison of the $O(^1D)$ rates expressed relative to N_2O with the rates expressed relative to neopentane and vice versa.

The neopentane technique also permits direct identification and measurement of any $O(^3P)$ formed during the reaction (2). In the case of N_2O it is thus possible to distinguish between the chemical reaction steps (2*a* and 2*b*) and the electronic deactivation step (2*c*),

[2c] $$O(^1D) + N_2O \rightarrow O(^3P) + N_2O$$

Although previous work (3, 4) has indicated that reaction 2*c* is not important, the more direct test for $O(^3P)$ atoms by the neopentane technique (2) has been applied in the present work and a very low upper limit for potential occurrence of reaction 2*c* has been established. This information was necessary since it appears from recent

For personal use only.

literature (15) that there is still some confusion[3] in this respect.

Experimental

The $O(^1D)$ atoms were formed by photolysis of N_2O with the 2139 Å zinc resonance line. The light was provided by two 93106 E Philips zinc lamps and was focused by two Ultrasil lenses. The cylindrical photolysis cell had a volume of 195.6 ml and suprasil quartz windows 5 cm in diameter.

The N_2 generated in reactions 1 and 2*a* was measured in every experiment by gas–solid chromatography on a 18 ft 13X Molecular Sieve column. Neopentanol was separated from the unreacted reactants and measured on a 300 ft long, 0.015 in. i.d. stainless steel capillary column coated with β,β'-thiodipropionitrile and equipped with a flame ionization detector. The vacuum systems used and the experimental and analytical techniques have been described elsewhere (16). In the present experiments a solid nitrogen trap (−220 °C), capable of trapping NO, was added before the Toepler pump. Neopentane and N_2O were of the same grade and purified in the same manner as described before (17).

Results and Discussion

The experiments were made at 25 ± 2 °C and at about 240 Torr, *i.e.* above the pressure at which the neopentanol is essentially completely stabilized (17). The ratio of neopentane/N_2O was varied from about 0.05 to about 1.

The following reaction scheme represents the main features of the reaction of $O(^1D)$ produced by photolysis of N_2O with N_2O and neopentane

$$[1] \quad N_2O + h\nu \xrightarrow{2139\ \text{Å}} N_2 + O(^1D)$$

$$[2a] \quad O(^1D) + N_2O \longrightarrow N_2 + O_2$$

$$[2b] \quad \longrightarrow 2NO$$

$$[2c] \quad \longrightarrow O(^3P) + N_2O$$

$$[3] \quad O(^1D) + RH \longrightarrow \alpha ROH + (1-\alpha)(R^{\cdot} + OH)$$

where RH and ROH are neopentane and neopentanol, respectively, α is the fraction of the $O(^1D)$ atoms interacting with neopentane which form neopentanol.

It has been shown in detail previously (6) that, when the extent of reaction is small, molecular oxygen does not affect the neopentanol yield from reaction 3 in any way other than by competing with neopentane for the $O(^1D)$. Under the conditions of the present experiments the neopentanol yield was entirely unaffected by the small amount of O_2 produced in reaction 2*a*. On the other hand the NO produced in reaction 2*b* was found to affect the yield of N_2. It is well known (18, 19) that NO reacts with alkyl radicals to form alkyl nitroso compounds which then react further with NO. In the presence of excess NO, alkyl radicals catalyze disproportionation of NO to N_2 and NO_2 according to the following stoichiometric equation

$$[4] \quad 4NO(+R) \rightarrow N_2 + 2NO_2(+R)$$

It has been shown by Christie and co-workers (19) that one free alkyl radical can lead to the disproportionation of several hundred molecules of NO and that at low concentrations of nitrosoalkanes the reaction of alkyl radicals with NO_2 is the important chain breaking step. In the present system neopentyl radicals, formed to the extent of about 25% of the $O(^1D)$ (17), are expected to catalyze the disproportionation of NO (18). It is also possible that NO_2 may react with neopentanol although it is more likely that it will be consumed in reactions with neopentyl radicals. Since the yields of N_2 and neopentanol are the experimental parameters used in the calculation of the relative rate, a number of experiments were made to establish the role of NO in the present system, *i.e.*, how NO affects the ratio neopentanol/N_2. In these experiments a mixture of neopentane/N_2O at a ratio of ≈4 was photolyzed in the absence and presence of NO. At this ratio practically all the $O(^1D)$ formed reacts with neopentane (17). The results are given in Table 1 and are plotted in Fig. 1.

In the absence of NO the N_2 yield is equivalent to the $O(^1D)$ produced in reaction 1. The average value of α = neopentanol/N_2 = 0.63, given in the first row of Table 1, agrees well with previous determinations (2, 17). When NO is added, the neopentanol/N_2 ratio decreases and it may be seen in Fig. 1 that the decrease is linear. The NO reacted was also measured in these experiments and the N_2 produced in reaction 4 may be calculated from the measured total N_2, the neopentanol yield and the value of neopentanol/N_2 when no NO is added (*i.e.* 0.63). The values of (NO reacted)/(N_2 produced in

[3]Bradley *et al.* (15) have assumed in a recent publication that reaction 2*c* is efficient and quote a paper by Preston and Cvetanović (8) in support of this assumption. However, in this latter paper (8) reference is clearly made to the *total* reaction of $O(^1D)$ with N_2O, *i.e.* to reactions 2*a*, 2*b*, and 2*c* combined, and *not* to deactivation (reaction 2*c*) separately. In fact, with the technique used by Preston and Cvetanović (8) it was not possible to distinguish between steps 2*a*, 2*b*, and 2*c*.

TABLE 1. Effect of the addition of NO on the ratio of neopentanol/N_2

Neopentane / N_2O	Total N_2 (μmol)	NO added		Neopentanol / N_2	NO reacted (μmol)	NO (reacted) / N_2 (produced in reaction 4)
		Torr	μmol			
4.18*	2.3–5.8*	none		0.633*	—	—
4.17	3.98	0.57	5.95	0.540	2.39	4.19

4.04	4.19	1.88	19.75	0.400	5.85	3.89
						Average = 4.08

*Average of four experiments.

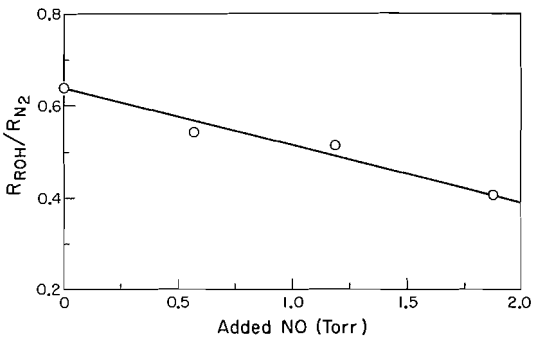

FIG. 1. Change of R_{ROH}/R_{N_2} with added NO.

reaction 4), calculated in this manner, are given in the last column of Table 1. The average value of 4.1 agrees very well with the reported (18, 19) stoichiometry of reaction 4. These results also suggest that in these experiments neopentanol is not consumed in reactions with NO_2, which is probably removed in reactions with neopentyl radicals.

If reaction 4 is neglected for the moment and taking[4] $k_{2a} = k_{2b}$ (4), the usual steady state assumption for $O(^1D)$, applied to reactions 1, 2*a*, 2*b*, and 3, leads to the following expression

$$\text{apparent}\ \frac{k_2}{k_3} = \frac{2}{3}\left(\alpha\frac{R_{N_2}}{R_{ROH}} - 1\right)\frac{[RH]}{[N_2O]}$$

where R_{N_2} is the rate of production of N_2 and R_{ROH} is the rate of production of neopentanol, R_{N_2}/R_{ROH} is the ratio of the yields of N_2 and neopentanol, and $\alpha = 0.633$ (see first row of Table 1). The ratio k_2/k_3 is called apparent because it is not expected to be constant, since reaction 4 has been neglected, but to decrease

[4]As was mentioned in the introduction, it has been established recently that $k_{2a}/k_{2b} = 1$ (4). However, if the previously reported (3) value of $k_{2a}/k_{2b} = 0.59$ is used, our results are increased only by about 10%.

TABLE 2. Values of the apparent k_2/k_3 from the photolysis of various mixtures of neopentane and N_2O at 2139 Å

Neopentane (Torr)	N_2O (Torr)	N_2 (μmol)	N_2 / Neopentanol	Apparent k_2/k_3
117	112	2.15	1.90	0.141
116	155	5.97	2.14	0.177
66.7	166	2.80	2.41	0.141
54.5	164	1.93	2.88	0.182
41.3	189	2.42	3.48	0.175
32.7	200	2.69	4.64	0.212
26.4	205	2.70	5.04	0.188

10.1	205	2.31	18.05	0.342

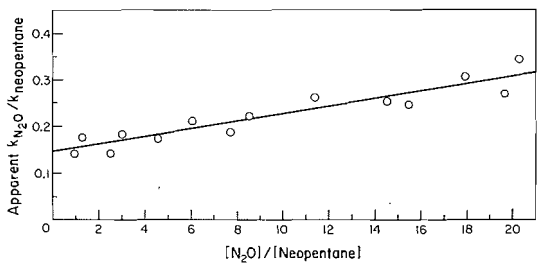

FIG. 2. Plot of the apparent $k_{N_2O}/k_{neopentanol}$ against $[N_2O]/[neopentane]$.

linearly with decreasing N_2O/neopentane, *i.e.*, with decreasing production of NO in accordance with the results presented in Table 1 and Fig. 1. The values obtained for the apparent k_2/k_3 are given in Table 2 and are plotted against N_2O/neopentane in Fig. 2. It may be seen that indeed the apparent k_2/k_3 decreases linearly with decreasing N_2O/neopentane. The intercept of the straight line at zero N_2O/neopentane, *i.e.*, zero NO production, should give the true value of

TABLE 3. Test for the formation of $O(^3P)$ atoms in the reaction $O(^1D) + N_2O$

Compound	Amount
N_2O	742 Torr
1-Butene	1.17 Torr
N_2 formed	4.00 μmol
$O(^1D)$	2.67 μmol*

Rate of product formation (per $O(^1D)$)

Product	Rate
1,2-Butene oxide	0.012
n-Butyraldehyde	0.008
Methylethyl ketone	Trace

*The total $O(^1D)$ generated, taken as $O(^1D) = N_2/1.5$ (for $k_{2a}/k_{2b} = 1$, the quantum yield of N_2 in the photolysis of N_2O is 1.5).

k_2/k_3. The least square value of the intercept is $k_2/k_3 = 0.145 \pm 0.010$. The error quoted is the standard deviation.

The possibility of deactivation of $O(^1D)$ to $O(^3P)$ by N_2O was examined in an experiment in which about 1 atm of N_2O was photolyzed in the presence of about 1 Torr of 1-butene, and the characteristic products of the addition of $O(^3P)$ to 1-butene (1,2-butene oxide, *n*-butyraldehyde, and methylethyl ketone) were measured as described in detail elsewhere (2). The results are given in Table 3, and it may be seen that the total amount of $O(^3P)$ characteristic products is about 2% of the $O(^1D)$ reacted.[5] This places an upper limit of 2% on the fraction of $O(^3P)$ in the system. The same limit of about 2% has been found with all the gases that react but do not deactivate $O(^1D)$, (*i.e.* H_2, CH_4, *iso*-C_4H_{10}, *neo*-C_5H_{12}, and H_2O) (2, 14, 16), and with those that apparently do not interact at all with $O(^1D)$ (*i.e.* SF_6 and He) (2). In the previous work (2, 14) N_2O and neopentane have always been present together with the other gas and it was not possible to distinguish between the reactions that may form $O(^3P)$. The present result tentatively suggests that the small amount of $O(^3P)$ may perhaps be formed in all cases in the initial photolysis of N_2O by the spin-forbidden reaction 1*a*.

$$[1a] \qquad N_2O + h\nu \xrightarrow{2139\ \text{Å}} N_2 + O(^3P)$$

However, the data are not sufficiently accurate and reaction 1*a* may be considered as merely a possibility.

The relative rates from this and other determinations are listed in Table 4. All the rates in this table are expressed relative to CO_2. For the present value use was made of the rate of CO_2 relative to that of neopentane determined previously by the same technique (2). It appears from the table that the lower value for k_{N_2O}/k_{CO_2} is favored by the greater number of determinations. If we ignore the last five values in the table, the first five values give an average $k_{N_2O}/k_{CO_2} = 1.15 \pm 0.04$ which is an excellent agreement in

TABLE 4. Comparison of the relative rates of the $O(^1D) + N_2O$ reaction determined by different techniques with $O(^1D)$ from different sources

Source of $O(^1D)$*	$\frac{k_{N_2O}}{k_{CO_2}}$	Reference
Photolysis of N_2O (2139 Å)	1.15	This work
Photolysis of NO_2 (2288 Å)	1.24	6
Photolysis of NO_2 (2288 Å)	1.11†	8†
Photolysis of N_2O (2139 Å) and O_3 (3132 Å)	1.10	12
Photolysis of O_3 (2537 Å)	1.14	11
Photolysis of O_2 (1470 Å)	0.76	10
Photolysis of O_2 (1470 Å)	0.98†	9†
Flash photolysis of O_3 (continuum > 2100 Å)	1.84	5
Photolysis of N_2O (1849 Å)	1.6‡	7‡
Flash photolysis of N_2O (1750–2200 Å)	1.6	13

*It should be noted that in addition to the sources of $O(^1D)$ used, the techniques by which $O(^1D)$ atoms were monitored are also of interest. These include a variety of physical and chemical methods identifying and measuring products of the reactions of $O(^1D)$. For details on these techniques the individual references should be consulted.

†The data of refs. 8 and 9 corrected for the more recent value (4) $k_{2a}/k_{2b} = 1.0$.

‡The value of 1.6 quoted here is obtained from the data in ref. 7 assuming free exchange of ^{18}O with NO formed in reaction 2*b*. In ref. 7 the value of 1.6 was tentatively ascribed only to k_{2a}/k_{CO_2} by neglecting the ^{18}O exchange with NO. In ref. 8 a value of 2.4 was indirectly inferred for $(k_{2a} + k_{2b})/k_{CO_2}$ from the same data, again without allowance for ^{18}O exchange with NO. The present value takes this exchange into account and therefore supersedes both these earlier values (7, 8).

[5]The possibility that the small yields of the characteristic products were not formed by addition of $O(^3P)$ to 1-butene but in another process was considered. These products may be formed to some extent in the presence of O_2, alkyl radicals, and 1-butene (6). Small amounts of O_2 are formed in reaction 2*a*, and it is possible although not very likely that minute amounts of alkyl radicals may be formed by photolysis of 1-butene. (Absorption of the 2139 Å light by 1-butene is very small (20) and in the present experiment the ratio N_2O/1-butene has been about 650.) In a separate experiment 1.2 Torr of butene and 0.3 Torr of O_2 were irradiated with light of 2139 Å under conditions exactly the same as those of the experiment in Table 3. No 1,2-butene oxide and *n*-butyraldehyde were detectable in the mixture.

view of the diverse experimental techniques used and the errors involved in them. If all the values in Table 4 are taken, the mean $k_{N_2O}/k_{CO_2} = 1.25 \pm 0.25$.

The Synthesis and Structural Studies of some Dialkyltin(IV) Salts of Strong Monobasic Acids

T. H. TAN, J. R. DALZIEL, P. A. YEATS, J. R. SAMS, R. C. THOMPSON, AND F. AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received September 28, 1971

A number of dialkyltin(IV)-bisfluorosulfates, -bistrifluoromethanesulfonates, and -bisdifluorophosphates are synthesized by solvolysis of dialkyltin(IV) chlorides in an excess of the corresponding acid according to $R_2SnCl_2 + 2HX \xrightarrow{25\ ^\circ C} R_2SnX_2 + 2HCl$; R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, and *n*-C_8H_{17}; X = SO_3F, SO_3CF_3, and PO_2F_2. The structural proposals, hexacoordination for tin with the alkyl groups in *trans*-octahedral position and bidentate bridging anionic groups with coordination through oxygen, are based on ^{119}Sn Mössbauer, infrared and, where obtainable, Raman spectra. The vibrational spectra of the difluorophosphates are discussed in detail. Variations in isomer shift and quadrupole splitting values with different alkyl groups in all three groups of compounds follow the same regular pattern as in the series R_2SnF_2. The results of point charge calculations are reported.

Un certain nombre de bisfluorosulfates, bistrifluorométhanesulfonates et bisdifluorophosphates de dialkyl-étain(IV) a été synthétisé par solvolyse des chlorures de dialkyl-étain(IV) dans un excès correspondant d'acide selon: $R_2SnCl_2 + 2HX \xrightarrow{25\ ^\circ C} R_2SnX_2 + 2HCl$; R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_5, et *n*-C_8H_{17}; X = SO_3F, SO_3CF_3, et PO_2F_2. Les propositions de structure, c'est-à-dire hexacoordination pour l'étain avec les groupes alkyles dans une position octaédrale *trans* et les groupes anioniques formant un pont bidentique se coordinant par l'oxygène, sont basées sur les spectres infrarouge, Mössbauer de ^{119}Sn et Raman lorsque cela était possible. Le spectre vibrationnel des difluorophosphates est discuté en détail. Les variations dues au changement d'isomère et les valeurs des multiplicités quadrupolaires avec divers groupes alkyles dans les trois séries de composés, suivent le même schéma régulier que dans les séries R_2SnF_2. Les résultats de calculs de charge ponctuelle sont rapportés.

Canadian Journal of Chemistry, **50**, 1843 (1972)

Introduction

The solvolysis of methyltin(IV)–chlorine compounds of the type $(CH_3)_nSnCl_{4-n}$ with *n* ranging from 1 to 4, in strong protonic acids such as HSO_3F (1–3), HSO_3CF_3 (1–4) and anhydrous HF (5) has been found recently to be a simple and convenient synthetic route to either binary tin(IV) compounds of the type $(CH_3)_nSnX_{4-n}$ or ternary derivatives of the type $(CH_3)_nSnCl_mX_{4-(n+m)}$, with X = SO_3F, SO_3CF_3 or F and *n* or *m* = 1, 2, or 3. A systematic study in these solvents has revealed that with the acid in moderate excess, disubstitution occurs at room temperature under evolution of CH_4 and/or HCl with preferential cleavage of the tin–chlorine over the tin–carbon bond. Consequently dimethyltin(IV) derivatives can be synthesized in three different ways as shown below:

$$\left.\begin{matrix}(CH_3)_4Sn\\(CH_3)_3SnCl\\(CH_3)_2SnCl_2\end{matrix}\right\} + 2HX \rightarrow (CH_3)_2SnX_2 + \left\{\begin{matrix}2CH_4\\CH_4 + HCl\\2HCl\end{matrix}\right.$$

with X = SO_3F, SO_3CF_3 or F.

As evidenced by infrared, Raman and ^{119}Sn Mössbauer spectra (1, 3, 5), a common structural type is found for all three dimethyltin(IV) derivatives. In sheet type polymers, the central tin atom has achieved hexacoordination, with the two methyl groups in *trans*-octahedral positions and the X groups acting as bidentate bridging ligands. These conclusions were in agreement with X-ray diffraction studies of $(CH_3)_2SnF_2$ (6) and $(CH_3)_2Sn(SO_3F)_2$ (7). The reported ^{119}Sn Mössbauer data (1, 3) for both $(CH_3)_2Sn(SO_3F)_2$ and $(CH_3)_2Sn(SO_3CF_3)_2$ are rather unusual, both the isomer shifts (~1.8 mm/s) and the quadrupole splittings (~5.5 mm/s) being the largest values yet reported for organotin(IV) derivatives. The vibrational spectra allowed assignments of fundamentals for bidentate bridging fluorosulfate and trifluoromethanesulfonate.

It became interesting to extend our work in two directions: (*a*) the use of other organyltin(IV) chlorides, primarily of the type R_2SnCl_2 as solutes, and, (*b*) the use of difluorophosphoric acid, HPO_2F_2, as solvent, in order to get some idea about the limitations of the synthetic route.

The expected compounds of the type R_2SnX_2 with $X = SO_3F$, SO_3CF_3, F, and PO_2F_2 are of structural interest. Vibrational spectra of difluorophosphates have only been reported for simple ionic salts $M^IPO_2F_2$, with M^I = Li, Na, K, Rb, Cs, or NH_4 (8). The fact that the SO_3F and the PO_2F_2 groups are isoelectronic leads one to expect some structural similarity for the diorganyltin(IV) compounds. Vibrational assignment for this group should be feasible.

A comparison of all vibrational spectra should allow for the oxyacid derivatives the detection of structural changes within a given series by using the fundamental frequencies of the anionic group as criteria.

For isostructural compounds, all trends of the ^{119}Sn Mössbauer parameters in a series of compounds should reflect primarily changes in the electron distribution around tin as affected by the change in R. A number of comparative studies for diorganyltin(IV) derivatives of the type R_2SnY_2, with Y as a polyatomic anionic group were reported previously. These include diorganotin(IV) thiocyanides (9), cyanates (10), and oxinates (11–13); however, no clear pattern seems to emerge, which at least in part is due to the different molecular structures suggested for the three anionic groups. The thiocyanates appear to show *trans*-octahedral coordination for tin (9), the oxinates are *cis*-octahedral complexes (11–16), and for the cyanates a distorted tetrahedral configuration was proposed (10). Of the dialkyltin(IV) halides only the fluorides can be safely included, since the *trans*-octahedral configuration for tin is present (5, 6). We have recently reported Mössbauer data for the series R_2SnF_2, with R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, and *n*-C_8H_{17} (5).

Experimental

I. Chemicals

Technical grade fluorosulfuric acid (Baker and Adamson) was doubly distilled under atmospheric pressure as described before (17). Trifluoromethane sulfonic acid was obtained from $Ba(SO_3CF_3)_2$ (3M Company) and sulfuric acid with subsequent purification by a reduced pressure distillation. Difluorophosphoric acid (Ozark-Mahoning Chemical Company) was purified by repeated distillations at reduced pressure (10 cm of mercury) in a Pyrex system as reported previously (8).

The dialkyltin(IV) chlorides $(CH_3)_2SnCl_2$, $(C_2H_5)_2SnCl_2$, $(n\text{-}C_3H_7)_2SnCl_2$, $(n\text{-}C_4H_7)_2SnCl_2$, and $(n\text{-}C_8H_{17})_2SnCl_2$ were all obtained from Alfa Inorganic Chemicals. Their purity was checked by melting points. Purification was carried out by vacuum sublimation or by recrystallization from petroleum ether where necessary. Freon 11, $CFCl_3$, was dried over Linde's Molecular sieve.

II. Instrumentation

Infrared spectra were recorded on a Perkin–Elmer 457 grating spectrophotometer. Silver chloride, cesium iodide, and KRS-5 windows (all from Harshaw Chemicals) were used either with Nujol or without any mulling agent.

Raman spectra on the solid samples were obtained with a Cary 81 spectrometer, equipped with a model 125 He–Ne gas laser (Spectra Physics Corp.). The 6328 Å wavelength line was used as exciting light. The samples were contained in 5 mm o.d. Pyrex tubes with flat bottoms.

The Mössbauer spectrometer has been described before in detail (18). Measurements were made with the absorber either at 80 or 298 °K and the Ba $^{119m}SnO_3$ source at 298 °K. All isomer shifts are reported relative to SnO_2 absorber at 80 °K. The confidence limit for both isomer shifts and quadrupole splittings is judged to be ± 0.03 mm/s.

All manipulations of solid materials were carried out in a Vacuum Atmosphere Corp. "Dri-Lab" model no. He-43-2 filled with purified dry nitrogen and equipped with "Dri-Train" model no. HE-93B.

III. Preparations

All preparations were carried out in about 100 ml two-part reaction flasks, fitted with Teflon coated magnetic stirring bars and Teflon stem stopcocks (Fisher and Porter). In all instances a small excess of the acid was added to a known amount of substrate either at atmospheric pressure (HSO_3F), reduced pressure (HPO_2F_2), or by transfer in an inert atmosphere box, resulting in instantaneous HCl evolution. In order to avoid side reactions and subsequently dark-colored substances, about 20–25 ml $CFCl_3$ were added to the reactions of the *n*-propyl and *n*-butyl compounds with the sulfonic acids.

After removal of all volatile products under vacuum and at room temperature, the dialkyltin(IV) salts were isolated as rather high-melting white crystalline solids. The remaining traces of acids were removed by prolonged pumping at slightly elevated temperatures (50–60 °C). All reactions were followed by weight. The obtained products were handled inside the dry box.

The previously reported (19) compounds $(CH_3)_2Sn(PO_2H_2)_2$ and $(CH_3)_2Sn(PO_2H(C_6H_5))_2$ were synthesized from aqueous solution as described.

Compounds of the type R_2SnF_2 were obtained from the solvolysis of the corresponding chlorides in aqueous HF solution. Details are described elsewhere (5).

IV. Analytical Results

All products were identified by C and H microanalysis, performed by Borda of this department. The results together with the melting or decomposition points are listed in Table 1.

More detailed analysis was carried out for $(CH_3)_2Sn(SO_3F)_2$ (3), $(CH_3)_2Sn(SO_3CH_3)_2$ (3), and $(n\text{-}C_3H_7)Sn(PO_2F_2)_2$ by Alfred Bernhardt, Microanalytical Laboratory, Elbach, West Germany. The results for the latter compound are listed below.

Anal. Calcd. for $(n\text{-}C_3H_7)_2Sn(PO_2F_2)_2$: P, 15.23; F, 18.68. Found: P, 15.36; F, 18.68.

TABLE 1. Analytical data for the series R_2SnX_2 with R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, and n-C_8H_{17} and X = SO_3F, SO_3CF_3, and PO_2F_2

	Compound	Melting point* (°C)	Analysis (%) C Calculated	C Found	H Calculated	H Found

*(d) denotes decomposition.

Results

The new dialkyltin(IV) salts are easily obtained by solvolysis of the corresponding dialkyltin(IV) dichlorides in the acids HSO_3F, HSO_3CF_3, and HPO_2F_2. All are moderately hygroscopic white solids, showing decomposition points generally higher than 200 °C.

Infrared spectra for all compounds were obtained in the region 4000–250 cm^{-1}. However, the discussion will be restricted to the region of 2000–250 cm^{-1}, and to the $R_2Sn(PO_2F_2)_2$ compounds only. Raman spectra on solid samples could be obtained only for the methyl derivatives and even here not all expected vibrational modes could be found.

The vibrational frequencies found for the dialkyltin(IV) bisdifluorophosphates are listed in Table 2 together with the frequencies for KPO_2F_2 (8) and a suggested assignment for the PO_2F_2 group in these compounds.

Well resolved ^{119}Sn Mössbauer spectra could be obtained for all compounds at 80 °K and for some also at room temperature. An example is shown in Fig. 1. The observed isomer shift, quadrupole splitting, and line-width values are listed in Table 3 together with data for some related compounds, *e.g.*, for the series R_2SnF_2 (5).

Discussion

I. Synthesis

As the results indicate, solvolysis proceeds readily for all three monobasic acids according to the general scheme: $R_2SnCl_2 + 2HX \xrightarrow{25\ °C} R_2SnX_2 + 2HCl$ for R = CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9, and X = SO_3F, SO_3CF_3, and PO_2F_2 under cleavage only of the tin–chlorine bonds. It appears that the reactions in HPO_2F_2 proceed slightly more slowly than in the two sulfuric acids. On the other hand discolorations and slightly brownish products are more readily formed in HSO_3F and HSO_3CF_3, necessitating the use of $CFCl_3$ as a dilutant. The fact that only in HPO_2F_2 a n-octyltin(IV) salt could be obtained indicates that side reactions appear to decrease in the weaker acid. Whereas in HSO_3F and HSO_3CF_3 it is possible to form the corresponding dimethyltin(IV) salts also from $(CH_3)_3SnCl$ with the acid in a slight excess (1, 3) indicating the cleavage of both an Sn—Cl and Sn—C bond, the analogous reaction in HPO_2F_2 does not proceed. Neither HCl nor CH_4 evolution could be noted at room temperature. It appears HPO_2F_2 is less capable of cleaving Sn—C bonds than the stronger sulfonic acids, thus reducing the chances for side reactions as mentioned above. The behavior of $(CH_3)_3SnCl$ in HPO_2F_2 is reminiscent of the solvolysis of this substrate in some carboxylic acids (20) where no reaction is noted at room temperature but cleavage of one Sn—C bond occurs at about 100 °C.

Attempts to extend the reaction to other solutes such as divinyl-, dibenzyl-, and diphenyltin(IV) dichloride failed for all three acids. Extensive side reactions and the formation of

black-brown products were observed. Microanalysis indicated the additional cleavage of Sn—C bonds in these reactions. This is not totally unexpected and was observed also in anhydrous hydrogen fluoride (5). An empirical series relating to the ease of cleavage of the Sn—C bond in tetraorganyltin(IV) compounds (21) suggests the order: phenyl > benzyl > vinyl > methyl > ethyl > propyl > butyl > hexyl > octyl. Assuming the correctness of this order, it appears that preferential cleavage of the Sn—Cl bonds in solutes of the type R_2SnCl_2 is found for methyl and the higher homologues C_nH_{2n+1} but not for the more labile C_2H_3-, $C_6H_5CH_2$-, and C_6H_5-derivatives.

II. Vibrational Spectra

Since the vibrational frequencies for a number of methyltin(IV) fluorosulfates and trifluoromethanesulfonates have been assigned and discussed extensively elsewhere (1–3), this part will be concerned primarily with the interpretation of the infrared spectra for the dialkyltin(IV) difluorophosphates. Infrared spectra of compounds in the series $R_2Sn(SO_3X)_2$ with R = C_2H_5, n-C_3H_7, and n-C_4H_9 and X = F and CF_3 are found to agree quite well with the spectra of the methyl compounds in respect to the SO_3X vibrations.

As pointed out before the SO_3F^- and the $PO_2F_2^-$ ions are isoelectronic but the free ions

have different symmetry: C_{3v} for SO_3F^- and C_{2v} for $PO_2F_2^-$ (22). For a bidentate bridging group the symmetry for the SO_3F group will be reduced to C_s whereas the PO_2F_2 group still retains C_{2v} symmetry, provided bridging occurs through oxygen in both instances. Following the assignment for bridging SO_3F groups (2), frequency shifts for the bridging PO_2F_2 groups are expected, notably in the stretching frequency region.

The nine expected modes (approximately described as PO_2 and PF_2 symmetric and asymmetric stretches, PO_2 and PF_2 bending, two POF rocking modes, and a torsion mode) have all been observed before except for the last one, which belongs to the group A_2 and should occur only in the Raman spectrum. Buehler and Bues (23) suggest an assignment of a Raman band in molten KPO_2F_2 at 300 °C as $\nu_5(A)_2$ found at 365 cm^{-1}, whereas the reported infrared spectra of all alkali difluorophosphates (8) suggest that $\delta PF_2(A_1)$ occurs in the same region. Since only one band is observed in the Raman spectrum at 360 cm^{-1}, it is impossible to make an unambiguous assignment for the missing torsion mode.

As can be seen from Table 2, assignment of the remaining eight fundamentals is possible for all $R_2Sn(PO_2F_2)_2$. Internal modes of the R groups are identified by comparison with the infrared spectra for the corresponding R_2SnCl_2 compounds. No attempt is made to interpret these modes in detail. The following features are interesting: (*a*) only one type of PO_2F_2 group seems to be present in the *n*-alkyltin(IV) bisdi-

fluorophosphates; (*b*) the narrow range for each fundamental within the series indicates the PO_2F_2 is relatively unaffected by the increasing size of R; and (*c*) positional changes have occurred when compared to the ionic $PO_2F_2^-$ in KPO_2F_2. This point merits further comment. It appears that in particular the stretching modes are affected to a different degree. As found for the corresponding fluorosulfates, the symmetric and asymmetric P—F (S—F) stretching modes are found at higher frequencies. Of the P—O stretching modes, the asymmetric one is lowered by about 40–50 cm^{-1} whereas the symmetric mode is slightly raised, resulting in a weak net lowering for the average P—O stretch throughout the series.

Since most certainly coordination through oxygen occurs, the expected lowering of νPO_{ave} can be explained partly by charge withdrawal from the P—O into the Sn—O bond region. Similar effects are observed for organyltin(IV) carboxylates (24) affecting here $\nu C{=}O$. However, back donation from lone electron pairs on oxygen and fluorine towards phosphorus can compensate the charge withdrawal at least partially, and can account for the observed increase in the P—F stretching frequency. A suitable model involving the empty 3d orbitals on phosphorus and sulfur has been introduced by Cruickshank (25).

Further structural information is obtained from the tin–carbon stretching modes for dimethyltin(IV) bisdifluorophosphate. The asymmetric Sn—C stretch at 603 cm^{-1} is found only in the infrared spectrum, and νSn—C sym at 535 cm^{-1} is found in the Raman spectrum only as a strong band. Similar band positions are found for $(CH_3)_2Sn(SO_3F)_2$ (1, 3), $(CH_3)_2Sn(SO_3CF_3)_2$ (1, 3), and $(CH_3)_2SnF_2$ (26). As for all these compounds, the validity of the mutual exclusion rule for $(CH_3)_2Sn(PO_2F_2)_2$ means that the molecule has a center of symmetry with the carbon–tin–carbon group in a linear or nearly linear arrangement.

The structural model most consistent with our observations is identical to the ones observed or suggested for the dimethyltin(IV) sulfonates (3, 7) and for $(CH_3)_2SnF_2$ (6): hexacoordination for tin with the methyl groups in *trans*-octahedral positions and the PO_2F_2 groups acting as bidentate bridging ligands, thus resulting in chain, or more likely, sheet-like polymers.

A monomeric model with bidentate chelating PO_2F_2 groups can not be ruled out on the basis of the vibrational spectra, but the observed high melting points and insolubility in non-polar solvents seem to favor a polymeric structure.

III. ^{119}*Sn Mössbauer Spectra*

The Mössbauer data listed in Table 4 support the general conclusion derived earlier that no structural change within any of the three series of oxyacid derivatives has occurred, when substituting CH_3 by C_2H_5, $n\text{-}C_3H_7$ and $n\text{-}C_4H_9$. This is not unexpected, since structural changes such as the breakdown of a polymeric structure and a change in the coordination number of tin caused by steric crowding will be more evident for triorganotin(IV) derivatives (9, 27, 28) where the C—Sn—C bond angles are expected to be between 109.5° and 120°.

For all compounds discussed here, a *trans*-octahedral coordination is evident from the quadrupole splitting values. For a distorted tetrahedral or *cis*-octahedral configuration, much smaller Δ values would be observed. Although the probable upper limits of Δ for the latter geometries are open to question (27, 29), the largest value yet recorded for a supposedly tetrahedral organotin(IV) compound is 3.06 mm s^{-1} (30) and *cis*-octahedral species show $\Delta < \sim 2.4$ mm s^{-1} (11). The expected bond angle for *trans*-octahedrally coordinated tin of 180° makes steric crowding less likely.

The oxyacid derivatives show at best only a weak room temperature resonance absorption, indicating stronger dependence of the recoilless fraction on temperature than is observed in many other organyltin(IV) polymers, *e.g.*,

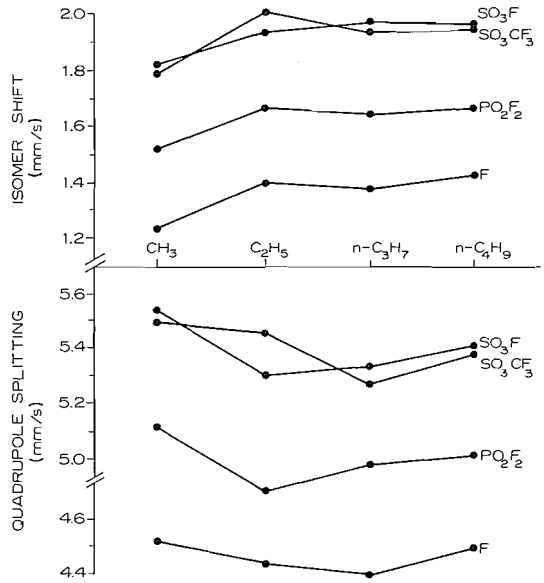

FIG. 2. Comparison of Mössbauer parameters of dialkyltin(IV) difluorides, bisdifluorophosphates, bisfluorosulfates, and bistrifluoromethylsulfonates.

$(CH_3)_2SnF_2$. (Since no effort was made to control carefully the absorber thickness, the R values in Table 4 are of semi-quantitative significance only.) There can be little question, however, that all the compounds are associated in the solid state and are essentially isostructural with $(CH_3)_2Sn(SO_3F)_2$ (7) and $(CH_3)_2SnF_2$ (6). It is of interest that whereas $(CH_3)_2SnF_2$ shows a strong anisotropy of the recoilless fraction (Gol'danskii–Karyagin effect) (31), no appreciable integral asymmetry of the quadrupole doublet lines was observed for any of the oxyacid derivatives. As illustrated by Fig. 2, the observed ^{119}Sn Mössbauer parameters show three rather interesting trends for both the dialkyltin(IV)oxyacid salts and the fluorides: (*1*) The numerical values for both δ and Δ decrease in the following order: $R_2Sn(SO_3F)_2 \approx R_2Sn(SO_3CF_3)_2 > R_2Sn(PO_2F_2) > R_2SnF_2$ for compounds with identical R; (*2*) The isomers shift values (δ) are found to increase from R = CH_3— to C_2H_5— and then stay relatively constant for R = n-C_3H_7— and n-C_4H_9— within each series; (*3*) The quadrupole splitting values (Δ) decrease from CH_3— to C_2H_5— within each series and again remain relatively constant for R = n-C_3H_7— and n-C_4H_9— even though here the pattern seems less regular than the one observed for δ.

The discussion will center mainly around these three points.

To explain the uncommonly high values of δ and Δ in $(CH_3)_2Sn(SO_3F)_2$ and $(CH_3)_2Sn(SO_3CF_3)_2$, we have proposed (3) a model involving essentially linear $(CH_3)_2Sn^{2+}$ cations interacting covalently with the SO_3X^- anions via rather weak polar 3-center–4-electron bonds, utilizing the p_x and p_y orbitals on tin.[2] This model, consistent with the results of the X-ray structure determination of $(CH_3)_2Sn(SO_3F)_2$ (7), and KSO_3F (22), is extensively discussed elsewhere (3) together with the effect on δ and Δ.

The decrease in both Mössbauer parameters in the series R_2SnX_2 with $X = PO_2F_2$, SO_3F, SO_3CF_3, and F, appears to be parallel to the decrease in acid strength of the parent acid, at least for the oxyacids. From conductivity studies in various protonic acids (32–34) the order $HSO_3F \approx HSO_3CF_3 > HPO_2F_2$ emerges, but for anhydrous HF while being a weaker acid than the two sulfuric acids, the position in respect to HPO_2F_2 is uncertain (34). It must be assumed that in $(CH_3)_2SnF_2$ appreciable charge density will remain in $5p_x$ and $5p_y$ on tin because F is monoatomic and electronic charge cannot be dissipated to the same extent that is possible for the oxyacid salts.

Substitution of CH_3— by C_2H_5— results as noted in increased isomer shifts. The observed value for $(C_2H_5)_2Sn(SO_3CF_3)_2$ is the highest reported value for any organotin(IV) derivatives (35), with the possible exception of some organotin(IV) transition metal compounds. Since no significant structural changes seem to occur, this increase can only be due to a decrease in electronegativities from CH_3 to C_2H_5. Reported values of group electronegativities (36) (CH_3 = 2.30 and C_2H_5 = 2.01) support this assumption, and other isostructural pairs of CH_3 and C_2H_5 organotin compounds show the same trend (35, 37). Since no significant change in δ occurs when going from C_2H_5 to n-C_3H_7 and n-C_4H_9 one can assume that the group electronegativities for these two groups will not be very different from the value for C_2H_5; however, no numerical values seem to be reported (36).

Whereas the trend in δ values within each series is therefore expected and certainly not unprecedented, the trend in Δ is somewhat

[2]The z-axis is assumed to coincide with the C—Sn—C bond axis.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

surprising. According to the bonding model presented here, increased electron donation into the $5sp_z$ hybrid orbital should also result in an even greater asymmetry of the electronic charge distribution between p_z and the pair p_x, p_y, thus increasing Δ. Moreover, the decrease in Taft's inductive constants, σ^* (38) from CH_3— to C_2H_5— leads one also to expect larger Δ values. From the observed trend for all four groups, it must be concluded that some of the additional electronic charge will go into the p_x and p_y orbitals on tin as well, thereby reducing the charge asymmetry. Previously reported Δ values for pairs of dimethyl- and diethyltin(IV) (or dibutyltin(IV) compounds, where far more data are published) show both increases and decreases in their Δ values when going from CH_3— to C_2H_5— (or *n*-C_4H_9—) (9–13, 35, 39); however, as pointed out before, these examples are not directly comparable because different structural types are encountered. The variations of Δ for different R within the four groups result in a slightly more irregular pattern than is observed for variations in δ, as mentioned before. This is not very surprising since the quadrupole splitting is far more sensitive to small distortions from ideal geometries than is the isomer shift. Such small distortions are evident from the reported crystal structure for $(CH_3)_2Sn(SO_3F)_2$ (7).

Finally it is interesting that a point-charge formalism (3, 11, 30) yields predicted quadrupole splitting values in excellent agreement with those observed. To calculate Δ values we have assumed a positive quadrupole coupling constant eQV_{zz} throughout, as found for $(CH_3)_2SnF_2$ (31). For *trans*-R_2SnX_4, $V_{zz} = 4[R] - 4[X]$, where [L] is the partial quadrupole splitting (p.q.s.) value for ligand L. We have previously derived (3) p.q.s. values for CH_3 (-0.93 mm s^{-1}) and SO_3CF_3 ($+0.45$ mm s^{-1}). These, with the above expression for V_{zz}, enable us to obtain p.q.s. values for C_2H_5, *n*-C_4H_9, PO_2F_2, and F from the observed splittings for compounds **2**–**4**, **9**, and **16**, respectively. Predicted Δ values for the remaining compounds are given in Table 4. Although based on a point-charge approach, the results in Table 4 are actually of much broader significance and show that the additivity condition, which is required in *any* general theory of Mössbauer quadrupole coupling constants (40), is closely followed by the present series of compounds.

Whether such subtle changes in the electron distribution around tin, responsible for the effects discussed above, can be detected by X-ray diffraction methods appears doubtful because the limits of error introduce considerable uncertainty.

Financial support by the National Research Council of Canada is gratefully acknowledged. We are also thankful to the 3M Company for a gift of $Ba(SO_3CF_3)_2$ and Mrs. B. Krizsan and Mrs. A. Sallos for technical assistance.

INDO Molecular Orbital Calculations on the Conformational Dependence of Long-range Spin–Spin Coupling of Methyl Protons in Toluene, *p*-Fluorotoluene, and the Xylenes

R. WASYLISHEN[1] AND T. SCHAEFER

Chemistry Department, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received December 29, 1971

The conformational dependence of the nuclear spin–spin coupling from methyl protons to ring protons, to the fluorine nucleus, and to protons of other methyl groups in toluene, *p*-fluorotoluene, and the xylenes is computed by the finite perturbation technique in the INDO approximation of molecular orbital theory. The calculated coupling over six bonds to the proton in the para position agrees quantitatively with experiment and its predicted dependence on the rotational angle of the methyl group supports a commonly assumed π electron mechanism for the transmission of spin information between the nuclei. Similar remarks apply to the fluorine nucleus in *p*-fluorotoluene. The couplings over five and four bonds to the protons in the meta and ortho positions display a more complex angular dependence and the former can be interpreted in terms of a dominant σ electron mechanism. The coupling between protons in different methyl groups in the ortho and meta xylenes is calculated as rather larger than the values observed in their derivatives and in the main shows the behavior expected from a π electron mechanism. Those conformations of ortho xylene in which the coupled protons are in close proximity yield computed values plausibly attributable to "direct" and/or "through-space" mechanisms. The preferred conformation of the methyl group in toluene is predicted to have a C—H bond eclipsing the plane of the aromatic ring and the calculated barriers to rotation of 0.013 kcal/mol in toluene and of 0.014 kcal/mol in *p*-fluorotoluene are in quantitative accord with microwave data.

Nous avons compilé la dépendance conformationnelle du couplage nucléaire spin–spin des protons méthyle aux protons du cycle, aux noyaux de fluor, et aux protons des autres groupes méthyle dans le toluène, le *p*-fluorotoluène, et les xylènes, par la technique de perturbation finie dans l'approximation INDO de la théorie des orbitales moléculaires. Le couplage calculé de six liens au proton en position para concorde quantitativement avec l'expérience et sa dépendance prédite sur l'angle de rotation du groupe méthyle supporte un mécanisme d'électron π qu'on suppose communément pour la transmission d'information de spin entre les noyaux. On peut appliquer les mêmes remarques dans le cas du noyau de fluor dans le *p*-fluorotoluène. Les couplages au travers de cinq et quatre liaisons à partir des protons en position méta et ortho occasionnent une dépendance angulaire plus complexe et le premier cas peut être interprété en termes d'un mécanisme à électron sigma (σ) dominant. Nous avons calculé que le couplage entre les protons des différents groupes méthyle des xylènes ortho et méta est plus grand que les valeurs observées chez leurs dérivés et le principal d'entre eux possède le comportement qui laisserait soupçonner un mécanisme d'électron π. Les conformations de l'ortho-xylène pour lequel les protons couplés sont rapprochés nous amènent à des valeurs compilées qu'on pourrait vraisemblablement attribuer à des mécanismes "directs" et/ou "à travers l'espace". Nous prédisons que la conformation la plus favorable du groupe méthyle dans le toluène possède une liaison C—H éclipsant le plan du noyau aromatique et les barrières à la rotation calculées de 0.013 kcal/mol dans le toluène et de 0.014 kcal/mol dans le *p*-fluorotoluène sont en accord quantitatif avec les résultats venant des microondes.

Canadian Journal of Chemistry, **50**, 1852 (1972)

Introduction

The "methyl group replacement" technique (1, 2) is often used (2–7) in estimating the π electron contribution to spin–spin coupling constants between protons and protons or other nuclei in conjugated systems. It is based on the idea (2), derived from arguments about proton–electron hyperfine coupling in organic radicals, that a replacement of a hydrogen atom in a C—H bond by a methyl group (under conditions where approximately free rotation of the methyl group occurs) yields a new coupling constant of the same magnitude as, but of different sign to, the original coupling of the replaced proton. This will be roughly true if a π electron mechanism operates to the exclusion of a σ electron mechanism of coupling. For example, in toluene the coupling over six bonds between the methyl protons and the para ring proton, ${}^6J_p^{H,CH_3}$ is 0.62 ± 0.02 Hz (8) while it is 0.62 ± 0.03 Hz in a derivative of *p*-xylene (6).

Such a result is encouraging but extension to the coupling between methyl and ring protons over four and five bonds is problematical in that

a σ electron contribution is now more difficult to exclude on theoretical grounds (9–11). Another view (8) holds that the ring–methyl proton coupling constants are transmitted by a mechanism independent of that operating to couple the ring protons themselves. This view is based on the fact that coupling between ring protons is markedly substituent dependent while this is not true of the ring–methyl proton couplings. It is then held that the methyl–ring couplings are propagated by a π electron mechanism.

The general success of the INDO molecular orbital calculations of nuclear spin–spin coupling constants (12–15), particularly in reproducing the observed substituent dependence of ring proton couplings in monosubstituted benzenes (15), encourages their extension to ring–methyl proton couplings in toluene and to the fluorine–methyl proton coupling in *p*-fluorotoluene for which accurate experimental data (7, 8) are available. Experimental methyl–methyl proton couplings are also known for derivatives of the xylenes (6). In this paper such couplings are computed as a function of the rotational angle of the methyl group with the intention of elucidating to some extent the mechanism of coupling and in the hope of their use in future conformational studies by n.m.r.

The discussion takes the view that computed numbers shall be related as closely as possible to the common concepts of the experimentalist, such as the separability of σ and π electron systems, conjugation, hyperconjugation and the like; which are used, for example, in the interpretation of chemical shifts, intensities of i.r. spectra of benzene derivatives, and of nuclear quadrupole frequencies (16). The INDO formulation, of course, treats all valence electrons on an equal footing but this is not to say that the semiquantitative concepts are no longer necessary or at least useful.

Computational Procedure

(1) Toluene and p-Fluorotoluene

Standard geometrics (17, 18) are used to calculate atomic coordinates. The finite perturbation method (12, 18) at the INDO level of approximation (18, 19) is employed with the convergence requirement that for all i

$$[1] \qquad 10^{-5} \leqslant (\rho_{ii}^{\text{old}} - \rho_{ii}^{\text{new}})/\rho_{ii}^{\text{old}}$$

where ρ_{ii} are diagonal elements of the spin density matrix. Such a criterion allows an estimate of the error in the computed coupling constant, J_{AB}, because J_{AB} is directly proportional to ρ_{AA}/h or ρ_{BB}/h depending on whether nucleus A or B is perturbing, h being the perturbation parameter. For example, in the parameterization given by Pople and Beveridge (18) one has

$$[2] \qquad J_{H,H} = 105.0447246\ \rho_{H,H}/h$$

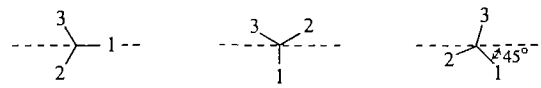
Consider the error in a calculated coupling of 1 Hz. Then since h is 10^{-3} one has $\rho_{H,H} \sim 10^{-5}$ and eq. 1 becomes

$$[3] \qquad 10^{-10} \leqslant \rho_{ii}^{\text{old}} - \rho_{ii}^{\text{new}}$$

Therefore ρ_{ii} is not changing by more than 10^{-10} in one SCF cycle and the change in $J_{H,H}$ is less than 0.0000105 Hz in that cycle.

When convergence is not reached in 90 SCF cycles, 100 cycles are carried out and the coupling constants are usually not changing by more than 10^{-3} Hz per cycle at that stage. It is felt that the present convergence criterion is more stringent (but also more costly) than one using all elements of the spin density matrices.

All coupling constants are computed in Hz for the conformations **1**, **2**, and **3** of the methyl group



1 **2** **3**

(the dashed lines representing the plane of the aromatic ring). The method can be checked by computing all coupling constants to one of the ring protons situated ortho to the methyl group. Satisfactory agreement with literature values is found (15).

In Table 1 the coupling constants are given as a function of the angle θ, defined as the $H_1C_4C_5C_6$ dihedral angle in **4***a* and *b*.

*The couplings to the ring protons over four and five bonds can be compared to those in Table 1 for $\theta = 90°$. The plane of the aromatic ring lies perpendicular to the plane of the paper and is indicated by dashed lines in **5**, **6**, and **7**.

(2) The Xylenes

Again, standard geometries are employed but the convergence parameter in eq. 1 is changed from 10^{-5} to 10^{-4}. Because of computational costs the coupling constants are calculated for a limited number of conformations, given in Tables 2–5. All computations were performed on an IBM 360/65 computer.

Results and Discussion

The computed couplings in Tables 1–5 are quoted to three decimal places in accord with the convergence criteria; experimental values are known to a precision of a few hundredths of a Hz. Note that there are checks on the internal consistency of the calculations; thus conformations **5** and **6** in Table 2 should and do show almost identical couplings from H_1 to the ring protons, H_4, H_5, and H_6. Similar checks can be found in the other tables.

Note also that a second methyl group does not appreciably change the magnitude of the ring–methyl proton couplings: compare, for example, Tables 1 and 2. This result may be in part due to the use of standard geometries but is also consistent with the observed insensitivity

(3, 6, 8, 20, 21) of the ring–methyl proton coupling constants to substituent effects.

(1) Ring–Methyl Proton Couplings in Terms of a π Electron Mechanism

By analogy to the McConnell–Heller equation (22) for the hyperfine interaction of methyl protons with the unpaired spin density in the π orbital of the contiguous carbon atom in the conjugated system, a π electron mechanism for the ring-methyl proton coupling suggests that the coupling may be written as

$$J = J_0 + J_1 \sin^2 \theta \qquad [4]$$

The angle θ is defined in **4** and J_0 is presumably small compared to J_1. Therefore J has its largest magnitude when the C—H bond of the methyl group containing the coupled proton lies in a plane perpendicular to the aromatic ring. For

*The C—H_1 and C—H_4 bonds lie in the plane of the aromatic ring in each of **11**, **12**, and **13**.

free rotation of the methyl group one has $\langle \sin^2\theta \rangle = 1/2$, a good assumption for toluene (and by implication for meta and para xylene) in which the barrier to rotation of the methyl group is 0.014 kcal/mol in the gas phase (23). J_1 is known from the computed value of J at $\theta = 90°$ (J_0 small).

(a) Toluene and p-Xylene

Considering now ${}^6J_p^{H,CH_3}$ one has from Table 1 that its average value is $-1.22/2 = -0.61$ Hz, in excellent agreement with the known value of -0.62 Hz (8). Alternatively, $\langle {}^6J_p^{H,CH_3} \rangle = \{-1.219 - (-0.075)\}/2 - 0.075 = -0.65$ Hz if one assumes that -0.075 Hz ($\theta = 0°$) corresponds to a J_0 term in eq. 4, present at all angles θ. Note also that the computed values of ${}^6J_p^{H,CH_3}$ in Table 1 quite closely obey a $\sin^2\theta$ dependence.

It follows that in *p*-xylene (Table 2) the coupling between the protons in the two different methyl groups should be $\langle {}^7J^{CH_3,CH_3} \rangle = 0.25(2.881 + 2.914)/2 = 0.72$ Hz where the mean is taken of the computed values at $\theta = 90°$ for conformations **5** and **6**. Or, in terms of a J_0 term, $\langle {}^7J^{CH_3,CH_3} \rangle = 0.25(2.898 - 0.141) + 0.140 = 0.83$ Hz (note that $0.141 \sim 2|0.075|$). The experimental value in *p*-xylene itself is unknown but in a *p*-xylene derivative it is 0.62 ± 0.03 Hz (6).

(b) Toluene and m-Xylene and o-Xylene

From the values of ${}^4J_o^{H,CH_3}$ and ${}^5J_m^{H,CH_3}$ for toluene in Table 1 it is likely that the computations are not in agreement with a sole π mechanism for these couplings. Each should then have equal magnitudes at $\theta = 0°$ and 180°, they do not, and they should have a maximum magnitude at $\theta = 90°$, but ${}^5J_m^{H,CH_3}$ has a maximum near 120°.

Nevertheless, application of the same argument as for *p*-xylene yields $\langle {}^5J_m^{H,CH_3} \rangle = 0.889/2 = 0.45$ Hz (Table 1) and $\langle {}^6J_m^{CH_3,CH_3} \rangle = -1.931/4 = -0.48$ Hz for *m*-xylene (Table 3). Similarly, $\langle {}^4J_o^{H,CH_3} \rangle = -1.467/2 = -0.73$ Hz (Table 1) and $\langle {}^5J_o^{CH_3,CH_3} \rangle = 2.720/4 = 0.68$ Hz for *o*-xylene (Table 4). These numbers compare with ${}^4J_o^{H,CH_3} = -0.75$ and ${}^5J_m^{H,CH_3} = 0.36$ Hz observed in toluene (8) and ${}^5J_o^{CH_3,CH_3} = 0.40$ and ${}^6J_m^{CH_3,CH_3} = -0.19$ Hz found in xylene derivatives (6).

One may conclude that on the basis of the "methyl group replacement" model and taking only those conformations where $\theta = 90°$, the computations imply a π electron mechanism for the ring–methyl proton couplings insofar[2] as $-\langle {}^4J_o^{H,CH_3} \rangle \sim \langle {}^5J_o^{CH_3,CH_3} \rangle$ and $-\langle {}^5J_m^{H,CH_3} \rangle \sim \langle {}^6J_m^{CH_3,CH_3} \rangle$, remembering that these averages are obtained by taking $\langle \sin^2\theta \rangle = 1/2$. The experimental data, on the other hand, imply that only a fraction of ${}^4J_o^{H,CH_3}$ and ${}^5J_m^{H,CH_3}$ are accounted for by a π mechanism.

[2]Valence bond studies (11), when calibrated on the experimental value of ${}^6J_p^{H,CH_3}$ in toluene, give precisely these equalities for a π electron mechanism.

One may now find the mean values over θ of the ring–methyl coupling constants in Table 1, a reasonable approximation to the true mean because numbers are given at 15° intervals. In this way one finds $^6J_p^{H,CH_3} = -0.64$, $^5J_m^{H,CH_3} = 0.69$, and $^4J_o^{H,CH_3} = 0.92$ Hz. Comparison of these close approximations to the true calculated mean with those obtained from $\theta = 90°$ indicates agreement of the computations with a sole π electron mechanism for $^6J_p^{H,CH_3}$ but disagreement for the other two couplings. It also suggests that the computed approximate equalities in the magnitudes of the ring–methyl and methyl–methyl proton couplings ($\theta = 90°$) is fortuitous for *o*-xylene and *m*-xylene. The observed values of the methyl–methyl proton couplings also imply as much. The matter is discussed further in sections 2 and 3.

(c) Ratio of Q_{CH} and Q_{CCH} from $^6J_p^{H,CH_3}$ and $^7J_p^{CH_3,CH_3}$

The McConnell formulation of π electron coupling between ring and methyl protons predicts that (24, 25)

$$[5] \qquad J^{\pi} \propto Q_{CH}Q_{CCH}$$

where Q_{CH} and Q_{CCH} are isotropic hyperfine coupling constants corresponding to the interaction between a π electron in carbon atomic orbital and the ring and methyl protons, respectively. If $^6J_p^{H,CH_3}$ and $^7J_p^{CH_3,CH_3}$ are dominated by π electron propagation of spin information then one may write

$$Q_{CH}/Q_{CCH} = (^6J_p^{H,CH_3}/^7J_p^{CH_3,CH_3})_{\theta=90°} = -1.219/1.449 = -0.84$$

from the computations in Tables 1 and 2 and as

$$Q_{CH}/Q_{CCH} = {}^6J_p^{H,CH_3}/{}^7J_p^{CH_3,CH_3} = -0.62/0.62 = -1.0$$

from experimental coupling. The e.s.r. data (26–29) suggest the former ratio as more reasonable, however. INDO methods are markedly successful in calculating unpaired spin distributions in free radicals (30). Of course, the ratios above assume the invariance of other parameters like mobile bond order to the insertion of a second methyl group into toluene.

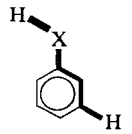
(d) Methyl Proton Couplings in p-Fluorotoluene

An inappreciable substituent effect on $^4J_o^{H,CH_3}$ and $^4J_m^{H,CH_3}$ may be inferred from the computed values in Table 1 and these parameters are indeed equal to within experimental error in toluene (8) and *p*-fluorotoluene (7).

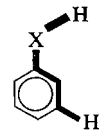
The mean value of $^6J_p^{F,CH_3}$ is 0.94 Hz in Table 1 while a π mechanism ($\theta = 90°$) yields $1.872/2 = 0.94$ Hz, hence in correspondence with such a mechanism. The experimental value is 1.15 ± 0.02 Hz (7). As the theory takes into account only the contact contribution to spin–spin coupling, the close agreement between experiments and theory suggests a minor contribution from magnetic dipole–dipole and orbital–dipole interactions between electron and nucleus.

(2) Angular Dependence of $^5J_m^{H,CH_3}$

Available experimental evidence (31–36) indicates that a proton on a sidechain, *e.g.*, an amino, hydroxyl, or aldehydic group, couples by 0.5–0.8 Hz over five bonds to a ring proton when $\theta = 180°$ as in **15***a* but does not couple by more than 0.1 Hz when $\theta = 0°$ as in **15***b*. For the

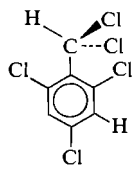


15*a* ($\theta = 180°$)

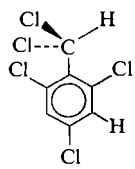


15*b* ($\theta = 0°$)

methyl group itself no direct evidence is available, of course, but in **16**, $^5J_m^{H,H}$ is 0.5–0.6 Hz while in **17**, $^5J_m^{H,H}$ is less than 0.1 Hz (37, 38).



16



17

$^5J_m^{H,CH_3}$ in Table 1 is computed as 0.234 Hz when $\theta = 0°$, suggesting an overestimate of about 0.2 Hz. A similar situation is found for benzaldehyde (36) where $^5J_m^{H,CHO}$ is calculated to be 0.20 Hz when $\theta = 0°$. Subtraction of 0.234 Hz from the computed value at $\theta = 180°$ yields 0.597 Hz, in better agreement with what is known experimentally. Subtraction of 0.234 Hz from each of the values of $^5J_m^{H,CH_3}$ in Table 1 yields a mean coupling of 0.46 Hz considerably closer to the experimental value of 0.36 Hz than

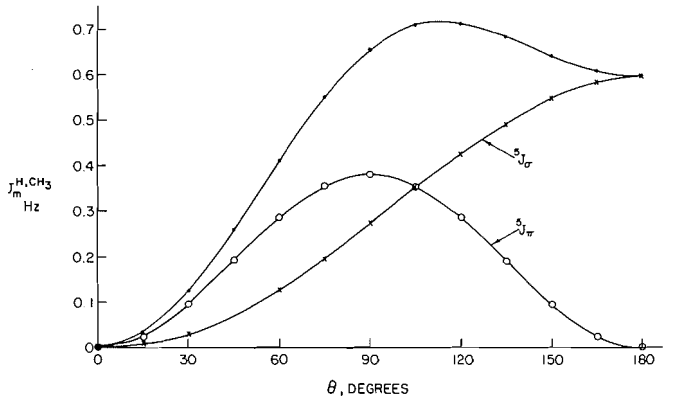


FIG. 1. The coupling over five bonds between ring and methyl protons in toluene $^5J_m^{H,CH_3}$, as adjusted by the procedure described in section 2 of the text, is plotted as closed circles *vs.* the dihedral angle θ defined in **4***a* and *b* of the text. The open circles give the π electron contribution to $^5J_m^{H,CH_3}$ as estimated in the text. The crosses give the resultant σ electron contribution to the coupling.

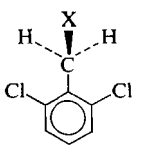
the mean of 0.69 Hz found without the subtraction.

These considerations allow a reasonable if somewhat arbitrary estimate of the actual angular dependence of $^5J_m^{H,CH_3}$ and, by implication, of the analogous coupling for protons on other sidechains. In Fig. 1 the empirically adjusted $^5J_m^{H,CH_3}$ numbers are plotted as a function of θ (closed circles) and it is clear that about 70% of the mean value of the coupling is accounted for by the region between 90 and 180° (this is also true, of course, for the unadjusted numbers). A reasonable check of the plot in Fig. 1 is available from data (39) on **18**, where $^5J_m^{H,CH_2X}$ is almost independent of the nature of



18

X and has a value of 0.35 Hz, the same as in toluene. From Fig. 1 the predicted value of 0.39 Hz is extracted, the average of $^5J_m^{H,CH_3}$ at $\theta = 30$ and 150°, to which the experimental value in **18** corresponds.

The shape of the plot in Fig. 1 is compatible with π mechanism ($\sin^2\theta$ curve) superimposed on a σ mechanism. An attempt at decomposing this plot into those of the two mechanisms could be undertaken by use of the data in Table 3 on $^6J_m^{CH_3,CH_3}$ were it not for the high probability that they would yield an overestimate of the π contribution (see section 1*b*). Consequently we take the experimental value of $^6J_m^{CH_3,CH_3} = -0.19$ Hz in an *m*-xylene derivative (6) and write $^5J_\pi^{H,CH_3} = 0.38 \sin^2\theta$. This function is plotted in Fig. 1 as open circles. The σ electron dependence of the coupling is obtained by difference as the plot consisting of crosses. Its period is twice that of the π dependence and it quite closely follows a $\sin^2(\theta/2)$ function. Such a dependence has not been predicted for coupling over five bonds in saturated systems (10).

(3) Angular Dependence of $^6J_m^{CH_3,CH_3}$

The computed coupling over six bonds between methyl protons in *m*-xylene is dominated by a π electron mechanism (Table 3) as can be seen from its θ dependence. Thus $^6J_m^{CH_3,CH_3} = -0.585$ Hz when $\theta_1 = 90$ and $\theta_2 = 30°$ for the two methyl groups. Therefore $4 \times 0.585 = -2.340$ Hz, not much larger than the -1.931 Hz for consistency with a π mechanism; the latter representing 80% of the former. Apparently theory overestimates the magnitude of the coupling substantially but qualitatively agrees with the "methyl group replacement" model.

(4) Angular Dependence of $^4J_o^{H,CH_3}$

Although in contrast to $^5J_m^{H,CH_3}$ the computed magnitude of $^4J_o^{H,CH_3}$ reaches a maximum at $\theta = 90°$ and although $-1.47/2 = -0.73$ Hz coincides with the measured datum in toluene, the substantial and different magnitudes at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

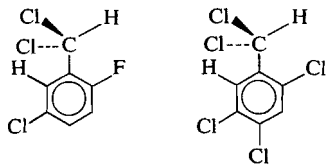
$\theta = 0$ and 180° again indicate that a π mechanism is modified by a σ electron contribution; albeit to a lesser extent than for $^5J_m^{H,CH_3}$. The mean value for $^4J_o^{H,CH_3}$ of -0.92 Hz in Table 1 can be brought into agreement with the observed value of 0.75 Hz by subtraction of -0.17 Hz from each calculated value. This may well be a reasonable procedure but there exists no unequivocal experimental data with which to test the computed values at $\theta = 0$ and 180°. The only data are for **19** and **20** where $^4J_o^{H,CHCl_2}$ is -0.4 Hz



19 **20**

(40), corresponding to $\theta = 180°$ and consistent with a subtraction of -0.17 Hz from the computed value. However, there probably exists an appreciable substituent effect from the chlorine atoms on the sidechain. In addition there probably occurs an appreciable torsional oscillation of the dichloromethyl group about the indicated conformation.

In any event the σ electron contribution to $^4J_o^{H,CH_3}$ is apparently negative at all angles θ but its numerical angular dependence depends on whether one takes the π contribution as $-2.720/2 = -1.36$ Hz from $\theta = 90°$ (*o*-xylene in Table 4) or as $-0.40 \times 2 = -0.80$ Hz from $\theta = 90°$ using the measured value of $^5J_o^{CH_3,CH_3}$ in an *o*-xylene derivative. One objection to these estimates recognizes the possibility of a significant σ contribution to the methyl–methyl proton coupling over five bonds, as implied by four different values of the computed coupling between H_1 and H_5 or H_6 in Table 4, ranging from 0.70–0.93 Hz. These couplings should be nearly equal in the event of a π mechanism, as is found in Table 3 for $^6J_m^{CH_3,CH_3}$. Another objection to the estimates cites an appreciable barrier of 2 kcal/mol to rotation of the methyl group (41) in *o*-xylene; arising from mutual hindrance of the two groups and thereby vitiating a simple averaging procedure based on free rotation.

It therefore appears unwise to attempt a numerical separation into σ and π mechanisms in the manner undertaken above for $^5J_m^{H,CH_3}$. One may note, however, that the computed curve implies a dominant π mechanism and, when adjusted by subtraction of -0.17 Hz from each value, predicts significant couplings for $\theta = 0$ and 180°. This contrasts with $^6J_p^{H,CH_3}$ and implies that a π mechanism operating by spin polarization, *i.e.*, along the H—C—C fragment and then into the π system by a one-center two electron exchange interaction, is unimportant for nuclear spin–spin coupling in toluene derivatives. The hyperconjugative π electron mechanism, involving interaction of the C—H bond of the methyl group with the π system and obeying a $\sin^2\theta$ relationship, is therefore implied by the INDO formulation. In consequence the computed values of $^4J_o^{H,CH_3}$ values at $\theta = 0$ and 180° may be accepted as σ electron effects.

(5) Comparison of the Computed $^4J_o^{H,CH_3}$ in Toluene and Propene

It is interesting to compare $^4J_o^{H,CH_3}$ in toluene in Table 1, with the analogous *cisoid* allylic coupling in propene, recently computed in the INDO approximation (42). Both couplings display a maximum magnitude at $\theta = 90°$ but the asymmetry about $\theta = 90°$ in propene is the reverse of that in toluene (Table 4 and Fig. 4 of ref. 42) in that the magnitude at $\theta = 0°$ is larger than at $\theta = 180°$ for propene. In addition the allylic coupling in propene is calculated to be larger in magnitude at all angles than is $^4J_o^{H,CH_3}$ in toluene, confirming the valence bond results (43) which characterize the aromatic π electron system as less effective than a linear polyene in transmitting spin information; as found experimentally (8, 44).

(6) Coupling Mechanism of $^5J_o^{CH_3,CH_3}$ in o-Xylene

In addition to the propagation of coupling via some or all of the intervening bonds, the close proximity of two methyl protons in some conceivable conformations of *o*-xylene can lead to "direct" interactions in the sense that *only* the two C—H bonds containing the coupled protons are involved. Normally such interactions are important in coupling over two or three bonds (10). If the proximity is high enough a "through-space" mechanism, proportional to an interaction integral between the two hydrogen 1s orbitals, also becomes possible (10). These two mechanisms need not be considered in the other compounds of this paper and they introduce a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

further complication into the use of $^5J_o^{CH_3,CH_3}$ as a measure of the π electron contribution to $^4J_o^{H,CH_3}$.

Consequently three other conformations of *o*-xylene, shown in Table 5, were examined in the hope of elucidating the matter. In each of **12**, **13**, and **14**, two of the methyl protons (H_1 and H_4) lie in the plane of the aromatic ring and the coupling is computed between two protons on one methyl group and the three protons on the other group. For symmetry reasons this yields six couplings for each conformation. The striking points about the computed couplings in **10** to **14** are that (*i*) they have a maximum when the C—H bonds containing the coupled protons lie in planes perpendicular to the ring, *e.g.*, 2.7 Hz in **10** and **11**; (*ii*) they have a minimum and are often almost zero when one or both of the coupled protons are situated in the ring plane, *e.g.*, J^{H_1,H_5} is 0.1 Hz in **12** to **14** and J^{H_1,H_4} is 0.1 Hz in **14**; but (*iii*) they may also be negative when both coupled protons lie in the aromatic plane or if they are spatially proximate, e.g., J^{H_2,H_6} is -0.2 Hz in **10** and **11**, J^{H_2,H_4} is -0.3 Hz in **12**; (*iv*) the most negative coupling occurs when the coupled protons are nearest one another, viz., J^{H_1,H_4} is -0.7 Hz in **13**.

Now the π mechanism does not operate if one of the coupled protons is coplanar with the ring. By analogy with the available valence bond formulation for a saturated hydrocarbon (10) a maximum positive σ contribution to the coupling between H_1 and H_4 is expected in **14**, the magnitude evidently being independent of the dihedral angle about the aromatic C—C bond (10). Yet J^{H_1,H_4} is computed as only 0.06 Hz in **14**. Therefore the observed negative couplings can probably be attributed to the "direct" and/or the "through-space" mechanism.[3] Their actual magnitude in *o*-xylene remains in doubt because unknown and unconsidered distortion of the molecule could in fact bend the methyl groups significantly away from a regular geometry.

[3]An exception may be the coupling of -0.4 Hz between H_1 and H_4 in **12** where the C—H_4 bond might interact with C—H_3 and C—H_2. As a point of interest, INDO calculations in which we bring a hydrogen or methane molecule to within van der Waals distances of a methane molecule predict negative couplings between protons in different molecules and imply that there two mechanisms yield negative couplings, at least for some configurations.

In general the computed couplings in Tables 4 and 5 support the dominance of the π mechanism in the methyl–methyl couplings in *o*-xylene (points *i* and *ii*), but in any event overestimate their magnitude. Thus the average of 45 values known from the calculations is 0.75 Hz whereas the observed value is 0.40 Hz in a derivative of *o*-xylene.

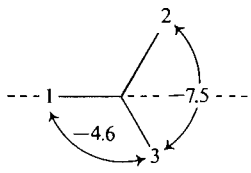
There remains the question whether such a simple averaging procedure is justified for *o*-xylene. Hot bands in the u.v. spectrum of *o*-xylene (41), heat capacities in the gas phase (45), neutron scattering results (46), far i.r. spectra (47*a*), and carbon-13 spin relaxation times (47*b*) agree in finding a barrier of 2 kcal/mol to rotation of the methyl group. The equilibrium structure is not known although **14** is assumed in the u.v. work. According to INDO the most stable of the five conformations, **10** to **14**, is indeed **14**, being more stable than **12** by 0.9 kcal/mol and more stable than **10** and **11** by 1.1 kcal/mol; while conformation **13** is less stable than **14** by 4.8 kcal/mol. At room temperature **14** is therefore weighted about 4 to 1 relative to **10**, **11**, or **12** while **13** need not be considered, probably because of strong nonbonded repulsion between H_1 and H_4. Perusal of the data in Tables 4 and 5, however, demonstrates that this weighing procedure will not change the computed $^5J_o^{CH_3,CH_3}$ appreciably from that obtained by a simple average. Even if **14** is more stable than all other conformations by 2 kcal/mol this conclusion stands.

(7) Barrier to Methyl Group Rotation in Toluene

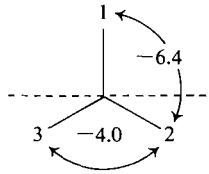
The present calculations predict that **1** is lower in energy than **2** by 0.013 kcal/mol and that **3** is of intermediate stability. The experimental barrier is 0.014 kcal/mol (23). For *p*-fluorotoluene the calculations similarly give 0.0138 kcal/mol in exact agreement with the experimental barrier (48). The chemical shifts of the alkyl protons in a series of alkylarenes are best interpreted in terms of a preferred conformation in which a C—H bond of the side-chain eclipses the aromatic plane, in qualitative agreement with the INDO predictions (49).

(8) Geminal Couplings between Methyl Protons, $^2J_g^{H,H}$

The experimental value of $J_g^{H,H}$ in methane is -12.4 Hz (50) while INDO calculates -6.13



21



22

Hz (18). In toluene $J_g^{H,H}$ is expected to depend on the conformation of the molecule (51). Present calculations are summarized in **21** and **22** where the dashed lines indicate the plane of the ring and for example, $J^{H_2H_3}$ is -7.5 Hz in **21**. Relative to methane a positive shift in the calculated J_g occurs when the line joining the coupled protons is parallel to the ring plane or when one of the coupled protons lies in this plane. A negative shift occurs when the joining line is perpendicular to the ring plane or when one of the C—H bonds containing the proton lies in a plane perpendicular to the ring. Experimental data (52) suggest that the observed negative shift in J_g in the presence of a π system is largest when the joining line is perpendicular to the ring plane, qualitatively bearing out the calculated value of -7.5 Hz in **21**.

In terms of an earlier molecular orbital theory (51) the negative shift in J_g arises from hyperconjugative withdrawal of electrons from the methyl group by the aromatic nucleus. The INDO calculations predict that the charge in the hydrogen orbital of the C—H bond of the methyl group decreases by 0.01 electron units (from -0.024 to -0.013 units) as θ goes from 0 to 90°; this change accurately following a $\sin^2\theta$ dependence and in agreement with a hyperconjugative effect. The earlier theory is not in qualitative agreement with the calculated coupling of -4.6 Hz between H_1 and H_3 in **21** because it predicts a negative shift from the methane value when one proton is situated in the ring plane. On the other hand, the earlier theory agrees with the positive shift calculated for the coupling between H_2 and H_3 in **22**.

Summary and Conclusions

The calculations by molecular orbital theory in the INDO approximation are in quantitative agreement with experiment for $^6J_p^{H,CH_3}$ in toluene and are in accord with a π mechanism for the propagation of the spin information; similarly for $^6J_p^{F,CH_3}$ in *p*-fluorotoluene. The calculations for $^5J_m^{H,CH_3}$ can be interpreted in terms of a predominant σ electron mechanism which, however, apparently makes a much smaller relative contribution to the calculated $^4J_o^{H,CH_3}$.

The calculated methyl–methyl proton couplings in the xylenes are dominated by a π electron mechanism but are rather larger in magnitude than the observed values in xylene derivatives. The computations indicate the likelihood of negative values for $^5J_o^{CH_3,CH_3}$, caused by "direct" or even "through space" mechanisms, in conformations where the coupled protons are in close proximity.

An earlier molecular orbital theory of the conformational dependence of geminal proton coupling in the methyl group of toluene is in rough qualitative agreement with the INDO formulation.

The calculated barriers to rotation of the methyl group in toluene and *p*-fluorotoluene are in quantitative accord with experiment. The preferred conformation is one in which a C—H bond of the methyl group eclipses the plane of the aromatic nucleus.

Proton Magnetic Resonance Spectrum of 1-Penten-3-yne. INDO and CNDO/2 Molecular Orbital Calculations on Long-Range Spin–Spin Coupling Constants in Enynes

L. ERNST,[1] H. M. HUTTON,[2] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received January 11, 1972

The high resolution p.m.r. spectra of 1-penten-3-yne in carbon disulfide and in benzene solution are analyzed. Long-range spin–spin coupling constants are discussed in terms of σ and π electron contributions. Comparisons are made with the isomeric 2-methyl-1-buten-3-yne and the parent compound, vinylacetylene. The results of INDO and CNDO/2 molecular orbital calculations are compared to the experimental coupling constants. It is concluded that the π electron contribution to ^5J in enyne systems is $+0.6$ to 0.7 Hz and that σ electron contributions are rather small, the *transoid* ("pseudo-zig–zag") being larger than the *cisoid* one. Observed allylic coupling constants in the propene derivative are compared with the calculated values, including those for propene and 2-cyanopropene, available in the literature.

Nous avons analysé le spectre à haute résolution de r.m.p. du 1-pentène-3-yne en solution dans le disulfure de carbone et dans le benzène. Nous avons discuté des constantes de couplage à longue distance spin–spin en termes de contributions électroniques σ et π. Nous avons fait la comparaison entre l'isomère 2-méthyl-1 butène-3-yne et le composé voisin vinylacétylène. Nous avons comparé les résultats des calculs d'orbitales moléculaires INDO et CNDO/2 aux constantes de couplage expérimentales. Nous concluons que la contribution de l'électron π à ^5J dans les systèmes enyne est de $+0.6$ à 0.7 Hz et que les contributions de l'électron σ sont plutôt petites, la *transoide* ("pseudo-zig–zag") étant plus grande que la *cisoide*. Nous comparons aussi les constantes de couplage allyliques observées pour le dérivé du propène aux valeurs calculées, incluant celles pour le propène et le 2-cyanopropène, qu'on peut d'ailleurs retrouver dans la littérature.

Canadian Journal of Chemistry, **50**, 1863 (1972)

Introduction

In view of the current interest in the mechanism of long-range spin–spin coupling in both aromatic (1–4) and nonaromatic (5–9) compounds, we analyze the p.m.r. spectrum of 1-penten-3-yne (**1**) to get further information on σ and π electron contributions to long-range couplings in enyne systems. Whereas considerable work has been done on diene systems (5–10), this seems to be less so for the enyne case (11–14). Encouraged by recent successful applications of INDO molecular orbital methods to calculations of long-range coupling constants (2, 3, 15), we apply them to some of the compounds which are relevant to the present study.

Experimental

1-Penten-3-yne was obtained from K & K Laboratories and used without further purification. A 5 mol % solution in carbon disulfide and a 10 mol % solution in benzene were prepared, both containing a small quantity of tetramethylsilane (TMS) as internal reference and locking substance. The samples were degassed by the usual freeze–pump–thaw technique. The p.m.r. spectra were taken on a Varian HA-100 D spectrometer operating in the frequency sweep mode at a probe temperature of 30 ± 1 °C. Sweep rates were 0.01 or 0.02 Hz/s. Peak positions were calibrated four times at intervals of less than 5 Hz using a Hewlett–Packard 5323A frequency counter. The resolution obtained was 0.11 Hz. Spin tickling experiments (16) were performed on the CS_2 solution, yielding the relative signs of the coupling constants. These experiments were straightforward since all multiplets had line separations exceeding 0.5 Hz, thus easily permitting the irradiation of certain lines without affecting neighboring ones. The spectra were analyzed using the iterative computer program LAME (17) on the IBM/360-65 computer of the University of Manitoba. The spectra were of the $ABCX_3$ type with the one in CS_2 solution somewhat more tightly coupled due to the smaller range of chemical shifts.

Results and Discussion

(1) Analysis of Proton Magnetic Resonance Spectra

The spectral parameters for **1** obtained in the iterative calculations are given in Table 1. Of the 113 calculated transitions, 95 were assigned for the benzene solution; for the CS_2 solution the corresponding figures are 115 and 92. The r.m.s. deviations between observed and calculated frequencies were 0.0200 Hz for the CS_2 solution

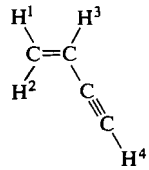
1

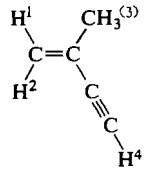
and 0.0203 Hz for the benzene solution. There are small differences between the coupling constants measured for **1** in benzene and the corresponding values in CS_2 solution. Although these differences are mostly somewhat larger than the calculated standard deviations they are probably not significant as they are smaller than the accuracy to which the line positions can be measured using a ruler. As analyses for the different solutions were carried out independently, the two sets of coupling constants indicate their reliability.

(2) Couplings via the Triple Bond

The long-range couplings[3] from the methyl group to the olefinic protons ${}^6J'_t(1,4) = -0.56$, ${}^6J'_c(2,4) = -0.72$, and ${}^5J'(3,4) = 2.31$ Hz may be compared to the acetylenic proton vinylic proton coupling constants in the parent compound vinylacetylene (**2**): ${}^5J_t(1,4) = 0.92$, ${}^5J_c(2,4) = 0.70$, and ${}^4J(3,4) = -2.17$ Hz (11). The reversal of sign and approximate retention of magnitude in going from **2** to **1**, Hoffman's "methyl group replacement technique" (18), suggests the π coupling to be the prevailing mechanism of these spin interactions. There are, however, small but significant differences between ${}^6J'_t$ and ${}^6J'_c$ in **1** and between ${}^5J_t$ and ${}^5J_c$ in **2** of 0.16 and 0.22 Hz, respectively, the *transoid* coupling being larger (less negative and more positive) in both cases. As coupling constants consisting entirely of π contributions should be independent of such geometric isomerism, according to Karplus' theory (19), this suggests a σ contribution of about 0.2 Hz to ${}^6J'_t$ and ${}^5J_t$. This can be easily rationalized since the path for these couplings bears some resemblance to the famous "zig–zag path" associated with high σ electron coupling (20). Both here and in the zig–zag case the C—H bonds of the coupling protons are parallel to each other. A similar situation holds for the five-bond couplings in 2-methyl-1-buten-3-yne (**3**), studied earlier in this laboratory (13). Here ${}^5J_t = 0.67$ and ${}^5J_c = 0.59$ Hz, the difference between these values being outside the error limits of the analysis. Their smaller magnitudes compared to **2** are possibly related to the mobile bond order of the intervening bonds calculated to be smaller for **3** than for **2** (or **1**) by the INDO procedure (described in section 3).



2



3

A striking feature in the comparison of **1**, **2**, and **3** is the following: as already mentioned, reversal of sign and approximate retention of magnitude is observed in replacing the acetylenic proton of **2** by a methyl group, *i.e.* ${}^4J(3,4) \simeq -{}^5J'(3,4)$; replacing the olefinic proton H^3 by methyl, however, decreases the coupling by a factor of 7, *i.e.* ${}^5J'(3,4)$ is only 0.3 Hz in **3**. This behavior can be understood in terms of the hyperconjugative model often applied to explain the so-called σ,π exchange mechanism. A valence bond structure **1***a* can be written for **1** involving hyperconjugation between the methyl group and both the double and the triple bonds,

[3]Notations for the coupling constants across multiple bonds are termed ${}^nJ_c$ or ${}^nJ_t$ where n gives the number of intervening bonds; c and t indicate whether the olefinic proton under consideration is *cis* or *trans* with respect to the acetylenic group. Primes indicate couplings involving a methyl group.

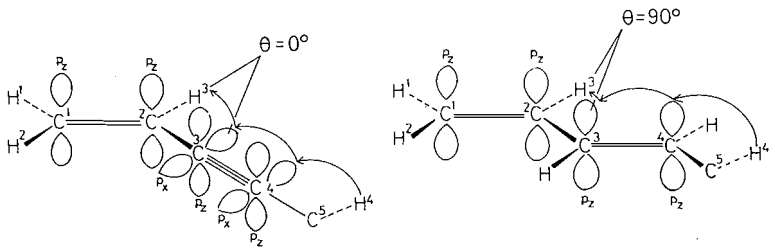

FIG. 1. Transfer of spin information through the π system in 1-penten-3-yne (left) and *trans*-pentadien-1,3 (right). The p_z orbitals are in the plane of the paper.

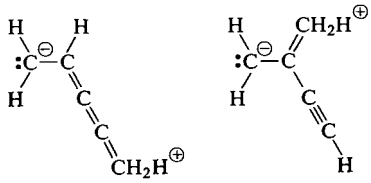
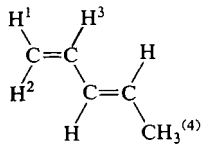


1*a* 3*a*

whereas the only hyperconjugative canonical structure for **3** is **3***a*, involving the methyl group and the double but not the triple bond. A structure for **3** comparable to **1***a* would be a very unfavorable one and would require the =C—C≡ bond to be broken. A more explicit rationalization is given further on in this section.

Another illustrative comparison is the one between 1-penten-3-yne and the corresponding diene compound *trans*-pentadiene-1,3 (**4**) which has been studied by Harris and co-workers (9). Including *cis*-pentadiene-1,3 is not useful because of rather different steric requirements in this molecule. The long-range coupling constants in **4** relevant to the present discussion are: ${}^6J'_{tt}(1,4) = -0.74$, ${}^6J'_{ct}(2,4) = -0.76$, and ${}^5J'_t(3,4) = 0.45$ Hz, respectively. It is evident that the six-



4

bond couplings are similar in both sign and magnitude for the diene and enyne systems. The same does not hold for the five-bond coupling which has the same sign in both compounds, but shows a considerable decrease in magnitude in **4** relative to **1**. Using a simplifying picture of how the spin information is transferred from the methyl protons to H^3 (Fig. 1), this can be accounted for in the following manner: The spin information of the methyl group in **1** can get through the π system of the triple bond either via the carbon p_z or p_x orbitals. Only the latter case, however, is favorable since the C^2—H^3 bond forms an "allylic" dihedral angle θ of 0° with the p_x orbitals. As shown by the well known $\cos^2\theta$ dependence of allylic coupling, this arrangement represents the most effective way of spin information transfer. On the other hand, the coupling has to go through the p_z orbitals of C^4 and C^3 in **4** which form a θ of 90° with the C^2—H^3 bond because the s-*trans*-conformation is the most stable: therefore ${}^5J'(\text{enyne}) \gg {}^5J'(\text{diene})$. The same kind of argument is not valid in discussing the six-bond couplings. Here the coupling path is only through the p_z orbitals in both **1** and **4**, spin information transfer from the C^3-p_x via C^3-p_z into the C^2-p_z orbital being forbidden because of the orthogonality of C^3-p_x and C^3-p_z. This rationalizes the fact that ${}^6J'(\text{enyne}) \simeq {}^6J'(\text{diene})$. Comparison of vinylacetylene (11) with butadiene (7) shows analogous features for the couplings over four and five bonds.

The scheme shown for **1** in Fig. 1 also rationalizes the small coupling of 0.3 Hz observed between the methyl protons and the acetylenic proton in **3**. When H^3 in **1** is replaced by a methyl group the β-interaction (in the language common in electron spin resonance) between the C^2—H^3 bond and the C^3-p_x orbital in **1** is replaced by a γ-interaction between the C—H bond of the methyl group and the C^3-p_x orbital in **3**. As in radicals, the latter interaction is expected to be a good deal smaller than the former.

(3) INDO and CNDO/2 Molecular Orbital Calculations

The bond lengths and angles used in the

TABLE 2. Observed and calculated long-range coupling constants via the triple bond for **1**, **2**, and **3** in Hz

	1			**2**			**3**		
	Obs.	INDO	CNDO/2	Obs.	INDO	CNDO/2	Obs.	INDO	CNDO/2
$J(1,4)$	−0.56	−0.84	0.08	0.92	1.09	0.39	0.67	1.17	0.44
$J(2,4)$	−0.72	−1.03	−0.07	0.70	0.73	0.13	0.60	0.77	0.17
$J(3,4)$	2.31	3.53	2.10	−2.17	−1.67	0.23	0.31	0.59	0.12

molecular orbital calculations were taken from the literature. The molecular geometry of **1** was obtained by electron diffraction (ref. 21*a*), those of **2** and **3** by microwave spectroscopy (ref. 21*b*, 22). Since the data were not quite complete, a few assumptions concerning bond angles had to be made. Furthermore, coupling constants in **3** were only calculated for the conformation known to be the most stable one, *viz.* with one of the methyl protons eclipsing the double bond (22). This does not seem to be a very satisfactory solution, but no information concerning stabilities of other possible conformations was available. For **1** free rotation about the C^4—CH_3 bond was assumed and possible small energy differences between the three different conformers were neglected. Coupling constants for these were calculated and averaged with regard to their statistical weights. A qualitative argument used in section 2 about the differences between the five-bond couplings in **1** and **4** is supported nicely by these calculations. The coupling in **1** of a methyl proton to H^3 is predicted by INDO to reach a maximum if the dihedral angle θ, H^4—C^5···C^2—H^3, is near 0 or near 180°, *i.e.* if the H^4—C^5 bond eclipses the p_x orbital of C^4, and has its minimum value at $\theta = 90°$ with the H^4—C^5 bond eclipsing the p_z orbital (see Fig. 1).

A summary of the results of the calculations (23) is given in Table 2. If one compares the calculated coupling constants with the experimental ones, it is obvious that the agreement is by no means quantitative, the absolute INDO values being too large by *ca.* 30–70% for all J's except $J(3,4)$ in **2**. Qualitatively, however, the INDO calculations in Table 2 give the correct sequence of the magnitudes of $J(1,4)$, $J(2,4)$, and $J(3,4)$ in each of **1**, **2**, and **3**. In all but one case in Table 2 the CNDO/2 results are much smaller than the observed ones, indicating the importance of π electron contributions to these coupling constants (15).

Taking $J(\text{INDO}) - J(\text{CNDO})$ as an approximate measure of the π contribution to the coupling constants (15) and considering the differences between observed and calculated couplings, one may arrive at a fairly constant $^5J_\pi$ for ^5J_c and ^5J_t in **2** and **3** of about +0.6 Hz and a $^6J'_\pi$ for $^6J'_c$ and $^6J'_t$ in **1** of about −0.6 Hz. These values compare to a $^5J_\pi$ of +0.7 Hz in diene systems as proposed by Harris and coworkers (7).

(4) The Allylic Couplings between Methyl and Olefinic Protons in **3**

These couplings over four bonds are measured (13) as $^4J'_c = -1.60$ and $^4J'_t = -1.08$ Hz. Following the procedure of Barfield in his analogous calculations for propene (24), the present calculations yield $^4J'_c = -1.83$ and $^4J'_t = -1.61$ Hz in the INDO approximation but $^4J'_c = 0.05$ and $^4J'_t = 0.39$ Hz in the CNDO/2 approximation. These results bear out the contention (24) that the *cisoid* is larger in magnitude than the *transoid* coupling because of a larger positive σ electron contribution to the *transoid* coupling. The INDO predictions for **3** have the same qualitative relationship to propene as do those for 2-cyanopropene (24), in that $^4J'_c$ is calculated to be larger in **3** than in propene but $^4J'_t$ smaller in **3** than in propene.

(5) Calculated and Observed Dipole Moments

The dipole moment of **1** is calculated to be 0.29 D by the INDO, and 0.42 D by the CNDO/2 approximation. The experimental value is unknown. For **2** we calculate 0.14 (INDO) and 0.20 D (CNDO/2) while the experimental value is 0.44 D in the gas phase (25). The calculated dipole moment of **3** in the conformation with one methyl C—H bond eclipsing the double bond is 0.32 (INDO) and 0.46 D (CNDO/2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

while the experimental value is 0.51 D in the gas phase (22). The computed moments are somewhat smaller than the observed moments, as found previously for other hydrocarbons (15).

We are grateful to Dr. J. B. Rowbotham and Mr. R. Wasylishen for help with the computer program and to the National Research Council of Canada for financial support.

A Kinetic Study of the Oxidative Addition of Substituted Benzenethiols Towards *trans*-Halocarbonylbis(triphenylphosphine)iridium(I)[1]

J. R. GAYLOR AND C. V. SENOFF[2]

Department of Chemistry, University of Guelph, Guelph, Ontario

Received January 13, 1972

The kinetics of the oxidative addition of a series of para-substituted benzenethiols, HSC_6H_4Y, where Y = 4-NO_2, 4-Br, 4-Cl, 4-F, 4-H, 4-CH_3, or 4-CH_3O towards the complexes, *trans*-$IrX(CO)(Ph_3P)_2$ where X = Cl, Br, or I have been studied in benzene between 15 and 45°. These reactions follow simple second order kinetics, rate = $k_2[IrX(CO)(Ph_3P)_2][HSC_6H_4Y]$. The two principal factors which influence the rates of these reactions are the mesomeric and inductive effects of the para-substituent and the nature of the ligand, X, coordinated to iridium. The rate of reaction increases as the substituent becomes more electron withdrawing and as X varies from Cl to Br to I. The kinetic data together with spectroscopic data (i.r. and n.m.r.) suggest that oxidative addition proceeds via a three-centered activated complex to give the *cis*-product.

Les cinétiques de l'addition oxydante d'une série de benzènethiols parasubstitués, HSC_6H_4Y avec Y = NO_2-4, Br-4, Cl-4, F-4, H-4, CH_3-4 ou OCH_3-4, sur les complexes $IrX(CO)(Ph_3P)_2$-*trans* avec X = Cl, Br ou I, ont été étudiées dans le benzène entre 15 et 45°. Ces réactions suivent une cinétique de second ordre simple dont la vitesse est $k_2[IrX(CO)(Ph_3P)_2][HSC_6H_4Y]$. Les deux facteurs principaux qui influent sur les vitesses de ces réactions sont les effets mésomère et inductif du substituant en para et la nature du ligand X coordiné à l'iridium. La vitesse de la réaction croît à mesure que le substituant devient plus électroattracteur et à mesure que X passe de Cl à Br puis à I. Les données cinétiques et spectroscopiques (i.r. et r.m.n.) font penser que l'addition oxydante passe par un complexe activé à trois centres pour conduire ensuite au produit *cis*.

Canadian Journal of Chemistry, **50**, 1868 (1972)

The activation of small covalent molecules by the complexes, *trans*-$[IrX(CO)(Ph_3P)_2]$ (X = Cl, Br, I, or a pseudohalogen) via oxidative addition has been the subject of numerous investigations in recent years (1–3). Several kinetic studies have been carried out in order to ascertain the mechanism of the oxidative addition towards these particular substrates (4–8). Previous work from this laboratory as well as others has shown that substituted benzenethiols will oxidatively add to *trans*-$[IrCl(CO)(Ph_3P)_2]$ to form $[IrHCl(SAr)(CO)(Ph_3P)_2]$ where ^-SAr is a substituted benzenethiolato ligand (9–11). As part of a general program investigating the reactivity of aromatic thiols towards low valent transition metal complexes, we have undertaken a kinetic study of reaction 1

[1] *trans*-$[IrX(CO)(Ph_3P)_2] + HSC_6H_4Y \rightarrow [IrHX(SC_6H_4Y)(CO)(Ph_3P)_2]$

where X = Cl, Br, or I and Y = a para-substituent, NO_2, F, Cl, Br, H, CH_3, or CH_3O. The results of this investigation are reported at this time.

Results and Discussion

The products of reaction 1 when X = Cl have been previously isolated and characterized (10). During the course of this kinetic study, the corresponding products when X = Br or I were isolated and characterized. Infrared and ^1H n.m.r. data are summarized in Tables 1 and 2. Examination of these data indicates that the spectral characteristics of $[IrHX(SAr)(CO)(Ph_3P)_2]$ (X = Br or I) follow the same pattern established for $[IrHCl(SAr)(CO)(Ph_3P)_2]$, *i.e.*, ν_{CO} is a linear function of the Hammett substituent parameter, σ_p, and τ(Ir—H) for a given ligand, X, is invariant to the nature of the para-substituent associated with the benzenethiolato-ligand, ^-SAr (10). These results indicate that the mode of addition of the para-substituted benzenethiols is *cis*- for all three substrates. It may also be noted that ν_{Ir-H} decreases with increasing *trans*- influence of the halogen, X (12). Also, the changes in τ(Ir—H) as X is varied follow the general trend noted recently in the literature (13).

Representative kinetic data for reaction 1 in benzene at 25° are given in Table 3. Kinetic data at various temperatures are summarized in Table 4. These data indicate that the rates of

$$[2] \quad \frac{-d[IrX(CO)(Ph_3P)_2]}{dt} = k_2[IrX(CO)(Ph_3P)_2][HSC_6H_4Y]$$

This rate law is similar to that commonly found for oxidative addition reactions of *trans*-$[IrX(CO)(Ph_3P)_2]$ (4–8).

As mentioned above, the rates of reaction are dependent on the nature of X; the second-order rate constants increase in the order Cl < Br < I. In fact, the reactions when X = I

were too fast to be reliably monitored with the available instrumentation. This order of reactivity parallels that observed for the reactions of H_2 and O_2 with these iridium(I) complexes (4, 6, 7). The rates of reaction also varied with the nature of the para-substituent on the benzenethiol; the trend is towards an increase in rate as the acidity of the substituted benzenethiol increases (14). For a given substrate the rates of reaction increase as the electron withdrawing ability of Y increases and *vice versa* for electron releasing substituents. A Hammett plot of ln k_2 versus σ_p for *trans*-[IrCl(CO)(Ph_3P)$_2$] is shown in Fig. 2 having a slope, $\rho = +3.2$. The corresponding Hammett plot for *trans*-[IrBr(CO)(Ph_3P)$_2$] had a ρ value of +2.8. The somewhat larger slope for the chlorocomplex suggests that it can better discriminate between the different substituent effects.

Activation parameters were calculated using the Eyring eq. 3 and are given in Table 5.

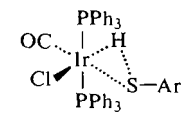
$$[3] \qquad k_2 = \frac{kT}{h} \exp\left(-\frac{\Delta H^*}{RT}\right) \exp\left(\frac{\Delta S^*}{R}\right)$$

The change in ΔH^* as X and Y are varied for reaction 1 is small. The change in ΔS^* is somewhat larger but there appears to be no simple correlation between these two parameters. The large negative entropies of activation suggest a highly constrained three-center transition state, A, comparable to that proposed when O_2 and



A

H_2 react with these iridium(I) substrates (4, 6–8). The rate of reaction of S-deuterated benzenethiol with *trans*-[IrCl(CO)(Ph_3P)$_2$] was also measured and these kinetic data are included in Table 3. The ratio, $k_2^H/k_2^D = 1.2$ represents a small kinetic isotope effect.

It is then apparent that the two major factors which influence the rate of formation of the oxidative addition product in reaction 1 are (*i*) the inductive and mesomeric effects of the para-substituent associated with the benzenethiol and (*ii*) the nature of the ligand, X, coordinated to iridium(I). Since the rates of reaction 1 are related to the acidity of HSC_6H_4Y, the kinetic data presented herein substantiate Vaska's "acid–base" concept for the oxidative addition reactions of *trans*-[IrX(CO)(Ph_3P)$_2$] (2). The breaking of the H—S bond may then be considered to be the "dominant inertial factor" in reaction 1 for a given X. The variation in rate as X is changed for a given substituent suggests that bond making must be the driving force in reaction 1 since iridium formally loses a pair of electrons to the incoming substituted benzenethiol. These changes in rate as X is varied also reflect the change in "basicity" of the substrate as well as the significant dependence of bond formation on the nature of X.

In view of the fact that the enthalpies of activation are ~8–10 kcal mol^{-1} and the average strength of the sulfur–hydrogen bond is ~80 kcal mol^{-1} (15), it is unlikely that the mechanism for reaction 1 involves dissociation

of the sulfur–hydrogen bond as a distinguishable step. This notion is also supported by the small kinetic isotope effect which was observed.

In conclusion, the kinetic data presented herein are consistent with a non-dissociative mechanism for reaction 1 which involves an activated complex similar to that previously proposed for the activation of O_2 and H_2 by *trans*-$[IrX(CO)(Ph_3P)_2]$ (4, 6, 7). The overall proposed mechanism is schematically shown below.

The initial step leading to the activated complex, **A**, may be regarded as a nucleophilic attack by the iridium(I) complex, **1**, at the sulfur atom of the thiol, **2** (or an electrophilic attack by the sulfur at iridium) accompanied by some electron transfer from iridium to sulfur, **3**, with concomitant formation of the iridium–hydrogen bond yielding the activated complex, **A**. Bond making and bond breaking then proceed further in the latter to eventually form the observed product, **4**.

Experimental

(1) Materials

Triphenylphosphine was purchased from Eastman Organic Chemicals, Inc., and was recrystallized from ethanol prior to use. Other chemicals were reagent grade unless otherwise indicated.

trans-Halocarbonylbis(triphenylphosphine)iridium(I), $IrX(CO)(Ph_3P)_2$

These complexes were prepared according to literature procedures (4, 16).

S-Deuterated Benzenethiol, C_6H_5SD

This reagent was prepared according to the method of Ellgen and Gregory (17). The extent of S-deuteration was determined by n.m.r. using a Varian A60 spectrometer. The product was found to be 96.6% deuterated.

(2) Isolation of Reaction Products

The products, $[IrHBr(SC_6H_4Y)(CO)(Ph_3P)_2]$ and $[IrHI(SC_6H_4Y)(CO)(Ph_3P)_2]$, were isolated by the procedure used to prepare $[IrHCl(SC_6H_4Y)(CO)(Ph_3P)_2]$ (10). Analytical data are given in Table 6.

(3) Kinetic Measurements

The kinetics of reaction 1 were followed spectrophotometrically by monitoring the consumption of the iridium(I) substrate at a fixed wavelength with a Bausch and Lomb 505 spectrophotometer. The absorption peaks used were 439 nm ($\varepsilon = 7.68 \times 10^2$ l mol^{-1} cm^{-1}) for *trans*-$[IrCl(CO)(Ph_3P)_2]$ and 444 nm ($\varepsilon = 7.33 \times 10^2$ l mol^{-1} cm^{-1}) for *trans*-$[IrBr(CO)(Ph_3P)_2]$. This procedure was modified when 4-nitrothiophenol was used as the incoming addendum since the spectrum of the product masked the absorption peaks at 439 and 444 nm for the iridium(I) substrates. However, the products of reaction with this particular thiol absorbed strongly at 420 nm ($\varepsilon \sim 14.5$ l mol^{-1} cm^{-1}) when X = Cl and at 424 nm ($\varepsilon \sim 14.5$ l mol^{-1} cm^{-1}) when X = Br. The corresponding substrates exhibited absorption minima at these wavelengths. Hence, the rate of appearance of product was monitored when 4-nitrobenzenethiol was the addendum.

All kinetic runs were carried out in benzene which had been dried over sodium, degassed, and then saturated with nitrogen. Individual solutions of substrate and thiol were thermostated for approximately 1 h prior to mixing. An aliquot (1.0 ml) of the solution containing the thiol was placed in a quartz cell in the thermostated cell compartment of the spectrophotometer and then an equal volume of the solution containing the appropriate substrate was quickly added by means of a hypodermic syringe to ensure rapid and complete mixing of the two solutions. The rate of reaction was then followed at a fixed wavelength as described above.

The concentration of *trans*-$[IrCl(CO)(Ph_3P)_2]$ used for the kinetic runs was 1.0×10^{-3} *M* and the concentration of the incoming thiol was varied from 0.01–0.75 *M* (at least a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

10-fold excess) in order to maintain pseudo first-order kinetic conditions. The corresponding concentration of *trans*-[IrBr(CO)(Ph_3P)$_2$] was 2.5×10^{-5} *M* and 1.0×10^{-3}–2.5×10^{-3} *M* for the incoming thiol. The pseudo first-order rate constants, k_{obs}, were obtained from plots of $\ln (A_t - A_\infty)$ or $\ln (A_\infty - A_t)$ *vs.* time where A_t is the absorbance at time t, and A_∞ is the absorbance at infinite time. Pseudo first-order rate constants were reproducible to $\pm 10\%$ or better.

Microanalyses were determined by A. G. Gygli, Toronto. Infrared spectra were recorded on a Beckman IR-12 spectrophotometer in $CHCl_3$ with 0.2 mm NaCl cells or as Nujol mulls between NaCl plates. Proton n.m.r. spectra were recorded on a Varian HA100 or A60 spectrometer.

We wish to acknowledge financial support from the National Research Council of Canada in the form of an operating grant to C.V.S. We are indebted to Mr. B. G. Sayer for obtaining the n.m.r. spectra and the Department of Chemistry, McMaster University, Hamilton, for the use of the Varian HA100 spectrometer. We also thank Dr. R. K. Boyd for helpful discussions throughout the course of this work and Dr. L. Vaska for providing some of his results prior to publication.

The Concentration Dependence at 1 atm Pressure and 300 °K of the Binary Diffusion Coefficients of the Systems Helium–Carbon Dioxide, Helium–Nitrous Oxide, and Helium–Sulfur Hexafluoride

KENNETH R. HARRIS AND T. N. BELL

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

AND

PETER J. DUNLOP

Department of Physical and Inorganic Chemistry, University of Adelaide, South Australia

Received December 30, 1971

Binary diffusion coefficients are reported for the systems He–CO_2, He–N_2O, and He–SF_6. In agreement with the Chapman–Enskog theory the concentration dependence of the diffusion coefficient of each system increases with the mole fraction of the heavier component.

Les coefficients de diffusion binaire sont rapportés pour les systèmes He–CO_2, He–N_2O, et He–SF_6. En accord avec la théorie de Chapman–Enskog, la dépendance du coefficient de diffusion de chaque système par rapport à la concentration, augmente avec la fraction molaire du composé le plus lourd.

Canadian Journal of Chemistry, **50**, 1874 (1972)

Giddings and Seager (1) have reported data at approximately 300 °K for the concentration dependence of the binary diffusion coefficient, D_{12}, of the systems He–N_2 and He–CO_2. Their results, obtained by a chromatographic technique, indicated that, while the binary diffusion coefficient for the former system *increased* with the mole fraction of the heavier component, D_{12} actually *decreased* with the mole fraction of CO_2 for the latter system. Since the Chapman–Enskog theory (2) for transport in dilute gases predicts that D_{12} should increase with the mole fraction of the heavier component (3–5), it seemed worthwhile to remeasure D_{12} for the system He–CO_2 with a technique we have developed (6), but which was originally proposed by Onsager (7) and used by Harned and co-workers (7, 8) to study transport in dilute electrolyte solutions.

In addition we have measured the concentration dependence of D_{12} for the systems He–N_2O and He–SF_6. N_2O was chosen as a component for the former system since like CO_2 it is a linear molecule, it is isoelectronic with CO_2, and it has a mass almost identical with that species; however, it differs in its polar characteristics and therefore probably in its interaction potential. SF_6 was chosen as a component for the latter system because it was a spherically symmetrical polyatomic molecule with a mass much greater than CO_2 and N_2O.

Experimental

The method used to measure the concentration dependence of D_{12} for each system has been previously described in detail (6). It is suggested that that paper be read in conjunction with this article. The temperature of the water-thermostat, in which the diffusion cell was placed, was controlled to approximately $\pm 0.001°$ at 300 °K, and we believe that this feature of our apparatus was mainly responsible for the precision of our measurements.

The purities of He, CO_2, N_2O, and SF_6 were stated by the suppliers to be better than 99.99, 99.99, 99.9, and 99.8%, respectively.

Since the above gases and their mixtures are non-ideal at 300 °K and 1 atm pressure, virial coefficient data for He–CO_2 in the literature (9) were used for the calculation of concentrations for that system. Similar data are not available for the systems He–N_2O and He–SF_6.

Results

Table 1 summarizes the experimental data for each system. In this table are given the experiment number; the mole fraction, x_2, of the heavy component in each experiment; the total pressure, P; the corresponding experimental value of D_{12} and that corrected to 1 atm pressure. The data may be represented by the following equations, where x_2 is the mole fraction of the heavy component and s the standard deviation:

*Corrected to 300 °K and 1 atm.

300 °K. Thus it would appear that, if the data in Table 1 are correct, the Chapman–Enskog theory may not be sufficient (at least to the second Kihara approximation) to describe the concentration dependence of D_{12} where one or both components possess internal degrees of freedom. In addition it seems that the Chapman–Enskog theory does indeed give the correct sign for the concentration dependence of the system He–CO_2.

Figure 1 indicates that the experimental technique employed in this study easily distinguishes between the systems He–CO_2 and He–N_2O. Because CO_2 and N_2O molecules are isoelectronic and have essentially identical masses, the observed differences in the diffusion coefficients of these two systems are due to differences in the collision cross-sections.

Analysis of ^{134}Cs Isomer Ratios in the Fission of ^{237}Np with Protons in the Energy Range 20–85 MeV[1]

C. L. RAO[2] AND L. YAFFE

Department of Chemistry, McGill University, Montreal 101, Quebec

Received February 1, 1972

An analysis has been made of the isomer ratio, $\sigma_m/(\sigma_m + \sigma_g)$ for ^{134}Cs isomers formed in the fission of ^{237}Np by protons of energies 20–85 MeV. Compound nucleus formation was assumed up to a bombarding energy of 50 MeV, with direct interaction as the mechanism at higher energies. Values of the root-mean-square angular momentum of $12\hbar$ at 20 MeV and $16–18\hbar$ at 60–85 MeV bombarding energy agree with the experimental results. The results are consistent with the hypothesis that angular momentum is generated in the fission process.

On a fait l'analyse du rapport $\sigma_m/(\sigma_m+\sigma_g)$ pour les isomères ^{134}Cs formés lors de la fission du ^{237}Np par des protons d'énergie de 20 à 85 MeV. La formation du noyau du composé est supposée jusqu'à une énergie de bombardement de 50 MeV, pour des énergies plus élevées le mécanisme est du type interaction directe. Le valeurs des racides carrées moyennes du moment angulaire de $12\hbar$ à 20 MeV et $16–18\hbar$ à 60–80 MeV sont en accord avec les résultats expérimentaux. Les résultats sont compatibles avec l'hypothèse que le moment angulaire est produit dans le processus de fission.

Canadian Journal of Chemistry, **50**, 1877 (1972)

Introduction

Studies of isomer ratios formed in nuclear reactions on various elements (1–5) and by nuclear fission of heavy elements (6–14) by particles with thermal, low, and medium energies have been carried out. These have been particularly helpful in the understanding of angular momentum effects in these various reactions.

In a number of cases these studies were made as a function of bombarding energy. In the simple nuclear reactions it was shown that the formation of the higher spin state is enhanced as the particle energy is increased (1) owing to a larger transfer of angular momentum. A similar trend is also observed in low and medium energy fission (7).

Huizenga and Vandenbosch (15, 16) used the following expression, based on a statistical model, to determine the dependence of the nuclear level density on the spin

$$[1] \quad \rho(J) = \rho(0)(2J+1)\exp[-(J+1/2)^2/2\sigma^2]$$

where $\rho(0)$ and $\rho(J)$ are respectively the densities of states with spin 0 and J, and σ is the spin cut-off factor which describes the angular momentum distribution of the level density and is related to the moment of inertia and temperature of the nucleus. The isomer ratio depends initially on the spin distribution of the compound nucleus which is subsequently altered by the emission of particles and the accompanying gamma cascade. Equation 1 has been used to calculate the angular momentum distribution after each of the above steps.

In the fission process the first step, which determines the initial spin distribution, is not easy to calculate since it involves a calculation of the angular momentum distribution of the pairing fragments formed in the fission process. According to Warhanek and Vandenbosch (8) the angular momentum distribution in fission can be described by the following functional form

$$[2] \quad F(J) = (2J+1)\exp(-J(J+1)/B^2)$$

where B, a factor similar to the spin cut-off parameter σ, is related to J, the root-mean-square angular momentum. The de-excitation steps which follow, *i.e.* particle and gamma emission, are treated as in the case of simple nuclear reactions, assuming some energy-dependent factor of σ, the spin cut-off parameter, and I, the nuclear moment of inertia.

The isomers of ^{134}Cs offer a convenient way of determining the formation cross sections of

TABLE 1. Experimental cross sections of $^{134}Cs^{m}$ and $^{134}Cs^{m+g}$ and their ratios in the fission of ^{237}Np with protons in the energy range 20–85 MeV

Proton energy (MeV)	σ		
	$^{134}Cs^{m}$	$^{134}Cs^{m+g}$	σ_m/σ_{m+g}
20	2.8±0.4	4.6±0.9	0.61±0.09
40	9.9±1.5	16.0±3.2	0.62±0.08
50	11.1±1.7	17.2±3.4	0.65±0.09
60	12.7±1.9	16.3±3.3	0.78±0.10
72	12.6±1.9	17.7±3.5	0.71±0.10
85	10.3±1.6	13.8±2.8	0.75±0.10

independently-formed isomers in fission, and these have been determined in the fission of a number of heavy nuclides (8, 10, 11). The present study deals with the analysis of data on isomer ratios in the fission of ^{237}Np by protons with energies 20–85 MeV, enabling this system to be compared with other fissioning systems.

Experimental

The experimental procedures are described elsewhere (17) and only a very brief outline is given here. Mixtures of NpO_2 and CuO were irradiated at various energies in the internal proton circulating beam of the McGill synchrocyclotron. The beam was monitored by the $^{65}Cu(p,pn)^{64}Cu$ reaction (18). After chemical separation of the cesium the activities of $^{134}Cs^{m}$ and $^{134}Cs^{g}$ were measured with a 30-cc Ge(Li) detector coupled to a 1600-channel pulse-height analyzer. Photo-peaks at 127 and 605 keV were used to measure the activities of the former and latter, respectively (19). The 605-keV peak was measured several months after the end of irradiation so that no serious interference from ^{136}Cs resulted. Corrections were made for chemical yields, branching ratios, and counting efficiencies to calculate the formation cross sections which are given in Table 1, along with the isomer ratio values.

Analysis of Data

The data were analyzed according to the energy-dependent model proposed by Saha and Yaffe (10). A brief outline of the method follows. The compound or residual cascade nuclei formed by the bombardment of the target nucleus with protons at different energies, undergo fission or neutron evaporation, depending on fission width, Γ_f, neutron emission width, Γ_n, and excitation energy. The fission branching ratios, $G_i = \Gamma_f/(\Gamma_f + \Gamma_n)$, of successive residual nuclei determine the fission probability at each step of the chain. The primary fragments formed from the fissioning nucleus have a wide spectrum of excitation energies and de-excite by neutron emission, followed by gamma emission. Angular momentum is thus carried off, the initial spin distribution of the fragments being changed at each step. The isomer ratio is calculated from the following expression

$$[3] \quad \frac{\sigma_m}{\sigma_g} = \frac{\sum_i G_i \sum_{A_iZ_i} P_{m_i} F_i(Z_i) Y_i(A_i) W_i(A_iZ_i)}{\sum_i G_i \sum_{A_iZ_i} P_{g_i} F_i(Z_i) Y_i(A_i) W_i(A_iZ_i)}$$

where G = fission probabilities of the i successive residual nuclei leading to the fragment (A,Z); P_m and P_g = formation probabilities of the metastable and ground states, respectively, from the fragment (A_iZ_i) through neutron and gamma emission; $F(Z)$ and $Y(A)$ = formation probabilities of the fragment of charge Z and mass A, respectively; $W(A,Z)$ = formation probability of the isomer from the primary fragment by neutron emission, and taken to be unity in this energy range.

The values of G used were those of Huizenga and Vandenbosch (20). In the energy range 20–50 MeV the excitation energy was determined by assuming compound nucleus formation. In the energy range 60–85 MeV the Vegas cascade calculation (21) was used. From the Step No model the average deposition energies were obtained, assuming these for the present system to be the same as those for protons interacting with ^{238}U. The average residual nucleus for ^{238}U in this energy range was found to be ^{238}Np, and in the present case, by analogy, ^{237}Pu was assumed. Successive excitation energies of the fissioning nuclei were obtained by subtracting the binding energy of the neutron, B_n, plus its kinetic energy, $2T$, from that of the preceding nucleus. The nuclear temperature, T, was obtained from the relationship

$$[4] \quad U' = aT^2 - 4T$$

where U' = effective excitation energy of the residual nucleus (22), a = level-density parameter, taken as 10.5 MeV^{-1}. Correction for the odd–even nature of the fissioning nucleus was made with a pairing energy value of 1.1 MeV (20). The values of G_i were all normalized so that their sum was unity. Values of B_n and those for fission barriers were taken from Myers and Swiatecki (23). The fission yields $Y(A)$ in the mass region 134–139 have not been determined for the present system, other than by summing

from the charge dispersion curves. These values show that the mass–yield curve is relatively flat in this very narrow mass region. The assumption of constant fission yield was made, with the further implicit assumption that the mass distribution for the products and fragments has the same shape for different fissioning nuclei, and varies only with excitation energy. Similarly the fractional yields, $F(Z)$, for various mass numbers are not known, since the charge dispersion for the primary fragments has not been determined. The Gaussian expression relating the fractional yields to the most probable charge, Z_p, and width d was used to calculate $F(Z)$ values. Values of Z_p were calculated on the basis of the u.c.d. postulate (24) and values of d obtained from the charge dispersion studies in the fission of ^{237}Np (17).

The total average excitation energy of the fragment is obtained by energy balancing:

$$[5] \quad \bar{E}^* = \Delta M^*(A,Z) - (\Delta M_L + \Delta M_H) - KE_{av}$$

where $\Delta M^*(A,Z)$ = mass excess of the excited compound nucleus (equal to the ground state mass excess plus the excitation energy due to the bombarding energy); and ΔM = mass excesses of the light, L, and heavy, H, complementary fragments (23). The average total kinetic energy of the two fragments was taken as the average value obtained from ^{237}Pu (25), considered constant at all energies. The excitation energy, $\bar{E}^*$, was assumed to be shared between the two fragments in proportion to their masses. A number of complementary fragment pairs, with cesium isotopes of masses 134–140 on the heavy side, were selected for each fissioning nucleus, and the excitation energies determined as outlined above. Neutron emission from these heavy fragments was followed, as outlined earlier, and those leading to ^{134}Cs as the final fragment were selected, the residual excitation energy being dissipated by a cascade of gamma rays. The average energy, E_γ, carried off by each γ-ray was based on the empirical relation given by Vonach *et al.* (22). When the residual energy is less than, or equal to, 1 MeV the isomer-deciding γ-ray is emitted. With these data on the numbers of neutrons and γ-rays emitted from each fragment leading to the isomer, the computer code of Hafner *et al.* (26) was used to calculate the formation probabilities of the metastable and ground state isomers, P_m and P_g, respectively. The transmission coefficient values, $T_l(E)$, for neutron emission from different fragments were calculated for a diffuse-edge, surface-absorption optical potential of Bjorklund and Fernbach (27) using Auerbach's ABACUS code (28). The photons were assumed to be dipole.

The primary spin distribution was taken to be of the form given by eq. 2, the value of B defining the width of the distribution, and for large values, $B = \sqrt{\overline{J^2}}$, the average root-mean-square angular momentum of the primary fragment. The spin cut-off factor, σ, is equated to the thermodynamic temperature through the moment of inertia, I_{eff}, of the excited nucleus (29). The value of I_{eff} has been shown to increase with excitation energy of the nucleus, approaching I_r, the rigid body value as an upper limit, where

$$[6] \quad I_r = \tfrac{2}{5}MAR^2$$

M = mass of a nucleon; A = mass number; and R = nuclear radius. From the work of Dudey and Sugihara (30) at energies about 10–15 MeV, the ratio $I_{eff}/I_r = 1$, the value decreasing with decreasing energy. Since neutron emission occurs in the higher excitation energy range and gamma emission at lower energies, the following spin cut-off values were used:

$$\sigma_n^2 = (I_r t/\hbar^2)$$

and

$$\sigma_\gamma^2 = (I_{eff} t/\hbar^2)\,,$$

values of I_{eff}/I_r being interpolated from the data of Dudey and Sugihara (30). Calculations for σ_n were also made with $I_{eff}/I_r = 0.75$ at one value to check the effect of a reduced moment of inertia on the isomer ratio predictions. Similarly, at one value of B, fixed values of $\sigma_n = 4$ and $\sigma_\gamma = 3$ were taken. As done by others (8, 10) the spin distribution following the emission of the final γ-ray was assumed to divide midway between the two isomeric states, ^{134}Cs^m(8−) and ^{134}Cs^g(4+).

Discussion

The calculated and experimental isomer ratios, $\sigma_m/(\sigma_m + \sigma_g)$ for ^{134}Cs are shown in Fig. 1 as a function of bombarding energy. The calculated results for different values of B, σ_n, and σ_γ are shown. The experimental values show a slight increase with energy initially and tend

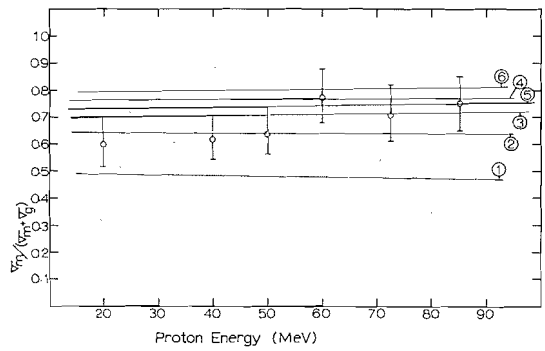

FIG. 1. ^{134}Cs isomer ratios in ^{237}Np fission with protons: ○, experimental values; solid lines are calculated values with different parameters as follows: (*1*) $B = 12$, $\sigma_n = 4$, $\sigma_\gamma = 3$; (*2*) $B = 12$, $\sigma_n^2 = I_r t/\hbar^2$, $\sigma_\gamma^2 = I_{eff} t/\hbar^2$; (*3*) $B = 14$, $\sigma_n^2 = I_r t/\hbar^2$, $\sigma_\gamma^2 = I_{eff} t/\hbar^2$; (*4*) $B = 16$, $\sigma_n^2 = I_r t/\hbar^2$, $\sigma_\gamma^2 = I_{eff} t/\hbar^2$; (*5*) $B = 16$, $\sigma_n^2 = 0.75 I_r t/\hbar^2$, $\sigma_\gamma^2 = I_{eff} t/\hbar^2$; (*6*) $B = 18$, $\sigma_n^2 = I_r t/\hbar^2$, $\sigma_\gamma^2 = I_{eff} t/\hbar^2$.

to level off at higher energies as observed for other fissioning systems (8, 10, 11). The isomer ratios obtained with different targets, in this energy range, are about the same at a given bombarding energy, irrespective of the spin of the target.

The underlying assumptions for each of the factors used in the above calculations have been discussed by Saha and Yaffe (10), who pointed out the difficulty involved in investigating the variation in calculated ratios with changes in all the parameters, owing to the wide spectrum of fissioning nuclei. However, some generalizations follow from the present calculations. For the same value of B the ratio $P_m/(P_m + P_g)$ varies from fragment to fragment, and increases with increased value of B for each fragment. With a reduced moment of inertia, reflected in smaller values of σ_n, for the same value of B the isomer ratio values drop (lines 4 and 5, Fig. 1). Dipole radiation only for γ-emission has been considered in these calculations, since cascade γ-rays of the pure quadrupole type have been shown to reduce the calculated isomer ratios greatly. It is possible that some admixture dipole and quadrupole radiations might be closer to reality, but it is difficult to take such an admixture into consideration in these calculations. The root-mean-square angular momentum, $\sqrt{\overline{J^2}}$, (equal to B for large values), for best agreement between experimental and calculated values is $12\hbar$ at 20 MeV and 16–$18\hbar$ at 60–85 MeV bombarding energy. Similar high values of angular momentum have been reported for ^{134}Cs isomers in the fission of several other heavy nuclides (8, 10, 11).

From the optical model calculations of proton transmission into a neptunium nucleus, with the parameters of Fricke *et al.* (31), it has been found that at 20 MeV only $6\hbar$ units of root-mean-square angular momentum are brought in. At 85 MeV the calculations of Chen *et al.* (21) give an average value of $12\hbar$. Vandenbosch *et al.* (32) have pointed out that a major fraction of the initial angular momentum is retained as the intrinsic spin of the primary fragments, and only a small amount as the orbital angular momentum. It is difficult to account, however, for a value of $\sqrt{\overline{J^2}} = 12\hbar$ at 20 MeV, as found in this work and by previous authors (7, 10) unless as Strutinski (33) has suggested, considerable intrinsic angular momentum is generated in the fission process itself.

From the Halpern and Strutinski model (34), the fission fragments are emitted along the symmetry axis of the fissioning nucleus and their intrinsic spins add vectorially to give the vector K, which is the projection of the spin of the fissioning nucleus along the symmetry axis. Following the above model, the average value of $\sqrt{\overline{K^2}}$, weighted with the fission probability of each fissioning nucleus in the fission chain, gave a value of $11.3\hbar$, as against a value of $12\hbar$ for $\sqrt{\overline{J^2}}$ at 20 MeV, associated with a single fragment. Accordingly, the spins of the fragments must be so oriented that only partial cancellation of spins of the complementary fragments occurs, and not entirely cancelled as would be the case if they were oriented antiparallel to each other. Hoffman (35) found the latter to be the case in the thermal fission of ^{235}U.

Our recent studies toward the synthesis of ryanodine (1) led us to consider and develop different routes for the synthesis of compounds having a tricyclic skeleton such as **1**. We wish now to report a successful synthesis of the tricyclic ketone 1.[3]

Condensation of sodiomalonate in dimethylformamide with α-chloroacetone during 18 h at room temperature gave the ketone ester **2** (2) in 55% yield which was converted into ketal ester **3**. The sodium salt of **3** dissolved in dimethoxyethane was then condensed with 2-chlorocyclopentanone yielding crude substituted cyclopentanone **4** in 90% yield.

Experimental conditions were then sought in order to transform **4** into **5** in a single operation. We selected a strong acidic medium and heat so the hydrolysis of the esters and ketal functions would certainly occur as well as the decarboxylation of the substituted malonic acid and it was hoped that under those conditions, aldol condensation followed by dehydration would also be observed. We found that when **4** was heated in a mixture of dioxane and 15% aqueous sulfuric acid for 52 h, the enone acid **5** was obtained in 80% yield. The crude acidic product **5** was esterified with diazomethane and the corresponding enone ester **6** was purified by distillation (80% yield). Ketalization of **6** with ethylene glycol gave the ketal ester **7** in 80% yield.

The introduction of a methyl group at the alpha position of the carbomethoxy group was then realized. Treatment of **7** in dry dimethoxyethane containing methyl iodide and sodium hydride at 35 °C during 12 h gave the desired compound **8** in 82% yield. The ketal alcohol **9** obtained in 95% yield by reduction of **8** with lithium aluminum hydride in ether was further oxidized with Collins reagent (3) giving the unstable ketal aldehyde **10** in 90% yield. Wittig condensation (4) of **10** with methoxymethylenetriphenylphosphorane gave in 65% yield a mixture of the *cis* and *trans* isomeric enol ether **11** in a ratio of 7:3. Mild hydrolysis of **11** with acetone and *p*-toluenesulfonic acid yielded the unstable ketal acetaldehyde **12** in 95% yield.

The crude ketal aldehyde **12** was then reduced with lithium aluminum hydride in ether (90% yield) to the ketal alcohol **13** which was then converted to the ketal mesylate **14** (95% yield) by reaction with methanesulfonylchloride and pyridine in dichloromethane. Hydrolysis of ketal mesylate **14** with a mixture of acetone and aqueous hydrochloric acid (3 *N*) during 2 h at room temperature gave the enone mesylate **15** in quantitative yield.

Treatment of crude enone mesylate **15** with sodium hydride in dimethoxyethane containing a small quantity of ethanol gave a major product which was isolated by v.p.c. (60% yield). It was shown to have structure **1** by analytical and spectral analysis.

The tricyclic ketone **1** is a liquid, its DNP derivative melts at 172–173 °C. Its i.r. spectrum exhibits an absorption at 1720 cm^{-1} for the six-membered ring ketone and its n.m.r. spectrum, a multiplet at 6.83 τ (1H) for the bridgehead proton and a singlet at 8.77 τ (3H) for the methyl group. Its mass spectrum shows a strong molecular ion at *m/e* 176.

Experimental

The i.r. spectra were taken on a Perkin–Elmer 257 spectrophotometer. The n.m.r. spectra (τ value) were recorded on a Varian A-60 spectrometer in solvent indicated and with TMS as internal standard. Mass spectra (m.s.) were

obtained on a Hitachi–Perkin–Elmer RMU-6 spectrometer. The u.v. spectra were measured on a Beckman DB-6 Grating spectrophotometer. The vapor phase chromatographic purification and analysis were done on a Hewlett–Packard 5750 Research chromatograph. Organic solutions were dried over anhydrous magnesium sulfate and Florisil was used in all the column and preparative layer chromatography. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y.

Commercially available α-chloroacetone (Eastman Organic Chemicals) and 2-chlorocyclopentanone (Aldrich Chemical Co.) was used in this work.

Ketone Ester **2**

Ethyl malonate (160 g, 1 mol) was added in small portions to dimethylformamide (1 l) containing sodium hydride (32 g, 1.32 mol) in suspension under an atmosphere of nitrogen. The mixture was then heated at 85° for 1 h. It was cooled to room temperature and α-chloroacetone (111 g, 1.2 mol) was slowly added and the reaction mixture was left for 18 h at room temperature. Water (6 l) was then added, the mixture was acidified with hydrochloric acid (3 *N*) and extracted several times with ether. The organic phase was washed twice with water, dried, and evaporated to dryness (180 g). Fractional distillation gave ketone ester **2** (118 g, 55% yield; b.p. 102–104° at 0.9 mm; lit. (2) b.p. 145–155° at 20 mm).

Ketal Ester **3**

A mixture containing ketone ester **2** (65 g, 0.306 mol), ethylene glycol (285 ml, 6.0 mol), and *p*-toluenesulfonic acid (2.6 g, 15 mmol) in benzene (3.5 l) was heated at reflux for 15 h with continuous azeotropic removal of water by means of a Dean–Stark trap. The cooled mixture was washed with saturated aqueous sodium carbonate and brine. The dried organic phase was evaporated to give crude ketal ester **3** (79 g, 98% yield). The analytical sample was obtained by distillation *in vacuo* (b.p. 118° at 0.9 mm). The i.r.: ν_{max} ($CHCl_3$) 1745 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.78 (4H, quadruplet, J = 7.0 Hz, —OCH_2CH_3) 6.06 (4H, singlet, OCH_2—CH_2O), 6.45 (1H, triplet, J = 7.0 Hz, methine hydrogen), 7.69 (2H, doublet, J = 7.0 Hz, methylene hydrogen), 8.67 (3H, singlet, CH_3), and 8.74 (6H, triplet, J = 7.0 Hz, —OCH_2CH_3).

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.74. Found: C, 55.28; H, 7.53.

Substituted Cyclopentanone **4**

Ketal ester **3** (75 g, 0.29 mol) dissolved in dry dimethoxyethane (85 ml) was slowly added under nitrogen to a suspension of sodium hydride (7.4 g, 0.30 mol) in dimethoxyethane (450 ml). The mixture was refluxed for ½ h, cooled to room temperature and 2-chlorocyclopentanone (40 g, 0.37 mol) dissolved in dimethoxyethane (85 ml) was slowly added. At the end of the addition, the reaction mixture was heated at reflux overnight. A portion of the dimethoxyethane (300 ml) was removed from the reaction mixture by evaporation *in vacuo*, water (2 l) was added and the mixture was thoroughly extracted with ether. Evaporation of the dried extract gave crude **4** (90 g, 90% yield). This product was found unstable on distillation *in vacuo*, an analytical sample was not prepared. The i.r.: ν_{max} ($CHCl_3$) 1745 cm^{-1};

n.m.r.: τ ($CDCl_3$) 5.80 (4H, quadruplet, $J = 7.0$ Hz, OCH_2—CH_3), 6.13 (4H, singlet, OCH_2CH_2O), 8.67 (3H, singlet, CH_3), and 8.75 (6H, triplet, $J = 7.0$ Hz, OCH_2CH_3).

Enone Acid **5** *and Enone Ester* **6**

A solution of the substituted cyclopentanone **4** (80 g, 0.234 mol) in dioxane (240 ml) was mixed with water (400 ml) containing concentrated sulfuric acid (62 g) and heated at reflux for 52 h. The cooled solution was made alkaline (p*H* 8–9) with aqueous sodium hydroxide (2 *N*) and extracted with ether which was discarded. The aqueous phase was acidified and thoroughly extracted with ether. The dried organic phase was evaporated to dryness giving the liquid enone acid **5** (35 g, 80% yield). The i.r.: ν_{max} ($CHCl_3$) 1720 and 1680 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.0 (1H, broad singlet, olefinic hydrogen); m.s.: *m/e* 180 (M^+).

Crude enone acid **5** (35 g, 0.194 mol) dissolved in ether (200 ml) was mixed with an excess of an ethereal solution of diazomethane for $\frac{1}{2}$ h at room temperature. Evaporation of the solvent gave a crude product which was purified by distillation giving pure enone ester **6** (33 g, 80% yield, b.p. 145° at 0.8 mm). The i.r.: ν_{max} ($CHCl_3$) 1740 and 1680 cm^{-1}; u.v.: λ_{max} (EtOH) 236 m (ε 10 280); n.m.r.: τ ($CDCl_3$) 4.0 (1H, broad singlet, olefinic hydrogen) and 6.25 (3H, singlet, OCH_3); m.s.: *m/e* 194 (M^+). The 2,4-dinitrophenylhydrazone had m.p. 141–142° (methanol).

Anal. Calcd. for $C_{17}H_{18}O_6N_4$: C, 54.54; H, 4.84; N, 14.98. Found: C, 54.67; H, 5.01; N, 15.12.

Ketal Ester **7**

A mixture containing enone ester **6** (16 g, 0.082 mol), ethylene glycol, and *p*-toluenesulfonic acid (1.3 g) in benzene (800 ml) was heated at reflux for 15 h with continuous azeotropic removal of water by means of a Dean–Stark trap. The cooled mixture was washed with saturated aqueous sodium carbonate and brine. The dried organic phase was evaporated to dryness and the resulting oil was purified by distillation (14 g, 80% yield). The analytical sample was obtained by distillation *in vacuo* (b.p. 100° at 0.3 mm). The i.r.: ν_{max} ($CHCl_3$) 1730 cm^{-1}; n.m.r.: τ ($CDCl_3$) 6.02 (4H, singlet, OCH_2CH_2O) and 6.30 (3H, singlet, OCH_3).

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.63: H, 7.65.

Methylated Ketal Ester **8**

The oily ketal ester **7** (29.5 g, 0.124 mol) was slowly added under nitrogen to dry dimethoxyethane (300 ml) containing sodium hydride (5.5 g, 0.124 mol) in suspension. Iodomethane (35.2 g, 0.248 mol) was then added by portion and the reaction was kept at 35° for 5 h. Sodium hydride (5.5 g, 0.124 mol) in suspension in dimethoxyethane (300 ml) was then added followed by a second addition of iodomethane (35.2 g, 0.248 mol) and the reaction mixture was kept again at 35° overnight. Excess sodium hydride was destroyed by careful addition of water. Most of the solvent was removed by evaporation, brine (1 l) was added, and the mixture was thoroughly extracted with ether. The dried organic phase was evaporated yielding the crude oily ketal ester **8** (25 g, 82% yield). The analytical sample was obtained by preparative t.l.c. The i.r.: ν_{max} 1730 cm^{-1}; n.m.r.: τ ($CDCl_3$) 6.04 (4H, multiplet, OCH_2CH_2O), 6.32 (3H, singlet, OCH_3), and 8.70 (3H, singlet, CH_3).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99. Found: C, 66.48; H, 8.16.

Ketal Alcohol **9**

Lithium aluminum hydride (8 g) added to an ethereal solution (200 ml) of ketal ester **8** (15.8 g, 0.063 mol) and the mixture was refluxed overnight. The excess hydride was carefully destroyed with a small quantity of water in order to get a precipitate. Magnesium sulfate was added, the solution was filtered and evaporated to dryness. The resulting oil was filtered through Florisil (13 g, 95% yield).

The analytical sample was obtained by preparative t.l.c. of the corresponding benzoate derivative (benzoyl chloride: pyridine). The i.r.: ν_{max} ($CHCl_3$) 1715 cm^{-1}; n.m.r.: τ ($CDCl_3$) 2.0 (2H, multiplet, benzoate hydrogens), 2.55 (3H, multiplet, benzoate hydrogens), 5.75 (2H, singlet, $—CH_2O$), 6.08 (4H, singlet, OCH_2CH_2O), and 8.82 (3H, singlet, CH_3); m.s.: *m/e* 224 (M^+).

Anal. Calcd. for $C_{13}H_{20}O_3$: C, 73.15; H, 7.37. Found: C, 72.88; H, 7.50.

Ketal Aldehyde **10**

A solution of ketal alcohol **9** (2 g, 9 mmol) in dry dichloromethane (10 ml) was added to a suspension of chromium trioxide–pyridine complex (11.5 g, 0.045 mol) (3) in dry dichloromethane (20 ml) and the mixture was stirred for 10 min at room temperature. Water (150 ml) was added and the mixture was extracted with dichloromethane. The organic phase was dried, filtered through celite, and evaporated to dryness yielding crude ketal aldehyde **10** (1.8 g, 90% yield) as an oil which decomposed on standing at room temperature. The i.r.: ν_{max} ($CHCl_3$) 2740 and 1720 cm^{-1}; n.m.r.: τ ($CDCl_3$) 0.4 (1H, singlet, CHO), 6.00 (4H, singlet, OCH_2CH_2O), and 8.84 (3H, singlet, CH_3); m.s.: *m/e* 222 (M^+).

Wittig Reaction on **10**

Sodium hydride (1.0 g, 0.04 mol) was mixed with dimethylsulfoxide (40 ml) and heated at 75° for $1\frac{1}{2}$ h. To the cooled solution was added dry (under P_2O_5) methoxymethyltriphenylphosphonium chloride (13.2 g, 0.042 mol) dissolved in dimethylsulfoxide (40 ml). After 30 min, ketal aldehyde **10** (1.8 g, 8.4 mmol) in dimethylsulfoxide (10 ml) was added dropwise and the reaction mixture was maintained at 45° during 15 h. Water (100 ml) was added and the mixture was thoroughly extracted with pentane. The dried organic phase was filtered and evaporated to dryness. The residue was purified by column chromatography with Florisil. Elution with pentane gave triphenylphosphine, elution with benzene gave the isomeric *cis* and *trans* enol ether **11** in a ratio of 7:3 as judged by n.m.r. (1.05 g, 63% yield). The i.r.: ν_{max}($CHCl_3$) 1650 cm^{-1}; n.m.r.: τ ($CDCl_3$) 3.68 (0.35 H, doublet, $J = 12.0$ Hz, $CH{=}CHOCH_3$ *trans*), 5.02 (0.35 H, doublet, $J = 12.0$ Hz, $CH{=}CHOCH_3$ *trans*), 4.27 (0.65 H, doublet, $J = 7.0$ Hz, $CH{=}CHOCH_3$ *cis*), 5.60 (0.65 H, doublet, $J = 7.0$ Hz, $CH{=}CHOCH_3$ *cis*).

The analytical sample was obtained on the *trans* isomer which was obtained pure by preparative t.l.c. followed by molecular distillation. The i.r.: ν_{max} ($CHCl_3$) 1650 cm^{-1}; n.m.r.: τ ($CDCl_3$) 3.68 (1H, doublet, $J = 12.0$ Hz, $—CH{=}CHOCH_3$) 5.02 (1H, doublet, $J = 12.0$ Hz, $—CH{=}CHOCH_3$), 6.02 (4H, singlet, $O—CH_2CH_2O$), 6.48

(3H, singlet, OCH_3), and 8.84 (3H, singlet, CH_3); m.s.: *m/e* 250 (M^+).

Anal. Calcd. for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86. Found: C, 71.13; H, 8.95.

Ketal Acetaldehyde **12**

The isomeric *cis* and *trans* enol ether **11** (932 mg, 3.7 mmol) was dissolved in acetone (250 ml) containing *p*-toluenesulfonic acid (4 mg) and two drops of water. The mixture was left for 6 h at room temperature. Water was added and the mixture extracted with ether. The dried organic phase was evaporated to dryness yielding crude ketal acetaldehyde (836 mg, 95%) which was used directly for the next operation. This product was found to decompose rapidly at room temperature. The i.r.: ν_{max} ($CHCl_3$) 2740 and 1715 cm^{-1}; n.m.r.: τ ($CDCl_3$) 0.4 (1H, triplet, $J = 2.0$ Hz, CHO), 6.05 (4H, singlet, OCH_2CH_2O), and 8.78 (3H, singlet, CH_3); m.s.: *m/e* 236 (M^+).

Ketal Alcohol **13**

Lithium aluminum hydride (197 mg, 5.2 mmol) was added to an ethereal solution (50 ml) of ketal acetaldehyde **12** (981 mg, 4.1 mmol) and the reaction was left at room temperature for 1 h. Excess lithium aluminum hydride was carefully destroyed by a small amount of water, magnesium sulfate was added, and the dried solution was filtered and evaporated to dryness. The resulting oil was purified by column chromatography with Florisil (elution with benzene–ether) (896 mg, 90% yield). The analytical sample was obtained by preparative t.l.c. The i.r.: ν_{max} ($CHCl_3$) 3610 and 3500 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.97 (4H, singlet, OCH_2CH_2O), 6.30 (2H, triplet, $J = 7.0$ Hz, CH_2O), and 8.87 (3H, singlet, CH_3); m.s.: *m/e* 238 (M^+).

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31. Found: C, 70.46; H, 9.11.

Ketal Mesylate **14**

Methanesulfonyl chloride (0.40 ml, 5.3 mmol) was added to a cold solution of ketal alcohol **13** (601 mg, 2.1 mmol) in methylene chloride (50 ml) containing pyridine (6 ml) and the reaction mixture was left at 5° for 2 days. Methylene chloride (200 ml) and a saturated sodium bicarbonate solution (25 ml) were added and the mixture was stirred for 15 min. The organic phase was separated, washed twice with water, dried, and evaporated to dryness yielding crude ketal mesylate **14** as an oil (840 mg, 95% yield). This product decomposed by distillation *in vacuo*. The i.r.: ν_{max} ($CHCl_3$) 1360 and 1170 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.70 (2H, triplet, $J = 7.0$ Hz, CH_2O), 5.98 (4H, singlet, OCH_2CH_2O), 6.97 (3H, singlet, CH_3SO_2O), and 8.84 (3H, singlet, CH_3); m.s.: *m/e* 272 (M).

Enone Mesylate **15**

A mixture of ketal mesylate **14** (665 mg, 2.1 mmol), acetone (150 ml), and aqueous hydrochloric acid (3 *N*, 4.2 ml) was left at room temperature for 2 h. Most of the acetone was then evaporated *in vacuo*, water was added and the aqueous phase was extracted with dichloromethane. The organic phase was washed with a saturated solution of sodium bicarbonate, water, dried, and evaporated to dryness. The resulting crude enone mesylate **15** (572 mg, ~100%) was not purified further and was used directly in the next operation. The i.r.: ν_{max} ($CHCl_3$) 1670, 1360, and 1170 cm^{-1}; n.m.r.: τ ($CDCl_3$) 3.95 (1H, broad singlet, olefinic proton), 5.60 (2H, triplet, $J = 7.0$ Hz, CH_2O), 6.94 (3H, singlet, CH_3SO_2O), and 9.07 (3H, singlet, CH_3); m.s.: *m/e* 272 (M^+).

Tricyclic Ketone **1**

Enone mesylate **15** (122 mg, 0.45 mmol) was added to a suspension of sodium hydride (13 mg, 0.56 mmol) in dry dimethoxyethane (15 ml) containing two drops of ethanol and the mixture was refluxed for 15 h under nitrogen. Water (15 ml) was added and the mixture was extracted with ether. The organic phase was dried and evaporated to dryness yielding an oil (71 mg). The v.p.c. analyses revealed the presence of two products in a ratio of 7:3. The major product was obtained pure by preparative v.p.c. (3 ft, 10% Carbowax 20 *M* column, 150°). It is a liquid. The i.r.: ν_{max} ($CHCl_3$) 1720 cm^{-1}; n.m.r.: τ ($CDCl_3$) 6.84 (1H, multiplet, bridgehead hydrogen) and 8.77 (3H, singlet, CH_3); m.s.: *m/e* 176 (M^+). The analytical sample was obtained on the 2,4-dinitrophenylhydrazone derivative (m.p. 172–173°, methanol).

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 60.66; H, 5.66; N, 15.72. Found: C, 60.55; H, 5.69; N, 15.83.

Studies in Solvolysis. Part IV.[1] Substituent and Solvent Isotope Effects in the Solvolysis of a Series of Benzyl Trifluoroacetates

JUNE G. WINTER AND J. M. W. SCOTT
Chemistry Department, Memorial University, St. John's, Newfoundland

Received December 17, 1971

The rates of neutral hydrolysis of a series of 4-substituted benzyl trifluoroacetates 4-X-$C_6H_4CH_2OCOCF_3$, X = NO_2, Cl, H, CH_3, and OCH_3 have been studied in water and deuterium oxide, both solvents containing 0.012 mol fraction of acetone. The alteration of the rates with the nature of the 4-substituent and the kinetic solvent isotope effect ($k(H_2O)/k(D_2O)$) are consistent with the proposal that the esters with X = NO_2, Cl, H, and CH_3 all react by an acyl–oxygen $B_{Ac}2$ mechanism. On the other hand, the same mechanistic criteria indicate that the 4-methoxybenzyl ester reacts by both the $B_{Ac}2$ and the S_N1 alkyl–oxygen fission paths in equal amounts.

Les vitesses de l'hydrolyse neutre d'une série de trifluoroacétates de benzyle substitués en 4-(X-4-$C_6H_4CH_2$-$OCOCF_3$ avec X = NO_2, Cl, H, CH_3, et OCH_3) ont été étudiées dans l'eau et dans l'eau lourde contenant toutes deux 0.012 fraction molaire d'acétone. La modification des vitesses avec la nature du substituant en 4 et l'effet isotopique du solvant sur la cinétique ($k(H_2O/k(D_2O)$) sont compatibles avec le mécanisme $B_{Ac}2$ proposé selon lequel les esters avec X = NO_2, Cl, H, et CH_3 réagissent tous par l'oxygène de l'acyle. De plus, ce même mécanisme montre que l'ester méthoxy-4 benzyle réagit à la fois par le schéma $B_{Ac}2$ et par le schéma S_N1 correspondant à la rupture de la liaison alkyl–oxygène, dans le même rapport.

Canadian Journal of Chemistry, 50, 1886 (1972)

Introduction

Using ^{18}O tracer studies Bunton and Hadwick (2) have deduced that the neutral hydrolysis of methyl trifluoroacetate takes place by a $B_{Ac}2$ acyl–oxygen fission reaction. On the other hand Moffat and Hunt (3) cite the extent of olefin formation in the solvolysis of *t*-butyl trifluoroacetate and conclude that the neutral hydrolysis of this substrate is mechanistically similar to *t*-butyl chloride, *i.e.*, the tertiary carboxylic ester is considered to react via an S_N1 carbonium ion mechanism involving alkyl–oxygen fission.

These views have been amply confirmed in more extended studies (4, 5) of the α-methylated series CF_3COOR (R = Me, Et, *i*-Pr, and *t*-Bu) using the kinetic solvent isotope effect (k.s.i.e. $k(H_2O)/k(D_2O)$), the thermodynamic parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ and secondary C—H/C—D isotope effects as mechanistic criteria. The summarized data from these studies are reported in Table 1 and the mechanistic conclusions to be derived from it are clear cut; the primary and secondary esters react by the $B_{Ac}2$ path and the tertiary ester reacts by an S_N1 route. A comparison of *t*-butyl chloride parameters with those for the corresponding trifluoroacetate is again useful (*c.f.* ref. 3).

The reasons for the change in mechanism $B_{Ac}2 \rightarrow S_N1$ in the α-methylated series must be energetic but even a qualitative analysis of the contributing factors is difficult. These factors are presumably a blend of electronic, steric, and solvation effects which alter as the structure of the alkyl group is varied. In the alkyl–oxygen fission reaction the alkyl group is the reaction seat and hence the S_N1 path must display greater sensitivity to the structure of the alkyl group than the competitive $B_{Ac}2$ process in which the same structural alterations are relatively remote from the reaction center. A combination of two reaction paths ($B_{Ac}2$ and S_N1) of widely disparate sensitivity to structural alterations is an ideal situation for mechanistic changes but in the α-methylated series does not provide the possibility of assessing the relative importance of the contributing factors mentioned above. On the other hand a sequence of 4-substituted benzyl trifluoroacetates provides a more tractable series of reactants in which solvation and steric factors remain constant to a first approximation, leaving the residual electronic factors as paramount in the emergence of the S_N1 process. The facility of heterolytic fission in the gas phase as measured by the enthalpy change

[1]Reference 1 is to be considered as Part III of the present series.

(ΔH_g^i) associated with the reaction

[1] $4\text{-X-}C_6H_4CH_2OCOCF_3 \rightarrow 4\text{-X-}C_6H_4CH_2^+ + CF_3COO^-$

should provide a useful guide as to which structures are likely to react by the S_N1 path. Unfortunately such data are not available for the trifluoroacetates. However, the values for the related series of benzyl chlorides in which the enthalpies of ionization are expected to parallel those of the related trifluoroacetates can be calculated from available thermochemical information. The data for the chlorides are recorded in Table 2 and the relatively low values for the 4-MeO and 4-CH_3 compounds suggest that the related trifluoroacetates would be likely candidates for the S_N1 reaction.

We proposed to detect such a change in mechanism via the k.s.i.e. (see Table 1) and also using the Hammett equation on the assumption that deviations from a linear free energy plot ($\log k$ *vs.* σ) would characterize any shift in mechanism $B_{Ac}2 \rightarrow S_N1$. The results of such experiments are reported below.

Experimental

General

Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer using carbon tetrachloride as solvent and tetramethylsilane as internal standard. Infrared

TABLE 2. Estimated gas phase enthalpies of ionization (ΔH_g^i) for a series of 4-substituted benzyl chlorides

X (4-X-$C_6H_4CH_2Cl$)	Ionization potential (kcal/mol)	ΔH_g^{i*} (kcal/mol)
NO_2	201	179
Cl	183	161
H	179	157
CH_3	172	150
OCH_3	157	135

*The gas phase enthalpies of ionization (ΔH_g^i) for the series of benzyl chlorides were calculated using the relationship $\Delta H_g^i = D(R—Cl) + I_p(R^\cdot) + E_f(Cl^\cdot)$ where D is the dissociation energy of the R—Cl band, I_p is the ionization potential of $R^\cdot$ and E_f is the electron affinity of $Cl^\cdot$. Bond dissociation energies for the chlorides were calculated from those for the bromides (9) with reference to the heats of formation (ΔH_f^0).

$$D(R—Cl) = \Delta H_f^0(R^\cdot) + \Delta H_f^0(Cl^\cdot) - \Delta H_f^0(RCl)$$
$$D(R—Br) = \Delta H_f^0(R^\cdot) + \Delta H_f^0(Br^\cdot) - \Delta H_f^0(RBr)$$

which gives on subtraction,

$$D(R—Cl) - D(R—Br) = \Delta H_f^0(Cl^\cdot) - \Delta H_f^0(Br^\cdot) - \Delta H_f^0(RCl) - \Delta H_f^0(RBr)$$

Reported heats of formation for several chlorides and bromides (10) lead to the average value of $D(R—Cl) - D(R—Br) = 13 \pm 2$ kcal/mol. Values of $D(R—Cl)$ that were calculated for the above series were constant to within the error reported below and an average value of 62 ± 2 kcal/mol was employed. The electron affinity for Cl was taken as 84 kcal/mol (11). The most significant contribution to changes in ΔH_g^i is the ionization potential of the $R^\cdot$ group. The values of ionization potentials quoted above are from the work of Lossing and co-workers (12), the value for the 4-nitrobenzyl radical being extrapolated from a least squares calculation of ionization potential *vs.* the Brown σ^+ parameter for a series of twelve 3- and 4-substituted benzyl radicals. The gas phase enthalpies of ionization are considered accurate to ± 4 kcal/mol.

TABLE 3. Physical properties of some esters derived from trifluoroacetic acid

*Theoretical value in brackets.
†Boiling point values quoted for vacuum of 0.05–0.1 mm unless stated otherwise.

spectra were recorded on a Perkin–Elmer model 237B grating spectrophotometer using a liquid cell technique with carbon tetrachloride as solvent. Mass spectra were recorded on a Hitachi Perkin–Elmer RMU6E spectrometer at 50 °C using an ionizing potential of 70 V with no appreciable difference between initial and final total ion current.

Materials

Esters were prepared by the usual method, either from trifluoroacetic anhydride/alcohol or silver trifluoroacetate/bromide and were distilled under vacuum. 4-Nitrobenzyl trifluoroacetate was recrystallized several times from petroleum ether (40–60 °C). All the esters were stored at 0 °C in a desiccator. The 4-methoxybenzyl trifluoroacetate was very unstable and tended to polymerize to a deep red tar if left at room temperature for more than 2–3 h before distillation and, consequently, this material was vacuum distilled immediately after preparation.

All kinetic measurements were made soon after purification. Purity was established by saponification, mass spectra, n.m.r., and infrared measurements. The excellent first order plots also vindicated the purity of the esters. The analytical and spectral data are recorded in Table 3.

Deuterium oxide was obtained from Atomic Energy of Canada and was used several times without appreciable loss of purity. The solvent was recovered after each kinetic run and was distilled, any acid present having been neutralized before hand with dried sodium carbonate. The first fraction containing acetone was discarded. The concentration of deuterium oxide was never less than 97%, determined by using n.m.r. spectrometry with purified acetonitrile as an internal standard.

Acetone was purified by treatment with small amounts of potassium permanganate until the pink color persisted. After drying with anhydrous potassium carbonate the material was distilled at 55.5–56 °C.

Kinetics

Rates were determined conductimetrically using apparatus described elsewhere (5). The concentration of ester in the kinetic determinations was *ca.* 10^{-4} *M* and the solvent systems used were water/acetone or deuterium oxide/acetone mixtures containing 0.012 mol fraction of acetone to facilitate dissolution of the ester. All rates were measured at 5.05 °C. A stock solution of the ester in acetone was prepared (*ca.* 0.002 *M*) and cooled to 5.05°. An aliquot (2 ml, 1.65 ± 0.02 g) of this solution was added, using a 2 ml syringe, to a measured volume of backing electrolyte (41 ml, 40.72 ± 0.06 g) at 5.05° in a stirred cell. The backing electrolyte was prepared by allowing a suitable amount of the appropriate ester to react with distilled water so as to reduce the initial resistance of the solution to a convenient value. The two weights quoted above, 1.65 ± 0.02 and 40.72 ± 0.06 g, are both averages of eight weight determinations. The backing electrolyte was introduced into the cell at room temperature using a 50 ml burette, the cell having been rinsed three times with backing electrolyte and then cleared of as much liquid as possible before refilling. The residual liquid on the sides of the cell weighed 0.2 g and did not vary from run to run. The amount of residual liquid is included in the weight of backing electrolyte quoted above.

For kinetic runs with deuterium oxide as the solvent, the volume of backing electrolyte used was adjusted so that the final reaction mixture contained 0.012 mol fraction of acetone.

Resistance readings were taken over approximately three half-lives and when the reaction was complete the infinity resistance was measured. At least four rate determinations were made for each ester and solvent combination.

The pseudo first order rate constants and k.s.i.e.'s are quoted in Table 4 for the 4-substituted benzyl esters along with those values for the methyl trifluoroacetate in the same solvent system for comparison. The k.s.i.e. of 3.4 for hydrolysis of this last ester in 0.012 mol fraction of acetone in water is in close agreement with the k.s.i.e. of 3.5 measured (4) in pure water. Therefore comparisons between the two solvent systems are considered legitimate.

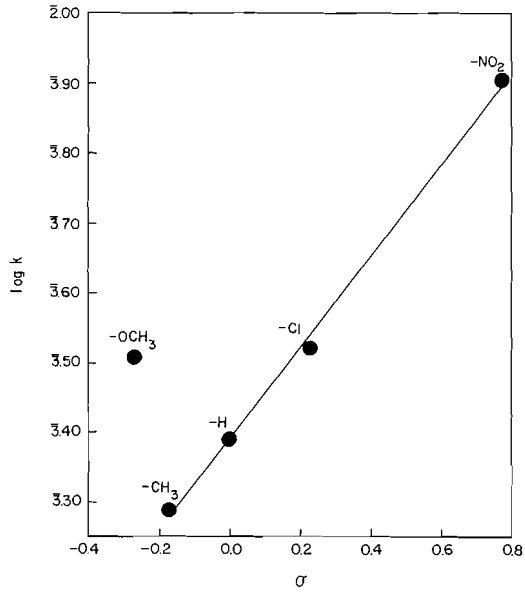

FIG. 1. Correlation of the rates of hydrolysis at 5.05 °C of 4-substituted benzyl trifluoroacetates with the Hammett σ parameter.

Discussion

We propose a useful rule which states that if the members of a series of substrates can each conceivably react by two distinct paths, A and B, and if both paths can be correlated by a linear free energy relationship using a common substituent scale, then deviations from the separate correlations, caused by a change in mechanism from A to B or vice versa, must be positive. This rule follows from the principle that if two reaction paths exist the path of minimum free energy will be the most important. The above rule is in accord with experience in the present study since the rate of solvolysis for the 4-methoxybenzyl trifluoroacetate deviates positively from a Hammett plot for which the remaining points are satisfactorily linear (see Fig. 1). From the sign of the ρ parameter we assume that this line corresponds to the $B_{Ac}2$ mechanism which is in agreement with the k.s.i.e's for the 4-CH_3 → 4-NO_2 compounds (see Table 4) and consistent with the fact that the sign of ρ for S_N1 reactions is always negative.

The deviation of the 4-OCH_3 compound from the $B_{Ac}2$ linear free energy correlation and the magnitude of the k.s.i.e. for this substance indicate that it reacts by a route different from that followed by the other structures but the relatively high value of the k.s.i.e. (1.8) is greater than those usually observed for S_N1 processes extensively studied by Laughton and Robertson (15). This possibly indicates "mixed kinetics", *i.e.*, the observed rate is the sum of $B_{Ac}2$ and S_N1 components. Indeed the results for the k.s.i.e. and the Hammett plot provide methods of calculating the relative contributions of the $B_{Ac}2$ and S_N1 processes to the observed rate for the 4-methoxybenzyl ester.

On the basis that the k.s.i.e. for S_N1 reactions is *ca.* 1.2 and for $B_{Ac}2$ reactions *ca.* 3.6 such a calculation can be made in the following way. Let k_S be the rate of the S_N1 reaction and k_B the rate of the $B_{Ac}2$ reaction; then if k_o is the observed rate we have,

$$[2] \qquad k_o = k_S + k_B$$

and hence for 4-methoxybenzyl trifluoroacetate

$$[3] \qquad \frac{k_o(H_2O)}{k_o(D_2O)} = \frac{k_S(H_2O) + k_B(H_2O)}{k_S(D_2O) + k_B(D_2O)} = 1.8$$

But

$$[4] \qquad \frac{k_S(H_2O)}{k_S(D_2O)} = 1.2 \text{ (average value)}$$

and

$$[5] \qquad \frac{k_B(H_2O)}{k_B(D_2O)} = 3.6 \text{ (average value)}$$

which, on combining eqs. 3, 4, and 5 gives

$$[6] \qquad k_S(H_2O) = k_B(H_2O)$$

i.e., the two paths are of equal importance for the 4-OCH_3 ester.

From the linear free energy relationship (Fig. 1) the extrapolated $B_{Ac}2$ rate for the 4-OCH_3 compound is 1.64×10^{-3} s^{-1} whereas the observed rate is 3.21×10^{-3} s^{-1} giving k_S equal to 1.57×10^{-3} s^{-1}. Thus both methods of calculation lead to the same conclusion, *i.e.*, $k_S(H_2O) = k_B(H_2O)$ for 4-methoxybenzyl trifluoroacetate.

Thanks are due to the Technical Services Department at Memorial University of Newfoundland for their continued care of the apparatus used in this work. We are grateful to Miss Marion Baggs and Mr. Earl Benson for measuring mass and n.m.r. spectra and to our colleagues for many useful discussions. We also express our thanks to the N.R.C.C. for their support of this work.

L'effet d'anions sur l'oxydation anodique du méthanol

GUY BELANGER
Institut de Recherche de l'Hydro-Québec, Varennes, Québec

Reçu le 13 décembre 1971

L'oxydation anodique du méthanol en milieu acide (1 *N* H_2SO_4) est passée brièvement en revue avec la présentation de courbes de polarisation et de courbes potentiodynamiques. Le mécanisme possible d'oxydation est présenté: on illustre le phénomène d'inhibition de l'oxydation par la formation d'oxydes à la surface du platine. La présence d'anions à faible concentration (10^{-3} à 10^{-4} *N*) modifie parfois le courant d'oxydation du méthanol. On tente de relier cet effet inhibiteur de certains anions à des valeurs théoriques de force de liaison, d'énergie du réseau cristallin et de chaleur d'hydratation. Une certaine corrélation sommaire peut s'établir entre l'importance de l'effet d'inhibition et la classification des anions en bases douces ou dures.

Anodic oxidation of methanol in acidic medium (1 *N* H_2SO_4) is briefly reviewed with the presentation of polarization and potentiodynamic curves. The possible mechanism of oxidation is presented: the inhibition phenomenon of oxidation is illustrated by the formation of oxides on the surface of platinum. The oxidation current of methanol is sometimes modified by the presence of anions in a low concentration (10^{-3} to 10^{-4} *N*). An attempt is made to relate the inhibitor effect of some anions to theoretical values of binding strength, crystal lattice energy, and heat of hydration. A succinct correlation can be set up between the importance of the inhibition effect and the classification of the anions in hard or soft bases.

Canadian Journal of Chemistry, **50**, 1891 (1972)

Introduction

Dans la mise au point d'une pile à combustible économique et fiable, l'oxydation anodique du combustible demeure un élément de recherche: le mécanisme de la réaction, le rôle d'oxydes à la surface des électrodes et leur participation à la réaction, l'effet du milieu réactionnel, l'effet des anions sont différents problèmes qui ne sont pas tout à fait résolus.

Plusieurs travaux ont été accomplis dans le domaine de l'oxydation anodique du méthanol en milieu aqueux (1–5). Il est à noter que le mécanisme de la réaction, quoique assez bien établi dans ses grandes lignes, pose encore quelques problèmes (6).

Un des aspects qui retiennent de plus en plus l'attention est l'effet de la présence de différents anions lors de l'oxydation anodique du méthanol et d'autres combustibles (7–10). Une étude mécanistique de l'effet des anions (autres que les halogénures) s'avère importante quant à la compréhension globale du mécanisme d'oxydation.

Partie expérimentale

Les mesures furent effectuées dans une cellule en Pyrex à trois compartiments isolés par des robinets non graissés. L'électrode de référence à hydrogène sur platine–platiné dans la solution fut utilisée. L'électrode de travail (platine) opérait sous atmosphère d'hélium (Grade Electrolytique de la compagnie Liquid Carbonic). L'hydrogène était désoxygéné par un catalyseur de palladium ("Dexo" de la compagnie Engelhard), l'hélium (Grade A, de la compagnie Liquid Carbonic) était désoxygéné sur du cuivre chauffé à environ 500 °C. Les lignes de gaz étaient en verre. Les autres aspects du montage et de la purification des gaz furent déjà décrits (11).

Le méthanol de meilleure qualité ("Fisher certified") fut employé directement de même que les sels de sodium ou de potassium des différents anions.

La solution de référence (1 *N* H_2SO_4) fut purifiée par une pré-électrolyse (environ 48 h minimum à 100 mA/cm^2) avec une anode de platine–platiné (2 cm^2) et une cathode de platine; ces deux électrodes étaient remplacées par de nouvelles électrodes de platine pour les mesures.

Les courbes de polarisation furent enregistrées comme nous l'avons décrit précédemment (12). Les différents instruments utilisés furent les suivants: le potentiostat Tacusel modèle PRT 10–20x, le potentiomètre motorisé Servovit 9B de Tacusel, l'amplificateur logarithmique Logalex 100B de Tacusel et un enregistreur *X*–*Y* de Honeywell modèle 550. L'intervalle de temps entre les mesures fut établi à 2 min.

Résultats

(a) Méthanol + 1 N H_2SO_4

Comme notre référence sera le système méthanol–1 *N* H_2SO_4, nous présenterons en premier lieu quelques données sur celui-ci. Notre "référence" est quelque peu arbitraire; nous l'avons choisie à cause du peu d'adsorption des sulfates. Les diminutions de courant illustrant l'effet des anions seront référées à ce système de base.

La fig. 1 illustre une courbe de polarisation typique pour une telle solution. On notera l'aspect quelque peu complexe de la relation courant–potentiel. Dans la partie ascendante

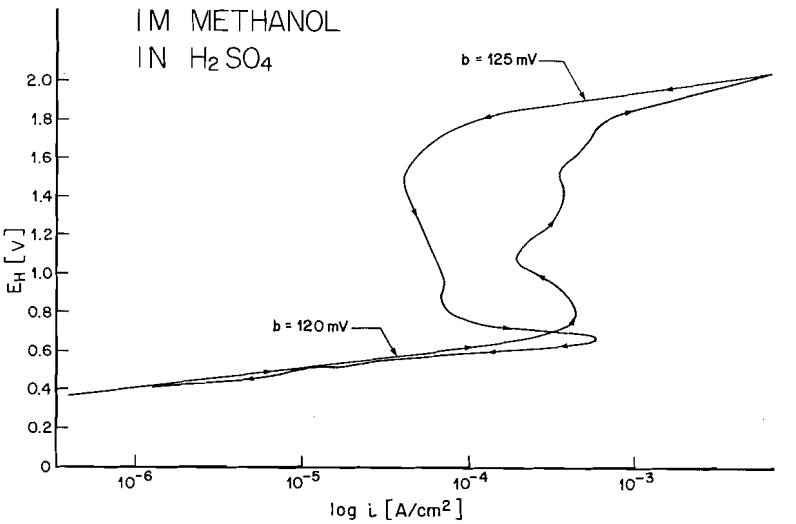

FIG. 1. Courbe de Tafel du méthanol dans l'acide sulfurique sur une électrode de platine: parties ascendantes et descendantes des valeurs de potentiel.

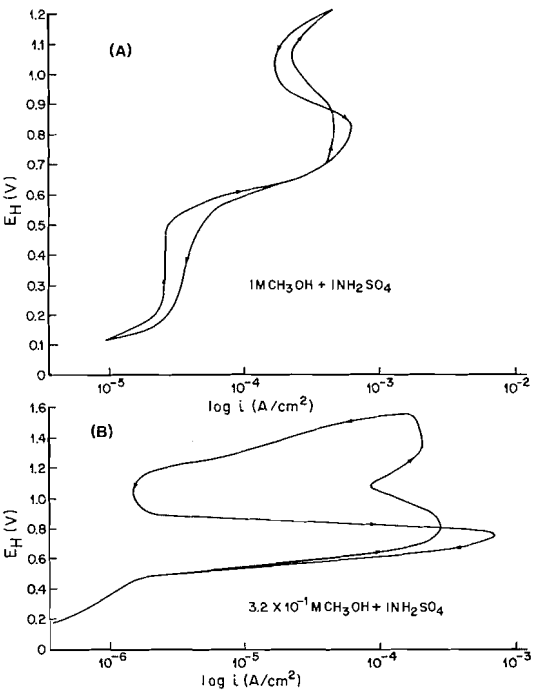

FIG. 2. (*a*) Courbe de Tafel de 0.1 à 1.2 V pour le méthanol dans l'acide sulfurique. (*b*) Courbe de Tafel de 0.2 à 1.6 V pour le méthanol dans l'acide sulfurique.

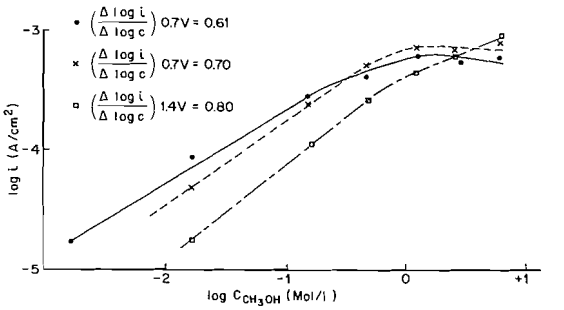

FIG. 3. Variation du courant à différents potentiels pour une série de concentrations de méthanol dans 1 *N* H_2SO_4; ●, 0.7 V pour la partie descendante de la courbe de Tafel; ×, 0.7 V, et □, 1.4 V pour la partie ascendante de la courbe.

(0.4 à 2.0 V) plusieurs aspects méritent d'être mentionnés. Le premier maximum de courant se manifeste à environ 0.75 V et correspond assez bien aux valeurs déjà observées pour ce système (3) et d'autres oxydations anodiques de composés organiques sur les électrodes de platine (2, 12, 13). A potentiel plus anodique, le courant décroît illustrant un phénomène d'inhibition. Il est maintenant reconnu que cette inhibition trouve son origine dans la présence d'oxydes de platine à la surface de l'électrode (3, 13, 14). Le même phénomène se reproduit à 1.4 V. La pente ($\Delta E/\Delta \log i$) pour l'intervalle entre 0.5 et 0.7 V est de 120 mV et se compare très bien avec la valeur rapportée par Bagotsky et Vasilyev (3): nous élaborerons plus en détail cette valeur au prochain chapitre.

L'influence d'une forme quelconque d'oxyde à la surface de l'électrode et son rôle dans le mécanisme d'oxydation sont illustrés par l'hystérésis très prononcée de la courbe. En effet, la

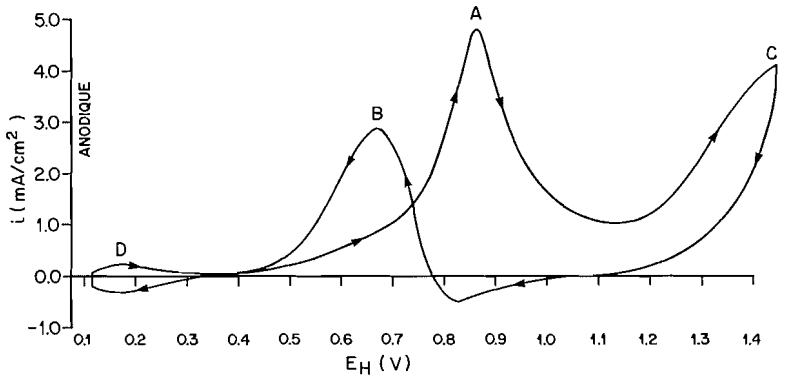

FIG. 4. Courbe potentiodynamique: vitesse de balayage de 260 mV/s. Concentration de méthanol 4.7×10^{-1} *M* dans 1 *N* H_2SO_4.

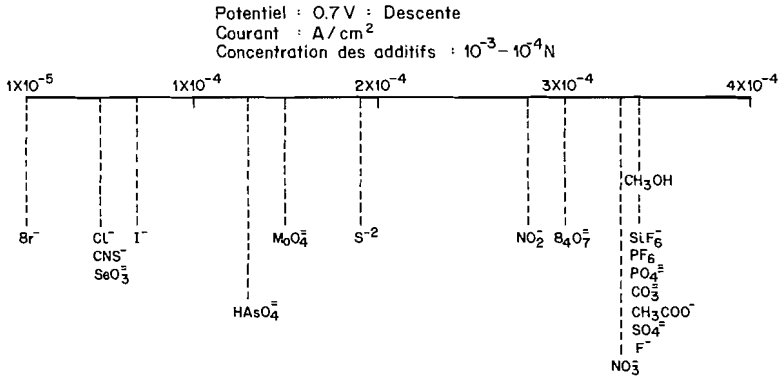

FIG. 5. Courant du pic à 0.7 V de la partie descendante de la courbe de Tafel en présence de différents anions.

partie descendante (2.0 à 0.4 V) de la courbe de polarisation, diffère grandement de la partie ascendante (fig. 1). L'aspect de la courbe est aussi différent. Le pic d'oxydation est beaucoup plus fin pour la partie descendante de la courbe illustrant le caractère d'adsorption du méthanol sur l'électrode. Une discussion plus élaborée sera reprise au prochain chapitre en utilisant la théorie d'inhibition de Gilroy et Conway (15).

Le rôle de la nature de la surface est illustré à la fig. 2*a*, où l'électrode est polarisée de 0.1 à 1.2 V. Pour cet intervalle de potentiel, on notera l'absence à toute fin pratique d'hystérésis: les pics d'oxydation ne sont pas tout à fait symétriques mais la différence est beaucoup moins grande que pour un balayage plus complet (figs. 1 et 2*b*). La fig. 2*b* indique le rétablissement de l'effet de surface même si le potentiel anodique ne dépasse pas 1.6 V.

La fig. 3 illustre la relation entre la densité de courant à l'équilibre et la concentration globale du méthanol et ceci à différents potentiels. On observe un ordre de réaction fractionnel et aussi à plus forte concentration, la vitesse de la réaction devient indépendante de la concentration globale du méthanol. Une explication plus approfondie sera tentée plus loin.

Pour compléter cette revue sur l'oxydation du méthanol en milieu acide, la fig. 4 montre la courbe potentiodynamique pour ce système. On note les deux pics d'oxydation, le pic du balayage anodique A et celui du balayage cathodique B. En C, c'est le deuxième pic anodique à environ 1.4 V, identique à celui observé pour les courbes à équilibre (fig. 1). Les pics en D illustrent l'adsorption et la désorption de l'hydrogène. Cette courbe potentiodynamique reproduit assez bien celle obtenue par Gilman et Breiter (16) et par Bagotsky et Vasilyev (2). Ici encore l'effet d'inhibition est très marqué.

(b) Méthanol + anions

La fig. 5 illustre d'une façon schématique l'influence de la présence d'anions (10^{-3}–10^{-4} *N*) sur le pic d'oxydation de la partie descendante de la courbe de Tafel. Ce pic à 0.7 V fut choisi car

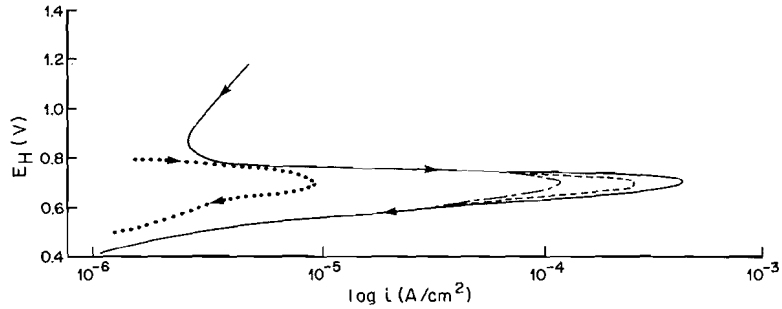

FIG. 6. Partie descendante de la courbe de Tafel avec différents anions; — 1 M CH_3OH + 10^{-3} N SiF_6^-; --- 1 M CH_3OH + 10^{-3} N NO_2^-; -·- 1 M CH_3OH + 10^{-3} N S^{2-}; ●●● 1 M CH_3OH + 10^{-3} N Br^-

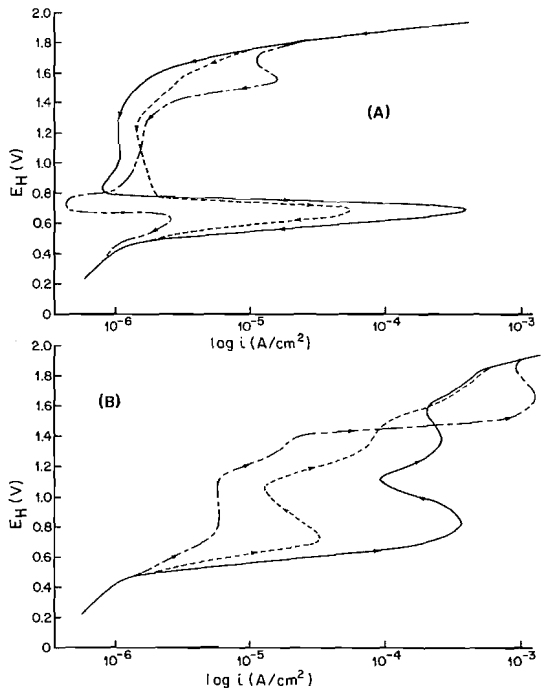

FIG. 7. (*a*) Partie descendante de la courbe de Tafel pour solution de 3×10^{-1} M CH_3OH dans 1 N H_2SO_4 avec différentes concentrations de NaCl: — 0 M NaCl; --- 2×10^{-4} M NaCl; --- 1×10^{-1} M NaCl. (*b*) Partie ascendante de la courbe de Tafel pour les mêmes solutions.

il est le mieux défini et le plus libre d'interférences par le recouvrement d'autres pics.

De la série des anions étudiés, il y a toute la gamme des activités. Certains n'ont aucune influence sur l'oxydation (*e.g.* SiF_6^-, F^-, CH_3COO^-, PO_4^{3-}), d'autres par contre inhibent presque totalement la réaction (*e.g.* Br^-, Cl^-, CNS^-) et enfin certains ont un effet intermédiaire (*e.g.* S^{2-}, $HAsO_4^{2-}$).

La fig. 6 fait voir d'une façon plus détaillée les courbes expérimentales en l'absence et en présence de différents anions avec des pouvoirs d'inhibition variés.

La fig. 7*a* et *b* montre l'effet de la concentration du chlorure sur la courbe complète de polarisation. On notera la variation des intensités de courant en fonction de la concentration du chlorure. A une concentration importante (0.1 N NaCl), la présence d'un pic à 1.6 V illustre le dégagement du chlore.

Discussion

Mécanisme d'oxydation du méthanol

(a) Courbes de polarisation

Comme nous l'avons mentionné précédemment, une pente de Tafel de 120 mV a été observée pour la partie ascendante de la courbe entre 0.5 et 0.7 V. On peut mettre de l'avant différents mécanismes de réaction qui nous mèneront à cette valeur de pente. Il faut en plus que d'autres résultats expérimentaux concordent avec ce mécanisme proposé.

Le mécanisme suivant a été proposé (2–4):

[1] $$4Pt + CH_3OH \rightleftharpoons Pt\{COH\} + 3Pt\{H\}$$

Cette première étape conduit à une déshydrogénation rapide de la molécule de méthanol (3, 17). L'hydrogène absorbé sur l'électrode est libéré grâce à la réaction suivante:

[1*a*] $$Pt\{H\} \rightarrow Pt + H^+ + e$$

Une autre réaction qui peut être considérée à l'équilibre (quasi-équilibre) implique la molécule d'eau et peut se formuler ainsi:

[2] $$Pt + H_2O \underset{i_{-2}}{\overset{i_2}{\rightleftharpoons}} Pt\{OH\} + H^+ + e$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

La réaction qui peut être considérée comme l'étape déterminante est la suivante:

[3] $\quad Pt\{OH\} + Pt\{COH\} \rightarrow 2Pt\{H\} + CO_2$

Les espèces $Pt\{OH\}$ et $Pt\{COH\}$ sont des entités transitoires et de nature mal définie. Les lois de Temkin (19) gouvernent l'adsorption de ces espèces à l'électrode. On peut dériver la relation courant–potentiel pour un tel système (13, 18, 19).

L'équation 1 peut être représentée comme suit:

$$[4] \qquad \ln K_1' + \ln C_{MeOH} = \frac{r\theta_{COH}}{RT}$$

où K_1' groupe une série de constantes de la réaction, C_{MeOH} est la concentration du méthanol, θ_{COH} est la fraction de l'électrode qui est recouverte par l'espèce $\{COH\}$, R et T sont la constante des gaz et la température respectivement. Le symbole r représente le paramètre de Temkin et tient compte de l'hétérogénéité de la surface ou des interactions entre les différentes espèces adsorbées (19).

Aussi réaction 2 peut être transcrite de la même manière:

$$[5] \qquad \ln K_2' + \ln C_{H_2O} + \frac{FV}{RT} = \frac{r\theta_{OH}}{RT}$$

où F est la constante de Faraday, V est le potentiel de l'électrode et θ_{OH} est le recouvrement de l'électrode par l'espèce $\{OH\}$. On peut, à titre d'exemple dériver de façon plus explicite cette dernière relation 5.

Le courant dans une direction pour l'éq. 2 est donné par la relation suivante (19):

$$[5a] \quad i_2 = k_2(1-\theta)C_{H_2O}\exp\left[\frac{\alpha F}{RT}V\right] \times \exp\left[-\frac{\alpha r}{RT}\theta_{OH}\right]$$

Le courant dans la direction opposée est donné comme suit (19):

$$[5b] \quad i_{-2} = k_{-2}\theta_{OH}C_{H^+}\exp\left[-\frac{(1-\alpha)}{RT}FV\right] \times \exp\left[\frac{(1-\alpha)}{RT}r\theta_{OH}\right]$$

Comme [2] est considéré étant à l'équilibre alors $i_2 = i_{-2}$ et donc

$$[5c] \quad \ln\frac{k_2}{k_{-2}} + \ln(1-\theta) + \ln C_{H_2O} - \ln\theta_{OH} - \ln C_{H^+} + \frac{FV}{RT} = \frac{r}{RT}\theta_{OH}$$

où k_2 et k_{-2} sont des constantes de la vitesse de la réaction, $1-\theta$ est la fraction de la surface qui est libre et α est coefficient de transfert qui est de l'ordre de 0.5 (19). En groupant les différents termes définis comme K_2', on obtient la relation 5.

De même on peut écrire pour la réaction 3, l'équation suivante:

$$[6] \quad \ln i_3 = \ln k_3 + \ln\theta_{OH} + \ln\theta_{COH} + \frac{r\alpha}{RT}(\theta_{OH} + \theta_{COH})$$

Ici les paramètres d'adsorption de Temkin ont été posés égaux comme cela se fait habituellement (19, 13). Il est certain cependant qu'ils sont différents mais pour la simplification de la dérivation des équations le même symbole a été utilisé. Il est à noter cependant que les conclusions générales tirées de ces équations ne seront pas modifiées car les valeurs de r n'apparaissent pas dans la pente de Tafel ou dans le calcul de l'ordre de la réaction.

Des éqs. 4 et 5, 6 peut se réécrire:

$$[7] \quad \ln i_3 = \ln k_3 + \ln\theta_{OH} + \ln\theta_{COH} + \alpha\ln K_1' + \alpha\ln K_2' + \alpha\ln C_{H_2O} + \alpha\ln C_{MeOH} + FV/RT$$

La relation 7 nous permet de tirer les conclusions suivantes: (*a*) la pente de Tafel: $\Delta V/\Delta\log i = 2.303\ RT/\alpha F = 120$ mV; (*b*) l'ordre de la réaction par rapport au méthanol: $\Delta\log i/\Delta\log C_{MeOH} = \alpha = 0.5$.

Expérimentalement, on observe une pente de 120 mV dans la région où la relation de Tafel est suivie. L'ordre de la réaction se situe aux environs de 0.6 (c.f. fig. 3) pour plusieurs potentiels.

La confirmation directe du mécanisme n'a pas été réalisée: des expériences avec le méthanol contenant de l'oxygène 18 pourrait indiquer plus exactement l'origine d'un des oxygènes dans le produit final, le CO_2. Il faut remarquer cependant que les évidences indirectes sont assez convaincantes pour justifier le mécanisme global (1 et les références incluses).

L'étape réaction 2 pourrait être l'étape déterminante et donnerait une pente de 120 mV mais

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dans ce cas-là, la relation courant–concentration de méthanol serait inexistante: la réaction serait d'ordre zéro ce qui n'est pas le cas. A forte concentration, l'ordre de la réaction par rapport à la concentration du méthanol devient d'ordre zéro ce qui est normal. Le mécanisme plus haut concorde assez bien dans ses grandes lignes avec celui proposé par Bagotsky et Vasilyev (2).

(b) Mécanisme d'inhibition

Comme nous l'avons déjà mentionné, la partie ascendante de la courbe de polarisation illustre le phénomène d'inhibition. Cet aspect de l'oxydation anodique de composé organique a été traité d'une façon extensive par Gilroy et Conway (15). Comme nous l'avons vu, l'étape réaction 2 fournit une espèce active du genre Pt—OH. Cependant, lorsque le potentiel de l'électrode augmente, une réaction subséquente se produit:

$$[8] \qquad Pt\{OH\} \rightarrow Pt\{O\} + H^+ + e$$

Cette dernière espèce Pt{O}, agit comme inhibiteur et empêche la réaction 3 de se produire. Dans la partie descendante de la courbe de polarisation de 2 à environ 0.8 V, il n'y a que l'oxyde Pt{O} sous une forme cristallographique inactive. A potentiel plus bas, il y a formation de l'espèce active Pt{OH}. C'est le cas (*iii*) dans cette publication: pour cette situation, les prédictions théoriques du traitement (15) prévoient une pente de 2 RT/F pour la partie non-inhibée et après le maximum de courant celui-ci décroît avec une pente de 2 $RT/3F$. Nous avons donc, un pic asymétrique. Ces valeurs de pentes sont valables pour le cas où les espèces adsorbées obéissent aux lois de Langmuir. Pour les isothermes de Temkin, la pente positive ne varie pas mais la pente négative peut varier selon la valeur du paramètre r dans les éqs. (4–6). La relation courant–potentiel obtenue par ces auteurs est de la forme suivante:

$$[9] \qquad \frac{i}{i_{max}} = [2 \exp \beta F \Delta V/RT] \Big/ \left(1 + \exp\left[\frac{3\beta F \Delta V}{RT}\right]\right)$$

où i_{max} est le courant maximum (à 0.75 V pour le méthanol) et $\Delta V = V - V_{max}$.

Un autre aspect lié au phénomène d'inhibition est l'hystérésis très prononcée des courbes de polarisation (figs. 1 et 2) et des courbes potentiodynamiques (fig. 4). Ce phénomène est lié à la présence d'oxyde sous forme cristallographique différente. En effet, comme nous l'avons noté à la fig. 2*a*, cette hystérésis est très légère si le maximum anodique ne dépasse pas 1.2 V. Cependant à 1.6 V, l'hystérésis est complète. Il semble qu'entre la forme d'oxyde dans la partie ascendante de la courbe et celle qui se manifeste pour la partie descendante, il y ait une différence catalytique très importante. Il semble donc y avoir un changement de phase entre ces potentiels.

Oxydation du méthanol en présence d'anions

Comme nous l'avons vu lors de la présentation des résultats, nous pouvons noter toute une gamme d'effets de différents anions sur la vitesse d'oxydation du méthanol.

Généralement on explique l'inhibition par les anions en invoquant une adsorption préférentielle de ceux-ci sur l'électrode par rapport à la molécule organique, (8–10). Le mécanisme exact d'adsorption des anions n'est pas encore très bien connu et les raisons qui militent en faveur d'une adsorption importante pour certains anions et négligeable pour d'autres portent aussi à controverse.

Graham (20) utilise la notion de liaison covalente entre l'anion et le métal (le mercure en l'occurence) comme critère d'adsorption. Pour Lévine, Bell et Calvert (21) c'est dans l'énergie d'image qu'il faut rechercher l'origine de l'adsorption: c'est un concept impliquant des forces électrostatiques. Bockris *et al.* (22) invoquent l'énergie de solvatation comme critère d'adsorption pour un ion donné.

Enfin, une autre façon d'aborder le problème fut présentée par Barclay (23) et repose sur les concepts d'acides ou de bases douces ou dures de Pearson (24) ("soft or hard acids or bases"). Sous cette classification les anions qui sont fortement adsorbés sont les bases douces et ceux qui ne sont pas adsorbés sont des bases dures. Les anions durs sont relativement petits, non polarisables et leurs électrons de valence ne sont pas facilement enlevés (*e.g.* F^-). Les anions doux par contre, sont relativement gros et facilement polarisables (*e.g.* S^{2-}). Il a été montré (23) qu'il existait une corrélation assez juste entre le déplacement du potentiel de charge zéro du mercure et le degré d'adsorption des différents anions. Ce déplacement est peu important pour

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLEAU 1

Anion	Classification	% inhibition
S^{2-}	Doux	55
I^-	Doux	80
CNS^-	Doux	85
Br^-	Intermédiaire	97
Cl^-	Intermédiaire	85
NO_2^-	Intermédiaire	20
NO_3^-	Dur	0
CH_3COO^-	Dur	0
F^-	Dur	0

des anions non-adsorbés mais il acquiert une valeur importante en présence d'anions fortement adsorbés (*e.g.* le p.c.z. est de 437 mV par rapport à l'électrode de calomel standard en présence de fluorure et il est de 880 mV en présence de sulfure, un déplacement de 443 mV). Bien que cette classification ait été faite que pour le mercure qui est un métal unique, on peut tenter une approche similaire pour le platine. Ici c'est l'effet inhibiteur qui sera notre critère. Le tableau 1 illustre cette classification entre certains anions doux ou durs et le degré d'inhibition. Ce pourcentage d'inhibition est calculé en posant le courant à 0.7 V de la courbe descendante (fig. 1) à 100% pour le méthanol 1 *M* en milieu 1 *N* H_2SO_4. Le courant à ce potentiel est lu en présence des différents anions et la différence entre cette valeur et le 100% est prise comme degré d'inhibition, c'est-à-dire:

$$[10] \quad \%\ \text{d'inhibition} = \frac{(i_{CH_3OH+1\ N\ H_2SO_4} - i_{CH_3OH+1\ N\ H_2SO_4+Anion}) \times 100}{i_{CH_3OH+1\ N\ H_2SO_4}}$$

La classification de Barclay (23) s'applique dans ses grandes lignes: les anions durs ont un effet négligeable sur l'oxydation du méthanol et les anions doux ou intermédiaires ont des effets variables sur la vitesse d'oxydation. Cette classification est loin d'être parfaite mais c'est déjà un pas de fait dans une tentative d'explication des résultats expérimentaux.

La chaleur d'hydratation est un deuxième type de corrélation possible avec le pourcentage d'inhibition. Cette valeur thermodynamique donne une idée de la stabilisation d'un anion par le solvant. Si cette stabilisation est faible, l'ion sera porté à être adsorbé sur l'électrode pour acquérir un état d'énergie minimum (22). La

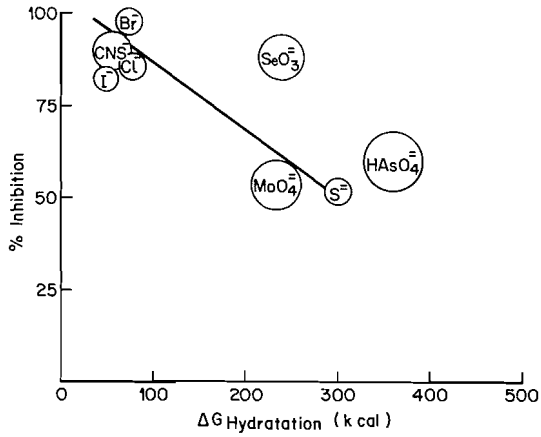

FIG. 8. Pourcentage d'inhibition du courant à 0.7 V de la partie descendante de la courbe de Tafel en fonction de la chaleur d'hydratation de différents anions.

chaleur d'hydratation est donnée par la relation suivante (25)

$$[11] \quad \Delta G_{HYD} = \frac{-164Z^2}{(r^- + 0.35)}$$

où ΔG_{HYD} est en kcal/mol, Z et r^-, sont la charge et le rayon ionique de l'anion, 0.35 est un facteur empirique tenant compte du rayon d'hydration des anions et 164 est un facteur de conversion incluant différentes constantes fondamentales. La fig. 8 illustre cette corrélation pour différents anions montrant une activité d'inhibition. Il existe un certain degré de dépendance entre cette valeur thermodynamique et le pourcentage d'inhibition. Il faut cependant noter que plusieurs anions ayant une valeur de ΔG_{HYD} relativement faible (donc ils seraient stabilisés par une adsorption sur l'électrode) n'influent pas sur l'oxydation du méthanol. Ce critère de faible valeur de ΔG_{HYD} n'est donc pas unique mais semble très important (23).

La force de la liaison covalente entre le métal et l'atome adsorbé (*e.g.* Pt—F, Pt—O—PO_3^{3-}, etc.) est une autre indication du degré d'adsorption d'un anion. On peut calculer une valeur d'énergie de liaison covalente en utilisant l'équation de Pauling (26):

$$[12] \quad D_{Pt-X} = 1/2\{D_{Pt-Pt} + D_{X-X}\} + 23\,(\chi_{Pt} - \chi_X)^2$$

où D_{Pt-Pt} et D_{X-X} sont les énergies de dissociation des liaisons simples platine—platine et

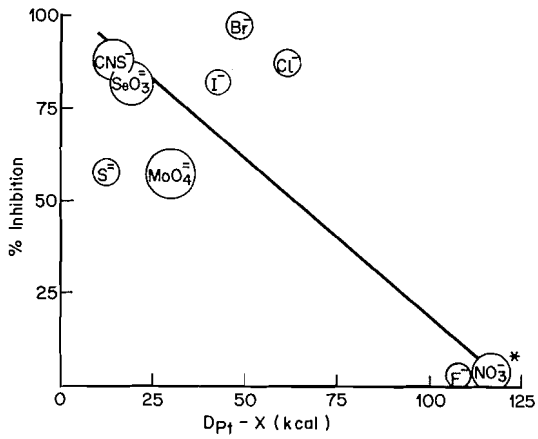

FIG. 9. Pourcentage d'inhibition du courant à 0.7 V de la partie descendante de la courbe de Tafel en fonction de l'énergie covalente de liaison platine–anion.
*Valeur pour la liaison Pt—O.

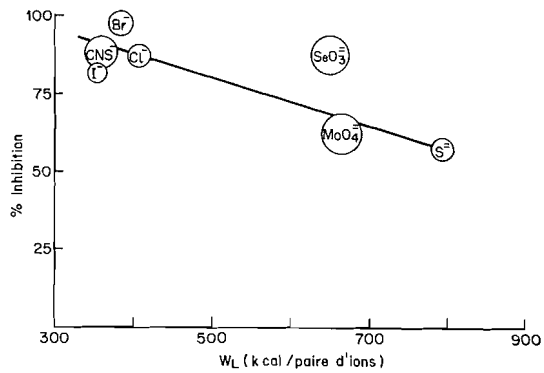

FIG. 10. Pourcentage d'inhibition du courant à 0.7 V de la partie descendante de la courbe de Tafel en fonction du réseau cristallin.

X—X respectivement, χ_{Pt} et χ_X sont les électronégativités. Toutes les valeurs utilisées pour ces déterminations sont tirées du volume de Sanderson (26). La fig. 9 indique la corrélation résultante entre cette énergie de liaison covalente et le pourcentage d'inhibition. Pour les anions composés de plusieurs atomes, le point d'ancrage de cet anion avec le platine est l'oxygène ou le fluore pour les cas suivants (NO_3^-, PO_4^{3-}, PF_6^-, SiF_6^-). Pour ces anions, le degré de saturation est complet et aucune liaison ne peut s'établir entre l'atome central et le platine.

La corrélation obtenue à la fig. 9 pose quelques problèmes d'interprétation: en effet une valeur d'énergie plus grande entre le platine et un anion donné impliquerait une stabilité accrue pour ce composé et causerait donc une inhibition plus marquée. Cependant cette relation ne se retrouve pas expérimentalement. Le problème d'une liaison du type Pt—F pour un anion comme le PF_6^- limite quelque peu la valeur de ce genre de corrélation. En effet, le fluore est déjà engagé dans une liaison covalente avec le phosphore et peut difficilement formé une liaison avec le métal car il est déjà dans son état de valence maximum. On peut calculer une interaction électrostatique entre les anions et l'électrode pour palier à la limitation de la méthode précédente. L'énergie du réseau cristallin, W_L entre un cation Pt(IV) et différents anions a été calculé à l'aide de la méthode de Kapustinski (27):

$$[13] \quad W_L = \frac{287.2\ (nn')}{r_c + r_a} \times \left[1 - \frac{0.345}{r_c + r_a}\right] \text{kcal/paire d'ion}$$

où n et n' sont les charges des ions, r_c et r_a sont les rayons ioniques du cation et de l'anion. La fig. 10 nous montre la corrélation possible entre certains anions étudiés et le pourcentage d'inhibition. Comme pour la comparaison avec les valeurs pour l'énergie de liaison covalente, la corrélation se situe dans le mauvais sens. Nous avons omis délibérément les anions qui ne montraient aucun effet d'inhibition pour toutes ces corrélations. Il est à noter que pour les valeurs de ΔG_{HYD} et W_L, les résultats sont très proches car la méthode de calcul est très semblable: les valeurs cherchées sont proportionnelles à la charge et inversement proportionnelles au rayon ionique.

Pour résumer ces différentes corrélations, on peut dire que celles impliquant le calcul des liaisons covalentes ou ioniques ne sont pas valables. La conclusion préliminaire qui s'impose est l'importance du facteur de stabilisation de l'anion par le solvant et non la stabilisation sur l'électrode. Cependant, une faible valeur de l'énergie de solvatation n'est pas l'unique critère d'adsorption. Klopman (28) a mis au point une méthode théorique où il fait intervenir à la fois l'énergie de solvatation et l'énergie de l'orbital de l'anion adsorbé. Le traitement théorique donné par cet auteur est relativement complexe mais offre des possibilités d'application pour les cas qui nous occupent. Cependant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

il n'entre pas dans le cadre de cet article d'élaborer cette théorie.

Le mécanisme d'inhibition est surtout par adsorption, c'est-à-dire, par blocage des sites actifs. C'est ainsi que l'on a expliqué les phénomènes d'interaction entre l'oxydation de composés organiques et différents anions (9, 10, 29–31). Les facteurs régissant cette adsorption ne sont pas entièrement élucidés mais il semble qu'il y ait toujours une série de paramètres à considérer (chaleurs d'hydration, énergie d'interaction anion-électrode, stabilité des espèces dans les solvants, etc.). Taylor *et al.* (8) ont montré qu'il y a plus qu'une simple adsorption d'anion inhibiteur qui réduit la vitesse oxydation de l'acide formique. En effet, pour un recouvrement très faible de l'électrode par le chlorure, ($\theta \simeq 0.1$), il y a une réduction de 80% dans le courant d'oxydation. Il semble donc qu'il y ait d'autres facteurs qui jouent lors de ces inhibitions.

Une étude plus approfondie par différentes techniques s'impose pour les anions qui montrent une certaine activité d'inhibition. Il est important de déterminer quelles espèces sont présentes sur l'électrode et quel est le mécanisme de blocage de la réaction.

L'auteur tient à remercier d'une façon particulière Monsieur Ashok K. Vijh pour la direction générale, les échanges de vue et l'encouragement au cours du présent travail.

Des remerciements s'adressent aussi à Messieurs P. Lenfant, J.-P. Randin et I. Morcos pour les discussions intéressantes lors de la réalisation de ce travail.

Isotopic Exchange Between Hydrogen and Water Vapor over Supported Metal Catalysts. Part I. Kinetics of the Exchange[1,2]

J. H. ROLSTON AND J. W. GOODALE

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received January 4, 1972

Some rate data for the transfer of a deuterium atom tracer between hydrogen and water vapor, catalyzed by platinum supported on γ-alumina, are reported. Above 100 °C the transfer rate measured at 1 atm total pressure is shown to be free of mass transfer effects, and obeys an initial first order dependence on water vapor for vapor pressures less than 10 Torr. A near zero order dependence is observed at higher water vapor pressures. At temperatures below 100 °C the transfer rate is essentially independent of water vapor pressure between 5 and 100 Torr suggesting that surface adsorbed water is involved in the rate limiting transfer step.

Nous rapportons quelques résultats de vitesse pour le transfert d'un atome de deutérium traceur entre l'hydrogène et la vapeur d'eau, catalysé par le platine sur un support d'alumine-γ. Nous montrons qu'au-delà de 100 °C, la vitesse de transfert mesurée à une pression totale d'une atmosphère est exempte d'effets de transfert de masse et obéit à une dépendance initiale de premier ordre de la vapeur d'eau pour des pressions de vapeur de moins de 10 Torr. Nous observons une dépendance d'ordre presque zéro à de plus fortes pressions de vapeur d'eau. A des températures au-dessous de 100 °C, la vitesse de transfert est essentiellement indépendante de la pression de vapeur d'eau entre 5 et 100 Torr, suggérant que l'eau adsorbée à la surface est impliquée dans l'étape limitante de la vitesse de transfert.

Canadian Journal of Chemistry, **50**, 1900 (1972)

Introduction

At moderate temperatures the partitioning of deuterium between water vapor and hydrogen,

$$[1] \qquad HDO(v) + H_2(g) \overset{K}{\rightleftarrows} HD(g) + H_2O(v)$$

is such that the equilibrium position favors concentration of the deuterium in the water with calculated values (1) of the equilibrium constant, K, varying between 0.239 at 0 °C and 0.412 at 125 °C. As this represents a substantial isotope fractionation the reaction has received consideration (2, 3) as the basis of chemical exchange processes for the recovery of deuterium from natural water. The success of such a process depends to a large extent upon the rate of isotope transfer between the two chemical species and it is clear from early studies (4, 5) that rapid exchange rates, at moderate temperatures, can only be achieved in the presence of a catalyst.

A search for a suitable catalyst under the auspices of the Manhattan Project (2) led to the adoption of platinum on charcoal and of chromia-promoted nickel as the two most promising catalysts for large scale operations. Both catalysts appear to lose catalytic activity when liquid water contacts the surface (6, 7) and with nickel-chromia catalysts (8) this has been attributed to the ease of vapor condensation in the catalyst pores. In the absence of such effects a surface reaction would appear to govern the exchange kinetics (9) although diffusion effects often complicate the observed exchange rates (10–12). Thus it has been necessary to show that the exchange rate is not limited by such effects before attempting to assess the role of vapor composition on this isotope exchange reaction and accordingly a single pass flow reactor has been constructed and used to define the necessary reaction conditions for characterizing the exchange rate over a supported platinum catalyst.

Experimental

Catalyst

A commercially available catalyst[3] consisting of a nominal 0.5 wt. % loading of platinum on alumina was used. This was supplied in the form of 3.2 mm diameter right cylinders with the metal impregnated only on the outer 0.3 mm layer of the pellets (13). The pellets were crushed in a mortar and sieved through standard screens to provide catalyst particles of known diameters, generally 0.05 mm. Clean Pyrex glass was crushed and sieved to a particle diameter between 0.10 and 0.15 mm for use as an inert diluent in maintaining a catalyst bed of fixed geometry.

Materials

The hydrogen source was Matheson Gold Label Hydrogen which was passed through a "Deoxo" unit[3] and a liquid nitrogen trap to minimize trace impurities. Water of natural isotopic abundance (10^6 D/H = 143) was triply distilled from sodium dichromate prior to use and was enriched with measured volumes of 99.48% deuterium oxide to provide saturator liquid of known isotopic abundance (nominal atom ratio: 10^6 D/H = 3000). The mole fraction of HDO present in the vapor was calculated from the known isotope content of the saturator liquid and the liquid–vapor separation factor (14). Dissolved gases were removed from the saturator liquid by a prior purge of the liquid with purified hydrogen.

Method

The stream of hydrogen was bubbled through the enriched water contained in the thermostated saturator column and the humidified stream was passed downward through a weighed amount of catalyst particles (5–25 mg). The latter was mixed with the Pyrex chips (950 mg) and supported in the reactor over a porous glass frit, forming a catalyst bed 9.0 mm in length and 10.5 mm diameter. A 2 mm deep layer of glass chips was placed on top of the catalyst bed to aid in establishing a uniform flow pattern. The catalytic activity of the crushed Pyrex was checked and shown to be negligible below 200 °C.

The temperature of the catalyst was measured by a thermocouple enclosed in a thin-walled glass tube located immediately above the catalyst bed and attached to the sealed end of a 21 cm section of 25 mm Pyrex tubing. The latter fitted concentrically over the open end of the inner 13 mm diameter Pyrex tube supporting the catalyst bed and provided an enclosed volume for preheating of the gas stream prior to its entry into the catalyst chamber. The outer chamber was surrounded by a length of copper tubing and the assembly was placed in a cylindrical electrical heater which was controlled by an electronic relay.[4] The control thermocouple was placed between the copper sheath and the outer glass tube and conditions were adjusted to maintain both thermocouples to within 1 °C of each other.

The effluent hydrogen flow was determined with a soap-film flowmeter after removal of the water vapor in a condenser and calcium chloride drying tube. The deuterium content of the hydrogen was measured on a Thompson-Houston 202 mass spectrometer, modified (15) to permit on-line deuterium analysis at near natural abundance levels with a precision of 0.1%. The calibration of the spectrometer was repeatedly checked against hydrogen standards of known isotopic content.

Catalysts were initially reduced in a stream (1 cm^3/s) of dry hydrogen over a period of 17 h at 300 °C and cooled to operating temperatures under hydrogen. A flow of partially humidified hydrogen was initiated and kinetic measurements were taken at temperatures between 75 and 200 °C with the quantity of deuterium transferred varying between 5 and 90% of the equilibrium value. The ratio of the partial pressures of hydrogen and water was varied from 150:1 to 7:1 by altering the temperature of the saturator liquid. Values of the equilibrium deuterium content in the effluent gas were determined by increasing the quantity of catalyst in the bed and reducing the flow rate. These were in good agreement with values calculated assuming conservation of deuterium between the two components and known values of K (1).

[4]Temperature Controller Model 5626, Bach Simpson, Toronto, Ontario.

Treatment of Data

With mixtures of hydrogen and water vapor of low deuterium content the exchange activity of a catalyst was characterized by a transfer coefficient k_r, as the moles of HD transferred per second per gram of catalyst. An expression for k_r was developed by considering a volume element of the reactor dV, of cross section A (cm^2) and height dz (cm) through which the hydrogen and the vapor streams flow co-currently (8). The increase in the flow of deuterium as HD, in the volume element is given as the product of the hydrogen flow F_{H_2} (mol/s) and the incremental change in the mole fraction dn, of HD. The rate at which deuterium is transferred to the hydrogen stream is equal to the rate at which it is depleted from the water stream as the total deuterium content of the volume element is conserved. Thus

$$[2] \qquad F_{H_2}\,dn + F_{H_2O}\,dN = 0$$

where F_{H_2O} is the molar flow of water vapor and dN the corresponding change in the mole fraction of HDO. The ratio of the partial pressure of water to hydrogen is π, hence $F_{H_2O} = \pi F_{H_2}$ and eq. 2 can be integrated to give

$$[3] \qquad N = N_0 - \frac{(n - n_0)}{\pi}$$

where n_0, N_0 and n, N are the mole fractions of HD and HDO in the hydrogen and water vapor streams which enter and leave the volume V of the catalyst bed. For a volume increment dV the rate of isotope transfer per unit volume has the form (16)

$$[4] \qquad \frac{1}{dV} F_{H_2}\,dn = k_r \rho (N - K^{-1} n)$$

where k_r is the transfer coefficient denoting the rate of isotope transfer per gram of catalyst, ρ is the number of grams of catalyst per cm^3 of reactor volume, K^{-1} is the reciprocal of the equilibrium constant of the exchange reaction and the term $(N - K^{-1}n)$ is the displacement from the equilibrium isotopic distribution. Substitution of eq. 3 and the expression $dV = A\,dz$ into eq. 4 and integrating over the length, z (cm), of catalyst bed leads to

$$[5] \qquad \log_e \left\{ \frac{\left(N_0 + \frac{n_0}{\pi}\right) - n_0\left(K^{-1} + \frac{1}{\pi}\right)}{\left(N_0 + \frac{n_0}{\pi}\right) - n\left(K^{-1} + \frac{1}{\pi}\right)} \right\} = \left(K^{-1} + \frac{1}{\pi}\right) k_r \rho \frac{Az}{F_{H_2}}$$

Simplification of eq. 5 is achieved in terms of the equilibrium isotope contents n_e and N_e which are related by

$$[6] \qquad (1 - n_e)N_e = K^{-1}(1 - N_e)n_e$$

Integration of eq. 2 between the initial and equilibrium

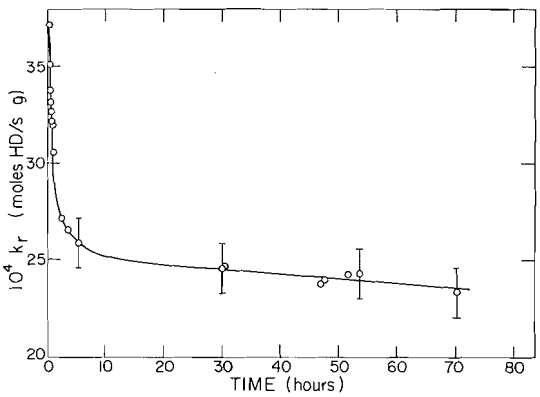

FIG. 1. Dependence of transfer coefficient upon time. $F_{H_2} = 3.5$ cm^3 S.T.P./s; $P_{H_2}/P_{H_2O} = 22.0$; $T = 125$ °C.

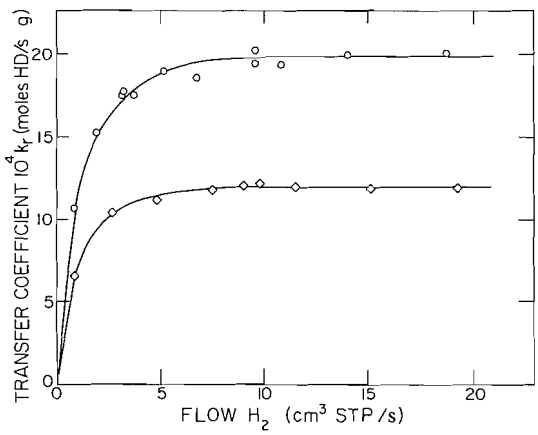

FIG. 2. Dependence of transfer coefficient upon hydrogen flow rate. (◇) 80 °C, ordinate ×2; (○) 180 °C.

boundary conditions leads to

$$[7] \qquad n_e = n_0 - \pi(N_e - N_0)$$

In streams of low deuterium concentration $n_e \ll 1$, $N_e \ll 1$ thus $N_e = K^{-1}n_e$ to a good approximation and eq. 7 can be written as

$$[8] \qquad \left(N_0 + \frac{n_0}{\pi}\right) = n_e\left(K^{-1} + \frac{1}{\pi}\right)$$

Substitution of eq. 8 into eq. 5 and recalling that the weight W(g) of catalyst in the reactor volume is ρAz results in the following expression for the transfer coefficient k_r

$$[9] \qquad k_r = \left(\frac{1}{K^{-1} + \frac{1}{\pi}}\right)\frac{F_{H_2}}{W}\log_e\left(\frac{n_e - n_0}{n_e - n}\right)$$

Results

The initial phase of this study was confined to an investigation of the conditions under which the effects of mass transfer on the isotope transfer rate could be eliminated. Preliminary studies indicated the exchange rate, as defined by the transfer coefficient k_r (mol HD/s g) in eq. 9 decreased rapidly over the first 2 h of operation (Fig. 1) after which rates were constant to within ±5% as indicated by the error bars. It was therefore necessary to "condition" the catalyst for 2–3 h before attempting further experiments with different flow rates. With hydrogen flows greater than 10 cm^3/s S.T.P. the transfer rate is independent of the gas velocity for catalyst temperatures less than 200 °C, (Fig. 2). The calculated transfer coefficient was also found to be independent of both the quantity of catalyst loaded in the reactor bed and of the deuterium content of the liquid water used to humidify the hydrogen (Table 1).

*$P_{H_2O} = 31.4$ Torr, $P_{H_2} = 729$ Torr with H_2 flow = 10.5 cm^3/s and $T = 126$ °C using 0.5% platinum–alumina catalyst.
†$P_{H_2O} = 34.5$ Torr, $P_{H_2} = 727$ Torr with H_2 flow = 10.5 cm^3/s and $T = 123$ °C using 0.5% platinum–alumina catalyst.

Although the measured transfer rates would appear to be free of external mass transport effects (Fig. 2), it was necessary to test for the absence of internal transport effects within the catalyst particles. This was accomplished by varying the average diameter of the particles of crushed catalyst over a ten-fold range. The data for two temperatures, plotted in Fig. 3, show that the transfer rates approach maximum values as the particle size decreases below 0.1 mm and decrease significantly with particles of larger size. This indicates that at these temperatures, internal mass transfer effects are not

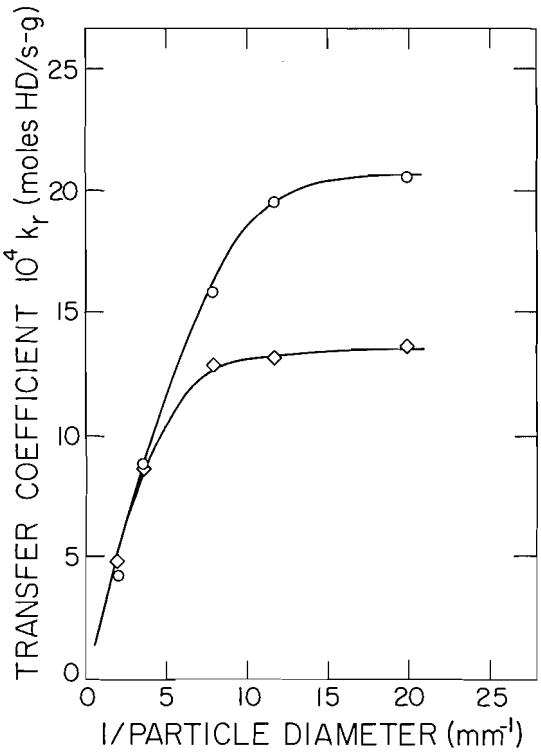

FIG. 3. Dependence of transfer coefficient upon diameter of catalyst particle. (◇) 80 °C, ordinate ×2; (○) 123 °C.

governing the transfer rate in particles with an average diameter of 0.05 mm. As a consequence of increased reaction rates at higher temperatures somewhat smaller particles appear necessary to achieve this condition at 123 °C than at 80 °C.

The dependence of the transfer coefficient upon the vapor composition was investigated by varying the partial pressure of water by a factor of 20 at four different temperatures (Fig. 4) with the total pressure fixed at 1 atm. This restriction reduces systematically the partial pressure of hydrogen as the water vapor pressure increases. The rate changes rapidly from first to zero order with respect to water vapor with the transition being most pronounced at temperatures below 100 °C, where the rate becomes independent of the water vapor pressure when the relative humidity exceeds 10%. Operation at 173 °C, with the relative humidity less than 2%, produces a near linear increase through the initial range of water vapor pressures studied.

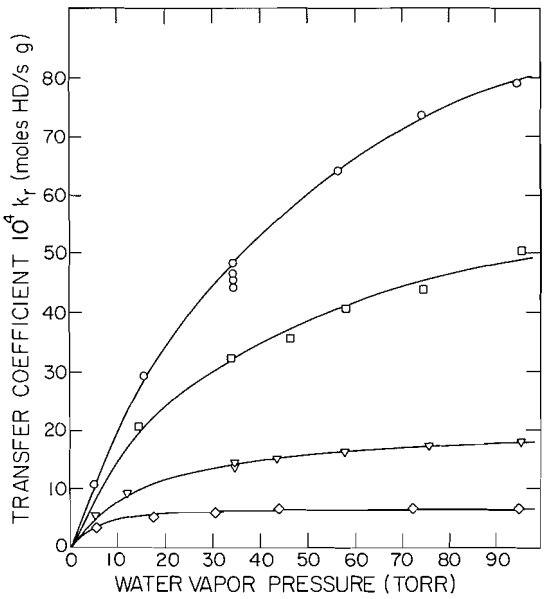

FIG. 4. Dependence of transfer coefficient upon partial pressure of water. (◇) 74 °C; (▽) 92 °C; (□) 126 °C; (○) 173 °C.

To assess the sensitivity of the transfer rate to changes in the partial pressure of hydrogen, a series of experiments was done under increased hydrogen partial pressures, with total pressures in excess of 1 atm and flow rates sufficient to ensure that the isotope transfer rates were independent of the hydrogen flow. The results are recorded in Table 2 and confirm that the measured transfer coefficients plotted in Fig. 4 are not significantly affected by the 100 Torr decrease in hydrogen partial pressure which accompanies the increases in the water vapor pressure. At 171 °C the transfer coefficient is not expected to decrease by more than 6% as a result of a drop in the hydrogen partial pressure from 750 to 650 Torr. Under these conditions the observed transfer rate is essentially independent of the hydrogen pressure.

The data in Table 2 also show that the transfer rates are not entirely independent of the hydrogen over pressure at higher temperatures. Thus a 30% increase in rate was obtained by doubling the hydrogen over pressure at 171 °C. Under these conditions the relative humidity of the gas mixture is less than 2% and the transfer rate is a function of both the hydrogen and water vapor pressures. In contrast at 80 °C the transfer rate is independent of the hydrogen over

pressure within the limits of experimental uncertainty ($\pm 5\%$) for water vapor pressures of 34.0 and 94.0 Torr which correspond to relative humidities of 9.6 and 26.5%, respectively.

Discussion

Measurement of the rate of isotope exchange in terms of the transfer coefficient k_r, permits assessment of catalyst activity as the moles of HD transferred to the hydrogen stream per unit weight of catalyst. The freshly reduced 0.5% platinum–alumina catalyst showed a rapid initial drop in activity of about 30% (Fig. 1), which suggests that the catalyst surface must be stabilized with respect to a flow of the mixture of hydrogen and water vapor. Since the commercial catalyst is extremely effective in catalyzing the exchange, special attention was taken to obtain transfer rates free of external mass transfer and diffusion effects. Thus hydrogen flows of 10 cm^3/s S.T.P. (Fig. 2) and a particle diameter of 0.05 mm (Fig. 3) are necessary to eliminate these effects over the temperature range 75 to 125 °C. Rate data obtained under these conditions can therefore be used in an assessment of the influence of the vapor composition on the exchange reaction.

Fig. 4 shows the dependence of the transfer coefficient upon the partial pressure of water and indicates that for temperatures below 100 °C the transfer rate is essentially independent of the water vapor pressure when the relative humidity exceeds 10%. With temperatures greater than 100 °C the transfer rate is initially first order with respect to water vapor but again approaches zero order as the relative humidity approaches 10%. In contrast the effect of hydrogen over pressures on the transfer rate is much less pronounced. The data in Table 2 show that hydrogen over pressures have a negligible effect on the transfer rates when the relative humidity exceeds 10% (80 °C) but increased transfer rates are noted at 171 °C when the relative humidity is less than 2%. This marked dependence of the transfer rate upon the partial pressure of water suggests that adsorbed water is involved in the rate limiting step. It would appear that the transfer rate is dependent upon the hydrogen partial pressure only when the humidity and the surface coverage of adsorbed water are low, $<10\%$. With a high surface coverage of water the rate is independent of the hydrogen partial pressure. Under conditions of low relative humidity the hygroscopic alumina can be expected to acquire a partial coverage of physically adsorbed water and the rate of isotope transfer will vary in proportion to the extent of surface coverage. The data presently available on the platinum alumina catalyst suggests that a rate limiting surface coverage is achieved at a relative humidity of about 10%.

A possible alternative explanation follows from observations of the exchange over nickel–chromia catalysts (8) in which condensation of water vapor in the pores of the catalyst is claimed to limit the exchange. If it is assumed that adsorbed water wets the walls of the capillaries then application of the Kelvin equation (17) predicts that only pores of radii less than 0.3 nm will be filled at a relative humidity of 10% at 75 °C. Mercury penetration studies indicate that the present catalyst has less than 10% of the total pore volume associated with pores of less than 1.5 nm. Capillary condensation does not therefore play a major role in limiting the transfer rates under these conditions even if the extreme assumption is taken that the catalytic surface of pores filled with condensate is totally inactive in isotope transfer and hence this explanation cannot be valid. We conclude that the major

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

portion of the active catalytic surface resides in pores with radii greater than 0.5 nm which are not filled by liquid condensate under the low relative humidities studied here.

The complex dependence of the exchange rate upon water vapor pressure can be explained satisfactorily in terms of a kinetic model involving surface exchange between hydrogen chemisorbed on the metal crystallites and mobile physically adsorbed water. Water vapor is not expected (18) to prevent hydrogen chemisorption on platinum crystallites. Thus the exchange can be viewed as the following sequence with the surface adsorbed species denoted by the subscript, a, and gas and vapor molecules by (g) and (v) respectively. Hydrogen is assumed to adsorb dissociatively on platinum (Type I) sites while water is physically bound on neighboring alumina (Type II) sites.

[10] $$H_2(g) + 2(I) \rightleftarrows 2H_a$$

[11] $$HDO(v) + (II) \rightleftarrows HDO_a$$

[12] $$HDO_a + H_a \rightleftarrows \left[\begin{array}{c} \diagdown D \\ Pt \\ | \quad O{-}H{\cdots}O \\ Pt \\ \diagup H \end{array}\right]^{\ddagger} \rightleftarrows H_2O_a + D_a$$

[13] $$D_a + H_a \rightleftarrows HD(g) + 2(I)$$

[14] $$H_2O_a \rightleftarrows H_2O(v) + (II)$$

If it is assumed that the transfer rate per gram of catalyst can be expressed in terms of the fractional coverages θ_i of the surface sites available to species i, then it follows from eq. 4 that

[15] $$k_r(N - K^{-1}n) = k_{12}\theta_{HDO}\theta_H - k_{-12}\theta_{H_2O}\theta_D$$

where k_{12} and k_{-12} are the kinetic constants for the forward and reverse steps of the surface exchange occurring at the exposed interfaces between crystallite and hydrated alumina support. As equilibria between the gas and surface phases are established throughout the course of the reaction

$$\theta_{HDO} = \theta_{H_2O}K_{11}K_{14}\frac{P_{HDO}}{P_{H_2O}}$$

and

$$\theta_D = \frac{\theta_H}{K_{10}K_{13}}\frac{P_{HD}}{P_{H_2}}$$

Since $P_{HDO} = NP_{H_2O}$ and $P_{HD} = nP_{H_2}$ it follows that

[16] $$k_r = k_{12}K_{11}K_{14}\theta_{H_2O}\theta_H$$

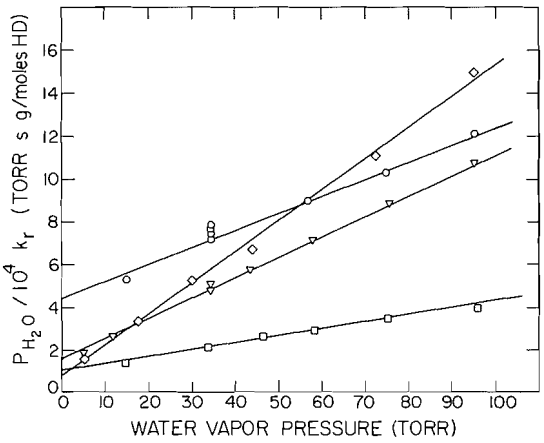

FIG. 5. Test of equation 18. (◇) 74 °C; (▽) ordinate ×2, 92 °C; (□) ordinate ×2, 126 °C; (○) ordinate ×10, 173 °C.

The data plotted in Fig. 4 were obtained under conditions in which the transfer rate was essentially independent of hydrogen pressure. In these circumstances it is assumed that θ_H is constant and that the coverage of Type II sites by water vapor is given by a Langmuir isotherm of the form

[17] $$\theta_{H_2O} = \frac{K_{14}^{-1}P_{H_2O}}{1 + K_{11}P_{HDO} + K_{14}^{-1}P_{H_2O}}$$

Since $K_{11}N \ll K_{14}^{-1}$ the dependence of the transfer rate on the water vapor pressure is given by the linear eq. 18

[18] $$\frac{P_{H_2O}}{k_r} = \frac{1}{k_{12}K_{11}\theta_H}\{1 + K_{14}^{-1}P_{H_2O}\}$$

The implied dependence of the exchange velocity upon the water vapor pressure is reasonably well obeyed by the data throughout the temperature and pressure range examined (Fig. 5). However, it is not possible at this stage to exclude entirely a second scheme suggested from the studies of Temkin (19) which involves dissociation of water vapor to hydrogen gas and a surface oxide. The latter has been suggested (9) as a scheme to rationalize the exchange over the chromia promoted nickel catalysts but it offers no advantage over that involving isotopic exchange between physically adsorbed water and dissociatively adsorbed hydrogen in accounting for the exchange over alumina supported platinum.

We would like to thank Mr. Warren Thurston, General Chemistry Branch, CRNL for his assistance and advice in the analysis of the hydrogen streams and Mr. Murray James, Chemical Engineering Branch, CRNL for maintenance and calibration of the spectrometer.

Bond Scission in Sulfur Compounds. V.[1] A Kinetic Study of Sulfur–Oxygen and Sulfur–Chlorine Bond Scission in the Methanolysis of *p*-Nitrophenyl Chlorosulfate

E. BUNCEL AND A. RAOULT

Department of Chemistry, Queen's University, Kingston, Ontario

Received December 29, 1971

A kinetic study of the reaction of *p*-nitrophenyl chlorosulfate with methoxide ion in methanol has been carried out over the temperature range 5–35°. The results are discussed in terms of two bond scission processes, S—O and S—Cl scission. A stereo-electronic factor is considered dominant in discussion of activation entropies.

L'étude cinétique de la réaction du chlorosulfate de *p*-nitrophényle avec l'ion méthylate en milieu méthanolique entre 5 et 35°, a permis de mettre en évidence la coupure des liaisons S—O et S—Cl. Les paramètres d'activation ont été mesurés pour chaque mode de coupure. Les entropies d'activation sont examinées en fonction d'un facteur stéréo-electronique.

Reaction of phenyl chlorosulfate with methoxide ion in methanol yields products resulting from S—O bond scission and from S—Cl bond scission (1). Nucleophilic substitution at sulfur in $C_6H_5OSO_2Cl$ hence is associated with leaving group tendencies of phenoxy and chlorine which are approximately equal, in contrast to the situation for substitution at aliphatic carbon (2). To substantiate this unusual order of leaving group tendencies (3), study has been extended to *p*-nitrophenyl chlorosulfate, in which system it was anticipated that the reaction proceeding with S—O bond scission would become relatively more important. Further, with this substrate it appeared possible that yet another process might occur, namely nucleophilic substitution at aromatic carbon (4–7) with OSO_2Cl as the leaving group. The results of the investigation are now reported.

Experimental

p-Nitrophenyl chlorosulfate was prepared from *p*-nitrophenol and sulfuryl chloride in anhydrous ether in presence of pyridine and purified by treatment with boron trichloride according to the method of Gerrard (8). The product obtained on final distillation, b.p. 137–138°/5 mm, slowly crystallized when kept in the refrigerator. The solid material was recrystallized twice from methanol – petroleum ether to yield pale yellow crystals, m.p. 28°; λ_{max} 254 nm (ε 10150) in methanol.

Anal. Calcd. for $C_6H_4O_5ClNS$: C, 30.33; H, 1.70; Cl, 14.92; N, 5.90; S, 13.50. Found: C, 30.84; H, 1.76; Cl, 15.02; N, 5.69; S, 13.27.

Methyl *p*-nitrophenyl sulfate was prepared from *p*-nitrophenyl diazonium fluoroborate and dimethyl sulfate by the method of Whiting and co-workers (9). The product was recrystallized from CCl_4, m.p. 45°; λ_{max} 258 nm (ε 9350) in ether.

Anal. Calcd. for $C_7H_7O_6NS$: C, 36.07; H, 3.03; N, 6.01; S, 13.76. Found C, 35.86; H, 2.59; N, 6.05; S, 13.70.

p-Nitrophenyl sulfate was obtained as the potassium salt from Sigma Chemicals. It was analyzed spectrophotometrically after complete acid hydrolysis to *p*-nitrophenol, which was obtained in 98% yield. (The commercial material was first shown to be free of *p*-nitrophenol.)

Preparation of reaction solutions and the details of the kinetic method were as described previously (1).

Results

Reaction of *p*-nitrophenyl chlorosulfate with methoxide ion in methanol as followed spectrophotometrically results in the appearance of an absorption at 390 nm due to the liberation of *p*-nitrophenoxide ion. However, the 390 nm absorption does not reach the maximum value corresponding to 100% formation of *p*-nitrophenoxide ion based on the initial stoichiometric concentration of substrate. At a given temperature the yield of *p*-nitrophenoxide ion remains constant as the methoxide ion concentration is varied but on increasing the temperature this yield increases (Table 1). Plots of log $(A_\infty - A_t)$ *vs.* time, where A_∞ is the experimental absorbance value at 390 nm on completion of reaction, are linear and yield the pseudo first-order rate constants (k_{obs}) at given methoxide ion concentrations (Table 1).

The probable identity of the second reaction product was considered to be methyl-*p*-nitrophenyl sulfate, resulting from concurrent S—Cl

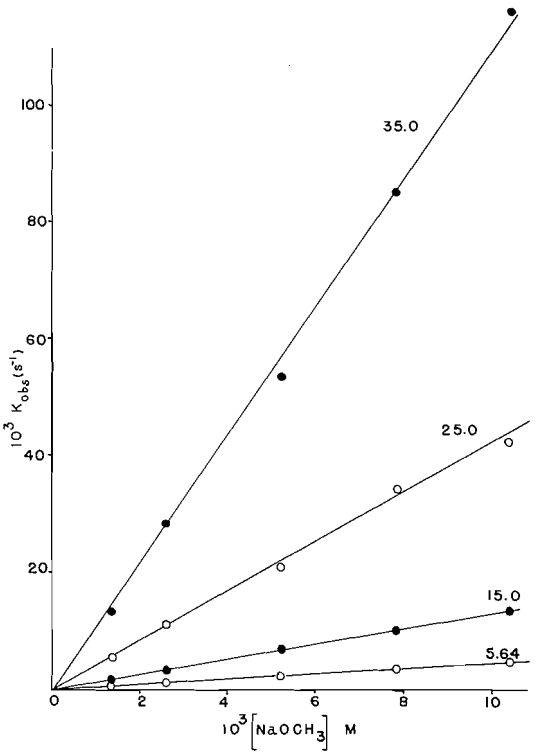

FIG. 2. Plots of k_{obs} *vs.* $[CH_3O^-]$ at various temperatures for reaction of *p*-nitrophenyl chlorosulfate with methoxide ion.

error with spectra of solutions resulting on completion of reaction between *p*-nitrophenyl chlorosulfate and methoxide. When *p*-nitroanisole was substituted for methyl-*p*-nitrophenyl sulfate (20% *p*-nitroanisole/80% *p*-nitrophenoxide), the spectrum was significantly different in the 300 nm region from that of the experimental infinity solution (in methanolic sodium methoxide *p*-nitroanisole has λ_{max} at 305 nm (ε 12 000) whereas methyl-*p*-nitrophenyl sulfate has λ_{max} at 260 nm (ε 9400) and only small absorption at 305 nm (ε 930)).

Further evidence indicating that the second reaction product was methyl-*p*-nitrophenyl sulfate was found in the consecutive solvolysis of the latter yielding *p*-nitrophenyl sulfate. This secondary reaction was detected spectrally in the *p*-nitrophenyl chlorosulfate – MeO^- reaction as a continuing increase in absorption in the 275–325 nm region once the absorption at 390 nm had reached *ca.* 90% of its maximum value. *p*-Nitrophenyl sulfate absorbs at 283 nm (ε 9200), it has negligible absorption at 390 nm, and is stable in the methanolic methoxide solutions (*cf.* refs. 10, 11). The increase in absorption was also seen in the "mock infinity" solution spectra prepared from *p*-nitrophenol and methyl-*p*-nitrophenyl sulfate. In contrast, the solutions containing *p*-nitrophenoxide and *p*-nitroanisole showed no spectral change, as expected.

Selected spectra obtained in a kinetic run with *p*-nitrophenyl chlorosulfate and methoxide ion are shown in Fig. 1 to illustrate the various spectral changes. It is seen that the reasonably good isosbestic behavior, which is maintained during most of the primary reaction, becomes progressively more poorly defined as the secondary solvolysis reaction takes over.

The evidence presented above is fully consistent with the occurrence of two parallel processes in the reaction of *p*-nitrophenyl chlorosulfate with methoxide ion: S—O scission yielding *p*-nitrophenoxide ion and S—Cl scission yielding methyl-*p*-nitrophenyl sulfate.

The dissected rate constants for the two parallel processes are obtained by standard methods (12, 13). The total second-order rate constant, $k_{tot} = k_{ArO^-} + k_{Cl^-}$, is obtained from the linear plot of k_{obs} *vs.* $[CH_3O^-]$, Fig. 2. The constituent rate constants, k_{ArO^-} and k_{Cl^-}, are then obtained from the fractional yields of the products. The resulting data at various temperatures are given in Table 1, while Table 2 contains the derived activation parameters. The Arrhenius plots for the two processes are presented in Fig. 3.

Discussion

The parallel reactions representing S—O bond scission and S—Cl bond scission are given by reactions 1 and 2. Nucleophilic displacement

[1] $O_2N-C_6H_4-O-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-Cl + CH_3O^- \rightarrow O_2N-C_6H_4-O^- + CH_3OSO_2Cl$

[2] $O_2N-C_6H_4-O-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-Cl + CH_3O^- \rightarrow Cl^- + CH_3O-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-O-C_6H_4-NO_2$

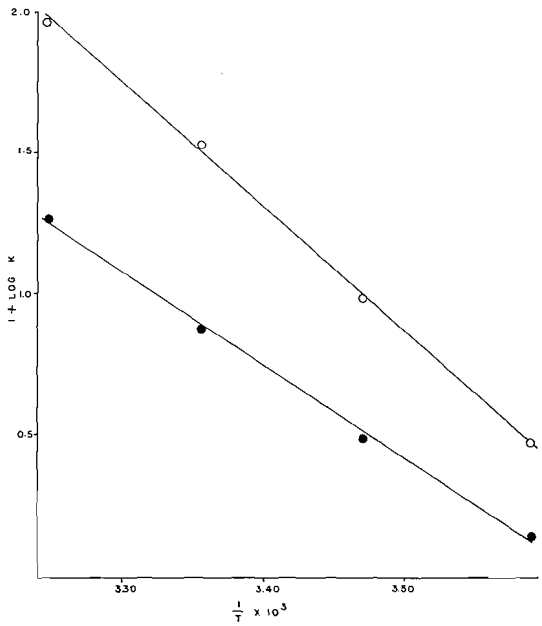

FIG. 3. Arrhenius plots for the two bond scission processes in the methanolysis of *p*-nitrophenyl chlorosulfate: *p*-nitrophenoxide ion leaving (open circles) and chloride ion leaving (full circles).

at aromatic carbon has not been detected. Reactions 1 and 2 are both followed by secondary processes. The methyl chlorosulfate formed in reaction 1 will undergo rapid solvolysis yielding dimethyl ether (14) (OSO_2Cl^- leaving group). The methyl-*p*-nitrophenyl sulfate produced in reaction 2 undergoes relatively slow solvolysis as described above (*p*-nitrophenyl sulfate leaving group).

Comparison with the phenyl chlorosulfate–methoxide system shows that S—O scission is relatively more important in the nitro-substituted case. For instance the 82% yield of *p*-nitrophenoxide ion at 25° (Table 1) compares with only 39% yield of phenoxide ion at this temperature (1). This observation is in accord with *p*-nitrophenoxide being the better leaving group compared to phenoxide. It is interesting that for S—O scission the rate constant ratio $(k'/k)_{S-O}$ at 25° for the two systems is 93, whereas for S—Cl scission the $(k'/k)_{S-Cl}$ ratio is 13, where k' and k are the constituent rate constants at 25° in reaction of *p*-nitrophenyl chlorosulfate and of phenyl chlorosulfate respectively. At the other temperatures the rate ratios take on somewhat different values, though the orders of magnitude remain unchanged. In energy terms S—O scission is favored for *p*-nitrophenyl chlorosulfate over the unsubstituted compound by a $\Delta\Delta F^{\ddagger}$ value of 2.8 kcal/mol, whereas the S—Cl scission process is favored in the same direction by a $\Delta\Delta F^{\ddagger}$ value of only 1.5 kcal/mol.

Clearly the sulfur center is more positively charged in *p*-nitrophenyl chlorosulfate than in the unsubstituted isomer, which should lead to a greater extent of bond formation between methoxide ion and sulfur in the transition state for the *p*-nitrophenyl chlorosulfate reaction. The resulting gain in bond energy is expected to make $\Delta H^{\ddagger}$ smaller in the case of *p*-nitrophenyl chlorosulfate for both S—O and S—Cl scissions, as observed experimentally (Table 2). Similarly, the concomitant greater desolvation of MeO^- in the *p*-nitrophenyl chlorosulfate case will result in a more positive $\Delta S^{\ddagger}$ value in that system compared with the phenyl chlorosulfate case, as observed.

It will be noted (Table 2) that a striking dissimilarity exists between the $\Delta S^{\ddagger}$ values for the S—O and the S—Cl pathways, the former being associated with a rather large positive entropy of activation. In the case of S—Cl scission, the entropy of activation is negative, as reported for the hydrolysis of sulfonyl chlorides (15–17). Though the greater solvation of the incipient chloride ion, compared with the aryloxide ion, in the transition state will tend to lead to a more negative $\Delta S^{\ddagger}$ in the former case, it appears unlikely that such differential solvation would account for a difference in $\Delta S^{\ddagger}$ of about 20 e.u. The positive $\Delta S^{\ddagger}$ for S—O scission is hence ascribed largely to a stereo-electronic effect.

The ground state conformation of aryl chlorosulfates (18), with the chlorine atom above the plane of the benzene ring, is associated with considerable internal strain and restricted rotation about the aryloxy–sulfur bond as well as about the carbon–oxygen bond. In the transition states (**1** and **2**) for nucleophilic attack by CH_3O^- at sulfur (trigonal bipyramidal configurations resulting from backside nucleophilic attack with respect to the departing ligand), S—O cleavage (**1**) will result in a relief of internal strain but S—Cl cleavage (**2**) does not lead to such relief of strain. Further, partial rupture of the S—O bond is accompanied by a

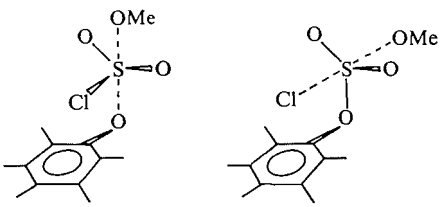
*Data for phenyl chlorosulfate are taken from ref. 1.

gain in vibrational and rotational degrees of freedom, an effect absent in S—Cl bond weakening. The combined result of these effects will be to yield a considerably more positive $\Delta S^{\ddagger}$ for aryloxide displacement.



1 2

The *p*-nitrophenyl chlorosulfate–methoxide ion reaction has been considered only within the framework of the two parallel processes mechanism. An alternative possibility, that a pentacoordinate intermediate (19–22) is formed which then partitions along two paths with *p*-nitrophenoxy and chlorine departing, is considered to be unlikely as has been discussed for the phenyl chlorosulfate–methoxide ion system (1).

Conformational Studies on the 1,2;5,6-Di-*O*-isopropylidene-D-hexoses

L. D. HALL
University of British Columbia, Vancouver 8, British Columbia
AND
S. A. BLACK, K. N. SLESSOR,[1] AND A. S. TRACEY
Simon Fraser University, Burnaby, British Columbia
Received January 28, 1971[2]

Nuclear magnetic resonance studies on the 1,2;5,6-di-*O*-isopropylidene-D-hexofuranose sugars have provided information on the conformational preferences of the five-membered rings in these molecules. They appear to have strong conformational preferences rather than existing as freely pseudorotating systems. The furanose rings of the 3-deoxy-*ribo* and *lyxo* derivatives are found to preferentially exist in an envelope conformation in which C-4 is displaced from the plane of the ring. The *arabino* and *xylo* derivatives are found to be much less distorted, with preferred conformations approaching twist forms involving displacements of C-1 and -2. Substitution of various *endo* and *exo* groups at C-3 appears to have only minor influence on the parent furanose conformation.

Les études r.m.n. sur les sucres de la série des di-*O*-isopropylidène-1,2;5,6-D-hexofuranoses ont fourni des renseignements sur les conformations privilégiées des cycles à cinq dans ces molécules. Plutôt que d'être en pseudo-rotation libre, ces systèmes apparaissent sous des conformations nettement préférentielles. Les cycles furanoses des dérivés déoxy-3 *ribo* et *lyxo* existent préférentiellement dans la conformation enveloppe dans laquelle le C-4 est au dehors du plan du cycle. Les dérivés *arabino* et *xylo* sont nettement moins tordus et adoptent la conformation privilégiée proche des formes "twist" impliquant les déplacements des C-1 et -2. La substitution des divers groupes *endo* et *exo* sur le C-3 semble n'avoir qu'une influence mineure sur la conformation du furanose parent.

Canadian Journal of Chemistry, **50**, 1912 (1972)

Introduction

The importance of 1,2;5,6-di-*O*-isopropylidene-D-hexoses as synthetic intermediates as well as an interest in conformational problems inherent in molecules containing a heterocyclic five-membered ring has prompted us to investigate the stereochemistry of these compounds and their 3-deoxy, 3-*O*-acetyl, and 3-keto analogues. Several specifically deuterated derivatives were prepared (1) since these allowed unambiguous assignment of proton resonance positions and thus aided in computer analysis of the n.m.r. spectra.

The inclusion of the 3-deoxy derivatives in this study is particularly important since the conformational properties of these compounds may be studied with the use of Dihedral Angle Estimation by the Ratio Method (DAERM) (2). DAERM is based on the assumption that the $\cos^2\theta$ term of the Karplus equation (3) is not significantly affected by various atomic and molecular parameters such as ring size and electronegativity. These perturbations would then have their major effect on the size of the Karplus constants. Using this approach, a consistent and complete solution of the conformations of the four furan rings (**1**, **4**, **7**, **10**) has been obtained (see Fig. 1). The preferred conformations of the di-*O*-isopropylidene-D-hexoses were obtained from correspondence in couplings between the deoxy sugars and their parent sugar derivatives.

In the following discussion, the section of the furan ring (*a*) is the focal point of the conformational discussions. In DAERM, ω is the projection angle of the methylene protons along the C_2—C_3 or C_4—C_3 bond (*b*). In a perfect tetrahedral system, ω is 120°. Internal angles between carbon atoms involved in a furan ring are known (4) to be smaller than the regular tetrahedral value of 109.5°. Assuming constant p-character in the carbon bonding, the angle subtended by the hydrogens on a methylene function of a furan ring will necessarily be greater than the tetrahedral angle (5). Recognizing this

effect, an ω value of 124° has been selected for the DAERM calculations as has a ratio k_1/k_2 of 0.9. Evidence is presented to show that considerable deviations of either the ratio or ω from their assigned values has minimal effect on conformational arguments.

Results

Spectral assignments were made on the basis of the easily recognized H-1 and -2 resonances at low field with assignment of the remaining protons being made by general procedures. Assignment of configuration to the methylene protons was made from the n.m.r. data and in one instance a specifically deuterated analogue was prepared to confirm these assignments. All n.m.r. spectra were computer simulated from first order data and an iterative fit to experimental data was performed using the LAOCN III program of Bothner-By and Castellano (6). The necessity of computer-analyzed data is indicated by a comparison of the first order (Fig. 2A), fitted (Fig. 2B), and experimental (Fig. 2C) spectra for 3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-*arabino*-hexose (**4**).

From a consideration of the general appearance of the n.m.r. spectra and their molecular architecture, the di-*O*-isopropylidene-hexoses are dealt with as four sets of compounds. These are the families derived from 3-substitution of the 3-deoxy-α-D-*ribo*-, -α-D-*xylo*-, -β-D-*lyxo*-, and -β-D-*arabino*-hexose derivatives. The chemical shift results which have not been published elsewhere (7, 8) are listed in Table 1 and the vicinal proton coupling parameters are listed in Table 2 (see also Fig. 3).

Conformational Assignments

1,2;5,6-Di-O-isopropylidene-α-D-xylo-hexose Derivatives

Considering first 3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*xylo*-hexose (**1**), four solutions for the couplings from H-2 to -3's are obtained from DAERM. In Table 3 and all subsequent discussion, *J*-1 is taken to be the *cis* coupling and θ-1 the corresponding angle.

Cases *i* and *iii* are both solutions for which few steric interactions within the molecule would be expected whereas cases *ii* and *iv* do not seem to be reasonable solutions since they represent conformations in which there is a large torsional twist on the C_2—C_3 bond. This places the "tail" (C-5, -6, and their substituents) in a position where large steric interactions with the 1,2-*O*-isopropylidene group would be expected. The rather large values for the calculated Karplus constants also indicate that solutions *ii* and *iv* are not valid. DAERM analysis of the $J_{3_1,4}-J_{3_2,4}$ couplings indicates that cases *vi* and *viii* can be eliminated since the Karplus constants are unacceptably large. As only very severe distortions of the furan ring could possibly make *ii* and *iv* compatible with any but cases *vi* and *viii*, cases *ii* and *iv* now must be eliminated and only *i* and *iii*, and *v* and *vii* remain as acceptable solutions.

The remaining problem is to decide which set

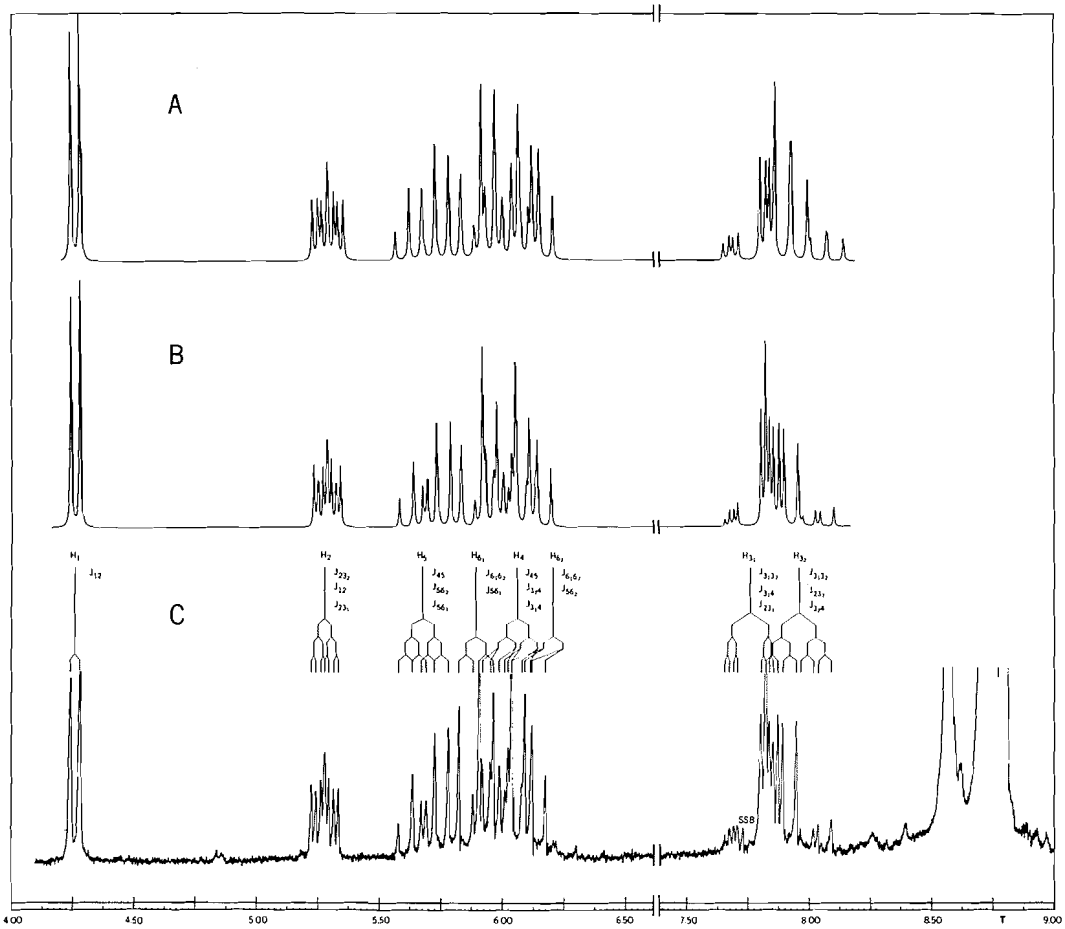

FIG. 2. The n.m.r. spectra for 3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-*arabino*-hexose (**4**). A, Computer drawn spectrum on first order data. B, Computer drawn spectrum on computer fitted data. C, 100 MHz experimental spectrum.

of solutions is valid, *i.e.*, *i/v* or *iii/vii*. The former (*i/v*) indicates a conformation in which the "tail" involves less steric interactions but requires a rather severe distortion towards the envelope ^{2}V form. The latter solution (*iii/vii*) appears less distorted although there are eclipsing interactions between the furan ring substituents.

To establish unequivocally the conformation of **1**, deuteration at the H_{3_1} position was carried out and the resulting disappearance of the large coupling (6.30 Hz) rather than the smaller (1.35 Hz) clearly indicates the conformation *iii/vii* is correct (see Fig. 4). This follows from the definition of *J*-1 and θ-1 as the *cis* coupling and dihedral angle respectively.

If the torsional twists of two adjacent bonds within a five-membered ring are defined, the geometry of the complete ring, within the limits of bond distortion, must be uniquely defined. Assignment of torsional angles between C-2, -3, and -4 thus indicates the position of C-1 and the ring oxygen. On this basis, the conformation of compound **1** has been assigned. 3-Deoxy-1,2;5,6-di-*O*-α-D-*xylo*-hexose (**1**) prefers a conformation $V_0 \rightleftarrows {}^1T_0 \rightleftarrows {}^1V$, where the conformational symbols are those defined by Hall *et al.* (9). The degree of distortion from planarity is slight in this molecule and inspection of a molecular model indicates that the H_1—H_2 dihedral angle is probably not more than 10° and may well be closer to 0°.

Since the value of $\omega = 124°$ has been estimated, the effect of varying ω over a 20° range was investigated. Evidence is presented in Table

4 which indicates that conformational assignments are not appreciably changed by varying ω through reasonable limits. Similarly, variation of the value k_1/k_2, as has been indicated before (2), results only in small changes in dihedral angle. Molecular models conveniently show that small changes in ω and the ratio result in little difference in the conformational assignment.

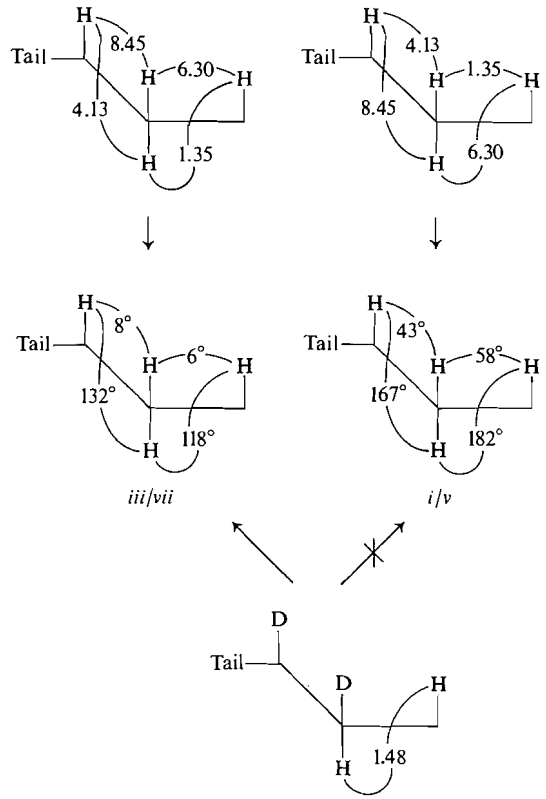

FIG. 4. DAERM analysis of 3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*xylo*-hexose (**1**).

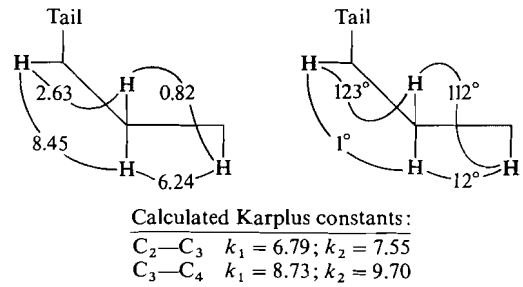
1,2;5,6-Di-*O*-isopropylidene-α-D-gulose (**2**) and -α-D-galactose (**3**) are assigned the same conformational preferences as the 3-deoxy analogue (**1**) on the basis of the close correspondence in n.m.r. coupling parameters for these three compounds. A large coupling of about 8 Hz for the $J_{4,5}$ couplings observed for this family indicates a rotational preference for the



Calculated Karplus constants:

C_2—C_3	$k_1 = 6.79$; $k_2 = 7.55$
C_3—C_4	$k_1 = 8.73$; $k_2 = 9.70$

FIG. 5. Conformation of 3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-*arabino*-hexose (**4**).

"tail". Obviously this preference is not regulated by hydrogen bond formation to the "tail" since the deoxy *xylo*-hexose (**1**) and galactose (**2**) derivatives cannot form such a bond.

1,2;5,6-Di-O-isopropylidene-β-D-arabino-hexose Family

The DAERM solutions for 3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-*arabino*-hexose (**4**) are shown in Fig. 5 and suggest the conformational preferences ${}^0T_1 \rightleftarrows V_1 \rightleftarrows {}^2T_1$. The distortion from planarity, as in the *xylo*-hexose case, is only slight. Again the 1,2 dihedral angle is probably less than 10–12°.

The coupling results, displayed in Table 2, strongly suggest that the conformational preferences of 1,2;5,6-di-*O*-isopropylidene-β-D-altrose (**5**) and -β-D-mannose (**6**) are not different from the 3-deoxy analogue (**4**). It is again clear that the "tail" prefers an orientation independent of possible hydrogen bonding interactions.

lyxo-hexose (**7**) are found in Table 5. Case *ii* can be rejected as a reasonable solution on the basis of the extreme distortion of the furan ring necessary to satisfy the angles. Cases *vi* and *viii* can be rejected because of their unacceptably large Karplus constants. Rejection of cases *vi* and *viii* leaves case *i* as an unacceptable solution as no reasonable conformation is possible from the solution of case *i* with *vii*. Similarly, case *vii* is not compatible with *iii* or *iv* as a *trans* coupling from H_2 to an H_3 proton must have a corresponding *cis* coupling from that H_3 proton to H_4. There remain two reasonable solutions, *iii*/*v*, or *iv*/*v* (Fig. 6). Conformation *iii*/*v* is taken as the correct conformation because *iv*/*v* requires a severe twisting in the furan ring and also the Karplus constants calculated for *iii*/*v* agree well with those calculated for the *xylo* (**1**) and *arabino* (**4**) derivatives at these positions. Thus,

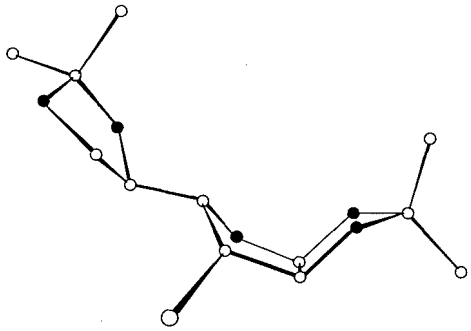

FIG. 7. Conformation of 3-chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idose in the crystalline state.

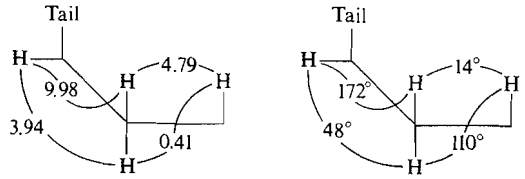
having defined the torsional angles about C-2, -3, and -4, the conformation of **7** must be $^4T_3 \rightleftarrows {}^4V \rightleftarrows {}^4T_0$. As in the previous cases the correspondence in couplings (Table 2) strongly suggests that replacement of hydrogen by hydroxyl at position 3 has little effect on the conformational preference.

The i.r. studies (1) indicate that a strong hydrogen bond between the "tail" and 3-OH of the idose derivative (**8**) is possible. The 4.1 Hz coupling into the hydroxyl group is consistent with formation of such a bond and in fact, such a bond would effectively lock the conformation into that proposed. The 9.0 Hz coupling into the hydroxyl group of 1,2;5,6-di-*O*-isopropylidene-β-D-talose (**9**) is consistent with hydrogen bond formation to the 2-oxygen of the 1,2-*O*-isopropylidene ring. All members of the β-D-*lyxo*-hexose family are thus expected to have the $^4T_3 \rightleftarrows {}^4V \rightleftarrows {}^4T_0$ conformational preference. A recently completed crystal structure (10) of 3-chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idose (Fig. 7) clearly shows C-4 to be out of the plane. A computer drawn representation of the atomic coordinates clearly indicates the ^4V conformation in the crystalline state.

1,2;5,6-Di-O-isopropylidene-α-D-ribo-hexose Derivatives

The DAERM calculations on the n.m.r. results obtained from this compound indicate that 3-deoxy-*ribo*-hexose (**10**) has the $^3T_4 \rightleftarrows V_4 \rightleftarrows {}^0T_4$ conformational preference. The similarity of the couplings reported in Table 2 indicates that the *endo* (**11**) and *exo* (**12**) hydroxylated derivatives of 3-deoxy-*ribo*-hexose (**10**) have



Calculated Karplus constants:

C_2—C_3	$k_1 = 5.39$; $k_2 = 5.99$
C_3—C_4	$k_1 = 9.42$; $k_2 = 10.46$

FIG. 8. Conformation of 3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexose (**10**).

a conformational preference identical to the parent compound. The 7.3 Hz coupling into the hydroxyl group of 1,2;5,6-di-*O*-isopropylidene-α-D-allose (**11**) is in agreement with an *anti* arrangement of H_3 and hydroxyl proton (11). This orientation of the hydroxyl group and the suggested conformation are completely consistent with the proposed hydrogen bond formation between the C-3 hydroxyl and the C-2 oxygen of the 1,3-dioxolane ring (1). In the allose compound the coupling constant $J_{4,5}$ of 4.55 Hz may reflect freedom of rotation of the "tail" whereas in glucose the coupling constant, $J_{4,5}$ of 7.3 Hz, indicates a more preferred conformer. All observations are in complete agreement with the assignment of $^3T_4 \rightleftarrows V_4 \rightleftarrows {}^0T_4$ for the conformational preferences of these *ribo*-hexose derivatives (Fig. 8).

Acetyl and Keto Derivatives

The 3-*O*-acetyl- and 3-keto-derivatives of the 1,2;5,6-di-*O*-isopropylidene-D-hexoses yield much more complex spectra than those obtained from the parent compounds. Complete analysis was not achieved in several cases. The results that were obtained are given in Table 1 (chemical shifts) and Table 2 (coupling constants).

Comparisons of the coupling data in Table 2 and the values presented in Fig. 3 appear to indicate that there is little change in conformation of the furan ring on acetylation of the C-3 hydroxyl group. It should be noted, however, that on acetylation of 1,2;5,6-di-*O*-isopropylidene-α-D-galactose (**3**), the position 3 to 4 coupling drops from 4.15 to 2.56 Hz. At the same time the position 2 to 3 coupling goes from 1.13 to 0.7 Hz. Comparison of these couplings with those obtained from the *arabino*-hexose family (**4**, **5**, **6**) indicates that the molecule shifts

its conformational preference after acetylation, from the $V_0 \rightleftarrows {}^1T_0 \rightleftarrows {}^1V$ of the parent to ${}^1T_0 \rightleftarrows {}^1V \rightleftarrows {}^1T_2$ of the derivative. Similar results are obtained for the benzoylated derivative, but not for 3-fluoro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-galactose (12).

Little information can be gained from the sparse results on the 3-keto compounds. A significant increase in the coupling $J_{1,2}$ to about 4.4 Hz in these compounds (**21**–**24**) can be attributed to the effect of carbonyl group electronegativity (J_2^V) as described by Cohen and Schaefer (13). The ketones (**21**–**24**) exhibited rather large long-range couplings from H_2–H_4 across the carbonyl function. Long-range couplings were found to be a general phenomenon in the 1,2;5,6-di-*O*-isopropylidene-D-hexose system. Both H_1–H_3 *cis* and H_1–H_3 *trans* couplings were observed with the latter being generally larger. Double resonance experiments were used to confirm some of the assignments and in one case, the H_1–H_3 *trans* coupling in 3-deoxy-3,4-dideutero-1,2;5,6-di-*O*-isopropylidene-α-D-galactose (Fig. 4) of −0.55 Hz was determined. Sign determination was simplified by deuterium decoupling. *trans* H_2–H_4 couplings were not observed, although H_2–H_4 *cis* couplings were quite common. Since both *trans* and *cis* H_2–H_4 long-range couplings were observed for the 3-keto-derivatives it seems likely that the preceding results are simply a reflection of the difference in ring conformations for the two ring systems. Table 6 lists some of the long range couplings which were observed.

"Tail" Conformational and Rotational Preference

In order to better evaluate the possible influence of hydrogen bonding on the orientation of the "tail" the temperature dependence of

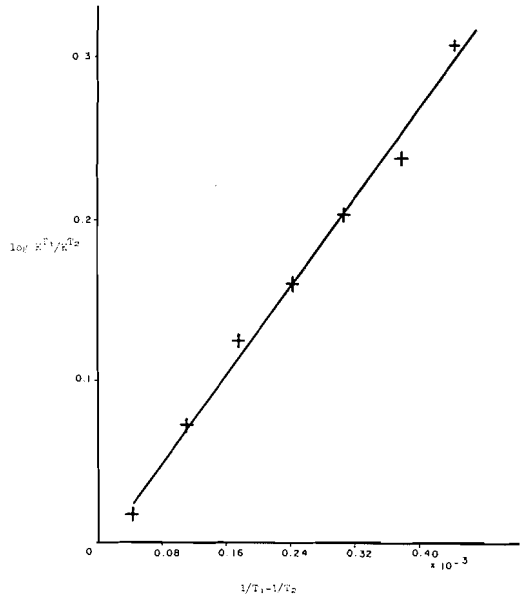

FIG. 9. Plot of log K^{T_1}/K^{T_2} *vs.* $1/T_1 - T_2$ for 1,2;5,6-di-*O*-isopropylidene-α-D-glucose (**12**) in the temperature range −14.1 to +19.5°; slope = 693.

hydrogen bond formation was investigated for several di-*O*-isopropylidene derivatives. The i.r. spectra of 1,2;5,6-di-*O*-isopropylidene-β-D-mannose (1) (**6**) and -β-D-idose (**8**) revealed no observable shift in equilibrium upon varying the temperature from −30 to +50°. The spectrum of 1,2;5,6-di-*O*-isopropylidene-α-D-glucose (**12**) indicated a continuous change with temperature. A ΔH of -3.1 ± 0.2 kcal/mol was calculated (Fig. 9) for this process, a value typical of H—O...H systems (14). The presence of free hydroxyl in the *gluco* derivative (**12**) and in the *ribo*-hexofuranos-3-ulose *gem* diol (**25**) and the presence of a second possible hydrogen bond in the *manno* derivative (**6**) indicate the presence of alternate forces which may provide some rotameric preference to the "tail". That such forces are present is indicated by many of the $J_{4,5}$ couplings, the magnitude of which cannot possibly represent freely rotating systems.

DAERM (2) calculations were performed on the position 5 to 6 couplings in order to evaluate the twist in the dioxolane ring of the "tail". The results are seen in Table 7 and indicate that the "tail" is distorted from planarity and that this distortion is 21–25° for all the compounds investigated. The X-ray crystal structure of 3-

*$\omega = 124°$, $k_1/k_2 = 0.9$.

chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idose (Fig. 7) shows a twist of 25° in the O_5—C_5—C_6—O_6 dihedral angle. Calculations on X-ray data from 3-deoxy-3,4-*C*-(dichloromethylene)-1,2;5,6-di-*O*-isopropylidene-α-D-galactofuranose (15), shows a twist of 24.9° for the "tail". Both these results are in excellent agreement with the n.m.r. conclusions.

Inspection of Table 7 reveals a surprising variation in the Karplus constants, particularly since ring size and substitution patterns in the "tail" are identical for all ten compounds. Recognizing that the n.m.r. spectra of D and L isomers are identical then these derivatives may be compared as five sets of C-5 isomers (D-C_5 D-C_4 *vs.* L-C_5 D-C_4). The sets are *gluco*/*ido*; *allo*/*talo*; *altro*/*galacto*; *manno*/*gulo*; and 3-deoxy-*arabino*/3-deoxy-*xylo*, and in each case the first member of each set has the lower Karplus constant. Inspection of the DAERM results for couplings from H_4 to the H_{3_1}, H_{3_2} protons in the 3-deoxy derivatives shows an identical pattern, indicating a proximity effect due to a preferential orientation of the "tail". The effect of solvent on Karplus constants, suggested in a previous paper (2), may well be a more general example of such proximity effects.

The magnitude of the coupling, $J_{4,5}$, for the *xylo*- and *arabino*-hexose derivatives (**13**–**16**), indicates that the rotameric preference of the "tail" is probably not significantly affected by the presence of the acetoxy group at C-3. It should be noted, though, that a change of rotameric preference from *anti* to eclipsed or vice versa would not have an appreciable effect on the n.m.r. couplings observed. H_4 to H_5 couplings for the 3-uloses (**21**, **22**, **25**) of 6–7 Hz indicate a reasonable degree of conformational purity of an eclipsed or *anti* nature. The $J_{4,5}$ (1.85 Hz) coupling in the *lyxo* ketone (**23**) is the only coupling observed for this position definitive enough to indicate a preferred rotamer other than the eclipsed or *anti* configurations previously discussed.

Discussion

The n.m.r. parameters obtained from spectra of flexible molecules represent a weighted average of the parameters of all individual conformers present. This allows two interpretations of a conformation assigned to a potentially flexible molecule from n.m.r. data. Either the molecule has a strong preference for the pseudorotational segment predicted or two or more conformations exist whose coupling parameters time-average to give the observed values resulting in a time-averaged conformational assignment.

In the case of the *ribo* and *lyxo* derivatives it is difficult to see how the presence of a significant percentage of conformations other than those predicted could provide *trans* H_2–H_3 couplings of about 0.5 Hz and at the same time retain large *trans* couplings H_3–H_4 of about 10 Hz.

This question is not so easily resolved in the case of the *xylo* and *arabino* derivatives. The presence of the large *cis* position 3 to 4 couplings (8.5 Hz) indicates a high percentage of a single conformer since alternate conformers could only reduce this value. It should be noted that if this value is already partially reduced from some higher value the conformational assignment would not be altered. Low temperature n.m.r. studies on the 3-deoxy-*xylo* and *arabino*

derivatives ($\sim -60°$) showed no significant deviations from the spectra obtained at room temperature. It seems unlikely, then, that the spectra of any of these compounds represent any significant degree of conformational averaging.

In this work the dihedral angle between H_1 and H_2 has been assigned a value of 10–12° or less based on the assigned conformational preference. Previous studies (16) have assigned values of from 40–50° on the basis of coupling constants. The smaller value of 0–12° is in excellent agreement with X-ray crystal structures exhibiting this structural feature. The crystal structure of the chloroidose derivative, previously mentioned, indicated a torsional angle of about 4° for the O_1—C_1—C_2—O_2 dihedral angle. Without gross deformation of the tetrahedral geometry about carbons one and/or two, the H_1—H_2 dihedral angle must be of this order. The chloro derivative exhibits a typical coupling, $J_{1,2}$ of 3.6 Hz in deuterochloroform solution. Other X-ray structure determinations confirm this work with O_1—C_1—C_2—O_2 dihedral angles of 4.6 (15) and 9.0° (17).

It is difficult to ascertain whether the differences in ring conformation for the two systems (*cis* or *trans* ring substitution) are important chemically since the overriding effect is undoubtedly that of *cis* or *trans* substitution. On the other hand it does appear that the "tail" can have a significant effect on the chemistry of these compounds. This is indicated in that the times required for enol acetate formation from the parent ketones (7) are faster for the D-C_5, D-C_4 configuration than for the D-C_5, L-C_4 configuration.

This effect is readily explained if it is assumed that the preferred rotamer of the "tail" is one in which the C-5 oxygen preferably sits on the same side of the molecule as the C-1 and ring oxygens, that is, O_5 prefers to sit *gauche* to the ring oxygen. The large H_4–H_5 couplings mean, then, that the C-4 and -5 protons are near eclipsed in the D-C_5, D-C_4 case and near *anti* in the D-C_5, L-C_4 case. The small 1.85 Hz coupling observed for the *lyxo* ketone (**23**) indicates a situation in which the *gauche* interaction puts the C_4—C_5 protons in a near 90° relationship. Thus both *gauche* rotamers are suggested from n.m.r. evidence. A *gauche* interaction of this type would leave the C-4 position more open to attack by base in the D-C_5, D-C_4 case and provide more steric interaction to the approach of base in the alternate case.

The i.r. spectra of ref. 1 are completely in accord with the above explanation. The gulose and idose derivatives at first sight seem anomalous with complete hydrogen bonding to the "tail" being indicated by the i.r. spectra. This hydrogen bonding is, of course, not possible if the *gauche* O_5–ring oxygen configuration is present. Optical rotatory dispersion studies of the gulose derivative in various solvents indicate a major change in conformation on going from a solvent such as chloroform to water. The positive curve of the former case $[\alpha]_D^{20}$ +10° (*c*, 0.4 $CHCl_3$) being replaced by a strongly negative curve in the second case $[\alpha]_D^{20}$ −34° (*c*, 0.4 H_2O) (18). Interestingly enough the n.m.r. spectrum changes very little in D_2O indicating that the "tail", now no longer forming a hydrogen bond to the C-3 oxygen, has simply rotated to the conformation preferred in the absence of such a bond (*i.e.*, from an eclipsed to an *anti* configuration of the C-4 and -5 protons). Optical rotatory dispersion studies of the idose derivative (**8**) showed a similar effect. Although the curve did not change sign when the solvent was changed to water, it went from a moderately positive curve to a very strongly positive curve, an effect in accord with the above explanation.

Conclusions

The studies on the conformations of the 1,2;5,6-di-*O*-isopropylidene-D-hexoses demonstrate clearly that the furan ring conformation is determined by the substitution pattern of the 1,2-*O*-isopropylidene unit and the "tail". If these units are substituted on the furan ring in a *cis* fashion, the furan ring tends to be flattened with one or two of the atoms C-1, -2, and the ring oxygen slightly displaced from the mean plane. Thus the *xylo* and *arabino* derivatives have conformational preferences most readily described as $V_0 \rightleftarrows {}^1T_0 \rightleftarrows {}^1V$ and ${}^0T_1 \rightleftarrows V_1 \rightleftarrows {}^2T_1$, respectively. If, however, the units are substituted on the furan ring in a *trans* fashion, the ring is considerably distorted with one or two of the atoms C-3, -4, or the ring oxygen displaced in the preferred conformers. Thus the *ribo* and *lyxo* derivatives have as conformation preferences the ${}^3T_4 \rightleftarrows V_4 \rightleftarrows {}^0T_4$ and ${}^4T_3 \rightleftarrows {}^4V \rightleftarrows {}^4T_0$ conformations respectively. Two X-ray crystal structures of compounds exhibiting this

For personal use only.

trans arrangement (10, 17) show C-4 to be the atom displaced. This work indicates an H_1–H_2 dihedral angle less than 10 to 12°, a result also in accord with X-ray analysis of related molecules.

Substitution of *endo* or *exo* groups at the C-3 position does not strongly influence the conformational preference of the furan ring. These derivatives generally show the same conformational preference exhibited by their parent deoxy analogues, although the *cis* substituted (*xylo* and *arabino*) derivatives seem more susceptible to influence from a substituent at C-3.

DAERM calculations on the "tail" (C_5—C_6 and substituents) have also been informative. The "tails" of the compounds investigated were twisted in the same manner and to the same extent (~24°). The sense and extent of this twist have been confirmed by two crystal structures (15, 10). The H_4–H_5 coupling parameters also indicate that the "tails" of these compounds have definite preferred rotamers. The n.m.r. results can be explained in terms of rotamers in which the ring oxygen and C-5 oxygen are preferably *gauche* to one another. This explanation correlates well with rates of enol acetate formation (7), with hydrogen bond formation, and with optical rotatory dispersion studies (18). This work lends strong support to the recently proposed "*gauche* effect" (19) and is in complete agreement with it.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected.

All compounds except 3-deoxy-1,2;5,6-di-*O*-isopropylidene-D-*lyxo*-hexose (**7**) gave spectra from a Varian HA-100 MHz spectrometer which were analyzable. Compound **7** was run on the Varian HR-220 MHz spectrometer of the National Research Council of Canada in Toronto, Ontario. All spectra were measured in deuterochloroform solution with TMS as an internal reference.

All spectra were analyzed using the LAOCN III n.m.r. program of Bothner-By and Castellano (6). Hydrogen bonding studies were performed in matched, jacketed cells of 1 cm path length on a Beckman IR 12. The absorbance traces were resolved on a Dupont 310 Curve Resolver to obtain the fraction of bonded and non-bonded material present.

Preparation of compounds **1**, **4**, **13**, and **16** has been described in ref. 7, **7** and **10**, in ref. 8, and **2**, **3**, **5**, **6**, **8**, **9**, **11**, **12**, **21**–**25** in ref. 1 and refs. therein.

cis-3,4-Dideutero-3-deoxy-1,2;5,6-di-O-isopropylidene-α-D-xylo-hexose

3-Deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*erythro*-hex-3-enose (2 g), prepared by the method of Weygand and Wolz (20) was dissolved in 95% ethanol (75 ml) and reduced over palladium black with deuterium at atmospheric pressure. After uptake of deuterium had ceased, t.l.c. (ethyl ether : toluene, 2:1) indicated the reaction complete. The reaction mixture was filtered and evaporated to a sirup which crystallized spontaneously. Recrystallization from petroleum ether (65–110°) yielded long needles (1.8 g), m.p. 79–80°, $[\alpha]_D^{22}$ −27° (*c*, 0.82 $CHCl_3$), lit. (7, 20) m.p. 81°, $[\alpha]_D$ −38.1° (*c*, 4.11 ethanol).

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-α-D-glucose (**20**)*

1,2;5,6-di-*O*-isopropylidene-α-D-glucose (**12**) (1 g) was dissolved in a mixture of pyridine (5 ml) and acetic anhydride (2 ml). The solution was kept overnight at room temperature. Repeated co-evaporation of the solution with toluene gave a slightly orange sirup free of acetylating reagents. The sirup was dissolved in chloroform (75 ml) treated with charcoal, filtered, and evaporated. The residue crystallized readily and was recrystallized from petroleum ether (65–110°) to yield 950 mg of product melting at 59–60°; $[\alpha]_D^{22}$ −38.4 (*c*, 1.07 $CHCl_3$), lit. (21) m.p. 62°, $[\alpha]_D^{24}$ −38.5 (*c*, 1.3 $CHCl_3$).

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-α-D-allose (**19**)*

Prepared from **11** in the same way as **20**; m.p. 74–75°, $[\alpha]_D^{22}$ +100.6° (*c*, 0.73 $CHCl_3$), lit. (22) m.p. 75.5–76.5°, $[\alpha]_D^{20}$ +107.6 (*c*, 1.0 $CHCl_3$).

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-β-D-idose (**17**)*

Prepared from **8** in the same way as **20**; m.p. 75.5–76.5°, $[\alpha]_D^{22}$ +16.6 (*c*, 0.67 $CHCl_3$), lit. (23) for the -L-isomer, m.p. 77–78°, $[\alpha]_D^{15}$ −12° (*c*, 0.75 $CHCl_3$).

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.63; H, 7.28. Found: C, 55.82; H, 7.30.

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-β-D-talose (**18**)*

Prepared from **9** in the same way as **20** except that **18** did not crystallize, $[\alpha]_D^{22}$ −7.4° (*c*, 0.38 $CHCl_3$).

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.63; H, 7.28. Found: C, 55.84; H, 7.32.

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-α-D-galactose (**14**)*

Prepared from **3** in the same way as **20** except that **14** did not crystallize, $[\alpha]_D^{22}$ −7.5° (*c*, 1.47 $CHCl_3$).

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.63; H, 7.28. Found: C, 55.50; H, 7.15.

*3-O-Acetyl-1,2;5,6-di-O-isopropylidene-β-D-altrose (**15**)*

Prepared from **5** in the same way as **20**. The m.p. 92–93°, $[\alpha]_D^{22}$ +14.4° (*c*, 0.68 $CHCl_3$).

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.63; H, 7.28. Found: C, 55.48; H, 7.37.

The Synthesis of Delphinine: A Stereoselective Total Synthesis of an Optically Active Advanced Relay Compound

K. WIESNER, E. W. K. JAY, T. Y. R. TSAI, C. DEMERSON, LIZZIE JAY, T. KANNO, J. KŘEPINSKÝ, A. VILÍM, AND C. S. WU

Natural Products Research Center, University of New Brunswick, Fredericton, N.B.

Received February 2, 1972

A stereoselective total synthesis of the optically active delphinine degradation product 3*b* is described.

La synthèse totale et stéréosélective du produit 3*b* optiquement actif et issu de la dégradation de la delphinine, est décrite.

Canadian Journal of Chemistry, **50**, 1925 (1972)

For personal use only.

Some time ago we deduced the structure **1***a* for the alkaloid delphinine (1). Among various degradative studies which led to this structure proposal a simple and comparatively high yield conversion of delphinine into the aromatization product **2** was discovered (2). It is clear that this aromatic degradation product or its derivatives constitute an extremely favorable advanced relay for the synthesis of delphinine. We wish to describe in the present paper in detail our total synthesis of this relay compound, the resolution of the synthetic racemate into optical antipodes, and the rigorous identification of one enantiomer with the naturally derived material of the same structure (3).

It will be seen in the sequel that the synthetic compounds which turned out to be identical with their "natural" counterparts had the configurations **2***b*, **3***b*, and **4***b* rather than **2***a*, **3***a*, and **4***a*. Thus, it is clear that the configuration of the ring A methoxyl in delphinine has to be reversed and this alkaloid has to be represented by the formula **1***b*.

The starting material for our synthesis was the methoxy tetralone **5** (4). This compound was converted by the Stork pyrrolidine–enamine procedure (5) to the allyl tetralone **6**[1] in a yield of 89%. A second alkylation with benzyl chloromethyl ether (6) and sodium hydride in benzene gave 70% of the geminally disubstituted tetralone **7** after purification by chromatography. Compound **7** was subjected to a catalytic osmylation with osmic acid – sodium chlorate in tetrahydrofuran (7). The two diastereoisomeric diols **8** (A, m.p. 108–109 °C; B, m.p. 125–130 °C) were obtained in equal amounts and practically quantitative yield. The absence of carbonyl absorption in the i.r. spectra of both products indicated that they existed as the hemiketal tautomers. The diastereoisomers **8** were treated with an excess of metaperiodate in aqueous tetrahydrofuran. The aldehyde **9** (i.r.: 1726, 1715 cm^{-1} (—CH=O, $\diagdown$C=O); n.m.r.: broad singlet (1H) τ 0.49 p.p.m. (—CH=O)) was obtained in both cases in a quantitative yield.

The next step which is actually the crucial operation of the synthesis involved a base-catalyzed aldol condensation portrayed by the arrows in formula **9***b*. The hydroxy ketone **10** obtained quantitatively in this manner was oily, but homogeneous in t.l.c. and sufficiently pure for further work. It showed a carbonyl maximum in the i.r. spectrum at 1755 cm^{-1} typical for the keto group in the apex of the benzobicyclooctane system. The cyclization **9** → **10** is thermodynamically controlled and thus the hydroxyl in compound **10** may be assigned the more stable *exo*-configuration. This is borne out by the n.m.r. spectrum of **10** which shows the hydrogen unshielded by the hydroxyl as a clean quadruplet centered at τ 5.7 p.p.m. The dihedral angle of this *endo*-hydrogen and the bridgehead hydrogen is 90° and consequently coupling occurs only with the methylenic protons on the other side of the hydroxyl.

We have now constructed three of the five rings of our target compound by an extremely simple reaction sequence. It should be pointed out that compound **10** was assembled in such a

[1]All spectral data and properties of all compounds are recorded in the Experimental. They are mentioned in the Theoretical only in specially relevant cases.

manner that the functional groups which are needed either for the continuation of the synthesis or as part of the functionality of the final product **2** automatically materialized in the correct positions. The hydroxy ketone **10** was converted to the ketal **11** (m.p. 95–97 °C) by treatment with ethylene glycol and *p*-toluenesulfonic acid in refluxing benzene. The yield of the recrystallized compound **11** was 88%.

The next operation which had to be executed was the transfer of the benzyl blocking group from the primary to the secondary alcoholic function, *i.e.* compound **11** had to be converted to its isomer **17**. While this process required a number of steps, it has to be emphasized that these were simple and nearly quantitative and thus *the overall yield was finally raised to 65%*.[2]

Acetylation of **11** with acetic anhydride and pyridine gave the acetoxy derivative **12** (m.p. 81–82 °C). Compound **12** was subjected to hydrogenolysis in ethanol with 10% palladium–charcoal. The oily product **13** was homogeneous in t.l.c. and immediately used for further work. The alcoholic function in **13** was now blocked by tetrahydropyranylation with dihydropyran in dry chloroform and a drop of hydrochloric acid. The product **14** was purified by chromatography and was homogeneous in t.l.c. The acetoxy group of **14** was cleaved by reduction with lithium aluminum hydride and the oily alcohol **15** was purified by chromatography on silica gel. The secondary alcoholic group in **15** was now benzylated in dry dioxane with sodium hydride and benzyl chloride at reflux temperature. Chromatography on silica gel yielded the pure oily compound **16**. The tetrahydropyranyl group was selectively removed by treating **16** with a large volume of methanol containing 1% concentrated hydrochloric acid at room temperature. The product **17** was purified by chromatography on silica gel and it was an oil homogeneous in t.l.c. The n.m.r. and i.r. spectra of **11** and **17** clearly showed the presence of an identical functional group system.

[2]Since the overall yield **11** → **17** was good, it did not seem worth while to start from the beginning with a modified starting material which would allow a much more direct conversion of **11** to **17**. One such modification which comes to mind would be the use of the acid sensitive *p*-methoxybenzyl group as R_1 in compound **11**. It would have been necessary to go back to step **6** → **7** to implement this modification.

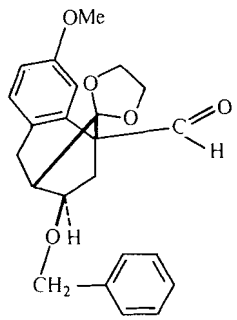
The primary alcohol **17** was oxidized by chromium trioxide in pyridine and the aldehyde **18** was obtained after chromatography on silica gel as an oil homogeneous in t.l.c. in a yield of 85% (i.r.: 2700, 1725 cm^{-1}; n.m.r.: singlet (1H) τ 0.17 p.p.m. (—CH=O)).

At this point the stage was set to attach the substituted butane derivative destined to form ring A. The synthesis of this element was carried out as follows.

1-Methoxy-3-cyano-2-propene (8) (mixture of *cis*- and *trans*-isomers) was added to a solution of sodium in benzyl alcohol and the mixture was stirred for a week at room temperature. The crude product **19** was purified by distillation and the pure material was obtained in a yield of 32%. Compound **19** was heated at reflux for 50 h with 10% sulfuric acid in methanol. The methyl ester **20** was obtained in a yield of 72%. Reduction of the ester **20** with lithium aluminum hydride in ether gave the alcohol **21** in a yield of 68%. Finally, tosylation of **21** with tosyl chloride and pyridine followed by exchange of the tosyl group with lithium bromide in acetone gave the bromo derivative **22** in a 75% yield.

Both moieties of the convergent synthesis (**18** and **22**) were now ready and it was possible to couple them and proceed with the construction of ring A with its substituents.

One mole of the aldehyde **18** in THF was added to 5 mol of the Grignard reagent prepared from the bromide **22** in the same solvent. Work-up and chromatography on silica gel gave the alcohol **23** in a yield of 91%. While compound **23** had an uncontrolled asymmetric center (benzyloxy group in the side chain), it was homogeneous in t.l.c., and all subsequent transformations (especially after the conversion of the side chain benzyloxy group into a ketone) proved that it was sterically homogeneous with respect to the R_1R_2 asymmetric center. It was thus clear that the Grignard reaction was stereospecific and produced only one of the two epimeric alcohols at the position of the future delphinine ring A methoxyl. At this point there was no completely reliable way to determine the configuration of this alcohol and to predict whether it corresponded (at the R_1R_2 asymmetric center) to the natural configuration of delphinine. It finally turned out that the configuration of **23** was in fact *epimeric* to the



18

28*b* $R_1 = H; R_2 = NH_2$

SCHEME 2

natural configuration of delphinine and as given in the formula.

With this knowledge we may now interpret the stereospecificity of the Grignard reaction by the assumption that the aldehyde group is fixed in a single conformation by a magnesium complex involving the carbonyl oxygen and one or both of the dioxolane oxygens. In this complex the carbonyl group is attacked by the Grignard carbanion from the less hindered side. With the large benzyloxy group providing effective steric hindrance the less hindered approach is clearly from the side of the flat anisole ring.

The epimer of the Grignard alcohol **23**, *i.e.* compound **25**, was prepared as follows. The alcohol **23** was oxidized to the ketone **24** by the Jones' reagent in a yield of 94%. The product was homogeneous in t.l.c. without purification. Reduction of compound **24** with lithium aluminum hydride in dioxane at 90 °C (the stereochemical outcome is temperature dependent) gave a mixture (yield 97%) of the alcohols **25** and **23** in a ratio 7:3. The products were acetylated for 8 h with acetic anhydride and pyridine at room temperature. Only the epimer **25** acetylated under these conditions. The acetate was separated by chromatography on silica gel and the pure epimer **25** was obtained by saponification with methanolic potassium hydroxide. The recovered epimer **23** was added to the next oxidation run and thus the entire material was ultimately converted to **25**.

Both alcohols **23** and **25** were methylated in refluxing dioxane with sodium hydride and an excess of methyl iodide. The corresponding methyl ethers **26***a* and *b* were obtained in almost quantitative yield. The n.m.r. peaks of the three methoxy groups in compounds **26***a* and *b* (τ 6.29, 6.47, 6.67 and 6.27, 6.59, 6.62 p.p.m. respectively) were all narrow singlets and sufficiently

For personal use only.

different to insure that the materials were completely homogeneous with respect to the R_1R_2 asymmetric center. Moreover, both compounds differ very strongly in t.l.c. and are easily separable by chromatography.

Since, as we already stated, there was no way to ascertain at this point which of the two compounds **26***a* and *b* corresponded to the natural configuration of the delphinine ring A methoxyl, we have decided to carry out the synthesis first with **26***a*.[3]

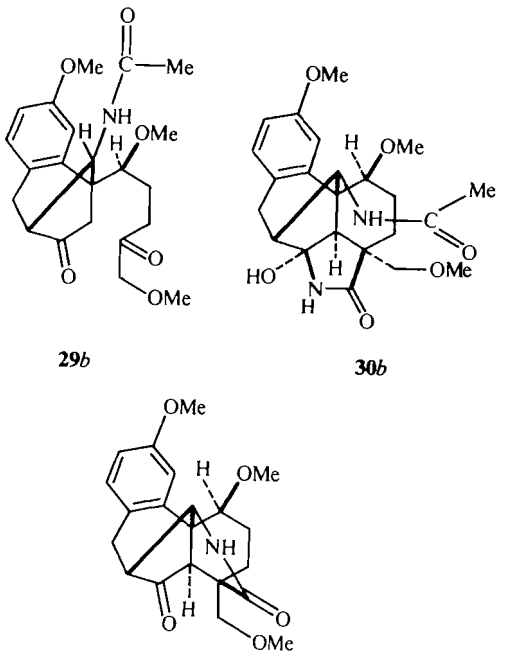
Proceeding via steps which will be outlined in the sequel we have synthesized the beautifully crystalline derivative **4***a* (m.p. 177 °C) and fully characterized it by high resolution mass spectrum and elemental analysis. While this synthetic racemate was very similar to the corresponding optically active delphinine derivative there were clear differences in t.l.c., i.r., and n.m.r. which made it certain that the two materials were not identical. On the other hand the synthetic and "natural" compound gave *identical* mass spectra and thus we concluded that the only difference between them was the configuration of the ring A methoxyl.

It was evident that, true to the proverb, the bread fell again on the buttered side, and it was necessary to repeat the synthesis starting with the epimer **26***b*. This time as expected the synthesis resulted in end-products which were identical with the naturally derived materials in every detail.

Since the individual steps in both series were performed in exactly the same manner, we shall describe only the sequence starting with **26***b*.[4] The conversion of compound **26***b* into the final products was executed as follows. The ketal was hydrolyzed under reflux with aqueous acetic acid and the product **27***b* was obtained in quantitative yield. It showed an i.r. maximum at 1755 cm^{-1}, typical for the keto group in the apex of the bicyclic system.

[3]It must be remembered that the configurations of the ring A methoxyl given in the formulae became known only after the completion of the synthesis.

[4]The description of both series may be found in the Experimental. For the sake of simplicity of the formula schemes we do not reproduce the structures of the intermediates belonging to the **26***a* series. In the Experimental these compounds are referred to by numbers with the subscript "a". Their structural formulae may be derived by inverting the configuration of the "ring A methoxyl" in the formula with the same number and the subscript "b".



29*b* **30***b*

31*b*

SCHEME 3

Compound **27***b* was now subjected to amination with Raney nickel in methanolic ammonia exactly as worked out in our model experiments (3, 9). However, in the present case the desired *anti*-isomer **28***b* was obtained stereoselectively (ratio *anti*:*syn* 10:1, overall yield 97%). The crude amine **28***b* was acetylated with acetic anhydride–pyridine, the benzyl groups removed by hydrogenolysis, and the two liberated alcoholic functions oxidized by chromium trioxide in pyridine.

The diketone **29***b* (m.p. 100–102 °C) was separated by chromatography on silica gel from the small amount of the undesired *syn*-epimer and purified by crystallization; (i.r.: 1745, 1720 cm^{-1} (ketones), 1660 cm^{-1} (amide); n.m.r.: singlets (3H each) τ 6.23, 6.52, 6.57 (3 OCH_3), singlet (2H) 5.93 p.p.m. (—CO—CH_2—O—)). The overall yield of pure **29***b* from the crude amine **28***b* was 50%.

The diketone **29***b* was now heated for 6 h with 5 mol of potassium cyanide in aqueous ethanol. The lactamol **30***b* (m.p. 238 °C) resulted stereospecifically in a yield of 91%.

While this reaction may seem remarkable it was fully anticipated from our extensive model

SCHEME 4

studies (9, 3). It is actually a sequence of simple steps all of which were part of our original plan. Thus, the only noteworthy feature of the transformation was the fact that conditions were found where all these steps occurred in high yield stereospecifically and in one reaction solution.

The mechanism of the conversion **29***b* → **30***b* may be visualized as follows. Base-catalyzed aldol condensation of **29***b* yielded first an $\alpha\beta$-unsaturated ketone. This intermediate, which we have not isolated, then added cyanide axially, in a thermodynamically controlled reaction. The nitrile group was subsequently hydrolyzed to a primary amide, which tautomerized to the lactamol **30***b*.

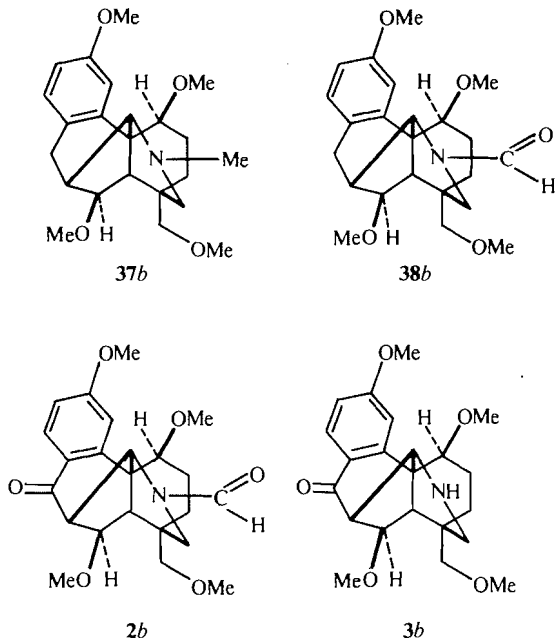
The conversion of the lactamol to the ketolactam **31***b* (m.p. 268 °C) was accomplished by heating in a mixture of methanol and concentrated hydrochloric acid in a yield of 64%; (i.r.: 1740 cm^{-1} (ketone), 1670 cm^{-1} (lactam); n.m.r.: singlets (3H each) τ 6.20, 6.57, 6.63 p.p.m. (3 OCH_3)).

With the synthesis of the ketolactam **31***b* accomplished, it remained only to modify the functional group system. This task was easy, since it required merely the reduction of the lactam group, the conversion of the ring B ketone into an *exo*-methoxy group, and the introduction of a keto group into the benzylic position. All these operations have been worked out previously in our model studies (3). The keto lactam **31***b* was reduced with lithium aluminum hydride in refluxing dioxane. The mixture of the two products **32***b* and **33***b* was separated by chromatography on alumina. The ratio of the two compounds was 1:1 and the yield was 76%.

The *exo*-alcohol **32***b* was crystalline (m.p. 228 °C); the *endo*-epimer **33***b* remained oily and it was converted to the ketone **34***b* by Jones oxidation. This last compound was subjected without purification to a reduction with sodium in refluxing absolute ethanol. The alcohols **32***b* and **33***b* were again obtained (yield 74%), but in this thermodynamically controlled reduction the desired *exo*-alcohol **32***b* predominated (ratio 7:3).

The *exo*-alcohol **32***b* was now acetylated with acetic anhydride in pyridine and the product hydrolyzed by heating with dilute methanolic potassium hydroxide. The crystalline alcohol **35***b* (m.p. 183 °C) was obtained in a yield of 95%.

Compound **35***b* was methylated in refluxing dioxane with sodium hydride and methyl iodide. The crystalline methoxy derivative **36***b* (m.p. 157 °C) was obtained in a yield of 87%. The n.m.r. spectrum of this material showed a singlet (11H) at τ 6.70 p.p.m. which includes



SCHEME 5

the three aliphatic methoxyls and the two hydrogens unshielded by the primary methoxyl. We have pointed out previously (3) that the ring B *endo*-methoxyl is located in the shielding region of the benzene ring and is consequently shifted upfield to τ 6.93 p.p.m. Thus, the n.m.r. spectrum of **36***b* is in agreement with the configuration portrayed in the formula. Compound **36***b* was converted into the final product **4***b* by Jones' oxidation in a yield of 89%. The racemate **4***b* was a crystalline sharply melting material (m.p. 188–190°C) and it was characterized by a high resolution mass spectrum and elemental analysis.

The i.r., n.m.r., u.v., and mass spectra of the synthetic racemate and the naturally derived compound of the same structure were superimposable. The two materials were also indistinguishable in several t.l.c. systems.

Since we wished to synthesize also the formyl derivative **2***b* and the secondary base **3***b* and since it turned out that the *N*-acetyl group of **4***b* is exceedingly difficult to hydrolyze, we have worked out a second variant of the final stages of the synthesis.

The *exo*-alcohol **32***b* was methylated in refluxing dioxane with sodium hydride and methyl iodide. The oily tetramethoxy *N*-methyl derivative **37***b* was obtained in a yield of 96%.

The conversion of **37***b* to the *N*-formyl derivative **38***b* was accomplished in a yield of 95% by oxidation with potassium permanganate in acetone at room temperature. Compound **38***b* was a highly crystalline, sharply melting solid (m.p. 158–160°C) and it was transformed into the final "delphinine aromatization product" **2***b* by Jones oxidation in a yield of 67%. A direct conversion of **37***b* to **2***b* was also accomplished by a prolonged oxidation with an excess of potassium permanganate in acetone acetic acid (yield 82%). The synthetic racemate **2***b* remained oily, but it was homogeneous in several t.l.c. systems and indistinguishable from the "natural" delphinine derivative. Both materials also gave identical i.r., n.m.r., and mass spectra.

The formyl derivative **2***b* was finally smoothly hydrolyzed to the secondary base **3***b* (m.p. 176°C, yield 94%) by refluxing with dilute hydrochloric acid. The synthetic racemate **3***b* was characterized by elemental analysis and high resolution mass spectrometry and it was found to be indistinguishable from the optically active "natural" derivative of the same structure by t.l.c., i.r., n.m.r., and mass spectrometry.

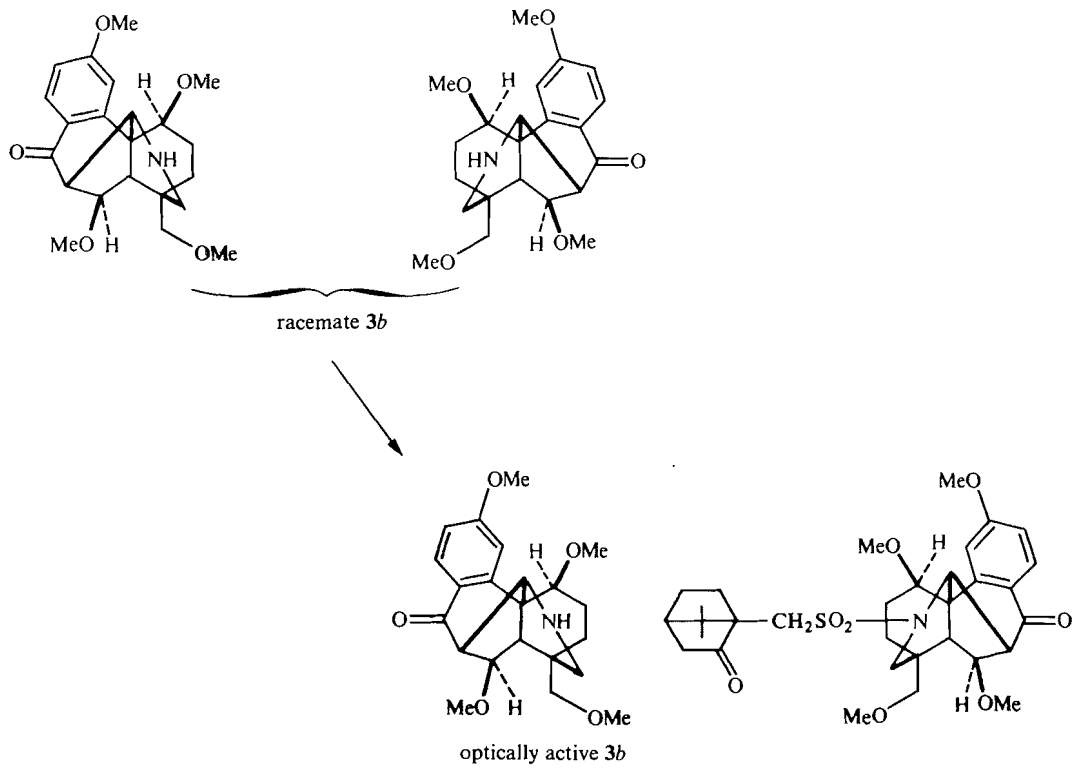
Thus, the stereoselective total synthesis of the racemic relay compound **3***b* was complete. In spite of the stereoselectivity of the entire process (including the setting up of the configuration of the ring A methoxyl) the synthesis did not provide any reliable information about the configuration of the ring A methoxy group.

The only point rigorously established about this asymmetric center was that its configuration in the synthetic products was the same as in the natural alkaloid and its derivatives.

The configuration **1***a* (Scheme 1) of the ring A methoxyl in delphinine was assigned (1*c*) on the basis of a direct correlation (10) of delphinine with aconitine, in the course of which this asymmetric center remained undisturbed. The corresponding ring A methoxyl of aconitine in turn was tentatively assigned the configuration *trans* to the nitrogen bridge on the basis of a conformational argument (11). A similar conformational argument seemed also to hold when this substituent was studied directly in delphinine (1*c*). It was quite clear to us that these assignments were not completely secure, since there was some uncertainty about the conformation of ring A in alkaloids of the delphinine type.

While our synthetic objective was reached, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 6

felt that we wished to know the configuration of the ring A methoxyl in the synthetic compounds directly and not merely by correlation with a natural derivative. Consequently we have prepared the beautifully crystalline acid oxalate of the *racemate*[5] **3***b* [m.p. 189–192 °C] and submitted it for X-ray crystallography to Dr. Maria Przybylska at the National Research Council of Canada Laboratories, Ottawa, Canada. The structure determination performed by Dr. Karin Bjåmer Birnbaum (12) corroborated all the features of the molecule and revealed the configuration of the ring A methoxyl to be as portrayed in formula **3***b*.

Since we wished to use **3***b* as a relay compound and draw our supplies of this material for the continuation of the synthesis from natural sources it was imperative to resolve the racemate into optical antipodes.

After numerous unsuccessful attempts at resolution by conventional methods, we have noticed that if the racemate was allowed to react with D-camphor–sulfonyl chloride in pyridine, the reaction stopped when approximately 50% of the secondary amine was consumed. Isolation of the unreacted free base yielded material which was optically active and showed an optical rotatory dispersion (o.r.d.) curve antipodal to the o.r.d. recorded for the natural degradation product.

Consequently, we have achieved the preparation of the totally synthetic optically active antipode **3***b* with the natural absolute configuration in the following manner. The racemate **3***b* was dissolved in dry pyridine and treated with 1 mol of L-camphor–sulfonyl chloride at 0 °C. The temperature was allowed to rise to 20 °C and the mixture was kept overnight. The unreacted free base was converted to the acid

[5]The X-ray structure determination of the synthetic *racemate* is also important as an independent verification of the synthesis. Since long laborious total syntheses unlike other work may never be repeated in independent laboratories and since X-ray methods are increasingly fast and effective it seems to the authors that an X-ray of the synthetic *racemate* in a synthesis like the present one should be almost a requirement.

oxalate, which was recrystallized to a constant melting point of 195–196 °C. This melting point was identical with the melting point of the "natural" degradation base oxalate and the two products did not show melting point depression. Both materials gave also superimposable i.r. and n.m.r. spectra and o.r.d. curves. The totally synthetic optically active oxalate was decomposed and the synthetic optically active base **3***b* was recrystallized to a melting point of 144.5 °C. This melting point was undepressed by admixture of the "natural" base which had the same melting point. Both materials showed superimposable i.r., n.m.r., and mass spectra and t.l.c. behavior.

Thus, our objective has been fully achieved and a stepping stone created for the synthesis of alkaloids of the delphinine type. It should be pointed out that while compound **3***b* is structurally complex, it is operationally very simple. After suitable blockade of the nitrogen the entire system is solid saturated and unreactive, all except the *p*-methoxy acetophenone group which must be used for building up the CD ring system. Thus, the obstacles in the remaining part of the synthesis are more financial than chemical in nature.

Experimental

Allyl Tetralone **6**

Distilled pyrrolidine (135 ml, 1.65 mol) was added to a stirred solution of 7-methoxy-2-tetralone (164 g, 0.93 mol) in benzene (1500 ml). The solution was refluxed under nitrogen until all the water produced by the reaction had been removed by a Dean Stark trap (3 h). The reaction mixture was then cooled to room temperature and allyl bromide (195 ml, 2.28 mol) was added dropwise. The mixture was refluxed for 17 h, at the end of which, water (2000 ml) was added and the reflux continued for another period of 3 h.

The organic phase was separated, washed with water (3 × 500 ml), dried over anhydrous magnesium sulfate, and taken to dryness *in vacuo*. The crude product (193 g) was distilled *in vacuo* and gave 178 g of the pure allyl tetralone **6** (b.p. 118–120 °C, 0.05 mm Hg); yield 89%.

I.r. (CCl_4): 1715 (C=O); 915 cm^{-1} (C=CH_2).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.80–3.50 (aromatic protons of the anisole ring); multiplet (3H) 4.20–5.20 (vinylic protons); singlet (3H) 6.28 p.p.m. (methoxyl protons).

Mass spectrum Calcd. for $C_{14}H_{16}O_2$: *m/e*, 216. Found: 216.

Disubstituted Tetralone **7**

The allyl tetralone **6** (66 g, 0.30 mol) was dissolved in dry benzene (500 ml). Sodium hydride (12.6 g, 0.31 mol; 60% suspension in mineral oil) was added and the resulting mixture was stirred under nitrogen at room temperature for 15 h then at 60° for 6 h. The mixture was cooled in an ice-water bath, and benzyloxymethyl chloride (59.4 g, 0.36 mol) in dry benzene (250 ml) was added dropwise. The mixture was then allowed to warm up to room temperature and stirring was continued for 18 h.

After addition of water (250 ml), the organic phase was separated and the aqueous phase was extracted with benzene (3 × 75 ml). The benzene extracts were combined, washed with water (3 × 150 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent *in vacuo* gave the crude disubstituted tetralone **7** (112 g). Chromatography on silica gel (3 Kg) in benzene gave the pure compound **7** (67.5 g); yield 68%.

I.r. (CCl_4): 1715 (C=O); 915 cm^{-1} (C=CH_2).

N.m.r. ($CDCl_3$): multiplet (8H) τ 2.81–3.14 (aromatic protons of the anisole ring and the benzyl group); multiplet (3H) 4.50–5.50 (vinylic protons); singlet (2H) 5.70 (benzylic methylene protons); singlet (5H) 6.26 p.p.m. (aromatic methoxyl and the methylene protons deshielded by the benzyloxyl group).

Mass spectrum Calcd. for $C_{22}H_{24}O_3$: *m/e*, 336.1726. Found: 336.1719.

Diols **8**

A solution of compound **7** (51.9 g, 0.17 mol) in tetrahydrofuran (250 ml) was combined with osmic acid (0.25 g, 0.001 mol) in tetrahydrofuran (25 ml) and stirred at room temperature for 10 min. A solution of sodium chlorate (26.6 g, 0.25 mol) in water (250 ml) was added in several portions, and the stirring was continued for 16 h at 60°.

After distilling off most of the tetrahydrofuran under reduced pressure, water (200 ml) was added and the solution was extracted with ether (3 × 150 ml). The combined ether extracts were washed with water (3 × 150 ml), dried over anhydrous magnesium sulfate, and evaporated to dryness *in vacuo* to give the crude diols. The dark viscous product was chromatographed on silica gel (2 Kg). Elution with a 2:8 ether–benzene mixture gave two epimeric diols (A, 22.4 g, m.p. 108–109 °C; B, 23.0 g, m.p. 125–130 °C). Both compounds were recrystallized from benzene; yield 79%.

I.r. of A and B (KBr pellet): 3200–3500 cm^{-1} (hydroxyl); no carbonyl absorption.

N.m.r. ($CDCl_3$): A and B multiplet (8H) τ 2.80–3.50 (aromatic protons); singlet (2H) A, 5.55, B, 5.58 (benzylic methylene protons); singlet (5H) A, 6.26, B, 6.34 p.p.m. (protons deshielded by the benzyloxyl and the aromatic methoxyl protons).

Mass spectrum Calcd. for $C_{22}H_{26}O_5$: *m/e*, 370. Found: 352 ($M^+ - H_2O$).

Keto Aldehyde **9**

The epimeric diols **8** (46.4 g, 0.14 mol) were dissolved in a 1:1 THF–water mixture (660 ml). Sodium metaperiodate (232 g, 1.08 mol) was added over a period of 15 min and the mixture was stirred at room temperature under nitrogen for 8 h. The resulting white precipitates were filtered off and washed well with ether. Water (300 ml) was added and the filtrate was extracted with ether (5 × 200 ml). The combined ethereal extracts were washed with water (2 × 200 ml) and dried over anhydrous magnesium sulfate. The crude keto-aldehyde **9** (41 g) was obtained after evaporation of the

For personal use only.

solvent *in vacuo*, and was used for the next step without further purification.

I.r. (CCl_4): 2720 (C—H, aldehyde); 1726 (C=O, aldehyde); 1715 cm^{-1} (C=O, ketone).

N.m.r. ($CDCl_3$): singlet (1H) τ 0.49 (aldehydic proton); multiplet (8H) 2.60–3.28 (aromatic protons of the anisole ring and the benzyl group); singlet (2H) 5.62 (benzylic methylene protons); singlet (5H) 6.21 p.p.m. (aromatic methoxyl and methylene protons deshielded by the benzyloxy group).

Hydroxy Ketone ***10***

A solution of the keto-aldehyde **9** (41 g, 0.12 mol) in methanol (3500 ml) was added to sodium hydroxide (5.32 g, 0.13 mol) in water (138 ml). The resulting brown solution was stirred at 55 °C under nitrogen for 30 h. Water (2000 ml) was added and the solution was neutralized with 20% hydrochloric acid. The methanol was partially evaporated *in vacuo* until the mixture just became cloudy. The mixture was extracted with ether (5 × 800 ml) and the combined ethereal extracts were washed with water (2 × 1000 ml), dried over anhydrous magnesium sulfate and evaporated to dryness *in vacuo* to give the crude hydroxy-ketone **10** (34.8 g). This material was purified by chromatography on silica gel (1 kg). Elution with benzene–ether gave the pure hydroxy ketone **10** (28.2 g).

I.r. (CCl_4): 3600, 3475 (O—H); 1755 cm^{-1} (five membered ketone).

N.m.r. ($CDCl_3$): singlet (5H) τ 2.78 (aromatic protons of the benzyl group); multiplet (3H) 3.25–3.50 (aromatic protons of anisole ring); singlet (2H) 5.42 (benzylic methylene protons); quadruplet (1H) centered at 5.70 (proton deshielded by the hydroxyl); singlet (2H) 6.08 (methylene protons deshielded by the benzyloxy group); singlet (3H) 6.31 p.p.m. (aromatic methoxyl protons).

Mass spectrum Calcd. for $C_{21}H_{22}O_4$: *m/e*, 338. Found: 338.

Both compounds **9** and **10** were rather unstable and had to be characterized by a derivative. The crystalline ketal **11** was used for this purpose.

Hydroxy Ketal ***11***

A mixture of the hydroxy ketone **10** (54.1 g, 0.16 mol), ethylene glycol (17.1 g, 0.27 mol), and *p*-toluenesulfonic acid (4.57 g, 0.034 mol) in benzene (1000 ml) was heated under reflux for 2 h using a Dean Stark water separator to remove the water produced by the reaction. The reaction mixture was cooled, washed with water (2 × 200 ml), then with 5% aqueous sodium bicarbonate (3 × 200 ml) and with water (2 × 200 ml). The organic phase was dried over anhydrous magnesium sulfate and evaporated to dryness under reduced pressure. The pure ketal **11** was obtained by crystallization from ether (53.2 g, m.p. 97–99 °C), yield: 88%.

I.r. (KBr pellet): 3600–3200 cm^{-1} (hydroxyl); no carbonyl absorption.

N.m.r. ($CDCl_3$): singlet (5H) τ 2.74 (aromatic protons of the benzyl group); multiplet (3H) 3.25–3.30 (aromatic protons of the anisole ring); singlet (2H) 5.48 (benzylic methylene protons); broad singlet (6H) 6.18 (ketal methylenes and methylene protons deshielded by the benzyloxy group); singlet (3H) 6.43 p.p.m. (aromatic methoxyl).

Tetrahydropyranyl Alcohol **15**

The tetrahydropyranyl acetate **14** (42.2 g, 0.10 mol) was dissolved in dry ether (2000 ml). Lithium aluminum hydride (3.95 g, 0.10 mol) was added and the resulting suspension was stirred at room temperature for 1 h. The reaction mixture was poured into wet ether (2000 ml) and a few drops of water were added. The solid material was filtered off and the filtrate was dried over anhydrous magnesium sulfate and evaporated to dryness. The crude product was chromatographed on silica gel (1.5 kg). The pure tetrahydropyranyl alcohol **15** (38.3 g, 98%) was eluted with 10% ether in benzene.

I.r. ($CHCl_3$): 3500 cm^{-1} (hydroxyl); no carbonyl absorption.

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.80–3.50 (aromatic protons of the anisole ring); broad singlet (1H) 5.30 (proton deshielded by the hydroxyl); multiplet (4H) centered at 6.00 (ketal methylenes); singlet (3H) 6.24 (aromatic methoxyl); broad singlet (6H) 8.33 p.p.m. (methylene protons of the tetrahydropyran ring).

Mass spectrum Calcd. for $C_{21}H_{28}O_6$: *m/e*, 376.1885. Found: 376.1882.

Tetrahydropyranyl Benzyl Ketal **16**

The tetrahydropyranyl alcohol **15** (37.6 g, 0.10 mol) was dissolved in absolute dioxane (1000 ml); sodium hydride (6.5 g, 0.15 mol, 56% suspension in mineral oil) and benzyl chloride (25.6 g, 0.15 mol) were added and the mixture was heated at reflux for 18 h. The suspension was then cooled to room temperature and filtered through Celite. The filtrate was partially evaporated (about 100 ml remained), water (200 ml) was added, and the solution was extracted with chloroform (4 × 300 ml). The chloroform extracts were washed with water (3 × 200 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The crude product was chromatographed on silica gel (1.5 kg). Elution with 2% ether in benzene gave the pure benzyl derivative **16** (37.5 g, 81%).

I.r. ($CHCl_3$): no hydroxyl absorption.

N.m.r. ($CDCl_3$): singlet (5H) τ 2.64 (aromatic protons of the benzyl group); multiplet (3H) 2.70–3.50 (aromatic protons of the anisole ring); multiplet (4H) centered at 6.00 (ketal methylenes); singlet (3H) 6.22 (aromatic methoxyl); broad singlet (6H) 8.32 p.p.m. (methylene protons of the tetrahydropyran ring).

Mass spectrum Calcd. for $C_{28}H_{34}O_6$: *m/e*, 466. Found: 466.

Hydroxy Ketal **17**

The benzyloxy compound **16** (46.6 g, 0.1 mol) was dissolved in a mixture of concentrated hydrochloric acid and methanol (1:99, 500 ml) and stirred at room temperature for 1 h. After neutralization with 5% aqueous sodium bicarbonate, the methanol was partially evaporated *in vacuo*, water (500 ml) was added, and the solution was extracted with chloroform (3 × 500 ml). The organic phase was washed with water (2 × 300 ml), dried over anhydrous sodium sulfate, and evaporated to dryness *in vacuo*. The crude alcohol was purified by chromatography on silica gel (1.5 kg). Elution with 15% ether in benzene gave the pure hydroxy ketal **17** (34.4 g, 90%).

I.r. (CCl_4): 3550 cm^{-1} (hydroxyl).

N.m.r. ($CDCl_3$): singlet (5H) τ 2.64 (aromatic protons of the benzyl group); multiplet (3H) 2.90–3.40 (aromatic protons of the anisole ring); singlet (2H) 5.50 (benzylic methylene protons); multiplet (4H) centered at 5.90 (ketal methylene protons); singlet (3H) 6.21 p.p.m. (aromatic methoxyl).

Mass spectrum Calcd. for $C_{23}H_{26}O_5$: *m/e*, 382.1780. Found: 382.1772.

Aldehyde **18**

A solution of the primary alcohol **17** (12 g, 0.03 mol) in dry dichloromethane (100 ml) was added in 1 min to a solution of chromium trioxide–pyridine complex (50.4 g) in dichloromethane (1000 ml). The resulting mixture was stirred at room temperature for 10 min. Ether (2000 ml) was added, the solid material was filtered off, and the filtrate was evaporated *in vacuo*. The crude product was chromatographed on silica gel (800 g). Elution with 5% ether in benzene gave the pure aldehyde **18** (12.7 g, 85%).

I.r. (CCl_4): 2720 and 1725 cm^{-1} (aldehyde), no hydroxyl absorption.

N.m.r. ($CDCl_3$): singlet (1H) τ 0.17 (aldehydic proton); doublet (5H) centered at 2.67 (aromatic protons of the benzyl group); multiplet (3H) 2.70–3.80 (aromatic protons of the anisole ring); singlet (2H) 5.50 (benzylic methylene protons); multiplet (4H) centered at 6.00 (ketal methylene protons), singlet (3H) 6.30 p.p.m. (aromatic methoxyl).

1-Methoxy-2-benzyloxy-3-cyano Propane **19**

Benzyl alcohol (300 g, 2.78 mol) and sodium (3.5 g, 0.155 mol) were stirred at room temperature until all the sodium was dissolved and then 1-methoxy-3-cyano-2-propene (8) (150 g, 1.55 mol) was added dropwise. The solution was stirred for a week at room temperature. After neutralization with acetic acid, ether (100 ml) and water (100 ml) were added and the mixture was extracted into ether (3 × 200 ml). The organic layer was washed with water (3 × 200 ml), dried over anhydrous magnesium sulfate, and finally the ether was evaporated *in vacuo*. The crude compound was distilled to give pure 1-methoxy-2-benzyloxy-3-cyano propane (102 g, b.p. 115–120 °C/0.3 mm Hg); yield: 32%.

I.r. (CCl_4) 2240 cm^{-1} (nitrile).

N.m.r. ($CDCl_3$): singlet (5H) τ 2.90 (aromatic protons of the benzyl group); singlet (2H) 5.39 (benzylic methylene protons); multiplet (1H) centered at 6.05 (proton deshielded by the benzyloxyl); doublet (2H) centered at 6.56 (protons deshielded by the methoxyl); singlet (3H) 6.65 (—OCH_3); doublet (2H) centered at 7.44 p.p.m. (C_3 methylene protons).

1-Methoxy-2-benzyloxy-3-carbomethoxy Propane **20**

A solution of 1-methoxy-2-benzyloxy-3-cyano propane (36 g, 0.175 mol) in methanol (1000 ml) and sulfuric acid (100 ml) was heated under reflux for 50 h. The excess of methanol was then evaporated *in vacuo*. The reaction mixture was poured into water (500 ml) and the product was extracted into ether (3 × 500 ml). The ethereal layer was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

washed with 5% sodium carbonate in water (3 × 200 ml), then with water (3 × 500 ml), and dried over anhydrous magnesium sulfate. After evaporation of the ether *in vacuo*, the crude ester was purified by distillation (29.5 g, 71.5%, b.p. 115–125 °C/0.01 mm Hg).

I.r. ($CHCl_3$): 1735 cm^{-1} (ester carbonyl).

N.m.r. ($CDCl_3$): doublet (5H) centered at τ 2.80 (aromatic protons of the benzyl group); singlet (2H) 5.40 (benzylic methylene protons); multiplet (1H) centered at 6.00 (proton deshielded by the benzyloxyl); singlet (3H) 6.37 (carbomethoxy methyl protons); doublet (2H) centered at 6.57 (protons deshielded by the methoxyl); singlet (3H) 6.70 (—OCH_3); doublet (2H) centered at 7.65 p.p.m. (C_3 protons).

Mass spectrum Calcd. for $C_{13}H_{18}O_4$: *m/e*, 238. Found: 238.

1-Methoxy-2-benzyloxy-4-hydroxybutane **21**

A suspension of lithium aluminum hydride (953 mg, 0.025 mol) in dry ether (200 ml) was stirred in an ice-water bath for 10 min. A solution of the ester **20** (5.0 g, 0.021 mol) in dry ether (80 ml) was added slowly and the reaction was stirred for 1.5 h at room temperature. The reaction mixture was then poured into wet ether (500 ml), the solid material was filtered off, the filtrate was dried over anhydrous magnesium sulfate, and finally, the solvent was evaporated *in vacuo*. The crude alcohol (5.0 g) was purified by chromatography on silica gel (200 g). Elution with 10–20% ether in benzene gave pure 1-methoxy-2-benzyloxy-4-hydroxybutane (2.0 g); yield 68%.

For large scale preparations, distillation was used as a purification method. The alcohol distilled at 120–125 °C/1 mm Hg.

I.r. ($CHCl_3$): 3600 cm^{-1} (OH); no carbonyl absorption.

N.m.r. ($CDCl_3$): singlet (5H) τ 2.65 (aromatic protons of the benzyl group); doublet (2H) centered at 5.37 (benzylic methylene protons); triplet (2H) centered at 6.28 (protons deshielded by the hydroxyl); doublet (2H) centered at 6.59 (protons deshielded by the methoxyl); singlet (3H) 6.70 (—OCH_3); broad singlet (1H) 7.24 (OH); quadruplet (2H) centered about 8.22 p.p.m. (C_3 methylene protons).

Mass spectrum Calcd. for $C_{12}H_{18}O_3$: *m/e*, 210.2156. Found: 210.2157.

1-Methoxy-2-benzyloxy-4-bromobutane **22**

The alcohol **21** (30.0 g, 0.143 mol) was dissolved in dry pyridine (30 ml) and the solution was stirred in an ice-water bath for 30 min, after which *p*-toluenesulfonyl chloride (32.8 g, 0.172 mol) was added and stirring was continued with cooling for 3 h. The reaction mixture was then poured into ice water (150 ml) and the product was extracted into ether (3 × 200 ml). The combined ethereal layers were washed with water (5 × 200 ml), dried over anhydrous magnesium sulfate, and finally the ether was evaporated *in vacuo* giving 1-methoxy-2-benzyloxy-4-tosyloxybutane (45.2 g) which was homogeneous on t.l.c.; yield: 87%.

I.r. ($CHCl_3$): 1364, 1179 cm^{-1}, no hydroxyl absorption.

N.m.r. ($CDCl_3$): two doublets (2H each) centered at τ, 2.23 and 2.76 (aromatic protons of the tosyl group; singlet (5H) 2.74 (aromatic protons of the benzyl group); doublet (2H) centered at 5.55 (benzylic methylene protons); triplet (2H) centered at 5.89 (protons deshielded by the tosyloxyl); multiplet (1H) centered at 6.42 (proton deshielded by the benzyloxyl); doublet (2H) centered at 6.65 (protons deshielded by the methoxyl); singlet (3H) 6.71 (—OCH_3); singlet (3H) 7.62 (tosyl methyl protons); quadruplet (2H) centered about 8.12 p.p.m. (C_3 methylene protons).

The tosylate (43.2 g, 0.124 mol) was dissolved in acetone (750 ml, distilled over potassium permanganate) and lithium bromide (43.0 g, 0.476 mol) was added. The resulting solution was heated under reflux for 3 h. The reaction mixture was cooled, excess acetone was evaporated, and water (1500 ml) was added. After extraction into ether (3 × 500 ml) the combined ethereal layers were washed with water (3 × 500 ml), and dried over anhydrous magnesium sulfate. Evaporation of the ether *in vacuo* gave the crude bromide (34 g) which was purified by chromatography on silica gel (1200 g). Elution with benzene gave 1-methoxy-2-benzyloxy-4-bromobutane **22** (33 g, 83.5%).

N.m.r. ($CDCl_3$): singlet (5H) τ 2.67 (aromatic protons of the benzyl group); doublet (2H) centered at 5.38 (benzylic methylene protons); multiplet (1H) 6.21 (proton deshielded by the benzyloxyl); doublet (2H) centered at 6.53 (protons deshielded by bromine); doublet (2H) centered at 6.58 (protons deshielded by the methoxyl); singlet (3H) 6.65 (—OCH_3); quadruplet (2H) centered at 7.95 p.p.m. (C_3 methylene protons).

Grignard Alcohol **23**

To a mixture of fine magnesium turnings (8.55 g, 0.35 mol) and a small grain of iodine in absolute tetrahydrofuran (700 ml), one third of a solution of 1-methoxy-2-benzyloxy-4-bromobutane **22** (95.5 g, 0.35 mol) in absolute tetrahydrofuran (700 ml) was introduced and the mixture was refluxed at 70° (bath temperature) under nitrogen. As soon as the color of the iodine had disappeared the remaining solution was added dropwise. The reaction mixture was then heated to 70 °C for 4 h, at the end of which most of the magnesium was dissolved and the mixture was cooled to room temperature. The benzyloxy-aldehyde **18** (22.8 g, 0.06 mol) in absolute tetrahydrofuran (180 ml) was added dropwise and the solution was stirred overnight.

The reaction mixture was poured into a saturated ammonium chloride solution (1000 ml) and extracted with chloroform (5 × 500 ml). The chloroform extract was washed with water (3 × 500 ml) and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo* and the crude product was chromatographed on silica gel (1.2 kg). Elution with a 2:8 ether–benzene mixture gave the pure Grignard alcohol **23** (31.3 g, 91%).

I.r. (CCl_4): 3510 cm^{-1} (hydroxyl); no carbonyl absorption.

N.m.r. ($CDCl_3$): singlet (10H) τ 2.68 (aromatic protons on two benzyl groups); two singlets (2H each) 5.38 and 5.52 (methylene protons of two benzyl groups); multiplet (4H) centered at 6.00 (ketal methylene protons), and two singlets (3H each) 6.31 and 6.66 p.p.m. (two methoxyls).

Ketone **27***a*

Compound **26***a* (25.4 g, 0.043 mol) was dissolved in 75% aqueous acetic acid (850 ml) and heated under reflux for 18 h. The acetic acid was evaporated *in vacuo* and chloroform (500 ml) was added. The solution was washed with 10% sodium bicarbonate (3 × 300 ml) and with water (2 × 300 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The ketone **27***a* (23 g) which was homogeneous on t.l.c. was obtained in quantitative yield.

I.r. (CCl_4): 1755 cm^{-1} (five-membered ketone).

N.m.r. ($CDCl_3$): two singlets (5H each) τ 2.68 and 2.70 (aromatic protons of the two benzyl groups); two singlets (2H each) 5.40 and 5.52 (benzylic methylene protons); three singlets (3H each) 6.27, 6.49, 6.67 p.p.m. (three methoxyls).

Mass spectrum Calcd. for $C_{34}H_{40}O_6$: *m/e*, 544.2824. Found: 544.2818.

Conversion of **27***a to the Diketone* **29***a*

The ketone **27***a* (23 g, 0.042 mol) was dissolved in methanol (90 ml) and cooled in a methanol – Dry Ice bath. Raney nickel (9.5 g) and liquid ammonia (125 ml) were added. The mixture was hydrogenated (165 °C, 4000 p.s.i. H_2) for 10 h. The catalyst was removed by filtration through Celite and washed thoroughly with methanol. The filtrate was evaporated to dryness and yielded the amine **28***a* (20.5 g, 90%) which was used without purification for the subsequent step.

I.r. (CCl_4): 3400 cm^{-1} (N—H), no carbonyl band.

N.m.r. ($CDCl_3$): two singlets (5H each) τ 2.70 and 2.77 (aromatic protons of the two benzyl groups); multiplet (3H) 3.0–3.40 (aromatic protons of the anisole ring); doublet (2H) centered at 5.42 (benzylic methylene protons); singlet (2H) 5.60 (benzylic methylene protons); three singlets (3H each) 6.30, 6.51, and 6.67 p.p.m. (three methoxyl).

Mass spectrum Calcd. for $C_{34}H_{43}O_5N$: *m/e*, 545.3141. Found: 545.3128.

The amine **28***a* (20 g, 0.036 mol) was dissolved in pyridine (60 ml) and acetic anhydride (60 ml). The mixture was allowed to remain at room temperature for 10 h. The pyridine and acetic anhydride were evaporated in high vacuum, chloroform (200 ml) was added, and the solution was washed with 5% aqueous sodium bicarbonate (3 × 150 ml), water (2 × 150 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The product (20 g, 95%) was homogeneous on t.l.c. and was used without further purification.

I.r. (CCl_4): 3395 (N—H); 1670 cm^{-1} (acetyl amino carbonyl).

N.m.r. ($CDCl_3$): multiplet (13H) τ 2.70–3.42 (aromatic protons of the two benzyl groups and the anisole ring); doublet centered at 5.74 (apex proton of *anti*-epimer); multiplet centered at 5.24 (apex proton of *syn*-epimer); singlet 8.05 (N—CO—CH_3, *anti*), singlet 8.24 p.p.m. (N—CO—CH_3, *syn*).

The above material (20 g, 0.034 mol) was dissolved in ethanol (1000 ml) and 10% palladium-on-charcoal (10 g) was added. The mixture was hydrogenated (1 atm H_2; room temperature) for 16 h. The catalyst was removed by filtration through Celite and washed thoroughly with ethanol. The ethanol was evaporated *in vacuo* and the crude diol (14 g), was purified by chromatography on silica gel (800 g). Elution with 2% methanol in chloroform yielded the pure material (12.5 g, 90%).

I.r. (CCl_4): 3645, 3435, and 3390 (O—H, N—H); 1660 cm^{-1} (acetylamino carbonyl).

Mass spectrum Calcd. for $C_{22}H_{33}O_6N$: *m/e*, 407.2308. Found: 407.2304.

The above material (12.25 g, 0.03 mol) in dry dichloromethane (100 ml) was added over 1 min to a stirred solution of the chromium trioxide – pyridine complex (100.8 g) in dry dichloromethane (2000 ml). The resulting mixture was stirred at room temperature for 20 min. It was then poured into ether (2000 ml) and the precipitate was removed by filtration. The filtrate was evaporated to dryness in high vacuum and the crude product was purified by chromatography on silica gel (1 kg). Elution with 2% methanol in chloroform gave the pure diketone **29***a*. After crystallization from ether the compound melted at 154–156 °C (7.85 g, 65%).

I.r. (KBr pellet): 3390 (N—H); 1740 (five-membered ketone); 1721 (ketone); 1666 cm^{-1} (*N*-acetyl).

N.m.r. Ketolactam 31a

The crystalline lactamol **30***a* (3.5 g, 0.008 mol) was dissolved in a 1:1 concentrated hydrochloric acid–methanol mixture (200 ml) and the solution was heated under reflux for 24 h. After cooling to room temperature, water (100 ml) was added and the methanol was evaporated *in vacuo*. The aqueous solution was extracted with chloroform (5 × 50 ml), and the chloroform extract was washed with 10% aqueous hydrochloric acid (2 × 50 ml) and with water (2 × 100 ml). The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness. The crude product **31***a* crystallized from a chloroform–ether mixture was recrystallized from methanol to a constant melting point of 244–248 °C (463 mg). The mother liquor and the aqueous phase were evaporated to dryness and dissolved in methanol–HCl for further reaction under exactly the same conditions. The yield was 846 mg of **31***a* in the first re-run and 470 mg in the second. The overall conversion into the ketolactam in three successive runs was 1.78 g (60%).

I.r. (KBr pellet): 3190, 3084 (lactam N—H), 1745 (five-membered ketone), 1665 cm^{-1} (six-membered lactam).

N.m.r. ($CDCl_3$): three singlets (3H each) τ 6.24 (aromatic methoxyl), 6.70 (ring A methoxyl), 6.80 (primary methoxyl), singlet (2H) 6.67 p.p.m. (methylenic protons deshielded by primary methoxyl).

Hydroxy Amines 32a and 33a

Lithium aluminum hydride (380 mg, 10 mmol) was added to the keto lactam **31***a* (371 mg, 1 mmol) dissolved in dry dioxane (50 ml). After stirring at room temperature for 15 min, the solution was heated under reflux for 3 h. The reaction mixture was cooled, poured into wet ether (300 ml), and a few drops of water were added. The precipitate was removed by filtration and the filtrate was evaporated to dryness. The product was a mixture of the α-hydroxy amine **33***a* and the β-hydroxy amine **32***a*. The two compounds were separated and purified by preparative t.l.c. on neutral alumina, with 10% methanol in chloroform as solvent. The pure α-hydroxy amine **33***a* (157 mg, crystallized from ether–chloroform, m.p. 155–156 °C) and the β-hydroxy amine **32***a* (145 mg, crystallized from methanol, m.p. 196–198 °C) were obtained in an 84% yield.

I.r. (KBr pellet) α-hydroxy amine **33***a*: 3580, 3375, 3160 (N—H, O—H), 1575 cm^{-1} (N—H bending); β-hydroxy amine **32***a*: 3600, 3390, and 3140 (N—H, O—H), 1565 cm^{-1} (N—H bending).

N.m.r. ($CDCl_3$) α-hydroxy amine **33***a*: singlet (3H) τ 6.20 (aromatic methoxyl), singlet (3H) 6.67 (ring A methoxyl at C_1), singlet (2H) 6.84 (protons deshielded by the primary methoxyl), singlet (3H) 6.93 p.p.m. (primary methoxyl); β-hydroxy amine **32***a*: singlet (3H) τ 6.22 (aromatic methoxyl), singlet (5H) 6.68 (ring A methoxyl at C_1 and the protons deshielded by the primary methoxyl), singlet (3H) 6.90 p.p.m. (primary methoxyl).

Mass spectrum Calcd. for $C_{21}H_{29}O_4N$: *m/e*, 359.2097. Found for **32***a*: 359.2090.

Anal. Calcd. for $C_{21}H_{29}O_4N$: C, 70.18; H, 8.13; N, 3.90. Found for **33***a*: C, 70.11; H, 8.08; N, 3.86. Found for **32***a*: C, 70.15; H, 8.08; N, 3.91.

The N-Acetyl Alcohol 35a

The β-hydroxy amine **32***a* (143.6 mg, 0.4 mmol) was dissolved in pyridine (1 ml) and acetic anhydride (1 ml) and the resulting mixture was allowed to stand at room temperature for 24 h. The pyridine and acetic anhydride were evaporated in high vacuum and the residue was dried at 60 °C in high vacuum for 5 h. The *N,O*-diacetyl derivative was obtained in a quantitative yield (175 mg) and it was homogeneous on t.l.c.

I.r. (CCl_4): 1745 (ester), 1645 cm^{-1} (amide).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.20–3.34 (aromatic protons of the anisole ring), singlet (3H) 6.20 (aromatic methoxyl), doublet (6H) 6.67, 6.70 (ring A methoxyl and the primary methoxyl), singlet (2H) 6.78 (protons deshielded by the primary methoxyl), singlet (3H) 7.84 (N—CO—CH_3), singlet (3H) 7.92 p.p.m. (O—CO—CH_3).

The *N,O*-diacetate (145 mg, 0.35 mmol) was dissolved in 5 ml of methanol and 5 ml of 0.2 *N* aqueous potassium hydroxide were added. The reaction mixture was heated to 50 °C for 2 h. The mixture was then cooled, extracted with chloroform (4 × 10 ml), the chloroform extracts were washed with water (2 × 10 ml), dried over anhydrous magnesium sulfate, and evaporated to dryness *in vacuo*. Compound **35***a* (130.5 mg, 93%) was recrystallized from ether–chloroform to a m.p. 229–231 °C.

I.r. (CCl_4): 3615, 3400 (O—H), 1640 cm^{-1} (amide).

N.m.r. ($CDCl_3$): singlet (3H) τ 6.20 (aromatic methoxyl); singlet (6H) 6.67 (ring A methoxyl and the primary methoxyl); singlet (2H) 6.78 (protons deshielded by the primary methoxyl); singlet (3H) 7.87 p.p.m. (N—CO—CH_3).

Mass spectrum Calcd. for $C_{23}H_{31}O_5N$: *m/e*, 401.2202. Found: 401.2196.

Compound 36a

A solution of compound **35***a* (125 mg, 0.31 mmol) and sodium hydride (89.68 mg, 1.86 mmol, 50% mineral oil suspension) in absolute dioxane was heated under reflux for 1 h. The reaction mixture was cooled, methyl iodide (1.5 ml) was added and the mixture was refluxed for another 3 h. The solution was cooled again, the precipitate was removed by filtration through Celite and the filtrate was evaporated to dryness. The crude product was purified by preparative t.l.c. on silica gel (5% methanol in chloroform). The pure compound **36***a* (110 mg, 85%) was crystallized from ether, m.p. 137–139 °C.

I.r. (CCl_4): 1650 cm^{-1} (amide), no hydroxyl absorption.

N.m.r. ($CDCl_3$): singlet (3H) τ 6.21 (aromatic methoxyl), doublet (9H) 6.68, 6.73 (ring A methoxyl, primary methoxyl and ring B methoxyl), singlet (2H) 6.76 (protons deshielded by the primary methoxyl), singlet (3H) 7.86 p.p.m. (N—CO—CH_3).

Mass spectrum Calcd. for $C_{24}H_{33}O_5N$: *m/e*, 415.2359. Found: 415.2351.

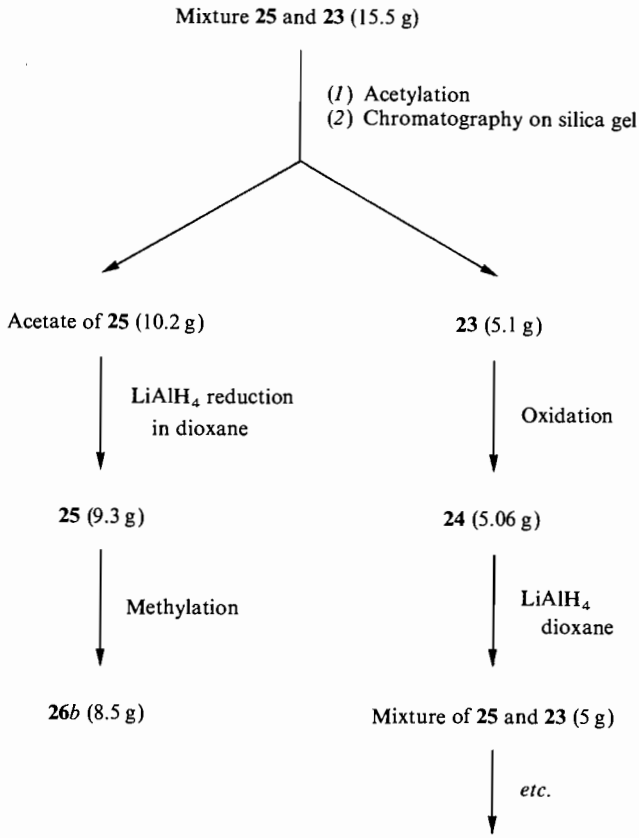

SCHEME 7

Compound 4a

Compound **36***a* (100 mg, 0.24 mmol) was dissolved in acetone (30 ml, distilled over $KMnO_4$) and Jones' reagent was added dropwise to the solution over a period of 6 h. Methanol (1.6 ml) was then added, the mixture was neutralized with 10% aqueous sodium bicarbonate and filtered. The filtrate was partially evaporated, saturated aqueous sodium chloride (15 ml) was added, and the aqueous solution was extracted with chloroform (4 × 15 ml). The chloroform extracts were dried over anhydrous sodium sulfate and evaporated to dryness. The crude product was purified by preparative t.l.c. on silica gel (5% methanol in chloroform). The pure *N*-acetyl ketone **4***a* (86.5 mg, 84%) was crystallized from ether to a m.p. 174–177 °C.

I.r. (CCl_4): 1690 (conjugated ketone), 1655 cm^{-1} (amide).

N.m.r. ($CDCl_3$): doublet (1H) τ 2.05 (aromatic proton deshielded by the benzylic ketone), multiplet (2H) 2.66–3.06 (aromatic protons), singlet (3H) 6.13 (aromatic methoxyl), doublet (11H) 6.68, 6.73 (three methoxyls and methylene protons deshielded by the primary methoxyl), singlet (3H) 7.90 p.p.m. (N—CO—CH_3).

Mass spectrum Calcd. for $C_{24}H_{31}O_6N$: *m/e*, 429.2151. Found: 429.2141.

Anal. Calcd. for $C_{24}H_{31}O_6N$: C, 67.11; H, 7.28; N, 3.26. Found: C, 66.97; H, 7.23; N, 3.68.

Ketone 24

The Grignard alcohol **23** (30 g, 0.052 mol) dissolved in acetone (1.5 l, distilled over potassium permanganate) was cooled in an ice bath. Jones' reagent (18 ml) was added dropwise over a period of 15 min. After 10 min stirring, methanol (10 ml) was added to destroy the excess of Jones' reagent. The inorganic precipitate was removed by filtration and the filtrate was neutralized with 10% aqueous sodium bicarbonate. Most of the acetone was evaporated under reduced pressure, water (500 ml) was added, and the solution was extracted with chloroform (4 × 400 ml). The chloroform extracts were washed with water (2 × 400 ml), dried over anhydrous sodium sulfate, and evaporated to dryness *in vacuo*. The ketone **24** (28 g, 94%) was homogeneous on t.l.c.

I.r. ($CHCl_3$): 1700 cm^{-1} (C=O), no hydroxyl absorption.

N.m.r. ($CDCl_3$): singlet (10H) τ 2.70 (aromatic protons of two benzyl groups); two singlets (2H each) 5.40, 5.53 (protons of two benzylic methylene groups); broad singlet (4H) 6.03 (ketal methylene protons), two singlets (3H each) 6.33 (aromatic methoxyl); 6.66 p.p.m. (primary methoxyl).

Mass spectrum Calcd. for $C_{35}H_{40}O_7$: *m/e*, 572.2774. Found: 572.2766.

Reduction of the Ketone 24

The ketone **24** (28 g, 0.049 mol) in absolute dioxane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(200 ml) was added dropwise to a suspension of lithium aluminum hydride (11 g, 0.24 mol) in absolute dioxane (2000 ml) which had been preheated to 90 °C. The reaction mixture was stirred at 90 °C for 1 h, cooled, and poured into wet ether (2000 ml, saturated with water). The inorganic precipitate was removed by filtration and the filtrate was evaporated under reduced pressure to dryness. The mixture (27.2 g, 97%) of alcohols **25** and **23** was homogeneous on t.l.c. and it was shown in the next methylation step to be in a ratio of 7:3.

I.r. (CCl_4): 3550 cm^{-1} (hydroxyl).

N.m.r. (CCl_4): singlet (10H) τ 2.70 (aromatic protons of the two benzyl groups); multiplet (3H) 2.80–3.40 (aromatic protons of the anisole ring); two singlets (2H each) 5.38, 5.52 (four benzylic methylene protons); multiplet (4H) centered at 6.07 (ketal methylene protons); two singlets (3H each) 6.32 (aromatic methoxyl), 6.67 p.p.m. (primary methoxyl).

Methylation of Alcohols **25** *and* **23**

The mixture of the alcohols **25** and **23** (25.8 g, 0.045 mol) was methylated under the same conditions used in the preparation of compound **26***a*. Work-up and chromatography on silica gel (1.5 kg, elution with 10–15% ether in benzene) gave compound **26***b* (17.5 g) (larger R_f) and compound **26***a* (7.7 g) (smaller R_f) in an overall yield of 95%.

I.r. (CCl_4): no hydroxyl absorption.

N.m.r. ($CDCl_3$): (for compound **26***b*) singlet (10H) τ 2.69 (aromatic protons of the two benzyl groups); multiplet (3H) 2.50–3.50 (aromatic protons of the anisole ring); doublet (2H) 5.39 (benzylic methylene protons); singlet (2H) 5.51 (benzylic methylene protons); multiplet (4H) centered at 6.10 (ketal methylene protons); three singlets (3H each) 6.29 (aromatic methoxyl), 6.47 (side chain methoxyl at C_1), 6.67 (primary methoxyl); singlet (2H) 6.55 p.p.m. (methylenic protons deshielded by the primary methoxyl).

Mass spectrum (**26***b*) Calcd. for $C_{36}H_{44}O_7$: *m/e*, 588.3075. Found: 588.3086.

Compound **26***b* was also obtained by the method shown in Scheme 7. While this process increased the stereoselectivity of the preparation of **26***b*, we have used the simpler less stereoselective method described in detail to supply large amounts of material with less effort.

Ketone **27***b*

Compound **26***b* (17.5 g, 0.03 mol) was deketalized under the same conditions used in the preparation of compound **27***a*. Work-up gave the ketone **27***b* (16.2 g) in a quantitative yield.

I.r. (CCl_4): 1755 cm^{-1} (ketone).

N.m.r. ($CDCl_3$): two singlets (5H each) τ 2.68, 2.70 (aromatic protons of the two benzyl groups); two singlets (2H each) 5.40 and 5.52 (benzylic methylene protons); three singlets (3H each) 6.27 (aromatic methoxyl); 6.48 (side chain methoxyl at C_1); 6.64 p.p.m. (primary methoxyl).

Mass spectrum Calcd. for $C_{34}H_{40}O_6$: *m/e*, 544. Found: 544.

Diketone **29***b*

The ketone **27***b* (16.2 g, 0.03 mol) was dissolved in 70 ml of methanol and subjected to reductive amination under the same conditions which were used in the preparation of compound **29***a*. Work-up gave the crude amine **28***b* (16 g, 97%) which was used without purification for the subsequent step.

I.r. (CCl_4): 3400 cm^{-1} (N—H); no carbonyl absorption.

N.m.r. ($CDCl_3$): two singlets (5H each) τ 2.63 and 2.66 (aromatic protons of the two benzyl groups); multiplet (3H) 2.40–3.50 (aromatic protons of the anisole ring); doublet (2H) centered at 5.41 (benzylic methylene protons); singlet (2H) 5.52 (benzylic methylene protons); three singlets (3H each) 6.28, 6.47, and 6.66 p.p.m. (three methoxyls).

The crude amine **28***b* (16 g, 0.029 mol) was acetylated under the same conditions used in the preparation of compound **29***a*. Work-up gave the *N*-acetyl derivative (16.4 g, 96%) which was homogeneous on t.l.c. and was used without further purification for the subsequent step.

I.r. (CCl_4): 3400 (N—H), 1675 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (13H) τ 2.40–2.70 (aromatic protons of the two benzyl groups and the anisole ring); doublet (1H) centered at 3.64 (—HN—CO—); doublet (2H) centered at 5.40 (benzylic methylene protons); singlet (2H) 5.50 (benzylic methylene protons); three singlets (3H each) 6.30, 6.47, and 6.64 (three methoxyls); singlet 8.05 (N—CO—CH_3 of the *anti*-epimer); singlet at 8.19 p.p.m. (N—CO—CH_3 of the *syn*-epimer).

The above material (16 g, 0.027 mol) was subjected to hydrogenolysis under the same conditions used in the "a" series. Work-up and chromatography on silica gel (600 g, 2% methanol in chloroform) gave the corresponding diol (10.1 g, 92%).

I.r. (CCl_4): 3400 (O—H, N—H), 1655 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (3H) τ 3.00–3.50 (aromatic protons of the anisole ring); two singlets (3H each) 6.26 and 6.48 (two methoxyls); singlet (5H) 6.63 (methoxyl and the protons deshielded by the primary methoxyl); singlet 7.95 (N—CO—CH_3 of the *anti*-epimer); singlet 8.15 p.p.m. (N—CO—CH_3 of the *syn*-epimer).

Mass spectrum Calcd. for $C_{22}H_{33}O_6N$: *m/e*, 407.2308. Found: 407.2313.

The above diol (9.8 g, 0.024 mol) was oxidized with the chromium trioxide – pyridine complex under the same conditions used in the preparation of the diketone **29***a*. Work-up gave the crude product which was purified by chromatography on silica gel (1 kg). Elution with 2% methanol in chloroform gave the pure diketone **29***b* which was crystallized from benzene–ether to a constant m.p. of 100–102 °C (6.5 g, 58%).

I.r. (KBr pellet): 3600–3300 (N—H), 1745 (five-membered ketone), 1720 (side chain ketone), 1660 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): doublet (1H) centered at τ 2.47 (—NH—CO—); multiplet (3H) 2.90–3.30 (aromatic protons of the anisole ring); singlet (2H) 5.93 (—CO—CH_2—OCH_3); three singlets (3H each) 6.23, 6.51, and 6.56 (3—OCH_3); singlet (3H) 7.92 p.p.m. (N—CO—CH_3).

Mass spectrum Calcd. for $C_{22}H_{29}O_6N$: *m/e*, 403.1995. Found: 403.1990.

Anal. Calcd. for $C_{22}H_{29}O_6N$: C, 65.49; H, 7.24; N, 3.47. Found: C, 65.03; H, 7.08; N, 3.34.

Lactamol **30***b*

The diketone **29***b* (4.068 g, 0.010 mol) was converted to the lactamol **30***b* under the same conditions used in the preparation of the lactamol **30***a*. Work-up of the reaction mixture gave 4.2 g of crude product which was crystallized from chloroform–ether to a constant m.p. of 235–238 °C (3.85 g, 90%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

I.r. (KBr pellet): 3550–3200 (O—H, N—H), 1720 (five-membered lactam), 1665 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.80–3.40 (aromatic protons); three singlets (3H each) 6.18, 6.60, and 6.67 (3 —OCH_3); singlet (3H) 8.07 p.p.m. (N—CO—CH_3).

Keto Lactam 31b

The pure lactamol **30***b* (3.44 g, 0.008 mol) was subjected to an acid-catalyzed cyclization under the same conditions used in the preparation of the ketolactam **31***a*. Work-up and crystallization in the same manner gave the pure ketolactam **31***b*, m.p. 266–268 °C (3.32 g) in a yield of 64%.

I.r. (KBr pellet): 3455 and 3335 (N—H), 1738 (ketone), 1670 cm^{-1} (lactam).

N.m.r. ($CDCl_3$): multiplet (3H) τ 3.00–3.50 (aromatic protons); three singlets (3H each) 6.20, 6.57, and 6.63 p.p.m. (3 —OCH_3).

The Hydroxy Amines 32b and 33b

The pure ketolactam **31***b* (1.484 g, 0.004 mol) was converted to the hydroxy amines **32***b* and **33***b* by exactly the same procedure used in the "a" series. Crystallization of the crude products from methanol gave the pure crystalline β-hydroxy amine **32***b* (442 mg). The mother liquor was purified by chromatography on neutral alumina (120 g). Elution with chloroform gave the oily α-hydroxy amine **33***b* (610 mg) and more of the β-hydroxy amine (150 mg), which was recrystallized from methanol to a constant melting point of 226–228 °C. The overall yield of recrystallized β-hydroxy amine was 625 mg.

I.r. ($CHCl_3$) α-hydroxy amine **33***b*: 3600–3400 cm^{-1} (N—H, O—H); β-hydroxy amine **32***b*: 3500–3320 cm^{-1} (N—H, O—H).

N.m.r. ($CDCl_3$) α-hydroxy amine **33***b*: singlet (3H) τ 6.22 (aromatic methoxyl); doublet (6H) 6.66, 6.70 (ring A methoxyl and primary methoxyl); singlet (2H) 6.87 p.p.m. (protons deshielded by the primary methoxyl); β-hydroxy amine **32***b*: singlet (3H) τ 6.28 (aromatic methoxyl); singlet (8H) 6.70 p.p.m. (two methoxyls and protons deshielded by the primary methoxyl).

Mass spectrum Calcd. for $C_{21}H_{29}O_4N$: *m/e*, 359. Found for α-hydroxy amine **33***b*: 359. Found for β-hydroxy amine **32***b*: 359.

The N-Acetyl-β-alcohol 35b

Compound **32***b* (359 mg, 1 mmol) was acetylated with acetic anhydride (2.5 ml) and pyridine (2.5 ml) as in the "a" series. The *N*-acetyl-β-acetate was obtained in a quantitative yield (441 mg).

I.r. (CCl_4): 1745 (—O—CO—CH_3), 1645 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.80–3.40 (aromatic protons); singlet (3H) 6.20 (aromatic methoxyl); singlet (8H) 6.72 (two methoxyls and the protons deshielded by the primary methoxyl); singlet (3H) 7.87 (N—CO—CH_3); singlet (3H) 7.95 p.p.m. (O—CO—CH_3).

The above material (400 mg, 0.9 mmol) was saponified exactly as in the "a" series. The *N*-acetyl-β-alcohol **35***b* (350 mg, 95%) was crystallized from ether to a m.p. of 182–183 °C.

I.r. (CCl_4): 3600–3200 (O—H), 1620 and 1645 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.87–3.30 p.p.m. (aromatic protons); singlet (3H) 6.20 (aromatic methoxyl); doublet (8H) 6.67, 6.72 (two methoxyls and the protons deshielded by the primary methoxyl); singlet (3H) 7.85 p.p.m. (N—CO—CH_3).

Compound 36b

The alcohol **35***b* (200 mg, 0.5 mmol) was methylated exactly as in the "a" series. Crystallization from hexane–ether gave compound **36***b* which melted at 155–157 °C in a yield of 87%.

I.r. (CCl_4): no hydroxyl absorption; 1640 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.89–3.33 (aromatic protons); singlet (3H) 6.20 (aromatic methoxyl); singlet (11H) 6.70 (three methoxyls and protons deshielded by the primary methoxyl); singlet (3H) 7.87 p.p.m. (N—CO—CH_3).

Compound 4b

The above material (120 mg, 0.29 mmol) was oxidized exactly as in the "a" series. Crystallization from *n*-hexane–ether gave compound **4***b* which melted at 188–190 °C in a yield of 89%.

I.r. (CCl_4): 1685 (ketone); 1650 cm^{-1} (N—CO—CH_3).

N.m.r. ($CDCl_3$): doublet (1H) τ 2.00 (aromatic proton deshielded by the benzylic ketone); multiplet (2H) 2.90–3.20 (aromatic protons); singlet (3H) 6.11 (aromatic methoxyl); doublet (11H) 6.70–6.72 (three methoxyls and protons deshielded by the primary methoxyl); singlet (3H) 7.90 p.p.m. (N—CO—CH_3).

The Amino Ketone 34b

Concentrated hydrochloric acid (five drops) was added to the α-hydroxy amine **33***b* (30 mg, 0.084 mol) in 5 ml of methanol and the solution was evaporated to dryness *in vacuo*. The residue was redissolved in acetone (25 ml, distilled over potassium permanganate) and cooled in an ice-water bath for 10 min. A slight excess of Jones' reagent was added and the solution was stirred for 10 min. Saturated aqueous sodium chloride (20 ml) was added, the solution was basified with bicarbonate and extracted with chloroform (3 × 10 ml). The chloroform extracts were washed with water (1 × 10 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The amino ketone **34***b* (29 mg) which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was homogeneous in t.l.c. was obtained in a quantitative yield.

I.r. (CCl_4): 1740 cm^{-1} (ketone).

N.m.r. (CCl_4): multiplet (3H) τ 3.00–3.50 (aromatic protons); two singlets (3H each) 6.27 and 6.61 (2 —OCH_3), singlet (5H) 6.74 p.p.m. (OCH_3 and protons deshielded by the primary methoxyl).

Mass spectrum Calcd. for $C_{21}H_{27}O_4N$: *m/e*, 357. Found: 357.

Hydroxy Amines 32b and 33b from the Amino Ketone 34b

Sodium (about 20 mg) was added in 0.5 h intervals to the amino ketone **34***b* (29 mg, 0.084 mmol) in refluxing absolute ethanol (2 ml). After 4 h under reflux, methanol (1 ml) was added followed by water (8 ml). The solution was extracted with chloroform (4 × 10 ml), and the combined chloroform extracts were washed with water (2 × 10 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The crude hydroxy amines were separated by preparative t.l.c. on silica gel (12% methanol in chloroform) to yield pure **33***b* (6.5 mg) and **32***b* (15.3 mg) in a ratio of 3:7.

Both materials were identical (m.p., i.r., and mass spectra) with the samples described above.

The Tertiary Amine 37b

Sodium hydride (202 mg, 4.2 mmol) was added to the solution of compound **32***b* (250 mg, 0.7 mmol) in absolute dioxane (50 ml) and the mixture was heated under reflux for 1 h. Methyl iodide (1 ml) was added and reflux was continued for another 3 h. The reaction mixture was cooled and filtered through Celite. The filtrate was evaporated to dryness, chloroform (50 ml) was added, and the solution was washed with water (3 × 20 ml). The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness to yield the crude methylated compound **37***b*. The crude product was purified by chromatography on silica gel (2% methanol in chloroform) and the pure tertiary amine **37***b* (260.5 mg) was obtained in a yield of 96%.

I.r. (CCl_4): no N—H and O—H absorption.

N.m.r. ($CDCl_3$): multiplet (3H) τ 2.90–3.40 (aromatic protons); four singlets (3H each) 6.23, 6.68, 6.73, and 6.77 (4 —OCH_3); singlet (3H) (7.73 p.p.m. (—N—CH_3).

Mass spectrum Calcd. for $C_{23}H_{33}O_4N$: *m/e*, 387.2410. Found: 387.2405.

The N-Formyl Compound 38b

A solution of the tertiary amine **37***b* (200 mg, 0.52 mmol) and potassium permanganate (200 mg) in acetone (40 ml, distilled over permanganate) and acetic acid (2 ml) was stirred at room temperature for 24 h. The precipitate was removed by filtration and washed thoroughly with chloroform. The filtrate was evaporated to dryness *in vacuo*, chloroform (50 ml) was added, and washed with water (2 × 30 ml), dried over anhydrous sodium sulfate, and evaporated to dryness. The crude product was purified by preparative t.l.c. on silica gel (5% methanol in chloroform) to give the pure *N*-formyl compound **38***b* (198 mg) which was crystallized from ether (m.p. 158–160 °C).

I.r. (CCl_4): 1662 cm^{-1} (—N—CH=O).

N.m.r. ($CDCl_3$): broad singlet (1H) τ 2.17 (—N—CH=O); multiplet (3H) 3.00–3.50 (aromatic protons); singlet (3H) 6.26 (aromatic —OCH_3); broad singlet (11H) 6.77 p.p.m. (3 —OCH_3 and protons deshielded by the primary —O—CH_3).

Mass spectrum Calcd. for $C_{23}H_{31}O_5N$: *m/e*, 401.2202. Found: 401.2200.

Anal. Calcd. for $C_{23}H_{31}O_5N$: C, 68.81; H, 7.78; N, 3.49. Found: C, 68.72; H, 7.69; N, 3.40.

The N-Formyl Ketone 2b

Compound **38***b* (180 mg, 0.45 mmol) was dissolved in acetone (50 ml, distilled over potassium permanganate). Jones' reagent was added dropwise over a period of 6 h. The reaction mixture was stirred at room temperature and a slight excess of the Jones' reagent was maintained during the entire period. A few drops of methanol were added and the precipitate was removed by filtration. Saturated aqueous sodium chloride (50 ml) was added to the filtrate and the solution was extracted with chloroform (3 × 40 ml). The organic layer was dried over anhydrous sodium sulfate and evaporated to dryness. The crude product was purified by t.l.c. on silica gel (5% methanol in chloroform) to yield the pure *N*-formyl ketone **2***b* (120 mg, 67%) which was identical with the corresponding derivative obtained from delphinine by i.r., n.m.r., and mass spectra. Identity was also established by t.l.c. in several systems.

I.r. (CCl_4): 1690 (—N—CH=O); 1655 cm^{-1} (ketone).

N.m.r. ($CDCl_3$): singlet (1H) τ 1.93 (N—CH=O); doublet (1H) centered at 1.96 (aromatic proton deshielded by the benzylic ketone); multiplet (2H) 3.00–3.50 (aromatic protons); four singlets (3H each) 6.12, 6.72, 6.74, and 6.77 p.p.m. (4 OCH_3).

Mass spectrum Calcd. for $C_{23}H_{29}O_6N$: *m/e*, 415.1995. Found: 415.1995.

Direct Conversion of Compound 37b to the N-Formyl Ketone 2b

A mixture of compound **37***b* (25 mg, 0.064 mmol) and potassium permanganate (250 mg) in acetone (15 ml, distilled over potassium permanganate) and acetic acid (0.75 ml) was stirred at room temperature for 5 days. Acetone (10 ml) was added and the precipitate was removed by filtration. The filtrate was evaporated to dryness *in vacuo*, the residue dissolved in chloroform (30 ml) and washed with water (2 × 10 ml). The chloroform was dried over anhydrous sodium sulfate and evaporated to dryness. The crude product was purified by preparative t.l.c. on silica gel (5% methanol in chloroform) to yield the *N*-formyl ketone **2***b* (21 mg, 82%) which was identical by its i.r., n.m.r., and mass spectra with the material obtained via the compound **38***b*.

The Amino Ketone 3b

The *N*-formyl ketone **2***b* (100 mg, 0.24 mmol) dissolved in a 1:9 concentrated hydrochloric acid methanol solution (30 ml) was heated under reflux for 24 h. The solution was evaporated to dryness, taken up in 5% sodium bicarbonate (20 ml), and extracted with chloroform (4 × 20 ml). The chloroform extracts were dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo*. The crude product (98 mg) was crystallized from ether to yield 72 mg of the pure amino ketone **3***b* (m.p. 176 °C). The mother liquor was purified by preparative t.l.c. on silica gel (5% methanol in chloroform) and gave another 19 mg of the amino ketone. This material was identical with the delphinine degradation product of the same structure by i.r., n.m.r., and mass spectroscopy and t.l.c. in several systems.

I.r. (CCl_4): 3400–3200 (N—H); 1683 cm^{-1} (ketone).

N.m.r. ($CDCl_3$): doublet (1H) centered at τ 2.04 (aro-

matic proton deshielded by the conjugated ketone); multiplet (2H) 2.80–3.30 (aromatic protons); four singlets (3H each) at 6.11, 6.68, 6.70, and 6.73 (4 —OCH_3).

Mass spectrum Calcd. for $C_{22}H_{29}O_5N$: *m/e*, 387.2046. Found: 387.2040.

Anal. Calcd. for $C_{22}H_{29}O_5N$: C, 68.19; H, 7.54; N, 3.62. Found: C, 68.22; H, 7.37; N, 3.68.

Resolution of 3b

The synthetic racemic ketone **3b** (125 mg, 0.32 mmol) was dissolved in absolute pyridine and the solution was cooled in an ice-water bath. L-camphor–sulfonyl chloride (69.7 mg, 0.32 mmol) was added and the solution was allowed to stand overnight. Water (0.5 ml) was added and the mixture was stirred for 0.5 h. The mixture was then evaporated to dryness and the products were separated and purified by preparative t.l.c. on silica gel (5% methanol in chloroform) to give 78 mg of sulfonamide and 56 mg of the unreacted amino ketone. This last material (56 mg) was dissolved in ether, a large excess of oxalic acid in ether was added, and the oxalate precipitated. The mixture was kept in the refrigerator overnight, and the ethereal solution was decanted. The oxalate was recrystallized from methanol ether five times until a constant m.p. of 195–196 °C was reached (34 mg). The resolved synthetic oxalate and the corresponding oxalate derived from the degradation of delphinine were compared as follows: (*1*) melting ranges (°C) 195–196 synthetic, 194–196 "natural", 194–196 mixture; (*2*) identical i.r. spectra in KBr and in $CHCl_3$; (*3*) identical optical rotatory dispersion curves, $[\alpha]^{26}_{295} = +1 \times 10^5$, $[\alpha]^{26}_{250} = -7 \times 10^4$.

Anal. Calcd. for $C_{24}H_{31}O_9N$: C, 60.36; H, 6.54; N, 2.93. Found: C, 60.38; H, 6.57; N, 2.82.

Synthetic Optically Active 3b Free Base

The optically active oxalate (28 mg) was dissolved in chloroform (2 ml) and passed through a short column of basic alumina (1 g). The free amine was obtained by eluting the column with 5% methanol in chloroform (50 ml). After evaporation *in vacuo* to dryness, absolute ether (1.5 ml) was added, and the mixture was kept in the refrigerator for 4 days. The mother liquor was removed by a pipette and the crystals were washed with ether and dried in high vacuum. The crystalline free base **3b** was recrystallized to a constant m.p. of 144.5 °C from ether.

Identity with compound **3b** prepared from delphinine was established as follows: (*1*) m.p. (°C) 144.5 synthetic, 143 "natural", 144 mixture; (*2*) identical i.r. (KBr and $CHCl_3$) spectra; (*3*) identical mass spectra; (*4*) identical n.m.r. spectra; (*5*) identical R_f in several t.l.c. systems.

Mass spectrum Calcd. for $C_{22}H_{29}O_5N$: *m/e*, 387.2040. Found: 387.2046.

Racemic Oxalate of 3b for X-Ray Analysis

The synthetic racemic compound **3b** (58 mg) was converted to the racemic oxalate by treating with a large excess of oxalic acid under the same conditions which were employed for the preparation of the optically active oxalate **3b**.

The salt was recrystallized from ether–methanol until a constant melting point (189–193 °C) was reached (32 mg).

Anal. Calcd. for $C_{24}H_{31}O_9N$: C, 60.36; H, 6.54; N, 2.93. Found: C, 60.52; H, 6.45; N, 2.90.

Approaches to the Synthesis of Triterpenoids. II. Some Tetracyclic Precursors Suitable for Conversion into Pentacyclic Triterpenoids[1]

J. W. ApSimon, P. Baker, J. Buccini, J. W. Hooper, and S. Macaulay
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received January 11, 1972

The stereoselective total synthesis of several partially reduced chrysene derivatives, suitable as precursors for a variety of triterpenoids, is described. The key reaction in the most efficient route involves the highly stereoselective reductive alkylation of a cyclic α,β-unsaturated ketone with allyl bromide in lithium–ammonia, using water as a proton donor.

La synthèse totale et stéréosélective de plusieurs dérivés partiellement réduits du chrysène est décrite; ces dérivés sont utilisés en tant que précurseurs d'un certain nombre de composés triterpéniques. La réaction cruciale, par la méthode la plus efficace, implique une alkylation par réduction hautement stéréosélective d'une cétone α,β-insaturée par le bromure d'allyle dans un mélange lithium–ammoniaque et en utilisant l'eau comme source de protons.

Canadian Journal of Chemistry, **50**, 1944 (1972)

Despite the many recorded total syntheses of natural products, relatively few of pentacyclic triterpenoids (1) have been reported (2). Recently, Ireland *et al.* (3, 4) and Stork *et al.* (5) have reported elegant highly stereoselective routes to some members of this class and the shortcomings as well as the general considerations involved in the total synthesis of such compounds have been summarized (3*a*). In this paper we report the completion of the first phase of our approach to the total synthesis of such compounds, a route designed to give intermediates that can be converted to several structural types. We describe routes to the tetracyclic compounds **1***a* and *b* (Schemes 1 and 2) containing two 1,3-diaxially disposed methyl groups and a *trans–transoid* arrangement of two carbocyclic rings,[2] both features being common to many triterpenoids. Scheme 1 indicates the possible utility of such compounds (*e.g.* 1*b*) taking advantage of the existing stereochemistry and the varied functionality at the termini leading to several structural types.

Our first route was based on the observations of previous workers (6) that alkylation of the dienolate anions of α,β-unsaturated ketones of type **3** occur with high stereoselectivity, yielding products, **4**, resulting from "equatorial" alkylation (see Scheme 3).

The tricyclic enone **3***a* was prepared by the Robinson annelation of **2** (7) with ethyl vinyl ketone.

The β-tetralone **2** preparation described herein (see Experimental) appears to be an improvement on the published procedure (2*a*). Base-catalyzed alkylations of **3***a* were performed using the known compounds **5***a* (8), *b* (8), and *c* (9) in order to produce compounds capable of conversion to tetracyclic species. Reaction with **5***a* and *b* gave less than 20% of unstable alkylation products, a reflection perhaps of the low nucleophilicity of the dienolate anions (10) and the low reactivity of the alkylating agents. When tosylate **5***c* was used and the anion of **3***a* was generated using potassium *t*-amyloxide in benzene, a 48% yield of diketone **6***a*[3] was obtained by direct crystallization after acidic hydrolysis of the ethylene ketal group.

Hydrogenation of the 10,10*a*-double bond[2] was expected to lead to the required *trans*-dihydrodiketone **7***a*, in accord with precedents

[1]Presented in part at the 53rd Canadian Chemical Conference, Toronto, Ontario, May 1970 and at the 54th Canadian Chemical Conference, Halifax, Nova Scotia, June 1971.

[2]Structural formulae of synthetic materials containing asymmetric carbon atoms depict one enantiomer only but refer to racemic compounds throughout. In the text the (±)-prefix is omitted and all intermediates are assumed to be racemic. Tricyclic materials are described using phenanthrene nomenclature and each racemate is arbitrarily represented by that enantiomer having the 4*a*-methyl group in the β configuration. Likewise the tetracyclic compounds are considered as chrysene derivatives.

[3]This material is stable in crystalline form but slowly decomposes in solution with the formation of polar substances. These appear to be products of autoxidation at the benzylic–allylic position.

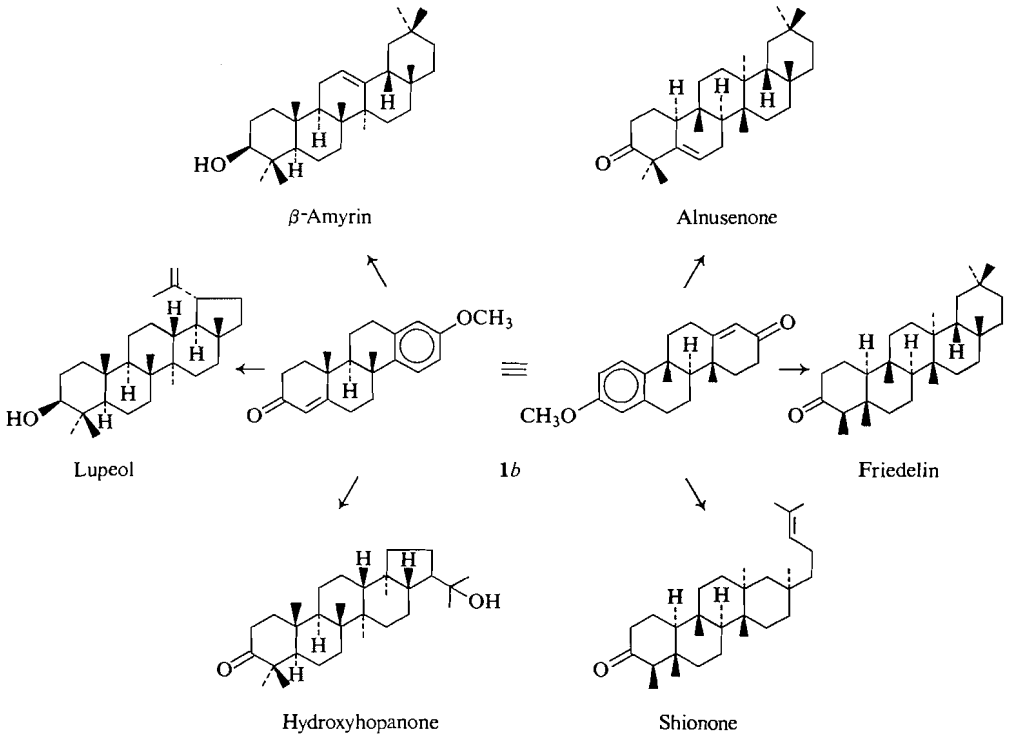
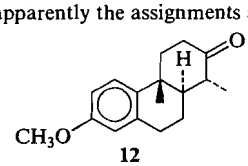


SCHEME 1

(2*a*, 6, 11). However, Ireland *et al.* (3*a*) have recently pointed out that these examples may be special cases and that for C-1α side chains longer than one carbon atom, one cannot make confident predictions of the stereochemistry of hydrogenation based on the "ease of approach to catalyst" argument (see footnote 5). Fortuitously, our parallel studies on the hydrogenation of **6***a* and *b* indicated that in fact our conditions led to behavior in accord with precedent. Thus, attempts at hydrogenation of **6***a* in acetic acid – sulfuric acid mixtures led to complex mixtures. In one case a low yield of crystalline material was obtained that appeared from spectral evidence to be a mixture of ketols **9***a* (12). These observations suggested the use of non-acidic solvents for the hydrogenation and since no hydrogen uptake was observed in boiling ethanol, the use of higher-boiling, non-polar solvents was investigated. At 100–110° in toluene using a palladium catalyst, **6***a* was slowly reduced to the dihydro-derivative **7***a* (55%). Boiling *p*-xylene as solvent gave rapid hydrogenation to **7***a* in 72% yield. The alternative *cis*-fused formulation **8***a* was discarded for the major reduction product on the basis of benzene-induced solvent shifts of the methyl peaks in the n.m.r. spectrum (3, 13). Throughout this work we have used benzene-induced solvent shifts as a probe for methyl group stereochemistry (14). Our observations are summarized in Table 1.[4] The shifts observed

[4]An obvious objection to this approach is our assignment of methyl signals. In general the lowest-field methyl signal attached to an aliphatic center is assigned to the C-4*a* methyl in the reduced phenanthrenes. Support for this assumption comes from the n.m.r. spectrum of **12** where the C-4*a* methyl singlet resonates at 1.35 δ while the C-1α methyl doublet appears at 1.10 δ. We assume that no signal crossover occurs. These working rules are supported by the nuclear Overhauser effects described in this paper and by the correlation established between our compounds and a compound whose stereochemistry is known from X-ray studies (*vide infra*). Thus the results in Table 1 are self-consistent and apparently the assignments are correct.



12

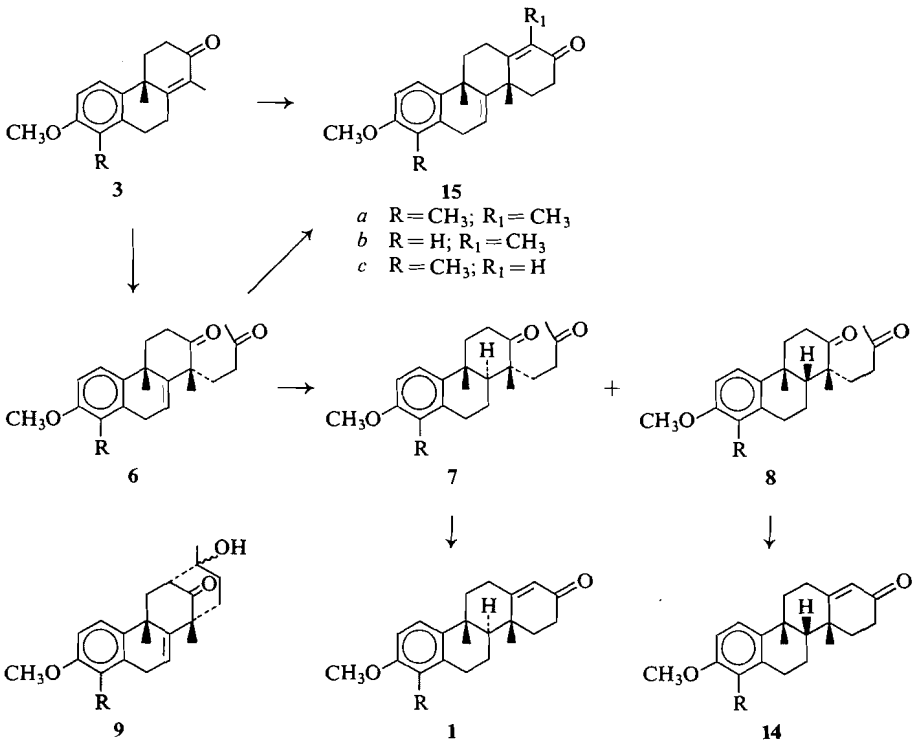
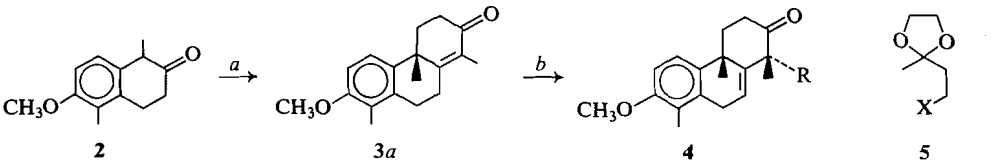


SCHEME 2. Series *a*, R = CH_3; series *b*, R = H

for **7***a* were +9 Hz for the C-1 methyl group and +12 Hz for the C-4*a* methyl group. These values can only be accommodated by a *trans* ring junction and axial methyl groups as in **10**. In the case of a *cis* ring fusion, molecular models indicate that the preferred conformation would be **11** with an equatorial C-1 methyl group which would show a small, negative benzene-induced solvent shift, if any.

Several compounds were hydrogenated using our conditions and the results are summarized in Table 2. These reactions proceeded in very high yield to give, in each case, a mixture of only two products (usually not separated), the major component of which was identified as the *trans*-fused isomer **10** on the basis of benzene-induced solvent shifts (Table 1). The minor components were assumed to be the *cis*-fused species **11**. These results are in direct contrast to those of Ireland *et al.* (3*a*) where hydrogenation of the olefinic ketone **13** gave mixtures in which the *cis*-fused isomer predominated (3:1 to 8:1). The reasons for our observations are unclear but could be a con-



SCHEME 3. Reagents: *a*, $CH_3CH_2COCH{=}CH_2$, KOH, MeOH; *b*, (*i*) base, (*ii*) RX.

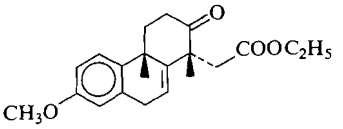
10 11



13

sequence of ring C conformational differences at higher temperatures in non-polar solvents.[5] It is interesting to note that our optimum conditions for the hydrogenation of **6***a* and similar compounds include a high catalyst:substrate ratio, a minimum of solvent, and high temperatures, all of which are quoted as leading to lower stereoselectivity (15).

Treatment of diketone **7***a* with aqueous methanolic potassium hydroxide gave the *trans–transoid* tetracyclic enone **1***a* in 90% yield. When the crude product of a hydrogenation of **6***a* (toluene 105°, non-optimum conditions) was subjected to base treatment, a mixture resulted from which was isolated an enone isomeric to **1***a*. This we consider to be the *cis–cisoid* isomer **14***a* arising from the cyclization of the *cis* isomer **8***a*. The n.m.r. spectra of **1***a* and **14***a* support the stereochemical assignments. The chemical shifts of their C-4*a* angular methyl groups together with those of two analogous steroids are listed in Table 3. In *cis–cisoid* steroids the C-19 methyl protons resonate at lower field than those of the *trans–transoid* series (16). The same behavior is noted for **1***a* and **14***a*. In the case of **14***a* a nuclear Overhauser effect of $13 \pm 2\%$ was detected between the C-10*b* methyl protons and the C-10 aromatic proton, whereas for **1***a* a negligible effect was detected. These data are only consistent with a BC-*cis* fused ring system (17) for **14***a*. The benzene-induced solvent shifts also support this assignment of stereochemistry (see Table 1).

When olefinic diketone **6***a* was treated with base an unstable substance was obtained whose spectral characteristics were consistent with the expected tetracyclic dienone **15***c*. The methyl analog **15***a* had previously been obtained as a by-product of the annelation of β-tetralone **2** with ethyl vinyl ketone. This stable, crystalline compound could also be obtained by reaction of **3***a* with ethyl vinyl ketone in boiling aqueous methanolic potassium hydroxide.[6] A similar sequence of reactions starting from enone **3***b* provided the non-crystalline tetracyclic compound **15***b*.

Tetracyclic enone **1***b* was prepared from **3***b* by the above route but in this series the compounds could not be completely purified and characterization was only possible by spectroscopic means. The alkylation product **6***b* proved particularly difficult to separate from unreacted tosylate **5***c* and very prone to autoxidation. This difference in stability compared to **6***a* is possibly due to easier access to the benzylic-allylic C-9 position in the absence of a methyl substituent on the aromatic ring. The best route, although not adjustable to large scale work, involved alkylation of **3***b* with **5***c* and chromatography to yield a fraction rich in olefinic diketone **6***b* which was hydrogenated without further purification (see Table 2) and then treated with base. The product was a mixture of the tetracyclic enones **1***b* and **14***b* (80:20 v.p.c.). Preparative t.l.c. afforded a pure sample of the *trans–transoid* isomer **1***b* as a colorless glass, identical in spectral properties to a crystalline sample

[5]Ireland's argument (3*a*) was that the bulky C-1α substituent ($-CH_2COOC_2H_5$) is eclipsed with the carbonyl group in the expected chair-like conformation of **13** thus leading to a preferred conformation with a β-face more available for catalyst approach. In this case the solvent was acetic acid and possibly solvation at the carbonyl group makes this even bulkier, favoring the conformational changes proposed.

[6]This double-annelation is an interesting reaction *per se* but incomplete studies in this laboratory indicate that this route is not a practical synthetic route to tetracyclic materials.

*Determined at 60 MHz. Shifts are given in Hz downfield from internal TMS.

prepared by annelation of the enol-lactone **20** described below.

It is apparent that the routes described so far, whilst providing tetracyclic species, do not lend themselves to relatively large scale work or to pure materials except for **1***a* and **15***a*. Thus, alternate routes were sought.

Our most successful route involves the reductive alkylation of **3***b*[7] which allows us to take advantage of the structural integrity of the

[7]Model studies on the Birch reduction and catalytic hydrogenation of ring A of **3***a* were disappointing (P. Baker, unpublished), thus we turned our attention to the demethyl series.

§Prepared by methylation of the corresponding acid, the synthesis of which has been reported (3*a*).

lithium enolate formed by the Birch reduction of the α,β-unsaturated ketone group (18) and its subsequent reaction with reactive alkylating agents (5). The attractiveness of such a route is that one reaction produces two asymmetric centers in the required orientation. In our case, the best conditions for formation of the enolate involved the use of one equivalent of water as the proton donor for the first formed radical anion (19), followed by reaction with a large excess of alkylating agent. The use of trideuteriomethyl iodide and enone 3*a* gave ketone **16** (Scheme 4) in which alkylation had occurred from the α-face (>90%) as indicated by the benzene-induced solvent shifts (Table 1) (5, 14, 20). Reductive alkylation of 3*b* with allyl bromide led to a non-crystalline product **17** containing over 80% of mono-alkylated species (v.p.c.). Ketalization of the crude reaction mixture with neat ethylene glycol yielded crystalline **18** (74% yield from 3*b*). Hydroboration–oxidation using disiamylborane (21) gave the terminal alcohol which, after oxidation with Jones reagent (22) and deketalization in acetone-

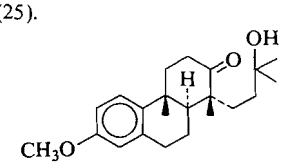
*Determined in $CDCl_3$ solutions and expressed in the δ scale. The values for the steroids were obtained from the data in ref. 16.

dilute sulfuric acid, yielded the crystalline keto-acid **19** in 72% yield from **18**. Conversion to the enol-lactone **20** was accomplished in two steps. Treating **19** with trifluoroacetic anhydride in acetonitrile led to the expected (23) ketone-mixed anhydride. The addition of a trace of 70% perchloric acid to this mixed anhydride in carbon tetrachloride (24) gave the crystalline enol-lactone **20** in 92% yield from **19**. Reacting **20** with methyl and ethyl Grignard reagents followed by base-catalyzed cyclization gave good yields of tetracyclic enones **1***b* and *c*, respectively.[8] The overall yield of tetracyclic species from the tricyclic enone **3***b* is 35%, making this a viable route to such intermediates.

As mentioned before, the one weak point in all of the above syntheses was the assignment of stereochemistry to our intermediates (*e.g.* **17**) based on solvent shift data and precedent. We have recently been able to establish that our proposals were correct by correlating **17** and **22**.[9] The synthesis of **22** has been reported (26) and its stereochemistry is known from X-ray studies of a conversion product (3). Reacting **18** with osmium tetroxide/sodium periodate gave the crystalline ketal-aldehyde **21** in 70% yield. This compound was reduced with sodium borohydride in ethanol, deketalized with acetone – dilute sulfuric acid, and again treated with sodium borohydride/ethanol to give the crystalline diol **22** as the major product. The sample of **22** prepared from **18** was identical in all respects to the authentic sample, thus verifying our stereochemical assignments.

[8]Attempting to form **1***b* using methyllithium instead of the Grignard gave only the carbinol **i** and unreacted **20**. Similar results were obtained under a variety of conditions with the ethylene ketal of **19** and the corresponding ketal-methyl ester (25).



i

[9]We thank Prof. R. E. Ireland for a generous sample of this compound.

Experimental

Melting points were determined on a Kofler hot stage and are corrected. The n.m.r. spectra were obtained on a JEOLCO C-60 or a Varian T-60 spectrometer with tetramethylsilane as internal standard. Chemical shifts are expressed in the δ scale and the following abbreviations apply: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The i.r. spectra were determined on a Perkin–Elmer 237B grating spectrophotometer. The g.l.c. was carried out on a Hewlett–Packard 402 gas chromatograph using 5% OV-210 on Diatoport S and 5% SE-54 on Chromosorb W columns at 265°. Mass spectra were obtained on an AEI MS 12 instrument. Combustion analyses were performed by the Spang Microanalytical Laboratory, Ann Arbor, Michigan. The t.l.c. was performed using pre-coated plates obtained from E.M. Reagents (silica gel F-254, 0.25 or 2.0 mm). The term "work-up" refers to the separation of an organic phase from an aqueous one, followed by drying with sodium or magnesium sulfate, and rotary evaporation of the volatile organic solvents to yield the organic product.

1,5-Dimethyl-6-methoxy-2-tetralone (2)

The method is due to Stork *et al.* (2*a*). Methyl magnesium iodide was prepared from magnesium (60 g) and methyl iodide (400 g) in ether (1 l) and allowed to react with 6-methoxy-5-methyl-1-tetralone (150 g) in benzene (500 ml)

for 2 h at room temperature. The addition of water and work-up gave crude 3,4-dihydro-1,5-dimethyl-6-methoxynaphthalene (157 g). A solution of this material (157 g) in ether (250 ml) was added to a solution of monoperphthalic acid (174 g) in ether (1200 ml) over 1.5 h and then stored at 5° for 16 h. The absence of starting material in the reaction mixture was confirmed by t.l.c. The solid deposit was dissolved by the careful addition of 10% aqueous sodium bicarbonate while stirring over a 4–8 h period. The organic layer and two ether extracts were combined, washed twice with water, and then stirred with 10% hydrochloric acid (500 ml) overnight. Work-up and distillation afforded the β-tetralone **2** (108 g, 67%) as a yellow viscous oil (b.p. 128–150°/0.4 Torr) which rapidly solidified, m.p. 46–50° (lit. (*2a*) 50°); ν_{max} (Nujol) 1720 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.40 (d, $J = 7$ Hz, 3H, —CH—CH_3), 2.15 (s, 3H, $ArCH_3$), 3.72 (s, 3H, —OCH_3).

1,4a,8-Trimethyl-7-methoxy-4,4a,9,10-tetrahydro-2(3H)-phenanthrone (3a)

A solution of the β-tetralone **2** (15.2 g) in methanol (70 ml) was added to a stirred solution of potassium hydroxide (5.7 g), water (10 ml), and methanol (30 ml) at 0° under nitrogen. The mixture was cooled to −20° and freshly distilled ethyl vinyl ketone (7.9 g, 1.25 equiv) in methanol (10 ml) was added dropwise with stirring. The temperature was allowed to rise to −5° and kept at $-3 \pm 2°$ for 2 h. After standing at room temperature overnight the mixture was refluxed for 4 h, cooled, and poured onto an ice/dilute sulfuric acid mixture. The organic materials were extracted with ether and work-up yielded a red oil (21 g) which crystallized from methanol in two crops affording the tricyclic enone **3a** as yellow needles (14.1 g, 70%) m.p. 123–124°; ν_{max} (Nujol) 1665 (C=O), 1625 (C=C), and 810 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.52 (s, 3H, C_{4a}—CH_3), 1.85 (s, 3H, C_1—CH_3), 2.13 (s, 3H, $ArCH_3$), 3.77 (s, 3H, —OCH_3).

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.97; H, 8.20. Found: C, 80.31; H, 8.32.

1,4aβ,7,10bβ-Tetramethyl-8-methoxy-4,4a,6,10b,11,12-hexahydro-2(3H)-chrysenone (15a)

Repeating the preceding preparation using large amounts of the β-tetralone **2** (122 g) and ethyl vinyl ketone (63 g, 1.25 equiv) gave the crystalline tricyclic ketone **3a** in 63% yield (104 g). Chromatography of the mother liquors on silica gel using increasing proportions of ether in hexane as eluent gave further **3a** (5.2 g) and then the tetracyclic ketone **15a** (6.6 g), crystallizing as pale yellow needles from methanol, m.p. 131–132°; ν_{max} (Nujol) 1660 (C=O), 1615 (C=C), and 785 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.31 (s, 3H, C_{10b}—CH_3), 1.55 (s, 3H, C_{4a}—CH_3), 1.75 (s, 3H, C_1—CH_3), 2.17 (s, 3H, $ArCH_3$), 3.77 (s, 3H, OCH_3), and 5.98 (q, $J_1 = J_2 = 3$ Hz, 1H, C-5 vinyl H).

1α-(3-Oxobutyl)-1β,4aβ,8-trimethyl-7-methoxy-3,4,4a,9-tetrahydro-2(1H)-phenanthrone (6a)

A mixture of potassium (1.83 g), *t*-amyl alcohol (10 ml) and benzene (200 ml) was refluxed under a nitrogen atmosphere to give a solution of potassium *t*-amyloxide. The tricyclic ketone **3a** (12.1 g) was added to the cooled solution and, while fresh benzene was being added, the reaction mixture was heated for 5 h to distil off a mixture of benzene–*t*-amyl alcohol. The resulting green–brown suspension of the potassium salt of **3a** was cooled to 0° and a 30% solution of the tosylate **5c** (9) (1 equiv) in toluene was added over a 10 min period. This mixture was stirred for 12 h at room temperature and then refluxed for 2 h, cooled, and acidified with 5% sulfuric acid. The organic materials were isolated with ether in the usual way to yield a red oil. A solution of this oil in acetone (250 ml) and 0.2 *N* sulfuric acid (25 ml) was refluxed for 2 h and, after removal of most of the acetone, extracted twice with dichloromethane. Routine work-up of the organic layers and crystallization of the residue from ether gave the olefinic diketone **6a** as yellow plates, m.p. 134–136° (7.05 g, 48%); ν_{max} (Nujol) 1715 (—$COCH_3$) and 1700 (ring C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.18 (s, 3H, C_1—CH_3), 1.33 (s, 3H, C_{4a}—CH_3), 2.05 (s, 3H, —$COCH_3$), 2.15 (s, 3H, $ArCH_3$), 3.80 (s, 3H, OCH_3), and 5.89 (m, 1H, C-10 H).

Anal. Calcd. for $C_{22}H_{28}O_3$: C, 77.57; H, 8.29. Found: C, 77.81; H, 8.49.

1α-(3-Oxobutyl)-1β,4aβ,8-trimethyl-7-methoxy-3,4,4a,9,10,10aα-hexahydro-2(1H)-phenanthrone (7a)

Olefinic diketone **6a** (0.50 g) in *p*-xylene (5 ml) was hydrogenated for 4 h at atmospheric pressure and 140° over (prehydrogenated) 10% Pd/C (0.20 g). The product obtained had two constituents (86:14) as judged by g.l.c. The diketone **7a** crystallized from ethanol as colorless needles, m.p. 147–149°, 97% pure by g.l.c. (0.35 g, 70%). Two recrystallizations from acetone/hexane gave the analytical sample, m.p. 158–159°; ν_{max} (Nujol) 1716 (C=O) and 790 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.12 (s, 3H, C_1—CH_3), 1.28 (s, 3H, C_{4a}—CH_3), 2.12 (s, 6H, —$COCH_3$ and $ArCH_3$), and 3.80 (s, 3H, OCH_3).

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 77.13; H, 8.83. Found: C, 77.06; H, 9.07.

4aβ,7,10bβ-Trimethyl-8-methoxy-4,4a,4bα,5,6,10b,11,12-octahydro-2(3H)-chrysenone (1a)

A suspension of the diketone **7a** (0.265 g), methanol (25 ml), water (4 ml), and potassium hydroxide (1.5 g) was refluxed under nitrogen for 2.5 h. The solid gradually dissolved and was later replaced by pale yellow prisms of the tetracyclic enone **1a** (0.190 g), m.p. 184–185°. Further crystalline **1a** (0.038 g) was obtained by dilution of the mother liquors, extraction with dichloromethane, and crystallization of the product from acetone/methanol (total yield 0.228 g, 90%); ν_{max} (Nujol) 1670 (C=O), 1625 (C=C), and 790 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.23 (s, 3H, C_{4a}—CH_3), 1.37 (s, 3H, C_{10b}—CH_3), 2.10 (s, 3H, $ArCH_3$), 3.77 (s, 3H, OCH_3), and 5.82 (broad s, 1H, C-1 vinyl proton).

Anal. Calcd. for $C_{22}H_{28}O_2$: C, 81.39; H, 8.70. Found: C, 81.48; H, 8.93.

4aβ,7,10bβ-Trimethyl-8-methoxy-4,4a,4bβ,5,6,10b,11,12-octahydro-2(3H)-chrysenone (14a)

The olefinic diketone **6a** (15.0 g) in toluene (100 ml) was hydrogenated for 6 days at atmospheric pressure and 110° over 10% Pd/C (1.0 g). The complex mixture obtained was dissolved in a solution of methanol (200 ml), water (20 ml), and potassium hydroxide (6.0 g) and refluxed under nitrogen for 3 h. The solution was cooled, diluted with water and extracted twice with dichloromethane to yield

For personal use only.

an orange gum on work-up. The previously characterized enone **1***a* crystallized from methanol (2.6 g). The mother liquors were chromatographed on silica gel using increasing proportions of ether in hexane as eluent. This gave further impure **1***a* and fractions containing mixtures of **1***a* and an unidentified substance, and then fractions rich in the enone **14***a*. Several recrystallizations of these fractions from methanol gave pure **14***a* (1.2 g) as small, yellow needles, m.p. 142–144°; ν_{max} (Nujol) 1665 (C=O), 1605 (C=C), and 790 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.51 and 1.53 (two s, 6H, C_{4a} and C_{10b}—CH_3), 2.05 (s, 3H, $ArCH_3$), 3.85 (s, 3H, OCH_3), and 5.71 (s, 1H, vinyl H); mass spectrum: M^+ at 324.

Anal. Calcd. for $C_{22}H_{28}O_2$: C, 81.39; H, 8.70. Found: C, 80.73; H, 8.89.

4aβ,7,10bβ-Trimethyl-8-methoxy-4,4a,6,10b,11,12-hexahydro-2(3H)-chrysenone (15c)

A solution of the diketone **6***a* (0.500 g), methanol (27 ml), water (3 ml), and potassium hydroxide (1.50 g) was refluxed under nitrogen for 16 h. The mixture was diluted with water, acidified (H_2SO_4), extracted with ether and worked-up to a brown gum which was shown to be a complex mixture by t.l.c. Chromatography on silica gel (40 g) using increasing proportions of ether in hexane as eluent gave various mixtures of unidentified substances and several fractions (total 0.12 g) containing essentially one substance (by g.l.c. and t.l.c.); ν_{max} 1670 (C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.33 (s, 3H, C_{10b}—CH_3), 1.52 (s, 3H, C_{4a}—CH_3), 2.16 (s, 3H, $ArCH_3$), 3.77 (s, 3H, OCH_3), 5.77 (s, 1H, C-1 vinyl proton), and 5.97 (m, 1H, C-5 vinyl proton). This appeared to be crude tetracyclic ketone **15***c* but it could not be purified further and deteriorated on standing.

4aβ,10bβ-Dimethyl-8-methoxy-4,4a,4bα,5,6,10b,11,12-octahydro-2(3H)-chrysenone (1b) from Tricyclic Enone 3b

A mixture of potassium (1.2 g, 30.7 mmol), *t*-amyl alcohol (5 ml), and benzene (50 ml) was refluxed under a nitrogen atmosphere to give a solution of potassium *t*-amyloxide. The tricyclic enone **3***b* (26) (6.0 g, 23.4 mmol) was added to the cooled solution and, while fresh benzene was being added, the reaction mixture was heated for 5 h to distil off a mixture of benzene – *t*-amyl alcohol. The resulting green–brown suspension of the potassium salt of **3***b* was cooled to 0° and a solution of the tosylate **5***c* (8.0 g, 30 mmol) in benzene (10 ml) was slowly added. This mixture was stirred for 18 h at room temperature, acidified with 1 *N* sulfuric acid (20 ml), and extracted twice with ether. Work-up of the organic extracts gave a red oil (12.6 g) which was refluxed for 24 h with a mixture of methanol (150 ml) and 10% sodium hydroxide (10 ml). The organic product was isolated and subjected to two more methanol/sodium hydroxide treatments to finally yield the alkylated product (6.6 g) free of tosylate **5***c*. A solution of this material in acetone (175 ml) and 0.2 *N* sulfuric acid (25 ml) was refluxed for 1 h and, after removal of most of the acetone, extraction with ether and work-up yielded a red oil (5.2 g). This was chromatographed on silica gel (260 g) using increasing proportions of ether in benzene as eluent. Non-crystalline diketone **6***b* (1.3 g, 17% from **3***b*) was eluted with 10% ether in benzene and appeared homogeneous on t.l.c. and g.l.c.; ν_{max} (neat) 1705 (C=O), 1660 (C=C), 1610 (Ar C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.17 (s, 3H, C_1—CH_3), 1.32 (s, 3H, C_4—CH_3), 2.02 (s, 3H, CO—CH_3), 3.40 (d, $J = 4$ Hz, 2H, C-9 protons), 3.74 (s, 3H, OCH_3), 5.87 (t, $J = 4$ Hz, 1H, C-10 vinyl H).

Non-crystalline olefinic diketone **6***b* (0.50 g, 1.53 mmol) in *p*-xylene (5 ml) was hydrogenated for 1 day at atmospheric pressure and 140° over (prehydrogenated) 10% Pd/C (0.15 g). The product obtained had two constituents (80:20) as judged by g.l.c. The absorptions for the olefinic bond in the i.r. (1660 cm^{-1}) and n.m.r. (5.87 δ) spectra of **6***b* were not found in the spectra of the product. As the product could not be crystallized or separated into its constituents on t.l.c., the product mixture was refluxed with methanol (50 ml), water (5 ml), and potassium hydroxide (1.5 g) for 3 h under a nitrogen atmosphere. The cooled reaction mixture was diluted with water and extracted with ether. Work-up gave non-crystalline tetracyclic material (0.37 g, 79% from **6***b*) which was greater than 90% **1***b* (g.l.c.). The spectra of this sample of **1***b* were almost identical to those of the crystalline sample of **1***b* obtained from the enol–lactone **20**.

1,4aβ,10bβ-Trimethyl-8-methoxy-4,4a,6,10b,11,12-hexahydro-2(3H)-chrysenone (15b)

To a refluxing solution of methanol (3 ml), water (1 ml), and potassium hydroxide (0.56 g) were added a solution of the tricyclic enone **3***b* (26) (2.0 g) in methanol (7 ml) and then a solution of ethyl vinyl ketone (1.45 g) in methanol (1.5 ml). The reaction mixture was refluxed under a nitrogen atmosphere for 1.5 h and then cooled, poured into dilute sulfuric acid, and extracted with ether. The g.l.c. showed the product to be a 5:2 mixture of the tetracycle **15***b* and starting material. Excess tricycle **3***b* was distilled off at 120°/0.5 Torr to yield a residue which was over 90% tetracycle **15***b* by g.l.c. (0.79 g); ν_{max} (neat) 1660 (C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.30 (s, 3H, C_{10b}—CH_3), 1.52 (s, 3H, C_{4a}—CH_3), 1.73 (s, 3H, C_1—CH_3), 3.35 (broad d, 2H, C-6 protons), 3.74 (s, 3H, OCH_3), 5.95 (broad t, 1H, C-5 vinyl proton).

1α-Trideuteromethyl-1β,4aβ,8-trimethyl-7-methoxy-3,4,4a,9,10,10aα-hexahydro-2(1H)-phenanthrone (16)

A solution of tricyclic enone **3***a* (540 mg, 2 mmol) in anhydrous tetrahydrofuran (25 ml) was added to a stirred mixture of lithium (170 mg, 24.3 mmol) and anhydrous liquid ammonia (50 ml). The resulting solution was stirred for 25 min and then quenched with a solution of trideuteromethyl iodide (5 g, 34.5 mmol) in anhydrous ether (10 ml). The ammonia was allowed to evaporate overnight. Saturated sodium chloride solution was added to the residue and the resulting mixture was extracted with ether. Work-up of the organic layer gave a mixture of **3***a* and **16** (40:60) as judged by g.l.c. The product was crystallized from methanol to give **16** as small clusters of yellow needles, m.p. 85–89°; ν_{max} (Nujol) 1700 cm^{-1} (C=O); n.m.r. ($CDCl_3$) δ 1.13 (s, 3H, C_1—CH_3), 1.33 (s, 3H, C_{4a}—CH_3), 2.13 (s, 3H, $ArCH_3$), 3.84 (s, 3H, OCH_3); mass spectrum: M^+ at 289.

1′α-Allyl-1′β,4′aβ-dimethyl-7′-methoxy-3′,4′,4′a,9′,10′,10′aα-hexahydro-spiro [1,3-dioxolane-2,2′(1′H)-phenanthrene] 18

A solution of tricyclic enone **3***b* (2.05 g, 8.0 mmol), water (143 mg, 7.9 mmol), and anhydrous tetrahydrofuran

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(150 ml) was added to a stirred mixture of lithium (320 mg, 46 mmol) and anhydrous liquid ammonia (150 ml). The blue solution was allowed to stir for 10 min and then quenched with a large excess of freshly distilled allyl bromide (14.5 g, 0.12 mol). *Caution*: this addition of allyl bromide can result in a very violent reaction! The ammonia was allowed to evaporate overnight. Saturated sodium chloride solution was added to the residue and the resulting mixture was extracted with ether. Work-up of the organic layer gave **17** as a colorless oil; ν_{max} (neat) 1700 (C=O), 1635 (vinyl C=C)cm^{-1}; n.m.r. ($CDCl_3$) δ 1.12 (s, 3H, C_1—CH_3), 1.37 (s, 3H, C_4—CH_3), 3.77 (s, 3H, OCH_3), 4.7–6.4 (m, 3H, —CH=CH_2).

A mixture of crude **17**, ethylene glycol (250 ml), and *p*-toluenesulfonic acid (100 mg) was heated and the bulk of the ethylene glycol was distilled off at 70°/0.05 Torr. The residue was diluted with benzene and washed successively with saturated sodium bicarbonate and aqueous sodium chloride. Work-up of the organic layer gave a colorless oil which yielded crystalline **18** upon the addition of methanol. Recrystallization from methanol gave the ketal–olefin **18** as colorless plates, m.p. 121–123° (2.02 g, 73.5% from **3***b*); ν_{max} (Nujol) 1630 (vinyl C=C), 1612 (aromatic C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.03 (s, 3H, C_1—CH_3), 1.20 (s, 3H, C_4—CH_3), 3.73 (s, 3H, OCH_3), 3.83–4.07 (m, 4H, O—CH_2CH_2—O), 4.7–6.4 (m, 3H, —CH=CH_2); M^+ at 342.

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 77.16; H, 8.83. Found: C, 77.26; H, 8.67.

*1β,4aβ-Dimethyl-7-methoxy-2-oxo-1,2,3,4,4a,9,10,10aα-octahydro-1α-phenanthrenepropionic Acid (**19**)*

Disiamylborane (21) was prepared by stirring a mixture of sodium borohydride (0.661 g, 17.5 mmol), 2-methyl-2-butene (5.00 ml, 47.3 mmol), and boron trifluoride etherate (2.92 ml, 23.2 mmol) in anhydrous tetrahydrofuran (THF) (75 ml) for 2 h at 0°. Then a solution of the ketal–olefin **18** (2.15 g, 6.3 mmol) in anhydrous THF (30 ml) was quickly added to the disiamylborane solution and the reaction mixture allowed to stir at room temperature for 3 h. The mixture was again cooled to 0°, followed by the cautious addition of 3 *N* sodium hydroxide (30 ml) and then 30% hydrogen peroxide (15 ml). The THF was removed by rotary evaporation and the resulting mixture extracted with ether. Work-up of the organic extract gave the ketal–primary alcohol as a colorless oil. ν_{max} (neat) 3400 cm^{-1} (OH); n.m.r. ($CDCl_3$) δ 3.55 (broad t, J = 6 Hz, 2H, CH_2—OH), 3.77 (s, 3H, OCH_3), 3.94 (m, 4H, —OCH_2-CH_2O—).

The crude alcohol was dissolved in acetone (50 ml), cooled to 0°, and oxidized with an excess of Jones reagent (22). Acetone was removed and the resulting mixture diluted with water and extracted (3 ×) with ether. The ether layer was extracted with 1 *N* sodium hydroxide (3 × 35 ml) and discarded. The alkaline solution was acidified with dilute hydrochloric acid and extracted with chloroform. Work-up of the chloroform extract gave ketal–acid as an oil. This material was refluxed with a mixture of acetone (30 ml) and 1 *N* sulfuric acid (10 ml) for 1 h and then diluted with water and extracted with chloroform. Work-up of the organic extract gave the keto-acid **19** as an oil which was crystallized from methanol as colorless needles, m.p. 171–173° (1.50 g, 4.53 mmol, 72% from **18**); ν_{max} (Nujol) 3200–2500 (acid OH), 1705–1690 (acid, ketone C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.15 (s, 3H, C_1—CH_3), 1.27 (s, 3H, C_4—CH_3), 3.80 (s, 3H, OCH_3), 9.04 (broad s, 1H, acid —OH); M^+ at 330.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93. Found: C, 72.63; H, 8.02.

*Enol–Lactone (**20**)*

A mixture of the keto–acid **19** (1.18 g, 3.59 mmol), acetonitrile (20 ml), and trifluoroacetic anhydride (3 ml) was stirred at room temperature for 0.5 h to give a clear solution. The solvents were removed and the resulting oil dissolved in carbon tetrachloride (15 ml) and cooled to 0°. One drop of 70% perchloric acid was added and the reaction mixture stirred for 20 min and then extracted twice with cold, saturated sodium bicarbonate (25 ml). Work-up of the organic layer gave a clear oil which slowly crystallized. Recrystallization from ether gave the enol–lactone **20** as colorless needles, m.p. 163–165° (0.85 g, 2.73 mmol, 76%); ν_{max} (Nujol) 1750 (C=O), 1680 (enol C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.17, 1.30 (two s, 3H each, angular CH_3), 3.77 (s, 3H, OCH_3), 5.36 (pair of d, 1H, —CH=C—O, J = 6, 2.5 Hz, unequal coupling to allylic H's); M^+ at 312.

Anal. Calcd. for $C_{20}H_{24}O_3$: C, 76.89; H, 7.74. Found: C, 76.96; H, 7.73.

The sodium bicarbonate extracts were acidified, extracted with chloroform, and worked-up to give crystalline keto–acid **19** (201 mg, 0.61 mmol, 17%). Thus, allowing for the recovered starting material, the yield of **20** from **19** is 92%.

*4aβ,10bβ-Dimethyl-8-methoxy-4,4a,4bα,5,6,10b,11,12-octahydro-2(3H)-chrysenone (**1b**) from Enol–Lactone **20***

A solution of the enol–lactone **20** (200 mg, 0.64 mmol) in anhydrous tetrahydrofuran (8 ml) was cooled to 0° and placed under a dry nitrogen atmosphere. A 1.8 *N* ethereal solution of methyl magnesium iodide (0.80 ml, 1.44 mmol) was then added by syringe and the reaction mixture left to warm to room temperature and stirred for 16 h. To this mixture were added saturated ammonium chloride (5 ml), water (10 ml), and ether (10 ml). Work-up of the organic layer gave a clear oil which was then refluxed for 24 h with a mixture of potassium hydroxide (460 mg), methanol (12 ml), and water (12 ml) under a nitrogen atmosphere. The cooled reaction mixture was extracted with ether and work-up gave an oil which was purified by t.l.c. on silica gel (benzene/ether = 3/1) and recrystallized from methanol to give the tetracyclic enone **1***b* as colorless plates, m.p. 137–139° (139 mg, 0.45 mmol, 70%); ν_{max} (Nujol) 1655 (C=O), 1602 (C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.26 (s, 3H, C_{4a}—CH_3), 1.37 (s, 3H, C_{10b}—CH_3), 3.78 (s, 3H, OCH_3), 5.84 (d, J = 2 Hz, 1H, C-1 vinyl proton); M^+ at 310.

Anal. Calcd. for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44. Found: C, 81.02; H, 8.31.

*1,4aβ,10bβ-Trimethyl-8-methoxy-4,4a,4bα,5,6,10b,11,12-octahydro-2(3H)-chrysenone (**1c**)*

Reacting ethereal ethyl magnesium bromide with the enol–lactone **20** under the same conditions used to prepare **1***b*, a 66% yield of **1***c* was obtained as colorless plates from methanol, m.p. 135–137°; ν_{max} (Nujol) 1675 (C=O), 1610 (C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.23 (s, 3H, C_{4a}—CH_3),

1.37 (s, 3H, C_{10b}—CH_3), 1.82 (s, 3H, C_1—CH_3), 3.78 (s, 3H, OCH_3); M^+ at 324.

Anal. Calcd. for $C_{22}H_{28}O_2$: C, 81.44; H, 8.70. Found: C, 81.59; H, 8.65.

*1′β,4′aβ-Dimethyl-7′-methoxy-3′,4′,4′a,9′,10′,10′aα-hexahydro-spiro [1,3-dioxolane-2,2′(1′H)-phenanthrene]-1′α-acetaldehyde (**21**)*

Sodium periodate (748 mg, 3.50 mmol) was added in portions over a 20 min period to a stirred suspension of the ketal–olefin **18** (512 mg, 1.50 mmol), osmium tetroxide (38 mg, 0.15 mmol), saturated sodium bicarbonate solution (1 ml), dioxane (18 ml), and water (6 ml). This mixture was stirred for 2.5 h at room temperature, poured into saturated sodium bicarbonate solution, and extracted with chloroform (3 × 50 ml). The combined chloroform extracts were washed with saturated sodium sulfite solution (2 × 50 ml) and then with saturated sodium bicarbonate (25 ml). Work-up of the chloroform layer gave a clear oil which proved to be a mixture of the desired ketal–aldehyde **21** and uncleaved ketal–diol. This crude product was dissolved in dioxane (10 ml) and reacted with a solution of periodic acid dihydrate (732 mg, 3.21 mmol) in water (2 ml). The reaction mixture was stirred for 2.5 h at room temperature, diluted with water, and extracted with chloroform. Work-up gave a clear oil which slowly crystallized. Recrystallization from ether gave the ketal–aldehyde **21** as clusters of colorless needles, m.p. 125–127° (358 mg, 1.04 mmol, 70%); ν_{max} (Nujol) 2740 (aldehyde C—H), 1710 (C=O), 1612 (Ar C=C) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.15 (s, 3H, C_1—CH_3), 1.22 (s, 3H, C_4—CH_3), 2.18 (d, $J = 3$ Hz, 2H, —CH_2CHO), 3.67–4.00 (m, 4H, OCH_2CH_2O), 3.70 (s, 3H, OCH_3), 9.60 (t, $J = 3$ Hz, 1H, —CHO); M^+ at 344.

Anal. Calcd. for $C_{21}H_{28}O_4$: C, 73.23; H, 8.19. Found: C, 73.31; H, 8.25.

*1α-(Hydroxyethylene)-1β,4aβ-dimethyl-2β-hydroxy-7-methoxy-1,2α,3,4,4a,9,10,10aα-octahydrophenanthrene (**22**)*

The ketal–aldehyde **21** (147 mg, 0.427 mmol) was dissolved in ethanol (5 ml), stirred with sodium borohydride (160 mg, 4.21 mmol) for 4 h at room temperature, and then diluted with water, and extracted with chloroform to yield a clear oil on work-up. This ketal–alcohol was immediately dissolved in acetone (50 ml) and 1 *N* sulfuric acid (5 ml) and warmed on a steam bath for 30 min to hydrolyze the ketal group. Removal of acetone followed by ether extraction and work-up gave the ketone–alcohol as an oil; ν_{max} (film) 3375 cm^{-1} (OH), no C=O absorption, indicating that this compound exists in the hemi-ketal form. The crude ketone–alcohol was dissolved in ethanol (5 ml), stirred with sodium borohydride (160 mg, 4.21 mmol) for 4 h at room temperature, and then diluted with water, and extracted with ether. Work-up gave a clear oil which was separated into two fractions by t.l.c. chromatography on silica gel (chloroform:methanol = 100:3). The minor component just separated from the major one (lower R_f). The major fraction was eluted and crystallized from acetone/hexane to give the diol **22** as tiny clusters of colorless needles, m.p. 135–137°. The authentic sample[9] of **22** had m.p. 131–133° and a mixture of the two samples had m.p. 132–134°. The i.r. and mass spectra of the authentic and synthetic samples of **22** were identical and the samples had the same R_f value on t.l.c. silica gel plates.

The minor component isolated from the t.l.c. plate had an i.r. spectrum very similar to that of **22** and a similar mass spectrum (M^+ at 304). It is presumed to be the 2α-OH isomer of **22**.

We thank the National Research Council of Canada for generous financial assistance. Professor R. A. Bell, McMaster University, Hamilton, Ontario kindly determined the nuclear Overhauser effects.

^{13}C Nuclear Magnetic Resonance of Oximes. I. Solvent and Isotope Effects on the ^{13}C Chemical Shifts of Acetoxime

N. GURUDATA

Department of Chemistry, Sir George Williams University, Montreal, Quebec

Received November 15, 1971

The ^{13}C n.m.r. spectrum of acetoxime has been obtained in five representative solvents and the chemical shifts of the three carbon atoms measured. The solvent effects on the chemical shifts are found to reflect specific solute–solvent interactions. The effect of deuteration of the α-protons on the chemical shift of the oximino carbon is also discussed.

Le spectre r.m.n. de ^{13}C de l'acétoxime a été obtenu dans cinq solvants judicieux, et les déplacements chimiques des trois atomes de carbone ont été mesurés. Les effets des solvants sur les déplacements chimiques rendent compte des interactions spécifiques soluté–solvant. Il est également discuté de l'influence d'une deutération des protons en α sur le déplacement chimique du carbone oximinique.

Canadian Journal of Chemistry, **50**, 1956 (1972)

Introduction

The stereochemistry of oximes has been investigated by a number of physical techniques including i.r. spectroscopy (1), n.m.r. spectroscopy (2–7), and X-ray spectrometry (8). The p.m.r. studies of Lustig (2) and Karabatsos and Taller (3) demonstrated the dependence of the chemical shift on the topography of the protons relative to the hydroxyl group. The shielding of the hydroxyl group is also sensitive (4) to the stereochemistry of the oxime, as are the $^{15}N–H$ coupling constants (5). Even with the aid of solvent effects (2, 3), however, the differences involved are comparatively small. Some enhancement of the chemical shift differences has been achieved by the addition of HCl (6) and, more recently, a lanthanide shift reagent has been used (7) to provide sufficiently large separations for direct examination of *syn* and *anti* isomers of a number of oximes. Unfortunately, there appears to be a considerable discrepancy between the reports of Wolkowski (*7a*) and Berlin (*7b*). For example, while the former author (*7a*) gives a $Eu(DPM)_3$-induced shift of 21.2 p.p.m. for the α-methyl group in *syn* methyl ethyl ketoxime, Berlin (*7b*) reports a relative shift of only 0.26 p.p.m. Since different solvents were used and Wolkowski's data are "after extrapolation to an equimolar ratio of $Eu(DPM)_3$ to oxime", some disagreement is expected. A difference approaching two orders of magnitude does, however, demand some clarification before this technique can be of general use.

Because of the well established large range of chemical shift values in ^{13}C magnetic resonance (^{13}C.m.r.) and the sensitivity of this parameter to molecular geometry, it can be expected that configurational differences will cause appreciable chemical shift differences in formally similar carbon atoms of oximes. In addition, a major reactive site of ketoximes, the sp^2 hybridized carbon atom, is accessible to ^{13}C.m.r. investigation. Further, while geminal deuterium isotopic shifts in p.m.r. are about 0.013 p.p.m. (9), an isotopic shift of 0.28 p.p.m. (0.047 p.p.m. per deuteron) has been found for the carbonyl carbon of acetone (10, 11).

In the present work acetoxime is used as a model to determine the magnitude of chemical shift changes due to configurational, solvent, and isotope effects, and to establish the feasibility of employing natural abundance ^{13}C.m.r. in investigating oximes.

Experimental

Acetoxime was prepared from acetone by standard techniques and recrystallized from 30–60° petroleum spirit. A sample of acetoxime-α,α'-d_6 with $95 \pm 1\%$ deuteration (12) was kindly provided by Dr. T. J. Adley.

The p.m.r. spectra were obtained in dilute CCl_4 solution

ΔBenzene	+0.17	−0.80	−0.86	−0.06
$\Delta CHCl_3$	+1.34	+0.04	−0.07	−0.11
ΔCH_3OH	+0.90	−1.26	−1.44	−0.18
$\Delta(CH_3)_2SO$	−1.28	+0.22	−0.11	−0.33

*From CS_2. Precision estimated to be better than ±0.04 p.p.m.
†$\Delta\delta = \delta(syn) - \delta(anti)$; $\Delta = \delta$ in $CCl_4 - \delta$ in other solvent.

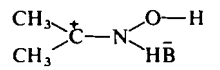
on a Varian HA100 Spectrometer operated in the "frequency sweep" mode. Proton decoupled ^{13}C.m.r. spectra were run at 25.15 MHz using the above spectrometer equipped with a VK-3512-1 Heteronuclear Noise Decoupler and a V-3530 wide sweep accessory. A C-1024 Computer of Averaged Transients was used for accumulation. Spectra for solvent effects were obtained from 3.0 *M* solutions. Isotope effects were measured in saturated benzene solution containing equimolar amounts of acetoxime and acetoxime-α-α′-d_6.

Results and Discussion

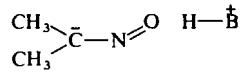
The observed proton chemical shifts ($\delta = 1.85$ and 1.86 p.p.m. for the methyl groups and 10.01 p.p.m. for the hydroxyl proton) are consistent with previous reports. Table 1 summarizes the ^{13}C.m.r. chemical shift data. The relative shifts of the methyl groups and the solvent effects are also shown. (A positive solvent effect indicates that the carbon atom is less shielded in the particular solvent than in carbon tetrachloride.) The oximino carbon atom absorbs in the range 37.27 to 37.88 p.p.m. (from CS_2). Of the methyl resonances, the higher field signal is assigned to the *cis* methyl group because of the screening effect of a neighboring hydroxyl group (13, 14). This can be rationalized in terms of sterically induced polarization of electronic charge (14–16). It is noteworthy that the relative shifts of the methyl groups are of similar magnitude ($\simeq$6.8 p.p.m.) to the shielding of a γ-carbon atom in cyclohexane by an axial hydroxyl group (14). The distance between the oxygen and carbon atoms is estimated to be approximately 3.0 Å in each case. Roberts' suggestion (14) that the C_β—C_γ bond in "axial cyclohexanol" is elongated seems unlikely in view of the known *compression* of the *syn* C—C bond in acetoxime (8).

Although the trend in the relative chemical shifts of the methyl groups [$\Delta\delta(CH_3)$] is in the same direction as that of the dielectric constants of the solvents, there is no simple correlation with this parameter. The solvent effects are best explained in terms of specific solvation.

The proton of chloroform can hydrogen bond to the oximino nitrogen. By comparison with analogous hydrogen bonding effects on the carbonyl carbon (17, 18), the deshielding of the oximino carbon is readily understood in terms of a contribution from structure **1**. The smaller

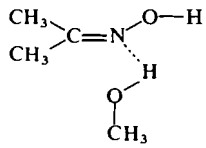


1



2

net deshielding effect of methanol at this carbon atom may be due to simultaneous solvation at nitrogen (deshielding) and at the oximino hydrogen as in **2** (shielding). Structure **2** also represents the type of species expected in dimethyl sulfoxide, and explains its shielding effects on the sp^2 carbon atom. The methyl carbon atoms are screened in methanol. One possible contributor to this effect is a solvent molecule oriented as in **3**. Steric perturbation



3

by the oxygen atom shields the *anti* methyl group. The high field shift of the *syn* methyl carbon reflects the compression of the C—C—N angle and consequent increased charge polarization by the oximino oxygen.

The effect of benzene can be explained in terms of previous models proposed (3, 19) for aromatic solvation of oximes and oxime ethers. Electron donation by benzene to the oximino carbon depolarizes the C=N bond giving a low field shift of 0.17 p.p.m. This is reasonable in comparison to the deshielding of the carbonyl group of acetone by 0.5 p.p.m. (18). Although Roberts has suggested (20) that anisotropy effects may be negligible at the carbon nucleus of the solute, there is ample evidence of appreciable ring current effects on carbon chemical shifts (21). The shielding of both methyl carbon

atoms may well be of this origin, with the small difference in relative shielding reflecting the asymmetric orientation of the solvent molecules necessitated by lone pair repulsions of the oximino oxygen.

Isotope Effects

Because of the wide application of deuterated species in organic chemistry, appreciable effort has been expended in elucidating deuterium isotope effects. Although accessible with modern instrumentation, the effect on H-1 chemical shifts and coupling constants is very small and not readily observable. The greater sensitivity of ^{13}C chemical shifts to structural features holds the hope of more tractable changes on deuteration. Surprisingly little work has been reported on isotope effects on ^{13}C spectra despite the extensive use of deuterated compounds as secondary references and the fact that deuterated compounds have been used to provide evidence critical to the assignment of carbon resonances (22). Maciel *et al.* (10) have reported a downfield shift of 0.28 p.p.m. for the carbonyl carbon of acetone-d_6 relative to the parent compound. In addition to confirming this result Reilly (11) measured appreciable deuterium induced shielding of the methyl carbon of acetone-d_6, dimethyl sulfoxide-d_6, and acetonitrile-d_3. While these findings are consistent with the dominance of an inductive effect, the absence of an observable effect on the sp carbon of acetonitrile (11) and the screening of the sp^2 carbon in acetoxime-α,α'-d_6 (0.08 ± 0.02 p.p.m.) found in the present study indicates clearly the need for a careful evaluation of the nature and magnitude of such perturbations.

The author wishes to thank Dr. T. J. Adley of this Department for a sample of acetoxime-α,α'-d_6, Dr. K. Berlin of Oklahoma State University for a preprint of his paper, and Dr. C. A. Reilly of Shell Development Company for his permission to quote his unpublished data.

Nature de la luminescence de la colchicine

H. ROIGT ET R. M. LEBLANC

Université du Québec à Trois-Rivières, Département de chimie-biologie, C.P. 500, Trois-Rivières, Québec

Reçu le 29 décembre 1971

Des mesures de décroissance et de polarisation d'émission ainsi que des observations d'effet de solvant et d'atome lourd permettent de conclure aux multiplicités des états excités d'absorption et d'émission de la colchicine.

Measurements of the emission decrease and polarization, as well as solvent and heavy-atom effect observations, have led us to determine the excited states multiplicity of absorption and emission in colchicine.

Canadian Journal of Chemistry, **50**, 1959 (1972)

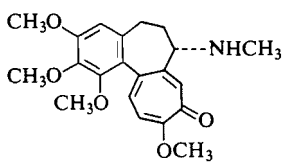
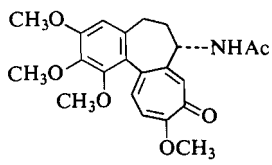
Récemment, Aronson et Inoué (1) ont déterminé un rendement photochimique de dégradation relativement faible pour la colcémide (**1**).



1



2

Notre étude qui porte sur la colchicine (**2**) montre également un rendement du même ordre de grandeur soit $\Phi_{366\,nm} = 3 \times 10^{-3}$ en solution aqueuse ($pH = 5.8$). Compte tenu de cette dégradation photochimique très faible, nous avons envisagé l'existence d'une luminescence comme autre mode de désactivation. Ainsi des mesures de fluorescence à température ambiante et dans différents solvants se sont avérées négatives, mais à 77 °K une importante luminescence a été décelée. Plusieurs résultats nous permettent de caractériser cette émission.

Partie expérimentale

Les solvants tels le 3-méthylpentane (Aldrich, "puriss."), l'iodure d'éthyle (Fisher, "Certified"), et le mélange diéthyléther, isopentane, éthanol, 5:5:2, (EPA mixed solvent, American Instrument Co. Inc.) ont été utilisés sans autre purification.

La colchicine (Sigma) a été purifiée par chromatographie sur couche mince et possédait les critères suivants: (*a*) $R_F = 0.60$ avec le méthanol (Fisher "spectrograde") comme éluant, chambre saturée, couches de gel de silice, 250 μ (Machrey, Nagel, et Co.). Le révélateur était en l'occurence le réactif de Dragendorff suivi d'une vaporisation d'acide sulfurique concentré (2). Les taches apparaissaient jaune–orange sur fond brun. (*b*) Point de fusion situé entre 145 et 150 °C (analyse différentielle thermique, et appareil de fusion de Fisher). (*c*) Coefficients d'absorption moléculaire dans l'éthanol, 95%, $\varepsilon_{351\pm1\,nm} = 16\,550\,1\ mol^{-1}\,cm^{-1}$ et $\varepsilon_{243\pm.5\,nm} = 29\,300\,1\ mol^{-1}\,cm^{-1}$, calculés par la méthode des moindres carrés, se comparent relativement bien aux valeurs de référence, soient $\varepsilon_{350\,nm} = 16\,740$, $\varepsilon_{244\,nm} = 30\,000$ (3); $\varepsilon_{350.5\,nm} = 16\,600$, $\varepsilon_{243\,nm} = 29\,600$ (4).

Les solutions de colchicine ont été préparées dans l'obscurité et dégazées par la technique du vide obtenu par pompage à la température de l'azote liquide, *i.e.* cycles "gel-dégel".

Les spectres d'absorption sont pris à l'aide d'un spectrophotomètre Unicam SP 1800 et ceux de luminescence avec un spectrofluorimètre Perkin–Elmer MFP 2A, équipé des accessoires de phosphorescence et de polarisation.

La phosphorescence est détectée au moyen d'un photomultiplicateur HTV R 106. Pour la mesure du temps de vie, nous utilisons une cellule photoélectrique du type "pin-diode, MRD 500" reliée à un oscilloscope au moyen d'un amplificateur différentiel (l'impédance d'entrée diode-amplificateur est supérieure à 20 MΩ), et la lampe du spectrofluorimètre est remplacée par une lampe éclair au Xénon de 100 W (Nihon–Kohden) donnant des éclairs de 10 μs.

Le temps de vie de phosphorescence est calculé par méthode graphique en posant le logarithme de l'intensité en fonction du temps.

Résultats et discussion

Par excitation de la colchicine à 370 nm, une bande d'émission relativement large est décelée à la température de 77 °K (fig. 1). La différence de 20 nm entre le maximum d'absorption et celui d'excitation est due au changement d'état du solvant. Il est à noter qu'aucune fluorescence n'a été détectée à la température ambiante dans les solvants tels que l'EPA, l'eau, l'éthanol, et le benzène.

A priori, la luminescence observée peut aussi bien être de la fluorescence à basse température que de la phosphorescence.

Il est à noter que le maximum d'absorption à 350 nm subit un déplacement bathochrome lorsque la polarité du solvant augmente. De plus compte tenu du coefficient d'absorption moléculaire élevé ($\varepsilon_{351} \sim 16\,000\,1\ mol^{-1}\ cm^{-1}$)

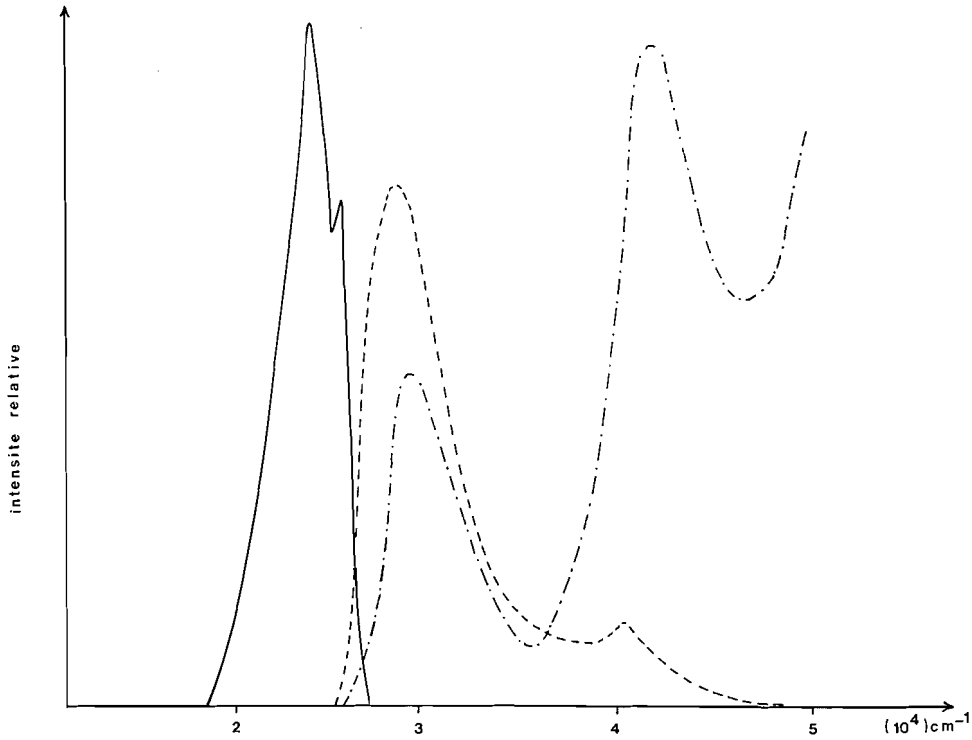

FIG. 1. Spectres d'absorption (—·—·—) à 25 °C, d'excitation (---) et d'émission (—) à −196 °C de la colchicine dans l'EPA.

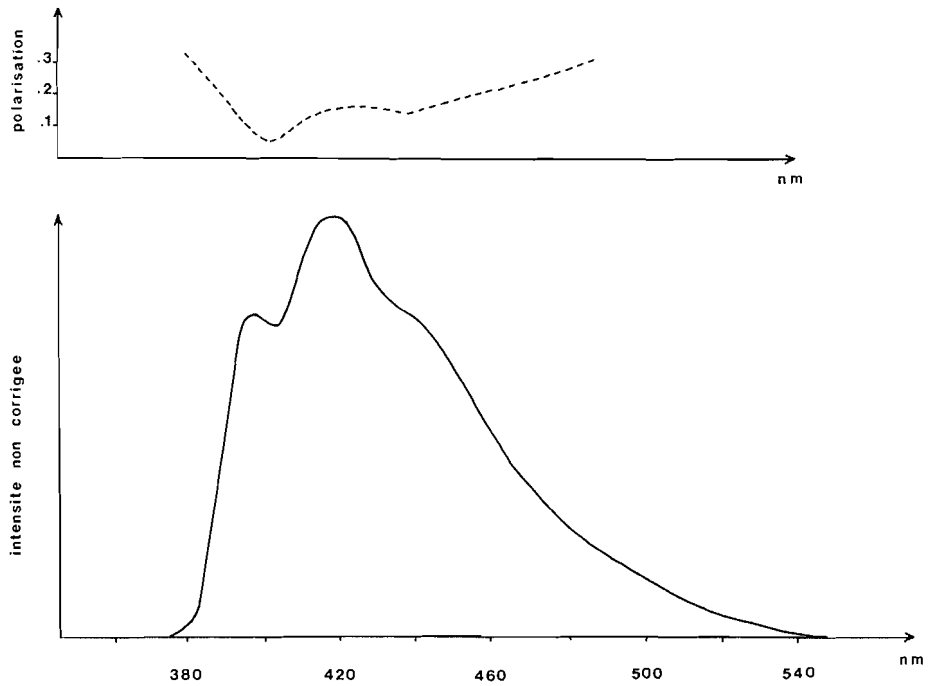

FIG. 2. Spectres d'émission et de polarisation de l'émission de la colchicine dans l'EPA à −196 °C.

la bande est identifiée comme étant une bande $\pi-\pi^*$ d'un état singulet.

En ce qui a trait à la bande de luminescence, on observe par contre un effet hypsochrome par augmentation de la polarité du solvant. D'autre part, l'augmentation du couplage spin-orbite par dissolution de la colchicine dans l'iodure d'éthyle n'apporte aucun changement du spectre. Un tel résultat a été commenté par McGlynn et coll. (5). Enfin des mesures de polarisation aux différentes longueurs d'onde de l'émission, il découle une valeur moyenne $P = +0.2$ (fig. 2).

Chacun de ces résultats présente une preuve directe de la présence d'une bande $n-\pi^*$ (probablement dûe à la délocalisation des électrons du groupement carbonyle de l'anneau tropolone) (6, 7).

Puisque la bande d'absorption à 350 nm possède un caractère $\pi-\pi^*$ et que celle d'émission revêt un caractère $n-\pi^*$, c'est qu'il existe une absorption $n-\pi^*$. Il nous a été cependant impossible de détecter la présence de cette bande, du fait de son faible coefficient d'extinction molaire ($\varepsilon_{n-\pi^*} < 2000$). De plus, la position de la bande 0–0 d'émission se situe à 402 nm, ce qui impliquerait une absorption vers la même longueur d'onde, absorption qui disparaît donc sous la bande $\pi-\pi^*$.

Afin de déterminer la multiplicité de l'état excité de la colchicine, le temps de vie a été mesuré, soit 2×10^{-4} s ce résultat permet d'identifier l'émission comme étant de la phosphorescence (8).

L'existence de cette forme de dégradation de l'état excité par émission de phosphorescence laisse entrevoir, pour la molécule de colchicine en particulier, de nombreuses possibilités d'explication de son mode d'action sur l'appareil mitotique cellulaire.

Pyrrole Chemistry. XIV. Some Chemical and Physical Properties of 3-Pyrrolecarbaldehyde and 1-Methyl-3-pyrrolecarbaldehyde

Hugh J. Anderson and H. Nagy

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received January 31, 1972

3-Pyrrolecarbaldehyde (1) has been prepared on an increased scale. A general survey of the physical and chemical properties of the 3-aldehyde and 1-methyl-3-pyrrolecarbaldehyde has been carried out. The results indicate similar chemical properties to those of the corresponding 2-aldehydes. The physical properties are generally predictable on the basis of earlier studies.

Le pyrrolecarbaldéhyde-3 (1) a été préparé sur une plus grande échelle. Une revue générale des propriétés physiques et chimiques de l'aldéhyde-3 et du méthyl-1 pyrrolecarbaldéhyde-3 a été menée à bien. Les résultats indiquent des propriétés chimiques semblables à celles des aldéhydes-2 correspondants. Les propriétés physiques sont en général prévisibles en se fondant sur les études précédentes.

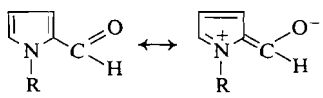
pounds have provided considerable discussion over the years (2–4).

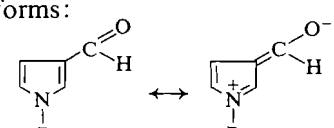
The necessary modifications for optimum yield in larger scale preparation of the 3-aldehyde are described in the Experimental. Standardization trials for the decarbonylation step were tedious and the best means of product analysis was careful filtration of an aliquot, evaporation, and p.m.r. examination of the residue for the various possible products (1). The readily available 1-methyl-2-aldehyde (5) could be formylated by the Friedel–Crafts method to the 1-methyl-2,4-dialdehyde but the yield was only 26%. Thus, although the subsequent decarbonylation step appeared to go satisfactorily, this method was not used to prepare the 1-methyl-3-aldehyde. Instead, this substance was isolated in about 6% yield as a by-product of the Vilsmeier preparation of the 1-methyl-2-aldehyde[1] being used in other work.

Herz and Brasch (3) compared the physical and chemical properties of the 2-aldehyde and its 1-methyl derivative and concluded that a resonance hybrid:



R=H or CH_3

best accounted for the observations made. Similar forms:



R=H or CH_3

may be drawn for the 3-aldehydes.

The 3-aldehyde carbonyl stretching frequency in carbon tetrachloride was found to be at 1683 cm^{-1} (6) while we find that of the 1-methyl derivative to be at 1685 cm^{-1}. The most recent values for the carbonyl bands of the 2-aldehyde and its 1-methyl derivative are 1667 and 1671.5 cm^{-1}, respectively, in the same solvent (7). These values support the usual statement that electron release is easier through the 2- than through the 3-position. However, the small, and similar, effect of the 1-methyl group on the carbonyl band positions makes it difficult to see that intramolecular hydrogen bonding is important to the low frequency of the 2-aldehyde carbonyl absorption (8).

In a footnote, Herz and Brasch (3) reported that the u.v. spectrum of the 2-aldehyde did not obey Beer's Law. However, we found no deviation greater than experimental error:[2] λ_{max} 290 nm (ε 16 500 $\pm$ 2.5%) in the range from 3.3×10^{-2} to 1.1×10^{-5} M in 95% ethanol, and λ_{max} 281 nm (ε 16 000 $\pm$ 6%) from 5.8×10^{-2} to 1.1×10^{-4} M in methylcyclohexane. Our spectra of the 2-aldehyde and its 1-methyl derivative in alcohol agree well with those reported by Andrisano *et al.* (9). The 3-aldehyde also obeys Beer's Law over a wide range of concentration in ethanol. Insolubility of the 3-aldehydes prevents u.v. measurement in hydrocarbon solvent. In ethanol there does not seem to be any consistent spectral change arising from the introduction of the 1-methyl group in these two aldehydes. Eisner and Gore (10) observed that the longer wavelength absorption band of 3-substituted compounds is much less intense than that of the 2-substituted ones. This is true here, although that band is a shoulder in the 3-aldehyde spectra and measurement is not precise. Also this band is 15–18 nm lower for the 3- than for the corresponding 2-derivative as noted before (10) in more highly substituted examples.

The p.m.r. spectra of the 3-aldehyde and 1-methyl-3-aldehyde of pyrrole showed no observable coupling of the aldehyde and ring protons at probe temperature. This contrasts with the spectra of the 3-aldehyde of furan (11) and of thiophene (12) where —C*H*O to H-5 and to H-4 coupling was observed. In both 2,4-pyrroledicarbaldehyde and its 1-methyl derivative the 2-C*H*O is coupled to H-5, but the 4-C*H*O signal is again a singlet.

The mass spectra of the four aldehydes were found to be entirely as expected on the basis of earlier work (13)[3]. In each, the important peaks are M^+, M − 1, M − CHO, as well as the peak at *m/e* 39 and, for the 1-methyl derivatives, the peak at *m/e* 53.

[1]Observed by Dr. C. E. Loader of this Department. In large scale preparations of 2-pyrrolecarbaldehyde, he also obtained about 1/2% of the 3-aldehyde from the residue.

[2]In a personal communication Professor Herz agrees that their observation may have been an effect of stray light at high absorbance.

[3]Under the instrument conditions we used, the spectrum of the 2-aldehyde showed good agreement with ref. 13 for higher masses but was less satisfactory for lower masses.

It has been reported (2, 3) that 2-pyrrolecarbaldehyde does not show positive Schiff's, Fehling's, or Tollen's tests. Herz and Brasch (3) stated that the 1-methyl-2-aldehyde also failed these tests. As the usual Fehling's test generally fails for aromatic aldehydes (14) that result is not surprising. We confirmed that the Schiff test fails for both the 2- and 3-aldehydes as well as their 1-methyl derivatives. However, Tollen's reagent with either the 2- or the 3-aldehyde gave a silver mirror rapidly on warming or within 5 min in the dark at room temperature. Surprisingly, neither 1-methyl derivative reacted within several hours, nor on warming. All four aldehydes may be converted to their acids using fresh silver oxide in the method of Hodge and Rickards (15).

Attempts to convert the 2- or the 3-aldehyde to its acetal failed. However, the ethylene acetal of the 3-aldehyde, 3-(1,3-dioxolan-2-yl)-pyrrole, could be made by conversion of ethyl 4-formyl-2-pyrrolethiolcarboxylate to its ethylene acetal followed by removal of the ethyl thiolcarboxylate group by Raney nickel. Both acetals were highly unstable toward light and to the most weakly acidic conditions. Similar instability of the ethylene ketal of methyl 4-acetyl-2-pyrrolecarboxylate has been observed (16). Attempts to convert the 3-acetal to a pyrrole Grignard reagent were unsuccessful.

It has been reported (17) that in Wittig reactions with the 2-aldehyde and with its 1-methyl derivative the yields are very sensitive to relative basicities and reaction conditions. We found that the yield of 1-methyl-3-styrylpyrrole from the 1-methyl-3-aldehyde was low under a variety of conditions and that the only apparently successful reaction of 3-pyrrolecarbaldehyde with triphenylbenzylphosphonium chloride could not be repeated.

Although the Knoevenagel reaction with ethyl malonate succeeded with the 3-aldehyde, the benzoin and Perkin condensations failed. The lithium aluminum hydride reduction was also unsuccessful, but Wolff–Kischner reduction to 3-methylpyrrole worked well. We have already reported the direct Wolff–Kischner conversion of ethyl 4-formyl-2-thiolcarboxylate to 3-methylpyrrole (18).

In general, the chemical reactivities of the 3-aldehyde of pyrrole and its 1-methyl derivative are not greatly different from those of the corresponding 2-aldehydes. In both simple aldehydes the N—H is decidedly acidic and this complicates some base-catalyzed reactions.

Experimental

Melting points (uncorrected) were determined on a Fisher–Johns apparatus. Elemental analyses were by Alfred Bernhardt, West Germany. The i.r. spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer using potassium chloride discs, while u.v. spectra were recorded on a Perkin–Elmer 202 spectrophotometer. The p.m.r. spectra were determined using a Varian A-60 or HA100 instrument. Values are given using the τ scale with tetramethylsilane as internal reference. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6E spectrometer using the direct inlet system. Spectra were normalized when the variation of total ion current was less than 6% peak. Peak intensities are given as a percentage of the base peak.

3-Pyrrolecarbaldehyde[4]

(a) Ethyl 4-Formyl-2-thiolcarboxylate

The dichloromethyl methyl ether was fractionated through a 50 cm Widmer column prior to use. The crude reaction product was extracted 48 h in a Soxhlet using petroleum (80–100°); yield about 88% starting from 10–25 g thiol ester.

(b) Raney Nickel W-5

The literature method (19) could be increased fourfold in scale by increasing the diameter of the washing chamber to 10 cm while other dimensions remained the same. A Teflon paddle gave good agitation of the nickel. Deionized water (40 l) was used for washing the catalyst.

(c) 3-Pyrrolecarbaldehyde

On the larger scale a short-path distillation of the product (132–142° at 1 mm) was more convenient than column chromatography for initial product isolation. Storage of the purified material in the dark over sodium hydroxide pellets was found most satisfactory; λ_{max} (ethanol) 246 (ε 10 800), 272 nm (sh ε 6500).

3-Pyrrolecarboxylic Acid

The 3-aldehyde was oxidized by the method of Hodge and Rickards (15) to the 3-acid (75%), m.p. 144–144.5°, lit. (20) m.p. 144.5–145.5°.

1-Methyl-3-pyrrolecarboxylic Acid (by N. C. Wang)

The 1-methyl-3-aldehyde was oxidized in the same manner to give 1-methyl-3-pyrrolecarboxylic acid (72%), m.p. 145–145.5° (benzene–hexane); λ_{max} (ethanol) 233 (ε 9160), 246 nm (sh ε 7250); p.m.r. ($CDCl_3$) τ 1.02 (s, 1H), 2.66 (m, 1H), 3.40 (m, 2H), 6.30 (s, 3H).

Anal. Calcd. for $C_6H_7NO_2$: C, 57.60; H, 5.60; N, 11.20. Found: C, 57.74; H, 5.69; N, 11.36.

1-Methyl-2,4-pyrroledicarbaldehyde

1-Methyl-2-pyrrolecarbaldehyde (2.75 g, 25 mmol) was dissolved in methylene chloride (25 ml). Nitromethane (3 ml) in methylene chloride (75 ml) was added, with stirring, followed by aluminum chloride (15.6 g, 117 mmol) and dichloromethyl methyl ether (7.6 g, 66 mmol) in methylene

[4]Modifications to method of ref. 1 for larger scale synthesis.

chloride (25 ml). The mixture was stirred at room temperature 1 h, then refluxed 10 min, cooled, and poured onto ice. The organic phase was separated and the aqueous phase extracted with chloroform. The combined organic phase was washed with water and dried ($MgSO_4$). Vacuum evaporation of the solvent was followed by distillation of unreacted starting material (680 mg). The black residue was chromatographed on neutral alumina using chloroform as eluant. The solid product was recrystallized from petroleum (80–100°) to give light yellow crystals (980 mg, 26%), m.p. 95°; λ_{max} (ethanol) 237 (ε 24 700), 260 (sh ε 9600), 290 nm (ε 15 400); p.m.r. ($CDCl_3$) τ 0.18 (s, 1H), 0.33 (d, 1H); 2.5 (m, 1H), 2.7 (m, 1H), 5.99 (s, 3H).

Anal. Calcd. for $C_7H_7NO_2$: C, 61.31; H, 5.15. Found: C, 61.30; H, 5.20.

1-Methyl-3-pyrrolecarbaldehyde

Following the Vilsmeier synthesis of 1-methyl-2-pyrrolecarbaldehyde on a 2-mol scale (4), the principal product was distilled at 45°/1 mm. The residue was then distilled at 75°/1 mm and was found to consist mainly of the 1-methyl-3-aldehyde. After redistillation the yield was 10.4 g (~6%). The material was dissolved in ether and chilled to −70° producing crystals from which the ether was decanted. The crystals melted well below 0° to a colorless oil that gave a single peak on the gas chromatograph; λ_{max} (ethanol) 254 (ε 12 000), 274 nm (sh, ε 8600); p.m.r. ($CDCl_3$) τ 0.25 (s, 1H), 2.72 (m, 1H), 3.37 (m, 2H), 6.32 (s, 3H).

Anal. Calcd. for C_6H_7NO: C, 66.03; H, 6.47. Found: C, 65.72; H, 6.42.

Ethyl 4-(1,3-Dioxolan-2-yl)-2-pyrrolethiolcarboxylate

Ethyl 4-formyl-2-pyrrolethiolcarboxylate (11.7 g, 0.075 mol) and ethylene glycol (192 ml) were added to benzene (940 ml) containing *p*-toluenesulfonic acid (768 mg). "Molecular Sieves" (10 g) were added and the mixture was refluxed, using a Dean and Stark separator, for 72 h. The benzene solution was washed with sodium bicarbonate solution and dried ($MgSO_4$). Evaporation gave a yellow solid which was recrystallized from petroleum (40–60°) to give pale yellow needles (12 g, 83%), m.p. 61–61.5°, λ_{max} (ethanol) 227 (ε 25 000), 260 (sh, ε 9900), 270 (ε 10 800), 298 nm (ε 20 600); p.m.r. ($CDCl_3$) τ 2.76 (m, 1H), 2.81 (m, 1H), 4.04 (s, 1H), 5.88 (m, 4H), 6.91 (q, 2H), 8.68 (t, 3H).

Anal. Calcd. for $C_{10}H_{13}NO_3S$: C, 52.86; H, 5.77. Found: C, 52.68; H, 5.77.

3-(1,3-Dioxolan-2-yl)pyrrole

W-5 Raney nickel (32 g) was washed with acetone (3 × 100 ml). Ethyl 4-(1,3-dioxolan-2-yl)-2-pyrrolethiolcarboxylate (2.0 g, 8.8 mmol) in acetone (125 ml) was added and the mixture stirred 70 min. After the Raney nickel was filtered off and washed well with acetone the filtrate was evaporated to give 950 mg oil. Solution in ether and cooling to −70° induced crystallization. The ethylene acetal of 3-pyrrolecarbaldehyde (650 mg, 53%), m.p. 63–63.5° (ether), p.m.r. ($CDCl_3$) τ 3.28 (m, 1H), 3.44 (m, 1H), 3.71 (m, 1H), 4.18 (s, 1H), 6.03 (m, 4H).

Anal. Calcd. for $C_7H_9NO_2$: C, 60.42; H, 6.52. Found: C, 60.41; H, 6.64.

1-Methyl-3-styrylpyrrole

Potassium (234 mg, 6 mmol) was dissolved in *t*-butyl alcohol (7 ml) under nitrogen. Ether (5 ml) was added, with stirring, followed by benzyltriphenylphosphonium chloride (1.94 g, 5 mmol). The mixture was cooled and 1-methyl-3-pyrrolecarbaldehyde (444 mg, 4 mmol) in ether (5 ml) was added dropwise to the mixture. The stirring was continued at room temperature for 3 h. The mixture was poured into water (30 ml), the phases separated and the aqueous layer extracted with ether. The combined organic phase was then washed with water and dried ($MgSO_4$). After evaporation, the crude product was chromatographed on silica gel (BDH) with benzene. The early fractions gave an oil which was crystallized from petroleum (80–100°) and then sublimed. Colorless crystals (130 mg, 13%), m.p. 95°, λ_{max} (ethanol) 314 (ε 28 300), 303 (sh, ε 26 600), 236 (sh, ε 12 700), 230 nm (ε 13 300); p.m.r. ($CDCl_3$) τ 2.5–2.8 (m, 5H), 3.09 (d, 2H), 3.27 (m, 1H), 3.41 (m, 1H), 3.51 (m, 1H), 6.39 (s, 3H).

Anal. Calcd. for $C_{13}H_{13}N$: C, 85.20; H, 7.15. Found: C, 85.01; H, 7.12.

Attempted Preparation of 3-Styrylpyrrole

The procedure used to prepare the 1-methyl derivative was applied to 3-pyrrolecarbaldehyde. Although a small amount of crystalline material with the expected p.m.r. and mass spectrum was obtained on one occasion the preparation could not be repeated. Several variations of the method were equally unsuccessful.

Ethyl 1-Carbethoxy-3-(3-pyrrolyl)acrylate

3-Pyrrolecarbaldehyde (200 mg, 2.1 mmol) was dissolved in a few drops of ethanol. Ethyl malonate (600 mg, 3.7 mmol), methylammonium chloride (100 mg, 1.3 mmol), and anhydrous potassium carbonate (200 mg, 1.5 mmol) were added. After 4 days at room temperature the mixture was poured into water and extracted with ether. The ether layer was washed with water and dried ($MgSO_4$). It was then evaporated giving 190 mg of yellow oil. Chromatography on neutral alumina (benzene) gave several fractions, one of which crystallized 3 months later. The product (89 mg, 18%) was pale yellow m.p. 62–63° (ether–petroleum (60–80°)), λ_{max} 314 nm (ε 15 100); p.m.r. ($CDCl_3$) τ 2.22 (s, 1H), 2.85 (m, 1H), 3.18 (m, 1H), 3.58 (m, 1H), 5.70 (m, 4H), 8.68 (m, 6H).

Anal. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37. Found: C, 60.56; H, 6.29.

The Conformational Enthalpy, Entropy, and Free Energy of The Formyl Group Determined by Low Temperature Proton Magnetic Resonance

G. W. BUCHANAN AND A. R. MCCARVILLE
Department of Chemistry, Carleton University, Ottawa, Canada

Received January 7, 1972

The low temperature proton n.m.r. peak area method has been applied to the formyl proton of cyclohexanecarboxaldehyde. The conformational enthalpy and entropy of the CHO group have been measured for the first time. The results indicate that the axial conformation has the higher entropy and $-\Delta G^0$ for the CHO function is about 0.8 kcal/mol.

La méthode de la surface des pics par r.m.n. à basse température a été appliquée au proton formyle du cyclohexanecarboxaldéhyde. L'enthalpie et l'entropie conformationnelle du groupe CHO ont été mesurées pour la première fois. Les résultats indiquent que la conformation axiale possède l'entropie la plus élevée et que $-\Delta G^0$ pour la fonction CHO est environ de 0.8 kcal/mol.

Canadian Journal of Chemistry, **50**, 1965 (1972)

Introduction

Considerable discrepancy exists between the published results for the conformational energy ($-\Delta G^0$) of the formyl group. Based on room temperature ^{1}H n.m.r. chemical shifts and couplings for the aldehyde proton of cyclohexanecarboxaldehyde and its *cis*- and *trans*-4-*t*-butyl derivatives, a value of 1.35 kcal/mol has been obtained (1, 2). A subsequent report by Eliel *et al.* gives a range of 0.56 to 0.78 kcal/mol as determined from equilibration experiments (3).

The n.m.r. procedure employing model compounds contains the inherent assumption that the 4-*t*-butyl group does not affect appreciably the properties of the axial and equatorial formyl groups respectively. In other substituted cyclohexanes, this method has been shown to be sometimes inaccurate for C-1 methine ring protons (4). No doubt similar perturbations exist for exocyclic protons although they are spatially further from the *t*-butyl group. This factor may be particularly important in these aldehydes, where the chemical shift difference between formyl protons in the *cis*- and *trans*-4-*t*-butylcyclohexyl compounds is only *ca.* 0.1 p.p.m.

The formyl group is not ideally suited for equilibration studies. Under some of the conditions employed in the previous work, condensation reactions occur and some doubt is cast on the assumption that true equilibrium was attained (3).

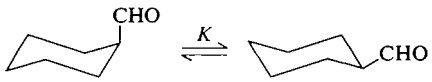
the methods, it is desirable to determine the conformational preferences of the CHO group by a more direct procedure. The low temperature n.m.r. peak area method offers this alternative. When ring inversion is slow on the n.m.r. time scale, integration of peak areas under non-saturating radiofrequency conditions allows determination of the equilibrium constant K directly.



Extensive work has been done on other monosubstituted cyclohexanes using the C-1 methine proton for this purpose (5, 6). In cyclohexanecarboxaldehyde the C-1 methine proton shift is not sufficiently different from that of other ring protons to permit such a study. It is possible, however, to employ the aldehyde proton and the present report is believed to be the first case in which protons on exocyclic carbons have been utilized in this way. From the temperature dependence of the equilibrium constant, estimates of the enthalpy difference, ΔH^0, and the entropy difference, ΔS^0, between axial and equatorial formyl groups have been obtained for the first time. The equilibrium has been studied in four representative solvent media.

Results and Discussion

Figure 1 shows the temperature dependence of the formyl proton resonance of cyclohexanecarboxaldehyde in solvent CD_2Cl_2. The axial and equatorial formyl proton resonances are clearly separated below -85 °C. The chemical shift difference observed (*ca.* 0.1 p.p.m.) is similar to that between the *cis*- and *trans*-4-*t*-butylcyclohexanecarboxaldehydes, with the axial formyl proton appearing at lower field. From examination of the spectra it can be seen that the equilibrium constant K increases as the temperature decreases. In solvents CD_2Cl_2, CS_2, and THF–MeOD, K was measured over a temperature range of about 30 °C. Such a study was prevented by viscosity broadening in toluene-d_8 below $-95°$. Accordingly we report only a free energy difference at low temperature for the formyl group in this medium.

A typical plot of ln K *vs.* $1/T$ is illustrated in Fig. 2 for the formyl group in CD_2Cl_2 solution. Computer analysis of the data via an unweighted least squares procedure gives a slope, $-\Delta H^0/R$, of 483.59 and an intercept, $\Delta S^0/R$, of -0.39. Multiplication by the constant R yields $-\Delta H^0 = 0.96$ kcal/mol and $\Delta S^0 = -0.77$ cal/deg mol. From these data, the conformational free energy of the formyl group at 25 °C can be calculated using the equation $\Delta G^0 = \Delta H^0 - T\Delta S^0$, and the results are summarized in Table 1. In toluene-d_8, the equilibrium constant at -93 °C is 8.8 ± 0.3 and the conformational energy is thus obtained using the equation $-\Delta G^0 = RT \ln K$. Errors quoted are standard deviations.

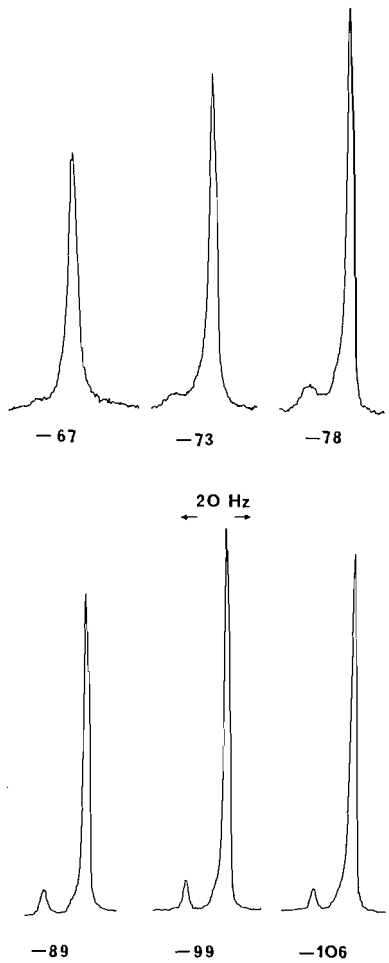


FIG. 1. Temperature dependence of the formyl proton resonance of cyclohexanecarboxaldehyde in CD_2Cl_2.

Clearly the precision of these measurements does not allow distinction between small differential solvent effects. These results suggest, however, that no dramatic solvent effects are opera-

C_7D_8			0.77±0.04*

*Value for −93 °C.

tive, in agreement with the earlier work (1–3). The two striking features, however, emerge from the data. Firstly, it is apparent that the formyl group has a negative conformation entropy in these three media. In general, one would predict that an equatorial substituent would have a larger number of populated rotamers than an axial one and would have, therefore, the higher entropy (7). Experimentally it has been found for related groups that equatorial $COOCH_3$, $COOC_2H_5$, and $COCH_3$ do indeed have higher entropies than their axial counterparts (8). In contrast, axial COO^-, COOH, and COCl groups are found to have substantially larger entropies (0.6 – 0.9 cal/deg mol) than the respective equatorial functions. It has been suggested that solvation and self-association are responsible for the latter findings (8). The more accessible equatorial isomer should be more strongly associated (or solvated) than its more sterically hindered axial counterpart. This restricted translational motion will cause a decrease in the entropy of the equatorial form. Presumably this rationale is correct for COO^- and COOH, but the situation is less clear for the COCl and now the CHO moieties.

The second important feature of the data concerns the observed free energy differences, which are smaller by *ca.* 0.5 kcal/mol than the values obtained using the *cis*- and *trans*-4-*t*-butylcyclohexanecarboxaldehydes as models for pure axial and equatorial CHO groups respectively. The present results are in reasonable accord with those obtained via equilibration, although the precision of the equilibration measurements was not reported (3). Since the present work involves no assumptions, we re-

gard the values presented in Table 1 as accurately representing the conformational thermodynamic parameters of the formyl group.

Experimental

Cyclohexanecarboxaldehyde was purchased from Frinton Laboratories, South Vineland, New Jersey. Degassed 0.2 *M* solutions were employed.

Spectra were recorded with a Varian XL-100-12 n.m.r. spectrometer equipped with a variable temperature probe. The temperatures were calibrated using a dummy n.m.r. tube containing a copper–constantan thermocouple and are believed to be accurate to ± 2 °C.

To ensure that non-saturating radiofrequency conditions were employed, spectra were initially recorded at widely different r.f. powers, and the relative peak areas were measured. Final conditions were then chosen where the slope of the relative peak area *vs.* r.f. power graph was zero. Integration of the areas under the peaks was done by the cutting and weighing procedure. Each value represents an average of six determinations at a given temperature.

Least squares analysis of the data was carried out with the aid of an XDS SIGMA 6 computer. Errors in $-\Delta G^0$ were calculated from the equation $\Delta\Delta G^0 = \Delta\Delta H^0 + T\Delta\Delta S^0 + \Delta T\Delta S^0$. Contributions from the last term are negligibly small since ΔT is ± 2 °C.

The standard deviations in the equilibrium constants measured at low temperature are depicted in Fig. 2. The computer program calculated the deviations in the slopes and the intercepts by standard statistical methods (9).

Received January 19, 1972

A new alkaloid ($C_{30}H_{42}N_2O_3S$), isolated from *Nuphar luteum*, is shown to be neothiobinupharidine sulfoxide. The mass spectra of neothiobinupharidine and the new alkaloid are discussed.

Un nouvel alcaloïde ($C_{30}H_{42}N_2O_3S$), isolé a partir du *Nuphar luteum*, s'est avéré être le néothiobinupharidine sulfoxyde. Les spectres de masse du néothiobinupharidine et du nouvel alcaloïde sont discutés.

Canadian Journal of Chemistry, **50**, 1968 (1972)

Several sulfur-containing alkaloids of Nuphar species have been described but for only one of them, neothiobinupharidine (**1**) has the structure and relative configuration been completely resolved. Neothiobinupharidine was isolated and studied in Poland (1) and some years later its structure was elucidated by X-ray analysis (2). An isomer of **1**, thiobinupharidine (3, 4), is also known. Recently, two alkaloids related in structure to **1** have been reported (5). The two alkaloids are bis-carbinolamines that on reduction give dideoxy compounds, isomeric with one

gard the values presented in Table 1 as accurately representing the conformational thermodynamic parameters of the formyl group.

Experimental

Cyclohexanecarboxaldehyde was purchased from Frinton Laboratories, South Vineland, New Jersey. Degassed 0.2 *M* solutions were employed.

Spectra were recorded with a Varian XL-100-12 n.m.r. spectrometer equipped with a variable temperature probe. The temperatures were calibrated using a dummy n.m.r. tube containing a copper–constantan thermocouple and are believed to be accurate to ± 2 °C.

To ensure that non-saturating radiofrequency conditions were employed, spectra were initially recorded at widely different r.f. powers, and the relative peak areas were measured. Final conditions were then chosen where the slope of the relative peak area *vs.* r.f. power graph was zero. Integration of the areas under the peaks was done by the cutting and weighing procedure. Each value represents an average of six determinations at a given temperature.

Least squares analysis of the data was carried out with the aid of an XDS SIGMA 6 computer. Errors in $-\Delta G^0$ were calculated from the equation $\Delta\Delta G^0 = \Delta\Delta H^0 + T\Delta\Delta S^0 + \Delta T\Delta S^0$. Contributions from the last term are negligibly small since ΔT is ± 2 °C.

The standard deviations in the equilibrium constants measured at low temperature are depicted in Fig. 2. The computer program calculated the deviations in the slopes and the intercepts by standard statistical methods (9).

We thank the National Research Council of Canada for financial support of this work.

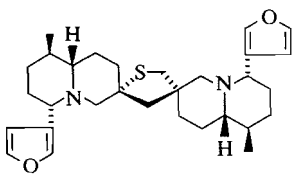
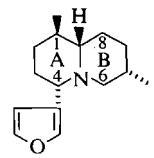
another and with neothiobinupharidine. Here we report the isolation and structure of a new sulfur alkaloid, **2**, $C_{30}H_{42}N_2O_3S$. Since only small quantities of the compound were available for structural study, physical methods, particularly mass spectrometry, was used to deduce the structure. Chemical methods were then used to confirm it.

The mass spectra of **1** and **2** were examined and compared. An earlier report of the mass spectrum of **1** appeared before its structure was established (6) and it is appropriate, therefore, to reexamine and reinterpret its spectrum in the light of the revised structure and to compare it with that of deoxynupharidine, **3** (6, 7). In the earlier report it was recognized that many of the ions present in the spectrum of deoxynupharidine were also prominent in the spectrum of **1** indicating that both alkaloids had structural features in common despite the disparity in their molecular weights.

In the high mass region of the spectrum of **1** there are peaks of low intensity corresponding to the loss of CH_3, C_2H_5, and C_3H_7 from the molecular ion just as there are in the spectrum of deoxynupharidine. Ions at *m/e* 461 and 447,



1 Neothiobinupharidine



3 Deoxynupharidine

which have no counterparts in the spectrum of **3**, owe their origin to the loss of SH and CH_2SH, respectively, from the molecular ion. An ion at *m/e* 359 formed by loss of $C_9H_{11}O$ from the molecular ion may be represented as in Scheme 1. The analogous ion in **3** appears at *m/e* 98. If hydrogen transfer does not occur and the charge remains with the furan moiety an ion at *m/e* 136 results of the same mass and composition as in the spectrum of **3**.

In the low and medium mass region the spectrum shows ions at *m/e* 230, 178, 107, and 94 besides that at *m/e* 136 already discussed. The ions at *m/e* 94 and 107 are also found in **3** and can be formed in this system in a similar way. The ions at *m/e* 230 and 178, however, deserve

m/e 359, $C_{21}H_{31}N_2OS$

SCHEME 1

further comment. The former, of composition $C_{15}H_{20}NO$, can be formulated and derived as shown in Scheme 2. If a hydrogen is transferred to the sulfur-containing fragment and charge is retained on this fragment one can account for the ion observed at *m/e* 264, ($C_{15}H_{22}NOS$) which is of low intensity compared to *m/e* 230. The most intense ion of the spectrum is found at *m/e* 178 corresponding in composition to $C_{11}H_{16}NO$. A proposal for its derivation is found in Scheme 3. Charge is also carried by the residual fragment, for a peak of low intensity is also present at *m/e* 316 ($C_{19}H_{26}NOS$). An ion of *m/e* 178 is present in **3** but its intensity is

SCHEME 3

relatively weak. The quaternary center present in **1** may be responsible for promoting fission in ring B thereby leading to the formation of this ion.

In their study of the reduction products of the thionuphlutines, Lalonde *et al.* (5) came to the same conclusion regarding the derivation of the ions at *m/e* 178 and 230.

The mass spectrum of the new alkaloid **2** shows losses of SOH and CH_3SO from the molecular ion at *m/e* 461 and 447 paralleling the losses of SH and CH_2SH from neothiobinupharidine. The spectrum shows an intense peak at *m/e* 493 corresponding to the loss of OH, a transformation supported by the presence of a metastable peak. Sulfoxides are known to lose OH from the molecular ion (8) and this fact coupled with the evidence that the oxygen is lost with sulfur on electron impact suggested that the alkaloid was a sulfoxide.

The rest of the spectrum of **2** is similar to that of neothiobinupharidine. Thus, the peaks at *m/e* 230, 178, 136, 107, and 94 are all present and have compositions identical with those found in the spectrum of **1**. Ions of low intensity are also present at *m/e* 280 ($C_{15}H_{22}NO_2S$), 262 (280-H_2O), 375 ($C_{21}H_{31}N_2O_2S$), and 357 (375-H_2O). The *m/e* 280 ion is cognate to *m/e* 230 while *m/e* 375 is cognate to *m/e* 136-H. Thus the mass spectral evidence indicates that the new alkaloid is a sulfoxide of a compound related in structure to neothiobinupharidine.

Chemical studies have confirmed that the new alkaloid is neothiobinupharidine sulfoxide for it has been both prepared from and converted to **1**. The configuration at sulfur has not been established, however, by these studies.

When **1** was treated with H_2O_2 in glacial acetic acid it yielded a compound identical with the natural base **2**. Their identity was established by comparison of their i.r., p.m.r., and mass spectra, their melting points, and a mixture melting point determination. The i.r. spectrum showed a band at 1020 cm^{-1} which is just below the region reported for sulfoxides (9) but considerably above that reported for *N*-oxides (10). An *N*-oxide structure is unlikely on the basis of the mass spectral evidence. The mass spectrum of deoxynupharidine is very different from its *N*-oxide, nupharidine (7), whereas the spectra of **1** and **2** are similar. Compound **2** is remarkably stable to reducing agents which argues further against its being an *N*-oxide. For example it is recovered unchanged after treatment with Zn in acetic acid, sulfur dioxide in aqueous solution, and sodium borohydride in alcohol. Nupharidine is converted, however, to deoxynupharidine with aqueous SO_2.

The natural base yielded **1** upon treatment with phosphorus trichloride in ethyl acetate, a reagent known to convert sulfoxides to sulfides (11). Thus, there seems little doubt that the new compound is a sulfoxide. It is the first representative of its class among the sulfur-containing

$C_{30}H_{42}N_2O_3S$

Experimental

Apparatus, Methods, and Materials

Mass spectra were determined on a C.E.C. 21-110B double-focusing mass spectrometer. Samples were introduced through a direct inlet system. The high resolution mass spectra (h.r.m.s.) were recorded on Ilford Q-2 photographic plates, which were developed in the usual manner. The spectra were then recorded on magnetic tape, using a Gaertner comparator-densitometer linked to a Datex system. They were processed on a CDC-6400 computer using a modified version of the HIRES program of Tunnicliff and Wadsworth (12). The composition of all ions discussed in this paper was established by high resolution measurements and agreed with calculated values within the limits, ±5 milli mass units.

A Perkin–Elmer 337 grating i.r. spectrometer was used to record i.r. spectra.

Melting points were determined on a Kofler hot stage and are uncorrected.

Isolation of Neothiobinupharidine Sulfoxide

The crude bases extracted from the rhizomes of *N. luteum* were adsorbed on neutral alumina (activity III) and the column eluted progressively with benzene, ether, chloroform, and methanol. The chloroform fraction was rechromatographed on a cellulose column using a citrate–acetate buffer of p*H* 4 and 1-butanol.[1] The sulfoxide, after separation from other bases, was recrystallized from methanol–acetone yielding colorless crystals melting at 240–242°.

Anal. Calcd. for $C_{30}H_{42}N_2O_3S$ (mol. wt. 510.291): C, 70.6; H, 8.2; N, 5.5. Found (510.286 (h.r.m.s.)): C, 70.2; H, 8.3; N, 5.3.

Mass spectrum (relative intensities in brackets): 511(5), 510(15), 495(10), 494(30), 493(66), 492(3), 461(2), 447(3), 375(1), 357(5), 280(1), 262(4), 231(20), 230(100), 179(4), 178(24), 136(5), 107(15), 94(31).

[1]Full details of the isolation procedure will be published elsewhere.

Oxidation of Neothiobinupharidine

A solution of neothiobinupharidine (110 mg) in glacial acetic acid (4 ml) was treated with 30% hydrogen peroxide (54 mg) at 20° for 1.5 h. The mixture was poured into water (20 ml), made alkaline with potassium hydroxide, and extracted repeatedly with benzene. Evaporation of the benzene gave a colorless oil which showed three spots on t.l.c. The mixture was separated by chromatography on alumina (25 g). The column was eluted successively with benzene–chloroform (9:1), followed by benzene–chloroform (1:1). The first solvent system gave neothiobinupharidine (22 mg) and the second gave first an oil (20 mg), not further investigated, and then a crystalline fraction (70 mg), m.p. 240–242°, identical with natural neothiobinupharidine sulfoxide.

Treatment of Neothiobinupharidine Sulfoxide with Phosphorus Trichloride

A solution of **2** (4 mg) in ethyl acetate (4 ml) was treated with PCl_3 (3–4 drops) and the mixture heated under reflux for 15 min, poured into water (5 ml), and made alkaline with aqueous KOH. The organic layer was separated and evaporated, and the crystalline residue obtained proved to be identical with an authentic sample of neothiobinupharidine.

Les équilibres solide–liquide dans des systèmes binaires formiate d'alcalin-formiate d'alcalino-terreux

G. BERCHIESI, A. CINGOLANI, D. LEONESI ET G. PIANTONI

Istituto Chimico dell'Università, 62032 Camerino (MC), Italy

Reçu le 8 novembre, 1971

Les températures d'équilibre entre la phase liquide et la phase solide des systèmes binaires $(HCOOMe)_2 + (HCOO)_2Me'$ (Me = Na, K, Tl; Me' = Mg, Ca, Sr, Ba) ont été déterminées. Les déviations de la courbe idéale $T = \Delta H_{fus}/(\Delta S_{fus} - R \ln x)$ ont été interprétées sur la base de l'effet de polarisation des cations.

The liquid–solid equilibrium temperatures of the $(HCOOMe)_2 + (HCOO)_2Me'$ (where Me = Na, K, Tl; Me' = Mg, Ca, Sr, Ba) binary systems were determined. The deviations from the ideal curve $T = \Delta H_{fus}/(\Delta S_{fus} - R \ln x)$ are explained by the polarization effect of the ions.

Introduction

Les formiates de Mg, Ca, Sr, Ba sont notoirement thermolabiles, mais les mélanges avec les formiates de Na, K, Tl ont montré une bonne stabilité jusqu'à des concentration de $(HCOO)_2$-Me, Me = Mg, Ca, Sr, Ba, supérieures à la concentration de mélange eutectique.

Nous avons mesuré les températures de première cristallisation des mélanges binaires des formiates de Na, K, et Tl avec les formiates de Mg, Ca, Sr, et Ba dans l'intervalle de concentration dans lequel la stabilité thermique permettait une bonne reproductibilité des mesures. Seul le système $(HCOONa)_2 + (HCOO)_2Mg$ n'a pas été étudié, à cause de la grande instabilité dans tout l'intervalle de concentration. La méthode expérimentale employée est largement décrite dans des notes publiées precédemment (1, 2). Les produits employés sont: HCOONa, HCOOK, et $(HCOO)_2Ca$, C. Erba R.P., HCOO-Tl, BDH, et $(HCOO)_2$ Mg, $(HCOO)_2Sr$, $(HCO-O)_2Ba$, K & K, dont le degré de pureté était au minimum de 99%.

Résultats et discussion

Les courbes d'équilibre entre la phase liquide et la phase solide, pour les 11 systèmes étudiés, sont représentées à la Fig. 1, et les coordonnées des points invariants sont données au Tableau 1.

Si les deux composants ont une solubilité négligeable à l'état solide et si la solution est idéale, les propriétés thermodynamiques de fusion ΔH et ΔS, fixent la température de fusion d'un mélange selon la formule

$$[1] \qquad T = \frac{\Delta H_{fus\,i}}{\Delta S_{fus\,i} - R \ln x_i}$$

où $\Delta H_{fus\,i}$ et $\Delta S_{fus\,i}$ représentent l'enthalpie et l'entropie molaires de fusion du corps pour i à la température T_i, et x_i la fraction molaire des corps i, qui pour tous les systèmes est représentée par une ligne continue; ΔH_{fus} et ΔS_{fus} relatifs aux formiates de Na, K, et Tl sont connus (3–5). ΔH_{fus} est connu à une précision de 2% et T_{fus} à une précision de 1%.

Comme on peut le remarquer, les systèmes binaires $(HCOOK, Na)_2 + (HCOO)_2Me$, Me = Mg, Ca, Sr, Ba s'écartent négativement de l'idéalité. Il est donc bien probable que ces mélanges binaires ne forment pas de cristaux mixtes. Au contraire les systèmes $(HCOOTl)_2 + (HCOO)_2Me$, Me = Ca, Sr, Ba s'écartent assez peu de l'idéalité et de façon positive tandis que le système $(HCOOTl)_2 + (HCOO)_2Mg$ montre un minimum de température de fusion et non un eutectique à cause de la formation probable de cristaux mixtes.

Pour les systèmes contenant les formiates de sodium et de potassium on a cherché une équation $T_{observée} = (\Delta H_{fus\,i} + A)/(\Delta S_{fus\,i} - R \ln x_i)$ pour les mélanges riches en formiate de Na ou K, où A est un terme correctif qui rend compte de la déviation négative de ces systèmes (3, 4). La dépendence de A (qui est toujours négatif) de la fraction molaire est répresentée sur la Fig. 2. Dans les systèmes $(HCOONa)_2 + (HCOO)_2Me$,

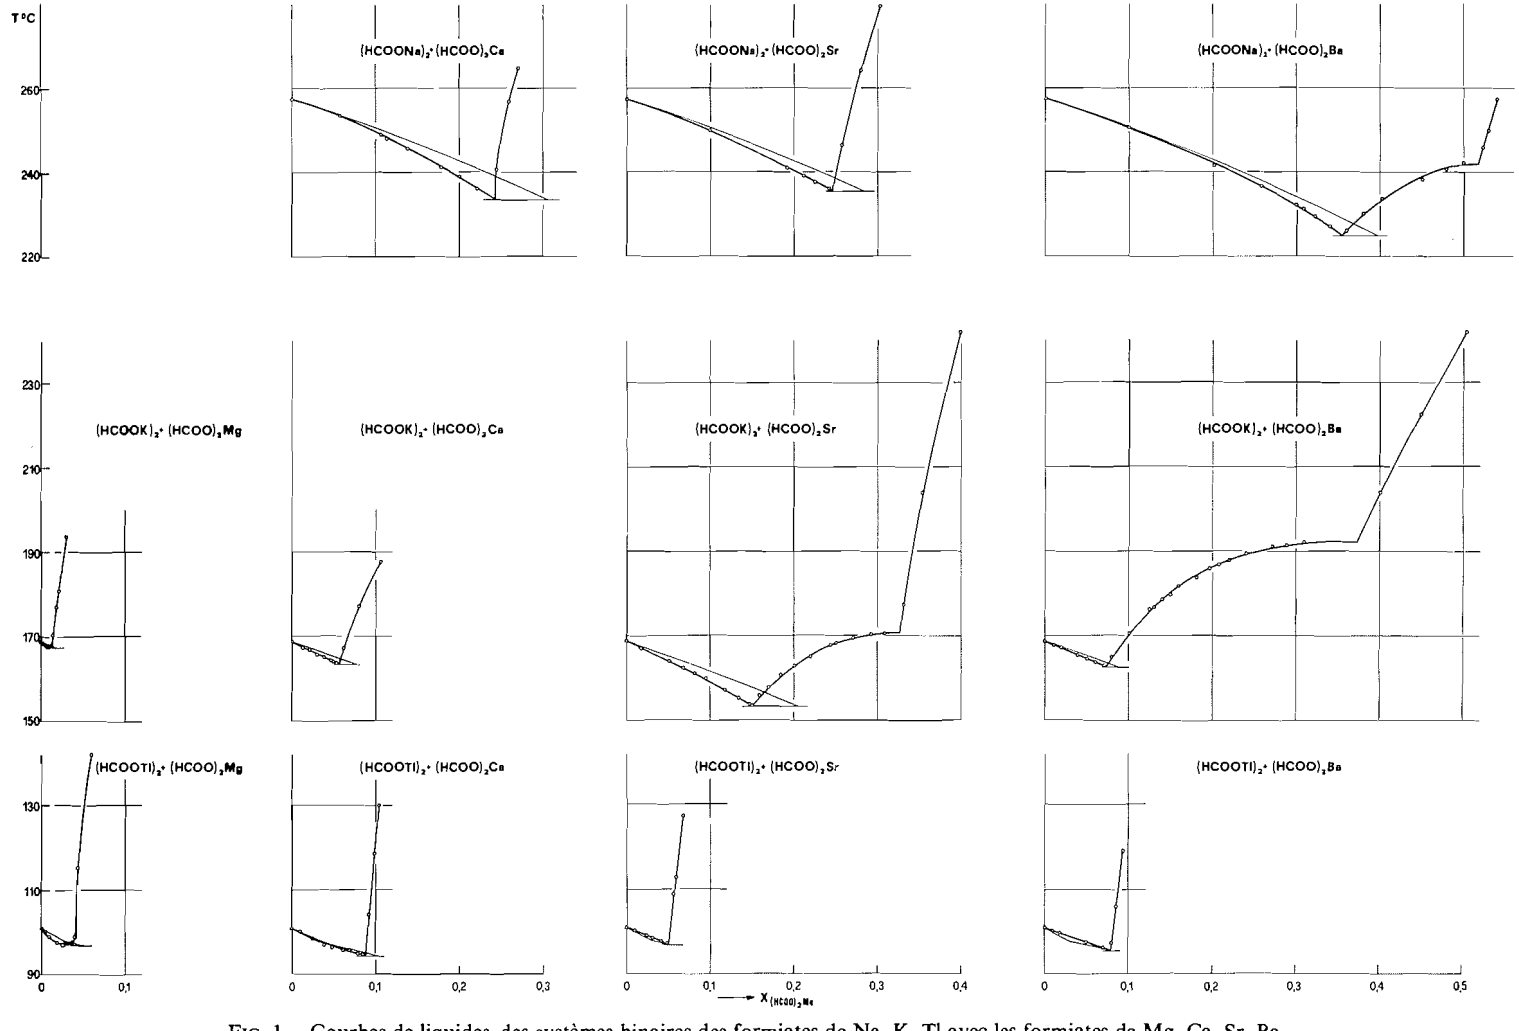

FIG. 1. Courbes de liquides des systèmes binaires des formiates de Na, K, Tl avec les formiates de Mg, Ca, Sr, Ba.

TABLEAU 1. Température de cristallisation et composition des mélanges eutectiques et péritectiques

	Paramètre	Valeur $(HCOOK)_2$	$(HCOONa)_2$	$(HCOOTl)_2$	
$(HCOO)_2Mg$	T	167.4		97.0	
	$X_{(HCOO)_2Mg}$	0.013		0.030	minimum
$(HCOO)_2Ca$	T	163.2	233.4	94.2	
	$X_{(HCOO)_2Ca}$	0.057	0.243	0.088	
$(HCOO)_2Sr$	T_{Eut}	153.2	235.4	96.8	
	$x_{(HCOO)_2Sr}$	0.150	0.246	0.051	
	T_{Per}	170.8			
	$X_{(HCOO)_2Sr}$	0.327			
$(HCOO)_2Ba$	T_{Eut}	162.6	224.8	95.4	
	$X_{(HCOO)_2Ba}$	0.074	0.354	0.079	
	T_{Per}	192.2	242.0		
	$X_{(HCOO)_2Ba}$	0.373	0.518		

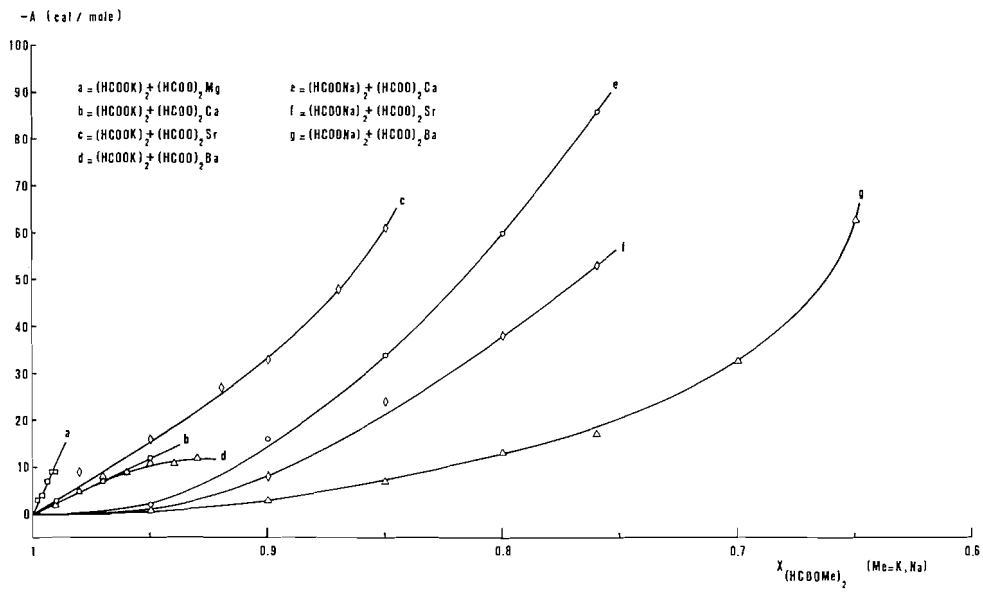

FIG. 2. Facteur correctif A, rélatif aux formiates de sodium et de potassium.

Me = Ca, Sr, Ba le terme de non idéalité A est plus petit que dans les systèmes $(HCOOK)_2 + (HCOO)_2Me$, Me = Mg, Ca, Sr, Ba. En effet, les ions sodium, plus petits que les ions potassium, ont une plus grande intensité de champ électrique et sont, en conséquence, plus polarisants que les ions potassium. A cause de la différence de pouvoir polarisant plus grande pour le couple K^+–Me^{2+} que pour le couple Na^+–Me^{2+} (6), le terme A est plus important dans les systèmes contenant le formiate de potassium que ceux contenant le formiate de sodium. Pour la même raison dans la série de systèmes $(HCOONa)_2 + (HCOO)_2Me$, Me = Ca, Sr, Ba,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A (en valeur absolue) diminue dans le sens Ca, Sr, Ba.

Dans les systèmes $(HCOOK)_2 + (HCOO)_2$-Me, Me = Mg, Ca, Sr, Ba, on a observé encore cette regularité sauf une exception: en effet A rélatif au système $(HCOOK)_2 + (HCOO)_2Ca$ est intermédiaire entre ceux rélatifs aux systèmes $(HCOOK)_2 + (HCOO)_2Sr$ et $(HCOOK)_2 + (HCOO)_2Ba$. Dans d'autres classes de systèmes (7, 8), une relation entre la composition eutectique et le rayon ionique avait été remarquée. Dans ces familles, cette régularité $X_{Eut} \propto r_{Me^{2+}}$ n'a pas été remarquée.

The ^{13}C-n.m.r. spectrum of tropolone has been obtained and it clearly shows that there is a rapid tautomeric equilibrium at room temperature. The peaks have been tentatively assigned using calculated π charge densities and nuclear Overhauser enhancements.

Le spectre r.m.n. du ^{13}C du tropolone a été obtenu; celui-ci indique clairement qu'à la température de la pièce, il se fait un équilibre tautomérique rapide. Les pics ont été provisoirement attribués en se servant des densités de charge π calculées et de l'exaltation de l'effet nucléaire Overhauser.

Canadian Journal of Chemistry, **50**, 1975 (1972)

Recently there has been a great upsurge of interest in ^{13}C-n.m.r. spectroscopy (1). To date ^{13}C-n.m.r. has been utilized in many ways similar to ^{1}H-n.m.r.; for example, use of chemical shifts, coupling constants, and partial decoupling in structural assignments, heteronuclear decoupling, and the use of shift reagents (2) have been applied successfully in both cases. Anet *et al.* have recently used ^{13}C-n.m.r. to study a conformational equilibrium and they were able to freeze out the two conformers of methylcyclohexane at low temperature (3). We would like to report the use of ^{13}C-n.m.r. for studying systems in which there is an equilibrium between two tautomeric forms and to show the useful simplification of these problems by ^{13}C-n.m.r. The ^{1}H-n.m.r. spectrum of tropolone (**1**) has been recorded and even at 100 MHz the spectrum contains over 20 lines (4). The computer analysis of this spectrum does fit an AA'BB'C system and this indicated that there is a rapid equilibrium between two tautomers, reaction 1. The electron diffraction data on

[1] 
1

tropolone are consistent with a symmetric structure (5). The barrier to interconversion of the two tautomers must be low since it could not be frozen out in the n.m.r. spectrum and also in light of the electron diffraction results.

The proton-decoupled ^{13}C-n.m.r. spectrum of tropolone is shown in Fig. 1. This spectrum consists of only four singlets (*cf.* ^{1}H-n.m.r. spectrum

A (en valeur absolue) diminue dans le sens Ca, Sr, Ba.

Dans les systèmes $(HCOOK)_2 + (HCOO)_2$-Me, Me = Mg, Ca, Sr, Ba, on a observé encore cette regularité sauf une exception: en effet A rélatif au système $(HCOOK)_2 + (HCOO)_2Ca$ est intermédiaire entre ceux rélatifs aux systèmes $(HCOOK)_2 + (HCOO)_2Sr$ et $(HCOOK)_2 + (HCOO)_2Ba$. Dans d'autres classes de systèmes (7, 8), une relation entre la composition eutectique et le rayon ionique avait été remarquée. Dans ces familles, cette régularité $X_{Eut} \propto r_{Me^{2+}}$ n'a pas été remarquée.

‡Average of charge densities from ref. 6 (*vide infra*).

of over 20 lines), and the shifts and assignments are given in Table 1. The assignments for the C-2,3,5 and 6 resonances are based on the calculated π charge densities (6). These calculations are for one of the tautomers in the equilibrium hence the charges given in the table are the average of the calculated values for the tautomerically related carbons. There is a good correlation between the observed ^{13}C chemical shifts and the calculated π charge densities; this is shown in Fig. 2. One might expect even better agreement when calculations including the σ electrons are used.

Note that there is a solvent effect on the relative chemical shifts in Table 1. The three high field singlets have a relative intensity ratio of 2:1:2 which indicated a similar nuclear Overhauser enhancement for carbons 2–6. The relative intensity of the low field singlet is *ca.* 1.3 indicating a much lower nuclear Overhauser enhancement which is in accord with the assignment of this signal to a carbon which is not directly connected to a proton. Clearly the simplicity of the ^{13}C-n.m.r. spectrum compared to the very complex ^{1}H-n.m.r. spectrum shows another advantage of ^{13}C-n.m.r. in studying problems of this type.

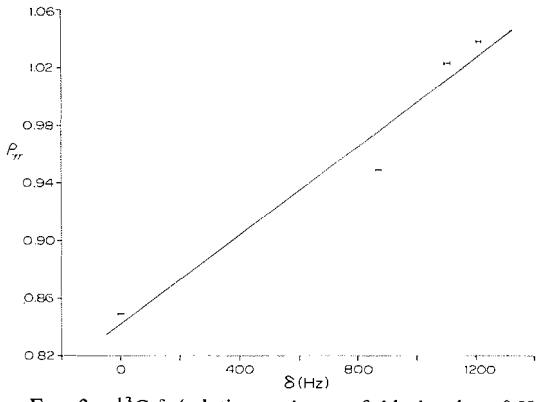

FIG. 2. ^{13}C-δ (relative to lowest field signal at 0 Hz) *vs.* π-electron charge density (ρ).

Experimental

The ^{13}C-n.m.r. spectra were recorded on a Varian XL-100 spectrometer using $CDCl_3$ or C_2D_6 as internal lock and 15 mm diameter n.m.r. tubes. The spectra were obtained using single scan at 2500 MHz sweep width. The n.m.r. solutions contained 1 g of tropolone in 5 ml of solvent.

The tropolone was recrystallized several times from petroleum ether to give white needles, m.p. 49.5–50.5°.

I am grateful to Roland Burton for running the ^{13}C-n.m.r. spectra and to the National Research Council of Canada and the University of British Columbia for financial support.

Vapor–Liquid Equilibria of Cyclohexane–*cis*-Decalin Mixtures at 25 °C[1]

TOMÁS BOUBLÍK

Institute of Chemical Process Fundamentals, Czechoslovak Academy of Science, Prague, Czechoslovakia

AND

G. C. BENSON

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received January 7, 1972

Vapor–liquid equilibria of cyclohexane–*cis*-decalin mixtures were determined at 25 °C in a circulation still. Excess Gibbs free energies derived from the experimental results are in reasonable agreement with values calculated from the theory of Flory.

Les équilibres vapeur–liquide de divers mélanges cyclohexane–*cis*-décaline furent déterminés a 25 °C dans un ébuillioscope à circulation. Les énergies libres d'excès de Gibbs, dérivant des résultats expérimentaux, sont en assez bon accord avec les valeurs calculées selon la théorie de Flory.

Canadian Journal of Chemistry, **50**, 1978 (1972)

This note reports results for the vapor–liquid equilibria of cyclohexane–*cis*-decalin mixtures at 25 °C. The work is an extension of a previous investigation (1) in which enthalpies and volumes of mixing were studied.

The component materials were cyclohexane (Lachema) which had been rectified in a 60-plate column, and *cis*-decalin (Fluka) which had been purified chromatographically. Values of their refractive indices measured at 20 °C and of their vapor pressures determined ebulliometrically at 25 °C, are compared with data from the literature (2, 3) in Table 1.

The design and operation of the still used for studying the vapor–liquid equilibria has been described previously (4). Values of the equilibrium pressure were obtained from measurements of the temperature of a water ebullioscope connected to the same manostat as the still. Estimates of the error in the values of the pressure vary from 0.02 mm Hg at low pressures to 0.05 mm Hg at the highest pressure encountered. Compositions of the equilibrium liquid and condensed vapor phases were obtained from measurements of their refractive indices using the relation

$$[1]\quad n_D^{20}(x_1) = 1.42622x_1 + 1.48100(1 - x_1) + x_1(1 - x_1)[0.02230 - 0.00629(1 - 2x_1) - 0.00077(1 - 2x_1)^2]$$

where x_1 is the mole fraction of cyclohexane. This equation represents the results for a series of mixtures of known composition with a standard error of estimate of 0.00004. The corresponding error in the estimate of the mole fraction from eq. 1 varies from 0.0004 to 0.0010 depending on the value of the mole fraction.

Experimental results obtained for the vapor–liquid equilibria of cyclohexane(1)–*cis*-decalin(2) mixtures, when the still was operated at a head temperature of 25.00 ± 0.01 °C, are summarized in Table 2. There, p is the total pressure; x_1 and y_1 are the mole fractions of cyclohexane in the liquid and vapor phases, respectively. No results are given for mixtures dilute in cyclohexane since it was impossible to obtain reproducible equilibria for $x_1 < 0.35$.

The activity coefficients of the components in the liquid phase are related to the vapor–liquid equilibria by the equation

$$[2]\quad \ln \gamma_i = \ln (y_i p/x_i p_i^0) + [(B_{ii} - V_i^0)(p - p_i^0) + (2B_{12} - B_{11} - B_{22})(1 - y_i)^2 p]/RT$$

where p_i^0 and V_i^0 are the vapor pressures and molar volumes of the pure components. The quantities B_{ij} are the second virial coefficients describing the deviation of the vapor phase from ideality. For cyclohexane at 25 °C, $B_{11} = -1650$ cm^3 mol^{-1} (5); values of $B_{22} = -8320$ and $B_{12} = -3510$ cm^3 mol^{-1} were estimated from an empirical correlation (6).

The molar excess Gibbs free energy of the

mixture can be calculated from

$$[3] \qquad G^E = RT(x_1 \ln \gamma_1 + x_2 \ln \gamma_2)$$

if values of the activity coefficients are available. However, eq. 2 is unsuitable for the direct evaluation of $\ln \gamma_2$ from the present experimental results, since the values of y_2 are small and are subject to relatively large errors. In order to obtain values of the excess Gibbs free energy from the vapor–liquid equilibria, it was assumed that the concentration dependence of G^E could be represented by the form

$$[4] \qquad G^E = x_1 x_2 \sum_{r=1}^{n} c_r (1 - 2x_1)^{r-1}$$

It follows from eq. 4 that

$$[5] \quad \ln \gamma_1 = (x_2^2/RT) \sum_{r=1}^{n} c_r (1 - 2rx_1)(1 - 2x_1)^{r-2}$$

Values of the coefficients c_r were determined by a weighted least squares calculation in which eq. 5 was fitted to values of $\ln \gamma_1$ obtained from eq. 2. This calculation led to the representation

$$[6] \quad G^E/\text{J mol}^{-1} = x_1 x_2 [163.2 + 53.8(1 - 2x_1)]$$

with a standard error of estimate equal to 6.5 J mol^{-1}. The values of the coefficients were not altered significantly by the use of other reasonable estimates for the virial coefficients B_{22} and B_{12}. Furthermore, a statistical analysis indicated that the use of more than 2 coefficients was unjustifiable. Adopting eq. 6, the values of y_1 and p were computed at the experimental values of x_1. Differences between the observed and calculated vapor phase compositions are given in the fourth column of Table 2; in most cases, these are of the same order as the uncertainty in y_1. Differences between observed and calculated total pressures are listed in the last column of the table; the average deviation of the pressures is somewhat larger than the estimated experimental error.

A plot of G^E, calculated from eq. 6, is given in Fig. 1. It can be seen from the latter that at 25 °C G^E is positive for all mole fractions. At higher temperatures (from 80 to 120 °C) the work of Dutta (7) indicates that the curves for G^E have a sigmoid shape and vary in a rather complicated way with temperature.

Previously (1), we used the theory of Flory (8)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

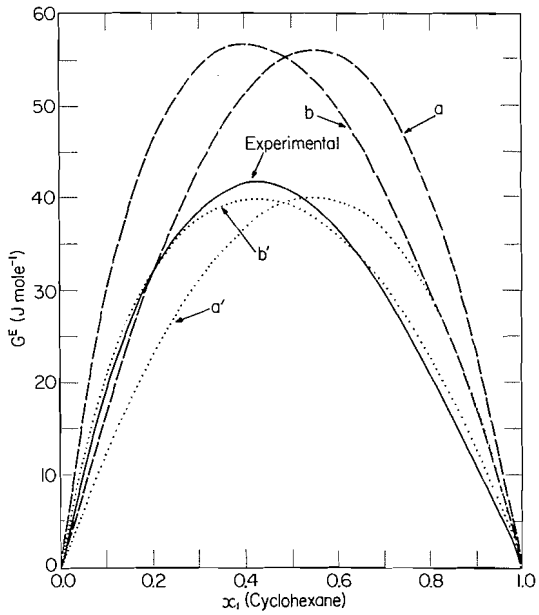

FIG. 1. Molar excess Gibbs free energy at 25 °C. Solid curve represents the experimental results. Broken and dotted curves were calculated from the theory of Flory using the following values of the parameters. Curve a: $s_1/s_2 = 1.147$, $X_{12} = 2.365$ J cm^{-3}, $Q_{12} = 0$. Curve b: $s_1/s_2 = 4.60$, $X_{12} = 5.351$ J cm^{-3}, $Q_{12} = 0$. Curve a': $s_1/s_2 = 1.147$, $X_{12} = 2.365$ J cm^{-3}, $Q_{12} = 2.19 \times 10^{-3}$ J cm^{-3} K^{-1}. Curve b': $s_1/s_2 = 4.60$, $X_{12} = 5.351$ J cm^{-3}, $Q_{12} = 5.06 \times 10^{-3}$ J cm^{-3} K^{-1}.

to correlate the excess enthalpies and volumes of cyclohexane–*cis*-decalin mixtures. Two calculations, (*a*) and (*b*), were described. In both of these, the energy parameter, X_{12}, was adjusted by the method of least squares to give the best fit between theoretical and experimental values of the excess enthalpy. In calculation (*a*), the ratio of the numbers of intermolecular contact sites, s_1/s_2, was estimated from the hard core molecular volumes of the two species; in (*b*), it was treated as a further adjustable parameter.

It is interesting to extend the calculations outlined above to estimate the excess free energy. In Fig. 1, the two broken curves marked *a* and *b* were computed from formulae given by Flory (8) and correspond to calculations (*a*) and (*b*), respectively. The numerical values used for the characteristic temperatures, pressures, and volumes were taken from ref. 1, and a polymer-type combinatorial term (8) was assumed. Both calculations lead to nearly the same maximum value of G^E (~ 56 J mol^{-1}). This is larger than the experimental result (~ 43 J mol^{-1}), but the discrepancy is only twice the standard error of estimate of the latter. Curve *b* reproduces the asymmetry of the experimental curve more closely than does curve *a*. This finding is in agreement with the better fit of the excess enthalpy obtained in calculation (*b*) (see ref. 1).

Orwoll and Flory (9) have added to the formula for G^E, an empirical term which allows for the fact that interactions between neighboring species may contribute to the entropy of mixing as well as to the enthalpy. The term, as formulated, contains another adjustable parameter Q_{12}.

Our calculations described so far correspond to setting Q_{12} equal to zero in the augmented formula for G^E. However, the theoretical estimates of G^E for both calculations can be brought into better agreement with the experimental results by using non-zero values of Q_{12}, as illustrated by the curves marked a' and b' in Fig. 1. The standard deviations of these curves from the experimental curve are 6.0 and 1.4 J mol^{-1}, respectively, for curves a' and b'.

Introduction

Photolysis of di-*tert*-butyl peroxide (BOOB) in oxygen-saturated alkanes (RH) has been used to prepare alkylperoxy radicals (ROO·) *in situ* in the sample cavity of an e.s.r. spectrometer (1). These radicals are generated by the following reaction sequence

$$[1] \qquad BOOB \xrightarrow{h\nu} 2BO^{\cdot}$$

$$[2] \qquad BO^{\cdot} + RH \longrightarrow BOH + R^{\cdot}$$

$$[3] \qquad R^{\cdot} + O_2 \longrightarrow ROO^{\cdot}$$

Monitoring the variation of the radical signal with time after interruption of the initiating light enables absolute termination rate constants, $2k_t$, for tertiary and secondary peroxy radicals to be measured (1).

$$[4] \qquad ROO^{\cdot} + ROO^{\cdot} \xrightarrow{2k_t} \text{Molecular products}$$

Photolysis of BOOB in air-saturated cyclopropane does not give detectable concentrations of cyclopropylperoxy radicals (2). Bennett and Summers (2) have, however, made the very interesting observation that when irradiation of this reaction is interrupted at 140 °K, a stable single line spectrum grows and is destroyed immediately upon re-photolysis. This spectrum was attributed to the *tert*-butylperoxy radical.

In this note we report the preparation of the *tert*-butylperoxy radical specifically labelled with ^{17}O on the terminal oxygen by photolysis of BOOB in perdeuterocyclopentane in the presence of ^{17}O enriched oxygen.

[1]NRCC No. 12564.

Experimental

Perdeuterocyclopentane (Merck, Sharpe and Dohme of Canada, Ltd.) was trap-to-trap distilled before use. Enriched oxygen (47% ^{17}O) was obtained from Yeda Inc., Israel. Di-*tert*-butyl peroxide was distilled and percolated through basic alumina to remove any adventitious hydroperoxidic impurity. Cyclopropane and Freon 11 were used as inert solvents to obtain liquid phase spectra at temperatures below the melting point of cyclopentane.

Electron spin resonance spectra were recorded on a Varian E-3 spectrometer at temperatures between 183 and 143 °K. The sample temperature was altered with a V-4557 variable temperature accessory. To improve spectra resolution solutions were degassed several times using the freeze (77 °K)–thaw (173 °K) technique. This is possible for the *tert*-butylperoxy radical because it does not decay irreversibly at 173 °K.

Results and Discussion

Photolysis of BOOB in air-saturated perdeuterocyclopentane at 183 °K generates perdeuterocyclopentylperoxy radicals by reactions 1 to 3. When the initiating light is interrupted these radicals decay *immediately* with a bimolecular decay constant of $\sim 3 \times 10^5\ M^{-1}\ s^{-1}$. Warming up to room temperature a reaction mixture that has been through the reaction sequence 1 to 4 generates a substantial concentration (*ca.* $10^{-5}\ M$) of *tert*-butylperoxy radicals. This radical is relatively easy to characterize by e.s.r. spectroscopy. It has a single line spectrum, a *g*-value of 2.0146 and is almost completely stable at 183 °K. No other radicals with these characteristics could possibly be generated by photolysis of BOOB, perdeuterocyclopentane and oxygen.

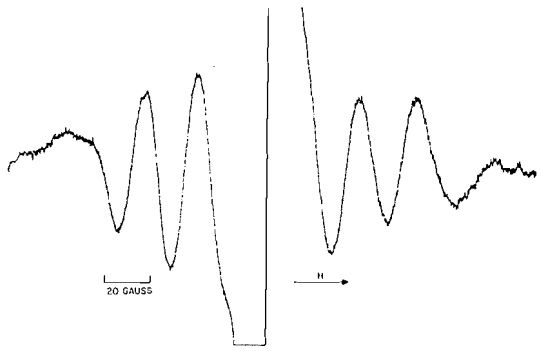

FIG. 1. Electron spin resonance spectrum of $B^{16}O^{16}O^{\cdot}$ and $B^{16}O^{17}O^{\cdot}$ in Freon 11 at 163 °K.

When this reaction is performed in the presence of ^{17}O enriched oxygen the *tert*-butylperoxy radical specifically labelled on the terminal oxygen with ^{17}O, $B^{16}O^{17}O^{\cdot}$, is produced. The e.s.r. spectrum of this species is given in Fig. 1.

There have been several recent reports of e.s.r. spectra of peroxy radicals enriched with ^{17}O (3–6). These spectra contain contributions from $R^{16}O^{17}O^{\cdot}$, $R^{17}O^{16}O^{\cdot}$, and $R^{16}O^{16}O^{\cdot}$ (where R is an alkyl group, F or CF_3O) which results in rather poor resolution of the ^{17}O hyperfine lines. Two ^{17}O hyperfine coupling constants have been determined, $|a'_O| = 22.17$ to 23.0 G and $|a''_O| = 14.5$ to 18.0 G and consequently the two O atoms are not equivalent. Because of the similarity of the values of the two coupling constants it has not been possible to assign positively the constants to the two positions. Adamic, Ingold, and Morton (6), however, deduced from their study of ^{17}O enriched *tert*-alkylperoxy radicals that $R^{16}O^{17}O^{\cdot}$ has the larger hyperfine interaction.

Only four of the six ^{17}O hyperfine lines of $B^{16}O^{17}O^{\cdot}$ are well resolved because the other two lines are obscured by the zero spin line. Within experimental error the widths of the 4 resolvable hyperfine lines in $B^{16}O^{17}O^{\cdot}$ are 12 G. The spectrum is slightly asymmetric with respect to position of the ^{17}O lines, the low field 5/2 line is 59.0 G down field from the zero spin line while the high field 5/2 line is 58.2 G up field from the zero spin line. The hyperfine splitting constant $|a_O| = 23.45 \pm 0.10$ G $(0.2 \times 117.2$ G) and is very similar to Adamic, Ingold, and Morton's corrected value[2] of $|a'_O| = 24.0$ G and Fessenden and Schuler's (3, 4) value of $|a'_O| = 23.0$ G for the peroxy radical produced by irradiation of 2,2,4-trimethylpentane containing ^{17}O enriched oxygen.

We can, therefore, conclude with certainty from this work that the larger ^{17}O hyperfine splitting obtained previously (3–6) from ^{17}O enriched peroxy radicals is produced by the $R^{16}O^{17}O^{\cdot}$ species and that the smaller hyperfine splitting is produced by the $R^{17}O^{16}O^{\cdot}$ species.

Bennett and Summers (2) have suggested that *tert*-butylperoxy radicals are formed when photolysis of BOOB in air-saturated cyclopropane is ceased, by decomposition of an unsymmetric trioxide, BOOOR. This trioxide can be produced by combination of a *tert*-butoxy radical, formed in the initiation step, and a *sec*-alkylperoxy radical derived from either cyclopropane or a trace hydrocarbon impurity.

[5] $$BO^{\cdot} + ROO^{\cdot} \rightleftharpoons BOOOR$$

BOOOR can decompose to the original radicals or it can decompose to give a *tert*-butylperoxy radical and an alkoxy radical, $RO^{\cdot}$,

[6] $$BOOOR \rightarrow BOO^{\cdot} + RO^{\cdot}$$

Bennett and Summers also observed a further production of *tert*-butylperoxy radicals at 200 °K which they attributed to the decomposition of di-*tert*-butyl trioxide (7), BOOOB, formed at low temperatures by the reaction

$$BO^{\cdot} + BOO^{\cdot} \rightarrow BOOOB$$

The production of $B^{16}O^{17}O^{\cdot}$ from photolysis of a mixture of perdeuterocyclopentane, BOOB and ^{17}O enriched oxygen confirms that trioxides are indeed formed during photolysis at low temperatures. This is because a specifically labelled radical can only be formed by the reaction sequence

[1] $$BOOB \xrightarrow{h\nu} 2BO^{\cdot}$$

[2] $$BO^{\cdot} + RH \longrightarrow BOH + R^{\cdot}$$

[3] $$R^{\cdot} + O_2 \text{ (enriched)} \longrightarrow R^{16}O^{16}O^{\cdot},\ R^{17}O^{17}O^{\cdot},\ R^{16}O^{17}O^{\cdot},\ R^{17}O^{16}O^{\cdot}$$

[2]The hyperfine splittings reported by Adamic, Ingold, and Morton (6) are low by ~10% because of an error in the sweep of the magnetic field.

$$[5]\quad \left.\begin{matrix} R^{16}O^{16}O^{\cdot} \\ R^{17}O^{17}O^{\cdot} \\ R^{16}O^{17}O^{\cdot} \\ R^{17}O^{16}O^{\cdot} \end{matrix}\right\} + BO^{\cdot} \longrightarrow \left\{\begin{matrix} R^{16}O^{16}O^{16}OB \\ R^{17}O^{17}O^{16}OB \\ R^{16}O^{17}O^{16}OB \\ R^{17}O^{16}O^{16}OB \end{matrix}\right.$$

$$[6]\quad \begin{matrix} R^{16}O^{16}O^{16}OB \longrightarrow R^{16}O^{\cdot} + B^{16}O^{16}O^{\cdot} \\ R^{17}O^{17}O^{16}OB \longrightarrow R^{17}O^{\cdot} + B^{16}O^{17}O^{\cdot} \\ R^{16}O^{17}O^{16}OB \longrightarrow R^{16}O^{\cdot} + B^{16}O^{17}O^{\cdot} \\ R^{17}O^{16}O^{16}OB \longrightarrow R^{17}O^{\cdot} + B^{16}O^{16}O^{\cdot} \end{matrix}$$

The yield of trioxide and hence the yield of $BOO^{\cdot}$ will of course depend on the strength of the labile hydrogen in RH. If it is too weak all the $BO^{\cdot}$ radicals will react with RH while if it is too strong $BO^{\cdot}$ will not react with RH. In either case a trioxide will not be formed.

The author thanks Dr. J. R. Morton for measuring the magnetic fields and the microwave frequency.

Received March 14, 1972

The photocycloaddition of β-substituted styrenes (*trans*-cinnamic acid (**1***b*), methyl *trans*-cinnamate (**1***c*), *trans*-cinnamonitrile (**1***d*), and *cis*-cinnamonitrile) to olefins occurs with retention of stereochemistry and involves the S_1 state. In certain cases (**1***b*, *c*) a photoene reaction competes with the cycloaddition. The triplet states of the β-substituted styrenes produced by sensitization give only *cis* ⇄ *trans* isomerization. Neither cycloadduct nor photoene reaction is observed from the triplet states. It is thus likely that both addition and photoene reactions involve the S_1 state of the β-substituted styrene.

La photocycloaddition des styrènes β substitués (acide *trans* cinnamique (**1***b*), cinnamate de méthyle *trans* (**1***c*), cinnamonitrile *trans* (**1***d*), et cinnamonitrile *cis*) aux oléfines se fait avec rétention de stéréochimie et passe par l'état S_1. Dans certains cas (**1***b*, *c*) la réaction photoène entre en compétition avec la cycloaddition. Les états triplets des styrènes substitués obtenus par sensibilisation, ne conduisent qu'à l'isomérisation *cis* ⇄ *trans*. La cycloaddition ainsi que la réaction photoène n'ont pas été observées à partir des états triplets. Il est donc probable que la réaction photoène et l'addition passent toutes deux par l'état S_1 du styrène β substitué.

Canadian Journal of Chemistry, **50**, 1984 (1972)

The mechanism of the photocycloaddition of *trans*-stilbene to tetramethylethylene involves reversible reaction of S_1 *trans*-stilbene with ground state tetramethylethylene giving an exciplex which demotes to the adduct with retention of the *trans*-stereochemistry (1). We now report that photocycloaddition of other β-substituted styrenes (**1***b–d*) occurs with retention

of stereochemistry and involves the S_1 state. In certain cases (**1***b*, *c*) a photoene reaction competes with the cycloaddition. The triplet states of the *β*-substituted styrenes produced by sensitization give only *cis* ⇄ *trans* isomerization. Neither cycloadduct nor photoene reaction is observed from the triplet states. It is thus likely that both addition and photoene reactions involve the S_1 state of the *β*-substituted styrene.[5]

Irradiation of benzene solutions of *trans*-stilbene (**1***a*), *trans*-cinnamic acid (**1***b*), methyl *trans*-cinnamate (**1***c*), and *trans*-cinnamonitrile (**1***d*) in the presence of tetramethylethylene give in each case an adduct (**2**) in which the *trans*-stereochemistry is maintained.[6] The corresponding *cis*-*β*-substituted styrenes, with the exception of *cis*-cinnamonitrile, do not add to tetramethylethylene sufficiently rapidly to compete effectively with *cis* → *trans* isomerization. Irradiation of *cis*-cinnamonitrile in the presence of tetramethylethylene gives an adduct in which the phenyl and nitrile groups are *cis*. Both *trans*- and *cis*-cinnamonitrile give linear $1/\Phi_{add}$ *vs.* 1/[olefins] plots. Irradiation of solutions of either nitrile and sensitizers (benzophenone, 2-acetylnaphthalene)[7] gives only *cis* ⇄ *trans* isomerization. The cycloaddition of these S_1 *β*-substituted styrenes is stereospecific with respect to the excited enophile.

Irradiation of *trans*-stilbene in the presence of *cis*-2-butene gives a single adduct which shows two methyl resonances in the n.m.r. spectrum.[8] In similar fashion, *trans*-stilbene in the presence of *trans*-2-butene gives a single, different adduct in which the n.m.r. spectrum shows equivalent methyl groups.[8] These photocycloadditions clearly occur with retention of stereochemistry on both the excited (S_1) enophile and the ground state olefin.

In the irradiation of *trans*-cinnamic acid and methyl *trans*-cinnamate in the presence of tetramethylethylene a second product was obtained in addition to the cycloadduct (**2**). The additional product in each was shown to be the terminal olefin expected from a photoene reaction to which we tentatively assign structure **3***b*, *c*. The ratio of cycloadduct to photoene product in neat tetramethylethylene was **2***c*/**3***c* = 1.5 and in benzene **2***b*/**3***b* = 5 and **2***c*/**3***c* = 1.6. In the other cases studied (**1***a* and *d*) photoene products were not observed. Polar solvents favored the photocycloaddition to a small extent (**2***c*/**3***c* = 3.2 in ethanol and 3.4 in acetic acid). The ratio of cycloadduct to photoene was insensitive to variation in light intensity. In the

[5]The fact that the triplet states do not give either the adduct or the photoene is consistent with reaction via either S_1 or vibrationally excited S_0. Rapid thermal equilibration of vibrationally excited species in solution makes reaction of an S_0 state unlikely. Furthermore, it has been shown that cycloaddition of *trans*-stilbene involves the S_1 state (1).

[6]Irradiations were carried out with a 450 W Hanovia medium pressure mercury vapor lamp through a Pyrex filter. The adducts all gave satisfactory element analyses and spectra consistent with the cyclobutane adduct structures (**3***b*–*d*). Saponification of the adduct from methyl *trans*-cinnamate gave the adduct (m.p. 129–130°) from *trans*-cinnamic acid. This adduct was converted by methyl lithium to the corresponding methyl ketone. The ketone did not epimerize under conditions which led to exchange of four protons for deuterium and hence must have the thermodynamically more stable *trans* arrangement of phenyl and acetyl groups. Oxidation of the methyl ketone gave the adduct from *trans*-cinnamic acid which thus must have *trans* phenyl and carboxyl groups. The adduct from *trans*-cinnamic acid was converted via the amide to the nitrile which was identical to the adduct obtained from *trans*-cinnamonitrile.

[7]The irradiation of solutions of 2-acetylnaphthalene with methyl cinnamate under these conditions leads to the adduct described previously (2).

[8]The adduct from *cis*-2-butene shows n.m.r. bands at *δ* 7.25 (10H, aromatic protons), 3.2–4.0 (2H, benzyl methine protons), 2.2–2.9 (2H, m, methine protons), 1.15 (3H, d, methyl protons), and 0.80 (3H, d, methyl protons). The adduct from *trans*-2-butene shows n.m.r. bands at *δ* 7.20 (10H, aromatic protons), 4.10 (2H, m, benzyl methine protons), 2.1–2.5 (2H, m, methine protons), and 0.95 (6H, d, methyl protons).

3 7 6

sensitized reactions neither cycloadduct nor photoene was observed. Heating methyl *trans*-cinnamate with tetramethylethylene at 200° for 24 h gave no detectable reaction.

The tentative structural assignment (**3***b*, *c*) for the photoenes rests primarily on the n.m.r. spectrum. The alternative structure **6** has not been rigorously excluded. The n.m.r. spectrum of the photoene (m.p. 114.5–115.5°) from *trans*-cinnamic acid shows non-equivalent methyl groups (δ 0.82 and 0.95), a vinyl methyl group (δ 1.78), and ABX pattern for the methylene and methine protons (AB centered at δ 2.51, X at 3.21), terminal methylene protons (δ 4.72), aromatic protons (5, δ 7.33), and a carboxyl proton (δ 11.25). The mixture of esters (**2***c* and **3***c*) from methyl *trans*-cinnamate is difficult to separate, but hydrolysis of the mixture and repeated crystallizations from heptane gave the acids **2***b* (25%) and **3***b*(7%). Catalytic reduction of the mixture of esters and v.p.c. separation gave **7***c*.

The demonstration that singlet addition of β-substituted styrenes to tetramethylethylene is a general phenomenon, the demonstration that the photocycloaddition of S_1 *trans*-stilbene to tetramethylethylene proceeds via an exciplex (1), and the demonstration that these photocycloadditions are stereospecific on both the excited enophile and the ground state olefin place stringent limits on the mechanisms which can be considered. The most probable mechanism is concerted decay of an exciplex to the adduct. If an intermediate such as a singlet 1,4-biradical is formed, the lifetime of this intermediate must be short with respect to the reciprocal of the rate constant for rotation about a single bond. This seems unlikely in view of the known behavior of singlet 1,4-biradicals (3, 4). It may be that unsymmetrically substituted olefins or olefins with radical stabilizing substituents will favor formation of long-lived biradicals. Studies directed to this point are in progress.

The stereospecificity of the addition of singlet excited styrenes to olefins together with the observed retention of stereochemistry in the dimerization of the isomeric 2-butenes upon direct irradiation (5) suggests that singlet cycloaddition may provide a useful tool for stereospecific synthesis of complex molecules.

Coupling of Amino Acids and Amino Sugars with Cyanuric Chloride (2,4,6-Trichloro-*s*-triazine)[1]

A. S. CHAUDHARI[2] AND C. T. BISHOP

Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received January 5, 1972

2,4,6-Trichloro-*s*-triazine (cyanuric chloride) has been used to couple glycine ethyl ester with seven carbohydrate derivatives that contain amino groups. The reactions proceed in high yield under mild conditions. The compounds serve as models for the coupling of carbohydrates to proteins by well-defined linkages through amino groups.

La 2,4,6-trichloro-*s*-triazine (chlorure cyanurique) a été utilisée pour coupler l'ester éthylique de la glycine avec sept dérivés de carbohydrates contenant des groupes amines. Les réactions se font avec d'excellent rendement et sous des conditions douces. Les composés sont utilisés en tant que modèles pour les couplages de carbohydrates avec des protéines au moyen de liaisons bien définies par l'intermédiaire de groupes amines.

Canadian Journal of Chemistry, **50**, 1987 (1972)

A recent preliminary communication (1) described the preparation of an antigenic polysaccharide–protein conjugate by the use of 2,4,6-trichloro-*s*-triazine (cyanuric chloride) as a coupling reagent. Gel electrophoresis and the production of antibody to the carbohydrate moiety showed that the polysaccharide and the protein were covalently linked. The linkage must have occurred through hydroxyl groups in the nitrogen-free polysaccharide and amino groups in the protein, but the extent and location of the cross-linkages were not determined. In the absence of amino groups in the polysaccharide, the cyanuric chloride must have reacted with hydroxyl groups at random. These factors are not important for the simple preparation of polysaccharide antigens. However, the introduction of specific determinant groups into a peptide or protein requires conjugates in which linkages are more closely defined. The present paper describes the preparation of some model compounds representing carbohydrate–protein conjugates in which the linkages are well-characterized.

[1]NRCC No. 12561.

[2]NRCC Postdoctorate Fellow, 1970–1972.

It is known that replacement of one chlorine atom in 2,4,6-trichloro-*s*-triazine by an amino, or substituted amino, group deactivates the remaining two so that stepwise reactions can be obtained by temperature control (2–5). However, the deactivating effects of alkoxy- or aryloxy-groups are weaker and the reaction of chlorotriazines with hydroxylated compounds yields mixtures from which it is difficult to isolate and characterize any product (4). This observation was confirmed during the present work by unsuccessful attempts to isolate characterizable products from the reaction of 2,4,6-trichloro-*s*-triazine with 2,3,4,6-tetra-*O*-acetyl-β-D-glucose or with methyl α-D-glucopyranoside. Furthermore, it has been established that 2,4,6-trichloro-*s*-triazine reacts preferentially with amino groups when both amino groups and hydroxyl groups are present in the same substrate molecule (4, 5).

From these results it was clear that successive replacement of two chlorine atoms from 2,4,6-trichloro-*s*-triazine by amino substituents offered the best possibilities for preparing well-defined, carbohydrate–protein conjugates. As there are several ways to introduce amino groups into

SCHEME 1

carbohydrates the method should be of general applicability.

The coupling of amino acids and amino sugars with cyanuric chloride according to Scheme 1, can be achieved in two ways by using either the amino sugar or the amino acid derivative in the first step, *i.e.* the introduction of NHR_1. Thus, replacement at 0 °C of one of the chlorine atoms of cyanuric chloride by the amino groups of glucosamine and galactosamine gave compounds **5** and **6** respectively. Further reaction of these compounds at 45 °C with glycine ethyl ester gave the disubstituted products **8** and **9**. The same compounds could also be prepared by the initial reaction of cyanuric chloride with the amino acid derivative to give compound **1**, and subsequent reaction of this at 45 °C with the amino sugars to give compounds **8** and **9**. Overall yields of these compounds were better by the latter route, probably because of the ease with which compound **1** can be made in high yield.

Compounds **2**, **3**, and **7** were prepared with the intention of having amino or hydroxyl groups available for subsequent reaction with acetobromo sugars. However, the difficulty with which these compounds (**2**, **3** and **7**) dissolve in organic solvents precluded attempts to extend the reaction sequence in that direction.

The 1-amino-1-deoxy alditols (NHR_2 on compounds **11**, **12**, and **13**) were prepared by the method of Kagan *et al.* (6) in which *N*-benzyl aminitols were formed by the reductive alkylation of benzylamine with the appropriate sugar. The *N*-benzyl-1-amino-1-deoxy-alditols were then hydrogenolyzed to the 1-amino-1-deoxy alditols which, on reaction with compound **1** yielded compounds **11**, **12**, and **13**. The *N*-benzyl-1-amino-1-deoxy-D-mannitol that was prepared for this series of reactions does not seem to have been reported previously; it was therefore characterized further as a crystalline acetate. The 2-amino-2-deoxy-D-glucose diethyldithioacetal was prepared by methods described (7); condensation of this derivative with compound **1** gave compound **14**. The other starting compounds were available commercially and were used without further purification.

The structures of these compounds follow from the method of synthesis because it is known that 2,4,6-trichloro-*s*-triazine or a monosubstituted dichloro-*s*-triazine reacts preferen-

tially with the amino group of hydroxylamines (4, 5). However, some of the compounds were examined in further detail to confirm that this generalization held for the carbohydrate derivatives used in the present study.

The structure of compound **1** was confirmed by the analysis that showed two atoms of chlorine remaining in the molecule and by n.m.r. spectroscopy that accounted for all of the protons as follows: N—H (singlet; one proton; δ, 7.2), C—CH_3 (triplet; three protons; δ, 1.32), 2 × CH_2 (quartet; four protons; δ, 4.30). Compound **4**, the disubstituted analogue of compound **1**, gave a similar n.m.r. spectrum with two nitrogen protons, eight methylene protons, and six C—methyl protons accounted for by integration.

With the structure of compound **1** established it was clear from the method of synthesis and from the chlorine analyses that the compounds of type B had to be disubstituted monochloro-*s*-triazine derivatives. The location of the linkage through the amino group in the carbohydrate moiety was confirmed for **8** and **14** as representative examples of these compounds. Thus, the n.m.r. spectrum of **14** showed nine C—CH_3 protons (δ, 1.3), five C—H protons (δ, 2.5–2.8), four OH protons (δ, 3.77), ten CH_2 protons (δ, 4.0–4.5), and two NH protons (δ, 7.2). The presence of four hydroxyl groups showed that the linkage must have been through the amino group of the diethyldithioacetal. Acetylation of **8** and **14** introduced four *O*-acetyl groups into each of them as determined by analysis and by the ratio of *C*-methyl to acetyl protons in the n.m.r. spectra. The method of acetyl analysis (8) and the absence of any absorption at 1618–1665 cm^{-1} in the i.r. established that all of the acetyl groups were *O*-acetyl and that no *N*-acetyls were present. These results prove that all of the hydroxyl groups in **8** and **14** were free and that the linkages were through the amino groups of the carbohydrate moieties. Compounds **8**, **9**, and **10**, were probably anomeric mixtures and it is likely that they were in the pyranose ring form.

The present results show that cyanuric chloride (2,4,6-trichloro-*s*-triazine) can be used for the selective coupling of compounds that contain amino groups. The reaction takes place preferentially with amino groups and any hydroxyl groups present need not be blocked. The condensations proceed in high yield (66–88%) and under mild conditions that makes the method amenable for use with sensitive compounds. In particular, this method of coupling would seem to offer an attractive alternative to diazotization (9–11) for introduction of determinant groups into peptides or proteins for use as artificial antigens or as immunoabsorbents.

Experimental

Solutions were evaporated under reduced pressure at bath temperatures not exceeding 40°. A Perkin–Elmer 140 polarimeter was used to measure optical rotations which are equilibrium values unless otherwise specified. Melting points were determined on a Fisher–Johns hot stage and are uncorrected. The t.l.c. was done on glass plates coated with silica gel G using the following solvent mixtures: (A) chloroform:ethanol, 3:1; (B) ethyl acetate:acetic acid:water, 9:2:2. Unless stated otherwise, compounds containing amino sugars were homogeneous by t.l.c. in both solvent systems. The u.v. spectra were recorded on aqueous solutions using a Cary Recording spectrophotometer. All of the compounds showed the same spectral characteristics due to the triazine absorption; λ_{max} 261 mμ, $\varepsilon = 3150 \rightarrow 3400$. The i.r. spectra were recorded with a Perkin–Elmer Infracord spectrophotometer using chloroform solutions of the compounds. The n.m.r. spectra were obtained in deuterochloroform solution using a Varian HA-60 spectrometer with tetramethylsilane as a standard.

*N-Benzyl-1-amino-1-deoxy-*D*-mannitol*

This compound does not seem to have been reported before. It was prepared in 76% yield by the method of Kagan *et al.* (5). The crystalline product, m.p. 162–163 °C, was recrystallized from methanol to a constant melting point of 164–165 °C; $[\alpha]_D^{22}$ +9.0° (*c*, 1.0 in water).

Anal. Calcd. for $C_{13}H_{21}O_5N$: C, 57.55; H, 7.80; N, 5.16. Found: C, 57.39; H, 7.90; N, 5.33.

*N-Benzyl-1-amino-1-deoxy-2,3,4,5,6-penta-O-acetyl-*D*-mannitol*

The *N*-benzyl-1-amino-1-deoxy-D-mannitol (1 g) was acetylated in acetic anhydride:pyridine (1:1, 20 ml) at room temperature. The product was recrystallized from ethanol: m.p. 76–77 °C, $[\alpha]_D^{22}$ +20° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{23}H_{31}O_{10}N_1$: C, 57.38; H, 6.44; N, 2.91. Found: C, 57.73; H, 6.73; N, 2.65.

2,4-Dichloro-6-(ethoxycarbonylmethylamino)-s-triazine (1)

Cyanuric chloride (2,4,6-trichloro-*s*-triazine) (5.3 g) was dissolved in hot acetone (10–12 ml) and poured into well-stirred ice water (20 ml). To this stirred solution was added a cold (0–5 °C) aqueous solution (20 ml) of glycine hydrochloride ethyl ester (4.0 g) and sodium bicarbonate (4.82 g). The mixture was stirred at 0 °C for 1 h. The white, crystalline product was filtered, washed with ice-cold water, and dried. The compound (85% yield) required no further purification because recrystallization from acetone did not change its properties: m.p. 85–86 °C.

Anal. Calcd. for $C_7H_8O_2N_4Cl_2$: C, 33.48; H, 3.21; N,

22.32; Cl, 28.24. Found: C, 33.20; H, 3.04; N, 22.10; Cl, 28.44.

2-Chloro-4-amino-6-(ethoxycarbonylmethylamino)-s-triazine (2)

Compound **1** (12 g) was dissolved in hot acetone (50 ml) and this solution was added with stirring to water (75 ml) through which ammonia gas was passed continuously. The temperature of the reaction was maintained at 45 °C. After 15–20 min the white, crystalline product was filtered off and dried; yield 10.2 g, 88%. Recrystallized from acetone: nitromethane (1:1), the product had m.p. 235–237 °C.

Anal. Calcd. for $C_7H_{10}O_2N_5Cl_1$: C, 36.28; H, 4.31; N, 30.23; Cl, 15.33. Found: C, 35.91; H, 4.57; N, 30.5; Cl, 15.18.

2-Chloro-4-(2-hydroxyethylamino)-6-(ethoxycarbonylmethylamino)-s-triazine (3)

Compound **1** (3 g) in hot acetone (20 ml) was added with stirring to water (10 ml) at 0–5 °C. A solution of ethanolamine (0.75 ml) in acetone (10 ml) was then added and the reaction mixture was allowed to warm up to room temperature (22 °C). An aqueous solution (5 ml) of sodium bicarbonate (1 g) was then added slowly to the stirred reaction mixture over a period of 30 min. The reaction was stirred at 45 °C for 1.5 h after which the product was filtered and dried; yield, 2.2 g, 85%. Recrystallized from acetone:ethanol (1:1), the compound had m.p. 197–199 °C.

Anal. Calcd. for $C_9H_{14}O_3N_5Cl$: C, 39.20; H, 5.08; N, 25.40; Cl, 12.88. Found: C, 39.08; H, 5.04; N, 25.18; Cl, 12.91.

6-Chloro-(2,4-di-ethoxycarbonylmethylamino)-s-triazine (4)

Cyanuric chloride (2,4,6-trichloro-*s*-triazine) (1.84 g) was condensed with glycine hydrochloride ethyl ester (2.8 g) in the presence of sodium bicarbonate (3.36 g) as described for compound **1** except that the temperature of the reaction was maintained at 45 °C instead of 0–5 °C. The disubstituted product which precipitated out in the reaction was filtered and dried; yield 2.3 g, 72%. When recrystallized from acetone it had m.p. 182–183 °C.

Anal. Calcd. for $C_{11}H_{16}O_4N_5Cl$: C, 41.58; H, 5.04; N, 22.04; Cl, 11.18. Found: C, 41.48; H, 5.08; N, 22.2; Cl, 11.27.

2-(2,4-Dichloro-s-triazin-6-yl)amino-2-deoxy-D-glucopyranose (5)

Cyanuric chloride (2,4,6-trichloro-*s*-triazine) (1.84 g) was condensed with 2-amino-2-deoxy-D-glucopyranose hydrochloride (2.16 g) in the presence of sodium bicarbonate (1.68 g) at 0–5 °C for 1.5 h as described for compound **1**. The solid product which precipitated out in the reaction was filtered, dried, and recrystallized from acetone; yield, 2.2 g, 67%; the compound decomposed with charring above 200 °C; $[\alpha]_D^{22}$ +45° (*c*, 1.4 in methanol).

Anal. Calcd. for $C_9H_{12}O_5N_4Cl_2$: C, 33.02; H, 3.67; N, 17.12; Cl, 21.71. Found: C, 32.60; H, 3.74; N, 17.50; Cl, 21.39.

2-(2,4-Dichloro-s-triazin-6-yl)amino-2-deoxy-D-galactopyranose (6)

The condensation of cyanuric chloride (2,4,6-trichloro-*s*-triazine) (0.925 g) and 2-amino-2-deoxy-D-galactopyranose hydrochloride (1.08 g) in the presence of sodium bicarbonate (0.84 g) was performed in the same way as for compound **5**. The product was recrystallized from acetone; yield, 1.03 g, 62%; the compound decomposed with charring above 200 °C; $[\alpha]_D^{22}$ +56.5° (*c*, 1.2 in methanol).

Anal. Calcd. for $C_9H_{12}O_5N_4Cl_2$: C, 33.02; H, 3.67; N, 17.12; Cl, 21.71. Found: C, 32.76; H, 3.44; N, 17.37; Cl, 21.42.

2,4-Dichloro-6-(2-hydroxyethylamino)-s-triazine (7)

Cyanuric chloride (2,4,6-trichloro-*s*-triazine) (1.84 g), ethanolamine (0.61 ml), and sodium bicarbonate (0.84 g) were stirred in acetone:water at 0–5 °C as described for compound **1**. The reaction mixture was clarified by filtration and the filtrate was evaporated leaving a solid residue. Recrystallization from methanol yielded compound **7**, 1.12 g, 53%; m.p. 113–115 °C.

Anal. Calcd. for $C_5H_6ON_4Cl_2$: C, 28.70; H, 2.86; N, 26.79; Cl, 33.97. Found: C, 28.84; H, 2.99; N, 26.64; Cl, 33.59.

2-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-2-deoxy-D-glucopyranose (8)

Compound **1** (3.23 g) in hot acetone (15 ml) and 2-amino-2-deoxy-D-glucopyranose hydrochloride (3.76 g) in water (10 ml) were added to well-stirred ice water at 0.5 °C. The temperature of the reaction mixture was allowed to rise to room temperature and then an aqueous solution (15 ml) of sodium bicarbonate (2.52 g) was added slowly over a period of 30 min. The reaction was stirred continuously for 1 h at 45 °C and was then clarified by filtration. The filtrate was evaporated to dryness and extracted with methanol. Evaporation of the methanol extract yielded compound **8** which was recrystallized from water, yield, 4.2 g, 71%; m.p. 125–127°; $[\alpha]_D^{22}$ +24° (*c*, 1.0 in ethanol).

Anal. Calcd. for $C_{13}H_{20}O_7N_5Cl$: C, 39.64; H, 5.08; N, 17.78; Cl, 9.02. Found: C, 39.46; H, 5.04; N, 17.66; Cl, 8.83.

2-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-2-deoxy-D-galactopyranose (9)

This compound was prepared from compound **1** (3 g), 2-amino-2-deoxy-D-galactopyranose hydrochloride (2.59 g), and sodium bicarbonate (2 g) as described for compound **8**. The product (4.8 g) was not homogeneous on t.l.c. and required purification by column chromatography on silica gel using solvent A; a large portion of the major product was lost due to overlap with the impurity. The purified compound, 2.5 g, 51%, was recrystallized from ethanol:water (1:1); m.p. 118-120 °C, $[\alpha]_D^{22}$ +25° (*c*, 1.0 in ethanol).

Anal. Calcd. for $C_{13}H_{20}O_7N_5Cl$: C, 39.64; H, 5.08; N, 17.78; Cl, 9.02. Found: C, 39.51; H, 5.01; N, 17.89; Cl, 8.92.

2-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-2-deoxy-D-mannopyranose (10)

Compound **1** (2.1 g), 2-amino-2-deoxy-D-mannopyranose hydrochloride (1.8 g), and sodium bicarbonate (1.4 g) were reacted as described for compound **8**. The reaction product (2.8 g) was purified on silica gel as for compound **9** to yield compound **10**, 2.4 g, 73%. Crystallized from ethanol this compound had m.p. 108–111 °C and $[\alpha]_D^{22}$ −2° (*c*, 1.0 in ethanol).

Anal. Calcd. for $C_{13}H_{20}O_7N_5Cl$: C, 39.64; H, 5.08; N, 17.78; Cl, 9.02. Found: C, 39.79; H, 5.14; N, 17.58; Cl, 8.88.

*1-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-1-deoxy-D-glucitol (**11**)*

Compound **1** (2.51 g) in acetone (15 ml) and 1-amino-1-deoxy-D-glucitol (6) (1.81 g) in water (12 ml) were mixed together with continuous stirring in a further 10 ml of water. An aqueous solution (10 ml) of sodium bicarbonate (0.84 g) was added slowly during 30 min. The reaction mixture was stirred at 45 °C for 1 h. The insoluble product was filtered and washed with cold water and cold acetone; yield, 2.5 g, 63%; m.p. 192–194 °C.; $[\alpha]_D^{22}$ −21° (*c*, 1.0 in ethanol:water (1:1)).

Anal. Calcd. for $C_{13}H_{22}O_7N_5Cl$: C, 39.44; H, 5.56; N, 17.69; Cl, 8.98. Found: C, 39.12; H, 5.84; N, 17.44; Cl, 9.4.

*1-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-1-deoxy-D-mannitol (**12**)*

Compound **1**, 1-amino-1-deoxy-D-mannitol, and sodium bicarbonate were reacted in the same quantities and under the same conditions as for compound **11**. However, in this instance the product was soluble so the reaction mixture was filtered and concentrated to a syrup which then crystallized. The crystalline product was filtered, washed with cold ethanol, and recrystallized from methanol; yield 2.68 g, 67%; m.p. 174–175 °C; $[\alpha]_D^{22}$ +15° (*c*, 1.2 in ethanol:water (1:1)).

Anal. Calcd. for $C_{13}H_{22}O_7N_5Cl$: C, 39.44; H, 5.56; N, 17.69; Cl, 8.98. Found: C, 39.41; H, 5.74; N, 17.69; Cl, 9.27.

*1-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-1-deoxy-D-galactitol (**13**)*

Compound **1** (2.51 g) in acetone (15 ml), 1-amino-1-deoxy-D-galactitol (6) (1.81 g) in water (15 ml), and sodium bicarbonate (0.84 g) in water (12 ml) were reacted as described for **11**. The reactants were dissolved by addition of ethanol (30–40 ml) and the solution was heated at 50° for 1.5 h. The solution was concentrated and the product crystallized when most of the acetone and ethanol had been removed. It was recrystallized from acetone:water (1:3); yield 3.1 g, 78%; m.p. 187–188 °C; $[\alpha]_D^{22}$ −18.5° (*c*, in ethanol:water (1:1)).

Anal. Calcd. for $C_{13}H_{22}O_7N_5Cl$: C, 39.44; H, 5.56; N, 17.69; Cl, 8.98. Found: C, 39.19; H, 5.68; N, 17.68; Cl, 8.81.

*2-(4-Chloro-2-ethoxycarbonylmethylamino-s-triazin-6-yl)-amino-2-deoxy-D-glucose Diethyl Dithioacetal (**14**)*

Compound **1** (3 g) in acetone (15 ml), 2-amino-2-deoxy-D-glucose diethyl dithioacetal hydrochloride (7) (3.8 g) in water (15 ml), and sodium bicarbonate (1 g) in water (10 ml) were reacted as described for compound **11**. The mixture was clarified by filtration and the filtrate was evaporated to dryness. The residue was extracted with ethanol and evaporation of the extract yielded a syrupy product that was purified by chromatography on silica gel in solvent A. The pure compound was crystallized from ether:light petroleum (1:1); yield, 3.5 g, 58%; m.p. 56–58 °C; $[\alpha]_D^{22}$ −25° (*c*, 1.0 in ethanol).

Anal. Calcd. for $C_{17}H_{30}O_6N_5ClS_2$: C, 40.84; H, 6.00; N, 14.01; Cl, 7.10; S, 12.81. Found: C, 40.98; H, 5.87; N, 13.69; Cl, 7.13; S, 12.61.

*Acetylation of Compounds **8** and **14***

The compound (100 mg) was added slowly to a heated mixture of acetic anhydride (5 ml) and anhydrous sodium acetate (75 mg). The mixture was heated under reflux for 1 h and was then poured into ice water (50 ml). The product was extracted into chloroform (2 × 25 ml); the extract was washed successively with saturated aqueous sodium bicarbonate and water, dried (anhydrous sodium sulfate), and evaporated. The acetates of both compounds crystallized spontaneously and were analyzed without recrystallization.

The acetate of compound **8** had m.p. 90–93 °C, $[\alpha]_D^{22}$ +29° (*c*, 2% in chloroform), and *O*-acetyl, 30.10%; calcd. *O*-acetyl, 30.66%. Integration of the well-resolved signals for C—CH_3 and C(=O)—CH_3 protons at 1.32 and 2.0–2.3 δ respectively in the n.m.r. spectrum gave a ratio of 3:12 in agreement with the proposed structure. There was strong absorption at 1740 cm^{-1} in the i.r. spectrum of this compound indicative of *O*-acetyl group; no absorption attributable to acetamido groups could be detected in the range 1618–1665 cm^{-1}.

The acetate of compound **14** had m.p. 52–54 °C and $[\alpha]_D^{22}$ 0° (*c*, 2% in chloroform). Integration of the signals for the C—CH_3 and C(=O)—CH_3 protons as before gave a ratio of 9:12 in agreement with the proposed structure.

Anal. Calcd. for $C_{25}H_{38}N_5O_{10}ClS_2$: C, 44.98; H, 5.70; N, 10.50; *O*-acetyl, 25.8. Found: C, 45.04; H, 5.86; N, 10.47; *O*-acetyl, 25.48.

We are grateful to Mr. H. Seguin for the microanalyses and to Mr. F. Cooper for the u.v. spectra of these compounds.

The Hydration of Ketones in Mixtures of Water and Polar Aprotic Solvents[1]

ROSS STEWART AND JOHN D. VAN DYKE[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received February 7, 1972

The hydration of a series of ring-substituted trifluoroacetophenones (Z) has been studied by means of u.v. and n.m.r. spectroscopy in DMSO–water and sulfolane–water mixtures. The W_0 function is defined as $W_0 = pK_d + \log [Z]/[ZH_2O] = -\log (f_Z/f_{ZH_2O} \cdot a_{H_2O})$, where K_d is the equilibrium constant for the reaction $ZH_2O \rightleftarrows Z + H_2O$.

Mixtures of water and sulfolane in all proportions have a dehydrating effect compared to water but mixtures of water and DMSO down to 15 mol % water are more hydrating with respect to the carbonyl group of trifluoroacetophenones than is pure water. An analysis of activity coefficient behavior indicates that the diol, ZH_2O, has a higher requirement for solvation by water molecules than does water itself.

The rate of the uncatalyzed hydration in aqueous sulfolane drops drastically as the water content of the medium decreases, whereas the rate of the acid-catalyzed reaction is not greatly affected by changes in the solvent composition; a plot of log k for both catalyzed and uncatalyzed reactions is approximately linear in W_0.

L'hydratation d'une série de trifluoroacétophénones substituées sur le cycle, a été étudiée par u.v. et r.m.n. dans des mélanges DMSO–eau et sulfolane–eau. La fonction W_0 est définie par $W_0 = pK_d + \log [Z]/[ZH_2O] = -\log (f_Z/f_{ZH_2O} \cdot a_{H_2O})$, où K_d est la constante d'équilibre pour la réaction $ZH_2O \rightleftarrows Z + H_2O$.

Les mélanges en toute proportion d'eau et de sulfolane ont un effet déshydratant comparé à l'eau mais les mélanges d'eau et de DMSO (limite inférieure 15% molaire en eau) sont plus hydratants vis-à-vis du carbonyle des trifluoroacétophénones que l'eau pure. L'analyse du comportement du coefficient d'activité indique que le diol, ZH_2O, est plus exigeant dans la solvatation par les molécules d'eau que ne le ferait l'eau elle-même.

La vitesse de l'hydratation non-catalysée dans le sulfolane aqueux tombe considérablement lorsque la teneur en eau décroît tandis que la réaction acidocatalysée n'est pas affectée de façon notable par des changements dans la composition du solvant; la courbe log K à la fois pour les réactions catalysée et non-catalysée est approximativement une droite dans W_0.

Canadian Journal of Chemistry, **50**, 1992 (1972)

Introduction

The first study of the hydration of aldehydes and ketones was made in 1886 by Ramsay and Young (1), who discovered that acetaldehyde and water mix with considerable heat and diminution of volume. With the advent of u.v. spectroscopy it was possible to show that this hydration involved a chemical reaction between water and the carbonyl compound, since the carbonyl absorption is almost zero in aqueous solution, whereas it is of normal intensity in solvents such as hexane. It is furthermore possible to isolate crystalline hydrates of certain aldehydes and ketones containing strongly electronegative substituents and n.m.r. and Raman (2) spectra provide direct evidence for the *gem*-diol formula, $R_2C(OH)_2$ (3).

A number of studies have been made of carbonyl hydration using u.v. spectroscopy to measure the concentration of unhydrated compound. Difficulties arise with regard to determining the exact extinction coefficient (ε) of the carbonyl compound since the rate of hydration in water may be very fast. Many ketones which are not appreciably hydrated show considerable variation in their ε values from solvent to solvent so that when dealing with a compound which undergoes partial hydration one cannot simply take the ε value in an inert solvent and apply it to aqueous systems.

$$R_2C{=}O + H_2O \rightleftarrows R_2CH(OH)_2$$

Bell and Clunie (4) have estimated ε values in water by combining calorimetric and spectroscopic data and Bloch and Rumpf (5) have used a kinetic method for the same purpose. Solvent correction parameters have also been used with considerable success, as indicated by the correspondence of equilibrium values based on such estimated ε values with the equilibrium values obtained by n.m.r. measurements (6). The advantage of n.m.r. in determining equilibrium values for hydration is that one can determine the concentration of both the *gem*-diol and the

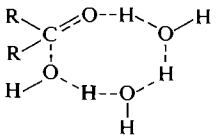
carbonyl compound. Its only disadvantage is that larger concentrations are required for accurate measurements than with u.v. spectroscopy.

Kinetics of hydration have been studied using dilatometry (7), u.v. (8) and n.m.r. spectroscopy (9), ^{18}O exchange (10), polarography (11), chemical scavenging (12), and thermal methods (13). The carbonyl hydration reaction is subject to both general acid and general base catalysis; in the case of acetaldehyde, the Brønsted coefficient for acid catalysis, α, is equal to 0.54; for base catalysis, the Brønsted coefficient, β, is equal to 0.45. The corresponding numbers for formaldehyde are 0.24 and 0.40 and for *s*-dichloroacetone, they are 0.27 and 0.53. It appears that the coefficient α is more influenced by the structure of the carbonyl compound than is β.

Eigen (14) has suggested that the spontaneous hydration reaction (the contribution to the overall rate that is independent of acid or base) occurs by way of a cyclic hydrogen-bonded transition state containing two or more water molecules as, for example, in the structure below.



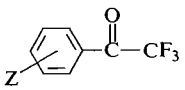
Kurz and Coburn's work (15) supports such an interpretation. For example, the entropy of activation for the spontaneous hydration of acetaldehyde is -38 e.u. compared to values of -4 and -7 e.u. for the routes catalyzed by hydrogen and hydroxide ions, respectively. Bell *et al.* (8) found that in aqueous dioxan and aqueous acetonitrile the order with respect to water molarity was close to three for hydration and two for dehydration. It is surprising that integral orders in water molarity are maintained over a fairly wide concentration range since freezing-point and vapor-pressure measurements reveal the presence of large deviations from ideal solution behavior.

It is known that polar aprotic solvents such as dimethyl sulfoxide (DMSO) and tetramethylene sulfone (sulfolane) cause drastic increases in the effective basicity of hydroxide ion, largely as a result of the solvents' inability to effectively hydrate such a small, "hard", ion. DMSO is considerably more effective than sulfolane in this regard (16).

DMSO appears to form strong hydrogen bonds with water molecules (17) as indicated by thermodynamic, dielectric, and viscometric data (18). Indeed, the value of the partial heat-of-mixing of water term at infinite dilution ΔH_w^∞, in DMSO, -1.28 kcal/mol, (19) indicates that the sulfoxide group is a strong acceptor of protons. Data for the activity of water at 70° (20) in DMSO–water mixtures show that, as the water content decreases and the DMSO content increases, both the activity of water and the activity coefficient of water, f_{H_2O}, steadily decrease. This indicates negative deviations from Raoult's law ($\Delta G < 0$). Thus DMSO–water interactions are stronger than the intermolecular association of water.

Sulfolane interacts quite differently with water. Here the partial heat of mixing at infinite dilution, ΔH_w^∞, is $+1.6$ kcal/mol (19). The activity coefficient of water, f_{H_2O}, increases rather than decreases as water is replaced by sulfolane in the solution. Thus, there are positive deviations from Raoult's law ($\Delta G > 0$) in sulfolane–water solutions.

The present study was undertaken to see if a hydration scale (W_0), analogous to the acidity function H_0, could be developed in solvents such as DMSO and sulfolane. Such scales would allow hydration equilibrium constants to be determined in media whose hydrating properties are far different from that of the standard state, water. We have previously shown in a brief communication that such scales can be used to generate K values for a series of ring-substituted trifluoroacetophenones,



and have shown that these values are correlated by the Hammett σ^+ substituent constant (21). In the present work we examine the factors that determine the hydrating and dehydrating properties of aqueous DMSO and aqueous sulfolane solutions with respect to these ketones and the effect of changing media on the spontaneous and acid-catalyzed hydration and dehydration reactions.

Experimental

Materials

Most of the α,α,α-trifluoroacetophenones were obtained either from commercial sources or prepared as previously described (21, 22, 26).

4-Dimethylamino-α,α,α-trifluoroacetophenone was prepared by slowly adding trifluoroacetic anhydride to a one-fold excess of *N,N*-dimethylaniline. Crystallization and sublimation gave a product of m.p. 75.5–77° (lit. (23), 76.5–77°).

2-Trifluoromethyl-2-(4′-methoxyphenyl)-1,3-dioxolane (**1**) was prepared by heating together 1 g (0.0049 mol) of 4-methoxy-α,α,α-trifluoroacetophenone, 0.78 g (0.0126 mol) ethylene glycol, and 0.22 g (0.00129 mol) 4-toluenesulfonic acid at 110° in a flask fitted with a total reflux separating head. When droplets of water were observed to form in the column, petroleum ether (60–100°) was introduced, and the mixture was refluxed for 24 h. The refluxing was then discontinued and 0.22 g sodium acetate was introduced. After stirring for 1 h, the solution was filtered and concentrated. The precipitated crystals were collected and recrystallized twice from petroleum ether, m.p.: 52–53°.

The purity was checked by dissolving the compound in ether and analyzing the solution by g.l.c.

The identity of the compound was established by i.r. and n.m.r. spectroscopy.

1

Solvent–water mixtures were prepared and stored as previously described (16) and the water content determined by Karl Fischer titration. Owing to the hygroscopic nature of these systems each solution was tested for water content immediately prior to dissolving the ketones for n.m.r. measurements. For u.v. measurements Karl Fischer titrations were carried out directly on the solutions being measured.

Equilibrium and Kinetic Measurements

Equilibrium constants were determined both by ^{19}F n.m.r. and by u.v. spectroscopy whereas only the latter was used in the rate studies. Equilibrium measurements were made in the presence of 0.1 *M* methanesulfonic acid, except in the case of the 4-dimethylamino ketone. The sealed n.m.r. tubes containing about 0.1 *M* substrate were kept for 2 days at the the appropriate temperature to allow equilibrium to be reached before the ^{19}F absorptions of the ketone and the hydrate were measured. To establish the W_0 scale, all measurements, both n.m.r. and ultraviolet, were made at 31.4°, the temperature within the n.m.r. probe at room temperatures, as measured by chromel–alumel thermocouple. For thermodynamic studies temperatures were adjusted to temperatures above 31.4° and measured in the same way. In the case of the 4-dimethylamino compound, where very little hydrate was found to be present, time averaging (28 n.m.r. scans) was carried out to facilitate measurement of the small hydrate peak.

The u.v. measurements, which were done on much more dilute solutions of substrate, require that the extinction coefficients (ε_0) at the carbonyl absorption maximum be known of the ketone and hydrate (for the latter these are close to zero). The extinction coefficients of the ketones measured were generally very large requiring a stock solution of the ketone to be prepared, which upon dilution in an u.v. cell would give a measurable concentration.

The procedure consisted of measuring the carbonyl absorbance of the two ketones whose equilibrium constants were measured by u.v. spectroscopy (the 4-methoxy- and 4-dimethylamino trifluoroacetophenones) in the appropriate solvent mixture. The extinction coefficient so obtained was due to hydrate and ketone. The absolute extinction coefficient of the ketone in this mixture was determined through the use of model compounds. First the extinction coefficient of the ketone was measured in 100% sulfolane or DMSO. This was always done after preparing the ketone stock solution so that small amounts of water that might be present would not be able to hydrate the ketone. (The rate of reaction is slow in 100% solvent.) Then the absorbance of a non-hydrating model compound (4-methoxyacetophenone or 4-dimethylaminoacetophenone) was measured both in 100% solvent and in the solvent mixture in which ε_0 was desired, and the change in absorbance noted. Assuming the same relative change to be applicable to the trifluoro ketone, the ketone absorbance measured in 100% inert solvent was corrected to give ε_0 for the solvent mixture.

For 4-methoxytrifluoroacetophenone, an experiment was conducted to see if any significant tailing of the small aromatic absorptions at 277 and 271 mμ lay at 299 mμ, the position of carbonyl absorbance. For this purpose, the ethylene glycol ketal of 4-$CH_3OC_6H_4COCF_3$ (2-trifluoromethyl-2-(4′-methoxyphenyl)-1,3-dioxolane) was prepared in order to simulate its hydrate. For the dioxolane, zero absorbance was observed at 299 mμ with retention of absorbance at 277 and 271 mμ. Thus, it could be assumed that the hydrate molecule had neither any carbonyl absorbance nor any tailing of phenyl peaks at 299 mμ in the specific case of the 4-CH_3O compound. The entire absorbance at 299 mμ is then due to the ketone. For the 4-$(CH_3)_2N$ compound, the carbonyl absorbance occurs far removed from the phenyl absorptions, rendering it unnecessary to prepare the comparable ketal.

The u.v. results were compared with the n.m.r. results wherever possible. Using the above technique for determining u.v. equilibrium constants, comparable results were obtained by the two techniques. For example, Fig. 1 contains a comparison of u.v. and n.m.r. equilibrium constants for the 4-CH_3O compound. In another experiment with the 4-dimethylamino compound, 28 time-averaging n.m.r. runs carried out on a dilute solution of the ketone in 80 mol % water yielded a value of 15 for $[Z][ZH_2O]$, compared to the u.v. result of 14.5.

Rate Constants

The rate of disappearance of the u.v. carbonyl absorption peak of the ketone Z was followed and the rate coefficients k_h and k_d for hydration and dehydration, respectively, were calculated as follows. Equation 1 on integration gives eq. 2 which can be used in the form of eq. 3. The rate constant for the hydration reaction, k_h, a pseudo first order rate constant, can be obtained from the experimental rate constant, k_{obs}, by using the relation given in eq. 4. (This

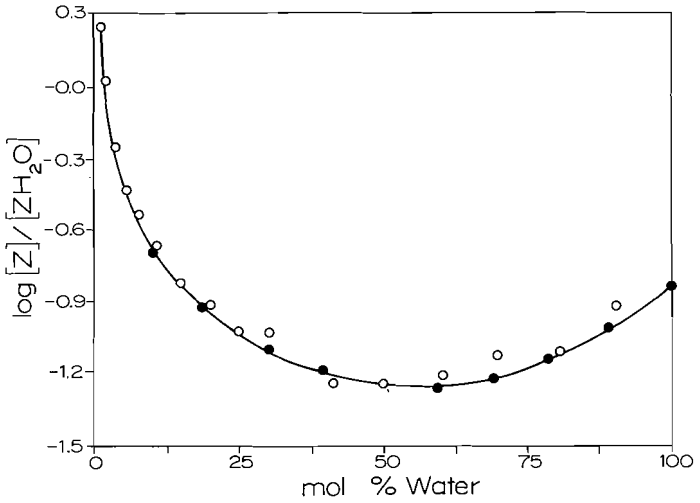

FIG. 1. A comparison of results determined by u.v. and n.m.r. techniques for the equilibrium hydration of 4-$CH_3OC_6H_4$-$COCF_3$ in DMSO; ○ n.m.r. values (0.1 *M* methanesulfonic acid present), ● u.v. values (no acid present).

relation can be shown to be valid at all solution compositions.)

$$[1] \qquad \frac{-\mathrm{d}[Z]}{\mathrm{d}t} = k_h[Z] - k_d[ZH_2O]$$

$$[2] \qquad \ln\left\{\frac{[Z]-[Z]_\infty}{[Z]_0-[Z]_\infty}\right\} = -(k_h + k_d)t$$

$$[3] \qquad \ln\left\{\frac{A-A_\infty}{A_0-A_\infty}\right\} = -(k_h + k_d)t$$

$$[4] \qquad k_h/k_d = [ZH_2O_\infty]/[Z_\infty]$$

The slopes were obtained by plots of ln $(A - A_\infty)$ against time, using the method of least squares. Excellent first-order plots were obtained.

Results and Discussion

The W_0 Function

When the Hammett stepwise technique (24) is applied to the hydration of ketones in a manner analogous to that applied to the ionization of weak acids or bases the equilibrium constant for dehydration, K_d, can be written as

$$[5] \qquad K_d = \frac{[Z]}{[ZH_2O]} \cdot \frac{f_Z}{f_{ZH_2O}} \cdot a_{H_2O}$$

If the negative logarithm of each side of eq. 5 is taken the following expression is obtained:

$$[6] \qquad pK_d = -\log\left(\frac{[Z]}{[ZH_2O]}\right) - \log\left(\frac{f_Z}{f_{ZH_2O}} \cdot a_{H_2O}\right)$$

From this, W_0 and w_0 can be defined as follows:

$$[7] \qquad W_0 = -\log\left(\frac{f_Z}{f_{ZH_2O}} \cdot a_{H_2O}\right)$$

$$[8] \qquad w_0 = \frac{f_Z}{f_{ZH_2O}} \cdot a_{H_2O}$$

Thus, for two ketones, Z_1 and Z_2, in the same solution

$$[9] \qquad pK_d^{Z_1} - pK_d^{Z_2} = \log\frac{[Z_2]}{[Z_2H_2O]} - \log\frac{[Z_1]}{[Z_1H_2O]} + \log\frac{f_{Z_2}f_{Z_1H_2O}}{f_{Z_2H_2O}f_{Z_1}}$$

If the Hammett treatment is successful for ketones in mixtures of water and polar aprotic solvents, the last quantity in eq. 9 will be zero regardless of the solvent composition, and eq. 9 will reduce to

$$[10] \qquad pK_d^{Z_1} - pK_d^{Z_2} = \log\frac{[Z_2]}{[Z_2H_2O]} - \log\frac{[Z_1]}{[Z_1H_2O]}$$

The relative pK_s's for two ketones that are partially hydrated in the same solution can be obtained by measuring the two quantities on the right-hand side of eq. 10. If the thermodynamic pK_d value for one ketone is known, the pK_d values for ketones with a wide range of pK_d's can

be determined depending on how effective the inert solvents are at reducing the extent of hydration.

The function, W_0, is determined from the same measurements of $[Z]/ZH_2O]$ that are used to determine the pK_d's (21) of the ketones. From eqs. 6 and 7 eq. 11 can be obtained. It can be

$$[11] \qquad W_0 = pK_d + \log \frac{[Z]}{[ZH_2O]}$$

seen that positive values of W_0 indicate a solution which is less hydrating than pure water; for negative values of W_0 the opposite is true. Furthermore, a plot of $\log [Z]/[ZH_2O]$ *vs.* W_0 will give a straight line of unit slope. This fact was used to test the validity of the Hammett postulate for ketones in polar aprotic solvents.

The W_0 values for sulfolane and DMSO mixtures with water are given in Table 1. It can be seen that sulfolane has a much larger dehydrating effect on *gem*-diols than does DMSO. Indeed aqueous solutions of the latter are *more* hydrating over most of the solvent composition range than is pure water (see Fig. 1). These results are surprising in view of the way that sulfolane and DMSO, particularly the latter, raise the activity of hydroxide ion and produce powerfully basic systems. The greater effect of DMSO in this regard has been ascribed to its ability to interact with water and lower the latter's activity. In Table 2 the activity coefficient of water, f_{H_2O}, is given as a function of solvent composition for aqueous sulfolane and DMSO. The changes in W_0 are in the *opposite* direction to what would be predicted on the basis of changes in the activity coefficient of water. The water system becomes more dehydrating as sulfolane is added yet f_{H_2O} rises (although a_{H_2O} decreases somewhat). On the other hand, water becomes a better hydrating medium as DMSO is added, even though both f_{H_2O} and a_{H_2O} decrease.

By using eq. 8 and the known values of the activity of water in DMSO–water and sulfolane–water systems we can determine the effect of changing media on the activity coefficient ratio of the ketone and its hydrate, f_Z/f_{ZH_2O} (Table 2).

It can be seen from the activity coefficient ratios in Table 2 how differently the two solvents, sulfolane and DMSO, behave. Carbonyl compounds are generally more soluble in sulfolane and DMSO than in water and hence we can assume that f_Z will decrease somewhat as the amount of water in the system decreases. This conclusion can only be reconciled with the trend in the values of f_Z/f_{ZH_2O} found in DMSO if the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

activity coefficient of the hydrate decreases drastically as the amount of water in the system falls. Presumably the hydrate is very much more effectively solvated by DMSO than it is by water.

In the case of sulfolane a different situation emerges. If f_Z is assumed to decrease as the water content of the system decreases (in line with the generally greater solubility of ketones in sulfolane than in water) then the decrease in f_Z/f_{ZH_2O} shown in Table 2 can be attributed, at least partly, to this factor. This, in turn, means that sulfolane, unlike DMSO, is not particularly efficient at solvating the hydrate. These results can be rationalized by assuming that the activity coefficient of the diol is affected by changing media in the same way as is that of water, only more so. This is presumably a consequence of the similarity in hydrogen-bonding requirements of the two hydroxylic molecules, water, and the diol, although the latter's appears to be the greater.

The variations in activity coefficient described above raise the suspicion that a hydration parameter such as W_0 may be a function not only of the solvent system but also of the type of substrate used. Although further work is needed to settle this question results with *s*-dichloroacetone are indicative. A plot of log $[Z]/[ZH_2O]$ for the hydration of this compound in sulfolane–water against W_0 values from Table 1 gives a roughly linear relation of unit slope only between 10 and 45 mol % water and a straight line of considerably higher slope (1.56) between 45 and 95 mol % water (correlation coefficient 0.9988).

Thermodynamic Parameters

The values of ΔH and ΔS for hydration of 4-methoxy-α,α,α-trifluoroacetophenone in water were determined to be -6.7 kcal mol^{-1} and -18.1 e.u., respectively. These values change to slightly more negative values as sulfolane is added to the system. For example, in 68.1 mol % water $\Delta H = -7.1$ kcal mol^{-1} and $\Delta S = -19.4$ e.u. These results are in line with the observations of Bell and McDougall (25) that both ΔH and ΔS for the hydration of *s*-dichloroacetone in dioxan–water are little affected by changes in solvent composition ($\Delta H = -5.7$ kcal, $\Delta S = -14.8$ e.u., in water in this case). The fairly large negative value of -18.1 for entropy of hydration reflects the reduction in the number of molecules from two to one and also, presumably, the higher solvation requirements of the diol than of the ketone.

Kinetics of Hydration

In Table 3 the rate constants, k_h and k_d, for hydration and dehydration respectively, are listed for mixtures of sulfolane and water, together with the activity of water in the various systems. It can be seen that the rate of hydration decreases drastically as water is removed from the system and that this decrease is much more marked than is the decrease in the activity of water. (A plot of log k_h against log a_{H_2O} gives a curved line whose slope rises from approximately 7 at 20 mol % water to over 20 at 80 mol % water; it is clear that water activity is not a useful parameter for correlating hydration and dehydration rates in this case, a conclusion Bell *et al.* (8) have also come to in connection with the hydration of *s*-dichloroacetone in dioxan–water mixtures.)

A plot of log k_h against the solvation parameter W_0 gives a reasonably linear relation (Fig. 2) suggesting that the transition state of the uncatalyzed hydration reaction has some of the character of the diol molecule. The slope of the line in Fig. 2 is -4.56. This indicates a much higher requirement for water solvation in the transition state than in the diol, although the number of solvating water molecules cannot simply be identified with the slope of the line.

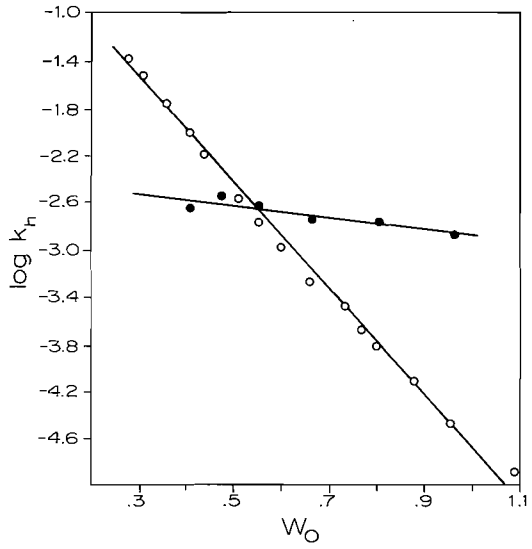

FIG. 2. The rate constants k_h^0 and $k_h^{H^+}$ for the spontaneous and acid-catalyzed hydration of 4-$CH_3OC_6H_4COCF_3$ in sulfolane–water as a function of the hydration parameter W_0; ○ no acid present, ● 0.025 *M* methanesulfonic acid present.

A plot of log k_h against the molar concentration of water in the manner of Bell *et al.* (8) yields a slope of 3.1 with a correlation coefficient of 0.9990 (Fig. 3). Bell *et al.* found that uncatalyzed carbonyl hydration and dehydration reactions in acetonitrile and dioxan give slopes near 3 and 2, respectively, when log *k* is plotted against water molarity and they conclude that three molecules of water are involved in the transition state for hydration and two for dehydration. (The fact that water molarity appears to give better correlations with hydration rates than does water activity can only be due to cancellation of activity coefficient effects.) In our case a plot of log k_d against water molarity for the dehydration reaction gives a straight line of slope 2.4 (correlation coefficient of 0.9998).

The acid-catalyzed hydration reaction in sulfolane–water is strikingly different from the uncatalyzed reaction in terms of its dependence on W_0. Figure 2 reveals that k_h for the reaction in the presence of 0.1 *M* methanesulfonic acid is only slightly dependent on W_0 over a considerable range of solvent composition.[3]

One can conclude that the transition state for spontaneous hydration of carbonyl compounds has a much higher requirement for water molecules than does the diol but that the transition state for the acid-catalyzed hydration has similar solvation requirements to the diol.

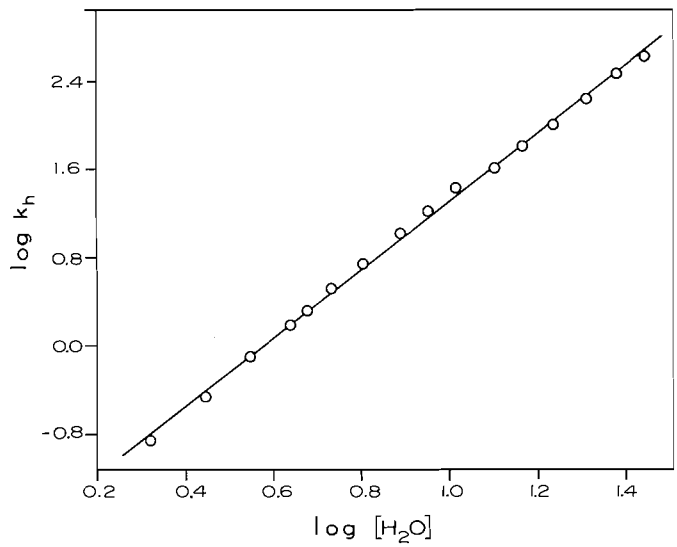

FIG. 3. The logarithm of the rate of the spontaneous hydration reaction of 4-$CH_3OC_6H_4COCF_3$ in sulfolane–water as a function of the logarithm of the water molarity.

[3]The values of k_h used in Fig. 2 for the acid-catalyzed reaction, that is $k_h^{H^+}$, are obtained by subtracting the rate for the spontaneous reaction in the same medium, that is k_h^0, from the overall rate. They thus are in the units of s^{-1}. Experiments at different methanesulfonic acid concentrations show that the acid-catalyzed rate is, in fact, directly proportional to the concentration of acid present in a given medium.

The Oxidation of 2-Propanol by Ruthenium Tetroxide

DONALD G. LEE AND MATTHIJS VAN DEN ENGH[1]

Department of Chemistry, The University of Saskatchewan Regina Campus, Regina, Saskatchewan, S4S 0A2

Received January 6, 1972

The kinetics of the oxidation of 2-propanol by ruthenium tetroxide in aqueous perchloric acid solutions have been investigated. The results indicate that the two mechanisms pertain; at moderate acidities (1–6.5 *M* $HClO_4$) the rate determining step involves hydride abstraction while at very high acid concentrations the rate determining step becomes carbonium ion formation.

Les cinétiques de l'oxydation du propanol-2 par le tétroxyde de ruthénium dans des solutions aqueuses d'acide perchlorique ont été étudiées. Les résultats indiquent que deux mécanismes sont concernés; à une acidité modérée (1–6.5 *M* $HClO_4$), l'étape qui détermine la vitesse implique un arrachement d'hydrure alors qu'à une concentration élevée en acide l'étape qui détermine la vitesse correspond à la formation d'un ion carbonium.

Canadian Journal of Chemistry, **50**, 2000 (1972)

Introduction

Ruthenium tetroxide is currently finding extensive use as an oxidant for alcohols (1), particularly carbohydrates (2), and steroids (3). With simple alcohols the reaction proceeds according to reaction 1 giving quantitative yields of ketone.

$$[1]\quad 2R{-}\underset{\displaystyle OH}{\underset{|}{C}}H{-}R' + RuO_4 \rightarrow 2R{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}R' + RuO_2 + 2H_2O$$

Water and carbon tetrachloride are the most commonly used solvents. Since it is a vigorous reagent, even under very mild conditions, ruthenium tetroxide has found particular application with alcohols which are normally resistant to oxidation (4).

The reaction can be carried out using a stoichiometric quantity of ruthenium tetroxide or by use of a catalytic amount of ruthenium dioxide in conjunction with a co-oxidant such as sodium periodate (3, 5). In the latter procedure, the co-oxidant continuously regenerates the tetroxide from the dioxide as in reaction 2.

$$[2]\quad RuO_2 + 2ClO_4^- \rightarrow RuO_4 + 2ClO_3^-$$

Despite its wide utility very little is known concerning the mechanisms of these and related reactions of ruthenium tetroxide. Consequently, we have undertaken an extensive study of the oxidation of organic compounds by ruthenium tetroxide and wish to report here the results obtained for the oxidation of 2-propanol in aqueous perchloric acid solutions.

Experimental

Reagents

Ruthenium tetroxide was prepared by the oxidation of hydrated ruthenium dioxide (0.5 g) obtained from Engelhard Industries Inc., with a solution of sodium periodate (2 g) in 25 ml of water. The mixture was shaken until the reaction was complete (as evidenced by the disappearance of the insoluble black ruthenium dioxide). The bright yellow product of this reaction, ruthenium tetroxide, was extracted into carbon tetrachloride and stored over sodium periodate. Just prior to a kinetic experiment an aliquot of the solution was removed and the ruthenium tetroxide extracted into an aqueous perchloric acid solution of the desired molarity.

2-Propanol was distilled from calcium oxide and a middle fraction boiling at 81.9–82.0° was collected and used in the kinetic experiments. 2-Propanol-2-*d* was prepared following the procedure of Leo and Westheimer (6) by reduction of acetone with lithium aluminum deuteride. The deuterium incorporation was verified by n.m.r. spectroscopy. 2-Propanol-2-C-14 was prepared in a similar way by the reduction of acetone-2-C-14 with lithium aluminum hydride. 1,1,1-Trifluoro-2-propanol and 2-butanol were both obtained commercially and purified via preparative gas chromatography prior to use.

Perchloric acid solutions were prepared by the dilution of 70% $HClO_4$ with doubly distilled water (7).

Kinetic Method

In a typical kinetic experiment 3.0 ml of a perchloric acid solution containing a specified amount of ruthenium tetroxide were pipetted into a cuvet which was placed in a thermostated cuvet holder for about 20 min. Then the desired quantity of 2-propanol was added using a microsyringe. The timer was started immediately and the absorption at either 386 or 310 nm was recorded periodically using a Unicam SP500 Spectrophotometer. As the reaction proceeded the color of the solution changed from bright yellow to brown.

Two different methods were used for analysis of the data. The differential method, which involves the use of initial rates as determined from the initial slopes of the plots of absorbance against time, was used to determine the order of the reaction with respect to each of the reactants (8). (A

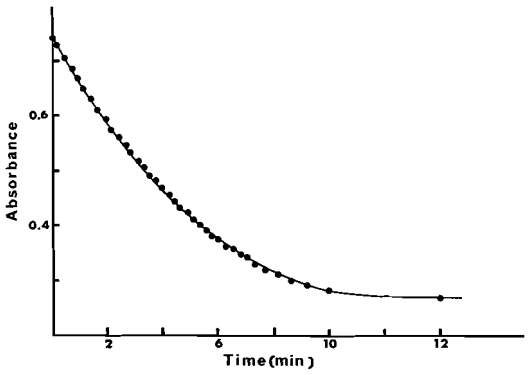

FIG. 1. Rate plot for the oxidation of 2-propanol by RuO_4 in 2.96 *M* $HClO_4$.

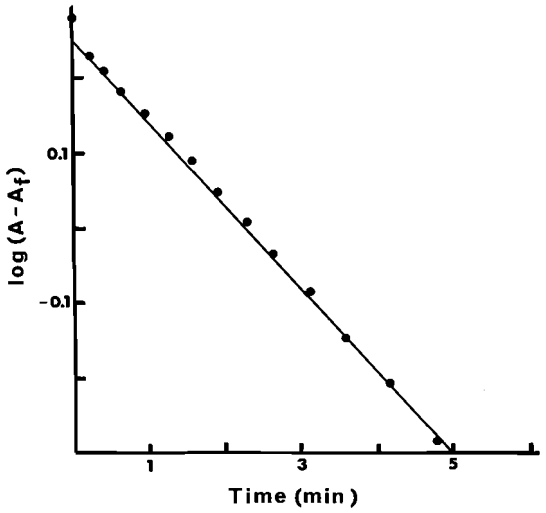

FIG. 2. Pseudo first order plot for the oxidation of 2-propanol by Ruo_4 in 1.86 *M* $HClO_4$.

typical plot of absorbance *vs.* time has been reproduced in Fig. 1.) Under conditions where the alcohol/oxidant ratio was high integral methods were used to verify the order with respect to ruthenium tetroxide; below about 7 *M* $HClO_4$ plots of log (absorbance – final absorbance) *vs.* time gave straight lines (Fig. 2) while above 9 *M* $HClO_4$ plots of absorbance *vs.* time were linear (Fig. 3), thus indicating that the order with respect to ruthenium tetroxide changes from unity to zero at high acid concentrations.

All rates and rate constants reported herein are the average of at least two determinations which agreed to within ± 5% or less.

Product Analysis

Ruthenium(III) was identified as one of the products of this reaction by an analysis of the ultraviolet spectrum of the final solution and from the observation that this solution would not oxidize iodide (9). The latter fact rules out ruthenium(IV) as a product because it is known to be reduced to ruthenium(III) by iodide. Consequently, it appears

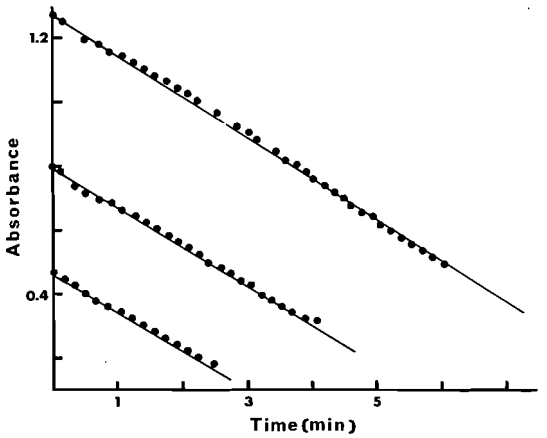

FIG. 3. Rate plots for the oxidation of 2-propanol by RuO_4 in 9.95 *M* $HClO_4$.

that under aqueous acidic conditions, the reaction involves a five electron change as indicated in reaction 3.

$$[3]\quad 5R{-}\underset{\displaystyle OH}{\underset{|}{C}}H{-}R' + 2RuO_4 \xrightarrow{H^+/H_2O} 5R{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}R' + 2Ru^{3+}$$

The organic products of the reaction were identified by use of isotope dilution techniques (10), which permitted the analysis to be carried out under conditions identical to those used in the kinetic experiments. 2-Propanol-2-C-14 was added to a solution of ruthenium tetroxide and allowed to react for 1 h. The product solution was divided into three portions and unlabelled acetone was added to the first portion, unlabelled acetaldehyde to the second, and unlabelled acetic acid to the third. Acetone and acetaldehyde were isolated as the 2,4-dinitrophenylhydrazones and acetic acid as the *S*-benzylthiuronium salt. Each derivative was repeatedly recrystallized to constant activity and compared with the activity of the starting material (2-propanol) which was counted as the 3,5-dinitrobenzoate derivative. Counting was accomplished by the planchet method using a Bechman Lowbeta counter (9). From the results, which are summarized in Table 1, it can be seen that a single product, acetone, was obtained in a quantitative yield in 3.0 *M* $HClO_4$ while in 10.2 *M* $HClO_4$ two products, acetone and acetaldehyde, were produced.

Results

Order of the Reaction with Respect to Ruthenium Tetroxide

The rate of the reaction at a particular acidity can be expressed as in eq. 4.

$$[4]\quad \frac{-d[RuO_4]}{dt} = k_2[RuO_4]^x[Alc]^y$$

When the concentration of 2-propanol is in excess eq. 4 can be restated as eqs. 5 and 6.

$$[5]\quad \frac{-d[RuO_4]}{dt} = k_{obs}[RuO_4]^x$$

TABLE 1. Product analysis

$[HClO_4]$ (M)	RuO_4 (mmol)	Specific activity of reactant and products	mmol of product* (Actual/theoretical)	Yield (%)
10.2	0.375	2-Propanol-2-C^{14} (122400 c.p.m./mmol)		
		Acetone-2-C^{14} (2158 c.p.m./mmol)	0.72/0.94	77
		Acetaldehyde-C^{14} (431 c.p.m./mmol)	0.21/0.94	22
		Acetic acid-C^{14} (0 c.p.m./mmol)	0/0.94	0
3.0	0.23	2-Propanol-2-C^{14} (94900 c.p.m./mmol)		
		Acetone-2-C^{14} (3937 c.p.m./mmol)	0.58/0.58	100

*Actual yields were calculated from the formula $x/(x+n) = A_1/A_2$, where n is the number of mmol of product added as diluent, x is the number of mmol of product formed, and A_1 and A_2 are the specific activities of the products and reactants respectively (10). Theoretical yields were calculated assuming that RuO_4 undergoes a loss of 5 electrons and that formation of the product involves a gain of 2 electrons by 2-propanol.

TABLE 2. Calculation of the order with respect to RuO_4 in the oxidation of 2-propanol at acid concentrations from 0.41 to 6.62 M $HClO_4$

[2-Propanol] $M \times 10^2$	$[HClO_4]$ (M)	N*	Order†	Correlation coefficient
1.29	1.25	3	1.06±0.01	1.00
1.71	1.25	3	1.19±0.02	1.00
1.71	1.08	6	1.08±0.01	1.00
1.71	1.86	3	1.14±0.01	1.00
1.71	0.41	3	1.07±0.04	0.97
1.71	0.76	3	1.08±0.01	1.00
1.71	1.50	3	1.13±0.02	1.00
1.71	6.62	3	1.16±0.07	0.96
2.12	3.22	3	1.02±0.01	1.00
2.13	3.22	3	1.16±0.01	1.00

*Number of points plotted.
†From the slope obtained by plotting log (absorbance) against log (initial slope).

$$[6] \qquad k_{obs} = k_2[\text{Alc}]^y$$

Since any absorbance due to products would be negligible during the initial stages of the reaction, it is convenient to express eq. 5 in terms of absorbance and extinction coefficients as in eqs. 7 or 8.

$$[7] \qquad \frac{-\mathrm{d}(A/\varepsilon)}{\mathrm{d}t} = k_{obs}(A/\varepsilon)^x$$

$$[8] \qquad \log\frac{-\mathrm{d}A}{\mathrm{d}t} = \log A + (1-x)\log\varepsilon + \log k_{obs}$$

Hence the order of the reaction with respect to ruthenium tetroxide can be determined from a plot of the logarithm of the initial slopes against the logarithm of the initial absorbances.

Ten such plots were prepared for acid concentrations varying from 0.41 to 6.62 M $HClO_4$. A summary of the results (presented in Table 2) indicates that below 6.62 M $HClO_4$ the order of the reaction with respect to ruthenium tetroxide is unity.

TABLE 3. Variation of initial rates with ruthenium tetroxide concentration in 9.95 M $HClO_4$, $T = 25.0 \pm 0.1$ °C

$[RuO_4]$ ($M \times 10^3$)	[2-Propanol] (M)	Initial rate ($M\ s^{-1} \times 10^6$)
1.35	0.338	1.96
1.84	0.338	2.07
0.50	0.338	2.00

At acidities greater than 9 M $HClO_4$ the initial rates of the reaction were found to be independent of the initial concentration of ruthenium tetroxide (Table 3) and straight lines were obtained for plots of absorbance against time (Fig. 3). Hence it is apparent that under highly acidic conditions the order of the reaction with respect to oxidant is zero.

Order of the Reaction with Respect to 2-Propanol

By making use of the observation that the order with respect to ruthenium tetroxide is unity at low acidities and zero at high acidities it is possible to combine eqs. 6 and 8 to give eqs. 9 and 10 for the reaction under conditions of "low" and "high" acidity respectively.

$$[9] \qquad \log\frac{-\mathrm{d}A}{\mathrm{d}t} = \log A + \log k_2 + y\log[\text{Alc}]$$

$$[10] \qquad \log\frac{-\mathrm{d}A}{\mathrm{d}t} = y\log[\text{Alc}] + \log k_2 + \log\varepsilon$$

The order of the reaction with respect to alcohol, y, can then be determined from a plot of the logarithm of the initial slope divided by the initial absorbance against the logarithm of

the concentration of alcohol at low acidities, or a plot of the logarithm of the initial slope against the logarithm of the concentration of alcohol at high acidities.

When this method of analysis was applied to four sets of results obtained at different acidities, ranging from 1.05 to 9.95 M $HClO_4$, it was clear that the order of the reaction with respect to alcohol is unity (see Table 4). Typical plots have been reproduced in Figs. 4 and 5.

Dependence of the Reaction on the Acidity of the Medium

The reaction was also found to be dependent on the acidity of the medium; below 7.5 M $HClO_4$ the second order rate constants decreased as the acidity of the medium increased as indicated by the data in Table 5. This is rather surprising since the converse is observed for most other oxidation reactions involving the use of transition metal oxides. In Fig. 6, log k_2 has

been plotted against the Hammett acidity function, $-H_0$ (11, 12), and although a reasonably good straight line is obtained, the nonintegral value, −0.35, for the slope suggests that the explanation for this inverse dependence on acidity may be complex.

Under more highly acidic conditions (8.5 M $HClO_4$ or greater), where the reaction is zero order with respect to ruthenium tetroxide, the rate of reaction increases with increasing acidity (Table 6). However, it is again found that a plot of log k_1 against $-H_0$ gives a straight line with a nonintegral slope of 0.68 (Fig. 7).

Isotope Effects

The oxidation of 2-propanol-2-*d* was carried out at three different acidities, 1.94, 8.47, and 9.52 M $HClO_4$. The observed rates were then compared with those for the oxidations of 2-propanol to determine a kinetic isotope effect. The results, summarized in Table 7, indicate that at 1.94 M $HClO_4$ a substantial primary kinetic isotope effect is observed ($k_H/k_D = 4.6 \pm 0.2$). Hence the C—H bond is broken in the rate determining step. However, at 9.52 M $HClO_4$ the isotope effect is unity (within experimental error), suggesting that cleavage of the C—H bond is not involved in the rate determining step. At 8.47 M $HClO_4$ an isotope effect of intermediate magnitude ($k_H/k_D = 1.9 \pm 0.1$) is observed, probably because of a contribution from two different mechanisms at this acidity.

Substituent Effects

The rates of oxidation of 2-butanol and 1,1,1-trifluoro-2-propanol by ruthenium tetroxide were determined and compared with those for 2-propanol in an attempt to determine the effect of substituents on the rate of the reaction. The resulting rate constants are presented in Table 8.

At high acidity (10.0 M $HClO_4$) it was impossible to obtain a meaningful initial slope for 2-butanol and 1,1,1-trifluoro-2-propanol, although it was evident that the oxidation of 2-butanol was faster and that the oxidation of 1,1,1-trifluoro-2-propanol was slower than the oxidation of 2-propanol.

*Second order rate constants (M^{-1} s^{-1}).
†First order rate constants (s^{-1}).

These results indicate that electron donating substituents increase the rate of the reaction, while electron withdrawing substituents decrease the rate of the reaction in the oxidation of secondary alcohols by ruthenium tetroxide.

Activation Parameters

From a knowledge of the way in which the rate of a reaction varies with changes in temperature, it is possible to calculate the activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ (8). The former is obtained from the slope and the latter from the intercept of a plot of $\ln k_2/T$ against $1/T$. When this was done for the oxidation of 2-propanol in 2.89 M $HClO_4$ $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were calculated to be 14.0 ± 0.1 kcal/mol and -20.3 ± 0.2 e.u. while in 9.10 M $HClO_4$ they were found to be 21.9 ± 0.4 kcal/mol and 2.8 ± 1.4 e.u., respectively. The data on which these calculations were based are found in Table 9 and the plots have been reproduced in Fig. 8.

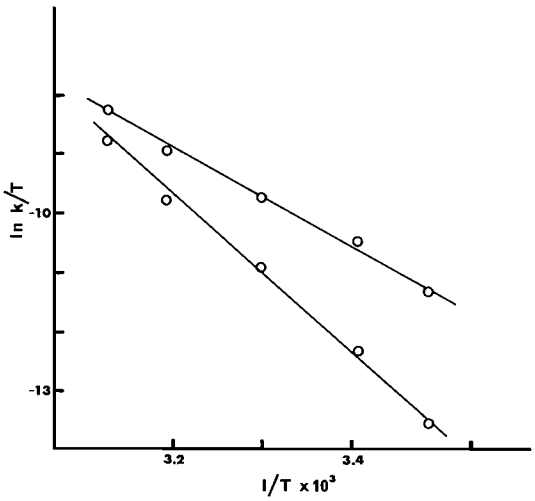

FIG. 8. Plots for calculating activation parameters. The top line is for k_2(M^{-1} s^{-1}) constants obtained in 2.89 M $HClO_4$ while the bottom line is for k_1(s^{-1}) constants obtained in 9.10 M $HClO_4$.

Influence of Oxygen on the Rate of Reaction

In order to determine if the presence of oxygen has any influence on the rate of oxidation several experiments were carried out in which different gases were bubbled through the solution at the start of the reaction. The results indicated that solutions flushed with helium, nitrogen, and oxygen all reacted at the same rate within the limits of experimental error. Since oxygen has no appreciable effect on the rate, it is not likely that the reaction involves formation of free radicals.

Discussion

It is apparent from the summary of results presented in Table 10 that two different reaction mechanisms pertain. The results obtained in the less acidic region are most easily explained in terms of a hydride transfer mechanism. The rate law, the isotope effect, and the effect of substituents are all consistent with this suggestion. The activation parameters are very similar to those obtained for other hydride transfer oxidation reactions (13) and the absence of any effect by oxygen on the rate eliminates a free radical mechanism. In addition it should be noted that ruthenium tetroxide oxidizes alcohols and ethers with approximately equal ease (9, 4); this property is also observed for other oxidants which are known to be reduced by hydride abstraction reactions (13).

The most unexpected of the results obtained in the lower acid region is the observation that the rate of reaction decreases as the acidity increases whereas most other oxidation reactions are subject to acid catalysis. Any possible explanation of this rather unique observation must be made while bearing in mind the fact that increasing the acid concentration of a solution has two effects, (*i*) it increases the hydrogen ion activity and (*ii*) it decreases the water concentration. Either or both of these effects might have an influence on the reaction rate.

The most likely consequence of an increase in

Substituent effects	Electron donating substituents increase the rate of reaction	Electron donating substituents increase the rate of reaction

acidity would be to shift the alcohol protonation equilibrium [11] to the left.

[11] $$CH_3-\overset{\overset{+}{O}H_2}{\underset{|}{C}}H-CH_3 \overset{K}{\rightleftharpoons} CH_3-\overset{OH}{\underset{|}{C}}H-CH_3 + H^+$$

If the protonated alcohol were unreactive (as might be expected for a hydride transfer reaction) the rate would be decreased as the solution became more acidic. A somewhat similar explanation for the inverse acidity dependence was given for the oxidation of ascorbic acid by osmium tetroxide (14).

The protonation of 2-propanol should be defined by an acidity function H_{ROH}, which has been recently proposed by Lee and Cameron (15). Although such a function has not been firmly established it appears from the available evidence (15, 16) that it is approximately equal to 0.25 H_0 in both sulfuric and perchloric acid solutions, and thus the pK_{BH^+} for equilibrium [11] which has been reported to be -5.16 in H_0 units (16) would be approximately -1.3 in H_{ROH} units.

The concentration of unprotonated alcohol can then be calculated as indicated in eqs. 12–15.

[12] $$K = \frac{[ROH]h_{ROH}}{[ROH_2^+]}$$

[13] $$[ROH] + [ROH_2^+] = [ROH]_{total}$$

[14] $$[ROH] + \frac{[ROH]h_{ROH}}{K} = [ROH]_{total}$$

[15] $$[ROH] = \frac{[ROH]_{total}}{1 + h_{ROH}/K} = \frac{K[ROH]_{total}}{K + h_{ROH}}$$

Hence if the rate of oxidation of 2-propanol is very fast compared with its conjugate acid the rate law would be given by eqs. 16 and 17

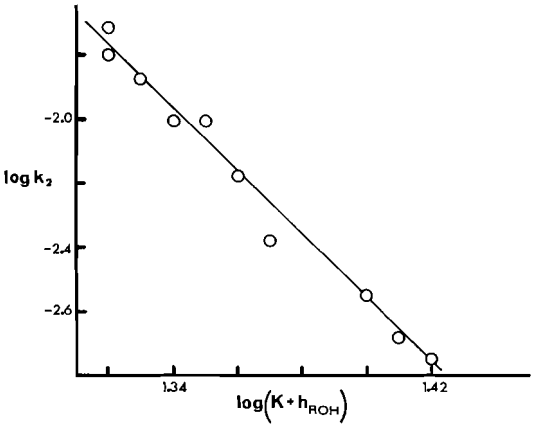

FIG. 9. Dependence of rate on acidity for the oxidation of 2-propanol by RuO_4 in 1–6.5 *M* $HClO_4$. Slope = -10.0.

[16] $$\frac{-d[RuO_4]}{dt} = \frac{kK[RuO_4][ROH]}{K + h_{ROH}}$$

[17] $$k_2 = \frac{kK}{K + h_{ROH}}$$

which suggests that a plot of log k_2 against log $(K + h_{ROH})$ should be linear with slope of -1. From Fig. 9, it can be seen that the magnitude of the slope is much greater than this (-10) suggesting that other factors are contributing to the decrease in rate; *i.e.*, the decrease in the activity of water may also be reponsible for part of the rate diminution. This would be so if the complete rate law were of the form given in eq. 18.

[18] $$\frac{-d[RuO_4]}{dt} = \frac{kK[RuO_4][ROH]}{K + h_{ROH}} a_{H_2O}^n$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

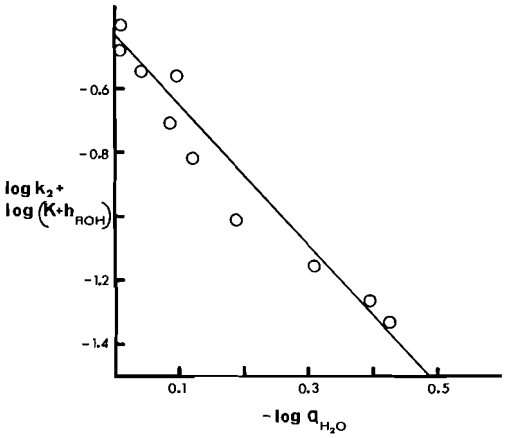

FIG. 10. Plot used for calculating the extent to which water is involved in the transition state for the oxidation of 2-propanol by RuO_4. Slope = 2.2.

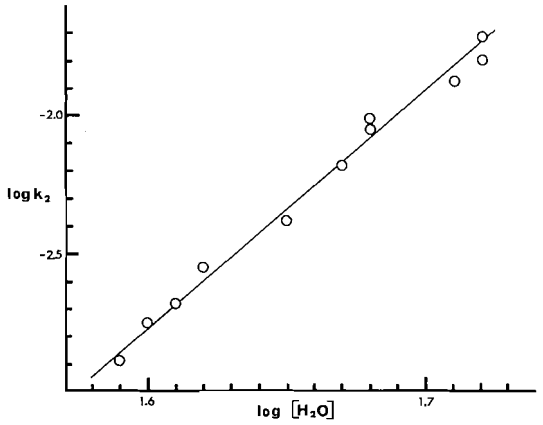

FIG. 11. Plot of log k_2 against log $[H_2O]$. Slope = 8.8.

If eq. 18 is, in fact, an accurate description of the rate law for the reaction it should be possible to estimate n, the order with respect to water activity, since the reported rate constants, k_2, would be given in eq. 19 from which eq. 20 can be derived.

$$[19] \qquad k_2 = \frac{kK}{K + h_{ROH}} a_{H_2O}^n$$

$$[20] \quad \log k_2 + \log (K + h_{ROH}) = n \log a_{H_2O} + \log (kK)$$

It then follows that a plot of log k_2 + log $(K + h_{ROH})$ against log a_{H_2O} should be linear with a slope equal to n. This plot has been reproduced in Fig. 10 and although there is some scatter, possibly because the abscissa is the difference between two fairly large numbers, it is obvious that the slope of the best straight line is positive (approx. 2). Consequently, the empirical rate law for this reaction under conditions of "low" acidity can be approximated by eq. 21.

$$[21] \qquad \frac{-d[RuO_4]}{dt} = \frac{kK[RuO_4][ROH]}{K + h_{ROH}} a_{H_2O}^2$$

This rate law indicates that the transition state of the reaction has a greater demand for solvation by water than do the reactants, thus suggesting that it may be quite polar. Furthermore it is not likely that RuO_4 is highly solvated, as indicated by the fact that it has the same spectral characteristics in the vapor state, in carbon tetrachloride solutions, and in aqueous acids (17), but it is known that reduced forms of ruthenium are highly solvated in water (18). Consequently, it is not unlikely that a polar transition state containing ruthenium in one of the lower oxidation states would require additional solvation.

It should be noted here that Bunnett has previously suggested an analogous approach for acid catalyzed reactions (19). He proposed that the role of water in a reaction mechanism could be determined by plotting log $k + H_0$ (or log k − log [HX]) against log a_{H_2O}. The slopes (ω or ω^*) of the resulting plots are thought to indicate the way in which water is involved in the rate determining steps (20). The principal difference between Bunnett's approach and the present one is simply that he was dealing with acid catalyzed reactions whereas in the present case the reaction is subject to acid inhibition.

As indicated in Fig. 11 a plot of log k_2 *vs.* log $[H_2O]$ also gives a straight line with a slope of 8.8 for the oxidation of 2-propanol and although such plots are not conventional it shows empirically that the transition state has a high demand for water. This is also indicated by a plot of log k_2 against log a_{H_2O} (see Fig. 12).

Now turning to a consideration of the reaction under highly acidic conditions, the observation that no primary isotope effect was observed indicates that the α-carbon—hydrogen bond is not broken in the rate determining step. This result is also consistent with the fact that the concentration of ruthenium tetroxide does not appear in the rate law. Evidently the rate determining step involves a reaction of 2-propanol prior to the transfer of electrons to ruthenium

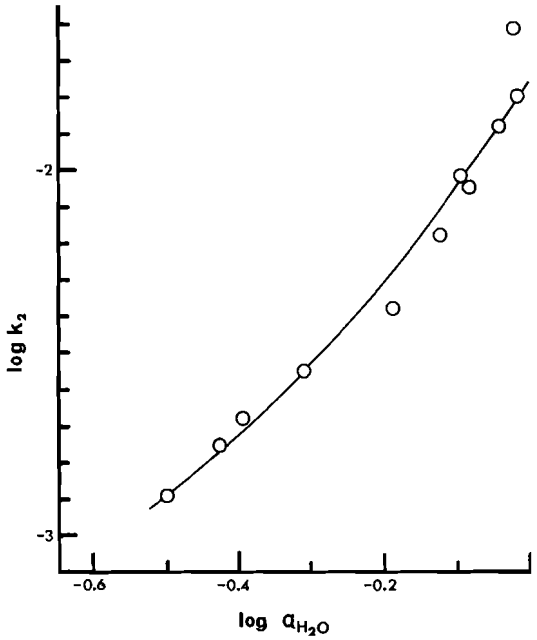

FIG. 12. Plot of log k_2 against log a_{H_2O}.

tetroxide. The substituent effects indicate an electron deficient reaction center, and thus suggest the probability of a carbonium ion intermediate.

The observation that the rate of reaction, under these conditions, is subject to acid catalysis (Fig. 7) is also consistent with rate determining carbonium ion formation, and the change in activation parameters verifies that hydride transfer is no longer the rate determining step.

The presence of acetaldehyde amongst the products of the reaction suggests that oxidation of the carbonium ion might be in competition with propene formation; the carbonium ion would be oxidized to acetone while propene would give acetaldehyde (1) as indicated in reaction 22.

$$[22]\quad CH_3\overset{OH}{\overset{|}{C}}HCH_3 + H^{\oplus} \xrightarrow[-H_2O]{\text{slow}}$$

$$CH_3\overset{\oplus}{C}HCH_3 \rightleftharpoons CH_3CH{=}CH_2$$
$$\downarrow RuO_4 \qquad\qquad \downarrow RuO_4$$
Acetone Acetaldehyde

The rate law for this reaction would be expressed by eq. 23 and a steady state approximation for the reactive intermediate (R^+) gives eq. 24

$$[23]\quad \text{rate} = k_2[RuO_4][R^+]$$

$$[24]\quad \text{rate} = \frac{k_1k_2[RuO_4][ROH]h_{R'}}{k_{-1} + k_2[RuO_4]}$$

where $h_{R'}$ is an acidity function defined by the equilibrium between aliphatic alcohols and the corresponding carbonium ions.

If $k_2[RuO_4] > k_{-1}$ then rate $= k_1[ROH]h_{R'}$. This expression is similar to the experimentally observed rate law, and the mechanism is also in accordance with the substituent effects, since electron donating substituents will increase k_1 with the converse being true for electron withdrawing substituents.

The observed value of k_H/k_D (1.3 ± 0.3) indicates that there might be a small isotope effect; however, on the basis of the proposed mechanism this could be attributed to a secondary isotope effect.

Summary

The reaction mechanism appears to involve a hydride transfer to the oxidant in the rate determining step under conditions of "low" acidity. Since protonated alcohols would be less reactive towards hydride transfer and because the transition state apparently requires added solvation by water the rate of the reaction decreases as the acidity of the medium increases. However, under conditions of very high acidity, carbonium ions and alkenes, which are very readily attacked by ruthenium tetroxide, begin to form and the reaction rate increases with the acidity of the solution. The rate determining step then becomes carbonium ion formation.

Photosensitization by $Cd(^3P_1)$ Atoms. II. Gas Phase Decomposition of Cyclohexane[1]

B. L. KALRA AND A. R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received December 2, 1971

The photodecomposition of cyclohexane sensitized by $Cd(^3P_1)$ atoms has been studied in the vapor phase at 355 °C. The primary decomposition gives hydrogen atoms and cyclohexyl radicals. The volatile products of the decomposition are H_2, cyclohexene, propylene, ethane, ethylene, methane, propane, butadiene, and methylcyclopentane. Products other than H_2 and cyclo-C_6H_{10} arise from unimolecular reactions of cyclohexyl radicals, the most important such process being the production of propylene and allyl radicals. Hydrogen yields decrease rapidly with time because of H-atom scavenging reactions involving olefinic products. The quantum yield of molecular hydrogen formation at the shortest exposure time examined is 0.53.

La photodécomposition du cyclohexane sensibilisée par des atomes de $Cd(^3P_1)$ a été étudiée en phase vapeur à 355 °C. La décomposition initiale donne des atomes d'hydrogène et des radicaux cyclohexyles. Les produits volatils de la décomposition sont H_2, le cyclohexène, le propylène, l'éthane, l'éthylène, le méthane, le propane, le butadiène et le méthylcyclopentane. Les produits différents de H_2 et du cyclo-C_6H_{10} proviennent de réactions unimoléculaires à partir des radicaux cyclohexyles; le processus le plus important étant la formation de radicaux propylènes et allyles. Les rendements en hydrogène diminuent rapidement avec le temps par suite des réactions qui piègent les atomes d'H et qui impliquent des produits oléfiniques. Le rendement quantique correspondant à la formation d'hydrogène moléculaire pendant le temps d'exposition examiné le plus court est de 0.53.

Canadian Journal of Chemistry, **50**, 2010 (1972)

Introduction

The decomposition of cyclohexane vapor by triplet cadmium atoms has not been investigated previously. In the present investigation we have utilized the techniques employed previously to study the acetone decomposition, to examine the reaction between cyclohexane and $Cd(^3P_1)$ atoms. Unlike the analogous reaction with triplet mercury atoms, the energy required for C—H bond cleavage with this substrate is larger than the excitation energy of the sensitizer and thus the formation of CdH may be involved if the decomposition occurs.

The mercury photosensitized decomposition of cyclo-C_6H_{12} has been examined previously in both the liquid and vapor phase. Gunning and co-workers (2) studied the vapor phase system at 30 °C, while Arai *et al.* (3) carried out an investigation over the temperature range 60 to 400 °C. The liquid phase decomposition has been studied by Cramer (4) and by Klots and Johnsen (5). In every case the data obtained indicated that the primary step is rupture of the C—H bond giving cyclohexyl radicals and hydrogen atoms. At temperatures in excess of 250 °C, cyclohexyl radicals decompose giving olefins and alkyl radicals (3). The results of a study of the Hg-sensitized decomposition of cyclopentane at temperatures up to 376 °C by Gunning and Stock (6) are also relevant to this investigation.

Experimental

The essential details of the apparatus and procedures have been given previously (1). In the present work the light source was a Model 1500 Spectroline cadmium spectral lamp, filtered to remove 2288 Å radiation, so that only the 3261 Å resonance line, giving rise to $Cd(^3P_1)$ atoms is absorbed in the cell. The reaction cell assembly was operated at 355 ± 2 °C, while the side-arm cadmium metal reservoir was maintained at 315 °C. At the latter temperature, the vapor pressure of cadmium is 140 μ. The percent absorption by cadmium vapor in the reaction cell was determined using a Zeiss Model PMQ-II monochromator and photocell module to be 60%. The cadmium metal employed was Alpha Inorganics, Inc. 99.9999% purity.

Cyclohexane (British Drug Houses, reagent) was purified by distillation at atmospheric pressure through a glass helix packed column, retaining the fraction distilling at 81 °C at 710 Torr. The substrate was degassed and further fractionated at low temperature in the vacuum line. Gas chromatographic analysis confirmed the absence of impurities. The maximum cyclohexene impurity that would remain undetected is 0.001%.

Nitric oxide (Matheson) was pre-purified by the method of Hughes (7) and subsequently fractionated between −161 °C and −196 °C in the vacuum line. The NO for each run was distilled once, immediately prior to use, from −161 °C to remove any traces of NO_2 formed in storage. Carbon

tetrafluoride (Matheson) was degassed and purified by low temperature distillation. *cis*-Butene-2 and *trans*-butene-2 (Matheson) were freed from impurities by distillation in the vacuum line before storage, and the appropriate amount of butene-2 purified by preparative gas chromatography before each actinometry experiment.

Products non-condensable at −196 °C, H_2 and CH_4, were measured together in a gas burette and analyzed by gas chromatography using a 5 Å molecular sieve column and helium carrier gas for CH_4 or nitrogen carrier for H_2. The fraction volatile at −117 °C, principally lower molecular weight hydrocarbons, was analyzed on an 8 ft silica gel column operated at 100 °C. The remaining condensable products and unreacted substrate were eluted on a 12 ft dimethylsulfolane column. Identification of products was by mass spectrometric analysis of the compounds trapped from the g.c. effluent.

In runs with added CF_4 the fraction non-condensable at liquid oxygen temperature was removed before further separation of products. The butene-2 isomers were separated on a 15 ft ethylene glycol – silver nitrate column.

Light intensities were determined by measuring the initial rate of *cis–trans* isomerization of butene-2 (8) at pressures of 6.5 and 10 Torr for exposure times of 60 min, taking a value of $\Phi = 0.50$ for the process (9). A small amount of thermal isomerization occurred in the reaction cell and therefore thermal blanks were run concurrently with each sensitized reaction. The absorbed intensity determined in this way was 4.0×10^{-3} μeinstein min^{-1}. Because the extent of the thermal reaction was not particularly reproducible, there may be an error in the absolute magnitude of the reported quantum yields of ±10%.

Results

The products of the reaction of cyclohexane with $Cd(^3P_1)$ atoms at 355 °C are H_2, C_3H_6, cyclo-C_6H_{10}, C_2H_6, C_2H_4, CH_4, cyclo-$C_5H_9CH_3$, and C_3H_8. Small amounts of butadiene were also observed but the yields were too minute for accurate analysis. The possible product bicyclohexyl would not have been detected in the analytical procedures used here. Because of the relatively high temperatures at which this study was conducted, the possibility of direct thermal decomposition of the substrate was investigated. Thermal blanks were run with the substrate itself and with the various substrate–addend combinations used. No detectable dark reactions were found.

Figures 1 and 2 give the quantum yields of product formation as a function of substrate pressure for exposure times of 8 h. Because of the low absorbed intensity long exposure times were required to produce sufficient product for

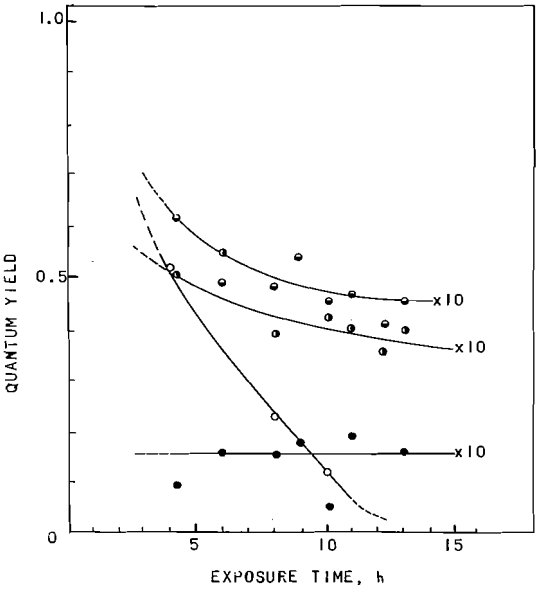

FIG. 3. Quantum yield of H_2, ○; cyclo-C_6H_{10} (× 10), ◒; cyclo-$C_5H_9CH_3$ (× 10), ◑; and CH_4 (× 10), ●; as a function of exposure time for the cadmium sensitized decomposition of cyclohexane at a pressure of 80 Torr and a temperature of 355 °C.

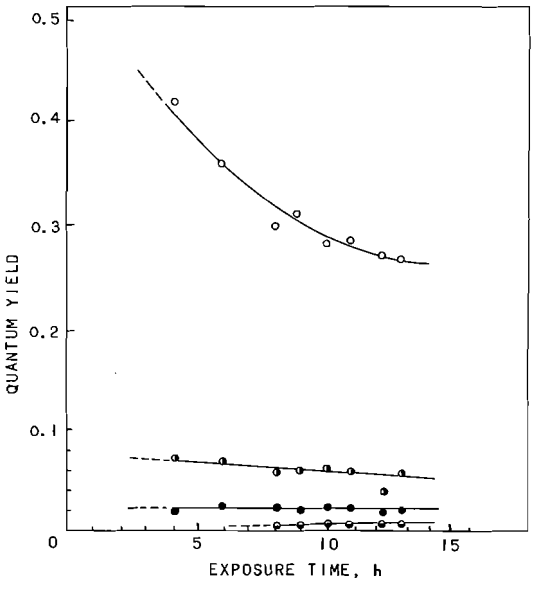

FIG. 4. Quantum yield of C_3H_6, ○; C_2H_6, ◑; C_2H_4, ●; and C_3H_8, ◒; as a function of exposure time in the cadmium sensitized decomposition of cyclohexane at a pressure of 80 Torr and a temperature of 355 °C.

analysis. At the highest substrate pressure examined, the amount of H_2 formed corresponds to 0.1% decomposition of the substrate.

Although there is some scatter in the observed hydrogen yields, it would appear that at 80 Torr substrate pressure the system is in, or very close to the substrate concentration region where there is complete quenching of $Cd(^3P_1)$ atoms. With the exception of C_2H_6, the products attain a constant rate of formation at lower pressures. The number of data for hydrogen is less than that for the other products since H_2 was determined separately in a second set of experiments.

Figures 3 and 4 show the results of a series of experiments in which the rate of formation of reaction products was determined as a function of exposure time. It is apparent that the yield of hydrogen is quite strongly dependent on time, as is that of cyclohexene and, to a lesser extent, methylcyclopentane. The rates for the other minor products appear to be constant within experimental error.

To assess the effects of radical scavenger on the reaction a series of runs was performed in the presence of nitric oxide. The observed quantum yields for products that could be analyzed are listed in Table 1. No attempt was made to identify or analyze products that may have resulted from the radical–NO reactions that are likely occurring in such a system. The data are a clear indication that the decomposition in general is free radical in character, although it is to be noted that the rate of formation of cyclohexene appears to be decreasing appreciably less rapidly than that of other products.

The possibility that the decomposition proceeds through a relatively long lived excited substrate molecule capable of being collisionally deactivated was explored in a series of experiments in which the effect of added carbon tetrafluoride as inert addend was determined. The results are listed in Table 2. Propylene, cyclohexene, and methylcyclopentane continue to be formed at the same rate. The reported ethane yields are subject to some uncertainty because of the mechanical difficulties in quantitatively separating this product from the large amount of addend.

Because of the indication from the radical scavenger studies that cyclohexene might be formed, along with H_2, in a molecular process, the rates of formation of products as a function

of added propylene, intended primarily as a scavenger of H-atoms, were determined. The quantum yield data are tabulated in Table 3. With the exception of the experiment at $P(C_3H_6) = 14$ Torr, where the addend is responsible for 65% of the quenching, *vide infra*, the yields of all products, apart from propane, decrease as the pressure of addend is increased. The rate of formation of propane increases as a result of H-atom abstraction by propyl radicals which result from the addition of hydrogen atoms, formed in the primary process, to propylene. Of particular interest in this series is the fact that the rate of H_2 formation becomes indetectably small at propylene pressures of 7 Torr or greater. The cadmium photosensitized decomposition of propylene itself has been investigated recently (10) and no chemical decomposition is observed, although there is detectable *cis–trans* isomerization of propylene-d_4.

For experiments with added gases it is necessary to correct the observed yields for competitive quenching of triplet cadmium atoms by

the addend. In the absence of a value for the quenching cross section of the substrate, σ^2(cyclohexane) was calculated from an additivity rule proposed by Darwent (11), using the measured cross section for cyclopropane, 0.71 Å^2 (12), as follows: σ for cyclo-C_3H_6 = 0.84 Å, and thus σ^2 for cyclo-$C_6H_{12} = (6 \times 0.84/3)^2 = 2.8$ Å^2. Thus the results obtained in the presence of propylene were corrected using that value of σ^2(cyclohexane) and the value of 29.1 Å^2 for σ^2(propylene) determined by Steacie and LeRoy (12).

Quenching cross sections have not been determined for NO or CF_4. The data obtained with added nitric oxide have therefore not been corrected for competitive quenching, and quantitative interpretation of those results is thus not possible. For CF_4 it has been assumed that, as in the case of Hg($^3P_1$)atoms, its quenching cross section for triplet cadmium is negligibly small. That assumption is consistent with our observation here that added CF_4 has virtually no effect on the rates of product formation.

Discussion

The nature of the observed reaction products indicates that the net result of the primary process is the production of H-atoms and cyclo-C_6H_{11} radicals, and that the products formed in lesser amounts arise from unimolecular decomposition of the latter species.

Two alternatives must be considered for the primary process: the decomposition giving H-atoms directly,

[1*a*] $Cd(^3P_1) + \text{cyclo-}C_6H_{12} \rightarrow Cd(^1S_0) + \text{cyclo-}C_6H_{11} + H$

or a sequence of two steps involving the intermediate formation of cadmium hydride,

[1*b*] $Cd(^3P_1) + \text{cyclo-}C_6H_{12} \rightarrow CdH + \text{cyclo-}C_6H_{11}$

[1*c*] $CdH \rightarrow Cd + H$

Energetic considerations do not give a clear indication of the relative importance of these two possibilities. Unlike the case of mercury photosensitization of hydrocarbons in general, cadmium hydride formation has been observed (13). The excitation energy of Cd($^3P_1$) atoms is 87.3 kcal/mol (3261 Å). The formation of CdH in the primary energy transfer process would make available an additional 15.5 kcal/mol, and the carbon–hydrogen bond energy in the substrate is 94 kcal/mol (14). Assuming classical vibrational energy contributions to the energy of cyclohexane at 355 °C, there would be available a total of *ca.* 15 kcal/mol vibrational energy in excess of that at 25 °C. If the usual assumption that about half of this energy would be available for rupture of an individual bond is made, there would be just sufficient energy for reaction 1*a* to occur. On the other hand, if the energy transfer process occurs through an abstractive type intermediate such as cyclo-C_6H_{12}····H···Cd, the vibrational energy partitioning may be appreciably altered in a way that reduces the net energy available for C—H bond rupture. Therefore, although there are attendant experimental difficulties, it would be instructive with respect to elucidating the role of reaction 1*b* to examine this system at lower temperatures where the contribution from thermal excitation is reduced.

The possibility of a primary process in which there is molecular hydrogen formation can be ruled out on the basis that this product is reduced to zero in the presence of sufficient propylene to scavenge the hydrogen atoms from whose abstraction reaction H_2 evidently arises.

A primary process of the excited molecule type in which cyclohexane molecules are formed in an excited state of sufficient longevity to be susceptible to collisional deactivation can also be excluded on the evidence that the overall extent of decomposition is unaffected by the addition of CF_4 up to 422 Torr.

Although their interpretation is complicated by the possible reactions of RNO type products that are involved and the absence of cross section data to permit competitive quenching corrections, the results obtained in the presence of nitric oxide strongly suggest that the decomposition proceeds via free radical rather than molecular reactions, and indeed the formation of all reaction products may be explained on that basis. Thus reaction 1 would be followed by

[2] $H + \text{cyclo-}C_6H_{12} \rightarrow H_2 + \text{cyclo-}C_6H_{11}$

[3] $2\ \text{cyclo-}C_6H_{11} \rightarrow \text{cyclo-}C_6H_{10} + \text{cyclo-}C_6H_{12}$

[4] $2\ \text{cyclo-}C_6H_{11} \rightarrow \text{bicyclohexane}$

The major product propylene arises via the unimolecular decomposition of cyclohexyl radicals,

[5] $\text{cyclo-}C_6H_{11} \rightarrow C_3H_6 + C_3H_5$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which would be followed by

[6] $C_3H_5 + \text{cyclo-}C_6H_{12} \rightarrow C_3H_6 + \text{cyclo-}C_6H_{11}$

and other radical–radical reactions of the resonance stabilized allyl radical. The activation energy for process 6 is likely rather high, the analogous process for H-atom abstraction from cyclopentane has an activation energy of 32 kcal/mol (15), and thus radical–radical reactions would be more important. Furthermore, if reaction 6 were important reactions 5 and 6 would give rise to a chain reaction and appreciably larger yields of propylene than were observed.

The strong dependence of rate of production of H_2, propylene, and cyclohexene indicates that H-atom scavenging reactions by olefinic products, a well established phenomenon in sensitized alkane decompositions in general (16, 17), is occurring to an appreciable extent here. Propylene is the olefin present in largest concentrations and therefore the most important reaction of this type will be

[7] $H + C_3H_6 \rightarrow C_3H_7$

The propyl radicals so formed account, via reaction 8,

[8] $C_3H_7 + \text{cyclo-}C_6H_{12} \rightarrow C_3H_8 + \text{cyclo-}C_6H_{11}$

for the observed production of propane. Propyl radicals also account, in part, for the formation of ethylene and products arising from CH_3 radicals, through the unimolecular decomposition process

[9] $C_3H_7 \rightarrow CH_3 + C_2H_4$

The reaction analogous to [7] with cyclohexene evidently occurs to a lesser extent, while ethylene, the olefin present in smallest concentrations, does not appear to compete successfully for H-atoms, as suggested by the time independence of its quantum yield.

Three other possible modes of unimolecular decomposition of the substrate radical should be considered in connection with the formation of the minor products CH_4, C_2H_6, and C_2H_4.

[10] $\text{cyclo-}C_6H_{11} \rightarrow C_4H_7 + C_2H_4$

[11] $\text{cyclo-}C_6H_{11} \rightarrow CH_3 + C_5H_8$

[12] $\text{cyclo-}C_6H_{11} \rightarrow C_2H_5 + C_4H_6$

Butene would have been detected here and its absence indicates that either reaction 10 is not occurring to a measurable extent, or that C_4H_7 radicals also undergo thermal decomposition at 355 °C, giving rise to additional ethylene via the sequence

[13] $C_4H_7 \rightarrow C_2H_4 + C_2H_3$

[14] $C_2H_3 + \text{cyclo-}C_6H_{12} \rightarrow C_2H_4 + \text{cyclo-}C_6H_{11}$

Pentadiene would be obscured by the large substrate peak in the g.c. analysis and thus the yield of CH_4 can be interpreted only as an upper limit for the contribution of reaction 11, since CH_3 radicals are also formed in process 9.

Ethane is produced in amounts greater than the trace quantities of butadiene found. The latter would be highly reactive towards H-atoms, but its small concentration suggests that the inequality $R(C_2H_6) > R(C_4H_6)$ arises because of an additional ethane source, for example CH_3 recombination, rather than significant C_4H_6 consumption. The mode of methylcyclopentane formation is not immediately apparent.

The quantum yields observed at the shortest exposure times that could be examined here, together with evidence for secondary consumption of H-atoms by olefins, suggests that the primary process likely occurs with unit efficiency, although precise measurements of quantum yields at short exposure times would be required to establish that characteristic.

Finally, comparison of the results obtained in this study with those reported previously for the Hg-sensitized decomposition of cyclohexane (3) and cyclopentane (6) at similar temperatures indicates that the decomposition proceeds through essentially the same mechanism despite the significant difference in the energy available from the sensitizer.

The authors gratefully acknowledge the financial support of the National Research Council of Canada for this research and the University of Saskatchewan for provision of a Graduate Scholarship to B.L.K.

The Photolysis of Benzoic Acid in the Vapor Phase

FRANCIS CHAU, CYRIL GIBBONS, AND DONALD BARTON

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received February 24, 1971[1]

The photolysis of benzoic acid in the vapor phase has been investigated in a flow system at temperatures ranging from 110–305 °C, pressures from 0.06–1.73 Torr, and at various incident light intensities. Carbon dioxide and benzene are the main products and carbon monoxide is a minor product. The rate of formation of carbon dioxide is proportional to the first power of the light intensity and is independent of benzoic acid concentration at pressures from 0.29–1.73 Torr. The activation energy for carbon dioxide formation is approximately 3 kcal per mol. A radical chain mechanism has been suggested, in which initiation results from decomposition of vibrationally excited ground state benzoic acid molecules, and termination occurs at the wall. A molecular mechanism is a possibility if the rate of formation of vibrationally excited ground state is a function of temperature.

La photolyse de l'acide benzoïque en courant gazeux a été examinée à des températures s'échelonnant de 110–305 °C, à des pressions de 0.06–1.73 Torr et pour diverses intensités de lumière incidente. Les produits majeurs sont le gaz carbonique et le benzène, l'oxyde de carbone est le produit mineur. La vitesse de formation du CO_2 est proportionnelle à la puissance première de l'intensité lumineuse et est indépendante de la concentration en acide benzoïque pour des pressions allant de 0.29–1.73 Torr. L'énergie d'activation pour la formation du gaz carbonique est approximativement de 3 kcal/mol. Un mécanisme en chaîne radicalaire a été suggéré dans lequel l'initiation résulte de la décomposition des molécules d'acide benzoique dont l'état fondamental est vibrationnellement excité et la terminaison se produit sur les parois. Un mécanisme moléculaire reste possible si la vitesse de formation de l'état fondamental vibrationnellement excité, dépend de la température.

Introduction

The primary reactions 1, 1*a*, 2, 3, and 4 have been shown to occur during the photolysis of organic acids in the vapor phase. The intra-

[1] $RCOOH \rightarrow RCO + OH$

[1*a*] $RCOOH \rightarrow RCO_2 + H$

[2] $R_2CHCR_2CR_2COOH \rightarrow R_2C=CR_2 + HCR_2COOH$

[3] $RCOOH \rightarrow RH + CO_2$

[4] $RCOOH \rightarrow R + COOH$

molecular process [3] accounted for a part of the CO_2 produced in the photolysis of acetic acid. Reactions 1 and 1*a*, variations of the Norrish type I split, as well as [4], were also suggested (1). Reaction 1 was proposed as the major primary reaction in the photolysis of formic acid (2). The primary reactions for *n*-butyric acid were found to be reaction 2, the Norrish type II split, and the variations of the type I split, reactions 1 and 1*a* (3).

The first absorption band of the aliphatic organic acids, a weak band lying in the near u.v., is thought to be due to an $n \rightarrow \pi^*$ singlet–singlet transition of a non-bonding electron of the oxygen atom (4). The absorption of radiation in this region is responsible for reactions 1–4 of the aliphatic acids. For benzoic acid, an intense absorption band ($\varepsilon \sim 10^4$ 1 mol^{-1} cm^{-1}) is observed in the near u.v. (5). This band is attributed not to an $n \rightarrow \pi^*$ transition but to a $\pi \rightarrow \pi^*$ transition of the phenyl ring, which is conjugated with the carboxyl group (6, 7).

As a contribution to the understanding of the photochemistry of the aromatic acids in the vapor phase, we report the results of an exploratory study of the photolysis of benzoic acid.

Experimental

Since the relevant extinction coefficient is large the pressure was maintained at ~0.06 Torr during the preliminary experiments, but the restriction was relaxed after the order with respect to light intensity had been observed (8). The vapor was composed substantially of monomeric benzoic acid over the selected temperature and pressure ranges (9). A flow system, composed of a reservoir of benzoic acid, cylindrical vitreosil reaction vessel (length 10 cm, diameter 5 cm), trap, mercury diffusion pump, toepler pump, and gas buret, was used. Analyses were carried out by gas buret, mass spectrometer, titration, and gas chromatograph. Reported gas temperatures are considered to be reliable within 2 °C (10, 11).

The light source was a Hanovia type A S-500 medium

[1]Revision received March 15, 1972.

pressure mercury arc. Neutral density filters of 50.0 and 31.6% (Oriel Optics Corp.), and Corning filters CS 9-54 (7910) and CS 7-54 (9863) were used. Pressures were measured by means of a capacitance manometer (Granville–Phillips Co.).

Benzoic acid (McArthur Chemical Co.) was melted, cooled, ground, and evacuated on the line at 0 °C.

Results

Products

The results of some preliminary experiments are summarized in Table 1. The yields of CO_2, averaging $(1.63 \pm 0.08) \times 10^{-6}$ mol, are moderately reproducible with a thermal contribution of the same order of magnitude as the average deviation. The yield of CO is less reproducible and the thermal contribution is relatively larger. There is no evidence for photochemically produced H_2. The yield of C_6H_6 is rather more erratic than was expected from tests of the procedure for recovery and analysis. Although unsuccessful attempts were made to identify biphenyl and phenol, small amounts of these and other products may be present; in fact, the presence of CO (and H_2, although no doubt a thermal contribution) is consistent with the presence of aromatic compounds in addition to C_6H_6.

The results of detailed studies reported below centered upon the rate of formation of CO_2, and to a smaller extent upon CO. The experiments were performed at a slightly different lamp intensity than was used in the preliminary experiments.

Effective Radiation

The near u.v. absorption bands of benzoic acid are reported to be, in ethanol–water solution for example, at 2020, 2280, and 2790 Å with extinction coefficients of 8000, 11 000, and 5501 $mol^{-1}\ cm^{-1}$ respectively (6). The mercury lamp emits radiation at intensities of the same order of magnitude over both of the longer wavelength bands. Two experiments were performed using a Corning CS 9-54 filter, which transmits from 75–85% of the radiation in the range 2600–2900 Å, ~5% at 2200, ~25% at 2300 and ~45% at 2400 Å. The results are compared in Table 2 with experiments performed without the filter and with some thermal reactions. A preliminary experiment in a static system at a benzoic acid pressure of ~40 mm, with no filter, resulted in a yield similar to those reported in Table 2. When a Corning CS 7-54 filter was used, which transmits ~0% of the radiation up to 2300 Å and ~15% at 2400 Å, no products were detected. The radiation responsible for the formation of CO and CO_2 in this study clearly corresponds to the intense absorption band near 2280 Å which is attributed to a $\pi \rightarrow \pi^*$ transition. This is not surprising, since the intensity of light

absorbed is very small over the longer wavelength band.

Light Intensity

The effect upon the rate of formation of CO_2 of changing the light intensity is shown in Fig. 1. The order for CO_2 formation with respect to light intensity is 1.06 ± 0.05 at 150° and 1.00 ± 0.05 at 205 °C. Results are similar for CO formation, shown in Fig. 2, although the thermal reaction makes a relatively large contribution. The experiments on the effect of light intensity were carried out before the installation of the capacitance manometer. Consequently the exact pressure is unknown, but was fixed at ~0.06 Torr for all experiments by regulating the temperature of the solid benzoic acid.

Order of Reaction for CO_2 Formation

The rates of formation of CO_2 were measured at various pressures of benzoic acid at 152 °C and the results are plotted in Fig. 3. Although the points are scattered it is apparent that the rate is insensitive to the concentration of benzoic acid over the range 1.0×10^{-5} to 6.5×10^{-5} mol l^{-1}. After making approximate corrections to the five results at the lowest pressures, at which the absorption of light is incomplete, by dividing by $(1 - \exp [C_6H_5COOH] \times 11\,000 \times 10)$, the slope of the log–log plot was found to be 0.02 ± 0.05. Comments on the scatter in the results will be found below.

Activation Energy

From the slopes of the plots in Fig. 1, the activation energy for CO_2 formation was estimated to be 2700 ± 600 cal mol^{-1}. Some additional data were obtained at temperatures of 110, 153, 209, and 305 °C and concentrations of 1.16, 1.09, 0.86, and 1.28×10^{-5} mol l^{-1} respectively. Since the rate of formation of CO_2 was shown to be insensitive to pressure, an Arrhenius plot of these data is justified. The results from a number of thermal reactions which were carried out at various temperatures and pressures showed that the thermal reaction rate was usually less than 5% of the photochemical rate, but was variable. Although corrections for the thermal reaction were not applied to the rates at the four temperatures, any such corrections up to ≈10% would not alter the conclusion reached regarding the temperature dependence of the

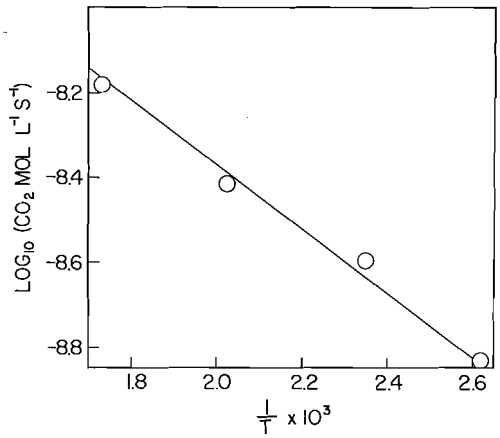

FIG. 4. Arrhenius plot for CO_2 formation.

photochemical reaction. The Arrhenius plot, from which the activation energy was found to be 3500 ± 400 cal mol^{-1}, is shown in Fig. 4.

An appreciable activation energy was also found in the reaction producing CO, as is apparent in Fig. 2.

Following exposure of the reaction vessel to air a fast thermal reaction was observed, up to 20 times as fast as the thermal contributions already reported. This phenomena had been observed previously during a study of the thermal reactions of benzoic acid in the gas phase (12).

Discussion

The effect of temperature on the rate probably rules out direct formation from the excited singlet state as the major reaction yielding CO and CO_2 (13). Chain mechanisms, which were adapted from those discussed by Noyes and Leighton (14), were at first considered. Reac-

[5] $C_6H_5COOH + h\nu \rightarrow C_6H_5 + COOH$

[6] $C_6H_5 + C_6H_5COOH \rightarrow C_6H_6 + C_6H_5CO_2$

[7] $C_6H_5CO_2 \rightarrow C_6H_5 + CO_2$

[8] $C_6H_5 + \text{wall} \rightarrow \text{products}$

[9] $2C_6H_5 \rightarrow (C_6H_5)_2$

tions 5–7 with the homogeneous termination reaction 9 yield the rate expression:

$$d[CO_2]/dt = (k_6/k_9)I_a^{1/2}[C_6H_5COOH]$$

and with the heterogeneous reaction 8 yield

$$d[CO_2]/dt = (2k_6/k_8)I_a[C_6H_5COOH]$$

The evidence favors the wall termination reaction 8 since the rate depends upon I_a, not upon $I_a^{1/2}$. The observed scatter in the results may reflect the variation in efficiency of reaction 8 due to changes in the condition of the wall of the reaction vessel.

Since the order with respect to benzoic acid is approximately zero, a modification of the mechanism is required. This order would be observed if the absorption of a photon is followed mainly by collisional deactivation by benzoic acid molecules rather than by reaction. Reaction 5 would be replaced by [10], [11], and [12]. The electronically excited state is repre-

[10] $C_6H_5COOH + h\nu \rightarrow C_6H_5COOH^*$

[11] $C_6H_5COOH^* \rightarrow C_6H_5 + COOH$

[12] $C_6H_5COOH^* + M \rightarrow C_6H_5COOH + M$

sented by $C_6H_5COOH^*$ and, in pure benzoic acid, M represents a molecule of benzoic acid. The radiative lifetime of the excited molecule would however be rather short, since the extinction coefficient is large. Using the expression

$$\tau \sim \frac{10^{-4}}{\varepsilon_{max}}$$

the radiative lifetime is estimated to be $\sim 10^{-8}$ s. The collision frequency at the pressures used would be such that radiative decay would be 10^2 or 10^3 more probable than collisional deactivation, and the radiative lifetime is too short to allow the molecule to undergo deactivating collisions. This problem has been discussed by Srinivasan (15). Since there is a large energy difference between the first excited singlet state and the first excited triplet state (16), the probability of intersystem crossing is small (17). For purposes of discussion the possibility of the existence of other triplet states below the first excited singlet state has been neglected.

We therefore propose that internal conversion is rapid, and that reaction takes place from the vibrationally excited ground state. A reasonable mechanism, which can serve as a basis for future work and discussion, is given.

[10] $C_6H_5COOH + h\nu \rightarrow C_6H_5COOH^*$

[13] $C_6H_5COOH^* \rightarrow C_6H_5COOH'$

[14] $C_6H_5COOH' + M \rightarrow C_6H_5COOH + M$

[15] $C_6H_5COOH' \rightarrow C_6H_5 + COOH$

[6] $C_6H_5 + C_6H_5COOH \rightarrow C_6H_6 + C_6H_5CO_2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[7] $C_6H_5CO_2 \rightarrow C_6H_5 + CO_2$

[8] $C_6H_5 + \text{wall} \rightarrow \text{products}$

The vibrationally excited ground state is represented as C_6H_5COOH'. The rate expression is

$$d[CO_2]/dt = (k_6k_{15}/k_{14}k_8)I_a,$$

if $k_{14}[M] \gg k_{15}$. The inequality may be rationalized by making a rough estimate of the rates of the two steps. The collision frequency was used to calculate the rate of deactivation, with an efficiency of one and a molecular diameter of 7 Å. The rate of decomposition was estimated by means of the classical expression, $-d[C_6H_5COOH']/dt = A(1 - E^*/E)^{s-1}[C_6H_5COOH']$, with $A = 10^{14}\ s^{-1}$, $E^* = 97$ kcal, $E = 125$ kcal, and $s = 20$. E^* is ΔH for reaction 15 (18–20) and E is the energy of the absorbed photon. The two calculated rates are equal at $\sim 10^{-3}$ mm, suggesting that deactivation predominates over the range of pressure used in this study.

The rate of reaction 15 is not strongly dependent upon temperature because the energy delivered by the photon is ~ 30 kcal greater than the heat of reaction. Since the rates of reactions 8 and 14 are also not strongly dependent upon temperature, the activation energy according to this mechanism, can be attributed largely to reaction 6.

Mechanisms which do not involve radicals may be invoked. If, for example, the internal conversion process [13] is affected by temperature a mechanism in which fluorescence competes with internal conversion is possible.

[10] $C_6H_5COOH + h\nu \rightarrow C_6H_5COOH^*$

[16] $C_6H_5COOH^* \rightarrow C_6H_5COOH + h\nu$

[13] $C_6H_5COOH^* \rightarrow C_6H_5COOH'$

[17] $C_6H_5COOH' \rightarrow C_6H_6 + CO_2$

The rate expression is

$$d[CO_2]/dt = (k_{13}I_a)/(k_{13} + k_{16})$$

Similar but more intricate mechanisms may be written.

The CO formation data suggest analogous mechanisms, although the effect of benzoic acid pressure was not obtained and the thermal contribution is rather large.

Clearly the system is an interesting one and further research into the quantum yields, effect of inert gases, and into the photophysical processes is in order.

We thank Dr. J. F. Ogilvie for his advice and the interest which he has shown in this work, and a referee for suggestions. Financial support from the National Research Council of Canada is gratefully acknowledged.

A New Synthesis of "Schöpf's Base VI" and Related 10*H*-Isoindolo[2,3-*c*]benzazepines

S. TEITEL, W. KLÖTZER,[1] J. BORGESE, AND A. BROSSI

Chemical Research Department, Hoffmann-La Roche Inc., Nutley, New Jersey 07110

Received January 24, 1972

The 10*H*-isoindolo[2,3-*c*][3]benzazepines, "Schöpf's base VI" (**4***a*) and its 4-methoxy derivative **4***b*, have been prepared by a new and facile synthesis which utilized intermediates derived from phthalideisoquinoline alkaloids.

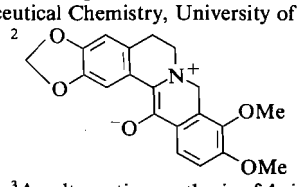
Les 10*H*-isoindole[2,3-*c*][3]benzazépines, la base VI (**4***a*) de Schöpf et son 4-méthoxy dérivé **4***b*, ont été préparés par une nouvelle synthèse et facile qui a utilisé des produits intermédiaires dérivés des alcaloïdes phthalideisoquinoléniques.

Canadian Journal of Chemistry, **50**, 2022 (1972)

The tetracyclic base, obtained as a minor product by reduction of neooxyberberine[2] with zinc and acetic acid (1), was shown by Schöpf and Schweickert (2) to be 8,9-dimethoxy-2,3-methylenedioxy-5,5*a*,12,13-tetrahydro-10*H*-isoindolo[2,3-*c*][3]benzazepine (**4***a*). Commonly referred to as "Schöpf's base VI", **4***a* is of interest because of its relationship with the papaverrubine alkaloids (3). We now describe a novel and facile synthesis of **4***a* as well as its 4-methoxy derivative **4***b*. This was accomplished by reaction sequences which utilized the dihydrobenzazepine sodium salts **1** previously obtained from the phthalide alkaloids (−)-β-hydrastine and (−)-α-narcotine (4, 5). The key intermediate lactams **3** were prepared from the saturated amino acids **2** by *N*-demethylation and cyclization with acetic anhydride (6, 7).[3]

Consecutive treatment of the dihydrobenzazepine sodium salt **1***a* (4) with acetic acid[4] and lithium borohydride in tetrahydrofuran afforded the saturated benzazepine carboxylic acid **2***a*. Reaction of **2***a* with refluxing acetic anhydride formed the lactam **3***a* which was reduced with diborane in tetrahydrofuran to provide the tetracyclic base **4***a*. The physical and spectral properties of **4***a* were identical with an authentic sample[5] of "Schöpf's base VI" (2). By the same reaction sequences, the methoxy-substituted dihydrobenzazepine sodium salt **1***b* (5) was transformed into the corresponding substituted tetracyclic base **4***b*.

[1]Visiting Professor, Institute of Organic and Pharmaceutical Chemistry, University of Innsbruck, Austria.



[3]An alternative synthesis of **4***a* involving photocyclization was recently reported (8).

[4]Mineral acid effects conversion to the phthalideisoquinoline (5).

Experimental

Melting points were taken on a Kofler microscope hot stage and are uncorrected. The u.v. spectra were measured in ethanol with a Cary recording spectrophotometer Model 14M and the i.r. spectra were determined with a Beckman Infrared Model IR-9 in KBr, unless otherwise noted. The n.m.r. spectra were obtained on a Varian HA-100 spectrophotometer using tetramethylsilane as internal reference. Chemical shifts are reported in δ with the following abbreviations: (s) singlet, (d) doublet, (m) multiplet, (b) broad. The mass spectra were taken with a CEF 21–110 mass spectrometer at 70 eV using a direct insertion probe. Extracts of products in organic solvents were washed with water and dried over anhydrous sodium sulfate prior to evaporation. Water of crystallization in compounds **2***a*, hydrobromide of **4***a*, **2***b*, and hydrochloride of **2***b* was determined with the Karl Fischer reagent.

*6-(7,8-Methylenedioxy-3-methyl-1,2,4,5-tetrahydro-3H-3-benzazepin-2-yl)-o-veratric Acid Hemihydrate (**2***a*)*

A solution of 6-(4,5-dihydro-7,8-methylenedioxy-3-methyl-3*H*-3-benzazepin-2-yl)-*o*-veratric acid sodium salt (**1***a*) (4) (20 g, 0.049 mol) in water (480 ml) was adjusted to p*H* 5 with acetic acid (12 ml), extracted with methylene chloride (three 80 ml portions) and the combined extracts evaporated. The residual oil was dissolved in tetrahydrofuran

[5]We are grateful to Professor G. Habermehl, Technische Hochschule Darmstadt, Germany, for providing us with a sample.

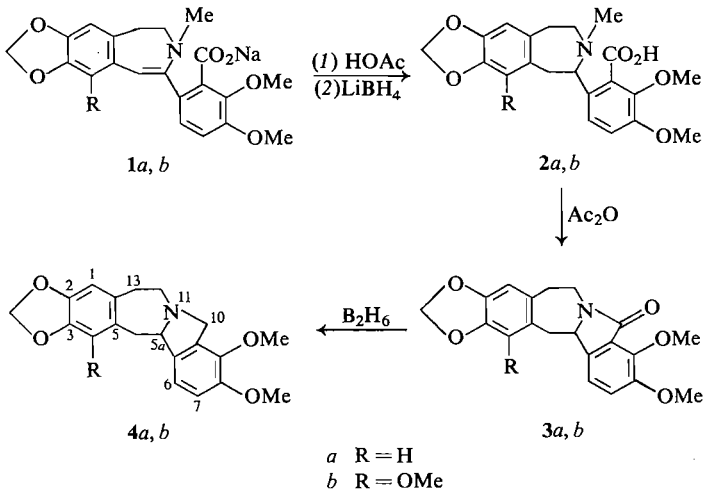
For personal use only.



(200 ml), cooled to 4°, and a solution of lithium borohydride (4.4 g, 0.202 mol) in tetrahydrofuran (100 ml) added over 15 min. The reaction mixture was allowed to warm to room temperature, stored for 2 h, and evaporated under reduced pressure. The residual oil was dissolved in water (160 ml), acetic acid (26 ml) added, the resulting suspension heated at 95° for 30 min and cooled. The crystals were collected to give **2***a* (17.1 g, 90%), m.p. 230–231°. An analytical sample prepared from methanol exhibited: m.p. 234–236°; u.v. max 235 (ε 12 500) (infl), 289 nm (6020); i.r. 2700–2400, 1700, 1575 cm^{-1}; n.m.r. (MeOD) δ 2.52 (s, 3, NCH_3), 2.75–3.50 (m, 6, 3 CH_2), 3.83 (s, 6, 2 OCH_3), 4.50 (m, 1, CH), 5.88 (s, 2, OCH_2O), 6.70 (s, 2, arom), 6.96, 7.07 (2d, 2, *J* (ortho) = 8 Hz, arom).

Anal. Calcd. for $C_{21}H_{23}NO_6 \cdot 0.5\ H_2O$ (394.42): C, 63.96; H, 6.13; N, 3.55. Found: C, 64.09; H, 5.99; N, 3.61.

8,9-Dimethoxy-2,3-methylenedioxy-5,5a,12,13-tetrahydro-10H-isoindolo[2,3-c][3]benzazepin-10-one (3a)

A mixture of the saturated benzazepine carboxylic acid **2***a* (9.8 g, 0.0256 mol) in acetic anhydride (140 ml) was refluxed in a nitrogen atmosphere for 1 h, water (250 ml) added, and allowed to cool to room temperature. The resulting crystals were filtered, washed with water, and dried to give **3***a* (5.8 g, 64%), m.p. 228–229°. An analytical specimen prepared from methanol exhibited: m.p. 228–229°; u.v. max 202 (ε 62 600), 213 (44 500) (infl), 233 (18 500) (infl), 293 nm (9500); i.r. 2780, 1678, 1290, 1265, 1590, 1492, 1480 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.90 (m, 4, 2 CH_2), 3.95, 4.09 (2s, 6, 2 OCH_3), 4.1–5.0 (m, 3, CH + CH_2N), 5.81 (s, 2, OCH_2O), 6.65, 6.72, 7.11 (3s, 3, arom).

Anal. Calcd. for $C_{20}H_{19}NO_5$ (353.36): C, 67.98; H, 5.42; N. 3.96. Found: C, 67.79; H, 5.36; N, 3.95.

8,9-Dimethoxy-2,3-methylenedioxy-5,5a,12,13-tetrahydro-10-H-isoindolo[2,3-c][3]benzazepine ("Schöpf's base VI") (4a)

A mixture of the lactam **3***a* (5 g, 0.014 mol) in tetrahydrofuran (250 ml) and a solution of 1 *M* diborane in tetrahydrofuran (25 ml) was refluxed for 48 h, cooled, and evaporated under reduced pressure. The residue was suspended in water (100 ml), extracted with chloroform (three 100-ml portions), the combined extracts evaporated, the residue dissolved in methanol (415 ml), refluxed for 2 h, and cooled. The crystals were filtered and dried to give **4***a* (3.58 g, 75%), m.p. 176–177°. An analytical specimen prepared by sublimation exhibited: m.p. 177–179° (lit. (2): m.p. 180–181°); i.r. 2815, 2760, 2745, 1618, 1500, 1263 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.5–3.5 (m, 7, 3 CH_2 + CH), 2.62 (d'd, 1, *J* = 13, 3Hz, CH of CH_2), 3.84, 3.86 (2s, 6, 2 OCH_3), 4.35 (d, 1, *J* = 13 Hz, CH of CH_2), 5.90 (s, 2, OCH_2O), 6.65, 6.74 (2s, 2, arom), 6.80, 6.88 (2d, 2, *J* (ortho) = 8 Hz, arom); mass spectrum *m/e* (relative intensity) 339 (100), 337 (10), 324 (29), 322 (4), 191 (5), 176 (6), 163 (35), 162 (23); identical in mixed m.p., t.l.c., and mass spectrum with an authentic sample[5] of "Schöpf's base VI" (2).

Anal. Calcd. for $C_{20}H_{21}NO_4$ (339.38): C, 70.78; H, 6.24; N, 4.13. Found: C, 70.62; H, 6.33; N, 4.03.

The hydrobromide of **4***a* was prepared in the usual manner and crystallized from 2% hydrobromic acid, m.p. 212–215° (lit. (2): m.p. 212–214°).

Anal. Calcd. for $C_{20}H_{21}NO_4 \cdot HBr \cdot 0.5\ H_2O$ (429.29): C, 55.96; H, 5.40; N, 3.26. Found: C, 55.83; H, 5.43; N, 3.16.

6-(9-Methoxy-7,8-methylenedioxy-3-methyl-1,2,4,5-tetrahydro-3H-3-benzazepin-2-yl)-o-veratric Acid Sesquihydrate (2b)

By the procedure described for **2***a*, 6-(4,5-dihydro-9-methoxy-7,8-methylenedioxy-3-methyl-3*H*-3-benzazepin-2-yl)-*o*-veratric acid sodium salt (**1***b*) (5) (19 g, 0.043 mol) afforded **2***b* (15.6 g, 88%), m.p. 160–165° (from methanol).

Anal. Calcd. for $C_{22}H_{25}NO_7 \cdot 1.5\ H_2O$ (442.44): C, 59.73; H, 6.38; N, 3.17. Found: C, 59.93; H, 6.53; N, 3.17.

The hydrochloride of **2***b* exhibited: m.p. 220–225° (from a mixture of methanol and 1 *N* hydrochloric acid); u.v. max 212 (ε 67 000), 239 (15 000) (infl), 285 nm (4000); i.r. 3400, 2670, 2620, 2520, 1714, 1270, 1227 cm^{-1}; n.m.r. (DMSO-d_6) δ 2.44 (s, 3, CH_3N) 3.82 (s, 6, 2 OCH_3), 3.92 (s, 3, OCH_3), 6.00 (s, 2, OCH_2O), 6.62 (s, 1, arom), 7.28, 8.03 (2d, 2, *J* (ortho) = 9 Hz, arom), 12.35 (b, 1, N^+H).

Anal. Calcd. for $C_{22}H_{25}NO_7 \cdot HCl \cdot 0.25\ H_2O$ (456.42): C, 58.00; H, 5.84; N, 3.07. Found: C, 58.02; H, 5.96; N, 3.05.

The Synthesis of Two Phenacetin Metabolites

A. FOCELLA, P. HESLIN, AND S. TEITEL
Chemical Research Department, Hoffmann–La Roche Inc., Nutley, New Jersey 07110

Received January 24, 1972

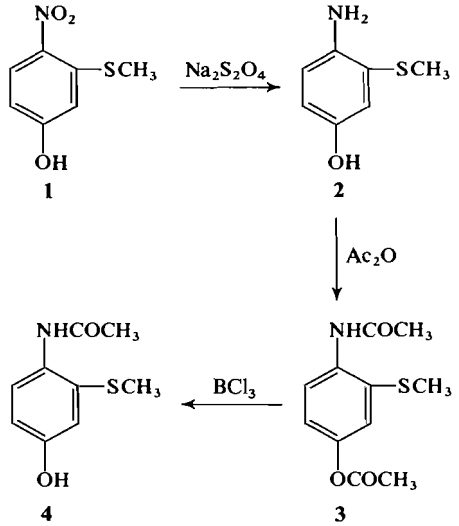
A new metabolite of phenacetin was identified as 4-hydroxy-3-methylthioacetanilide (**11**). The synthesis of **11** and the isomeric 4-hydroxy-2-methylthioacetanilide (**4**) as well as that of the previously reported phenacetin metabolite 3-[(5-acetamido-2-hydroxyphenyl)thio]alanine (**18**) is described.

Un nouveau métabolite de phénacétine a été identifiée comme 4-hydroxy-3-méthylthioacétanilide (**11**). La synthèse de **11** et celle du 4-hydroxy-2-méthylthioacétanilide isomérique sont décrites, aussi bien que celle du métabolite préalablement rapporté de phénacétine, 3-[(5-acétamido-2-hydroxyphényl)thio]alanine (**18**).

Canadian Journal of Chemistry, **50**, 2025 (1972)

In connection with a recent study on the metabolism of phenacetin (*p*-ethoxyacetanilide), a new metabolite isolated from dog urine[1] (1) exhibited n.m.r. and mass spectra[2] compatible with either 4-hydroxy-2-methylthioacetanilide (**4**) or 4-hydroxy-3-methylthioacetanilide (**11**). It therefore became necessary, in order to establish unequivocally the structure of this metabolite, to synthesize in an unambiguous manner both isomers.

The 2-methylthio isomer **4** was prepared (Scheme 1) as follows. Reduction of the known 4-nitrothioether **1** (2) with sodium hydrosulfite in alkaline solution provided the substituted aniline **2**. Conversion of **2** with acetic anhydride into the acetoxyacetanilide **3** followed by *O*-deacetylation with boron trichloride afforded 4-hydroxy-2-methylthioacetanilide (**4**).



SCHEME 1. Synthesis of 4-hydroxy-2-methylthioacetanilide (**4**).

The isomeric 4-hydroxy-3-methylthioacetanilide (**11**) was prepared (Scheme 2) from the key intermediate **9** which was obtained by two methods. Diazotization of the aminonitrophenol **5** in fluoboric acid gave the known (3)[3] diazooxide **6** which was converted by a Sandmeyer reaction with sodium thiomethylate to the thioether **7**. Subsequent reduction of the nitro group with sodium hydrosulfite afforded **9**. Alternatively, treatment of the thiophenol **8** with diazotized sulfanilic acid followed by sodium hydrosulfite reduction yielded **9** more directly. Treatment of **9** with acetic anhydride in the presence of *p*-toluenesulfonic acid gave a separable mixture of the desired hydroxyacetanilide **11** and its *O*-acetoxy derivative **10**. Saponification of **10** with aqueous alkali also afforded **11**.

A comparison of the pertinent n.m.r. and m.s. data for the metabolite and the synthesized isomers **4** and **11** (Table 1) indicates that the metabolite and compound **11** are identical. The data for the metabolite and **4** are unlike; there are large differences in the chemical shifts of the aromatic protons in the n.m.r. and in the relative intensities for the three major peaks in the mass spectra.

Having established the structure of this metabolite as 4-hydroxy-3-methylthioacetani-

[1]Made available by Dr. A. Klutch of Burroughs Wellcome & Co.

[2]We are grateful to Dr. F. Vane and Mr. R. Pitcher of our Physical Chemistry Department for these determinations.

[3]Previously characterized only by a thermal decomposition study.

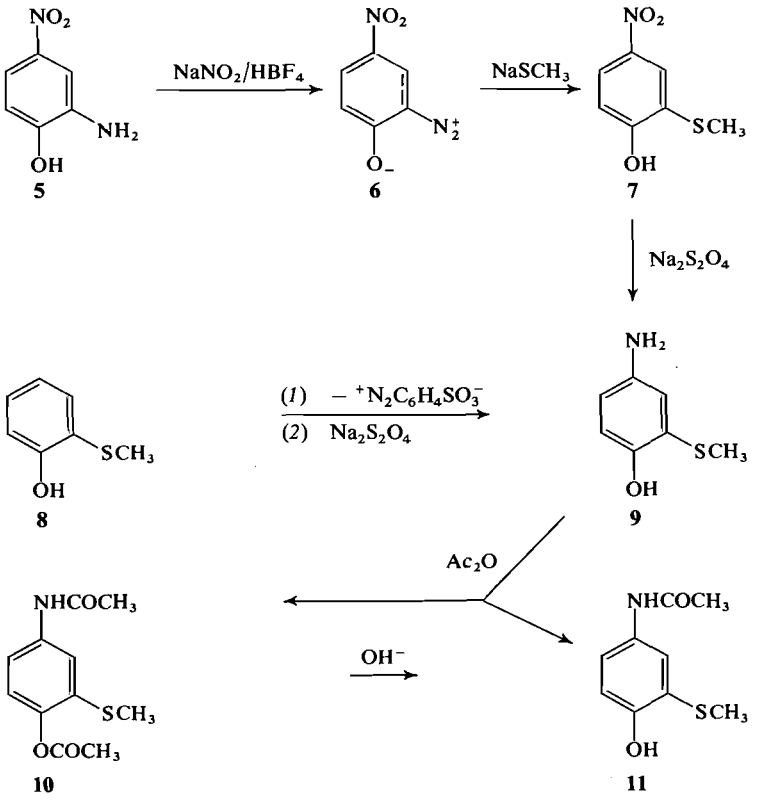
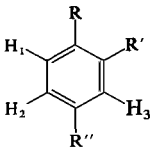


SCHEME 2. Synthesis of 4-hydroxy-3-methylthioacetanilide (**11**).

TABLE 1. Comparison of n.m.r. and mass spectrum data for the metabolite (1) with **4** and **11**

	Nuclear magnetic resonance (δ)*						Mass spectrum (m/e)‡		
			Aromatic protons†			NH or			
Compound	$COCH_3$	SCH_3	H_1	H_2	H_3	OH	197 (M^+]	155 [$M-C_2H_2O$]	140 [$M-C_2H_2O$, CH_3]
Metabolite (1)	2.15	2.35	6.90	—	~7.70	~6.48	100	70–72	68–75
4	2.20	2.38	7.85	6.65	6.83	5.06	75–100	88–97	94–100
11	2.16	2.36	6.93	7.22	7.67	6.41	100	70–90	67–92

*Obtained in chloroform-*d* solutions with a Varian HA-100 spectrometer using a C-1024 time averaging computer.
†H_1, H_2, and H_3 correspond to the following protons:



H_2 of the metabolite was obscured by a chloroform impurity peak.
‡The low resolution mass spectra were obtained with a CEC 21–110 mass spectrometer operating at 70 eV. The large range in the relative intensities observed for the three major peaks in the mass spectra of the metabolite and the two isomers **4** and **11** may be a temperature effect. Intensities are given in % base peak.

lide (**11**), it appeared reasonable that another phenacetin metabolite previously identified as *S*-(1-acetamido-4-hydroxyphenyl)cysteine (**4**) was probably related to **11** and therefore should be 3-[(5-acetamido-2-hydroxyphenyl)thio]alanine (**18**). To prove this hypothesis, we synthe-

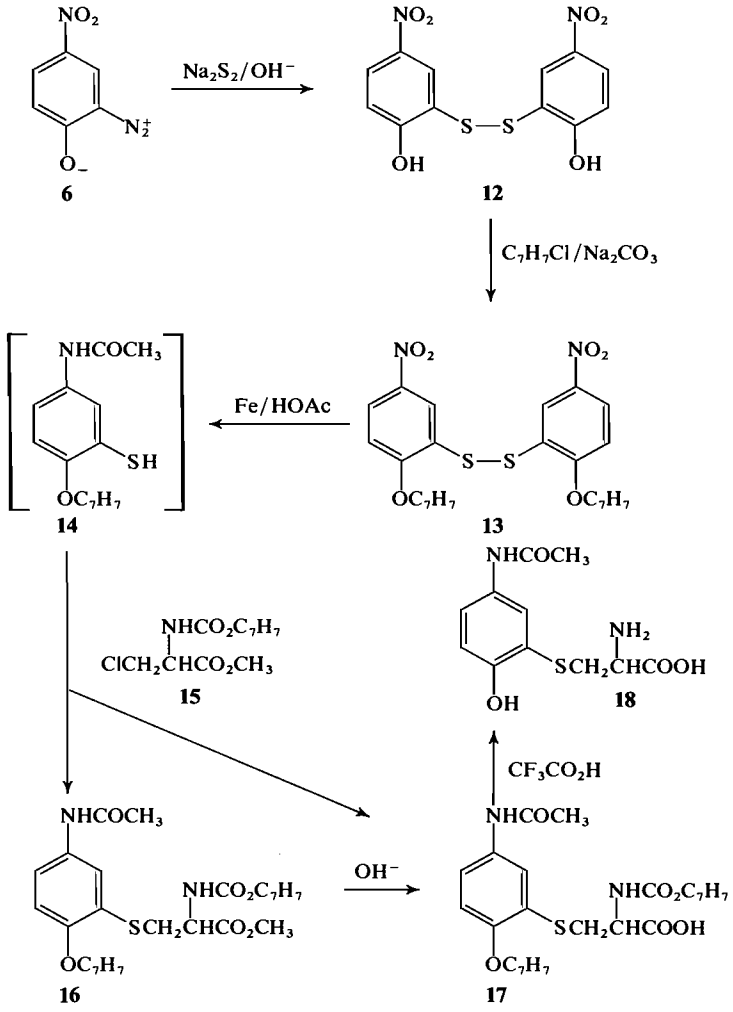

SCHEME 3. Synthesis of 3-[(5-acetamido-2-hydroxyphenyl)thio]alanine (**18**).

sized **18** as follows (Scheme 3). A Sandmeyer reaction carried out by treating the diazo-oxide **6** with sodium polysulfide provided the disulfide **12** which was converted into the di-*O*-benzyl derivative **13**. Reaction of **13** with iron[4] in acetic acid effected simultaneously reduction, acetylation, and cleavage of the disulfide to afford the unstable thiophenol **14**. *S*-Alkylation of **14** in ethyl acetate[5] with α-benzyloxycarbonylamino-β-chloropropionic acid methyl ester (**15**), obtained from 3-chloroalanine methyl ester, yielded a separable mixture of the methyl ester **16** and a minor amount of the corresponding acid **17**. Saponification of **16** also provided the acid **17** which was selectively debenzylated and decarbobenzylated with trifluoroacetic acid to the desired compound **18**.

Comparison of the physical data reported for the metabolite *S*-(1-acetamido-4-hydroxyphenyl)cysteine (4) and those exhibited by **18** (Table 2) indicates their similarity in these respects. However, we could not unequivocally establish their identity since a sample of the metabolite was not available for a more direct correlation.

[4]In contrast to iron, zinc reductively cleaved the disulfide **13** in very poor yield.

[5]Attempts to *S*-alkylate the unstable **13** in other conventional solvents gave mainly the corresponding disulfide.

TABLE 2. Physical data of metabolite *S*-(1-acetamido-4-hydroxyphenyl)cysteine and **18**

Compound	Melting point (°C)	Ultraviolet absorption (λ_{max}, nm) 0.1 *N* HCl	0.1 *N* KOH	Infrared absorption (μ) Amine	Amide	Paper chromatography* (R_f) Ascending	Descending
Metabolite (4)	187–188 (needles)	203 243 295	270 313	6.2	6.0 6.5	0.70	0.28
18	192–193 (needles)	200 240 292	268 312	6.2	6.0 6.5	0.68	0.26

*Paper chromatography was carried out according to the conditions described (4) using Whatman No. 1 chromatography paper employing butan-1-ol : acetic acid : water (4:1:1) for ascending development and phenol : water : concentrated ammonium hydroxide (800:200:1) for descending development and detected with ninhydrin.

Experimental

All melting points (uncorrected) were taken in open capillary tubes in a Thomas–Hoover melting point apparatus. The i.r. spectra were determined with a Beckman IR-5 or IR-9 recording spectrophotometer and the u.v. spectra with a Carey 14 spectrophotometer. The n.m.r. spectra were obtained with either a Varian A-60A, Varian HA-100, or a Jeolco C-60H spectrometer using tetramethylsilane as internal standard.

4-Amino-3-methylthiophenol (2)

To a stirred solution of 3-methylthio-4-nitrophenol (**1**) (27 g, 0.146 mol) in 10% NaOH (250 ml) at 60°, sodium hydrosulfite (75 g, 0.430 mol) was cautiously added. The mixture was stirred and heated at 95° for 40 min, allowed to cool to room temperature, and the crystalline precipitate collected to give 20 g (88%) of **2**, m.p. 145–148°. An analytical sample prepared from ethyl acetate exhibited: m.p. 148–150°; i.r. (KBr) 3330, 3300 (NH_2), 2780–2570 cm^{-1} (associated OH of phenol); n.m.r. (DMSO-d_6) δ 2.31 (s, 3, CH_3), 4.40 (br. s, 2, NH_2), 6.66 (br. s, 1, H_2), 6.53 (br. s, 2, $H_{5,6}$), 8.50 (s, 1, OH).

Anal. Calcd. for C_7H_9NOS: C, 54.17; H, 5.84. Found: C, 54.25; H, 5.55.

4-Acetoxy-2-methylthioacetanilide (3)

A mixture of the substituted aniline **2** (15 g, 0.0965 mol), *p*-toluenesulfonic acid (15 g), and acetic anhydride (200 ml), was stirred overnight at room temperature. The excess acetic anhydride was distilled under reduced pressure and the residue partitioned between water and ethyl acetate. The organic phase was washed successively with water, two 100-ml portions of 1% NaOH, 0.1 *N* HCl, and evaporated under reduced pressure. The crystalline residue of **3** weighed 15.5 g (67%) and melted at 103–106°. An aliquot prepared from ether exhibited: m.p. 100–102°; i.r. ($CHCl_3$) 3380 (NH), 1760 (phenolic ester), 1685, 1510 cm^{-1} (amide); n.m.r. ($CDCl_3$) δ 2.20, 2.30, 2.40 (s, 9, 3 CH_3), 7.00 (d of d), 7.20 (d), 8.30 (d) (ABX, 3, J_{AB} meta 2.5, J_{AX} ortho 7 Hz, aromatic), 8.05 (br. s, 1, NH).

Anal. Calcd. for $C_{11}H_{13}NO_3S$: C, 55.21; H, 5.47. Found: C, 55.17; H, 5.65.

4-Hydroxy-2-methylthioacetanilide (4)

To a solution of the acetanilide **3** (2 g, 84 mmol) in methylene chloride (100 ml) at −78° was slowly added with stirring a methylene chloride solution (21 ml) containing boron trichloride (10 mmol). The mixture was allowed to stir 4 h at room temperature, methanol (4 ml) added dropwise, washed with water and 1 *N* hydrochloric acid, and extracted with 2% sodium hydroxide. Neutralization of the alkaline solution with dilute hydrochloric acid precipitated 1.1 g (67%) of crystalline **4**, m.p. 147–149°. A sample crystallized from acetone gave: m.p. 148–149°; i.r. (KBr) 3230 (OH + NH), 1626, 1520 cm^{-1} (amide); n.m.r. (DMSO-d_6) δ 1.95, 2.32 (s, 6, 2 CH_3), 6.61 (d of d), 6.48 (d), 6.98 (d) (ABX, 3, J_{AB} meta 2.5, J_{AX} ortho 7 Hz, aromatic), 8.95, 9.33 (s, 2, NH + OH); mass spectrum (70 eV) *m/e* (relative intensity) 197 (75–100), 155 (88–97), 140 (94–100).

Anal. Calcd. for $C_9H_{11}NO_2S$: C, 54.80; H, 5.67. Found: C, 54.94; H, 5.85.

4-Nitrobenzene-2-diazo-1-oxide (6)

To a stirred suspension of 20 g (0.130 mol) of 2-amino-4-nitrophenol (**5**) (20 g, 0.13 mol) in 48% fluoboric acid (50 mol), maintained at 4°, a cold solution of sodium nitrite (9 g, 0.13 mol) in water (18 ml) was added dropwise. The mixture was stirred for 30 min at room temperature, the solid collected, washed once with cold fluoboric acid solution (10 ml), then with two 15-ml portions of cold water, and sucked dry. The solids were suspended in acetone (200 ml), collected, and dried under P_2O_5 to yield 15 g (70%) of **6**, m.p. 120° (with violent decomposition[3]). A sample recrystallized from water and acetone had m.p. 120°; u.v. max (2-propanol) 238 (ε 11 620), 259 (12 610), 324 (11 350), 400 (6650), 490–500 nm (1000) (sh); n.m.r. (MeOD + DCl) δ 7.22 (d, 1, *J* ortho 10 Hz, aromatic), 8.60 (d of d, 1, *J* meta 3, *J* ortho 10 Hz, aromatic), 9.27 (d, 1, *J* meta 3 Hz, aromatic).

Anal. Calcd. for $C_6H_3N_3O_3$: C, 43.63; H, 1.83; N, 25.45. Found: C, 43.62; H, 1.68; N, 25.45.

4-Hydroxy-3-methylthionitrobenzene (7)

To a vigorously stirred mixture of sodium hydroxide (20 g), copper powder (3 g), and methanethiol (25 g, 0.52 mol) in water (70 ml) was added slowly[6] at about 4° a suspension of the diazo-oxide **6** (15 g, 0.091 mol) in ice water (60 g). The reaction mixture was stirred at room temperature for 1 h, filtered, and the cake washed with 5% sodium hydroxide (50 ml). The combined filtered material was acidified to p*H* 5 with 6 *N* hydrochloric acid and the resulting precipitate was filtered, washed with water, and purified by means of semi-dry column chromatography (5) as follows.

[6]Ether was added as necessary to control the foaming.

The solids were dissolved in ethyl acetate (100 ml), 35 g of chromatographic grade silica gel (0.05–0.02 mesh) deactivated with 8% of water was added and the mixture evaporated to dryness. The residue was deposited on top of a column (20 × 3 in.) packed with 300 g of the deactivated silica gel, followed by the addition of a 1:1 mixture of ethyl acetate and benzene (70 ml). The column was eluted with benzene (200 ml) and the eluate evaporated to give 7 g (42%) of **7** of m.p. 58–62°. An analytical sample prepared from petroleum ether showed: m.p. 64–65°;[7] i.r. (KBr) 3330 (bonded OH of phenol), 1510, 1335 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) δ 2.44 (s, 3, CH_3), 8.43 (d), 8.16 (d of d), 7.09 (d) (ABX, 3, J_{AB} meta 2.5, J_{BX} ortho 9 Hz, aromatic), 7.30 (s, 1, OH).

Anal. Calcd. for $C_7H_7NO_3S$: C, 45.38; H, 3.81. Found: C, 45.63; H, 4.13.

*4-Hydroxy-3-methylthioaniline (**9**)*

(a) Preparation from 7

A stirred solution of 35 g (0.190 mol) of the thioether **7** (35 g, 0.19 mol) in 10% sodium hydroxide (200 ml) was heated to 45–50° and sodium hydrosulfite (76 g, 0.44 mol) was added cautiously in two portions. The mixture was heated on a steam bath for 25 min and allowed to cool to room temperature. The crystals were filtered, washed with water, and dried in a vacuum oven at 60° to give 22 g (75%) of **9**, m.p. 170–175°. An analytical sample prepared from ethyl acetate exhibited: m.p. 190–192°; i.r. (KBr) 3356, 3300 (NH_2), 2500 cm^{-1} (associated phenolic OH); n.m.r. (DMSO-d_6) δ 2.28 (s, 3, CH_3), 4.28 (br, 2, NH_2), 6.42, (d of d), 6.25 (d), 6.53 (d) (ABX, 3, J_{AB} meta 2.5, J_{AX} ortho 8 Hz, aromatic), 8.40 (br. s, 1, OH).

Anal. Calcd. for C_7H_9NOS: C, 54.17; H, 5.84; N, 9.03. Found: C, 54.51; H, 5.92; N, 8.93.

(b) Preparation from 8

To a stirred mixture of 2-(methylmercapto)phenol (**8**) (20 g, 0.14 mol) and sodium hydroxide (32 g) in water (210 ml) was added at 7–12° a diazonium salt suspension prepared by diazotization (6) of sulfanilic acid (41 g, 0.21 mol). The stirred mixture was allowed to warm to room temperature, heated to 45–50° and sodium hydrosulfite (130 g, 0.74 mol) was added in two portions. The mixture was stirred and heated on a steam bath for 45 min, allowed to cool to room temperature, and the resulting crystalline precipitate collected and recrystallized from ethyl acetate to give 16.4 g (74%) of **9**, identical in mixed m.p. and n.m.r. with **9** obtained from **7**.

*4-Acetoxy-3-methylthioacetanilide (**10**)*

A mixture of 4-hydroxy-3-methylthioaniline (**9**) (15.5 g, 0.1 mol), *p*-toluenesulfonic acid (15.5 g), and acetic anhydride (200 ml) was stirred at room temperature overnight. The excess acetic anhydride was distilled under reduced pressure and the residue partitioned between water and ethyl acetate. The organic phase was washed with water, with two 75-ml portions of 1% sodium hydroxide (this alkaline solution contained **11**), and with water until neutral p*H*. The ethyl acetate solution was dried (Na_2SO_4), the solvent evaporated, and the residue crystallized from ethyl acetate to give 14.4 g (58%) of **10**: m.p. 146–147°; i.r. (KBr) 3280 (NH), 1765 (ester CO), 1653, 1550 (amide), 1212, 1180 cm^{-1} (C—O—C of ester).

[7]Dimorphic; another crystalline form exhibited m.p. 93–94°.

Anal. Calcd. for $C_{11}H_{13}NO_3S$: C, 55.21; H, 5.47. Found: C, 55.53; H, 5.54.

*4-Hydroxy-3-methylthioacetanilide (**11**)*

(a) Preparation from 9

The alkaline phase from the preparation of **10** was neutralized with dilute hydrochloric acid and the resulting crystals, recrystallized from ethyl acetate, gave 2.8 g (14%) of **11**: m.p. 130–131°; i.r. ($CHCl_3$) 3230 (OH, NH) 2400 (associated OH of phenol), 1690, 1570 cm^{-1} (amide); u.v. max (2-propanol) 234 (ε 19 850), 301 nm (4450); u.v. max (0.1 *N* HCl) 227 (ε 18 650), 294 nm (3750); u.v. (0.1 *N* KOH) 222 (ε 19 730), 265 (9320); 309 nm (6400); n.m.r. ($CDCl_3$) δ 2.16 (s, 3, CH_3CO), 2.32 (s, 3, CH_3S), 7.22 (d of d), 6.93 (d), 7.67 (d) (AMX, 3, J_{AM} ortho 8, J_{AX} meta 2.5 Hz, aromatic); mass spectrum (70 eV) *m/e* (relative intensity) 197 (100), 155 (70–90), 140 (67–92).

Anal. Calcd. for $C_9H_{11}NO_2S$: C, 54.88; H, 5.62. Found: C, 54.89; H, 5.50.

(b) Preparation from 10

A suspension of the acetanilide **10** (6 g, 0.025 ml) in 2.5% sodium hydroxide (100 ml) was stirred at 50° for 30 min, cooled, and extracted with two 75-ml portions of ethyl acetate. The aqueous layer was acidified to p*H* 5 with dilute hydrochloric acid, re-extracted with two 100-ml portions of ethyl acetate, dried (Na_2SO_4), and the extracts evaporated. The residue was crystallized from ethyl acetate to give 3.0 g (61%) of **11**, m.p. 129–131°; identical in mixed m.p. with **11** obtained from **9**.

*Bis(2-hydroxy-5-nitrophenol)disulfide (**12**)*

To a vigorously stirred solution, maintained at 0–10°, of sodium polysulfide (prepared by dissolving a mixture of sodium sulfide monohydrate (130 g, 1.35 mol) and sulfur powder (17 g, 0.53 mol) in 40% sodium hydroxide (50 ml) and water (140 ml) and heating on a steam bath) was added portionwise over 45 min a suspension of the diazo-oxide **6** (55.9 g, 0.39 mol) in ice water (150 ml). The resulting solution was allowed to warm to room temperature and stirred overnight. The reaction mixture was cooled, acidified with concentrated hydrochloric acid, ethyl acetate (600 ml) added, stirred for 45 min, and the amorphous solids filtered. The organic extract was concentrated to about 350 ml and stirred overnight with a solution of sodium carbonate (53 g, 0.5 mol) in water (200 ml). The precipitate was filtered, washed with two 100-ml portions of ethyl acetate, and dried (Na_2SO_4) to give 90 g (68.5%) of **12** as the disodium salt which was used for the next step. An aliquot was acidified with 1 *N* hydrochloric acid, extracted with ethyl acetate, and the extracts evaporated. The residue was crystallized from ethyl acetate to give yellow crystals of **12**: m.p. 174–176°; i.r. (KBr) 3375 (OH), 1602, 1474 (aromatic), 1510, 1330 cm^{-1} (NO_2); n.m.r. (MeOD) δ 6.93 (d), 8.00 (d of d), 8.36 (d) (AMX, 3, J_{AM} meta 2.5, J_{MX} ortho 9 Hz, aromatic).

Anal. Calcd. for $C_{12}H_8N_2O_6S_2$: C, 42.35; H, 2.37; N, 8.23; S, 18.84. Found: C, 42.67; H, 2.70; N, 8.00; S, 18.86.

*Bis(2-benzyloxy-5-nitrophenyl)disulfide (**13**)*

A mixture of the crude disodium salt of **12** (60 g, 0.155 mol), sodium carbonate (40 g, 0.38 mol), and benzyl chloride (60 g, 0.48 mol) in ethanol (600 ml) was stirred and refluxed for 24 h. The yellow crystals were filtered, washed with cold ethanol (35 ml), and then with water until the washings were neutral to litmus paper and dried to give

60 g (74.4%) of **13**, m.p. 172–174°. An analytical sample prepared from ethyl acetate exhibited: m.p. 176–177°; u.v. max (2-propanol) 207 (ε 42 400), 225 (21 500) (infl), 258 (21 800), 293 (18 350), 330 nm (10 800) (sh); i.r. (KBr) 1596, 1474 (aromatics), 1510, 1335 (NO_2), 1270 cm^{-1} (C—O—C).

Anal. Calcd. for $C_{26}H_{20}N_2O_6S_2$: C, 59.99; H, 3.87; N, 5.38; S, 12.32. Found: C, 60.12; H, 3.89; N, 5.32; S, 12.43.

α-Benzyloxycarbonylamino-β-chloropropionic Acid Methyl Ester (15)

To a vigorously stirred mixture of 3-chloroalanine methyl ester hydrochloride (30 g, 0.173 mol), ethyl acetate (300 ml), and saturated sodium bicarbonate solution (100 ml) was added benzyl chloroformate (60 g, 0.35 mol). The mixture was maintained at 5° and rendered slightly alkaline by the addition of saturated sodium bicarbonate as needed. The mixture was stirred at room temperature for 2 h, cooled to 5°, and a solution of piperidine (25 g, 0.29 mol) in water (50 ml) was added dropwise. The reaction was allowed to warm to room temperature, the organic phase separated, washed with two 75-ml portions of 3 *N* hydrochloric acid, then with water, dried (Na_2SO_4), and evaporated under reduced pressure. The oily residue was crystallized from petroleum ether to give 35 g (75%) of **15**, m.p. 51–52°. An analytical sample prepared from petroleum ether gave: m.p. 51–52°; i.r. (KBr) 3445 (NH), 1760 (ester CO), 1730 (urethane), 1520 cm^{-1} (amide).

Anal. Calcd. for $C_{12}H_{14}ClNO_4$: C, 53.05; H, 5.19; Cl, 13.05. Found: C, 53.04; H, 5.14; Cl, 13.15.

rac-3-[(5-Acetamido-2-benzyloxyphenyl)thio]-N-benzyloxycarbonylalanine Methyl Ester (16)

A mixture of the di-*O*-benzyl derivative **13** (14 g, 0.027 mol), glacial acetic acid (200 ml), and iron powder (30 g) was stirred and refluxed for 3 h, cooled to 60°, and filtered through a thin pad of Hyflo. The cake was washed with acetic acid (50 ml) and the combined filtrates were evaporated under reduced pressure. The residue was partitioned between ethyl acetate (120 ml) and 2% hydrochloric acid (50 ml) and the organic extract washed with water (30 ml), dried (Na_2SO_4), decanted and redried (anhydrous $CaSO_4$). To the ethyl acetate solution in a nitrogen atmosphere, the methyl ester **15** (15 g, 0.055 mol) was added. The mixture was stirred and slowly heated to reflux under N_2 while maintaining the p*H* between 7 and 8 by addition of a solution of 17% of sodium methoxide in methanol as needed. After stirring and refluxing for a total of 6 h, the mixture was allowed to stand overnight at room temperature. The resulting crystals were filtered, washed with water, and dried to give 12 g of **16**, m.p. 133–135°. The organic filtrate was extracted with two 100 ml portions of sodium carbonate solution and the aqueous extract acidified to precipitate 2.4 g (9%) of **17**, m.p. 188–192°. The spent ethyl acetate solution was evaporated under reduced pressure and the residue crystallized from ethyl acetate to give an additional 3 g (total 52.1%) of crude **16**, m.p. 132–134°. An analytical sample of **16** prepared from ethyl acetate exhibited: m.p. 141–142°; i.r. (KBr) 3300, 3280 (NH), 1730 (ester), 1717 (urethane), 1650, 1530 cm^{-1} (amide); n.m.r. (DMSO-d_6) δ 2.03 (s, 3, CH_3CO), 3.67 (s, 3, CH_3O), 4.22 (m, 1, CH), 5.06, 5.16 (s, 4, 2 CH_2O), 6.90–7.70 (m, 13, aromatic), 9.84 (s, 1, NH).

Anal. Calcd. for $C_{27}H_{28}N_2O_6S$: C, 63.76; H, 5.55; N, 5.51. Found: C, 63.62; H, 5.57; N, 5.46.

rac-3-[(5-Acetamido-2-benzyloxyphenyl)thio]-N-benzyloxycarbonylalanine (17)

A mixture of rac-3-[5-acetamido-2-benzyloxyphenyl)-thio]-*N*-benzyloxycarbonylalanine methyl ester (**16**) (5 g, 0.01 mol), 5% sodium hydroxide (100 ml) was heated on a steam bath for 20 min, Norit added, and the solution filtered hot through a thin pad of Hyflo. The cake was washed with 5% sodium hydroxide (20 ml) and the combined filtrates neutralized with 1 *N* hydrochloric acid. The mixture was allowed to stand for 4 h, the precipitate filtered, washed with water, and dried to give 3.46 g (70%) of **17**, m.p. 188–190°. An analytical sample prepared from ethyl acetate exhibited: m.p. 198–200°; i.r. (KBr) 3320 (NH, OH), 2700–2600 (acid OH), 1730–1705 (acid CO), 1670, 1550 cm^{-1} (amide); n.m.r. (DMSO-d_6) δ 2.03 (s, 3, CH_3CO), 3.28 (d, 2, $J = 6$ Hz, CH_2S), 4.12 (m, 1, CH), 5.04, 5.14 (s, 4, $2CH_2O$), 6.90–7.70 (m, 13, aromatic), 9.78 (s, 1, NH).

Anal. Calcd. for $C_{26}H_{26}N_2O_6S$: C, 63.14; H, 5.30; N, 5.66. Found: C, 63.36; H, 5.37; N, 5.67.

rac-3-[(5-Acetamido-2-hydroxyphenyl)thio]alanine (18)

A mixture of the acid **17** (4 g, 0.008 mol), trifluoroacetic acid (100 ml), and boron trifluoride etherate (12 drops) was stirred at reflux under N_2 for 4 h and then at room temperature overnight. The solvent was evaporated under reduced pressure, the oily residue dried by azeotropic distillation with benzene, the semi-solid residue was suspended in warm ethyl acetate (20 ml), and the mixture stored at room temperature for 2 h. The supernatant solution was decanted, and the residue crystallized from a mixture of methanol (20 ml) and benzene (50 ml) to give 0.78 g of **18**, m.p. 184–186° dec. From the mother liquor, a second crop of 0.25 g, m.p. 178–182° (dec.) (total 47%) was obtained. An analytical sample prepared from a mixture of water and ethanol exhibited: m.p. 192–193°; u.v. max (0.1 *N* KOH) 268 (ε 9580), 312 nm (6200); i.r. (KBr) 3200 (OH, NH), 3070–2600 (NH_3^+), 1650 (amide), 1610 (COO^-), 1500 (amide), 1410 cm^{-1} (COO^-); n.m.r. (DMSO-d_6) δ 1.99 (s, 3, CH_3CO), 2.80–3.40 (m, 2, CH_2), 6.82, (d), 7.35 (d of d), 7.59 (d) (AMX, 3, J_{AM} ortho 8.5, J_{MX} meta 2.5 Hz, aromatic), 9.84 (s, 1, NH); mass spectrum, thermal decomposition.

Dielectric Relaxation of Bromoalkanes in Cyclohexane Solution

SING PIN TAY AND JOHN CROSSLEY
Department of Chemistry, Lakehead University, Thunder Bay, Ontario
Received February 7, 1972

Mean relaxation times, Cole–Cole distribution parameters and apparent dipole moments, obtained from dielectric constant and loss measurements at 2 MHz and 1.5, 2.0, 2.5, 9.3, 16, 24, 35, 70, and 145 GHz, are reported for 1-, 2-, and 4-bromooctane, 1-bromodecane, 1-bromododecane, 1-bromohexadecane, 1-bromooctadecane, and 1,10-dibromodecane in cyclohexane solution at 25 °C.

Les temps de relaxation moyens, les paramètres de distribution de Cole–Cole et les moments dipolaires apparents, obtenus à partir des constantes diélectriques et des mesures de perte à 2 MHz et 1.5, 2.0, 2.5, 9.3, 16, 35, 70 et 145 GHz sont rapportés pour les bromooctanes 1, 2, et 4, le bromo-1 décane, le bromo-1 dodécane, le bromo-1 hexadécane, le bromo-1 octadécane et le dibromo-1,10 décane en solution dans le cyclohexane à 25 °C.
Canadian Journal of Chemistry, **50**, 2031 (1972)

Introduction

Dipole reorientation by the intramolecular rotation of polar groups has been extensively investigated for substituted benzenes and naphthalenes (1). Aliphatic molecules are far more flexible, intramolecular rotation may occur about many bonds and involve molecular segments of different size, and their dielectric behavior has not been studied in such great detail. This paper presents results which form part of a systematic investigation of the dielectric relaxation of aliphatic compounds in solution. Our initial studies (2, 3) revealed that dipole reorientation in 1-aminoalkanes ($R—NH_2$) and 2-alkanones ($R—COCH_3$) occurs primarily by the intramolecular rotation of the polar end group. Rotational orientation of the whole molecule makes a significant contribution to the absorption of secondary and tertiary amines, but only becomes evident for relatively long ketones in which the carbonyl group is well removed from the chain end. The results indicate that whole molecule rotation only makes a significant contribution to the dispersion of ketones and amines when the intramolecular process is sterically restricted.

The interpretation of the comparatively large amount of dielectric absorption data for pure liquid haloalkanes has been complicated by the viscosity, internal field and molecular interaction effects and some conflict has arisen regarding the nature of their distribution function (4–12). The former problems may be largely eliminated in dilute solution but little data has been available. In *n*-heptane solution the dielectric absorption of 1-bromooctane has been satisfactorily represented by a symmetrical distribution function (13). However, the absorptions, at only three microwave frequencies, of some α,ω-dibromoalkanes in dilute solution have been represented by a skewed arc function and discussed in terms of a superposition of two Debye-type dispersions (14).

The present study examines the dielectric relaxation of eight alkylbromides in cyclohexane solution. As before (2, 3), the position of the polar group and the length of the hydrocarbon chain are varied.

Experimental

The apparatus and procedure used to determine dielectric constants (ε') and dielectric losses (ε'') at 1–2.5 (15), 9–35 (16), and 70–145 GHz (17) have been described previously. Refractive index measurements at the sodium D-line were made with an Abbe refractometer. Static dielectric constants (ε_0) were measured at 2 MHz using a WTW Dipolmeter.

Results

The experimental $\varepsilon'(\pm 0.5\%)$ and $\varepsilon''(\pm 5.0\%)$ values measured at 25 °C are given in Table 1. For all the systems it is possible, within experimental error, to draw smooth depressed center semicircular arcs through the experimental points, when plotted in the complex plane. The data for each system were analyzed for a most probable relaxation time (τ_0), Cole–Cole distribution parameter (α), and very high frequency dielectric constant (ε_∞) using a computer fit to the Cole–Cole equations (18). Apparent dipole

moments (μ) were calculated from

$$[1] \qquad \mu^2 = \frac{9kT}{4\pi N} \frac{(\varepsilon_0 - \varepsilon_\infty)(2\varepsilon_0 + \varepsilon_\infty)}{\varepsilon_0(\varepsilon_\infty + 2)^2}$$

in which N is the number of solute molecules per ml of solution.

Table 2 lists the values of τ_0, μ, ε_∞, and n_D^2 for each of the alkylbromides at mol fraction f_2 in cyclohexane solution at 25 °C.

Discussion

Figure 1, which is typical of all the systems, shows that the experimental dielectric constant and loss data are adequately described by a Cole–Cole symmetrical distribution function. There is no evidence of the skewed arc behavior which has been reported for pure liquid haloalkanes (11) and dibromoalkanes in solution (13). Furthermore, the ε_∞ and n_D^2 values, Table 2,

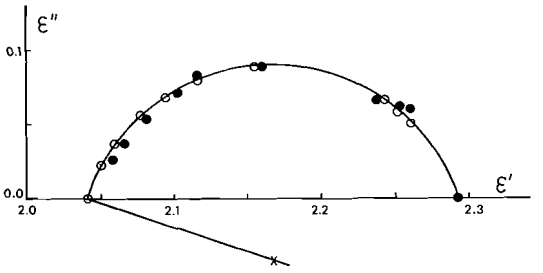

FIG. 1. Cole–Cole plot for 1-bromodecane in cyclohexane at 25 °C. Solid circles represent experimental points and the hollow circles represent points calculated from the parameters given in Table 2.

are similar and the apparent dipole moments compare favorably with those obtained by classical methods (19). We were unable to obtain any sensible analyses of the data in terms of two discrete relaxation times.

The τ_0 values in Table 2 are considerably longer than those for analogous amines and ketones which, under the same conditions, have values of about 3 and 7×10^{-12} s, respectively, almost independent of the size of the alkyl group (2, 3). These results suggest that polar end group rotation is not as dominant a mechanism of dipole reorientation for bromoalkanes as it is for primary amines and 2-alkanones. However, the mean relaxation times in Table 2 only lengthen slightly with increased molecular size and the contribution from intramolecular rotation, especially for the larger molecules, is not negligible. Potential barriers to rotation of the polar group in CH_3—NH_2, CH_3—$COCH_3$, and CH_3—CH_2Br of 1.94, 0.78, and 3.57 kcal mol^{-1}, respectively, have been reported (20). The values for the amine and ketone are considerably smaller than the barrier height in saturated aliphatic hydrocarbons, about 3 kcal mol^{-1}, and rotation of the polar end group in 1-amino alkanes and 2-alkanones should be faster than any segmental rotations within their hydrocarbon chain. Consequently, dipole reorientation by intramolecular rotation will be dominated by the former process with little or no contribution from longer segments. Conversely, rotation of the terminal CH_2Br group may be slightly slower than segmental rotations for alkylbromides, and dipole reorientation about the long axis of these molecules is likely to involve a variety of segments which contain the CH_2Br group. The dielectric absorption of the pure liquids has been considered in these terms (7). The relaxation times of the pure liquids are longer, and lengthen much more markedly with increased molecular size, than those for the dilute solutions. This is probably due to differences in viscosity; curves for macroscopic viscosity and τ_0, for the pure liquids, plotted against the number of carbon atoms are very similar (4). The viscosities of all the systems under investigation are essentially the same, *i.e.*, the viscosity of cyclohexane at 25 °C.

It is interesting to observe that the relaxation times for 1,10-dibromodecane and 1-bromodecane are almost the same. Furthermore, the location of the dipole has little effect on the relaxation times for bromooctanes, which is also the case for the nonanones and nonylamines. However, the α values for 1,10-dibromodecane and 2- and 4-bromooctane are significantly smaller than those for the 1-bromoalkanes. This may be due to a reduction in the number of molecular segments of different length which have a terminal CH_2Br group. The α values for the 1-bromoalkanes do not display any significant increase with increased chain length, and the relaxation times for the C_{16} and C_{18} bromides are essentially the same. These results suggest that intramolecular reorientation is dominated by the smaller segments. In addition, increased coiling will occur with increased chain length and the molecular relaxation time may not lengthen appreciably with increased molecular size for the longer molecules.

An Investigation of Long-range Proton–Proton Coupling Constants in Phenylacetylene Derivatives

C. J. MACDONALD
Department of Chemistry, Brandon University, Brandon, Manitoba
AND
G. K. HAMER,[1] I. R. PEAT,[2,3] AND W. F. REYNOLDS
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 30, 1971

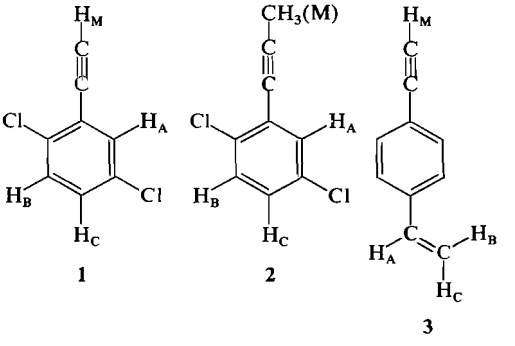
Signs and magnitudes of long-range coupling constants in three phenylacetylene derivatives have been determined. Values of the coupling constants are discussed in terms of the McConnell formulation and compared with results of MO–INDO–FPT calculations. Coupling constants are dominated by π contributions. Estimated values of hyperfine interaction constants for acetylene and methylacetylene groups are respectively $Q_{CC\equiv CH} = -12$ and $Q_{CC\equiv CCH} = +12$ G. The theoretical calculations are in excellent agreement with experimental results. Both approaches allow quantitative estimation of nine bond couplings in 4-vinylphenylacetylene.

Les signes et les amplitudes des constantes de couplage à longue distance de trois dérivés du phénylacétylène ont été déterminés. Les valeurs des constantes de couplage sont discutées en terme de la formulation de McConnell et comparées avec les résultats des calculs MO–INDO–FPT. Les constantes de couplage sont dominées par les contributions π. Les valeurs estimées des constantes d'interaction hyperfine pour les groupes acétylène et méthylacétylène sont respectivement $Q_{CC\equiv CH} = -12$ et $Q_{CC\equiv CCH} = +12$ G. Les calculs théoriques sont en excellent accord avec les résultats expérimentaux. Les deux approches permettent une estimation quantitative des couplages de neuf liaisons dans le vinyl-4 phénylacétylène.

Canadian Journal of Chemistry, **50**, 2035 (1972)

Introduction

The observed magnitudes and signs of long-range couplings between side chain protons and ring protons in styrenes (1) and benzaldehydes (2) are well predicted by theoretical computations using MO–INDO wave functions (3) and finite perturbation theory (MO–INDO–FPT) (4). McConnell's conceptually similar, but much simpler, MO formulation for alternate hydrocarbons (5) has been found to give good agreement with experiment for acenaphthenes (6), toluenes (7, 8), fluorobenzenes (9), pyridines (10), benzaldehydes (11), and xylenes (12). This latter method gives coupling constants in terms of mobile bond orders, mean excitation energies to triplet states, and proton hyperfine interaction constants. Its simplicity makes it attractive when considering more extended coupling paths. However, little data is available to test this extension. Experiments which yielded the signs and magnitudes of long-range coupling constants in the substituted phenylacetylenes **1**, **2**, and **3** are described below. The results are interpreted in terms of the McConnell formulation and are compared with MO–INDO–FPT calculations.



1 **2** **3**

Experimental

(a) Preparation of Compounds

(2,5-Dichlorophenyl)-acetylene

This compound was synthesized using the method of Drehfahl and Plotner (13). Bromination of the vinyl group of 2,5-dichlorostyrene yielded 1-(2,5-dichlorophenyl)-1,2-dibromoethane. Dehydrobromination using potassium hydroxide in *t*-butanol (13) gave crude (2,5-dichlorophenyl)-acetylene (**1**). Chromatography of the crude product on neutral alumina followed by vacuum sublimation gave **1** as

white plates, m.p. 40 °C. The structure of **1** was confirmed by its characteristic n.m.r. spectrum. The latter showed a one proton singlet (at low resolution) at δ 3.25 in CCl_4 (δ 4.4 in C_5D_5N), characteristic of an acetylenic proton, and a three proton ABC spectrum in the phenyl region. Detailed analysis in C_5D_5N (see below) showed the presence of one ortho (8.68 Hz), one meta (2.58 Hz), and one para (0.37 Hz) ring proton coupling constant, confirming retention of the 1,2,5-trisubstitution pattern of the phenyl group. These three coupling constants are almost identical with those for the parent 2,5-dichlorostyrene (8.54, 2.53, and 0.34 Hz (1)). The structure was further confirmed by the magnitudes of the long-range coupling constants to the acetylenic proton which are nearly identical to those for phenylacetylene (14) (see below).

1-(2,5-Dichlorophenyl)-propyne

This compound was prepared using standard procedures (13, 15). Acylation of *p*-dichlorobenzene with $AlCl_3$/propionyl chloride gave 2,5-dichloropropiophenone. Reaction with PCl_5, followed by dehydrochlorination using potassium hydroxide in *t*-butanol gave 1-(2,5-dichlorophenyl)-propyne (**2**) and other products. Preparative t.l.c. followed by vacuum sublimation gave a small yield of pure **2** as white needles, m.p. 28–30 °C. The compound was characterized by its n.m.r. spectrum which showed a three proton singlet (at low resolution) at δ 2.0 due to the propyne methyl group and a three proton ABC multiplet in the phenyl region. The latter multiplet showed ortho (8.64 Hz), meta (2.59 Hz), and para (0.38 Hz) coupling constants. These are identical, within experimental error, to the values for **1** and confirm the 1,2,5-trisubstitution pattern of the phenyl group.

4-Vinylphenylacetylene

This compound was synthesized as one of a series of 4-substituted styrenes. Full details are provided elsewhere (16).

(b) Nuclear Magnetic Resonance Experiments

Ten mole percent solutions of **1** and **2** in pyridine-d_5 and a 5 mol % solution of **3** in acetone-d_6 (with 3 mol % TMS for lock and reference signal) were degassed by several freeze–pump–thaw cycles and sealed under vacuum in n.m.r. tubes. Pyridine-d_5 was chosen for **1** and **2** since it gave nearly first order spectra. Acetone-d_6 was used for **3** since it collapsed the AA′BB′ spectrum of the ring protons to a sharp singlet (line width $\approx$ 0.3 Hz), allowing complete decoupling of the ring protons at moderate power levels.

Single, double, and triple resonance spectra (frequency sweep, internal lock) were obtained using Varian HA-100 and HA-100D spectrometers and one or more Hewlett–Packard 4204A oscillators. Techniques used were identical to those previously reported (1, 12). Spectra were recorded at a sweep rate of 0.01 Hz/s and calibrated at <5 Hz intervals with a frequency counter. Line widths of non-degenerate peaks were 0.10–0.12 Hz. The ambient temperature was 30 ± 1 °C.

(c) CNDO/2 and MO–INDO–FPT Calculations

Calculations were performed on an IBM 360/65 computer, using the Quantum Chemistry Program Exchange program no. 141 and standard parameters (17). For the finite perturbation calculations, the program was modified to give a more rigorous convergence criterion (4). The modified program reproduced published results (4).

Results

Proton labelling schemes for **1**, **2**, and **3** have been shown above. They are labelled conventionally, in order of increasing field (decreasing frequency). Final parameters are shown in Table 1. The signs and magnitudes of the long-range coupling constants for **1** are in good agreement with previously reported results for phenylacetylene (14). In that report, signs were determined by analysis. We have confirmed the signs by double-irradiation experiments.

The relative signs of the long-range coupling constants in **1** and **2** were established relative to the known positive signs of intra-ring coupling constants in benzene derivatives (18) and in **3** relative to the known positive signs of the vinyl proton coupling constants in styrene (19). For **1**, the sign determinations involved observation of Overhauser effects caused by very weak "tickling" double irradiation (20, 11*a*),[4] showing $J_{AM}, J_{CM} > 0, J_{BM} < 0$. For **2**, double resonance experiments analogous to those used to determine signs in 2-bromo-5-chlorotoluene (21) were employed, showing $J_{AM}, J_{CM} < 0, J_{BM} > 0$. In **3**, triple irradiation was employed: strong irradiation to decouple the ring protons and very weak irradiation yielding Overhauser effects (20, 11*a*) or decoupling (12). These showed J_{BM}, $J_{CM} > 0$, with no information about J_{AM}. Slight broadening of the A peaks suggested $|J_{AM}| \approx 0.05$ Hz. A typical experiment for sign determination is shown in Fig. 1. Irradiation of peak B_1 (low field peak of the B octet) decreased C_1 and increased C_3 while irradiation of B_2 decreased C_2 and increased C_4. This experiment proved that J_{BM} and J_{CM} had the same sign. Figure 1 illustrates the usefulness of the Overhauser "tickling" technique for determination of signs of small couplings since B_1 and B_2 are separated by only 0.11 Hz.

Spectra were analyzed by the iterative computer programs LAOCN3 (22) and LAME (23), giving the parameters in Table 1. The only point worthy of note concerns **1**. Proton B gave sharp peaks with no observed coupling to M. (The line width at half height was $\approx$0.12 Hz, almost identical to that for known singlet peaks.) However, the iterative computer fit gave $J_{BM} = -0.07$ Hz. In calculations where J_{BM} was fixed

[4]A typical H_2 power level was 2 mV under load (measured on the oscilloscope).

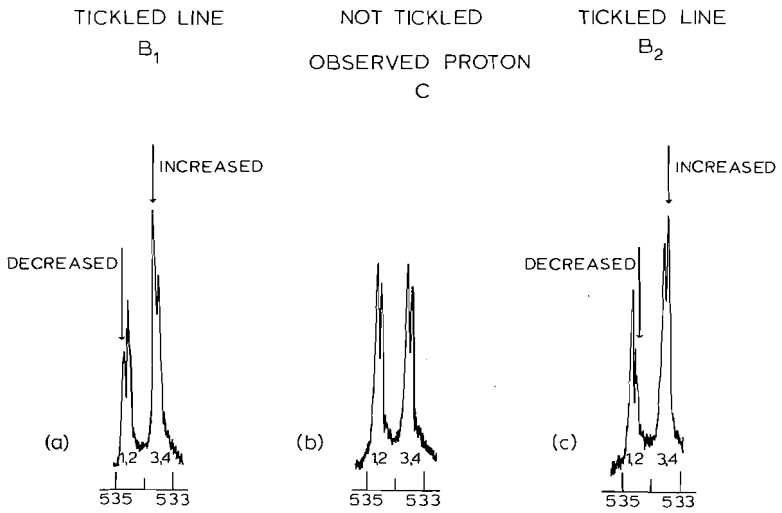

FIG. 1. Triple resonance Overhauser experiments used to determine relative signs of J_{BM} and J_{CM} in 4-vinylphenylacetylene. Ring protons are decoupled in all three spectra. (*a*) Lowfield quartet (C_1–C_4) of C proton octet with triple resonance frequency at B_1 (592.28 Hz); (*b*) C_1–C_4 without triple resonance; (*c*) C_1–C_4 with triple resonance frequency at B_2 (592.17 Hz).

at 0.00 Hz or +0.07 Hz, the fit between calculated and experimental spectra was significantly worse, particularly in the M proton region. The computed sign is consistent with the double resonance experiments and with previous results for phenylacetylene (14).

Results of MO–INDO–FPT calculations of long-range coupling constants are given in

TABLE 2. Long-range coupling constants (in Hz) obtained from MO–INDO–FPT calculations

Coupling constant*	Compound		
	Phenylacetylene	1-Phenylpropyne	4-Vinylphenylacetylene (3)
J_{AM}	+0.46	−0.38	−0.08
J_{BM}	−0.09	+0.27	+0.11
J_{CM}	+0.20	−0.26	+0.11

*Labelling of protons is identical to that previously given for 1, 2, and 3.

Table 2. For **1** and **2**, calculations were performed for the parent compounds, phenylacetylene and 1-phenylpropyne, for reasons of computational economy. For **1** and **2**, the perturbation was placed on the acetylenic proton. A repetition of the calculation for **1** with the perturbation on the four proton, C, gave a value of J_{CM} which differed by less than 0.001 Hz from the original value. For **2**, four calculations were performed for two conformations of the methyl group (see Fig. 2). The results in Table 2 are a weight average (allowing for the number of equivalent protons) of the four calculations.

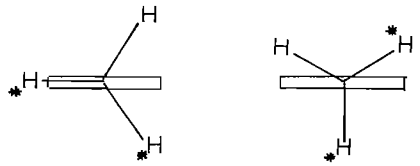

FIG. 2. Conformations of methyl group in 1-phenylpropyne for which MO–INDO–FPT calculations were performed. Protons on which pertubations were placed are marked with asterisks.

4-Vinylphenylacetylene	−0.3089

Discussion

The McConnell relationship for calculation of π contributions to coupling constants in benzene is (5):

$$[1] \qquad J_{HH'} = \beta^2 \rho^2_{NN'} Q_{CH} Q_{CH'} / h\Delta E$$

where β = Bohr magneton, $\rho_{NN'}$ = mobile bond order between carbon atoms to which hydrogens are bonded, Q_{CH} is the proton hyperfine splitting constant, and ΔE is an average excitation energy to low-lying triplet states. This approach has been extended to several benzene derivatives (6–12). For example, for toluene, [1] may be written (6, 10)

$$[2] \qquad J_{H,CH_3} \propto Q_{CH} Q_{CCH}$$

where Q_{CCH} is the methyl hyperfine splitting constant.

If it is assumed that the same proportionality constant can be used for different compounds, then possible σ and π contributions to long-range coupling constants can be discussed in terms of equations of the same type as [2] (9–12). This assumption requires that $\rho^2_{NN'}/\Delta E$ must be constant for the compounds under investigation. Bond orders for a series of compounds which are relevant to this discussion have been estimated by CNDO/2 MO calculations (see Table 3). $\rho_{NN'}$ is nearly constant. The observation that J_{H,CH_3} values in toluene derivatives are nearly substituent independent (19, 21) suggests that the variation in $1/\Delta E$ must also be small. Therefore, it is reasonable to use the same proportionality constant for different compounds.

The McConnell relationship applies specifically to π electron contributions. For toluene, $J^{\pi}_{H,CH_3} = -0.6$ Hz (21, 24) while $Q_{CCH} = +25$ G (10). It has been shown that J^{π}_{H,CH_3} contains a negligible σ contribution (12). If it is assumed that J_{CM} for **1** also contains only π contributions, then $Q_{CC\equiv CH}/Q_{CCH} = J_{CM}/J^{\pi}_{H,CH_3}$. The average of J_{CM} from the two sets of experimental results is +0.28 Hz. Consequently, the estimated value of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$Q_{CC\equiv CH}$ is $(0.28 \times 25/(-0.6)) = -12$ G. This value can be checked by calculating the long-range coupling constants for **3**. The corresponding long-range coupling constants for the para proton to the vinyl group in styrene derivatives are $J^p_A = -0.24$, $J^p_B = +0.26$, and $J^p_C = +0.28$ Hz. Assuming $Q_{CH} = -23$ G (10), $Q_{CC\equiv CH}/Q_{CH} = 12/23$ and estimated coupling constants for **3** are $J_{AM} = -0.12$, $J_{BM} = +0.13$, and $J_{CM} = +0.14$ Hz. The magnitude of J_{AM} is slightly overestimated but J_{BM} and J_{CM} are in excellent agreement with the experimental values. This strongly suggests that the estimated value of $Q_{CC\equiv CH}$ is accurate and that J_{CM} for **1** is dominated by π effects. Consequently the acetylenic linkage appears to be about half as effective as a methyl group in transmitting spin information from a phenyl π electron system. It is almost equal in effectiveness to a vinyl group since in the latter case, the corresponding para to β hydrogen coupling constants (which are also dominated by π effects (1)) are identical in sign and magnitude to J_{CM} for **1** (see above).

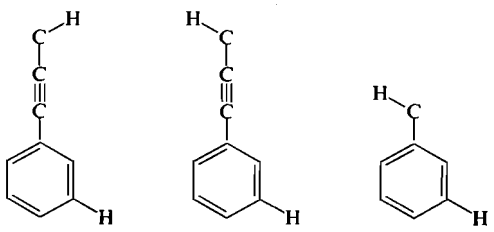
Further information concerning π contributions to coupling constants can be obtained by the methyl group replacement technique (25). If a coupling constant to a proton is transmitted through the π system, then replacement of the proton by a methyl group should give a coupling constant opposite in sign but nearly equal in magnitude (since $Q_{CH} \approx -Q_{CCH}$). For example, J^p_{H,CH_3} in toluene $= -0.6$ Hz while $J^p_{CH_3,CH_3}$ in *p*-xylene $= +0.6$ Hz (12). It is not obvious, *a priori*, that the methyl group replacement technique will work when the methyl group is bonded to an acetylenic linkage rather than directly to a phenyl group. However, the averaged values for the two sets of coupling constants for **1** ($J_{AM} = +0.28, J_{BM} = -0.09, J_{CM} = +0.28$ Hz are nearly identical in magnitude and opposite in sign to those for **2**. This strongly suggests that the methyl group replacement technique can be applied to this system and that the observed long-range coupling constants in **1** and **2** are all transmitted primarily through the π system. All of the determined signs of coupling constants are entirely consistent with π contributions.

Assuming $Q_{CC\equiv CH} = -12$ G, the observed coupling constants for **2** indicate that $Q_{CC\equiv CCH} = +12$ G. By comparing hyperfine e.p.r. coupling constants for γ-phenylpropargyl and benzyl radicals, Kochi and Krusic (26) concluded that the interposition of an acetylenic linkage reduced the transmission of spin density from a methylene group to a phenyl group by 47%. Since this corresponds to $Q_{CC\equiv CCH} = (0.47 \times 25) = +12$ G, our conclusions are in quantitative agreement with those obtained from e.p.r. measurements.

The MO–INDO–FPT calculations were performed to determine whether they could reproduce the long-range coupling constants for **1**–**3** and consequently provide insight into the mechanism of transmission of these coupling constants. For **1**, J_{CM} and J_{AM} are respectively under- and overestimated but the overall agreement between calculation and experiment is very good. The agreement is even better for **2** although J_{AM} and J_{BM} are slightly overestimated. The agreement for **3** is excellent, assuming that J_{AM} has the expected negative value. The overall agreement for the three compounds is extremely good with four of the eight long-range coupling constants whose signs were determined estimated within the probable experimental error (0.03 Hz).

The conformational dependence of the calculated long-range coupling constants for **2** provides insight into the mechanism of transmission of these interactions. J_{CM} varied from -0.05 Hz for the C—H bond coplanar to the phenyl group to -0.46 Hz for the C—H bond perpendicular to the phenyl group with a $\sin^2 \phi$ dependence (defining ϕ as the projection angle between the C—H bond and the phenyl group). Similar behavior has been noted for α C—H bonds in toluene (27), styrene (1), and benzaldehyde (11) and attributed to a σ–π configuration interaction (27). The fact that the same behavior is noted for a methyl group bonded to an acetylenic linkage suggests that the spin information is only transmitted through the extended π system. This could account for both the success of the methyl group replacement technique for **2** and the conclusion that vinyl and acetylenic linkages are equally effective in transmitting spin information.

J_{AM} and J_{BM} showed similar, although less marked conformational dependence. For the planar forms ($\phi = 0°$), J_{BM} was predicted to have a slightly larger value for conformation I ($+0.24$ Hz) than for conformation II ($+0.17$ Hz). For α proton couplings, an enhanced positive con-



I II III

tribution has been found for the all-*trans* conformation III (28, 29, 1). It would be difficult to check the prediction concerning I and II.

In summary, the McConnell formulation has proved useful for extended coupling paths, since starting from results for a six bond coupling constant in toluene it has proved possible to derive Q values which quantitatively predict the nine bond couplings, J_{BM} and J_{CM} in **3**. MO–INDO–FPT also predict these couplings accurately. Even more extended coupling paths are under investigation.

Benzene Radical Cation Formation on Hydrogen Mordenite. The Role of Adsorbed Oxygen[1,2]

N. H. SAGERT, R. M. L. POUTEAU, M. G. BAILEY, AND F. P. SARGENT

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba R0E 1L0

Received February 21, 1972

The e.p.r. spectrum of benzene on hydrogen mordenite (Zeolon H) has been studied as a function of coverage, degassing temperature, and hydrogen and oxygen treatment. The initial spectrum observed was that due to the benzene cation radical dimer. The maximum number of spins was formed when the solid was completely saturated with benzene. Large yields were obtained only when the zeolitic water and water of hydration of the protons were removed. The largest yields were observed where significant dehydroxylation had occurred. Chemisorbed oxygen was essential, and there was a 1:1.2 ratio between the maximum number of spins observed in the presence of excess oxygen and the amount of oxygen chemisorbed. The largest concentration of radical cations noted (2×10^{18}/g) was much smaller than the number of acid sites known to be present (10^{21}/g). In fact, only one unit cell of the hydrogen mordenite in 100 had a site capable of oxidizing benzene to the cation. Hence these sites must be in special positions in the solid.

Le spectre r.p.e. du benzène sur l'hydrogène mordenite (Zeolon H) a été étudié en fonction du recouvrement de la température de dégazage et du traitement à l'hydrogène et à l'oxygène. Le spectre initialement observé est celui du radical cation dimère. Le nombre maximum de spins est produit lorsque le solide est complètement saturé en benzène. Les rendements élevés ne sont obtenus qu'après élimination des eaux zéolitique et d'hydratation des protons. Les rendements les plus élevés ont été observés là où une des hydroxylations significatives s'est produite. L'oxygène chimisorbé est essentiel et il existe un rapport de 1 à 1.2 entre le nombre maximum de spins observés en présence d'oxygène en excès et la quantité d'oxygène chimisorbé. La concentration la plus élevée en radical cation (2×10^{18}/g) est beaucoup plus petite que le nombre de sites acides connus pour être présents (10^{21}/g). En fait seule une unité d'hydrogène mordenite sur cent possède un site capable d'oxyder le benzène en cation. En conséquence ces sites doivent occuper des positions spéciales dans le solide.

Canadian Journal of Chemistry, **50**, 2041 (1972)

Introduction

The species formed when various substances are adsorbed on alumino-silicates have been studied by e.p.r. techniques (1–3). Stanmires and Turkevich (1) observed cation radicals of triphenylamine on Y-type zeolites, and Rooney and Pink (2) observed e.p.r. signals from both anthracene and perylene cation radicals on silica–alumina. They did not observe signals from benzene or methyl substituted benzenes adsorbed on silica–alumina. Hirschler *et al.* (3) reported signals from benzene on calcium and rare earth exchange Y zeolites and cerium exchanged X zeolites. However, their spectra were poorly resolved. More recently Corio and Shih (4) and Kurita *et al.* (5) observed better resolved spectra from benzene adsorbed on hydrogen mordenite. They identified the initial spectrum as the benzene radical cation dimer.

It has been generally agreed that, for silica–aluminas, treatment with hydrogen suppresses the e.p.r. signals (6–8). Initially it was reported that oxygen decreased the signals (2, 9), but Dollish and Hall (8) showed that this is due to a physical interaction which broadens the lines and changes their shape. Porter and Hall (7) then showed that radical ion concentrations on silica–alumina increased on adding oxygen and Dollish and Hall (10) demonstrated that chemisorbed oxygen is actually essential for the generation of radical ions from perylene on NH_4^+Y zeolites, NH_4^+X zeolites, and $Ca^{2+}Y$ zeolites.

The work presented here examines the effect of hydrogen, oxygen, and evacuation temperature on the benzene cation radical dimer formation over hydrogen mordenite. This was done to obtain more information about the sites responsible for the one-electron oxidation.

Experimental

The synthetic hydrogen mordenite, trade name Zeolon H,

was obtained from Norton Chemical Products. Emission spectrographic analysis revealed 100 p.p.m. of iron, 5 p.p.m. of nickel, 10 p.p.m. of chromium, and 150 p.p.m. of titanium. It was heated in air at 500 °C for 16 h to remove carbonaceous material and was then re-hydrated by exposure to atmospheric moisture for several days. As a standard treatment, about 0.5 g was weighed out into a 6 mm (o.d.) e.p.r. tube. The tube was attached to a mercury and grease-free vacuum line and the mordenite was evacuated while the temperature was raised to the desired level. It was continuously evacuated at this temperature for 16 h, reaching pressures below 2×10^{-6} Torr. This was the normal treatment. Samples designated "hydrogen treated" were then contacted with 1 atm of hydrogen for 15 min at the evacuation temperature, and the hydrogen was pumped out. This was repeated twice, followed by evacuation at the same temperature for about 3 h. The tubes were then allowed to cool under vacuum.

The Reagent Grade benzene was degassed by the freeze–pump–thaw technique. It was then distilled under vacuum through a P_2O_5 bed onto the zeolite which was kept at 77 °K. The tube was sealed off under vacuum and kept at 77 °K until 10 min before the e.p.r. measurements were made.

The e.p.r. measurements were normally made at room temperature with a Varian V-4500 series X-band spectrometer operating at about 9.3 GHz with a modulation frequency of 100 KHz. The power level was 0.4 ± 0.1 mW. Spectra were obtained as the first derivative of the absorption, and concentrations were obtained by doubly integrating the spectra numerically, using the method of Wyard (11). The minimum detectable concentration of benzene radical cation dimers was less than 10^{15}/g. A Varian high concentration pitch standard, placed in the back cavity of the Varian dual cavity accessory, was used as a working standard. The peak height of this standard was related to the number of spins in the hydrogen mordenite by doubly integrating the signals from solid mixtures of finely ground 1,1-diphenyl-2-picrylhydrazyl (DPPH) with hydrogen mordenite. These mixtures were contained in tubes identical to those used for samples and were placed in the front cavity. The amount of DPPH in them was adjusted to give first derivative peak heights similar to those obtained from samples being studied. The DPPH was re-crystallized twice before use, and its purity was determined spectrophotometrically (12).

The surface areas were measured by nitrogen adsorption at 77 °K using the B.E.T. technique, taking the area of the nitrogen molecule as 16.2 Å^2. The amount of nitrogen adsorbed was measured by the pulse desorption method using a Perkin–Elmer 212D Sorptometer. Benzene and oxygen adsorption isotherms at 28 °C were measured with a grease-free volumetric adsorption apparatus incorporating a quartz spiral manometer capable of measuring pressure changes to $\pm 3\ \mu$.

Results

The spectra obtained are shown in Fig. 1 and are similar to those obtained by Corio and Shih (4) and Kurita *et al.* (5). After 3 min at room temperature a spectrum shown as 1*a* was obtained with line spacings of 2.2 G. This spectrum has been identified as due to the benzene cation radical dimer (4, 5). After 1 h

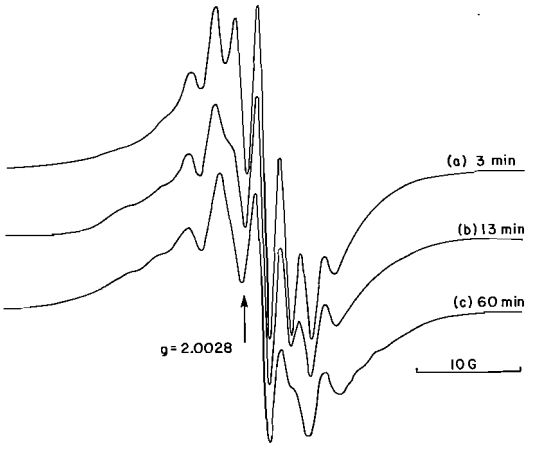

FIG. 1. The e.p.r. spectra of benzene on hydrogen mordenite degassed at 550 °C (*a*) after 3 min, (*b*) after 13 min, and (*c*) after 60 min. The spectra are displaced along the *Y*-axis for clarity.

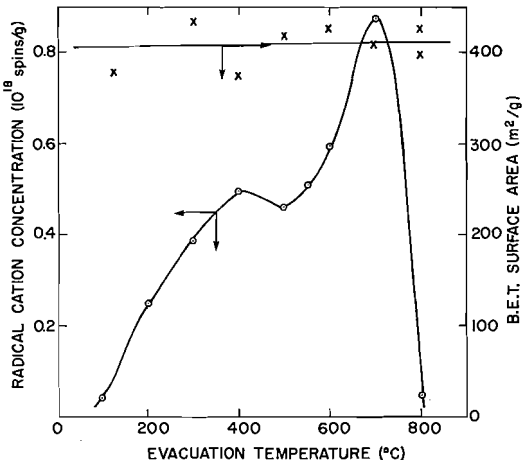

FIG. 2. Spin concentrations in the presence of 0.5 ml/g benzene (○), and B.E.T. surface areas (×) for hydrogen mordenites evacuated at different temperatures.

the spectrum shown as 1*c* was obtained. It has been identified by Kurita *et al.* (5) as the biphenyl cation radical. The total number of spins in Fig. 1*a* and 1*c* is the same to within 8%. The method of integration is only claimed to be accurate to within 5% (11), and other uncertainties probably increase this error considerably. Our reproducibility was about 10%. Thus, to within the error of our measurements, the spin concentration remained constant while the spectrum changed during the 60 min.

Figure 2 shows the number of spins per gram

For personal use only.

as a function of the degassing temperature of the hydrogen mordenite. The B.E.T. surface area, measured by nitrogen adsorption at 77 °K is given on the same figure as a function of degassing temperature. The number of spins per gram increased up to 700 °C, and then fell rapidly. The apparent maximum at 400 °C may be a result of experimental scatter as the reproducibility of our spin concentrations was at best ±10%. However, there was some evidence, as mentioned below, that samples degassed at 300 and 600 °C behaved differently when treated with hydrogen.

Experiments with varying benzene concentrations on hydrogen mordenite degassed at 500 °C showed that the maximum number of spins was obtained using about 0.1 ml of liquid benzene per gram. Smaller spin concentrations were obtained with smaller amounts and no changes (±10%) were obtained with larger amounts. The 0.1 ml of benzene corresponds to 6.8×10^{20} molecules, but only 6×10^{17} spins/g were produced, *i.e.*, about 0.1% of the benzene was converted. Benzene adsorption experiments indicated that the full adsorption capacity of benzene corresponded to 0.083 ml/g at 28 °C, in agreement with the 0.09 ml/g at 25 °C obtained by Barrer and Peterson (13). Thus the full adsorption capacity appears necessary to develop the maximum number of spins, and benzene is not selectively adsorbed on the sites capable of oxidizing it. The amount of adsorbed benzene (0.083 ml/g) if adsorbed as a monolayer would correspond to a surface area of 232 m^2/g if the area of benzene molecule is taken as 41 $Å^2$ (14). As the surface areas measured by nitrogen adsorption are about 400 m^2/g, over half the total area seems accessible to benzene.

To assess the role of oxygen, samples degassed at 550 °C were prepared with from 2–11 Torr of oxygen present. The spin concentration quadrupled (Table 1) compared to the spin concentration from a normal sample degassed at 550 °C (Fig. 2). When 6.0 Torr of oxygen was added to a sample degassed at 800 °C, a very large increase in spin concentration compared to that in the absence of oxygen was noted. Some samples were then treated with hydrogen to remove chemisorbed oxygen completely. This decreased the number of spins by a factor of 4 in the case of a sample degassed at 300 °C and to an undetectable level in the case of a sample degassed at 500 °C (Table 1). Thus samples prepared at higher temperatures seem more susceptible to hydrogen treatment.

TABLE 1. Effect of hydrogen treatment and oxygen pressure on the yield of radical ions

Evacuation temperature (°C)	Hydrogen treatment	Oxygen pressure (Torr)	Radical concentration (10^{17} spins/g)
550	no	2.7	21.0
550	no	9.5	17.5
550	no	11.0	20.4
800	no	6.0	6.1_9
300	yes	0	1.1_8
500	yes	0	<0.01

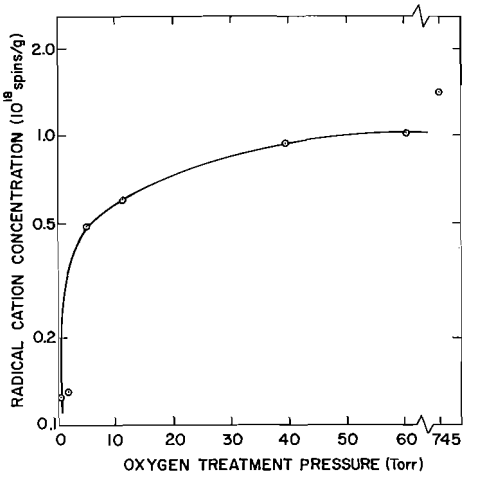

FIG. 3. Increase in spin concentration when a sample given the "hydrogen treatment" at 550 °C is exposed to varying oxygen pressures.

Finally, a series of hydrogen mordenites degassed at 550 °C and given the hydrogen treatment was allowed to contact oxygen at various pressures for 15 min. The oxygen was pumped out at room temperature, and benzene added in the usual way. Figure 3 shows the results obtained, plotting the number of spins produced against the pressure of oxygen used. About 5 Torr of O_2 restored the spin concentration to its normal value obtained without hydrogen treatment. High pressures gave yields of the order of those obtained in the actual presence of oxygen gas. An oxygen adsorption isotherm after hydrogen treatment (Fig. 4) showed that at 28 °C 2.5×10^{18} molecules of O_2 were chemisorbed per gram after hydrogen treatment. This was estimated by extrapolating

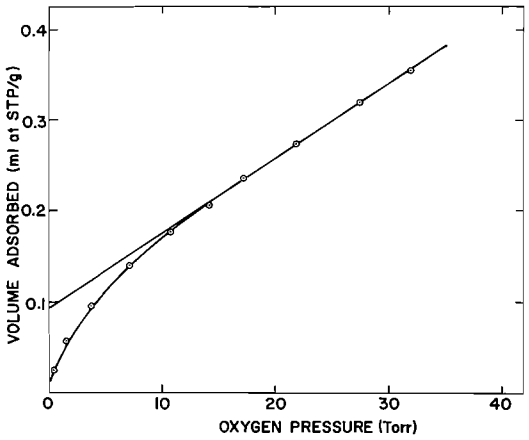

FIG. 4. Adsorption isotherm of O_2 on hydrogen mordenite given the "hydrogen treatment" at 550 °C; $T = 28$ °C.

the high pressure part of the isotherm to zero pressure, and is to be compared with the 1.45×10^{18} spins/g maximum obtained in Fig. 3 and the 2.0×10^{18} spins/g measured in the presence of oxygen gas (Table 1).

No spins were observed when perylene was adsorbed from *n*-hexane solution onto hydrogen mordenite degassed at 550 °C, and the *n*-hexane distilled off.

Discussion

(i) General Features

Ordinary silica–alumina cracking catalysts are not capable of oxidizing benzene (2). As the gas phase ionization potential of benzene is 9.24 eV (15), strong oxidation sites of about this energy are probably required to form cations. Both Corio and Shih (4) and Kurita *et al.* (5) have observed that hydrogen mordenite can oxidize benzene. Both groups agree that the initially observed seven-line spectrum with a line spacing of 2.2 G is from the benzene radical cation dimer, formed by the removal of a π electron from benzene. They also agree that this converts into a different radical ion with a line spacing of 3.8 G within 1 h. Corio and Shih assumed an equilibrium was formed between the radical cation dimer and the monomer. On the other hand Kurita *et al.* presented strong evidence that the final product was the biphenyl cation radical. Our spectra are quite similar to those obtained by both groups and we have nothing to add to this controversy. Our results indicate that the conversion of cation dimer to the other species occurs without decrease in the total number of radical ions, since there is no significant decrease in the total number of spins as the spectrum changes. Peak heights, of course, vary considerably in 1 h but the doubly integrated first derivative spectrum measured after 10 min seems to be a reasonable measure of the number of oxidizing sites on the hydrogen mordenite.

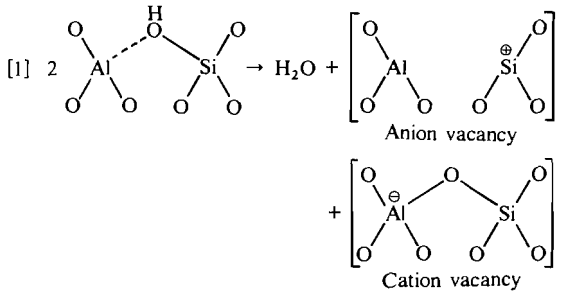
(ii) Water Content of the Zeolite

The formation of sites able to abstract electrons from benzene can be related to the removal of strongly held water from the hydrogen mordenite. Hydrogen mordenite is made from sodium mordenite by ion-exchanging with ammonium and heating. Ammonia is eliminated leaving most of the sodium exchanged for H_3O^+. The unit cell of the sodium mordenite mineral is $Na_8 \cdot (AlO_2)_8 \cdot (SiO_2)_{40} \cdot 24H_2O$ (16). In making hydrogen mordenite, almost one aluminum ion is lost from the unit cell along with the cations (13, 17), leading to an approximate formula for hydrogen mordenite:

$$(H_3O)_{7-n}Na_nAl_7Si_{40}O_{92}(OH)_4 \cdot 15H_2O$$

where $0.5 < n < 1$. This formula identifies four sources or potential sources of water. Zeolitic water, the $15H_2O$, accounts for 7.4% of the formula weight, and is removed between room temperature and 360 °C (13). The water of hydration of the protons, the $(H_2O)_{7-n}$, accounts for about a 3.6% weight loss and is also removed by 360 °C (13). Much of the hydroxyl water, the $(OH)_4$, may be removed by 360 °C as well. A 2% weight loss between 500 and 900 °C has been ascribed to the attack of bare protons, $(H^+)_{7-n}$, on the alumino-silicate structure (13), and some hydroxyl water was thought to be lost at these temperatures as well. Attack of protons on the alumino-silicate structure presumably initially forms anion and cation vacancy pairs (10). Dollish and Hall (10), suggest that this structure readjusts to a system of lower energy. Kerr (18) has proposed that, for hydrogen Y zeolite, some of the alumina lost from the unit cell is present as $Al(OH)_3$ and the positive vacancy may be located on this aluminum hydroxide as $Al(OH)_2^+$. A significant amount of this dehydroxylation (eq. 1) may occur at lower temperatures as well since Lefrancois and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



Malbois (19) have shown that on hydrogen mordenite the number of Lewis acid sites increases between 200 and 450 °C.

Our results as a function of degassing temperature (Fig. 2) suggest that removal of water, and the accompanying formation of Lewis acid sites, is necessary to create the site capable of oxidizing benzene. Because the spin concentration begins to increase again at degassing temperature higher than 550 °C, it appears that some of the vacancy sites created by this treatment (eq. 1) can oxidize benzene also. Thus there may be two types of sites capable of oxidizing benzene. The existence of two types of sites is also suggested by the resistance to hydrogen treatment: the sites formed at 300 °C seem more resistant to hydrogen than those formed at 500 °C (Table 1). The drop in spin concentration at the highest temperatures probably results from removal of chemisorbed oxygen, as discussed below. It does not result from a loss of surface area. Analogous observations by Flockhart *et al.* (20) have led them to suggest that amorphous silica–alumina also has two types of sites capable of oxidizing perylene.

(iii) Role of Chemisorbed Oxygen

The results of Table 1 and Fig. 3 show that chemisorbed oxygen is necessary to develop the sites capable of oxidizing benzene. We found a 1:1.2 ratio between the maximum number of spins produced (2.1×10^{18}/g) and the amount of oxygen chemisorbed after hydrogen treatment (2.5×10^{18} molecules/g). The hydrogen treatment probably removes most of the chemisorbed oxygen present after a normal treatment. Thus there is almost a 1:1 ratio between spins produced and chemisorbed oxygen. This suggests that a molecule of oxygen must be chemisorbed at, or close to, a special site in the solid, and that this combination of original site and oxygen molecule forms a new electron accepting site capable of oxidizing benzene. As the ionization potential of benzene is 9.24 eV, the new site is probably almost this strong.

Oxygen is likewise needed for the oxidation of perylene on X and Y zeolites (10) and on silica–alumina (6). Dollish and Hall (10) also showed that on NH_4^+Y zeolite, one oxygen molecule was required to form the oxidizing site because they obtained a 1:1 ratio between the number of spins produced and the number of molecules of oxygen added.

In our experiments pumping off oxygen adsorbed at 745 Torr at room temperature prior to adding benzene reduced the cation dimer yield by only 30%, compared to the yield observed in the presence of excess oxygen (Table 1 and Fig. 3). This confirms that chemisorbed and not physically adsorbed oxygen is needed for cation dimer formation.

(iv) Number and Nature of Sites

For a sample exposed to 745 Torr oxygen at room temperature and then evacuated, a yield of 1.45×10^{18} spins/g was obtained. With NH_4^+Y zeolite, Dollish and Hall (10) obtained a yield of 5.8×10^{18} spins/g for perylene oxidation under comparable conditions. Thus fewer oxidizing sites are available in the hydrogen mordenite than in the NH_4^+Y zeolite.

A measure of the total number of acid sites is obtained from the ammonia adsorption work of Eberly *et al.*, (21). They showed that, at 371 °C and 8 Torr, 9.4×10^{20} molecules of NH_3 were adsorbed per gram, and that this adsorption was a measure of the acidity of the surface. This number of sites is almost 500 times larger than the largest number of spins which we observed. A number of explanations are possible for this large discrepancy.

The hydrogen mordenite consists of tubes with an elliptical cross section of about 7 × 6 Å connected by side pockets which have diameters of 3–4 Å. Thus benzene, which has a diameter of 6.6 Å (13) could conceivably be barred from access to the interior of the solid. Adsorption isotherms measured by us and by others (13, 22, 23) show that this is not the case. Benzene is adsorbed throughout the large channels, although it is excluded from the small side pockets of the main channels (13).

It is most likely that radical cation formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is limited by the amount of chemisorbed oxygen which is available. A sample evacuated at 500 °C and given the hydrogen treatment chemisorbed 2.5×10^{18} molecules O_2/g at 28 °C. This corresponds to 0.012 molecules per unit cell, assuming the unit cell for dehydrated hydrogen mordenite (Zeolon H) to be

$$8.42\{Na_{0.08}H_3O^+_{0.75}Al_{0.83}Si_{4.75}O_{10.82}OH_{0.68}\}$$

as determined by Barrer and Murphy (17). Thus only about one unit cell in 80 has a site capable of chemisorbing oxygen. The maximum number of spins formed under any conditions was 2.1×10^{18}/g. Therefore only about one unit cell in 100 has a site capable of oxidizing benzene. These sites must correspond to special positions possibly at the edge of crystal faces or at points of special strain in the lattice. Their exact nature has yet to be determined. However, it is well established that benzene is excluded from the side pockets of the mordenite. Therefore the sites are likely located in the main channels. Furthermore, no spins were observed from perylene on the hydrogen mordenite. As perylene is known to be more easily oxidized (2) but is probably excluded from the main channels of the mordenite, it is likely that the oxidizing sites are not on the exterior surface of the solid. The exterior area is almost 20% of the total area (23), so that if perylene was oxidized on the exterior of the solid, it should have been observed.

We would like to thank A. G. Wikjord and C. F. Musick of the Analytical Science Branch of our laboratory for measuring the nitrogen surface areas. Helpful discussions on the structure of mordenites with E. V. T. Murphy are also gratefully acknowledged. E. V. T. Murphy and M. Tomlinson are thanked for their frank comments on earlier versions of this manuscript.

Ceric Ammonium Nitrate Oxidation of Cyclic Ketones

P. SOUCY, TSE-LOK HO, AND P. DESLONGCHAMPS[1]

Laboratoire de Synthèse Organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received January 13, 1972

Ceric ammonium nitrate oxidation of cyclohexanone, cyclopentanone, and norbornanone gives nitrato-carboxylic acids, oxidation of adamantanone and adamantan-2-ol gives the lactone **14**.

Par oxydation avec le nitrate cérique d'ammonium, la cyclohexanone, la cyclopentanone, et la norbornanone donnent des acides nitrato-carboxyliques correspondants. L'oxydation de l'adamantanone ou de l'adamantanol-2 conduit à la lactone **14** correspondante.

Ceric ion in various coordinated forms is a strong oxidizing agent. Numerous reports of utilizing Ce(IV) to oxidize organic compounds have appeared in the literature (1). In particular, Ce(IV) oxidation of alcohols has received much attention in recent years, as an outgrowth of the colorimetric detection and quantitative determination of these substrates. It is known that Ce(IV) ion forms 1:1 complexes with alcohols which rapidly collapse to the products.

The studies by Trahanovsky and coworkers, *inter alia*, on ceric ammonium nitrate (CAN) oxidation of a number of organic compounds have uncovered some useful applications. Thus, benzylic and cyclopropylcarbinyl alcohols are oxidized to the corresponding aldehydes (2) in good yields, α-glycols are cleaved (3) in analogy to the lead tetraacetate reaction and cycloheptatriene has been oxidized to benzaldehyde, benzene, and carbon monoxide (4). CAN also oxidizes benzylic methylene groups to the carbonyl derivatives (5) and it has also been used in regeneration of the parent ketones from their oximes and semicarbazones (6). More recently, oxidative cleavages of bicyclo-[2.2.1]-2-heptanols and bicyclo[2.2.2]-2-octanol (7), of alkylphenylcarbinols (8), of 1,2-diaryl-ethanols and 1-aryl-2,3-diphenylpropan-2-ols (9) have also been reported.

Under more drastic conditions, carbonyl compounds such as aliphatic aldehydes and ketones are attacked by Ce(IV) ions to yield formic acid and carbon dioxide as ultimate products (1). Consequently, almost all the pertinent investigations have been limited to reaction kinetics and mechanistic aspects, without probing into the synthetic utility of these oxidations.

In connection with a certain synthetic program, we have been interested in the oxidation of cyclic ketones with ceric salts, specifically with CAN. At present, we wish to report the results of such oxidation performed on a few representative cyclic ketones.

Results and Discussion

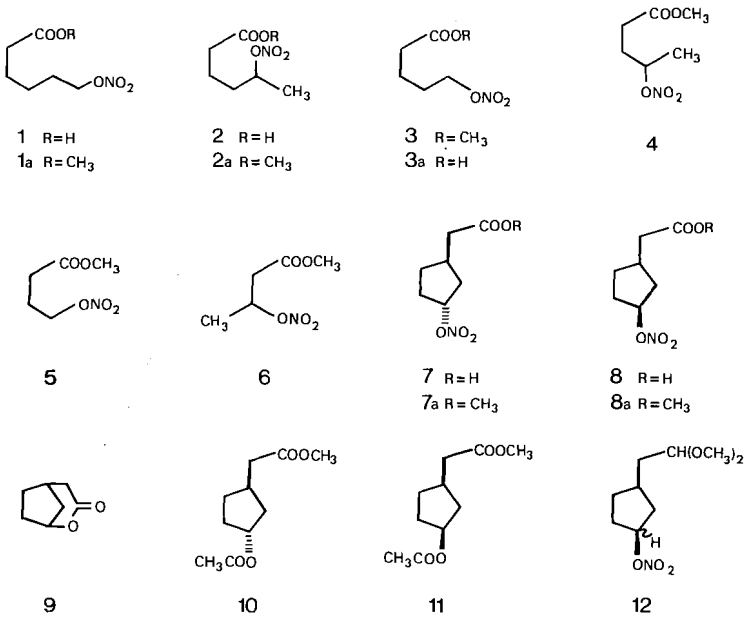
Our standard conditions of oxidation involve the treatment of ketone with 4 mol equiv of CAN at 60° in aqueous acetonitrile, until discoloration of the orange solution is complete. The major fractions isolated from oxidation of cyclohexanone, cyclopentanone, and norbornanone are acidic in nature. The combined yields of these products are of *ca.* 50%.

Cyclohexanone gave a mixture of 6- and 5-nitratohexanoic acids in a ratio of 3:2. The structures of these compounds were deduced from the i.r., n.m.r., and mass spectra, and have been verified by comparison of their methyl esters **1***a* and **2***a* with authentic specimens prepared by unambiguous routes.

Cyclopentanone yielded a more complex mixture of acidic products. The v.p.c. analysis of the derived methyl esters indicated the presence of four major components in the ratio of 24:16:34:26 identified as **3**, **4**, **5**, and **6** respectively, on basis of spectral data. Authentication of **3** has been made by its preparation from methyl 5-hydroxypentanoate.

Next we focused our attention to the oxidation of 2-norbornanone. Two nitrato-carboxylic acids **7** and **8** were obtained. The v.p.c. analysis of the derived methyl esters (**7***a* and **8***a*) indicated that the *trans*-epimer was present in larger

[1]A. P. Sloan Fellow, 1970–1972.



quantity (ratio of 3:2). Hydrolysis of the crude acidic products (**7** and **8**) furnished a mixture of hydroxyacids which was subsequently esterified and oxidized by Collins reagent (10) to methyl 3-oxocyclopentane acetate, identical with a sample prepared from 2-oxabicyclo[3.2.1]octan-3-one (**9**). Characterization and stereochemical assignments of the oxidation products were carried out as the following. Saponification of **7***a* and **8***a* and treatment with *p*-toluenesulfonic acid in benzene gave a mixture of lactone **9** and *trans*-3-hydroxycyclopentane acetic acid, which were readily separated. The *trans*-acid has been converted to the acetoxyester **10**; the lactone **9** was similarly transformed into the epimeric *cis*-acetoxyester **11**.

It was reported that the *exo*- or *endo*-norbornanol probably gives only *cis*-3-nitratocyclopentane acetaldehyde besides two cyclopentene acetaldehydes (7). We have, therefore, repeated the oxidation and converted the higher boiling aldehyde fraction into the dimethyl acetal **12**, thence to the methyl ester by ozonolysis (11). This ester sample has been shown by v.p.c. to contain two components corresponding to **7***a* and **8***a*, the *trans*-epimer being slightly predominant.

The rates of CAN oxidation of all three ketones mentioned above are similar; the reaction is generally complete within 1–1.5 h at 60°. However, camphor was found to be stable under the same conditions for at least 20 h, during which time CAN was slowly consumed (solvent oxidation). This observation led us to believe that the oxidation requires a close approach of the ketone and CAN, perhaps a complex formation is involved. Since Ce(IV) is coordinated by 8 to 12 atoms and thus the cerium species is fairly bulky, complex formation with camphor must be difficult. The success of isoborneol in undergoing CAN oxidation (7) is somewhat understandable, if one takes into consideration the great stability difference between a Ce(IV) alkoxide and a weakly coordinated (C=O → Ce(IV)) complex in judging the relative reactivities.

We envision that nitratocarboxylic acids arise from electron-transfer from the carbonyl oxygen to Ce(IV) within the CAN–ketone complex to generate a cation-radical **A** (Scheme 1). This cation-radical would then suffer a C—C bond fission (**A** → **B**) and react with water in the medium (**B** → **C**); the free radical can be further oxidized by electron transfer (**C** → **D**) or by ligand-transfer (12) to yield the final products. Generation of nitrato derivatives *via* this mechanism has previously been discussed by Trahanovsky *et al.* (7).

In order to account for the formation of acids having a secondary nitrato group, a

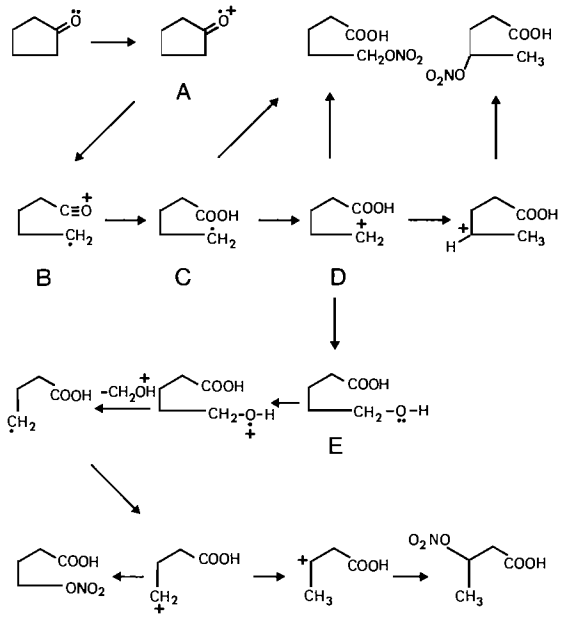
For personal use only.



SCHEME 1

competitive oxidation of **C** by an electron-transfer process is proposed. The incipient carbonium ion **D** could undergo 1,2-hybride shift prior to its capture by the nitrate anion.

Degradation of one-carbon fragment observed during CAN oxidation of cyclopentanone poses an interesting problem. 5-Nitratopentanoic acid (*3a*) was recovered unchanged when exposed to CAN, hence it is not a precursor of the other three nitratocarboxylic acids. A similar result was obtained with δ-valerolactone. However, oxidation of the sodium salt of 5-hydroxypentanoic acid with CAN gave γ-butyrolactone in 50% yield. Consequently, loss of a one-carbon fragment might be explained by partial capture of the carbonium ion **D** to give **E** which can then be further oxidized and fragmented as outlined in Scheme 1.

We have also studied the CAN oxidation of adamantanone (**13**)[2] which is structurally unique with respect to its rigid and nonenolizable nature. Thus adamantanone was allowed to react with 4 equiv of CAN in aqueous acetonitrile at 60°; discoloration (orange to faintly yellow) was observed at the end of 3 h. The rate of the reaction is slower than those of the ordinary ketones such as cyclopentanone and cyclohexanone; yet the reaction was quite clean, for only a single spot was detected by t.l.c. The product was isolated in 73% yield after sublimation, and was shown to be identical with the lactone **14** (13) obtained from *m*-chloroperbenzoic acid oxidation of adamantanone.

It is instructive to consider the above finding in light of a similar reaction of norbornanone. Whereas the result of adamantanone oxidation may be interpreted as illustrated in Scheme 2, in the case of norbornanone, lactonization of a possible intermediate such as **F** would be discouraged by the introduction of strain in reforming a bridged ring system. Furthermore, the entropy factor must play an important role in suppressing lactone formation. Consequently, monocyclic nitrato-carboxylic acids resulted.

Structurally constrained ketones are expected to behave in analogy to adamantanone; thus the present work may indicate a welcoming alternative to the classical Baeyer–Villiger oxidation, particularly where peracid-sensitive groupings such as olefinic linkages are present in the molecule.

CAN oxidation of adamantan-2-ol also afforded the lactone **14** in 50% yield. Adaman-

[2]In our laboratories, this reaction has been named "CANADA" reaction.

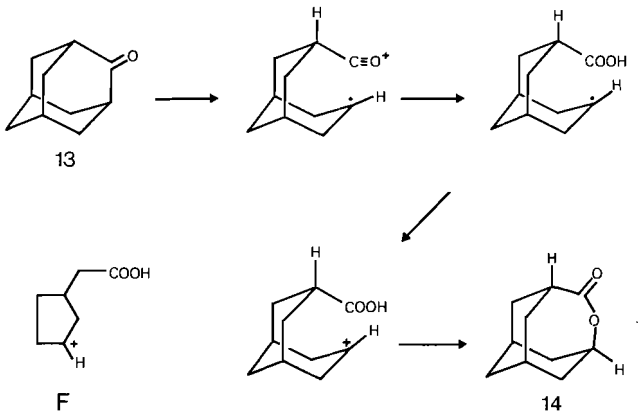

SCHEME 2

tanone was shown to be the intermediate (v.p.c.). In sharp contrast to the oxidation of bicyclic alcohols (7) which led to exclusively ring cleavage products at a fast rate, the conversion of adamantan-2-ol into the ketone, even in the presence of excess oxidizing agent, was not complete before a considerable amount of the lactone had been accumulated. In other words, the reaction cannot be stopped cleanly at the ketone stage for further oxidation takes place at a competitive rate.

From the foregoing results, one might conclude that CAN oxidations of bridged bicyclic alcohols are rather special cases (7). In general, CAN oxidations of secondary alcohols give rise to ketones which are susceptible to oxidative cleavage. Hintz and Johnson (14) reported the oxidations of cyclopentanol and cyclohexanol to the corresponding ketones with ceric sulfate.

Experimental

The i.r. spectra were taken on a Perkin–Elmer 257 Spectrophotometer; n.m.r. spectra (τ-value) were recorded on a Varian A-60 spectrometer in solvent indicated and with TMS as standard. The m.s. were run in a Hitachi–Perkin Elmer RMU-6 Spectrometer. The v.p.c. analyses were done on a Hewlett–Packard 5750 Research Chromatograph. Organic solutions were dried over anhydrous magnesium sulfate and Florisil was used in all the column chromatography. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y.

CAN Oxidation of Cyclohexanone

A solution of cyclohexanone (4.0 g, 40 mmol) in acetonitrile (100 ml) was treated with ceric ammonium nitrate (87.7 g, 160 mmol) in water (300 ml). The resulting solution was heated at 60° with stirring for 1 h. It was saturated with sodium chloride and extracted with chloroform. The acidic products (2.33 g) were isolated from the chloroform solution by extraction with aqueous sodium bicarbonate followed by reacidification and extraction with ether. From the chloroform layer, cyclohexanone (1.54 g) was recovered. The crude acidic mixture (2.33 g) was esterified with ethereal diazomethane and separated by preparative v.p.c. (6 ft, 10% Carbowax 20 M column, 165°).

Compound **1***a*, retention time 19.0 min; i.r.: ν_{max} ($CHCl_3$) 1735, 1635, and 1280 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.45 (2H, triplet, $J = 6.0$ Hz, CH_2ONO_2), 6.28 (3H, singlet, $COOCH_3$), 7.62 (2H, triplet, $J = 6.0$ Hz, CH_2COO), and 7.95–8.70 (6H, multiplet, CH_2); m.s.: *m/e* 160 ($M^+ - OCH_3$) and 129 ($M^+ - ONO_2$).

Anal. Calcd. for $C_7H_{13}NO_5$: C, 43.98; H, 6.80. Found: 44.25; H, 7.05.

Compound **2***a*, retention time 11.6 min; i.r.: ν_{max} ($CHCl_3$) 1735, 1630, and 1280 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.90 (1H, multiplet, —CH-ONO_2), 6.31 (3H, singlet, $COOCH_3$), 7.62 (2H, multiplet, CH_2COO), 8.27 (4H, multiplet, CH_2), and 8.63 (3H, doublet, $J = 6.0$ Hz, CH_3); m.s.: *m/e* 160 ($M^+ - OCH_3$) and 129 ($M^+ - ONO_2$).

Anal. Calcd. for $C_7H_{13}NO_5$: C, 43.98; H, 6.80. Found: C, 44.25; H, 6.98.

Methyl 6-Nitratohexanoate (1a)

To the nitrating agent (15) prepared from 70% nitric acid (40 ml, 0.96 mol) and acetic anhydride (304 ml, 3.2 mol) at −5° was added methyl 6-hydroxyhexanoate (3.5 g, 24 mmol) during 20 min. The excess reagent was carefully destroyed with water and the resulting mixture was extracted with chloroform. The organic phase was separated, washed with water until neutral to litmus, dried, and evaporated. Short-path distillation gave **1***a* (3.88 g, 84.3%).

Methyl 5-Nitratohexanoate (2a)

The nitrating agent (15) was prepared from 70% nitric acid (20 ml, 0.48 mol) and acetic anhydride (152 ml, 1.6 *M*) at −5°. Treatment of methyl 5-hydroxyhexanoate (1.70 g, 12 mmol) with the nitrating agent for 20 min, and work-up as described in the preceding paragraph furnished the crude ester **2***a*. Column chromatography yielded the pure ester (1.68 g, 76%).

CAN Oxidation of Cyclopentanone

Cyclopentanone (8.4 g, 0.1 mol) in acetonitrile (200 ml) was oxidized with CAN (219.3 g, 0.4 mol) in water (600 ml)

at 60° for 4 h. Chloroform extraction of the reaction mixture saturated with sodium chloride, yielded a mixture of acidic and neutral products. The acidic material (4.8 g) was isolated by extraction with aqueous sodium bicarbonate followed by acidification and extraction with ether. Esterification of the acids with ethereal diazomethane followed by column chromatography gave a mixture of methyl esters (4.8 g). The v.p.c. analysis (6 ft, 10% Carbowax 20 M column, 130°) showed the presence of four major compounds which were isolated by preparative v.p.c.

Ester **3**, 24%, retention time 52.5 min; i.r.: ν_{max} ($CHCl_3$), 1735, 1635, and 1280 cm^{-1}; n.m.r.: τ (CCl_4) 5.55 (2H, diffuse triplet, $J = 6.0$ Hz, CH_2ONO_2), 6.38 (3H, singlet, $COOCH_3$), 7.68 (2H, diffuse triplet, $J = 6.0$ Hz, CH_2COO), and 8.1–8.5 (4H, multiplet, CH_2); m.s.: *m/e* 146 ($M^+ - OCH_3$) and 115 ($M^+ - ONO_2$).

Anal. Calcd. for $C_6H_{11}NO_5$: C, 40.67; H, 6.21. Found: C, 40.80; H, 6.25.

Ester **4**, 16% (>92% pure) retention time 26.7 min; i.r.: ν_{max} ($CHCl_3$) 1735, 1635, and 1280 cm^{-1}; n.m.r.: τ (CCl_4) 4.93 (1H, sextet, $J = 6.0$ Hz, $CHONO_2$), 6.37 (3H, singlet, $COOCH_3$), 7.3–8.4 (4H, multiplet, CH_2), and 8.62 (3H, doublet, $J = 6.0$ Hz, CH_3); m.s.: *m/e* 146 ($M^+ - OCH_3$) and 115 ($M^+ - ONO_2$).

Ester **5**, 34% (97% pure), retention time 30.0 min; i.r.: ν_{max} ($CHCl_3$) 1735, 1635, and 1280 cm^{-1}; n.m.r.: τ (CCl_4) 5.50 (2H, triplet, $J = 6.0$ Hz, CH_2ONO_2), 6.34 (3H, singlet, $COOCH_3$), and 7.4–8.2 (4H, multiplet, CH_2); m.s.: *m/e* 132 ($M^+ - OCH_3$) and 101 ($M^+ - ONO_2$).

Ester **6**, 26%, retention time 15.0 min; i.r.: ν_{max} ($CHCl_3$) 1740, 1640, and 1280 cm^{-1}; n.m.r.: τ (CCl_4) 4.59 (1H, sextet, $J = 6.5$ Hz, $CHONO_2$), 6.33 (3H, singlet, $COOCH_3$), 7.40 (2H, octet, $J_{AB} = 16$, $J_{AX} = J_{BX} = 6.5$ Hz, CH_2COO), and 8.57 (3H, doublet, $J = 6.5$ Hz, CH_3); m.s.: *m/e* 132 ($M^+ - OCH_3$) and 101 ($M^+ - ONO_2$).

*Methyl 5-Nitratopentanoate (**3**)*

The nitrating agent (15) prepared from 70% nitric acid (13.3 ml, 0.32 mol) and acetic anhydride (101 ml, 1.06 mol) at −5° was mixed thoroughly with methyl 5-hydroxypentanoate (1.05 g, 8 mmol) for 20 min. After addition of water, the reaction mixture was extracted with chloroform to give the crude nitrato ester. Column chromatography yielded methyl 5-nitratopentanoate (**3**, 1.20 g, 85%).

CAN Oxidation of Sodium 5-Hydroxypentanoate

δ-Valerolactone (1.009 g, 0.01 mol) was heated to reflux with an aqueous solution (20 ml) of sodium hydroxide (400 mg, 0.01 mol) during 48 h. Ceric ammonium nitrate (21.93 g, 0.04 mol) was dissolved in water (10 ml), acetonitrile (60 ml) then added, and the mixture was heated at 60° for 18 h. Sodium chloride was then added and the mixture was extracted with ether. The organic phase was washed with an aqueous solution of sodium bicarbonate, dried, and evaporated to dryness yielding a neutral substance (486 mg) which was identified as γ-butyrolactone by comparison (i.r., n.m.r., and v.p.c.) with an authentic sample.

Acidification of the aqueous phase and extraction with ether gave a small quantity (10 mg) of acidic material which was not further investigated.

Methyl 3-Nitratocyclopentane Acetate (7a and 8a)

(a) CAN Oxidation of Norbornan-2-one

A solution of norbornanone (1.1 g, 10 mmol) in acetonitrile (20 ml) was warmed at 60° with CAN (22.0 g, 40 mmol) in water (60 ml), for 1.5 h. It was cooled, saturated with sodium chloride, extracted with chloroform. An acidic mixture was obtained from the chloroform extract. Esterification of this mixture with diazomethane gave the crude methyl esters 7*a* and 8*a* (935 mg). The v.p.c. analysis (6 ft, 10% Carbowax 20 M column, 165°) showed the presence of two compounds (retention time: 28.0 and 29.4 min) in a ~3:2 ratio; i.r.: ν_{max} ($CHCl_3$) 1735, 1635, and 1280 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.50 (1H, multiplet, $CHONO_2$), 6.27 (3H, singlet, $COOCH_3$), 7.56 (2H, multiplet, CH_2COO), and 7.70–8.90 (7H, multiplet); m.s.: *m/e* 172 ($M^+ - OCH_3$) and 141 ($M^+ - ONO_2$).

*(b) Ozonolysis of 3-Nitratocyclopentane Acetaldehyde Dimethyl Acetal (**12**)*

A mixture of 3-nitratocyclopentane acetaldehyde (7) (2.08 g, 12 mmol), trimethyl orthoformate (1.27 g, 12 mmol), *p*-toluenesulfonic acid (40 mg) in anhydrous methanol (5 ml) was kept under reflux for 4 h. It was cooled, diluted with ether (300 ml) and washed with water. Evaporation of the dried ethereal solution gave an oil which was further purified by column chromatography to give the dimethyl acetal **12** (2.02 g, 77%); i.r.: ν_{max} ($CHCl_3$) 1630 and 1280 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.55 (1H, multiplet, $CHONO_2$), 5.56 (1H, triplet, $J = 5.5$ Hz, $CH(OMe)_2$), 6.65 (6H, singlet, OCH_3), and 7.2–8.9 (9H, multiplet); m.s.: *m/e* 188 ($M^+ - OCH_3$).

The dimethyl acetal **12** (1.0 g, 4.5 mmol) in ethyl acetate (100 ml) was ozonyzed at 0° for 2h. The solvent was stripped off and the residue was dissolved in ether, washed with aqueous sodium carbonate and water. The dried ethereal solution was evaporated *in vacuo* and the product was chromatographed to give the methyl esters 7*a* and 8*a* (850 mg, 91%). The v.p.c. analysis indicated a mixture of two compounds in a ~3:2 ratio.

*2-Oxabicyclo[3.4.1]octan-3-one (**9**) and Methyl trans-3-Acetoxycyclopentane Acetate (**10**)*

A mixture of esters 7*a* and 8*a* (5.0 g) and aqueous sodium hydroxide (200 ml, 0.75 *N*) was refluxed for 15 h. It was cooled, acidified, and extracted with ether. On evaporation of the dried organic phase a yellow oil (2.7 g) was obtained. This oil was dissolved in benzene (175 ml) containing a trace of *p*-toluenesulfonic acid, and heated for 3 h under a Dean–Stark trap to convert the *cis*-hydroxy acid into the lactone **9**. The benzene solution was extracted with sodium bicarbonate which upon reacidification and ether extraction yielded *trans*-3-hydroxycyclopentane acetic acid (1.4 g). The neutral compound obtained by concentration of the benzene layer was shown to be 2-oxabicyclo[3.3.1]octan-3-one (**9**) (0.8 g).

An ethereal solution of *trans*-3-hydroxycyclopentane acetic acid (1.4 g) described in the preceding paragraph, was treated with an excess diazomethane to afford the methyl ester (1.41 g); i.r.: ν_{max} ($CHCl_3$) 3710, 3470, and 1730 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.73 (1H, multiplet, CHOH), 5.93 (1H, singlet, OH), and 6.34 (3H, singlet, $COOCH_3$). Acetylation of the crude product with acetic anhydride (10 ml) and pyridine (10 ml) at room temperature for 24 h yielded methyl *trans*-3-acetoxycyclopentane acetate (6 ft, 10% SE-30 column, 150°, retention time 9.5 min); i.r.: ν_{max} ($CHCl_3$) 1735 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.75 (1H, multiplet, CHOAc), 6.28 (3H, singlet, $COOCH_3$), and 7.97 (3H, singlet, $OCOCH_3$); m.s.: *m/e* 169 ($M^+ - OCH_3$), 157 ($M^+ - CH_3CO$), and 140 ($M^+ - CH_3COOH$).

Methyl cis-3-Acetoxycyclopentane Acetate (11)

2-Oxabicyclo [3.2.1]octan-3-one (**9**) (2.44 g, 19 mmol) dissolved in anhydrous methanol (50 ml) was stirred with sodium methoxide (1.04 g, 19 mmol) at room temperature for 2 h. The solvent was removed *in vacuo* and the residue was distributed between chloroform and water. Acidification of the alkaline solution followed by extraction with ether yielded the starting lactone **9** (1.06 g). Concentration of the chloroform solution gave methyl *cis*-3-hydroxycyclopentane acetate (1.82 g); i.r.: ν_{max} ($CHCl_3$) 3610, 3460, and 1735 cm^{-1}; n.m.r.; τ (CCl_4) 5.73 (1H, quintet, $J = 5.0$ Hz, CHOAc), 5.93 (1H, singlet, OH), and 6.34 (3H, singlet, $COOCH_3$). Acetylation of the hydroxy ester (0.80 g) with acetic anhydride and pyridine furnished methyl *cis*-3-acetoxycyclopentane acetate (**11**) (0.85 g, 84%). The analytical sample was collected from v.p.c. (6 ft, 10% SE-30 column, 150°, retention time 8.72 min); i.r.: ν_{max} ($CHCl_3$) 1735 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.86 (1H, multiplet, CHOAc), 6.35 (3H, singlet, $COOCH_3$), and 8.04 (3H, singlet, $OOCH_3$); m.s.: *m/e* 157 ($M^+ - CH_3CO$) and 140 ($M^+ - CH_3CO_2H$).

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.00; H, 8.00. Found: C, 59.78; H, 8.09.

Methyl 3-Oxocyclopentane Acetate

(a) From Methyl cis-3-Hydroxycyclopentane Acetate

To an ice cooled Collins reagent (10) (9.75 g, 38 mmol) in dry methylene chloride (200 ml) was added a solution of methyl *cis*-3-hydroxycyclopentane acetate (1.0 g, 6.3 mmol) in methylene chloride (20 ml). After stirring at room temperature for 20 min, water was added. The organic phase was treated with activated charcoal and dried. Removal of solvent and short-path distillation (bath temperature 105°/0.1 mm) of the residue afforded methyl 3-oxocyclopentane acetate (862 mg, 86%); i.r.: ν_{max} ($CHCl_3$) 1745 and 1740 cm^{-1}; n.m.r.: τ (CCl_4) 6.30 (3H, singlet, $COOCH_3$), and 7.20–8.70 (9H, multiplet); m.s.: *m/e* 156 (M^+).

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.54; H, 7.69. Found: C, 61.34; H, 7.83.

(b) From cis- and trans-3-Hydroxycyclopentane Acetic Acid

A mixture of the 3-hydroxycyclopentane acetic acid (*cis*-, *trans*-epimers) (1.12 g, 7.8 mmol), potassium carbonate (1.33 g, 9.6 mmol) and iodomethane (6 ml) in acetone (40 ml) was kept under reflux (16). An additional quantity (6 ml) of iodomethane was added after 1.5 h and the total heating time was 5 h. Acetone was removed, the residue was taken up with chloroform and washed with water. The dried chloroform solution was evaporated to give the epimeric methyl 3-hydroxycyclopentane acetates (926 mg, 75%). Oxidation of a portion of the crude product (690 mg, 4.3 mmol) with Collins reagent (6.66 g, 25.8 mmol) in methylene chloride (150 ml) at room temperature gave a ketoester (552 mg, 86%) identical with methyl 3-oxocyclopentane acetate described above.

CAN Oxidation of Adamantanone

To a solution of adamantanone (1.0 g, 6.6 mmol) in acetonitrile (15 ml) was added ceric ammonium nitrate (15.0 g, 27.3 mmol) in water (30 ml). The resulting solution was stirred magnetically at 60° for 3 h during which time the orange color faded to faintly yellow. It was cooled, poured into brine, and extracted with chloroform. The extracts were dried and evaporated to give a soft solid mass (t.l.c. homogeneous). Sublimation of this material at 130–150° (bath temperature) under water aspirator pressure furnished lactone **14** (815 mg, 73.4% yield, m.p. 285–287°; lit. (13) m.p. 288–290°); i.r.: ν_{max} ($CHCl_3$) 1718 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.43 (1H, quintet, $J = 3.0$ Hz), 6.88 (1H, quintet, $J = 3.5$ Hz), and 7.8–8.3 (12 H, multiplet).

CAN Oxidation of Adamantan-2-ol

Adamantanol (475 mg, 3.2 mmol) in acetonitrile (10 mg) was treated with CAN (14.25 g, 26 mmol) in water (30 ml) during 3 h at 60°. After cooling to room temperature, the reaction mixture was extracted with chloroform. Evaporation of the dried extracts yielded a yellowish waxy solid which was sublimed to give lactone **14** (250 mg, 50% yield).

Evaluation of Some of the Factors Involved in the Selective Hydrolysis of Aromatic Ester Protecting Groups by α-Chymotrypsin[1]

J. Bryan Jones and Yong Yeng Lin

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received January 27, 1972

Studies have been carried out which delineate some of the factors involved in the exploitation of α-chymotrypsin as a catalyst for the specific hydrolysis of selected aromatic ester protecting groups under mild conditions with a specificity not achievable by non-enzymic reagents. The reactions can be carried out under heterogeneous conditions and examination of a series of diesters has shown dihydrocinnamyl to be the most satisfactory of the hydroxyl protecting groups evaluated so far. The degree of specificity achievable is demonstrated by the fact that α-chymotrypsin-catalyzed hydrolysis of 2-acetoxyethyl dihydrocinnamate at p*H* 7.8 stops when the latter function has been cleaved. In addition, some guidelines have been developed regarding the application of literature specificity data for predicting the course and rate of preparative scale reactions.

Des études ont été menées en vue de délimiter quelques uns des facteurs liés à l'exploitation de l'α-chymotrypsine en tant que catalyseur dans l'hydrolyse spécifique de groupes protecteurs constitués par certains esters aromatiques, avec une sélectivité non-réalisable par des réactifs non enzymatiques. Les réactions peuvent être faites dans des conditions hétérogènes et l'examen d'une série de diesters montre que le dihydrocinnamyle est le groupe protecteur de l'hydroxyle le plus satisfaisant jusqu'ici. Le degré de spécificité réalisable est démontré dans l'hydrolyse à p*H* 7.8 catalysée par l'α-chymotrypsine du dihydrocinnamate d'acétoxy-2 éthyle, qui s'arrête après clivage de cette fonction. De plus, quelques exemples ont été développés concernant l'application des données de la littérature sur la spécificité, pour prévoir le cours et la vitesse des réactions à l'échelle préparative.

Canadian Journal of Chemistry, **50**, 2053 (1972)

Although the capacity of α-chymotrypsin (α-CT) for preferential and stereospecific hydrolysis of a broad range of acyclic and cyclic aliphatic and aromatic esters and amides, and also some hydroxamides and hydrazides, is well documented (1–5), preparative exploitation of α-CT's properties has so far been relatively limited in scope. From the organic chemical viewpoint one of the most obvious areas for α-CT application is in the selective removal of protecting groups from hydroxyl and amino functions and in the latter connection the use of α-CT to catalyze the hydrolytic cleavage of acyl protecting groups has already been explored in the nucleotide field (6–8).

The above data (1–8) encouraged us to consider that selective hydrolysis by α-CT might be usefully applied during synthetic and other studies on a broad range of organic compounds and accordingly, a systematic investigation of the preparative advantages and limitations of the approach was initiated. This communication is primarily concerned with some of the experimental factors concerned with the protecting group aspect and with developing guidelines for the application of literature specificity data to competitive preparative scale reactions.

The acetate esters **3** were selected for the preparative scale specificity comparisons. Diesters of this type were considered superior to the monofunctional compounds usually employed (1) since, while they continued to allow easy analysis of α-CT specificity towards the various aromatic functions, the presence of the acetate ester provided an internal reference standard. Aliphatic acetates are hydrolyzed very sluggishly by α-CT (9) and it was considered that the extent of α-CT-catalyzed acetate hydrolysis of **3***a–f* would provide a measure of the practicability of achieving selective cleavage of the various aromatic acyl functions when the method was applied to compounds in which other relatively α-CT-insensitive ester groups were present. Furthermore, since the k_{-OH} values for each of the ester moieties of compounds **3** should not differ significantly (10), the degrees of differential hydrolysis observed were expected to be a direct reflection of the preparative α-CT specificity (9, 10) for each of the acyl groups.

[1]This work was presented in part at the 54th Canadian Chemical Conference, Halifax, Nova Scotia, June 1, 1971.

The predilection of α-CT for aromatic L-amino acid derivatives (1) suggests that their application as acyl protecting groups for alcohols and amines should afford the highest degree of hydrolytic specificity. However, in the nucleotide studies referred to previously (6, 7) practical difficulties were encountered with L-phenylalanyl esters and use of the dihydrocinnamyl analogues was found to be more satisfactory (8). In view of this it was assumed that α-CT would exhibit a still greater preference for the corresponding β-(*p*-hydroxyphenyl)-propionyl and β-indolylpropionyl analogues of the even better (1) tyrosyl and tryptophan substrates.[2] Accordingly, attention was directed initially towards the preparation of the diesters **3***a* and *b*. The presence of phenolic —OH and indolyl —NH functions precluded attempts to prepare **3***a* and *b* by condensation of **2** with the acid chlorides **1***a* and *b*, X = Cl; and, although some of the desired diesters were formed during a survey of acid-catalyzed (14) and dicyclohexylcarbodiimide (15, 16) mediated esterifications of 2-hydroxyethyl acetate (**2**) with the acids **1***a* and *b*, X = OH, only low yields of impure **3***a* and *b* could be isolated. In view of the above difficulties it was decided that the feasibility of employing β-(*p*-hydroxyphenyl)-propionyl and β-indolylpropionyl functions for the protection of hydroxyl groups was too limited to warrant their further consideration at this time.

In contrast, preparation of the diester **3***c* incorporating the dihydrocinnamyl group of proven value (8) was accomplished without complication.[3] The compound was immiscible with the types of aqueous media preferred for α-CT-catalyzed hydrolysis (1) but became readily soluble in water containing 30% of methanol or acetonitrile. Although α-CT kinetics have been studied in aqueous solutions containing these and even higher levels of organic solvents (4, 5), marked reductions in hydrolysis rates on addition of organic solvents[4] are well documented (1) and for **3***c*, the rates of reaction in the above homogeneous solutions were found to be too slow to be of preparative value. However, in view of the preparative scale resolutions successfully effected by α-CT on aqueous suspensions of racemates (3–5, 19, 20) it was decided to study the hydrolysis of **3***c* in the absence of organic solvents under heterogeneous conditions. It was found that under such conditions, α-CT-catalyzed hydrolysis of **3***c* proceeded extremely readily with specific cleavage of the dihydrocinnamate ester function. A range of reaction conditions was surveyed and optimum results were obtained at p*H*

[2]The correspondence in α-CT specificity towards the dihydrocinnamyl and phenylalanyl groups probably reflects their identity of interaction with the hydrophobic aromatic binding locus, ρ_{ar}, of the active site (1, 3, 11, 12) and the situation with respect to the tyrosine and tryptophan side chains and their analogues would be expected to be similar. The X-ray data available (13) support this view.

[3]All of the diesters **3***c–f* were readily purified and were obtained in good (*ca.* 80%) yields either by acid-catalyzed esterification of 2-hydroxyethyl acetate (**2**) with **1***c–f*, X = OH or via the acid chlorides **1***c–f*, X = Cl.

[4]Some of the organic solvent disadvantages of this and other enzymes are overcome by their stabilization on insoluble supports (17, 18) and studies are being carried out on the preparative applications of insolubilized α-CT.

7.8 (1) in aqueous 0.1 *M* potassium chloride at 25° with a substrate to enzyme ratio (w/w) of ~40:1. Satisfactory rates of hydrolysis were achievable using solutions containing 0.5–2 mg/ml of α-CT and little loss of activity was observed when enzyme solutions of this concentration were kept under the above reaction conditions for extended periods (> 24 h). As the reaction proceeded, the degree of heterogeneity gradually diminished and a clear solution was obtained when all of the dihydrocinnamyl moiety had been hydrolyzed.

From the preparative point of view the specificity of hydrolysis at p*H* 7.8 is virtually absolute and, as Fig. 1 illustrates, the reaction almost stops when 96–98% of the dihydrocinnamyl acyl group has been removed. The rate of hydroxide ion catalyzed hydrolysis of **3***c* at p*H* 7.8 was found to be negligibly small. Unfortunately, owing to its water solubility, 40–50% yields only of the 2-hydroxyethylacetate (**2**) product could be recovered. It was hoped that the latter situation would be improved using the slightly more hydrophobic 1,3-propyleneglycol analogue of **3***c* but, although the specificity of cleavage paralleled that of **3***c*, again the solubility of the 3-hydroxypropyl acetate product posed similar analytical and isolation problems.[5]

The specificity data in the literature (1, 22, 23) indicate that the dimensions of the dihydrocinnamyl group are close to the optimum for good binding in the ρ_{ar} locus and that an increase or decrease in chain length is reflected in raised K_m (or K_i of analogous inhibitors (24)) and/or lower k_{cat} values (1, 22, 23). That this was also broadly applicable to the preparative aspects of α-CT specificity and hydrolysis rates was confirmed by comparison of the homologous series of diesters, **3***c–e*. As Table 1 shows, decreasing the size of the aromatic function in the progression dihydrocinnamyl (**3***c*), phenylacetyl (**3***d*), and benzoyl (**3***e*) results in dramatic reductions in the hydrolysis rates for each methylene group

[5]Use of other α,ω-glycols of sufficiently high CH_2 content to ensure satisfactory recovery of the monoacetate from the aqueous reaction media was considered. However, in view of the adverse effect to be expected on the already low water-solubility of the types of diesters being evaluated, this aspect was not pursued further. In subsequent applications of the method for the selective hydrolysis of a selection of higher molecular weight esters of structural interest to organic chemists, 90%-quantitative yields of the alcohol moieties were isolated (21).

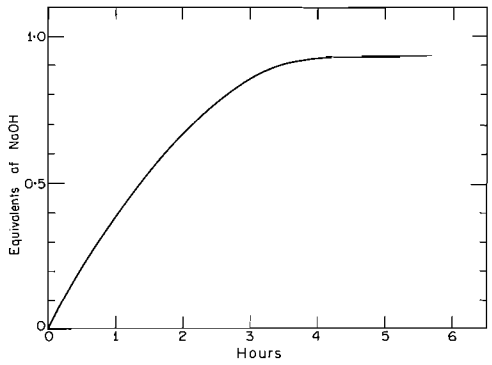

FIG. 1. A typical preparative scale p*H*-stat plot for the α-CT-catalyzed hydrolysis of dihydrocinnamate acetate diesters at p*H* 7.8. The termination of the reaction following uptake of ≃1 equiv of base illustrates the effectively absolute specificity of the cleavage with respect to the dihydrocinnamyl moiety. The above plot was recorded for a hydrolysis at 25° under nitrogen of **3***c* suspended in 0.1 *N* KCl containing 1.25 mg/ml of α-CT. The base used to maintain the p*H* at 7.8 was 1 *N* NaOH.

TABLE 1. Apparent rate constants for preparative scale α-CT-catalyzed hydrolyses of compounds **3***c–f*

Compound	k_{app} ($s^{-1} \times 10^3$)*
3*c*	96
$C_6H_5(CH_2)_2COO(CH_2)_3OCOCH_3$	113
3*d*	13.0
3*e*	<0.002
3*f*	7.9

*The rates of reactions were measured at 25° at p*H* 7.8 on stirred heterogeneous mixtures of 0.5×10^{-3} mol of substrate and aqueous 0.1 *N* KCl (10 ml) containing 0.5×10^{-6} mol (1.25 mg/ml) of α-CT. k_{app} values were calculated by dividing the observed initial velocity by the enzyme concentration.

lost. Although for the benzoyl derivative **3***e* the extent of hydrolysis observable during a preparative run was negligibly small, selective hydrolysis was still observed for the phenylacetyl ester **3***d*. However, with the latter compound some competitive acetate cleavage of the water-soluble 2-hydroxyethyl acetate initial product also occurred and preferential hydrolysis of the phenylacetyl moiety was achievable to a maximum extent of only 78%.

From the K_m and k_{cat} values of its ester derivatives (1, 9) the cinnamyl group would be expected to be a fairly good α-CT-sensitive protecting group (7). Surprisingly, however, the cinnamate acetate diester **3***f* proved to be a poor substrate under preparative conditions having a k_{app} (Table 1) more than an order of magnitude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

smaller than that of **3***c*. Furthermore, subsequent cleavage of the 2-hydroxyethyl acetate produced initially became significant and accordingly, no further consideration was given to cinnamyl as a hydroxyl protecting group.

From the above and previous data (6–8) it is evident that of the α-CT-sensitive protecting groups surveyed so far the dihydrocinnamyl function is the most attractive, and the results of our studies on its applicability to a selection of compounds of general organic chemical interest will be reported shortly (21).

The above results also allow some preliminary conclusions to be drawn regarding application of the α-CT literature specificity and kinetic data for predicting the rate and course of a preparative scale hydrolysis. It is obviously unrealistic to expect that data usually obtained on homogeneous solutions under Michaelis–Menten conditions (*i.e.*, $[S] \gg [E]$, and often with $[S] \simeq 0.1\text{–}10\ K_m$) would be directly extrapolatable to preparative reactions of the types described above where the reaction media are heterogeneous and, in the aqueous layer, [S] is unlikely to be much, if at all, greater than [E]. In addition, at the concentrations of α-CT used, the significant proportion ($\simeq 10\%$) of oligomeric enzyme expected to be present cannot be ignored in any truly quantitative kinetic analysis (25, 26). Thus the variations in the values of k_{app} (Table 1), which is a composite rate constant in which the influence of solubility, specificity, and rates of acylation and deacylation are all reflected, cannot be regarded as being meaningful in any physical-organic or enzyme-kinetic sense. Nevertheless, analysis of the total data revealed certain encouraging correlations with some of the literature constants.

The two constants regarded as being most meaningful for α-CT-catalyzed hydrolyses of esters are k_{cat}/K_m, and k_3 or k_{cat} (the deacylation rate constant) (9). Unfortunately, the data on ester substrate analogues of **3***c–f* are too limited to permit an evaluation of the feasibility of using literature k_{cat}/K_m values for forecasting of the course of preparative reactions. In contrast, many k_3 constants of esters comparable with **3***c–f* are available and are found to parallel the rate and selectivity results observed in the preparative scale experiments. For example, the relative k_3's for the *p*-nitrophenyl esters of dihydrocinnamic acid, phenylacetic acid, cinnamic acid, and acetic acid are in the ratios 18:1.9:1.26:1 (9, 23). A similar pattern emerges for the corresponding methyl esters (9). These ratios are broadly consistent with the preparative scale observations that (*a*) **3***c* is hydrolyzed specifically at the dihydrocinnamyl group at a rate 7.5 times greater than that of **3***d*, (*b*) selective cleavage of the phenylacetyl function of **3***d* is possible but that competitive hydrolysis of the acetate ester begins to become important, and (*c*) as a result of the further reduction in hydrolysis rate of **3***f* (1.6 times slower than **3***d*) selective removal of the cinnamyl group without significant concomitant hydrolysis of the acetate ester is not a practical proposition. Although the correlation of the literature k_3's with the rates and selectivities of the preparative experiments appears to deny the importance of binding factors, for each of **3***c*, *d*, and *f*, good, predominantly productive binding would be expected (1, 11) and in such cases reliance on literature k_3 data seems justified. Further evaluations of the predictive value of literature k_3 and k_{cat}, and k_{cat}/K_m constants for preparative applications of α-CT are in progress.

Experimental

Each of the commercially available compounds used was recrystallized or redistilled before use. In addition, 2-hydroxyethylacetate was purified by column chromatography on Florisil prior to the final redistillation. All distillations were carried out using Nester–Faust spinning band columns. All liquids were purified until <1% impurity could be detected by spectroscopic and t.l.c. (on silica gel G) and g.l.c. analyses. The g.l.c. analyses were performed on an F and M 400 chromatograph equipped with 3.8% SE 30 or 1% QF-1 on Chromosorb G glass columns and n.m.r. spectra were determined on $CDCl_3$ (TMS internal standard) solutions with a Varian T-60 instrument. Solvent removals were effected by rotary evaporation. α-Chymotrypsin (crystallized three times) was purchased from the Worthington Biochemical Corp.

Preparation of the Diesters 3c–f

Each of the diesters was prepared from 2-hydroxyethylacetate (0.1 mol) by reaction with the appropriate acid chloride (0.1 mol), or acid (0.1 mol) in the presence of toluene-*p*-sulfonic acid (200 mg). Approximately eighty percent yields were obtained and the products were purified by spinning band distillation. The properties recorded for each were as follows:

2-Acetoxyethyl dihydrocinnamate (3c), b.p. 92–93°/0.05 Torr; n.m.r. δ 2.02 (3H, s), 2.80 (4H, A_2B_2 m), 4.25 (4H, apparent s), and 7.23 p.p.m. (5H, s).

Selective α-Chymotrypsin-catalyzed Hydrolyses of the Diesters on a Preparative Scale

Kinetic Runs

The relative rates of hydrolysis of each diester surveyed were measured on heterogeneous reaction mixtures containing 0.5 mmol of diester, 0.5×10^{-6} mol (12.5 mg) of α-CT and 0.1 *M* aqueous KCl (10 ml). The kinetic measurements were made at 25° with stirring under a nitrogen atmosphere using a Radiometer p*H*-stat (comprised of a TTTlc p*H*-meter, SBR2c titrigraph, SBUla syringe burette, and GK2024c combination electrode) to maintain the p*H* at 7.8. The base used was Fisher certified 1.0 *N* aqueous sodium hydroxide which had been freshly standardized by titration against potassium hydrogen phthalate. Initial velocities, v_0, taken directly from the p*H*-stat traces were used to calculate the apparent rate constants, k_{app} ($= v_0/[E]$). Each kinetic run was carried out at least in duplicate and the initial velocities were reproducible to within ±10% for any one diester. The k_{app} data recorded in Table 1 are mean values.

Preparative Procedure and Product Analysis

The procedure described below for 2-acetoxyethyl dihydrocinnamate (**3***c*) is representative of the analytical and product isolation method applied to each diester studied. The conditions described have been found satisfactory for quantities up to 2 g of diester.

2-Acetoxyethyl dihydrocinnamate (**3***c*, 795 mg, 3.4 mmol), 0.1 *M* aqueous KCl (40 ml), and aqueous α-CT (10 ml, containing 50 mg α-CT) were placed in a 60 ml p*H*-stat reaction vessel fitted with a rubber stopper through which the combination electrode, the needle of a 5 ml syringe (filled with 1 *N* aqueous NaOH), and a nitrogen line were introduced. The p*H*-stat was set to maintain a p*H* of 7.8 and the heterogeneous reaction mixture was magnetically stirred (avoiding cavitation of the liquid) at room temperature under a nitrogen atmosphere (with the nitrogen passing *over*, not through, the mixture in order to avoid enzyme denaturation) until base uptake (≃0.95 equiv) had almost stopped (≃6 h). The reaction mixture, which had gradually become homogeneous during this time, was then washed with ether (3 × 25 ml). The ether washings were extracted with saturated aqueous sodium bicarbonate (25 ml) and the combined aqueous solutions acidified to p*H* 2 with 2 *N* aqueous HCl and extracted with ether (3 × 25 ml). Quantitative g.l.c. analysis of the latter solution showed it to contain 3.1 mmol (98% of base consumption) of dihydrocinnamic acid. Isolation of the latter acid followed by distillation afforded a pure sample (100 mg), b.p. 105°/0.2 Torr, m.p. 47–48°, identical in all respects with an authentic sample. The g.l.c. analysis of the initial ether washings showed them to contain some of the diester **3***c* (< 5% of starting material used) together with 1.5 mmol (44% of theoretical[6]) of 2-hydroxyethyl acetate (**2**). The identity of the latter compound was confirmed by comparisons of its i.r. and n.m.r. spectra with those of authentic material.

p*H*-Stat control of the hydrolysis provided the most convenient means for monitoring the course of the reaction. However, in view of the fact that the hydrolysis was so selective for the dihydrocinnamyl group, use of a p*H*-meter, and a burette for periodic adjustment of the p*H* to 7.8 until hydrolysis ceased, also proved quite satisfactory.

The rate and specificity of hydrolysis of 3-acetoxypropyl dihydrocinnamate, and yields of products isolated, were virtually identical with those recorded for **3***c*. For 2-acetoxyethyl phenylacetate (**3***d*) slow hydrolysis up to the consumption of 1 equiv of base was only 78% specific for the phenylacetate group and for the still more sluggishly hydrolyzed cinnamate ester **3***f*, the effective selectivity of cinnamate cleavage was of an even lower order (< 50%). Phenylacetic acid, b.p. 104–105°/0.4 Torr, m.p. 73–74° and cinnamic acid, m.p. 134–135° (both identical with authentic samples) were isolated from the latter two reactions. Hydrolysis of **3***e* proceeded so slowly that kinetic studies only were carried out.

We are grateful to Mr. D. N. Palmer for his contributions to the studies on compound **3***a–c*. Financial support for this work was provided by the National Research Council of Canada.

A Transient Intermediate in the Bimolecular Reaction of Hydrated Electrons

N. Basco, G. A. Kenney-Wallace,[1] S. K. Vidyarthi, and D. C. Walker

Chemistry Department, University of British Columbia, Vancouver

Received December 24, 1971

Further studies are reported which attempt to identify the transient species (X) produced from hydrated electrons which may be photodissociated to re-form e^-_{aq}. The method used involves the production of e^-_{aq} by u.v. flash photolysis of aqueous OH^-/H_2 solutions followed, after any specified delay, by a second and third photoflash of restricted wavelengths. Photoregeneration of e^-_{aq} is effected by light in the spectral range 320 to 400 nm, not at $\lambda > 700$ nm as earlier reported (1). The species X is much longer lived than e^-_{aq}, having a mean lifetime of ~ 5 ms at pH 11, but this is very dependent on the lifetime of e^-_{aq} in the system. Two conditions seem to be necessary in order to detect the presence of X, (*i*) e^-_{aq} must decay to a considerable extent through the bimolecular dimerisation reaction and (*ii*) the lifetime of e^-_{aq} with respect to all other reactions must be $>$ *ca.* 200 μs. Thus it is not expected to be observable in most pulse radiolysis studies. Its extinction coefficient in that part of its absorption band which leads to photodissociation (320–400 nm) is estimated to average $>2000\ M^{-1}\ cm^{-1}$, may be as high as $6000\ M^{-1}\ cm^{-1}$ at 347 nm but does not exceed $12\,000\ M^{-1}\ cm^{-1}$ at any wavelength. Its identity is discussed and it is concluded that X is probably the hydrated electron dimer, $(e_2^{2-})_{aq}$, or a product formed therefrom by association with a cation.

Des études plus poussées sont rapportées en vue d'identifier l'espèce transitoire (X) produite à partir d'électrons hydratés qui pourraient être photodissociés pour redonner e^-_{aq}. La méthode employée met en oeuvre la production de e^-_{aq} par photolyse flash u.v. de solutions aqueuses OH^-/H_2 suivie, après un temps déterminé, d'une seconde puis d'une troisième photolyse flash de longueurs d'onde réduites. La photoregénération de e^-_{aq} est effectuée par la lumière dans l'intervalle 320–400 nm et non pour $\lambda > 700$ nm comme il a été précédemment rapporté (1). L'espèce X a une durée de vie supérieure à e^-_{aq} (environ 5 ms à pH 11) et dépend étroitement de la durée de vie de e^-_{aq} dans le système. Deux conditions semblent nécessaires à la détection de la présence de X, (*i*) la disparition de e^-_{aq} par une réaction de dimérisation bimoléculaire doit être considérable. (*ii*) la durée de vie de e^-_{aq} par rapport à toutes les autres réactions doit être $>$ ca. 200 μs. Aussi ne doit-on pas s'attendre à l'observer dans la plupart des études de radiolyse par impulsion. Son coefficient d'extinction dans la zone de la bande d'absorption qui conduit à la photodissociation (320–400 nm) est estimé à une moyenne $>2000\ M^{-1}\ cm^{-1}$ pouvant atteindre $6000\ M^{-1}\ cm^{-1}$ à 347 nm mais en tout cas $< 12\,000\ M^{-1}\ cm^{-1}$ quelle que soit la longueur d'onde. L'identité de X est discutée, il s'agit probablement de l'électron hydraté dimère, $(e_2^{2-})_{aq}$, ou d'un produit qui en découle par association avec un cation.

Canadian Journal of Chemistry, **50**, 2059 (1972)

Introduction

In a previous communication (1) we reported evidence for a comparatively long-lived species whose precursor was the hydrated electron. This species was postulated to be $(e_2^{2-})_{aq}$, a hydrated electron dimer. In these experiments $\sim 10^{-6}\ M$ concentrations of hydrated electrons were produced by u.v. flash photolysis of $\sim 10^{-3}\ M$ NaOH in very pure water saturated with H_2 gas. This is a particularly "clean" chemical system because there is no overall chemical change and, apart from trace amounts of impurities, the only chemical species present are Na^+, OH^-, H_2, e^-_{aq}, and OH together with their reaction products. This long-lived intermediate could be of some interest from the point of view of radiation chemistry, particularly in the context of intra-spur reactions; perhaps also in the reaction of alkali metals with water and in cathodic electrolytic decompositions at high pH, in which e^-_{aq} could be involved in comparable reaction schemes (2).

For these reasons we built an improved and more versatile double-flash photolysis arrangement for this study and have examined the intermediate in more detail. One of our new findings concern the wavelength band responsible for the photoregeneration of e^-_{aq}. Contrary to our earlier report, for reasons we shall discuss, we believe this to be $320 < \lambda < 400$ nm rather than $\lambda > 700$ nm. Our data are largely consistent with some recent results of Gopinathan *et al.* (3) in a related type of experiment (but using considerably lower concentrations of e^-_{aq}) and it is highly probable that the same

species is involved. However, our results would not support the species they propose.

Experimental

Experiments were performed with the apparatus shown schematically in Fig. 1. The reaction vessel, V, was 42.5 cm long made of Suprasil quartz and carried filling and emptying ports at its extremities. Quartz windows were fused onto the vessel. Aqueous solutions were prepared in an all-glass, sealed system where they were deoxygenated by continuous bubbling with H_2 or He and flowed through the reaction vessel under slight pressure when required. Adjacent to and on either side of V were two 50 cm long Suprasil quartz flash photolysis lamps; L and A. L will be described as the Main lamp and A as the Auxiliary lamp. These lamps were discharged typically at 4 to 8 kV, through 33 or 50 μF capacitors, thus yielding from 300 to 1000 J energy flashes having a width at half-height of about 20 μs. The lamps and reaction vessel were encased in a close-fitting metal reflector within a cylindrical container. A variety of Corning Color Glass light filters F, held in an aluminum frame which fitted snugly in a slot in the outer container, restricted the wavelength range of light from the Auxiliary lamp entering the reaction vessel.

Lamps L and A could be fired with any preselected time interval from 1 μs to 100 ms by means of electronic delay circuits, or at longer times by manual firing (4). An additional feature of this double-flash apparatus permitted the Auxiliary lamp to be discharged twice with any interval between consecutive flashes. This was achieved by connecting the lamp in parallel to two isolated capacitors each held off by a spark gap as indicated in Fig. 2. A capillary spectroflash Lamp S could also be fired at any time after any of the three photoflashes, and the absorption spectra of transient absorbing species recorded on a low dispersion spectrograph G. Various spectrographs were used including "Medium" and "Small" Hilger and Watts quartz prism instruments and a grating spectrograph built on the design of Bass and Kessler (5) in conjunction with a 35 mm camera. Two types of photographic films and plates were used covering different spectral regions, Ilford HP3 plates (320–650 nm), and Kodak Fast Infrared film (500–850 nm).

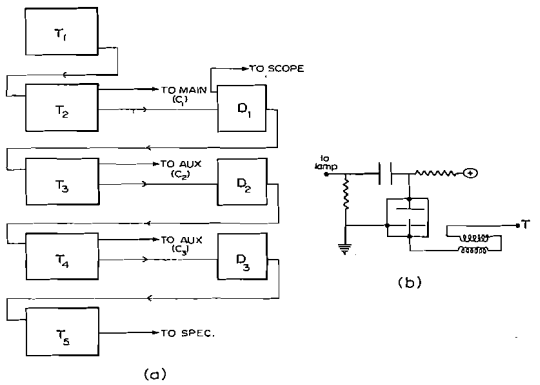

FIG. 2. (*a*) Triggering and time delay sequence for three photoflashes and a spectroflash. T_1 is a manually operated trigger pulse generator; T_2, T_3, T_4, and T_5 are trigger pulse generators for the Main, Auxiliary (first flash), Auxiliary (second flash), and spectroflash, respectively. D_1, D_2, and D_3 are variable time delays. Any unit may be bypassed. (*b*) Capacitor–spark gap assembly circuits for the Main and Auxiliary lamps (C_1, C_2, and C_3 in Fig. 1). T is the trigger pulse input.

For kinetic photometry studies at $\lambda = 632.8$ nm (where e^-_{aq} absorbs strongly, $\varepsilon = 1.2 \times 10^4\ M^{-1}\ cm^{-1}$ (6)) a 9 mW He/Ne CW laser, H, was used. Transient changes in the transmitted laser beam intensity were monitored by a photomultiplier, P, (either RCA 1P28 or Hamamatsu R213, using load resistances typically of 1 or 10 kΩ) coupled to an oscilloscope O. An advantage of using the laser as a light source is that there is sufficient intensity at 632.8 nm to employ a very narrow band-pass ($\sim$3 nm) interference filter as a window to the detector and virtually eliminate scattered light from the flash lamps. In this way the concentration of e^-_{aq} could be monitored *during* the photoflashes.

Figure 3 shows the transmission characteristics (7) of the various color glass filters used in F.

The solutions were prepared from distilled water which had been redistilled from dilute acidified dichromate solution, γ-irradiated with a dose of 2 Mrad and then refluxed

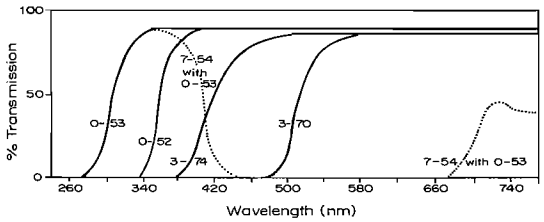

FIG. 3. Transmission curves for the various Corning Glass filters used at F in Fig. 1 (7).

continuously from very dilute alkaline permanganate solution until just prior to use. The NaOH, $NaClO_4$, $Ba(OH)_2$, HCOONa and isopropanol were Analar grade chemicals. As much of the residual carbonate content as possible was removed from the alkaline solutions by precipitating out carbonate in the concentrated stock supply. The NH_3 gas was 99.8% pure (Matheson), the H_2 was Matheson Prepurified grade and was passed through an activated Pd catalyst to remove traces of oxygen.

Results

(a) Chemical System

Following some preliminary experiments using the photolysis of I^- as the source of hydrated electrons and various alcohol scavengers to remove the oxidizing radical species, the OH^-/H_2 system was found to be the most satisfactory and nearly all the work reported was done with these solutions. In the iodide system other molecular and ionic photolysis products absorb in the visible which make interpretations of the spectral data ambiguous. The hydroxyl ion absorbs light of $\lambda < 220$ nm to produce e^-_{aq} and OH radicals according to reaction 1

$$[1] \qquad OH^- \xrightarrow[\lambda < 220\ nm]{h\nu} OH + e^-_{aq}$$

with a fairly low quantum yield within the accessible and useful wavelength range ($\sim$185 to 220 nm). The concentration of e^-_{aq} produced can be adjusted somewhat by altering the energy of the Main flash and by choosing the appropriate $[OH^-]$. If the latter is too high the absorption of the u.v. light occurs predominantly near the edge of the reaction vessel and a nonuniform concentration of e^-_{aq} results. One further advantage of using the laser therefore is that the analyzing light beam is very narrow (<2 mm diameter) and providing it is parallel to the axis of the vessel the kinetic measurements will not be seriously complicated by a concentration gradient across the cell diameter (10 mm). In all the experiments reported, the beam passed down the long axis of the cell.

A further consideration in the choice of hydrated electron concentration to be used arises from the lifetime of this species. For reasons which will become evident later we required that e^-_{aq} reacted predominantly by reaction 2

$$[2] \quad e^-_{aq} + e^-_{aq} \rightarrow [X] \xrightarrow{2H_2O} H_2 + 2\ OH^-, \qquad k_2 = 5 \times 10^9\ M^{-1}\ s^{-1}$$

rather than with either OH or with the inevitable low concentration of impurities present.[2] The extent to which this was achieved is indicated by the lifetime of e^-_{aq}. To avoid reaction 3

$$[3] \quad e^-_{aq} + OH \rightarrow OH^-_{aq}, \qquad k_3 = 3 \times 10^{10}\ M^{-1}\ s^{-1}$$

as much as possible the solution was saturated with H_2 gas, which converts OH to e^-_{aq} by reactions [4] and [5].

$$[4] \quad OH + H_2 \rightarrow H + H_2O, \qquad k_4 = 5 \times 10^7\ M^{-1}\ s^{-1}$$

$$[5] \quad H + OH^-_{aq} \rightarrow e^-_{aq}, \qquad k_5 = 2 \times 10^7\ M^{-1}\ s^{-1}$$

Reaction 3 nevertheless imposes the upper limit on the concentration of e^-_{aq} which may be used because of the comparatively low values of k_4 and k_5 and the fact that the apparatus was limited to H_2 pressures of 1 atm ($[H_2] = 7 \times 10^{-4}\ M$). At this $[H_2]$, however, there should be no serious complications arising from H_2O_2 which could otherwise be formed in reaction 6

$$[6] \quad OH + OH \rightarrow H_2O_2, \qquad k_6 = 5 \times 10^9\ M^{-1}\ s^{-1}$$

From these considerations we chose $(OH^-]$ in the range 10^{-3} to $3 \times 10^{-3}\ M$, $[H_2] = 7 \times 10^{-4}\ M$ and Main flash energies $\sim$500 J. This combination created e^-_{aq} at up to $2 \times 10^{-6}\ M$ with mean lifetimes of 200 to 100 μs. Although reaction 2 should be the dominant reaction of e^-_{aq} under these conditions, reaction 3 will contribute to some extent. Furthermore reaction 7

$$[7] \quad e^-_{aq} + H \rightarrow [H^-_{aq}], \qquad k_7 = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}$$

cannot be entirely ignored because of H produced in reaction 4. In order to examine the role of reactions 3 and 7 some experiments are reported in which the OH radicals were scavenged using low concentrations of sodium formate or 2-propanol.

Most experiments were performed with OH^-/H_2 solutions because this is a particularly "clean" system in which to study e^-_{aq} (9) and is

[2]All rate constants are taken from the Tables presented in ref. 8.

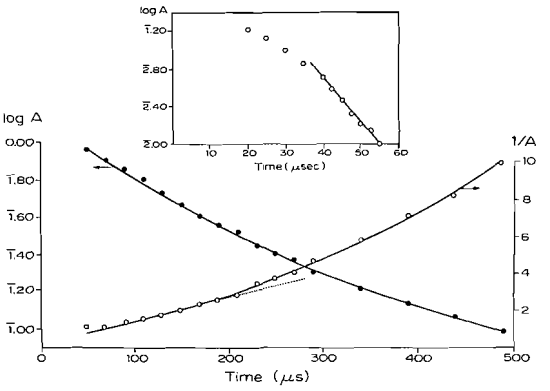

FIG. 4. First- and second-order kinetic plots for the decay of e^-_{aq} following the Main flash. Insert shows first-order plot for a solution containing 1.1×10^{-5} *M* $NaNO_3$, 10^{-4} *M* HCOONa at p*H* 11.5.

essentially unchanged (even cleaned up) by repeated flashing.

(b) Decay of e^-_{aq} Following the Main Flash

Figure 4 shows typical first- and second-order kinetic plots for the decay of absorbance due to e^-_{aq} at 632.8 nm following the Main flash in a OH^-/H_2 solution. The first 70 μs are complicated both by the tail of the light flash and by the occurrence of reactions 4 and 5. For times longer than 70 μs the decay was treated according to a method of combined first- and second-order reactions (10) by plotting $A_{t+\theta}^{-1}$ against A_t^{-1}, where θ is a constant time interval. Straight lines were obtained for these plots. Using a value of $\theta = 200$ μs the line obtained had a slope of 1.67 ± 0.02 and an intercept of 2.53 ± 0.1, from which one calculates a second-order rate constant (k_s) of $(4.9 \pm 0.2) \times 10^9$ M^{-1} s^{-1} and a first-order rate constant (k_f) of $(2.5 \pm 0.1) \times 10^3$ s^{-1}. This value of k_s (defined by $-dc/dt = k_s c^2 + k_f c$), which approximates the limiting slope in Fig. 4 (6.5×10^9 M^{-1} s^{-1}), should be compared with the published values of $2k_2$. In this experiment e^-_{aq} was produced at $\sim 2 \times 10^{-6}$ *M* so that, from k_s and k_f, one calculates that 60% of e^-_{aq} reacted by the bimolecular combination reaction 2. (For experiments in which e^-_{aq} was produced at 1×10^{-6} *M* reaction 2 would consume only 45% of e^-_{aq}.)

The mean lifetime of e^-_{aq} with respect to the pseudo first-order component, given by k_f, is thus 400 μs. This reaction is only 2.8 times faster than the slowest reaction computed for the decay of e^-_{aq} at nanomolar concentrations by pulse radiolysis and attributed to the reaction of e^-_{aq} with H_2O (11). We must presume that k_f represents reaction with an impurity which we could not eliminate. For that reaction to be reasonably well described by a pseudo first-order rate the impurity must be present at greater than ~ 2 times the initial $[e^-_{aq}]$ and consequently its concentration must be $> 4 \times 10^{-6}$ *M* and its reaction with e^-_{aq} must have a rate constant $< 6 \times 10^8$ M^{-1} s^{-1}.

The absorption spectrum presented later shows that the absorption monitored at 632.8 nm is due to e^-_{aq}. This is confirmed by the decay data at 632.8 nm shown as the insert on Fig. 4 which pertains to an aqueous solution at p*H* 11.5 containing 1.1×10^{-5} *M* $NaNO_3$, 10^{-4} *M* sodium formate, and deoxygenated by saturating with He gas. Under these conditions the $HCOO^-$ scavenges the OH radical and the NO_3^- reacts with e^-_{aq}. The first 40 μs are complicated because of the tail of the Main flash but thereafter a good first-order decay is obtained, from the slope of which one obtains $k(e^-_{aq} + NO_3^-) = 1.1 \times 10^{10}$ M^{-1} s^{-1}. This compares most favourably with published values for this reaction which range from (0.92 to 1.1) $\times 10^{10}$ M^{-1} s^{-1}.

In experiments conducted on various very low NO_3^- solutions, at concentrations where e^-_{aq} still decayed largely by pseudo first-order kinetics, no absorption at all could be detected when the Auxiliary lamp was flashed at any delay with the 0–53 filter placed in F. This verifies that either the occurrence of reaction 2 or a long-lived e^-_{aq} is a prerequisite for photoregeneration of e^-_{aq}. Apparently both conditions are necessary, though this is not easy to test directly.

(c) Light Filter Experiments

Figure 5 shows three typical oscilloscope traces for the double flash photolysis of OH^-/H_2 solutions, monitored at 632.8 nm, in which a Pyrex glass filter (0–53) was incorporated between the Auxiliary lamp and reaction vessel. The position of the arrow indicates the moment at which the Auxiliary lamp (photolyzing only at $\lambda > 260$ nm) was fired. A second absorption signal was recorded in Fig. 5 (*a*), (*b*), and (*c*). As the delay time was increased the second absorption signal decreased and was barely detectable for times greater than ~ 20 ms. Figure 5(*d*)

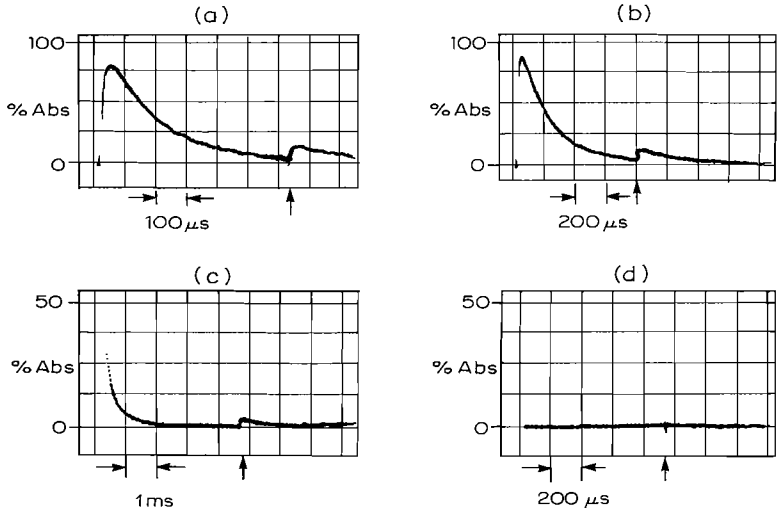

FIG. 5. Reproductions of oscilloscope traces showing the absorption at 632.8 nm as a function of time in an OH^-/H_2 solution as described in the text. The arrows indicate when the Auxiliary flash ($\lambda > 260$ nm) occurred. In (*d*) the Main lamp was not fired.

shows a trace in which the Main flash was not fired but the oscilloscope time-base triggered by the Main lamp's triggering circuit. In this case no absorption was created by the Auxiliary lamp at $\lambda > 260$ nm.

It is clear then that hydrated electrons must be created by the u.v. flash before a second peak may be observed. Kinetic plots of the absorbance created by the Auxiliary flash indicate neither simple first- nor second-order decays for the species responsible. The absorbances measured for the Auxiliary-induced peak have never exceeded 20% of the absorbance due to e_{aq}^- in the Main peak. Furthermore the height of the Auxiliary peak depends strongly on both the $[e_{aq}^-]$ produced initially by the Main lamp and on the lifetime of e_{aq}^-, increasing as the lifetime increases. When the lifetime of e_{aq}^- was $< 10^{-4}$ s with respect to the first-order component no Auxiliary-induced absorbance could be detected at all.[3] For these reasons it is impossible for us to quote a lifetime for the intermediate species X which is very meaningful. In a good "clean" system it is certainly > 1 ms and may typically be ~ 5 ms. There are experimental indications that X was being both formed and decomposed during the lifetime of e_{aq}^- and that its maximum concentration is reached when the e_{aq}^-, and the OH, H, and H_2O_2, have been largely destroyed at about 500 μs after the Main flash.

Less than a 20% change in the Auxiliary absorption peak was obtained on changing from one to two layers of the 0–53 filter in F. This suggests that X does not have a strong narrow absorption band between 280 and 320 nm (or that there is enough light and absorption at other wavelengths to dissociate X completely). On exchanging the 0–53 light filter for the other filters shown in Fig. 3 we find the following results. One layer of 0–52 reduces the Auxiliary peak to about 70% of that obtained with 0–53 and 2 layers reduces it further. Filters 3–74 and 3–70 eliminate the Auxiliary absorption peak completely. This finding is contrary to data reported in our previous communication (1). At that time we concluded from the use of filter 7–54 that it must be wavelengths > 700 nm that were responsible for the second peak, rather than the "window" of that filter at 260–420 nm, because we also saw the second absorption peak using filter 3–70. We cannot explain the erroneous results obtained with the 3–70

[3]Czapski and Peled (12) have shown that, in the pulse radiolysis of an alkaline aqueous solution containing 10^{-2} *M* alcohol, there was no evidence for a species which was *both* long-lived and absorbed light in the region 600–1100 nm. This conclusion is consistent with our present filter data indicating the different wavelength range. However, it should be noted that it could equally well have arisen from the requirement of a long-lived e_{aq}^- because in their system (12) e_{aq}^- itself decayed through ~ 14 half-lives in 200 μs by reaction with other solutes present (Czapski and Peled suggest these may be H_2O_2 or aldehydes).

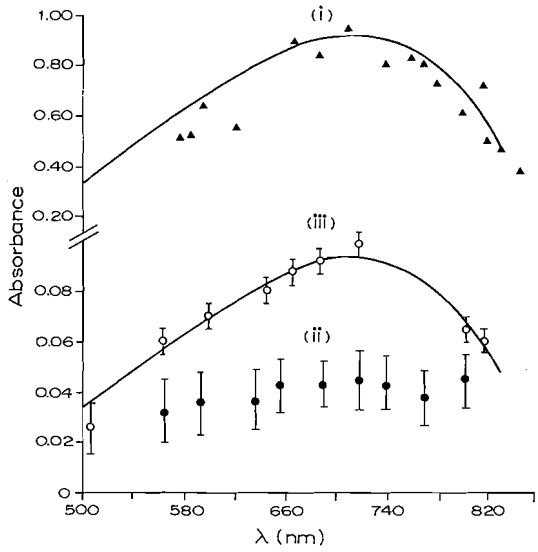

FIG. 6. Absorption spectra of an OH^-/H_2 solution: (*i*) 70 μs after the Main flash; (*ii*) 600 μs after the Main flash; (*iii*) 55 μs after the Auxiliary flash ($\lambda > 260$ nm) which was fired 600 μs after the Main flash.

filter at that time except by concluding that some stray u.v. light must have by-passed that filter in those experiments, which were performed on another flash photolysis apparatus.

It is evident then that the Auxiliary absorption peak is produced by wavelengths largely in the range 320 to 400 nm. In this respect our observations are in reasonable accord with results recently reported by Gopinathan *et al.* who found that $\sim 10^{-9}$ *M* e^-_{aq} may be generated by flash photolysis using similar wavelengths when a H_2-saturated solution at p*H* 11 was concurrently exposed to the u.v. light from a Hg lamp (3). It seems highly probable that the same intermediate is produced in these two experiments (but not the one they suggest).

(d) Absorption Spectra

The absorption spectra of species present at any preselected time after either photoflash may be measured spectrographically using the spectroflash lamp S as a white light source. The film or plate densities were converted to solution absorbance data using characteristic curves constructed for each wavelength. Figure 6 shows the absorbance of the solution between 500 and 850 nm, (*i*) 70 μs after the Main flash, (*ii*) 600 μs after the Main flash (no Auxiliary flash), and (*iii*) 55 μs after the Auxiliary flash (with 0–53 filter in F) which was fired 600 μs after the Main flash. These data were recorded on Kodak Fast Infrared film using the Bass-Kessler spectrograph.

The wavelength range 300 to 500 nm was investigated using the Hilger spectrographs and Ilford HP3 photographic plates. For this wavelength range the scatter in the background plate density resulting from small fluctuations in the spectroflash lamp intensity was more severe and placed a lower limit of absorbance ~ 0.1 on the sensitivity for detection of absorbing species. The same three experiments yielded the following information: in (*i*) the tail of the band shown in Fig. 6 decreased continuously from 500 to 300 nm; in (*ii*) and (*iii*) no absorbance could be detected.

Several conclusions may be drawn from the data in Fig. 6. Firstly, in (*i*) the absorption band determined corresponds very closely to the known spectrum of the hydrated electron. In conjunction with the kinetic evidence this enables us to attribute the absorbance measured using the He/Ne laser to e^-_{aq}. Secondly, the weak absorption observed in (*iii*) also resembles that of e^-_{aq}, thus strongly suggesting that hydrated electrons are being regenerated by the Auxiliary flash. Thirdly, no absorption could be detected ($A < 0.1$) for species X in (*ii*). This fact will be used later to place an upper limit of $\sim 1.2 \times 10^4$ M^{-1} cm^{-1} on the absorption coefficient of this species over the range 300 to 850 nm.

(e) Triple-flash Experiments

Why could only 20% of the hydrated electrons be regenerated even under the most favorable circumstances within our experimental limitations? Was it because the extinction coefficient of X was small or flash intensity was too low, or did only 20% of the initial e^-_{aq} generated by the Main flash form X? To try to answer this we discharged the Auxiliary lamp twice, at about the same energy, with 100–400 μs separation. Figure 7(*a*) shows the oscilloscope trace using laser photometry at 632.8 nm when there was no light filter present between the Auxiliary lamp and reaction vessel. This indicates that the u.v. light intensity was comparable in the two Auxiliary flashes. Figure 7(*b*) shows a trace taken under similar conditions, but with the 0–53 filter in F. Evidently the second Auxiliary flash regenerates <20% as much e^-_{aq} as is pro-

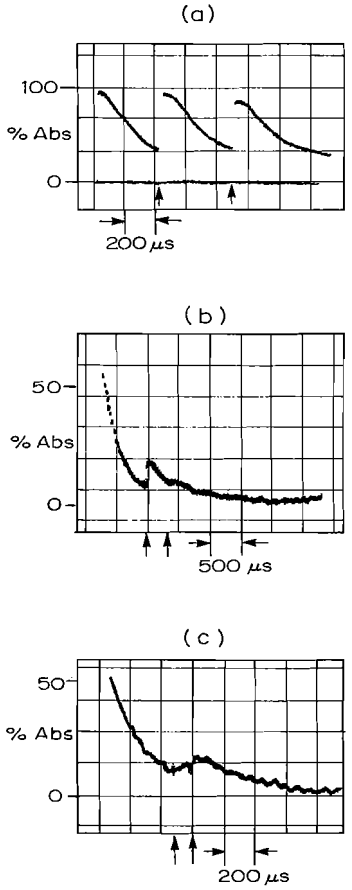

FIG. 7. Reproductions of oscilloscope traces showing the absorption at 632.8 nm in the triple flash experiments described in the text on an OH^-/H_2 solution: (*a*) no filter in F; (*b*) filter 0–53 in F. Arrows indicate the times at which the Auxiliary lamp was fired (Auxiliary lamp fired at 7 kV both times); (*c*) as in (*b*) except that the Auxiliary lamp was fired at 3 kV first time and at 7 kV 110 μs later.

duced by the first Auxiliary flash. This does not however arise from the normal decay of X during the extra 340 μs delay from the Main flash, as indicated by the relative magnitudes of peaks obtained from single Auxiliary flashes at 530 and 870 μs delays. This latter point is further corroborated by the trace shown in Fig. 7(*c*). In this experiment the Auxiliary was fired at 3 kV, 630 μs after the Main flash then fired again 110 μs later but this time at 7 kV charging voltage. The difference in light intensities produced in the range 300–400 nm by these two flashes should be more than the factor of 5.5 calculated simply from $(7/3)^2$. Absorption produced by the first Auxiliary flash in this case is barely detectable.

We interpret these triple flash experiments to mean that ~80% of X is normally photodissociated by the Auxiliary flash and thus that less than 24% of the hydrated electrons initially formed yield X molecules which can survive 600 μs in our system.

Therefore, in a typical experiment, the concentration of X after 600 μs must be only $\sim 2 \times 10^{-7}$ *M*. When combined with the absorbance limit, $A < 0.1$, this yields an upper limit of $1.2 \times 10^4\ M^{-1}\ cm^{-1}$ on the absorption coefficient over the wavelength range where it is photodissociated to give e^-_{aq}, and also over the whole visible region of the spectrum.

From these results it may be argued as well that the mean extinction coefficient ($\bar{\varepsilon}$) within the wavelength range 320 to 400 nm cannot be very small. Since the absorbance of the solution across the cell is very small, the fraction of incident light absorbed by X following the discharge of the Auxiliary lamp may be approximated to

$$\Delta I/I = 2.3\ \bar{\varepsilon} l[X]$$

where *l* is the mean optical path length traversed in the solution by light originating from the Auxiliary lamp. A reasonable value for *lI* may be obtained from the measured extent of photolysis of gaseous bromine at 1 Torr pressure (13) using the previously described apparatus (1). From the known absorption spectrum of bromine it could then be calculated that $2.3lI \approx 6 \times 10^{-6}$ einstein cm nm^{-1}. Assuming the same output for the range 320–400 nm, similar efficiency for the apparatus, and putting $\Delta I \approx [X]$, one calculates $\bar{\varepsilon}$ for X to be $\sim 2 \times 10^3\ M^{-1}\ cm^{-1}$. In fact this is probably a lower limit because the new apparatus is somewhat larger (to accommodate the filters in F).

Within the wavelength range responsible for photodissociation X appears to have a mean extinction coefficient $> 2000\ M^{-1}\ cm^{-1}$; but it does not exceed 12 000 $M^{-1}\ cm^{-1}$ at any λ.

(f) Frequency-doubled Ruby Laser Data

Some further evidence that these solutions contain a relatively long-lived intermediate species X comes from experiments performed using the frequency-doubled Ruby laser line at 347 nm. The He/Ne laser was replaced by a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Q-switched ruby laser incorporating a frequency doubling crystal which converted about 1% of the 75 MW pulse of 20 ns duration at 694.3 nm to 347.1 nm light. In these experiments the 694 nm flux was eliminated by the use of a $CuSO_4$ absorber and the 347 line was attenuated with a $K_2Cr_2O_7$ filter to an intensity level where it would not cause photodissociation of X. Unfortunately this laser could be fired only up to delay times of 500 μs after the Main flash because of the triggering mechanism. Absorbance measurements were made by comparison of the transmitted 347 nm light from the Main flash with that obtained at various time delays after the Main flash. Because of the small absorbance and slight variations in the laser light from pusle to pulse there is considerable scatter in the data obtained. Nevertheless, the absorbance seemed to be ~ 0.1 at all delay times up to 500 μs. These data are given in Fig. 8, together with the time dependence of the absorbance measured separately for the particular solution and Main flash energy used in this experiment as monitored at 632.8 nm by the He/Ne laser. Also shown in Fig. 8 is the absorbance that would be expected at 347 nm due to e^-_{aq}, calculated from the measured absorbance at 632.8 nm by multiplying the latter by the ratio of extinction coefficients of e^-_{aq} at 347 and 632 (*i.e.* multiplied by 0.11 (6)).

The initial concentration of e^-_{aq} was $\sim 2 \times 10^{-6}$ M in these experiments, so that if we assume 20% conversion to X then the extinction coefficient of X at 347 nm must be ~ 6000 M^{-1} cm^{-1}.

(g) Added Solutes

Experiments performed on different chemical systems using laser photometry and typically an 800 μs delay between the u.v. and Auxiliary flash (only $\lambda > 260$ nm) led to the following observations:

(i) Excess Na^+

When the $[Na^+]$ was varied from 10^{-3} to 1 M by adding $NaClO_4$ to the $NaOH/H_2$ system, no marked change could be detected in the height of the Auxiliary absorption peak.

However, we did note the following. When H_2 saturated water (p$H \sim 7$) was flash photolyzed no absorption at all was observed at 632.8 nm either following the Main flash (u.v.) or Auxiliary flash ($\lambda > 260$ nm). When 1 M $NaClO_4$ at p$H \sim 7$ was photolyzed some aborption at 632.8 nm could be detected ($\sim 10\%$ that found at pH 11) following the Main flash but again none following the Auxiliary flash. This suggests that direct u.v. photolysis of our $NaClO_4$ solutions produced small concentrations of e^-_{aq}. Similar effects may have been observed in the experiments of Gopinathan *et al.* (3) who found $NaClO_4$ increased the concentration of photogenerated e^-_{aq} to $\sim 10^{-8}$ M. The presence of $NaClO_4$ in their experiments may have increased the steady state concentration of e^-_{aq}, thus yielding more X to be photodissociated, and thereby placing a different interpretation on the role of Na^+ ions.

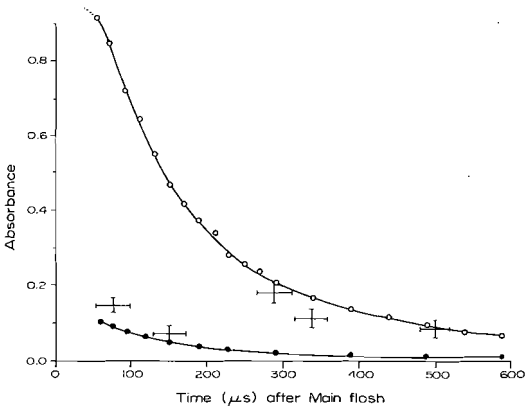

FIG. 8. Absorbance as a function of time: +, absorbance measured at 347 nm using the Ruby Laser (see text); ○, absorbance measured at 632.8 nm using the He/Ne laser; ●, absorbance calculated for e^-_{aq} at 347 nm from the He/Ne data using $\varepsilon_{633}/\varepsilon_{347} = 0.11$.

(ii) NH_4OH Solutions

When metal ions were eliminated from the system by using a solution containing only NH_4OH saturated with H_2 the Auxiliary peak was formed in comparable yield to that obtained in NaOH solutions of the same pH.

(iii) Ba^{2+} Ions

A solution made of $Ba(OH)_2$ and H_2 also gave similar results, confirming that the same effects can be observed with various cations. This further shows that the carbonate radical anion, CO_3^-, which could be formed by attack of OH on any CO_3^{2-} present in the NaOH solutions, is not responsible for the absorption at 632.8 nm.

(iv) H_2O_2 Solutions

When various concentrations of H_2O_2 in the range 10^{-5} to 10^{-3} M were added to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$NaOH/H_2$ solutions no Auxiliary-induced absorption signal was detected. This indicates that the second absorption peak does not arise by photolysis of H_2O_2 or HO_2^- formed in these solutions by reaction 6. Furthermore, this corroborates our earlier conclusion that if the lifetime of e_{aq}^- is curtailed by the presence of an e_{aq}^- scavenger then no Auxiliary peak could be observed.

(v) Formate Ions and 2-Propanol as OH Scavengers

In most of the experiments discussed so far the OH radicals produced in the u.v. photolysis of OH^- were scavenged by H_2 at 7×10^{-4} *M* and converted to e_{aq}^- by reactions 4 and 5 only rather slowly (mean lifetimes of OH and H being about 30 μs each). In order to establish whether OH or H were involved in the formation of X, some experiments were performed using sodium formate or isopropanol to reduce the lifetime of OH to ~ 1 μs and exclude the formation of H. These solutions consisted of 2×10^{-3} *M* NaOH, 3×10^{-5} *M* HCOONa (or 3×10^{-4} *M* 2-propanol) and deoxygenated by bubbling with pure He gas. Following the Main flash the initial absorption at 632.8 nm was smaller than in the OH^-/H_2 solutions (as would be expected since none was formed via reactions 4 and 5) and the decay rate somewhat faster. However, in both cases Auxiliary-induced absorption was obtained in yields quite similar to that found in OH^-/H_2 solutions having the same initial $[e_{aq}^-]$ and comparable decay rates. Furthermore, light filter 3–70 eliminated the Auxiliary peak and 0–52 reduced it markedly, as in the H_2/OH^- systems. It was clear, however, that by adding much higher concentrations ($\sim 10^{-2}$ *M*) of alcohols or formate the lifetime of e_{aq}^- was curtailed (presumably due to impurities introduced with these solutes) and no Auxiliary-induced photodissociation of X was observed.

Summary of Results

A transient species, X, is produced from hydrated electrons under conditions where e_{aq}^- is itself quite long-lived (greater than ~ 200 μs with respect to pseudo first-order processes including impurities and added solutes) and when it decays predominantly in the bimolecular combination reaction 2. Species X is photodissociated to regenerate e_{aq}^- by light largely in the range 320 to 400 nm. Filter experiments indicate that the absorption band responsible for photodissociation is fairly broad, perhaps covering most of this range. Absorption measurements suggest that the mean extinction coefficient between 320 and 400 nm is at least 2000 M^{-1} cm^{-1}, that it may be as high as 6000 M^{-1} cm^{-1} at 347 nm but that it does not exceed 12 000 M^{-1} cm^{-1} at any wavelength.

From the measured concentration of e_{aq}^- regenerated by the Auxiliary flash at various delay times, it is deduced that the life-time of X is very sensitive to the yield and lifetime of e_{aq}^- created initially and that in a "good" experiment its half-life is ~ 5 ms. However, its decay rate cannot be described by simple first- or second-order kinetics and a 20% yield of regenerated hydrated electrons was the largest ever found. Triple flash experiments showed that there was enough light in the first Auxiliary flash to dissociate 80% of the X molecules present 600 μs after the Main flash.

Similar results were obtained when the OH radical was scavenged by H_2 (7×10^{-4} *M*), 2-propanol (3×10^{-4} *M*) or $HCOO^-$ (3×10^{-5} *M*), thereby proving that the OH radical is not involved in the formation of X. Furthermore, different cations (vast excess of added Na^+ ions or the use of NH_4OH or $Ba(OH)_2$ as the source of OH^-) had almost no effect on the yield of photoregenerated e_{aq}^-.

Spectral measurements have confirmed the kinetic evidence that the species responsible for absorption at 632.8 nm in the Main and Auxiliary flashes are hydrated electrons. However, the absorption spectrum of X could not be detected spectrographically; thus on upper limit of 1.2×10^4 M^{-1} cm^{-1} may be placed on its extinction coefficient over the spectral range 300 to 850 nm.

Discussion

Our previous postulate that the comparatively long-lived species found in these systems was a hydrated electron dimer, formed in reaction 8,

[8] $$e_{aq}^- + e_{aq}^- \rightarrow (e_2^{2-})_{aq}$$

which could be photodissociated in the process

$$(e_2^{2-})_{aq} \xrightarrow{h\nu} 2e_{aq}^-$$

This was based partly on the kinetic information but largely on the understanding that this species absorbed light of wavelengths > 700 nm. For such a species to in fact absorb strongly in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

range 320 to 400 nm does not immediately gain credence from comparisons with F' centers in alkali halide crystals (14) and other dielectron species in solids (15), where the dimers have broad bands which are red-shifted with respect to the monomeric species. However, it should be noted that in the case of solids the size of the cavity constituting the F or F' center is fixed by the lattice parameters, whereas for liquids the cavity may adjust its size to the constraints imposed by the presence of two electrons (in either singlet or triplet state, the latter presumably requiring a large cavity). The polarization of the medium could then correspond to the solvation of a doubly charged species. Indeed calculations by Fueki on trapped dielectron species predict a small blue-shift for λ_{max} in liquid water (16).

It is interesting (and perhaps significant) that the photon energy found for the regeneration of e^-_{aq} from X ($\sim$3.5 eV) is about twice the solvation energy of e^-_{aq} (1.7 eV (17), which also equals the photon energy of the absorption band maximum). ΔG for reaction 8 will be governed by the small change in entropy expected for the reaction as written but mainly by the difference in heats of solvation of the species involved. (This assumes of course that the bond energy of e_2 is negligible.) Reaction 8 would thus be quite endoergic if the dimeric species had a lower solvation energy than the monomeric species; *i.e.* if the e_2 species had a red-shifted absorption band maximum. On this basis a solvation energy for $(e_2^{2-})_{aq}$ of $\sim$3.5 eV is consistent, thermodynamically, with its formation in reaction 8. In solids, the e_2 species which have been observed did not arise from a "chemical reaction" such as reaction 8; but rather by trapping of a free electron (from a comparatively high energy state) at a site already containing a trapped electron.

It might be argued that an e_2 species would be expected to have a much broader absorption band than our filter experiments indicate. However, it should be recalled that the 320 to 400 nm range only represents that wavelength range which is observed to lead to photoionization. This may be merely the high energy tail of a much broader band involving bound–bound transitions at longer wavelengths.

It has not been possible for us to establish the identity of X. As indicated above we feel that a hydrated electron dimer is still a strong candidate. The kinetic evidence suggests that X is either $(e_2^{2-})_{aq}$ or a species formed therefrom; perhaps by proton abstraction from water, reaction 9

$$[9] \qquad (e_2^{2-})_{aq} + H_2O \rightarrow H^-_{aq} + OH^-_{aq}$$

or association with a cation according to reaction 10.

$$[10] \qquad (e_2^{2-})_{aq} + M^{n+} \rightarrow M^{(n-2)+}_{aq}$$

H^-_{aq} seems to be a likely possibility since it is merely the conjugate acid of $(e_2^{2-})_{aq}$ as given by equilibrium [11]

$$[11] \qquad (e_2^{2-})_{aq} + H^+_{aq} \rightleftarrows H^-_{aq}$$

but, because the pH was $\sim$11 in our experiments, it would have to be formed by reaction 9 rather than reaction 11. H^-_{aq} should also be formed from OH radicals by reactions 4, 5, and 7 when H_2 was used as the OH scavenger. Calculations show that 10 to 20% of e^-_{aq} could be consumed by reaction 7 in a typical OH^-/H_2 experiment. When 2-propanol or formate ions were used to scavenge OH, reaction 7 was excluded and yet we observed very comparable photoregeneration of e^-_{aq}. Thus it may be stated that if H^-_{aq} is formed in both reactions 7 and 9 then X is not H^-_{aq}. As a rider to this one should add that, although it is generally accepted that the reaction between H_2 and OH may be written as reaction 4, if it in fact proceeds by the one-step reaction 12 at pH 11,

$$[12] \qquad H_2 + O^-_{aq} \rightarrow e^-_{aq}$$

or through the formation of H_3O rather than H by reaction [4], then H^-_{aq} cannot be discounted.

In the presence of Na^+, NH_4^+, or Ba^{2+} dielectrons may undergo reaction 10 to form $(e^-.M^{n+}.e^-)_{aq}$ species. It is conceivable that the absorption band of such species is not influenced much by the nature of the cation and that they all absorb in the 320 to 400 nm range with comparable extinction coefficients. It is also possible that X may be Na^-_{aq} in all these systems since the solutions were deoxygenated in Pyrex glass vessels and therefore probably all contained $\sim 10^{-5}$ M of Na^+ ions. For solutions of Na in various amines (18) and hexamethylphosphoramide (19) evidence has been presented for the occurrence of Na_s^- having fairly strong absorption bands centered at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

photon energies about twice that of the maximum in the solvated electron band.

If X is to be attributed to the analogous aqueous species, Na^-_{aq}, then we must conclude from our experiments with added Na^+ that it is formed in sequence 13

$$[13] \qquad 2e^-_{aq} \rightarrow (e_2^{2-})_{aq} \xrightarrow{Na^+} Na^-_{aq}$$

with the first step being rate determining. Our data is not consistent with the intermediate formation of a simple $(Na^+e^-)_{aq}$ complex formed by direct reaction of e^-_{aq} with Na^+ (3).

We cannot of course eliminate the possibility that the effects observed arise from the formation of a transient species produced by the reaction of e^-_{aq} with a trace impurity. However, we would have to conclude that this impurity has always been present in our especially purified water at about the *same concentration* throughout this entire study. Furthermore, it is not consistent with our qualitative observation that the fraction of e^-_{aq} regenerated by the Auxiliary flash decreases as the fraction of initial e^-_{aq} reacting by the pseudo first-order component decreases following the Main flash.

Another possibility for X is the product of the reaction of e^-_{aq} with water, reaction 14,

$$[14] \qquad e^-_{aq} + H_2O \rightarrow ? \qquad k_{14} = 16\ M^{-1}\ s^{-1}\ (11)$$

or an adduct formed therefrom. If this spontaneous decomposition reaction of e^-_{aq} has the value k_{14} attributed to it (11) then 10–20% of the original e^-_{aq} could undergo that reaction following the Main flash, and its yield would increase with the mean lifetime of e^-_{aq}, as observed. However, we can conclude that X does not arise from reaction 14 if the product of that reaction is an H-atom, as postulated (11), because of the results obtained with added H-atom scavengers such as OH^-, 2-propanol, and sodium formate.

The possibility of e^-_{aq} being formed during the second flash from long-lived triplet states of H_2O or OH^- is discarded on the basis of the following factors: (*i*) e^-_{aq} cannot be detected by photolysis of pure water during the Main or Auxiliary flashes; (*ii*) solutes other than OH^- (specifically I^- or SO_4^{2-}) show comparable results; and (*iii*) very small concentrations of NO_3^- and H_2O_2, which are good e^-_{aq} scavengers, eliminate the formation of a second absorption peak indicating that e^-_{aq} is a necessary precursor.

As indicated earlier it is not possible to alter the p*H* significantly because the OH^- ions are involved in the primary photolysis 1 and in reaction 5. Nevertheless, the p*H* probably has an important influence on the lifetime of species X. This would certainly be expected if X is $(e_2^{2-})_{aq}$, H^-_{aq}, or Na^-_{aq}.

It is not clear which of the following possibilities imposes the 20% maximum on the observed regeneration of e^-_{aq}. (N.B. This represents ~30% of e^-_{aq} reacting by reaction 2.) (*i*) This constitutes the yield of X initially formed; (*ii*) under all conditions only a fraction of X survive the multifarious reactions which occur following the Main flash; (*iii*) photolysis of X has alternative decomposition paths so that the quantum yield for dissociation to give e^-_{aq} is substantially less than unity; or (*iv*) X is formed in more than one spin state (e_2, for instance, could be a singlet or triplet), only one of which is photodissociated by the light used. It should be noted with regard to (*iii*) that all wavelengths >400 nm were also illuminating the solution during the Auxiliary flash. It is conceivable that a bound photoexcited state e_2, for instance, may abstract a proton from the solvation shell.

Our experiments indicate that in order to observe the photoregeneration of e^-_{aq} from X in this system it is necessary to have two conditions fulfilled: (*a*) e^-_{aq} must decay to a considerable extent by the bimolecular combination reaction 2; and (*b*) the mean lifetime of e^-_{aq} with respect to all *other* reactions (with solutes, impurities, reaction products, etc.) must exceed ~200 μs. This latter requirement suggests that X is quite as reactive towards reducible solutes as is e^-_{aq}. Consequently, if X is formed by intra-spur reactions in the radiolysis of aqueous solutions it will be destroyed by other radiolysis products, such as OH radicals, H^+_{aq} ions and H_2O_2, and by reducible solutes. Thus it may be rather short-lived in a radiolysis system and not easily detected by pulse radiolysis methods, especially in the presence of $\sim 10^{-2}\ M$ alcohols at high p*H* (12, 20). In 1965 Dorfman concluded that if a dielectron species is formed in pulse-irradiated water it either has a lifetime <0.2 μs or its absorption band is not in the same region of the spectrum as e^-_{aq} (21). The flash photolysis of OH^-/H_2 solutions seems to be much more favorable to the formation and longevity of X than is a radiation chemical system. Conse-

quently its probable role in molecular H_2 formation by radiolysis is not easy to deduce.

The effect of added e_{aq}^- scavengers on X is ambiguous. They could interfere with the formation of X; but they could also be quite reactive towards X. Indeed one might expect an e_2 species (even if it is protonated or associated with other cations) to be about as strong a reducing agent as is e_{aq}^-. It has been suggested that e_2 may be more effective than e_{aq}^- in reducing solutes, such as Tl^{3+}, which can readily accommodate two electrons (22); but unfortunately that cannot be tested in the present system because of the p*H*, concentrations, and timescales to which we are restricted.

If these conclusions are correct then, in the absence of e_{aq}^- scavengers, X is apparently more stable with respect to the solvent and itself than is e_{aq}^-. Consequently X probably plays an important role in any chemical or physical process by which water is reduced to H_2 through the creation of hydrated electrons in high local concentrations.

The authors are most grateful to Mr. Eric Fisher for technical assistance and to the National Research Council of Canada and the Defense Research Board of Canada for financial support of this research.

Department of Chemistry, Aligarh Muslim University, Aligarh (U.P.) India

Received August 10, 1971

A new, thermally stable, and highly strontium-specific inorganic ion exchanger, titanium(IV) vanadate, has been prepared by mixing 0.5 *M* solution of titanic chloride and sodium vanadate at p*H* 0–1. Its ion exchange capacity is 0.65 mequiv./g at 400 °C. Separation factors of Sr^{2+} with respect to Ba^{2+}, Ca^{2+}, and Mg^{2+} are 8, 11.8, and 33.3, respectively. Binary mixtures of Sr^{2+} with Ba^{2+}, Ca^{2+}, and Mg^{2+} have been separated. Calcium and magnesium are eluted with 0.001 *M* HNO_3. Barium and strontium are eluted with 0.01 and 0.1 *M* HNO_3, respectively. A new parameter $\Delta C/\Delta T$ is proposed for the study of structural changes in inorganic ion exchangers.

Un échangeur d'ion inorganique nouveau, thermiquement stable et hautement spécifique pour le strontium et le vanadate de titane(IV) a été préparé en mélangeant une solution 0.5 *M* de chlorure de titane et de vanadate de sodium à p*H* 0–1. Sa capacité d'échange d'ion est de 0.65 mequiv./g à 400 °C; les facteurs de séparation du Sr^{2+} par rapport à Ba^{2+}, Ca^{2+}, et Mg^{2+} sont respectivement de 8, 11.8 et 33.3. Les mélanges binaires de Sr^{2+} avec Ba^{2+}, Ca^{2+}, et Mg^{2+} ont été séparés. Le calcium et le magnésium sont élués par HNO_3 0.001 *M*, le strontium et le barium par HNO_3 0.01 et 0.1 *M*, respectivement. Un nouveau paramètre $\Delta C/\Delta T$ est proposé pour étudier les changements de structure dans les échangeurs d'ion inorganique.

Canadian Journal of Chemistry, **50**, 2071 (1972)

Introduction

The selectivity of an ion exchange material depends considerably on the specific interaction of the counter ions with the exchanger. This interaction varies with the chemical composition of the exchanger which can be altered with greater ease and facility in inorganic materials than in the organic ones. The synthesis of new inorganic ion exchangers is therefore of outstanding analytical interest.

Of the various inorganic ion exchangers studied earlier the vanadates are probably the least well investigated. Some studies have been made on the vanadates in connection with their use as a catalyst (1). Alkali vanadates have been used for the amperometric titrations of uranyl (2) and thorium (3) ions. The probable species formed in solution have also been postulated. However, the first mention of the ion exchange properties of vanadates is in the work of Phillips and Kraus (4) who made a cursory study of the vanadates of uranium, thorium, thallium, niobium, zirconium etc., and reported their selectivity for cesium and rubidium. Weiss and co-workers (5, 6) studied the exchange behavior of the mineral uranite and determined the crystal structure of tetrathiovanadate. Shichko and Biochinova (7) synthesized an inorganic ion exchanger based on zirconium and vanadium and concluded that its ion exchange capacity depends on the chemical composition of the samples, thermal treatment, and size of the grains. However, a detailed and systematic study on the ion exchange properties of titanium(IV) vanadate is lacking. Bishop and co-workers (8, 9), synthesized it only when they investigated the mixed oxides of groups III, IV, and V as selective ion exchangers for incorporation into electrodialysis membranes. We have therefore synthesized titanium(IV) vanadate and are reporting the ion exchange properties, sorption behavior, and thermal dehydration results.

Experimental

Reagents

Titanium dioxide and a 15% (w/v) solution of titanium(IV) chloride were obtained from B.D.H., England while vanadium pentoxide was a Reidel product. All other chemicals used in this study were of reagent grade.

Apparatus

The various instruments used for spectrophotometry, X-ray studies, i.r. studies, p*H* measurements, and thermogravimetry were the Bausch and Lomb Spectronic-20 colorimeter, the Philips X-ray unit, the Perkin–Elmer model-137 spectrophotometer, the ELICO (India) p*H*-meter model LI-10 and a Stanton thermobalance type-H4, respectively. A temperature controlled shaker from SICO, India was used for equilibrium studies.

TABLE 1. Condition of preparation and some properties of titanium(IV) vanadate samples

Serial No.	Concentration of mixing solution (*M*)	Volume ratio of mixing	Adjusted p*H*	Reagent used to adjust p*H*	Appearance	Ion exchange capacity mequiv./g
1	0.5	1:1	0	NaOH	Dark brown shiny	0.68
2	0.5	1:2	0	NaOH	Dark brown shiny	0.69
3	0.05	1:1	1.0	Urea	Orange-yellow	0.70
4	0.05	1:1	0.5	Urea	Yellow	0.60
5	0.05	1:1	0	Urea	Yellow + heating	0.60

Preparation of Reagent Solutions

Dilute (0.5 *M*) solution of titanium(IV) chloride was prepared from the stock solution by diluting with 1.5 *M* HCl. The 0.5 *M* vanadium(V) solution was prepared by dissolving vanadium pentoxide in 1 *M* NaOH and then neutralizing the excess alkali with nitric acid. Stock titanium sulfate solution was prepared by dissolving 8 g of titanium dioxide in 250 ml of hot concentrated H_2SO_4 containing 100 g ammonium sulfate with constant stirring.

Preparation of Titanium(IV) Vanadates

(a) Using Titanium(IV) and Vanadium(IV) Solutions

Four samples were prepared by mixing in the cold the *M*/40 solution of titanium(IV) sulfate and vanadyl sulfate in the volume ratio 1:1 at p*H* values 10, 6.8, 4.8, and 2.7. The p*H* value was adjusted with ammonia or sodium hydroxide. The gels were digested at room temperature for 48 h. They were filtered and washed with demineralized water until the p*H* of the washings was about 6. They were dried at 40 °C in an oven and immersed in water to yield small granules. The granules were then dried and placed in 1–2 *M* HNO_3 or HCl for 24 h, occasionally replacing the supernatant liquid, to convert them into the hydrogen form. During this operation the samples prepared at p*H* 4.8, 6.8, and 10 dissolved completely. The gel prepared at p*H* 2.7 produced brown shiny particles which dissolve slightly in 1–2 *M* HNO_3. Its ion exchange capacity for Na^+ was 0.34 mequiv./g.

Some samples were also prepared by heating the precipitates in the presence of oxidizing agents such as HNO_3 and H_2O_2. The procedures are summarized below:

(*i*) A mixture of 500 ml of *M*/40 titanium(IV), 500 ml of *M*/40 vanadium(IV) solution, and 100 ml of 1 *M* HNO_3 was refluxed for 12 h. Only a small amount of yellow precipitate was obtained which dissolved readily in 1 *M* HNO_3 when kept for 24 h.

(*ii*) 500 ml of *M*/40 titanium(IV) sulfate and 500 ml of *M*/40 vanadyl sulfate were heated in presence of 100 ml of 4 *M* HNO_3 for 4 h. The p*H* was then adjusted to 2.7 by the addition of NaOH. A yellow colored sample which was slightly soluble in HNO_3 was obtained. Its ion exchange capacity for Na^+ was 0.32 mequiv./g of dry exchanger.

(*iii*) 400 ml of *M*/40 vanadyl sulfate were heated with 50 ml of 4 *M* HNO_3 till the solution became yellowish indicating the oxidation of V(IV) to V(V). Now, 450 ml of *M*/40 titanium(IV) sulfate were added and the p*H* was adjusted to 2.7. A yellowish muddy precipitate was obtained which was soluble in HNO_3 on keeping for 24 h.

(*iv*) 50 ml of H_2O_2 (20 vol) were added to a mixture of 500 ml of *M*/40 titanium(IV) sulfate and 500 ml of *M*/40 vanadyl sulfate solution. The contents were refluxed for 8 h. The yellow precipitates obtained were soluble in HNO_3.

(b) Using Titanium(IV) and Vanadium(V) Solution

0.5 *M* solutions of titanium(IV) chloride and of vanadium(V) were mixed in two volume ratios (1:1 and 1:2). The p*H* (0) was adjusted by adding NaOH. The precipitates thus obtained were digested at room temperature for 24 h, washed and decanted several times and filtered. They were washed again with demineralized water until the filtrate was free from titanium and vanadium. After drying at 40 °C in an oven, the material was immersed in water to crack it into small uniform particles. They were then sieved to obtain particles of appropriate mesh size. The ion exchanger, thus prepared, was converted into H^+ form with 1–2 *M* HNO_3 as usual and subjected to ion exchange studies after washing with demineralized water and drying at 40 °C. Three samples were also prepared by adjusting the p*H* (1, 0.5, and 0) with urea instead of NaOH. Urea gives ammonia on slow hydrolysis. Table 1 summarizes the conditions of preparation and some properties of these samples.

Chemical Stability

Out of the five samples listed in Table 1 sample No. 1 was found to be fairly stable in water and mineral acids. Other samples dissolved continuously on prolonged standing with these solvents. Further ion exchange studies were, therefore, performed on sample 1.

Chemical stability of titanium(IV) vanadate (sample 1) heated to different temperatures was determined in water and 0.5 *M* HNO_3. For this purpose 500 mg of the sample were heated to the specified temperature and then shaken in 50 ml of the solvent for 6 h at room temperature. A shaking period of 6 h was chosen because it is the maximum time usually required in a column operation during separations. The dissolved amounts of titanium and vanadium were determined simultaneously (10) by spectrophotometry. Table 2 summarizes the results.

Composition

100 mg of the exchanger were dissolved in 10 ml of concentrated HCl and diluted to about 100 ml with water. Titanium was separated from vanadium by the sodium peroxide method (11). The precipitate of titanium peroxyhydroxide so obtained was redissolved in 10 ml of concentrated HCl; titanium was determined volumetrically with ferric ammonium sulfate (ref. 12, p. 1104). The filtrate containing vanadium was made acidic by adding HCl followed by 10 ml of 10% H_2SO_4. Vanadium(V) was reduced

TABLE 2. Chemical stability of titanium(IV) vanadate heated to different temperatures

Serial No.	Temperature (°C)	Amount dissolved (%) in 0.5 *M* HNO_3 Ti(mg)	in 0.5 *M* HNO_3 V(mg)	In water Ti(mg)	In water V(mg)
1	40	0.94	1.76	0.00	0.00
2	100	0.92	1.55	0.00	0.00
3	200	1.52	1.28	0.00	0.00
4	300	0.76	2.38	0.026	0.06
5	400	0.22	6.5	0.004	0.04
6	500	1.76	15.95	0.02	1.09
7	700	0.25	1.64	0.04	0.45

to vanadium(IV) by passing SO_2 into the solution at room temperature. Excess of SO_2 was completely removed by heating the solution for a long time and bubbling CO_2 through it to hasten the removal. Vanadium was determined volumetrically (ref. 12, p. 1212) with $KMnO_4$. Repetition of experiments showed that the results were consistent and reproducible. Thus, the Ti:V mole ratio in the titanium vanadate was observed to be 1:3.9 as determined on the basis of this elemental analysis.

Physical Properties

Titanium(IV) vanadate is in the form of darker brown opaque particles which can be used for column operations. They suffer no change in physical appearance when immersed in dilute mineral acid solution (up to 0.5 *M*). The material is unstable in 1 *N* NaOH. Strong acid solutions also dissolve it to some extent.

(a) Ion Exchange Properties. Ion exchange capacity of the exchanger for Na^+, K^+, Ba^{2+}, and Mg^{2+}, determined as usual by the column method, was found to be 0.65, 0.72, 0.61, and 0.42 mequiv./g, respectively. The initial p*H* values of Na^+, K^+, Ba^{2+}, and Mg^{2+} solutions were 6–7, 6–7, 5–6, and 5–6, respectively.

(b) Concentration and Elution Curves. It was observed that the elution of hydrogen ions from a column of the exchanger depends upon the eluent concentration. As the eluent (KCl) concentration increased, so were the milliequivalents of hydrogen ions eluted, attaining a maximum value with 1 *M* KCl. On taking a column of 1 g titanium vanadate in H^+ form and eluting it with 1 *M* KCl it was found that almost all H^+ ions are eluted in the first 60 ml of the KCl solution.

(c) pH-Titration. The p*H* titrations were performed by the method of Topp and Pepper (13).

(d) Thermogravimetry. Figure 1 shows the thermograms for titanium(IV) vanadate in the hydrogen as well as in the potassium form. The heating rate was kept at 4 °C per min.

(e) X-Ray Studies. The X-ray diffraction pattern of titanium vanadate reveals the fact that the exchanger is noncrystalline.

(f) Infrared Spectroscopy. This study was made by the KBr disk method. The spectrum is shown in Fig. 2.

(g) Distribution Coefficients. Distribution studies on the exchanger were performed by taking 0.5 g of the exchanger and shaking it with 100 ml of the solution containing 0.5 ml of the stock solution of the cation concerned for 6 h. Equilibrium is attained within 6 h since the K_d value does not change on shaking the exchanger with the solution of the cation concerned for more than 6 h. The amount of the cation present in the solution did not exceed 3% of the total ion exchange capacity of the exchanger. The amount of the

5	Sr(II)	20 400	12	Sm(III)	12 400
6	Ba(II)	2 560	13	Zr(IV)	377.7
7	Pb(II)	25 800	14	Th(IV)	944

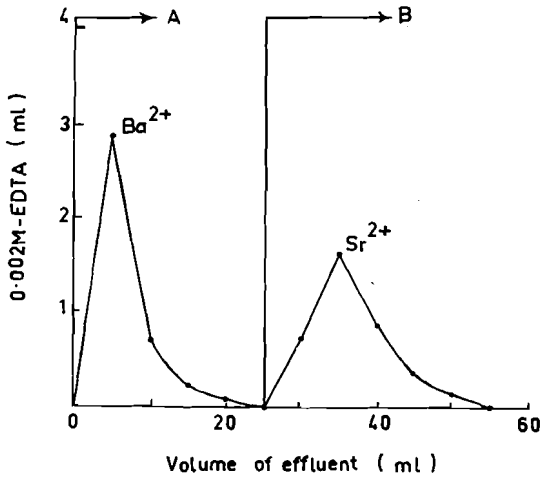

FIG. 3. Separation of Ba^{2+}–Sr^{2+}. *A*, 0.01 *M* HNO_3; *B*, 0.1 *M* HNO_3.

cations before and after equilibrium were determined by titrating with 0.002 *M* EDTA. The distribution coefficients were then calculated by the formula:

$$K_d = \frac{I - F}{F \times W} \times 100$$

where I = volume of EDTA used before equilibrium; F = volume of EDTA used after equilibrium, W = weight of the exchanger taken in g.

Table 3 lists the K_d values.

Separations

Depending upon the K_d values the following quantitative separations were achieved on a 3.9 mm (i.d.) column taking 2 g of the exchanger. A constant flow rate of 4–5 drops per min was maintained.

(a) Separation of Ba^{2+} from Sr^{2+}. A mixture of 308.4 μg of Sr^{2+} and 533.0 μg of Ba^{2+} was applied to the column. Ba^{2+} and Sr^{2+} were eluted using 0.01 and 0.1 *M* HNO_3, respectively (Fig. 3).

(b) Separation of Mg^{2+} from Sr^{2+}. 190.7 μg of Mg^{2+} with 308.4 μg of Sr^{2+} were applied to the column. 0.001 *M*

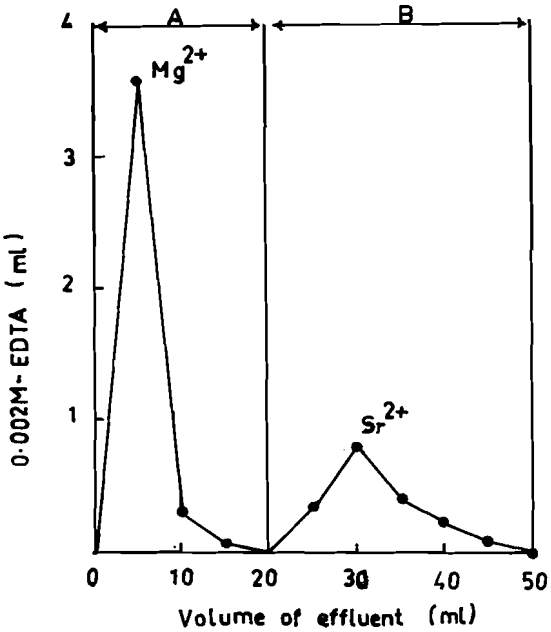

FIG. 4. Separation of Mg^{2+}–Sr^{2+}. *A*, 0.001 *M* HNO_3; *B*, 0.1 *M* HNO_3.

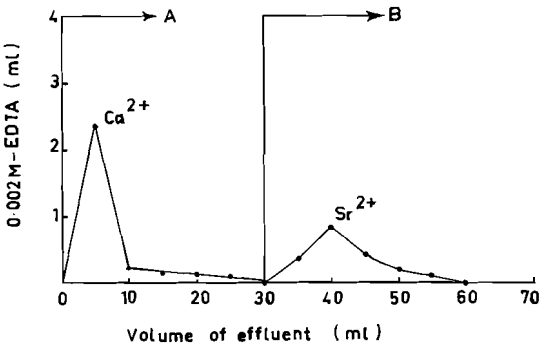

FIG. 5. Separation of Ca^{2+}–Sr^{2+}. *A*, 0.001 *M* HNO_3; *B*, 0.1 *M* HNO_3.

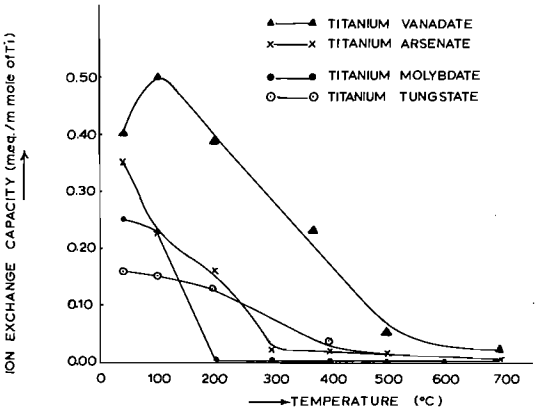

FIG. 6. Ion exchange capacity as a function of temperature for some titanium-based ion exchangers.

HNO_3 and 0.1 *M* HNO_3 were used as eluents for Mg^{2+} and Sr^{2+}, respectively (Fig. 4).

(c) Separation of Ca^{2+} from Sr^{2+}. A mixture of 229.25 μg of Ca^{2+} and 308.4 μg of Sr^{2+} was applied. Ca^{2+} and Sr^{2+} were eluted with 0.001 and 0.1 *M* HNO_3, respectively (Fig. 5).

Effect of Temperature on Ion Exchange Capacity

The sample previously dried at 40 °C was heated to different temperatures and the ion exchange capacity of the substances obtained was determined as usual. Figure 6 shows the effect of heating on the ion exchange capacity of some ion exchangers based on titanium.

Results and Discussion

The high thermal stability and the specificity for strontium are two unique features of titanium vanadate and in these aspects it stands out from other titanium based exchangers. Figure 7 compares the separation factors of Mg^{2+}, Ca^{2+}, and Ba^{2+} with respect to Sr^{2+} on titanium vanadate, arsenate (14), molybdate (15), antimonate (16) and tungstate (17). It is very interesting to see that the general trend is the same *i.e.*, the separation factor first decreases and then increases as we go from vanadate to tungstate. The values of α^{Sr}_{Mg} and α^{Sr}_{Ba} are highest for titanium vanadate and show the specificity of the exchanger for strontium. The α^{Sr}_{Ca} is greater for titanium arsenate than for vanadate. This is misleading, however, since the actual K_d values of Sr and Ca on titanium arsenate are low (Fig. 8) and do not have much significance. In fact strontium could not be separated from calcium on its columns. Titanium vanadate, on the other hand, is highly selective for Sr^{2+} and therefore strontium has been easily separated from Mg^{2+}, Ca^{2+}, and Ba^{2+} on this ion exchanger (Figs. 3–5). The unusually strong adsorption of Sr^{2+} on titanium vanadate can be explained on the basis of the solubility of the

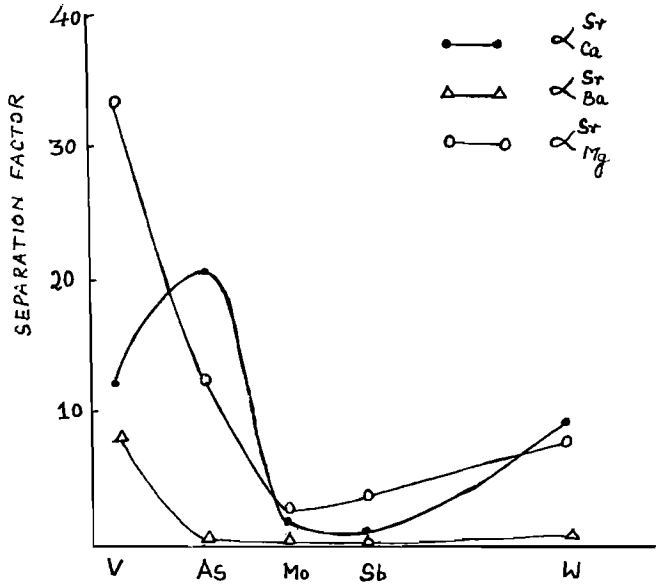

FIG. 7. Separation factors *vs.* atomic number of the main acidic element in the exchanger.

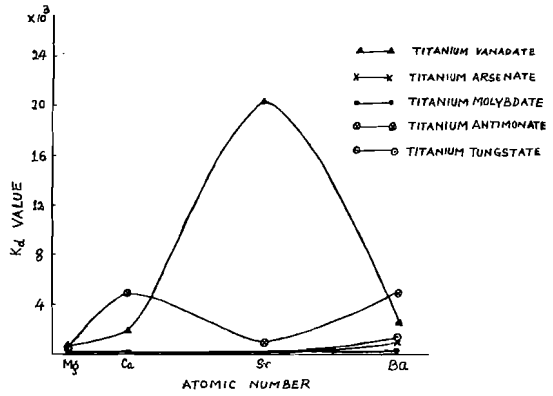

FIG. 8. K_d values of alkaline earths on some titanium-based ion exchangers.

alkaline earth vanadates. Accurate solubility data are not available. The records (18) show, however, that strontium metavanadate is sparingly soluble in water while calcium metavanadate is more soluble than the strontium salt. Barium and magnesium metavanadates are described as soluble and freely soluble. The K_d values faithfully correspond to the solubility data. It appears probable that the high K_d value of strontium is due to the specific interaction of Sr^{2+} ions with the exchanger resulting in ion-pair formation. However, further studies are in progress to prove this point.

Distribution coefficients of metal ions on an ion exchanger depend upon their ionic radii. Thus, the normal sequence for K_d values of alkaline earths should be

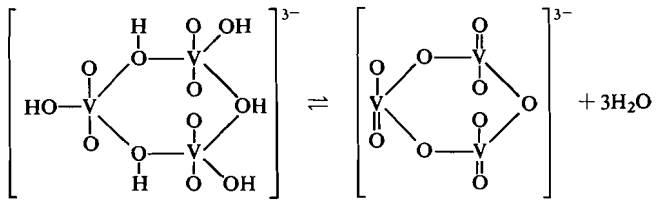
$$Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$$

A comparative study of the K_d values on the most stable samples of different titanium-based ion exchangers shows that the molybdate, tungstate, and arsenate follow the above sequence. On titanium antimonate calcium has a higher K_d value than strontium. This exchanger has been used for the separation of Mg^{2+} from Ca^{2+} and Sr^{2+}. On titanium vanadate the K_d value of strontium is greater than that of barium while other ions follow the normal sequence. The unique feature of this exchanger is that this is the only exchanger on which strontium has a higher K_d value than barium, calcium, and magnesium. In fact the K_d value for Sr^{2+} is unusually high and its separation from Ba^{2+}, Ca^{2+}, and Mg^{2+} has been practically achieved.

The titanium(IV) vanadate exchanger is prepared at p$H < 1$. The elemental analysis indicates that the product has the Ti/V ratio 1:4 although the solutions were mixed in 1:1 mole ratio. The excess of titanium is washed out during filtration and the acid treatment of the exchanger. The following equilibrium is known to exist (ref. 19, p. 812) for vanadium at the pH of the preparation of titanium(IV) vanadate:

$$3[VO_3(OH)]^{2-} + 3H^+ \rightleftharpoons V_3O_9^{3-} + 3H_2O \quad (K = 10^{-30.7})$$

The trimeric species may be considered to be built up from VO_2^+ ions and the following equilibrium probably exists



Also, in 1 M acid the titanium species in the solution would be basic consisting of $(TiO)_n^{2+}$ or $Ti(OH)^{3+}$ chains (ref. 19, p. 803). Since the Ti:V ratio is 1:4 in the sample a tentative formula may be suggested on the basis of the possible aqueous species in acidic media:

$$[Ti_3(V_3O_9.1.5\ H_2O)_4.13\ H_2O]_n$$

The number of external water molecules per mole of the exchanger has been calculated by the method of Alberti *et al.* (20) from thermogravimetric analysis (Fig. 1). These molecules are lost from the exchanger when it is heated to 180 °C (% wt loss at this temperature = 14.4). Above this temperature condensation begins. This process continues up to 370 °C when six more water molecules are lost. After 370 °C the weight becomes constant due to the formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

anhydrous titanium vanadate (21) in which the weight loss continues up to 371 °C when anhydrous barium vanadate [$Ba(VO_3)_2$] is obtained. In amperometric studies on thorium vanadate, Saxena and co-workers (3) also found Th:V ratio of 1:4 in acidic medium and suggested the formula [$ThO_2.2V_2O_5$] for the metavanadate formed. The pH titration curve shows only one break. The exchanger is therefore a monofunctional weak cation exchanger like other ion exchangers reported from this laboratory. The exchange reactions are reversible and the resolution of the cation occurs with consequent regeneration of titanium vanadate on washing with acid.

The effect of temperature on the ion exchange capacity of some titanium based exchangers has been plotted in Fig. 6. The ion exchange capacity of all exchangers is calculated in terms of mequiv./mmol of Ti per fixed weight of the exchanger taking into consideration different chemical transformations based on thermogravimetric studies. These curves clearly show that in comparison with other ion exchangers of this class, titanium vanadate has the highest ion exchange capacity and thermal stability. There is an increase in ion exchange capacity when the sample is heated to 100 °C owing to the irreversible loss of some external water molecules. If we assume that the unbridged hydroxyl groups are the exchangeable groups, then the ion exchange capacity would approach 1 mequiv./mmol of Ti. However, the observed value at 100 °C is 0.5. After this temperature the capacity decreases and at ~200 °C it becomes 0.43 mequiv./mmol of Ti which is equal to the value at room temperature. Thus, the removal of external water molecules does not, obviously, effect the ion exchange capacity. Above this temperature, the capacity decreases, probably because of the loss of exchangeable hydroxyl groups during condensation. At 370 °C the capacity is 0.23 mequiv./mmol of Ti although all of the exchangeable sites have been lost at this temperature according to the following chemical transformation

$$Ti_3(V_3O_9.1.5H_2O)_4 \rightarrow 3[TiO_2.2V_2O_5] + 6H_2O$$

The exchange capacity further decreases until it becomes negligibly small (0.05 at 500 °C). The persistance of the ion exchange capacity even after the exchanger has been heated to a

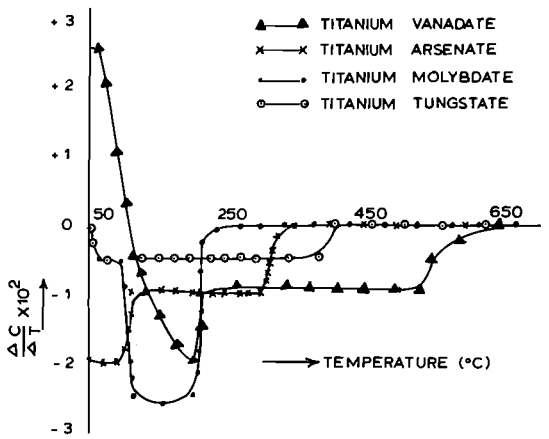


FIG. 9. Plot of $\Delta C/\Delta T$ *vs.* temperature.

temperature when the condensation has taken place can be explained on the basis of the surface hydroxyl groups present on the $(TiOH)^{3+}$ chains. After heating, the surface can rehydrate in water to re-establish these groups, thus showing the ion exchange capacity. Other ion exchangers lose their ion exchange capacity almost completely at much lower temperatures (Fig. 6). The unique thermal behavior of titanium vanadate is made clearer by considering Fig. 9. $\Delta C/\Delta T$ is defined as the rate of change of capacity with temperature, the capacity being measured in mequiv./mmol of Ti per fixed weight of the exchanger. It is quite interesting to note that except for titanium vanadate all the ion exchangers based on titanium suffer a loss in ion exchange capacity on heating as the negative value of $\Delta C/\Delta T$ suggests, the rate of loss being maximum for titanium molybdate at 100 °C. For titanium vanadate $\Delta C/\Delta T$ becomes zero at 100 °C indicating the maximum ion exchange capacity at this temperature.

Contrary to our earlier experience with titanium tungstate (17) there is no significant increase in stability on heating the exchanger to higher temperatures. When the exchanger is heated to 500 °C it dissolves more in water than if it is heated to either 400 or 700 °C (Table 2). It is difficult to explain this behavior satisfactorily. The thermogram shows that on heating, the exchanger in K^+ form suffers a greater weight loss than the one in H^+ form. This is probably because the sample is more hydrated in K^+ form. This behavior is similar to that of stannic molybdate (22).

From i.r. spectrum of the titanium vanadate (Fig. 2) we draw the following conclusions:

There are four peaks observed in the spectrum at the frequency ranges ~ 3400, ~ 1600, ~ 1000, and $\sim 500\ cm^{-1}$. The strong but broad peak at $3400\ cm^{-1}$ is characteristic (23) of free water and OH groups. The strong peak at $1600\ cm^{-1}$ also represents the free water molecules. Vanadate has its characteristic frequency (24) between 800 and $1000\ cm^{-1}$. It is therefore represented by the third sharp peak at $1000\ cm^{-1}$. The last strong peak at $\sim 500\ cm^{-1}$ is due to the presence of Ti—O bonds (25) in the structure.

The authors thank Dr. S. M. F. Rahman for research facilities. Dr. B. Rama Rao (RRL, Hyderabad) and Dr. H. V. K. Udupa (C.E.C.R.I. Karaikudi, Madras) are thanked for their help in X-ray and thermogravimetric studies. An Electron Paramagnetic Resonance Study of a fast Lewis Acid–Base Reaction between Copper(II) bis(Diethyldithiocarbamate) and Pyridine in Benzene

J. B. FARMER, F. G. HERRING,[1] AND R. L. TAPPING

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received February 4, 1972

The fast Lewis acid–base reaction between copper(II) bis(diethyldithiocarbamate) and pyridine

$$Cu(DDC)_2 + \text{pyridine} \rightleftharpoons Cu(DDC)_2.\text{pyridine}$$

has been studied from 280 to 320 °K in benzene. The method employed is the analysis of electron paramagnetic resonance line positions and line widths using the solutions of the modified Bloch equations in the fast exchange limit. Arrhenius plots, over the temperature range employed, gave values for the thermodynamic data of the process.

La réaction rapide acide de Lewis acid–base entre le bis(diéthyldithiocarbamate) de cuivre(II) et la pyridine

$$Cu(DDC)_2 + \text{pyridine} \rightleftharpoons Cu(DDC)_2.\text{pyridine}$$

a été étudiée dans le benzène entre 280 et 320 °K. La méthode utilisée est l'analyse par résonance paramagnétique électronique des positions de raies et des largeurs de raies en utilisant les solutions des équations modifiées de Bloch dans la limite d'un échange rapide. Les courbes d'Arrhenius, sur l'échelle de température utilisée, donnent les valeurs qui se rapportent aux données thermodynamiques du processus.

Canadian Journal of Chemistry, **50**, 2079 (1972)

Introduction

The effects of adduct formation on the electronic and magnetic properties of neutral bis chelates of the cupric ion have been the subject of recent investigations (1–10). Of particular interest here is the interaction of Lewis bases with four coordinate square planar Cu(II) chelates to form five coordinate adducts in solution.

Adduct formation is often characterized by an equilibrium of the type

$$[1] \qquad ML_2 + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} ML_2B$$

where ML_2 is the metal bis chelate and B the Lewis base. If both the species ML_2 and ML_2B are paramagnetic and the forward (k_f) and back (k_r) reaction rates are in the range 10^7 to 10^9 s^{-1} then such an equilibrium can be treated as a two jump system on the e.p.r. time scale. An e.p.r. line width variation can therefore be expected if there is sufficient difference between the spin Hamiltonian parameters of ML_2 and ML_2B. Provided that these various conditions are met and if the system is studied over a temperature range the equilibrium constant (K), the rate constants (k_f and k_r), and thermodynamic data can be extracted from the line positions and line widths using the solutions to the Bloch equations in the fast or near-fast exchange limit (11–14). Some complications may arise due to rotational correlation times and non-secular terms (15) in the expression for $1/T_2$; these are discussed later.

The work of Aasa *et al.* (6) suggested that the interaction between copper(II) bis(diethyldithiocarbamate) [$Cu(DDC)_2$] and various organic bases in suitable solvents would be an appropriate system to study the applicability of the approach outlined in the previous paragraph. Aasa *et al.* noted line position and line width shifts that varied with ligand concentration but did not interpret them in terms of a Lewis acid–base equilibrium. Whilst this work was in progress two other studies appeared in the literature by Corden and Rieger (9) and Shklyaev and Anufrienko (10). The former workers studied the e.p.r. of copper(II) bis(di-*n*-butyldithiocarbamate) with a number of bases and obtained equilibrium constants, rate constants, and thermodynamic data but also observed certain inconsistencies in the interpretation of their experimental data. Shklyaev and Anufrienko studied $Cu(DDC)_2$ and pyri-

dine in toluene (10); their results will be compared to ours later.

Experimental

The determination of equilibrium and reaction rate constants requires an analysis of line positions and line widths. To avoid the complication of the two naturally occurring isotopes of copper (^{63}Cu and ^{65}Cu) in such an analysis, copper(II) bis(diethyldithiocarbamate) was prepared from isotopically pure ^{63}Cu, this being obtained from UKAEA, Harwell, England. The pure copper metal was converted to copper(II) nitrate by reaction with nitric acid. The nitrate anions were replaced by chloride anions by repeated reaction with hydrochloric acid. The pure $CuCl_2.2H_2O$ so obtained was then added to an excess of sodium diethyldithiocarbamate in absolute ethanol. The resultant crude $Cu(DDC)_2$ was recrystallized several times from benzene, yielding shiny dark green – brown needles.

The solvents, benzene and pyridine, used in the study were of spectro-grade quality and were kept under nitrogen. Gas chromatographic analysis showed no trace of impurity. It is important to note here that benzene and pyridine are miscible in all proportions and that $Cu(DDC)_2$ is soluble in both of them. Further, since the results were to be least-squares fitted, the number of solutions (usually about 12) was always three times greater than the number of parameters to be fitted. A series of solutions containing the required solvent mixture and a weighed amount of $^{63}Cu(DDC)_2$ were prepared. These solutions were placed in silica sample tubes suitable for an e.p.r. machine and then degassed on a vacuum line. All e.p.r. spectra were recorded within 1–2 h of sample preparation; no decomposition was apparent. Typically the copper ion concentration was 10^{-4} M, exchange broadening being absent at such concentrations.

Spectra were recorded on a Varian E-4 spectrometer, equipped with a Varian (V6040) variable temperature accessory. Figure 1 shows the effect on the line widths upon adding pyridine to a sample of $Cu(DDC)_2$ in benzene. Field calibration was made with a proton resonance magnetometer. The microwave frequency was monitored with a Hewlett–Packard 5425L counter equipped with an X-band plug-in unit. Absolute field position measurements were accurate to ± 0.2 G and the frequency reproducible to ± 20 kHz in 9 GHz. The g-value measurements are reliable to ± 0.0002 and hyper-fine splittings to ± 0.05 G. Calibration of the thermocouple used in temperature measurement indicated that the maximum absolute error in the thermocouple was less than 0.02 °C and that the temperature variation over a particular spectrum was never more than ± 0.2 °C. The error in actual sample temperature as compared to the thermocouple reading was usually $\leqslant \pm 0.5$ °C.

The calculations reported in this work were carried out on an IBM360/67 using programs written in this laboratory.

The line widths measured in the present study were corrected for the effect of modulation amplitude using Wahlquist's equation (16).

Results

The chemical equilibrium considered here

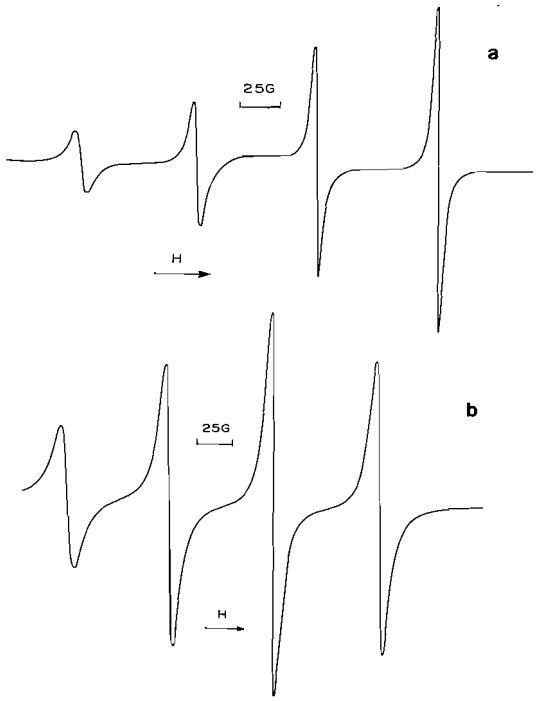

FIG. 1. (*a*) Electron paramagnetic resonance spectrum of $Cu(DDC)_2$ in benzene at 300 °K; (*b*) e.p.r. spectra of $Cu(DDC)_2$ with approximately 1 M pyridine in benzene at 300 °K.

can be treated by the modified Bloch equations as a two jump problem between the two inequivalent sites ML_2 and ML_2B, designated A and B, respectively. The general solution to this problem (13) yields the total complex magnetic moment

$$[2] \quad G = G_A + G_B = \frac{-i\gamma H_1 M_0[\tau_A + \tau_B + \tau_A\tau_B(\alpha_A P_A + \alpha_B P_B)]}{(1 + \alpha_A\tau_A)(1 + \alpha_B\tau_B) - 1}$$

where $\alpha_A = T_{2A}^{-1} - i(\omega_A - \omega)$, ω_A is the Larmor frequency of site A, T_{2A}^{-1} is the inverse of the transverse relaxation time of site A, τ_A is the mean lifetime for a stay on the site A, and P_A is the fractional population of site A ($P_A = 1 - P_B = \tau_A/(\tau_A + \tau_B)$).

When τ_A and τ_B are small compared to the inverse of the difference between the respective Larmor frequencies then eq. 2 has the solution

$$[3] \quad G = \frac{-i\gamma H_1 M_0}{P_A\alpha_A + P_B\alpha_B}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which corresponds to the limit of fast exchange. The absorption line shape is proportional to the imaginary part of eq. 3, v, and is specifically

$$[4]\quad v = -\gamma H_1 M_0 \times \frac{T_2}{1 + (T_2)^2(P_A\omega_A + P_B\omega_B - \omega)^2}$$

i.e., we have a Lorentzian line shape. Equation 3 represents a single exchange signal centered at a mean frequency

$$[5a]\quad \langle\omega\rangle = P_A\omega_A + P_B\omega_B$$

with a mean line width

$$[5b]\quad T_2^{-1} = P_A T_{2A}^{-1} + P_B T_{2B}^{-1}$$

Experimentally it is nearly always impossible to reach the extreme fast exchange limit represented by eq. 4 and in general the observed line may not be completely collapsed so that the observed width will be greater than that given by eq. 5*a*. The line will still be centered at $\langle\omega\rangle$, however. To take this fact into account an effective transverse relaxation time can be given (13, 18, 19)

$$[6a]\quad T_2^{-1} = P_A T_{2A}^{-1} + P_B T_{2B}^{-1} + P_A^2 P_B^2(\tau_A + \tau_B)(\omega_A - \omega_B)^2$$

$$[6b]\quad = P_A T_{2A}^{-1} + P_B T_{2B}^{-1} + P_A^2 P_B \tau_B(\omega_A - \omega_B)^2$$

Consider first the determination of the equilibrium constant $K = (k_f/k_r)$. Let T_{ML_2} and T_B be the total concentrations of complex and base respectively, then $K = C/(T_{ML_2} - C)(T_B - C)$ where C is the equilibrium concentration of the adduct. Under the present experimental conditions $T_{ML_2} \ll T_B$, consequently $T_B \gg C$; whence $K = C/T_B(T_{ML_2} - C)$. Remembering that $\tau_B = 1/k_r$ and $\tau_A = 1/k_f(T_B - C) \simeq 1/k_f T_B$ we have $P_A = 1/(1 + KT_B)$ and $P_B = KT_B/(1 + KT_B)$; thus

$$[7]\quad \langle\omega\rangle = \frac{1}{(1 + T_B K)}\omega_A + \frac{KT_B}{(1 + KT_B)}\omega_B$$

using eq. 5*a*.

The $\langle\omega\rangle$ values for each hyperfine line as a function of ligand concentration were obtained by carrying out a least-squares fit of the isotropic form of Bleaney's equation (up to second order in the hyperfine coupling constant (A_0) and the **g**-tensor ($\mathbf{g}_0$))

$$[8]\quad \mathrm{H}(m_I) = H_0 - A_0 m_I - \frac{A_0^2}{2H_0}[I(I+1) - m_I^2]$$

in the usual notation (17).

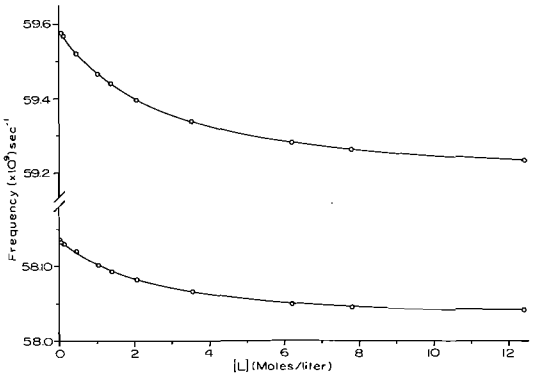

FIG. 2. Variation of e.p.r. line position with pyridine concentration [L]. The top and bottom curves correspond to +3/2 line and +1/2 lines, respectively, at 300 °K.

With these exchange averaged values of A_0 and $\mathbf{g}_0$ the frequency of any hyperfine line could be computed for any chosen microwave frequency. The variation of the position of the +3/2 and +1/2 lines is shown in Fig. 2. These plots confirm that eq. 5*a* is applicable to the present investigation. It should be noted here that only the high fields +3/2 and +1/2 ($A_0 < 0$) were employed in the line position and line width analysis since the other two lines are often considerably broadened and tend to overlap.

The equilibrium constant and the values of ω_A and ω_B were obtained from the line position data by means of a three parameter least-squares fit of eq. 7 with T_B as the independent variable and $\langle\omega\rangle$ as the dependent variable. This procedure obviates any necessity of determining ω_A and ω_B from measurements in pure solvents (benzene and pyridine in this case). A rigorous test of this procedure, and its efficacy, is that the determined values of ω_A and ω_B could be used in the estimation of the rate constants (see later); Corden and Rieger (9) found this impossible. In addition these workers found it necessary to constrain $(\omega_A - \omega_B)$ to be constant over the range of temperatures they studied; obviously, we did not find this necessary. The free variation of ω_A and ω_B in the analysis of the line position and line width data gives internally consistent results in the present work.

*Value obtained from least-squares fit.
†Value obtained from measurement in neat solvent.
‡The value of K is the average between the values for the two hyperfine line studies; uncertainty ± 0.02.

The results of fitting the line position data, for the particular temperature 300 °K, to eq. 7 are shown in Fig. 2 as an example. The fit is seen to be excellent. The line position measurements were carried out over the temperature range 280 to 325 °K. The determined values of ω_A, ω_B, and K for this temperature range are given in Table 1; also contained in this table are the values of ω_A and ω_B obtained from measurements on the pure solvents. Table 2 contains the thermodynamic data, for the temperature of 300 °K, obtained from the Arrhenius plot for the equilibrium constant; see Fig. 3.

We note here that it is also possible to obtain K from a similar fit to the expression

$$\langle A \rangle = P_A A_A + P_B A_B$$

for the average value of the isotropic hyperfine splitting. This was in fact carried out and entirely consistent results for K were obtained. This is the method employed by Shklyaev and Anufrienko (10). The values of A_A and A_B are given in Table 3 together with the corresponding equilibrium constants.
