We turn now to a discussion of the determination of the rate constant k_r. The estimation of a rate constant requires the analysis of line width data in conjunction with an equation of the type given in eq. 6. It was found, however, that eq. 6 does not adequately fit the line width behavior observed in the present case. An order of magnitude calculation indicated that the non-secular terms included by Atherton and Luckhurst (15) become important at low pyridine concentrations. The reason for this can be seen if we consider the equation for T_2^{-1} given by Atherton and Luckhurst (15).

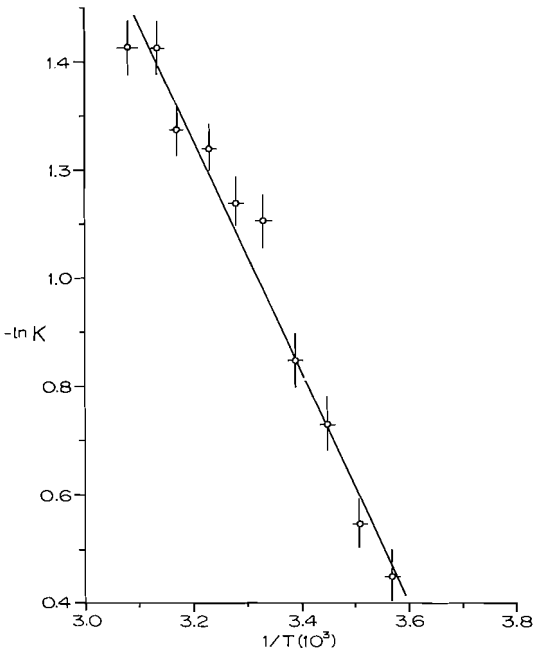

FIG. 3. Arrhenius plot for the equilibrium constant (K).

[9] $$T_2^{-1} = P_A T_{2A}^{-1} + P_B T_{2B}^{-1} + P_A^2 P_B \tau_B \times \left\{ (\omega_A - \omega_B)^2 + \frac{\Delta A}{2} \frac{[I(I+1) - m^2]}{(1 + \omega_0^2 P_A^2 \tau_B^2)} \right\}$$

where $\Delta A = A_A - A_B$. At low temperatures ΔA increases to the point where this non-secular contribution approaches 20% of the transverse relaxation time for the system under study here.

Corden and Rieger, however, found it necessary to include extra terms derived from eq. 2. We have found that these terms afforded only a small improvement which did not warrant their inclusion since this greatly increased the computational time involved. In any event these corrections are certainly smaller than the errors introduced by neglecting non-secular, pseudo-secular, and rotational terms (14, 15).

Accordingly, the line width data were fitted by applying the least-squares techniques to eq. 9 with T_{2A}, T_{2B}, and τ_B as parameters, the values of A_A, A_B, ω_A, and ω_B having been determined previously from the line position data. The values of T_{2A}, T_{2B}, and k_r obtained in this way are given in Table 4. A comparison of the experimental and fitted line width data is given in Fig. 4 and it is seen that the overall fit is quite satisfactory. The rate constants were obtained at various temperatures; the Arrhenius plot that can be constructed from this data is shown in Fig. 5. The thermochemical data estimated, for the temperature 300 °K, from the temperature variation of the rate constants are given in Table 2. Line widths were also measured in neat solvents and are reported in Table 4.

Discussion

The results of the least-squares fitting of the line position data, given in Table 1, show that the line positions measured in pure benzene are somewhat less than those obtained by the fit; similarly those measured in neat pyridine are

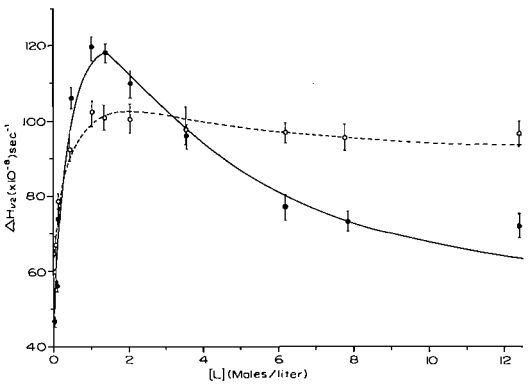

FIG. 4. Variation of e.p.r. linewidth data at 300 °K for the +3/2 line (solid) and +1/2 (dotted) line.

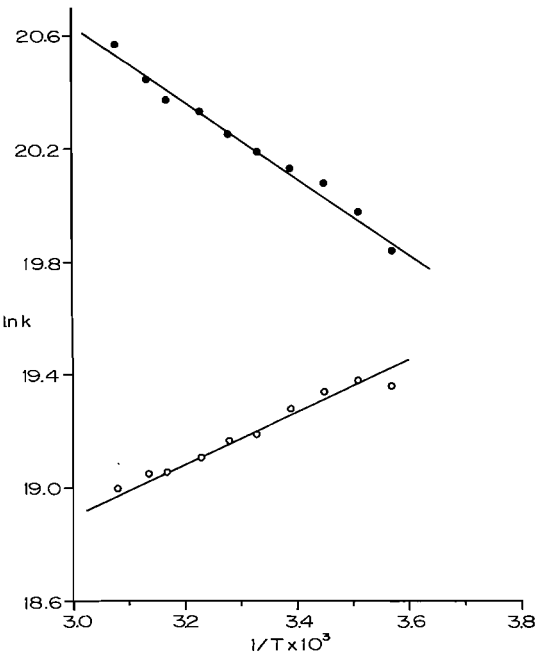

FIG. 5. Arrhenius plots for the forward (open circles) and reverse (solid circles) rate constants.

less than the fitted values. The latter result is readily understood when one appreciates that even in pure pyridine the equilibrium concentration of ML_2B is only 80% of that of ML_2, *i.e.*, fast exchange is still in evidence. The fitted value of $\langle\omega\rangle$ at 12.4 M pyridine is 63.76×10^6 s^{-1} at 285 °K which is well within experimental error of that measured in neat pyridine (62.86×10^6 s^{-1}). This result suggests that it is inappropriate to fix the value of ω_B to that measured in the pure solvent and that fitting involving a free variation of ω_B (and ω_A) is the preferred procedure.

The fact that ω_A measured in pure benzene is less than that obtained by the least-squares technique would imply that there is indeed an interaction between the benzene solvent molecules and the $Cu(DDC)_2$. The pure benzene results were checked several times, always with the same finding. In order to check the behavior of the curve shown in Fig. 2, line position measurements were carried out at very low pyridine concentration (5×10^{-4} M). It was found that the measured line position fell on the extrapolation of the curve toward zero base concentration, *i.e.*, the curve did not turn down toward the value of ω_A measured in pure benzene. Thus it would appear that there is a small change in the solvation of $Cu(DDC)_2$ effected by the addition of pyridine. This result does not appear to have been observed by other workers (9, 10) who used ω_A measured in pure solvent. This finding supports the contention that ω_A and ω_B should be regarded as solvent interaction free parameters valid only in the fast exchange region and in fact are unattainable experimentally.

The isotropic hyperfine coupling, as expected, since the isotropic g-value varies little, exhibits a similar "anomalous" behavior. The difference between A_B measured in pure pyridine and least squares fitted can be explained in the same way as for ω_B. The fact that A_A in benzene is less than the fitted value suggests that the interaction between the solute and the solvent is such as to reduce the spin density on the copper atom; this in turn implies a delocalization of spin density into the benzene solvent molecules. It is tempting to suggest that there is in fact a fast exchange between the benzene solvent molecules and $Cu(DDC)_2$ but the line width data shown in Table 3 indicate that the temperature dependence of the line widths T_{2A} is dominated by a spin-rotational term (21, 22) so this can be discounted.

The results given in Table 4 show that fitting line width data to eq. 9 leads to values of T_{2A} and T_{2B} which vary over the temperature range studied in a manner that is quite consistent with what might be expected for the line widths based on the theory of Kivelson (22, 23). This fact lends support to the approach taken in analyzing the trends in line width data over varying ligand concentration. We note that

there are differences between the T_{2A}'s measured in neat benzene and those fitted; again this may be indicative of some sort of solute–solvent interaction but is more likely a result of the approximation inherent in our method of analysis.

The application of the Bloch equations to the study of chemical exchange is not always possible. Atherton and Luckhurst (15) have shown that when any of the lifetimes in an exchanging process become comparable to the rotational reorientation time of the complex in solution, then a relaxation matrix analysis of the reorientation–exchange problem does not reduce to a solution of the Bloch equations. The Bloch equations are generally valid, when the reorientational correlation time, τ_c, is much smaller than the exchange lifetime τ_{ex}, except for non-secular and pseudo-secular terms that can become important under certain conditions (14).

In the present case, analysis of our line width data in terms of the parameters derived by Kivelson suggests that the rotational reorientation time is $\sim 10^{-11}$ s, thus being several orders of magnitude shorter than τ_{ex} ($\sim 10^{-9}$ s). This result supports our use of the modified Bloch equation. In viscous solvents, or for reactions involving large molecules great care must be exercised to ensure the validity of any approximate procedures employed.

The viscosity dependence of line widths is well known and it is implicit in the present work that the variation in viscosity as the base concentration varies is small. This assumption, as pointed out by Corden and Rieger (9) means that the value of T_{2B} obtained corresponds to some average value and this may well be the reason for the discrepancy between T_{2A} fitted and measured in neat benzene.

The results of previous work (9, 10) and our own are collected in Table 2. The results for the equilibrium constants for the reactions

$$\text{Cu(DnBDC)}_2 + \text{pyridine} \rightleftharpoons \text{Cu(DnBDC)}_2\text{.pyridine}$$

$$\text{Cu(DDC)}_2 + \text{pyridine} \rightleftharpoons \text{Cu(DDC)}_2\text{.pyridine}$$

are in reasonable agreement. The amount of data reported so far is too small to reach any conclusions as to the acid-strength of the two copper complexes studied or as to the different solvent effects between benzene and toluene (10). The temperature dependence of the equilibrium constants is also similar and consequently leads to comparable values of ΔH^0 and ΔS^0.

The value of the reverse rate constant (k_r) will depend critically on the method of analysis of the line width data. The difference in the method employed by Corden and Rieger and the present work is quite marked. Thus for their study of the reaction between Cu(DnBDC)_2 and pyridine they (*a*) assumed that $(\omega_A - \omega_B)$ does not vary with temperature and (*b*) used the value for piperidine as they were unable to get a realistic fit of the line width data with pyridine; no such problems were met in the present work. We therefore feel that we cannot reasonably compare their lifetime data with ours except to say that theirs appear to be quite low in comparison with that measured here. The work of Shklyaev and Anufrienko (10) gave a rate of reaction in the reverse direction very similar to that obtained here (see Table 2).

The forward rate at 25 °C measured is about 2.2×10^8 s, and the question arises whether or not this reaction is diffusion controlled. Clarke and Wanye (20) indicate that diffusion considerations can only be safely ignored if $k_{obs} < 10^7$. The rates here are of the order of 10^8; consequently a diffusion controlled mechanism cannot be ruled out. This is the conclusion reached by Shklyaev and Anufrienko.

One interesting aspect of the present results is the fact that ΔH_f^* is negative. Corden and Rieger (9) obtained a value of approximately zero and felt that this result contradicted the idea of a diffusion controlled mechanism. The fact that k_f, measured here, decreases with increasing temperature also does not appear to correspond to a diffusion controlled mechanism since a diffusion controlled rate constant should increase with increasing temperature. The existence of an apparent negative energy of activation may reflect either an artifact of the approximations involved in the determination of $k_f(Kk_r)$, or may indicate that ΔS^* is varying over the temperature range studied. The reliability of the present result can only be established by further studies and these are being embarked upon.

Implicit throughout this work has been the assumption that only a 1:1 adduct is formed. Corden and Rieger (9) consider the possibility of 1:2 adduct formation (CuL_2B_2), but consideration of previous results (24–28) indicates

that a 1:2 adduct is not formed to an extent sufficient to affect the e.p.r. results, even in neat pyridine solution.

The formation of two adducts is very likely to be a step-wise process (24), involving a very fast 1:1 followed by a relatively slow 1:2 adduct formation. Stereochemical arguments have been invoked to show that in solution the addition of a sixth ligand is extremely unfavorable for planar Cu(II) complexes (25–28) and undoubtedly the second stepwise formation constant will be much less than the first (24), so that very little, if any, 1:2 adduct would be formed. The effects of such a slow modulation on an existing fast exchange e.s.r. spectrum would not be evident unless the concentration of the 1:2 adduct was a significant fraction of the 1:1 adduct concentration, in which case two distinct spectra would be observable. This has not been observed here, but if it were, the effect of the second equilibrium process on the fast exchange situation would simply be a very small additional line broadening proportional to the lifetime of the 1:2 adduct.

Further, several authors have demonstrated that square planar complexes of copper(II), while definitely showing penta-coordination in solution with appropriate ligands, do not show any evidence of the formation of a hexa-coordinate complex in solution (25, 27, 28). It is likely, also, that any hexa-coordinate Cu(II) species would have properties significantly different from a penta-coordinate adduct, and would thus be readily observable by the methods utilized so far.

The Ultraviolet Absorption Spectrum of Furazan

B. J. FORREST AND A. W. RICHARDSON

Chemistry Department, Bishop's University, Lennoxville, Quebec

Received March 1, 1972

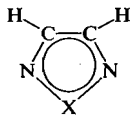
The ultraviolet absorption spectrum of furazan (1,2,5-oxadiazole) in the region 2500–2300 Å has been recorded and analyzed as a $\pi \rightarrow \pi^*$ transition from the planar ground state to a non-planar excited state having a potential barrier to planarity of about 215 cm^{-1}.

Le spectre d'absorption ultraviolet du furazane (1,2,5-oxadiazole) a été enregistré dans la région de 2500 à 2300 Å. L'analyse indique qu'il s'agit d'une transition $\pi \rightarrow \pi^*$ de l'état planaire fondamental vers un état excité non planaire ayant une barrière de potentiel de 215 cm^{-1} environ vis à vis de la planéité.

Canadian Journal of Chemistry, **50**, 2088 (1972)

Introduction

Furazan (1,2,5-oxadiazole) (**1**, X = O) has been shown by a microwave spectroscopic study (1) to be a planar molecule of C_{2v} symmetry with some aromatic character, and study of its infrared and Raman spectra (2, 3) has lead to assignments for all 15 normal modes of vibration. This paper reports the results of an investigation of the 2430 Å absorption spectrum of furazan. This study is of particular interest in light of a recent report of an investigation of the first u.v. absorption spectrum of 1,2,5-thiadiazole (**1**, X = S) which showed that, although the ground state is planar, the excited state is non-planar and has a barrier to planarity of about 460 cm^{-1} (4).



1

Experimental

Furazan was prepared by heating a mixture of solid glyoxime and succinic anhydride to 150–170 °C, as described by Olofson and Michelman (5), and purified by triple distillation. The i.r. spectrum of the liquid and vapor showed no signs of impurities and g.l.c. indicated a purity in excess of 99%.

The majority of the spectra were recorded on a Hitachi–Perkin–Elmer model 139 single beam spectrometer (modified for scanning and equipped with a photomultiplier) at a slit width giving a band pass of about 20 cm^{-1}. Some spectra were also recorded on a Bausch and Lomb 1.5 m grating spectrograph using a 150 W high pressure xenon lamp and Spectrum Analysis No. 1 film. Measurements of these spectra were made from prints enlarged about 15 times by interpolation between iron standards.

The spectra were obtained for the vapor in a 1 m fused silica absorption cell at sample pressures ranging from the vapor pressure at 0 °C to that at about 100 °C. Spectra were also taken with the sample pressure equal to the vapor pressure at 25 °C but with the vapor at a number of temperatures between 25 and 200 °C on the Hitachi–Perkin–Elmer spectrometer.

Results and Assignments

A tracing of the u.v. absorption spectrum of furazan obtained with the Hitachi–Perkin–Elmer spectrometer is shown in Fig. 1, and the vacuum wavenumbers of the bands are given in Table 1. The listed wavenumbers of almost all bands are the averages of measurements from at least four spectrometer traces. The precision of the measurements ranges from ± 5 to ± 10 cm^{-1} because of the weakness or diffuseness of most of the bands. The spectra taken on the Bausch and Lomb spectrograph (theoretical resolution < 1 cm^{-1}) show that only the bands at 40 497, 41 105, 41 296, 41 751, 41 879, and 42 042 cm^{-1} have sharp band heads; the bands at low wavenumber were too weak to observe clearly, and the bands at high wavenumber are definitely diffuse.

Comparison of the spectrometer traces obtained for a fixed pressure of vapor at temperatures between 25 and 200 °C indicates that all bands at wavenumbers less than 41 105 cm^{-1} are hot, thus placing the origin band at 41 105 cm^{-1}. All but two hot bands can be related to bands at higher wavenumber by use of the ground state vibration $\nu_5'' = 1006$ cm^{-1}, a symmetric ring in-plane bending mode (2), as shown in Table 1. This is completely in accord with the observations in 1,2,5-thiadiazole where the strongest hot bands involve the analogous vibration $\nu_5'' = 805$ cm^{-1} (4).

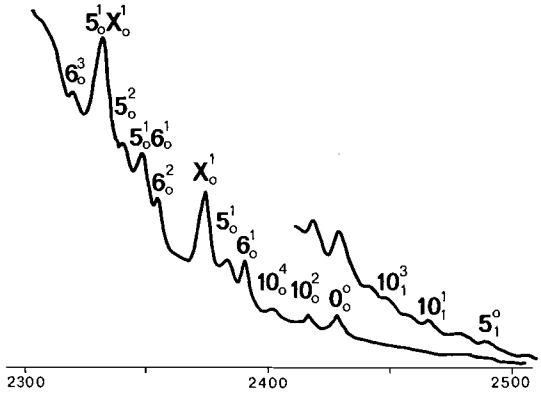

FIG. 1. Ultraviolet absorption spectrum of furazan as recorded on the Hitachi–Perkin–Elmer model 139 spectrometer. Lower trace, vapor at 25 °C; upper trace, vapor at about 150 °C.

All but three bands to high wavenumber of 41 105 cm^{-1} can be explained using three excited state vibrations of frequencies 646, 774, and 937 cm^{-1}. The 646 and 774 cm^{-1} vibrations occur in progressions and therefore must be totally symmetric A_1 modes. Since 774 cm^{-1} is the most active excited state vibration, it seems reasonable to correlate it with $\nu_5'' = 1006$ cm^{-1}, the only totally-symmetric vibration giving hot bands. This is supported by the fact that the decrease going from the ground to excited state is about 25%, which is about the same as in 1,2,5-thiadiazole where ν_5 decreases from 805 to 604 cm^{-1} (4). A possible assignment for 646 cm^{-1} is ν_6' since $\nu_6'' = 872$ cm^{-1} (2).

The 937 cm^{-1} vibration occurs only as a single quantum with a progression in ν_5' based on it. This suggests that 937 cm^{-1} may be due to a non-totally symmetric vibration active in Herzberg–Teller intensity stealing (6).[1] This vibration is most likely one of the b_2 in-plane vibrations (7–9) probably correlating with $\nu_{13}'' = 1177$ cm^{-1}, a C—H in-plane bend, or $\nu_{14}'' = 952$ cm^{-1}, a ring in-plane bend (2). Since nothing definite can be said about this on the basis of the evidence available, the 937 cm^{-1} vibration has been denoted by X in Table 1. It is interesting to note

*The listed intensities are only approximate. Errors may be large especially for bands at higher wavenumbers which are diffuse and seem to be superimposed on continuous absorption.
†A $v'-v''$ transition in the Kth normal mode is labelled $K_{v''}^{v'}$.
‡$\nu_5'' = 1006$ cm^{-1}, $\nu_{10}'' = 631$ cm^{-1} (2), $\nu_5' = 774$ cm^{-1}, $\nu_6' = 646$ cm^{-1}, $\nu_x' = 937$ cm^{-1}.

that the bands due to the 937 cm^{-1} vibration and the ν_5' progression based on it are stronger than other bands near them. This implies that the forbidden component of the spectrum is about as strong as or stronger than the allowed component. Similar observations have been made in the spectra of ethynylbenzene (9) and naphthalene (10) where the forbidden component is estimated to be about three and ten times, respectively, as intense as the allowed component.

At this stage, there are only four important bands left unassigned, namely those at 40 497, 40 780, 41 296, and 41 584 cm^{-1}. By analogy to the assignments made for 1,2,5-thiadiazole (4), these bands may be given the assignments 10_1^1, 10_1^3, 10_0^2, and 10_0^4, respectively, where ν_{10} is a b_1 out-of-plane ring bending vibration.[2] That is, the excited state of furazan is taken to be nonplanar as shown in 1,2,5-thiadiazole (4). With

[1]In the spectra taken on the Bausch and Lomb spectrograph, the origin band at 41 105 cm^{-1} has a definite double-headed appearance while the band at 42 042 cm^{-1} (= 41 105 + 937) does not. However, with these spectra, it is not possible to tell whether this difference is due to a different band contour, as the assignment requires, or to the onset of diffuseness.

[2]In ref. 4, the b_1 out-of-plane ring bending vibration was designated ν_{15} instead of ν_{10} as it should have been.

TABLE 2. Observed and calculated term values $G_0'(v_{10}')$ for v_{10}' (cm^{-1})

	v_{10}' (cm^{-1})			
		Calculated		
Term	Observed	(*i*)	(*ii*)	(*iii*)
0	0	0	0	0
1	23±2	22.9	23.0	23.0
2	190±2	190.0	190.0	190.0
3	313±10	314.4	306.7	298.2
4	479±10	480.9	464.6	447.6
5	—	659.1	628.7	597.5

	Calculated value		
Parameter	(*i*)	(*ii*)	(*iii*)
$G(0)$	113.9	111.1	108.7
ρ	0.60	0.90	1.20
B	0.8406	1.0664	1.2781
v_0	255.72	204.26	173.87
b	214.96	217.82	222.22

these assignments and the value $v_{10}'' = 631$ cm^{-1} from the i.r. (2), the vibrational term values $G_0'(v_{10}')$ can be calculated. Table 2 lists these values together with estimated uncertainties. The uncertainties in $G_0'(1)$ and $G_0'(2)$ are relatively small since the appropriate bands are relatively strong and have sharp heads, and so could be measured to about ± 1 cm^{-1} on spectra taken with the Bausch and Lomb spectrograph; the uncertainties in $G_0'(3)$ and $G_0'(4)$ are much greater because the bands are weaker and could not be as accurately measured.

The origin band at 41 105 cm^{-1} has a definite double-headed appearance consisting of a sharp narrow feature at high wavenumber separated by about 13 cm^{-1} from, and having a relative intensity about twice that of, a broader feature at low wavenumber. The appearance of this band is very similar to that of the origin band of 1,2,5-thiadiazole (4). This suggests that the transition is $\pi \rightarrow \pi^*$ in nature as is that for 1,2,5-thiadiazole.

Calculations

The $G_0'(v_{10}')$ term values have been fitted to a double-minimum potential function of the form

$$V(Q) = \tfrac{1}{2}\lambda Q^2 + A \exp\{-a^2Q^2\}$$

using tables of eigenvalues in the literature (11). Because of their smaller uncertainties, the term values $G_0'(1)$ and $G_0'(2)$ have been used to determine the parameters. The term values calculated for several sets of parameters are compared to the observed values in Table 2. The agreement of the observed and calculated values is as good as expected in light of the uncertainties in the observed $G_0'(v_{10}')$ values. The values indicate that the barrier to planarity in furazan is in the order of 215 cm^{-1} which is rather less than the values of 460 cm^{-1} determined for 1,2,5-thiadiazole (4).

Discussion

Microwave studies of furazan (1) and 1,2,5-thiadiazole (12) have shown that although both molecules have significant electron delocalization (aromatic character) in the ground electronic state, it is greater in 1,2,5-thiadiazole than in furazan, presumably as the result of sulfur atom d orbital participation in the π bonding of the ring (13). The observation that the first $\pi \rightarrow \pi^*$ excited state in both molecules is non-planar indicates that the change in electronic structure is sufficient to destroy the aromatic π bonding of these cyclic compounds.

The increase in the excited state barrier to planarity in going from furazan to 1,2,5-thiadiazole shows the same trend as observed in the ground states of trimethylene oxide (14) and trimethylene sulfide (15) where the barriers are about 15 and 274 cm^{-1}, respectively. The change in the four-membered rings is explained in terms of two opposing forces in the molecules. One is the torsional interaction between adjacent methylene groups which favors a non-planar configuration and is about the same in trimethylene oxide and sulfide. The second is the ring strain which tends to favor a planar configuration since puckering the ring decreases the ring angles and increases the ring strain. The latter is smaller for trimethylene sulfide since normal angles for sulfides are smaller than for corresponding ethers, thus leading to a more non-planar equilibrium position and a higher barrier to planarity in the sulfide. In the five-membered rings discussed here, there are no torsional (non-bonded) interactions to consider and so it must be a purely electronic effect which leads to non-planarity. Presumably as in the four-membered rings, the ring strain is less for 1,2,5-

thiadiazole than for furazan and leads to a larger barrier to planarity in the former than in the latter.

The authors thank the National Research Council of Canada for financial support of this work. One of us (B.J.F.) thanks Hoffman-LaRoche Ltd. for the Professor A. L. Keuhner Memorial Scholarship. The authors thank Miss E. Crepeau who prepared the sample of furazan used for this investigation and recorded some preliminary spectra.

Studies of Organophosphorus Derivatives. Part I. Nuclear Magnetic Resonance Studies of the 2-Oxo-1,3,2-dioxaphosphorinane System[1]

L. D. HALL AND R. B. MALCOLM[2]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 19, 1971[3]

The n.m.r. spectra of a series of simple derivatives of the 2-oxo-1,3,2-dioxaphosphorinane system are discussed in terms of the favored conformations of the derivatives and the stereospecific dependencies of *vicinal* $^{31}P—O—C—^{1}H$ couplings. Attention is drawn to a type of "deceptively-simple" ABX spectrum which is commonly found for the n.m.r. spectra of substances containing one or more heteronuclear species.

Les spectres r.m.n. d'une série de dérivés simples du système 2-oxo-1,3,2-dioxaphosphorinane sont discutés à la lumière des conformations priviligiées des dérivés et des dépendances stéréospécifiques des couplages *vicinaux* $^{31}P—O—C—^{1}H$. L'accent est mis sur un type de spectre ABX "anormalement simple" que l'on retrouve dans les substances qui contiennent une ou plusieurs espèces hétéronucléaires.

Canadian Journal of Chemistry, **50**, 2092 (1972)

Introduction

Organophosphate esters are a fundamentally important class of compounds. Especially, they play key roles in many biosynthetic pathways and comprise structural sub-units of many physiologically important materials. Although the conformational analysis of such molecules is of considerable interest, a satisfactory method for studying the conformational properties intrinsically associated with the phosphate moiety has not yet been developed. High-resolution n.m.r. studies associated with the ^{31}P nucleus have not yet been thoroughly investigated to this end, and in the present paper we describe some model studies.

For several derivatives of the synthetically available 2-oxo-1,3,2-dioxaphosphorinane system (**A**), we have been able to relate heteronuclear magnetic resonance coupling constants to geometrical properties via both established ^{1}H n.m.r. parameter dependencies and an X-ray structure determination for 2-oxo-2-phenoxy-1,3,2-dioxaphosphorinane (**1**). In particular, we have determined the partial angular dependencies of $^{31}P—O—C—^{1}H$ and $^{31}P—O—C—C—^{1}H$ coupling constants. A number of these derivatives gave interesting examples of a class of deceptively-simple ABX spectra which appears not to have been widely recognized so far; an analysis of this type of spectrum is given separately elsewhere.[4]

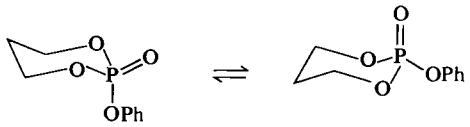
specificities and, where appropriate, discussion of their results accompanies our own. As we shall mention later, further detailed n.m.r. studies are required before the present results can be extended to determine more general ^{31}P n.m.r. stereospecific dependencies.

Discussion

Geise (6) has reported an X-ray study of 2-oxo-2-phenoxy-1,3,2-dioxaphosphorinane (**1**) and has shown that in the solid state, this molecule favors a slightly flattened chair conformation having the phenoxy substituent axially oriented. The pertinent data from that study are summarized in Table 1.

The magnitudes of the *vicinal* $^1H-^1H$ coupling constants of **1**, listed in Table 2, suggest that this derivative favors one chair form almost exclusively. Thus the 4a,5a coupling (11.4 Hz) is well within the range anticipated (7) for a *trans–diaxial* disposition of the two protons. The remaining $^1H-^1H$ couplings are also consistent with the chair conformation.

If we assume that the activation energy associated with the conformational inversion process **B** ⇄ **C**, is available at room temperature in



B **C**

solution, it follows that the measured couplings of **1**, and of the other derivatives described here, are weighted, time-averaged values. Our results for **1** thus imply a greater than 95% predominance of one chair form over the other. All attempts to confirm the presence of other conformations by low temperature measurements have so far been unsuccessful.

It is important to note that the analysis of the n.m.r. spectrum of **1** suggests a partial angular

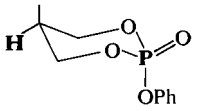
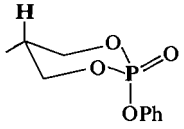
dependence of *vicinal* $^{31}P—O—C—^{1}H$ coupling constants as depicted in **D**, **E**. We shall discuss this later. The ^{4}J, $^{31}P—O—C—C—^{1}H$ couplings also exhibit a stereospecific dependence as depicted in **F**, **G**.



$|^{4}J| = 2.7$ Hz

F



$|^{4}J| = 0.9$ Hz

G

We have assumed that the predominant chair conformation of **1** is that depicted in **B**, having the phenoxy group axially oriented. This *tentative* assignment is in accord with the result for the solid state (6). Furthermore, it has the merit of effectively minimizing any dipolar interactions between the P—O(Ph) bond and the $C_6—O_1$, $C_4—O_3$ bonds, should such interactions determine conformational preferences in this system.[5] Until a satisfactory method of configurational assignment at phosphorus is perfected this assignment must remain tentative. However, it is important at this juncture to recognize that, whatever the correct configurational assignment, the phosphorus moiety of **1** has a conformational preference of at least 1.8 Kcal/mol.

The ^{1}H n.m.r. spectrum of **2**, the cyclic phenyl phosphate of *o*-hydroxybenzyl alcohol, is shown in Fig. 1. It is a deceptively-simple type of ABX spectrum as discussed elsewhere.[4] Results of the analysis of this spectrum are given in Table 3. Both direct analysis and spin-tickling experiments confirmed that both *vicinal* $^{31}P–^{1}H$ couplings had the same sign, a result we assume is reasonable also for **1**. Presumably these couplings are absolutely positive in sign, in accord with the established result for acyclic systems (10).

[5]This type of interaction, or a version thereof, has been invoked previously to rationalize the conformational preference of certain carbohydrate derivatives when it is familiarly termed the "anomeric effect" (8). Similar dipolar interactions have been considered to govern the conformational preference in a number of other organic systems (9).

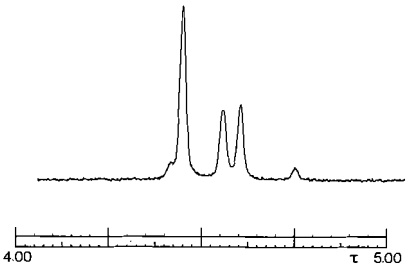


FIG. 1. Partial ^{1}H n.m.r. spectrum (100 MHz) of the cyclic, phenylphosphate ester of *o*-hydroxybenzyl alcohol in $CDCl_3$ solution.

TABLE 3. The n.m.r. parameters for the cyclic phenyl phosphate (**2**) of 2-hydroxybenzyl alcohol

Coupling constants (Hz)		
J_{AB}	J_{AP}	J_{BP}
−14.4	6.8*	19.6*

*± 1 Hz.

Inspection of the n.m.r. parameters given in Tables 4 and 5 shows that the 2-phenoxy-(**3**) and 2-chloro-(**4**) derivatives of 5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinane also have a marked conformational preference. Thus their *vicinal* $^{31}P–^{1}H$ couplings show a similar, marked steric dependence. Again it is not possible to assign unequivocally the configuration at phosphorus although rationales, similar to that applied for **1**, can be given.

The 60 MHz ^{1}H n.m.r. spectrum of **4** in $CDCl_3$ solution, is of the deceptively-simple type observed for **2**. At 100 MHz a "normal" AA′-BB′X spectrum, similar to that obtained for **3** is observed. Both types can be analyzed independently to give a set of identical chemical shifts and coupling constants. That $^{3}J_{trans}$[6] (~28 Hz) is significantly larger than that for **1** and **3** (~22 Hz), is not readily explained. A

[6]For simplicity throughout the remaining discussion, we shall refer to the *vicinal* $^{31}P—O—C—^{1}H$ coupling constants in these systems as J_t and J_g for equatorial and axial protons respectively. The terms J_{180} and J_{60} will be used to denote similar couplings referred to P—O—C—H dihedral angles of 180 and 60° respectively.

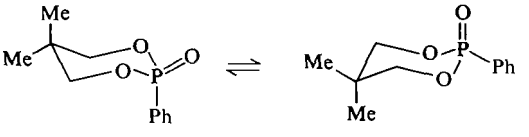
greater "anomeric effect" associated with the chloro substituent could result in a significantly lower population of the inverted conformer, a larger P—O—C—H dihedral angle in the preferred conformer, or both. A direct effect of substituent electronegativity on these couplings may also be operative; unfortunately no direct distinction[7] between these alternatives is possible at this juncture.

The n.m.r. spectrum of 5,5-dimethyl-2-hydroxy-2-oxo-1,3,2-dioxaphosphorinane (**5**) suggests that this derivative undergoes rapid interconversion at room temperature between equally populated chair conformers of the type **B**, **C**. Thus the observed ^{31}P–^1H coupling constant of 12.0 Hz corresponds almost precisely to the average of J_t and J_g for **1** (12.4 Hz) and for **3** (12.1 Hz).

[7]In this regard, however, the ^1H–^1H couplings of **1** are not compatible with significant time-averaging and a recent X-ray study (11) of a 2-bromo-derivative, which similarly has a very large J_t (12), is similar to that for **1**.

We were somewhat surprised, however, to find that 5,5-dimethyl-2-oxo-2-phenyl-1,3,2-dioxaphosphorinane (**6**) similarly had nearly equal ^3J couplings of 11.0 and 12.6 Hz. Subsequent analysis at −80 °C provided values of 7.8 and 15.9 Hz respectively. These changes reflect, at least in part, the expected change in relative populations of the two conformers **H**, **I**



H **I**

on decreasing temperature. Unfortunately, as yet, we have been unable to "freeze-out" this interconversion process. We hope to return to this type of experiment in future.

While it is evident from our n.m.r. results for **1** and **3** that *vicinal* ^{31}P—O—C—^1H coupling constants show a marked steric dependence, it is also evident from our results for **4** that a careful

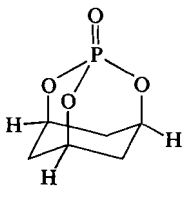
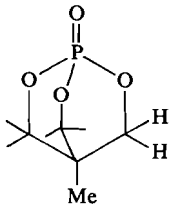
consideration of specific substituent effects on these coupling constants must be made before this dependence can be widely extended outside the cyclic phosphate system. Further studies in this series will attempt to systematically extend our present results and apply them to pertinent conformational problems. At this time, however, it does seem appropriate to discuss some of the apparent inconsistencies that have developed in the literature and offer some clarification of these in light of our own results and other established data.

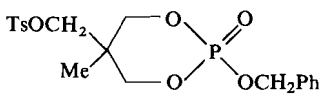


$J_{180} = 20$ Hz
J

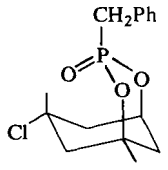


$J_{120} = 6$ Hz
K

The original n.m.r. data **J**, **K**, that should have elucidated a *vicinal* $^{31}P—O—C—^1H$ coupling constant stereospecific dependence was published (13) in 1962. Unfortunately, this result[8] was not used in considering the conformational properties of a series of derivatives of the type **L**, **M**, which seem to be undergoing a greater or lesser amount of conformational "time-aver-



L



M

[8]The J_{120} value is as later corrected (14). Our J_t values for **1** and **3** clearly do not agree *quantitatively* with the above J_{180}; presumably some special effect attributable to the polycyclic structure, previously discussed (2) in the trivalent phosphorus series, is responsible.

For personal use only.

aging" by analogy with **6** of the present study.[9] Thus equal, 11.6 Hz (15), ^3J couplings for **L** indicate a nearly equal proportion of the two chair conformers in solution. Molecules of this type had also previously (16) been thought to exist in a single chair conformation. The 17.5 Hz $^{31}P—O—C—^1H$ coupling observed for **M** in solution is comparable to our J_t for **1** and **3** and suggests that this compound exists *predominantly* in the chair–chair conformation illustrated above rather than the boat–chair conformation rationalized (17) from other data.

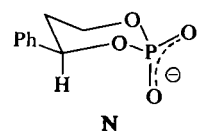
Derivatives of the type **L**, **M** were unfortunately later chosen as model systems for a survey (18) of data pertinent to the conformational sensitivity of the i.r., phosphoryl bond, stretching frequency. It was concluded at that time that "... $\nu_{P=O}$ suffers little from conformational environment". It thus seems quite likely that more recent i.r. studies (19, 20) of 2-oxo-1,3,2-dioxaphosphorinane ring systems *in solution,* could lead to the establishment of a general dependence of $\nu_{P=O}$ on conformational preference at the phosphorus moiety. Such a dependence, combined with an n.m.r. conformational analysis of the ring system, could be a valuable aid in assigning configuration at phosphorus in these derivatives.

Another laboratory (5) has recently shared our interest in developing stereospecific dependencies of ^{31}P n.m.r. parameters with a view to their subsequent application to polynucleotide conformational analysis in solution.

We feel it is appropriate to point out some of the very important problems that can arise from premature quantitative application of an incompletely determined $^{31}P—O—C—^1H$ coupling constant–dihedral angle dependence, similar to that we have suggested for **1**, **3**.

The ^1H n.m.r. spectrum of **N** exhibited (21) a 1.5 Hz splitting due to coupling with the phosphorus nucleus. This value of J_g was combined with the fully time-averaged value ($J_{av} = 10.4$ Hz)[10] for an acyclic methyl phosphate group, to predict[11] a J_{180} value of 28.2 Hz. A more complete analysis (22) of the n.m.r. spectrum of **N** later resulted in observed $J_t = 22.1$ and $J_g = 2.3$ Hz values.[12] In the same study, the ^{31}P n.m.r. spectra of inosine-5′-monophosphate and guanosine-5′-monophosphate were found to exhibit 4.5 Hz triplets due to coupling between the ^{31}P and $^1H_{5'}$ nuclei. Using the J_t, J_g values for **N** and these J_{av} values[13] for the mononucleotides, the relative populations of the rotamers around the $O–C_{5'}$ bond were calculated.[14] Thus a_t, the fraction of the rotameric population having a *trans* orientation with respect to the $P—O—C_{5'}—C_{4'}$ bond, was calculated to be 0.78 (22). In a subsequent publication (24), the n.m.r. parameters for **N** were revised[15] to give $J_t = 22.3$ and $J_g = 1.9$ Hz, and some account of the anticipated difference between these values and J_{180}, J_{60} values was taken. Unfortunately, the suggested, revised couplings, $J_{180} = 23.5$, $J_{60} = 4.5$ Hz,[16] led to contradictory implications in their subsequent application via an assumed type of "Karplus curve" (7) to the study (5) of a dinucleotide conformation in solution. Clearly, an experimental coordinate pair used to derive a ^3J *vs.* dihedral angle curve must be consistent with data derived from the curve. The co-ordinate pair, $J_{65} = 1.9$ Hz from **N** (24), should thus be consistent with the co-ordinate pair, $J_{64} = 3.4$ Hz (5), derived.[17]

Unfortunately, the first, incorrect $J_t = 28.2$



N

[9]Throughout this discussion we have made the implicit assumption that our J_t, J_g stereospecific dependence for **1** and **3** is general for both the phosphate and phosphonate series. Although subtle differences undoubtedly occur, sufficient data exist at this time (*vide infra*) to justify this assumption in the present context.

[10]Actually the averaged value between sodium methyl phosphate and barium dimethyl phosphate (21).

[11]Thus $J_{av} = (J_{180} + 2J_{60})/3$. The assumption that $J_g = J_{60}$ has been made by the authors. Our own values of J_t and J_g did not adequately *quantitatively* predict J_{av} when we made (1) the assumption that $J_t = J_{180}$ and $J_g = J_{60}$; this is also not strictly compatible with the X-ray data (6) for **1**.

[12]Coupling with the H_6 protons. The $^1H–^1H$ couplings are compatible with a single predominant chair conformation.

[13]A triplet X resonance of an ABX spin system implies equal AX and BX coupling constants only if the chemical shift difference between the A and B nuclei is significant (23).

[14]The choice made between the two different J_g values in the same molecule has not been rationalized.

[15]Presumably as a result of proper ABX treatment of the spin system.

[16]It was assumed that, since the mononucleotides above had equal couplings of 4.5 Hz, these couplings must correspond directly to J_{60}. This assumes $a_t = 1.0$, in contrast to the previously determined value of 0.78 (22).

[17]Clearly the $J_{60} = 4.5$ Hz co-ordinate point is unjustified and leads to serious uncertainty in the J *vs.* dihedral angle plot, being one of the only two co-ordinate pairs used.

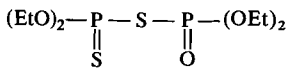
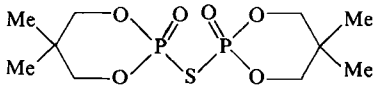
and $J_g = 1.5$ Hz values derived for **N**, have been used recently by other workers (25, 26) to justify particular choices of J_{av} for acyclic derivatives and a further study (27) has depended on one of these choices. Thus it has been suggested (25) that fully time-averaged J_{av} values for *ethyl* derivatives of the type **O** are more appropriate



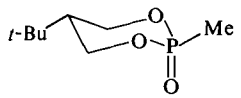
O



P

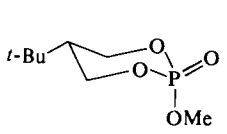
than J_{av} values for *methyl* derivatives, when considering the particular choice of J_t and J_g that is expected to correctly predict the conformer populations of derivatives of the type **P** in solution.[18]

A wealth of n.m.r. data related to cyclic *phosphonate* derivatives of the type **6** and **L** has been published (12, 27–29) more recently. The suggestion, based on ^{1}H chemical shift data, that several derivatives were essentially conformationally homogeneous in solution (29), was later revised (27) and clarified by other workers (25). It does seem appropriate however that calculations of conformer populations for these derivatives should be based on J_t and J_g values directly observed for conformationally *homogeneous* derivatives, rather than the somewhat unsatisfactory assumption that $J_t = J_{180}$ and $J_g = J_{60}$. In this regard, the n.m.r. results $J_t = 20.2$ and $J_g = 4.14$ Hz, have recently been published (30) for the thermodynamically stable isomer **Q**.

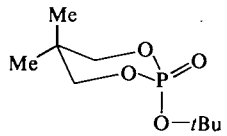


Q

Two other recent results are pertinent to this study. A conformationally stable phosphate isomer, *cis*-5-*t*-butyl-2-methoxy-2-oxo-1,3,2-dioxaphosphorinane (**R**), has $J_t = 22.8$ and $J_g = 1.14$ Hz (30) and 2-*t*-butoxy-5,5-dimethyl-



R



S

2-oxo-1,3,2-dioxaphosphorinane (**S**) has $J_t = 21.0$ and $J_g = 3.3$ Hz (12). The ^{1}H–^{1}H coupling constants of **Q** and **R** are consistent with the presence of one dominant chair conformer in solution, similar to our results for **1**.

In summary, several important statements relating to the conformational properties of cyclic phosphate and cyclic phosphonate derivatives *in solution*, can be derived from the above considerations of our own results in relation to those of other laboratories.

It is clear that the sum of the observed *vicinal* ^{31}P—O—C—^{1}H couplings in phosphate derivatives (24.1 Hz[19]) and the sum in cyclic phosphonate derivatives (22.4 Hz[20]) are quite similar. This is consistent with the suggestion that these derivatives exist as equilibrium mixtures of two rapidly interconverting, "flattened-chair" conformations as generally depicted by several X-ray determinations (6, 31–33) for crystalline derivatives.

In general, the conformational preference associated with a *phosphate* moiety is considerably greater than that associated with a *phosphonate* moiety. This difference is sufficient that the former tend to exist in one predominant conformer in contrast to the latter.

For *phosphate* derivatives, J_t and J_g are in the range 21.0–22.8 and 1.2–3.3 Hz respectively. For *phosphonate* derivatives, J_t and J_g are in the range 18.2–20.2 and 3.2–4.7 Hz respectively.

It is not yet clear whether the slight variations in the ^3J parameters indicated above are due to subtle conformational changes, to specific substituent effects on the coupling constants, or to both.

A sufficient range of n.m.r. data does not yet exist for compounds of known or readily predictable geometry to warrant quantitative definition of a function relating ^3J to dihedral angle in these systems. The n.m.r. and X-ray data that do exist for the *phosphates* **1**, **5**, *trans*-**R**, and

[18]These authors seem to have failed to realize that their justification for choosing *ethyl* derivative models rests on the choice of *methyl* derivative models by the workers who derived the above values for *N*.

[19]Average over eight derivatives, ^3J range 23.4–24.8 Hz (12, 24, 30, this study).

[20]Average over 29 derivatives, ^3J range 20.6–23.6 Hz (12, 27–30, this study).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the *phosphonate cis*-**Q**, are however, consistent with the suggestion that such a function would be qualitatively similar to that derived (7) by Karplus for ^{1}H—C—C—^{1}H couplings.

Coupling constants, J_{180} and J_{60}, corresponding to idealized rotameric conformations, are not directly determined by these systems. However, if the above suggestion relating ^3J *vs.* dihedral angle is correct, then $J_{180} > J_t$ and $J_{60} > J_g$. It also seems likely that $J_{180} + 2J_{60} =$ 31–33 Hz, from considerations of acyclic methyl derivative couplings.

Clearly, the above statements reveal a sufficiently self-consistent, sensitive dependence of *vicinal* ^{31}P—O—C—^{1}H coupling constants on dihedral angle to justify their *semi-quantitative* use in 1,3,2-dioxaphosph(V)orinane conformational problems of chemical significance.

The interested reader is referred to leading references (3, 4, 34) of similar studies in the 1,3,2-dioxaphosph(III)orinane series.[21]

Although several other n.m.r. laboratories have evidenced (35) an awareness of the type of deceptively-simple ABX spectrum (referred to elsewhere[4]), these articles have been overlooked by some workers in the organophosphorus area. The n.m.r. spectra of several derivatives, which are of this deceptively-simple form, have been reported (24, 28) to be unsuitable for ABX analysis and in other instances have been incorrectly assigned (22, 36). We have derived approximate n.m.r. parameters from two of the published spectra that have appeared. Thus 2-chloro-2-oxo-4-phenyl-1,3,2-dioxaphosphorinane (24) has $J_t = 26.6$ and $J_g = 6.3$ Hz, and 5,5-dimethyl-2-isopropoxy-2-oxo-1,3,2-dioxaphosphorinane (28) has $J_t = 20.6$ and $J_g = 4.3$ Hz. Although not very accurate as we have derived them, these parameters compare favorably with those of similar derivatives we have discussed previously.

This type of deceptively-simple system also occurs frequently as a sub-spectrum of more complex spin systems when its characteristic pattern can be a very valuable simplifying feature. The n.m.r. spectrum of **1** is just one of the many examples that we have encountered in measuring the spectra of derivatives containing a ^{31}P or ^{19}F heteronucleus.

Experimental

All melting points were measured on a Fischer–Johns heating stage and are uncorrected. Satisfactory microanalyses, performed by Mr. P. Borda of this Department, were obtained for all compounds.

The 100 MHz ^{1}H n.m.r. spectra were measured with a modified Varian HA-100 spectrometer operating in the "locked" frequency-sweep mode. The 60 MHz ^{1}H n.m.r. spectra were measured with a Varian A-60 spectrometer. Tetramethylsilane was used as internal reference. All ^{31}P n.m.r. spectra were measured at 40.477 MHz with a Varian HA-100 spectrometer operating in the "extended-offset locked" field sweep mode. The ^{31}P chemical shifts are reported in p.p.m. relative to an internal capillary of P_4O_6.

Heteronuclear double resonance experiments in which the ^{31}P resonance was strongly irradiated while observing the ^{1}H resonances, were carried out routinely to assist in spectral assignment. The equipment consists (37) of a double-tuned probe adaptor, a Hewlett Packard Frequency Synthesizer, and a Hewlett Packard Power Amplifier (Model 230A).

With the exception of those for **1**, the n.m.r. parameters for all derivatives were derived from the spectra both by "long-hand" direct analysis and also using a modified version of the LAOCN3 computer program. A plotting program SCRIBE was used both directly and coupled to LAOCN3 to simulate the results of the analyses for comparison with the experimental spectra. The plot program was also used to provide the simulated spectra of Fig. 2.[22]

The methylene proton resonances of **3** and **4** were assigned using the established (38) steric dependence of long-range H—C—C—CH_3 coupling constants. Thus the low field (axial) methylene resonances were noticeably sharpened on irradiation of the downfield (axial) methyl resonances. This method was also applied to **6** but with less observable result.

*2-Oxo-2-phenoxy-1,3,2-dioxaphosphorinane (**1**)*

This compound was prepared by the method of Meston (39) in good yield (m.p. 75 °C). Although the n.m.r. spin system associated with **1** is quite complex (AA′BB′MNX), assignment of the H_5 region was quite straightforward. The H_4, H_6 region is very complex but exhibits four very intense single resonances which are characteristic of deceptively-simple ABX sub-spectra.[4] The presence of these sub-spectra was a valuable aid to analysis in that certain quantitative

[21]A referee pointed out that our discussion had not included detailed comparisons of our results with those related from the laboratory of Professor J. G. Verkade. Studies from that laboratory are, however, cited as references 2, 3, 12–15, 17, and detailed comparisons were not made because of space restrictions. It seems worthwhile commenting here that Professor Verkade's laboratory and our own appear to have followed independently, and simultaneously (see ref. 1) closely similar lines and both laboratories appear to have reached closely similar conclusions. The same referee drew our attention to an X-ray study of a derivative related to **M**, which was shown (42) to have the chair–boat conformation. We do not feel able to comment on the relevance of this observation.

[22]A copy of Fig. 2 may be obtained on request from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

relationships between the n.m.r. parameters are implied. Assignment was further aided by homonuclear and heteronuclear double resonance experiments and a set of "guess", first-order n.m.r. parameters was obtained. These parameters were iterated using LAOCN3 with as many experimental transition frequencies as could be assigned. The parameter set of Table 2 was obtained as a result of several cycles of the iterative procedure, spanning the uncertainty limits in assignment of the experimental frequencies. A SCRIBE plot of the transitions associated with the final parameter set was in close agreement with the experimental spectrum. Despite this "good-fit", however, the spectrum proved relatively insensitive to changes in some of the parameters. The error limits of Table 2 reflect either the accuracy problems associated with the deceptively-simple subspectrum[4] or those associated with assigning transition frequencies in the very complex "normal" sub-spectrum.

o-Hydroxybenzyl Alcohol Cyclic Phenyl Phosphate (2)

Phenyl phosphorodichloridate (4.0 g) was added dropwise, with stirring to a cooled (ice bath) solution of *o*-hydroxybenzyl alcohol (2.0 g) in anhydrous pyridine (40 ml). The mixture was left to stand *ca.* 20 h at ~4 °C. Water (40 ml) was added to dissolve precipitated pyridinium hydrochloride and the solution was extracted with $CHCl_3$ (3 × 20 ml). The combined $CHCl_3$ extracts were washed repeatedly with water (5 × 20 ml), dried over anhydrous Na_2SO_4, and concentrated under reduced pressure to give highly crystalline **2** (1.80 g, 69%, m.p. 79.5–81.0 °C).

5,5-Dimethyl-2-oxo-2-phenoxy-1,3,2-dioxaphosphorinane (3)

Structure **3** was prepared by the methods for **1** and **2** and had m.p. 132–133 °C.

2-Chloro-5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinane (4) and 5,5-Dimethyl-2-hydroxy-2-oxo-1,3,2-dioxaphosphorinane (5)

Structures **4** and **5** were prepared by the methods of Edmundson (40).

5,5-Dimethyl-2-oxo-2-phenyl-1,3,2-dioxaphosphorinane (6)

Structure **6** was prepared by the method of McConnell and Coover (41).

It is a pleasure to thank the National Research Council of Canada for their generous financial support of this work via regular operating grants (A 1905), a special operating grant (A 5456) and an equipment grant (E 1338). We would also like to thank Professor C. A. McDowell for his interest in this work.

A Novel Class of Isomeric Phosphate Esters[1]

L. D. HALL AND R. B. MALCOLM[2]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received August 20, 1971

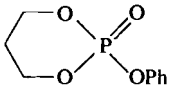
Reaction of phenyl phosphorodichloridate with pentane-2,4-diol affords a mixture of isomeric cyclic phosphates. These have been separated and characterized. Analysis of the ^1H and ^{31}P n.m.r. spectra of these derivatives has confirmed the stereospecificity of several sets of ^{31}P–^1H coupling constants.

La réaction du phosphorodichloridate de phényle avec le pentanediol-2,4 conduit à un mélange de phosphates cyclique isomères. Ceux-ci ont été séparés et caractérisés. Les analyses r.m.n. des spectres ^1H et ^{31}P de ces dérivés ont confirmé la stéréospécificité de plusieurs groupes de constantes de couplage ^{31}P–^1H.

Canadian Journal of Chemistry, **50**, 2102 (1972)

Introduction

During the course of a study of phosphate esters (1–3) we had found that reaction between propane-1,3-diol and phenyl phosphorodichloridate afforded a single, crystalline, cyclic phenylphosphate[3] (**1**) in high yield. We were surprised,

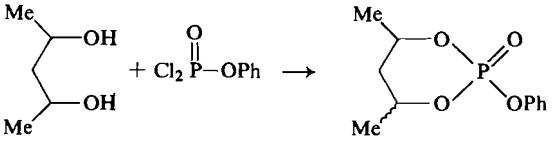


1

therefore, to find that reaction of phenyl phosphorodichloridate with pentane-2,4-diol afforded a mixture of *three* products. We now describe the separation and characterization of these substances.

Results and Discussion

Reaction of phenyl phosphorodichloridate with a commercially available sample of pentane-2,4-diol afforded a syrupy material (**2**),



2

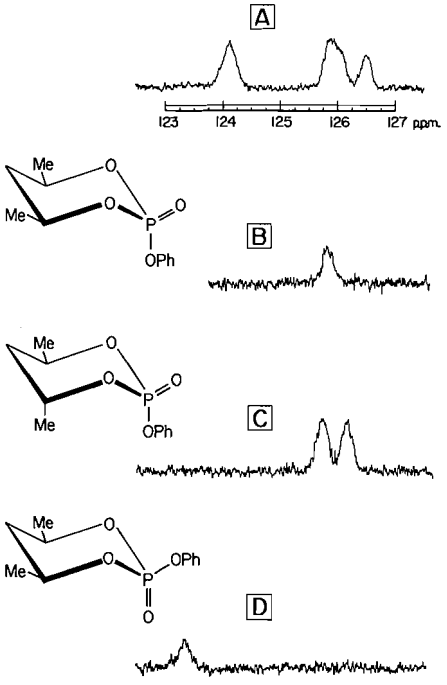


FIG. 1. The ^{31}P n.m.r. spectra (40.5 MHz) of the isomeric 4,6-dimethyl-2-oxo-2-phenoxy-1,3,2-dioxaphosphorinanes in $CDCl_3$ solutions. [A], spectrum of the unseparated mixture of isomers; [B], isomer **2***a*; [C], isomer **2***b*; [D], isomer **2***c*.

shown by t.l.c. to have three components. The ^{31}P n.m.r. spectrum of the mixture (Fig. 1) showed three separate resonances, one of these having a large, $\simeq$17 Hz, splitting. Column chromatography (silica gel/ethyl acetate) of the syrupy mixture, monitored by t.l.c., provided an efficient means of separating the three components, labelled **2***a*, *b*, and *c*, in order of de-

[1]A full account of this study was given at the 155th meeting of the American Chemical Society, San Francisco, March 31–April 5, 1968. For a preliminary communication, see ref. 1. Descriptions have also been given by R. B. Malcolm, see ref. 2. This paper constitutes Part 2 of a series entitled "Studies of organophosphorus derivatives". For Part 1 see ref. 3.

[3]Strictly this should be referred to as 2-oxo-2-phenoxy-1,3,2-dioxaphosphorinane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

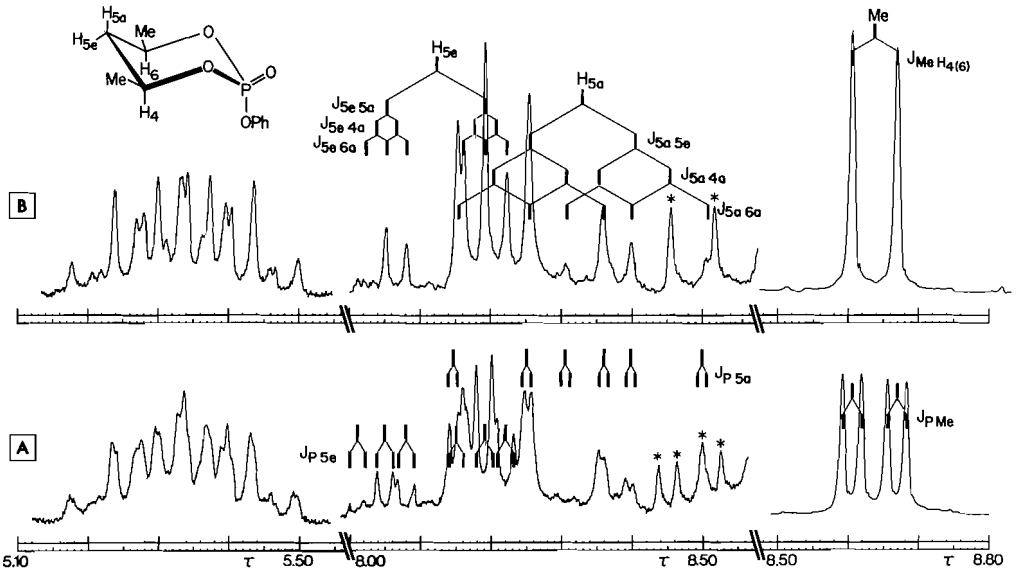

FIG. 2. Partial ^{1}H n.m.r. spectrum (100 MHz) of isomer **2***a* in $CDCl_3$ solution. [A], normal spectrum; [B], spectrum obtained with continuous-wave irradiation at the phosphorus frequency. The peaks marked with an asterisk are spinning side-bands from the methyl peaks. The first-order assignment provides an approximate indication of the multiplet structures.

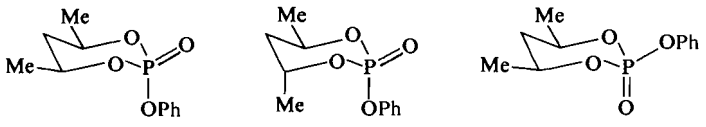
creasing R_f value. The resulting, crystalline component **2***a* had m.p. 94° and δ ^{31}P chemical shift +125.8 p.p.m. (relative intensity *ca.* 1) while the syrupy components **2***b* and *c* had ^{31}P +126.0 (relative intensity *ca.* 1) and +123.6 p.p.m. (relative intensity *ca.* 1), respectively. These phosphorus chemical shifts are consistent with those of phosphate triesters in general. The elemental analyses of all three components are identical and consistent with that expected for structure **2**.

The 100 MHz p.m.r. spectra (Figs. 2–4) of all three components are very similar and the general features of these spectra are also consistent with assignment of the three components to the three possible *geometrical* isomers of 4,6-dimethyl-2-oxo-2-phenoxy-1,3,2-dioxaphosphorinane depicted below. Two of these are derived from *meso*-pentane-2,4-diol and one from *d,l*-pentane-2,4-diol. Thus the spectra of all three products show a complex multiplet centered in the τ 5.2–5.4 range, of relative intensity 2, due to protons on C-4 and -6 being coupled to virtually every other magnetic nuclear species present. A further complex multiplet centered in the range τ 8.0–8.2, of relative intensity 2, due to the methylene ring protons, is followed by methyl proton resonances of relative intensity 6 centered in the range τ 8.5–8.7. The phenyl resonances at *ca.* τ 2.8 of relative intensity 5, have not been illustrated. The complete assignment of these p.m.r. spectra was facilitated by heteronuclear decoupling and the spectra obtained while irradiating the phosphorus resonances (4) demonstrate, in comparison with the normal spectra, removal of extensive long-range, ^4J coupling of this nucleus into the methyl and methylene protons. Detailed spectral data for each of the isomers has been obtained in part, by a first order analysis, and in part with the aid of computer-simulated spectra. This data is presented in Table 1.

The appearance of a large, $\simeq$17 Hz splitting in the ^{31}P n.m.r. resonance of isomer **2***b* implies a *trans* POCH coupling in accord with the result



2*a* **2***b* **2***c*

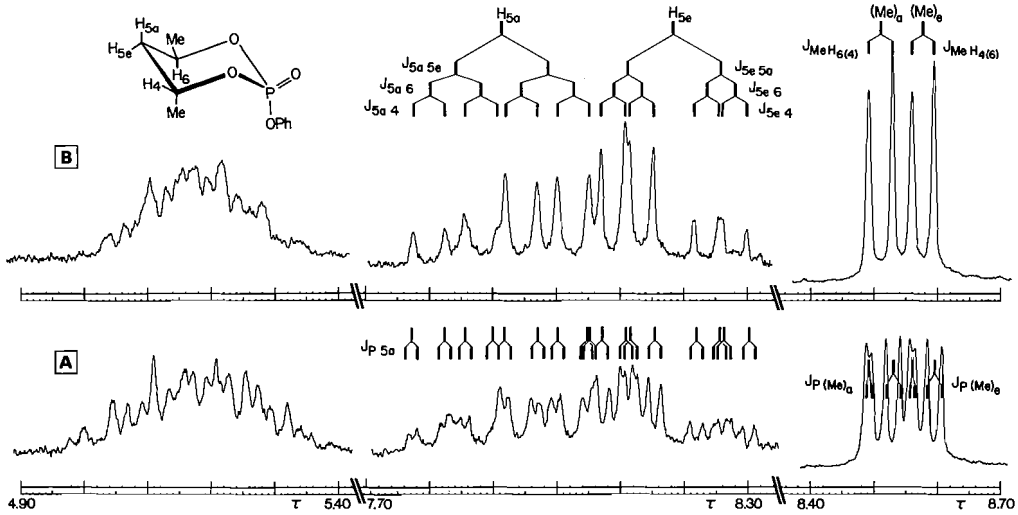

FIG. 3. Partial ^{1}H n.m.r. spectrum (100 MHz) of isomer **2***b* in $CDCl_3$ solution. [A], the normal spectrum; [B], the spectrum obtained with continuous-wave irradiation at the phosphorus frequency. An approximate, first-order, peak assignment is given.

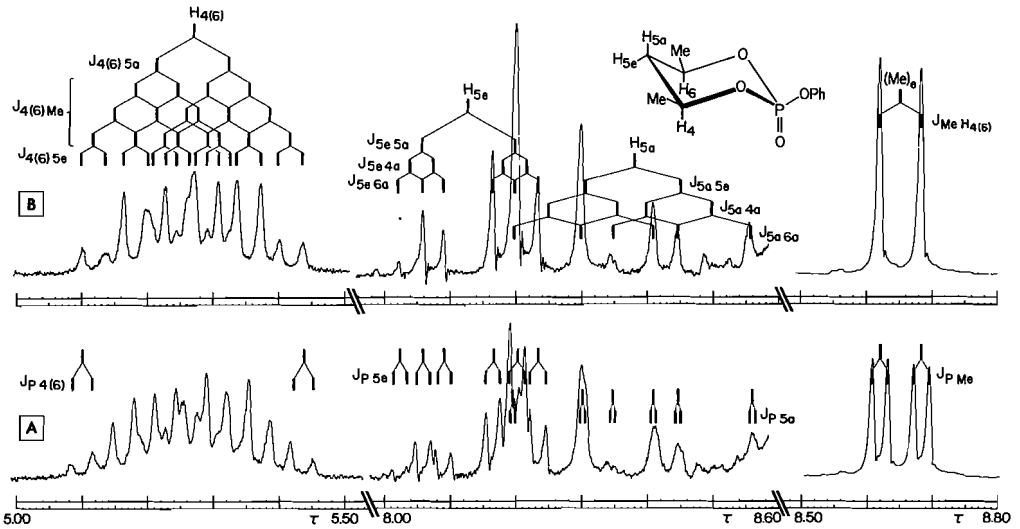

FIG. 4. Partial ^{1}H n.m.r. spectrum (100 MHz) of isomer **2***c* in $CDCl_3$ solution. [A], normal spectrum; [B], spectrum obtained with continuous-wave irradiation at the phosphorus frequency. An approximate, first-order assignment is given.

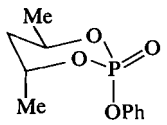
from compound **3**, Table 2. This enables assignment of the structure **2***b*, the cyclic phenyl phosphate ester of *d,l*-pentan-2,4-diol, to this product. The presence of *two*, non-equivalent methyl resonances in the p.m.r. spectrum confirms this assignment.



The absence of any large splittings in the ^{31}P resonances of components **2***a* and *c* suggests *gauche* POCH coupling relationships (3) for these isomers. The p.m.r. spectra of these two isomers are virtually identical and the single methyl resonance is consistent with the structures **2***a* and *c*, which have isomeric configurations at the phosphorus.

It is not possible at this time to assign unequivocally the configuration *at phosphorus* for any of these derivatives. However, some circum-

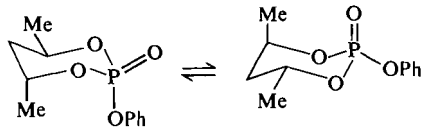
stantial data can be cited. An X-ray study (5) of **1** has shown that this derivative exists in a slightly flattened, chair conformation having the phenoxy group axially oriented. As in our previous discussion (3), we have assumed for the present that this steric preference also pertains to **1** in solution. *With this sole assumption*, assignment of configuration at phosphorus necessitates only the relationship of **1** with the other derivatives. This can be established by comparison of ^{31}P chemical shifts. Two of the derivatives (**2***a* and *b*) derived from pentane-2,4-diol have chemical shifts close to those of **1** and **3**, whereas that of **2***c* is *ca.* 2.5 p.p.m. to low field. This suggests that the configuration of **2***c* differs from those of **1**, **2***a*, **2***b*, or **3**. Insofar as the configuration, having the phosphoryl oxygen substituent equatorially oriented and the phenoxy group axially oriented, appears to be the more stable in the crystal state, it seems reasonable to assign the phosphorus configurations of **2***a*, *b*, and *c* as outlined above.

Clearly an unequivocal evaluation of this point must await an X-ray crystallographic evaluation of **2***a*.[4] However, at this time we can comment on the conformations in solution of several of these derivatives. It should be appreciated at the outset of this discussion that we have assumed that the same flattening of the six-membered ring observed for **1** in the solid state, occurs for all of these derivatives. This seems reasonable in view of the length of the ring, P—O bonds (1.56 Å). We anticipate also that the activation energy for "chair–chair" conformational inversion is sufficiently low that this process is accessible at room temperature. Thus all of the compounds to be discussed will have a greater, or lesser, degree of conformational time-averaging. As we shall see, most of these derivatives have a remarkable preference for one particular "chair" conformation (*vide infra*).

Isomers **2***a* and **2***c* have very similar n.m.r. spectra and the data of Table 1 are similar for each isomer. The differences which do exist for $J_{4a,5e}$ and $J_{4a,5a}$ are not sufficiently significant, beyond experimental error, to attribute to any difference in the conformations of the two molecules. In comparison with the data for **1**, Table 2, it is seen that only the *geminal*, 5e–5a, coupling constant does not agree within experimental error. Since the 4a–5e and 4a–5a coupling constants of **2***a* and *b* agree well with those of **1**, the conformation of the C_4—C_5—C_6 parts of these molecules is taken to be the same. The similarity of the J_{POCH} *gauche* couplings (P,4a) is taken to mean that the P—O—C—H dihedral angles are similar. Thus, isomers **2***a* and *c* exist predominantly in the flattened-chair conformation (5) typical of **1**. A satisfactory measure of the accuracy of this statement, based on other similar applications would be a $\pm 5\%$ limit on possible changes in dihedral angle for the relevant bonds.

The p.m.r. data for isomer **2***b* is perhaps more interesting, since there are more comparisons possible due to asymmetry of the molecule. The *trans*-diaxial 4e–5a coupling constant for **2***b* is smaller than for **1** (by *ca.* 2.5 Hz), $J_{4e,5e}$ is larger (by *ca.* 1.6 Hz) as is, perhaps, $J_{6a,5e}$ (by *ca.* 0.5 Hz). The *trans* POCH coupling of 17.0 Hz is somewhat smaller than for **1** and **3** (by *ca.* 3 Hz). Such data can usually be explained in one of three ways. Either the molecule is undergoing a rapid conformational inversion as in **A1** $\rightleftharpoons$ **A2**, or it exists in a distorted conformation, or both. For **A**, in which the molecule exists in two now "typical", flattened chair conformations which differ only in the configuration at the phosphorus atom, the room temperature n.m.r. data is expected to be the weighted average of that for each conformation. The observed n.m.r. coupling constants for **2***b* are consistent with



A1 **A2**

conformational "time-averaging" between the two "typical" conformations as in **A**. The 4a–5a coupling constant (8.6 Hz) would be expected to be somewhere between the values of 4e–5e (2.7 Hz) and 4a–5a (11.4 Hz) for **1**, depending on the relative populations of the two conformers. Similarly, the value for 4e–5e is somewhere between that of 4e–5e and 4a–5a for **1**. The experimental values for $J_{4e,5a}$ and $J_{4a,5e}$ as well as those for J_{POCH} and J_{POCCH} also agree well with the suggestion of a conformationally inverting system.

By assuming that the configuration at the

[4]So far we have not obtained a suitable crystal of **2***a*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

phosphorus atom does not affect seriously the magnitudes of the individual couplings,[5] the relative populations at room temperature of the two conformations of **2***b* may be calculated.

The expression $J_{average} = \alpha J_{A1} + (1 - \alpha)J_{A2}$, where α is the fraction of the population in conformation **A1**, J_{A1} is the value of the coupling constant for **A1**, and J_{A2} is the value of the coupling constant for conformation **A2**, can be used. For the conformational equilibrium between **A1** and **A2**, the value for α can be calculated using five different sets of coupling constants. The results, using **1** as the standard are as follows:

	J_{POCH}	J_{P,CH_3}[6]	J_{P,H_5}[6]	$J_{5a,6a}$	$J_{4e,5a}$
$\alpha =$	0.74	0.78	0.74	0.75	0.86

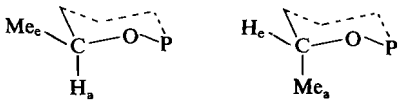
It is felt that the variation of these values is mainly due to the variation in the accuracies of the proton–proton coupling constants as determined for **1** and **2***b*. That the values calculated from the two phosphorus couplings agree well, can be taken as a measure of the sensitivity with which these couplings depend on dihedral angles. Fortunately, the phosphorus–hydrogen coupling constants can often be accurately determined in systems for which the remaining p.m.r. analysis is difficult.

The low temperature n.m.r. spectrum (−80°) of **2***b* was not entirely satisfactory[7] and values for $J_{4e,5e}$ and $J_{6a,5e}$ were not significantly different from the room temperature values given in Table 1.

At this time it is not possible to firmly decide that **2***b* is conformationally time-averaging though the above observations tend to suggest this. The isomer **A1**, having the same configuration at phosphorus as **3**, **2***a*, and **1**, is expected to be the preferred one.

If **2***b* is undergoing a rapid, chair–chair inversion process it is necessary to offer some rationalization for the fact that **1**, for example, appears to be conformationally homogeneous. It is necessary to postulate that the interaction between the axial methyl group and the phenoxy group of conformer **A1** is now sufficiently large to partially destabilize **A1** with respect to **A2**. Furthermore, it is a necessary condition that the interaction of the axial methyl group and the phosphoryl oxygen of conformer **A2** does not further destabilize an already unfavorable situation.

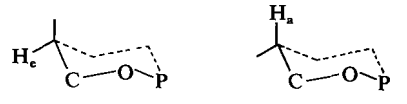
A considerable number of long-range ^{31}P–^{1}H couplings were observed for these derivatives. The magnitude of the ^4J coupling from ^{31}P, through oxygen, to a methyl group is dependent on the dihedral angle between the P—O and C—CH_3 bonds. Thus compounds **2***a* and *c*, which have the stereo-relationship depicted in **B** in which the P—O and C—Me bonds are



B **C**

trans anti-planar, give a coupling of *ca.* 2.5 Hz. In contrast, a coupling of less than 0.8 Hz[8] is observed for compound **2***b* which has a *gauche* relationship between the P—O and C—Me bonds, as in **C**.

The ^4J couplings between phosphorus and the C-5 methylene protons of **1**, **2***a*, and **2***c* also exhibit a marked stereospecificity, where coupling into the equatorially oriented proton, as in **D**, ranges from 2.4–2.7 Hz while coupling into



D **E**

the axially oriented proton, **E**, ranges from 0.7 to 0.9 Hz. The couplings for **2***b* are, as we now would anticipate, intermediate between these ranges. Presumably the sign of all of these long range couplings is positive, in accordance with the result (6) for acylic derivatives. It is also interesting that the coupling between the phosphorus and the methyl protons corresponds to the average of the phosphorus couplings to H_{5e} and H_{5a}.

[5]A good approximation in view of the similarity of the couplings for **2***a* and *c*.

[6]See later for a discussion of these couplings. The values of J_{P,CH_3} for isomer **2***a* were used for these calculations. Except for the value derived from J_{POCH}, the values of α are the average of the values derived from the two couplings available.

[7]The spectra were measured in CH_2Cl_2 solution. At low temperatures the Varian HA-100 does not give the best resolution, and in this case the situation was further aggravated by the increased viscosity of the solution.

[8]Likely zero in the absence of conformational time-averaging.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

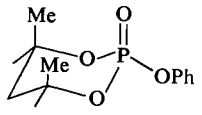
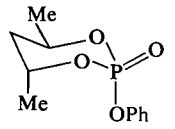
The formation of just the three products **2***a*, **2***b*, and **2***c* from the commercially available mixture of *meso*- and *d,l*-pentane-2,4-diols can now be rationalized. Both alcohols give rise to the two products which are isomeric at phosphorus. The products from the *meso* alcohol, **2***a* and *c*, have no tendency to invert conformation because this would introduce a severe non-bonded interaction between the methyl groups attached to C-4 and -6 (as in **F**).

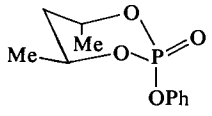


F

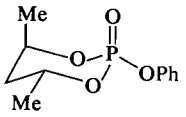
The initially formed products from the *d,l*-alcohol are depicted in **G**, **H**, **J**, and **K**. Derivatives **G** and **H** are indistinguishable by normal n.m.r. means; similarly, the pair **J** and **K** cannot



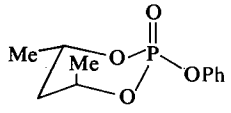
G



H



J



K

be differentiated. Inversion of conformation is now possible in this system, since it no longer introduces any serious non-bonded interactions. Hence, the conformational preference of the phosphate moiety can become effective and the product **2***b* is thus a racemic mixture of two derivatives, with the populations of conformers **G** and **H** favored to an extent of approximately 70%.

Geometric isomerism of the type we have described here has also been detected by other workers (7–9). In some instances isomeric mixtures have been separated (8) and some derivatives have been prepared by stereospecific syntheses (9).

Experimental

The general methods used in this study have been summarized previously (3).

The n.m.r. spectra for compounds **2** were iterated using the LAOCOON III computer program to best fit. The only parameters that could not be iterated were the P,4e and P,4a coupling constants. These couplings, as estimated from the phosphorus spectra and the band-widths of the 4,6 protons, are thought to be accurate to within 0.5 Hz for **2***a* and *c* and within 1.0 Hz for **2***b*. The assignment of 4e,5e and 4a,5e for **2***b* is not unambiguous. These numbers could be reversed. Unfortunately, homonuclear double resonance experiments in which the methyl resonances are irradiated, have not been successful due to the proximity of the methylene protons. The removal of the methyl coupling into the C_4,C_6 protons would have permitted assignment of these couplings. The remaining coupling constants for **2***b* and **2***c* are thought to be well within the stated limits above. For **2***a* the coupling constants from the computer program are slightly less accurate but should be within 0.2 Hz for the smaller couplings. $J_{4a,5a}$ and $J_{5e,5a}$ are probably within 0.5 Hz, having "probable errors" of 0.34 and 0.53 Hz respectively. The chemical shift assignment for 4e and 6a of **2***b* may also be reversed.

Reaction between Phenyl Phosphorodichloridate and Pentane-2,4-diol

Phenyl phosphorodichloridate[9] (3.0 g) was added dropwise with stirring to a solution of pentane-2,4-diol (1.0 g)[10] dissolved in anhydrous pyridine (40 ml) cooled in an ice-bath. The reaction mixture was left to stand in a refrigerator (*ca.* 3°) overnight. A small quantity of water (*ca.* 10 ml) was added to the reaction mixture to dissolve precipitated pyridinium hydrochloride and the entire solution was added to water (*ca.* 100 ml) in a separatory funnel. The resulting solution was extracted with chloroform (5 × 20 ml). The combined chloroform extracts were dried (Na_2SO_4) and concentrated to a syrupy residue (2.1 g, 90%). This material showed three spots on t.l.c. corresponding to the three isomers **2***a*, *b*, and *c* in order of decreasing R_f value.

Column chromatography of 0.5 g of the mixture was carried out using a silica gel column[11] (45 × 1.6 cm). Ethyl acetate was used as eluant and 2 ml fractions were collected. The fractions were monitored by t.l.c. and appropriate series of fractions were combined, and evaporated to give pure (t.l.c., ^1H and ^{31}P n.m.r.) samples of the three isomeric 4,6-dimethyl-2-oxo-2-phenoxy-1,3,2-dioxaphosphorinanes. Isomer **2***a* crystallized spontaneously, m.p. 93.0–95.5°; the other isomers have failed to crystallize over the past three years. The ^{31}P chemical shifts of the isomers **2***a*, *b*, and *c* were respectively, +125.8, +126.0, and +123.6 p.p.m.

Anal. Calcd. for $C_{11}H_{15}O_4P$: C, 54.6; H, 6.2. Found: **2***a*: C, 54.3; H, 6.4. **2***b*: C, 54.3; H, 6.3. **2***c*: C, 54.4; H, 6.3.

The proof of structure of these derivatives is discussed in the text.

It is a pleasure to thank the National Research Council of Canada for their generous support of this study. In particular the award of a Special Grant (no. A 5456) and an equipment grant (No. E 1338) greatly facilitated our progress.

Conformational Studies of Acyclic Organophosphate Esters using Nuclear Magnetic Resonance Spectroscopy[1]

BRUCE DONALDSON AND L. D. HALL[2]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received December 3, 1971

The *vicinal* $^{31}P—O—C—^{1}H$ couplings of a series of acyclic phosphate esters have been measured and rationalized in terms of varying populations of individual rotamers. Variable temperature measurements have been interpreted in terms of the enthalpy and entropy differences between *gauche* and *trans* rotational isomers.

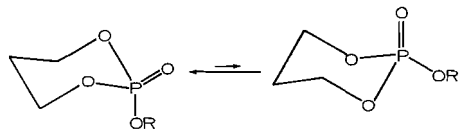
Les couplages *vicinaux* $^{31}P—O—C—^{1}H$ d'une série de phosphate esters acyliques ont été mesurés et rationalisés en termes de populations variables pour des rotomères donnés. Les mesures à températures variables ont été interprétées en termes de différences d'enthalpie et d'entropie entre les isomères de rotation *gauche* et *trans*.

Canadian Journal of Chemistry, **50**, 2111 (1972)

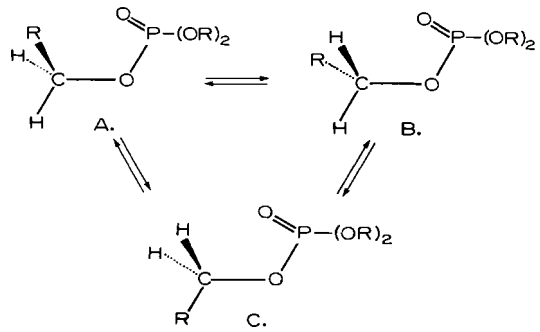
Introduction

Previous studies from this (1, 3) and other (4, 8) laboratories have recognized the potential of *vicinal* $^{31}P—O—C—^{1}H$ couplings as a basis for conformational studies of organophosphate esters. Many such studies have made the *a priori* assumption that cyclic systems such as the 2-oxo-1,3,2-dioxaphosphorinanes (Scheme 1) can serve as acceptable models for acyclic phosphates (Scheme 2). The experimental data available in the literature clearly indicates that there is indeed a semi-quantitative relationship between the coupling constants of these two systems; however the data also imply that a simple quantitative relationship does not exist.

In the present paper we review briefly the coupling constants available in the literature for derivatives of the 2-oxo-1,3,2-dioxaphosphorinane system, and compare these with data from series of specifically prepared acyclic phosphates. The couplings observed for the acyclic compounds are interpreted in terms of the populations of the *gauche* (**A** and **B**) and *trans* (**C**) rotational isomers, and in terms of the free energy differences between these isomers. The changes in the observed coupling with temperature for selected representatives of these compounds are studied and interpreted in terms of the enthalpy and entropy differences between the rotational isomers. Since this study was completed another group has published n.m.r. data for some acyclic phosphates (5); we shall discuss their work later on in this paper because we disagree with some of their interpretations.



SCHEME 1. Conformational isomers of 2-oxo-1,3,2-dioxaphosphorinane.



SCHEME 2. Rotational isomerism in acyclic phosphates.

Results and Discussion

The *vicinal* $^{31}P—O—C—^{1}H$ coupling data for three series of acyclic phosphotriester derivatives are shown in Table 1. The monotonic decrease in these values with increasing size of the alkyl group **R** is attributed to an increasing population of the rotational isomer having the R group *trans* to the phosphate moiety (as in **C**, Scheme 2).

*Private communication. J. Campbell of this laboratory.

In order to place these observations on a quantitative basis it is necessary to know the magnitudes of the couplings corresponding to dihedral angles between the P—O and C—H bonds, of 180 and 60° ($J_{180°}$ and $J_{60°}$, respectively). These two values, or an estimate thereof, may be obtained from the *vicinal* $^{31}P{-}O{-}C{-}^{1}H$ couplings of derivatives of the 2-oxo-1,3,2-dioxaphosphorinane system; a summary of the data available in the literature for such derivatives is given in Table 2.

It is evident that although there is a considerable spread in the values for J_{trans} (J_t) and J_{gauche} (J_g), the sum of the couplings is nearly constant. This suggests that the variations in the observed values are due to averaging of the couplings arising from varying populations of the different conformations of the phosphorinane ring. Assuming that only chair conformations are involved, a conformational inversion process will cause the observed *trans* coupling value, J_t (obs), to be lower than the true value J_t (real) and the observed *gauche* coupling value, J_g (obs), to be larger than the true value J_g (real).

These values are related to the extent of population time averaging by the expressions

$$\alpha J_t\,(\text{real}) + (1-\alpha)J_g\,(\text{real}) = J_t\,(\text{obs})$$

$$\alpha J_g\,(\text{real}) + (1-\alpha)J_t\,(\text{real}) = J_g\,(\text{obs})$$

where α is the population of one conformer and $(1-\alpha)$ the population of the other. This process would however leave the sum of the two observed couplings unchanged.

We believe that compound **1** undergoes only a very small amount of conformational inversion because it contains both the axial electronegative substituent on the phosphorous atom (such a substituent favours an axial configuration, with a ΔG of *ca.* 1500 cal (compound **2**, Table 2;

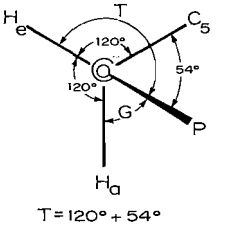
see also X-ray data ref. 6) and the equatorial substituent on C-5. Hence the experimental values of J_t 22.8 and J_g 1.4 Hz from this compound approximate J_t (real) and J_g (real).[3] These values in conjunction with the observed couplings can therefore be used to calculate the extent of time-averaging $(100 - \alpha)$ and hence the free energy difference (ΔG) between the two conformers: all of these data are listed in Table 2.

Using the percentage time-averaging we have approximated what the couplings would be for these compounds if no time-averaging were to occur. These calculated, non time-averaged couplings are seen to differ from those for compound **1** only in so far as their J_{sum} values differ; and thus support our premise that $^{31}P—O—C—^{1}H$ couplings in 2-oxo-1,3,2-dioxaphosphorinanes are largely independent of the ring substituents, but vary mainly as a function of conformational time-averaging.

It now remains to take these values of J_t (real) and J_g (real) and relate them to the required couplings $J_{180°}$ and $J_{60°}$.

X-Ray studies on compound **1** (6) have shown that the P—O—C_6—C_5 and P—O—C_4—C_5 dihedral angles are 54° rather than the 60° that would occur for an "ideal" cyclohexane geometry. Assuming that C-6 and -4 are tetrahedral centers, the P—O—C—H dihedral angles become 120° − 54° = 66° for the axial proton and 120° + 54° = 174° for the equatorial proton (Scheme 3).

It is well established that the $\cos^2 \phi$ relationship between the magnitude of the vicinal



T = 120° + 54°
G = 120° − 54°

SCHEME 3. P—O—C—H dihedral angles in 2-oxo-1,3,2-dioxaphosphorinane.

[3]Compound **8** in Table 2 of Bentrude and Hargis (10) has slightly more extreme couplings, however we calculate that compound **8** time averages to an extent only 0.5% less than compound **3** and it may therefore be taken as good supporting evidence for our choice of J_t and J_g.

coupling constant and the dihedral angle, suggested by Karplus (7) exists for H—C—C—H couplings. *Assuming that a similar relationship also exists for* $^{31}P—O—C—^{1}H$ *vicinal couplings* we can calculate $J_{180°}$ and $J_{60°}$ from J_t (real) and J_g (real). Thus:

$$J_{180°} = J_t \text{ (real)} \times \cos^2 180/\cos^2 174 = 22.9 \text{ Hz}$$

$$J_{60°} = J_g \text{ (real)} \times \cos^2 60/\cos^2 66 = 2.1 \text{ Hz}$$

Using these data, and assuming that they are applicable to acyclic phosphate rotamers we can calculate the coupling exhibited by methyl phosphates.

$$J_{av} = 1/3(J_{180°} + 2J_{60°}) = 9.0 \text{ Hz}$$

The observed values, however, lie in the range 11.0 to 11.5 Hz.

Thus it is not possible to compare directly data from cyclic phosphates with that from acyclic phosphates. Several possible reasons for this lack of quantitative agreement have been considered:

(*a*) That the phosphorinane ring system is flatter in solution than in the crystalline phase. The P—O—C—H_{ax} dihedral angle would thus be increased, causing the calculated $J_{60°}$ to be increased; the P—O—C—H_{eq} dihedral angle would decrease causing the calculated $J_{180°}$ to increase; thus J_{av} would increase. However, the calculated J_{av} for methyl rotamers is still less than the observed value when $J_{60°}$ (the more rapidly changing quantity) reaches the lowest observed coupling for the acyclic rotamers (trineopentyl phosphate 4.05 Hz at 185 °K) a coupling that still contains some *trans* contribution. This value therefore acts as a maximum limit for $J_{60°}$.

(*b*) That the energy minima for the acyclic rotamers do not occur at P—O—C—H dihedral angles of 60 and 180°, but at $(60 + \phi)°$ and $(60 - \phi)°$ and at $(180 \mp \phi)°$. The observed coupling J_{obs} is then given by $1/3(J_t + 2J_g)$, where

$$J_t = J_{180°} \times \cos^2 (180 \pm \phi)°/\cos^2 180°$$

$$2J_g = J_{60°} \times \cos^2 (60 + \phi)°/\cos^2 60° + (J_{60°} \times \cos^2 (60 - \phi)°/\cos^2 60°$$

From which it follows that J_t is less than $J_{180°}$ and J_g is less than $J_{60°}$, and hence that J_{obs} is less than J_{av}. The J_{obs} in the phosphorinanes 11–11.5

For personal use only.

Hz is in fact more than the calculated 9.0 Hz and indicates that such asymmetric rotational isomers are not the cause of the inconsistency in the data.

(*c*) That the electronegative phosphoryl oxygen selectively reduces the coupling into the equatorial proton by 8–10 Hz due to the all *trans* transmission pathway; no similar effect being operable for the axial proton. If this effect were to operate, conformers with an axial phosphoryl oxygen would have to show a J_t of *ca.* 30 Hz. The axial preference of OR substituents on phosphorus precludes direct observation of these conformers; however any phosphorinane which significantly time-averages should show an increase in both J_t and J_{sum}. Inspection of the data in Table 2 shows no evidence of such an effect.

(*d*) That a significant amount of twist conformation is present in the phosphorinane ring; in this case both dihedral angles are 120° and exhibit small *vicinal* couplings. The presence of twist conformations would thus produce a decrease in J_{sum}. The observed constancy of J_{sum} indicates that the population of twist conformers either is constant for all the compounds studied or more reasonably that it is zero.

None of these approaches is able to account for the only semi-quantitative agreement between the data obtained from the two sources. The only obvious difference between these systems is that free rotation about the P—O bond can occur in the acyclic rotors but not in the phosphorinanes; it seems likely that this is in some way responsible for the discrepancy.

We have therefore calculated the populations of the *trans* rotational isomers of the compounds in Table 1 using, first the derived values for $J_{180°}$ and $J_{60°}$ (lines A_1, A_2, and A_3, Fig. 1) and second using the ratio of $J_{180°}/J_{60°}$ and the observed coupling value for the methyl representative of each set of compounds. In this case a different set of J_t and J_g values, J_T and J_G, have been derived for each set of compounds. These normalized data which all fall very close to line B, are given in Table 3.

Assuming that a $\cos^2$ relationship exists between dihedral angle and *vicinal* coupling, the rate of change of the coupling with angle will be greatest for the *gauche* angle of 60°. Thus J_g, the parameter upon which the calculated rotamer

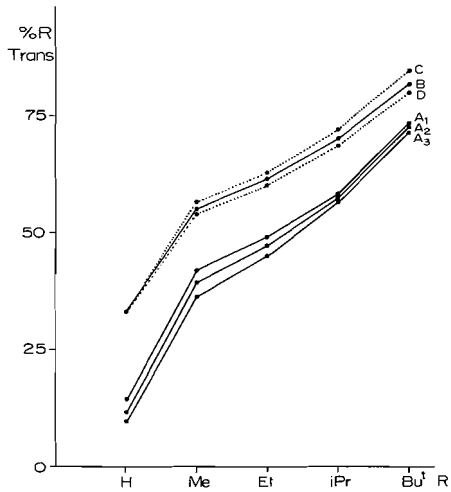

FIG. 1. *trans*-Populations of acylic rotamers as a function of substituent size R.

Line A_1 (compound set 1, $RCH_2O—\overset{\overset{O}{\|}}{P}—(OPh)_2$), line A_2 (compound set 2, $(RCH_2O)_2\overset{\overset{O}{\|}}{P}—OPh$), and line A_3 (compound set 3 $(RCH_2O)_3P{=}O$) obtained using J_{180} and J_{60} values derived from the 2-oxo-1,3,2-dioxaphosphorinane system. Line B using J_T and J_G values normalized to give a 33.3% rotameric population for the methyl phosphate of each compound set; set 1, J_T 29.0, J_G 2.7; set 2, J_T28.6, J_G 2.6; set 3, J_T 27.9, J_G 2.55. populations are most sensitive, is the one with the greatest uncertainty. The lines C and D in Fig. 1 represent the calculated *trans* rotamer populations for the likely extremes of J_g ($\pm$0.5 Hz). The uncertainties in J_T and the sensitivity of the populations toward it are considerably smaller and are ignored. The derivation of the relationships that we have used to calculate the *trans* rotamer population and the equilibrium constants are given in the Appendix.

Regardless of the J_t and J_g values used, the observed monotonic decrease in J_{obs} with increasing bulkiness of the substituent R is reflected in a considerable increase of the *trans* rotamer population. We would point out that the differences between the rotamer populations calculated using the normalized and unnormalized data decreases with increasing population of the *trans* rotamer, thus in studying systems of potential biochemical interest for which this

present work acts as a model study, the R groups encountered are usually large enough to give *trans* rotamer populations not seriously altered in a semi-quantitative way by the choice of J_t and J_g.

The data represented by line B, Fig. 1 are, we believe, the best available at present. Using these parameters we have calculated the *trans–gauche* interconversion equilibrium constants and also the free energy differences between the *gauche* and *trans* rotational isomers (Table 3).

The quantitative agreement between the data from the three sets of acylic rotamers is excellent and exemplifies the independence of J $^{31}P—O—C—^{1}H$ upon phosphorus substituents in phosphotriesters. Thus we discount the rationale of Axtmann *et al.* (11) that decreases in couplings arise from electronegativity effects. We also discount the attempt by Katritsky *et al.* (8) to rationalize the data from cyclic and acyclic compounds by assuming that the steric effect of the R group is zero and hence that no nonequivalent rotational isomers occur.

Temperature Studies

Invariance of J_{obs} with temperature, observed for methyl diphenyl phosphate is the behavior expected from the assumption of the equivalence of the rotational isomers in methyl phosphates. The decrease of J_{obs} with decreasing temperature observed for the ethyl and neopentyl derivatives arises from an increasing proportion of the *trans* rotamer at lower temperatures. (Table 4, columns 1 and 2).

It is convenient to express the J_{obs} temperature relationship as a plot of J_{obs} *vs.* $1/T$ (Fig. 2). Over the temperature range experimentally accessible the relationship between J_{obs} and $1/T$ appears linear, and has been so reported (5). However, from the expression for the equilibrium constant K derived in the Appendix to this paper it can be seen that at very high temperatures when the rotational isomers tend to equivalence and K approaches unity, J_{obs} approaches J_{av}. At low temperatures when the *trans* rotamer becomes populated exclusively K becomes very large and then J_{obs} asymptotically approaches J_g. Combining the expression for K and the expression relating the equilibrium constant with temperature it can be seen that the relationship between J_{obs} and $1/T$ is indeed non-linear except when J_{obs} is equal to J_{av}. The conclusions drawn by the workers in ref. 5, that with increasing temperature compounds such as tri-neopentyl phosphate will never attain equal populations of the rotational isomers, are based on a linear relation-

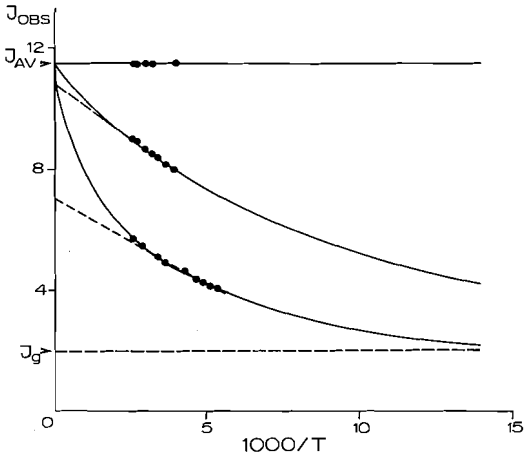

FIG. 2. Variation of the observed rotamer coupling J_{obs} with $1000/T$ for (A) methyl diphenyl phosphate, (B) diethyl phenyl phosphate, (C) *neo*-pentyl diphenyl phosphate. The dashed straight lines passing through the data points of B and C represent interpretation of similar data made in the study, ref. 5.

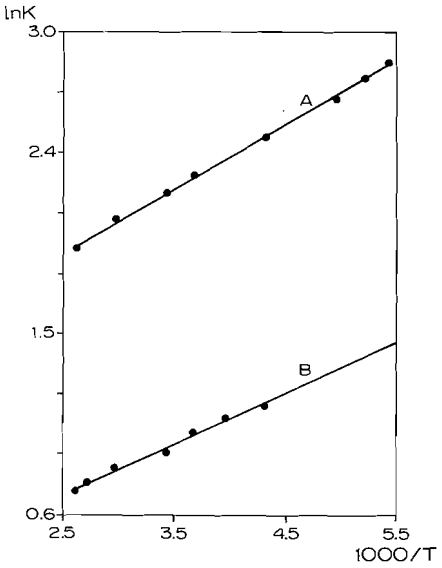

FIG. 3. Plot of log of the rotameric equilibrium constant ln K against the reciprocal of the absolute temperature T. (A) *neo*-pentyl diphenyl phosphate, (B) diethyl phenyl phosphate.

ship between J_{obs} and $1/T$, and are therefore incorrect.

By plotting ln K *vs.* $1/T$ and ΔG *vs.* T (Figs. 3 and 4) we have estimated the enthalpy and entropy differences between the rotational states about the O—C bond. The ln K *vs.* $1/T$ plots have correlations greater than 0.996 and yield values of ΔH of 650 cal for neopentyl diphenyl phosphate and 500 cal for diethyl phenyl phosphate. The plots ΔG *vs.* T have correlations of 0.999 for neopentyl diphenyl phosphate, 0.988 for diethyl phenyl phosphate and >0.999 for methyl diphenyl phosphate yielding values of 650, 480, and 0 cal respectively for ΔH and 2.2, 0.2 and 0 cal/degree mol for the entropies.

In summary then, we have confirmed that a qualitative relationship exists between the *trans* and *gauche* $^{31}P—O—C—^{1}H$ couplings of derivatives of the 2-oxo-1,3,2-dioxaphosphorinane system and the couplings of acyclic phosphate esters. This relationship accords with variations of rotamer populations which follow conven-

tional conformational tenets. However, it must be emphasized that a precise quantitative relationship does not exist and we can at present offer no acceptable reason as to why this should be.

Experimental

The following general method was used for the preparation of the acyclic phosphate esters. Phosphorus oxychloride, phenylphosphorodichloridate, or diphenylphosphorochloridate as appropriate (1 equiv) was added slowly to a solution of the alcohol (1.2 equiv) in pyridine solvent, the rate of addition being adjusted to keep the temperature below 40°. After standing for 2 h, unreacted phosphorochloridate was destroyed by the addition of 5 volumes of water. After a further 30 min the mixture was extracted into chloroform and evaporated to a small volume and traces of pyridine were removed as the toluene azeotrope. The crude alkyl phosphate was purified by vacuum distillation (180–220° at 0.1 mm). Yields of crude product in excess of 80% were obtained. Compounds in set 1 (Table 1) were characterized by elemental micro-analysis in addition to the n.m.r. measurements. The remaining compounds were shown to be pure by t.l.c. and were characterized by comparison of the n.m.r. spectra with the appropriate compound of set 1.

Room temperature n.m.r. spectra were run on *ca.* 15% solutions in $CDCl_3$ using a Varian HA 100 spectrometer in the frequency sweep mode. Spectral assignment was simplified by means of phosphorus decoupling experiments (9) and true couplings obtained using the LAØCQØN-3 iterative computer programme. Variable temperature studies were conducted in *ca.* 5% solutions in CH_2Cl_2 for temperatures below 25° and on neat oils at high temperatures using a Varian XL-100 spectrometer.

The t.l.c. experiments were on silica gel G plates in 5% methanol in chloroform solvent.

Measurements were not made with diethyl phosphate below 233 °K because the magnitude of the phosphorus coupling approached that of the proton vicinal coupling.

The plots shown in Figs. 3 and 4 are least squares analyses made with a Hewlett Packard model 9100 programmed calculator and model 9125A plotter.

Appendix

This gives the derivation of expressions for the *trans* population and the *trans–gauche* rotamer equilibrium constants in terms of $J_{180°}$ and $J_{60°}$.

The observed coupling for the rotational isomers shown in Scheme 2 which interconvert rapidly on the n.m.r. time scale is given by the weighted sum of the coupling occurring in each isomer:

$$J_{obs} = J_C[C] + J_A[A] + J_B[B]$$

where [C] is the concentration of the *trans* rotamer (C); [B] = [A] concentrations of the *gauche* rotamers (A and B); and [C] + [B] + [A] = 1.

The couplings occurring in each rotational isomer are given by:

$$J_C = \frac{J_G + J_G}{2} \qquad J_A = J_B = \frac{J_G + J_T}{2}$$

thus

$$J_{obs} = J_G[C] + (J_G + J_T)[A]$$

and hence

$$J_{obs} = J_G[C] + (J_G + J_T)\left(\frac{1 - [C]}{2}\right)$$

Rearranging this equation yields the percentage concentration of the *trans* rotamer:

$$[C] = \frac{J_T + J_G - 2J_{obs}}{J_T - J_G} \times 100$$

The equilibrium constant is given by:

$$\frac{[C]}{[A]} = \frac{2[C]}{1 - [C]}$$

Yielding

$$K = \left[\frac{J_T - J_{obs}}{J_{obs} - J_G}\right] - 1$$

It is a pleasure to thank the National Research Council of Canada for their generous financial support via operating grants (A-1905), via a special grant (A-5456) and an equipment grant (E-1338).

Evaluation of the Binding Constants, Bound Chemical Shifts, and Stoichiometry of Lanthanide–Substrate Complexes[1]

IAN ARMITAGE,[2] G. DUNSMORE, L. D. HALL,[3] AND A. G. MARSHALL

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received November 4, 1971

A theoretical analysis of the equilibrium between a lanthanide shift reagent, L, and a substrate, S, is presented. When $[S]_0 \gg [L]_0$, then a plot of $[S]_0$ *vs.* $(1/\delta)$ at constant $[L]_0$ gives a straight line whose slope is $[L]_0\Delta_B$ and whose *y*-intercept is $-\{(1/K_B) + [L]_0\}$, where K_B is the equilibrium binding constant, δ is the induced chemical shift, and Δ_B is the bound chemical shift. A more general and accurate solution using a computer programme is applicable for all ratios of $[L]_0/[S]_0$. It is also shown that the conventional procedure for evaluating Δ_B leads to varying values for Δ_B that are generally too small, even under the most optimal conditions. $Eu(DPM)_3$[4] has a K_B of *ca.* 34.2 l mol^{-1} with *n*-propylamine and K_B of *ca.* 9.7 l mol^{-1} with *neo*-pentanol. These values increase by at least 10-fold (to $\geqslant$100 l mol^{-1}) for the corresponding complexes with $Eu(FOD)_3$[4] shift reagent. However, the bound chemical shifts for the $Eu(FOD)_3$ complexes are nearly the same as for the $Eu(DPM)_3$ complexes. Finally, it is shown *definitively* that the association between $Eu(DPM)_3$ and either *n*-propylamine or *neo*-pentanol has 1:1 stoichiometry; with $Eu(FOD)_3$ a *tentative* assignment of 1:1 stoichiometry can be made.

Une analyse théorique est présentée sur l'équilibre entre un réactif lanthanide shift L et un substrat S. Pour $[S]_0 \gg [L]_0$, la courbe de $[S]_0$ en fonction de $(1/\delta)$ pour différents $[L]_0$ constants, est une droite dont la pente est $[L]_0\Delta_B$ et l'ordonnée à l'origine $-\{(1/K_B) + [L]_0\}$ où K_B est la constante d'équilibre de liaison, δ le déplacement chimique induit, et Δ_B le déplacement chimique de liaison. Une solution plus générale et plus précise utilisant un programme, est applicable pour tout rapport $[L]_0/[S]_0$. On a également montré que le procédé conventionnel pour évaluer Δ_B conduit à des valeurs variables généralement trop petites, même dans les conditions les plus optimales. L'$Eu(DPM)_3$ a un K_B de 34.2 l mol^{-1} avec la *n*-propylamine et un K_B de 9.7 l mol^{-1} avec le *néo*-pentanol. Ces valeurs croissent au moins de 10 fois (jusqu'à $\geqslant$ 100 l mol^{-1}) pour les complexes correspondants avec l'$Eu(FOD)_3$. Cependant les déplacements chimiques de liaison pour les complexes avec l'$Eu(FOD)_3$ et l'$Eu(DPM)_3$ sont pratiquement les mêmes. En définitive on a montré que l'association entre l'$Eu(DPM)_3$ et la *n*-propylamine ou le *néo*-pentanol est de stoéchiométrie 1:1; avec l'$Eu(FOD)_3$ cette stoéchiométrie possible peut être avancée.

Canadian Journal of Chemistry, **50**, 2119 (1972)

Introduction

The extraordinary surge of interest which has followed from Hinckley's discovery (3) of the lanthanide "shift-reagents" attests to the great importance of this area. Indeed it is already clear that applications using these substances will revolutionize ^1H n.m.r. studies of complex organic systems, at least for those which are soluble in a suitable organic solvent. For the vast majority of these present applications, the details of the mechanism by which the shift-reagent acts are unimportant — it suffices that such changes make a spectral assignment or analysis possible. Nevertheless, beyond the intrinsic interest which would follow from a fundamental description of the binding process, knowledge of the binding stoichiometry and equilibrium constants provides for an unequivocal determination of the "bound" chemical shift for each proton of an organic substrate (S) bound to a lanthanide shift reagent (L). When reliable bound chemical shifts have been determined for such complexes, it should be possible to establish with some confidence the conformation of the complex and hence of the organic moiety itself.

The present paper contains a detailed analysis of the equilibrium process which occurs when a lanthanide shift reagent combines with a substrate molecule having a suitable binding site. In particular, we show how to calculate the equilibrium binding constant (K_B) and stoichiometry, as well as the bound chemical

shift (Δ_B) of the substrate molecule when it is associated with the lanthanide. Predictions based on this theory are subjected to rigorous experimental test.

As a consequence of the theory, it will be evident that the slope of a plot of observed shift *vs.* $[L]_0/[S]_0$ gives an empirical number (4) which can differ greatly from the actual Δ_B, and that the error can even be different for different protons in the same molecule.

Theory

(I) Fast Exchange Limit

The first step in analyzing the chemical shifts for the system,

$$[1] \qquad L + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} LS,$$

(in which L denotes lanthanide, S denotes ligand or substrate, and LS is the lanthanide–substrate complex whose chemical shift we would like to obtain) is to establish whether the exchange rates are fast or slow on the n.m.r. time scale (5).

If k_{-1}, $k_1[L] \gg (\delta_{LS} - \delta_S)$, the fast-exchange limit, then there will be a single resonance centered at

$$[2] \qquad \delta_{obs} = f_S\delta_S + f_{LS}\delta_{LS}$$

where δ_S and δ_{LS} are the respective chemical shifts for S and LS, and f_S and f_{LS} are the respective concentration fractions of S at the two sites. But $f_S = 1 - f_{LS}$, so an "induced chemical shift", δ, may be defined as

$$[3] \qquad \delta = \delta_{obs} - \delta_S = f_{LS}(\delta_{LS} - \delta_S)$$

or simply

$$[4] \qquad \delta = f_{LS}\Delta_B$$

where Δ_B is the chemical shift for the LS complex relative to the chemical shift for free S.

Experimentally, the observation of a single resonance whose chemical shift varies linearly with the fraction of substrate present as complex is direct evidence that the fast-exchange limit applies. Using this criterion, it was found that the fast-exchange limit was valid for all data reported in this paper.

(II) Experiments in which $[L]_0$ is Varied at Constant $[S]_0$

Let $[L]_0$ and $[S]_0$ be the initial concentrations of lanthanide and substrate (see Experimental for mixing procedure). Then

$$[5] \qquad \delta = \frac{[LS]\Delta_B}{[LS] + [S]} = \frac{[LS]}{[S]_0}\Delta_B$$

Next, let the binding constant for process [1] be K_B:

$$[6] \qquad K_B = \frac{[LS]}{[L][S]} = \frac{[LS]}{([L]_0 - [LS])([S]_0 - [LS])}$$

It is now necessary to solve eq. 6 for [LS] and then substitute for [LS] in eq. 5, so as to determine the desired quantity Δ_B in terms of the measured parameters $[L]_0$, $[S]_0$, and δ. In order to avoid solving the quadratic eq. 6, it is convenient simply to restrict the experiments to the range,

$$[7] \qquad [S]_0 \gg [L]_0,$$

thus guaranteeing that $([S]_0 - [LS]) \simeq [S]_0$ in eq. 6. Using [7] to solve [6] for [LS], and substituting for [LS] in [5] gives,

$$[8] \qquad \delta = \frac{K_B[L]_0\Delta_B}{1 + K_B[S]_0}$$

Equation 8 is the principal result of this section. The immediate question now becomes, what will happen if one plots δ *vs.* $[L]_0/[S]_0$? The answer is clear for two simple limits:

(*a*) $K_B[S]_0 \gg 1$, *i.e.*, strong binding or high substrate concentration. In this limit, eq. 8 reduces to

$$[9] \qquad \delta = \Delta_B[L]_0/[S]_0$$

so that a plot of δ *vs.* $[L]_0/[S]_0$ will be a straight line through the origin, with slope, Δ_B.

(*b*) $K_B[S]_0 \ll 1$, *i.e.*, weak binding or low substrate concentration. In this limit, eq. 8 reduces to

$$[10] \qquad \delta = K_B\Delta_B[S]_0\left(\frac{[L]_0}{[S]_0}\right)$$

In other words, a plot of δ *vs.* $[L]_0/[S]_0$ will give a straight line whose slope is proportional to $[S]_0$.

Results *a* and *b* from eq. 8 suggest that in carrying out several sets of experiments (each set at a different $[S]_0$ level), then for low $[S]_0$ the slope of a plot of δ *vs.* $[L]_0/[S]_0$ will be proportional to $[S]_0$, while for large $[S]_0$ the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

slope will simply be Δ_B independent of $[S]_0$. Therefore, *only at high substrate concentrations* is it permissible to take the slope of a plot of δ *vs.* $[L]_0/[S]_0$ as Δ_B. This conclusion is of quite practical significance, as shown in the Results section.

(III) Experiments in which $[S]_0$ is Varied at Constant $[L]_0$

Since it is now clear that there is no simple way to extract Δ_B from a single plot of δ *vs.* $[L]_0/[S]_0$ at constant $[S]_0$, one is led to seek out some other simple experiment which will yield the bound chemical shift. Returning to eq. 6, suppose that only the $[LS]^2$ term is neglected (6), then

$$[11] \qquad \delta = \frac{K_B[L]_0\Delta_B}{1 + K_B[S]_0 + K_B[L]_0}$$

which may be re-grouped to give

$$[12] \quad [S]_0 = [L]_0\Delta_B(1/\delta) - ((1/K_B) + [L_0])$$

Equation 12 gives the important fact that a plot of $[S]_0$ *vs.* $(1/\delta)$ gives a straight line whose slope is $[L]_0\Delta_B$ and whose *y*-intercept is $-((1/K_B) + [L]_0)$. Such a plot thus yields both Δ_B and K_B unambiguously.

However, as pointed out by Dahlquist and Raftery for analogous enzyme kinetics experiments (6), the approximations, $(1/K_B) \geqslant [S]_0$ and $\delta \ll \Delta_B$, are necessary to reach eq. 12. The safest procedure is therefore to solve the full quadratic eq. 6 according to the following computerized procedure first suggested by Sykes (7). First, guess a value for K_B and use this value to compute [LS] from eq. 6; this gives [LS] expressed as a function of $[L]_0$ and $[S]_0$. Next, perform experiments in which $[L]_0$ is fixed and $[S]_0$ is varied. Use the expression for [LS] to compute [LS] for each of the experimental $[S]_0$ values. Next, plot δ *vs.* $[LS]/[L]_0$ to obtain Δ_B from eq. 5. This plot (since the wrong value of K_B was probably guessed in the first place) will usually give a curve rather than a straight line. Thus, as a criterion of how well K_B was chosen, let the computer calculate a least mean square slope for the plot and also the standard deviation for the slope. This whole procedure is now repeated for say, 100 values of K_B spanning three powers of 10 in magnitude, and the standard deviation of the slope is plotted as a function of K_B. The correct value of K_B is then taken as the one which gives the smallest standard deviation in the plots of δ *vs.* $[LS]/[L]_0$.

For practical purposes, we have found that for low $[S]_0$ concentrations (see Discussion) the graphical treatment based on eq. 12 gives reasonable agreement with the full computer treatment outlined above, and may often be preferable, inasmuch as precise values for K_B from the computer treatment seem to require quite accurate shift measurements.

All values of K_B and Δ_B reported in this paper were taken from low-concentration experiments in which $[S]_0$ was varied at constant $[L]_0$. In principle, one might hope to extract K_B and Δ_B from experiments in which $[L]_0$ is varied at constant $[S]_0$, based on the slopes of plots of δ *vs.* $[L]_0$ according to eq. 8. There are two reasons why this procedure is impractical. First, the slope of such a plot depends on $[S]_0$, so one would have to carry out several series of experiments at different $[S]_0$ values, necessitating many more experimental measurements than a single "run" in which $[S]_0$ is plotted *vs.* $(1/\delta)$. Second, when $[L]_0$ is changed, substantial changes in the bulk magnetic susceptibility of the solution are introduced, and even an internal standard may not compensate properly for them.

(IV) Stoichiometry

In this section, the implications of a one-step binding process,

$$[13] \qquad L + 2S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} LS_2$$

are discussed. The actual binding process might involve several steps; in writing [13], it is simply assumed that there is a single step which is associated with the large change in chemical shift between "free" and "bound" substrate. It is only this step which will affect n.m.r. measurements (5). It is easy to imagine multi-step binding phenomena which will not satisfy eq. 13 even on an n.m.r. basis — such phenomena are not treated here, because it will be not possible in general to obtain separate binding parameters for even a two-step process, when the n.m.r. data fall in the fast-exchange limit.

For the one-step 2:1 binding model, [13], the criterion for fast exchange is readily shown to be the same as for the case of 1:1 binding; thus an observed proportionality between δ and f_{LS_2}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is direct evidence that the fast-exchange limit is satisfied.

The equilibrium binding constant for process [13] is

$$[14] \qquad K = \frac{[LS_2]}{[L][S]^2}$$

and it follows that

$$[15] \qquad \delta = \frac{[LS_2]}{[S]_0}\Delta_B$$

if we assume that both S molecules have the same chemical shift when bound to the lanthanide. Solving [15] for $[LS_2]$ and substituting into [14] as in section III, and again restricting experiments to the range $[S]_0 \gg [L]_0$ (so that $(\delta/\Delta) \ll 1$), yields

$$[16] \qquad [S]_0^2 - \frac{\Delta}{\delta}[L]_0[S]_0 + (1/K) = 0$$

(It may be noted that eq. 16 has the same form as eq. 12 if one makes the correspondence, $K[S]_0 = K_B$; the $[L]_0$ term in eq. 12 is usually negligible.)

A criterion for stoichiometry is now available. One need simply specify $[L]_0$, Δ_B, and K, and then use eq. 16 to compute a set of δ-values from a given range of $[S]_0$-values; the values may then be used to construct a plot of $[S]_0$ *vs.* $(1/\delta)$ as shown in Fig. 1. The figure shows the result for several choices of K_B which span the range of K_B-values actually determined in the present experiments. To facilitate comparison with the result for 1:1 binding, a plot of $[S]_0$ *vs.* $(1/\delta)$ for 1:1 binding is also shown; to make the comparison as direct as possible, values of $K_B = 0.1K$ were chosen since typical experimental $[S]_0$ values were about 0.1 *M*. The plots clearly show that for either large K_B (strong binding) or large $[S]_0$, one cannot distinguish between 1:1 binding and 2:1 binding from a plot of this type. On the other hand, when K_B is small enough to be measurable, there are readily observable differences between 1:1 and 2:1 binding. Since our present $[S]_0$ *vs.* $(1/\delta)$ plots (*vide infra*) are linear, it is evident at once that the binding is either strong and/or 1:1. If the experimental extrapolations to $(1/\delta) = 0$ give a *y*-intercept which is more negative than $-[L]_0$, then a straight-line experimental plot is definitive proof that the binding is 1:1 rather than 2:1.

When K_B is large (strong binding), there are no well-controlled measures of stoichiometry. However, some information may be obtained from (high-concentration) experiments in which δ is determined as a function of $[L]_0$ at constant $[S]_0$, and the data are displayed in a plot of δ *vs.* $[L]_0/[S]_0$. If either K_B or $[S]_0$ were infinitely large, such a plot would simply be a straight line from the origin to the end point, $\delta = \Delta_B$ at $[L]_0/[S]_0 = 1$. For smaller $[S]_0$, there will no longer be a sharp end point and one will observe a family of curves which converge for large $[S]_0$ (see Results). Experimentally, then, one need construct several such plots at increasing $[S]_0$ until the lines begin to converge; extrapolation of the limiting line to $\delta = \Delta_B$ (where Δ_B has been determined reliably from low-concentration data according to the method of section III) will then give an *x*-intercept of $(1/n)$.[5]

In conclusion, the most critical test for 1:1 stoichiometry is the linearity of a plot of $[S]_0$ *vs.* $(1/\delta)$, where the range of $[S]_0$ values should cover an order of magnitude in concentration, and include the lowest accessible concentrations for best results.

Experimental

It must be emphasized that all apparatus and materials used in these experiments were carefully dried before use. Any lapse in such precautions has always led to poor results.

Materials Used

Tris(dipivalomethanato)europium(III) was prepared from europium oxide[6] (99.99%) following the method of Eisentraut and Sievers (8). The material from the reaction was stored in a vacuum desiccator over phosphorus pentoxide. A small sample was vacuum sublimed at 145° immediately prior to an experiment. All manipulations after sublimation were carried out in a glove-bag which had been flushed several times with dry nitrogen. Tris(2,2-dimethyl-6,6,7,7,8,8,8-heptafluoro-3,5-octanedionato)europium(III) was also prepared from europium oxide, but by the method of Springer *et al.* (9). The complex was recrystallized twice from methylene chloride and was thereafter stored in a vacuum desiccator as described above. This is important because it has been reported (10) that this compound can absorb 1 mol equiv of water from the atmosphere. *n*-Propyl-

[5]In principle, one might hope to obtain K_B in strong-binding situations by fitting the δ *vs.* $[L]_0/[S]_0$ curve of the preceding paragraph. In the Discussion, it is shown that this method may not work, even if an independently determined Δ_B is used for the fit.

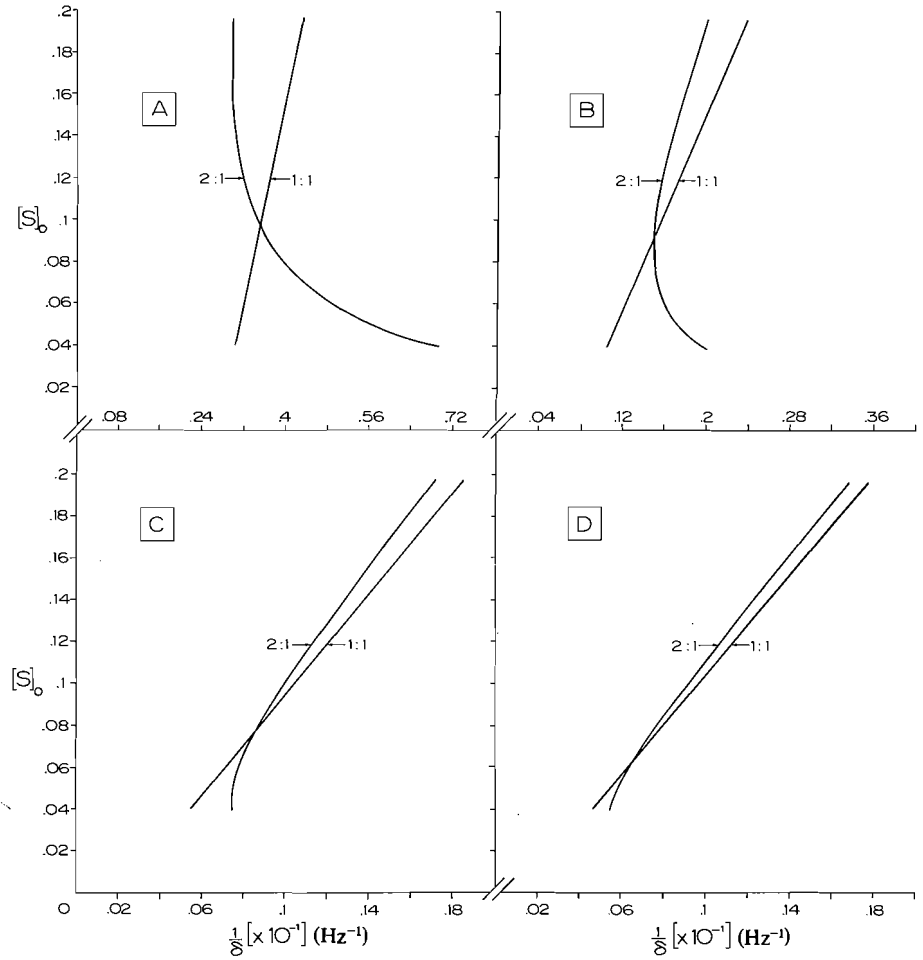

FIG. 1. Graphs of initial substrate concentration $[S]_0$ *vs.* $(1/\delta)$ for a hypothetical substrate of $\Delta_B = 2000$ Hz in the presence of shift reagent of concentration $[L]_0 = 0.006$ *M*. For each graph, the binding is assumed to be either 1:1 (with corresponding binding constant, K_B or 2:1 with binding constant, K). (A) $K = 32$, $K_B = 3.2$; (B) $K = 126$, $K_B = 12.6$; (C) $K = 501$, $K_B = 50.1$; (D) $K = 1000$, $K_B = 100$.

amine (**1**) from Eastman Organic Chemicals was purified by distillation from KOH pellets into a sealed receiver also containing KOH pellets. The material had b.p. 49.0°. *neo*-Pentanol (**2**) was purchased from Matheson Coleman and Bell and was purified by distillation from calcium hydride. The material had b.p. 114 °C. Deuterochloroform (99.8%) from Merck Sharp and Dohme, Montreal was stored over Linde molecular sieve (4A) which had been heated in an oven at 100° for 24 h.

Nuclear Magnetic Resonance Measurements

All measurements were made with a Varian XL-100 instrument operating in the frequency-swept mode with a probe temperature of 38.8°. Deuterochloroform was used as solvent with tetramethylsilane as the internal reference. The preparation of all solutions was conducted under dry nitrogen in a glove-bag using apparatus that had been baked at 110° immediately prior to use.

Method 1. Constant $[S]_0$, Varying $[L]_0$

A series of standard solutions, each containing a known amount of the substrate (*ca.* 0.6, 0.2, 0.08, 0.04 *M*) was prepared. One particular standard solution was then selected and 1.0 ml of this solution was then used to dissolve a known quantity of the lanthanide reagent (*ca.* 0.015 g, 0.02 *M* of $Eu(DPM)_3$; *ca.* 0.190 g, 0.175 *M* of $Eu(FOD)_3$). The spectrum of this mixture then gave the maximum shift. Further spectra were run after each successive addition of a 0.10 ml aliquot of the standard substrate solution. In each case the observed shift decreased.

Method 2. Constant $[L]_0$, Varying $[S]_0$

The lanthanide reagent (0.042 g, 0.012 *M* of $Eu(DPM)_3$;

*Values of Δ_B (p.p.m.) and K_B (l mol^{-1}) derived from a least-squares fit of a plot of $[S]_0$ *vs.* $(1/\delta)$; precision of either result is ±10%.
†Values of Δ_B and K_B derived (from the same raw data) by a more exact formula, based on an iterative computer program (see text); precision of either result is ±10%.
‡These values should be regarded with some skepticism (see text).

ca. 0.070 g, 0.012 *M* of $Eu(FOD)_3$) was dissolved in deuterochloroform (4.8 ml) and tetramethylsilane (0.2 ml). The substrate was separately dissolved in 5.0 ml of deuterochloroform. Aliquots (0.50 ml) of the lanthanide solution were then added to each of a series of 5–10 graduated 1.0 ml flasks. To each of these flasks was now added varying amounts of the stock solution of substrate; *e.g.*, vial 1, 0.5 ml; vial 2, 0.4 ml; etc. The content of each flask was then made up to 1.0 ml by further addition of deuterochloroform. Each solution was then placed in a separate n.m.r. tube which was capped and stored in a thermostatted water bath prior to measurement.

All plots of the experimental data were made with a Hewlett–Packard Calculator (model 9100 B) and a Hewlett–Packard Calculator Plotter (model 9125 A). We are indebted to Professor Ross Stewart of this Department for making this equipment available to us.

Results and Discussion

It is convenient first to discuss the methods which we believe provide for general and accurate evaluation of Δ_B and K_B, followed by a demonstration that the slope of a plot of δ *vs.* $[L]_0/[S]_0$ (4) will not in general be a good measure of Δ_B, and that the error can vary even among different protons in the same molecule for those measurements. Finally, determination of the stoichiometry of ligand–lanthanide complexes is indicated, followed by a discussion of the interesting ligand-dependence of the K_B and Δ_B values.

Solutions of *n*-propylamine, **1**, and of *neo*-pentanol, **2**, each with $Eu(DPM)_3$, were prepared according to the procedure outlined in the Experimental as method 2. The chemical shifts of these solutions were then measured, and the results plotted on a graph of $[S]_0$ *vs.* $(1/\delta)$; the plot for *n*-propylamine is shown in Fig. 2. The values of K_B and Δ_B were obtained from these plots following the relationship given in eq. 12; the numerical values for these parameters are shown in Table 1. It is expected that the same value should be obtained for K_B regardless of which proton is used for its determination. This may be confirmed experimentally by noting that the plots for protons H_1, H_2, and H_3 in Fig. 2 all intercept the *y*-axis at the same point. It may also be noted that the Δ_B-values obtained by this method vary inversely with distance from the coordination site, as expected for a pseudo-contact shift.[7]

Similar results were obtained for *neo*-pentanol, and the values of Δ_B and K_B for that substrate are also summarized in Table 1. Again, the high internal consistency between the evaluations of K_B based on different proton resonances is evident.

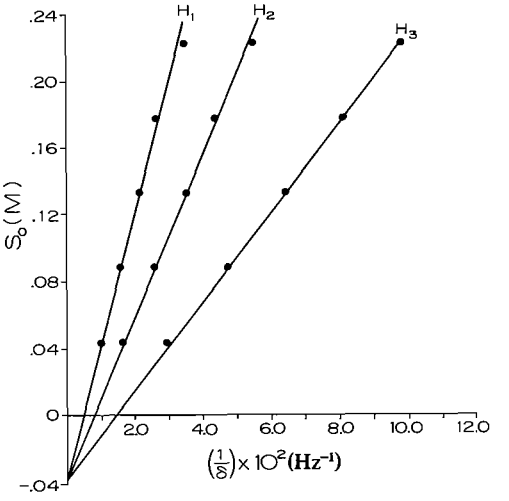

FIG. 2. Graph of $[S]_0$ *vs.* $(1/\delta)$ for the interaction of *n*-propylamine (0.23 to 0.04 *M*) with $Eu(DPM)_3$ (*ca.* 0.006 *M*) in deuterochloroform solution. The separate lines are for protons H_1, H_2, and H_3 of *n*-propylamine. The precision of the K_B evaluation is indicated by the close convergence of the three lines to the same *y*-intercept.

The experimental data obtained for the interaction of **1** and **2** with $Eu(DPM)_3$ were then analyzed by the computer-based method outlined in section III of the Theory. The values of K_B and Δ_B calculated in this way are compared in Table 1 with the values obtained by the more approximate graphical method. The excellent agreement between the two sets of values indicates that the conditions which are implicit in the graphical analysis are satisfied in these experiments; this point will be explored more fully later in this section.

Attention was next directed to the interaction of **1** and **2** with $Eu(FOD)_3$. Following the above methods, attempts were made to process the experimental data by both the graphical and computer-based methods. With either treatment, it was possible to obtain Δ_B, but K_B was too large to be measured. Figure 3 shows why. Δ_B is taken from the slopes of the lines in Fig. 3 and is readily determined. However, the *y*-intercept depends on $(1/K_B)$, and when K_B is large, the *y*-intercept is so close to zero that K_B cannot

[7]However, it must be remembered that an angular dependence is also involved.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

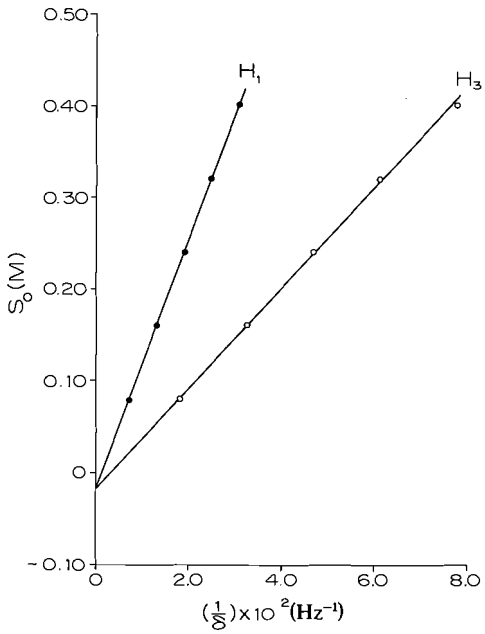

FIG. 3. Plot of $[S]_0$ *vs.* $(1/\delta)$ for the interaction of *neo*-pentanol (0.4 to 0.08 *M*) with $Eu(FOD)_3$ (*ca.* 0.006 *M*) in deuterochloroform solution. The separate lines are for protons H_1 and H_3 of *neo*-pentanol; the different slopes of the two lines are due to the different values of Δ_B for the two respective protons.

be determined with any confidence; in this case only a lower limit for K_B may be deduced. Moreover, the estimate for K_B depends critically on the presence of any inactive shift reagent, as discussed at the end of this section.

It should be appreciated that the graphical method is an approximation which is not expected to be valid when K_B is large. The computer-based method involves no approximations, but simply becomes numerically insensitive when the limit, $(1/K_B) \geqslant [S]_0$, is not satisfied. For the $Eu(FOD)_3$ experiments just mentioned, $(1/K_B) \leqslant 10^{-2}$ mol l^{-1}, while $[S]_0 =$ 0.1 mol l^{-1}, so that even the computer method will yield only a lower limit for K_B.

Similar experiments with *n*-propylamine and $Eu(FOD)_3$ also gave precise linear plots. Again it was possible to obtain the Δ_B values graphically to yield the data listed in Table 1, but again K_B was too large to be measured; all that can be stated with certainty is that K_B is at least 100 l mol^{-1}.

It is now useful to consider the evaluation of Δ_B from plots of δ *vs.* $[L]_0/[S]_0$ according to method 1 of the Experimental to show why the slope of such a plot (4) should not be taken as Δ_B. Recent work by Andersen and Uebel (11), Williams and coworkers (12), and Armitage *et al.* (1) has shown that the slope of such a plot can vary markedly with the *absolute* concentration of substrate in a set of experiments with different $[S]_0$-values. This variation is readily accounted for by reference to two possible limiting cases of eq. 8 of section II of the Theory.

For the interaction of $Eu(DPM)_3$ with **1** and **2**, the limiting condition, $K_B[S]_0 \ll 1$ pertains up to an $[S]_0$ level of at least *ca.* 0.04 *M*, so that eq. 8 reduces to eq. 10 rather than to the anticipated eq. 9. Only for the highest *neo*-pentanol concentration of 0.6 *M*, for which $K_B[S]_0 = 5.8$, is the desired limit of $K_B[S]_0 \gg 1$ effectively reached, since at this concentration the Δ_B-value of 20.5 p.p.m. is within experimental error of the true value of 19.7 p.p.m. (derived from the H_1 proton resonance by the method of section III of the Theory). It is thus neither correct, nor does it suffice to report values of Δ_B for different substrates, even if the molarity of a given substrate is kept constant, unless experimental evidence shows that the molarity of the substrate involved is large enough to satisfy the limit, $K_B[S]_0 \gg 1$, so that eq. 8 reduces to eq. 9. Even under these optimum conditions, K_B cannot be reliably determined (see below).

One issue of continuing concern is the purity of the lanthanide reagent used. It follows from the Theory section that a plot of δ *vs.* $[L]_0$ for any particular fixed concentration of $[S]_0$ should intercept the *x*-axis at the origin if the lanthanide reagent is "pure"; if it is not, then the *x*-intercept of the plot should indicate the amount of "impurity" or "inactive" reagent, as shown clearly for the present experiments in Fig. 4.

With regard to the "activity" of the lanthanide reagent itself, it will be noted that the data listed in Table 1 differ somewhat from those previously reported in a preliminary communication. This is because the lanthanide reagents used in the present study were purified and the solutions prepared under more rigorously anhydrous conditions than were employed[8] during

[8]The present experiments were performed in a polythene glove bag which was continuously flushed with dry nitrogen

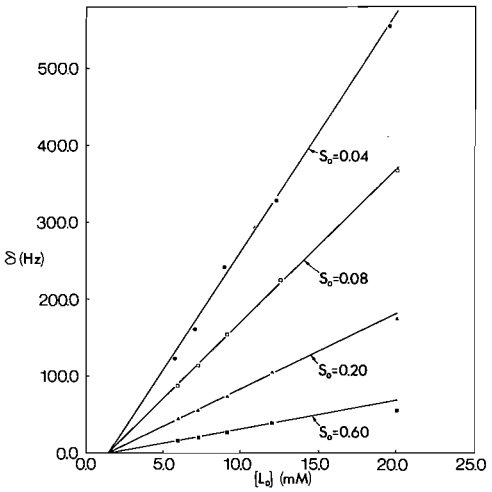

FIG. 4. Plot of δ *vs.* $[L]_0$ for the interaction of *neo*-pentanol (whose concentration was fixed at the value stated for each line) with $Eu(DPM)_3$ (*ca.* 0.02 to 0.005 *M*) in deuterochloroform solution. All shifts are for the H_1 proton of *neo*-pentanol. The lines converge to a point on the *x*-axis which accurately indicates the amount of inactive $Eu(DPM)_3$.

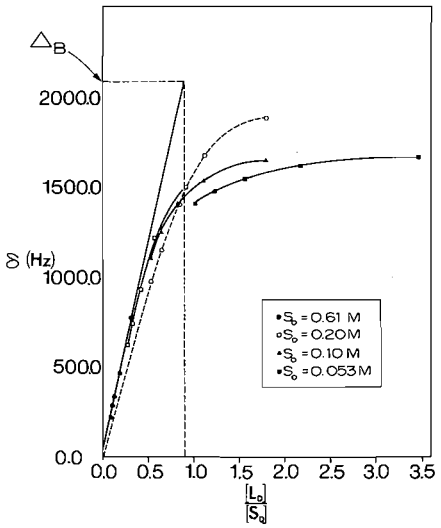

FIG. 5. Plot of δ (induced chemical shift for the H_1 proton) *vs.* ratio of the initial concentration of $Eu(FOD)_3$, $[L]_0$, to *neo*-pentanol, $[S]_0$, in deuterochloroform solvent. The solid lines represent experiments in which $[L]_0$ was varied while keeping $[S]_0$ constant at the value listed for that curve. The dotted line (see text) is a theoretical fit to the $[S]_0 = 0.1$ *M* curve, based on a known value for Δ_B and with K_B magnitude chosen to fit the middle data point of that curve exactly.

the experiments previously described (1). However, it must be emphasized that both the present measurements and those described previously are precisely reproducible. The important conclusion here is that although it is possible to obtain data which are *internally consistent* in a given laboratory, these data may differ significantly from data obtained elsewhere. Our Fig. 4 affords a simple test for the "activity" of a given batch of lanthanide reagent, and such plots may prove useful in standardizing shift reagent results.

It is now appropriate to consider the stoichiometry for the combination of a substrate with a lanthanide shift reagent. Prior to this study, the stoichiometry was unknown, although Rondeau and Sievers' experiments (10) with $Eu(FOD)_3$ leave the impression that the leveling-off of a graph of δ *vs.* $[L]_0/[S]_0$ at a mole ratio of approximately 1:1 might be taken to indicate a 1:1 stoichiometry. In the Theory section, it was shown that such a conclusion is warranted only for cases where K_B and $[S]_0$ are large; Fig. 5 illustrates several such plots determined at different $[S]_0$ levels, for the interaction of *neo*-pentanol with $Eu(FOD)_3$. In this case, the limiting line (the left-most points in Fig. 5) extrapolated to the known Δ_B-value gives a corresponding L/S ratio of 0.9:1, or about 1:1. However, the data points correspond to different $[L]_0$ concentrations, and when $[L]_0$ is changed there will be large changes in the bulk magnetic susceptibility of the solution, and these changes may not be compensated correctly even by an internal standard. Indeed, the poor internal consistency of the results is clearly evident in the dotted line of Fig. 5. This line was obtained by using the middle data point in the $[S]_0 = 0.1$ *M* data set to compute K_B; this value of K_B was then used to obtain the dotted line by using eq. 5 and the full quadratic form of eq. 6. It is evident that the dotted line gives a poor fit to the remaining data points in the $[S]_0 = 0.1$ *M* set. Since it is now obvious that experiments in which $[L]_0$ is varied can give inconsistent results, it is not surprising that for the interaction of *n*-propylamine with $Eu(FOD)_3$, the stoichiometry deduced from similar experiments is not even

and which was located in an airconditioned room. Previously, the glove bag alone was used in an ordinary laboratory. In both instances the apparatus was baked in an oven at 110° and all solvents were rigorously dried.

integral. In conclusion, when the binding is strong (large K_B), these experiments do not reliably predict stoichiometry.

For the weaker binding of **1** or **2** to $Eu(DPM)_3$, the outlook is much improved. As argued in section IV of the Theory, the linearity of a plot of $[S]_0$ *vs.* $(1/\delta)$ is direct proof of 1:1 binding (compare Figs. 1 and 2). Since the range of choices of K_B illustrated in Fig. 1 brackets the observed K_B-values (see Table 1) for binding of **1** or **2** to $Eu(DPM)_3$, there can be no doubt that the binding is 1:1 in each of these two cases.

Practically speaking, then, when the binding is weak ($K_B < 100\ l\ mol^{-1}$), it is possible to obtain reliable, consistent values for Δ_B, K_B, and solution stoichiometry; when the binding is strong ($K_B \geqslant 100\ l\ mol^{-1}$), Δ_B may still be determined accurately, a lower bound for K_B can be proposed, but the stoichiometry may be indicated only approximately.

It is possible that the solvent (chloroform) used in these studies may bind to the shift reagents; if such binding were present, the apparent K_B computed by our methods would be smaller than the K_B which would be observed in a totally inert solvent. This in no way vitiates the fact that our reported K_B-values correctly measure the binding constant for the stated substrates to the stated shift reagent in the stated solvent.

This discussion may be terminated with some comments on the chemical significance of the above findings. When this study was initiated, it was already known (10) that for any particular substrate, a given quantity of $Eu(FOD)_3$ would produce a greater shift than an equal amount of $Eu(DPM)_3$. From the data listed in Table 1, it is clear that the principal source of this enhanced effectiveness is the roughly 10-fold increase in binding constant, since the bound chemical shifts are nearly the same for a given substrate.

A second significant feature derived from the data of Table 1 is that *n*-propylamine has a higher K_B-value (stronger binding) than *neo*-pentanol for association with either $Eu(DPM)_3$ or $Eu(FOD)_3$. In the case of $Eu(DPM)_3$, for which accurate values of K_B are available, the amine binds 3.5 times as strongly as the alcohol. These results suggest that the sequence of observed shifts for various substrates given by Sanders and Williams (13) may be correlated primarily with variation in the binding constants. This speculation may readily be subjected to experimental test, as can also the generality concerning K_B-differences between $Eu(DPM)_3$ and $Eu(FOD)_3$.

Summary

In this paper, we have developed and tested a method for evaluating Δ_B and K_B values as well as stoichiometry for binding of substrates to lanthanide shift reagents. Our results exemplify the potential utility of these parameters in elucidating the mechanism of action of two useful shift reagents; specifically, there is preliminary indication of the effect of changes in either the type of binding site of the substrate or the chelating group attached to the metal. Clearly a number of other chemical variables can now be examined with a perspective not previously possible. Included in this category are the effects which accompany changing either the lanthanide metal or solvent used: these and other possibilities are under investigation.

One final cautionary statement must be reiterated. Much of the quantitative treatment used in this paper is formally analogous to that used in enzyme inhibition studies. Pressing the analogy further, it now seems clear that variations in the "activity" of lanthanide shift-reagents are to be expected, and that these activity differences will be reflected in the calculated K_B and Δ_B. As in enzyme studies, then, one expects consistent results from a given shift-reagent preparation, but one is not alarmed to find differences between results from different preparations. For example, in a previous preliminary communication, (1) we reported data corresponding to some of the numbers in Table 1; in the earlier work, a plot of the type shown in Fig. 4 of this paper showed that the earlier preparation of shift reagent was less pure than that used in the present work. This explains why the present Δ_B-values are smaller while the K_B-values are larger than those obtained with a shift-reagent of lower purity. It was noted in the Discussion that there were *detectable* amounts of "inactive" material in the present shift-reagents; if this impurity can be removed, the Δ_B-values in Table 1 should decrease slightly and the K_B-values increase slightly.

The Crystalline Structure of Poly-β,D(1→4′)mannose: Mannan I

I. NIEDUSZYNSKI[1] AND R. H. MARCHESSAULT

Département de Chimie, Université de Montréal, C.P. 6128, Montréal, Québec

Received January 24, 1972

The crystallographic structure of mannan I has been examined by X-ray fiber diffraction, polarized i.r. spectroscopy, and computer chain-packing methods. The combination of X-ray intensity data and the chain packing analyses have shown that the overall number of permissible structures is very limited so that van der Waals' forces play a major role in packing. It was concluded that the chain senses are anti-parallel. The interpretation of the polarized i.r. spectra in the OH stretching region is in line with the presence of an intra-molecular hydrogen-bond between O(3)...O(5′). The awkward "knobby" shape of the mannan molecule, largely a result of the axial disposition of O(2)—H, lends itself to a close packing mainly determined by van der Waals' forces. The considerable similarity between X-ray and i.r. data from mannans and glucomannans would indicate that structural conclusions about the former might relate to the latter.

La structure cristallographique du mannan I a été réexaminée par la diffraction aux rayons-x de fibre, par la spectroscopie i.r. en lumière polarisée et par les méthodes de calcul d'entassement des chaînes dans la maille. La combinaison des données sur l'intensité des rayons-x et les analyses des chaînes compactes, ont montré que le nombre global de structures permises est très limité de sorte que les forces de van der Waals jouent un rôle majeur dans l'entassement. On a conclu à l'antiparallélisme des directions des chaînes. L'interprétation du spectre i.r. polarisé, dans la région d'élongation du OH, est conforme à la présence d'une liaison hydrogène intramoléculaire entre O(3)...O(5′). La forme "noueuse et disgracieuse" de la molécule de Mannan, en grande partie due à la disposition axiale de O(2)—H, se prête elle-même à un tassement serré, déterminé surtout par les forces de van der Waals. La grande similitude dans les données des rayons-x et de l'i.r. entre les mannans et les glucomannans, indiquerait que les conclusions sur les structures du premier seraient liées au second.

Canadian Journal of Chemistry, **50**, 2130 (1972)

Introduction

Polymers of β,(1 → 4′)-linked D-mannose residues (1) are abundant in nature: mannan, which comprises solely D-mannose residues is a major constituent of the endosperms of palm (2), date (3), and coffee beans (4) and is also able to replace cellulose as the crystalline structural component in the cell walls of certain green algae (5–6); glucomannans and galactoglucomannans (both containing about 75% of D-mannose) are amongst the principal wood hemicelluloses (7), accounting for approximately 20% of the weight of softwoods.

Ivory-nut mannan is believed to occur in two forms, A and B, which differ in their solubility in dilute alkali. Meier (3) found that while mannan A has a degree of polymerization ($\overline{DP}_n$) of about 20 and appears granular in the electron microscope, mannan B has a $\overline{DP}_n$ of 80 and has a fibrillar structure. Mackie and Sellen (8) determined that the $\overline{DP}_w$ of mannan from the cell wall of the green alga *Codium fragile* ranges from below 20 to above 10 000, the peak in the distribution curve occurring at about 600.

The first X-ray diagram of mannan (9) was observed in 1928, but it was not until 1961 that Frei and Preston (5) reported the first oriented pattern. These authors subsequently assigned the spacings to an orthorhombic unit cell with

$$a = 7.21, \quad b(\text{fiber axis}) = 10.27, \quad c = 8.82 \text{ Å}$$

and proposed a provisional parallel chain structure on the basis of the observed X-ray reflections. They were also able to recrystallize mannan into a different lattice after treatment with alkali, which they characterized and named mannan II by analogy with cellulose. They showed that mannan II has a hydrated structure with an uniplanar orientation. Bittiger and Marchessault (10) have proposed a folded-chain structure for a mannan II prepared from *Tubera salep* by precipitation from an alkaline solution. Recently, Bittiger (11) has shown that when mannan is precipitated from aqueous butanol lamellar structures of mannan I are formed. It seems likely that this is a classical polymer single crystal structure (12) since the lamellae were

about 200 Å thick when material of degree of polymerization of 200–300 was precipitated. Very little i.r. spectroscopy of mannan has been recorded except for the band assignments of ivory-nut mannan (13).

Although D-mannose only differs from D-glucose in the configuration at C(2), mannan differs from cellulose in several respects: it has a considerably lower average degree of polymerization, its microfibrils are much more sensitive to physical and chemical treatment than those of cellulose (14), and in woody plants it is a hetero-copolysaccharide with glucose in the backbone and galactose as side-group (7). Both polymers are positively birefringent but the cellulose X-ray diagram frequently displays evidence of a selective uniplanar orientation which is absent in mannan I (6). The conformational analyses of cellulose and mannan (15–17) have shown that the mannan chain has a slightly larger range of preferred conformations in terms of the conformational angles (ϕ, ψ) which govern rotation at the glycosidic linkage.

In the present investigation the crystallographic structure of mannan I has been examined by X-ray fiber diffraction, polarized i.r. spectroscopy, and computer chain-packing methods.

Materials and Methods

The materials used in this investigation were an oriented mannan from the green alga *Cymopolia barbata*, mannan from ivory-nut (*Phytalephas macrocarpa*), and a glucomannan[2] from white pine (*Pinus strobus*). X-Ray diffraction and i.r. spectroscopy were used to identify the two former as typical β,(1 → 4′)-poly-D-anhydromannose.

The algal cells were first treated with cold 0.1 *N* hydrochloric acid to remove the calcite encrustations and then with successive aliquots of boiling water. The latter treatment diminished the level of diffuse scattering, particularly near the second meridional reflection. The inner wall layers of the basal cells were stretched by about 10–20% before X-ray examination. X-Ray fiber photographs were taken with nickel-filtered CuKα radiation at 40 kV and 20 mA; the humidity being controlled with saturated salt solutions during the exposures.

X-Ray fiber diagrams similar to those presented by Frei and Preston (6) were obtained. In view of the high level of diffuse scattering it was not generally possible to record reliable intensities with the microdensitometer. A Joyce–Loebl Mk. IIIC microdensitometer was, nevertheless, used to monitor a few of the more clearly defined reflections while other intensities were established visually by means of the multiple film method. The observed intensities were corrected for Lorentz and polarization factors, the temperature factor corrections being made on the calculated intensities. Since no uniplanar orientation was observed (nor could it be induced), the intensity values were considered to be cylindrically-averaged.

The i.r. spectra were recorded with a Perkin–Elmer 621 spectrometer equipped with a gold-grid polarizer. Oriented lamellae of the algal mannan walls were aligned on a silver chloride plate which was mounted into a deuteration cell. The specimen was deuterated by bubbling purified nitrogen gas through a solution of 99.7% D_2O and then through the cell.

Given the backbone conformation of the mannan chain (see below), trial chain-packing models were computer-generated for both packing (parallel and anti-parallel chains) by means of two independent chain rotational parameters,[3] α and β, and one translational parameter which moved the center chain along its centroid. The parameters were varied in discrete intervals. The two chains of each packing model were not assumed to be symmetry related. For each generated structure, all of the calculated intensities were compared with the observed ones so that models giving good agreement could be selected. Similarly, for each trial structure the distances between all atoms in neighboring chains were compared with the following contact distances (Å) (18):

Normal limit
C...C 3.2, C...O 2.8, O...O 2.8,
C...H 2.4, O...H 2.4, H...H 2.0

Extreme limit
C...C 3.0, C...O 2.7, O...O 2.7,
C...H 2.2, O...H 2.2, H...H 1.9

In order to establish the most probable conformations of the O(6) hydroxyl group, the intra- and inter-chain close contacts were determined at 10° intervals of rotation (χ)[4] about the C(6)—C(5) bond. Distances (O...O) and angles, related to non-linearity, were calculated for all possible hydrogen-bonds.

Structure Investigation

For convenience in computer programming the unit cell of Frei and Preston was re-indexed as

$$a = 8.82, \quad b = 7.21, \quad c \text{ (fiber axis)} = 10.27 \text{ Å}$$

A schematic of the mannan I diagram is shown

[2]This sample, which had a specific rotation $[\alpha]_D^{19} -32.0°$ in 4 *N* NaOH, was kindly provided by Professor T. E. Timell of the College of Forestry, Syracuse, N.Y. It is a typical softwood glucomannan.

[3]A chain rotation of 0° was defined by superimposing the vector between the axis of rotation of the chain and the C(5) atom on the *x*-axis of the coordinate system; α and ß correspond to central and corner chain rotations respectively, clockwise rotations being positive for parallel chains, *i.e.* looking down the corner chains of the unit cell.

[4]The position where O(6) is *cis* to C(4) is taken to be $\chi = 0°$ and looking down the C(6)—C(5) bond anticlockwise rotation corresponds to positive values of χ.

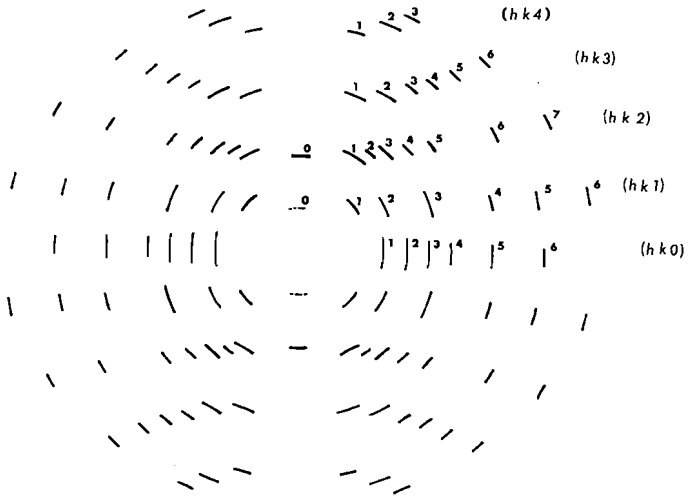

FIG. 1. Schematic of mannan I X-ray fiber diagram. The numbering of the reflections corresponds to the notation in Table 2.

in Fig. 1. Examination of the meridional reflections reveals the presence of an extremely weak (001) and a weak to medium intensity (002), the (003) and (004) being absent. Despite the unpromising nature of these meridionals a twofold screw axis has been incorporated into the mannan backbone conformation as a first approximation, since the fiber repeat of 10.27 Å is very similar to that found for cellulose and chitin in which this symmetry element is believed to occur. It was considered that the presence of the (001) was attributable either to the lack of a twofold screw relationship between O(6) positions in adjacent mannose residues or to the non-stoichiometric occurrence of water within the lattice. The equatorial reflections show systematic absences for (h00) and (0k0) when h and k are odd respectively. This suggests that the chains as projected into the *ab* plane are exactly or very nearly related by two mutually perpendicular twofold screw axes and are anti-parallel. Since the equatorial reflection data terminate at 2.3 Å the resolution is probably insufficient to distinguish between parallel and anti-parallel chain structures on this basis alone.

Following the conformational analysis of Sundararajan and Rao (16), a bridge oxygen angle of 117.5° and (φ, ψ) dihedral angles of (30.1, −30.6°),[5] (that is (38.9, −22.3°) by the convention of the above authors), were selected to give a conformation corresponding to a two-fold screw axis, the required axial repeat and an intra-molecular O(3)...O(5′) hydrogen-bond of length 2.55 Å. The bond lengths and angles used to establish the atomic coordinates corresponds to the average values determined for various β-sugars (18). The O(6) atom was initially positioned *cis* to C(4), ($\chi = 0°$), with a C(6)—O(6) bond length of 1.42 Å and a C(5)—C(6)—O(6) angle of 112°.

The calculated density of dry mannan of 1.65 g cm^{-3} is rather high compared to other polysaccharides (similar to that of algal cellulose) and would make the incorporation of water within the lattice seem improbable. This is the more so since the observed density of mannan was 1.57 g cm^{-3}, in complete agreement with the previously reported value (6).

The approach used in this investigation has been to examine the X-ray data, and then consider the packing merits of all structures which might be consistent with this data. Refinement was then performed from all sterically permissible models. Three structural types may be distinguished (see Fig. 2.) each model representing a group of structures with *ab* projections which would satisfy the equatorial reflection intensities and absences.

(1) Model P1 (as proposed by Frei and Preston (6))

This model involves parallel chains with the

[5]The conformation with (φ, Ψ) = (0, 0°) is chosen as the one in which the C(1)—H(1) bond is *cis* to the O—C(4) bond and the C(4′)—H(4′) bond is *cis* to the C(1)—O bond.

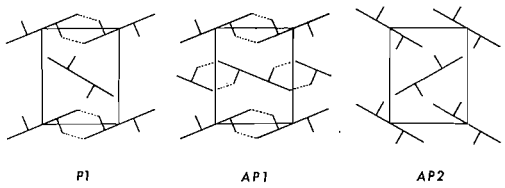

FIG. 2. Three structural types of chain-packing corresponding to *ab* projections in the mannan I unit cell.

corner chains on the (100) plane being bonded via O(6)...O(2) atoms. For the bond to form the O(6) atom may lie at $\chi = 175°$ (*gt* position) or $\chi = 275°$ (*tg* position), however the latter position is not favored by structure factor calculations. Closer examination of the O(6)...O(2) inter-chain hydrogen-bond distance as a function of the corner chain rotation, shows that no satisfactory bond can be formed for $\beta > 69°$ since the hydrogen-bond would be too short and steric hindrance would be encountered between the O(6) of one chain and the H(1) and H(4) atoms of the next. When the corner chain rotation is 69° or less, short contacts between the C(6) and O(6) of this chain and atoms of the central chain are already serious for all chain translations which give a favorable intensity agreement. It is difficult to find any positions for the central chain O(6) atoms which are not sterically hindered. Although a few structures of this type give some measure of intensity agreement, a serious discrepancy arises in that the unobserved (201) reflection is always calculated to be of medium intensity. No completely unhindered structure was found.

(2) Model AP1

This type of structure may correspond to space group $P2_12_12_1$ and involves sheets of chains of similar sense bonded together in the (200) plane via the O(6)...O(2) atoms. The model was readily discarded from consideration since the intensity agreement was generally poor, the unobserved (201) reflection is calculated to be strong and, as with the *P*1 model, whenever the O(6)...O(2) bond is of acceptable length severe short contacts attributable to the C(6) and O(6) atoms arise.

(3) Model AP2

The final model which may also correspond to space group $P2_12_12_1$ does not involve a hydrogen-bond between corner chains. Examination of the chain rotations and relative translations showed very good intensity agreement for a structure which was also favored on packing considerations (see Table 1). This structure has an O(2)...O(5) inter-chain hydrogen-bond between corner and center chains which, although long at 3.03 Å, is very nearly linear. Since there is also an intra-molecular hydrogen-bond wherein O(5) is acceptor, this implies that this atom is a double acceptor. Investigation of all possible positions for the O(6) atoms shows that the least encumbered position is for $\chi = 170–180°$ (*gt* position). No inter-molecular hydrogen-bond can be formed in this position, but it is possible that the O(6) is an acceptor in a bifurcated intra-molecular bond with the O(3) hydrogen atom of the adjacent residue (as recently found in the crystal structure of methyl-β-cellobioside-methanol (19)).

TABLE 1. Mannan close contact map ($\beta - 60°$)

Translation*	α-Rotation (°)

0.1	3	3	1	2	2	4	6
0.0	3	3	2	3	2	2	6

*Translation is represented as fractions of the fiber repeat.

The atom O(6) may also be involved in an inter-molecular hydrogen-bond with O(3) of the adjacent chain of the same sense if the position $\chi = 50°$ (*gg* position) is adopted. This position is slightly hindered for the conformation (ϕ, ψ) = (30.1, −30.6°) and gives a poorer level of agreement with the intensity data, but the possibility of its occasional occurrence cannot be eliminated. This would represent an element of disorder in the structure.

Both X-ray intensity and steric considerations strongly support this structure (Figs. 3 and 4), for which the intensity values are given in Table 2 and the coordinates of the asymmetric unit in Table 3. While Fig. 3 and the top section of Fig. 4 represent the same unit cell, the latter

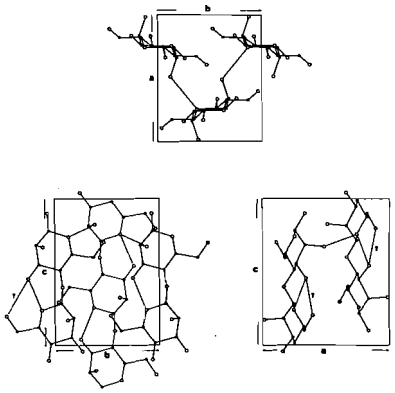

FIG. 4. Three principal projections of mannan I unit cell; origin is halfway between three pairs of non-intersecting screw axes. Inter- and intra-molecular hydrogen-bonds are shown.

corresponds to the correct choice of origin for the space group but the former is included as it shows more clearly how the inter-chain hydrogen-bonding involving O(2) provides cross-sectional cohesion to the mannan crystal.

Infrared Spectroscopy

The spectrum of mannan from *Cymopolia barbata* is almost identical to that from ivory-nut mannan (13), so that only the O—H stretching vibrations will be discussed at present. Comparison of the frequencies of these vibrations in mannan and cellulose indicates that the hydrogen-bonding is much weaker in the former. Also the degree of accessibility of deuterium oxide into the sample suggests that the mannan crystallinity is rather low.

In the spectrum of oriented mannan I (Fig. 5) the following frequencies and polarizations were observed:

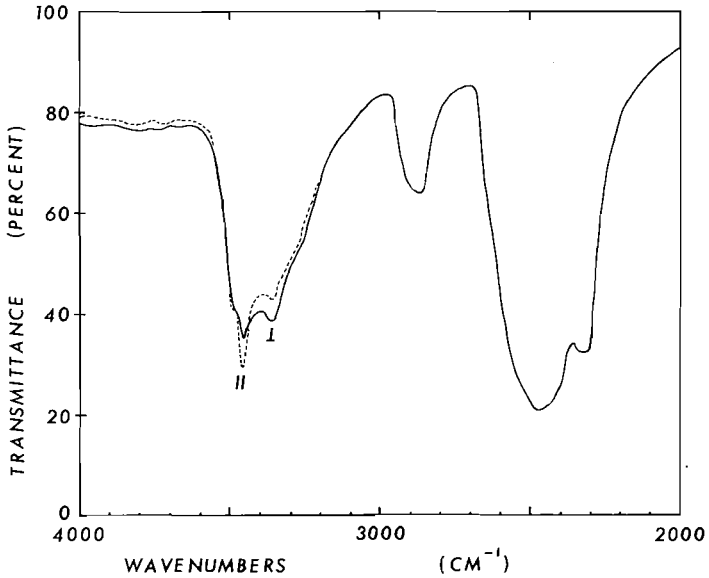

FIG. 5. Polarized i.r. spectrum of partially deuterated and oriented *Cymopolia* cell walls: — electric vector perpendicular to the chain direction; ... electric vector parallel to chain direction.

Frequency (cm^{-1})	Polarization	Interpretation
3497	?	O(6)—H stretching
3462	∥	O(3)—H stretching
3365	⊥	O(2)—H stretching
3280	? weak	(see text)

The first two bands are very similar to those observed in both chitin (20) and cellulose II (21), so that on the basis of its strong parallel dichroism the peak at 3462 cm^{-1} may be assigned to the O(3)—H stretching mode. In the structure proposed for mannan, the O(6)—H does not take part in any inter-molecular hydrogen-bond and it is, therefore, to be expected that the stretching vibration would be of high frequency. The chitin molecule gives rise to two O—H stretching bands at 3447 and 3480 cm^{-1} which presumably correspond to the O(3)—H and O(6)—H vibrations. Therefore, the band at 3497 cm^{-1} can most probably be assigned to the O(6)—H vibration. The perpendicular band at 3365 cm^{-1} can therefore be assigned to the O(2)—H stretching, these atoms forming an inter-molecular hydrogen-bond with O(5) in the proposed structure.

Finally, the band at 3280 cm^{-1} which is rather weak and is even less prominent in some of the spectra recorded, cannot be explained by any structure of mannan which corresponds to the space group $P2_12_12_1$. It is possible that this band relates to the O(6)—H stretching vibration which might arise if certain O(6) atoms were to take up the conformation $\chi = 50°$, (*gg*). In this conformation a short inter-molecular hydrogen-bond of 2.55 Å might be formed with an O(3) atom.

observed and calculated intensities is very good and the proposed structure does not involve steric hindrance (a condition which was only met by 1% of the 1500 structures considered), the very weak (001) reflection is not explained by this model and the fourth i.r. hydroxyl stretching frequency is difficult to account for. Evidently the structural differences between the true mannan structure and the one proposed here would need to be such as to destroy the exact twofold screw axis parallel to the fiber direction, and be consistent with a weak fourth hydroxyl stretching band.

The following structural deviations seem possible:

(*i*) The O(6) atoms in contiguous residues may not be screw related; this might be a statistical feature of the structure.

(*ii*) The backbone conformation of mannan does not have a precise twofold screw axis, a situation which might arise if a more stable form of intra-molecular hydrogen-bonding could be achieved, and would involve the presence of a very slow super-helix.

(*iii*) Some non-stoichiometric lattice water be present, although this is unlikely in view of the high density of packing.

(*iv*) The (001) reflection is related to paracrystalline material which is due to the presence of numerous chain ends, folds, or comonomer (6) glucose and galactose included in the main chain.

The latter explanation appears pertinent in view of the abundance of glucomannans in the plant world. Thus mannan in wood has been shown to be a glucomannan with a 1:3 or 1:4 ratio to glucose to mannose. The presence of a small amount of glucose in the mannan I lattice would almost certainly destroy some of the crystalline symmetry which is responsible for systematic absences. Actually the mannan I crystalline structure is quite pertinent to the glucomannan field as will be seen in the following section.

Glucomannan

Glucomannans are typically extracted (22, 23) at 25 °C with 18% NaOH to which 5% H_3BO_3 is added. This material shows very diffuse X-ray scattering so that only two or three reflections may be observed (9, 24–26).

In this investigation we have treated the prepared glucomannan by successively more hydrolytic reagents and monitored the changes in crystallization by X-ray powder diffaction. The following results were obtained:

	Treatment	Interplanar Spacings (Å)
(*i*)	As extracted	4.41
(*ii*)	1 h/70 °C in H_2O	2.68, 4.32, 5.63, 7.7
(*iii*)	1 h/100 °C in H_2O	2.68, 4.34, 5.62, 7.8
(*iv*)	5 h/100 °C in H_2O	2.68, 4.40, 5.60, 7.8
(*v*)	1 h/100°C in 0.2 *N* HCl	2.68, 3.46, 3.72, 4.30, 4.89, 5.58, 7.5

It is clear that except for the reflection at 7.7 Å the data are compatible with the lattice dimensions of mannan I. It is possible that the extra reflection corresponds to a glucomannan phase similar to mannan II (6). The mannan II lattice is sensitive to variation in water content.

Attempts were made to prepare a glucomannan II form by mercerization with alkali and a number of specimens giving crystalline reflections were obtained; however, it is probable that these were soda-glucomannans analogous to the soda-celluloses.

The considerable similarity between both the i.r. spectra and the X-ray data from mannans and glucomannans poses a question. Is there a crystalline glucomannan phase, or are the glucose and mannose residues sufficiently segregated so that only a crystalline mannan phase is involved? At any rate, the presence and development of mannan crystallinity has been shown to be of technological importance (29). A large yield increase in pulping of softwood can be obtained if a mild prehydrolysis precedes the delignification treatment. In view of the now well established crystallizability of glucomannan it seems reasonable to attribute this yield increase to a decrease in accessibility of glucomannan to pulping liquor.

With respect to the above structural investigation it was rather surprising to note that the principal crystalline reflections for glucomannan which were observed in this study and were reported by other workers correspond to mannan I, *i.e.* native mannan. In 1968, Frei and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Preston clearly showed that a mercerized mannan which they labeled mannan II could be obtained following suitable alkaline treatment of the algal specimen which they were examining. In view of the fact that various workers report crystalline glucomannan X-ray patterns corresponding to mannan I, it would seem that mannan II is much more difficult to prepare than cellulose II. The presence of organic solvents in the precipitating solutions are reported (11) to favor formation of the anhydrous mannan I lattice. Perhaps the presence of borate which is generally used in the extraction schemes for glucomannan influences the formation of mannan I in preference to mannan II, more probably it is the alcoholic system used for precipitating the alkali solved glucomannan. Not investigated so far is the influence of temperature and alkali strength combined which are now well understood for cellulose (27) mercerization.

Conclusion

The crystalline conformation of mannan resembles that of cellulose with respect to screw symmetry along the chain and intra-molecular hydrogen-bonding of the O(3)...O(5′) type. The awkward "knobby" shape of the mannan molecule, largely a result of the axial disposition of O(2)—H, lends itself to a close-packing mainly determined by van der Waals's forces. The high density of the material and the small frequency shift of the O—H stretching bands strongly support this conclusion. It is of interest that the recently proposed structure for poly-β,D(1 → 4′)mannuronic acid (28) also incorporates anti-parallel chains whose rotational and translational parameters are very similar to those proposed here for mannan. The anti-parallel chain structure is consistent with the occurrence of polymer single crystals (11) of mannan I.

The "contact distance" criterion is of great value in the determination of polymer structures where X-ray information is insufficient (see Fig. 6) and the polymer density is high.

The mannan I structure is obtained when glucomannans are precipitated from solution with organic solvents (11) while mannan II is found when crystallization occurs in aqueous alkaline solution (10). This emphasizes the importance of solvation in selection of crystalline polymorphs of polysaccharides.

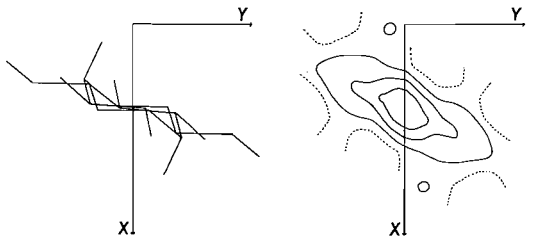

FIG. 6. Fourier synthesis of mannan chain in 001 projection (right); the left side shows the proposed chain orientation arrived at in this study.

Applications of Lanthanide Shift Reagents to the Identification of ^{13}C Resonances[1]

IAN ARMITAGE,[2] JOHN R. CAMPBELL,[3] AND L. D. HALL[4]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received September 21, 1971

The ^1H and ^{13}C shifts of 2,2-dimethyl-1-propanol (**1**) have been measured by the ^1H–{^{13}C} INDOR technique in the presence of various concentrations of the tris{dipivalomethanato} derivatives of europium (**2**), thulium (**3**), and praseodymium (**4**). All sets of shifts vary with the concentration of added lanthanide; the methylene-^{13}C resonance is shifted more than the methyl-^{13}C resonance. It is shown that tris{dipivalomethanato}gadolinium(III) does not induce chemical shift changes and this further supports the contentation that the pseudo-contact mechanism predominates for lanthanide shift reagents.

Les déplacements chimiques de ^1H et du ^{13}C du diméthyl-2,2 propanol (**1**) ont été mesurés par la technique ^1H–{^{13}C} INDOR en présence de concentrations diverses en tris{dipivalométhanato} d'europium (**2**), de thulium (**3**), et de praseodymium (**4**). Les déplacements chimiques varient avec la concentration de lanthanide ajouté; le pic correspondant à la résonance du méthylène-^{13}C est davantage déplacé que celui correspondant à la résonance du méthyle-^{13}C. On a montré que le tris{dipivalométhanato}gadolinium(III) ne provoque aucun déplacement chimique et ceci confirme le fait d'après lequel le mécanisme de pseudo-contact prédomine avec les réactifs de déplacement.

Canadian Journal of Chemistry, **50**, 2139 (1972)

Introduction

Recent advances in n.m.r. instrumentation have made facile the observation of *natural abundance* ^{13}C n.m.r. spectra of complex organic substances. The principal problem which now inhibits the generality of applications of this technique is the assignment of individual ^{13}C resonances. At present these assignments are generally made on the basis of either "off-resonance" ^{13}C–{^1H} heteronuclear decoupling experiments (2), by the internal consistency of the shifts of a series of closely related derivatives, or by studies of specifically deuterated derivatives. We now report that the lanthanide "shift-reagents", which were first discovered by Hinckley (3) and which have since shown considerable promise in ^1H n.m.r. spectroscopy, may greatly facilitate assignments of ^{13}C n.m.r. spectra. Since this work was completed a preliminary communication has been published (4) that outlines a similar study; we shall discuss this later in this paper.

Discussion

A ^1H–{^{13}C} INDOR spectrometer (5) has been used to measure the ^{13}C shifts of 2,2-dimethyl-1-propanol (**1**) in the presence of varying concentrations of either tris(dipivalomethanato)europium(III) (**2**) or of the related thulium (**3**) or praseodymium (**4**) derivatives. These measurements also provided automatically the ^1H shift changes.

A typical plot of the changes in ^1H and ^{13}C shifts which accompany addition of a lanthanide reagent is given in Fig. 1 and the data are summarized in Table 1. It is quite clear from Fig. 1 that for both ^1H and the ^{13}C resonances a direct relationship exists between the observed shift and the amount of added europium reagent (**2**), at least up to *ca.* 0.15 *M* added lanthanide; the same is also true for the thulium reagent (**3**) up to *ca.* 0.05 *M* and praseodymium reagent (**4**) up to *ca.* 0.15 *M*.

From the standpoint of ^{13}C spectral assignments several points are noteworthy. First, it is encouraging to note that ^{13}C shifts appear to be sufficiently sensitive to added lanthanide for

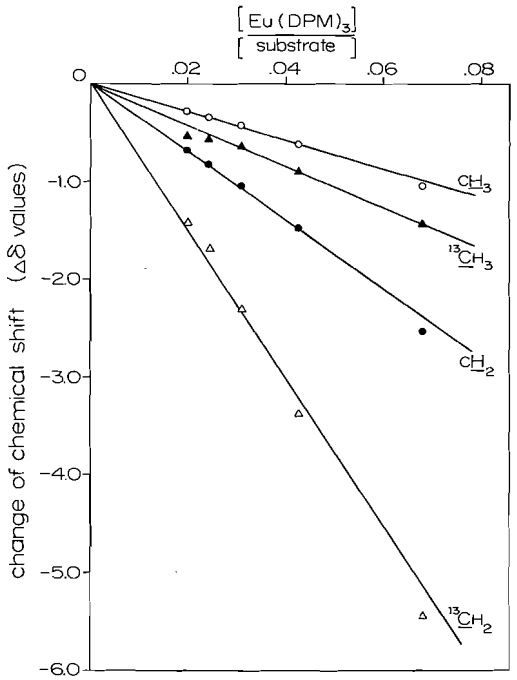

FIG. 1. Plot of the ^1H and ^{13}C chemical shifts of 2,2-dimethyl-1-propanol (**1**) in the presence of varying concentrations of tris{dipivalomethanato} europium(III) (**2**) using chloroform as solvent.

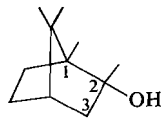
this approach to have some generality. Furthermore, it is important to note that the carbon nearest to the donor function of the organic substrate (C-1 in this case) undergoes a significantly larger shift than the more remote one. However, in the context of cyclic organic substances it must be remembered that *pseudo-contact* shifts have (6) an angular-dependence, and this can be expected to modulate any simple relationships based on distance alone. This is clearly demonstrated by the work of Briggs and co-workers (4); for borneol (**5**), both C-1 and -3 are adjacent to the carbon bearing the hydroxyl function, yet their Δ_{Eu} shift-changes as calculated by Demarco's method (7) are −14.0 and −21.8 p.p.m. respectively.



5

Again, from the view of spectral assignments it is important to recognize that whereas both europium (**2**) and thulium (**3**) induce shifts to *lower* field, the praseodymium reagent (**4**) produces *high*-field shifts. Thus it should be possible to use these reagents to remove unwanted degeneracies in ^{13}C spectra. Subsequent extrapolations of suitable shift *vs.* concentration plots can then be used to determine the original positions of individual resonances. This approach should be extremely useful in a number of areas and we are particularly interested in applying it to carbohydrate derivatives.

The use of $Gd(DPM)_3$ in the above study resulted in severe broadening of the resonances for H-1 and -3 which prohibits the detection of the ^{13}C resonance via the INDOR technique, but at the same time no shift was observed for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the H-1 and -3 resonances of *neo*-pentanol. Applying similar assumptions to those used in previous studies of main group transition metals (8*a*,*b*), this result would seem to further support the evidence that the nature of the shifts induced by lanthanide–$(DPM)_3$ reagents is predominantly pseudo-contact.

Experimental

A sample of 2,2-dimethyl-1-propanol (**1**, *neo*-pentanol) was purified by distillation from calcium hydride.

The tris(dipivalomethanato) derivatives of europium(III) (**2**), thulium(III) (**3**), and praseodymium(III) (**4**) were prepared by the standard literature methods (9).

All n.m.r. measurements were made with a modified (5) Varian HA-100 instrument using internal tetramethylsilane as the lock signal for measurements with **2** and **3**, and chloroform for those with **4**.

It is a pleasure to thank the National Research Council of Canada for their generous financial support via operating grants (A 1905) and two equipment grants (E 1338 and E 1854).

An Electron Spin Resonance Study of the Radical Cations Derived from Dialkoxybiphenyls

PAUL D. SULLIVAN AND LOUIS J. NORMAN
Department of Chemistry, Ohio University, Athens, Ohio 45701

Received December 24, 1971

The e.s.r. spectra of the cation radicals of various alkyl substituted 4,4′-dihydroxybiphenyls have been studied. These spectra give information regarding the molecular motions occurring in these compounds.

Les spectres e.s.r. des radicaux cationiques de plusieurs 4,4′-dihydroxybiphényles substitués par des groupes alkyles ont été étudiés. Les spectres donnent des informations sur les mouvements moléculaires qui se font dans ces composés.

Canadian Journal of Chemistry, **50**, 2141 (1972)

Radical cations derived from 4,4′-dialkoxybiphenyls belong to the same class of radicals as the Wurster and Weitz radicals, and it has been proposed by Hunig (1) that all radical ions of this type should be termed "violenes". It is the purpose of this note to report on the observation by electron spin resonance of the cation radicals of various alkyl substituted 4,4′-dihydroxybiphenyls, and, in addition, to make a number of suggestions regarding the structure and chemistry of formation of these radicals.

The radicals studied are indicated in Table 1 together with their e.s.r. hyperfine splitting constants and *g* factors. The neutral compounds were either commercially available (**1** and **7**) or were prepared by lead dioxide oxidation of the appropriate phenols (2). The compounds were oxidized with the aluminum chloride–nitromethane system (3). Their behavior in this oxidizing medium could be divided into two types. For compounds **1**, **3**, and **7** when only a slight excess of $AlCl_3$ was used the initial concentrated solution in the e.s.r. tube was dark blue (λ_{max} 800–850 mμ) and exhibited only a broad unresolved e.s.r. signal. Dilution of this concentrated solution at room temperature yielded a green solution (λ_{max} 420–440 and 800–850 mμ) which yielded a well resolved e.s.r. spectrum. On

the H-1 and -3 resonances of *neo*-pentanol. Applying similar assumptions to those used in previous studies of main group transition metals (8*a*,*b*), this result would seem to further support the evidence that the nature of the shifts induced by lanthanide–$(DPM)_3$ reagents is predominantly pseudo-contact.

Experimental

A sample of 2,2-dimethyl-1-propanol (**1**, *neo*-pentanol) was purified by distillation from calcium hydride.

The tris(dipivalomethanato) derivatives of europium(III) (**2**), thulium(III) (**3**), and praseodymium(III) (**4**) were prepared by the standard literature methods (9).

All n.m.r. measurements were made with a modified (5) Varian HA-100 instrument using internal tetramethylsilane as the lock signal for measurements with **2** and **3**, and chloroform for those with **4**.

It is a pleasure to thank the National Research Council of Canada for their generous financial support via operating grants (A 1905) and two equipment grants (E 1338 and E 1854).

An Electron Spin Resonance Study of the Radical Cations Derived from Dialkoxybiphenyls

PAUL D. SULLIVAN AND LOUIS J. NORMAN
Department of Chemistry, Ohio University, Athens, Ohio 45701

Received December 24, 1971

The e.s.r. spectra of the cation radicals of various alkyl substituted 4,4′-dihydroxybiphenyls have been studied. These spectra give information regarding the molecular motions occurring in these compounds.

Les spectres e.s.r. des radicaux cationiques de plusieurs 4,4′-dihydroxybiphényles substitués par des groupes alkyles ont été étudiés. Les spectres donnent des informations sur les mouvements moléculaires qui se font dans ces composés.

Canadian Journal of Chemistry, **50**, 2141 (1972)

Radical cations derived from 4,4′-dialkoxybiphenyls belong to the same class of radicals as the Wurster and Weitz radicals, and it has been proposed by Hunig (1) that all radical ions of this type should be termed "violenes". It is the purpose of this note to report on the observation by electron spin resonance of the cation radicals of various alkyl substituted 4,4′-dihydroxybiphenyls, and, in addition, to make a number of suggestions regarding the structure and chemistry of formation of these radicals.

The radicals studied are indicated in Table 1 together with their e.s.r. hyperfine splitting constants and *g* factors. The neutral compounds were either commercially available (**1** and **7**) or were prepared by lead dioxide oxidation of the appropriate phenols (2). The compounds were oxidized with the aluminum chloride–nitromethane system (3). Their behavior in this oxidizing medium could be divided into two types. For compounds **1**, **3**, and **7** when only a slight excess of $AlCl_3$ was used the initial concentrated solution in the e.s.r. tube was dark blue (λ_{max} 800–850 mμ) and exhibited only a broad unresolved e.s.r. signal. Dilution of this concentrated solution at room temperature yielded a green solution (λ_{max} 420–440 and 800–850 mμ) which yielded a well resolved e.s.r. spectrum. On

*Temperature 0°.
†Temperature −40°.
‡Temperature −50°.
§Temperature −30°.
‖Not analyzed in detail, but spectrum is the sum of two species.

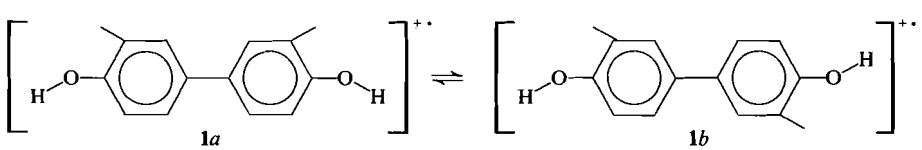
lowering the temperature the solution was observed to change color reversibly from green to royal blue and simultaneously the intensity of the e.s.r. spectrum was observed to decrease rapidly being essentially unobservable below −50°. Compound **3**, for example, lost a factor of ten in amplitude over the range −10 to −30°. If these compounds were reacted with an excess of $AlCl_3$ a dark yellow solution was obtained which showed no e.s.r. signal even after dilution.

Compounds **2**, **4**, **5**, and **6** on the other hand, gave a red solution on reaction with a slight excess of $AlCl_3$. Dilution of this solution gave a well resolved e.s.r. spectrum. The intensity of the e.s.r. signal from these compounds did not vary greatly with temperature down to −60°, and no color change was noted on cooling. Addition of a large excess of $AlCl_3$ resulted in the loss of the e.s.r. signal.

The above results are consistent with an equilibrium at room temperature between the radical cation and the dication which depends on the concentration of $AlCl_3$. The change in e.s.r. intensity and color of **1**, **3**, and **7** with temperature can be explained in terms of the formation of a diamagnetic dimer at low temperatures. This interpretation is supported by the absence of an e.s.r. signal in the field range 0–4000 G, from frozen solutions of these compounds. This result is not unexpected when the behavior of other "violene" radicals is considered (4, 5).

The structure of the dimer can be inferred from the observation that the sterically hindered compounds **2**, **4**, **5**, and **6** do not form such a dimer. One can therefore postulate that the dimer results from a stacking of the biphenyl rings on top of each other such that the π systems can interact.

Information on the molecular structure of the cation radicals can also be obtained from their e.s.r. spectra. It has been reported (6) previously that the e.s.r. spectrum of **1** shows line-width alternation effects which appear consistent with a *cis–trans* isomerization. In support of this we observe that the e.s.r. spectrum of **7** is very complex and is apparently interpretable in terms of two species (**1***a* and **1***b*). This indicates a slow rotation about the central C—C bond indicating



1*a* **1***b*

1*c*

a considerable double bond character, undoubtedly due to the importance of structures of the type **1***c*. Molecular orbital calculations using the McLachlan perturbation corrections to HMO theory (7) support this interpretation, since in order to reproduce the experimental spin densities it is necessary to increase the resonance integral of the central C—C bond to a value of 1.25 β_o, where β_o is the standard carbon–carbon resonance integral.

No effects due to rotational isomerism were noted for compounds **2–6**, in the temperature range studied. This is not surprising since in these compounds the potential barrier to rotation for the hydroxyl groups is expected to be decreased considerably (8).

One further observation which merits comment concerns the lifetime of the radical derived from 4,4′-dihydroxyoctamethylbiphenyl (**2**). This radical is considerably shorter lived than the other radicals studied, at 0° it's half-life is approximately 8 min compared to half-lives of several hours for the other radicals at this temperature. If radical **2** is allowed to stand at room temperature for several hours a different e.s.r. signal develops which has been identified as that of the 1,4-dihydroxy 2,3,5,6-tetramethylbenzene (duroquinol) cation radical. Additionally radical **2** also shows strongly temperature dependent hydroxyl and methyl group splitting constants while the other radicals show only temperature dependent hydroxyl group splitting constants. These observations indicate that the torsional oscillations of this molecule manifest themselves in subtle ways in the e.s.r. spectra. Further study of this molecule may be warranted.

2 1

have been published, but these have been performed in the presence of strong bases (3, 4).

The diimide **1** was obtained by oxidation of the hydrazide **2** (1) with lead tetraacetate in methylene chloride solution. For the kinetic measurements, toluene solutions *ca.* 1.4×10^{-2} *M* in **1** were employed, and the disappearance of **1** was followed by monitoring the decrease of the absorbance of the n–π^* band at *ca.* 400 nm. These decompositions were performed without the exclusion of air. Runs were followed to between one and two half-lives and gave good first-order plots; decompositions at higher concentrations of **1** indicate that the amount of induced decomposition is negligible. Manometric rate constants were in approximate agreement with those obtained as above, but consistent results were difficult to obtain.

The least-squares rate constants thus obtained for the decomposition of **1** at seven temperatures between 81 and 102° are given in Table 1. A plot of $\log_e k$ *vs.* $1/T$ gave an excellent straight line from which the Arrhenius expression $k = 10^{15.08} e^{-32.54 \pm 1.35/RT}$ was obtained. It is notable that at 100.0°, the rate of decomposition of dibenzoyl diimide (7.7×10^{-6} s^{-1} (5)) is *ca.* 13 times slower than that of **1**, while bis-(1-cyanocyclohexyl) diimide at 80.3° decomposes at approximately the same rate (6.5×10^{-6} s^{-1} (6)) as **1** (9.2×10^{-6} s^{-1}).

Removal of the toluene from completely decomposed samples of **1** gave an oil from which a crystalline solid, $C_{14}H_{17}NO_2$, m.p. 159.5–160.5°, was isolated by trituration with pentane followed by crystallization from ether. The mass spectrum of this material (*m/e* 231 (40%) (molecular ion), 122 (100%), 110 (40%), 105 (88%), and 77 (58%)) together with the n.m.r. (δ 1.7 (broad methylene envelope), 3.3 (broad singlet), 9.0 p.p.m. (broad singlet, removed on D_2O was)) and i.r. (ν_{max} 3400 (w, —NH—), 1695 (s, shoulders at 1710 and 1750 cm^{-1}), 1460 (m), 1230 cm^{-1} (m)) spectra of the crude product, suggested this compound to be *N*-benzoyl-*N*-cyclohexane carbonyl imide, **3** (lit. (7) m.p. 157), a compound which has previously been isolated from treatment of 2-phenyl-4-cyclohexylidene-5-oxazolone with sodium azide in aqueous acetic acid (7). Confirmation of the structure **3** was obtained by its independent synthesis from benzamide and cyclohexane carbonyl chloride. The authentic material, m.p. 161.5–163°, had a mass spectrum identical to that of the $C_{14}H_{17}NO_2$ compound and its n.m.r. and i.r. spectra were similar to those of the crude product. Compound **3** is estimated to constitute *ca.* 30% of the crude product, and is presumably formed via addition of water to the acyl ketenimine **4**.

TABLE 1. Least squares rate constants and their standard deviations for the decomposition of **1** in toluene

Concentration ($\times 10^{-2}$ mol l^{-1})	Temperature (°C)	$k \times 10^5$ (s^{-1})
1.44	81.3	1.01±0.05*‡

1.43	102.2	13.32±0.30*

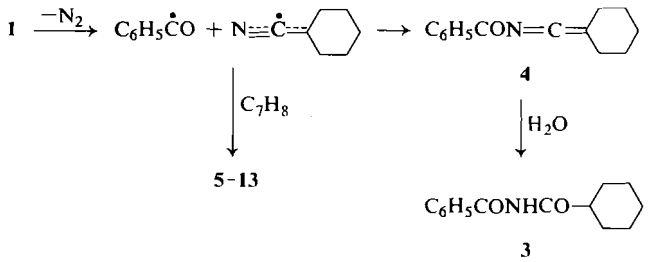
*Average of two runs.
†From one run.
‡Taken to 0.6 half-lives.

The g.l.c. analysis of the residue after removal of the toluene showed the product mixture to be complex (*ca.* 19 components); however, it was possible to establish the presence of small amounts of benzaldehyde (**5**), bibenzyl (**6**), 1,1′-dicyano-1,1′-bicyclohexyl (**7**), 1-cyanocyclohexene (**8**), cyanocyclohexane (**9**), cyclohexanone (**10**), and cyclohexanol (**11**), together with a component with the same retention time as biphenyl (**12**), and a possible trace of benzil (**13**).[2]

Decomposition of **1** (200 mg, 8.3×10^{-4} mol) in degassed benzene (2 ml) containing water (28.6 mg, 1.6×10^{-3} mol, to trap the presumed intermediate, the ketenimine **4**, and simplify the products) in an evacuated sealed tube at 104° for 24 h followed by direct g.l.c. analysis led to identification of the following products (approximate mole ratios in parenthesis): cyclohexa-

[2]At the temperatures at which the decompositions were performed, the partial pressure of O_2 in the solvent should be small, thus formation of radical coupling and H-abstraction products is not surprising.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



none (1.1), cyanocyclohexane (1.0), benzaldehyde (0.2), 1-cyanocyclohexene (0.3), cyclohexane carboxamide (0.9), 1,1′-dicyano-1,1′-bicyclohexyl (0.1), benzamide (5.6), and the imide **3** (5.2), accounting for *ca.* 65% of the total product observable by g.l.c.; absent were biphenyl, benzil, benzophenone, and cyclohexanol. The amides most probably arise by hydrolysis of the imide by excess water.

Thus both the kinetic and the product studies are consistent with a thermal homolytic fragmentation of **1** to nitrogen and the benzoyl and 1-cyanocyclohexyl radicals which, in turn, react largely by coupling to give the acyl ketenimine **4**.

Experimental

Melting points are uncorrected. Spectroscopic instruments employed were as previously reported (1).

N-Benzoyl-N′-1-cyanocyclohexyl Diimide (1)

A solution of lead tetraacetate (4.35 g, 9.84 mmol) in methylene chloride (125 ml) was poured into a stirred solution of the hydrazide **2** (2.12 g, 8.72 mmol) in methylene chloride (80 ml) cooled to −20°, and the mixture stirred for 30 min at −20°. The yellow orange solution was then poured into water (100 ml), and the layers separated. The organic layer was washed with 5 × 100 ml aliquots of water, once with 100 ml saturated aqueous sodium bicarbonate, and once with water. After drying, the solvent was removed, and the yellow orange solid was recrystallized from pentane (1.92 g, 91%), m.p. 68–69.5°.

Decomposition Studies on 1

The toluene used was dried by standing over sodium wire followed by distillation, and then was stored over molecular sieves. Solutions of **1** in toluene in a 100 ml round-bottomed flask fitted with condenser and a drying tube were then immersed in a Neslab Instruments Inc. Model TE-9HT constant temperature bath, with the bath liquid, ethylene glycol, maintained at the appropriate temperature. Toluene samples were withdrawn at known time intervals and the absorbance of the band at 400 nm measured. First-order rate constants were obtained from the slope of the plot of $\ln (A_0/A)$ *vs.* t(s), where A_0 and A are the absorbances at $t = 0$ and $t = t$ s. respectively. Solutions of **1** in toluene were found to obey Beer's Law.

Isolation of 3 from the Decomposition of 1

Toluene was removed from a completely decomposed sample of **1**, and the residue was triturated with pentane. The pentane was decanted, and the pentane-insoluble material was dissolved in a small quantity of ether. On cooling in the refrigerator overnight, **3** crystallized out and was purified by several further crystallizations from ether, m.p. 159.5–160.5°.

Anal. Calcd. for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06. Found: C, 72.78; H, 7.28; N, 6.03.

Synthesis of N-Benzoyl-N-cyclohexane Carbonyl Imide (3)

Cyclohexane carbonyl chloride (13.9 g, 0.095 mol, Eastman Kodak) was added dropwise to a solution of benzamide (11.0 g, 0.091 mol) in pyridine (60 ml). The temperature was maintained at 10–15° throughout the addition. When all the acid chloride had been added, the reaction mixture was stirred for a further 0.5 h at room temperature and then poured on to ice (100 g). The precipitate so obtained was filtered off, digested in ice-cold ether (150 ml), and the aqueous layer was run off. Removal of the solvent after drying gave the crude product (8.5 g, 37%), a sample of which after three crystallizations from ethanol had m.p. 161.5–163°; ν_{max} 3390 (w), 1695 (s, shoulders at 1710 and 1753 cm^{-1}), 1460 (m) and 1230 cm^{-1} (m); n.m.r.: δ 1.7 (broad envelope, 10 H, cyclohexyl —CH_2—), 3.4 (broad singlet, 1 H, methine —C(—H)—), 7.7 (multiplet, 5 H, aromatic =C(—H)—), and 9.0 (broad singlet, 1 H, NH, removed on D_2O wash); λ_{max} (EtOH): 235 (13 600), 274 (sh, 1000) nm.

Miscellaneous

1,1′-diCyano-1,1′-bicyclohexyl (**7**), 1-cyanocyclohexene (**8**), and cyanocyclohexane (**9**) were synthesized by literature methods.

Gas liquid chromatography (g.l.c.) was performed on a Varian Model 1740 Gas Chromatograph, equipped with a flame ionization detector and products were identified by comparison of their retention times with those of authentic samples. Columns used were: A, 5 ft × 1/8 in. 5% DEGSE on acid washed 80/100 mesh Chromosorb W, B, 5 ft × 1/8 in. 3% SE-30 on 100/120 mesh VarAport 30, C, 5 ft × 1/8 in. 5% Carbowax 20M on DMCS treated 80/100 mesh Chromosorb W.

Compounds **5**, **7**, **8**, **9**, and **10**, and the amides were identified on columns B and C, compound **6** on columns A and B, and compound **3** on column B. Positive identification of benzoic and cyclohexane carboxylic acids on columns B and C was not possible due to peak overlap.

^{13}C Chemical Shifts of Highly Substituted Bicyclo[2.2.1]heptanes

N. H. WERSTIUK, R. TAILLEFER, R. A. BELL, AND B. G. SAYER

Department of Chemistry, McMaster University, Hamilton, Ontario

Received November 29, 1971

The ^{13}C chemical shifts have been determined for a series of highly substituted norbornanes. A comparison of the observed values with the expected chemical shifts, determined as described by Lippmaa, establishes that ^{13}C shifts may be predicted reasonably accurately even in highly substituted norbornyl systems. Since substituted norbornanes definitely exist in *synchro* or *contra* twist forms as shown by Altona, the results show that Lippmaa's substituted shift parameters must already account for the major part of the increments that arise via hybridization changes resulting from the distortion of the [2.2.1]-skeleton.

Les déplacements chimiques du ^{13}C ont été déterminés pour une série de norbornanes hautement substitués. La comparaison des valeurs observées avec les déplacements chimiques attendus selon Lippmaa, montre que les déplacements chimiques du ^{13}C peuvent être prévus avec une précision raisonnable même pour des systèmes norbornyles hautement substitués. Il a été montré par Altona que les norbornanes substitués existent sous des formes twist *synchro* et *contra*, les résultats montrent que les paramètres de Lippmaa associés aux déplacements chimiques des substituants doivent expliquer le fait que la majeure partie des incréments provient des changements d'hybridation résultant de la distorsion du squelette[2.2.1].

Canadian Journal of Chemistry, **50**, 2146 (1972)

Introduction

Recently, expansion in the application of ^{13}C n.m.r. spectroscopy to organic chemistry has been dramatic (1–7). The accumulated chemical shift data have yielded, in addition to data for the determination of theories of ^{13}C chemical shifts, important information about ground state steric and electronic substituent effects in acyclic and cyclic molecules. Furthermore, ^{13}C–H and ^{13}C–^{13}C coupling constants have been used to gain hybridizational information at the carbon atom (1, 8–10).

Through our interest in the chemistry of the bicyclic diones **2**, **5**, and **9**, and the enones **7** and **11** (11) we have applied ^{13}C.m.r. to determine whether or not the diones and enones, which certainly exist in *synchro* or *contra* twist forms (12) are hybridizationally unusual at the bridgeheads with the angle described by the bonds C_6—C_1—C_2 deviating substantially from the normal 109.5°. Since ^{13}C shifts for sp^3 and sp^2 hybridized carbon are 15–60 and 90–160 p.p.m. (13) downfield from tetramethylsilane respectively, the C-1 and -4 shifts would serve as hybridization probes. The ^{13}C shifts determined experimentally for a series of substituted bicyclic systems are listed in Table 1.

Discussion and Conclusions

In Table 2 a comparison is made between the observed chemical shifts for C-1, -4, -6, and -7 and those predicted by application of Lippmaa's (2) substituent shift parameters. The good agreement indicates that the ^{13}C shifts may be predicted reasonably accurately even in highly substituted systems (*cf.* **9** and **14**, Table 2).

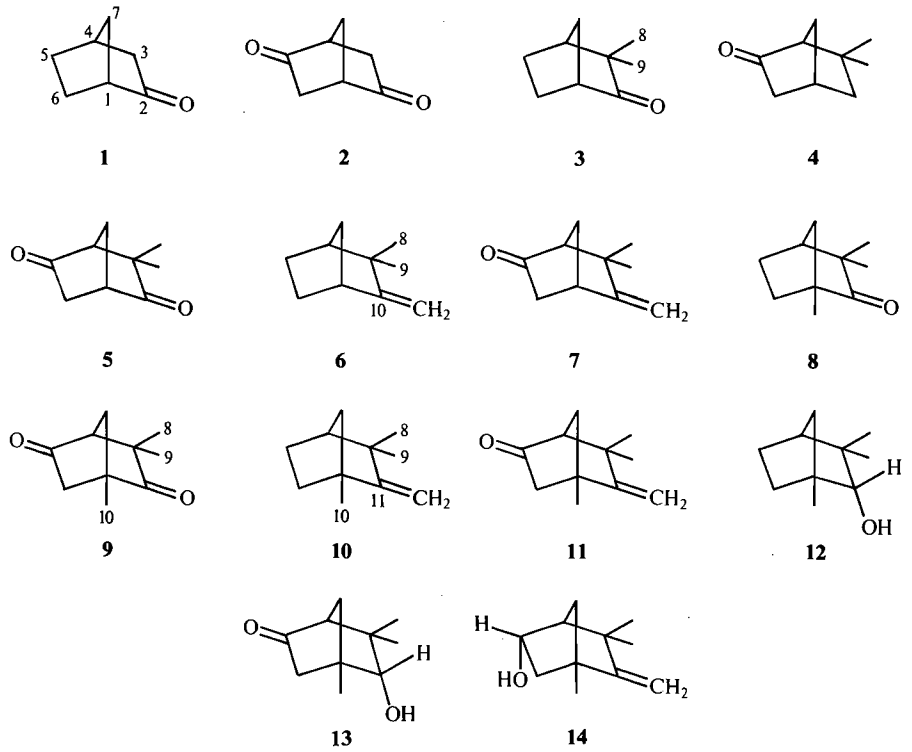
*In p.p.m. (±0.1) downfield from tetramethylsilane.
†Not determined; estimated from **6** and **7**.



Since the predicted shifts of the diones **2**, **5**, and **9** and the enones **7** and **11** compare favorably with the observed values, several interpretations are possible: (*a*) the diones and enones exist in *synchro* or *contra* twist forms with $90° < \phi < 109.5°$, but that the hybridization change at the bridgeheads is minimal; (*b*) that Lippmaa's parameters account sufficiently for hybridizational changes which arise from distortion of the [2.2.1]-system through incorpora-

TABLE 2. Predicted and observed shifts differences

*Plus and minus indicate upfield and downfield shifts relative to the expected position.
†2-Methylenenorbornane used as substrate.

tion of substituents. That (*b*) is the case can be seen from a consideration of the predicted and observed shift differentials for C-4, -6, and -7. For **5**, **9**, **7**, and **11**, C-4 and -6 are consistently 2.0–2.6 and 1.6–2.7 p.p.m. downfield and C-7, 1.3–3.7 p.p.m. upfield, respectively, from the predicted positions. Carbon-1 appears 1.0–1.6 p.p.m. upfield from the expected position in **2**, **5**, and **7** and at the exact position, within experimental error, in **9** and **11**. Since no consistent upfield–downfield differentials are evident in the other compounds, with special attention drawn to the 2,5-systems **13** and **14**, the shift differentials for **5**, **9**, **7**, and **11** do perhaps indicate the operation of some effect not completely accounted for by the shift parameters. However, to decide conclusively whether or not the 2,5-diones and enones are unusual hybridizationally at the bridgeheads and to determine the magnitude of the effect, requires further studies.

Interestingly, the carbonyl carbons in the 2,5-diones experience a 2.4–4.3 p.p.m. diamagnetic shift relative to the monoketones (*cf.* **1** and **2**, Table 1). A decrease in the dipolar structure of the carbonyl groups due to the 1,4 dipolar interaction of the positive ends of the $\diagdown C{=}O$ dipole would explain this observation.

Also of interest is that C-7 in the diones and enones experiences a diamagnetic shift (1.2–4.3 p.p.m.) relative to the predicted values with a maximum differential of 4.3 in the 5-oxo-camphenilone (**5**). The effect of the carbonyl groups on C-7 contrasts with that of the double bonds in norbornadiene which cause a large paramagnetic shift (2).

Experimental

Apparatus

Spectra were recorded with a Varian Associates HA 100 spectrometer at 23.5 kG and 25.1 MHz. The operating probe temperature was +55 °C. Field frequency stabilization was achieved by use of an external (1.5 mm capillary) $^{13}CS_2$ lock and chemical shift measurements were made initially relative to internal dioxane (67.3 p.p.m.), benzene (129.7 p.p.m.), and then to internal tetramethylsilane. A sample volume of 0.2–0.3 ml was used in a 5 mm o.d. sample tube, with dioxane as solvent where necessary. Normally a signal accumulation of 4–16 scans with a Varian Associates C-1024 time averaging computer, was sufficient to give an adequate signal to noise enhancement. Proton decoupling was carried out using a Varian Associates V-3512-1 noise decoupler. Carbon atom assignments were accomplished by examination of off-resonance decoupled spectra which were obtained by accumulation of 100–300 scans. Deuterium substitution was used in **5** to establish the carbon assignments.

Stereochemistry of 3-Methyl-4-phenylpiperidines Derived from Corresponding 4-Phenyl-4-piperidinols

K. M. J. MCERLANE AND A. F. CASY

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta

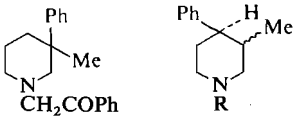
Received October 21, 1971

Catalytic reduction of 3- and 5-methyl-4-phenyl-1,2,5,6-tetrahydropyridines is stereospecific and gives *cis*-3-methyl-4-phenylpiperidines. Hydrogenolysis of 1-*t*-3-dimethyl-4-*r*-hydroxy-4-phenylpiperidine (*β*-prodinol) by Raney nickel also gives a *cis* product. Stereochemical assignments are made on the basis of p.m.r. spectroscopic data. Hot-plate activities in mice of 1-methyl- and 1-phenethyl-*c*-3-methyl-4-phenylpiperidine are reported.

La réduction catalytique des méthyl-3 et -5 phényl-4 tétrahydro-1,2,5,6 pyridines est stéréospécifique et conduit au méthyl-3 phényl-4 pipéridine *cis*. L'hydrogénolyse de la diméthyl-1-*t*-3 hydroxy-4-*r* phényl-4 pipéridine (*β*-prodinol) par le nickel de Raney donne aussi un produit *cis*. Les attributions stéréochimiques sont faites sur la base des données r.m.n. Les activités biologiques sur les souris de la méthyl-1 et phénéthyl-1 méthyl-*c*-3 phényl-4 pipéridine sont rapportées.

Canadian Journal of Chemistry, **50**, 2149 (1972)

A feature common to all narcotic analgesics based on 4-phenylpiperidine is an oxygenated function at C-4; this may be CO_2Et, OCOEt, COEt, or OEt (1). In view of the fact that analgesics of the morphinan and 6,7-benzomorphan class lack a non-aromatic oxygen function as do also certain 3-phenylpiperidine analgesics such as **1**, a series examined by Kugita *et al.* (2), it was of interest to determine if analgesic activity were retained in analogs of reversed esters of pethidine in which the 4-propionyloxy group was replaced by hydrogen as in **2**. Of special interest were the derivatives **2** with *cis* 3-Me/4-Ph geometry, since these isomers are more active than the *trans* forms in the 3-methylpethidine and prodine series (3, 4).[1]



1 **2**

a R = Me
b R = Et
c R = H
d R = $(CH_2)_2Ph$

The first approach to preparing the diastereoisomers **2** was to reduce the acid catalyzed dehydration products of 3-methyl-4-phenyl-4-piperidinols; these were composed of mixtures of the tri- (**3**) and tetra-substituted alkenes (**4**). Single isomeric forms of **2** resulted when the

[1]Pethidine (meperidine) is 4-carbethoxy-1-methyl-4-phenylpiperidine hydrochloride; α- and *β*-prodine (reversed ester analogs of pethidine) are *c*-3-Me- and *t*-3-Me,*r*-4-OCOEt isomers of 1,3-dimethyl-4-phenyl-4-propionyloxypiperidine hydrochloride respectively, while α- and *β*-prodinol are the corresponding 4-piperidinol bases.

The first approach to preparing the diastereoisomers **2** was to reduce the acid catalyzed dehydration products of 3-methyl-4-phenyl-4-piperidinols; these were composed of mixtures of the tri- (**3**) and tetra-substituted alkenes (**4**). Single isomeric forms of **2** resulted when the

[1]Pethidine (meperidine) is 4-carbethoxy-1-methyl-4-phenylpiperidine hydrochloride; α- and β-prodine (reversed ester analogs of pethidine) are *c*-3-Me- and *t*-3-Me,*r*-4-OCOEt isomers of 1,3-dimethyl-4-phenyl-4-propionyloxypiperidine hydrochloride respectively, while α- and β-prodinol are the corresponding 4-piperidinol bases.

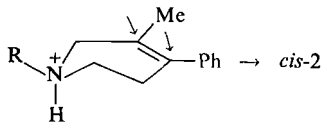
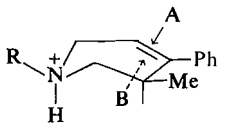
alkene hydrochloride salts (R in **3** and **4** = Me, Et, CH_2Ph, $(CH_2)_2Ph$, mixture or pure isomer) were shaken with hydrogen at atmospheric pressure in the presence of palladized charcoal. The isomers **2** were assigned a *cis* 3-Me/4-Ph configuration on the basis of the 3-methyl signals of their p.m.r. spectra undergoing a downfield shift of about 0.3 p.p.m. when the basic center of the molecule was protonated; shifts of these magnitudes in 3-methylpiperidines are evidence for an axial *C*-methyl orientation as in the preferred conformation **5** (3, 5, 6). In the *trans* isomer **2***a* (see later), the 3-methyl shift after *N*-protonation was negligible (0.07 p.p.m.), the substituent being well removed from the deshielding $^+$NH feature of the molecule when it has an equatorial orientation. Assuming that catalytic hydrogenation of **3** and **4** proceeds by *cis* addition from the least hindered side of the molecule (7), the stereospecificity of these reactions may be elaborated as follows. Clearly *cis* addition of hydrogen to the double bond of the 3-methyl-

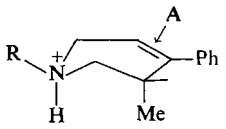


6

tetrahydropyridine **6** must give rise to a *cis* 3-Me/4-Ph product whatever face of the molecule is attacked. The product of *cis* addition to the protonated trisubstituted alkene **3**, however, depends on the conformation of the conjugate acids at the catalyst surface. If it be **7**, a *trans* product results when addition takes place in direction A, and a *cis* derivative if



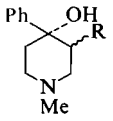
7



8

approach is from B. If it be **8**, the *cis* product will result (in this case only approach from A need be considered because this is clearly the less hindered route). There is good evidence for the existence of high populations (50% or more) of conformer **8** in solutions of salts of the tetrahydropyridines **3** (8).

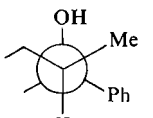
In an attempt to obtain the *trans* isomer of **2***a*, hydrogenolysis of the 4-piperidinols **9** by



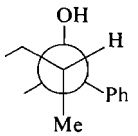
9

a R = H
b R = Me

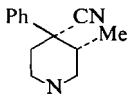
means of Raney nickel was investigated. Although this method of replacing hydroxyl by hydrogen in benzylic alcohols may occur with inversion of configuration (9), it generally proceeds with retention in the absence of competitive reduction pathways and when high reaction temperatures are avoided (10, 11). The piperidinols **9***a* and 3-*t*-Me,*r*-OH **9***b* (*β*-prodinol) were smoothly hydrogenolyzed by Raney nickel in boiling ethanol, no reaction occurring at room temperature. In the latter case, the product was *cis*-**2***a*, hence the reaction was stereospecific and proceeded with retention. The 3-*c*-Me piperidinol **9***b* (*α*-prodinol) proved resistant to Raney nickel even when the reaction period was extended. This result is attributed to steric hindrance of the hydroxyl function by the gauche 3-methyl group (**10**) whereby ap-



10(*α*)



11(*β*)



12

proach of the molecule to the catalyst surface is impeded. In *β*-prodinol, the 3-methyl substituent is well removed from the OH function (**11**). Other examples which illustrate the greater accessibility of the hydroxyl group in 3-*t*-Me,*r*-OH prodinol are available (12–15). The *trans*-piperidine **2***a* was finally obtained by cleavage of 4-*r*-cyano-1,3-*c*-dimethyl-4-phenylpiperidine (**12**) with sodamide.

The *c*-3-methyl derivative **2***a* was half as active as pethidine in the hot-plate test performed on mice (ED_{50} valves after subcutaneous injection were 8.6 and 4.7 mg/kg respectively). The corresponding 1-phenethyl analogue **2***d* was inactive in this test at a dose level of 100 mg/kg. Hence, since the potency of narcotic analgesics derived from *N*-methyl cyclic bases increases when the *N*-substituent is replaced by 1-phenethyl (1), *c*-3-methyl-**2***a* probably has a general depressant rather than morphine-like action in this test.[2]

Experimental

The p.m.r. spectra were recorded on a Varian A-60D spectrometer at the ambient temperature using $CDCl_3$ or DMSO-d_6 as solvents and TMS as standard. Salts were crystallized from ethanol–ether unless otherwise stated.

Reduction of 3- and 5-Methyl-4-phenyl-1,2,5,6-tetrahydropyridines (3 and 4)

The mixture of **3***a* and **4***a* hydrochlorides (6 g) obtained from α-prodinol (8) was dissolved in ethanol (50 ml) and shaken with 10% palladium-on-charcoal (0.4 g) and hydrogen at room temperature and pressure. When gas absorption ceased the mixture was filtered and the filtrate evaporated. The residue was recrystallized to give *cis (3-Me/4-Ph) 1,3-dimethyl-4-phenylpiperidine hydrochloride* (5 g), m.p. 243–245°, $\delta_{3\text{-Me}}$ 1.14, 0.73 (base) in $CDCl_3$.

Anal. Calcd. for $C_{13}H_{20}ClN$: C, 69.3; H, 8.8. Found: C, 69.2; H, 8.9.

No evidence of a second isomer could be obtained from the mother liquors.

The following analogues of *cis*-**2***a* were similarly prepared from the appropriate alkenes **3** and **4** or alkene mixtures (reduction of the *N*-benzyl derivatives also removed the *N*-substituent).

2*b hydrochloride*, m.p. 260–263°, $\delta_{3\text{-Me}}$ 1.12, 0.8 (base) in $CDCl_3$.

Anal. Calcd. for $C_{14}H_{22}ClN$: C, 70.1; H, 9.25; N, 5.8. Found: C, 70.4; H, 9.1; N, 5.5.

2*c hydrochloride*, m.p. 216–217°, $\delta_{3\text{-Me}}$ 1.05, 0.8 (base) in $CDCl_3$.

Anal. Calcd. for $C_{12}H_{18}ClN$: C, 68.1; H, 8.6; N, 6.6. Found: C, 67.8; H, 8.5; N, 6.8.

2*d hydrochloride*, m.p. 235–236°, $\delta_{3\text{-Me}}$ 1.11, 0.78 (base) in $CDCl_3$.

Anal. Calcd. for $C_{20}H_{26}ClN$: C, 76.05; H, 8.3. Found: C, 76.0; H, 8.5.

Hydrogenolysis of the 4-Piperidinols (9)

A mixture of Raney nickel (5 g) (Grace, Chattanooga, active grade) **9***a* (0.5 g) and ethanol (50 ml) was stirred and heated under reflux for 4 h. The product was cooled, filtered, and the filtrate evaporated to give 1-methyl-4-phenylpiperidine (0.5 g) (in all these experiments completion of hydrogenolysis was checked by the absence of a ν_{OH} band near 3150 cm^{-1} in the i.r. spectrum of the product), isolated as a *hydrochloride*, m.p. 197–198°.

Anal. Calcd. for $C_{12}H_{18}ClN$: C, 68.1; H, 8.6; N, 6.6. Found: C, 68.2; H, 8.6; H, 6.6.

It formed a picrate, m.p. 238° from ethanol, lit. 239–240° (16).

The same treatment of β-prodinol gave *cis*-**2***a*, m.p. and mixed m.p. 242–243°, while α-prodinol was unaffected.

Cleavage of the Isomeric 4-Cyanopiperidines 12 (by K. K. Khullar)

A mixture of 4-*r*-CN,3-*c*-Me **12** (3.1 g) (3), sodamide (5.85 g), and toluene (150 ml) was heated under reflux for 8 h. Water was added to the cooled product and the toluene separated and extracted with dilute hydrochloric acid. The free base was recovered as usual giving *t*-3-Me **2***a* (2.5 g), isolated as a *hydrochloride*, m.p. 232–235°.

Anal. Calcd. for $C_{13}H_{20}ClN$: C, 69.3; H, 8.8; N, 6.2. Found: C, 68.9; H, 9.2; N, 6.3.

It formed a *methiodide*, m.p. 143–146°.

Anal. Calcd. for $C_{14}H_{22}IN$: C, 50.8; H, 6.6; N, 4.2. Found: C, 51.0; H, 6.5; N, 4.2.

The same treatment of 4-*r*-CN,3-*t*-Me **12** gave *c*-3-Me **2***a*, m.p. and mixed m.p. 237–238°.

We thank the Medical Research Council of Canada for financial support, Dr. A. P. Parulkar for samples of **3***b*, **3***c*, **4***b*, and **4***c*, and Dr. K. K. Khullar for carrying out cleavage experiments on the isomers **12**.

On the Extent of Transannular Rearrangement in the Formolysis of 1,5-Cyclooctadiene Monoepoxide

JOHN M. MCINTOSH
Department of Chemistry, University of Windsor, Windsor, Ontario
Received January 13, 1972

Formolysis of 1,5-cyclooctadiene monoepoxide (**1**) has been shown to give only *ca.* 25% of products of transannular reactions. The difference between this result and those from the solvolyses of cyclooctene oxide and 4-cyclooctenyl brosylate is attributed to conformational and ring-strain effects.

La formolyse du monoépoxyde (**1**) du cyclooctadiène-1,5 conduit à 25% seulement de produits résultant de réactions trans-annulaire. La différence entre ce résultat et ceux issus de la solvolyse de l'époxyde du cyclooctène et du brosylate du cyclooctényl-4 est attribuée à des effets conformationnels et de tension du cycle.

Canadian Journal of Chemistry, **50**, 2152 (1972)

Transannular reactions involving hydride migrations and π-electron participation in medium-sized ring solvolyses are well-documented (1). Perhaps the most thoroughly investigated case is the formolysis of cyclooctene oxide (2) where the competing reactions of 1,3- and 1,5-hydride migrations have been separated and shown to be in the ratio of 2:3 (3). Attempts to extend the reaction to the migration of other groups have met with limited success (4, 5).

The preparation of 5-cyclooctene-1,2-diol (**2**) in 73% yield by the acid-catalyzed hydroxylation of 1,5-cyclooctadiene has been reported in the patent literature (6). The presumed intermediate in this reaction is 1,5-cyclooctadiene monoepoxide (**1**). The amount of normal epoxide opening reported in this case is surprising when compared with that of cyclooctene oxide (2) since the presence of the double bond might be expected to facilitate 1,3-hydride migrations by stabilization of the developing positive charge. Moreover, transannular π-electron participation might be expected to provide an energetically favorable pathway to bicyclic products. It should be noted that the acetolysis of 4-cyclooctenyl brosylate has been reported (7) to give 74% of rearranged products. Therefore we have reinvestigated the formolysis of 1,5-cyclooctadiene monoepoxide.

When 1,5-cyclooctadiene monoepoxide (**1**) (8) was solvolyzed in either 85 or 98% formic acid, a mixture of hydroxyformates was obtained. Saponification and distillation of the mixture afforded an alcohol fraction and a higher-boiling diol fraction as the only volatile components (Scheme 1). The yields are summarized in Table 1.

The alcohol fraction contained 50% of 3,5-cyclooctadienol (**3**) (9) which was distinguished from its isomer **4** (10) by its u.v. spectrum. The remainder of the fraction was composed of a mixture of bicyclooctenols as was shown by elemental analysis, mass spectrometry, and by integration of the n.m.r. spectrum.

The diol fraction was treated with acetone and the isopropylidene ketal of 5-cyclooctene-1,2-diol (**5**) was separated from the mixture by distillation. The yields are summarized in Table 1. That the residual diol mixture consisted only of saturated bicyclooctanediols was shown by (*a*) the absence of n.m.r. absorptions below $\delta = 5.2$, (*b*) the lack of reaction with dilute bromine solution, and (*c*) the lack of hydrogen absorption in the presence of a palladium catalyst. Acetylation of the mixture gave a mixture of diacetates which contained at least eight components, many of which were incompletely resolved under all v.p.c. conditions utilized. Two of the components were separated and the diols obtained by hydride reduction were identified as bis-*endo*-bicyclo[3.3.0]octan-2,6-diol (**6**) and a mixture of 2,5- and 2,6-epoxycyclooctanol (**7**).

The comparison of the amount of transannular reaction in this case and those of cyclooctene oxide and 4-cyclooctenyl brosylate is shown in Table 2. Clearly the introduction of the π-bond into this cyclooctane ring effectively negates the proclivity for transannular hydride shift reactions found in cyclooctene oxide. The only product isolated compatible with such a

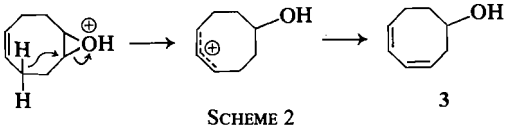
mechanism is dienol **3** (Scheme 2). However, the data do not allow the assignment of this difference to the presence of a preferred pathway involving π-electron participation. Two arguments can be advanced to rationalize these results. Models suggest that (*a*) in a suitable transition state for 1,3-hydride migration, the protons on C-3 and -7 are in very close proximity and (*b*) the conformation required for π-electron participation in the opening of the epoxide ring



SCHEME 2

also required the eclipsing of the C_3—C_4 and the C_7—C_8 protons. These energetically unfavorable situations may be responsible for the observed increase in the amount of "normal" epoxide opening. Alternately, it has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

pointed out that the introduction of one double bond into the cyclooctane ring reduces the ring strain. The experimental evidence on this point has been summarized (7). Although precise thermochemical data are not available, it has been suggested (7) that the ring strain in the bicyclo[3.3.0]octanes and the bicyclo[4.2.0]-octanes (which should be reflected in the transition state leading to them) may be large enough to make their formation from an incipient cyclooctenyl carbonium ion slow relative to the usual epoxide-opening reaction.

If the products from **1** arise by attack of formate directly on the protonated epoxide, the difference in the products from **1** and 4-cyclooctenyl brosylate is understandable since the latter is thought to proceed via a more carbonium ion-like transition state which allows greater flexibility of the ring and thus more π-participation in the product-forming step.

Experimental

Melting points and boiling points are uncorrected; v.p.c. analyses were performed on an F and M Model 720 instrument; i.r. spectra were recorded in chloroform solution; and n.m.r. spectra in deuteriochloroform unless otherwise noted. Microanalyses were performed by Dr. S. M. Nagy and Associates (M.I.T.) and by A. B. Gygli, Microanalysis Laboratory (Toronto).

Solvolysis of 1,5-Cyclooctadiene Monoepoxide (1)

(A) With 85% Formic Acid

To 500 ml of hot (95°) formic acid was added 60 g (0.48 mol) of **1** dropwise with stirring. An exothermic reaction ensued. The temperature was maintained at 95° for 1 h after the final addition and then most of the acid was removed by distillation at 80 mm. The residual brown oil was treated with 150 ml of cold 50% aqueous sodium hydroxide and stirred at room temperature overnight. The thick mass was extracted with four 200 ml portions of chloroform and the extracts were dried, evaporated, and carefully distilled to give an alcohol fraction (2.6 g, 4.3% as dienol), b.p. 45–59° (0.25 mm), a main fraction (48.5 g, 70.1% as cyclooctene diols), b.p. 83–98° (0.23 mm), and a non-distillable residue which was discarded.

(B) With 98% Formic Acid

The reaction was carried out in the same manner except the temperature was maintained at 60°. Fractionation of the saponified mixture gave no alcohol fraction, 47.2 g (68% as cyclooctene diols) of a viscous oil, b.p. 85–100° (0.25 mm), and some residue which was discarded.

The alcohol fraction was separated into two components by preparative v.p.c. (8 ft × 0.25 in. 20% SE30, 150°), one of which was identified as 3,5-cyclooctadienol (**3**) (9) which was distinguished from 2,4-cyclooctadienol (**4**) (10) by its u.v. spectrum: λ_{max} (EtOH) 230 nm (ε 4070).

Anal. Calcd. for $C_8H_{12}O$: C, 77.38; H, 9.74. Found: C, 77.13; H, 9.63.

Catalytic reduction over 10% palladium-on-charcoal resulted in a hydrogen absorption of 2 equiv and furnished cyclooctanol, identical in all respects with an authentic sample.

The n.m.r. spectrum of the remainder of the fraction showed an integrated intensity of 1.4 for the vinyl protons (total of 12) but was otherwise uninformative. Catalytic reduction resulted in a hydrogen absorption of 95% of 1 equiv. Analysis of the product on several v.p.c. columns showed one very broad peak. The n.m.r. spectrum was blank below δ 5.15 and a test with bromine in carbon tetrachloride was negative.

Anal. Calcd. for $C_8H_{12}O$: C, 77.38; H, 9.74. Found: C, 77.37; H, 9.61.

A solution of 40.0 g (0.282 mol) of the fraction of b.p. 83–98° (0.23 mm) in 500 ml of acetone was shaken with 60 g of anhydrous cupric sulfate for 22 h at room temperature. The solution was filtered, the residue washed with acetone and the solvent removed by distillation. Fractionation of the residue afforded 5.8 g (21.2%) of a viscous glycol mixture, b.p. 96–124° (0.4 mm) and 39.4 g (77%) of 5-cyclooctene-*trans*-1,2-diol isopropylidene ketal (**5**), b.p. 66–68° (2.0 mm); n_D^{25} 1.4699; i.r. 3020, 2985, 2940, 2860 1100 cm^{-1}; n.m.r. 5.64 (2H, mult), 3.90 (2H, mult), 2.24 (8H, mult), 1.33 (6H, sing).

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.46; H, 9.95. Found: C, 72.50; H, 9.87.

5-Cyclooctene-trans-1,2-diol (2)

Five grams (0.027 mol) of ketal **5** were hydrolyzed with 85% formic acid at reflux for 2 h. After saponification of the product with aqueous sodium hydroxide, distillation gave 3.12 g (80%) of **2**, b.p. 88–89° (0.12 mm); n_D^{25} 1.5110; i.r. 3320 cm^{-1}; n.m.r. 5.59 (2H, trip $J = 4$), 4.38 (2H, broad), 3.53 (2H, mult), 1.1–2.75 (8H, mult).

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.72; H, 10.11.

Acetylation of the remainder of the diol in the usual manner afforded a mixture of diacetates. We were unable to completely resolve the mixture under any v.p.c. conditions. There were at least eight components present, none of which corresponded to diol **2**. The lack of reaction of this mixture with dilute bromine solution, the absence of n.m.r. absorptions below δ 5.4 and the absence of a significant peak at *m/e* 224 showed that the mixture was composed of saturated materials only. Two components were isolated, reduced with lithium aluminum hydride, and the products shown to be bis-*endo*-bicyclo[3.3.0]octan-2,6-diol (**6**) identical with an authentic sample (see below) and a mixture of 2,5- and 2,6-epoxycyclooctanol, also identical with an authentic sample (11).

Bis-endo-bicyclo[3.3.0]octan-2,6-diol (6)

Bicyclo[3.3.0]octan-2,6-dione (12) (3.53 g, 0.026 mol) was reduced over prereduced platinum oxide in 75 ml of methanol at 80° and 1450–1300 p.s.i. for 12 h. Filtration and evaporation of the solvent gave residue which was distilled to give **6** (3.36 g, 93%), b.p. 102–103° (0.38 mm); n_D^{25} 1.5095.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.42; H, 9.72.

The bis-phenylurethane had m.p. 196–197°.

Anal. Calcd. for $C_{22}H_{24}O_4N_2$: C, 69.45; H, 6.63; N, 7.37. Found: C, 69.63; H, 6.39; N, 7.12.

The author wishes to express his appreciation to the late Prof. A. C. Cope who initiated these investigations, and to Dr. B. S. Fisher who obtained some of the preliminary results while a student at M.I.T. The technical assistance of Mr. D. Hill and the financial assistance of the National Research Council of Canada is also greatly appreciated.

The Magnetic Susceptibilities of Some Oxyhalide Ions

M. B. KENNEDY AND M. W. LISTER

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 3, 1972

Diamagnetic susceptibilities are reported for aqueous sodium hypochlorite, chlorite, hypobromite, and bromite. The results, combined with data from the literature for compounds of general formula $NaXO_n$, show a small increase for $n = 0$ to 2, and a much larger increase thereafter. The interpretation of these results in terms of bond orders is discussed, and comparisons are made with the enthalpies of formation, distances, and force constants of these compounds.

Les susceptibilités diamagnétiques des solutions aqueuses d'hypochlorite, de chlorite, d'hypobromite et de bromite de sodium sont décrites. Les résultats, combinés aux données de la littérature concernant les composés de formule générale $NaXO_n$, montrent un faible accroissement de $n = 0$ à 2 et une croissance plus marquée au-delà. L'interprétation de ces résultats en fonction de l'ordre de liaison est discutée et les comparaisons sont faites avec les enthalpies de formation, les distances et les constantes de force de ces composés.

Canadian Journal of Chemistry, **50**, 2155 (1972)

In an earlier paper (1), one of the present authors attempted to relate the contribution of oxygen atoms to the molar diamagnetic susceptibility with the type of bonding of the oxygen. The compounds then considered contained oxygen linked to nitrogen and phosphorus, and these were considered with special reference to the bond orders of the bonds to oxygen. The present note deals with compounds containing oxygen linked to chlorine or bromine, particularly in the sodium salts of oxyhalide ions.

Since some of the compounds in question are difficult to obtain as pure crystals (*e.g.*, sodium hypobromite), the measurements of susceptibility were made on aqueous solutions. Earlier work (2, 3) has shown that the susceptibilities of salts are not very different depending on whether they are crystals or in solution, at least for uni-univalent salts; typically the susceptibility of the salt in solution is 4 to 5% higher. The susceptibility varies very little with concentration (4), so it was thought to be justifiable to compare salt solutions of different concentrations.

Experimental

Chemicals

Sodium Hypochlorite

A stock solution (about 1.2 *M*) was purified by filtration through sintered glass, and then adding a 5% solution of barium chloride dropwise with stirring, until no more

barium carbonate precipitated. The solution contained a little sodium carbonate (from the original sodium hydroxide), and it was known (5) that coprecipitation with barium carbonate removed heavy metal impurities. The solution was then filtered again, and was analyzed as described earlier (6).

Sodium Hypobromite

Stock solutions were prepared by adding bromine slowly to cold sodium hydroxide solutions, and the solutions were purified as for sodium hypochlorite. The analyses of these solutions, and also those of sodium bromite, were carried out by the methods of refs. 7 and 8. In addition, the sodium bromide content was found by adding excess 3% hydrogen peroxide to an aliquot (to destroy sodium hypobromite and bromite), adjustment of the p*H* to about 8, and titration with silver nitrate. This titration measures the total of sodium bromide, hypobromite, and bromite.

Sodium Bromite

Crystals of sodium bromite ($NaBrO_2.3H_2O$) were kindly supplied by la société d'études chimiques pour l'industrie et l'agriculture of Argenteuil, France. These were dissolved in dilute sodium hydroxide to give a stock solution, analyzed as above.

Sodium Chlorite

This was an analytical grade supplied by Matheson, Coleman and Bell Company. It was recrystallized from water and dried before use. It gave the correct equivalent weight, within experimental error, from iodometric titration.

Apparatus

The magnetic susceptibilities were measured as described earlier (1), both benzene and water being used as calibrating liquids. In general three measurements were made on each sample and the average taken. The temperature of the samples was 25 °C, and the density measurements, which are needed to convert the results to molar susceptibilities, were also made at 25 °C. It was assumed that the various components of the solutions contributed to the susceptibility in a simple additive manner. Since some of the solutions very slowly evolve oxygen, they were deoxygenated by bubbling nitrogen through them, and were measured immediately in an atmosphere of nitrogen.

Results

Sodium Hypochlorite

The solution (density 1.156 g/ml) contained 2.102 *M* NaCl, 1.156 *M* NaClO, 0.190 *M* $NaClO_3$, 0.0041 *M* NaOH, and 0.051 *M* Na_2CO_3. Its volume susceptibility was found to be -0.773×10^{-6} e.m.u./ml. If we take the molar susceptibilities of the compounds in solution to be: NaCl, −30.7 (2); $NaClO_3$, −34.6 (9); NaOH, −16.0; Na_2CO_3, −41.0 (10); and H_2O, −12.97 (all $\times 10^{-6}$ e.m.u./mol), then the calculated molar susceptibility of sodium hypochlorite is -31.7×10^{-6} e.m.u./mol. However, the value reported (9) for solid sodium chlorate is −34.7, and the usual difference of about 5% between solid and solution would suggest a value of about −36.4 for the solution. This is supported by the measurements of Trew *et al.* (11) who found a difference of −12.48 (or −6.24 per ion) between the susceptibilities of magnesium chloride and chlorate, both as crystalline hexahydrates. If this difference is correct, aqueous sodium chlorate would have a molar susceptibility of -36.9×10^{-6} e.m.u./mol. These values would lead to a molar susceptibility of -31.5 or -31.4×10^{-6} e.m.u./mol for sodium hypochlorite. Probably the best value to take is -31.5×10^{-6} e.m.u./mol.

Some confirmation of this was obtained from the susceptibility of a sample of crystalline calcium hypochlorite (purified by recrystallization from water) which gave a molar susceptibility of -58.8×10^{-6} e.m.u./mol, after allowing for the presence of small amounts of calcium chloride and chlorate and water, as found by analysis. If the susceptibility in aqueous solution is assumed to be 5% higher, and if the susceptibility of a calcium ion is 2×10^{-6} e.m.u./mol more positive than that of two sodium ions, then the calculated value of aqueous sodium hypochlorite is about -32×10^{-6} e.m.u./mol.

Sodium Chlorite

The molar susceptibility was found to be -31.2×10^{-6} e.m.u./mol for the crystal, and -32.7×10^{-6} e.m.u./mol in solution.

Sodium Hypobromite

Two different solutions were used, and the susceptibilities given are the averages of the measurements on each. The first solution contained NaBr, 1.2487 *M*; NaBrO, 1.259 *M*; NaOH, 0.863 *M*; Na_2CO_3, 0.197 *M*; density 1.2488 g/ml, and had a volume susceptibility of 0.785×10^{-6} e.m.u./ml. The second contained NaBr, 1.799 *M*; NaBrO, 1.810 *M*; NaOH, 0.845 *M*; Na_2CO_3, 0.171 *M*; density 1.3386 g/ml, and had a volume susceptibility of -0.8077×10^{-6} e.m.u./ml. Neither solution contained appreciable amounts of sodium bromate. If we take the molar susceptibility of aqueous sodium bromide to be -41.1×10^{-6} e.m.u./mol, the calculated molar susceptibilities of sodium hypobromite (aqueous) are −41.9 for the first

TABLE 1. Molar susceptibilities for $NaXO_n$

	Molar susceptibility $\times 10^{-6}$ e.m.u./mol	
n	X = Cl (ref. 13)	X = Br (this work)
0	−30.7	−41.1
1	−31.5	−41.7
2	−32.7	−42.5
3	−36.4	−44.2
4	−39.0	—

solution and -41.5×10^{-6} e.m.u./mol for the second; the average value is therefore -41.7×10^{-6} e.m.u./mol.

Sodium Bromite

The solution used contained 1.708 *M* $NaBrO_2$, 0.385 *M* NaBr, 0.045 *M* NaBrO, 0.443 *M* $NaBrO_3$, and 0.109 *M* NaOH; density 1.240 g/ml, and had a volume susceptibility of -0.752×10^{-6} e.m.u./ml. This leads to a value of -42.0×10^{-6} e.m.u./ml for the molar susceptibility of sodium bromite.

Discussion

The results for the molar susceptibilities obtained above, together with results from the literature for the susceptibilities of aqueous $NaXO_n$ may be summarized in Table 1. The possible error is probably around 1% though this depends somewhat on the accuracy of the auxiliary data which were used. The value for sodium perchlorate is a fairly early one, and more recent measurements (11) on $MgCl_2.6H_2O$ and $Mg(ClO_4)_2.6H_2O$ give a difference of −8.96 per ion between chloride and perchlorate ions. The difference in susceptibility between crystalline hexahydrates and solution is only about 1%; hence one would deduce a value of −39.7 to −39.8 for aqueous sodium perchlorate. This is somewhat higher than the value quoted above.

In both series the values rise slowly to $NaXO_2$, and more rapidly thereafter. It is tempting to suggest that this indicates largely double bonding up to XO_2^- (with 12 electrons round X), and that in XO_3^- and XO_4^- the structures involve resonance between single and double bonds, perhaps with no more than 12 electrons round the halogen. If we use observed enthalpies of formation of the aqueous compounds (8, 14, 15) to calculate the mean bond strength of the X—O bond (defined as ΔH for $(1/n)XO_n^-(aq) \rightarrow (1/n)X^-(aq) + O(g)$), we get the values shown in Table 2.

TABLE 2. Mean bond strength of the X—O bond

	Bond strength (kcal/mol)	
n	X = Cl	X = Br
1	44.4	52.0
2	47.3	49.0
3	54.0	54.8
4	56.7	51.0

In both series there is a moderate increase in stability at XO_3^-, perhaps indicating the beginning of a considerably greater degree of electron delocalization. At $n = 2$, there is a much smaller increase for chlorine and a decrease for bromine.

However, this interpretation does not seem to fit the data on bond lengths or force constants (16): the bond lengths decrease steadily in the ClO_n^- series with increasing n, while the force constants increase. These results were interpreted (16) as indicating a steadily increasing bond order with increasing n. At first sight this appears inconsistent with the magnetic results since oxygen in double bonds (as in ketones) makes a very low (or sometimes reverse) contribution to the diamagnetic susceptibility. However this is not true for compounds where other oxygens which are singly bonded to the central atom, as in carboxylic esters and phosphate esters are also present. Presumably XO_3^- and XO_4^- ions fall into this class, and the problem is really why XO^- and XO_2^- species have susceptibilities so little different from the corresponding X^- ions. At present the reason for their magnetic behavior is not clear.

The Racemization of *trans*-1,2-Divinylcyclopropane

MANNOSUKE ARAI AND ROBERT J. CRAWFORD
Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received December 7, 1971

The synthesis of (−)-*trans*-1,2-divinylcyclopropane and the kinetics of its racemization and conversion to 1,4-cycloheptadiene, presumably through *cis*-1,2-divinylcyclopropane, are described. It is concluded that the ring opening is not an electrocyclic process.

La synthèse du (−)-*trans*-divinyl-1,2 cyclopropane ainsi que la cinétique de sa racémisation et transformation en cycloheptadiène-1,4, probablement via le *cis*-divinyl-1,2 cyclopropane, sont rapportées. Il en a été déduit que l'ouverture du cycle n'est pas un processus électrocyclique.

Canadian Journal of Chemistry, **50**, 2158 (1972)

Introduction

In attempting to discern whether the *O,O*-trimethylene species (1) is an important intermediate for the isomerization of cyclopropane we have examined the racemization of (*1S:2S*)-*trans*-1,2-divinylcyclopropane (**1**). This compound offers the advantage that the reactivity in thermal processes is primarily confined to the cyclopropane bond situated between the two vinyl groups. While there are numerous possible configurations for diradicals (2) we shall consider two measurable manifestations of diradical formation from **1**; (*a*) racemization and (*b*) geometrical isomerization. Geometrical isomerization of **1** leads to *cis*-1,2-divinylcyclopropane (**2**) which isomerizes rapidly and quantitatively to 1,4-cycloheptadiene (**3**). If there is a preferred mode of ring opening and closing, either dis- or conrotatory, then the rate of racemization should exceed the rate of formation of **3** by more than that expected from steric factors alone. Thus kinetically we would predict that for Scheme 1, $2k_1 > k_2$ (where $k_{rac} = 2k_1$). There remains the possibility of the formation of **3** directly from **1** via either a concerted or diradical process. The former seems unlikely in that *trans-trans*-1,4-cycloheptadiene would result from that conformation in which the termini of the vinyl groups are closest in **1**. There are ten possible *O,O*-trimethylene species resulting from dis- and

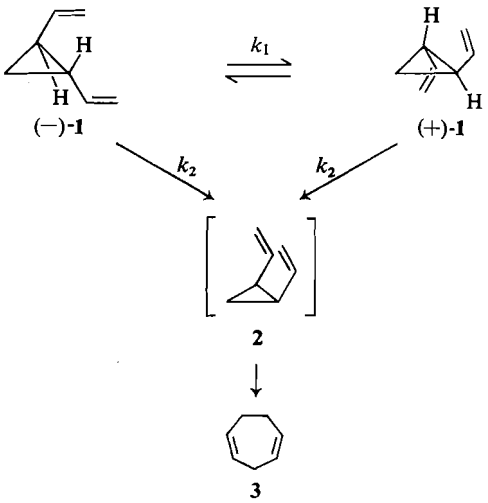
Canadian Journal of Chemistry, **50**, 2158 (1972)

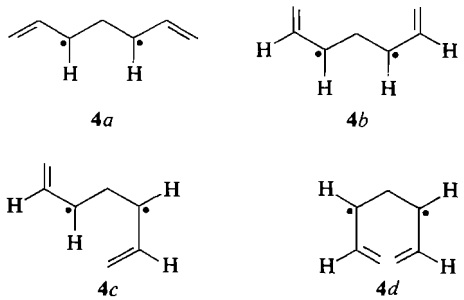
Introduction

In attempting to discern whether the *O,O*-trimethylene species (1) is an important intermediate for the isomerization of cyclopropane we have examined the racemization of (*1S:2S*)-*trans*-1,2-divinylcyclopropane (**1**). This compound offers the advantage that the reactivity in thermal processes is primarily confined to the cyclopropane bond situated between the two vinyl groups. While there are numerous possible configurations for diradicals (2) we shall consider two measurable manifestations of diradical formation from **1**; (*a*) racemization and (*b*) geometrical isomerization. Geometrical isomerization of **1** leads to *cis*-1,2-divinylcyclopropane (**2**) which isomerizes rapidly and quantitatively to 1,4-cycloheptadiene (**3**). If there is a preferred mode of ring opening and closing, either dis- or conrotatory, then the rate of racemization should exceed the rate of formation of **3** by more than that expected from steric factors alone. Thus kinetically we would predict that for Scheme 1, $2k_1 > k_2$ (where $k_{rac} = 2k_1$). There remains the possibility of the formation of **3** directly from **1** via either a concerted or diradical process. The former seems unlikely in that *trans-trans*-1,4-cycloheptadiene would result from that conformation in which the termini of the vinyl groups are closest in **1**. There are ten possible *O,O*-trimethylene species resulting from dis- and



SCHEME 1

conrotatory ring opening of **1**; of these, **4***b*, *c*, and *d* have the requisite configurations such that rotation about a single bond (=CH—CH_2—) will generate the product **3**. Of these, **4***c* and *d* seem unlikely in that the alkyl group has moved inwards, a process known to be unfavorable from the racemization of oxiranes (3). The form **4***b* remains and the consequence of this, and the others if they still pertain, is to overemphasize k_2 and reduce the severity of this test for the *O*,*O*-trimethylene species.



4*a* **4***b* **4***c* **4***d*

Synthesis and Absolute Configuration of **1**

Optically active **1** was prepared by resolving the known *trans*-2-vinylcyclopropanecarboxylic acid via its quinine salt. The resolved acid was then converted to *trans*-1,2-divinylcyclopropane as indicated in Scheme 2. The absolute configuration and optical purity of **1** was ascertained by oxidation to *trans*-1,2-cyclopropanedicarboxylic acid. Thus (*1S:2S*)-*trans*-1,2-divinylcyclopropane of 14% optical purity has a rotation $[\alpha]_{365}^{25}$ −40.2° (*c* 3.70, isopropyl alcohol).

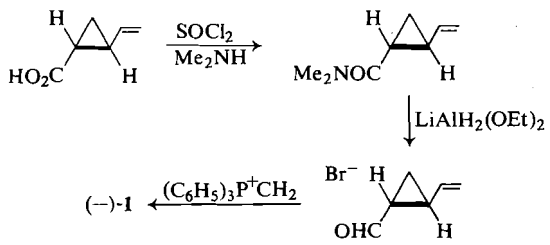
Experimental

(−)-trans-2-Vinylcyclopropanecarboxylic Acid

The method of Vogel *et al.* (4) was used for the preparation of ethyl *cis*- and *trans*-2-vinylcyclopropanecarboxylate from ethyl diazoacetate and butadiene. The *cis* isomer was converted to the *trans* by refluxing the ester (50 g, 0.36 mol) with sodium ethoxide (made by adding 1.0 g of sodium metal to 100 ml absolute ethanol) in ethanol for 60 h. After saponification the acid was then partially resolved via its quinine salt by recrystallization from water. The acid, b.p. 82–83°/2–3 Torr gave $[\alpha]_D^{25}$ −60.0° (*c* 1.49, acetone).

N,N-Dimethyl-trans-2-vinylcyclopropanecarboxamide

trans-2-Vinylcyclopropanecarboxylic acid (28.1 g, 0.25 mol) was added slowly with stirring to freshly distilled thionyl chloride (140 g, 1.0 mol) and dry benzene (15 ml). The solution was maintained at 80° for 3 h and the excess thionyl chloride and benzene was distilled off. The remaining acid chloride was slowly added with stirring to a 25% solution of dimethylamine (180 g). The resulting amide was extracted with ether, washed with water and dilute sulfuric acid, and then dried over anhydrous sodium carbonate. After filtration the ether was removed and the amide distilled, b.p. 79–80°/2.5 Torr; yield 27.7 g, 80%.



SCHEME 2

trans-2-Vinylcyclopropanecarboxaldehyde

The aldehyde was prepared utilizing lithium diethoxyaluminohydride by the procedure of Brown and Shoaf (5). Ethyl acetate (9.7 g, 0.11 mol) was added slowly to a solution of lithium aluminum hydride (4.2 g, 0.11 mol) in 100 ml of dry ether. The resulting solution was transferred over a period of 30 min to a stirred solution of *N,N*-dimethyl-*trans*-2-vinylcyclopropanecarboxamide (27.2 g, 0.2 mol) in 40 ml of dry ether at 0°. The reaction mixture was stirred for an additional hour and then decomposed, with cooling, by adding to a 10% solution of sulfuric acid. The ether layer was washed, then dried over anhydrous sodium carbonate. The aldehyde distilled at 57.8°/30 Torr; yield 10.6 g, 58%.

trans-1,2-Divinylcyclopropane (1)

A solution of *trans*-2-vinylcyclopropanecarboxaldehyde (10 g, 0.11 mol) in 20 ml ether was added, under nitrogen, to a solution of methylenetriphenylphosphorene, which had been prepared by the addition of methyltriphenylphosphonium bromide (105 g, 0.28 mol) to butyl lithium (0.2 mol) in 100 ml of ether. The resulting complex was refluxed with 100 ml of tetrahydrofuran for 1 h and then the ether soluble portion, after addition to water, was carefully fractionated. The crude product was subjected to preparative gas chromatography using a 10 ft × 3/8 in., β,β′-oxydipropionitrile column operated at 35°. The n.m.r. and i.r. spectra correspond to those described in the literature (3), yield 50%, $[\alpha]_{365}^{25}$ −40.2° (*c* 3.70, isopropyl alcohol).

Oxidation of (−)-1 to (1R:2R)-(−)-trans-1,2-Cyclopropanedicarboxylic Acid

(−)-*trans*-1,2-Divinylcyclopropane (0.47 g, 5 mmol) was added to a 500 ml solution of sodium metaperiodate (15.05 g, 3 mmol) potassium permanganate (0.20 g, 1.2 mmol) in water (6). The reaction mixture was stirred at room temperature for 20 h and then acidified with 10% sulfuric acid. Ether extraction followed by drying and evaporation gave 0.31 g of a solid which upon recrystallization from water gave needles, m.p. 174–175° (lit. value 175° (7)) $[\alpha]_D^{25}$ −34.5° (*c* 2.26, water). The optical purity is thus 14% based on −247° and the absolute configuration is *1R:2R* (8). Thus the absolute configuration of (−)-**1** is *1S:2S*.

Kinetic Measurements

Samples of (−)-**1** (*ca.* 37 mg) were placed in break-seals of 20 ml volume, degassed, sealed, and placed in an air-bath

			$\log A^2 = 13.1$

controlled to ±0.03°. The tubes were removed at the appropriate times and quenched in an ice-water bath. The sample was then re-attached to the vacuum line and after a pressure of 10 μ was attained in the manifold the break-seal was opened and the contents transferred to a pre-weighed 1 ml volumetric flask that had been attached to the vacuum line by means of a finely ground 7/16 ⅋ male joint. The stoppered flask was then reweighed and isopropyl alcohol was added up to the 1 ml line. The total solution was weighed and the specific rotation $[\alpha]_t$ at time t was calculated using the expression (9):

$$[\alpha] = \frac{100\alpha}{lpp_s}$$

where α is the observed angle, l is the length of the polarimeter tube in dm, p the concentration of product in g/100 g of solution, and p_s the density of the solution. The density of the solution was not measured as it cancels in the kinetic expression. The rotations were measured using a thermostated polarimeter cell in a Perkin–Elmer 141 Polarimeter set at 365 nm. Infinity tubes were left to greater than ten half-lives and displayed no rotation. A sample corresponding to $t = 0$ was subjected to all of the manipulations except heating. No residual material was observed in any of the break-seals and a sample run using cyclohexane as a standard indicated that the transfer was greater than 95% efficient.

After measuring the rotation the solutions were analyzed by g.c. on a Varian Aerograph 1200 using a 10 ft column of SF-96 on Chromasorb-W. The peaks corresponding to **1** and **3** were integrated using a planimeter. No additional peak other than that of solvent was observed. An example run at 169.98° is given in Table 1. The rate constants were calculated on a point by point basis and the value for k_1 was obtained by using the expression: $k_1 = 2.303/2t(\log a/a_0 - \log \alpha/\alpha_0)$, where a is the fraction of *trans*-1,2-divinylcyclopropane at time t.

Results and Discussion

The rate constants for the interconversion of enantiomers, k_1, and for those assumed to be representative of the *trans* to *cis* isomerization, k_2, are listed in Table 2 along with their probable errors (10) and activation parameters. The precision in determining k_1 is poor since both the errors from the gas chromatographic assessment of the geometrical isomerization and the polarimetric errors for the racemization process are incorporated. The differences between the activation parameters for the two processes cannot be considered to be significant.

Operationally if the racemization is an electrocyclic process and only one mode of rotation (either con- or disrotatory) to the intermediate diradical, **4***a* being the most probable structure, is preferred, then the rate constant for the geometrical isomerization will be infinitely smaller than the rate constant for the racemization process. If however both con- and disrotatory modes are equally accessible, then, invoking the principle of microscopic reversibility, we can state that the racemization rate constant will be twice that of the rate constant

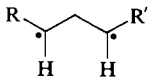
Smith mechanism	∞

for the geometrical isomerization.[1] If only one chiral center of the reactant (−)-**1** is rotated through 180° (the Smith mechanism (11)) then the starting material is not racemized but is only converted to **3**. This is summarized in Table 3.

The k_2/k_1 ratio observed at 160° for **1** is 2.8. The kinetic data indicate that within the assumptions made in the introduction, the more random diradical process is favored over that wherein only one mode of ring opening and closure is operative.

A problem arises in just what one might expect of a diradical that is free to close to either *cis*- or *trans*-1,2-divinylcyclopropane. If we are to use the definition of Hayes and Siu (12) then from the diradical we are equally likely to get closure to the *cis*-isomer as to the *trans*. This does not take into account the relative thermodynamic stabilities of the *cis*- and *trans*-isomers. If we assume that our diradical has a structure such as **5** where the



5

alkyl groups R and R′ are in the more stable W-configuration and that it is free to close to either *cis*- or *trans*-dialkylcyclopropane, *sans orbital-symmetry factors*, then it would seem reasonable that those factors which control the relative thermodynamic stability of the ring closure product (*i.e.*, of ΔG_{eq}) will be playing a role in the transition state leading to those products. If, for example, R and R′ are methyl then it is known that the *trans*-isomer is more stable than the *cis* ($\Delta G_{eq} = 1.0$ kcal mol^{-1}) by a factor of 5.5 at 30° (13). Thus if the magnitude of the steric effects were the same for the transition states as for the ground states we would have $\Delta\Delta G^{\ddagger} = \Delta G_{eq}$. This is likely to be too large an estimate and the effect will probably be attenuated. One possible indication of the attenuation is that the ring closure from triplet diradicals (14) gives a 1.55:1 ratio of *trans*- to *cis*-1,2-dimethylcyclopropane and thus $\Delta\Delta G^{\ddagger} = 0.26\ \Delta G_{eq}$. If instead of methyl we consider the case of 1,2-diphenylcyclopropane we find that ΔG_{eq} is 2.34 kcal mol^{-1} at 205° (15, 16). Upon attenuating this value by 0.26 we find that for every mole of substrate going to a diradical 0.65 mol (or the equivalent of $2k_1$ in Scheme 1) will end up as racemic *trans*-1,2-diphenylcyclopropane and 0.35 mol as the *cis*-isomer. This suggests that the analogous k_2/k_1 for the diphenylcyclopropane is such that for any value greater than 1.08 the process is diradical and for smaller values than this that we have some electrocyclic character. The value observed at 205° for the ratio of the rate constants for the loss of optical activity to the rate constant for *trans* to *cis* isomerization (the equivalent of $(2k_1 + k_2)/k_2$ in Scheme 1) is 1.42 (16) which gives a value of k_2/k_1 of 4.8. The divinylcyclopropane may be expected to demonstrate steric effects intermediate between the methyl and phenyl groups, and thus assuming a value of ΔG_{eq} of 1.7 kcal mol^{-1} we get an analogous value for the k_2/k_1 ratio of 1.20. The value observed in this work for 1,2-divinylcyclopropane at 160° is 2.8, again implying that the isomerization has no electrocyclic component.

It has been observed that *cis*- and *trans*-2,3-diaryloxiranes have nearly the same equilibrium value as the diarylcyclopropanes (3). Using these arguments we would expect a value of $k_2/k_1 = 1.08$ or greater for a diradical process. The observed value of 0.0045 for *trans*-2-phenyl-3-*p*-tolyloxirane indicates that it has less than 1% diradical character for the racemization process, and it is thus an electrocyclic process (3). There seems to be little evidence that the thermal isomerization of cyclopropanes is an electrocyclic process for Willcott and Cargle (17) found that while their results were most readily rationalized in terms of simultaneously changing the configuration at two of the ring carbons they were not compatible with a preferred dis- or conrotation. Similarly Berson and Balquist (18) and Bergman and Carter (19) have found that their results are more readily rationalized in terms of competitive free rotation and ring closure from a diradical having no

[1]As indicated in the Introduction this assumes that there is no path by which **1** may be converted directly to **3**.

preference for the mode in which the rotation occurs. We conclude that there is no evidence for the use of the *O,O*-trimethylene species in the thermal reactions of cyclopropanes.

Acid-catalyzed Ring Opening of Halo-nortricyclanes[1]

FRANK P. CAPPELLI, GEORGE TIMMINS, AND NICK H. WERSTIUK[2]
Department of Chemistry, McMaster University, Hamilton, Ontario

Received March 23, 1972

The acid-catalyzed ($CH_3COOH-0.1\ M\ H_2SO_4$) opening of the cyclopropyl ring in nortricyclyl chloride and nortricyclyl bromide gives in each case the *anti*-7-, *syn*-7-, *exo*-5-, and *endo*-5-halo-*exo*-2-norbornyl acetates as the major products. When the reactions are carried out in deuterated medium the deuterium is situated *endo* at C-6 in the *anti*- and *syn*-7- haloacetates and establishes that at least 75% of the products arise from *initial edge protonation* of the cyclopropane.

L'ouverture acido catalysée ($CH_3COOH-0.1\ M\ H_2SO_4$) du cycle cyclopropyle dans le chlorure et bromure de nortricyclyle, donne dans chaque cas comme produits majeurs les acétates d'*anti*-7, *syn*-7, *exo*-5, et *endo*-5-halo *exo*-2-norbornyl. Quand les réactions sont faites en milieu deutérié, le deutérium est situé en *endo* sur le C-6 dans les 7-haloacétates *anti* et *syn* et montre ainsi que 75% au moins de produits proviennent d'une protonation initiale sur le site cyclopropane.

Canadian Journal of Chemistry, **50**, 2163 (1972)

The chemistry of protonated cyclopropane has commanded much interest. Electrophilic cleavage of a strained cyclopropane σ bond by the reagents $DOAc-D_2SO_4$, DCl, DBr, and Br_2 (2–6) has been studied extensively to determine the site of attack of the electrophile and the stereochemistry of the addition of the electrophile and nucleophile. The nature of the products and the stereochemical information obtained from the D^+X^- additions were then used to establish the nature of the first formed intermediate resulting either from initial edge or corner protonation. Results from studies on the nortricyclane systems **1***a* (1) and *b* (2) have been interpreted in terms of corner-protonated nortricyclane intermediates but did not establish whether initial protonation occurred cornerwise or edge-wise.

Our interest in the preparation of the 7-halo-*exo*-2-norbornyl brosylates-6-d_1 for γ-deuterium isotope effect studies has led us to a study of the electrophilic cleavage ($HOAc-H_2SO_4$; $DOAc-D_2SO_4$) of the cyclopropane ring in 3-bromo- and 3-chloro-nortricyclane (**1***c* and *d*). We report results which establish that (*a*) the σ bond farthest removed from the electron-withdrawing halogen is cleaved preferentially via initial *edge protonation*, (*b*) the ring opening occurs with retention and inversion at the carbon atoms bearing the electrophile and nucleophile, respectively, and (*c*) the pathways of product formation are as described in Scheme 1.

Reaction of nortricyclyl bromide (**1***c*) in CH_3COOD, 0.1 M D_2SO_4 at 75° for 70 h gives *anti*-7-bromo-*exo*-2-norbornyl acetate-d_1 (49%), *syn*-7-bromo-*exo*-2-norbornyl acetate-d_1 (26%), *exo*-5-bromo-*exo*-2-norbornyl acetate-d_1 (10%), *endo*-5-bromo-*exo*-2-norbornyl acetate-d_1 (8%), 3% of unidentified material,[3-5] and 4% un-

[2]Author to whom enquiries may be addressed.

[3]The *syn*- and *anti*-bromoacetates, obtained from a non-deuterated-run, were identified by spectral comparison and by the melting points of the 2,4-dinitrophenylhydrazones of the corresponding bromoketones (7, 8). The *syn*- and *anti*-chloroacetates were identified by comparison of spectral data to those of authentic samples prepared via addition of HOCl to norbornene (9) followed by acetylation. The *exo*-5-halo-*exo*-2-acetates were identified through the haloketones by comparison of spectral data to authentic samples prepared by the addition of anhydrous HCl and HBr to nortricyclanone in carbon tetrachloride (10). The *endo*-5-halo-*exo*-2-acetates were identified through spectral data comparison of the haloketones to authentic samples prepared by hydroboration of the corresponding *endo*-5-halonorbornene to give the halohydrin followed by chromic acid oxidation.

[4]Reduction of the total chloroacetate and bromoacetate mixtures with sodium in iso-propanol gave a mixture of 97–98% *exo*-norborneol and 2–3% *endo*-norborneol estab-

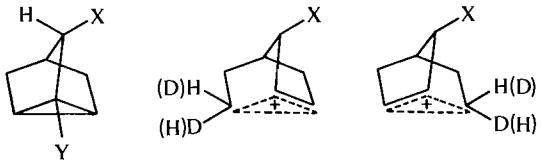
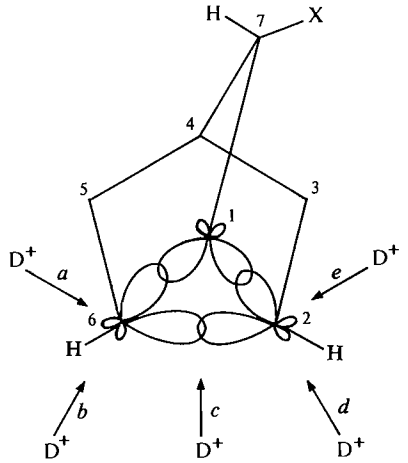
reacted **1***c*. Reaction of nortricyclyl chloride (**1***d*) in CD_3COOD, 0.1 *M* D_2SO_4 at 70° for 500 h gives *anti*-7-chloro-*exo*-2-norbornyl acetate-d_1 (44%), *syn*-7-chloro-*exo*-2-norbornyl acetate-d_1 (26%), *exo*-5-chloro-*exo*-2-norbornyl acetate-d_1 (14%), and *endo*-5-chloro-*exo*-2-norbornyl acetate-d_1 (14%).[3-5]

Infrared fingerprint analysis[6] of the *exo*-norborneols-d_1 obtained from lithium aluminum hydride reduction of the *syn*-7- and *anti*-7-bromo- and chloro-*exo*-2-norbornyl acetates-d_1 showed that the deuterium at C-6 was at least 90% stereochemically pure *endo*. The haloacetates-d_1 obtained from **1***c* and *d* were converted to the corresponding haloketones.[7] Mass spectrometric deuterium assay showed that the 2,5-haloketones contained 8–15% less deuterium than did the 2,7-isomers and thus established the deuterium content at C-2. The norborneols-d_1, obtained from the chloroketones by lithium aluminum hydride reduction, were subjected to n.m.r. (100 MHz, CCl_4) deuterium position analysis (integration) using $Eu(DPM)_3$ (12). The combined mass spectral and n.m.r. data establish that (*a*) the deuterium in the *syn*-7- and *anti*-7-chloro-*exo*-2-norbornyl acetates is situated at C-6 (>90%) with at least 95% *endo* stereochemical purity and (*b*) that the deuterium is positioned at *exo*-6 (0.20 ± 0.05), *endo*-6 (0.20 ± 0.05), C-1 (0.10 ± 0.05), C-2 (0.10 ± 0.05), *exo*-3 (0.20 ± 0.05), *endo*-3 (0.20 ± 0.05) in the *exo*-5-chloro-*exo*-2-norbornyl acetate and at *exo*-6 (0.55 ± 0.05), *endo*-6 (0.25 ± 0.05), C-1 (0.10 ± 0.05), and C-2 (0.15 ± 0.05) in the *endo*-5-chloro-*exo*-2-norbornyl acetate. This establishes the percent contribution (rounded to 0.5%) of the major product-forming pathways as described in Scheme 1.[8]



1 **2** **3**

a X = Y = H
b X = H; Y = Me
c X = Br; Y = H
d X = Cl; Y = H



SCHEME 2

These data therefore establish the mechanistic details shown in Scheme 1 for the acid-catalyzed ring opening of nortricyclyl chloride. That a similar scheme operates for nortricyclyl bromide is indicated by the nature of the products and the position and stereochemistry of the deuterium in the *syn*- and *anti*-bromoacetates.

Since there is no significant amount of deuterium at *exo*-6 in the 7-haloacetates, the data establish that corner protonation (via paths *a*, *b*, *d*, *e* (Scheme 2)) to give **2** and **3** is not important unless paths *b* and *d* are preferred stereoelec-

lishing the *exo*- to *endo*-acetate ratio. Control experiments with each of the *syn*- and *anti*-7-haloacetates showed that there is only 3–4% isomerization to the other haloacetates. Also, control experiments with *endo*-5-chloro-*exo*-2-norbornyl acetate under the reaction conditions showed 10–15% isomerization to the *exo*-5-chloro-*exo*-2-norbornyl acetate. Within our limits of detection (2–3%) we did not detect 2,3-haloacetates in the reaction of **1***d*, although the 3% of the unidentified material from **1***c* may be 2,3-compounds. To check for the possibility that 2,3-chloroacetates were formed in quantity from **1***d*, but were not detected due to rearrangement, the *exo*-3-chloro- and *endo*-3-chloro-*exo*-2-norbornyl acetates were prepared via acetylation of the chlorohydrins (11) and subjected to the reaction conditions. Less than 3% isomerization to other acetates occurs.

[5]Mass spectral analysis showed that there was, on the average, only 1–2% of d_2 species in the haloacetates.

[6]We thank Prof. A. Nickon for the spectra of *exo*-norborneol-6-*exo*-*d* and 6-*endo*-*d*.

[7]Control experiments with the deuterio-*exo*-5-chloronorbornan-2-one under the chromic acid oxidation conditions showed no significant amount of deuterium is lost from C-3 via acid-catalyzed enolization.

[8]A, B, C, D, E, and F represent either the norbornonium ion or the appropriate pair of classical ions. Since there is some isomerization of the *endo*-5-chloroacetate to the *exo*-5-chloroacetate (10–15%) the partitioning (of A, B, C, D, E, and F) to the 2,5-systems is not exactly that given by deuterium position analysis, and therefore is represented as totals leading to A, B, C, D, E, and F.

tronically. Possibly, formation of a symmetrical *exo*-chloronium-3-ion (13) could account for such a stereoelectronic preference for path *b*. However, at least 50% of the deuterium in the *syn*-7-haloacetate would be situated at C-5 if this pathway was important and this is not what is observed experimentally. *endo*-Chloronium-3-ion formation for path *d* would not be favorable.

Therefore, at least 75% of the products arise from initial *edge protonation* of the C_2—C_6 bond.[9]

Interestingly, the formation of the *exo*-5-chloroacetates-*exo*-3-d_1 (3.5%) and *endo*-3-d_1 (3.5%) shows that some leakage to the symmetrical chloronium ion occurs. That the *endo*-chloronium-3-ion does not form is shown by the lack of deuterium in the 3-position in the *endo*-5-chloroacetates.

Our study thus should give information on the mechanism of formation of the 2,5-products isolated from the solvolysis of the 7-chloro-*exo*-2-norbornyl tosylates as described by Gassman and Hornback (14) and Goering and Degani (15).

[9]The numbering system employed for the substituted nortricyclanes is used only for clarity to relate to that of the product haloacetates.

Canadian Journal of Chemistry

Published by THE NATIONAL RESEARCH COUNCIL OF CANADA

VOLUME 50 JULY 15, 1972 NUMBER 14

Chemistry of the Transition Metals. II. Reaction of Branched Alkyl Chlorides with Titanium[1]

W. R. SUMMERS[2] AND J. F. HARROD

Chemistry Department, McGill University, Montreal, Quebec

Received December 21, 1971

Except for *t*-butyl chloride, the 1- and 2-methyl substituted ethyl chlorides reacted at ambient temperatures with clean titanium surfaces to produce mixtures of the corresponding alkanes and alkenes; *t*-butyl chloride gave only isobutene. At elevated temperatures (80–150 °C depending on reactant) the branched alkyl chlorides underwent clean, catalytic dehydrochlorination on hydrochlorinated titanium films to give gaseous olefin and hydrogen chloride, in contrast to the previously observed dehydrohalogenation of *n*-alkyl halides, where metal was consumed continuously in a non-catalytic fashion.

The kinetics of the dehydrochlorination were exceptionally simple and reproducible for a heterogeneous reaction and all reactions were first order in reactant. The reactivity order was *t*-butyl > *i*-propyl > neopentyl > *i*-butyl (*ca.* $10^6:6:3:1$). Although a slight dependence of activation energy on reactant pressure was observed, all reactants gave a limiting activation energy of 15.5 ± 0.5 kcal/mol and the large variation in activity is attributed to differences in the Arrhenius pre-exponential factor.

It is proposed that the non-catalytic and catalytic dehydrohalogenation reactions proceed by different mechanisms, the former via a dissociative chemisorption of the carbon–halogen bond and the latter via a concerted, surface-assisted HCl elimination.

Sauf pour le chlorure de *t*-butyle, les chlorures d'éthyle substitués en -1 et -2 par un méthyle réagissent à la température ambiante sur les surfaces de titane propres pour conduire à des mélanges d'alcanes et d'alcènes correspondants; le chlorure de *t*-butyle donne seulement l'isobutène.

Aux températures élevées (80–150 °C en fonction du réactant) les chlorures d'alkyles ramifiés subissent une déhydrochloration catalysée et propre, sur des films de titane hydrochloré, en donnant des oléfines gazeuses et de l'HCl, à l'opposé de la déhydrohalogénation précédemment observée pour les halogénures de *n*-alkyle, où le métal était consommé de façon continue et non catalysée.

Les cinétiques de la déhydrochloration sont exceptionnellement simples et reproductibles pour une réaction hétérogène et toutes les réactions sont du premier ordre par rapport au réactant. L'ordre de réactivité est *t*-butyle > *i*-propyle > néopentyle > *i*-butyle (environ $10^6:6:3:1$). Bien qu'on observe une légère influence de la pression du réactant sur l'énergie d'activation, tous les réactants donne une énergie d'activation limitée à 15.5 ± 0.5 kcal/mol et la grande variation dans l'activité est attribuée aux différences du facteur préexponentiel d'Arrhénius.

On propose que les réactions de déhydrohalogénation non catalysées et catalysées procèdent selon des mécanismes différents, la première via une chimisorption dissociative de la liaison carbone–halogène et la seconde, via une élimination concertée d'HCl assistée par la surface métallique.

Canadian Journal of Chemistry, **50**, 2167 (1972)

Introduction

In the first paper of this series we described the reactions of normal alkyl halides with metallic titanium prepared by evaporation under ultra-high vacuum (1). In all cases the reaction observed was a non-catalytic dehydrohalogenation in which the metal scavenged one halogen atom per molecule of alkyl halide reacted, and a fraction of a hydrogen atom, depending on reaction conditions. The hydrogen atoms not

For personal use only.

scavenged by the metal were consumed in the production of paraffin molecules from alkyl radicals and the gas phase product consisted of an approximately equimolar mixture of alkane and alkene. No other products were detected.

The kinetics of the *n*-alkyl halide reactions were, for a heterogeneous reaction, strikingly consistent and reproducible. *n*-Propyl fluoride was unique in giving a first order rate law; the other halides followed a one-half order rate law. The difference in order of reaction was ascribed to the fact that the scission of the strong C—F bond was rate limiting in the case of the fluoride, whilst in the other cases the various transport processes between phases were rate-limiting.

Since the proposed mechanisms for the *n*-alkyl halide reactions required the elimination of a 2-hydrogen atom from an adsorbed alkyl radical as one of the critical steps, we undertook a systematic study of the reactions of all of the possible derivatives obtainable by substitution of methyl groups at the 1- or 2-carbon atom of ethyl chloride. Although we did not forsee the result at the outset, this group of reactants provided an entirely new class of reaction in addition to providing further support for the mechanism previously proposed for the *n*-alkyl halide reactions.

Experimental

The experimental procedures were the same as described previously (1).

Results

Reactions on Clean Surfaces at Ambient Temperatures

The results are most conveniently discussed by contrasting the 1-methyl with the 2-methyl substituted alkyl chlorides for reactions at ambient temperatures on clean titanium surfaces, and the normal and branched chain alkyl chlorides for reactions at elevated temperatures on pre-reacted surfaces.

(a) The 1-Methyl Series

The reaction of ethyl chloride has previously been described (1). This reaction resulted in the adsorption of approximately one monolayer equivalent of reactant and the liberation of ethane and ethylene in a ratio of *ca.* 30:70. After reaction of about one monolayer the film was completely deactivated and reaction ceased.

Adsorption and reaction of a monolayer equivalent of isopropyl chloride was rapid and complete at 0 °C. The reaction product was a mixture of propane and propene (20:80). After reaction of the first monolayer equivalent the titanium exhibited much reduced, but finite, activity towards subsequent doses of isopropyl chloride. Figure 1 illustrates the course of reaction of second and third monolayer equivalent doses of isopropyl chloride at 0 °C. The rate of reaction of the first dose was too rapid to follow. The function $(P_0 - P)$ in Fig. 1 represents the combined total of isopropyl chloride that had reacted, subsequent to the reaction of the first aliquot, with the virgin metal surface, and it can be seen that the data fit very well the parabolic rate law:

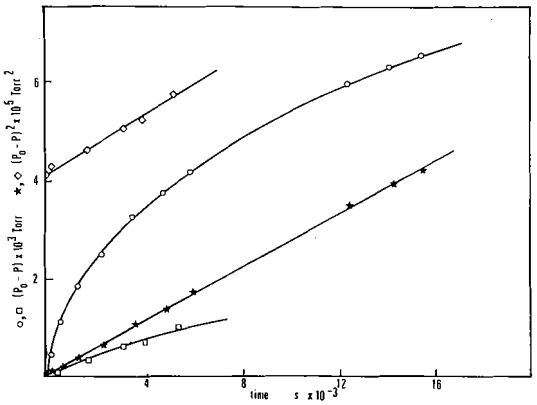

FIG. 1. Reactions of second and third monolayer equivalent doses of isopropyl chloride with a titanium film at 0 °C: P_0 = initial reactant pressure; P = pressure at time t; ○, ★ = second dose; □, ◇ = third dose.

$$[1] \qquad (P_0 - P)^2 = kt + \text{constant}$$

characteristic of a solid phase diffusion controlled reaction.

The adsorption and reaction of a monolayer equivalent of *t*-butyl chloride on a titanium film at 0 °C was rapid and complete. Only isobutene was observed as reaction product. A second dose of *t*-butyl chloride continued to react, but at a considerably enhanced rate compared to the first dose. During the reaction of the second and subsequent doses appreciable amounts of hydrogen chloride appeared in the product.

(b) The 2-Methyl Series

The reactions of ethyl and propyl chlorides have previously been described (1).

The only products detected in the reaction of

Neopentyl	0	100.0	trace	0.0	neopentane:isobutylene:methane 90:10:trace

*All measurements made 300 s after admission of reactant to virgin film. Initial pressure 1.0×10^{-2} Torr. Film area *ca.* 400 cm^2.

isobutyl chloride at 0 °C were isobutane and isobutene. Approximately one monolayer equivalent of isobutyl chloride reacted rapidly and completely, but the surface was completely deactivated towards further reaction.

A monolayer equivalent of neopentyl chloride adsorbed rapidly and completely at 0 °C. Only a trace of gaseous reaction product appeared and this consisted primarily of neopentane with a minor amount of isobutene and a trace of methane. Adsorption of approximately one monolayer of neopentyl chloride completely deactivated the surface with respect to further reaction.

Some observations on the behavior of the 1- and 2-methyl series are summarized in Table 1.

Reactions at Elevated Temperatures

At elevated temperatures (*ca.* 200 °C) the *n*-alkyl chlorides underwent reaction to many monolayer equivalents with reproducible rates to give mixtures of alkane and alkene. No hydrogen, or hydrogen chloride was detected and no loss of carbon to the film was observed. The rate laws for these reactions remained strictly half-order in reactant through complete reaction of a given dose and over many monolayer equivalents of reaction (1).

Each of the branched alkyl chlorides investigated in the present study behaved in a quite different way from the *n*-alkyl chlorides. In each case the observed reaction was a *catalytic* dehydrochlorination reaction. After an initial settling down period each of the branched alkyl chlorides reacted to give a stoichiometric mixture of hydrogen chloride and an unsaturated hydrocarbon in the gas phase. In addition, the rate laws for these reactions were all first order.

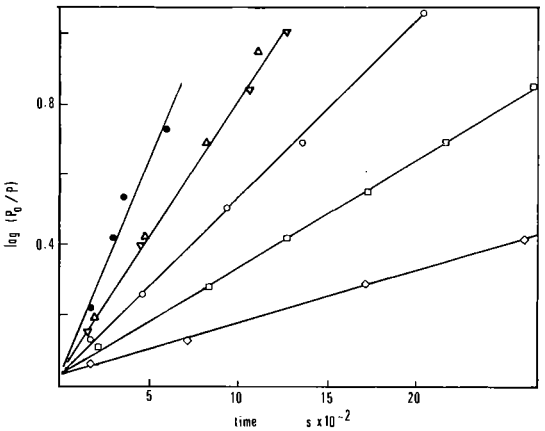

FIG. 2. Reaction of isopropyl chloride with titanium at elevated temperature: ◇, 100°; □, 118°; ○, 134.5°; ▽,△, 157° (duplicate runs performed before and after temperature sweep); ●, 180°.

At elevated temperatures (100–180 °C) the catalytic dehydrochlorination of isopropyl chloride on titanium to give propylene and hydrogen chloride occurred rapidly and in a highly reproducible fashion. The reaction was followed by monitoring the disappearance of reactant and the appearance of products mass spectrometrically and also by simply following the pressure change due to formation of two molecules of product from one of reactant. Both measurements yielded the same results and showed the reaction to be first order in reactant over a wide range of conditions. Figure 2 shows data from runs at several temperatures plotted as a first order reaction.

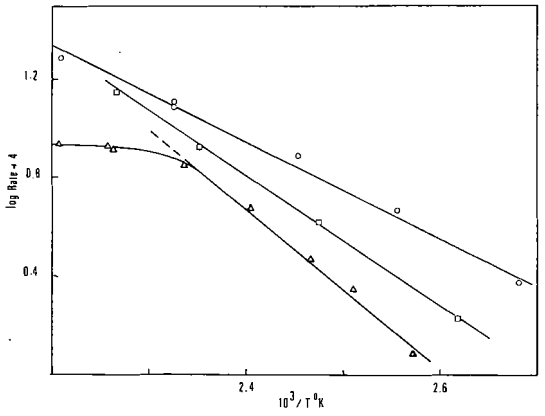

FIG. 3. Arrhenius plots for the reaction of isopropyl chloride on titanium at elevated temperature: ○, $P_0 = 10^{-2}$ Torr; □, 5×10^{-2} Torr; △, 2.5×10^{-1} Torr. The upper curve and points have been displaced upwards by 0.2 log units for purposes of clarity. The ordinate is the logarithm of the slopes of the first order plots shown in Fig. 2.

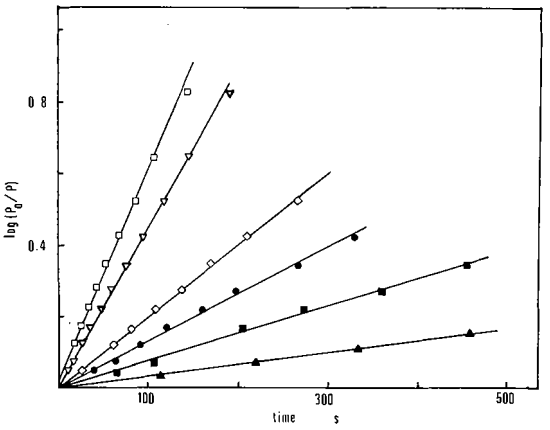

FIG. 4. Catalytic reaction of *t*-butyl chloride on halided titanium surfaces: ▲, 33.5°; ■, 42°; ●, 51.5°; ◇, 56.5°; ▽, 67.5°; □, 80°. $P_0 = 2.8 \times 10^{-2}$ Torr.

Arrhenius plots for three different initial reactant pressures, shown in Fig. 3, show a distinct rise in activation energy with increasing initial reactant pressure. This change in activation energy is well outside the experimental uncertainty, is reproducible over several temperature sweeps, and contrasts with the behavior of *n*-alkyl halides where no change in overall activation energy was observed for a tenfold change in initial reactant pressure. The levelling off of the 2.5×10^{-1} Torr plot at high temperatures in Fig. 3 is an artefact due to the appearance of a rate-controlling diffusion of products from the reactor to the detector. Similar behavior was noted for other reactions where the rates became unduly high, *e.g.*, tertbutyl chloride.

The foregoing description of the isopropyl chloride reaction ceased to be valid above 180 °C. Above this temperature propane and diisopropyl appeared in the gas phase products; the amount of hydrogen chloride produced was less than stoichiometric and the kinetics deviated from strict first order behavior.

Tert-butyl Chloride

The reaction of *t*-butyl chloride followed much the same pattern as isopropyl chloride except that the reaction rate was much greater and hydrogen chloride was produced even at room temperature. Some first order plots for the disappearance of *t*-butyl chloride at several temperatures are shown in Fig. 4. It should be noted that these data span a temperature range some 70–80 °C lower than the comparable set of data for isopropyl chloride shown in Fig. 2.

Because of severe corrosion problems with this reactant in the gauges and mass analyzer, the effect of initial reactant pressure on overall activation energy was not measured. The only reaction products detected throughout the entire experimental range were isobutene and hydrogen chloride.

Isobutyl Chloride

After an initial settling down period, isobutyl chloride underwent smooth catalytic dehydrochlorination in the temperature range 120–220 °C. The kinetics of the catalytic reaction were strictly first order in reactant and only isobutene and hydrogen chloride were detectable in the gas phase.

Like the isopropyl chloride reaction, that of isobutyl chloride gave an activation energy dependent on pressure in the range 1.0 to 5.0×10^{-2} Torr (see Table 2).

Neopentyl Chloride

In the chemistry of transition metal alkyl compounds, the neopentyl compounds show an exceptional stability due to their inability to decompose to olefin and metal hydride by β-hydride elimination from the alkyl group. This stability probably explains the lack of gas phase products in the room temperature reaction. On halided titanium surfaces, neopentyl

chloride showed no reluctance to react in the higher temperature range and underwent facile dehydrochlorination to produce 2-methylbutene-2 and hydrogen chloride. The kinetics of the catalytic reaction were strictly first order after an initial settling down period, and the activation energy was almost identical to that found with the other branched alkyl halides. A rather small change in activation energy with pressure in the range 1.0 to 2.5 × 10^{-2} Torr was observed.

The difference in behavior of the first few monolayer equivalents from that of later doses was more marked with neopentyl chloride than with any of the other reagents investigated in the present study. The reaction of the first dose, after an initial rapid adsorption of reagent, was extremely slow. The disappearance of reactant was, however, autocatalytic and the rate of reaction was augmented by several orders of magnitude before steady first order kinetics and clean stoichiometry were achieved on a well-halided surface. These effects are illustrated in Fig. 5.

Some relevant data for the reactions of branched alkyl chlorides are summarized in Table 2. The data for ethyl and propyl chloride are also included for comparison.

Discussion

Catalytic Reactions

The reaction free energies for dehydrochlorination of the reactants used in our studies follow the sequence isopropyl chloride > *t*-butyl chloride > *n*-propyl chloride > isobutyl chloride > neopentyl chloride.[3] It is thus quite clear that

[3]Free energies for these dehydrochlorination reactions were calculated using standard free energies of formation for reactants and products derived from the following sources: olefins, ref. 10; HCl, ref. 11; alkyl halides, ref. 12. The floor temperatures ($\Delta G^0 = 0$) for some of the dehydrochlorination reactions of the present study at 0.01 Torr were calculated to be: C_2H_5Cl (27 °C); $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}Cl$ (−18 °C); $CH_3{\cdot}CHCl{\cdot}CH_3$ (35 °C); $(CH_3)_2{\cdot}CH{\cdot}CH_2Cl$ (−43 °C); $(CH_3)_3CCl$ (20 °C).

the appearance of gas phase hydrogen chloride through catalytic dehydrohalogenation is not merely dependent on whether or not HCl production is thermodynamically allowed. This being the case, it seems most likely that the two different kinds of reaction proceed by independent mechanisms.

It was previously suggested that the initial step in the reaction of *n*-alkyl halides at elevated temperatures was the dissociative adsorption of the carbon–halogen bond (1). The branched alkyl chlorides used in the present study span the range of primary, secondary, and tertiary carbon–chlorine bonds and neither the stoichiometry nor the kinetics shows a correlation with such structural variation in the substrate. The general reactivity patterns follow those observed for acid, base, and free radical elimination reactions (3).

The activation energies for the catalytic and the non-catalytic reactions fall into two distinct ranges. The former show maximum values in every case within the range 15.5 ± 0.5 kcal/mol and exhibit a dependence on reactant pressure below a critical pressure, whilst the latter are quite independent of pressure over a decade range. The dependence of the activation energy on pressure diminished in the sequence *i*-C_3H_7Cl > *i*-C_4H_9Cl > neo-$C_5H_{11}Cl$. Since the activation energy variation most probably arises from a contribution from the heat of adsorption of the reactant on the surface, the observed sequence may be rationalized on the basis that the heat of adsorption diminishes with increasing bulkiness of the adsorbate.

Since we did not measure the number of active surface sites involved in our reactions we do not have accurate estimates of true rate constants, or of Arrhenius pre-exponential factors. It has been our experience, however, that reaction rates for independent runs under identical conditions are reproducible to within a factor of two and certainly to better than an order of magnitude. Also, activation energies are highly reproducible for both ascending and descending temperature sweeps. In view of this we attach a high level of confidence to the proposition that the extraordinary variations in relative rates of reaction are due primarily to changes in the pre-exponential factors within the two classes of reaction. For example, the eight orders of magnitude difference in relative rate between propyl chloride ($E^{\ddagger} \approx 23$ kcal/mol) and propyl fluoride ($E^{\ddagger} \approx 21$ kcal/mol) arises mostly due to differences in the pre-exponential factors (1); the same is true for the seven orders of magnitude difference between isobutyl chloride and tertiary butyl chloride, both reactions having essentially the same activation energy.

A second assertion that may be made regarding the trends in relative reactivities is that the magnitude of the pre-exponential factor increases significantly in the series: primary < secondary < tertiary chloride, for catalytic reactions. This trend suggests that there are spacial constraints on the transition state that are less severe as the degree of methyl substitution at the α-carbon atom increases. If the pre-exponential factors for the catalytic dehydrochlorination of the *n*-alkyl halides are a few orders of magnitude less than that of isopropyl chloride, the rate for the catalytic mechanism is not competitive with the competing diffusional mechanism previously proposed to explain the non-catalytic dehydrochlorination. Indeed, isopropyl chloride was found to be a borderline case, since at the upper temperature limit of the present study both the order of reaction and the stoichiometry were intermediate between those expected for the catalytic and the non-catalytic reaction.

In the homogeneous gas phase dehydrohalogenation of alkyl halides the behavior of the activation energies and pre-exponential factors is quite different from that observed in the present study (2, 3). For the gas phase reactions the variation in rate for the series ethyl, isopropyl, and tertiary butyl (*ca.* $1:10^2:10^5$) is due almost entirely to a large change in activation energy, whilst the pre-exponential factors vary by less than 10^2 over the series. The same appears to be true of base promoted E2 eliminations, but the difficulty of separating the S_N2 and E2 reactions in this case has resulted in a greater sparsity of reliable kinetic parameters (3). Although acid-catalyzed elimination reactions are well known, we are unaware of any systematic study of activation parameters for such reactions. There seems to be no compelling reason why the large variation in rate between primary, secondary, and tertiary halides in acid-catalyzed elimination should be due to activation entropy, rather than enthalpy differences. In any case, the occurrence of an ionic mechanism in a solvent-free system is most unlikely.

For personal use only.

Reduction of alkyl halide by one-electron transfer to yield a free radical and an adsorbed chlorine atom, reaction 2, is unlikely in view of the complete absence of alkane in the reaction products (S = active surface site).

$$[2] \qquad R\cdot Cl + S \rightarrow R^{\cdot} + S\cdot Cl$$

Solution reactions analogous to [2] are well known and always produce substantial amounts of alkane except in the presence of hydrogen atom scavengers (4, 5). An alternative to reaction 2 would be the immediate capture of the alkyl radical by a second active surface site to yield a surface alkyl species, reaction 3

$$[3] \qquad R\cdot Cl + 2S \rightarrow R\text{-}S + S\text{-}Cl$$

In fact, reaction 3 has already been suggested as the first step in the non-catalytic reactions of primary alkyl halides with titanium (1). If such a mechanism is correct for the non-catalytic reactions, it is difficult to imagine how the catalytic reactions could proceed via similar initial step and yet be so mechanistically different. In particular, it is difficult to explain how reaction 3 could lead to liberation of HCl in one case, but not in another.

In our opinion the catalytic reactions most probably proceed via a mechanism involving concerted elimination of HCl, analogous to an E_i mechanism, but that the weakening of the C—H and C—Cl bonds is in some way assisted by the adsorption process. Such a mechanism is consistent with the observed variation of activation energy with pressure, which can be attributed to a heat of adsorption contribution to the activation energy.

The concerted elimination of HCl from an alkyl halide is a symmetry-forbidden process (7). Almost any strong, low symmetry interaction with such a molecule will reduce the "forbiddeness" and consequently reduce the activation energy for concerted elimination. The ubiquitous catalytic activity of surfaces, a factor which makes studies of homogeneous gas phase eliminations so difficult, may be in part due to the intrinsic asymmetry of the adsorption process (3). It has been recognized that transition metals, and their compounds, may be particularly effective in removing the symmetry forbiddeness of both concerted addition and elimination reactions, by virtue of their possession of orbitals of appropriate symmetry (8). On the basis of such a model, the large variation in Arrhenius pre-exponential factors observed in the present study may be partly explained as a purely statistical effect of the available hydrogen atoms on the 2-carbon atom of the alkyl halide. The details of metal-assisted elimination reactions parallel exactly those previously developed for the cyclobutanation of olefins (9).

The constancy of the limiting activation energies for the catalytic reactions is surprising in view of the considerable structural variations in the reactants. It is in fact difficult to imagine a simple, common transition state that would give rise to a common activation energy. A more likely explanation is that the activation energies are adventitiously constant due to compensating effects.

The organic product resulting from dehydrochlorination of neopentyl chloride, namely 2-methylbutene-2, is the one normally produced from neopentyl eliminations. The similarity of the activation energy to those observed for the other catalytic reactions suggests that the methyl migration is a low energy process having little influence on the overall activation energy.

Reactions on Clean Titanium

Clean titanium reacts rapidly with alkyl halides at room temperature and below. With the exception of neopentyl chloride, any alkyl titanium species produced at the surface are unstable and many of the hydrocarbon groups are rapidly returned to the gas phase as mixtures of alkane and alkene. In the case of neopentyl chloride, although extremely rapid chemisorption occurred at room temperature, almost no gas phase products appeared. Such behavior is in accord with that observed for molecular alkyltitanium compounds (6).

All of the catalytic reactions were preceded by a "settling-down period", during which the behavior of the reactions was intermediate between that of the stoichiometric and catalytic extremes. This period was probably coincidental with a gradual rise in the average effective oxidation state of the surface and the catalytic species was probably titanium in at least oxidation state +2. Studies to allow a clearer definition of the chemical nature of these surface halide phases are presently under way in our laboratory.

Studies in Solvolysis. Part V. Further Investigations Concerning the Solvolysis of Primary, Secondary, and Tertiary Trifluoroacetates[1]

D. J. BARNES, M. COLE (née Morrissey), S. LOBO, J. G. WINTER, AND JOHN M. W. SCOTT
Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland

Received March 7, 1972

The rate of solvolysis of ethyl trifluoroacetate has been investigated in a series of H_2O/D_2O mixtures at 9.97 °C. The secondary isotope effects related to the hydrolysis of the isotopic pairs, methyl/methyl-d_3, ethyl/ethyl-d_5, *i*-propyl/*i*-propyl-β-d_6 and *t*-butyl/*t*-butyl-d_9 trifluoroacetates have been established as well as the temperature dependence for the hydrolysis of *t*-butyl trifluoroacetate. The significance of all these measurements with respect to the mechanism of these reactions is discussed.

La vitesse de la solvolyse du trifluoroacétate d'éthyle a été étudiée dans divers mélanges H_2O/D_2O à 9.97 °C. Les effets isotopiques secondaires concernant les paires isotopiques des trifluoroacétates de méthyle/méthyl-d_3, d'éthyle/éthyl-d_5, d'*i*-propyle/*i*-propyl-β-d_6 et de *t*-butyle/*t*-butyl-d_9, ont été établis ainsi que l'influence de la température sur l'hydrolyse du trifluoroacétate de *t*-butyle. La signification de toutes ces mesures, quant au mécanisme de ces réactions, est discutée.

Introduction

In a previous communication (1) the temperature dependence for the rates of uncatalyzed (neutral) hydrolysis of a series of esters CF_3COOR(R = Me, Et, *i*-Pr and *t*-Bu) was reported in water and deuterium oxide. An examination of the thermodynamic parameters $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta C_p^{\neq}$ which characterize the thermal activation of these molecules suggested that the methyl, ethyl, and *i*-propyl esters all react by a $B_{Ac}2$ acyl–oxygen cleavage mechanism whereas the tertiary ester reacts by an S_N1 alkyl–oxygen fission path or a mechanism which involves mixed kinetics, *i.e.* both the $B_{Ac}2$ and S_N1 routes. The mechanistic pattern based on the thermodynamic parameters was completely substantiated by the kinetic solvent isotope effects (k.s.i.e.) measured in light and heavy water.

The designations $B_{Ac}2$ and S_N1 for these reactions are, however, only partly adequate. The former description merely emphasizes the fact that the "basic" or nucleophilic properties of the solvent are important driving forces for the reaction with at least one water molecule in the transition state for the rate determining step. The latter (S_N1) description offers no indication as to whether the ester itself or the tetrahedral intermediate postulated for the $B_{Ac}2$ reaction reacts further by an alkyl–oxygen fission mechanism and also leaves the question of the incursion of ion pairs etc. unresolved.

[1]For Part IV, see ref. 20.

The inadequacy of the $B_{Ac}2$ description is apparent when a more detailed specification of the overall reaction is attempted. A simplified mechanistic description for the $B_{Ac}2$ process is

$$\text{[I]}\quad \text{Ester} + \text{N} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{sp}^3 \text{ intermediate} + \text{E} \xrightarrow{k_3} \text{products}^2$$

where N and E are respectively nucleophilic and electrophilic reagents which, in the case of the uncatalyzed hydrolysis, are provided by the solvent acting in both roles.

In the two step mechanism represented by reaction 1 the observed kinetic behavior for any particular ester will depend on the relative magnitudes of the rate constants associated with the individual steps. With strong nucleophiles *e.g.* the lyate ion, the observed kinetics provide a standard example of a second order reaction and presumably k_1 is the rate determining step. On the other hand, if the nucleophilic strength of N is reduced as is the case when water replaces the hydroxide ion, the kinetic behavior may be modified in such a way as to make k_1, k_2 and k_3 all kinetically significant. In cases where k_3 is kinetically significant the B designation of the $B_{Ac}2$ category will be only partly justified. The indeterminacy of the reaction order with respect to the solvent in the neutral hydrolysis excludes the possibility of locating the rate determining step in the overall process. Indeed, the

[2]We regard reaction 1 as a minimal mechanistic description for the $B_{Ac}2$ process.

pseudo first order hydrolyses of the trifluoroacetate esters raise all the classical conundrums associated with processes where the reaction medium also provides the attacking reagent or reagents. In spite of these difficulties we hope to show that mixed k.s.i.e.'s and secondary isotope effects provide useful probes to examine these perennial questions. As a prerequisite to some resolution of the problems posed above we report below the rates of hydrolysis of ethyl trifluoroacetate in H_2O/D_2O mixtures as well as the secondary isotope effects for the isotopic ester pairs methyl/methyl-d_3, ethyl/ethyl-d_5, *i*-propyl/*i*-propyl-d_6, and *t*-butyl/*t*-butyl-d_9. A more detailed investigation of the temperature variation of the rate of hydrolysis of *t*-butyl trifluoroacetate is also reported and this particular study suffices to establish the temperature dependence of the enthalpy of activation for this substance.

Experimental

Materials and Methods

The experimental methods for rate determinations were identical to those described in Part I of the present series. The isotopic solvent mixtures were prepared by weight from deuterium oxide of known water content. The ethyl trifluoroacetate used in this study was the same sample used previously (1). Deuterium oxide was obtained from the Atomic Energy of Canada Ltd. and deuterated materials used in the preparation of the esters were obtained from Merck, Sharp, and Dohme Ltd.

The methyl and ethyl trifluoroacetates and their respective deuterated analogs were prepared by reacting the appropriate methyl or ethyl halide with silver trifluoroacetate in purified benzonitrile (1). The *i*-propyl and *t*-butyl trifluoroacetates and the related deuterium compounds were prepared by reacting trifluoroacetic anhydride and the appropriate alcohol in the presence of a small amount of silver trifluoroacetate (2). The *i*-propyl alcohol used was purified with magnesium in the usual way. The *t*-butyl alcohol was purified by fractional freezing and the commercial *t*-butyl alcohol-d_9 was used without further purification. The *i*-propyl alcohol-d_6 was obtained in good yield (*ca.* 90%) by the reduction of acetone-d_6 with lithium aluminum hydride using *n*-butyl carbitol to decompose the alcoholate (3). The usual physical and spectroscopic properties indicated that the eight esters were sufficiently pure for meaningful kinetic studies. The b.p.'s and n.m.r. τ values are recorded in Table 1. When supersaturation of the ester solution was avoided (see below) the excellent Guggenheim plots obtained provided a further check of the homogeneity of the substrates. The rate constants obtained from these studies are recorded in Tables 2, 3, and 4. The rate *vs.* composition profile for ethyl trifluoroacetate reacting in a series of H_2O/D_2O mixtures is illustrated graphically in Fig. 1.

The agreement between the rate constants reported here and those reported previously (1) is generally satisfactory and where minor differences are apparent the new results are to be preferred.

*Literature values in parentheses are from ref. 4.
†Literature values in parentheses are from ref. 1.

The temperature dependence of the rates of hydrolysis of the methyl, ethyl, and *i*-propyl trifluoroacetates and their deuterated analogs can be represented over a short temperature range by the equation

$$[2] \qquad \log k/T = A/T + B$$

The parameters ΔH^* and ΔS^* were determined from least squares values of A and B in the usual way (1) and the thermodynamic quantities so calculated are reported in Table 5.

For the *t*-butyl trifluoroacetate the temperature dependence of the rates could be expressed by the equation

$$[3] \quad \log k = -10612/T - 38.35 \log T + 127.63$$

The numerical coefficients were determined by a least squares method using the individual rates rather than the average experimental rates quoted in Table 3. The least squares calculation and the evaluation of the thermodynamic parameters from the numerical coefficients in eq. 3 were carried out using a computer program available in Dr. Robertson's laboratory at the University of Calgary.

As mentioned above the supersaturation of the substrate is a bothersome feature in the determination of the rates of hydrolysis of the esters of trifluoroacetic acid. In consequence the yield of reproducible rate constants obtained in the present study is less than that obtained with other substrates such as sulfonates and halides. The supersaturation problem also probably accounts for the relatively large error in the heat capacity of activation reported for *t*-butyl trifluoroacetate.

Discussion

(a) Mixed Solvent Isotope Effects

The theory of rate and equilibrium processes in H_2O/D_2O mixtures has been developed by Kresge, Long, and co-workers and others (4–9) and has been reviewed by Robertson and

Laughton (10). The more recent developments in the theory use the fractionation factor (ϕ) formalism which provides a means of considering the variation of the ratios $k(n)/k(H)$ (rates) or $K(n)/K(H)$ (equilibria) in terms of "n", the atom fraction deuterium in the solvent and the fractionation factors (ϕ) mentioned previously. The "n" parameter requires no further discussion but some explanatory remarks concerning the ϕ parameter are helpful.

Essentially the fractionation factors (ϕ) are isotopic equilibrium constants for all the labile protons associated with each equilibrium state, either ground or activated, which define any particular rate or equilibrium process. The fractionation factor for each labile proton is defined by the equation

$$[4] \quad \phi = ([D]/[H])_{substrate}/([D]/[H])_{solvent}$$

In applications of the Kresge–Long theory no attempt is made to relate the various ϕ parameters to the more fundamental statistical quantities (vibrational frequencies etc.) which must ultimately determine their magnitude. Rather, the ϕ's are considered as disposable parameters which can be estimated from the rate or equilibrium constants observed in the pure isotopic solvents. The ϕ values so calculated are then

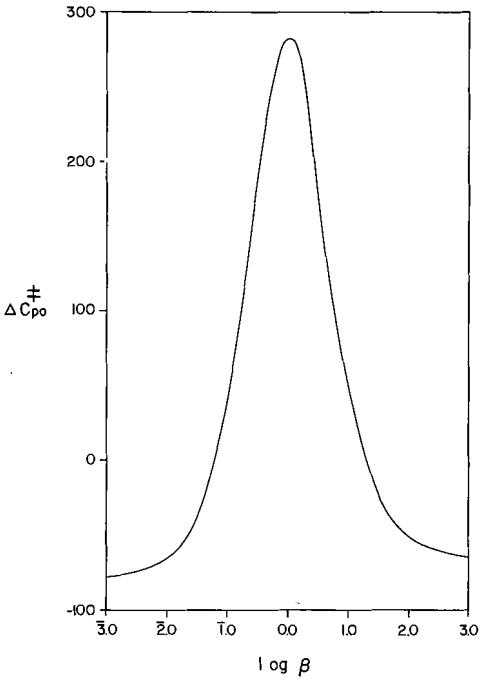

FIG. 1. Correlation between the rate ratios, $k(n)/k(H)$ and the atom fraction, n, of D_2O for the solvolysis of ethyl trifluoroacetate in H_2O/D_2O mixtures.

used to establish the variation of the rate or equilibrium constants as a function of the isotopic composition of the solvent.

Fractionation factors which are less than unity correspond to normal isotope effects and those greater than unity inverse effects.[3] In processes which involve the cooperative attack of several water molecules, and in which both the nucleophilic and hydrogen bonding (electrophilic) properties of the solvent are important, the net weakening of hydrogen–oxygen bonds compared with those of bulk water should lead, on the basis of a simple zero-point treatment (11, 12), to normal effects. This implies that the appropriate fractionation factors will be less than unity.

The application of the Kresge–Long theory requires some assumptions concerning the path between the reactants and products for the chemical reaction studied. In the case of ethyl trifluoroacetate, we have adopted the mechanism

[3]This is a consequence of the fact that the Kresge–Long theory considers isotopic ratios with the light atom quantities in the denominator. The opposite convention is more usual.

TABLE 5. Thermodynamic parameters (at 10 °C) for the solvolysis of deuterated and non-deuterated trifluoroacetates in water

R (CF_3COOR)	ΔH^* (kcal mol^{-1})	ΔS^* (cal mol^{-1} deg^{-1})
CH_3	10.35 ± 0.02	-33.2 ± 0.2
CD_3	10.26 ± 0.02	-33.6 ± 0.2
CH_2CH_3	10.53 ± 0.04	-34.5 ± 0.4
CD_2CD_3	10.49 ± 0.03	-34.7 ± 0.4
$CH(CH_3)_2$	10.68 ± 0.05	-36.5 ± 0.6
$CH(CD_3)_2$	10.62 ± 0.07	-36.7 ± 0.9

represented by reaction 1 with the further assumption that the nucleophile (N) and the electrophile (E) are respectively represented by "p" and "q" water molecules, *i.e.* the bonding of $2p$ labile protons is modified in the first step to give an intermediate containing $2p$ labile protons which then decomposes into the products.

The application of the Kresge–Long theory to this model is straightforward and gives

$$[5] \quad \frac{k(n)}{k(H)} = \frac{(1-n+n\bar{\phi}_1^{\ddagger})^{2p}(1-n+n\bar{\phi}_2^{\ddagger})^{2q}(1+\gamma)}{\gamma(1-n+n\bar{\phi}_1^{\ddagger})^{2p}+(1-n+n\bar{\phi}_2^{\ddagger})^{2q}}$$

in which $\bar{\phi}_1^{\ddagger}$ and $\bar{\phi}_2^{\ddagger}$ are respectively mean fractionation factors for the first and second transition states in reaction 1. The parameter γ is related to the rate constants k_2 and k_3 by the equations

$$[6] \quad k_2/k_3 = \gamma$$

with

$$[7] \quad k_2/(k_2+k_3) = \gamma/(1+\gamma)$$

and

$$[8] \quad k_3/(k_2+k_3) = 1/(1+\gamma)$$

To simplify the present theoretical treatment it was assumed that the fractionation factors are all equal (ϕ), and that $2q = 2p + 2$, *i.e.* one water molecule is involved in the k_3 step. Equation 5 is then reduced to

$$[9] \quad \frac{k(n)}{k(H)} = \frac{(1-n+n\phi)^{2q}(1+\gamma)}{\gamma+(1-n+n\phi)^2} = R$$

TABLE 6. A comparison of the theoretical and observed dependence of the rate of hydrolysis of ethyl trifluoroacetate in light and heavy water mixtures

	$\delta \times 10^3$ for $\gamma =$						
q	10^{-3}	10^{-2}	10^{-1}	1	10	10^2	10^3
1	432	367	224	81.3	84.0	29.9	29.6
2	29.6	30.3	32.0	23.2	15.4	14.3	14.3
3	14.3	14.3	14.7	13.7	12.8	12.7	12.7
4	12.7	12.7	12.9	13.0	13.4	13.6	13.5
5	13.5	13.6	13.6	13.6	14.2	14.3	14.3

When $\gamma < 10^{-2}$ eq. 9 reduces to

$$[10] \qquad \frac{k(n)}{k(\mathrm{H})} = (1 - n + n\phi)^{2q-2} = R$$

and when $\gamma > 10^2$ eq. 8 becomes

$$[11] \qquad \frac{k(n)}{k(\mathrm{H})} = (1 - n + n\phi)^{2q} = R$$

Equations 10 and 11 are identical in form but are out of phase with respect to the variable q. This has important consequences when eq. 9 is used to analyze the experimental data (see below).

For $n = 1$, which corresponds to the pure isotopic rate ratio $k(D_2O)/k(H_2O)$, values of ϕ were determined for five integral values of q in the range $1 < q < 5$ and six integral values of $\log\gamma$ in the range $-3 < \log\gamma < 3$ together with $\log\gamma = 0$ giving a total of seven different values of γ. This leads to thirty five values of ϕ appropriate to $n = 1$. Each of these values ϕ with the appropriate values of q and γ gives rise to a family of theoretical curves relating $k(n)/k(H_2O)$ to n. The derived theoretical curves may be compared with the experimental curve using a least squares criterion such as

$$[12] \qquad \delta = \{\Sigma(R_{\mathrm{calc}} - R_{\mathrm{obs}})^2\}^{1/2}$$

to search for the best values of γ and q in the γ–q grid (Table 6). Minima in δ are evident in the grid at $q = 4$ and $\gamma = 10^{-2}$ or 10^{-3} and at $q = 3$ with $\gamma = 10^2$ or 10^3. The identity of the values of δ at these minima arises merely from the fact that the exponents of eqs. 10 and 11 are out of phase. Since eq. 9 does not provide a unique minimum, mechanistic conclusions based on this criterion are of limited significance. However, of the two alternatives suggested by the above analysis we find the sequential attack of a total of three water molecules ($q = 3$) on both the substrate and the intermediate involved in a pre-equilibrium mechanism ($\gamma = 10^2$ or 10^3) to be more likely than the attack of four water molecules on the substrate in a unitary step ($q = 4$ and $\gamma = 10^{-2}$ or 10^{-3}). The pre-equilibrium model is also in accord with Bender's mechanistic description of ester hydrolysis involving a tetrahedral intermediate (13).

TABLE 7. Thermodynamic parameters for the hydrolysis of *t*-butyl trifluoroacetate in water at various temperatures

T (°K)	ΔH_T^* (kcal/mol)	ΔS_T^* (e.u.)
273.15	27.20	19.9
298.15	25.24	13.0

348.15	21.33	0.92
373.15	19.38	−4.58

*$\Delta C_{p0}^* = -78 \pm 16$ cal mol^{-1} deg^{-1}. The conversion of the numerical coefficients of eq. 3 to enthalpies, entropies, and heat capacities of activation was made in the usual way (see ref. 1).

(b) The Thermodynamic Parameters

The new thermodynamic parameters reported here include the $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the deuterated primary and secondary esters and the heat capacity of activation for *t*-butyl trifluoroacetate (see Tables 5 and 7). The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values for the deuterated esters do not call for any particular comment but the $\Delta C_{p0}^{\neq}$ for the tertiary ester is of considerable interest.

The observed heat capacity of activation $\Delta C_{p0}^{\neq}$ for a process proceeding simultaneously by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

two distinct mechanisms with rate constants k_1 and k_2 is given by the expression

$$[13]\quad \Delta C_{p0}^{\ddagger} = \frac{1}{1+\beta}\Delta C_{p1}^{\ddagger} + \frac{\beta}{1+\beta}\cdot\Delta C_{p2}^{\ddagger} + \frac{\beta}{(1+\beta)^2}\cdot\frac{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})^2}{RT^2}$$

where $\beta = k_1/k_2$ and $\Delta C_{p1}^{\ddagger}$, $\Delta C_{p2}^{\ddagger}$, $\Delta H_1^{\ddagger}$, and $\Delta H_2^{\ddagger}$ are respectively the heat capacities and enthalpies of activation associated with the individual paths. Thus if a situation exists in which both paths contribute to the observed rate such that[4] $0.01 < \beta < 100$ then the observed heat capacity of activation will be made up of real and spurious terms. The first two terms of the r.h.s. of eq. 13 are real and the final term is spurious (see ref. 14). If the "average" heat capacities of activation for $B_{Ac}2$ and S_N1 processes are respectively -65 and -80 cal mol^{-1} deg^{-1} (1, 15) and the difference in the enthalpies of activation for the two processes is taken as 15 kcal mol^{-1} (1), then the calculated expression for $\Delta C_{p0}^{\ddagger}$ as a function of β *i.e.* mechanism, is illustrated in Fig. 2. The strongly positive heat capacities of activation calculated for the region $0.01 < \beta < 100$ suggest that the *t*-butyl ester reacts primarily by an S_N1 mechanism which agrees with other evidence presented in this paper and elswehere (1).

(c) Secondary Isotope Effects

The secondary isotope effects reported in Table 2 are considered in the light of previous mechanistic conclusions based on other evidence. Since the alkyl group is the reaction seat in the S_N1 process and is relatively remote from the reaction center in the $B_{Ac}2$ process, deuteration of the alkyl group is likely to be more potent in the former reaction. This analysis is consistent with the experimental observations. The rate ratio for the normal and d_9 *t*-butyl trifluoroacetates is very similar to that of the related chlorides and is fully consistent with the S_N1 description based on $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and k.s.i.e. parameters.

The isotope effects observed with the primary esters are more complex. We first draw attention to the fact that deuteration in the methyl groups of the methyl halides or sulfonates leads

[4]These limits define the mixed region. Outside the limits the mechanisms are not mixed. The limits are, of course, quite arbitrary.

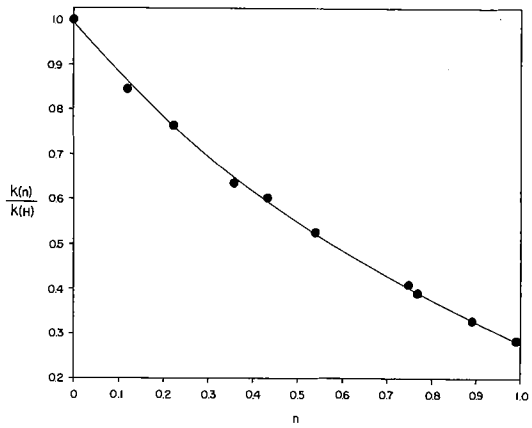

FIG. 2. Variation of the observed heat capacity of activation for a reaction proceeding partly by the $B_{Ac}2$ and S_N1 routes.

to inverse effects (16). Thus the normal effect in the case of methyl trifluoroacetate is entirely consistent with attack at a position other than the methyl group. Any further analysis of the isotope effects observed with the primary and secondary esters must be made in terms of the Bender (13) pre-equilibrium mechanism mentioned above, which is

$$[14]\quad k_o = K_e k_3 \quad \text{where} \quad K_e = k_1/k_2$$

It may be readily shown that the observed isotope effect for the pre-equilibrium mechanism is influenced only by vibrational-force constant changes between the initial state and the second transition state. We assume reasonably that the vibrational changes in the alkyl group of the ester arise primarily from the increasing oxonium character of the alkyl oxygen in the second transition state as a consequence of electrophilic attack at this position. Since bond angles in oxonium compounds are similar to those involving divalent oxygen the isotope effects are primarily a consequence of electronic changes rather than changes which derive from concomitant electronic and geometrical alterations. Differential hydrogen–deuterium inductive electron release (17) to the incipient oxonium center should lead to the increased reactivity of the deuterium compounds in the case of the methyl/methyl-d_3 and the ethyl/ethyl-d_5 esters, assuming that the net isotope effect in the ethyl compounds is dominated by the deuterium atoms on the carbon adjacent to the alkyl oxygen atom. Since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the isotopic methyl esters demonstrate a normal effect and the net effect in the case of the ethyl esters is also normal, the inductive hypothesis is reasonably rejected. The decreasing isotope effect with increasing homology of the alkyl group in the case of the primary and secondary esters is more consistent with the hyperconjugation hypothesis developed by Shiner and coworkers (17, 18). However, such an interpretation is not clear-cut because γ contributions are present in the case of both the ethyl and *i*-propyl esters and the hyperconjugation hypothesis is only applicable to deuteration which is β to the reaction site.

Isotopic substitution γ to the reacting center has been shown to lead to inverse effects in reactions which involve substitution at a saturated carbon atom (19). In contrast, complete deuteration of the γ positions in the *i*-propyl esters, *i.e.*, deuteration of the two methyl groups, leads to a normal effect. Thus there is no correlation between the influence of γ isotopic substitution in nucleophilic substitution reactions and ester hydrolyses. This is not surprising. Although reacting oxygen and carbon centers become more positive in the transition state in both types of reaction, any further resemblance between the two processes is slight, particularly with respect to geometrical reorganization which is virtually absent in the case of ester hydrolyses (see above).

Clearly the main value of the secondary isotope effects in the present study is to further emphasize the distinction between the primary and secondary esters on the one hand and the tertiary ester on the other. The finer differences displayed within the primary and secondary esters as a group are less amenable to unequivocal theoretical interpretation.

The authors wish to thank Dr. R. E. Robertson for his help in various phases of the present study and Dr. W. J. Albery for some useful advice concerning reactivity in mixed isotopic solvents. We also wish to thank the Technical Services group at Memorial University for their continued assistance. Finally we thank Memorial University and the National Research Council of Canada for financial support.

The Preparation of Iron Carbonyl Complexes of Fluorocarbon-Bridged Ligands

L. S. CHIA, W. R. CULLEN, AND D. A. HARBOURNE

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received February 1, 1972

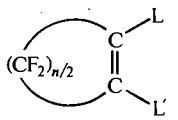
The reactions of the ligands $L\overline{C{=}CL'(CF_2)_{n/2}}$ ($L = (CH_3)_2As$, $(C_6H_5)_2P$; $L' = (CH_3)_2As$, $(C_6H_5)_2P$; $n = 4$, 6, 8; but not all combinations) with iron carbonyls are described in detail. The nature of the products is discussed as a function of the reaction conditions and the ligands. The mixed ligands yield eight different types of complexes which have been characterized. Two of these types $(L{-}L')_2Fe_2(CO)_4$ and $(L{-}L')_2Fe(CO)_3$ were previously unknown.

Les réactions des ligands $L\overline{C{=}CL'(CF_2)_{n/2}}$ ($L = (CH_3)_2As$, $(C_6H_5)_2P$, $L' = (CH_3)_2As$, $(C_6H_5)_2P$; $n = 4$, 6, 8 mais pas toutes les combinaisons) avec les fer carbonyles sont décrites en détail. La nature des produits est discutée en fonction des conditions de réaction et des ligands. La combinaison des ligands donne huit types de complexes différents qui ont été caractérisés. Deux d'entre eux $(L{-}L')_2Fe_2(CO)_4$ et $(L{-}L')_2Fe(CO)_3$ étaient jusqu'ici inconnus.

Canadian Journal of Chemistry, **50**, 2182 (1972)

Introduction

A number of iron carbonyl derivatives of fluorocarbon-bridged ditertiary arsines and phosphines have been described in recent years (1–4). Of special interest have been the complexes formed by $f_4$fars and $f_4$fos **1***a* and **1***b*. The



1

a L = $(CH_3)_2As$ = L′, *n* = 4, $f_4$fars
b L = $(C_6H_5)_2P$ = L′, *n* = 4, $f_4$fos
c L = $(CH_3)_2As$, L′ = $(C_6H_5)_2P$, *n* = 4, f_4AsP
d L = $(CH_3)_2As$, L′ = $(C_6H_5)_2P$, *n* = 6, f_6AsP
e L = $(C_6H_5)_2P$ = L′, *n* = 6, $f_6$fos
f L = $(C_6H_5)_2P$ = L′, *n* = 8, $f_8$fos

former has the ability to displace two terminal carbonyl groups from $Fe_3(CO)_{12}$ to give the complex $f_4farsFe_3(CO)_{10}$, **2**, (L′ = $(CH_3)_2As$) (3, 5). Furthermore, this $Fe_3(CO)_{10}$ derivative on mild heating breaks down to a complex of formula $f_4farsFe_3(CO)_9$ in which the ligand has undergone rearrangement **3** (L′ = $(CH_3)_2As$) (3, 6). Complexes of these types are not formed by $f_4$fos or by related ditertiary phosphines with larger bridging fluoroalicyclic groups. A further difference between $f_4$fos and $f_4$fars is that only the former gives a chelated complex $f_4$fos-$Fe(CO)_3$ (1).

Because of these differences and because of the general lack of knowledge about iron carbonyl complexes of mixed ligands, the new ligands f_4AsP **1***c* and f_6AsP **1***d* were synthesized (7, 8) to investigate their reactions with iron carbonyls. In general the results which follow show that the products of the reactions are similar to those obtained from their symmetrical analogues. However, it has been found that f_4AsP behaves more like $f_4$fars than $f_4$fos in yielding $f_4AsPFe_3(CO)_{10}$ and $f_4AsPFe_3(CO)_9$, although it also acts like $f_4$fos in giving the chelate complex $f_4AsPFe(CO)_3$.

In view of critical dependence of the products on the reaction conditions and on the ratio of the reactants, we now give comprehensive lists of the reactions of these ligands, including the ditertiary phosphine **1***f* $f_8$fos (9), with the iron carbonyls and discuss the various trends that are apparent in ligand behavior. In addition we describe some interconversion reactions of the

complexes, especially those of the mixed ligand f_4AsP.

Experimental Section

The preparation of the ligands has been previously described (7–10). Volatile reactants and products were manipulated in a standard vacuum system. Ultra violet irradiations were done with a 200 W Hanovia 654A-36 lamp situated 20 cm from the reaction vessel. The detailed preparations of new complexes described below are selected from a large number of reactions which are given in tabular form in Tables 5–7. The conditions are those found to result in highest yields of the desired compounds coupled with maximum ease of work-up. Tables 5–7 also include bare details of previously unpublished experiments involving the symmetrical ligands $f_4$fars, $f_4$fos, and $f_6$fos. No new techniques were used, most separations being made by chromatography on Florisil (1–3). Qualitative analyses were made by spectroscopic means. When necessary, quantitative analysis of mixtures was made using n.m.r. spectroscopy. Microanalyses were performed by Mr. Peter Borda of this Department.

(1) Preparation of $f_4AsPFe(CO)_4$

A tetrahydrofuran solution (20 ml) containing 4.0 g (9.6 mmol) f_4AsP and 10.0 g (51 mmol) iron pentacarbonyl was heated at 100° in a Carius tube for 4 days. The tube was opened, the brown-red reaction solution filtered, and then the solvent was removed at reduced pressure. The resulting brown-red oil was dissolved in a small volume of diethyl ether and chromatographed on Florisil. Elution with 2% diethyl ether–98% petroleum ether afforded a yellow-orange band of the desired compound ($f_4AsPFe_2(CO)_8$ and $f_4AsPFe(CO)_3$ may contaminate the tail of this band). The $Fe(CO)_4$ derivative was recrystallized from cold petroleum ether to give yellow crystals, m.p. 115° (4.5 g, 78%).

(2) Preparation of $f_4AsPFe_2(CO)_8$

Iron pentacarbonyl (15 g, 76 mmol), f_4AsP (3.0 g, 7.2 mmol), and acetone (30 ml) were sealed under vacuum in a thick-walled Pyrex tube. The tube was irradiated for 120 h with ultraviolet light while shaking. The tube was then opened and the volatile contents were removed. The residue, a brown-red oil, was dissolved in a small volume of methylene chloride and chromatographed on Florisil. Elution with 2–5% diethyl ether–98–95% petroleum ether yielded an orange-red solution. This was concentrated and cooled to give yellow crystals of $f_4AsPFe(CO)_4$ (1.90 g, 45%).

The mother liquors were combined, concentrated, and cooled to give orange-red crystals which were recrystallized from hexane to yield red crystals of $f_4AsPFe_2(CO)_8$, m.p. 98° (1.10 g, 20%).

(3) Preparation of $f_4AsPFe_3(CO)_9$ and $f_4AsPFe_2(CO)_6$

Triiron dodecacarbonyl (5.2 g, 10.3 mmol) and f_4AsP (2.5 g, 6.0 mmol) were refluxed together in cyclohexane (50 ml) under nitrogen for 5 h. The solution was evaporated to dryness and the residue was chromatographed on Florisil. After eluting the initial yellow band which contained traces of $f_4AsPFe(CO)_4$ and $f_4AsPFe_2(CO)_8$ with 2% diethyl ether–98% petroleum ether, a deep violet band was eluted with 2–5% diethyl ether–98–95% petroleum ether. The solvent was removed and a deep violet powder was obtained which was rechromatographed and recrystallized from carbon disulfide to give deep violet crystals of $f_4AsPFe_3(CO)_9$, m.p. 175° (dec.) (1.3 g, 26%). An orange band was eluted with 5–10% diethyl ether–95–90% petroleum ether. The orange solid was purified by rechromatography and/or recrystallization from methylene chloride to give orange-red crystals of $f_4AsPFe_2(CO)_6$, m.p. 212° (dec.) (2.0 g, 51%).

(4) Preparation of $f_4AsPFe_3(CO)_{10}$

Triiron dodecacarbonyl (4.0 g, 8.0 mmol) and f_4AsP (1.0 g, 2.4 mmol) were refluxed together in cyclohexane (50 ml) for 45 min. The resulting solution was evaporated to yield a dark brown oil. This was chromatographed in Florisil. Petroleum ether eluted an initial brown band (traces of $f_4AsPFe(CO)_4$, $f_4AsPFe_3(CO)_9$, etc.) and $Fe_3(CO)_{12}$. A 5% diethyl ether–95% petroleum ether mixture eluted $f_4AsPFe_3(CO)_{10}$ as a gray-green band. The compound was purified by rechromatography and recrystallization from carbon disulfide to give deep green crystals, m.p. 135° (dec.) (1.80 g, 87%).

(5) Preparation of $(f_4AsP)_2Fe(CO)_3$ and $(f_4AsP)_2Fe_2(CO)_4$

Triiron dodecacarbonyl (1.0 g, 2.0 mmol) and f_4AsP (2.5 g, 6.0 mmol) were refluxed together in cyclohexane (60 ml) for 2 h. The cyclohexane was removed. The residue (a brown-red oil) was dissolved in a small volume of methylene chloride and chromatographed on Florisil. Petroleum ether eluted an initial brown-red band (traces of $f_4AsPFe(CO)_4$ and $f_4AsPFe_3(CO)_9$, etc.). 2–5% diethyl ether–98–95% petroleum ether eluted a yellow band which gave a yellow-orange sample of $(f_4AsP)_2Fe(CO)_3$. This was purified by rechromatography and recrystallization from carbon disulfide to give yellow-orange crystals, m.p. 153° (dec.) (0.25 g, 9%).

Diethyl ether–petroleum ether up to 50% eluted a red band which gave a brick-red powder of $(f_4AsP)_2Fe_2(CO)_4$. This was rechromatographed and recrystallized from diethyl ether–petroleum ether to yield brick-red crystals, m.p. 205° (dec.) (0.15 g, 5%).

(6) Preparation of $f_4AsPFe(CO)_3$

Diiron enneacarbonyl (3.0 g, 8.2 mmol), f_4AsP (2.0 g, 4.9 mmol), and acetone (50 ml) were sealed under vacuum in a thick-walled Pyrex tube. After irradiation for 8 days with ultraviolet light while shaking, the tube was opened. The reaction mixture was filtered and the solvent removed. The resulting dark brown oil was dissolved in a small volume of methylene chloride and chromatographed on Florisil. After eluting the initial yellow band ($f_4AsPFe(CO)_4$), a brown-yellow band was eluted with 2–5% diethyl ether–98–95% petroleum ether. This was evaporated and recrystallized from petroleum ether to give brown-yellow crystals of $f_4AsPFe(CO)_3$, m.p. 136° (dec.) (1.00 g, 36%).

(7) Preparation of $f_6AsPFe(CO)_4$

Iron pentacarbonyl (7.0 g, 36 mmol) and f_6AsP (0.46 g, 1.0 mmol) were refluxed together in cyclohexane (30 ml) for 10 h. The volatile contents were then removed and the residue was extracted with petroleum ether. The resulting solution was filtered and evaporated to dryness to give a yellow-brown oil. This was then purified by chromatography. A 2% diethyl ether–98% petroleum ether mixture eluted

$f_6AsPFe(CO)_4$ as a yellow band ($f_6AsPFe(CO)_3$ may contaminate the tail of this band). The compound was recrystallized from *n*-hexane as yellow crystals, m.p. 51° (0.10 g, 16%).

(8) Preparation of $f_6AsPFe(CO)_3$

Iron pentacarbonyl (15 g, 76 mmol) and f_6AsP (0.93 g, 2.0 mmol) were sealed under vacuum with acetone (15 ml) in a Pyrex tube. The tube was irradiated with u.v. light for 2 days while shaking. The tube was opened and the solution was filtered and evaporated to dryness. The dark brown residue was extracted with petroleum ether. This extract was evaporated to dryness, dissolved in a small volume of methylene chloride, and chromatographed on Florisil. Diethyl ether–petroleum ether mixtures eluted a dark brown band which yielded a dark brown powder of $f_6AsPFe(CO)_3$. This was recrystallized from diethyl ether–petroleum ether as dark brown crystals, m.p. 137° (dec.) (0.62 g, 57%).

(9) Preparation of $f_6AsPFe_2(CO)_6$

Triiron dodecacarbonyl (1.0 g, 2.0 mmol) and f_6AsP (0.5 g, 1.1 mmol) were refluxed together in cyclohexane (50 ml) for 4 h. The solvent was removed. The brown residue was extracted with petroleum ether and filtered to remove a brown solid. (The filtrate was evaporated to dryness, dissolved in a small volume of methylene chloride, and chromatographed on Florisil to give $f_6AsPFe(CO)_4$ (~5%) and $f_6AsPFe(CO)_3$ (22%).)

The brown solid was extracted with acetone. The resulting brown-red solution was filtered and evaporated to yield an orange powder of $f_6AsPFe_2(CO)_6$. This was purified by chromatography using diethyl ether as eluent. Recrystallization from methylene chloride–*n*-hexane gave orange crystals, m.p. 215° (dec.) (0.41 g, 50%).

(10) Reaction of cis-$(CH_3)_2AsC(CF_3)$=$C(CF_3)As(CH_3)_2$ with $Fe_3(CO)_{12}$

The ditertiary arsine (1.1 g, 0.30 mmol) and $Fe_3(CO)_{12}$ (1.9 g, 0.38 mmol) in acetone solution (20 ml) were irradiated with ultraviolet light for 24 h. The solvent was removed and chromatography of the solid residue gave two bands which were eluted with petroleum ether. The first band off the column gave a red-brown solid which was identified as $(CH_3)_2AsC(CF_3)$=$C(CF_3)As(CH_3)_2Fe(CO)_3$ (1.0 g, 66%). The mass spectrum showed a parent ion followed by loss of three CO groups. The carbonyl infrared spectrum (C_6H_{12} solution) consisted of the expected pattern of three bands at 2001(8), 1933(7), 1917(10) cm^{-1}.

Anal. Calcd. for $C_{11}H_{12}As_2F_6FeO_3$: C, 25.8; H, 2.3; F, 22.3. Found: C, 25.8; H, 2.3; F, 22.4.

The second band gave a yellow-red solid which was identified as $(CH_3)_2AsC(CF_3)$=$C(CF_3)As(CH_3)_2Fe_2(CO)_6$ (0.1 g, 5%) after purification by sublimation (160°, 10^{-2} mm). The mass spectrum showed a parent ion followed by loss of six CO groups. The carbonyl infrared spectrum showed absorption in the usual pattern as follows: 1956(2), 1968(1), 1986(4), 1996(6), 2024(10), 2062(4) cm^{-1}.

Anal. Calcd. for $C_{14}H_{12}As_2F_6Fe_2O_6$: C, 25.8; H, 1.8. Found: C, 26.0; H, 1.7.

(11) Reaction of f_8fos with $Fe_2(CO)_9$

The ligand (0.36 g, 0.6 mmol) (7) and $Fe_2(CO)_9$ (0.59 g, 1.6 mmol) were stirred in benzene solution (15 ml) for 12 h. The resulting dark solution was filtered and the solvent was evaporated to leave an oil which solidified on trituration with petroleum ether. The brown product was recrystallized from benzene–petroleum ether to give 0.6 g (82%) of $f_8fosFe(CO)_3$, m.p. 158–161 (dec.). The carbonyl infrared spectrum had absorption at 1933(9), 1949(7), and 2009(10) cm^{-1}. The ^{19}F n.m.r. spectrum showed two equal area broad resonances at 134 and 103 p.p.m. upfield from $CFCl_3$.

Anal. Calcd. for $C_{33}H_{20}F_8FeO_3P_2$: C, 54.0; H, 2.8; P, 8.4. Found: C, 54.3; H, 2.8; P, 8.0.

Results and Discussion

Characterization of the Complexes of Unsymmetrical Ligands

The new complexes of the unsymmetrical ligands can be classified into eight groups: (L—L′)$Fe(CO)_4$, (L—L′)$Fe_2(CO)_8$, (L—L′)$Fe(CO)_3$, (L—L′)$_2Fe(CO)_3$, (L—L′)$Fe_2(CO)_6$, (L—L′)$_2Fe_2(CO)_4$, (L—L′)$Fe_3(CO)_{10}$, and (L—L′)$Fe_3(CO)_9$ where (L—L′) is f_4AsP, **1***c*, and/or f_6AsP, **1***d*. All these types except (L—L′)$_2Fe_2(CO)_4$ and (L—L′)$_2Fe(CO)_3$ are known for complexes of the symmetrical ligands f_4fars, **1***a* and f_4fos, **1***b*. The range of known hydrocarbon-bridged ditertiary phosphine and arsine complexes is considerably less (11).

Appropriate analytical and spectroscopic data for the new complexes are listed in Tables 1–4. The mass spectra of all the new compounds showed a parent ion followed by loss of the appropriate number of carbonyl groups. Since the rest of the cracking pattern was not very useful as an aid to the structure determination the spectra are not described further here although fairly complete assignments have been made elsewhere (12).

(1) (L—L′)$Fe(CO)_4$ Complexes

Both f_4AsP and f_6AsP give complexes of this type. The Mössbauer spectra, Table 4, consist of a quadrupole doublet whose isomer shift and quadrupole splitting are characteristic of monosubstituted $Fe(CO)_5$ derivatives (1). The ^1H n.m.r. data, Table 3, indicate that it is the $(C_6H_5)_2P$ moiety that is coordinating since the chemical shift of the $(CH_3)_2As$ group is virtually unchanged on coordination. If the complex were formed by donation of the arsenic lone pair then a downfield shift (~0.5 p.p.m.) of the $(CH_3)_2As$ resonance would be expected. For example, the ^1H n.m.r. spectrum of f_4fars is a singlet at 1.40 p.p.m. The complex $f_4farsFe(CO)_4$ absorbs at 1.90 p.p.m. (coordinated $As(CH_3)_2$ group) and at 1.44 p.p.m. ("free" $(CH_3)_2As$ group) (1).

*Spectra were run using a Perkin–Elmer model 457 spectrometer. The solvent was cyclohexane and the numbers in parentheses are relative peak heights.

The carbonyl infrared spectra of both compounds show four band patterns. This is probably due to the asymmetry of the ligands causing a splitting of the E mode in the spectrum expected for an axially substituted (C_{3v}) trigonal bipyramidal structure (1, 13). A similar four band spectrum is seen for other (L—L)$Fe(CO)_4$ complexes (1). The predicted structure for $f_4AsPFe(CO)_4$, **4**, has recently been verified by an X-ray investigation (14).

(2) $f_4AsPFe_2(CO)_8$

The suggested structure for this molecule is shown in **5**. The Mössbauer spectrum consists of two quadrupole doublets indicating the presence of iron atoms in two different environments. The only reasonable assignments given in Table 4 result in values δ and Δ which are in the range expected for monosubstituted $Fe(CO)_5$ derivatives (1) such as the analogous f_4fars-$Fe_2(CO)_8$. The iron atom with the greater

*Spectra were run on a Varian T60 spectrometer. Chemical shifts are reported in p.p.m. downfield from internal TMS (^1H spectra) or upfield from external $CFCl_3$ (^{19}F spectra).

isomer shift is believed to be the one coordinated to the $(CH_3)_2As$ moiety on the grounds that the arsine end would be the weaker π-acceptor. Other spectroscopic properties are in agreement with the proposed structure.

(3) (L—L)Fe(CO)$_3$ Complexes

These are obtained for both f_4AsP and f_6AsP. Again their Mössbauer and infrared spectra indicate a five coordinate iron(0) derivative. The n.m.r. data show that both ends of the ligands are coordinated and that the ligands have the same symmetry in the complexes as in the free ligands. It is probable that, in solution, these derivatives, like the other (L—L)$Fe(CO)_3$ and (L—L)$Ru(CO)_3$ complexes (1, 15) are undergoing positional exchange possibly by the "turnstile" mechanism (16). In the solid the ligands are probably coordinated at an axial and equatorial position giving an L—Fe—L angle of $\sim 90°$ (as is reported for diars$Fe(CO)_3$ (17), diars = 1,2-$((CH_3)_2As)_2C_6H_4$). Angles of $\sim 90°$ are found in the chelate complexes

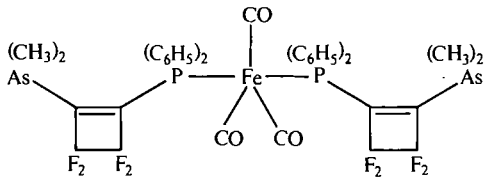
	295	0.10	2.85	0.23
$f_6AsPFe(CO)_4$	80	0.17	2.59	0.26
$f_6AsPFe(CO)_3$	80	0.21	2.61	0.27

*δ: Isomer shift, relative to sodium nitroprusside; Δ: Quadrupole splitting; $\bar{\Gamma}$: Full width at half maximum, average of the two resonance lines. Spectra were determined and processed as described in ref. 1.

$[(f_6fos)_2Rh]^+[Rh(CO)_2Cl_2]^-$ (18) and $f_6fosFe(NO)_2$ (19). In the latter case a P—Fe—P angle closer to 109° might have been expected. Equatorial–equatorial substitution in a trigonal bipyramidal (L—L′)$Fe(CO)_3$ complex would require the ligand to subtend an angle of ~120° at the iron atom.

(4) $(f_4AsP)_2Fe(CO)_3$

The spectroscopic data are consistent with the structure indicated in **6**. In particular the

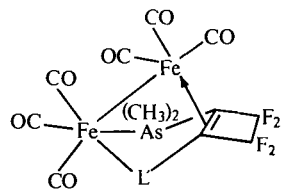


6

n.m.r. spectrum indicates that both ligands are P-bonded. The carbonyl infrared spectrum shows two strong bands of similar frequency (1913, 1898 cm^{-1}) and a weaker band at higher energy (1986 cm^{-1}). An ideal D_{3h} molecule would give just one infrared active band. In the case of **6**, it is probable that the weak band is the A_1' mode which is made weakly infrared active by the asymmetry of the ligand. The two strong frequencies are possibly due to splitting of the E mode for the same reason or, alternatively, they are due to the presence of rotamers in solution corresponding, for example, to "eclipsed" or "staggered" orientations of the ligands with respect to the central planar $Fe(CO)_3$ group. Rotation about other bonds such as the P—cyclobutene could also result in rotamers.

(5) $(L—L')Fe_2(CO)_6$

These compounds were isolated using both ligands. They are orange solids with high (>200°) melting points. The pattern of infrared bands for these complexes is very similar to that described for other complexes of the same formula (2). The Mössbauer spectra, which will be discussed in detail in another publication (20), are also typical showing four equal intensity lines indicating two different iron environments, and the ^1H n.m.r. spectra show two singlet resonances in the As—CH_3 region. Thus the



7

structures are analogous to that found for $f_4farsFe_2(CO)_6$ **7** (L′ = $As(CH_3)_2$) (21) and the f_4AsP analogue would have L′ = $P(C_6H_5)_2$.

(6) $(f_4AsP)_2Fe_2(CO)_4$

This complex is also an orange-red solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

which suggests that it is a derivative of $f_4AsPFe_2(CO)_6$. This is confirmed by its synthesis from $f_4AsPFe_2(CO)_6$ and f_4AsP when an acetone solution of the two reactants is irradiated (20). The Mössbauer spectrum shows two different iron atoms (20). This and other spectroscopic data are consistent with a structure in which the second f_4AsP ligand is bridging the two iron atoms of **7** ($L' = (C_6H_5)_2P$). An alternative structure with the second ligand chelated to the 6-coordinated iron atom can be eliminated since this has been obtained from other experiments (20) and its structure confirmed by X-ray methods (22).

(7) $f_4AsPFe_3(CO)_{10}$

The structure proposed for this compound is **2** ($L' = P(C_6H_5)_2$). The spectroscopic properties are very similar to those of $f_4farsFe_3(CO)_{10}$ **2** ($L' = As(CH_3)_2$). Thus the $As(CH_3)_2$ moiety in $f_4AsPFe_3(CO)_{10}$ is coordinated and its ^1H n.m.r. resonance is a singlet. The carbonyl infrared spectrum shows the presence of weak bridging carbonyl bands.

(8) $f_4AsPFe_3(CO)_9$

This was believed to have the structure **3** ($L' = P(C_6H_5)_2$) because of the similarity of its spectroscopic properties with those of the known $f_4farsFe_3(CO)_9$ **3** ($L' = As(CH_3)_2$) (6). However, one feature of the ^1H n.m.r. spectrum, an $As—CH_3$ resonance at high field ($\sim$0.10 p.p.m.), seemed to suggest that perhaps the structure was different and that an $Fe—CH_3$ bond was present. A subsequent X-ray investigation (23) has shown that **3** is indeed the correct structure and the origin of the upfield shift of the arsenic–methyl resonance is probably that it is situated directly over a phenyl ring (23).

Preparation of Fluorocarbon-bridged Complexes

In general, the products obtained by reacting the iron carbonyls with fluorocarbon-bridged

ligands (Tables 5–7) are very dependent on the reaction conditions. As might be expected, the reactions of $Fe(CO)_5$ mainly produce complexes in which the ligands are monoligate ((L—L′)-$Fe(CO)_4$), biligate bimetallic ((L—L′)Fe_2-$(CO)_8$), or biligate monometallic ((L—L′)Fe-$(CO)_3$), Table 5.

One ligand, $f_4$fars, does not form the chelate complex $f_4$farsFe$(CO)_3$; but when chelate complexes are known their formation seems to be favored by prolonged ultraviolet irradiation. Mild irradiation or reflux conditions usually afford greater yields of the (L—L′)Fe$(CO)_4$ and (L—L′)$Fe_2(CO)_8$ types, respectively, although the yield of the latter is never very high.

The ease of formation of the chelate complexes (L—L′)Fe$(CO)_3$ appears to be in the sequence (L—L′)=$f_4$fars < f_4AsP < f_6AsP ≤ $f_4$fos < $f_6$fos ≈ $f_8$fos. Since the carbonyl infrared spectra of the complexes $f_n$fosM$(CO)_4$ (M = Cr, Mo, W) are little affected by the increasing ring size of the bridging group, it can be concluded (9) that electronic effects are probably not responsible for the absence of $f_4$farsFe$(CO)_3$ and the low yield of f_4AsPFe$(CO)_3$. Instead it seems that the bite of the ligand is the main reason. Thus the donor groups are at their maximum distance apart with a cyclobutene bridging group coupled with longer C—As bonds. In agreement with this notion is the result that

8

$f_6$fars$((CH_3)_2$AsC=CAs$(CH_3)_2(CF_2)_2CF_2)$(8) *does* form $f_6$farsFe$(CO)_3$ (24). Also the ligand **8**[1] (25) which must be electronically similar to $f_4$fars also gives a chelated $Fe(CO)_3$ complex in good yield as described in the Experimental section. Here the acyclic bridging group allows the two arsenic atoms to come closer together.

The only other products from the reaction of the ligands with $Fe(CO)_5$ are the complexes (L—L′)$Fe_2(CO)_6$ where the ligand is acting as a chelating group to one $Fe(CO)_3$ group and is coordinated to the second $Fe(CO)_3$ group through the double bond, the two iron atoms being linked by an Fe—Fe bond as shown in **7** (2, 21).

This type of complex is known for all the ligands except $f_8$fos although $f_6$fos$Fe_2(CO)_6$ is not obtained by reaction with $Fe(CO)_5$. The highest yields of these $Fe_2(CO)_6$ complexes are obtained by reaction of the ligands with $Fe_3(CO)_{12}$. In this way $f_4$fos$Fe_2(CO)_6$ can be prepared in 76% yield. The interconversion reactions (Table 8) indicate that these stable complexes are probably formed from (L—L′)$Fe(CO)_4$ and (L—L′)$Fe_2(CO)_8$.

The ease of formation of the $f_n$fos$Fe_2(CO)_6$ complexes decreases as n increases which suggests that the ring size is a factor, since the

[1]A preliminary communication describing the iron carbonyl complexes of this ligand has appeared (ref. 26).

tendency to relieve ring strain in the ring by coordinating the double bond to a second iron atom would then decrease as the size increased. However, the yields of $f_6AsPFe_2(CO)_6$ and $f_4AsPFe_2(CO)_6$ are comparable and are greater than those of $f_6fosFe_2(CO)_6$ which suggests that reduction of steric hindrance by replacing bulky $P(C_6H_5)_2$ groups with $As(CH_3)_2$ groups is an important factor in encouraging the formation of this type of complex. The recent synthesis of $f_6farsFe_2(CO)_6$ and $f_8farsFe_2(CO)_6$ in 70 and 45% yield, respectively (20), lends support to arguments invoking steric hindrance. That ring strain in the starting ligand is not necessary for the formation of $(L—L')Fe_2(CO)_6$ type complexes is shown by the isolation of *cis*-$(CH_3)_2AsCCF_3{=}CCF_3As(CH_3)_2Fe_2(CO)_6$ from the reaction of **8** with $Fe_3(CO)_{12}$.

The use of $Fe_2(CO)_9$ as reagent (Table 6) has much the same result as $Fe(CO)_5$, and the only new complex type is $f_6fosFe_2(CO)_7$ which is unique to this ligand. It is believed to be

bonded through the phosphorus to a $Fe(CO)_4$ group and through the double bond to the $Fe(CO)_3$ moiety (3).

When the ligands are treated with $Fe_3(CO)_{12}$ (Table 7) mild conditions result in the isolation of $(L—L')Fe_3(CO)_{10}$, (L—L')=$f_4$fars, and f_4AsP, where the ligand bridges the two iron atoms that are also carbonyl bridged, **2**. A very surprising result is that when the ligand-to-carbonyl ratio is 1:3 the greatest yield of $f_4farsFe_3(CO)_{10}$ is obtained. Previously we have reported a maximum yield of 7% (3). In the ruthenium carbonyl reaction the same conditions were found to give a maximum yield (63%) of $(f_4fars)_2Ru_3(CO)_8$ (27) whose structure retains the Ru_3 triangle (28).

The high yield of $f_4AsPFe_3(CO)_{10}$, **2** (L' = $P(C_6H_5)_2$), is unexpected and it seems that here the low tendency to chelate coupled with the bite of the ligand is just right to allow the ligand to "clip" on to the Fe_3 fragment. Like $f_4farsFe_3(CO)_{10}$ which is easily converted to $f_4farsFe_3(CO)_9$ in which a $(CH_3)_2As$ group is displaced from the cyclobutene ring as in **3** (L' = $As(CH_3)_2$), f_4AsP also undergoes this reaction to afford $f_4AsPFe_3(CO)_9$ **3** (L' = $P(C_6H_5)_2$). However, although $f_4farsFe_3(CO)_9$ is unstable with respect to loss of fluorocarbon groups giving eventually $(CH_3)_2As_2CH_2Fe_3(CO)_9$ and other products, $f_4AsPFe_3(CO)_9$ is stable under the same condition (Table 8). This indicates that the breakdown of $f_4farsFe_3(CO)_9$ occurs by way of cleavage of the one remaining As–cyclobutene ring in **3** (L' = $As(CH_3)_2$). Cleavage reaction of this type also occurs when $f_4farsMn_2(CO)_8$ is heated (29, 30).

The other ligands, as pointed out above, have a strong tendency to chelate and the main products from their reactions with $Fe_3(CO)_{12}$ are $(L—L')Fe(CO)_3$ and $(L—L')Fe_2(CO)_6$ type complexes, although $f_6$fos does give $f_6fosFe_2(CO)_7$. It is worth noting that since $f_4AsPFe_3(CO)_9$ is moderately stable by itself (Table 8) the formation of derivatives such as $(f_4AsP)_2Fe(CO)_3$ **6**, and $(f_4AsP)_2Fe_2(CO)_4$ (a bridged derivative of $f_4AsPFe_2(CO)_6$ described above) and $f_4AsPFe(CO)_3$ with fewer iron atoms per molecule could well arise through reaction of the $(L—L')Fe_3(CO)_9$ compound with the ligand.

Finally, some of the other interconversion reactions described in Table 8 are worthy of note. Thus the bridged complex $f_4AsPFe_2(CO)_8$ is obtained in moderate yield when $f_4AsPFe(CO)_4$ is treated with $Fe(CO)_5$ and u.v. irradiation. However, if the $Fe(CO)_5$ is omitted, the chelated $f_4AsPFe(CO)_3$ is produced. This shows that f_4AsP, like $f_4$fars, has a strong tendency to bridge rather than chelate. Nevertheless when the bridged complex is heated, an $Fe(CO)_4$ moiety is lost and $f_4AsPFe(CO)_4$ is obtained:

Attempts at the Synthesis of the Penicillin Ring System by Transannular Reactions[1]

M. H. BENN AND ROBIN E. MITCHELL[2]

Department of Chemistry, The University, Calgary 44, Alberta

Received October 19, 1971

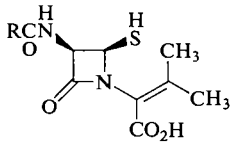
Attempts were made to achieve new syntheses of the penicillin ring system by effecting the transannular cyclization of 3D-carbomethoxy-*N*-chloro-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-1,4-thiazepine sulfone. However the products obtained were those resulting from ring cleavage and elimination reactions.

Des essais ont été entrepris afin d'effectuer une nouvelle synthèse du cycle de la pénicilline par cyclisation trans-annulaire de la 3D-carbométhoxy-*N*-chloro-2,2-diméthyle-5-oxoperhydro-6L-phtalimido-1,4-thiazépine sulfone. Cependant, les produits obtenus sont ceux résultant des réactions d'élimination et de clivage du cycle.

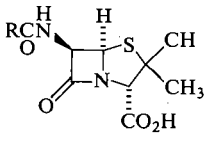
Canadian Journal of Chemistry, **50**, 2195 (1972)

Introduction

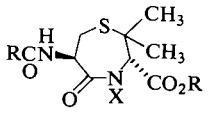
Five years ago, Woodward described the problem of achieving direct, highly-efficient routes to totally synthetic penicillins (**1**) as "one of the most challenging and recalcitrant synthetic objectives of our generation" (1). The challenge remains, and continues to fascinate chemists in much the same way that the Matterhorn attracted mountaineers. Although circumstantial evidence suggests that the biosynthesis of penicillins most probably proceeds from an acyclic peptide precursor or monocylic derivative such as **2** (2, 3), synthesis via a transannular bridging of the relatively readily available perhydrothiazepine system **3***a* stands out as a spectacular *diretissima* approach and this was the objective of the work which we describe here.



2



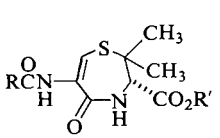
1



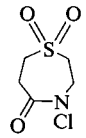
3

a X = R = H
b X = Cl; R = H

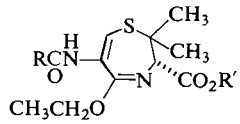
The overall concept was not new. The most obvious possibility, transannular nucleophilic displacement of halogen from C-7 by anionic nitrogen, has been attempted by several groups (4–6) but the products were usually tetrahydrothiazepines (**4**). The reverse process involving displacement of a leaving group on nitrogen by anionic C-7 seems to have been attempted only by Lillya, on the compound **5**, and also failed to produce a β-lactam (6). Similarly, various attempts to achieve the photochemical cyclization of tetrahydrothiazepines (**4**) and dihydrothiazepines (**6**) have been unsuccessful (4, 6, 7).



4



5



6

Our plan was to attempt to utilize the then recent discovery by Edwards and his co-workers that argentous ion induced the cyclization, albeit in low yield, of the *N*-chloro derivatives of medium-ring lactams to bicyclic lactams with bridgehead nitrogen (8); and also examine the reverse Knunyants reaction: *i.e.*, we would attempt the transformation **3***b* → **1**.

Success or failure appeared to depend on the ability to surmount various obstacles. Critical to

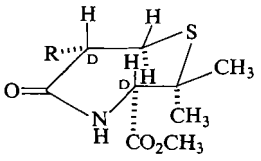
success by the first approach, and completely unprecedented, the Edwards reaction would have to give reasonable yields of a β-lactam; even then formation of a pair of compounds epimeric at C-7 would be anticipated. The other approach appeared fraught with many dangers, consequent upon the use of bases to generate an anionic center for the transannular nucleophilic displacement reaction; among these were the known base-lability of the penicillin β-lactam system as well as the possibility of base-catalyzed epimerization at C-3 and -6, and elimination to give an acylimine.

Materials

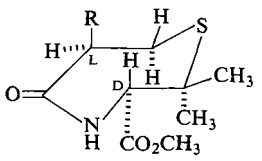
Since we needed a C-6 nitrogen function inert to chlorinations, we decided to carry out our experiments with 3D-carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-1,4-thiazepine. A mixture of the 6D- and 6L-epimers was obtained by the Woodward K reagent induced condensation and cyclization of D-penicillamine methyl ester and α-phthalimidoacrylic acid, and separated by column chromatography and fractional crystallization.

The C-6 configurations of the diastereomers were deduced from their p.m.r. spectra. Thus, if the stable conformations of the two compounds



7

a R = phthalimido
b R = phenylacetamido



8

a R = phthalimido
b R = phenylacetamido

are the pseudo-chairs **7** and **8** an analysis of the C-6 and -7 proton couplings should provide a method for assigning the stereochemistry at C-6.

In fact, the C-6 proton signal of one isomer revealed couplings of 11.8 and 7.5 Hz consistent with the axial–axial and axial–equatorial couplings expected for **7***a*. Other data, chemical shift and specific rotation, for the two isomers also correlated well with the values recorded for the analogues **7***b* and **8***b* (see Table 1) whose absolute configurations had been established by degradation (9).

The product ratio of the unwanted 3D,6D (**7***a*) to the desired 3D,6L-epimer (**8***a*) was about 2:1.[3]

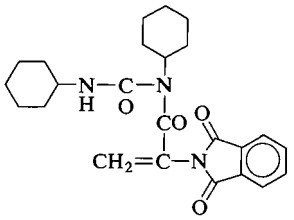
TABLE 1. Comparison of some data for **7***a*, **7***b*, **8***a*, and **8***b*

Thiazepine	$\tau(CH_3)_2$	(α_D)	Concentration in ethanol	T °C
7*a*	8.75, 8.37	−50.0°	0.12	29
7*b*	8.72, 8.64	−39.7°	0.6	25
8*a*	8.55, 8.55	−90.0°	0.12	29
8*b*	8.62, 8.62	−57.1°	0.6	25

The reaction of **7***a* or **8***a* with chlorine in methylene chloride solution gave the same tetrahydrothiazepine **9**,[4] m.p. 179–182°,[5] thus establishing their C-6 epimeric relationship.

Under mild conditions the reaction of **7***a* with chlorine afforded the 7-chloro derivative **10**[4,6] (under these conditions the product from **8***a* was **9**); **10** readily decomposed to **9**.

A side product from the reaction with **8***a* was a substance assigned[4] structure **11***a*. However,



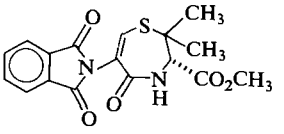
i

[3]A similar ratio was obtained when dicyclohexylcarbodiimide was used instead of the Woodward K-reagent, but the overall yield was lower, and isolation of pure **7***a* and **8***a* was difficult. In addition, a side-product from this reaction was identified as (i) indicating that the known reaction of carboxylic acids with the carbodiimide (10) was a competing process.

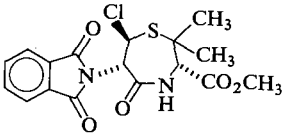
[4]See Experimental for the analysis of data which lead to this conclusion.

[5]Sheehan and Cruickshank have described a compound assigned structure **9**, but with m.p. 237–237.5° (11).

[6]The stereochemistry of **10** was revealed by its p.m.r. spectrum which, while similar in some respects to that of **7***a* had in place of the three proton AMX system a two proton AB quartet at τ 4.75 and 3.47 (J = 11.5 Hz) which may be attributed to C-6 and -7 methine protons in a pseudo-*trans*-diaxial relationship. Therefore C-7 bears the chlorine substituent in a pseudo-*trans*-diequatorial relationship to the phthalimido substituent at C-6, which has the D-configuration. Absence of a compound isomeric with **10** in the reaction of the 6L-phthalimido epimer **8***a* seems significant: it is likely that a 7-chlorothiazepine forms in this reaction too, but the C-6 hydrogen and C-7 chlorine substituents probably are able to assume a *trans*-diaxial relationship with ease, thus promoting the elimination which leads to **9**.

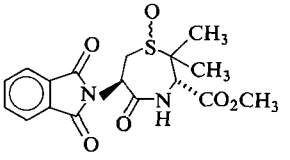


9

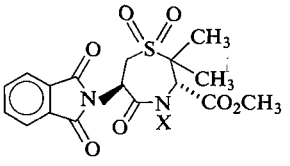


10

sodium periodate oxidation of **8***a* gave a sulfoxide (**11***b*) apparently diastereomeric with **11***a*. We have tentatively designated **11***a* as the α-, and **11***b* as the β-isomer.[7]



11
a α-sulfoxide
b β-sulfoxide



12 X = H
13 X = Cl

Since it was necessary to mask the sulfide function of the tetrahydrothiazepine during preparation of the *N*-chloro derivative, and preliminary chlorination experiments with the sulfoxide **11***b* were unpromising (13), **8***a* was oxidized with potassium permanganate in acetic acid to the sulfone **12**.

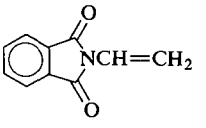
The reaction of **12** with *t*-butyl hypochlorite in acetic acid solution gave, after removal of the solvent, a glass completely soluble in benzene (a solvent in which **12** is very sparingly soluble). This product gave a strong "active chlorine" reaction[8] and its i.r. spectrum was devoid of NH absorptions, and when a solution in 2-propanol was boiled for a few minutes, **12** was obtained in *almost quantitative yield*.

In conjunction with the above evidence a p.m.r. spectrum conclusively established the identity of the product as the required *N*-chloro-6L-phthalimido sulfone **13**: particularly significant was the appearance of the C-3 methine as an unsplit singlet.[9]

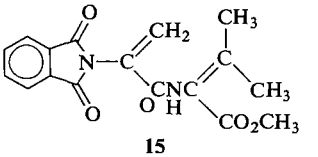
Results and Discussion

With the completion of the syntheses of **13** the stage was set for our attempts at the transannular cyclization reactions.

We first tried the Edwards reaction. The *N*-chloro substituent of the sulfone **13** was shown to be very labile in "protic" solvents. However, in dry DMF or benzene solution little decomposition occurred over a period of several hours. When a reaction vessel containing a solution of **13** in dry DMF and containing suspended silver carbonate (14) was inserted in an oil-bath held at 45°, a negative active-chlorine analysis was obtained within 3 min. Upon work-up, a 47% yield of the parent thiazepine (**12**) was obtained. The mother liquor remaining after removal of this material contained two major components which proved[4] to be **14**[10] and **15**. No trace of a β-lactam could be found.[11]



14



15

When **13** was illuminated with tungsten light in refluxing benzene solution, tests for active chlorine were negative after 7 h. The crude reaction product had no NH band in the i.r. spec-

[7]*Sodium periodate oxidation of various penicillins has* been shown to give exclusively one stereomer: the β-sulfoxide (12).

[8]The presence or absence of "active chlorine" (N—Cl or O—Cl) compounds was determined by a starch–potassium iodide spot-test.

[9]In the cases of all other perhydrothiazepines which we examined, the C-3 methine signal appeared as a doublet (J = 6–7 Hz) if the adjacent lactam nitrogen was unsubstituted.

[10]We did not find a compound corresponding to the fragment lost from the thiazepine during the formation of *phthalimidoethylene; presumably this was lost during the* evaporation of DMF from the reaction mixture.

[11]As judged by the i.r. of the crude reaction product.

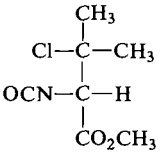
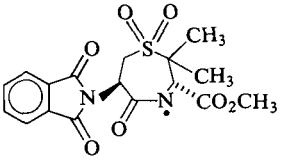
trum, and apparently no lactam CO band, but a very intense band at 2255 cm^{-1}. The products were identified[4] as **14** and **16**. Again there was no evidence for any β-lactam formation.



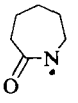
16

At the time of its discovery the Edwards reaction was thought to involve nitrenium ions and a transannular hydride shift; indeed it was this aspect of the reaction which attracted us to it. However under the conditions which we employed homolysis of the N—Cl bond occurs, with subsequent hydrogen atom transfer and the formation of *C*-chloro intermediates.[12]

Presumably the amidyl radical (**17**) generated from **13**, like its analogue **14**, is unable to adopt a conformation which permits intramolecular hydrogen abstraction.[13] Instead, hydrogen atom extraction from solvent, and fragmentation with



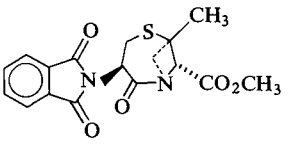
17



18

[12]Thus we had returned to a Knunyants approach in which the cyclization was to be induced by silver ion rather than strong base.

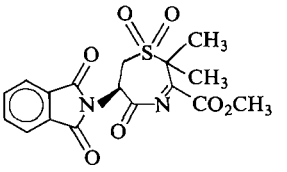
[13]The next higher homologue of **18** undergoes efficient intramolecular hydrogen transfer (14) and we had hoped that the slight increase in ring size consequent upon replacing a CH_2 unit in **18** by $—SO_2—$ might have permitted sufficient conformational mobility in **17** that it might behave similarly except that, in the absence of δ-, a γ-situated hydrogen (at C-7, or C-2 methyl) might have been abstracted by the amidyl nitrogen. However, models suggested that this was unlikely, and if the abstraction did occur that it would be the undesired one, *i.e.*, from the α-oriented methyl group to give **ii**. In the event we could find no evidence for either attack.



ii

extrusion of sulfur dioxide compete, and are respectively dominant in DMF and benzene.

The oxidation level of sulfur, necessary for the preparation of **13** probably aids the undesirable fragmentations, extrusion of sulfur dioxide being facile. Such an extrusion from **19**, itself produced either from **17** or by heterolysis of **13**, would account for the formation of **15**, while **16** is probably derived from **17** by a radical-chain mechanism.[14]



19

Thwarted on the Edwards reaction approach, we turned to the base induced cyclizations of **13** but failed to obtain any β-lactam: with potassium fluoride or sodium carbonate in DMF, the products isolated were the parent lactam **12** and the unsaturated acyclic amide **15**; while with *t*-butyl lithium in anhydrous THF, at Dry Ice–acetone temperature, **13** gave a product mixture from which the lactam **12** was isolated in 50% yield. The residue, which consisted of at least six components but which again failed to exhibit β-lactam i.r. absorption, was not investigated further.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 327 grating spectrometer. The p.m.r. spectra were measured with Varian A-60 or HA-100 instruments in deuteriochloroform solution with tetramethylsilane as internal standard, unless otherwise specified. The u.v. spectra were recorded with a Perkin–Elmer model 202 spectrometer with ethanol (95%) as solvent. The mass spectra were recorded on an AEI-MS-9 instrument, with a direct inlet, at 70 eV ionization potential, and significant ions at higher *m/e* values as well as ions with a relative abundance of 20% or more of the base peak, are quoted as *m/e* values, with their relative abundance in parentheses. The o.r.d. curves were recorded on a Durrum–Jasco ORD-UV/5 spectro-polarimeter in ethanol (95%) solution and specific rotations were measured from these curves at the sodium D-line (589.5 nm). For t.l.c. and p.l.c. we used Merck silica gel G (0.25 mm thickness) and Merck silica gel PF_{254} (1 mm thickness) respectively and, for column chromatograms, Florisil (Fisher Scientific Co., 100–200 mesh).

[14]The fragmentation of amidyl radicals to yield isocyanates has been observed before (14).

D-Penicillamine Methyl Ester Hydrochloride

D-Penicillamine (Aldrich, m.p. 208–210°) was esterified according to the patent literature (15). Recrystallization of the crude solid from 2-propanol yielded colorless needles (75–80% yield) m.p. 180–182° (dec.) (lit. (15) 184° (dec.)); ν_{max} (KBr) 3450 (NH), 2495 (SH) and 1750 cm^{-1} (ester CO); τ (D_2O) (TMS external ref.) 8.50 (3H) (s), 8.43 (3H) (s) ($\rangle C(CH_3)_2$), 6.12 (3H) (s) ($—CO_2CH_3$), and 5.78 (1H) (s).

α-Phthalimidoacrylic Acid

This compound was prepared from cysteine (24 g) by the method of Sakakibara (16) in comparable yield. A modified work-up procedure was followed which was much less tedious than the original; the crude fusion product was extracted with boiling ethyl acetate (*ca.* 600 ml), filtered, and the filter-cake washed with boiling ethyl acetate (3 × 100 ml). The combined extracts and washings were washed with saturated aqueous sodium bicarbonate solution (3 × 150 ml) which was then back-washed with ethyl acetate (2 × 100 ml), adjusted to p*H* 1.5 with 2 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 100 ml). The combined ethyl acetate extracts from the acidic aqueous phase were finally washed with brine (3 × 50 ml), dried ($MgSO_4$), and evaporated. The residue was extracted with boiling chloroform (*ca.* 500 ml) and filtered hot. Upon cooling, the filtrate deposited off-white needles, 20 g. Concentration of the mother liquor (to *ca.* 150 ml) afforded a further 8.5 g of material. The total product was recrystallized once from chloroform affording colorless needles, 18.5 g, in 45% yield, m.p. 172–176° raised to 174.5–177.5° upon further recrystallization (lit. (16) 169–171°); ν_{max} (KBr) 3280 (br) (carboxylic acid OH), 1800 (w, sharp) (phthalimido CO asym. str), 1725 (br, st) (phthalimido CO and carboxylic acid CO), 1645 and 885 ($\rangle C{=}CH_2$), and 1615 and 715 cm^{-1} (phthalimido aromatic); τ (CD_3COCD_3) 3.88 (1H) (s), 3.30 (1H) (s) (two vinylic methylene protons), and 2.09 (4H) (s) (aromatic).

3D-Carbomethoxy-2,2-dimethyl-6D- and 6L-Phthalimido-5-oxoperhydro-1,4-thiazepine (7a, 8a)

A solution of phthalimidoacrylic acid (10.71 g, 49.3 m*M*), neutralized with triethylamine (6.83 ml, 49.3 m*M*), in anhydrous acetonitrile (675 ml) was added to *N*-ethyl-5-phenylisoxazolium-3′-sulfonate (Woodward reagent K) (12.49 g, 49.3 m*M*). The mixture was stirred until all the solids had dissolved. A second solution was prepared from D-penicillamine methyl ester hydrochloride (9.85 g, 49.3 m*M*) and triethylamine (6.83 ml, 49.3 m*M*) in acetonitrile (675 ml). Both solutions were filtered, then simultaneously added dropwise to acetonitrile (61) containing Triton B (40% in methanol, 12.3 ml), under a slow steady stream of dry nitrogen at room temperature, agitated with a Vibromixer, over a period of 8 h. Stirring was continued for 12 h after the addition was complete. Removal of the solvent (bath <40°) afforded a residue which was partitioned between chloroform (250 ml) and water (25 ml). The aqueous extract was washed with chloroform (50 ml) and the combined chloroform extracts were washed with 2*N* hydrochloric acid (3 × 50 ml), then with saturated aqueous sodium bicarbonate (4 × 50 ml), and finally dried ($MgSO_4$) and evaporated to afford an off-white glass (16 g). Recrystallization from 95% ethanol afforded colorless needles, 11.25 g, demonstrated by t.l.c. (R_f with methyl formate–benzene, 25:75 (v/v)) to be a mixture of **7***a* (R_f 0.22) and **8***a* (R_f 0.29), in ratio *ca.* 2:1 by subsequent isolation. Evaporation of the mother liquors gave a viscous yellow oil showing several components on t.l.c. (R_f 0.42, 0.35, 0.29, 0.22, 0.15, and 0.02); no more of **7***a* and/or **8***a* could be crystallized from this oil which was not further investigated. The crystalline mixture of **7***a* and **8***a* was separated by multiple recrystallizations, one "cycle" being described as follows. Slow crystallization over 24 h at room temperature, from a solution obtained by dissolving the solid in boiling isopropyl acetate, and one similar recrystallization afforded pure **7***a* homogeneous on t.l.c. at high spotting concentrations. The filtrates were evaporated, the residue dissolved in boiling ethanol, and allowed to crystallize slowly at room temperature over 24 h. One similar recrystallization of the colorless needles so obtained afforded pure **8***a*, also homogeneous on t.l.c. at high spotting concentrations.

Compound **7***a*, colorless prisms, m.p. 205.5–207° had ν_{max} (KBr) 3370 (lactam NH), 1780 and 1745 (sh) (phthalimido CO), 1730 (ester CO), 1670 (lactam CO), 1620 (w) and 720 cm^{-1} (phthalimido aromatic); τ ($CDCl_3$) 8.75 (3H) (s), 8.37 (3H) (s) ($\rangle C(CH_3)_2$), 6.12 (3H) (s) ($—CO_2CH_3$), 7.29 (1H) (q, $J_{AM} = 15$, $J_{AX} = 7.5$ Hz), 6.73 (1H) (q, $J_{AM} = 15$, $J_{MX} = 11.75$ Hz) (A and M quartets for C-7 geminal protons), 4.87 (1H) (q, $J_{AX} = 7.5$, $J_{MX} = 11.75$ Hz) (X quartet for C-6 methine), 5.12 (1H) (d, $J = 6$ Hz) (C-3 methine), 3.29 (1H) (br, mult.), and 2.20 (4H) (mult.) (phthalimido aromatic protons); at 100 MHz, irradiation at τ 4.87 decoupled the A and M quartets to two doublets at 7.31 and 6.76 ($J_{AM} = 15$ Hz); $[\alpha]_D^{29} - 51.3°$ (*c* 0.12) and a negative Cotton effect curve with trough at 368 and peak at 332 nm; *m/e* 362 (M^+) (8), 189 (100), 173 (82), and 74 (48).

Anal. Calcd. for $C_{17}H_{18}N_2O_5S$: C, 56.35; H, 5.09; N, 7.72. Found: C, 56.04; H, 5.24; N, 7.31.

Compound **8***a*, colorless needles, m.p. 206–208° had ν_{max} (KBr) 3380 (lactam NH), 1785 and 1750 (phthalimido CO), 1730 (ester CO), 1680 (lactam CO), 1620 (w) and 720 cm^{-1} (phthalimido aromatic); τ ($CDCl_3$) 8.55 (6H) (s) ($\rangle C(CH_3)_2$), 6.14 (3H) (s) ($—CO_2CH_3$), 7.00 (1H) (q, $J_{AM} = 15.5$, $J_{AX} = 4.5$ Hz), 6.12 (1H) (q, $J_{AM} = 15.5$, $J_{MX} = 8.75$ Hz) (A and M quartets for C-7 geminal protons), 5.31 (1H) (d) (C-3 methine), 4.62 (1H) (q, $J_{AX} = 4.5$, $J_{MX} = 8.75$ Hz) (X quartet for C-6 methine), 3.63 (1H) (br, d, $J =$ *ca.* 7 Hz), and 2.17 (4H) (complex mult.); at 100 MHz, irradiation at τ 4.60 decoupled the A and M quartets to two doublets at 7.09 and 6.22 ($J_{AM} = 15.5$ Hz); $[\alpha]_D^{29} - 90.0°$ (*c* 0.12) and a negative Cotton effect curve with a trough at 334 and a peak at 306 nm; *m/e* 362 (M^+) (11), 330 (13), 189 (86), 173 (100), 104 (34), 76 (32), 74 (54), and 59 (30).

Anal. Calcd. for $C_{17}H_{18}N_2O_5S$: C, 56.35; H, 5.09; N, 7.72. Found: C, 55.95; H, 5.25; N, 7.24.

Alternatively the mixture (4 g) of **7***a* and **8***a* could be separated by chromatography on a column (*ca.* 3 cm diameter) of Florisil (150 g) packed in benzene, by eluting with ether (**7***a* commenced eluting), ether–acetone (99:1 (v/v)) (**7***a* and **8***a* mixture, followed by **8***a* eluting), and finally ethyl acetate. The column was monitored by t.l.c. and appropriate fractions were combined. Thus **8***a* (0.7 g), **7***a* (1.1 g), and a mixture of these (2.2 g), were obtained.

An alternative, but less successful, preparation of **7***a* and

8*a* utilized dicyclohexylcarbodiimide as the condensing agent. Dicyclohexylcarbodiimide (0.58 g, 2.80 m*M*) in acetonitrile (5 ml) was added dropwise over 12 min to a stirred solution of α-phthalimidoacrylic acid (0.53 g, 2.45 m*M*), penicillamine methyl ester hydrochloride (0.5 g, 2.50 m*M*), and triethylamine (0.38 ml, 2.75 m*M*) in anhydrous acetonitrile (15 ml), at room temperature. After the reaction mixture had been stirred for 7.5 h and cooled in the refrigerator for 4 h the dicyclohexylurea which had precipitated (0.435 g) was filtered off and washed with a small volume of acetonitrile. Evaporation of the combined filtrate and washings gave an amorphous solid which was dissolved in chloroform (*ca.* 25 ml), then washed with 2 *N* hydrochloric acid (2 × 20 ml), saturated brine (20 ml), and aqueous sodium bicarbonate (2 × 20 ml). The chloroform solution was then dried ($MgSO_4$) and evaporated to yield an off-white amorphous solid (1.17 g) which could not be induced to crystallize. The total product dissolved in benzene was entered onto a column (15 × 2.6 cm) of Florisil (35 g) packed in benzene, and the column eluted first with benzene, then with increasing concentrations of ethyl acetate in benzene; 100, then 200 ml (after fraction 8) fractions were collected.

Fractions 11 and 12 eluted with ethyl acetate–benzene (10:90 (v/v)) were combined, evaporated, and the residue recrystallized from ethanol, affording pure **8***a* (by i.r., n.m.r., and t.l.c. R_f, comparison).

Fractions 14–16, eluted with ethyl acetate–benzene (10:90 and 15:85 (v/v)), were combined, evaporated and the residue purified by p.l.c. (two elutions with methyl formate–benzene, 15:85 (v/v)) and subsequent recrystallization from carbon tetrachloride, affording pure 7*a* (by i.r. and t.l.c. comparison).

Fractions 17–21 were a mixture of 7*a* and **8***a* as indicated by t.l.c. The approximate total yield of 7*a* and **8***a* mixture (fractions 11–21 total) was *ca.* 40% in *ca.* 2:1 ratio.

Fractions 6 and 7 were combined and evaporated to yield 12 mg of residue which was recrystallized from ethanol yielding 4 mg colorless needles, m.p. 163.5–165.5°; R_f 0.51 on t.l.c. with methyl formate–benzene (15:85 (v/v)) as eluent. An analysis of the i.r. spectrum of this product led to its formulation as *N*-(α-phthalimido)acrylyl-*N*,*N*′-dicyclohexyl urea, and the i.r. spectrum was superimposable on that of an authentic sample (see below).

*N-(α-Phthalimido)acrylyl-N,N′-dicyclohexyl Urea (**i**)*

To a solution of dicyclohexylcarbodiimide (238 mg, 1.15 m*M*) in pyridine (5 ml), at 80°, a solution of α-phthalimidoacrylic acid (250 mg, 1.15 m*M*) in pyridine (10 ml) was slowly added over the course of 45 min. After stirring at 80–95° for a further 2 h, the solution was cooled to room temperature, diluted with chloroform (25 ml), and extracted with 2 *N* hydrochloric acid until the washings were strongly acidic (*ca.* 6 × 10 ml HCl), then with saturated aqueous sodium bicarbonate solution (3 × 10 ml). The chloroform extract was dried ($MgSO_4$), evaporated, and the residue recrystallized three times from 95% ethanol, affording colorless needles, 230 mg (325 mg after the first recrystallization), m.p. 162.5–165°; ν_{max} (KBr) 3345 (amide NH), 3030 (w) (>C=CH—), 1640 and 885 (>C=CH_2), 1615 and 735 (phthalimido aromatic), 2930 and 2855 (—CH_2—), 1795 (phthalimido asym CO str), 1770 (w), 1720, and 1715 (sh) (carbonyl CO), 1655 (amide CO), 1640 (possibly urea CO with double bond C=C str), and 1530 cm^{-1} (acyclic amide); τ ($CDCl_3$) 9.0–8.0 (2OH) (complex), *ca.* 6.4 (1H) (br, mult.), *ca.* 5.8 (1H) (br, mult.), 4.27 (1H) and 4.14 (1H) (d, d, J = 1.5 Hz) (vinylic methylene protons), 3.08 (1H) (br, d, J = 8 Hz) (NH), and 2.15 (4H) (mult.).

*The Reaction of Chlorine with 7a: Isolation of 3D-Carbomethoxy-2,2-dimethyl-5-oxo-6D-phthalimido-2,3,4,5-tetrahydro-1,4-thiazepine (**9**) and 3D-Carbomethoxy-7L-chloro-2,2-dimethyl-5-oxoperhydro-6D-phthalimido-1,4-thiazepine (**10**)*

(*a*) Under the conditions described by Leonard and Wilson (4), a reaction of 7*a* (200 mg) with chlorine in methylene chloride afforded, after p.l.c. of the product (two successive elutions with methyl formate–benzene, 1:4 (v/v)), a 55% yield of the tetrahydrothiazepine **9**, colorless needles from benzene–ether, m.p. 180–182°, ν_{max} (KBr) 3380 (lactam NH), 1780 and 1740 (phthalimido and ester CO), 1680 (lactam CO), 1620 (w, sh) (aromatic) and 1595 cm^{-1} (w) (—COC(=CH)—); λ_{max} 217 (ε 4.39 × 10^4), 229 (sh) (ε 2.58 × 10^4), 237 (sh) (ε 2.07 × 10^4), and 285 nm (ε 1.30 × 10^4); τ ($CDCl_3$) 8.50 (3H) (s), 8.45 (3H) (s) (>C(CH_3)$_2$), 6.13 (3H) (s) (—CO_2CH_3), 5.42 (1H) (d, J = 7 Hz) (C-3 methine), 3.20 (1H) (d, J = 7 Hz) (NH), 2.95 (1H) (s) (vinylic proton) and 2.17 (4H) (mult.); *m/e* 360 (M^+) (37), 132 (36), 104 (100), 98 (39), 76 (68), and 74 (35).

Anal. Calcd. for $C_{17}H_{16}N_2O_5S$: C, 56.65; H, 4.48; N, 7.77. Found (consistent with **10**): C, 56.84; H, 4.78; N, 7.92.

(*b*) In a second reaction of pure 7*a* (0.5 g, 1.38 m*M*) in methylene chloride (10 ml) with a carbon tetrachloride solution 0.52 *M* in chlorine (2.93 ml, 1.52 m*M*), stirring was maintained for 3 h at a reaction temperature of −77° and then for 1.5 h while the reaction mixture was allowed to warm to 0° when it was immediately evaporated to yield a colorless glass. The t.l.c. examination (R_f after elution with methyl formate–benzene, 1:3 (v/v)) of this crude product indicated the presence of unchanged 7*a* (R_f 0.25) and compound **10** (R_f 0.32), and only a trace of **9** (R_f 0.2). A minor contamination (R_f 0.45) was also present. Rapid chromatography on a column (1.8 × 18 cm) of Florisil (20 g), packed in benzene, and elution with ether–benzene (1:5 (v/v)) (and finally acetone), gave two main fractions.

Fraction 1, upon evaporation yielded a colorless glass, 230 mg, (R_f 0.32, containing a trace of a contaminant, R_f 0.45) which, when triturated with ether afforded colorless glassy crystals. These, after recrystallization from warm ethanol, had m.p. 160–163.5°, gave a positive Beilstein test for halogen, and had ν_{max} (KBr) 3370 (lactam NH), 1780 and 1725 (phthalimido and ester CO), 1670 (lactam CO), and 1610 (w) and 720 cm^{-1} (phthalimido aromatic); τ ($CDCl_3$) 8.81 (3H) (s), 8.20 (3H) (s) (>C(CH_3)$_2$), 6.11 (3H) (s) (—CO_2CH_3), 5.03 (1H) (d, J = 5.5 Hz), (C-3 methine), 4.75 (1H) and 4.47 (1H) (AB quartet, J_{AB} = 11.5 Hz) (C-6 and -7 methines), 3.24 (1H) (br) (NH), and 2.17 (4H) (mult.); *m/e* 396 (M^+) (1), 360 (28), 132 (39), 104 (100), 76 (69), and 74 (40); all consistent with the structure **10**.

Fraction 2 was evaporated to yield a residue, *ca.* 300 mg, which was a mixture (*ca.* 1:1) of 7*a* and **9** as judged by t.l.c. The appearance of **9** after chromatography on Florisil indicated that elimination of HCl had occurred during column chromatography.

The Reaction of Chlorine with Pure 8a: Isolation and Data on Compound 11a

A reaction, as above, of pure **8***a* (200 mg) with chlorine, led to a reaction mixture which, when cooled and diluted with CCl_4, deposited colorless plates, 20 mg, of **11***a*. The filtrate was subjected to p.l.c. (two successive elutions with methyl formate–benzene, 1:4 (v/v)) and yielded **9**, 41 mg (i.r. spectrum identical to **9** from *7a*), and impure fractions not further purified. Compound **11***a* recrystallized from ethanol as colorless plates, with m.p. 208–210.5° dependent on time of heating;[15] ν_{max} (KBr) 3500–3000 (several w–m bands), 1780 and 1750 (phthalimido CO), 1730 (ester CO), 1695 (lactam CO), 1615 and 715 (phthalimido aromatic), and 1034 cm^{-1} (s) (sulfoxide SO); τ ($CDCl_3$) 8.63 (3H) (s), 8.57 (3H) (s) ($>C(CH_3)_2$), 6.15 (3H) (s) ($—CO_2CH_3$), 6.50 (1H) (complex), 6.13 (1H) (complex), 4.87 (1H) (complex), 5.75 (1H) (d, $J = 7$ Hz, collapsing to a singlet after shaking with D_2O) (C-3 methine), 3.66 (br, d, $J = ca.$ 7 Hz disappearing on shaking with D_2O) (lactam NH), and 2.19 (4H) (mult.) (phthalimido aromatic protons); *m/e* 378 (M^+) (12), 329 (36), 221 (54), 200 (35.5), 173 (100), 172 (44), 130 (31.5), 104 (54), 76 (46), 70 (38), and 51 (40.5); consistent with **11***a* being a sulfoxide of *7a*, diastereomeric with the sulfoxide **11***b* on the basis of different i.r. spectra and t.l.c. behavior, yet closely similar mass spectra.

3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-1,4-thiazepine-1-monoxide (11b)

An aqueous solution (10 ml) of sodium periodate (256 mg, 1.2 m*M*) was added to a stirred suspension of 6L-phthalimido perhydrothiazepine **8***a* (400 mg, 1.1 m*M*) in methanol (25 ml) at room temperature. The suspension was stirred for 24 h then extracted with chloroform (4 × 10 ml). The combined chloroform extracts were dried ($MgSO_4$), evaporated, and the residue recrystallized twice from 95% ethanol affording colorless plates, m.p. 221.5–223.5°, 314 mg, in 75% yield; with λ_{max} (KBr) 3325 (lactam NH), 1795 and 1740 (phthalimido and ester CO), 1700 (lactam CO), 1620 and 719 (phthalimido aromatic), and 1040 cm^{-1} (sulfoxide SO); *m/e* 378 (M^+) (16), 360 (2), 329 (44.5), 297 (30), 221 (55), 200 (30.5), 173 (100), 172 (42.5), 104 (52), and 76 (44.5).

Anal. Calcd. for $C_{17}H_{18}N_2O_6S$: C, 53.95; H, 4.79; N, 7.40. Found: C, 53.57; H, 4.84; N, 7.54.

3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-1,4-thiazepine-1,1-dioxide (12)

A solution of potassium permanganate (5% w/v), in aqueous 80% (v/v) acetic acid (19 ml), was added quickly to 6L-phthalimidoperhydrothiazepine **8***a* (1 g). After stirring for 30 min excess permanganate was destroyed by the dropwise addition of 30% hydrogen peroxide, and water was added (*ca.* 50 ml). The colorless microneedles which deposited were collected, washed with water, and dried, affording 1.058 g, 97% yield, m.p. 269–274°; t.l.c. homogeneous (R_f 0.35 after elution with methyl formate–benzene, 3:7 (v/v)) with ν_{max} (KBr) 3310 (lactam NH), 1790 and 1750 (phthalimido CO), 1725 (ester CO), 1705 (sh) (lactam CO), 1330 and 1106 cm^{-1} (sulfone SO): *m/e* 394 (M^+) (5.5), 330 (5.5), 174 (58.5), and 173 (100); "metastable" *m/e* 276.5.

[15]The value quoted is optimum, obtained from *ca.* 5 min heating after insertion of sample at *ca.* 200°.

Anal. Calcd. for $C_{17}H_{18}N_2O_7S$: C, 51.77; H, 4.60; N, 7.10. Found: C, 51.07; H, 5.17; N, 6.83.

3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-N-chloro-1,4-thiazepine-1,1-dioxide (13)

A solution of **8***a* (0.5 g) in acetic acid (13 ml) containing *t*-butyl hypochlorite (2 ml) was allowed to stand at room temperature for *ca.* 36 h. Evaporation of the reaction mixture, under reduced pressure and finally in a vacuum desicator over KOH pellets and H_2SO_4, yielded a colorless glass, which gave a strongly positive active chlorine test, and had ν_{max} ($CHCl_3$) 1790 and 1770 (phthalimido CO), 1730 (ester and lactam CO), 1615 (w) and 710 cm^{-1} (phthalimido aromatic); τ ($CDCl_3$) 8.43 (3H) (s), 8.25 (3H) (s) ($>C(CH_3)_2$), 6.15 (3H) (s) ($—CO_2CH_3$), 6.60 (1H) (apparent q, $J_{AX} \leqslant 1$ Hz, $J_{AB} = 15$ Hz), 5.57 (1H) (q, $J_{BX} = 11.5$, $J_{AB} = 15$ Hz) (A and B quartets, respectively, for the C-7 geminal protons), 4.27 (1H) (apparent q, $J_{BX} = 11.5$, $J_{AX} \leqslant 1$ Hz) (C-6 methine), 4.60 (1H) (s) (C-3 methine), and 2.20 (4H) (mult.) (phthalimido aromatic protons); irradiation at τ 4.27 or 6.60 decoupled the B quartet centered at 5.57 to doublets $J = 15$ and $J = 11.5$ Hz respectively.

The Protolysis of 13

When **13** (50 mg) was refluxed in 2-propanol (10 ml) for 30 min and the suspension cooled for several hours at 0° then filtered, it afforded **12**, 45.5 mg (i.r. spectrum identical to authentic **12**).

The Reaction of 3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-N-chloro-1,4-thiazepine-1,1-dioxide (13) with Silver Carbonate

The *N*-chlorolactam **13** (prepared from 0.5 g of **12**) dissolved in anhydrous DMF (20 ml) was stirred with silver carbonate (2 g) and glass beads and the reaction vessel was inserted in an oil bath held at 45°. Within 3 min a negative active chlorine test was obtained. Filtration (Celite) and evaporation of the reaction mixture afforded a gummy crystalline solid, which was recrystallized from ethanol to give colorless needles, 234 mg, R_f 0.31 (on t.l.c. after elution with methyl formate–benzene, (30:70 v/v)), of **12** (identical t.l.c. R_f and i.r. spectra). The mother liquors had no trace of an i.r. absorption band for a β-lactam, but showed two major components on t.l.c. (R_f 0.75 and 0.29); these were separated by p.l.c. (one elution with methanol–chloroform, 10:90 (v/v)).

The higher R_f component was recrystallized from hexane and obtained as colorless needles, 25 mg, m.p. 83–86°; ν_{max} (KBr) 1780 (m) and 1735 (str) (phthalimido CO), and 1630 cm^{-1} (double bond); τ (CCl_4) 5.05 (1H) (d, $J_{cis} = 10$ Hz), 3.98 (1H) (d, $J_{trans} = 17$ Hz) ($—CH=CH_2$) and 3.17 (1H) (q, $J = 10$; $J = 17$ Hz) ($—CH=CH_2$); *m/e* 173 (M^+) (100), 104 (44), and 76 (57); "metastable" *m/e* 123, 62.5 (w), 55.5 and 33; consistent with the assignment of structure **14** to this product.

The lower R_f component was recrystallized from 95% ethanol to yield colorless needles, 30 mg, m.p. 173.5–176.5°; ν_{max} (KBr) 3260 (—NH), 1795 and 1740 (phthalimido CO), 1725 (ester CO, possibly conjugated), 1680 and 1530 (acyclic amide), 1635 and 884 cm^{-1} (methylene $>C=CH_2$); τ ($CDCl_3$) 8.04 (3H) (s), 7.77 (3H) (s) ($>C=C(CH_3)_2$)

6.23 (3H) (s) ($-CO_2CH_3$), 4.12 (1H) and 3.71 (1H) (2d, $J = 1.4$ Hz) ($>C=CH_2$), and 2.15 (4H) (mult.) (phthalimido protons); *m/e* 328 (M^+) (12), 200 (30.5), 173 (22.5), 172 (100), 128 (42), 104 (50.5), and 76 (31); "metastable" *m/e* 123 and 122–120.5, 93.5, and 50 (w); consistent with the structure **15**.

*The Action of White Light on 3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-N-chloro-1,4-thiazepine-1,1-dioxide (**13**)*

The *N*-chlorolactam **13** (prepared from 0.5 g of **12**) in refluxing benzene solution (50 ml) contained in a Pyrex flask was illuminated with a 300 W tungsten filament lamp under a steady stream of dry nitrogen, for 7 h, after which time all active chlorine had been lost. The reaction mixture was cooled to room temperature and then evaporated under reduced pressure to yield a colorless glass, with no ν_{max} ($CHCl_3$) assignable to a β-lactam carbonyl, and no ν_{max} 3050–4000, but ν_{max} 2255 cm^{-1} (isocyanate). The crude product was recrystallized from a small volume of hexane–ether affording colorless crystals, 180 mg, m.p. 76–83° after one further recrystallization from hexane, identified as phthalimidoethylene (**14**) (the i.r. spectrum was identical to that of **14** obtained as described above). The mother liquors from the above recrystallization were evaporated, affording an oil which had ν_{max} ($CHCl_3$) 2255 cm^{-1}. After boiling with ethanol and evaporating an oil was obtained with ν_{max} ($CHCl_3$) 3440 (NH), 1785 (w) and 1750 (sh), 1725 (carbonyl), and 1510 cm^{-1} (possibly acyclic amide band); τ (CCl_4) 8.74 (3H) (t, $J = 7$ Hz) ($-OCH_2CH_3$), 8.38 (3H) (s), 8.30 (3H) (s) ($>C(CH_3)_2$), 6.23 (3H) (s) ($-CO_2CH_3$), 5.90 (2H) (q, $J = 7$ Hz) ($-OCH_2CH_3$), 5.60 (1H) (d, $J = 10$ Hz) ("C-3" methine), and 4.51 (1H) (d, broadened *J ca.* 9 Hz) (NH); *m/e* 275 (0.16), 273 (M^+) (0.5), 180 (15.5), 178 (50), 161 (46), 160 (73), 129 (39.5), 88 (100), 70 (51), 56 (55), 45 (34.5), 43 (38), and 41 (44); consistent with this product being the ethyl urethane corresponding to **16**.

*The Reaction of 3D-Carbomethoxy-2,2-dimethyl-5-oxoperhydro-6L-phthalimido-N-chloro-1,4-thiazepine-1,1-dioxide (**13**) with Some Bases*

A solution of **13** (75 mg, 0.17 m*M*) and anhydrous sodium carbonate (19 mg, 0.185 m*M*) in anhydrous DMF (10 ml) was stirred at room temperature for 1.5 h, then evaporated and the residue extracted into chloroform. Evaporation of the filtered chloroform solution and recrystallization of the residue from 95% ethanol afforded colorless needles; 15 mg of **12**. Evaporation of the mother liquors yielded a residue, 22 mg, which was recrystallized from benzene–petroleum ether (b.p. 65–110°) affording colorless crystals, 8 mg, m.p. 166–170°, identified as **15** (i.r. spectral comparison). No β-lactam carbonyl band was detected in the i.r. spectrum of any of the reaction product fractions, crude or pure.

A similar reaction of **13** with potassium fluoride over 6 h resulted in the isolation of the same products as above.

The work described here was supported in part by an operating grant from the National Research Council of Canada, whom we also thank for the award of a Research Scholarship (1968–1969) to R.E.M.

We are indebted to a referee for drawing our attention to ref. 6, and to Dr. Lillya who most courteously made available to us a copy of his thesis.

Base-catalyzed Degradations of Carbohydrates. II. β-Elimination Reactions of 4-*O*-Substituted Methyl (Methyl 2,3-Di-*O*-methyl-β-D-glucopyranosid)uronates[1]

G. O. ASPINALL[2] AND P. E. BARRON

Department of Chemistry, Trent University, Peterborough, Ontario

Received February 21, 1972

The action of various bases on the three hexuronic esters, methyl (methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosid)uronate (**12**), methyl (methyl 4-*O*-methanesulfonyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**13**), and methyl (methyl 4-*O*-acetyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**14**), leading to elimination of the 4-*O*-substituents and formation of methyl (methyl 4-deoxy-2,3-di-*O*-methyl-α-L-*threo*-hex-4-enopyranosid)uronate (**15**) has been studied. It is concluded that effectiveness of 4-*O*-substituents as leaving groups is in the sequence, methanesulfonyloxy > acetoxy > methoxy.

L'action de diverses bases sur trois esters hexuroniques (méthyl tri-*O*-méthyl-2,3,4-β-D-glucopyranoside) uronate de méthyle (**12**), (méthyl *O*-méthanesulfonyl-4 di-*O*-méthyl-2,3-β-D-glucopyranoside) uronate de méthyle (**13**), et le (méthyl *O*-acétyl-4 di-*O*-méthyl-2,3-β-D-glucopyranoside) uronate de méthyle (**14**) qui mène à l'élimination des *O*-substituants en 4 avec formation du (méthyl déoxy-4 di-*O*-méthyl-2,3-α-L-*thréo*-hexèno-4 pyranoside) uronate de méthyle (**15**) a été étudiée. On a conclu que l'ordre d'efficacité des *O*-substituants en 4 en tant que "leaving group" suit la séquence méthanesulfonyloxy > acétoxy > méthoxy.

Canadian Journal of Chemistry, **50**, 2203 (1972)

Neukom (1, 2), Northcote (3, 4), Rees (5, 6), Kiss (7, 8) and their collaborators have shown that esterified hexuronates are susceptible to base-catalyzed degradation with the formation of unsaturated hexuronates and with the exposure of new reducing groups. When reaction is performed in aqueous solution competing ester hydrolysis occurs with loss of the driving force of the carboalkoxy group towards elimination, and only limited degradation is achieved. This difficulty may be partially overcome by using a non-aqueous system such as sodium methoxide in methanol, in which instance the ester function is regenerated by base-catalyzed ester exchange. The value of this approach in obtaining new structural information on polysaccharides has been demonstrated by Rees and co-workers (6) in studies on colanic acid. Nevertheless, the full potential of this type of reaction for the degradation of polysaccharides has not been realized because of the limited solubility of the substrates, unless etherified or esterified, in non-aqueous solvents. 4-*O*-Substituted methyl (methyl 2,3-di-*O*-methyl-β-D-glucopyranosid)-uronates (**12**, **13**, **14**) have been prepared, and the action of bases on these compounds has been studied in order to assess the relative effectiveness of 4-*O*-substituents as leaving groups in the β-elimination reaction. The 4-*O*-acetyl (**14**) and 4-*O*-methyl (**12**) derivatives provide models for the behavior of D-glucuronic acid end groups in acetylated or methylated polysaccharides.

The well-known methyl (methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosid)uronate (**12**) was most satisfactorily prepared from methyl 6-*O*-trityl-β-D-glucopyranoside (**1**) by successive methylation, de-*O*-tritylation, oxidation with chromium trioxide and sulfuric acid in acetone (9), and esterification with diazomethane. The other hexuronates were prepared from methyl 2,3-di-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**3**). Thus, the trityl ether (**3**) was mesylated, de-*O*-tritylated, oxidized with chromium trioxide and sulfuric acid in acetone, and esterified with diazomethane to give methyl (methyl 4-*O*-mesyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**13**). A similar sequence of reactions furnished methyl (methyl 4-*O*-acetyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**14**).

Treatment of methyl (methyl 4-*O*-mesyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**13**) with sodium methoxide in methanol or ethanolic potassium hydroxide, as described by Kiss (10) for the preparation of related unsaturated

esters, gave the crystalline unsaturated ester, methyl (methyl 4-deoxy-2,3-di-*O*-methyl-α-L-*threo*-hex-4-enopyranosid)uronate (**15**), in 84–87% isolated yield. The structure of the ester was fully supported by u.v., i.r., n.m.r., and mass spectra. The ease with which β-elimination of methanesulfonic acid takes place with formation of the unsaturated hexuronate (15) when the mesyl ester (**13**) is treated with base was strikingly emphasized during g.l.c. examination of the mesyl ester (**13**). Whereas g.l.c. of the mesyl ester (**13**) on a column coated with neutral silicone gum SE-30 gave a single peak of substantially higher retention time than that of the unsaturated ester (**15**), g.l.c. on a column coated with the nitrile silicone gum XE-60 as liquid phase gave a single peak of the same retention time as the unsaturated ester (**15**). Gas–liquid chromatography – mass spectrometry supported the conclusion that unsaturated ester had been formed on the g.l.c. column.

Bases chosen for the study of their action on the acetylated (**14**) and methylated (**12**) esters were either those of low nucleophilicity towards ester functions which would catalyze elimination with minimum de-esterification or those which would regenerate hexuronic ester functions by base-catalyzed ester exchange although in the latter case de-*O*-acetylation of the 4-*O*-acetate could take place. The results are summarized in Tables 1 and 2.

Treatment of the acetylated ester (**14**) with DBU (1,5-diazabicyclo[5.4.0]undec-5-ene) in benzene at room temperature afforded the crystalline unsaturated ester (**15**) in 83% isolated yield.[3] The unsaturated ester (**15**) was also isolated in 66% yield as the major detectable product when the acetylated ester (**14**) was treated with sodium hydride in ether. The effect of other bases on the acetylated ester was studied only in small-scale experiments in which products were analyzed by g.l.c. and t.l.c. Treatment of the ester (**14**) with methanolic sodium methoxide resulted in both de-*O*-acetylation and β-elimination. This observation has significance for studies on polysaccharides since the reaction conditions, which are those commonly used for the de-*O*-acylation of acylated derivatives, could result in structural modification of hexuronic ester residues. It was also observed that treatment of the acetylated ester (**14**) with acetic anhydride and potassium acetate at 100° caused some β-elimination. A similar observation was made previously by Schmidt and Neukom (11). Although these conditions are harsher than those which need be used for acetylation it is clear that care should be exercized in the acetylation of carbohydrates containing hexuronic ester units lest inadvertent degradation takes place. Alkali metal fluorides may act as strong bases in dipolar aprotic solvents (12), and some β-elimination was observed on prolonged treatment of the acetylated ester (**14**) with cesium fluoride in methyl sulfoxide at room temperature. In contrast, the unusually strong organic base, 1,8-bis (*N*,*N*-dimethylamino)naphthalene (13), was without effect on the acetylated ester (**14**).

The crystalline unsaturated ester (**15**) was isolated in 58% yield on treatment of the methylated ester (**12**) with methylsulfinyl carbanion in methyl sulfoxide. An unknown substance was formed as a minor reaction product and a substance of similar retention time was also detected amongst the products from the action of potassium *t*-butoxide in methyl sulfoxide on the methylated ester (**12**) but in neither

[3]Recently, Llewellyn and Williams (23) have reported a similar reaction of a 4-*O*-acetyl hexuronic ester with DBU.

[a]See footnote to Table 1.
[b]C, D, and E are unidentified compounds whose relative retention times are quoted in the Experimental section; C* and D* have the same relative retention times as C and D respectively but no other criteria of identity are yet available.
[c]No reaction was observed under the following conditions: (*i*) Ac_2O/NaOAc, 9 days, r.t.; (*ii*) Ac_2O/KOAc, 24 h, 100°; (*iii*) bis(DMA)N/benzene, 10 days r.t.; (*iv*) bis(DMA)N/DMF, 7 days, r.t.; (*v*) DBU/benzene, 9 days, r.t.; (*vi*) DBU/DMF, 7 days, r.t.; (*vii*) CsF/DMSO, 7 days, r.t.; (*viii*) MeI/Ag_2O, 3 days, 35°; (*ix*) MeI/Ag_2O/DMF, 8 days, r.t.; (*x*) NaH/benzene, 4 h, r.t.; (*xi*) NaH/ether, 70 min, r.t.

case was it possible to obtain definite evidence for structure. It was noted, however, that the unsaturated ester (**15**) remained unchanged on treatment with methylsulfinyl carbanion in methyl sulfoxide. Of other bases examined only sodium methoxide in methanol caused formation of the unsaturated ester (**15**) from the methylated ester (**12**). Yoshimura and coworkers (14) have shown that when methyl (methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranosid)uronate is treated with sodium methoxide in methanol under a variety of conditions less than 50% conversion into the corresponding unsaturated ester is achieved and that some of the original ester is saponified. In our hands similar treatment of the β-anomer (**12**) with methanolic sodium methoxide in the presence of 2,2-dimethoxypropane to remove traces of water (5) still led to the formation of acidic products. In addition g.l.c. showed that unsaturated ester (**15**) was formed together with two unknown compounds, but under none of the conditions used was methylated ester completely transformed to other products. Treatment of the methylated ester with potassium *t*-butoxide in methyl sulfoxide proceeded to completion with formation of the unsaturated ester as the major product and two unidentified substances as minor products. The absence of detectable β-elimination when the methylated ester (**12**) was treated with silver oxide in methyl iodide alone or with silver oxide and methyl iodide in *N*,*N*-dimethylformamide is significant in view of the widespread use of the Purdie (15) and Kuhn (16) procedures for the methylation of carbohydrates.

The results of these studies on the three 4-*O*-substituted methyl (methyl 2,3-di-*O*-methyl-β-

D-glucopyranosid)uronates clearly indicate that mesylate > acetate > methoxide represents the order of effectiveness of leaving groups in base-catalyzed β-eliminations leading to formation of the unsaturated hexuronate (**15**). A full assessment of the potential degradative applications of β-elimination reactions on interior units within acidic polysaccharide chains cannot be made until the effectiveness of 4-*O*-glycosyl substituents has been examined. Model experiments, presently in progress, will assess both the initial elimination and the effect of bases on the reducing sugar residues which may be exposed as a consequence of such eliminations.

Experimental

Melting points are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter at $20 \pm 2°$. The i.r. and u.v. spectra were measured on Unicam SP 200 and SP 800A spectrophotometers. The n.m.r. spectra were recorded on a JEOL C-60HL spectrophotometer with tetramethylsilane as internal standard. The t.l.c. was performed with Kieselgel HF 254 as the adsorbent and the dried plates were sprayed with ethanol containing 5% of sulfuric acid and 5% of 1-naphthol and heated at about 150°. Solvent systems used for t.l.c. were chloroform–acetone (20:1 and 4:1) and benzene – light petroleum (b.p. 30–60°) (5:1). Preparative layer separations were performed using ether – light petroleum (b.p. 30–60°) (5:1). Column chromatography was carried out on silica gel (Davison grade 950, 60–200 mesh). Unless otherwise stated light petroleum refers to the fraction of b.p. 30–60°. Solutions were concentrated below 50° under reduced pressure.

Mass spectra were recorded on an A.E.I. MS 12 mass spectrometer, with an ionization potential of 70 eV. The g.l.c. was performed with a Hewlett–Packard model 5750 chromatograph using columns of dichlorodimethylsilane-treated Celite coated with (*a*) 5% of silicone gum XE-60 (operating temperature 150°) and (*b*) 5% of neopentylglycol adipate polyester (operating temperature 200°). For g.l.c. – mass spectrometry column *a* was used in a Pye 104 chromatograph and attached to the mass spectrometer via a Watson–Biemann separator. The mass spectra were recorded at an inlet temperature of 200°, an ionization temperature of 70 eV, and an ion source temperature of *ca.* 150°. Retention times (R_{Me}) of methyl (methyl glycopyranosid)uronates are quoted relative to methyl (methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosid)uronate (**12**).

Methyl (Methyl 2,3,4-Tri-O-methyl-β-D-glucopyranosid)-uronate (12)

Sodium hydride (22 g) was added with stirring to methyl 6-*O*-trityl-β-D-glucopyranoside (**1**) (17) (17.15 g) in *N*,*N*-dimethylformamide (350 ml) at 0°, and the mixture was stirred for 20 min. Methyl iodide (90 ml) was added dropwise during 15 min to the cooled solution, and the mixture was kept at room temperature for 18 h. The t.l.c. showed that reaction was complete and methanol was added to destroy excess of sodium hydride. Insoluble material was removed by filtration, the filtrate was concentrated to remove methanol and diluted with chloroform, and the chloroform solution was washed with water, dried, and concentrated to give crude methyl 2,3,4-tri-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**2**) (14.4 g, 76.6%), $[\alpha]_D$ −95° (*c*, 2.0 in chloroform); n.m.r. data ($CDCl_3$): τ 2.52–2.97 (15-proton multiplet, trityl), 5.91 (1-proton doublet, splitting 7 Hz, H-1), 6.47 (9-proton singlet, 3 OMe), 6.78 (3-proton singlet, OMe).

Hydrogen bromide (40–45%) in acetic acid (6.5 ml) was added with stirring to the foregoing trityl ether (**2**) (14.1 g) in acetic acid (25 ml). After 3 min trityl bromide was removed by filtration, and the filtrate was poured with stirring into ice-cold, saturated, aqueous solid sodium hydrogen carbonate. Solid material was removed by filtration, the filtrate was extracted with chloroform (3 × 250 ml), and the chloroform solution was washed with saturated sodium hydrogen carbonate solution and twice with water, dried and concentrated to give a crystalline residue. Recrystallization from light petroleum (b.p. 40–65°) – ether (19:1) afforded methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**6**) (5.29 g, 76%), m.p. 92–94°, $[\alpha]_D$ −24.2° (*c*, 2.0 in methanol) (lit. (18); m.p. 93–94°, $[\alpha]_D$ −22.9° (methanol)); ν_{max} (Nujol) 3520 cm^{-1} (OH); n.m.r. data ($CDCl_3$): τ 5.89 (1-proton doublet, splitting 7 Hz, H-1), 6.43 (3-proton singlet, C-1 OMe), 6.48–6.53 (3 × 3-proton singlets, 3 OMe).

Chromium trioxide (4.21 g) in 3.75 *N* sulfuric acid (20 ml) was added dropwise with stirring to methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**6**) (3.6 g) in acetone (20 ml) at 5°. After 2 h at room temperature the reaction mixture was poured into ethanol (200 ml) containing ice and the supernatant liquid was decanted from the inorganic deposit into water. The aqueous solution was extracted with chloroform (12 × 100 ml) until the aqueous layer gave only a faint Molisch test. The chloroform extracts were washed once with water, dried, and concentrated to a crystalline residue which was recrystallized from ether – light petroleum (b.p. 30–60°) to yield methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosiduronic acid (**9**) (2.58 g, 77%), m.p. 132–134°, $[\alpha]_D$ −37.1° (*c*, 1.0 in water) (lit. (19); m.p. 133°, $[\alpha]_D$ −38° (water)); ν_{max} (Nujol) 2800 (broad), 1710 cm^{-1} (CO_2H).

Diazomethane (0.055 g) in ether (20 ml) was added with swirling to the foregoing acid (**9**) (0.25 g) in ether (10 ml). The t.l.c. showed complete disappearance of the acid after a few minutes. Concentration of the solution gave a crystalline mass which was recrystallized from light petroleum to give methyl (methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranosid)uronate (**12**) (0.248 g, 94%), m.p. and mixed m.p. 52–53°, $[\alpha]_D$ −36.4°; ν_{max} (Nujol) 1750 cm^{-1} (ester C=O); n.m.r. data ($CDCl_3$): τ 5.88 (1-proton doublet, splitting 7 Hz, H-1), 6.25 (3-proton singlet, ester OMe), 6.45, 6.50, 6.53, 6.57 (4 × 3-proton singlets, 4 OMe). The g.l.c. showed that the ester was anomerically pure. The mass spectra of the ester by direct insertion on the probe and by g.l.c. – mass spectrometry were identical with that reported by Kováčik *et al.* (20) [M^+, 264].

Methyl 2,3-Di-O-methyl-6-O-trityl-β-D-glucopyranoside (3)

Methyl 2,3-di-*O*-methyl-β-D-glucopyranoside (**21**) (12.7 g) and trityl chloride (16.0 g) in pyridine (100 ml) were heated on a boiling-water bath for 1 h and kept at room temperature for 48 h. Water (3 ml) was added to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solution which was kept for 1 h before being poured into ice-water to give a gummy deposit which was dissolved in chloroform. The chloroform solution was washed with water, dried, and concentrated with repeated addition of toluene in order to remove pyridine to give a syrup (28.2 g) which was shown by t.l.c. to contain the desired trityl ether and tritanol. Chromatography of the syrup on silica gel (1000 g) with light petroleum (b.p. 30–60°)–ether (2:1) as eluant to give methyl 2,3-di-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**3**) (24.7 g, 93.2%) as a glassy solid, $[\alpha]_D$ −36.7° (*c*, 2.0 in chloroform) (lit. (22); $[\alpha]_D$ −35° (chloroform)) ν_{max} (Nujol) 3600 cm^{-1} (OH); n.m.r. data ($CDCl_3$): τ 2.52–2.97 (15-proton multiplet, trityl), 5.87 (1-proton doublet, splitting 7 Hz, H-1), 6.47, 6.48 (9 protons, 3 OMe).

*Methyl 4-O-Mesyl-2,3-di-O-methyl-6-O-trityl-β-D-glucopyranoside (**4**)*

The trityl ether (**3**) (9.53 g) was treated with methanesulfonyl chloride (2.0 ml) in pyridine (50 ml) for 14 h at room temperature. The mixture was poured into ice-water, saturated aqueous sodium hydrogen carbonate was added with vigorous stirring, the separated syrup was dissolved in chloroform, and the aqueous solution was extracted with chloroform. The combined chloroform extracts were washed with water, dried, and concentrated to a yellow syrup. Chromatography of the syrup on silica gel with chloroform as eluant gave methyl 4-*O*-mesyl-2,3-di-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**4**) (10.4 g, 93%) as a syrup, $[\alpha]_D$ −10.8° (*c*, 2.0 in chloroform) (lit. (22); $[\alpha]_D$ −12° (chloroform)); ν_{max} (film) 1335, 1180 cm^{-1} (S=O); n.m.r. data ($CDCl_3$): τ 2.45–3.00 (15-proton multiplet, trityl), 5.87 (1-proton doublet, splitting 7 Hz, H-1), 6.45 (9-proton singlet, 3 OMe), 7.33 (3-proton singlet, mesyl).

*Methyl 4-O-Mesyl-2,3-di-O-methyl-β-D-glucopyranoside (**7**)*

Hydrogen bromide (40–45%) in acetic acid (4.6 ml) was added to the preceding mesyl ester (**4**) (10.22 g) in acetic acid (25 ml) and after 3 min trityl bromide was removed by filtration and the filtrate was worked-up in the usual way to give a crystalline solid (4.79 g) which was recrystallized from ether – light petroleum (b.p. 30–60°) to furnish methyl 4-*O*-mesyl-2,3-di-*O*-methyl-β-D-glucopyranoside (**7**) (4.40 g, 81.1%), m.p. 84.5–85.5°, $[\alpha]_D$ −29.4° (*c*, 2.0 in chloroform) (lit. (22); m.p. 85.5–86.5°, $[\alpha]_D$ −28° chloroform)); ν_{max} (Nujol) 3530 (OH), 1350, 1185 cm^{-1} (S=O); n.m.r. data ($CDCl_3$): τ 5.85 (1-proton doublet, splitting 7 Hz, H-1), 6.42, 6.46, 6.49 (3 × 3-proton singlets, 3 OMe), 6.89 (3-proton singlet, mesyl).

Anal. Calcd. for $C_{10}H_{20}O_8S$: C, 39.9; H, 6.71; S, 10.68. Found: C, 39.88; H, 6.84; S, 10.52.

*Methyl 4-O-Mesyl-2,3-di-O-methyl-β-D-glucopyranosiduronic acid (**10**)*

Chromium trioxide (1.20 g) in 3.75 *N* sulfuric acid was added dropwise with stirring to the mesyl ester (**7**) (1.20 g) in acetone at 5°, and the mixture was kept at room temperature for 2.5 h. The reaction mixture was neutralized with solid sodium hydrogen carbonate and extracted with chloroform (4 × 75 ml). The aqueous solution was acidified to p*H* 2 and extracted with chloroform (10 × 100 ml) until the aqueous layer gave only a faint Molisch test. The dried chloroform extract was concentrated to a crystalline residue which was recrystallized from ether – light petroleum (b.p. 30–60°) to give methyl 4-*O*-mesyl-2,3-di-*O*-methyl-β-D-glucopyranosiduronic acid (**10**) (1.05 g, 83.3%), m.p. 93–95°, $[\alpha]_D$ +10° (*c*, 2.0 in chloroform); ν_{max} (Nujol) 1740 (acid C=O), 1360, 1180 cm^{-1} (S=O); n.m.r. data ($CDCl_3$): τ 2.25 (1-proton, broad, CO_2H), 5.78 (1-proton doublet, splitting 7 Hz, H-1), 6.44, 6.47, 6.52 (3 × 3-proton singlets, 3 OMe), 6.97 (3-proton singlet, mesyl).

Anal. Calcd. for $C_{10}H_{18}O_9S$: C, 38.11; H, 5.77; S, 10.20. Found: C, 37.91; H, 5.82; S, 10.09.

*Methyl (Methyl 4-O-Mesyl-2,3-di-O-methyl-β-D-glucopyranosid)uronate (**13**)*

Diazomethane (0.15 g) in ether (5 ml) was added with swirling to the mesylated acid (**10**) (0.98 g) in ether (20 ml). The t.l.c. showed that reaction was complete after a few min, and work-up of the solution followed by recrystallization from ethanol gave methyl (methyl 4-*O*-mesyl-2,3-di-*O*-methyl-β-D-glucopyranosid)uronate (**13**) (0.96 g, 94%), m.p. 110–112°, $[\alpha]_D$ −31.6° (*c*, 2.0 in chloroform); ν_{max} (Nujol) 1750 (ester C=O), 1340, 1180 cm^{-1} (S=O); n.m.r. data ($CDCl_3$): τ 5.87 (1-proton doublet, splitting 7 Hz, H-1), 6.27 (3-proton singlet, ester OMe), 6.46, 6.50, 6.54 (3 × 3-proton singlets, 3 OMe), 6.99 (3-proton singlet, mesyl); M^+, 328.

Anal. Calcd. for $C_{11}H_{20}O_9S$: C, 40.24; H, 6.14; S, 9.77. Found: C, 40.11; H, 6.16; S, 9.64.

The g.l.c. on a column coated with silicone gum SE-30 at 152° showed that the ester was homogeneous (R_{Me} 3.16) and g.l.c. – mass spectroscopy, using the same column, gave a mass spectrum identical with that obtained by direct insertion on the probe (found: M^+, 328). The g.l.c. on column *a* gave a single peak of the same retention time (R_{Me} 1.31) as the unsaturated ester, methyl (methyl 4-deoxy-2,3-di-*O*-methyl-α-L-*threo*-hex-4-enopyranosid)uronate(**15**). The g.l.c. – mass spectrometry showed that this component gave a mass spectrum identical with that of the unsaturated ester (**15**) (Found: M^+, 232).

*Methyl 4-O-Acetyl-2,3-di-O-methyl-6-O-trityl-β-D-glucopyranoside (**5**)*

Methyl 2,3-di-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**3**) (9.36 g) and acetic anhydride (2.3 ml) in pyridine (50 ml) were kept at room temperature for 14 h, when t.l.c. showed that reaction was complete. The mixture was poured into ice-water containing solid sodium hydrogen carbonate and the gummy deposit which separated was dissolved in chloroform. The chloroform solution was washed with saturated sodium hydrogen carbonate solution and with water, dried, and concentrated to give methyl 4-*O*-acetyl-2,3-di-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**5**) (9.53 g, 93.4%), $[\alpha]_D$ −2.1° (*c*, 2.0 in chloroform), as a pale yellow syrup; ν_{max} (film) 1745, 1225 cm^{-1} (acetate); n.m.r. data ($CDCl_3$): τ 2.55–3.00 (15-proton multiplet, trityl), 6.43, 6.47, 6.57 (3 × 3-proton singlets, 3 OMe), 8.24 (3-proton singlet, OAc). The sample prepared for analysis crystallized on standing at 0° and had m.p. 92–94°.

Anal. Calcd. for $C_{30}H_{34}O_7$: C, 71.12; H, 6.76. Found: C, 71.16; H, 6.79.

*Methyl 4-O-Acetyl-2,3-di-O-methyl-β-D-glucopyranoside (**8**)*

Hydrogen bromide (40–45%) in acetic acid (4.3 ml) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

added to the foregoing acetylated trityl ether (**5**) (8.95 g) and after 3 min trityl bromide was removed by filtration and the reaction mixture was worked-up in the usual way to give a crystalline residue (3.90 g). The t.l.c. indicated the presence of a major component and two faster moving minor components. Column chromatography on silica gel with chloroform–ether (2:1) as eluant followed by recrystallization from ether – light petroleum (b.p. 30–60°) afforded methyl 4-*O*-acetyl-2,3-di-*O*-methyl-β-D-glucopyranoside (**8**) (3.48 g, 75%), m.p. 84.0–84.5°, $[\alpha]_D$ −57.1° (*c*, 2.0 in chloroform); ν_{max} (Nujol) 3480 (OH), 1735 cm^{-1} (ester C=O); n.m.r. data ($CDCl_3$): τ 5.84 (1-proton doublet, splitting 7 Hz, H-1), 6.40, 6.46, 6.49 (3 × 3-proton singlets, 3 OMe), 7.91 (3-proton singlet, OAc).

Anal. Calcd. for $C_{11}H_{20}O_7$: C, 50.00; H, 7.63. Found: C, 50.50; H, 7.69.

Methyl 4-O-Acetyl-2,3-di-O-methyl-β-D-glucopyranosiduronic acid (11)

Chromium trioxide (1.80 g) in 3.75 *N* sulfuric acid was added dropwise with stirring to the acetate (**8**) (1.57 g) in acetone (8 ml) at 5° and the mixture was stirred at room temperature for 2 h. The reaction mixture was neutralized with solid sodium hydrogen carbonate and extracted with chloroform. The aqueous solution was acidified to p*H* 2 and extracted with chloroform (10 × 100 ml) until the aqueous layer gave only a faint Molisch test. The chloroform extract was dried and concentrated to a pale yellow syrup which crystallized on standing. Recrystallization from ether – light petroleum (b.p. 30–60°) furnished methyl 4-*O*-acetyl-2,3-di-*O*-methyl-β-D-glucopyranosiduronic acid (**11**) (1.23 g, 75%), m.p. 101–103°, $[\alpha]_D$ −46.8° (*c*, 2.0 in chloroform); ν_{max} (Nujol) 1735, 1235 (acetate), 1700 cm^{-1} (shoulder) (CO_2H); n.m.r. data ($CDCl_3$): τ 0.22 (1-proton singlet, CO_2H), 5.73 (1-proton doublet, splitting 7 Hz, H-1), 6.44, 6.46, 6.49 (3 × 3-proton singlets, 3 OMe), 7.91 (3-proton singlet, OAc).

Methyl (Methyl 4-Deoxy-2,3-di-O-methyl-α-L-threo-hex-4-enopyranosid)uronate (15)

(*a*) Methanolic 1.14 *N* sodium methoxide (0.75 ml) was added with swirling to the mesylated ester (**13**) (0.25 g) in methanol (5 ml). After 5 min sodium methanesulfonate began to precipitate and after 20 min the reaction mixture was only slightly alkaline. Benzene (25 ml) was added and the solution was filtered and concentrated to a syrup which crystallized on standing. Recrystallization from cyclohexane furnished methyl (methyl 4-deoxy-2,3-di-*O*-methyl-α-L-*threo*-hex-4-enopyranosid)uronate (**15**) (0.154 g, 87%), which was homogeneous on g.l.c. and t.l.c. and had m.p. 51–53°, $[\alpha]_D$ +48° (*c*, 2.0 in methanol); ν_{max} (Nujol) 1735 (ester C=O), 1635 cm^{-1} (C=C); λ_{max} (MeOH) 236 nm (ε 6200); n.m.r. data ($CDCl_3$): τ 3.83 (1-proton doublet, splitting 4 Hz, H-4), 5.07 (1-proton doublet, splitting 4 Hz, H-1), 6.26 (3-proton singlet, ester methoxyl), 6.50, 6.53, 6.60 (3 × 3-proton singlets, 3 OMe); M^+, 232; g.l.c. – mass spectrometry of the ester gave a spectrum (M^+, 232) identical to that obtained by direct insertion on the probe.

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94. Found: C, 51.66; H, 6.99.

(*b*) Ethanolic 0.5 *N* potassium hydroxide (1.1 ml) was added with swirling to the mesylated ester (**13**) (0.156 g) in ethanol (5 ml). After 10 min potassium methanesulfonate had precipitated and after 30 min the reaction mixture was only slightly alkaline. Benzene (20 ml) was added and the solution was filtered, concentrated, and recrystallized from cyclohexane to give the unsaturated ester (**15**) (0.092 g, 83.6%), m.p. and mixed m.p. 51–52°, $[\alpha]_D$ +48.5° (*c*, 2.0 in methanol); ν_{max} (Nujol) 1735 (ester C=O), 1635 cm^{-1} (C=C); λ_{max} 236 nm (ε 6170); M^+, 232.

(*c*) Sodium hydride (11 mg) in ether (5 ml) was added to the acetylated ester (**14**) (0.085 g) in ether (10 ml) and the mixture was stirred vigorously at room temperature for 70 min. A calculated quantity (1.2 *M* excess with respect to hydride) of benzoic acid (1.1 mg/ml) in ether was added to destroy excess of hydride. The solution was shaken with saturated aqueous sodium hydrogen carbonate, dried, and concentrated to a syrup. The t.l.c. showed the presence of a major component with the mobility of the unsaturated ester (**15**), traces of starting material (**13**), and a minor component of lower mobility. The g.l.c. on column *a* showed that the major component had the retention time (R_{Me} 1.32) of the unsaturated ester (**15**) and that a trace of starting material (R_{Me} 4.15) was present while g.l.c. – mass spectrometry of the major component gave a mass spectrum identical with that of the unsaturated ester (**15**). The syrup was separated by preparative layer chromatography to give the unsaturated ester (**15**) (0.044 g, 66%), m.p. and mixed m.p. 51–53°, whose i.r. and n.m.r. spectra were identical with those of previously prepared samples.

(*d*) 1,5-Diazabicyclo[5.4.0]undec-5-ene (0.020 g) was added to the acetylated ester (**14**) (0.130 g) in benzene (2.5 ml), and the solution was kept at room temperature for 5 days when t.l.c. indicated disappearance of starting material and g.l.c. on column *a* showed the presence of unsaturated ester (R_{Me} 1.35) as the major component together with an unknown substance (R_{Me} 1.78). The solution was neutralized by the addition of methanolic hydrogen chloride, diluted with chloroform, washed with water, dried, and concentrated to a syrup (0.094 g). The syrup was separated by preparative layer chromatography and the major fraction was recrystallized from cyclohexane to give the unsaturated ester (**15**) (0.085 g, 83%), m.p. and mixed m.p. 50–52°, which was homogeneous on t.l.c. and g.l.c.

(*e*) Sodium hydride (0.026 g) was dissolved in methyl sulfoxide (10 ml) and the solution of the methylsulfinyl carbanion was added slowly with stirring to the methylated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ester (**12**) (0.238 g) in methyl sulfoxide (15 ml) and the reaction mixture was kept at room temperature for 4 h when t.l.c. showed complete disappearance of starting material and g.l.c. on column *a* indicated the formation of unsaturated ester (R_{Me} 1.35) and an unknown substance C (R_{Me} 1.54). The reaction mixture was neutralized by the addition of a slight excess of 0.033 *N* hydrochloric acid, excess of acid was destroyed with sodium hydrogen carbonate, and the solution was extracted twice with chloroform. The dried chloroform extract was concentrated to a syrup which was separated by preparative layer chromatography to give a semi-crystalline material which was recrystallized from cyclohexane to give the unsaturated ester (**15**) (0.122 g, 58%), m.p. and mixed m.p. 51–53°, $[\alpha]_D$ +47° (*c*, 2.0 in methanol); ν_{max} (Nujol) 1740 (ester C=O), 1650 cm^{-1} (C=C); λ_{max} 236 nm (ε 6140); whose n.m.r. and mass spectra were identical to those of previously prepared samples.

A sample of the unsaturated ester (**15**) was treated with methylsulfinyl carbanion in methyl sulfoxide under the above conditions. The g.l.c. showed unchanged starting compound and no other detectable product.

*Action of Other Bases on Methyl (Methyl 4-O-Acetyl-2,3-di-O-methyl-β-D-glucopyranosid)uronate (**14**)*

Methanolic 1.42 *N* sodium methoxide (0.30 ml) containing 5% of 2,2-dimethoxypropane was added to acetylated ester (**14**) (0.017 g) in methanol (1 ml) containing 5% of 2,2-dimethoxypropane and the reaction mixture was kept at room temperature. Aliquot portions were withdrawn, neutralized with methanolic hydrogen chloride, and diluted with chloroform, and the chloroform solution was washed with water, dried, concentrated, and examined by g.l.c. and t.l.c. After 90 min starting material had virtually disappeared and g.l.c. on column *a* showed the formation of unsaturated ester (**15**) (R_{Me} 1.33) and an unknown substance A (R_{Me} 2.55) in the relative proportions of 1.3:1. The t.l.c. showed the presence of an immobile component corresponding to acidic products in addition to two mobile components. Since the g.l.c. columns failed to reveal even standard samples of methyl (methyl 2,3-di-*O*-methyl-β-D-glucopyranosid)uronate, the presence of this compound in the reaction mixture was demonstrated by re-acetylation with acetic anhydride in pyridine. The g.l.c. examination of this product on column *a* showed the presence of unsaturated ester (**15**), unknown substance A, and acetylated ester (R_{Me} 4.17) in the relative proportions of 1.3:1:4.1.

Potassium *t*-butoxide (0.012 g) in methyl sulfoxide (0.6 ml) was added with stirring to acetylated ester (**14**) (0.018 g) in methyl sulfoxide (1 ml). The reaction products were examined in the same general way as above and after 90 min starting material had virtually disappeared. Re-acetylation of the reaction product followed g.l.c. on column *b* showed the presence of unsaturated ester (**15**) (R_{Me} 1.10) and acetylated ester (**14**) (R_{Me} 3.70) in the relative proportions of 1:1:4.

The acetylated ester (**14**) was treated with other bases under the conditions summarized in Table 1 and reactions were assessed by g.l.c. and t.l.c.

*Action of Other Bases on Methyl (Methyl 2,3,4-Tri-O-methyl-β-D-glucopyranosid)uronate (**12**)*

Methanolic 1.14 *N* sodium methoxide (0.18 ml) containing 5% of 2,2-dimethoxypropane was added with stirring to methylated ester (**12**) (0.018 g) in methanol (2 ml) containing 5% of 2,2-dimethoxypropane. The reaction mixture was worked-up after 90 min at room temperature and the u.v. spectrum showed a broad band at 236 nm. The g.l.c. examination of the reaction product on column *a* showed the presence of methylated ester (**12**), unsaturated ester (**15**) (R_{Me} 1.32), and unknown substances D (R_{Me} 0.87) and E (R_{Me} 1.22) in the relative proportions of 10.5:1.9:1.0:2.9. When examined by g.l.c. – mass spectrometry the peak of R_{Me} 1.32 gave a mass spectrum identical to that of the unsaturated ester (**15**). The t.l.c. showed a similar mixture of products together with an immobile component characteristic of uronic acids. The reaction was repeated at 60° for 90 min and g.l.c. of the products showed the presence of the same volatile components in the relative proportions of 5.9:2.8:1.0:2.8.

Potassium *t*-butoxide (0.010 g) in methyl sulfoxide (2 ml) was added with stirring under a stream of nitrogen to methylated ester (**12**) (0.015 g) in methyl sulfoxide (2 ml). Starting material had disappeared after 70 min at room temperature and g.l.c. of the reaction product on column *a* showed the presence of unsaturated ester (**15**) and unknown compounds C* (R_{Me} 0.86) and D* (R_{Me} 1.55) in the relative proportions of 25.6:1.0:2.6.

The methylated ester (**12**) was treated with other bases under the conditions summarized in Table 2 and reactions were assessed by g.l.c. and t.l.c.

An Addition Reaction of Indane with Nitric Acid in Acetic Anhydride

A. FISCHER, C. C. GREIG, A. L. WILKINSON, AND D. R. A. LEONARD
Department of Chemistry, University of Victoria, Victoria, British Columbia

Received February 7, 1972

cis- and *trans*-5-Acetoxy-7*a*-nitro-5,7-dihydroindane are formed as well as the 4- and 5-nitroindanes when indane is reacted with nitric acid and acetic anhydride. These adducts both decompose on standing by loss of nitrous acid forming 5-acetoxyindane. The *cis* isomer is obtained in greater amount and it undergoes elimination less readily than the *trans*.

Les acétoxy-5 nitro-7*a* dihydro-5,7 indanes *cis* et *trans* sont formés ainsi que les nitro-4 et -5 indanes quand l'indane est mis en réaction avec l'acide nitrique et l'anhydride acétique. Ces produits d'addition se décomposent au repos par perte d'acide nitreux en donnant l'acétoxy-5 indane. L'isomère *cis* est obtenu en plus grosse quantité et subit l'élimination moins facilement que le *trans*.

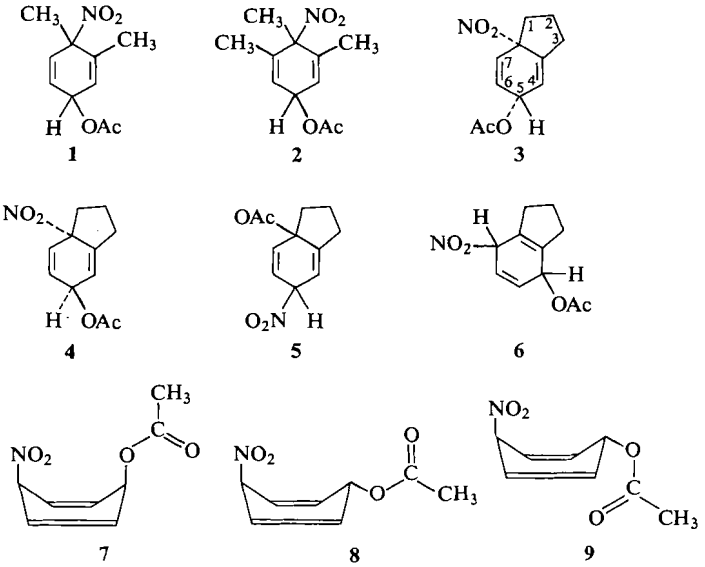
Reaction of indane with nitric acid and acetic anhydride has been reported to give 5-acetoxyindane as well as the expected 4- and 5-nitroindanes (1). The similar formation of 3,4-xylyl acetate (4-acetoxy-*o*-xylene) and of 3,4,5-trimethylphenyl acetate (5-acetoxyhemimellitene) when *o*-oxylene and 1,2,3-trimethylbenzene (hemimellitene) are treated with nitric acid and acetic anhydride (2) has recently been shown to occur via the 1,4-diene adducts, **1** and **2**, each of which occurs in *cis* and *trans* diastereoisomeric forms (3, 4). It is these dienes, together with the nitroarenes, that are the primary products of the reactions of the arenes. Thermolysis of the dienes, or heating them in acetic acid causes the elimination of nitrous acid and the formation of the aryl acetate which is thus a product of secondary reaction. These results have prompted us to re-examine the reaction of indane.

When indane was reacted with nitric acid in acetic anhydride at temperatures below $-20°$ the product isolated after removal of the anhydride exhibited n.m.r. absorption in the region (τ) 3.5–4.6 p.p.m., indicative of the presence of a diene, as well as absorption in the aromatic region. The predominant diene **3** crystallized when the product was allowed to stand overnight at $-20°$. The diastereoisomer **4** was obtained when the residue was subjected to low temperature chromatography on alumina. The structures assigned to the dienes are based on spectral and chemical evidence. The i.r. absorptions at 1540 and 1380 cm^{-1} and at 1735 and 1230 cm^{-1} establish the presence of nitro and acetoxy groups in **3**. Diene **4** has corresponding i.r. absorptions at 1550 and 1375 and at 1750 and 1225 cm^{-1}. The n.m.r. absorption in the region τ 3.5–4.5 p.p.m., which integrated for four protons, and the absence of absorption in the aromatic region show that **3** and **4** are dienes. That they are 1,4- rather than 1,3-dienes is indicated by the u.v. absorption: λ_{max} is 202 nm (ε 980 m^2 mol^{-1}) for **3** and 199.5 nm (ε 1440 m^2 mol^{-1}) for **4**. 1,3-Cyclohexadienes absorb above 250 nm (5). There are three structurally isomeric 1,4-diene adducts (**3**/**4**, **5**, and **6**), each of which is potentially capable of existing as *cis*–*trans* diastereoisomers, which might be obtained by addition of nitro and acetoxy groups to indane. Structure **6** is not compatible with the coupling constants derived from the n.m.r. spectra (see below) and on chemical grounds is an unlikely structure since it contains an acid proton α to the nitro group. Such a proton would be readily removed by the basic reagents used during work-up with concomitant elimination of the acetate group and formation of 4-nitroindane. Structures **3**/**4** and **5** are consistent with the spectral information, but **5** should readily eliminate acetic acid, like **6**, to form 5-nitroindane. However, elimination of acetic acid does not occur under the strongly basic work-up conditions, and the elimination which does occur on standing results in the loss of nitrous acid and the formation of 5-acetoxyindane. Thus only the structure **3**, and its diastereoisomeric structure **4** are consistent with both the spectral evidence and the chemistry of the dienes.

The assignment of structure **3** to the diene produced in greater amount, *i.e.* that which crystallized preferentially from the reaction product, and of structure **4** to the less easily



isolated diene is based on the magnitudes and signs of the three- and four-bond vinyl-allylic proton coupling constants of each diene. Agreement between measured and calculated dipole moments provides independent support for these assignments. Dreiding models of the indane adducts show that the five-membered ring locks the six-membered diene ring into a fixed boat conformation.[1] The dihedral angle (ϕ) between the $H_5—C_5—C_6$ and $C_5—C_6—H_6$ planes is $\sim 27°$ in the *cis* adduct **3** and $\sim 93°$ in the *trans* adduct **4**. The dependence of the three-bond and four-bond coupling constants of an allylic system on ϕ are given by Garbisch's equations (8) which are written in the following more simple equivalent forms.

$$\left.\begin{array}{ll}[1] & {}^3J = 4\cos^2\phi + 2.6 \\ [2] & {}^4J = 3.9\cos^2\phi - 2.6\end{array}\right\} 0^0 \leqslant \phi \leqslant 90°$$

$$\left.\begin{array}{ll}[3] & {}^3J = 9\cos^2\phi + 2.6 \\ [4] & {}^4J = 2.6\cos^2\phi - 2.6\end{array}\right\} 90° \leqslant \phi \leqslant 180°$$

[1]Dreiding models of 1,4-cyclohexadiene suggest that there are two rigid boat forms which are interconvertible by a ring flip. The models also suggest that there would be considerable angle strain in planar cyclohexadiene. Although the boat form for 1,4-cyclohexadiene has been supported, or at least assumed, by some authors (6) there is evidence which points to a planar structure (7). In the case of **3** and **4**, where the cyclohexadiene has a cyclopentene ring fused at the 3,4-bond, the requirement of planarity in the cyclopentene ring would force the cyclohexadiene ring into the boat form, even if this were not the preferred form in the unsubstituted 1,4-cyclohexadiene.

For the specified angles, J_{45} and J_{56} (three-bond coupling constants) are predicted to be 5.8 Hz for the *cis* adduct **3** and 2.6 Hz for the *trans* adduct **4**. The four-bond coupling constant J_{57} is predicted to be 0.5 Hz for the *cis* adduct and -2.6 for the *trans*. Comparison of these predicted values and those observed (Table 1) clearly shows that diene **3** is indeed the *cis* adduct and diene **4** is its *trans* isomer. The difference between the J_{45} and J_{56} values of **3**, together with the fact that these values are lower than predicted, may reflect a distortion of the diene ring caused by the repulsion between the diaxial nitro and acetoxy groups. Such distortion may be expected to be larger at C-6 than C-4 because the latter is closer to the restraining fused cyclopentene ring. The structural assignment is not affected by the choice of the particular set of coupling constants for each diene. Although there are two solutions in each case the only significant difference between the two pairs is in the sign of the J_{46} value. In saturated systems coupling constants between protons in the equatorial "W" relationship (as are the H-4 and -6 in **3** and **4**) are positive and in the range 1–2 Hz (9) and we therefore suggest that the first (for **3**) and third (for **4**) solutions in Table 1 are the more likely.

Mention has been made above that structure **6** is inconsistent with the coupling constants of Table 1. For the purposes of the immediately following argument we take the subscripts in the headings of Table 1 as proton labels only and not

*Subscripts are both proton labels and position indicators.
†Deviation (Hz) of the calculated line positions from those observed.

as position indicators and the compound numbers in that table as labels of parameter sets. The large coupling (J_{67}) must be assigned to the vinyl protons of **6**. The other two protons are thus 4 and 5. Either J_{47} or J_{57} must be a three-bond allylic coupling constant the minimum value for which is 2.6 Hz according to Garbisch's equations. This requirement, which is clearly inconsistent with the J_{47} and J_{57} values of Table 1, follows from the structural requirement of **6** that either protons 4 and 7 or 5 and 7 be adjacent. Structure **6** is therefore ruled out.

The measured dipole moment of **3** (2.56 D) is markedly lower than that of **4** (4.09 D). Dipole moments for **3** and **4** were calculated on the assumption that the hexadiene ring is in the rigid boat form. The calculations assume that (*i*) the acetoxy group is in the *s-trans* conformation (10) and that the group moment of the CH—$OCOCH_3$ fragment is the same as the dipole moment of methyl acetate (1.70 D orientated at 66° to the C—O bond with the negative end towards carbon (10)); (*ii*) the group moment of the C—NO_2 fragment is the same as the dipole moment of nitromethane (3.10 D directed along the C—N bond with the positive end towards carbon (10)); (*iii*) the group moment of the rest of the molecule, involving only C—H and C—C bonds, is negligible; (*iv*) the angle between the 1,4-diaxial bonds, estimated from Dreiding models, is 10°. We suggest that the predominant conformation of **3** is as depicted in partial structure **7** with the carbonyl oxygen at the extreme position from the nitro group. Severe steric interactions between carbonyl and nitro oxygens should prevent free rotation above the acetate C—O bond and destabilize structures in which the carbonyl oxygen approaches closely to the nitro group. In contrast conformations **8** and **9** of **4** should both be allowed as there are no marked steric interactions introduced as the acetate group rotates. Thus **4** would be expected to be a free rotation

TABLE 2. Measured and calculated dipole moment values (μ)

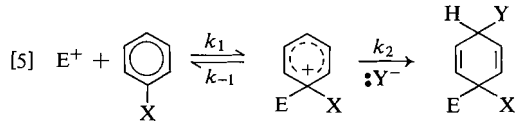
mixture. There is excellent agreement between the calculated dipole moments for these conformations and the measured values for **3** and **4** (Table 2) confirming the structural assignments of **3** and **4** based on the n.m.r. coupling constants.

It was possible to detect the presence of each diene in the reaction product by n.m.r. However, because the spectra of the dienes overlap, it was not possible to determine the ratio in which the dienes were produced, although it was obvious that **3** was formed in greater amounts than **4**. The **3**:**4** ratio (4:1) was determined by measurement of the dielectric constant of the product diene mixture, after separation from nitroindanes and a small amount of acetoxyindane by chromatography. Both dienes decompose on standing by elimination of nitrous acid to give 5-acetoxyindane. Decomposition is accelerated by acids. The relative reactivity of **4**:**3** in carbon tetrachloride containing 1% trifluoroacetic acid is 2.6:1. The greater reactivity of the *trans* adduct parallels the observations of Cristol *et al.* (11) on the thermal and base-catalyzed decompositions of *cis*- and *trans*-1,5-dichloro-9,10-dihydro-9,10-anthradiols and their derivatives. Thus, the *trans* diacetate and dibenzoate decomposed at their melting points to give the 1,5-dichloro-9-anthryl acetate and benzoate respectively while the *cis* isomer did not decompose. Similarly, in the base-catalyzed 1,4-conjugate elimination, the *trans* isomer was much more reactive than the *cis*.

It seems likely that the dienes are formed via

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

attack of the nitrating electrophile at the position of attachment of the five-membered ring (*ipso* attack). Perrin and Skinner (12) have discussed the possible reaction paths from a σ complex (Wheland) intermediate formed by attack at the *ipso* position, but they have not explicitly recognized the possibility encountered in the present work, *viz.* combination of a nucleophile with the σ complex leading to an overall addition reaction, eq. 5. It is consistent with this two-step



mechanism that a mixture of diastereoisomeric dienes is obtained. What is not obvious is why the *cis* diene should predominate: Dreiding models suggest that steric interactions in **3** (*cf.* partial structure **7**) should be more marked than in **4** (partial structures **8** and **9**) and this should also be true for the respective transition states leading to **3** and **4**. Exclusive formation of *cis* adduct (**3**) could be accounted for by a one-step concerted cycloaddition mechanism but this mechanism cannot account for the formation of the *trans* isomer (**4**). We therefore regard the two-step mechanism, [5], as being the more likely. Earlier work (13) on the kinetics of the acetoxylation reaction of *o*-xylene demonstrated that nitration and acetoxylation (*i.e.* diene formation) have a common intermediate whose formation is rate determining.[2] It is now clear that a nitrating electrophile, and in particular, nitronium ion, the most likely species, would be a common intermediate if the addition followed the two-step path. Addition, by this mechanism, is a nitration which has been diverted in the final step. It would be more difficult to propose a common intermediate if the addition were a concerted process with a mechanism necessarily quite different from that of nitration.

Using the product ratios of Vaughan *et al.* (1) (27 mol % 5-acetoxyindane, 19 mol % 4-nitroindane, and 54 mol % 5-nitroindane) and making the assumption that the fraction of acetoxy product is equal to the fraction of dienes initially formed, the relative reactivity of the 3*a*, 4, and 5 positions of indane to attack by the nitrating electrophile is 1.4:1:2.8. Change of the electrophile will change the relative reactivity of the positions because of change in reaction constant (Hammett ρ) but, unless there are large changes in the relative steric effects, the reactivity order $5 > 3a > 4$ should be the same. Thus a significant fraction of *ipso* attack is to be expected in other electrophilic substitution reactions of indane which give detectable amounts of the 4-substituted indane. Products of *ipso* attack, *e.g.* diene products or products involving diene intermediates, were not observed in the bromination of indane (1). It is possible that such products were formed but not detected but it is more likely that in [5] for bromination $k_{-1} > k_2[Y^-]$ and thus the *ipso* σ intermediate dissociates to reactants before combination with the nucleophile occurs to form an addition product. Bromination, in contrast to nitration, is normally reversible. We attribute the apparent ease with which addition occurs in the course of nitration to the slowness of the reverse reaction of the initial electrophilic attack, *i.e.* $k_2[AcOH] \gg k_{-1}$. Addition does not occur when the electrophile attacks the 4 or 5 positions because in these cases the σ complex is readily deprotonated to give the aromatic substitution product, a reaction pathway not open to the complex formed by *ipso* attack.

Nitrous acid is a weak acid and nitrite anion is not a good leaving group. It is therefore not surprising that the loss of nitrous acid from the diene adduct should be acid-catalyzed. Present information does not allow a distinction to be made between a two-step mechanism involving a σ complex intermediate (E1 type) and a concerted elimination (E2 type).

[2]The kinetics were followed by shaking samples of the reaction mixture with 2 *M* sodium hydroxide solution and extraction of the nitroarenes with carbon tetrachloride. The concentrations of phenoxide ion, in the aqueous phase, and nitroarenes, in the extract, were determined by u.v. spectroscopy. The phenoxide ion was formed by hydrolysis of the phenyl acetate. The latter was presumably formed by elimination of nitrous acid from the diene adduct. The diene adduct could not have eliminated nitrous acid before the sample for analysis was added to the sodium hydroxide since the product, 3,4-dimethylphenylacetate, reacts further with nitric acid to give a nitrodienone (14). Considerable heat was evolved when the sample (acetic anhydride solvent) was added to the sodium hydroxide solution and it is not surprising that decomposition of adduct to phenyl acetate and further hydrolysis of the latter to phenoxide was substantially quantitative. In ref. 13, it is observed that the ratio of the rate of formation of phenyl acetate to that of nitroarenes is constant when the absolute rates vary over a wide range. The observation should be restated that there is a constant ratio of the rate of formation of diene adduct to that of nitroarene.

Experimental

The u.v. spectra were determined on a Unicam SP 700 spectrometer. The i.r. spectra were determined on a Perkin–Elmer Model 337 spectrometer calibrated with polystyrene. The n.m.r. spectra were determined on Varian HA-60-IL, Varian XL-100, and Perkin–Elmer R12A spectrometers with tetramethylsilane as internal standard. Molecular weights were determined in methylene dibromide using a Hitachi Perkin–Elmer Model 115 molecular weight apparatus. Microanalyses were by Mr. M. Yang, Simon Fraser University, Burnaby, B.C. Melting points are uncorrected. Alumina was deactivated with 3% of 10% acetic acid.

cis (3) and trans (4) 5-Acetoxy-7a-nitro-5,7-dihydroindane

Fuming nitric acid (300 cm^3) was distilled at 1 mm from urea (10 g) and sulfuric acid (500 cm^3). Distilled nitric acid (3.2 cm^3, 0.075 mol) was added to acetic anhydride (20 cm^3) at −30°. The solution was allowed to warm to 0° to complete the formation of acetyl nitrate (15) and then re-cooled to −30°. This solution was added slowly, with stirring, to a solution of indane (6 cm^3, 0.05 mol) in acetic anhydride (20 cm^3) maintained at a temperature below −60°. The mixture was allowed to warm to −30° and maintained at that temperature for 10 min. It was then cooled in Dry Ice–acetone, ether (100 cm^3) added, and ammonia condensed into the solution. The cooling bath was removed, excess ammonia allowed to evaporate, and the residue poured onto ice and extracted with ether. The ether extract was washed (×6) with water, dried over magnesium sulfate, and the ether evaporated at 14°. The residue was allowed to stand overnight at −20° and the crystals which formed were washed with cold pentane and recrystallized from pentane to give white crystals of **3**, m.p. 61.5–62.5°, u.v. max (CH_3OH) 202 nm (ε 980 m^2 mol^{-1}); i.r. (Nujol) 1735 and 1230 ($OCOCH_3$), 1540 and 1380 cm^{-1} (NO_2); n.m.r. (CCl_4) τ 3.60 (d, 1, H-7), 3.83, 3.94 (m, 2, H-6 and -4), 4.4 (m, 1, H-5), 7.3, 8.2 (m, 6, $CH_2CH_2CH_2$), 7.99 p.p.m. (s, 3, $OCOCH_3$).

Anal. Calcd. for $C_{11}H_{13}NO_4$ (M_r 223): C, 59.19; H, 5.87; N, 6.28. Found (218): C, 59.28; H, 6.03; N, 6.19.

The combined mother liquors were evaporated at 14° and the residue chromatographed on alumina maintained below −30°. Elution with pentane gave a mixture of 4- and 5-nitroindane.

4-Nitroindane has two triplets in the benzylic region (16) with the characteristic lower field one centered at τ 6.7 p.p.m. 5-Nitroindane crystallized from the mixture, i.r. (Nujol) 1550 and 1340 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 2.3 (m, 2, Ar-*H*), 2.92 (m, 1, Ar-*H*), 7.2 (t, 4, $ArCH_2$), 8.0 p.p.m. (m, 2, $CH_2CH_2CH_2$). The benzylic protons were decoupled from the aromatic protons by irradiation at 7.2 p.p.m. Coupling constants and chemical shifts were evaluated for the decoupled spectrum following the procedure described below for the dienes and gave the data $\nu_4 = 2.26$, $\nu_6 = 2.30$, $\nu_7 = 2.95$, $J_{46} = 2.20$, $J_{47} = 0.65$, $J_{67} = 8.15$. The chemical shift values show that there are two low field protons which must therefore be ortho to the nitro group and that the compound must be 5-nitroindane rather than its 4 isomer. The coupling constants show that the aromatic protons are in the *ortho*, *meta*, and *para* relationship which is consistent only with a 5-substituted indane.

Further elution was with ether–pentane mixtures. Trace amounts of 5-acetoxyindane were eluted with 10% ether–pentane, i.r. (film) 1750 and 1220 cm^{-1} ($OCOCH_3$), n.m.r. (CCl_4) τ 3.2 (m, 3, Ar-*H*), 7.2 (t, 4, Ar-CH_2), 7.90 (s, 3, $OCOCH_3$), 7.9 p.p.m. (m, 2, $CH_2CH_2CH_2$). The benzylic protons were decoupled from the aromatic protons by irradiation at 7.19 p.p.m. Coupling constants and chemical shifts were evaluated from the decoupled spectrum and gave $\nu_7 = 2.99$, $\nu_6 = 3.34$, $\nu_4 = 3.22$, $J_{67} = 7.90$, $J_{47} = 0.50$, $J_{46} = 2.15$. The coupling constants show that the three protons are in the *ortho*, *meta*, and *para* relationship and are thus only consistent with a 5-substituted indane.

The dienes **3** and **4** were eluted with 20% ether–pentane. The diene fraction was rechromatographed using an alumina:substrate ratio of 150:1 and pure diene **4** was eluted with 18% ether–pentane. Diene **4** gave white crystals from pentane, m.p. 57.5–58.5°, u.v. max (CH_3OH) 199.5 nm (ε 1440 m^2 mol^{-1}); i.r. (Nujol) 1750 and 1225 ($OCOCH_3$), 1550 and 1375 cm^{-1} (NO_2); n.m.r. (CCl_4) τ 3.75, 3.84 (m, 2, H-7 and -6), 4.08, 4.15 (m, 2, H-4 and -5), 7.4, 8.15 (6, CH_2CH_2-CH_2), 7.97 p.p.m. (s, 3, $OCOCH_3$).

Anal. Calcd. for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87; N, 6.28. Found: C, 58.76; H, 5.70; N, 6.46.

The n.m.r. spectrum of each diene was taken at 100 MHz with the cyclopentane ring protons decoupled from the diene protons by irradiation at τ 7.50 for **3** and τ 7.52 for **4**. Line positions for the diene protons were measured and corrected for Bloch–Siegert shift (17). The computer program UEAITR (18) was used to refine estimated coupling constants and chemical shifts. Two sets of parameters (Table 1) led to good agreement between the calculated and the observed spectra. Not all of the peaks in the diene region could be resolved and this difficulty was compounded by the broadening of the spectrum caused by the decoupling of the cyclopentane ring protons. For these reasons J_{47} and J_{57} of **3** are not significantly different from 0.

Total yield of reaction products (nitro compounds and dienes) was in the range 75–85%. Gas–liquid chromatography of the decomposition product of each diene (SE 30 column at 200°) showed only 5-acetoxyindane and none of the nitroindanes. Integration of the n.m.r. spectrum of the product mixture in the diene and aromatic regions indicated that about 48% of the mixture was dienes. This is rather larger than the 26% of 5-acetoxyindane obtained by Wright after thermolysis of the reaction product. It is likely that analysis of dienes by n.m.r. is less accurate than Wright's chromatographic analysis of the acetate.

The relative reactivity of **3** and **4**, at 27° in carbon tetrachloride containing 1% trifluoroacetic acid as catalyst, was determined by following the rate of disappearance of the acetate peak of each (7.99 and 7.97 p.p.m., respectively) in the HA 60 spectrometer. At the same time the appearance of the acetate peak (7.90 p.p.m.) in the product 5-acetoxyindane was also followed. First order plots (in which concentration was taken as proportional to measured peak height) gave the rate constants $10^5k_3 = 3.7 \pm 0.6$ s^{-1}; $10^5k_4 = 9.6 \pm 0.9$ s^{-1}; $10^5k_{ArOAc} = 12 \pm 1$ s^{-1}. Within experimental error the rate constant for formation of the acetoxyindane is equal to the sum of the rate constants for disappearance of **3** and **4** and the relative reactivity of **4** to **3** is 2.6:1.

Dielectric Constant Measurements and Dipole Moment Calculations

Dielectric constants of benzene solutions of each diene were determined using a Sargent Chemical Oscillometer Model V with inductive cell-compensator. The compensator was adjusted so that a linear relationship between oscillometer reading (capacitance) and (ε − 1) for benzene, chlorobenzene, and dichloroethane was obtained. Diene (100 mg)

was added in weighed increments (15 mg) to a known weight (7 g) of benzene in the capacitance cell and the instrument reading determined after each addition. The slope and intercept of the linear plot of instrument reading *vs.* mole fraction of diene (n_2) was obtained by a least squares fit and the ratio of these is

$$\frac{1}{\varepsilon_1 - 1} \cdot \frac{\Delta\varepsilon}{\Delta n_2} = \frac{\alpha}{\varepsilon_1 - 1}$$

(subscript 1 refers to solvent benzene and subscript 2 to solute diene). The density of the solution after each addition of diene was measured with a Westphal balance and a plot of specific volume (v) *vs.* n_2 gave the slope β. The dipole moments were then evaluated using the expression (19)

$$[6] \quad \mu = 0.01281\ (P_{2\infty} - P_e - P_a)^{1/2} T^{1/2}$$

where

$$[7] \quad P_{2\infty} = \frac{3\alpha v_1 M_1}{(\varepsilon_1 + 2)^2} + (v_1 M_2 + \beta M_1)\frac{\varepsilon_1 - 1}{\varepsilon_1 + 2}$$

P_e was calculated from bond contributions (20) and P_a was taken as zero (21). The dipole moment was also evaluated from Higasi's simple formula, for benzene solvent at 25° (22, 23).

$$[8] \quad \mu = 0.828\alpha^{1/2}$$

Dipole moments are shown in Table 2. Dipole moments determined in solution are normally reported to ±0.05 to 0.1 D. Values of α were precise to 2% leading to a 1% precision of the derived moment and we therefore believe that the measured moments are within the accepted normal precision. It is to be noted that the values obtained using Higasi's simple expression agree with those evaluated from the more elaborate formula within the accepted precision.

For the mixture of isomers the polarization is related to the polarizations of each isomer by the expression,

$$[9] \quad P = n_3 P_3 + n_4 P_4$$

where n_3 is the mole fraction of **3** in the mixture of **3** and **4**. Since β has the same value for **3** and **4** it follows from [7] that dP/dn is proportional to $d\alpha/dn$ and hence the isomer ratio is given by

$$[10] \quad \frac{n_3}{n_4} = \frac{\alpha - \alpha_4}{\alpha - \alpha_3}$$

Using [10] and the measured values of α for the mixture and for each isomer the ratio $n_3 : n_4$ was found to be 4:1.

Direct Photolysis of 2-Propanol Vapor[1]

O. S. HERASYMOWYCH AND A. R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received November 24, 1971

The photolysis of 2-propanol vapor in the 1800–2000 Å wavelength range has been investigated. The volatile products of the reaction and their quantum yields at 80 °C and 200 Torr substrate pressure are H_2 (0.64), CH_3COCH_3 (0.34), CH_4 (0.39), CH_3CHO (0.29), CO (0.15), and C_2H_6 (0.08). A mechanism is proposed that accounts for the observed rate variations with substrate pressure, exposure time, temperature, and pressure of inert addend. Acetone and acetaldehyde undergo significant secondary decomposition and this is the source of CO, CH_4, and C_2H_6. Acetaldehyde is formed in the unimolecular decomposition of C_3H_7O radicals produced in the primary process.

The effects of CO_2 and CF_4 as inert addends have been examined and it has been established that the quantum yield enhancement through collision induced predissociation that has been reported to occur in methanol is not a characteristic of the 2-propanol photolysis.

La photolyse en phase vapeur du propanol-2, dans l'intervalle 1800–2000 Å, a été étudiée. Les produits volatils de la réaction et leurs rendements quantiques à 80 °C, sous une pression de substrat 200 Torr, sont H_2 (0.64), CH_3COCH_3 (0.34), CH_4 (0.39), CH_3CHO (0.29), CO (0.15), et C_2H_6 (0.08). Un mécanisme est proposé qui rend compte des variations observées pour la vitesse avec la pression du substrat, la durée d'exposition, la température et la pression de l'additif inerte. L'acétone et l'acétaldéhyde subissent une décomposition secondaire notable et constituent la source de CO, CH_4, et C_2H_6. L'acétaldéhyde est formé dans la décomposition unimoléculaire des radicaux C_3H_7O issus du processus primaire.

Les effets de CO_2 et CF_4, en tant qu'additifs inertes, ont été examinés et on a établi que l'accroissement du rendement quantique par l'intermédiaire d'une prédissociation due à la collision, qui se produit dans le méthanol, n'est pas une caractéristique de la photolyse du propanol-2.

Canadian Journal of Chemistry, **50**, 2217 (1972)

Introduction

The direct photolysis of 2-propanol vapor in the near vacuum u.v. has not been investigated previously although the mercury photosensitized decomposition at 2537 Å has been studied (1). The methanol system, however, has been examined in both direct photolysis (2–4) and photosensitization (5, 6).

Recently, Hagege *et al.* (7) reported that in the direct photolysis of CH_3OH at 1849 Å, added inert gases increased the decomposition quantum yields. These workers suggested that this enhancement occurs through a collision induced predissociation. There is no evidence, however, that such processes occur in the sensitized reaction (5, 6).

To investigate whether quantum yield increases occur when inert gases are present during the photolysis of other alcohols, we have examined the vapor phase photolysis of 2-propanol in the 1800–2000 Å wavelength region. This substrate was chosen for initial study in perference to methanol itself since the study of methanol photochemistry is complicated by the spontaneous reaction that occurs between methanol vapor and ordinary Pyrex glass giving appreciable amounts of trimethyl borate (6, 8).

Experimental

The photolysis experiments were conducted in a conventional grease- and mercury-free vacuum system with a cylindrical quartz reaction cell. The light source was a Hanovia medium pressure mercury lamp, type 30 620. The effective (with respect to substrate absorption) wavelength range was confined to the *ca.* 1800–2000 Å range by the transmission characteristics of the cell window and the absorption spectrum of the substrate 2-propanol (9). In that spectral region the effective lamp emission is the relatively weak and self-reversed Hg resonance line at 185 nm and a continuum. The region between the photolysis lamp and cell was sealed and continuously flushed with N_2 gas to avoid absorption by atmospheric oxygen. The cell and valve connection to the vacuum system were heated by an aluminum block furnace.

At the end of each experiment the products non-condensable at −196 °C were transferred to an attached vacuum system and determined in a gas burette and subsequently analyzed for H_2 and CH_4, or CO and CH_4, by gas chromatography. In the two procedures, CO and H_2 respectively were determined by difference. Condensable products were

distilled directly into the g.c. sampling volume. Pressures in the system were determined using an N.R.C. Alphatron ion gauge which was calibrated separately for all gases used in this study. Non-condensable products were analyzed using a 5 Å molecular sieve column, while condensables were eluted on a 12 ft Carbowax 20M column. In experiments with added gases the addends were separated from products and unreacted substrate by low temperature distillation. Products were identified by g.c. retention time comparisons and confirmed by mass spectrometric analysis.

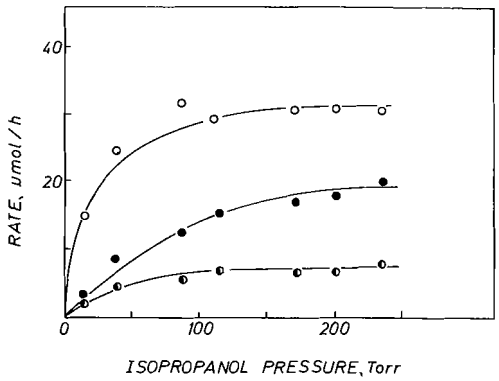

FIG. 3. Rate of formation of H_2, ○; CH_4, ●; and CO, ◐; as a function of pressure in the photolysis of 2-propanol at 80 °C.

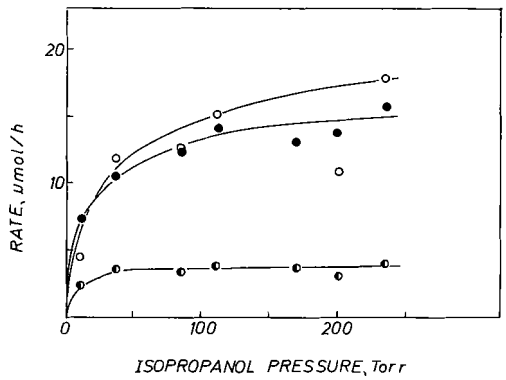

FIG. 4. Rate of formation of CH_3COCH_3, ○; C_2H_6, ◐; and CH_3CHO, ●; as a function of pressure in the photolysis of 2-propanol at 80 °C.

2-Propanol (Shawinigan reagent) was degassed in the vacuum line and had no impurities detectable by g.c. analysis. Carbon tetrafluoride, carbon dioxide, and nitrous oxide (Matheson) were degassed and freed from impurities by successive low temperature fractionations in the vacuum line.

Results

The volatile products of the photolysis of 2-propanol at 30 °C with $\lambda = 1800$–2000 Å are H_2, CH_3COCH_3, CH_3CHO, CH_4, CO, and C_2H_6. After prolonged irradiations very small amounts of pinacol and its isomers were detected by g.c. analysis of ether solutions obtained by successive washings of the reaction cell. The lengthy irradiations required to produce sufficient material for analysis by flame ionization g.c. at maximum sensitivity likely give rise to secondary decomposition of the originally formed C_6 fraction. Stoichiometric

calculations of the possible range of values for Φ(pinacol), *vide infra*, do not give a good mass balance. This may be due in part to secondary decomposition and to a minor surface effect since the adequacy of the mass balance has been reported to depend on the shape of the reaction cell in the case of methanol (3). Since actual pinacol yields could not be determined in the present system this effect was not investigated.

Figures 1 and 2 show the rate of formation of the volatile products at 30 °C. It is evident that at the maximum 2-propanol pressure that could be employed at that temperature, absorption of incident radiation is not complete. To permit examination of higher substrate pressures, a series of experiments was carried out at 80 °C where product yields could be determined up to 220 Torr alcohol vapor. The results are shown in Figs. 3 and 4. Under the conditions of these experiments it would appear from the variation in the rate of H_2 formation that absorption is probably complete at around 200 Torr substrate pressure.

To compare these results with others obtained at room temperature, and as well to identify products whose formation is temperature dependent, rates were measured in a series of photolysis of 11 Torr pressure, measured at 30 °C, of 2-propanol from 30 to 185 °C. These data are listed in Table 1. An Arrhenius plot for methane is linear and indicates an apparent activation energy for the formation of this product of 3.8 kcal/mol.

Another series of experiments was conducted at 30 °C to evaluate the effects of exposure time and the results are shown in Figs. 5 and 6. Although there is some uncertainty in determining whether the yield curves are linear at short exposure times, within experimental error the yields of hydrogen, methane, and carbon monoxide are linearly dependent on exposure time. Because of the relatively small amounts of

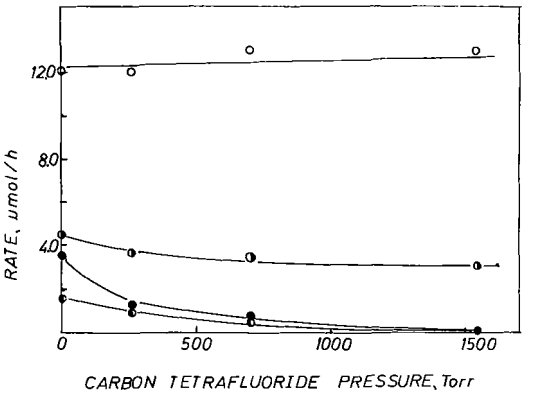

FIG. 10. Rate of formation of CH_4, ●; CO, ◐; CH_3CHO, ◑; and CH_3COCH_3, ○; as a function of pressure of added carbon tetrafluoride for the photolysis of 100 Torr of 2-propanol at 48 °C.

the latter two products it is not possible to determine definitively if their initial rates are zero, although the yield curves suggest that such is the case. For acetone and acetaldehyde, however, it is clear that there is a pronounced decrease in their rate of formation with reaction time, while $R(C_2H_6)$ evidently increases at longer exposure times. An additional series of experiments was carried out with 8.5 Torr substrate pressure and showed the same trends in the yields of all products as found at 11 Torr.

To determine if decomposition rates were enhanced in the presence of inert addends, three sets of runs were conducted. In the first series, 11 Torr of 2-propanol was photolyzed in the presence of up to 1 atm of CO_2. Carbon dioxide was chosen because Hagege *et al.* (7) found that it was the most effective addend in increasing quantum yields in the methanol decomposition. The results obtained in the present study are shown in Figs. 7 and 8. Ethane was not analyzed for in this series. Apart from a slight increase in R(CO) all rates either decline or remain essentially constant. The most significant alteration is the substantial decrease in the rate of acetaldehyde formation.

In the two other series of experiments, rates were determined at substrate pressures of 11 and 100 Torr in the presence of CF_4 examining addend pressures up to 1550 Torr. The results are given in Figs. 9 and 10. Hydrogen was not determined in these runs since it was not possible to separate it quantitatively from the large

For personal use only.

amount of CF_4 which has a small but finite vapor pressure at -196 °C. Again the rates of formation of all products remain constant within experimental error or decline with the exception of $R(CH_3COCH_3)$, in the case of the photolysis of 100 Torr substrate, which may have increased somewhat at the higher CF_4 pressures.

Because a monochromatic light source was not employed in this study it was not possible to obtain definitive values for the quantum yields. However, it was possible to determine first approximation values because of the coincidence that both the substrate and the nitrous oxide used as actinometer are both essentially transparent at wavelengths greater than 2000 Å and both absorb down to the 1800 Å cutoff. The absorption coefficient of N_2O rises rather slowly in this wavelength region, while that of 2-propanol increases rather sharply with decreasing wavelength, and therefore it is possible to obtain more or less complete absorption in the substrate case at relatively low pressures. The rate of N_2 formation from the photolysis of N_2O was determined as a function of pressure up to 2400 Torr. Consistent with the absorption characteristics outlined above, it was found that at least 800 Torr of actinometer was required for complete absorption as evidenced by the constant $R(N_2)$ value found at this and higher pressures. Taking $\Phi(N_2) = 1.44$ (10, 11) the observed pressure independent rate of nitrogen formation indicated an effective intensity for the system of 0.82 μEinstein min^{-1}. Utilizing the observed rates of product formation at 80 °C and 200 Torr 2-propanol pressure, assuming that there is complete absorption of the same effective intensity by the substrate under these conditions as by the actinometer, the calculated quantum yield values are as follows: H_2, 0.64; CH_4, 0.39; CH_3COCH_3, 0.34; CH_3CHO, 0.29; CO, 0.15; and C_2H_6, 0.08. The data for CH_4, CO, and C_2H_6 are, in effect, rates relative to that of the primary decomposition rather than true Φ values since, as will be demonstrated below, these products arise from secondary photolyses at wavelengths not absorbed by the substrate or the actinometer.

Discussion

The nature of the products observed in this study and the previously determined behavior of this substrate and methanol in direct and sensitized photolysis would indicate that the primary decomposition may proceed by two routes,

[1*a*] $(CH_3)_2CHOH + h\nu \rightarrow C_3H_7O + H$

[1*b*] $(CH_3)_2CHOH + h\nu \rightarrow (CH_3)_2CO + H_2$

where the radical represented as C_3H_7O may be either $(CH_3)_2\dot{C}OH$ or $(CH_3)_2CH\dot{O}$. An investigation of the photolysis of deuterated 2-propanols would be required to distinguish between the three possibilities and to assess their relative contributions to the primary decomposition. The net chemical effect of reaction 1*a*, however, will be the same whether isopropoxy radicals or hydroxyisopropyl radicals are formed in that H-atoms and $(CH_3)_2COH$ radicals will result, the latter from the rapid exchange reaction

[2] $(CH_3)_2CHO + (CH_3)_2CHOH \rightarrow (CH_3)_2CHOH + (CH_3)_2COH$

shown previously to be important in both this substrate (1) and methanol (6).

The results obtained in the present study, however, show that the rate of primary decomposition is not increased by added inert gases, even at relatively high pressures. There is no obvious explanation of why this system does not exhibit the same behavior as methanol. The absorption spectrum of both alcohols in the 1800–2000 Å region is a continuum, although Hagege *et al.* (7) have suggested that there may be fine structure in the CH_3OH spectrum that would be detected only in high resolution and at low pressure. Thus it may be possible that the initially attained electronic excited state of $(CH_3)_2CHOH$ is more dissociative in character than the analogous state proposed as being involved in CH_3OH. One additional factor may be important. The experiments with CH_3OH (7) were carried out in a Pyrex system and it may be possible that the photolysis was complicated by the presence of trimethyl borate. This possibility cannot be ruled out until the phenomenon is demonstrated to occur in a system wherein CH_3OH vapor does not come into contact with boron containing glass.

The observed products and their rate characteristics found in the present investigation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2-propanol can be explained on the basis of reactions 1 and 2 followed by reactions 3–12.

[3] $H + (CH_3)_2CHOH \rightarrow H_2 + (CH_3)_2COH$

[4] $2(CH_3)_2COH \rightarrow CH_3COCH_3 + (CH_3)_2CHOH$

[5] $2(CH_3)_2COH \rightarrow (CH_3)_2C(OH)C(OH)(CH_3)_2$

[6] $C_3H_7O \rightarrow CH_3CHO + CH_3$

[7] $CH_3COCH_3 + h\nu \rightarrow CH_3CO + CH_3$

[8] $CH_3CO \rightarrow CH_3 + CO$

[9] $CH_3CHO + h\nu \rightarrow CH_3 + CHO$

[10] $CHO \rightarrow CO + H$

[11] $CH_3 + (CH_3)_2CHOH \rightarrow CH_4 + (CH_3)_2COH$

[12] $2CH_3 \rightarrow C_2H_6$

Reaction 6 is suggested as the source of CH_3CHO. This process has been observed in the photolysis of isopropyl propionate at 2537 Å (12), so that in the present system there should be ample energy from the primary process to have it occur. The dependence of the rate of formation of acetaldehyde on pressure of added CO_2, and to a lesser extent pressure of added CF_4, as well as the marked increase in its rate with temperature, support the proposal that CH_3CHO arises from the unimolecular decomposition of C_3H_7O radicals with energies in excess of thermal excitation. The mechanism, however, does not account for all observations associated with C_3H_7O decomposition. A reduction in the rate of reaction 6 in the presence of inert addends should give rise to a decrease in CO and CH_4 formation. While that is indeed observed with added CF_4, R(CO) and $R(CH_4)$ show an increase or remain constant with added CO_2. There is no obvious explanation of this difference in the effect of the two addends.

The data in Fig. 7 show that $R(H_2)$ declines as $P(CO_2)$ is increased. This may be ascribed to decreasing importance of reaction 3. The H-atoms formed in reaction 1*a* will have, with $\lambda = 1800$–2000 Å as the photolyzing wavelength, some excess energy and the relatively small temperature dependence of $R(H_2)$ is consistent with that expectation. In the presence of addends, these H-atoms will be thermalized and therefore more readily removed in radical–radical reactions, such as, for example the reverse of reaction 1*a*. Furthermore, the production of H-atoms from process 10 would be expected to decrease at higher system pressures.

Acetone and acetaldehyde are both subject to secondary photolysis by lamp emissions at $\lambda > 2000$ Å (principally at 2537 Å) where there is no absorption by the substrate. The marked decrease in the rate of formation of both these products as exposure times are increased is evidence that such secondary decomposition is occurring. The observed rates for CO, CH_4, and C_2H_6 are consistent, within experimental error, with the stoichiometry of the reactions associated with these secondary photolyses. Methyl radicals are formed in reactions 6–9, and the total rate of formation of CH_3 can be computed as follows. The value of $\Phi(CH_3)$ from processes involving formation and secondary photolysis of CH_3CHO will be the sum of $(\Phi(CH_3CHO) + \Phi(CO)_{[10]})$ and $\Phi(CO)_{[10]}$; the former term accounts for CH_3 production in reaction 6, while the latter indicates the extent of CHO formation and consumption and is therefore representative of $\Phi(CH_3)$ in reaction 9. The processes involving acetone also give CH_3 radicals and for these reactions the CH_3 quantum yield is $\Phi(CH_3)_{[7]} + \Phi(CH_3)_{[8]} = 2\Phi(CO)_{[8]}$. Therefore the total $\Phi(CH_3)$ value is given by eq. 13. It is not possible to evaluate the last two

[13] $$\Phi(CH_3) = \Phi(CH_3CHO) + 2\Phi(CO)_{[8]} + 2\Phi(CO)_{[10]}$$

terms directly. However, if it is assumed that CH_3COCH_3 and CH_3CHO undergo secondary photolysis to an extent proportional to their concentrations, then $\Phi(CO)_{[8]} = 1.13\,\Phi(CO)_{[10]}$. Since $\Phi(CO)_{obs.} = \Phi(CO)_{[8]} + \Phi(CO)_{[10]}$, the individual values are $\Phi(CO)_{[8]} = 0.08$ and $\Phi(CO)_{[10]} = 0.07$. Solution of eq. 13 on that basis gives $\Phi(CH_3) = 0.59$. Methyl radicals are consumed in reactions 11 and 12 whence

[14] $$\Phi(-CH_3) = \Phi(CH_4) + 2\Phi(C_2H_6)$$

and the calculated $\Phi(-CH_3)$ value here is 0.56. The formation of methane through abstraction in reaction 11 is consistent with the observed apparent activation energy for CH_4 production considering the lability of the α-hydrogen atom in 2-propanol.

An upper limit for the contribution of reaction 5 can be obtained from stoichiometric calculations involving C_3H_7O radicals. These determinations evidently depend on the contribution of primary process 1*b*.

If that process does occur, the yield on substrate radicals can be determined from their rate of formation in reactions 1*a* and 3 and via

abstraction by CH_3 in reaction 11, so that

[15] $$\Phi(C_3H_7O) = 2\Phi(H_2) + \Phi(CH_4) = 1.67$$

employing quantum yield values at 80 °C and 200 Torr substrate pressure. The value of $\Phi(C_3H_7O)$ can also be obtained from the Φ values for products responsible for the consumption of this radical; that is, pinacol in reaction 5, acetone in reaction 4, and acetaldehyde in reaction 6. It is also necessary to include in the sum the CO yields indicative of the amount of the latter two products that undergo secondary photolysis. On that basis the quantum yield relation is

[16] $$\Phi(C_3H_7O) = 2[\Phi(CH_3COCH_3) + \Phi(CO)_{[8]}] + 2\Phi(\text{pinacol}) + \Phi(CH_3CHO) + \Phi(CO)_{[10]}$$

Calculating the $\Phi(CO)$ values as before, and taking $\Phi(C_3H_7O) = 1.67$ from eq. 15, eq. 16 gives a value of 0.24 for Φ(pinacol). This represents an upper limit.

If reaction 1*b* is included in the stoichiometry and assumed to occur to the same extent as for methanol (25%), eqs. 15 and 16 can be altered to include the appropriate Φ (reaction 1*b*) terms and yield a value of 0.15 for Φ(pinacol).

Finally, it is of interest to compare the main features of the direct and sensitized photolysis of this substrate. Although the products are the same, acetaldehyde and products arising from secondary photolysis of carbonyl compounds are formed in relatively smaller quantities at 2537 Å. The total quantum yield of acetone formation is given by $\Phi(CH_3COCH_3) + \Phi(CO)_{[8]}$ and is equal to 0.42. Thus for the direct photolysis $\Phi(H_2)/\Phi(CH_3COCH_3) = 1.52$. In the mercury photosensitized decomposition, Knight and Gunning (1) found $\Phi(H_2) = 0.72$ and $\Phi(H_2)/\Phi(CH_3COCH_3) = 2.9$, while in a more recent determination of the quantum yields in the 2-propanol–Hg $6(^3P_1)$ reaction, Kato and Cvetanović (13) found $\Phi(H_2) = 0.77$ and $\Phi(H_2)/\Phi(CH_3COCH_3) = 1.29$.

The fundamental difference between the methanol and 2-propanol systems with respect to quantum yield enhancement by inert gases remains unresolved and to that end we have initiated a study of the CH_3OH system in an all-quartz vacuum system.

The authors gratefully acknowledge the financial support of the National Research Council of Canada for this work and also a grant from the Research Corporation for another project which provided much of the apparatus employed in the present study.

The Thermal Behavior of Some Resin Acids at 400–500 °C

RAY F. SEVERSON AND WALTER H. SCHULLER
Naval Stores Laboratory,[1] Olustee, Florida 32072

Received October 12, 1971

The hot tube pyrolysis of dehydroabietic acid (**1**) at 400–500 °C was found to produce as major products the three possible A-ring olefins (19-norabieta-4,8,11,13-tetraene (**2**); 19-norabieta-4(18),8,11,13-tetraene (**3**); and 19-norabieta-3,8,11,13-tetraene (**4**)) resulting from the elimination of the carboxylate moiety. The i.r., n.m.r., u.v., and mass spectrum of each olefin was obtained and discussed. The pyrolysis of abietic acid (**7**) and levopimaric acid (**8**) under identical conditions was found to yield A-ring olefins; to isomerize to yield varying mixtures of palustric, **7**, and neoabietic acids; to dehydrogenate to yield **1**; and to eliminate propylene to form deisopropyldehydroabietic acid (**15**). A mechanism to explain the formation of **15** from the dienoic resin acids is given.

On a trouvé que la pyrolyse en tube de l'acide déhydrobiétique (**1**) à 400–500 °C fournit comme produits majeurs les trois oléfines possibles sur le cycle A (nor-19-abiéta tétraène-4,8,11,13 (**2**); nor-19 abiéta tétraène-4(18),8,11,13 (**3**); et nor-19 abiéta tétraène-3,8,11,13 (**4**)) résultant de l'élimination du fragment carboxylate. Les spectres i.r., r.m.n., u.v., et le spectre de masse de chaque oléfine ont été obtenus et discutés. La pyrolyse de l'acide abiétique (**7**) et de l'acide lévopimarique (**8**) dans des conditions identiques donne des oléfines sur le cycle A, des isomérisations conduisant à des mélanges variables d'acides palustrique **7** et néoabiétique, une déshydrogénation conduisant à **1** et une élimination du propylène pour former l'acide desisopropyl-déhydroabiétique (**15**). Un mécanisme expliquant la formation de **15** à partir des acides résines diénoiques est donné.

Canadian Journal of Chemistry, **50**, 2224 (1972)

Our studies on the high temperature (600–800 °C) behavior of dehydroabietic acid (**1**), abietic acid (**7**), and levopimaric acid (**8**) (1, 2) led us to conclude that the elimination of the carboxylate moiety to yield A-ring olefins was the initial primary fragmentation in the thermal decomposition of these acids (or methyl esters). The conjugated dienoic acids were assumed to rapidly isomerize and the dehydrogenation would occur to produce an aromatic C-ring.[2] It thus seemed feasible that under milder conditions, the pyrolysis of resin acids would produce isolatable A-ring olefins.

Because of the recent interest in a facile conversion of resin acids to 19-norabieta-4(18),8,11,-13-tetraene (**3**) (a decarboxylated A-ring olefin) to be used as a possible precursor in steroid synthesis (4) and pyrolytic mechanism considerations, we are reporting in this paper the behavior of **1**, **7**, and **8** under pyrolytic conditions which should minimize further decomposition of the possible initial decarboxylation product.

Experimental

The pyrolysis apparatus was similar to that previously used (2). Five grams of the resin acid in 25 ml benzene were added dropwise over 40 min (N_2 flow 50 ml/min). When the addition was complete, the pyrolysate was quantitatively removed with acetone and stripped to 90 mm Hg at 30° on a rotoevaporator. The product was treated with an ethyl ether – diazomethane solution and analyzed by g.l.c. using a 15 ft × 3/16 in. 10% OV-17 column (60/80 mesh Gas Chrom Q, 120 ml/min He, temperature program 80–280° at 4°/min).

Ethylene and propylene were trapped by means of their 1,2-dibromide derivatives by passing the pyrolysis exhaust gases through a gas dispersion trap containing Br_2 in acetic acid. After extraction with ethyl ether and water, 1,2-dibromoethane and 1,2-dibromopropane were separated by g.l.c. (OV-17 column at 90°) and identified by means of retention time (comparison with authentic compounds) and i.r. data (after collection from g.l.c.).

Methyl palustrate, dehydroabietate, abietate, and neoabietate were identified by means of retention times and u.v. spectra (collected from OV-17 at 260°). The methyl ester of **15** was collected (as a white solid) from the OV-17 column at 260°; i.r. (KBr), 1723 (C=O) and 759 cm^{-1} (four adjacent ArH); n.m.r. δ (CCl_4), 1.21 (s, 3, C_{10}-Me), 1.25 (s, 3, C_4-Me), 3.65 (s, 3, OCH_3), and 7.0 p.p.m. (m, 4, aromatics); λ_{max} (95% EtOH), 264.5 (log ε 2.72) and 272 mμ (log ε 2.70) (lit. (5), 265 (log ε 2.68) and 273 mμ (log ε 2.65)); $[\alpha]_D^{25}$ +54° (*c* 0.25, 95% EtOH) (lit. (5), $[\alpha]_D^{25}$ +60.5°). Mass

[1]One of the laboratories of the Southern Marketing and Nutrition Research Division, Agricultural Research Service, U.S. Department of Agriculture.

[2]Previous work at this laboratory has shown that at 200° the four conjugated dienoic resin acids, neoabietic, palustric, abietic, and levopimaric, thermally isomerize to yield an equilibrium mixture of palustric, abietic, and neoabietic acids and that disproportionation to yield dehydroabietic acid occurs in a very slow irreversible step (3).

A-Ring Olefins

A portion of the pyrolysate was placed on neutral alumina (Woelm Activity Grade 1) and eluted with benzene. The neutral material which eluted in a yellow band was collected and the solvent removed under a stream of nitrogen. The A-ring olefins were collected from the OV-17 column and rechromatographed and collected[3] as colorless oils.

Compound **2** (retention time 23.2 min)[4]: i.r. (neat), 1616 and 1498 (C=C, Ar), 880 (isolated ArH), and 820 cm^{-1} (two adjacent ArH); n.m.r. δ (CCl_4), 1.21 (d, 6, $J = 7$ Hz, $(Me)_2CH$), 1.24 (s, 3, C_{10}-Me), 1.33 (s, 3, C_4-Me), 6.80 (s, 1, C_{14}-H), 6.88 (d, 1, $J = 6.5$ Hz, C_{12}-H), and 7.12 p.p.m. (d, 1, $J = 6.5$ Hz, C_{11}-H); λ_{max} (95% EtOH), 266.5 and 274.5 mμ.

Compound **3** (retention time 26.6 min): i.r. (neat), 3070 (=CH_2 stretch), 1648 (C=C, vinylidene), 1612 and 1500 (C=C, Ar), 883 (C=CH_2), 860 (isolated ArH), and 820 cm^{-1} (two adjacent ArH); n.m.r. δ (CCl_4), 0.97 (s, 3, C_{10}-Me), 1.20 (d, 6, $J =$ Hz, $(Me)_2CH$), 4.56 (broad s, =CH, syn), and 4.80 p.p.m. (broad s, 1, =CH, anti) (aromatics as given for **2**); u.v. λ_{max} (95% EtOH), 266.5 and 274.5 mμ.

Compound **4** (retention time 27.8 min): i.r. (neat), 1668 (R_1R_2C=CHR), 1616 and 1500 (C=C, Ar), 886 (isolated ArH), and 820 cm^{-1} (two adjacent ArH); n.m.r. δ (CCl_4), 1.02 (s, 3, C_{10}-Me), 1.20 (d, $J = 7.0$ Hz, $(CH_3)_2CH$), 1.27 (s, 3, C_4-Me), and 5.45 p.p.m. (broad s, 1, C_3-H) (aromatics as given for **2**); λ_{max} (95% EtOH), 267 and 275.0 mμ.

Results and Discussion

Analysis of the products obtained from the pyrolysis runs (400–500°) is shown in Table 1. The three major products in the neutral fraction all had a molecular ion at 254 amu and exhibited

[3]The fact that the pure alkenes were not isomerized under the g.l.c. conditions justifies this method for determining the product ratio in the olefin mixture.

[4]Retention data measured from point of injection.

maxima in the u.v. at 266 and 276 mμ (typical of the aromatic ring system in dehydroabietic acid). Similarly, the 900–675 cm^{-1} region of the i.r. spectrum of each compound indicated the presence of an aromatic system with two adjacent hydrogens (820 cm^{-1}) and an isolated hydrogen (860 cm^{-1}) (6). The above data clearly show that the **B**- and C-rings of the parent molecule are unaltered and suggest that the three isolated olefins are identical to those obtained by Huffman (4) from the lead tetraacetate decarboxylation of **1** (see Scheme 1).

A more detailed study of the i.r., n.m.r., and mass spectra made it possible to assign structure **2** (19-norabieta-4,8,11,13-tetraene) to the most volatile A-ring olefin (relative retention time, 1.50). This compound failed to show any i.r. absorption in the olefin C=C stretching region or vinyl protons in the n.m.r., but did have a deshielded methyl group, as expected for a compound with a tetrasubstituted double bond. The mass spectral fragmentation pattern of **2** is also consistent with the assigned structure (see Table 2). The base peak of **2** found at *m/e* 239 can be readily formed by the loss of the C-10 methyl from the molecular ion to form a benzyl-allyl-stabilized ion (**5**).

The presence of the $=CH_2$ asymmetric stretch (5070 cm^{-1}) and the very strong vinylidine carbon hydrogen wag at 883 cm^{-1} in the i.r. and the presence of two vinyl protons in the n.m.r. of the olefin, with relative retention time of 1.54, are consistent with the structure assigned to compound **3** (19-norabieta-4(18),8,11,13-tetraene). The base peak observed in the mass spectrum of this olefin was found at mass 197 (see Table 2). A metastable at 162 amu indicates that the fragment at mass 197 is the daughter ion of the M-15 peak (*m/e* 239, probably from loss of the C-10 methyl). The work of Genge (7) indicates that the main fragmentation pathway which leads to the base peak does not involve subsequent loss of the aromatic isopropyl group as propylene. However, a reasonable alternate pathway resulting in the loss of propylene from the A-ring to produce an allyl, benzyl, cyclobutyl resonance-stabilized ion (*m/e* 197) (8) which then loses ethylene to yield an isopropylnaphthalene ion (*m/e* 169) can be proposed.[5]

The structure for compound **4** was assigned because of its weak i.r. absorption at 1668 cm^{-1} (consistent with C=C stretch of $C_2C{=}CHC$) and the presence of a vinyl proton and a deshielded methyl group in its n.m.r. spectrum. The high intensity peak (100%) at *m/e* 236 in the mass spectrum of norabieta-3,8,11,13-tetraene (**4**) can be explained by methyl loss followed by double bond migration to yield a vinyl benzyl-

[5]The mass spectral fragmentation mechanism for 19-norabieta-4(18),8,11,13-tetraene may be obtained from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

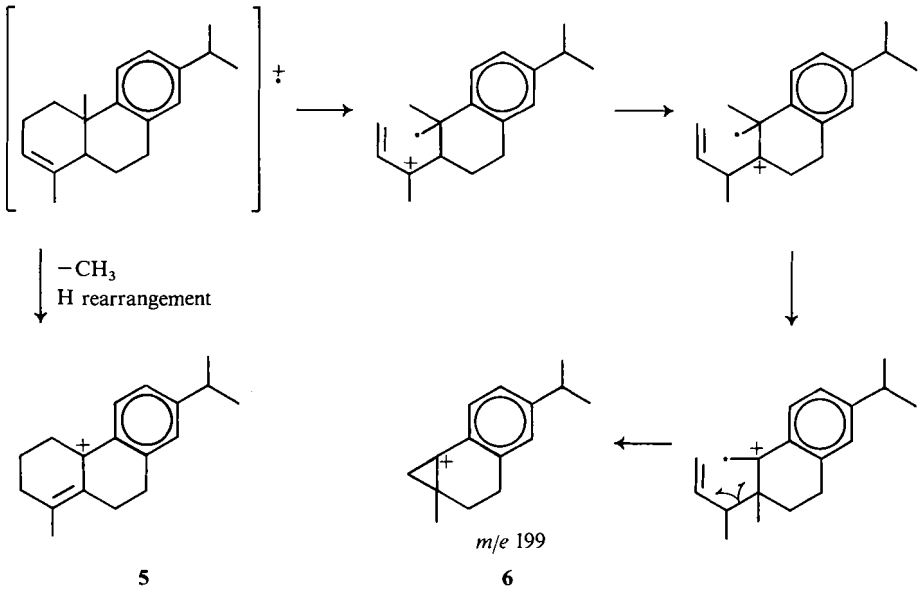

SCHEME 2

stabilized ion **5**. The other major fragment at *m/e* 199 (**6**) may be formed as indicated in Scheme 2.

The A-ring olefins from **1** discussed here have not been previously isolated and characterized in the pure state. They were identified in the olefin mixture by means of n.m.r. spectroscopy (3). The i.r. data reported on **3** and n.m.r. data on the crude mixture (9) are in accord with our findings.

Inspection of the data in Table 1 would appear to indicate that during the thermal decarboxylation of **1**, the formation of the less thermodynamical stable olefins (**3** and **4**) is favored. In contrast to our yield data, one would expect that with increasing pyrolysis temperature the less stable olefins would isomerize to the Δ^4 compound (**2**). However, we feel that since **2** has the structural requirements to undergo a thermal retro-Diels–Alder reaction (10) by the elimination of ethylene, it is probably being decomposed by this reaction at a greatly increased rate at the higher temperatures. The isolation of ethylene (as its 1,2-dibromo derivative) from the pyrolysis exhaust gases substantiates such an argument. Thus, the increased yield of the multi lower molecular weight unidentified neutrals with increasing temperature can be rationalized by the isomerization of the initially formed **3** and **4** to olefin **2** which then thermally decomposes. The constant olefin ratio in the 400 and 450 °C pyrolysates and the failure to isolate any A-ring olefins under higher temperature (600–800 °C) pyrolysis conditions (2) are also consistent with such a mechanism.

The inspection of Table 1 definitely confirms our earlier assumption (2) that the conjugated dienoic acids rapidly isomerize and disproportionation occurs at a much slower rate during hot tube pyrolysis. We also confirmed that in the case of dehydroabietic acid, very little thermal fragmentation occurs until the carboxylate moiety is lost. However, we found that with the conjugated dienoic acids that there are two primary equally important thermal fragmentation pathways. As initially assumed (2), aromatization to dehydroabietic acid does take place along with the unpredicted formation of a lower molecular weight acid (**15**). The strong i.r. absorption at 759 cm^{-1} and a four aromatic proton multiplet in the n.m.r. spectrum of the acid indicated an ortho-disubstituted aromatic ring. Its 264.5 and 272 mμ u.v. absorption maxima, characteristic of a tetralin chromo-

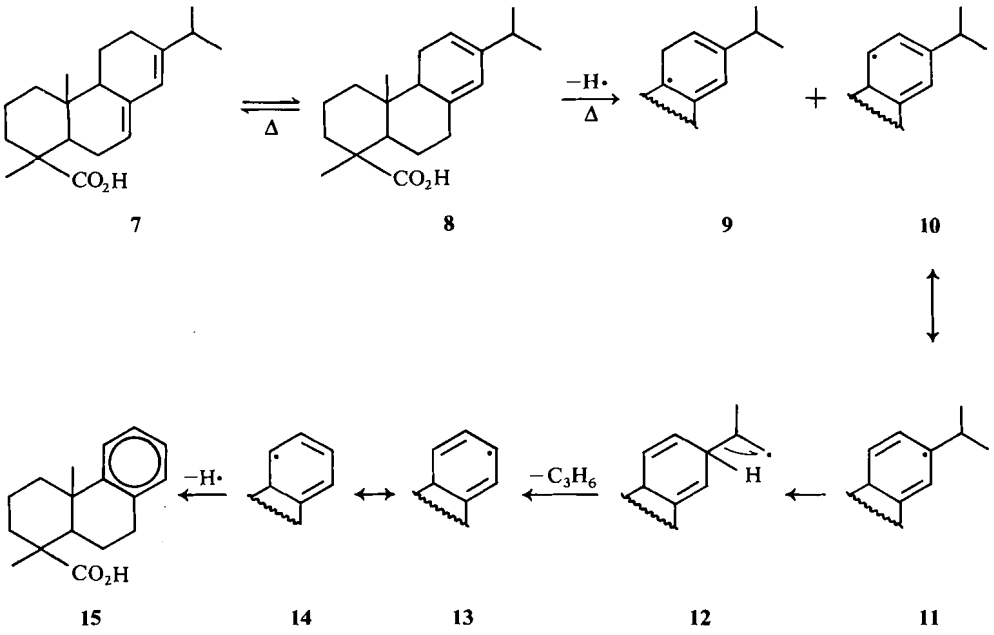

SCHEME 3

phore (11, 12), and its molecular ion at *m/e* 272 suggested that thermal deisopropylation and aromatization of the C-ring had occurred. By comparison of the above data and optical rotation ($[\alpha]_D^{25} + 54°$) with the data given for the minor product formed during the aluminum chloride-induced dialkylation of dehydroabietic acid (5, 13), the identity of **15** was established to be deisopropyldehydroabietic acid.

A somewhat surprising observation is the almost complete lack of formation of the deisopropyl acid during the pyrolysis of dehydroabietic acid. A mechanism which takes this face into acount is given in Scheme 3. Upon heating, levopimaric acid (**8**) would be expected to initially fragment by the loss of one of the allylic hydrogen atoms in the C-ring. A reaction with a previously formed radical would be expected, due to steric considerations (14), to form radical intermediate **10**, while thermal degradation should result in the loss of a hydrogen atom from C-9 to yield **10**. Aromatization could now take place from either **9** or **10** to form the experimentally observed **1**. Resonance stabilization of **10**[6] would be expected to occur to yield the tertiary-diallyl radical **11**. A hydrogen atom rearrangement from one of the isopropyl methyls to the C-13 radical would yield intermediate **12**, which could readily eliminate propylene to produce **13**. Aromatization via **14** would result in the formation of the experimentally observed deisopropyldehydroabietic acid (**15**). This mechanism is substantiated by the isolation of propylene, as 1,2-dibromopropane, from the pyrolysis gases.

The authors wish to thank Mr. James B. Stanley and Mr. Verne W. Tripp of the Southern Regional Research Laboratory, SMNRD, for mass spectral analysis, and Mr. Gordon J. Boudreaux and Mr. Verne W. Tripp of the Southern Regional Research Laboratory, SMNRD, for determining the n.m.r. data.

[6]It is highly probable that **9** and **10** would thermally equilibrate via a hydrogen rearrangement.

Kinetics and Rate Constants of Reactions Leading to Hydration of NO_2^- and NO_3^- in Gaseous Oxygen, Argon, and Helium Containing Traces of Water

J. D. PAYZANT, A. J. CUNNINGHAM, AND P. KEBARLE
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received January 31, 1972

The rate constants for the forward and reverse components of gas phase reactions:

[1] $NO_2^- + H_2O + M \rightleftharpoons NO_2^-(H_2O) + M$

[2] $NO_2^-(H_2O) + H_2O + M \rightleftharpoons NO_2^-(H_2O)_2 + M$

[3] $NO_3^- + H_2O + M \rightleftharpoons NO_3^-(H_2O) + M$

were measured with a pulsed electron beam, time resolved detection high pressure mass spectrometer at 300 °K. O_2, Ar, and He at pressures from 1–7 Torr were used as third gas M. The forward reactions were found to be third order and the reverse reactions second order. Establishment of the equilibria could also be observed.

Les constantes de vitesse des réactions directes et inverses, en phase gazeuse:

[1] $NO_2^- + H_2O + M \rightleftharpoons NO_2^-(H_2O) + M$

[2] $NO_2^-(H_2O) + H_2O + M \rightleftharpoons NO_2^-(H_2O)_2 + M$

[3] $NO_3^- + H_2O + M \rightleftharpoons NO_3^-(H_2O) + M$

ont été mesurées à 300 °K par la spectrométrie de masse utilisant un faisceau d'électrons pulsés et une détection par temps d'envol. On utilise comme troisième gaz M, O_2, Ar, et He sous des pressions de 1 à 7 Torr. Les réactions directes ont été trouvées du troisième ordre et les réactions inverses du deuxième ordre. L'établissement de l'équilibre a pu également être observé.

Canadian Journal of Chemistry, **50**, 2230 (1972)

Introduction

The present work is a continuation of studies dealing with the association of ions with polar molecules. An earlier paper (1) in this journal described measurements of the temperature dependence of hydration equilibria involving: $NO_2^-(H_2O)_n$, $NO_3^-(H_2O)_n$, $CN^-(H_2O)_n$ and $OH^-(H_2O)_n$. These studies led to the evaluation of the enthalpy and entropy changes: $\Delta H_{n,n-1}$ and $\Delta S_{n,n-1}$ for the reactions $(n, n-1)$ where n was generally 1, 2, or 3.

$$(n, n-1) \quad A^-(H_2O)_n = A^-(H_2O)_{n-1} + H_2O$$

The present study deals with the kinetics of the reactions leading to the hydration equilibria of the NO_2^- and NO_3^- ions.

The hydrates of the nitrite and nitrate ions are of particular interest since they are both involved in the negative ion chemistry of the ionosphere. Recent rocket borne mass spectrometer measurements (2, 3) indicate that the $NO_3^-(H_2O)_3$ species is the dominant negative ion at altitudes below 90 km.

Kinetic measurements of the reactions leading to the establishment of ionic equilibria in the gas phase are also of considerable general interest since they provide a useful store of thermochemical data (4). On the basis of such information, unknown rate constants for related reactions can be estimated, and with these, order-of-magnitude time requirements for the achievement of the equilibrium can be obtained. This is an invaluable aid in the selection of proper experimental conditions for the measurement of ionic equilibria. However, the need for careful selection of the experimental conditions ensuring lifetimes of the ions which are longer than the half-lives of the equilibrium reactions, the need for proper sampling conditions, etc., seem not to have been fully appreciated (5).

Experimental

(a) Apparatus and Experimental Conditions

The apparatus used has been described earlier (1, 6); therefore only a brief description will be given here.

A major gas, O_2, Ar, or He at pressures of 1–7 Torr containing known pressures of water (0.8–30 mTorr) was flowed (~ 0.3 l s^{-1} at 4 Torr) through the stainless steel ion source. Ionization was obtained with 2000 V electrons

produced in an electron gun and entering the ion source through a narrow slit (12 μ × 2 mm). The electron beam was pulsed "on" for 10 μs and "off" for 6 ms. Each pulse contained some 10^6 electrons. The resulting ions diffuse through the field free ion source. Some of them come to the vicinity of the molecular flow ion exit slit (12 μ × 2 mm, razor blade edges), escape through the leak into the evacuated region (10^{-4} Torr), and are subjected to magnetic mass analysis (15 cm radius, 90° tube) and electron multiplier detection. The amplified multiplier pulses are collected in a multiscaler whose sweep is triggered by the electron beam "on" pulse. In most runs, the dwell time per channel was 20 μs. The time of flight of ions outside the ion source is short (less than 15 μs for all ions studied) compared to the residence time in the ion source (several ms). The time of flight of ions of different mass was corrected for with a pulse delay circuit. The plane of the electron beam was roughly 2 mm above the ion exit slit.

(b) Measurement of Water Pressure in Ion Source

The achievement of equilibrium for the reaction [4]

[4] $$(2,3)\quad O_2^-(H_2O)_2 + H_2O \rightleftharpoons O_2^-(H_2O)_3$$

could be observed in all runs involving O_2 as a carrier gas (see Results and Discussion section). The observed $O_2^-(H_2O)_3$ and $O_2^-(H_2O)_2$ intensities (normalized ion counts at long reaction times) were substituted in eq. 5 in order to determine the water pressure (Torr) in a given run.

[5] $$K_{2,3} = \frac{O_2^-(H_2O)_3}{O_2^-(H_2O)_2 . P_{H_2O}} = 20 \quad (T = 300.5\,^\circ\mathrm{K})\ \text{(Standard state, 1 Torr)}$$

The value of $K_{2,3}$ was determined in a number of calibration runs involving weight loss based water concentration determinations (7).

The value of $K_{1,2}$ of the NO_2^- ion was found to be reproducible in all runs involving O_2 as the carrier gas. The water concentration in the experiments where Ar and He were used as carrier gas (and where the O_2^- hydrates were not present) was calculated on basis of the $K_{1,2}$ expression for NO_2^- obtained in the oxygen runs.

Results and Discussion

(a) Reactions Leading to NO_2^-, NO_3^-, O_2^-, $C_2H_3O^-$

The NO_2^- and NO_3^- ions were produced by the dissociative electron capture of ethyl nitrate. This method was used in earlier work (1). A few mTorr of ethyl nitrate was added to the major gas (O_2, Ar, or He). When O_2 was the major component, the principle ions observed were NO_2^- and hydrates, O_2^- and hydrates, and $C_2H_3O^-$ and hydrates. The NO_3^- and hydrates were also observed but at somewhat lower yield (~20% of the NO_2^- abundance).

The NO_2^- and $C_2H_3O^-$ are probably produced by reactions 6 and 7.

[6] $$e + C_2H_5ONO_2 \rightleftharpoons NO_2^- + \text{neutral products}$$

[7] $$\rightleftharpoons C_2H_3O^- + \text{neutral products}$$

The electron capture cross section of ethyl nitrate is large only for near thermal electrons (8). The electrons involved in the reactions 6 and 7 are probably secondary electrons brought to near thermal energies by collisions with the major gas. NO_2^- and $C_2H_3O^-$ were the two major ions observed by Kriemler and Butrill (9) in the low pressure mass spectra of ethyl nitrate obtained with low energy electrons. The O_2^- ion and hydrates observed in the present work were probably produced in third body electron capture by oxygen (10), *i.e.*, reaction 8. The ratio of ethyl nitrate

[8] $$2O_2 + e \rightleftharpoons O_2^- + O_2$$

derived ions to O_2^- derived ions could be increased by increasing the ethyl nitrate concentration. Thus in the regime of a few Torr of O_2 and a few mTorr of ethyl nitrate, third body capture by O_2 and dissociative capture by $C_2H_5ONO_2$ proceed at similar rates. The $O_2^-(H_2O)_n$ equilibria were used for calibrations of the water pressure (see Experimental section).

According to Kriemler and Butrill (9), NO_3^- is produced by ion–molecule reactions of $C_2H_3O^-$ (and other minor products of the dissociative electron capture) with ethyl nitrate. Most likely, the NO_3^- observed in the present experiments was due to such a reaction. However, the present observations indicate that an appreciable fraction of $C_2H_3O^-$ does not react with ethyl nitrate, since the sum of the $C_2H_3O^-$ and its hydrates was found to remain a constant proportion of the total ionization after some 50 μs reaction time. Furthermore the NO_2^- and hydrates and the NO_3^- and hydrates each remained a constant proportion of the total ion intensity. The relative negative ion changes in the first 50 μs reaction time were not observed reliably with the present apparatus and conditions, since this is a period of rapid increase of total negative ion intensity (this interval probably corresponds to the time required for the thermalization of the secondary electrons). Since the observed concentration of $C_2H_3O^-$ and hydrates was considerably larger than that of NO_3^- and hydrates, a major part of the $C_2H_3O^-$ does not react with ethyl nitrate.

In the experiments with Ar and He as major gas, $C_2H_3O^-$ and hydrates were the major ion

group, followed by NO_2^- and hydrates. The NO_3^- and hydrates were observed at much lower concentrations. Thus in argon, the intensity of the NO_3^- and hydrates was only 5% of that of the NO_2^- and hydrates while in oxygen the NO_3^- was some 20% of the NO_2^- and hydrates. The dependence of the NO_3^- yield on the nature of the major gas and the inertness of some of the $C_2H_3O^-$ for reactions with ethyl nitrate might be understood if one assumed that two different $C_2H_3O^-$ species are produced in the dissociative electron capture by ethyl nitrate and that one of these is unable to react with ethyl nitrate. The two species might be true isomers or differ only in the degree of internal excitation. It is likely that different proportions of these two species will be present when different major gases are used. Thus the electron thermalization will depend on the nature of the major gas (11) and so electrons of different energies will be captured by the ethyl nitrate and lead to different yields of the fragment ions (8).

Rate Constant Measurements

The determination of the rate constants for the forward and reverse reactions 1, 2, and 3 will be described in this section.

$$[1] \qquad NO_2^- + H_2O + M \underset{-1}{\overset{1}{\rightleftharpoons}} NO_2^-(H_2O) + M$$

$$[2] \qquad NO_2^-(H_2O) + H_2O + M \underset{-2}{\overset{2}{\rightleftharpoons}} NO_2^-(H_2O)_2 + M$$

$$[3] \qquad NO_3^- + H_2O + M \underset{-3}{\overset{3}{\rightleftharpoons}} NO_3^-(H_2O) + M$$

Shown in Fig. 1 is the time dependence of the ion signal for the species NO_2^-, $NO_2^-H_2O$, and $NO_2^-(H_2O)_2$ observed in a typical experiment with oxygen as the major gas. The ion signal for a given ion, such as NO_2^-, has been normalized to the total ion signal for the NO_2^- and hydrates. This is in accordance with the observation (see previous section) that the NO_2^- and hydrates system was independent of the other ions present, *i.e.*, the total relative concentration of the NO_2^- and hydrates remained constant with time. The data in Fig. 1 will be treated as if they represented concentration changes in a reaction vessel in which the total ion concentration is constant with time (12). The figure shows the decrease of NO_2^-, the appearance of the

○, NO_2^-; □, $NO_2^-(H_2O)$; △, $NO_2^-(H_2O)_2$. The solid line connecting the experimental points represents a computer fit of reaction system 1–2, see text. $p(O_2) = 2.14$ Torr, $p(H_2O) = 27$ mTorr, $T = 300$ °K.

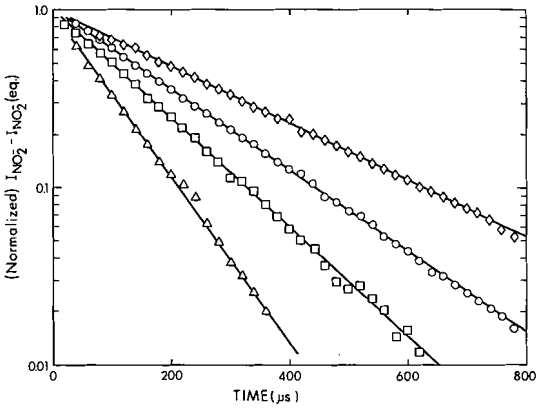

FIG. 2. Determination of k_1 and k_{-1}. Slopes of plots are equal to: $-(\nu_1 + \nu_{-1})/2.3$, where $\nu_1 = k_1[H_2O][O_2]$ and $\nu_{-1} = k_{-1}[O_2]$. In legend below first number given: O_2 pressure in Torr; second number: H_2O pressure in mTorr; third number: $\nu_1 \times 10^{-3}$ in s^{-1}: □, 5.4, 14, 6.53; ○, 1.47, 30.2, 5.16; ◇, 3.8, 9.2, 3.42; △, 3.61, 32.7, 10.67.

hydrate $NO_2^-H_2O$, followed by the dihydrate and the achievement of equilibrium for reaction times longer than ~ 500 μs.

The solid lines connecting the experimental points are analogue computer calculated concentrations obtained by programming the computer to reproduce the reversible reaction system represented by reactions 1 and 2. As can be seen, a very satisfactory fit of the data was obtained. The reactions in an experiment (*e.g.*, Fig. 1), are all first order, so that the computer

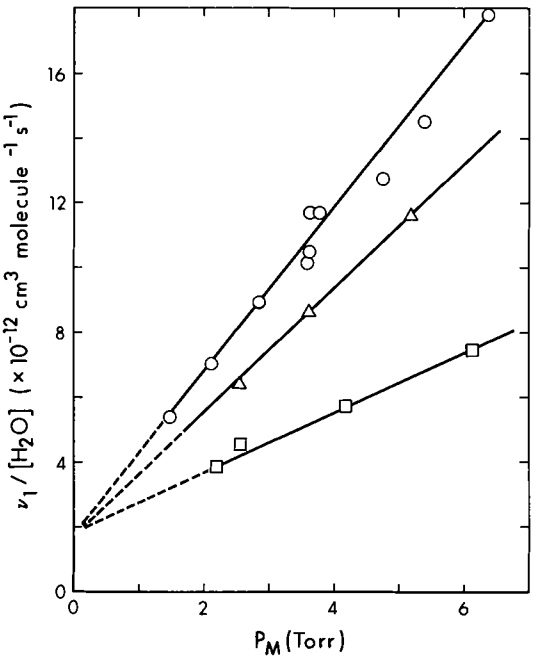

FIG. 3. Plots used to establish whether reaction 1,

$$NO_2^- + H_2O + M \rightleftharpoons NO_2^- H_2O + M$$

obeys relationship $v_1 = k_1[H_2O][M]$. Results indicate that this is correct, *i.e.*, reaction is third order. ○, M = O_2; △, M = Ar; □, M = He.

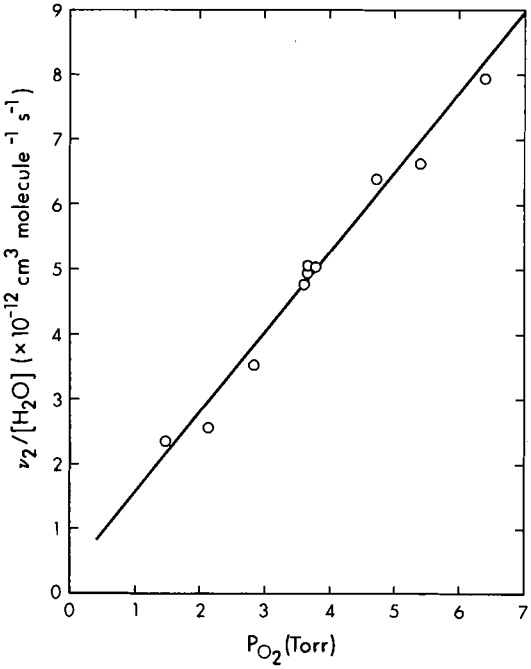

FIG. 4. Plot used to establish whether reaction 2,

$$NO_2^-(H_2O) + H_2O + O_2 \rightleftharpoons NO_2^-(H_2O)_2 + O_2$$

obeys relationship $v_2 = k_2[H_2O][O_2]$. Results show that this is correct, *i.e.*, reaction 2 is third order.

fit provides pseudo first order rate constants (or reaction frequencies) v. Thus, one obtains $v_1 = k_1[M][H_2O]$, $v_{-1} = k_{-1}[M]$, etc. from a given fit. One can then calculate k_i from v_i and the known concentrations of the neutral species. In all, ten runs with O_2 and seven runs with Ar or He as a major gas were made. The pressure of the major gas was varied from 1.5–6.4 Torr and the H_2O pressure from 0.8–30 mTorr. The results are summarized in Figs. 2–4.

Figure 2 illustrates a method by which v_1 and v_{-1} can be evaluated without the use of the computer. For a general reversible reaction:

$$A \underset{v_{-1}}{\overset{v_1}{\rightleftharpoons}} B \underset{v_{-2}}{\overset{v_2}{\rightleftharpoons}} C$$

in which [A] + [B] + [C] = constant, it can be shown (13) that the concentration of reactant A obeys eq. 9.

$$[9] \quad 2.3 \log([A^-] - [A_{eq}^-]) = -(v_1 + v_{-1})t + \text{constant}$$

where $[A_{eq}^-]$ is the equilibrium concentration of A^- and $[A^-]$ is the concentration at time t. The use of eq. 9 for the NO_2^- system is illustrated in Fig. 2. The $[NO_{2eq}^-]$ was determined from time dependence plots similar to those shown in Fig. 1, but extended to much longer reaction times (typically in excess of 2000 μs) where a constant concentration of NO_2^- could be observed over a wide time interval. The four straight lines shown in Fig. 2 are representative of the type of data obtained and the range of concentrations used. The slopes which correspond to $-(v_1 + v_{-1})/2.3$, combined with the measured equilibrium ratio and the relationship: $[NO_2^-(H_2O)_{eq}]/[NO_{2eq}^-] = v_1/v_{-1}$, gave values for v_1 and v_{-1} and thus for k_1 and k_{-1}. These values were very close to those obtained from the computer fit. The computer fit yielded (for the four runs shown in Fig. 2) the values: v_1 = 3.5(3.4), 5.6(5.2), 6.8(6.5), 10.6(10.7) (in units of 10^3 s^{-1}), while the values shown in brackets were obtained from the graphical plot. The linear graphical plot has the advantage of not

$K_3 = 4.9 \times 10^{-15}$ cm^3 molecule^{-1} (previous determination; ref. 1)

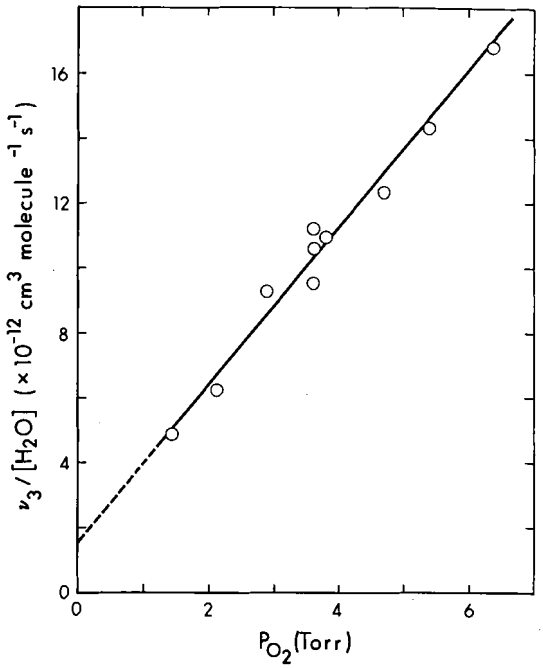

FIG. 5. Plot used to establish whether reaction 3,

$$NO_3^- + H_2O + O_2 \rightleftharpoons NO_3^-(H_2O) + O_2$$

obeys relationship $v_3 = k_3[H_2O][O_2]$. Results indicate that this is correct, *i.e.* reaction 3 is third order.

being affected by subjective error as is the case with the visual fitting of the computer curves to the measured time dependence of the ion concentrations.

Figure 3 shows a plot of $v_1/H_2O]$ *vs.* the pressure of the major gas M. The plots give a linear increase with the pressure of M, but yield a positive intercept. It is not clear whether this effect is real, revealing a complex dependence of reaction on third body pressure, or whether it is due to some insufficiency of the experimental technique. Assuming the latter, values for the third order rate constants $k_1 = v_1/[H_2O][M]$ were obtained from the slopes of the linear portion of the plots. These values are shown in Table 1.

Since reaction 1 appears third order, reaction -1 must be second order, *i.e.*, $v_{-1} = k_{-1}[M]$. The values of k_{-1} obtained from the slope of plots of v_{-1} *vs.* [M] are given in Table 1.

The data for the reaction 3 are summarized in the plot shown in Fig. 4 which gives $v_2/[H_2O]$ plotted against the pressure of the major gas O_2. The v_2 values were obtained from computer fits of the experimental runs. The linear dependence observed in Fig. 4 shows that reaction 2 is third order. The slope of the plot leads to k_2 given in the table. No determinations of k_2 were made with He and Ar as major gas. The second order rate constant k_{-2} given in the table was obtained from the slope of a plot of $v_{-2}/[H_2O]$ *vs.* the oxygen pressure.

The methods applied for the study of reaction 3 and -3 involving the NO_3^- ion and its monohydrate were essentially the same as those used for the analogous reaction 1 involving the NO_2^- ion. The pseudo first order v_3 obtained by graphical plots like those in Fig. 2 are shown in Fig. 5. The plot of $v_3/[H_2O]$ *vs.* the oxygen pressure gives a straight line showing that the reaction is third order. The slope leads to k_3 shown in the table. The second order k_{-3} was evaluated by methods similar to those used for the evaluation of k_{-1}.

The experimental conditions were not favorable for the observation of the higher hydrates of NO_3^- and therefore, the corresponding rate constants were not measured.

The rate and equilibrium constants shown in Table 1 summarize the results of the present work and include previous determinations. Literature information is available only for k_1 which was determined by Puckett and Lineberger (14) with NO as a third body. This value is slightly higher than the present value with O_2. There is no clear *a priori* reason to suggest why NO should be a more efficient third body than O_2. The observed difference between the two values might reflect either a higher efficiency for NO or an experimental error. The lower efficiencies of Ar and He observed in the present work are consistent with previous determinations in similar systems (15).

The forward association rate constants k_1, k_2, and k_3 (Table 1) are seen to be quite close to each other. The binding energies of the hydrates, measured earlier (1), were: $\Delta H_{1,0}(NO_2^-) = 14.3$, $\Delta H_{2,1}(NO_2^-) = 12.9$, and $\Delta H_{1,0}(NO_3^-) = 12.4$ kcal/mol. Thus the formation of the $NO_2^-(H_2O)$ is associated with the largest binding energy, which considered by itself should lead to a higher forward rate constant. The proximity of the observed rate constants indicates that the bond energy effect is at least partially offset by the larger number of degrees of freedom available in the $NO_2^-(H_2O)_2$ and $NO_3^-H_2O$ species.

The equilibrium constants $K_{0,1}$, $K_{1,2}$ for NO_2^- and $K_{0,1}$ for NO_3^- shown in Table 1 are close to those obtained previously (1). The values obtained in the earlier determination were measured with H_2O as the major gas at water pressures in the Torr range, *i.e.*, hundred times higher than the water pressure used in the present work. The lower stability of the $NO_3^-(H_2O)$ and the $NO_2^-(H_2O)$—H_2O relative to the $NO_2^-H_2O$ is reflected in the values of the corresponding equilibrium constants and in the rate constants for the cluster dissociation reactions. The dihydrate of NO_2^- has the highest dissociation rate constant (k_{-2}).

Thermal Decomposition of Stereoisomeric 3-Aroyl- and 3-Carbomethoxyaziridines in Acetonitrile

J. W. LOWN AND M. H. AKHTAR[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received August 27, 1971[2]

The thermal decomposition of 1-alkyl-3-benzoyl-2-(*m*-nitrophenyl)aziridines in dry acetonitrile results in a series of autocatalytic hydrolytic cleavages, 1,3-dipolar additions, condensations, and rearrangements to give products including oxazolidines, 1,2-dihydropyrazines, pyrrolo-[3,4-*d*]-4-oxazolines, and α-aminoketones. The marked differences in product type and distribution from *cis*- and *trans*-aziridines are ascribed to preferential hydrolytic opening at the aziridinium ion stage. Complete equilibration of the stereoisomeric azomethine ylides takes place prior to 1,3-dipolar additions.

Thermal decomposition of *cis*- and *trans*-methyl 1-isopropyl-2-(*m*-nitrophenyl)aziridine-3-carboxylates in acetonitrile is not autocatalytic (and can be suppressed) and produces three stereoisomeric oxazolidines in identical yields and ratios, and methyl *N*-isopropylglycine by selective hydrolytic attack at the 2-aziridine position. This result is ascribed to equilibration of the stereoisomeric aziridines prior to hydrolytic cleavage by adventitious moisture only.

La décomposition thermique des alkyl-1 benzoyl-3 *m*-nitrophényl-2 aziridines dans l'acétonitrile sec conduit à une série de clivages hydrolytiques autocatalysés, d'additions dipolaires-1,3, de condensations et de réarrangements donnant des produits comprenant des oxazolidines, des dihydro-1,2 pyrazines, des pyrroles[3,4-*d*] oxazolines-4 et des α-aminocétones. Les différences notables dans le type de produit et leur distribution à partir des aziridines *cis* et *trans* sont attribuées à l'ouverture préférentielle par hydrolyse au stade de l'ion aziridinium. L'équilibration complète des ylures azométhine stéréoisomères se fait avant les additions dipolaires-1,3. La décomposition thermique des carboxylates d'isopropyl-1 *m*-nitrophényl-2 aziridine-3 de méthyle *cis* et *trans*, n'est pas autocatalytique (et peut être supprimée) et conduit à trois oxazolidines stéréoisomères dans des rapports et des rendements identiques et à la méthyl-*N*-isopropylglycine par hydrolyse sélective sur la position-2 de l'aziridine. Ce résultat est attribué à l'équilibration des aziridines stéréoisomères avant clivage par hydrolyse causée seulement par une humidité accidentelle.

Canadian Journal of Chemistry, **50**, 2236 (1972)

The thermal conrotatory and photochemical disrotatory cleavage of the carbon–carbon bond of aziridines to azomethine ylides proceeding according to strict orbital symmetry control is now firmly established (1). Hitherto such reactions and the subsequent 1,3-dipolar additions have been examined largely in nonpolar solvents, *e.g.* benzene or toluene, in which many *cis*- and *trans*-aziridines undergo configurational equilibration without complication (2–6).

For many cycloadditions, particularly with heterocumulene dipolarophiles, more polar solvents, *e.g.* CH_3CN or CH_3NO_2, are desirable for reasons of solubility. It was therefore necessary to examine the controlled decomposition of aziridines in such solvents and elucidate possible side reactions which would be particularly important in cycloadditions of aziridines with less reactive dipolarophiles.

The decomposition of certain aziridines in dry acetonitrile shows a surprisingly facile series of hydrolytic cleavages, 1,3-dipolar additions, condensations, and rearrangements and a marked difference in behavior of *cis*- and *trans*-aziridines is apparent. Configurational assign-

ments of *cis* and *trans* pairs of aziridines in this paper are based on the n.m.r. correlations of Pohland *et al.* (7).

Heating of a solution of pure **1***a* in dry acetonitrile under reflux for 24 h and chromatographic separation of the products afforded (*i*) the stereoisomeric oxazolidines **3***a* and **4***a* in a ratio of (80:20) (one of which could be obtained stereoisomerically pure) in 56% yield, (*ii*) the 1,2-dihydropyrazine derivative **5** in 10% yield,

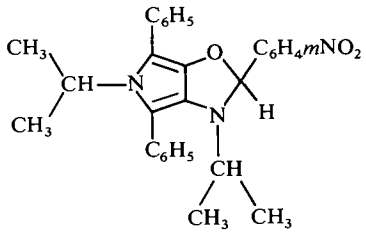
6

m-$NO_2C_6H_4CH_2NHCH(CH_3)_2$

7

and other minor basic products to the extent of 10%.

In contrast, reaction of pure **2***a* under precisely the same conditions gave a mixture of products which were separable by column chromatography affording (*i*) the oxazolidines **3***a* and **4***a* in only 5.4% yield, (*ii*) the pyrrolo-[3,4-*d*]-4-oxazoline **8** in 8.5% yield, (*iii*) the 1,2-dihydropyrazine **5** in 12.5% yield, (*iv*) *N*-(isopropyl)phenacylamine **6** in 26.5% yield, (*v*) *m*-nitrobenzaldehyde **9** in 6.3% yield, and (*vi*) a fraction consisting of a mixture of amines in 8% yield, which was very similar to that obtained from **1***a*.



8

It was demonstrated independently that both **1***a* and **2***a* suffer cleavage of the 2–3 carbon–carbon bond in acetonitrile under the reaction conditions since reaction of each separately with an equimolar quantity of *N*-phenylmaleimide gave a single pyrrolidine **10**. Similar products formed in benzene have been reported by Woller and Cromwell (2). The n.m.r. spectrum of **10** closely resembled that of the *N*-cyclohexyl analog **11***a* which was similarly prepared and the full stereochemistry of which was established by examination of the deuterated analog **11***b*, prepared from 1-cyclohexyl-3-benzoyl-3-deutero-2-(*m*-nitrophenyl)aziridine (containing 54% of deuterium label).

Diminution of the 8.5 Hz doublet at 5.30 confirmed the assignment of the 5-pyrrolidine proton. The smaller H_2–H_3 coupling (4.5 Hz) established a *trans* arrangement and proved that the larger groups at the 2- and 5-positions are *trans* related. The assignments of the *cis* and *trans* couplings in these pyrrolidines are based on strong literature analogies (2, 8, 9).

The structures of **3***a* and **4***a* were proven by independent reaction of either **1***a* or **2***a* with an equimolar quantity of *m*-nitrobenzaldehyde. Precisely the same 80:20 ratio of **3***a* to **4***a* was obtained as from the decomposition experiment. The regiospecific cycloaddition of activated

b X = D

aldehydes to azomethine ylides to form oxazolidines in nonpolar solvents is firmly established (10–12).

The orientation of addition of the *m*-nitrobenzaldehyde was proven by deuterium labelling at the 3-position of the aziridine. The 2-oxazolidine singlets were unaffected while the 4.66 and 5.61 branches of the AB quartets due to the 4,5-protons were diminished. The magnitude of the two 4,5-proton couplings was not sufficiently characteristic to allow for an unambiguous assignment of the position of the 5-*m*-nitrophenyl group relative to the succinimide bridge.

When *cis*-3-benzoyl-1-cyclohexyl-3-deutero-2-(*m*-nitrophenyl)aziridine was heated in acetonitrile it afforded the single oxazolidine **12***b* in 53% yield containing the deuterium label at the 4-position. It is noteworthy that in the experiments involving deuterium labelled aziridines in acetonitrile in this study, quantitative transfer of the deuterium was often observed. This is in contrast to previous work in nonpolar solvents where appreciable leakage of deuterium label was observed (10, 13–16).

The relative positions of the 2 and 4 oxazolidine substituents in **3***a*, **4***a*, and **12** were assigned *trans* by analogy with **10** and **11**, the stereochemistry of which is unambiguous. Aromatic aldehydes are relatively weak dipolarophiles and in the case of addition to *cis*- and *trans*-3-aroylaziridines the corresponding azomethine ylides equilibrate to the more stable *trans*-azomethine ylide prior to cycloaddition. Confirmation is obtained by employing much more reactive dipolarophiles, namely azoesters which even in a 15 *M* equiv excess in acetonitrile are unable to suppress the equilibration of the *cis*-azomethine ylide to the *trans*. The products of these reactions are the 1,2,4-triazolidines **13** consisting of single 3,5-*trans*-configurations in each case.

a $R_1 = CH_3CH_2$; $R_2 = C_6H_{11}$; X = H
b $R_1 = CH_3CH_2$; $R_2 = C_6H_{11}$; X = D
c $R_1 = CH_3CH_2$; $R_2 = CH(CH_3)_2$; X = H
d $R_1 = C_6H_5$; $R_2 = CH(CH_3)_2$; X = H

Assignment of the 3 and 5 ring protons in **13** is simplified by the observation of significant line broadening of the former due to coupling to the ortho protons of the adjacent *m*-nitrophenyl ring and was confirmed by deuterium labelling.

The deuterated compounds **12***b* and **13***b* did not epimerize nor exchange any deuterium label upon separate refluxing in acetonitrile with either an equivalent of the aziridine or of the corresponding primary amine, isopropylamine, or cyclohexylamine. It is concluded that epimeri-

For personal use only.

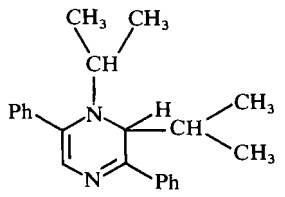
zation at the 4-position of these compounds does not occur under the reaction conditions compared with those in **20** despite the greater acidity of the C-4 hydrogen in **3**, **4**, and **12** and **13**. Therefore cycloaddition of the *m*-nitrobenzaldehyde has taken place to the more stable *trans*-azomethine ylide exclusively from either *cis*- or *trans*-aziridine. Even the most stringent precautions to exclude moisture did not suppress formation of the various products indicated above, although examination of the nature of some of the products, *e.g.* **3**, **4**, **6**, **8**, and *m*-nitrobenzaldehyde clearly indicates that hydrolysis is involved. A clue to the course of the reaction in anhydrous acetonitrile is provided by the isolation of the pyrrolo[3,4-*d*]-4-oxazoline **8**. Previous work has shown **8** can arise in the addition of *p*-nitrosophenol to 3-aroylaziridines in two consecutive 1,3-dipolar additions in which the second regiospecific addition is autocatalytic in that the subsequent Paal–Knorr condensation releases 2 equiv of water to further promote hydrolysis in an earlier step (6). The water thus released in the formation of **8** and of **5** (see Scheme 1) becomes available to initiate the hydrolysis of the aziridines. These reactions are interpreted in Scheme 1.

Previous work has shown that uncatalyzed hydrolysis of 2,3-disubstituted aziridines takes place via the aziridinium ion by a predominantly S_N2 process (17–19). Water is sufficiently acidic to provide a very low concentration of the aziridinium ion **14** from most aziridines which initiates attack by the weakly nucleophilic water (20). The nature of the products requires hydrolytic opening at both C-2 and -3 of the aziridinium ion **14** as was found previously by Cromwell and Wankel, in that hydrolysis of *trans*-1-benzyl-2-phenyl-3-*p*-toluoylaziridine results in almost equal attack at these two positions (21).

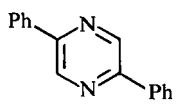
Water made available in the formation of **5** and **8** therefore, hydrolyzes **14** by attack at C-2 to give *m*-nitrobenzaldehyde **9** and *N*-isopropylphenacylamine **6**. Part of the *m*-nitrobenzaldehyde is trapped regiospecifically by the *trans*-azomethine ylide (which has a low equilibrium concentration relative to the aziridine); the rest of the *m*-nitrobenzaldehyde is isolated.

The structure of **6** was proven by its preparation from phenacyl bromide and isopropylamine and careful neutralization of the salt with base. The n.m.r. spectrum of **6** indicates the presence in solution of a large number of tautomers, the position of equilibrium of which depends on solvent polarity. Such a phenomenon is characteristic of substituted α-aminoketones (22–25). Compound **6** self-condenses very readily at room temperature to a 1,4-dihydropyrazine **15** which is not isolated but rearranges to the 1,2-dihydropyrazine **5**. The latter was identical with the material isolated from the controlled decomposition of the aziridine. Chen and Fowler have recently shown that the 1,4-dihydropyrazine structure previously assumed to be isolated from such dimerizations is incorrect in that the intermediate 1,4-dihydropyrazine suffers a 1,3-alkyl shift to the more stable (*i.e.*, possibly not antiaromatic) 1,2-dihydro form (26).

The n.m.r. spectrum of **5** shows two distinct isopropyl group doublets and two clean septets for the corresponding methines. This discounts the alternative structure **16** which would correspond to migration of the isopropyl group to an unsubstituted position. Chen and Fowler found, for a structure comparable with **16**, appreciable



16



17

coupling between the adjacent methine protons. Additionally no signal ascribable to the N—C*H*—R proton is seen in the n.m.r. spectrum of **5**. Finally pyrolysis of **3** at 280° resulted in elimination of the elements of 2,3-dimethylbutane and afforded the known 2,5-diphenylpyrazine **17**.

Hydrolytic cleavage of the aziridinium ion **14** at C-3 would give rise to phenylglyoxal and *m*-nitrobenzylisopropylamine. It has been demonstrated independently that phenylglyoxal will undergo a regiospecific 1,3-dipolar addition to aziridines to form intermediates like **18** which may in certain cases be isolated and characterized (6). Subsequent treatment with a primary amine results in a rapid Paal–Knorr condensation (28) to form pyrrolo [3,4-*d*]-4-oxazolines like **8** with the release of 2 equiv of water. The source of the isopropylamine in the scheme is

not clear at the present time. However it may be noted that often in the direct reaction of phenylglyoxal with aziridines, pyrrolo[3,4-*d*]-4-oxazolines are isolated directly, indicating the aziridine is readily hydrolyzed to provide sufficient primary amine.

A control decomposition of **2***a* in dry acetonitrile at 50° (*i.e.* at a temperature below that at which the 2–3 aziridine bond suffers cleavage indicated by the lack of equilibration of the recovered aziridine) gave rise only to products of hydrolysis, *i.e.* **6** and **9** and not to those of cycloaddition **3**, **4**, and **8**. This suggests, but does not prove, that the primary products of hydrolysis arise from the aziridinium ion **14** and not from the azomethine ylide. Also since it has been shown that the *cis*-azomethine ylide equilibrates rapidly to the *trans* form prior to cycloaddition to form **3**, **4**, and presumably **18**, then the differences in the nature and distribution of the products from *cis*- and *trans*-aziridines result mainly from hydrolysis at the aziridine stage.

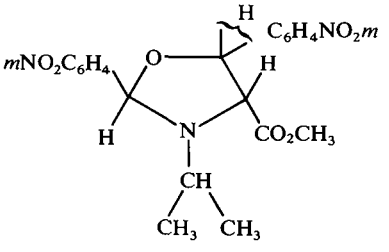
Precedents exist for differences in the preferred position of attack and rates of hydrolysis of *cis–trans* pairs of aziridines (18, 21). For example in the case of 1-benzyl-3-*p*-toluoyl-2-phenylaziridine, whereas the *trans* gave rise to hydrolysis at both positions to approximately equal extents, the *cis* isomer resulted in nucleophilic cleavage at C-3 only. In the present work, the *cis*-3-benzoylaziridine shows a marked preference for hydrolytic cleavage at C-2 leading to *ca.* 10 times as much oxazolidine (via *m*-nitrobenzaldehyde) as for the *trans* isomers.

A different situation obtains in the case of 3-carbomethoxyaziridines. Aziridine **1***b*, upon refluxing in acetonitrile, afforded a mixture of three stereoisomeric oxazolidines **20***a*, *b*, and *c*, and methyl *N*-isopropylglycine isolated as the acid. Compounds **20***a*, *b*, *c* were separable and were found in the ratio of 58:35.5:6.5 (*a*:*b*:*c*). Their structures as oxazolidines were proven by independent reaction of the *cis*- or *trans*-aziridines with *m*-nitrobenzaldehyde which afforded **20***a*, *b*, and *c* in virtually the same proportion 54:39:7.0 (*cis*) and 52:40:8.0 (*trans*). The orientation of addition of the aldehyde to the intermediate azomethine ylides was established unambiguously as before by specific deuterium labelling at the 3-position of the aziridine. The fact that all three oxazolidines correspond to the same orientation of addition of the aldehyde requires that in this instance both *cis*- and *trans*-azomethine ylides have been trapped (see below for supporting evidence). The same series of product oxazolidines **20***a*, *b*, and *c* in virtually the same ratio 55:37.5:7.5 are also obtained from **2***b*, implying that the *m*-nitrobenzaldehyde produced by hydrolysis of the aziridines adds to an equilibrium mixture containing both *trans*- and *cis*-azomethine ylides.

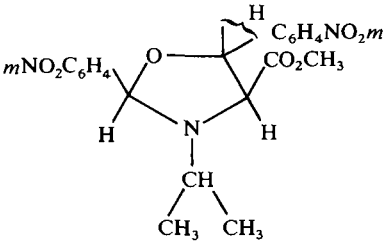
The compounds **20***a*, *b*, and *c* did not epimerize upon separate refluxing in acetonitrile with either an equivalent of the corresponding aziridine or isopropylamine, *i.e.* under the conditions of their formation. This confirms that the ratio of products observed is derived by the addition of *m*-nitrobenzaldehyde to the equilibrium mixture of ylides.

The configurational assignments with respect to the aziridine moiety in **20***a*, *b*, and *c* were established by experiments in which aziridines **1***b* and **2***b* were respectively treated with a large excess of *m*-nitrobenzaldehyde to trap the predominant ylide prior to complete equilibration. The pure *trans*-aziridine with 10.5 equiv of *m*-nitrobenzaldehyde in acetonitrile at 115–117° afforded **20***a*, *b*, and *c* in a ratio of 20.5:18:61.5 confirming that **20***c* arises from the predominant *cis*-azomethine ylide.

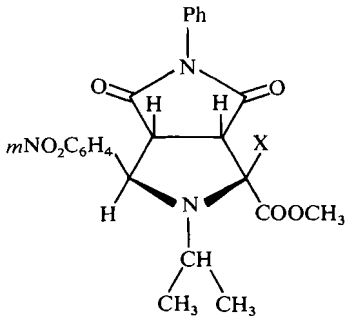
Similarly the pure *cis*-aziridine reacted with 7.5 *M* equiv of *m*-nitrobenzaldehyde to give



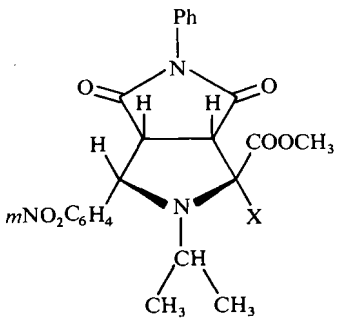
20*a* and *b*



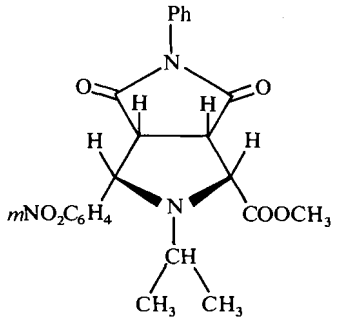
20*c*



21
a X = H
b X = D



22
a X = H
b X = D



23
a X = H
b X = D

20*a*, *b*, and *c* in the proportion 60:40:0 with no **20***c* detectable. This proves that like **3***a* and **4***a*, both **20***a* and *b* arise from the more stable *trans*-azomethine ylide. A constant orientation of addition of the aldehyde having been established by deuterium labelling, this requires **20***a* and *b* to differ only in the mode of addition of the aldehyde. However the n.m.r. evidence does not allow a distinction between the *trans–cis* and *trans–trans* structures for **20***a* and *b*. Aziridine **1***b* reacted with *N*-phenylmaleimide in refluxing acetonitrile to give a mixture of the two pyrrolidines **21***a* and **22***a* in a ratio of 63:37. The isomeric **2***b* in contrast gave **21***a*, **22***a*, and **23***a* in a ratio of 54:40:6 indicating a small amount of the *cis*-azomethine ylide has been captured.

The n.m.r. line assignments of the methine protons were proven by deuterium labelling at the 3-position of the aziridine ring from which the stereochemical assignments could be made unambiguously. The major product in each case **21***a* corresponded in structural type to that of the sole products **10** and **11***a* obtained from the 3-aroylaziridines. Thus the *N*-phenylmaleimide is only marginally successful in suppressing the equilibration to the *trans*-azomethine ylide. The more reactive dipolarophile dimethyl azodicarboxylate with **1***b* in equimolar proportion gave a mixture of the stereoisomeric triazolidines **24** and **25** in a ratio of 62:38. An experiment performed with 3 equiv of the dipolarophile and **1***b* now gave **24**:**25** in a ratio of 82:18 showing as the concentration of the dipolarophile is increased more of the orbital symmetry controlled *trans*-azomethine ylide is trapped, proving **24** has the stereochemistry shown. Reaction of **2***b* with 1 equiv of dimethyl azodicarboxylate gave **24** and **25** in a ratio of 43:57 while an experiment using 3 equiv of the dipolarophile gave **24** and **25** in a ratio of 25:75. This similarly confirms **25** as having the *cis* geometry of the aziridine moiety.

Control reactions were carried out involving reaction of **1***b* and **2***b* separately with one added equivalent of water in acetonitrile at 115–117° for 24 h. Identical results were obtained, *i.e.* all three stereoisomeric oxazolidines **20***a*, *b*, and *c* were obtained in the proportion of 26:20:54 together with some *m*-nitrobenzaldehyde.

In contrast to the case of the 3-benzoylaziridines stringent exclusion of water from the system succeeded in suppressing the hydrolysis

of the ester aziridines to a great extent. After 24 h refluxing of the *trans* ester aziridine in dry acetonitrile only 15% decomposition occurred whereas the recovered 85% of aziridine had equilibrated to give a *cis–trans* mixture of 63:37, *i.e.* virtually identical with the equilibrium composition obtained in toluene 64:36. Identical results were obtained starting with pure **1***b*. These results are consistent with the scheme in that decomposition of the ester aziridine, since it does not involve autocatalytic condensations and decompositions, is entirely dependent on adventitious moisture. Hydrolysis is therefore slower than for the aroylaziridines, allowing prior equilibration of the stereoisomeric aziridines and accounting for the identity of the products from **1***b* and **2***b* in contrast to the case of **1***a* and **2***a*. Hydrolysis is also more selective in **1***b* and **2***b* than in **1***a* and **2***a* occurring exclusively at the 2-position of the former.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (W/V) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

General Preparation of 3-Aroylaziridines

The 3-aroylaziridines used in this study were prepared by the Gabriel synthesis involving Claisen–Schmidt condensations to form chalcones, addition of bromine to form the dibromochalcones, and treatment of the dibromochalcones with an excess of a primary aliphatic amine to provide 3-aroylaziridines (29).

Synthesis of cis- and trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)-3-aziridinecarboxylate (1b, 2b)

(a) Methyl 2,3-Dibromo-3-(m-nitrophenyl)propionate

This compound, m.p. 87–89°, was obtained in 90% yield by the bromination of methyl *m*-nitrophenyl cinnamate in chloroform.

Anal. Calcd. for $C_{10}H_9Br_2NO_4$ (mol. wt. 364.8888): C, 32.71; H, 2.47; N, 3.81; Br, 43.57. Found (364.8898, mass spectrum): C, 32.89; H, 2.50; N, 3.75; Br, 43.63.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.92 (s, 3H, CO_2CH_3); 4.83 and 5.43 (d each, 1H, $J = 12.5$ Hz, C_2H and C_3H respectively). The i.r. spectrum ν_{max} ($CHCl_3$): 1745 (C=O); 1525 and 1350 cm^{-1} (NO_2).

(b) Methyl α-Bromo-m-nitrophenylcinnamate

Dehydrohalogenation of methyl 2,3-dibromo-3-(*m*-nitrophenyl)propionate with potassium acetate in refluxing methanol for 18 h gave methyl α-bromo-*m*-nitrophenyl cinnamate in 90% yield, m.p. 97–98.5°.

Anal. Calcd. for $C_{10}H_8BrNO_4$ (mol. wt: 284.9636): C, 42.0; H, 2.85; N, 4.88; Br, 28.30. Found (284.9630, mass spectrum): C, 41.87; H, 3.10; N, 4.81; Br, 28.17.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.91 (s, 3H, CO_2CH_3); 7.44–8.63 (m, 5H, aromatic protons).

(c) cis- and trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)-aziridine-3-carboxylate

A solution of 18.25 g (0.05 mol) of methyl 2,3-dibromo-3-(*m*-nitrophenyl)propionate in 50 ml of dry benzene containing 17.7 g (0.3 mol) of isopropylamine was stirred at room temperature for 24 h. The reaction mixture was diluted with ether, the precipitated salt collected, and the filtrate washed with water. Removal of the solvent *in vacuo* gave a red oil trituration of which with methanol precipitated pure *trans*-methyl 1-isopropyl-2-(*m*-nitrophenyl)aziridine-3-carboxylate (**2***b*) 6.2 g (48.1% yield), m.p. 87–88.5°.

Anal. Calcd. for $C_{13}H_{16}N_2O_4$ (mol. wt. 264.1110): C, 59.09; H, 6.10; N, 10.57. Found (264.1108, mass spectrum): C, 58.84; H, 6.23; N, 10.23.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.04, 1.16 (2d, 6H, $J = 6.5$ Hz, $CH(CH_3)_2$); 2.74 (d, 1H, $J = 2.5$ Hz, C_3H); 3.02 (m, 1H, $J = 6.5$ Hz, $CH(CH_3)_2$; 3.33 (d, 1H, $J = 2.5$ Hz, C_2H); 3.79 (s, 3H, CO_2CH_3); 7.35–8.22 (m, 4H, aromatic protons). The i.r. spectrum ν ($CHCl_3$): 1725 (C=O); 1525 and 1343 cm^{-1} (NO_2).

The methanol extract was evaporated and the remaining oil was diluted with benzene–hexane (40:60). Chilling of the solution produced a low melting solid which was recrystallized twice from benzene–hexane to give the pure methyl *cis*-1-isopropyl-2-(*m*-nitrophenyl)aziridine-3-carboxylate (**1***b*) 3.2 g (24.2% yield), m.p. 52–53.5°.

Anal. Calcd. for $C_{13}H_{16}N_2O_4$ (mol. wt. 264.1110): C, 59.09; H, 6.10; N, 10.57. Found (264.1110, mass spectrum): C, 58.82; H, 6.14; N, 10.73.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.25 (d, 6H, $J = 5.2$ Hz); 1.96 (m, 1H, $CH(CH_3)_2$); 2.61 (d, 1H, $J = 6.5$ Hz, C_3H); 3.06 (d, 1H, $J = 6.5$ Hz, C_2H); 3.49 (s, 3H, CO_2CH_3); 7.25–8.33 (m, 4H, aromatic). The i.r. spectrum ν ($CHCl_3$): 1730 (CO); 1520 and 1342 cm^{-1} (NO_2).

(d) cis- and trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)-3-deuteroaziridine-3-carboxylates

These compounds were prepared by reaction of methyl α-bromo-β-(*m*-nitrophenyl)cinnamate with a 15 fold excess of isopropylamine-*N*-d_2 in ether. The isomeric aziridines were isolated as described above. The integrals of the ring proton spectra indicated 82% deuterium incorporation at C-3.

Thermal Decomposition of cis-3-Benzoyl-1-isopropyl-2-(m-nitrophenyl)aziridine (1a) in Acetonitrile

(a) At Reflux

A solution of 0.932 g (3 mmol) of the pure *cis*-aziridine **1***a* in 50 ml of dry acetonitrile was heated under reflux for 24 h. Removal of the solvent *in vacuo* and trituration of the residue with methanol deposited a white crystalline solid,

*Parent molecular ion minus *m*-nitrobenzaldehyde ion.
†Parent molecular ion minus benzoyl.

m.p. 148–153°. The t.l.c. and n.m.r. analyses confirmed the presence of the two stereoisomeric oxazolidines **3***a* and **4***a* (80:20), 0.386 g (56% yield).

The solid was subjected to chromatography on 50 g of BDH alumina. Elution with benzene–hexane (40:60) gave a fraction (100 mg) consisting of a 70:30 mixture of **3***a*:**4***a* which crystallized from methanol as a white solid, m.p. 159–162.5°.

Mol. Wt. Calcd. for $C_{25}H_{23}N_3O_6$ (base peak $C_{25}H_{23}N_3O_6$—$C_7H_5NO_3$): 310.1317. Found (mass spectrum): 310.1321.

The n.m.r. spectrum ($CDCl_3$) δ_{TMS} major component (**3***a*) 0.92 (2d, 6H, $CH(CH_3)_2$, $J = 6.5$ Hz); 3.33 (m, 1H, $CH(CH_3)_2$); 5.70 (ABq, 2H, $J = 6.2$ Hz, C_4H and C_5H); 6.30 (s, 1H, C_2H); and 7.18–8.62 (m, 13H, aromatic). The i.r. spectrum ($CHCl_3$) 1667 (C=O), 1530 and 1350 cm^{-1} (NO_2).

Further elution with benzene gave a second fraction (260 mg) of pure **4***a* which crystallized from methanol, m.p. 139–140.5°.

Anal. Calcd. for $C_{25}H_{23}N_3O_6$ (base peak $C_{25}H_{23}N_3O_6$—$C_7H_5NO_3$ = 310.1317): C, 65.08; H, 4.99; N, 9.11. Found (310.1314, mass spectrum): C, 65.24; H, 4.88; N, 9.47.

The n.m.r. spectrum ($CDCl_3$) δ: 1.16 (d, 6H, $CH(CH_3)_2$, $J = 6.5$ Hz); 3.26 (m, 1H, $CH(CH_3)_2$); 4.66 (d, 1H, $J = 6.0$ Hz, C_4H); 5.57 (d, 1H, $J = 6.0$ Hz, C_5H); 6.24 (s, 1H, C_2H); and 7.12–8.64 (m, 13H, aromatic). The i.r. spectrum ν ($CHCl_3$): 1664 (C=O), 1527 and 1345 cm^{-1} (NO_2).

The original filtrate was evaporated and the residue subjected to chromatography on 50 g of BDH alumina. Elution with hexane–benzene (25:75) gave 1,6-diisopropyl-3,6-diphenyl-1,2-dihydropyrazine **5**, 0.043 g (10% yield). The n.m.r. and i.r. spectra of this material were superimposable with those of the independently synthesized material (see below).

Further elution of the column with benzene gave *N*-(isopropyl)phenacylamine **6**, 0.107 g (20% yield), m.p. 71–74°. The n.m.r. and i.r. spectra of this material were superimposable with those of an authentic sample of *N*-(isopropyl)phenacylamine (see below).

Further elution with benzene–chloroform (60:40) gave a red oil, 0.132 g. This basic nitrogen-containing fraction is as yet unidentified but the n.m.r. spectrum shows δ_{TMS} ($CDCl_3$): 1.01–1.86 (m, 6H, $CH(CH_3)_2$); 4.73 (s, 2H); 5.12–5.45 (b, 2H; exchangeable by D_2O, NH_2?); and 7.04–8.35 (m, 12H aromatic).

(b) At 50 ± 1°

A solution of 0.622 g (2 mmol) of the aziridine **1***a* in 40 ml of acetonitrile was heated at 50 ± 1° for 24 h. Removal of the solvent *in vacuo* gave a light orange oil which was subjected to chromatography on 75 g of BDH alumina. Elution with hexane–benzene (75:25) gave some unreacted *cis*-aziridine, 0.341 g (55% yield).

Further elution with hexane–benzene (50:50) gave *m*-nitrobenzaldehyde as an oil which solidified on standing 0.097 g (32% yield), m.p. 51–53°. The n.m.r. and i.r. spectra of this material were superimposable with those of an authentic sample.

Continued elution with benzene gave *N*-(isopropyl)-phenacylamine **6** as an orange oil 0.124 g (35% yield). This material was identical with an authentic sample.

Thermal Decomposition of cis-3-Benzoyl-1-cyclohexyl-3-deutero-2-(m-nitrophenyl)aziridine in Acetonitrile

A solution of 0.350 g (1 mmol) of the labelled aziridine (54% deuterium) in 50 ml of acetonitrile was heated under reflux for 24 h. Work-up of the reaction mixture as described above gave **12***b*, 0.132 g (52.8% yield) of 4-benzoyl-3-cyclohexyl-3-deutero-2,5-di(*m*-nitrophenyl)oxazolidine, m.p. 147–149°.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 0.83–2.20 (m, 10H,

cyclohexyl CH_2); 2.51–3.17 (m, 1H, cyclohexyl CH); 4.74 (d, 0.57 H, $J = 7$ Hz, C_4H); 5.47 (d, 1H, $J = 7$ Hz, C_5H); 6.23 (s, 1H, C_2H); and 7.25–8.53 (m, 13H, aromatic).

*Thermal Decomposition of trans-3-Benzoyl-1-isopropyl-2-(m-nitrophenyl)aziridine (**2a**) in Acetonitrile*

(a) At Reflux Temperature

A solution of 3.11 g (10 mmol) of the aziridine **2a** in 100 ml of acetonitrile was heated under reflux for 24 h. Removal of the solvent *in vacuo* gave an orange oil, which was subjected to chromatography on 160 g of BDH alumina. Elution with hexane–benzene (75:25) gave 1,6-diisopropyl-3,6-diphenyl-1,2-dihydropyrazine **5** as an oil which solidified on trituration with methanol to an orange solid, m.p. 82–84°, 0.201 g (12.5% yield). The identity of this material was established by comparison with an authentic sample (see below).

Further elution with hexane–benzene (50:50) gave *m*-nitrobenzaldehyde 0.095 g (6.3% yield) as an oil which solidified on standing 48–51°.

Continued elution with benzene gave light orange oil, 0.467 g (26.5% yield) which was identified as *N*-(isopropyl)-phenacylamine **6** by comparison with an authentic sample.

Further elution with benzene–chloroform (90:10) gave a mixture of the stereoisomeric oxazolidines **3a** and **4a** as a solid, m.p. 138–140.5°, 0.124 g (5.4% yield).

Continued elution with benzene–chloroform (75:25) gave a red oil, 0.341 g. This basic nitrogen-containing fraction is as yet unidentified but the n.m.r. spectrum shows δ_{TMS} ($CDCl_3$): 1.04–1.61 (m, 6H); 4.73 (s, 2H); 5.52–5.81 (b, 2H, exchangeable by D_2O, NH_2?).

Further elution with benzene–chloroform (50:50) gave 3,5-diisopropyl-2-(*m*-nitrophenyl)-4,6-diphenylpyrrolo-[3,4-*d*]-4-oxazoline **8** as an orange oil, 0.198 g (8.5% yield) which resisted crystallization. The identity of this compound was established by its independent synthesis by a previously described procedure from the reaction of the aziridine with phenylglyoxal and then treating the 1,3-dipolar addition product with isopropylamine (6).

Anal. Calcd. for $C_{29}H_{29}N_3O_3$ (mol. wt. 467.2209): C, 74.51; H, 6.21; N, 8.99. Found (467.2197, mass spectrum): C, 74.04; H, 6.41; N, 9.21.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.01 (d, 6H, $CH(CH_3)_2$, $J = 6.0$ Hz); 1.22 (d, $CH(CH_3)_2$, $J = 6.0$ Hz); 2.81–3.22 (septet, 1H, $CH(CH_3)_2$); 3.93–4.21 (septet, 1H, $CH(CH_3)_2$); 6.85–8.03 (m, 15H, aromatic and C-2 proton). The i.r. spectrum ($CHCl_3$): 1530 and 1348 cm^{-1} (NO_2).

(b) At 50 ± 1°

A solution of 1.57 g (5 mmol) of the pure *trans*-aziridine **2a** in 50 ml of dry acetonitrile was heated at 50 ± 1° for 24 h. Removal of the solvent *in vacuo* gave an orange oil which was subjected to chromatography on 80 g of BDH alumina. Elution with hexane–benzene (25:75) gave some unreacted *trans*-aziridine **2a**, 0.98 g (62.5% yield). Further elution with hexane–benzene (50:50) gave *m*-nitrobenzaldehyde as a light yellow oil which solidified on standing, m.p. 53–54°, 0.160 g (20% yield). The n.m.r. and i.r. spectra of this material were superimposable with those of an authentic sample.

Further elution with benzene gave *N*-(isopropyl)phenacylamine **6** as a light orange oil, 0.214 g (24.5% yield) which on trituration with petroleum ether crystallized as yellowish-white needles, m.p. 72–74.5°. This material was identified by comparison with an authentic sample. The mass spectrum of this fraction also exhibits a peak at *m/e* 318 ascribed to 1,6-diisopropyl-3,6-diphenyl-1,2-dihydropyrazine **5** which is expected owing to the facile dimerization and rearrangement of *N*-(isopropyl)phenacylamine recorded below.

General Procedure for Preparation of 1,3-Dipolar Adducts in Acetonitrile

The reactions of aziridines with aldehydes to form oxazolidines and with *N*-phenylmaleimide and diethyl azodicarboxylate to form adducts were carried out according to established procedures. The analytical and spectral data on these compounds are summarized in Tables 1 and 2.

Control Attempted Epimerization/Exchange of 1,3-Dipolar Adducts

Experiments were performed with **12b**, **13a**, **13b**, **24**, and **25** in which solutions of 0.100 g of the adducts in 10 ml of acetonitrile were refluxed for 24 h in the presence of 1 equiv of the corresponding aziridine or primary amine. In all cases examination of the product by n.m.r. showed no detectable evidence of deuterium exchange or epimerization.

*Preparation of N-(Isopropyl)phenacylamine (**6**) and 1,6-Diisopropyl-3,6-diphenyl-1,2-dihydropyrazine (**5**)*

Isopropylamine (5.9 g, 10 mmol) was added to a cold ethereal solution of 10 g (5 mmol) of phenacyl bromide and the mixture allowed to react for 24 h. The precipitated salt was removed and the filtrate washed successively with 10% aqueous potassium carbonate solution, twice with cold water, and dried ($MgSO_4$). Removal of the solvent *in vacuo* afforded an orange oil. Trituration with methanol deposited 1,6-diisopropyl-3,6-diphenyl-1,2-dihydropyrazine (**5**) as an orange solid, m.p. 83–84.5°, 1.42 g (17.9% yield).

Anal. Calcd. for $C_{22}H_{26}N_2$ (mol. wt. 318.2096): C, 82.96; H, 8.22; N, 8.82. Found (318.2101, mass spectrum): C, 82.63; H, 8.14; N, 8.74.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 0.79 (d, 3H, $CH(CH_3)_2$, $J = 6.5$ Hz); 1.31 (d, 3H, $CH(CH_3)_2$, $J = 6.5$ Hz); 2.90 (septet, 1H, $CH(CH_3)_2$); 6.81 (s, 1H, C-2 proton); 7.23–7.85 (m, 11H, aromatic and C-5 protons).

Concentration of the methanol filtrate left a red oil which on dilution with petroleum ether (30–60°) and chilling for 2 days deposited *N*-(isopropyl)phenacylamine **6**, m.p. 73–75.5°, 2.64 g (30% yield).

Mol. Wt. Calcd. for $C_{11}H_{15}NO$: 177.1154. Found (mass spectrum): 177.1157.

The i.r. spectrum ($CHCl_3$): 3410 (NH), 1658 cm^{-1} (C=O).

*Thermolysis of 1,6-Diisopropyl-3,6-diphenyl-1,2-dihydropyrazine (**5**)*

The dihydropyrazine **5** (0.500 g) was heated in a sealed tube at 280° for 1 h. The resulting red oil solidified on cooling and was taken up in chloroform. Removal of the solvent *in vacuo* and examination of the oil by n.m.r. revealed the presence of a small amount of unreacted 1,2-dihydropyrazine. The crude reaction mixture was subjected to sublimation at 80°/10 mm to give 2,5-diphenylpyrazine **17** as a light orange solid, m.p. 187–189° (lit. (26) m.p. 192–194°). The melting point of this material was not depressed by admixture with an authentic sample prepared by heating a solution of ω-aminoacetophenone hydrochloride (Aldrich Chemicals, Ltd.) and 10% aqueous potassium carbonate at 100° for 2 h according to a literature procedure (26).

Decomposition of cis-Methyl 1-Isopropyl-2-(m-nitrophenyl)-aziridine-3-carboxylate (1b) in Acetonitrile

A solution of 2.64 g (10 mmol) of the aziridine **1***b* in 100 ml of acetonitrile was heated at 115–117° in a pressure vessel for 24 h. Removal of the solvent *in vacuo* gave a red oil. The n.m.r. and t.l.c. analysis of the crude reaction mixture confirmed the formation of three products **20***a*, *b*, and *c* in the ratio of 58:35.5:6.5. Trituration of the oil with methanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

resulted in the precipitation of a solid **20***c* 0.104 g (5.1% yield), m.p. 110–112°.

Anal. Calcd. for $C_{20}H_{21}N_3O_7$ (mol. wt. 415.1386): C, 57.82; H, 5.09; N, 10.11. Found (415.1366, mass spectrum): C, 57.78; H, 5.11; N, 10.12.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.13 (d, 6H, $J = 6.5$ Hz, $CH(CH_3)_2$); 3.25 (m, 1H, $CH(CH_3)_2$); 3.75 (d, 1H, $J = 7.0$ Hz, C_4H); 3.78 (s, 3H, OCH_3); 5.12 (d, 1H, $J =$ 7.0 Hz, C_5H); 5.93 (s, 1H, C_2H); and 7.02–8.63 (m, 8H, aromatic). The i.r. spectrum ν ($CHCl_3$): 1730 (C=O), 1525 and 1350 cm^{-1} (NO_2).

Concentration of the methanol filtrate left a red oil which was subjected to chromatography on 80 g of BDH alumina. Elution with benzene–hexane (60:40) gave a pale yellow oil, 1.07 g (51.5% yield) which on trituration with methanol – petroleum ether crystallized to give a white solid **20***a*, *b*, m.p. 114–115.5°.

Anal. Calcd. for $C_{20}H_{21}N_3O_7$ (mol. wt. 415.1386): C, 57.82; H, 5.09; N, 10.11. Found (415.1374, mass spectrum): C, 57.75; H, 5.11; N, 10.03.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.06 (2d, 6H, $CH(CH_3)_2$, $J = 6.5$ Hz); 3.34 (m, 4H, $CH(CH_3)_2$ and CO_2CH_3); 4.57 (d, 1H, $J = 5.0$ Hz, C_4H); 5.71 (d, 1H, $J =$ 5.0 Hz, C_5H); 6.10 (s, 1H, C_2H); and 7.31–8.62 (m, 8H, aromatic). The i.r. spectrum ($CHCl_3$) ν ($CHCl_3$): 1730 (C=O); 1520 and 1350 cm^{-1} (NO_2).

Further elution with benzene gave light yellow oil of **20***a*, *b*, 0.627 g (30.2%), which resisted crystallization.

Anal. Calcd. for $C_{20}H_{21}N_3O_7$: (mol. wt. 415.1386): C, 57.82, H, 5.09; N, 10.11. Found (415.1391, mass spectrum): C, 57.61; H, 5.21; N, 9.98.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 0.95 (2d, 6H, $CH(CH_3)_2$, $J = 6.2$ Hz); 3.12 (m, 1H, $CH(CH_3)_2$); 3.92 (s, 3H, CO_2CH_3); 4.25 (d, 1H, C_4H $J = 3.0$ Hz); 5.36 (d, 1H, C_5H, $J = 3.0$ Hz); 6.02 (s, 1H, C_2H); and 7.50–8.66 (m, 8H, aromatic). The i.r. spectrum ν ($CHCl_3$): 1727 (C=O), 1530 and 1345 cm^{-1} (NO_2).

Similarly the decomposition of *trans*-methyl 1-isopropyl-2-(*m*-nitrophenyl)-3-aziridine carboxylate **2***b* in acetonitrile gave the same compounds in the ratio of 55:37.5:7.5 by n.m.r. analysis.

Decomposition of trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)aziridine-3-carboxylate (2b) in Acetonitrile

A solution of 1.34 g (5 mmol) of the aziridine **2***b* in 50 ml of acetonitrile was heated at 115–117° for 24 h. The bulk of the liquid was distilled into a flask containing 2 ml of concentrated hydrochloric acid. The distillate was allowed to evaporate at room temperature to give methyl *N*-isopropylglycine hydrochloride as a white solid, 0.187 g, m.p. 134–138°. The n.m.r. spectrum of this salt in deuterium oxide showed δ: 1.28 (d, 6H, $J = 6.0$ Hz, $(CH_3)_2CH$); 3.48 (septet, 1H, $(CH_3)_2CH$); 3.78 (s, ester); 3.89 (s, $CH_2CO_2CH_3$); 4.0 (s, CH_2CO_2H). The spectrum suggested that the methyl ester group had been partially hydrolyzed. The hydrolysis was completed by heating an acidified aqueous solution of the salt at 80° for 14 h. Removal of the solvent *in vacuo* gave a white solid which had an n.m.r. spectrum in deuterium oxide δ: 1.27 (d, 6H, $J = 6.0$ Hz, $(CH_3)_2CH$); 3.48 (septet, 1H, $(CH_3)_2CH$); 4.05 (s, 2H, CH_2CO_2H) which was superimposable with that of an authentic sample of *N*-isopropylglycine hydrochloride obtained by the reaction of equimolar quantities of chloroacetic acid and isopropylamine in ether.

Traces of acetonitrile were removed *in vacuo* from the distillation residue to give a mixture of the stereoisomeric oxazolidines **20***a*, *b*, and *c*.

Decomposition of trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)aziridine-3-carboxylate (2b) in Acetonitrile with Water Added

A solution of 0.265 g (1 mmol) of the aziridine **2***b* and 18 mg (1 mmol) of water in 50 ml of acetonitrile was refluxed for 24 h. Removal of the solvent *in vacuo* gave an oil. The n.m.r. analysis of the crude reaction mixture showed the formation of all three oxazolidines **20***a*, *b*, and *c* in the ratio of 26:20:54, and that all the *m*-nitrobenzaldehyde had been trapped.

Thermal Decomposition of trans-Methyl 1-Isopropyl-2-(m-nitrophenyl)aziridine-3-carboxylate (2b) in Absolute Acetonitrile

A solution of 0.790 g (3 mmol) of the aziridine **2***b* in 50 ml of absolute acetonitrile (freshly distilled over calcium hydride) was heated at 115–117° in a sealed vessel for 24 h. Removal of the solvent *in vacuo* gave a red oil, n.m.r. analysis of which showed the isomeric aziridines **1***b* and **2***b* in a ratio of 63:37 to the extent of 85% yield and the oxazolidines **20***a* and *b* in a ratio of 60:40 in 15% yield.

Similarly thermal decomposition of **1***b* in absolute acetonitrile afforded the same products in virtually identical ratios.

In a separate control experiment both **1***b* and **2***b* equilibrated at the reflux temperature of toluene to give a mixture of **1***b*: **2***b* of (64:36).

This research was supported by a National Research Council of Canada grant to J.W.L. We thank Mr. R. Swindlehurst and Dr. A. Hogg for the n.m.r. and mass spectra.

A General Synthesis of 8,2′-Thioanhydropurine Nucleosides[1]

K. K. OGILVIE, L. SLOTIN,[2] J. B. WESTMORE, AND D. LIN
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 26, 1972

The synthesis of 8,2′-anhydro-8-mercapto-9-β-D-arabinofuranosyladenine, 8,2′-anhydro-8-mercapto-9-β-D-arabinofuranosylguanine, and 8,2′-anhydro-8-mercapto-9-β-D-arabinofuranosylhypoxanthine is described. The anhydro ring is formed by simultaneous displacement of bromine from position-8 and carbonate from the 2′-position of the parent nucleoside using either sodium hydrogen sulfide or thiourea.

La synthèse de l'anhydro-8,2′ mercapto-8 arabinofuranosyl-9-β-D adénine, de l'anhydro-8,2′ mercapto-8 arabino furanosyl-9-β-D guanine, de l'anhydro-8,2′ mercapto-8 arabinofuranosyl-9-β-D hypoxanthine est décrite. Le cycle anhydro est formé par déplacement simultané du brome de la position-8 et du carbonate de la position-2′ du nucléoside parent, par l'utilisation du bisulfite de sodium et du thiourée.

Cyclonucleosides are important analogues of natural nucleosides. They are characterized by having in addition to the *N*-glycoside linkage a covalent linkage either directly or via bridging atoms between the 2′, 3′, or 5′ carbons of the sugar and a carbon or nitrogen atom (other than the nitrogen of the glycoside bond) of the purine or pyrimidine ring. Acid or base hydrolysis of the cyclo-linkage normally leads to ribo, arabino, or xylo nucleosides (1). Nucleophilic displacement of the cyclo-linkage leads to nucleosides modified on the sugar moiety (1–3) and sometimes on the base moiety (1, 4–6). Arabino cytidine (7, 8) and cordycepin (6) are but two of the important biologically active compounds obtained from cyclonucleosides. Cyclonucleosides have even been detected as intermediates in proposed prebiotic syntheses (9, 10) and have been used as intermediates in the chemical synthesis of nucleotides (11–13). Investigation of the spectra of cyclonucleosides may lead to useful structural information on nucleic acids (14, 15).

Because of the interest in cyclonucleosides, numerous syntheses have been reported, particularly in the pyrimidine series. Hampton and Nichol (16) developed an exceedingly simple synthesis of O^2,2′-anhydrouridines and other procedures have been developed for the synthesis of 5′- and 3′-cyclouridines (17–19) as well as cycloderivatives of thymidine (20, 21) and cytidine (7, 8, 9, 22). In the purine series, progress has been slower. Ikehara (6) has extensively investigated the cycloadenosines describing syntheses of *O* and *S* 8,2′- (23–26), 8,3′- (6, 25), and 8,5′- (27) cycloderivatives. Recently the synthesis of 8,2′-*N*-cycloadenosine has been described (28).

Cyclonucleosides of purines other than adenosine have received little attention. This probably reflects the complexity of the synthetic methods developed to date. Ikehara has reported syntheses of three derivatives of guanosine cyclonucleosides (29, 30) and we have recently described the first synthesis of 8,2′-thioanhydroguanosine (31). The syntheses of purine cyclonucleosides developed so far are all (*a*) multistep procedures, (*b*) specific for only one nucleoside, (*c*) involve low overall yields or a combination of all three.

We wish to describe a simple, efficient, and general synthetic method for the synthesis of 8,2′-thioanhydropurine nucleosides. A brief preliminary account of this work has appeared (32).

Discussion and Results

The most efficient syntheses of 8,2′-thioanhydropurine nucleosides have employed simultaneous displacement of a halogen from the 8-position of the base and a good leaving group (such as a sulfonate) from the 2′-position of the sugar of the parent nucleoside (26). The difficulty has arisen in the selective introduction of a good leaving group at the 2′-position of the ribose sugar. Unless the 5′-hydroxyl possesses a bulky substituent, sulfonating agents show only a

[1]Part VI in a series on anhydronucleosides. Part V is ref. 31.

slight preference for the 2′-hydroxyl over the 3′-hydroxyl. The combination of a bulky substituent at the 5′-hydroxyl and the use of a sterically hindered sulfonating agent increases the degree of reaction at the 2′-position relative to the 3′-position (26, 31). However, placing a bulky substituent at the 5′-hydroxyl usually introduces several additional steps into the synthesis. Ikehara and Uesugi (33) partially overcame this problem with some adenosine 5′-phosphates by using sodium hydroxide in dioxane with a sulfonating agent. Under these conditions sulfonation appeared to occur exclusively at the 2′-position. However, this still necessitated the blocking of the 5′-position with phosphate since other 5′-protecting groups led to varying degrees of 3′-sulfonation (26).

We had noted that a 2′,3′-carbonate on a pyrimidine nucleoside is readily displaced by nucleophilic groups on the base ring (34). Further it has been found that there is no need to block either the 5′-hydroxyl or amine groups on the base ring in forming 2′,3′-carbonates of purine nucleosides (16, 35). This suggested the possibility of introducing a good leaving group (CO_2) on the 2′-position of any 8-halopurine nucleoside in a single step. Simultaneous displacement of the 8-halogen and the carbonate from the 2′-position should lead to the 8,2′-cyclonucleosides. This would represent an extremely simple general route to such compounds. On this basis we have developed a general procedure (outlined in Scheme 1) for the synthesis of 8,2′-thioanhydropurine nucleosides.

8-Bromopurine nucleosides are readily available by standard procedures. Formation of cyclic carbonates from the 8-bromonucleosides requires a short (30 min) treatment of the 8-bromonucleoside with a slight excess of diphenyl carbonate in DMF at 150 °C in the presence of a small amount of sodium bicarbonate. Yields ranged from slightly above 70% for 8-bromoadenosine 2′,3′-carbonate (**2**) and 8-bromoinosine 2′,3′-carbonate (**5**) to 98% for 8-bromoguanosine 2′,3′-carbonate (**8**). Compounds **2**, **5**, and **8** all possess the characteristic carbonyl absorption at 5.5 μ in the i.r.

The final step in Scheme 1 involves simultaneous displacement of the bromine from the 8-position and the carbonate from the 2′-position. This was accomplished in two ways: method A using sodium hydrogen sulfide in hot DMF and method B using thiourea in refluxing *n*-butanol. We found that method A gave higher yields in all cases.

8,2′-Thioanhydroadenosine (**3**) was obtained in 79% yield from **2** using method A but the yield dropped to 66% using method B. Compound **3** was identical to authentic 8,2′-thioanhydroadenosine prepared by the method of Ikehara and Kaneko (26).

8,2′-Thioanhydroinosine (**6**) was obtained in several ways. From compound **5**, **6** was prepared in 73% yield by method A and 69% by method B. Further, 8,2′-thioanhydroadenosine was readily deaminated by adenosine deaminase (39) to produce **6** quantitatively. These results represent the first reported chemical syntheses of 8,2′-thioanhydroinosine which was further characterized by Raney nickel reduction to 2′-deoxyinosine.

Compound **8** was converted to 8,2′-thioanhydroguanosine (**9**) in 56% yield by method A while the yield was 41% using method B. Compound **9** was identical to authentic 8,2′-thioanhydroguanosine (31) and was converted to 2′-deoxyguanosine using Raney nickel.

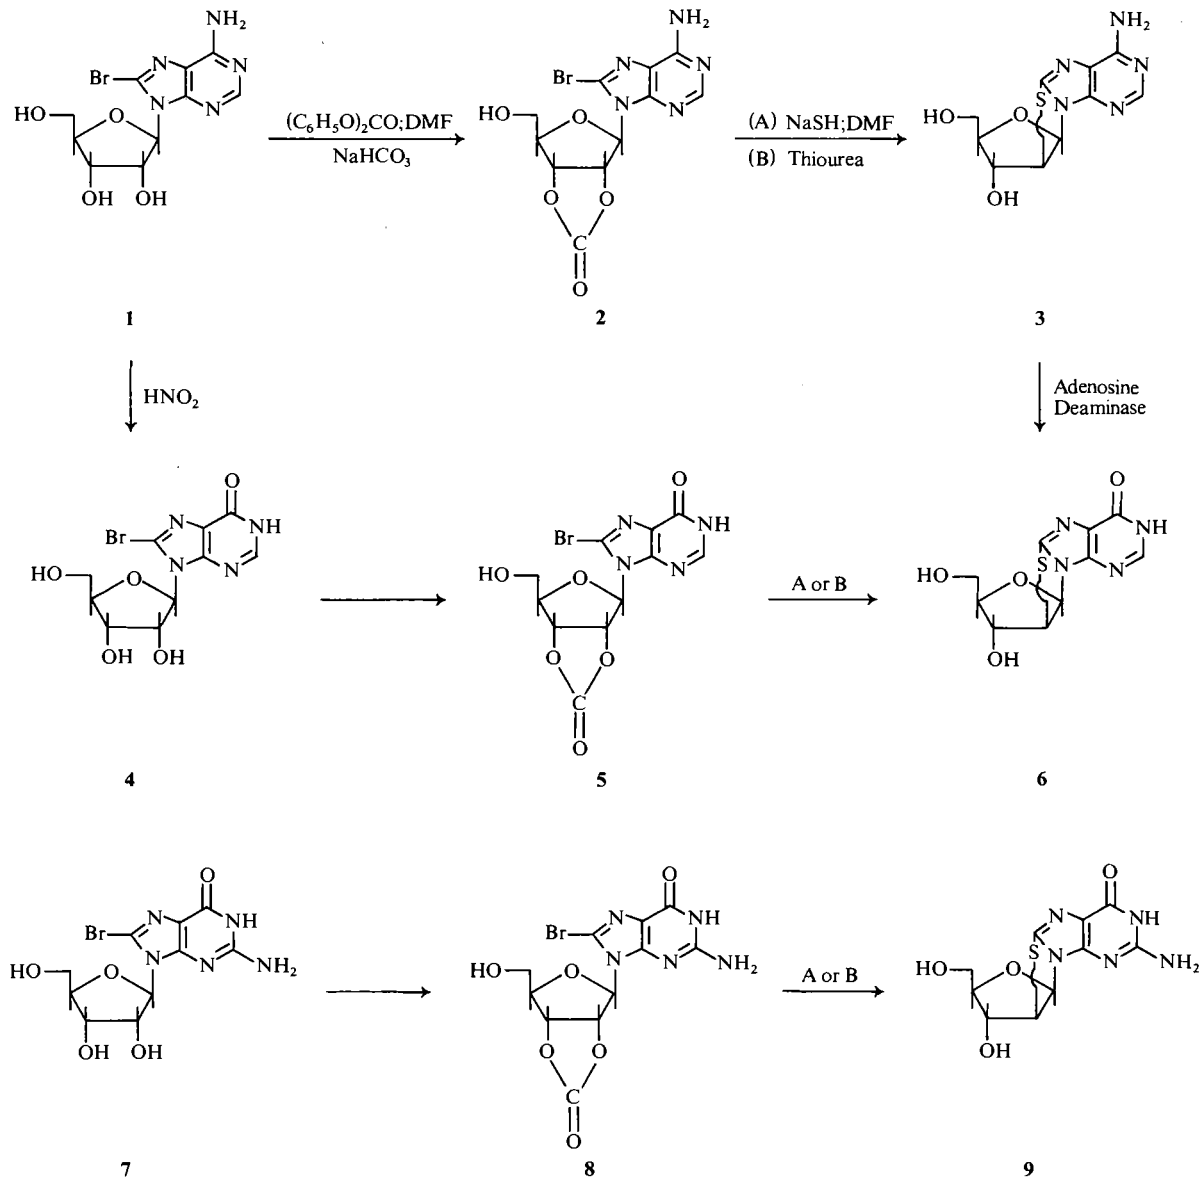
This report has described the first simple general route to the 8,2′-thioanhydropurine nucleosides all of which are easily converted to the respective 2′-deoxypurine nucleosides. We will shortly describe the incorporation of these molecules into oligonucleotide chains.

Experimental

General Methods

Descending paper chromatography was carried out on Whatman 3MM paper. The solvent systems employed were: solvent A, *n*-butanol – ethanol – water (3:1:5, organic phase used); solvent B, ethanol–water (7:3). The solvents were prepared on a volume basis. Thin-layer chromatography was carried out at room temperature employing the ascending technique. All t.l.c. was run on Eastman Chromagram Sheets 6060 (silica gel with fluorescent indicator) on strips 10 × 2 cm. Thick-layer chromatography was carried out on glass plates (20 × 20 cm) coated with 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd.). Nucleosides and their derivatives were detected on paper chromatograms, thin- and thick-layer sheets, using a u.v. source (Mineralite output 254 mm).

The i.r. spectra were obtained on a Perkin–Elmer 337 recording spectrophotometer using KBr disks for sample preparation. The u.v. spectra were obtained on a Cary Model 14 recording spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6D instrument. Melting points were determined on a Fisher–Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tenn.



SCHEME 1

Samples submitted to them were prepared by crystallization, lyophilization, or precipitation from tetrahydrofuran with hexane followed by heating in a drying apparatus over P_2O_5. In some cases the molecular formula includes fractional moles of solvent as a correction for the analysis. These corrections were added only when a corresponding weight loss was detected on extensive drying of the sample.

Reagent grade *N,N*-dimethyl formamide (DMF) was dried by distillation from calcium hydride and stored over Linde Molecular Sieve. 8-Bromoadenosine (26, 71%) and 8-bromoguanosine (38, 89%) were prepared as described in the literature. 8-Bromoinosine (37) was obtained by the deamination of **1** using the method of Ikehara (36, 73%).

*8-Bromoadenosine 2',3'-Carbonate (**2**)*

8-Bromoadenosine (1 g, 2.9 mmol), diphenyl carbonate (0.82 g, 3.8 mmol), and sodium bicarbonate (15 mg) were heated in DMF (3 ml) at 150 °C for 30 min. The mixture was cooled to room temperature and applied to eight thick-layer plates which were developed first in ether and then in

*Solvents described in General Methods.

ethyl acetate. A band at R_f 0.35 was eluted with tetrahydrofuran and on precipitation with hexane yielded 0.75 g (70%, m.p. 159–162 °C) of compound **2** (R_f 0.70 (THF), R_f 0.53 (EtOAC)). Principal bands in the i.r. spectrum occurred at 5.55, 6.80, 8.85, and 9.25 μ. The u.v. and chromatographic properties are shown in Table 1.

Anal. Calcd. for $C_{11}H_{10}N_5O_5Br \cdot 0.2THF$: C, 36.66; H, 3.02; Br, 20.67. Found: C, 36.91; H, 2.94; Br, 21.18.

8-Bromoinosine 2′,3′-Carbonate (5)

Compound **5** was prepared from 8-bromoinosine in the same manner as described for the preparation of **2** above. A 74% yield of **5** (m.p. >218 °C (dec.)) was obtained (i.r. 5.55, 5.75, 8.75, and 11.6 μ). Chromatographic and u.v. properties are shown in Table 1. The compound was not further purified but was used directly to prepare 8,2′-thioanhydroinosine as described below.

8-Bromoguanosine 2′,3′-Carbonate (8)

8-Bromoguanosine (1.0 g, 2.76 mmol), diphenyl carbonate (1.21 g, 5.52 mmol), and sodium bicarbonate (50 mg) were heated in DMF (10 ml) at 150 °C for 30 min. The mixture was cooled to room temperature and poured into ether. A gummy precipitate was obtained which was washed with ether and then precipitated several times from DMF using ether. The solid was then collected and dried to yield 1.03 g (98%) of compound **8** (m.p. >228 °C (dec.)). Compound **8** (R_f 0.14 (THF)) showed principal bands at 5.50, 6.60, 8.65, and 9.25 μ in the i.r. Chromatographic and u.v. properties are shown in Table 1.

Anal. Calcd. for $C_{11}H_{10}N_5O_6Br$: C, 34.04; H, 2.60. Found: C, 33.80; H, 2.59.

8,2′-Thioanhydropurine Nucleosides. General Procedures

Method A

In a typical experiment 1 mmol of the cyclic carbonate dissolved in DMF (2 ml) was added to a 40% solution of sodium hydrogen sulfide (6 equiv of NaSH) and the solution was heated at 70 °C for 18 h. The solution was then either applied directly to thick-layer plates or paper chromatograms.

Method B

In a typical experiment 1 mmol of the cyclic carbonate and 2 equiv of thiourea were refluxed in freshly distilled *n*-butanol (15 ml) for 5 h. The solvent was then removed at reduced pressure and the residue dissolved in ethanol and applied to either thick-layer plates or paper chromatograms.

8,2′-Thioanhydroadenosine (3)

The products from both methods A and B were worked-up in the same way. The reaction products were applied to thick-layer plates which were developed first in ether, then ethyl acetate, and finally tetrahydrofuran. The band at R_f 0.30 was eluted with ethanol, the solvent removed at reduced pressure, and the residue was crystallized from water to yield 8,2′-thioanhydroadenosine (see Table 1) identical to authentic material (26). The yield from method A was 79% and 66% from method B. The mass spectrum had parent peak at *m/e* 281.

8,2′-Thioanhydroguanosine (9)

The reaction products from both methods A and B were separated in the same manner. The reaction products were applied to paper chromatograms which were developed in solvent A. The band at R_f 0.24 was eluted with water which was lyophilized to yield 8,2′-thioanhydroguanosine (Table 1) identical to authentic material (31). The yield was 56% from method A and 41% from method B. The mass spectrum of the trimethylsilyl derivative had a parent peak at *m/e* 585.

8,2′-Thioanhydroinosine (6)

Method A

The reaction mixture was applied to paper chromatograms and developed in solvent A. The band at R_f 0.34 was eluted with water and the product collected by lyophilization to yield **6** (73%, Table 1, m.p. >217 °C (dec.)). Principal bands in the i.r. spectrum occurred at 5.9, 6.3, 9.3, and 12.8 μ. The mass spectrum of the trimethylsilyl derivative had a parent peak at *m/e* 498.

Anal. Calcd. for $C_{10}H_{10}N_4O_4S \cdot 1.2H_2O$: C, 39.52; H, 4.11; S, 10.55. Found: C, 40.07; H, 4.63; S, 9.91.

Method B

The reaction mixture was applied to thick-layer plates which were developed in chloroform–ethanol (7:3). The band at R_f 0.68 was eluted with ethanol, the solvent was removed at reduced pressure, and the residue crystallized from water to yield **6** (69%).

Method C

The procedure for converting 8,2′-thioanhydroadenosine into 8,2′-thioanhydroinosine using adenosine deaminase has been previously described (39).

Raney Nickel Reduction of the 8,2′-Thioanhydronucleosides

The thioanhydronucleosides were dissolved in water and heated at reflux with Raney nickel for 3 h. The products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

were isolated by paper chromatography in solvent A. Compounds **3**, **6**, and **9** led respectively to 2′-deoxyadenosine, 2′-deoxyinosine, and 2′-deoxyguanosine which were identified by comparison to authentic material (40).

The Measurement of the Activity Coefficient Ratios of Protonated and Neutral Forms of Hammett Indicators in Several Strong Acids

T. R. ESSIG[1] AND J. A. MARINSKY[2]

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

Received October 4, 1971

The activity coefficient ratio for several indicators has been estimated for the protonated and neutral forms of the same indicator molecule over a large range of acidity in H_2SO_4, $HClO_4$, and HCl systems. The activity coefficient (f_B) of the neutral form of a number of Hammett indicators was determined via solubility measurements. The observed linear relationship between $\log f_B$ and $pK_A^{BH^+}$ then permitted estimate by extrapolation of $\log f_B$ not experimentally accessible for the more basic indicators. Solubility studies of the pentacyanopropenide (PCP^-) salts of these more basic protonated indicators were referred to a reference standard, tetraethylammonium pentacyanopropenide (TEA^+PCP^-) according to the method developed by Boyd to obtain the activity coefficient ratio f_{BH^+}/f_{TEA^+}. By synthesizing the term $f_{BH^+}/f_B\ (f_{PCP^-}/f_{TEA^+})^{1/2}$ the approach to a meaningful value of f_{BH^+}/f_B is believed to be facilitated. This function is uniquely related to the water activity of the various acid systems examined to support the suggestion by Hammett that f_{BH^+}/f_B is a constant for primary aniline indicators at a specified acid concentration.

Le rapport du coefficient d'activité pour plusieurs indicateurs a été évalué pour les formes protonée et neutre de la molécule, sur un grand intervalle d'acidité, dans les systèmes H_2SO_4, $HClO_4$, et HCl. Le coefficient d'activité (f_B) de la forme neutre d'un certain nombre d'indicateurs de Hammett a été déterminé par des mesures de solubilité. La relation linéaire observée entre le $\log f_B$ et le $pK_A^{BH^+}$ permet alors d'évaluer par extrapolation le $\log f_B$ non accessible expérimentalement pour les indicateurs plus basiques. Les études de solubilité des sels du pentacyanopropenide (PCP^-) pour ces indicateurs plus basiques sous la forme protonée, ont été rapportées à la référence standard, le tétraéthylammonium pentacyanopropenide (TEA^+PCP^-) selon la méthode de Boyd, pour obtenir le rapport du coefficient d'activité f_{BH^+}/f_{TEA^+}. En construisant le terme $f_{BH^+}/f_B\ (f_{PCP^-}/f_{TEA^+})^{1/2}$, on pense qu'il est plus facile d'approcher une valeur significative de f_{BH^+}/f_B. Cette fonction est uniquement en relation avec l'activité de l'eau dans les divers systèmes acides examinés pour soutenir la suggestion de Hammett que f_{BH^+}/f_B est une constante pour les indicateurs aniline primaire à une concentration acide fixée.

Canadian Journal of Chemistry, **50**, 2254 (1972)

Introduction

The concept of an acidity function (H_0) to measure the ability of a concentrated acid to monoprotonate a neutral Brønsted base was introduced by Hammett and Deyrup (1) in 1932. The general utility of this function has received much investigation in the ensuing years (2–10). Its applicability has been found to be quite limited (5–11) and this has led to the introduction of other acidity functions (12–20). Differences between the various functions have been attributed to hydration effects (21–30) in attempts to generalize the Hammett (H_0) acidity function by identifying its relationship with the others.

Another approach to resolving differences between the different acidity functions and one which has been the subject of this research has concerned itself with the evaluation of activity coefficient terms in the various expressions (31, 32). Solubility measurements as a function of acid concentration have been made for this purpose. For the unprotonated indicator molecule the reference state is the aqueous saturated solution. In the case of the protonated form of the indicator the solubility of the salt has been measured. The 1,1,2,3,3-pentacyanopropenide (PCP^-) anion has been considered by Boyd (32) a most suitable counterion for such studies because of (*1*) the low solubility of its product salt, (*2*) its resistance to protonation over a wide range of acid concentration (33), and (*3*) its absorption maximum in the visible range of the spectrum. The tetraethylammonium (TEA^+) salt of PCP^- is selected as a reference standard in these studies because of its low solubility and resistance to solvent interaction (16). The

activity coefficient of the protonated indicator molecule by this modus operandi is defined as

$$[1] \qquad f^*_{BH^+} = \frac{f^2_{\pm}(BH^+PCP^-)}{f^2_{\pm}(TEA^+PCP^-)}$$

Sweeting and Yates have used this approach to study the activity coefficient behavior of amides in sulfuric acid (34).

One cannot measure directly the activity coefficient of the protonated and neutral form of the same indicator molecule. Only weak bases can be used to measure activity coefficients of the neutral form, f_B, over a large range of acid concentration since the equilibrium must be sufficiently suppressed to avoid excessive protonation of the indicator. Conversely only the stronger bases can be used to measure $f^*_{BH^+}$. As a consequence there is an intrinsic uncertainty in expressing the ratio of the activity coefficient terms, $f^*_{BH^+}/f_B$ since f_B values obtained from different indicator molecules must be used. Boyd's use of this term in this manner in the acidity equations (32) suffers from this serious disadvantage.

In this research it was our objective to circumvent this problem in order to obtain more meaningful $f^*_{BH^+}/f_B$ ratios. An extrapolation technique was developed to deduce f_B values not experimentally accessible and activity coefficient ratios of four indicator molecules were obtained as a function of acid concentration in sulfuric, perchloric, and hydrochloric acid by using the extrapolated f_B values for these indicator molecules. An attempt was made as well to cancel the contribution of the standard TEA^+ ion in this ratio to provide an estimate of f_{BH^+}/f_B.

Experimental

Neutral Indicators

Of the seventeen indicators comprising the set that was used by Hammett and Deyrup in their first paper on acidity functions (1), only the eight substituted primary anilines, *p*-nitroaniline, *o*-nitroaniline, 4-chloro-2-nitroaniline, 2,4-dinitroaniline, 6-bromo-2,4-dinitroaniline, 2,4,6-trinitroaniline, 2,4-dichloro-6-nitroaniline, and 2,5-dinitro-4-methylaniline were considered appropriate for this research. Additional reason for excluding benzalacetophenone, 2-benzoylnaphthalene, 4-benzoylbiphenyl, and anthraquinone arose from the expectation that the ketone functional group would further complicate examination of the class of nitroanilines selected for study in this work. The *N,N'*-dimethyl-2,4,6-trinitroaniline had already been shown to be unsuitable for use in conjunction with substituted anilines (5). Azobenzene and azodiphenylamine were believed capable of the addition of a second proton and 4-nitroazobenzene was too insoluble.

The Hammett indicators were purchased as a set from the Aldrich Chemical Company. Additional indicator, purchased as needed, was recrystallized before use until its absorbance matched that of the indicator in the purified set. Purity was also checked by measuring the melting points of the indicators with a Thomas Hoover melting point apparatus. The melting points of the indicators used agreed with the literature values for the pure compounds.

The maximum absorbance of saturated solutions of the eight indicators chosen for this work were measured. Numerous readings at various time intervals were made to assure reproducibility of results.

Indicator Salts

The salts of *p*-chloroaniline, *m*-nitroaniline, *o*-chloroaniline, and *p*-nitroaniline were prepared by using equimolar solutions of the protonated indicator and sodium pentacyanopropenide (Na^+PCP^-) dissolved in warm water. These mixtures were cooled in an ice bath to precipitate the salt (BH^+PCP^-) which was then washed with acid, filtered, and dried. The standard reference salt, TEA^+PCP^-, was prepared similarly from tetraethylammonium chloride.

The purity of each product was monitored by careful examination of its solution absorption spectrum in the visible and ultraviolet region. Any changes in a product, such as the dissociation of the cation at low acid concentrations, were discernable by this approach as well.

Attempts to prepare the PCP^- salt of *o*-nitroaniline ($pK_A^{BH^+} = -0.29$) and 4-chloro-2-nitroaniline ($pK_A = -1.03$) repeatedly resulted in the dissociation of the cation into neutral base and HPCP upon isolation of the salt. For these mixtures the PCP^- absorption peak at 396 mμ was obscured by the formation of the neutral species which absorbed in the visible region of the spectrum as well. The preparation of salts of weaker bases in the series was not attempted since cation dissociation is more appreciable with decreasing base strength.

Preparation of Na^+PCP^- for use in the isolation of the indicator salts consisted of first converting tetramethylammonium pentacyanopropenide, (TMA^+PCP^-), obtained from Distillation Industries as a custom synthesis, to the acid by passing the salt solution through a bed of BIO-RAD AG 50W-X2 ion-exchange resin in the H^+-ion form. The resin column, prewashed with ethanol to remove impurities, was maintained at a temperature of 80 °C with a steam jacket throughout the operation. The complete removal of tetramethylammonium ion from the product was assured by the absence of precipitate when sodium tetraphenylborate, which forms a white precipitate with quaternary ammonium cations, was periodically added to aliquot portions of the eluant. The acid product, converted next to the sodium salt by potentiometric titration with sodium hydroxide, was evaporated to dryness. Almost quantitative recovery of the sodium pentacyanopropenide (Na^+PCP^-) product was obtained.

Acids

Acid solutions were prepared by dilution of Allied Chemical Reagent C.P. acids with triply distilled water. Concentrations were checked initially and at the end of the testing procedure by titration with Fisher Standard sodium hydroxide.

Solubility Measurements

After it was experimentally shown that equivalent results were obtained by approaching saturation from the unsaturated and supersaturated condition, saturated solutions of the neutral indicators or salts were prepared by mixing an excess of the powdered solid with approximately 5 ml of the acid solution. The sample, agitated for 1 h, was stored for 24 h at 25.00 ± 0.01 °C in a constant temperature air bath. The constancy of absorbance readings after longer time intervals showed that all of the samples reached equilibrium within the 24 h period.

The samples were then prepared for measurement inside the constant temperature bath by filtering the saturated solutions through a thermostated fritted glass filter into a thermostated vial. A 1 ml sample was then withdrawn from the filtered solution and was diluted when necessary with acid of the same concentration to obtain a convenient optical density. Absorbance readings were made by using a Beckman DU Spectrophotometer fitted with a thermostated cell compartment. The spectrophotometer was checked for accuracy with a set of Beckman Standard Cells and the absorbance cells used for the measurements were corrected to read zero absorbance over the entire spectrum.

Neutral Indicators

All measurements on the neutral indicators were made at λ_{max} which was ascertained by scanning the spectrum at each acidity. Slight shifts in λ_{max} due to the changing medium could not be neglected. The 4-chloro-2-nitroaniline ($pK_A = -1.03$) was the most basic indicator which could be used in a direct measurement over the entire acid concentration range of this study. As pK_A values become more positive than -1.03 protonation increases and the acid concentration range in which a measurable absorbance for the neutral form of the indicator is possible becomes smaller and eventually disappears. For example, *o*-nitroaniline ($pK_A = -0.29$) could be used over a narrow range of acid concentrations to obtain f_B by direct measurement. In the case of *p*-nitroaniline ($pK_A = 0.99$), however, log $[BH^+]/[B]$ is already approximately 2.0 at 20% by weight sulfuric acid. At higher acid concentrations, the absorbance peak at 396 mμ for the neutral molecule is completely obscured.

Indicator Salts

All solubility measurements, except those for the reference state of *p*- and *m*-nitroanilinium pentacyanopropenide, were made by measuring the absorbance peak of the PCP^- ion at 396 mμ. The solubility of these two salts in water was obtained by indirect estimate of absorption at 396 mμ from absorbance readings taken at 245 mμ. This estimate was based upon the ratio $R = \lambda_{max\ vis}/\lambda_{max\ \mu v}$ measured in 10% acid solution. In water the cations of these two salts partially dissociate to the neutral indicator forms which absorb in the visible region of the spectrum to obscure the PCP^- peak. By measuring the ratio, *R*, of the absorption maxima at 396 and 245 mμ for these salts in 10% H_2SO_4 where such dissociation is absent, a true estimate of the relative absorption values for these indicator–salt molecules at these wavelengths was obtained and the absorption readings at 245 mμ in water solution, multiplied by *R*, provide the correct absorption value at 396 mμ.

The reference state of all of the salts was corrected for deviation from ideality by employing a modified form of the Debye–Hückel equation.

TABLE 1. Reference states of indicator salts

PCP^- salt of	log f_1*	A_{396} mμ

*From the Davies modification of the Debye–Hückel equation.
†Corrected for dissociation of the cation into neutral B by: $A_{396\ m\mu} = A_{245\ m\mu} \times R$ where $R = A_{396\ m\mu}/A_{245\ m\mu}$ as measured in 10% H_2SO_4; $A_{396m\mu}(p\text{-}NO_2^+) = 509 \times 1.83 = 945$; $A_{396m\mu}(m\text{-}NO_2^+) = 942 \times 1.93 = 1800$.

$$[2] \qquad \log f_{\pm} = \frac{-A\sqrt{I}}{I + Ba\sqrt{I}} + bI$$

where $b = 0.1\ Z_1Z_2$; $a = 3$ Å; $B = 0.3288$ (36); $A = 0.5065$ (36); and *I*, the ionic strength of the saturated aqueous solution, is obtained from the absorption measurements.

The results of these calculations are shown in Table 1.

The utility of the above method for solubility measurement was carefully documented in preliminary studies with Na^+PCP^-, TEA^+PCP^- and the indicator salts. With Na^+PCP^- it was shown that the visible spectrum of the PCP^- anion exhibited maxima at 396 and 412 mμ, the peak at 396 mμ being the larger of the two, in agreement with the results reported by Middleton (35). A plot of absorbance *vs.* sodium pentacyanopropenide concentration showed that Beer's Law was obeyed over the concentration range tested (1.52×10^{-4} *M* to saturation). In the 24 h interval of the solubility measurements these spectral characteristics persisted in H_2SO_4 and $HClO_4$ solutions less than 40% by weight. Beyond this acid concentration a small increase in absorption in the ultraviolet region of the spectrum was observed: no change in intensity at the longer wavelength ($\varepsilon_{PCP^-} = 2.04 \times 10^{-4}$ at 396 mμ) was detectable to assure the validity of this measurement for quantitative estimate of the solubility of the indicator salts of pentacyanopropenide in these acids. The Na^+PCP^- solution, however, was not stable in concentrated HCl solutions. A new peak appeared at 280 mμ which shifted the maxima at 396 and 245 mμ making accurate absorbance readings at the two wavelengths impossible.

Similar examination of the indicator salts and TEA^+PCP^- in the three acid systems confirmed these observations. The absorption ratio at $\lambda_{max\ vis}$ and $\lambda_{max\ \mu v}$ in sulfuric and perchloric acid in samples up to 50% weight acid did not indicate any gross changes in their composition to substantiate Boyd's observations (33) and the earlier observations with Na^+PCP^- that the PCP^- anion is not protonated in this acid concentration range. At the highest acid concentration greatest change in absorption ratio was observed. This is consistent with the increased absorption observed in the ultraviolet region of the spectrum obtained with Na^+PCP^- in the more concentrated H_2SO_4 and $HClO_4$ solutions. The ratio change was sufficiently small, however, to attest to the fact that the salts tested in sulfuric and perchloric acids have suitable stability. Ratio changes were within acceptable limits

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in up to 20% HCl for most salts to confirm the results obtained with Na^+PCP^- as well. At higher acidities, however, a gross change in sample composition (formation of a new species, $\lambda_{max} = 280$ mμ) occurred. It is due either to the degradation of BH^+PCP^- or to an addition reaction with PCP^- that is catalyzed by the chloride ion. The addition of chlorine to cyanoethylene (35), which is believed to be catalyzed by chloride ion (37), is an example of this kind of reaction. At these higher acidities absorbance readings at 396 or 245 mμ could not be used because of interference from the peak at 280 mμ.

An estimate of the behavior of the activity coefficients of the salts in hydrochloric acid solutions above 20% by weight had to be made by extrapolation of log $f^*_{BH^+}$ *vs.* log a_{H_2O} curves determined at the lower acid concentrations. The data are thus uncertain for salts in HCl solutions greater than 20% by weight and comparison of log f^*_{BH} behavior between the salts in HCl above this acid strength are suspect.

The absorption ratio observed for the *p*-NO_2^+ and *m*-NO_2^+ salts ($R \simeq 1.9$) is smaller than for the other salts ($R \simeq 4.2$). This is due to the fact that their protonated form absorbs in the u.v. The small change in ratio with increasing acid concentration is more pronounced for the salts with cations absorbing near the visible region.

Results

Measurement of f_B

By using the aqueous solution saturated with the indicator as the reference state, the activity coefficient of B at any acid concentration is obtained by the relationship

$$[3] \qquad f_B(\text{acid}) = f_B(H_2O)A_{H_2O}/A_{\text{acid}}$$

This equation gives the activity coefficient as the reciprocal of absorbances (A) of the two saturated solutions since both saturated solutions are at equal activity and $f_B(H_2O)$ is defined as unity in the reference state. The molar concentrations of the saturated aqueous solutions are of the order of 10^{-4}. Since the variation of activity coefficient with concentration of these uncharged species is negligible, the assignment of ideal behavior to these saturated aqueous solutions introduces minimal error in the computation of f_B as a function of acid concentration.

The solubility data obtained with the six most weakly basic indicators employed in this research are presented in Table 2 for the three acid systems studied. In the first column of compilation of data for a particular indicator the wt. % concentration of the acid is presented. The absorbance measurement is given in column 2. The experimentally based log f_B values are listed in column 3. The last column gives an adjusted value of log f_B (at the experimental acid concentration) that is obtained by drawing the best smooth curve through the experimental points (log f_B plotted against acid concentration). Deviations from this smooth curve at high acidities are attributed to uncertainty arising from protonation of some of the indicators.

The variation of the activity coefficient of the neutral species (f_B) behaves in a regular manner for each of the bases studied. Even though the behavior of f_B is different in H_2SO_4 as compared to $HClO_4$ and HCl, the constant variation between members of the class of indicators is maintained. The nature of this negative deviation in activity coefficient has been attributed to the salting-in of the neutral base which is quite sensitive to the structure of the base: Hammett (38) and Deno (31) have suggested the interaction of the nitro group with the solvent as an explanation of this behavior.

When the log f_B obtained at each acid concentration for all but one of the indicators (2,6-dinitro-4-methylaniline) is subtracted from the corresponding log f_B value obtained for the weakest indicator, 2,4,6-trinitroaniline ($pK_A = -9.41$) and this difference (Δ log f_B) is plotted against the difference in base strength (ΔpK_A) for each indicator relative to 2,4,6-trinitroaniline, a family of essentially straight lines that extend over 8.33 pK units appears to describe best the data that are obtained for the three different acids. Even though insufficient data are available to provide a statistical verification of this linear relationship, it appears to provide a reasonable approximation of the real situation to justify extrapolation of these lines over an additional 4.99 pK_A units to estimate f_B for the more basic indicators used in this study. The various values of log f_B that have been estimated for these indicators by such extrapolation for each acid system are given in Table 3. The slope of each of the lines that were drawn for this purpose is presented together with the standard deviation of the experimental values in Table 4.

The uncertainty limits of f_B evaluated by extrapolation as described above is difficult to assess. All solubility measurements of f_B are believed to have had a precision range of 2 to 3% when experimental conditions were optimum. However, the experimental points deviate

considerably more than this from the best straight line that can be drawn through them. Dispersion of points by as much as 0.15 log units in the region of measurement far exceeds the projected experimental error range. Additional bias in the extrapolated log f_B values can arise as well from uncertainty in selection of the slope of the line that is drawn through the experimental points. A conservative estimate of the possible uncertainty range in the extrapolated log f_B values is believed to be of the order of 0.2 log units.

TABLE 5. Comparison of experimental and extrapolated log f_B values for *o*-nitroaniline

To estimate further the reliability of the linear relationships derived by visual inspection of the data extrapolated values of log f_B were compared with the experimental log f_B values obtained for *o*-nitroaniline ($pK_A = -0.29$), the strongest base that could be used to obtain solubility data in a limited acid concentration range. These comparisons are presented in Table 5. Correlation is poorest in the H_2SO_4

†Obtained by extrapolation and interpolation.

system. However, when the lines to represent this system at the three acid concentrations are redrawn with slopes of 0.0188, 0.0422, and 0.0705 instead of 0.020, 0.0485, and 0.0747 standard deviation of the experimental points from the redrawn lines remain essentially unchanged (0.011, 0.035, and 0.038 as compared to 0.013, 0.034, and 0.036) while prediction and observation are in better agreement (0.049 *vs.* 0.063 instead of 0.074, 0.058 *vs.* 0.095 instead of 0.151, and 0.080 *vs.* 0.096 instead of 0.131).

Though there is a sizeable error in the predictions by this approach, it is within the uncertainty limits that have been projected for the extrapolation procedure. Some satisfaction has to be derived from the fact that f_B values of an indicator as a function of acid concentration that are otherwise completely unaccessible are at least approachable with this kind of treatment. Further investigation to provide sufficient data for a statistically valid analysis of the ΔpK *vs.* $\Delta \log f_B$ relationship is without a doubt desirable to improve the predictive quality of this approach.

The observation that the deviation in log f_B can be linearly related to the pK_A of the base at a fixed water activity in all three acid systems appears to indicate that the substituent effects that determine base strength affect the activity coefficient in a parallel manner.

The 2,6-dinitro-4-methylaniline solubility behavior, since it does not conform, is believed not to be a representative member of the family of indicators under investigation. Possibly it should be considered to belong to a class of substituted *p*-toluidines.

Measurement of $f^*_{BH^+}$

Experimental values of $\log f^{\pm}_{BH^+PCP^-}$ obtained for the reference and indicator salts from the solubility data are presented in Table 6 for the three acid systems studied. The value of $f^{\pm}_{BH^+PCP^-}$ is obtained from the solubility data with eq. 3 modified by multiplying the right hand term of this equation by the $f^{\pm}_{BH^+PCP^-}$ values computed earlier for the saturated aqueous systems. Correction for deviation from ideality in the reference aqueous solution is, by this manner of computation, incorporated in the values listed. Also included in Table 6 is the corresponding log $f^*_{BH^+}$ (*i.e.* log f_{BH^+}/f_{TEA^+}) value obtained from the ratio $f^{\pm 2}_{BH^+PCP^-}/f^{\pm 2}_{TEA^+PCP^-}$ (eq. 3) to provide an estimate of the behavior of f_{BH^+} relative to the standard ion (f_{TEA^+}).

The behavior of $f^*_{BH^+}$ is quite different from that of the neutral species. In all cases there is

first a positive deviation from ideality. This result is undoubtedly due to hydration of the BH^+ cation since the PCP^- contribution has been cancelled and the tetraethylammonium ion is expected to be free of solvent interaction.

The experimental error in measuring the solubility of the various salts is estimated to be less than ± 0.02 log units and the uncertainty range of $f^*_{BH^+}$ is believed to be no more than 0.08 log units. Error in the estimate of deviations from ideality for each indicator salt at the saturation concentration in water is believed to be minimal at the level of salt concentrations that is encountered.

Discussion

It has been the ultimate objective of this research program to obtain f_{BH^+}/f_B ratios for the same indicator molecule. This goal is not fully realized with the $f^*_{BH^+}/f_B$ values listed in Table 6 since all ratios are referred to the standard TEA^+ ion. However if $f^*_{BH^+}/f_B$ is multiplied by $f^{\pm 2}_{BH^+PCP^-}/f_B$ we obtain the expression $(f^2_{BH^+}f_{PCP^-})/(f^2_B f_{TEA^+})$. By taking its square root the term $(f_{BH^+}/f_B)(f_{PCP^-}/f_{TEA^+})^{1/2}$ is resolved and the value of f_{BH^+}/f_B is approached if the ratio of f_{PCP^-}/f_{TEA^+} is not too far removed from unity. For example, if $f_{PCP^-} < 2f_{TEA^+}$ or the reverse is true the value of the above expression is less than 40% different from the value of f_{BH^+}/f_B. This is within the uncertainty limit of the function itself. Both PCP^- and TEA^+ are bulky ions of low charge density and they are not likely to be solvated. It is conceivable that their deviation from ideality may be similar.

The values obtained for $\log (f_{BH^+}/f_B) \times (f_{PCP^-}/f_{TEA^+})^{1/2}$ are presented in Table 7 for the four indicators studied in three different acid systems. By comparing the values of this term for these indicators at each fixed acid concentration it is noticeable that reasonable accord is obtained, in many cases more often than not, falling within the uncertainty limit of about 0.3 log units that is projected to be likely in the evaluation of this term. With the indicator *m*-nitroaniline, however, there is an unusually large discrepancy from the values observed for this term in H_2SO_4 with the three other indicators studied. More careful scrutiny shows as well that this term obtained with the *o*- and *p*-chloroaniline indicators for $HClO_4$ correlates better with each other than does this term derived from the *p*- and *m*-nitroaniline data. Good agreement in this term is obtained for both pairs of indicators in HCl although there is considerable disagreement between the term

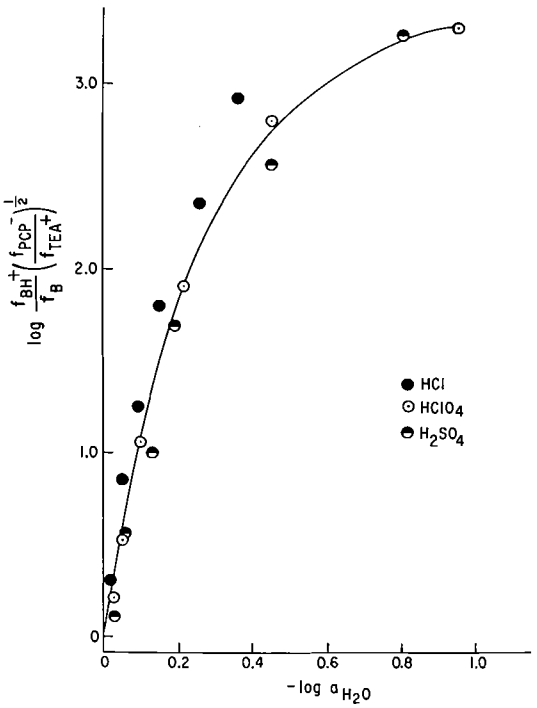

FIG. 1. Plot of $\log (f_{BH^+}/f_B)(f_{PCP^-}/f_{TEA^+})^{1/2}$ *vs.* $-\log a_{H_2O}$.

derived from these indicator pairs. Since the indirect means (dissociation of the nitroanilines obscures the PCP^- peak at 396 mμ) used to measure the absorption of the nitro-substituted anilines in their reference state (saturated aqueous solution) could introduce bias to this solubility measurement, the data obtained with the chloroanilines are believed to provide the more meaningful results. As a consequence, only these data have been used to construct Fig. 1 where the averaged term $\log (f_{BH^+}/f_B) \times (f_{PCP^-}/f_{TEA^+})^{1/2}$ is plotted versus $-\log a_{H_2O}$ for the three systems studied. The term obtained for the HCl system beyond 19.6% by weight concentration is not included in this figure because of the extra uncertainty of the solubility measurements beyond this concentration value.

All of the points in the figure fall within the tolerance limit of ± 0.15 log units that is prescribed for this term. This result indicates that the term is essentially independent of the nature of the acid employed in the system, a result predicted by the pioneer work of Hammett. In addition to this substantiation of the estimate that the ratio of f_{BH^+}/f_B is the same for indicators of similar structure in strong acids at equal water activity it is suggested that evaluation of the term $(f_{BH^+}/f_B)(f_{PCP^-}/f_{TEA})^{1/2}$ for the same indicator molecule markedly improves on the attempt of Boyd to deduce f_{BH^+}/f_B from his construction of $f^*_{BH^+}/f_B$ that is based on two different indicator molecules. The deficiency of his approach is apparent from the large variation of f_B with pK_B that was demonstrated in this research. Even with the considerable uncertainty that is inherent in the extrapolation of f_B values in this research more meaningful values of $f^*_{BH^+}/f_B$ than are reported by Boyd are believed to have been measured here. Also, unless f_{PCP^-} is much different from f_{TEA^+}, computation of this term provides a rather good approximation of f_{BH^+}/f_B. If this is indeed the case the activity of hydrogen ion in strong acids should be calculable from the definition of H_0.

Reçu le 11 février 1972

Avec le cholestérol, les phosphites triméthylique et triéthylique conduisent au phosphonate de dicholestéryle $HP(O)(OCholest)_2$ (**6**) et à un phosphonate mixte $HP(O)(OR)(OCholest)$ (**5**, $R = CH_3$ et C_2H_5 respectivement) alors que le phosphite triphénylique donne exclusivement le phosphonate **6**. Ces résultats sont discutés en termes de mécanismes possibles de ces réactions.

With cholesterol, trimethyl and triethyl phosphites afford dicholesteryl phosphonate $HP(O)(OCholest)_2$ (**6**) and an unsymmetrical phosphonate $HP(O)(OR)(OCholest)$ (**5**, $R = CH_3$ and C_2H_5 respectively) while triphenyl phosphite gives exclusively the phosphonate **6**. Those results are discussed in terms of a possible mechanism of these reactions.

Canadian Journal of Chemistry, **50**, 2264 (1972)

Les phosphites de trialcoyle $P(OR)_3$, réagissent sur des alcools aliphatiques pour donner des produits de transestérification (1, 2). Ces réactions sont d'autant plus faciles qu'il y a plusieurs fonctions hydroxyles et qu'un phosphite cyclique à 5 ou 6 chaînons a la possibilité de se former (3). Dans certains cas, les phosphites $P(OR)_3$ peuvent conduire à la formation de phosphonates avec des rendements suffisamment bons pour que ces réactions soient utilisables en synthèse. Ainsi, par exemple, avec le méthanol, le phosphite triéthylique **1** conduit au méthylphosphonate diéthylique **2**, au phosphonate diéthylique **3** et au phosphate triéthylique (4). Pour expliquer la formation du composé **2**, les auteurs proposent un intermédiaire de type quasi-phosphonium $MeP^{+}(OEt)_3$, OH^-.

Le mécanisme de ces réactions est mal connu et il nous a semblé utile d'étudier la réaction de divers phosphites $P(OR)_3$ (R = Me, Et, Ph) avec le cholestérol, une réactivité du type [1] pouvant éventuellement conduire à des stéroylphosphonates, accessibles jusqu'à présent par un nombre limité de méthodes (5).

Résultats

Lorsqu'un mélange de cholestérol **4** et de phosphite triméthylique en excès est chauffé à reflux pendant 24 h, on isole, par chromatographie sur colonne de silice, deux produits principaux auxquels nous avons attribué les

[1] $$P(OEt)_3 + MeOH \rightarrow MeP(O)(OEt)_2 + HP(O)(OEt)_2 + P(OEt)_3$$

structures **5** (R = Me) et **6** (éq. 2).[1] Ces produits sont obtenus avec des rendements de 77 et de 8% respectivement (par rapport au cholestérol qui a réagi). Les structures de ces deux composés ont été déduites de la façon suivante.

Le phosphonate de dicholestéryle (structure **6**) a été identifié (p.f., c.c.m., i.r., r.m.n.) à un échantillon authentique préparé par réaction[2] de PCl_3 sur le cholestérol (6). La liaison P—H est visible en i.r. (2420 cm^{-1} (7)) ainsi, qu'en r.m.n. ou elle apparaît sous forme d'un doublet centré à 6.88 p.p.m. (J_{PH} = 689 Hz)[3]. Ce couplage est compatible avec les valeurs de 630 à 707 Hz décrites dans la littérature (8) pour les phosphonates de type $HP(O)(OR)_2$.

La structure du phosphonate de méthyle et de cholestéryle, **5** (R = CH_3) a pu être établie par analyse centésimale, i.r. (ν_{P-H} 2400, $\nu_{P=O}$ 1265 cm^{-1}) et surtout par r.m.n. Le spectre à 100 MHz montre un doublet à 3.71 p.p.m. attribuable au groupe méthoxy et dont la surface correspond à 3H; l'hydrogène 3α donne un signal très élargi (notamment par couplage *P*—O—C—*H*) et l'hydrogène attaché directement au phosphore donne un doublet centré à 6.80 p.p.m. ($^1J_{PH}$ = 719 Hz).

Lorsque le phosphite de triméthyle est remplacé par du phosphite de triéthyle, on obtient les produits correspondants **5** (R = C_2H_5) et **6** dans des proportions comparables (66 et 15%, respectivement, par rapport au cholestérol qui a réagi).

Les résultats sont très différents avec le phosphite de triphényle et le cholestérol. Dans ce cas, en effet, on ne décèle aucune trace d'un phosphite mixte correspondant à **5** (R = C_6H_5) alors que l'on isole du phosphonate de dicholestéryle (50% par rapport au cholestérol consommé). On isole, outre du phénol, un peu de cyclo-3α,5-cholestène-6 et des produits non identifiés.

Discussion

La formation des phosphonates **5** et **6** est inattendue. Il ne s'agit pas, en effet, d'une simple réaction de transestérification qui aurait conduit à des phosphites trialcoyliques du type $P(OR)_2(OCholest)$, $P(OR)(OCholest)_2$, ou $P(OCholest)_3$. Ce dernier composé ne se forme pas et cela pour des raisons stériques évidentes; dans les conditions habituelles de formation des phosphites trialcoyliques, d'ailleurs (ROH + PCl_3, en présence de pyridine (9)), seuls les phosphonates dialcoyliques se forment, avec le cholestanol (10), comme avec le cholestérol (6).

En gros, deux types de mécanismes peuvent être envisagés: (*a*) transestérification préalable des phosphites puis protonation pour donner les sels d'alcoxyphosphonium **10** et **11** (Schéma 1); ou (*b*) protonation préalable des phosphites par le cholestérol suivie de désalcoylation pour conduire aux phosphonates **12** qui donnent lieu à des réactions de transestérification (Schéma 2).

Dans le Schéma 1, les alcoxyphosphoniums **10** et **11** intermédiaires, du type de ceux postulés par Chopard dans la réaction de $P(OCH_3)_3$ avec les cétones α-halogénées (11), pourraient conduire, par attaque nucléophile de l'alcoolate RO^- sur un reste R, au phosphonate mixte **5** (R = CH_3, C_2H_5, réaction [5]) ou au phosphonate de dicholestéryle **6** (réaction [7]). Une autre possibilité de formation du composé **5** par attaque sur le radical cholestéryle (réaction [6]) peut être écartée parce que d'une part, une substitution nucléophile directe en C-3 est difficile (attaque axiale (12)) d'autre part une attaque de type S_N2 sur les hydrogènes en 7 conduiraient au cyclo-3α,5-cholestène-6 ("isocholestadiène") (**14**) dont nous n'avons pu déceler aucune trace dans le cas où R = CH_3 ou C_2H_5.

Le second type de mécanisme (Schéma 2) suppose la formation d'un éther méthylique (R = CH_3) ou éthylique (R = C_2H_5) du cholestérol. Pour le cas ou R = C_6H_5, ce mécanisme est exclu car il équivaudrait à une substitution *nucléophile* sur un benzène monosubstitué. En revanche, les intermédiaires de type alcoxyphosphonium tels que **10** ou **11**, dans le cas ou R = C_6H_5, sont d'autant plus faciles à former que le phénol est plus acide que le méthanol ou l'éthanol. Le passage au phosphonate de dicholestéryle **6** ne peut se faire que par attaque sur le reste cholestéryle dans une réaction de type [14]: on isole effectivement de l'isocholestadiène **14** dans le cas où R = C_6H_5.

La transestérification, suivie de protonation (Schéma 1) nous semble être favorisée par rap-

[1]Dans la suite de l'article, on représentera le cholestérol sous la forme HOCholest.

[2]Ce phosphonate a été décrit (réf. 6) mais non caractérisé.

[3]Les déplacements chimiques sont exprimés en unités δ et en p.p.m. par rapport au tétraméthylsilane (TMS) pris comme référence interne.

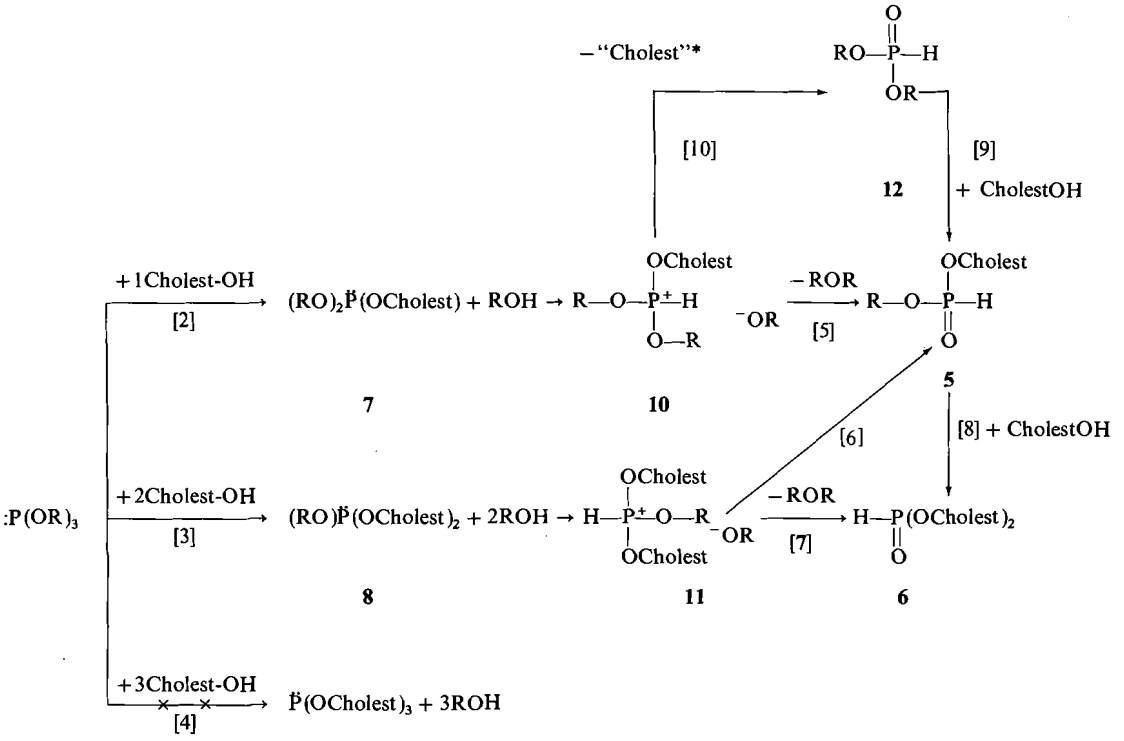

SCHÉMA 1. Formation des composés **5** et **6** par transestérification des phosphites. *Par "cholest", nous entendons perte d'un radical stéroïde: cholestadiène ou cyclo-3α,5-cholestène-6.

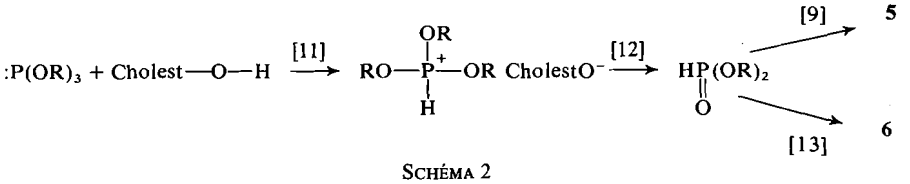

SCHÉMA 2

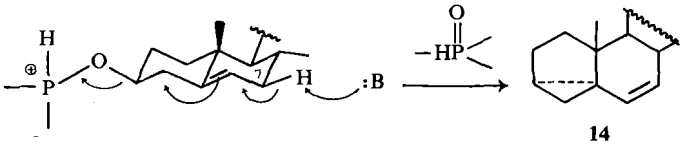
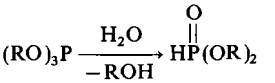
[14]



port au Schéma 2 car on n'isole que des traces d'éther ROCholest (R = CH_3 ou C_2H_5) d'une part et que, d'autre part le proton du cholestérol est moins acide que celui du méthanol, de l'éthanol, ou du phénol.

Nous avons pu écarter la possibilité d'une hydrolyse préalable des phosphites selon



12

en séchant au préalable le cholestérol et en distillant les phosphites avant utilisation.

En conclusion, avec des alcools de haut poids

moléculaire tels que le cholestérol, les phosphites trialcoyliques ($R = CH_3$, C_2H_5) conduisent à des phosphonates dialcoyliques symétrique (composé **6**) ou mixtes (composés **5**).[4] Le phosphite de triphényle donne seulement le phosphonate de dicholestéryle, **6**.

Partie expérimentale

Indications générales

Les spectres de r.m.n. ont été effectués sur spectromètre Varian HA-100 à 100 MHz. Les déplacements chimiques des spectres de r.m.n. sont indiqués en p.p.m., en unités δ par rapport au tétraméthylsilane, pris comme référence interne. Le découplage de ^{31}P a été réalisé à 40 MHz avec un découpleur de spin hétéronucléaire "NMR Specialties". Les absorptions des spectres i.r. sont exprimées en cm^{-1}. Les mesures de pouvoir rotatoire, $[\alpha]_D$, ont été effectuées à 25 °C dans le chloroforme. Les microanalyses ont été faites par "Organic microanalyses", Dr. C. Daesslé, 5757 Décelles Ave., Montréal. Les chromatographies sur colonne ont été effectuées sur gel de silice 0.05–0.2 mm Merck. Les chromatoplaques (c.c.m.) qui ont permis de suivre l'évolution des réactions sont des plaques finies Sil. G. 25 UV 254 de MacRerey-Nagel. Le cholestérol et les phosphites (diméthylique, triméthylique, triéthylique, et triphénylique) sont des produits Aldrich. Les phosphites ont été, selon les cas, distillés ou non avant utilisation.

Les conditions pour la réaction des phosphites avec le cholestérol sont indiquées dans le tableau 1; les propriétés physiques et spectrales des composés obtenus sont résumées dans le tableau 2.

Préparation du phosphonate de dicholestéryle à partir du cholestérol et de PCl_3

A 1.00 g (2.58 mmol) de cholestérol dissous dans 10 ml de pyridine, on ajoute 0.20 g (1.45 mmol) de PCl_3. Le mélange est laissé à température ambiante pendant 1 h, puis il est étendu avec de l'eau et extrait trois fois à l'éther. Les phases éthérées réunies sont lavées successivement avec une solution de HCl 2 *N*, à l'eau, avec une solution saturée de $NaHCO_3$, à l'eau, avec une solution saturée de NaCl, puis séchées sur Na_2SO_4. Par évaporation de l'éther on obtient 0.57 g (0.70 mmol, 54%) de phosphonate de dicholestéryle, le produit obtenu est identifié (r.m.n., i.r., c.c.m., p.f.) au produit **6** obtenu précédemment.

Afin de vérifier la possibilité d'une transestérification du phosphonate de diméthyle, éventuellement formé, la réaction suivante a été effectuée.

Réaction du cholestérol et du phosphonate diméthylique

Le cholestérol (5.00 g; 12.9 mmol) est dissous à chaud dans 10 ml de $HP(O)(OCH_3)_2$. Le mélange obtenu est chauffé à 100 °C pendant 30 h. On décèle en C.C.M. la présence des trois produits habituels ainsi que celle d'un produit que l'on identifie à l'éther méthylique du cholestérol (méthoxy-3β cholestène-5). On évapore sous vide l'excès de phosphite et on chromatographie le résidu sur une colonne de 200 g de silice. On élue successivement: 0.135 g (0.34 mmol, 3%) d'éther méthylique du cholestérol au mélange de 20% d'éther dans l'éther de pétrole, 0.190 g (0.24 mmol, 4%) de phosphonate de dicholestéryle **6** à l'éther, 0.270 g (0.70 mmol) de cholestérol au mélange de 5% de méthanol dans l'éther et enfin 4.020 g (8.65 mmol, 71%) de phosphonate de cholestéryle et de méthyle **5** ($R = CH_3$), au mélange de 10% de méthanol dans l'éther. (Taux de conversion du cholestérol: 95%.) Les phosphonates de dicholestéryle et de cholestéryle et méthyle sont identifiés aux produits obtenus précédemment; l'éther (méthoxy-3β cholestène-5) méthylique du cholestérol est identifié à un échantillon préparé par réaction du cholestérol et de l'orthoformiate de triméthyle en présence de $HClO_4$ (14).

Ce travail a été rendu possible grâce à l'aide financière du Conseil National de Recherches du Canada (octroi A-5596). Une partie de cette étude a été effectuée au laboratoire du Professeur G. Ourisson à Strasbourg.

[4]A propos de ces derniers produits, il faut noter leur particulière instabilité. Ils se conservent difficilement et semblent être très sensibles à l'hydrolyse. C'est le groupe RO ($R = CH_3$ ou C_2H_5) qui part en premier, conduisant probablement à l'acide phosphonique HP(O)(OH)(OCholest); dans le cas où $R = CH_3$, ceci a été vérifié en traitant cet acide avec du diazométhane: on obtient de nouveau le composé **5** ($R = CH_3$).

Effect of Pressure on the Solvolysis of Dimethyl-*t*-butyl Sulfonium Iodide in Ethanol–Water Mixtures

CLAUDE S. DAVIS AND J. B. HYNE

Department of Chemistry, University of Calgary, Calgary, Alberta

Received February 18, 1972

The pressure dependence of the rate of solvolysis of dimethyl-*t*-butyl sulfonium iodide has been studied in ethanol–water mixtures at 60.00 °C. Determination of the partial molal volume of the substrate ions has enabled the volumes of activation to be dissected into initial and transition state components. The solvent composition dependence of the partial molal volumes of the two states provides further details of the nature of the reaction mechanism.

L'influence de la pression sur la vitesse de solvolyse de l'iodure de diméthyl-*t*-butylsulfonium a été étudiée dans des mélanges eau-alcool à 60.00 °C. La détermination du volume molaire partiel des ions substrats a rendu possible la division des volumes d'activation en composantes état initial et état de transition. L'influence de la composition du solvant sur les volumes molaires partiels des deux états fournit des détails supplémentaires sur la nature du mécanisme de la réaction.

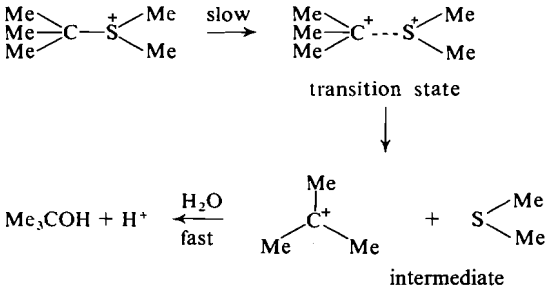
Introduction

The solvent dependence of the partial molal volume of a solvolytic transition state obtained by the dissection of the observed activation volume using the measured partial molal volume of the initial state has been shown to be useful in the characterization of reaction mechanisms (1, 2). Such dissections have been performed on the solvolyses in aqueous ethanol solvents for the substrates *t*-butyl chloride, benzyl chloride, and *p*-chlorobenzyl chloride. These substrates solvolyze by mechanisms which traditionally have been described as varying from S_N1 to S_N2 (1, 3).

The variation of the partial molal volume of the transition state, $\bar{V}_t$, with solvent composition showed a pronounced minimum in $\bar{V}_t$ for *t*-butyl chloride (1). Such a minimum has been shown to be characteristic of the partial molal volume of salts such as Me_4NCl (4) indicating that the transition state in the *t*-butyl chloride solvolysis has considerable charge separation not unlike two oppositely charged ions, *i.e.* an S_N1 type mechanism. The maximum in $\bar{V}_t$ for *p*-chlorobenzyl chloride was similar to that shown by polar substrates such as benzyl fluoride (1) indicating a more polar transition state as a result of the concurrent bond making and breaking, *i.e.* S_N2 type mechanism. Benzyl chloride $\bar{V}_t$ behavior suggested intermediate charge development (1) characteristic of a mechanism lying between the traditionally defined S_N1 and S_N2 limits.

The substrates mentioned above are all non-electrolytes; thus to further test the hypothesis that the behavior of $\bar{V}_t$ in binary solvents is indicative of mechanism (1, 2), the pressure dependence of the solvolysis of an ionic substrate was examined in a similar manner. The solvolysis of the dimethyl-*t*-butyl sulfonium ion, $Me_2tBu\overset{+}{S}$, has been cited as a classic example of a cationic substrate which reacts via a carbonium ion intermediate (5).



If, as has been claimed previously (1), the partial molal volume behavior of the initial and transition states reflects reaction mechanism in a very specific manner the present study should confirm or dispute the proposed S_N1 type behavior for this cationic solvolysis, and provide, in addition, a more detailed description of

the process as far as interaction with the solvent environment is concerned.

Experimental

Reagents

Water

Deionized water with a specific conductance no greater than $8 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ was used throughout.

Ethanol

Absolute ethanol was dried by distillation from magnesium ethoxide (6). Binary mixtures with water were prepared by weight and stored in well stoppered polythene or glass bottles.

Dimethyl-t-butyl Sulfonium Iodide

The sulfonium salt was prepared from *t*-butylmethyl sulfide and methyl iodide as described by Hyne and Wolfgang (7). Samples were protected from light and stored over ether at −10 °C.

Alkylammonium Salts

Eastman reagent grade tetra-*n*-alkylammonium chlorides R_4NCl (R = Me, Et, *n*-Pr, *n*-Bu) and tetramethylammonium iodide were recrystallized and dried as described by Conway *et al.* (8).

Kinetics

The rates of solvolysis were determined in ethanol–water binaries at 60.00 ± 0.01 °C over the pressure range 1–2746 atm. The solvent compositions used were 0.0, 0.100, 0.200, 0.300, 0.400, and 0.500 mole fraction ethanol. The initial concentration of the sulfonium salt was in the range $1\text{–}4 \times 10^{-4}$ *M*. All solutions were degassed by the conventional freeze–pump–thaw technique before being loaded into the reaction cells. The solvolysis was monitored conductimetrically. The high pressure system, reaction cells, and the conductance measuring equipment used have been described previously (1, 9). Pseudo first-order rate constants were determined graphically by analysis of the conductance data using the Guggenheim method (10).

Partial Molal Volumes

Apparent molal volumes were determined by measuring the densities of solutions of known concentration. The densities were measured with a magnetic float densimeter similar to that described by Millero (11). The design was altered so that the sensitivity of the apparatus could be altered without changing the number of turns on the main solenoid. This was achieved by varying the height of the solution container (and hence the position of the magnetic core of the float in the magnetic field of the solenoid) by supporting the solution container on a threaded brass screw. Because of the wide range in densities of the solvents (0.99–0.83 g/ml) three floats were constructed with the appropriate densities for the various solutions. The system was calibrated as described by Millero. The hold down current was determined by measuring the voltage across a National Bureau of Standards calibrated standard 1 Ω resistor using a Leeds and Northrup Potentiometer. The densities of the solutions are considered accurate to ±2 p.p.m. All solutions (0.005 to 0.15 *M*) were made up by weight. The concentrations were calculated from the known molalities and the measured densities. Apparent molal volumes, ϕ, were calculated using the equation

$$\phi = \frac{M}{d_0} - \frac{1000\Delta d}{d_0 c} \quad [1]$$

where *M* is the molecular weight, d_0 the density of the solvent, and Δd is the difference between the density of the solution and the solvent.

Partial molal volumes, $\bar{V}^0$, were evaluated by extrapolation of ϕ to zero concentration on a plot of ϕ *vs.* $c^{1/2}$ in the relation

$$\phi = \bar{V}^0 + Sc^{1/2} \quad [2]$$

Results

Rates and Activation Parameters

The rate constant for the solvolysis of Me_2tBuS^+ in water and at atmospheric pressure and 60.0 °C is in excellent agreement with the values obtained by Leffek *et al.* at the same temperature (12). The rate constants at the various pressures for different solvent compositions are presented in Table 1. The errors indicated represent average deviations resulting from at least three replicate rate determinations. For each solvent the volume of activation, ΔV^*, and its pressure coefficient, $\partial\Delta V^*/\partial p$, were obtained from the rate-pressure data by a least squares computer fit of the rate-pressure data to the equation

$$\log k = A + Bp + Cp^2 \quad [3]$$

The activation volume in water obtained in this study, 9.9 ± 0.3 ml mol^{-1} (60.00 °C), compares well with values reported by Brower (13) of 9 ± 1 (71.0 °C).

Partial Molal Volumes

In the solvolysis of the sulfonium salt only the cation is involved in the reaction so determining the partial molal volume of the ground state involves an evaluation of the partial molal volume of Me_2tBuS^+, whereas the quantity obtained experimentally is the partial molal volume of the *salt* Me_2tBuSI. The partial molal volume of Me_2tBuS^+ was obtained as follows. The data of Lee and Hyne (4) for the partial molal volumes of tetraalkylammonium chlorides in ethanol–water mixtures were extended to 0.5 mole fraction ethanol. Partial molal volumes of tetramethylammonium iodide were measured in all the aqueous ethanol solvents up to 0.5 mole fraction ethanol. Using the known

values for $\bar{V}_{Me_4N^+}$ (4), those for $\bar{V}_{I^-}$ and hence $\bar{V}_{Me_2tBuS^+}$ were determined at each solvent composition by using the relationships shown in eq. 4.

$$[4] \qquad \bar{V}_{Me_2tBuS^+} = \bar{V}_{Me_2tBuSI} - V_{I^-}$$

where $\bar{V}_{I^-} = \bar{V}_{Me_4NI} - \bar{V}_{Me_4N^+}$

Partial molal volumes of dimethyl-*t*-butyl sulfonium iodide and tetramethylammonium iodide in various ethanol–water mixtures are shown in Table 2. The partial molal volume data for the tetra-*n*-alkylammonium chlorides at 0.5 mole fraction ethanol are presented in Table 3.

The partial molal volume of the chloride ion $\bar{V}^0_{Cl^-}$ at 0.5 mole fraction was obtained by the Conway method (8) in which $\bar{V}^0_{R_4NCl}$ is extrapolated to zero cation molecular weight in a linear plot of $\bar{V}^0_{R_4NCl}$ *vs.* molecular weight. Column 2 of Table 4 shows the $\bar{V}^0_{Cl^-}$ values obtained by least-squares fits of the present data at 0.5 mole fraction ethanol along with the data of Lee and Hyne (4) at the other solvent compositions. The other entries in Table 4 were obtained by the appropriate subtractions.

Partial molal volumes for the sulfonium salt were determined at 25.0 °C rather than at 50.0 °C because of the effect the reaction had on the density determinations. In the time required to complete a density measurement (about 1.5 h) some 5–7% of the sulfonium ion would undergo solvolysis at 50.0 °C. The half lives for the reaction at 50.3 °C are ~30 h ($k = 6.3 \times 10^{-6}$ s^{-1}) in water and ~22 h ($k = 8.5 \times 10^{-6}$ s^{-1}) in 0.325 mole fraction ethanol (14). The partial molal volumes of Me_4NI were also determined at 25 °C so that the errors in the value used for V_g, *i.e.* $\bar{V}^0_{Me_2tBuS^+}$, would be minimized. Analysis of the data shows that the difference between the true value for $\bar{V}^0_{Me_2tBuS^+}$ at 50 °C and the value quoted in column 5 of Table 4 is

$$25\left(\frac{(d\bar{V}^0)}{(dT)_{S^+}} - \frac{(d\bar{V}^0)}{(dT)_{Me_4N^+}}\right)$$

where the subscripts S^+ and Me_4N^+ refer to the sulfonium and tetramethylammonium ions, respectively. Since the sign of the temperature dependence of the partial molal volumes of the two ions is the same, the errors will tend to cancel

so that the difference between the quoted and true values will be very small.

Discussion

The primary purpose of activation parameters dissection studies of the type reported here is to obtain information on the behavior of some property of the transition state of the reaction with a view to further elucidating the mechanism of the chemical process in question. The dissection of ΔV^* shown in Fig. 1 provides such information on the behavior of the partial molal volume of Me_2tBuS^+ as a function ethanol–water solvent composition. To be of value in revealing the mechanism of the reaction, however, it is necessary to compare the behavior of the partial molal volume of the transition state with that of stable ionic and molecular species as well as the volume behavior of other solvolysis states. Appropriate data for use in such comparisons are available from the earlier work of Mackinnon, Lateef, and Hyne (1) and Lee and Hyne (15) and reproduced schematically in the lower portion of Fig. 1 for convenience.

Before discussing the detailed behavior of

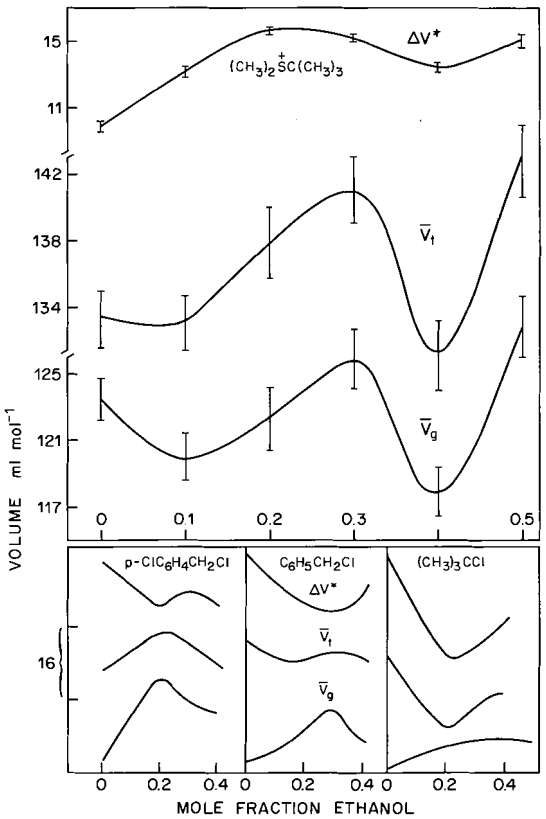

FIG. 1. ΔV^* dissection into initial and transition state components for the solvolyses of Me_2tBuS^+ and some alkyl halides. For details see ref. 1.

$\bar{V}_t$ and $\bar{V}_g$ for the sulfonium salt system shown in Fig. 1, it is worth noting that the overall volume of activation ΔV^* passes through a *maximum* in the 0.2–0.3 mole fraction ethanol region. This behavior contrasts with the minimum in ΔV^* observed in the cases of solvolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of such non-ionic substrates as *t*-butyl chloride, benzyl chloride, and *p*-chlorobenzyl chloride (1). This reversal of behavior of ΔV^* parallels that of ΔH^* as noted by Hyne (16) where the variation of ΔH^* with solvent composition exhibits a maximum for the sulfonium salt solvolysis, but a minimum for alkyl chloride solvolysis. The sign of the pressure coefficient of ΔV^*, *i.e.* $\partial \Delta V^*/\partial P$, is also different for the sulfonium solvolysis compared to the alkyl chloride solvolysis. In both cases, however, the sign of $\partial \Delta V^*/\partial P$ is such that the rate constants tend to a limiting value at high pressure. The reversal is also evident in the sign of ΔV^* being negative, presumably due to electrostriction of solvent in the activation process, in all the alkyl halide cases, but positive for the sulfonium salt solvolysis. The greater volume of the transition state compared with the initial state in the sulfonium salt solvolysis is a clear indication that solvent electrostriction about the transition state is no greater than, and probably less than, that around the ionic initial state. Since the intrinsic volume of the solvolyzing substrate will increase due to bond stretching in the activation process, one cannot state at this stage of the argument that the greater $\bar{V}_t$ value reflects the predominance of solvation shell release, *i.e.* reverse electrostriction. What can be asserted, however, is that *increased* electrostriction on activation sufficient to outweigh the volume increase due to bond stretching does not take place in the sulfonium case as is considered to occur in the alkyl halides. The extent to which the independent carbonium ion is developed in the transition state would appear to be small, and charge *dispersal* between the S and C atoms rather than charge *transfer* from S to C appears to predominate. Despite the fact that the positive charge is dispersed, the transition state will still have an essentially ionic character.

Examination of Fig. 1 immediately reveals that the partial molal volume behavior of the initial and transition states is remarkably similar. This is again in contrast to the corresponding situation for the solvolysis of *t*-butyl chloride and benzyl chloride, although comparable with the behavior of the volume of the kinetic states of *p*-chlorobenzyl chloride. In this latter case the similarity in volume behavior of the two states as a function of solvent composition suggests corresponding similarity in polarity and vice versa. Thus in the sulfonium salt case both the initial and transition states are predominantly ionic in character and in the *p*-chlorobenzyl chloride solvolysis both states are dipolar. In the two alkyl halide systems the initial states are dipolar and the transition states pseudo ionic.

If the kinetic states in the sulfonium salt solvolysis are essentially ionic in character, considerable solvent electrostriction can be expected around both; apart from volume differences due to bond extension on activation, therefore, rather similar values for the partial molal volume of both the initial and transition states might be expected. The similar feature of the two states as a function of solvent composition shows that although the two states are essentially ionic and in the crude sense similar, they differ in detail as a consequence of the interaction with the ethanol–water environment.

It is at this point in the argument that the behavior of $\bar{V}_t$ and $\bar{V}_g$ must be compared with that of stable ionic and dipolar states and other kinetic states. The partial molal volume of the initial state is virtually identical in form to that reported for Et_4N^+, nPr_4N^+, and nBu_4N^+ ions in ethanol–water (4). In particular the characteristic initial decrease in $\bar{V}$ of some 4–8 ml from pure water to 0.1 mole fraction ethanol is present. Many of the initial state volume features are maintained in the behavior of $\bar{V}_t$, but the characteristic initial minimum is almost eliminated. The absence of this minimum is typical of the behavior of polar but non-ionic substrates as illustrated by the $\bar{V}_g$ plots for the benzyl halides and *t*-butyl chloride (Fig. 1). This change in $\bar{V}_t$ behavior therefore supports the argument that while the transition state for the sulfonium salt solvolysis retains its essentially ionic character, its charge density and hence its solvent electrostrictive interaction ability has been weakened.

An Intermediate in the Conversion of an Acetylene to a Vinyl Derivative: The Crystal and Molecular Structure of *trans*-Chloromethylbis(trimethylarsine)-platinum(II) Hexafluorobut-2-yne

BRIAN W. DAVIES, RICHARD J. PUDDEPHATT,[1] AND NICHOLAS C. PAYNE

Department of Chemistry, University of Western Ontario, London, Ontario

Received December 15, 1972

The crystal and molecular structure of *trans*-chloromethylbis(trimethylarsine)platinum(II) hexafluorobut-2-yne has been determined from three dimensional X-ray diffraction data recorded by diffractometric methods. The structure has been refined by full-matrix least-squares methods on F using 1156 reflections to an agreement factor $R = 0.077$. The crystals are monoclinic, space group $P2_1/c, C_{2h}^5$, with $a = 6.803(8)$, $b = 14.93(2)$, $c = 20.20(2)$ Å, $\beta = 104.9(1)°$, and $Z = 4$. The coordination of the platinum atom is trigonal bipyramidal, with the acetylene considered a monodentate ligand, and the two trimethylarsine ligands occupying the equatorial plane. The chlorine atom and the methyl ligand occupy the apical positions, with Pt—Cl and Pt—C distances of 2.47(1) Å and 2.10(4) Å, respectively. The long Pt—Cl bond length indicates the strong *trans*-influence of the methyl ligand. The observed C—C bond length of 1.32(4) Å in the acetylene ligand is lengthened from the value of 1.22(9) Å measured in the free ligand. The geometry of the coordinated ligand is discussed in terms of the bonding scheme proposed by Greaves *et al.*

La structure moléculaire et cristalline du *trans*-chlorométhyl bis(triméthylarsine)platine(II) hexafluorobutyne-2 a été déterminée à partir des données de la diffraction de rayons-X tridimensionnelle enregistrées par les méthodes diffractométriques. La structure a été perfectionnée par la méthode des matrices des moindres carrés sur F utilisant 1156 réflexions jusqu'au facteur d'accord $R = 0.077$. Les cristaux sont monocliniques, de groupe $P2_1/c, C_{2h}^5$, avec $a = 6.803(8)$, $b = 14.93(2)$, $c = 20.20(2)$ Å, $\beta = 104.9(1)°$ et $Z = 4$. La coordination de l'atome de platine est bipyramidale trigonale avec l'acétylène, considéré comme ligand monodentique, et les deux ligands triméthylarsine, occupant le plan équatorial. L'atome de chlore et le ligand méthyle occupent les positions du sommet avec les distances Pt—Cl et Pt—C respectivement de 2.47(1) et 2.10(4) Å. La grande longueur de la liaison Pt—Cl indique la forte influence *trans* du ligand méthyle. La longueur observée pour la liaison C—C de 1.32(4) Å dans le ligand acétylène est allongée par rapport à la valeur de 1.22(9) Å mesurée dans le ligand libre. La géométrie du ligand coordiné est discutée en fonction du schéma proposé par Greaves *et al.*

Canadian Journal of Chemistry, **50**, 2276 (1972)

Introduction

The methylplatinum bond in methylplatinum(II) complexes of the type *trans*-$PtClCH_3L_2$ (L = tertiary phosphine or arsine) can add across the multiple bond of hexafluorobut-2-yne, $CF_3—C{\equiv}C—CF_3$, or tetrafluoroethylene (1, 2). In most cases an intermediate of the reaction in which the acetylene or olefin is complexed to the platinum atom may be isolated allowing an overall reaction mechanism to be proposed (eq. 1).

It was found that the intermediate complexes (**1**) were stabilized by electron releasing groups bound to the platinum atoms and by electron withdrawing substituents on the olefin or acetylene ligand. The relative stabilities of the complexes formed between *trans*-$PtXClL_2$ and the unsaturated compound were found to be

(2, 3) $L = As(CH_3)_3 > As(CH_3)_2C_6H_5 > P(CH_3)_3 > P(CH_3)_2C_6H_5 > P(C_6H_5)_3$; $X = CH_3 \gg Cl$; and the unsaturated ligand = $(CN)_2C{=}C(CN)_2 > CF_3{-}C{\equiv}C{-}CF_3 > CF_2{=}CF_2 > CF_2{=}CFCF_3$, $CF_2{=}CFCl$. This stability sequence, and especially the greater stability of the platinum complexes over similar palladium compounds, which could not be isolated or detected, led to an interpretation of the formation of the complexes by a "partial oxidative addition" reaction (1, 4) indicating that the chief component of the platinum–olefin or platinum–acetylene bond strength was due to the donation of electrons from filled platinum d orbitals into antibonding π^* orbitals of the olefin or acetylene. The same substituent sequence was found for the reactivity towards formation of the addition product (**2**) indicating that the rearrangement (**1**) → (**2**) was favored by a strong platinum–acetylene interaction in the intermediate complex (**1**).

We have completed a three dimensional single crystal X-ray structure analysis of the hexafluorobut-2-yne complex (**1**), where L = $As(CH_3)_3$. The intermediate complexes (**1**) represent a new class of platinum–acetylene complex (5), and structural data can be expected to contribute towards a better understanding of the bond between a transition metal and a π-bonding ligand, and to a clarification of the influence of the ligand L on the stability of the intermediate and the reactivity of (**1**) towards the rearrangement reaction.

Experimental

Crystals of *trans*-chloromethylbis(trimethylarsine)platinum(II)-hexafluorobut-2-yne were prepared by the method of Clark and Puddephatt (2). All crystals examined were mounted in thin-walled glass capillaries. A preliminary photographic examination of reciprocal lattice layers (0–2)*kl*, *h*(0–2)*l*, and *hk*(0–3) showed the crystals to be monoclinic, Laue symmetry 2/*m*. Systematic extinctions for reflections *h*0*l* with *l* odd, and 0*k*0 with *k* odd are consistent with space group $P2_1/c, C_{2h}^5$ (6). The unit cell dimensions, and their estimated standard deviations at 21 °C were determined from a least-squares refinement of the angular settings of 16 reflections centered on a four-circle computer-controlled Picker diffractometer. The density of the crystals was measured by flotation in a mixture of chloroform and ethylene dibromide. The value observed, 2.06(2) g cm^{-3} is only in fair agreement with the calculated value 2.21 g cm^{-3} assuming four molecular units per cell. There are no crystallographic symmetry constraints imposed upon the molecule. Crystal data are as follows:

$PtAs_2ClF_6C_{11}H_{21}$ f.w. = 647.7
Monoclinic, $a = 6.803(8)$, $b = 14.93(2)$, $c = 20.20(2)$ Å, $\beta = 104.9(1)°$, $V = 1982.3$ Å^3, $\rho_o = 2.06(2)$ g cm^{-3}, $Z = 4$, $\rho_c = 2.21$ g cm^{-3}, (21 °C, MoKα_1, $\lambda = 0.70926$ Å).

During the course of the preliminary photographic examination, it became apparent that the crystals suffered from radiation damage. On average one week's continuous photographic exposure resulted in destruction of the crystal lattice.

The sensitivity of the crystal to radiation damage necessitated the collection of data from two crystals in order to obtain sufficient observations. The two data sets were collected under similar conditions. Both crystals were mounted in thin-walled capillaries. Crystal I was of approximate dimensions 0.26 mm × 0.20 mm × 0.09 mm, elongated along [100]. An optical examination identified crystal faces (012), (0$\bar{1}$1), (0$\bar{1}\bar{1}$), (0$\bar{1}$2), (00$\bar{1}$), (01$\bar{2}$), (010), (011), ($\bar{1}\bar{1}$1), (10$\bar{2}$), and those of the form {100}. Crystal II was of dimensions 0.22 mm × 0.17 mm × 0.13 mm, also elongated along [100], with crystal faces (001), and the forms {010}, {100}, and {012}. Both crystals were accurately measured with a filar micrometer eyepiece in preparation for an absorption correction. The linear absorption coefficient for MoKα radiation is $\mu = 105.0$ cm^{-1}.

Intensity data were collected on a Picker computer-controlled four-circle automatic diffractometer using MoKα radiation. Both crystals were mounted with [100] roughly parallel to the diffractometer ϕ axis. The orientation matrix and the refined cell dimensions for Crystal I were obtained from a least-squares refinement of 16 reflections manually centered at 21 °C. Prior to data collection a number of ω-scans of intense, low-angle reflections were performed, using a narrow source and wide-open counter. A mean width at half height of 0.1° was considered suitable (7). The θ–2θ scan technique was employed, with a scan range of 1.4° at a rate of 1° per min. The diffracted beam was filtered through a niobium filter, of thickness 0.08 mm, and collected through an aperture 4 mm × 4 mm placed 32 cm from the crystal. Background counts were made with a stationary crystal, and a stationary counter for ten seconds at the limits of each scan. A take-off angle of 1.3° was employed for the source, under which conditions an intensity of 87% of the maximum attainable for a selected reflection was observed. In view of the crystal decomposition data were collected from Crystal I in the octants *hkl* and *hk*$\bar{l}$ out to a 2θ maximum of 30°. Nine hundred and seventy-nine reflections were recorded. During collection of these data, three intense axial reflections, (400), (040), and (004) were monitored at regular intervals. All three reflections showed a linear decay in intensity, on average 13%.

A second shell of data was then collected from Crystal II under the same conditions. The mosaicity of the crystal, as measured by ω-scans of average width 0.09° was considered acceptable. The orientation matrix was determined as before, and instrumental conditions were unchanged for data collection. The same three reflections were monitored every 100 observations as standards. Linear decay occurred again, to an average extent of 33% after the collection of 1596 data over the 2θ range $25° \leqslant 2\theta \leqslant 40°$. After each data collection, the centering of the crystal was checked, and it was confirmed that the decay of the standards resulted from radiation damage and not from instrumental

factors, or crystal movement. A correction was applied to each data set assuming a linear decay in intensity with time.

The two data sets were then processed, and corrections applied for background, Lorentz and polarization factors.[2] Standard deviations were assigned to each observation $(\sigma(I))^2 = COUNT + \frac{1}{4}(t_c/t_b)^2(b_1 + b_2) + (pI)^2$ where the total count is given by *COUNT*, measured in a time t_c. b_1 and b_2 are the background counts each measured in a time t_b. The constant p was chosen as 0.05 for each data set, and $I = COUNT - \frac{1}{2}(t_c/t_b)(b_1 + b_2)$. Those reflections with a corrected intensity value greater than three times the estimated standard deviation were considered to be observed; 721 of the 979 reflections from crystal I, and 839 of the 1596 reflections from crystal II. The linear absorption coefficient for MoKα radiation is 105.0 cm^{-1}, and absorption correction trials on both crystals showed transmission factors varying by as much as 46% for crystal I and 50% for crystal II. Accordingly an absorption correction was applied independently to each data set. The two sets of data were then interscaled by a least-squares refinement of scaling factors derived from a comparison of reflections common to both sets in the range $25° \leqslant 2\theta \leqslant 30°$. Reflections of the types *0kl* and *0kl̄*, which are related by symmetry, were not averaged. The data set used in solution and refinement of the structure contained 1165 "observed" reflections.

Structure Solution and Refinement

The position of the platinum atom was located from a three dimensional Patterson synthesis. One cycle of full-matrix least-squares refinement on F, minimizing the function $\sum\omega(|F_o| - |F_c|)^2$ led to agreement factors $R_1 = 0.39$ and $R_2 = 0.47$. $|F_o|$ and $|F_c|$ are the observed and calculated structure amplitudes, the weight assigned an observation is defined as $\omega = 4F_o^2/\sigma^2(F_o^2)$, and $R_1 = \sum(|F_o| - |F_c|)/\sum|F_o|$ and $R_2 = (\sum\omega(|F_o| - |F_c|)^2/\sum\omega F_o^2)^{1/2}$. Atomic scattering factors for Pt, As, Cl, F, and C were taken from Cromer and Waber's tabulation (8), those for H from Stewart *et al.* (9). An anomalous dispersion correction, using the values of $\Delta f'$ and $\Delta f''$ of Cromer (10) for Pt, As, and Cl was included in the calculated structure factors (11). A series of least-squares refinements and difference Fourier syntheses located all 21 non-hydrogen atoms. In subsequent refinement of the structure (89 parameters and 1165 observations) agreement factors $R_1 = 0.089$ and $R_2 = 0.121$ were obtained. At this stage, with anisotropic thermal parameters assigned to the Pt, As, and Cl atoms, and isotropic parameters to the remaining F and C atoms, the geometry of the molecule was considered satisfactory. Attempts were then made to locate the hydrogen atoms using difference Fourier syntheses. The most intense peak, $1.8 \pm 0.2\ e^-$ Å^{-3}, was associated with the Pt atom, and others were observed at the Cl and As positions. A series of difference Fourier planes were then calculated for each of the seven methyl carbon atoms, assuming tetrahedral geometry at each atom (C—H 1.09 Å, H—C—H 109.47°) and examined for evidence of hydrogen atoms. A possible set of peaks was evident for the Pt—CH_3 linkage, but no unequivocal evidence was obtained to warrant the inclusion of the hydrogen atoms in the model. Refinement was continued, using anisotropic thermal parameters for all atoms. Under these conditions non-positive definite thermal parameters were sometimes observed for the carbon atoms; this, and the failure to locate the 21 hydrogen atoms is probably attributable to the effect of the crystal decomposition on the quality of the data. With only the carbon atoms assigned isotropic thermal parameters, two cycles of least-squares refinement (135 parameters, 1165 observations) gave agreement factors $R_1 = 0.062$ and $R_2 = 0.084$. A statistical examination of the structure amplitudes (in terms of F, $\lambda^{-1}\sin\theta$ and indices) showed no major abnormal trends. Seven reflections were discarded at this stage, which were seriously in error, and refinement converged under these conditions at $R_1 = 0.059$ and $R_2 = 0.072$.

A study of the bond distances and bond angles showed this refinement to be subject to errors resulting from crystal decomposition. For example, the platinum–acetylene carbon atom distances of 2.13 and 2.01 Å were significantly different. Also, As—C distances of 1.82, 1.89, and 1.98 Å, with C—As—C angles of 96.9, 103.9, and 106.9° showed greater variation than is to be expected. In particular, the C—C σ-bond lengths in the coordinated acetylene ligand, C(7)—C(8) and C(9)—C(10) (the atom numbering scheme is given in Fig. 2), of 1.57 and 1.39 Å respectively differed considerably from the mean value observed in the free ligand, 1.46(5) Å (12) and markedly from the value of 1.54 Å expected for a σ-bond. An examination of the data suggested these deviations to be due

[2]Computing was carried out on the PDP-10 at the University of Western Ontario, and the CDC6600 at Multiple Access Limited, Toronto. Programs used include versions of Hamilton's GONO absorption correction program, Ibers' NUCLS least-squares program, Busing and Levy's ORFFE function and error program, and Johnson's ORTEP crystallographic illustration program.

to the quality of data collected, and in order to derive more meaningful geometrical data on the acetylene ligand it was decided to constrain the CF_3 groups in the acetylene ligand to the geometry observed in the electron-diffraction study of the free ligand, and to refine them as groups (C_{3v} symmetry, C—F 1.33 Å, and F—C—F angles of 107.5°) in subsequent least-squares refinements (13). Individual isotropic thermal parameters were assigned to each group atom (anisotropic thermal parameters gave non-positive definite ellipsoids). The refinement on F converged at $R_1 = 0.077$ and $R_2 = 0.081$ (93 parameters, 1156 observations). No evidence for extinction was observed. A total difference Fourier synthesis contained eleven peaks of electron density exceeding 1.0 e^- Å^{-3}, the largest of these, 1.9(2) e^- Å^{-3} at (0.028, 0.335, 0.118) is associated with the Pt atom.

In Table 1 a listing of $|F_o|$ and $|F_c|$ is given in electrons, with the weight assigned to each reflection.[3] The final non-group atom positional and thermal parameters, and the group parameters are listed in Table 2. In Table 3 the derived group atom positional and thermal parameters are presented. The root-mean-square amplitudes of vibration of the Pt, As, and Cl atoms are listed in Table 4. All atomic positional parameters refer to one molecular unit.

Description of the Structure

The crystal decomposition, and the consequent need to collect data from two crystals have affected the determination of accurate bond distances and bond angles. A selection of bond distances and bond angles is given in Table 5, together with estimated standard deviations (e.s.d.'s). The values without e.s.d.'s were constrained to an ideal geometry in the least-squares refinement. The structure consists of discrete molecules of $Cl(CH_3)[As(CH_3)_3]_2Pt.C_4F_6$. The shortest intermolecular non-bonding attraction is 3.16 Å between a methyl carbon atom, C(4), and F(4). The shortest Pt—Pt distance of approach is 6.80 Å.

An overall view of the molecule is given in Fig. 1. The inner coordination sphere geometry at the platinum atom is trigonal bipyramidal.

[3]Photocopies of Table 1 of structure amplitudes may be obtained upon request from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, K1A 0S2.

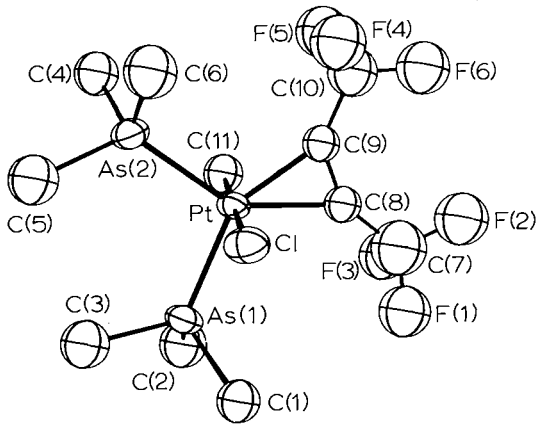

FIG. 1. Overall view of the molecule showing the atom numbering scheme. Hydrogen atoms are omitted. For clarity, thermal ellipsoids are drawn at the 30% probability level.

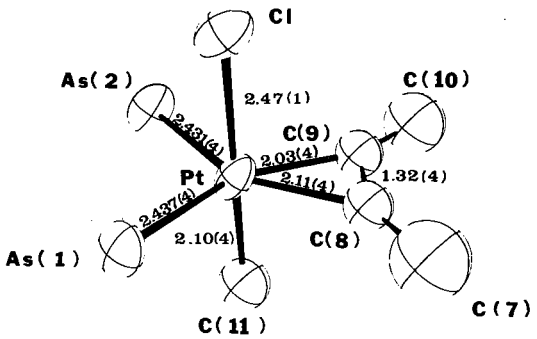

FIG. 2. Inner coordination sphere of the molecule. Thermal ellipsoids are drawn at the 30% probability level.

The *cis*-trimethylarsine ligands and the coordinated acetylene (considered to be unidentate) occupy the equatorial positions. The atom numbering scheme and a view of this geometry are presented in Fig. 2. A least-squares plane containing Pt, As(1), As(2), and the two acetylene carbon atoms, C(8) and C(9), has been calculated and the results are presented in Table 6. All five atoms lie in the plane within experimental error.

The Pt—Cl bond length observed in this structure, 2.47(1) Å, is longer than most other Pt—Cl bond lengths determined. A value of 2.300(2) Å was observed in *trans*-dichloro-(π-di-*t*-butylacetylene)-*p*-toluidine platinum(II) (14), where the chlorine atom is *trans* to another chlorine atom. In the structure of Zeise's salt, $K[Cl_3Pt(C_2H_4)]H_2O$, the Pt—Cl distance *trans*

C(8)	−0.03(4)
C(9)	0.04(4)

the chloride ligand. A series of Pt—Cl bond lengths has also been examined by McWeeny *et al.* in planar platinum(II) complexes (16, 17). The longest Pt—Cl bond length observed, 2.45(1) Å, is in the structure of *trans*-[ClPt{P-$(C_6H_5)(CH_3)_2$}$_2${$Si(C_6H_5)_2(CH_3)$}], where the chlorine atom is *trans* to the diphenylmethylsilane ligand (17). Although a direct comparison is hindered by the different geometries at the platinum atoms, it is clear that the *trans* influence of the methyl ligand is considerable. If the covalent radius of Pt(II) in a trigonal bipyramidal environment is assumed the same as that in a square planar arrangement, 1.33 Å, then the Pt—CH_3 bond length of 2.10(4) Å is close to the expected value 2.09 Å calculated for a Pt—C σ-bond.

The mean Pt—As bond length of 2.433(4) Å lies in the expected range, between the sum of the covalent radii, 2.49 Å, and the values of 2.308(2) Å found in di-μ-chloro-[dichlorobis-(trimethylarsine)]platinum(II) (18) and that of 2.375(4) Å determined in the bis(*o*-phenylene-bisdimethylarsine)platinum(II) cation (19).

The decomposition of the crystals appears to have contributed to the variance in the geometries at the As atoms. The mean As—C bond length is 1.95(3) Å, the mean C—As—C angle is 102(2)°. Of the six values averaged three lie outside the estimated standard deviation on the mean, suggesting the data suffers from systematic errors. Comparable means of 1.948(18) Å and 106.0(7)° respectively were observed in $[Cl_2Pt(As(CH_3)_3)]_2$ (18).

The geometry of the coordinated acetylene ligand is of importance in light of the bonding information it supplies. The difference in the Pt—C(8) and Pt—C(9) bond lengths, 0.08(5) Å, is not significant, and the ligand is symmetrically π-bonded. The Pt, As(1), As(2), C(8), and C(9) atoms all lie close to the equatorial plane (Table 6), the largest deviation being that of C(9) of 0.04(4) Å. The carbon–carbon triple bond of the acetylene has apparently lengthened upon coordination to 1.32(4) Å, compared to the value of 1.22(9) Å observed in the free ligand (11). The large standard deviation on the C≡C bond length in the free ligand precludes a more definite comparison. The observed C≡C bond length however is longer than the average value, 1.203(3) Å, quoted for a series of triple bonds observed in simple alkynes (6), at the 3σ level.

The acetylene adopts the *cis*-bent configuration, and the C(10)—C(9)—C(8) and C(7)—C(8)—C(9) angles are observed with values of 135(4) and 150(4)°, respectively. An equivalent configuration was reported in a preliminary communication of the structure of bis(triphenylphosphine)platinum(0)diphenylacetylene, where the analogous angles were 140 and 139°. The platinum, two phosphorous atoms, and one of the acetylene carbon atoms are co-planar, with the other acetylene carbon atom lying out of the plane so that the acetylene carbon–carbon triple bond makes an angle of 14° with the plane (20). No such angle is observed in the present determination. In the di-*t*-butylacetylene complex, the coordinated acetylene C≡C bond makes an angle of 85.2° with the coordination plane of the platinum atom (14). There is a short C≡C bond length, 1.235(18) Å, and the departure from linearity of the acetylene is less, angles of 162(1) and 165(1)° being observed.

The two C—CF_3 bond lengths of 1.48(4) and 1.47(4) Å agree well with the mean value of 1.46(5) Å determined in the free ligand (11).

Discussion

There has been extensive interest of late in the bonding in compounds formed by olefins, acetylenes, and other π-bonding ligands with transition metal complexes, particularly of the nickel triad. To date, although structural information on complexes with simple alkenes as the π-bonding ligand is available, the data on acetylene complexes are more limited. Chatt and his co-workers in their original studies of acetylene complexes (21, 22) characterized two types of complex, using as a criterion the

change in $\nu_{C\equiv C}$ which occurred upon coordination. The first type considered, Cl_2LPt(acetylene), where L is Cl^- or an amine, is formally a platinum(II) complex. A decrease in $\nu_{C\equiv C}$ of about 200 cm^{-1} was observed, and a structure was proposed and later confirmed by X-ray analysis (14) of equivalent geometry to the ethylene complex, Zeise's salt. The relatively small frequency decrease was taken to imply a weak metal–acetylene bond, and a small distortion of the acetylene ligand. The second type of complex studied, $(PR_3)_2Pt$(acetylene), formally platinum(0), showed a strong infrared absorption band around 1800 cm^{-1}, which was assigned to the $\nu_{C\equiv C}$ of the coordinated acetylene. The decrease in $\nu_{C\equiv C}$, around 400 cm^{-1}, was considered to represent a much stronger metal–acetylene bond, with a consequent greater distortion of the acetylene geometry. The planar PtP_2C_2 geometry proposed has also been confirmed by X-ray analysis (20). The present analysis therefore represents the first structural analysis of an acetylene complex in which the geometry at the metal atom is trigonal-bipyramidal, and formally platinum(II).

Two bonding schemes were proposed by Chatt to describe the two types of compound. For the first type, a σ- and π-bonding scheme was suggested, in which the metal–acetylene bond consisted of two components. Donation of electrons from π bonding molecular orbitals of the acetylene to empty metal p or d orbitals occurred, forming a σ-bond. This was accompanied by back donation of electron density from filled metal d or dp hybrid orbitals to π^* antibonding orbitals on the acetylene ligand. For the second type of complex a σ-bonding model was proposed, with two Pt—C σ-bonds forming a "metallocyclopropene ring". The possibility that there existed a series of complexes in which the bonding was intermediate between these two types was later suggested by Chatt (23).

Further suggestions on the bonding were combined in an elegant treatment by Greaves *et al.*, who described how these two extreme cases could be discussed in terms of one model (24). From a consideration of the relative energies of the acetylene π and π^* molecular orbitals and the energy of the metal orbitals, and the symmetries of the orbitals, a continuum of bond types was suggested, and five particular relative orbital energy orderings were considered in detail. Firstly, the energy of the metal orbitals could be comparable to that of the π^* molecular orbitals on the acetylene, in which case the bonding would be mainly due to donation of metal electrons into the π^* molecular orbitals of the acetylene. Secondly, the energy of the metal orbitals could be intermediate between the energies of the acetylene π and π^* molecular orbitals, in which case the bonding would be equivalent to the π-bonding scheme first proposed by Chatt. Further lowering of the metal orbital energies, to a value comparable to that of the acetylene π molecular orbitals results in a bond dominated by the σ-bond component. Two further cases were considered, in which the metal orbital energies were first of lower energy than the acetylene π molecular orbitals, but still able to form a bond, and finally much lower, in which case no bond is formed.

The geometry of the coordinated acetylene in the present study is more comparable to that of the diphenylacetylene ligand in $(P(C_6H_5)_3)_2$-Pt(diphenylacetylene) (20), than to that of the di-*t*-butylacetylene ligand. Both acetylenes adopt a *cis*-bent configuration. The mean angular deviation from linearity in the coordinated diphenylacetylene is 40.5(5)°, while values of 30(4) and 45(4)° are observed for the hexafluorobut-2-yne ligand. In contrast, comparable values of 17(1) and 15(1)° were observed in the formally platinum(II) complex *trans*-$Cl_2(CH_3$-$C_6H_4NH_2)$Pt(di-*t*-butylacetylene) (14). Although the precision of the angular measurements in the hexafluorobut-2-yne complex has been hindered by crystal decomposition, it is apparent that there is a close resemblance between the bonding in the trigonal platinum(0) complexes and the present trigonal bipyramidal complex, and we may therefore discuss the bonding of the acetylene ligand in terms of the scheme proposed by Greaves *et al.*. We suggest, on the basis of the structural data, that the present structure is best described by the relative orbital energy ordering in which the metal orbitals used for bonding are intermediate between the acetylene π and π^* molecular orbitals. Thus, as suggested by Greaves *et al.* molecular orbitals containing metal and both π and π^* acetylene character may be written. There is a transfer of electron density from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

acetylene π orbitals to the metal orbitals, and an accompanying back donation from filled metal orbitals to the acetylene π^* orbitals. This electron transfer results in a reduction of the C≡C bond order, and an angular distortion of the acetylene from linearity.

It is important to elucidate the extent of the electron transfer. Recent ESCA studies (25, 26) indicated that the electron transfer from the platinum atom to the acetylene in $(P(C_6H_5)_3)_2Pt$-(diphenylacetylene) is 0.7 electron (25) although this value has been questioned (26). The extent of transfer in Zeise's salt is lower, 0.3 electron being transferred from the metal to the acetylene, and also from the acetylene to the metal, leaving the acetylene essentially electrically neutral. The extent of the electron transfer should be reflected in both structural and stability changes. Thus, it is interesting that the platinum–olefin bond strength in $(P(C_6H_5)_3)_2Pt$(olefin), as indicated by the C—C bond length, varies as olefin = $C_2H_4 < C_2Cl_4 > C_2F_4 > C_2(CN)_4$. The series is apparently determined by the balance in the metal–ligand bond strength due to σ-donor and π-acceptor components being maximized at C_2Cl_4 (27). However, in platinum(II) compounds the order of bond strength as determined by stability and equilibrium studies (2, 3) is olefin = $C_2(CN)_4 > C_2F_4 > C_2Cl_4$. It appears that a different balance is reached, and that the critical factor in determining the stability is the π-acceptor property of the olefin or acetylene ligand. The different bond strengths are apparent in the greater stability of the platinum(0) complexes. Thus $(As(CH_3)_3)_2Pt$(hexafluorobut-2-yne) can be sublimed *in vacuo* without decomposition at 90°, while *trans*-$Cl(CH_3)(As(CH_3)_3)_2Pt$(hexafluorobut-2-yne) at this temperature readily evolves hexafluorobut-2-yne. The difference is also reflected in the different $\nu_{C\equiv C}$ stretching frequencies for these complexes, being 1765 cm^{-1} for the platinum(0) complex (28) and 1838 cm^{-1} for the platinum(II) complex (2). However, the decrease in $\nu_{C\equiv C}$ of 473 cm^{-1} observed for *trans*-$Cl(CH_3)(P(C_6H_5)_3)_2Pt$-(hexafluorobut-2-yne) is greater than the value of 462 cm^{-1} observed for the arsenic complex, indicating a stronger metal–acetylene bond, a conclusion contradicted by J(Pt—F) measurements (2), and small differences in $\nu_{C\equiv C}$ should therefore be interpreted with care (29). We are initiating further structural studies on platinum—acetylene complexes to explore the dependence of the bonding upon the geometry at, and the formal oxidation state of, the metal atom.

Absolute Rate Constants for Hydrocarbon Autoxidation. XXI. Activation Energies for Propagation and the Correlation of Propagation Rate Constants with Carbon–Hydrogen Bond Strengths[1]

S. KORCEK,[2] J. H. B. CHENIER, J. A. HOWARD, AND K. U. INGOLD

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received January 28, 1972

The rate constants, k_p, for the abstraction of a hydrogen atom from a wide variety of organic substrates at 30° have been correlated with the strengths of the C—H bond that are broken, D[R—H] (in units of kcal/mol). Two empirical relations have been derived, one for tertiary peroxy radicals,

$$\log [k_p^{t\text{-ROO}} \text{ per active hydrogen}/(M^{-1}\ s^{-1})] = 15.4 - 0.2D[\text{R—H}]$$

and one for secondary peroxy radicals,

$$\log [k_p^{s\text{-ROO}} \text{ per active hydrogen}/(M^{-1}\ s^{-1})] = 16.4 - 0.2D[\text{R—H}]$$

These equations hold extremely well for hydrocarbons and reasonably well for substrates containing heteroatoms. The activation energies and pre-exponential factors for the oxidation of some hydrocarbons by *t*-butylperoxy radicals have been measured and the empirical relation

$$E_p^{t\text{-ROO}}/(\text{kcal/mol}) = 0.55(D[\text{R—H}] - 62.5)$$

derived. If D[*t*-ROO—H] is taken as 88 kcal/mol, this yields the Polanyi equation,

$$E_p^{t\text{-ROO}}/(\text{kcal/mol}) = 14 + 0.55\,\Delta H_p^{t\text{-ROO}}$$

where ΔH is the heat of the hydrogen abstraction reaction. These empirical equations permit the calculation of the rate constants for chain propagation in the autoxidation of many organic substrates at 30° and also at other temperatures.

Les constantes de vitesse k_p d'arrachement d'un atome d'hydrogène sur une grande variété de substrats organiques à 30°, ont été reliées aux longueurs de la liaison C—H impliquée D[R—H] (en kcal/mol). Deux relations empiriques ont été déduites, l'une pour les radicaux peroxy tertiaires

$$\log [k_p^{t\text{-ROO}} \text{ par hydrogène actif } (M^{-1}\ s^{-1})] = 15.4 - 0.2D[\text{R—H}]$$

et l'autre pour les radicaux peroxy secondaires

$$\log [k_p^{s\text{-ROO}} \text{ par hydrogène actif}/(M^{-1}\ s^{-1})] = 16.4 - 0.2D[\text{R—H}]$$

Ces équations s'appliquent très bien aux hydrocarbures et de façon raisonnable aux substrats contenant des hétéroatomes. Les énergies d'activation et les facteurs préexponentiels pour l'oxydation de quelques hydrocarbures par les radicaux *t*-butyl peroxy ont été mesurés et la relation empirique

$$E_p^{t\text{-ROO}}/(\text{kcal/mol}) = 0.55\ (D[\text{R—H}] - 62.5)$$

a été déduite. Si on prend D[*t*-ROO—H] égal à 88 kcal/mol, on obtient l'équation de Polanyi

$$E_p^{t\text{-ROO}}/(\text{kcal/mol}) = 14 + 0.55\,\Delta H_p^{t\text{-ROO}}$$

où ΔH est la chaleur de la réaction d'arrachement de l'hydrogène. Ces équations empiriques permettent le calcul des constantes de vitesse de la propagation de chaîne dans l'autooxydation de beaucoup de substrats organiques à 30° et également à d'autres températures.

Canadian Journal of Chemistry, **50**, 2285 (1972)

Introduction

A linear relation between activation energies, E, and exothermicities, ΔH, for bimolecular homolytic substitutions was first proposed in 1938 (1). This relation is referred to as the Polanyi equation and usually takes the form,

$$E = C + \alpha\Delta H$$

where C and α are constants.

Attempts to verify the Polanyi equation have been hindered until recently by a lack of accurate kinetic data and of reliable bond dissociation energies. The equation is obeyed in the gas phase

for hydrogen abstraction by methyl radicals from simple alkanes (2). It also appears to hold for hydrogen abstraction from alkanes by $Br^{\cdot}$, $I^{\cdot}$, and $F_2N^{\cdot}$ radicals, reactions which are all endothermic (3).

The Polanyi equation should only be obeyed if, through a series of reactants, there is no resonance stabilization (or alternatively, an equal amount of stabilization) in the transition state (4) and is therefore only applicable to a series of rather closely related compounds (5). Both simpler (6) and more complex (7) relations between E and ΔH have been proposed but since most exothermic atom abstractions have activation energies of *ca.* 8 ± 3 kcal/mol, it would take a fairly sophisticated rule to be of any predictive value (5).

The Polanyi equation was first applied to hydrogen abstractions in solution in 1950 by Bolland during his study of olefin autoxidation (8). The overall activation energy of an autoxidation, E_0, is related to the activation energies of the individual steps in the chain by the equation,

$$E_0 = E_p + \tfrac{1}{2}E_i - \tfrac{1}{2}E_t$$

where E_p is the activation energy for the chain propagation step,

$$ROO^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$$

E_i is the activation energy for chain initiation (by benzoyl peroxide)

$$PhC(O)OOC(O)Ph \rightarrow \text{radicals}$$

and E_t is the activation energy for chain termination,

$$ROO^{\cdot} + ROO^{\cdot} \rightarrow \text{non-radical products}$$

The activation energy of interest, E_p, was derived from the measured E_0 by assuming that $E_i = 31$ kcal/mol in all the olefins and that $E_t = 0$ for all the olefin peroxy radicals. Unfortunately, neither of these assumptions is justified. It is improbable that E_i will be exactly the same in all olefins since even the "well-behaved" di-*t*-butyl peroxide shows a solvent dependent activation energy for decomposition (9). The assumption that E_t is always zero can often be very far from the truth (10). Bolland correlated his E_p values with the olefin C—H bond strengths available at that time and derived an α value of 0.39 in the Polanyi equation. Although this value must be regarded as being *very* approximate there have been no subsequent attempts to check on whether the Polanyi equation can be applied to the chain propagation step of autoxidations. However, the absence of experimental data has rarely hindered kineticists for long. Two versions of the Polanyi equation have been proposed for hydrogen abstraction by peroxy radicals from alkanes. Benson (11) suggested

$$E_p/(\text{kcal/mol}) = 6.0 + \Delta H_p$$

However, Knox (12) has proposed that α is unlikely to be as large as 1.0 and has suggested that

$$E_p/(\text{kcal/mol}) = 10.0 + 0.60\,\Delta H_p$$

This relationship is based on the reasonable assumption that the electrophilicity of $ROO^{\cdot}$ will be similar to that of $RO^{\cdot}$ in reactions of the same ΔH and therefore E_p should lie on an extension of the curve relating E and ΔH for the $RO^{\cdot}$ radical (12).

Comparatively few direct measurements of autoxidation propagation rate constants have been made over a range of temperature (13). Consequently, there are few directly determined values of E_p. Furthermore, when more than one set of workers have measured E_p for the same hydrocarbon their agreement is generally very poor (*e.g.*, the reported E_p values for tetralin range from 4.5 to 8.3 kcal/mol and for cumene from 6.5 to 12.4 kcal/mol (13)). Such data are obviously unsuited for testing the Polanyi equation and are of little value in predicting propagation rate constants.

During the last few years we have measured absolute rate constants for the reaction of many organic compounds with their peroxy radical (13)

[1] $$ROO^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$$

Rate constants have also been determined for the reaction of organic compounds with the peroxy radical derived from a different substrate

[2] $$R'OO^{\cdot} + RH \rightarrow R'OOH + R^{\cdot}$$

This has been achieved by oxidizing RH in the presence of concentrations of the hydroperoxide R'OOH in the range 0.1–4.0 *M*. Under these conditions all the peroxy radicals derived from RH undergo a fast hydrogen atom transfer reaction with R'OOH.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[3] $$ROO^{\cdot} + R'OOH \rightarrow ROOH + R'OO^{\cdot}$$

Therefore, only $R'OO^{\cdot}$ radicals are involved in the rate controlling propagation and termination reactions for the oxidation of RH. For example, addition of *t*-butyl hydroperoxide to an autoxidation enables the rate constant for the reaction

[4] $$Bu^tOO^{\cdot} + RH \xrightarrow{k_p^{Bu^tOO}} Bu^tOOH + R^{\cdot}$$

to be determined. This hydroperoxide is ideally suited for measuring "cross" propagation rate constants because it is commercially available and easily purified. Moreover, the rate constant for chain termination by *t*-butylperoxy radicals,

[5] $$2\ Bu^tOO^{\cdot} \xrightarrow{2k_t^{Bu^tOO}} \text{Molecular products}$$

is lower than for any other known alkylperoxy radical. Addition of this hydroperoxide therefore allows many unreactive substrates to be autoxidized at reasonable chain lengths.

Relative "cross" propagation rate constants are generally more accurate than relative homopropagation rate constants because inaccuracies involved in the determination of $2k_t$ are unimportant. We have therefore attempted to measure activation energies for reaction 4 for substrates with labile C—H bond strengths in the range 70–100 kcal/mol so that the Polanyi equation could be put to a proper test for autoxidations.

Experimental

The general experimental procedures employed have been adequately described in previous papers in this series.

Results

Determination of Rate Constants and Arrhenius Parameters

Rates of oxidation and rates of chain initiation have been measured over a range of temperature for seven hydrocarbons in the presence of a sufficient concentration of *t*-butyl hydroperoxide to ensure that the rate controlling chain propagation and chain termination steps involved only the *t*-butylperoxy radical. The oxidations were initiated with azo-bis-isobutyronitrile, AIBN, and the rate of chain initiation, R_i, was determined in each run with 2,6-di-*t*-butyl-4-methoxyphenol, BMeOP. Rates of oxidation, R_s, were obtained from the expression

TABLE 1. AIBN-induced decomposition of Bu^{t}OOH in *o*-dichlorobenzene

Temperature (°C)	$R_i \times 10^7$ ($M\ s^{-1}$)	$\frac{(d[O_2]/dt)_t}{R_i}$ [a]
10	0.02	1.1
20	0.06	1.5

40	0.8	3.2
50	3.4	3.8
60	11.9	4.8
70	29.3	5.2

[a] $(d[O_2]/dt)_t$ is the rate of oxygen evolved by terminating *and* non-terminating interactions of *t*-butylperoxy radicals and can of course be greater than 1.

[6] $$R_s = -\frac{d[O_2]}{dt} = (R_{O_2})_{net} + \left[\frac{d[N_2]}{dt}\right]_i - \left[\frac{d[O_2]}{dt}\right]_i + \left[\frac{d[O_2]}{dt}\right]_t$$

where $(R_{O_2})_{net}$ is the measured rate of oxygen absorption, $\{d[N_2]/dt\}_i$ and $\{d[O_2]/dt\}_i$ are the rates of nitrogen evolved and oxygen absorbed by the initiator and $\{d[O_2]/dt\}_t$ is the rate of oxygen evolved from the mutual reaction of *t*-butylperoxy radicals (14–17). Values of $\{d[O_2]/dt\}_t$ were determined at each temperature from rates of oxygen evolution for the AIBN induced decomposition of *t*-butyl hydroperoxide in *o*-dichlorobenzene. Values of $\{d[O_2]/dt\}_t/R_i$ found in this work are summarized in Table 1.

The correction term $\{d[O_2]/dt\}_t$ is negligible for the readily oxidized hydrocarbons, *e.g.*, tetralin, oct-1-ene, *p*-xylene and cyclohexa-1,4-diene. However, for paraffinic hydrocarbons this "correction" is about *three* times as large as the measured rates of oxygen absorption. The corrected rates of oxidation of paraffinic hydrocarbons containing *t*-butyl hydroperoxide are therefore about four times as large as their measured rates and, because of the size of the correction, they cannot be determined with high accuracy.

Values of $k_p^{Bu^tOO}$ for highly reactive hydrocarbons such as cyclohexa-1,4-diene are also difficult to measure. This is because at normal substrate concentrations the rate of oxidation is so high that it depends on the partial pressure of oxygen above the liquid. The autoxidation chain length can be reduced by lowering the substrate

concentration. However, the concentration of some hydrocarbons has to be lowered so much that the overall rate of oxidation slows down rapidly as oxygen is absorbed because of depletion of the substrate. This leads to difficulties in the accurate determination of $k_p^{Bu^tOO}$.

The rates of oxidation of some compounds which do not oxidize particularly rapidly, *e.g.*, triphenylmethane, depend on the partial pressure of oxygen even at 1 atm. It is not possible to obtain accurate values of $k_p^{Bu^tOO}$ for such compounds.

In spite of these difficulties, the corrected rates of oxidation of all the hydrocarbons studied in this work can be described by the kinetic expression

$$\frac{-d[O_2]}{dt} = \frac{k_p^{Bu^tOO}[RH]\,R_i^{1/2}}{(2k_t^{Bu^tOO})^{1/2}}$$

Values of $k_p^{Bu^tOO}$ at various temperatures were calculated from the ratio $k_p^{Bu^tOO}/(2k_t^{Bu^tOO})^{1/2}$ using values of $2k_t^{Bu^tOO}$ calculated from the expression

$$\log [2k_t^{Bu^tOO}/(M^{-1}\,s^{-1})] = 9.2 - 8.5/\theta$$

where $\theta = 2.3RT$ kcal/mol, which is based on previously published data (18). Measured termination rate constants in *p*-xylene at 10 and 40° and in hexadecane at 40° were found to be in reasonable agreement with the values calculated from this expression. Propagation rate constants per abstractable hydrogen, $k_p^{Bu^tOO}$ per H, for seven hydrocarbons are given in Table 2. Plots of log ($k_p^{Bu^tOO}$ per H) against the reciprocal of the absolute temperature gave excellent straight lines from which the activation energies and pre-exponential factors listed in Table 2 were derived. For the saturated hydrocarbons the correction factor discussed above is so large that systematic errors are not unlikely and so their E and log A values are more uncertain than would be indicated by their Arrhenius plots.

Comparison of Arrhenius Parameters with Previously Published Data for Autoxidations

There are very few Arrhenius parameters in the literature with which the present work may be compared. Our own direct measurements of k_p by the rotating sector method gave for tetralin $E_p = 8.3$ kcal/mol and log (A_p per H/M^{-1} s^{-1}) = 6.1 and for cumene (which presumably is roughly comparable to tetralin or *p*-xylene) $E_p = 12.4$ kcal/mol and log (A_p per H/M^{-1} s^{-1}) = 8.2 (13). Hendry (19) has given $E_p = 10$ kcal/mol and log (A_p per H/M^{-1} s^{-1}) = 6.5 for cumene.

Of considerably more interest are the data of Allara *et al.* on the oxidation of isobutane (20) and *n*-butane (21).

For isobutane (20*a*), $E_p - \frac{1}{2}E_t = 11.3$ kcal/mol and since propagation and termination involve the *t*-butylperoxy radical, $E_p = 15.5$ kcal/mol (based on the E_t value used in this paper). At 50°, $k_p/(2k_t)^{1/2}$ is given as 2.7×10^{-3} (M^{-1} min^{-1})$^{1/2}$. At this temperature $2k_t$ for *t*-butylperoxy radicals is 3.2×10^3 M^{-1} s^{-1} = 1.92×10^5 M^{-1} min^{-1}, from which k_p at 50° is calculated to be 1.2 M^{-1} min^{-1} = 2×10^{-2} M^{-1} s^{-1}.

This yields log (A_p per H/M^{-1} s^{-1}) = 8.8 and k_p per H at 30° = 4.2×10^{-3} M^{-1} s^{-1}. Computational modeling studies of alkane oxidation (*20b*) indicate that log (A_p per H/M^{-1} s^{-1}) = 9.4 for this reaction, a value in excellent agreement with that found in the present work for *t*-butylperoxy radical abstraction of secondary hydrogens from saturated hydrocarbons.

For *n*-butane (21) $E_p - \frac{1}{2}E_t = 15.3 \pm 3$ kcal/mol which yields $E_p = 16.3$ kcal/mol if E_t is assumed to have the same value as has been found for *s*-heptylperoxy radicals, *viz.* 1.9 kcal/mol (22). Now *t*-butylperoxy radicals are less reactive in hydrogen atom abstraction than *s*-alkylperoxy radicals by an amount which causes k_p to be lower by a factor of 10 at 30° (see Fig. 1). If this lowered reactivity is ascribed to a higher activation energy, as seems most reasonable, then this factor of 10 corresponds to 1.4 kcal in E_p. That is, the activation energy for the abstraction of a secondary paraffinic hydrogen by a *s*-alkylperoxy radical should, according to our results, be 17.8 − 1.4 = 16.4 kcal/mol in excellent agreement with Allara *et al.*'s (21) value of 16.3 kcal. These workers also give $k_p/(2k_t)^{1/2} = 7.6 \times 10^{-4}$ (M^{-1} min^{-1})$^{1/2}$ at 100°. Taking $2k_t = 4 \times 10^6$ M^{-1} s^{-1} at this temperature yields $k_p = 11.3$ M^{-1} $min^{-1} = 0.19$ M^{-1} s^{-1} from which a value is calculated for log (A_p per H/M^{-1} s^{-1}) = 8.3 and for k_p per H at 30° of 3×10^{-4} M^{-1} s^{-1}. The value of A_p per H is an order of magnitude less than that found in the present work for *t*-butylperoxy radical attack on saturated secondary hydrogens.

Polanyi Relation

Since only a small range in R—H bond strengths could be covered in the present work, a dependable investigation of the Polanyi equation was not possible. However, if it is assumed that this relation is obeyed for the endothermic reactions with the paraffins and the exothermic reactions with tetralin, *p*-xylene and oct-1-ene (*i.e.*, neglecting the activation energy found for cyclohexa-1,4-diene which would appear to be far too large), then plotting $E_p^{Bu^tOO}$ against D[R—H] yields the relation

$$[7] \quad E_p^{Bu^tOO}/(\text{kcal/mol}) = 0.55(D[\text{R—H}] - 62.5)$$

On the assumption that the O—H bond strength in *t*-butyl hydroperoxide is 88 kcal/mol (23) this equation can be rewritten in the form,

$$E_p^{Bu^tOO}/(\text{kcal/mol}) = 14 + 0.55\,\Delta H_p^{Bu^tOO}$$

where $\Delta H_p^{Bu^tOO}$ is the heat of the reaction and is equal to the difference in the C—H and O—H bond strengths of the substrate and the resultant hydroperoxide, respectively,

$$\Delta H_p^{Bu^tOO} = D[\text{R—H}] - D[\text{R'OO—H}]$$

This equation is in surprisingly close agreement with that suggested by Knox (12), *i.e.*

$$E_p/(\text{kcal/mol}) = 10.0 + 0.60\,\Delta H_p$$

If it is assumed that the ten fold greater reactivity of secondary peroxy radicals compared with tertiary peroxy radicals results from a 1.4 kcal/mol smaller activation energy for hydrogen abstractions then

$$[8] \quad E_p^{s\text{-}ROO}/(\text{kcal/mol}) = 0.55(D[\text{R—H}] - 65.0)$$

Although eqs. 7 and 8 are probably the best currently available for predicting E_p values on the basis of R—H bond strengths they should be applied with caution until additional data are available. It is also important to remember that the A factors are not constant in the range where eqs. 7 and 8 were derived. A more sophisticated treatment of our experimental data which would make allowance for this effect seems unwarranted.

Pre-exponential Factors

The pre-exponential factors (per active hydrogen), $A_p^{Bu^tOO}$ per H, listed in Table 2 show a surprisingly large variation. They are all about 2 orders of magnitude lower than the pre-exponential factors, A^1 per H, reported by Golden and Benson (24) for the gas phase reaction of iodine atoms with hydrocarbons of comparable structure (see Table 3).

$$I^{\cdot} + RH \rightarrow IH + R^{\cdot}$$

This holds true over a range of hydrocarbon structures for which the A factors change by 3 orders of magnitude. For both abstraction reactions the higher A factors for the paraffins indicate that these transition states have a less rigidly defined geometry than do the transition states for hydrocarbons yielding resonance stabilized radicals.

The $A_p^{Bu^tOO}$ per H values for the saturated hydrocarbons are unexpectedly large for hydro-

[c]Reference 38.

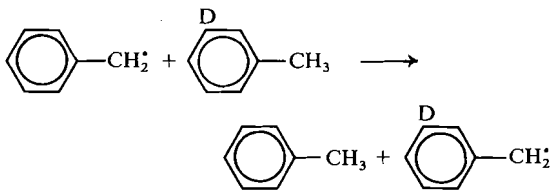
gen abstractions by a polyatomic, non-linear, free radical (12, 25).[3] Possibly they are in error because of systematic errors in the correction factor (see above). On the other hand, if they are correct they will explain an apparent anomaly in the E_p values for saturated hydrocarbons calculated from gas phase and from liquid phase autoxidations that has been pointed out by Benson (26).

The data of Baldwin *et al.* (27) on the high temperature (400–500°) gas phase oxidation of aldehydes containing small amounts of added hydrocarbons permit rate constants to be calculated for attack on the hydrocarbons by the hydroperoxy radical. For the reaction

$$HOO^{\cdot} + CH_3CH_2CH_3 \rightarrow HOOH + CH_3\dot{C}HCH_3$$

k_p^{HOO} per H = 1×10^5 M^{-1} s^{-1} at 440°. If A_p^{HOO} per H is taken to have the "normal" value of $\sim 2 \times 10^8$ M^{-1} s^{-1} which is typical of many hydrogen abstractions by radicals (25), then E_p^{HOO} for this reaction can be calculated to be ~10 kcal/mol. As discussed above, the liquid phase data yields $E_p^{s\text{-ROO}} \approx 16.4$ kcal/mol for analogous reactions involving *s*-alkylperoxy radicals. This disturbing anomaly can be partially resolved if we assign log (A_p^{HOO} per H/M^{-1} s^{-1}) the "high" value of 9.4 found in this work for the liquid phase reaction. The value of E_p^{HOO} is then calculated to be 14.4 kcal/mol. The remaining difference of 2 kcal/mol is hardly significant in view of the assumptions involved in these calculations, which include the assumption that HOO· radicals and *s*-ROO· radicals have equal reactivities.

[3]Large *A* factors have occasionally been reported by other workers (20*b*), even for hydrogen abstractions from hydrocarbons yielding resonance stabilized radicals. Thus, for the reaction



log (A/M^{-1} s^{-1}) = 10.5 and E = 19.9 kcal/mol (53).

Correlations of Propagation Rate Constants with C—H Bond Strengths at 30°

Although the Polanyi equation could not be reliably tested, a simple modification yields another empirical equation that could be tested with some of our previously published rate constants. The Arrhenius equation for chain propagation is

$$\log k_p = \log A_p - E_p/\theta$$

Provided the pre-exponential factors are constant for a series of substrates or, alternatively, vary smoothly with changes in the activation energies, then at any one temperature,

$$\log k_p \propto E_p$$

and hence, if the Polanyi equation is obeyed,

$$\log k_p \propto \Delta H_p$$

i.e.,

$$\log k_p \propto D[\text{R—H}] - D[\text{R'OO—H}]$$

It has been suggested that the O—H bond strength in alkyl hydroperoxides is independent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

of the nature of the alkyl group (28), and hence we can write

$$\log k_p \propto D[\text{R—H}]$$

Our published propagation rate constants at 30° (13) were found to give two surprisingly good correlations when values of log k_p per active hydrogen (log k_p per H) were plotted against the estimated strength of the weakest C—H bond in the organic substrates. One relation applied to attack by tertiary peroxy radicals and the other, with k_p values for the same substrate about an order of magnitude higher, for attack by secondary (and primary) peroxy radicals. These correlations of already published and of some new, unpublished, values for k_p per H at 30° with estimated values of D[R—H] form the subject of the remainder of this paper.

The C—H bond strengths used to correlate the measured propagation rate constants were obtained principally from the radical stabilization energies, E_s, reported by Golden and Benson (24). More recent work by these authors and by a few others who have used equally accurate techniques were also utilized (29–43). These data, which are listed in Table 4, appear to be internally consistent and to provide the most accurate source of C—H bond strengths that is currently available. Even so, it must be realized that none of these stabilization energies are known to better than ±1 kcal/mol and few are known to this degree of accuracy. In calculating an unknown bond strength it was assumed that stabilization energies were additive unless evidence to the contrary exists. For example

$$D[C_6H_5C(CH_3)H\text{—}H] = D[(CH_3)_2CH\text{—}H] - E_s[C_6H_5\dot{C}H_2]$$
$$= 95 - 13 = 82 \text{ kcal/mol}$$

$$D[C_6H_5CHCl\text{—}H] = D[CH_3CH_2\text{—}H] - E_s[C_6H_5\dot{C}H_2] - E_s[\dot{C}H_2Cl]$$
$$= 98 - 13 + 3 = 88 \text{ kcal/mol}$$

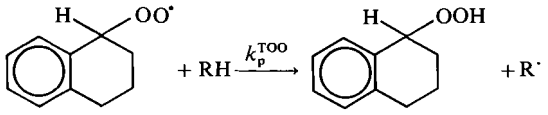
However, for diphenylmethane the assumption that

$$D[(C_6H_5)_2CH\text{—}H] = D[(CH_3)_2CH\text{—}H] - 2E_s[C_6H_5\dot{C}H_2]$$
$$= 98 - 26 = 72 \text{ kcal/mol}$$

is clearly unacceptable since $D[(C_6H_5)_3C\text{—}H]$ is known to be 75 kcal/mol. The C—H bond strength in diphenylmethane was therefore arbitrarily assigned a value of 81 kcal/mol. In a few cases where no E_s values estimated by Benson's methods were available data were taken from Kerr's review (4).

The measured rate constants for chain propagation in the autoxidation of hydrocarbons, RH, at 30° and the estimated R—H bond strengths are given in Table 5. Similar data for organic substrates containing a heteroatom are listed in Table 6. In these tables the rate constants have been statistically corrected for the number of labile hydrogens in the substrate, *i.e.*, for 3 in toluene and for 12 in cyclohexane. The rate constants refer to the following processes

$$ROO\cdot + RH \xrightarrow{k_p^{ROO}} ROOH + R\cdot$$



(α-tetralylperoxy)

$$(CH_3)_3COO\cdot + RH \xrightarrow{k_p^{Bu^tOO}} (CH_3)_3COOH + R\cdot$$

$$C_6H_5(CH_3)_2COO\cdot + RH \xrightarrow{k_p^{COO}} C_6H_5(CH_3)_2COOH + R\cdot$$

(cumylperoxy)

Rate constants for reaction of the substrates listed in Tables 5 and 6 with secondary (and primary) peroxy radicals can be approximately described by the equation

[9] $$\log [k_p^{s\text{-}ROO} \text{ per active H}/(M^{-1}\text{ s}^{-1})] = 16.4 - 0.2(D[\text{R—H}] + \Delta)$$

In this equation Δ represents the correction (in kcal/mol) that is required to the assigned R—H bond strength to place the measured log (k_p per H) exactly on the line defined by eq. 9 with Δ = 0. A negative value of Δ means that log (k_p per H) is greater than predicted while a positive value of Δ means that it is less than predicted.

Reaction of the same substrates with tertiary peroxy radicals yields a very similar equation

[10] $$\log [k_p^{t\text{-}ROO} \text{ per active H}/M^{-1}\text{ s}^{-1})] = 15.4 - 0.2(D[\text{R—H}] + \Delta)$$

[a]Units of D[R—H] and Δ are kcal/mol. Units of k_p per H are M^{-1} s^{-1}. Data are from ref. 13 unless otherwise specified. The D[R—H] values are derived from the E_s values in Table 4.
[b]Deviation from eq. 9 unless otherwise noted.
[c]This work unless otherwise noted.
[d]Deviation from eq. 10.
[e]Calculated from (k_p^{ROO} per H) = 0.044 M^{-1} s^{-1} at 60° (ref. 13) taking log (A_p^{ROO} per H) = 9.4 (see Table 2). This gives E_p^{ROO} = 16.4 kcal/mol and (k_p^{ROO} per H) = 4×10^{-3} M^{-1} s^{-1}.
[f]From data in ref. 20*a*. See text.
[g]Based on an assumed value for $2k_t^{ROO}$, see ref. 13.
[h]Based on an average $2k_t^{ROO} = 2.5 \times 10^7$ M^{-1} s^{-1} at 30°.
[i]Rate dependent on oxygen pressure.
[j]Minimum value for k_p estimated by extrapolation to infinite pressure of values obtained in the range 150–760 mm [O_2].
[k]k_p per H for abstraction. At 30°, 27% of propagating steps are abstractions and 73% are additions.
[l]HOO· radical.

This equation represents a line parallel to that defined by eq. 9 but displaced by 5 kcal/mol in D[R—H] (which is equivalent to an order of magnitude in k_p per H). The two lines and some of the data from Table 5 are shown in Fig. 1.

The excellent correlations of log ($k_p^{t\text{-}ROO}$ per H) and of log ($k_p^{s\text{-}ROO}$ per H) with D[R—H] for hydrocarbons is quite surprising in view of the fact that log (A_p per H) is far from being a constant over the range of structures studied (see Table 2). Presumably there is an approximately linear correlation of log (A_p per H) with E_p which arises because an increase in the resonance stabilization of R·, which decreases D[R—H] and E_p, requires a more rigid geometry of the transition state and hence reduces log

[a]Units of D[R—H] and Δ are kcal/mol. Units of k_p per H are M^{-1} s^{-1}. Data are from ref. 13 unless otherwise specified.
[b]Estimates based on E_s values in Table 4 and on data contained in ref. 4. D[R—H] for ethers have been calculated using $E_s = 4$ kcal/mol for the effect of the ethereal oxygen (the mean of the 5 kcal for dimethyl ether and 3 kcal for tetrahydrofuran), except for tetrahydrofuran where D[R—H] was taken directly from Table 4.
[c]Deviation from eq. 9 unless otherwise noted.
[d]Deviation from eq. 10.

(A_p per H). Any deviation of a hydrocarbon from this linear log (A_p per H) *vs.* E_p relation would, of course, result in a deviation from the log (k_p per H) *vs.* D[R—H] relation. For example, log (A_p per H) for *p*-xylene (and, presumably, toluene, etc.) is less than for oct-1-ene and tetralin and, in consequence, *p*-xylene and toluene are less reactive towards peroxy radicals than would be predicted from their R—H bond strengths.

Other possible causes of a deviation from the log (k_p per H) *vs.* D[R—H] relations include an error in the measurement of k_p, an incorrect assignment of D[R—H], or some special factor arising from conformational (44), steric or polar effects in the peroxy radical or substrate. However, it must be emphasized that k_p cannot be determined with an absolute accuracy of much better than a factor of two, while even the most accurate C—H bond strengths are uncertain by $\sim \pm 2$ kcal/mol. In consequence, a deviation (Δ) of log (k_p per H) of 2 kcal from eqs. 9 or 10 (Tables 5 and 6) is not significant.

Possible Reasons for Large Deviations from Equations 9 and 10

The difficulty described above in determining values of $k_p^{Bu^tOO\cdot}$ for cyclohexa-1,4-diene is encountered for all highly reactive substrates and only approximate values of $k_p^{Bu^tOO}$ per H can be assigned to these substrates. This problem is not as pronounced with cumene hydroper-

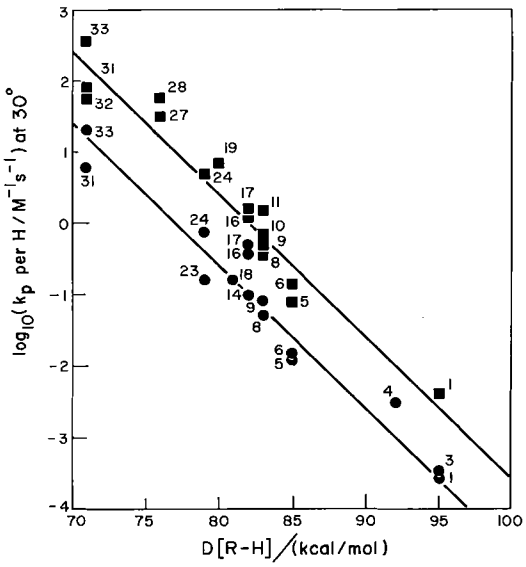

FIG. 1. log [k_p per active H/(M^{-1} s^{-1})] plotted against D[R—H]/(kcal/mol). Equation 10 is represented by the lower line and the circles represent rate constants for tertiary peroxy radicals. Equation 9 is represented by the upper line and the squares represent rate constants for secondary peroxy radicals. The numbers refer to the compounds listed in Table 5 (not all the data in this table have been plotted).

oxide because the stationary state concentration of cumylperoxy radicals is lower ($2k_t^{COO} > 2k_t^{Bu'OO}$). The low reactivity of ethylbenzene and bibenzyl as hydrogen atom donors compared with tetralin or indan is well known and has been related to conformational effects in these molecules (44).

Hydrocarbons yielding *t*-alkyl radicals are less reactive (positive Δ values) than those yielding secondary or primary alkyl radicals. If the correct C—H bond strengths have been assigned a significant steric effect is retarding these reactions.

Ethers are, in general, more reactive to peroxy radicals than eqs. 9 or 10 would predict. The major exception is α-methylbenzyl ether which is relatively unreactive presumably for steric reasons (45). Benzyl phenyl ether is slightly less reactive than would be predicted but the peculiarities which have been noted previously in the oxidation of this ether (45, 46) make the reason for this uncertain. The Δ values for *t*-butylperoxy radicals and for the peroxy radicals derived from the ethers are in excellent agreement (Table 6). The reactivities of α-alkoxyalkylperoxy radicals and alkylperoxy radicals are therefore similar (45). The C—H bond strengths of the ethers were calculated on the basis of a 4 kcal/mol stabilization energy due to the ethereal oxygen (the mean of 5 kcal for dimethyl ether and 3 kcal for tetrahydrofuran, Table 4). If we exclude α-methylbenzyl ether and tetrahydrofuran and its derivatives (2,5-dimethyltetrahydrofuran and phthalan), the Δ values for the remaining ethers average about −3 kcal/mol. That is, the majority of the ethers would fit eqs. 9 and 10 if E_s were 7 kcal/mol for an α-alkoxyalkyl radical. This would give $D[CH_3OCH_2—H] = 91$ kcal/mol rather than the 93 kcal/mol found by the gas phase iodine atom method (32). In view of the reported difficulties arising from surface effects when the iodine atom method is applied to oxygen-containing organic substrates (24), an E_s value of 7 kcal/mol is not altogether unreasonable. However, there is other evidence that α-oxygen substitution imparts relatively little stabilization to alkyl radicals (47, 48) and so an alternative explanation for the enhanced reactivity of ethers is desirable. The most obvious possibility is that the values of A_p per H for ethers are higher than for hydrocarbons of comparable bond strength. However, such an explanation could hardly account for the exceptionally high reactivity of tetrahydrofuran and its derivatives. This ether is also an unexpectedly good hydrogen donor to *t*-butoxy radicals (49) and phenyl radicals (50), so there is a distinct possibility that its C—H bond strength is less than the 92 kcal/mol found by the iodine atom method (24).

The high reactivities of benzyl chloride, benzyl acetate, benzyl benzoate and, particularly, benzaldehyde towards their own peroxy radicals are due to the exceptional reactivities of these radicals which arise from the presence of the electron withdrawing α-substituents (51, 52). Towards the *t*-butylperoxy radical these substrates exhibit a normal pattern of reactivity which implies that polar effects in the hydrogen donor are of less importance in determining k_p than polar effects in the peroxy radical.

Conclusion

The correlation of propagation rate constants for the autoxidation of organic substrates at 30° with the strengths of the weakest C—H bonds in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the molecule by means of the empirical equations

[9] $\log [k_p^{s\text{-ROO}} \text{ per active H}/(M^{-1}\ s^{-1})] = 16.4 - 0.2\ D[\text{R—H}]$

and

[10] $\log [k_p^{t\text{-ROO}} \text{ per active H}/(M^{-1}\ s^{-1})] = 15.4 - 0.2\ D[\text{R—H}]$

with D[R—H] in kcal/mol, has been surprisingly successful for hydrocarbons and reasonably successful for substrates containing heteroatoms. These equations can be used to predict k_p values not only at 30° but also at other temperatures when combined with the estimated pre-exponential factors and with activation energies calculated from the relations

[7] $E_p^{t\text{-ROO}}/(\text{kcal/mol}) = 0.55\ (D[\text{R—H}] - 65.0)$

and

[8] $E_p^{s\text{-ROO}}/(\text{kcal/mol}) = 0.55\ (D[\text{R—H}] - 62.5)$

Overall rates of oxidation of organic substrates at specified rates of chain initiation are determined by the values of k_p and $2k_t$. Sufficient data now exist (13) for $2k_t$ to be estimated with reasonable certainty provided the structure of the chain terminating peroxy radical is known. Since k_p can be estimated from the above equations it should now be possible to predict the "oxidizability" $(k_p/(2k_t)^{1/2})$ of a hydrocarbon with reasonable accuracy over a wide range of temperature provided D[R—H] is known. Less accurate predictions could be made about organic substrates containing heteroatoms.

Absolute Rate Constants for Hydrocarbon Autoxidation. XXII. The Autoxidation of some Vinyl Compounds[1]

J. A. HOWARD

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received January 28, 1972

Absolute propagation and termination rate constants have been determined for the autoxidation of some vinyl compounds at 30°. Rates of propagation depend on the structure of both the peroxy radical and the vinyl compound. The reactivity of peroxy radicals towards addition increases as the electron-withdrawing capacity of the α-substituent increases. Rate constants for addition of *t*-butylperoxy radicals to vinyl compounds, $k_{add}^{Bu^tOO}$, fit the equation

$$\log [k_{add}^{Bu^tOO}/(M^{-1}\ s^{-1})] = 0.2\ E_s - 4.3$$

where E_s is the estimated stabilization energy of the β-peroxyalkyl radical (in kcal/mol) formed in the addition reaction.

Les constantes absolues de vitesse de propagation et de terminaison ont été déterminées pour l'autoxydation de quelques composés vinyliques à 30°. Les vitesses de propagation dépendent à la fois de la structure du radical péroxy et du composé vinylique. La réactivité des radicaux peroxy pour l'addition croît avec le pouvoir électroattracteur du substituant en α. Les constantes de vitesse de l'addition des radicaux *t*-butylpéroxy aux composés vinyliques, $k_{add}^{Bu^tOO}$, satisfont l'équation

$$\log\ [k_{add}^{Bu^tOO}/(M^{-1}\ s^{-1})] = 0.2\ E_s - 4.3$$

où E_s est l'énergie de stabilisation mesurée du radical β-peroxyalkyl (en kcal/mol) formé dans la réaction d'addition.

Canadian Journal of Chemistry, **50**, 2298 (1972)

Introduction

Recent work in these laboratories (1) has shown that the magnitude of the rate controlling propagation constant for the autoxidation of α-monosubstituted toluenes, k_p, depends on the nature of the peroxy radical, ROO·, as well as the nature of the toluene, RH.

[1] $$ROO\cdot + RH \xrightarrow{k_p} ROOH + R\cdot$$

Thus it was shown that the reactivity of peroxy radicals increases with the increasing electron-withdrawing capacity of the α-substituent in the order

$C_6H_5C(O)OO\cdot > C_6H_5CH(OC(O)R)OO\cdot > C_6H_5CH(Cl)OO\cdot > C_6H_5CH(CN)OO\cdot > C_6H_5CH(OH)OO\cdot > C_6H_5CH(OR)OO\cdot \sim C_6H_5CH_2OO\cdot$

Vinyl compounds, $CH_2{=}C(X)R$ (where R = CH_3 or H and X = CN, C_6H_5, $OC(O)CH_3$, etc.) react with molecular oxygen at ambient temperatures by a free radical chain process (2). The rate controlling propagation step is

[2] $$-CH_2\overset{R}{\underset{|}{C}}(X)OO\cdot + CH_2{=}\overset{R}{\underset{|}{C}}X \xrightarrow{k_p^{rr}} -CH_2-\overset{R}{\underset{|}{C}}(X)OOCH_2\overset{R}{\underset{|}{C}}X\cdot$$

In order to compare the relative reactivities of α-substituted alkylperoxy radicals towards addition with their relative reactivities towards abstraction we have now measured absolute rate constants for the reaction of a number of vinyl compounds towards their own peroxy radical, k_p^{rr}, and towards the *t*-butylperoxy radical, $k_{add}^{Bu^tOO}$.

[3] $$Bu^tOO\cdot + CH_2{=}\overset{R}{\underset{|}{C}}X \xrightarrow{k_{add}^{Bu^tOO}} Bu^tOOCH_2-\overset{R}{\underset{|}{C}}X\cdot$$

Experimental

Absolute rate constants for the autoxidation of the undiluted vinyl compounds were determined using the rotating sector method (3, 4). Rate constants for reaction of the vinyl compounds with *t*-butylperoxy radicals were determined from autoxidations in the presence of *t*-butyl hydroperoxide

(1, 5). All the rate constants reported in this work were measured at 30°.

α,α′-Azo-bis-isobutyronitrile and α,α′-azo-bis-cyclohexane carbonitrile were used as thermal and photochemical initiators, respectively. 2,6-Di-*t*-butyl-4-methoxyphenol was the scavenger used to determine rates of chain initiation by the induction period method (6).

The vinyl monomers were, whenever possible, purified by distillation from a sample that was partially polymerized in the absence of oxygen. Non-polymerizable substrates and solvents were purified by fractional distillation and percolation through alumina. *t*-Butyl hydroperoxide was dried and purified by crystallization from pentane.

Results and Discussion

(i) Pure Vinyl Compounds

Steady state rates of oxidation, R_s, of several vinyl compounds at various partial pressures of oxygen, rates of chain initiation, R_i, and substrate concentration, [RH], are summarized in Tables 1 and 2. The values of R_s for vinyl compounds can be approximately described by the usual kinetic expression for autoxidations

$$[4] \qquad R_s = \frac{-d[O_2]}{dt} = \frac{k_p^{rr}[RH]R_i^{1/2}}{(2k_t^{rr})^{1/2}}$$

where k_p^{rr} and $2k_t^{rr}$ are the rate controlling propagation and termination rate constants. However, photochemically initiated oxidations of vinyl acetate, 2,3,3-trimethylbut-1-ene, methyl acrylate, isopropenyl acetate, and ethyl vinyl ether gave values of the ratio of the rate of an oxidation that is subjected to flashes of light of very short duration, *i.e.*, at very fast speeds of sector rotation, to the rate under continuous illumination, R_∞/R_s, of *ca.* 0.4 and eq. 4 is not strictly obeyed for these compounds. Absolute values of k_p^{rr} and $2k_t^{rr}$ in these cases were determined on the basis of the assumption that the oxidation chains are terminated by reactions that are first and second order in the concentration of peroxy radicals (3, 4).

Vinyl compounds can be arranged in the following order of decreasing oxidizability, *i.e.*, decreasing $k_p^{rr}/2k_t^{rr})^{1/2}$)

2,3,3-trimethylbut-1-ene < methyl acrylate < isopropenyl acetate < methyl methacrylate ~ vinyl acetate < acrylonitrile < ethyl vinyl ether < methyl acrylonitrile < styrene < α-methylstyrene

Rate constants for the mutual termination reaction of the peroxy radicals derived from vinyl compounds, $2k_t^{rr}$, lie in the range 6×10^5 to 10^8 M^{-1} s^{-1}. Values of $2k_t^{rr}$ for the radicals with an α-hydrogen atom are similar to rate constants for the secondary peroxy radicals derived from acyclic hydrocarbons, ethers, thioethers, and α-monosubstituted toluenes (7). α-Substitution therefore has very little influence on $2k_t^{rr}$ for the secondary peroxy radicals derived from vinyl compounds. We previously reached the same conclusion from a study of the autoxidation of α-monosubstituted toluenes (1).

Termination rate constants for the peroxy radicals derived from methyl methacrylate, methyl acrylonitrile, isopropenyl acetate, and 2,3,3-trimethylbut-1-ene are in the range $1 \times 10^6 - 1 \times 10^8$ M^{-1} s^{-1}. These rate constants are significantly larger than termination rate constants for the peroxy radicals derived from hydrocarbons, alcohols, and ethers with labile tertiary hydrogens (7). It is well known from the work of Russell (8) that the presence of a small percentage of secondary (or primary) peroxy radicals in the chain drastically reduces the rate of oxidation of a substrate with a labile tertiary hydrogen. This suggests that the relatively high termination rate constants for the α-methyl substituted vinyl compounds are due to peroxy radical attack at the α-methyl group with the consequent production of primary peroxy radicals.

$$[5] \quad ROO^{\cdot} + CH_2{=}C(X)CH_3 \xrightarrow{O_2} ROOH + CH_2{=}C(X)CH_2OO^{\cdot}$$

This reaction is feasible because allylic hydrogens are readily abstracted by peroxy radicals, *e.g.*, k_p^{rr} for oct-1-ene = 1.0 M^{-1} s^{-1} at 30° (7). However, it is also possible that electron-withdrawing α-substituents in peroxy radicals with the structure —CH_2—$C(X)(CH_3)OO^{\cdot}$ directly increase the termination rate constant. For example, the value of $2k_t$ for the 2-cyano-2-propylperoxy radical (9) is *ca.* 3 orders of magnitude larger than for the *t*-butylperoxy radical.

Propagation rate constants, k_p^{rr}, for the vinyl compounds fall in the range 0.6–5.0 M^{-1} s^{-1}. Interpretation of these rate constants is complicated by differences in both peroxy radical and substrate reactivity.

(ii) Autoxidation of Vinyl Compounds in the Presence of t-Butyl Hydroperoxide

The vinyl compounds discussed in the previous section have been oxidized in the presence of *t*-butyl hydroperoxide. At hydroperoxide

concentrations above *ca.* 1 M, the rate controlling propagation and termination reactions involved in the autoxidation are

$$Bu^tOO^\cdot + CH_2{=}\underset{\displaystyle R}{\overset{\displaystyle R}{C}}{-}X \xrightarrow{k_{add}^{Bu^tOO}} Bu^tOOCH_2{-}\underset{\displaystyle R}{\overset{\displaystyle R}{C}}(X)^\cdot$$

and

$$Bu^tOO^\cdot + Bu^tOO^\cdot \xrightarrow{2k_t^{Bu^tOO}} \text{Molecular products}$$

Measurement of rates of oxidation of vinyl compounds in the presence of *t*-butyl hydroperoxide at known rates of chain initiation enables absolute values of $k_{add}^{Bu^tOO}$ to be calculated. Kinetic data obtained by this procedure are summarized in Table 3.

The last column in Table 3 compares the reactivity of a vinyl compound towards its own peroxy radical and towards the *t*-butylperoxy radical. The following conclusions can be drawn from this comparison.

(a) Peroxy Radical Reactivity

α-Substituted secondary peroxy radicals, R—CH(X)OO·, are significantly more reactive towards addition than the *t*-butylperoxy radical and increase in reactivity in the order

—CH(OC(O)CH_3)OO· > —CH(CN)OO· > —CH(OC_2H_5)OO· > —CH(C(O)OCH_3)OO· ~ —CH(C_6H_5)OO·

This reactivity sequence is identical with the one previously obtained for the reactivity of some α-monosubstituted benzylperoxy radicals towards hydrogen atom abstraction (1). α-Substituted tertiary peroxy radicals RC(CH_3)(X)OO· are also more reactive than the *t*-butylperoxy radical but are less reactive than the corresponding α-substituted secondary peroxy radicals. These tertiary radicals can be arranged in the following order of increasing reactivity

$CH_3C(R)(CN)OO^\cdot > CH_3C(R)(OC(O)CH_3)OO^\cdot > CH_3C(R)(C(O)OCH_3)OO^\cdot$

(b) Substrate Reactivity

The vinyl compounds listed in Table 3 have been arranged in order of increasing reactivity towards the *t*-butylperoxy radical. It is apparent that the reactivity decreases as the electron-withdrawing capacity of the substituent increases. Thus the influence of α-substitution on substrate reactivity is the reverse of the influence of α-substitution on peroxy radical reactivity. For example, the peroxy radical derived from vinyl acetate is the most reactive peroxy radical considered in this work while vinyl acetate is the least reactive vinyl compound towards reaction with the *t*-butylperoxy radical. This effect is analogous to that found in free radical polymerizations where it has been observed that the order of reactivity for polymer radicals is approximately the inverse of that for monomers (10).

It has been proposed (11, 12) for radical addition reactions to olefins

$$[7] \qquad R^\cdot + \diagup C{=}C \diagdown \rightarrow R{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{}^\cdot$$

that changes in the heat of reaction (ΔH) and activation energy (E_a) may be related to the stabilization energies of the attacking radical (R_a), the olefin (R_m), and the radical formed

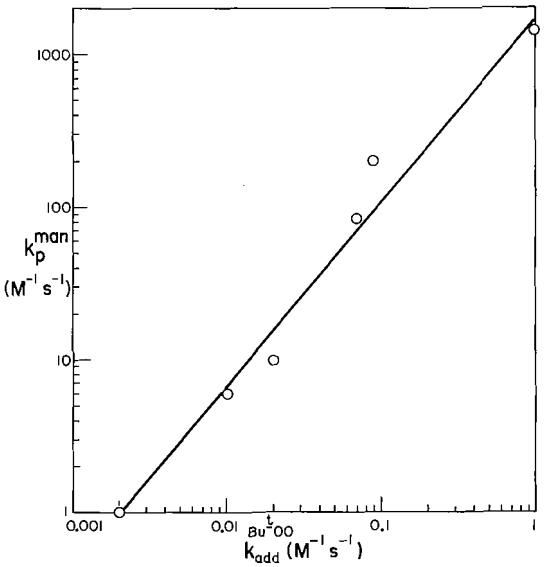

FIG. 1. A free energy plot for the reaction of olefins with the *t*-butylperoxy radical and the poly(methylacrylonitrile) radical.

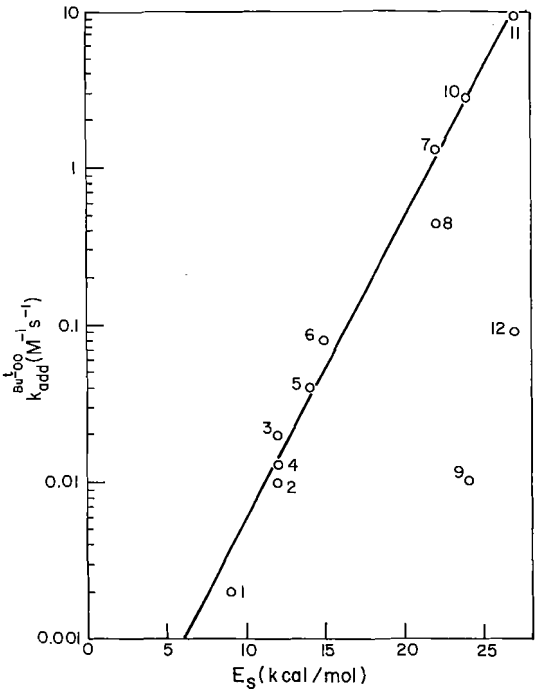

FIG. 2 A plot of the logarithms of the rate constants for addition of *t*-butylperoxy radicals to olefins against estimated stabilization energies of the radical formed upon addition. The numbers refer to the compounds listed in Table 3.

on addition (E_s) by the equation

$$[8] \qquad E_a = \alpha \Delta H = \alpha(R_a + R_m - E_s)$$

This equation has been modified (13) for the addition of a given radical to a series of olefins at a constant temperature to give

$$[9] \qquad \log k = A + B[R_m + D[\mathrm{R'—H}]]$$

where k is a relative rate constant for addition, A is a constant providing the pre-exponential factors for the additions are the same, $B = \alpha/2.303\ RT$ and D[R′—H] is the strength of the

R$\underset{|}{\overset{|}{\mathrm{C}}}$C—H bond. Relative rate constants for the

addition of methyl radicals to olefins (14–18) correlate quite well with eq. 9 and fit the expression

$$[10] \quad \log k = 11.36 - 0.104\,[R_m + D[\mathrm{R'—H}]]$$

The logarithms of the rate constants for addition of *t*-butylperoxy radicals to olefins do not give a linear free energy correlation with the logarithms of the rate constants for addition of methyl radicals and other electroneutral radicals, *e.g.*, phenyl and polystyryl. This implies that eq. 9 does not hold for the electrophilic *t*-butylperoxy radical. Fairly good correlations are, however, obtained between the *t*-butylperoxy radical and the more polar polymeric radicals from methyl acrylonitrile, methyl methacrylate, acrylonitrile, and methyl acrylate (see, *e.g.*, Fig. 1). The slope of the line shown in this figure can be described by the equation

$$[11] \quad \log [k_{add}^{Bu^tOO}/(M^{-1}\,s^{-1})] = 1.2 \log [k^{man}/(M^{-1}\,s^{-1})]$$

where k^{man} represents the rate constant for addition of the poly(methylacrylonitrile) radical to the olefin. This equation indicates that the the *t*-butylperoxy radical is slightly more selective than the poly(methylacrylonitrile) radical towards addition.

Although rate constants for the addition of *t*-butylperoxy radicals to olefins do not obey eq. 9, an excellent correlation is obtained when the logarithms of $k_{add}^{Bu^tOO}$ are plotted against the estimated stabilization energies of the radical formed on addition (Fig. 2). This implies that the rate of addition of the *t*-butylperoxy radical to olefins depends principally on the stability of the incipient radical. The stabilization energies of the β-peroxyalkyl radicals have been assumed to be equal to the stabilization

*Numbers in parentheses identify the radicals with the vinyl compounds listed in Table 3.

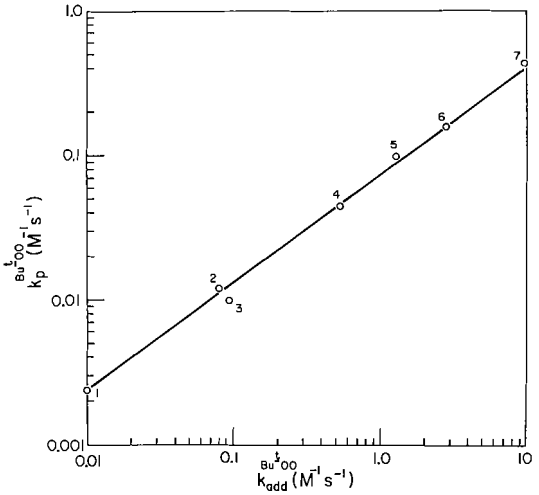

FIG. 3. A plot of log $[k_{add}^{Bu^tOO}/(M^{-1}\,s^{-1})]$ against log $[k_p^{Bu^tOO}/(M^{-1}\,s^{-1})]$ for the reaction of the *t*-butylperoxy radical with olefins and their hydrogenated analogues. The numbers refer to the pairs of compounds listed in Table 5.

energies of the analogous alkyl radical, *e.g.*, E_s for $Bu^tOOCH_2\dot{C}HC_6H_5$ has been assumed to equal E_s for $CH_3\dot{C}HC_6H_5$. The values of E_s used in this work are listed in Table 4 and were calculated from the expression

$$E_s = D[CH_3\text{—}H] - D[XCH_2\text{—}H]$$

using a value of $D[CH_3\text{—}H]$ equal to 104 kcal/mol (19). The values of $D[XCH_2\text{—}H]$ that were used are the most accurate currently available (20). The best line through the points in Fig. 2 fits the equation

$$\log [k_{add}^{Bu^tOO}/(M^{-1}\,s^{-1})] = 0.2\,E_s - 4.3$$

with most of the rate constants lying within a factor of 2 of this line. The obvious exceptions are acrylonitrile and methyl acrylonitrile. We have used Shapiro and Turk's (21) recent E_s value of *ca.* 20 kcal/mol for the $\dot{C}H_2CN$ radical to estimate E_s values for $CH_3\dot{C}H(CN)$ and $(CH_3)_2\dot{C}CN$. Our kinetic data imply that these resonance energies may be too high by *ca.* 10 kcal/mol.

trans-1,2-Diphenylethylene is approximately 4 times as reactive as the *cis*-isomer towards *t*-butylperoxy radicals. This order of reactivity for *cis-trans* isomers of 1,2-disubstituted olefins is often found in free radical co-polymerization reactions despite the fact that the *cis* isomer is the thermodynamically less stable form. Such results have been rationalized by assuming that the radical formed from the *cis*-isomer is less stable than the radical formed from the *trans*-isomer because of steric hindrance to resonance. Our results imply that the *trans*-1,2-diphenylethyl radical is *ca.* 3 kcal/mol more stable than the *cis*-radical.

The reactivity of some olefins, $k_{add}^{Bu^tOO}$, and their hydrogenated analogues, $k_p^{Bu^tOO}$, towards the *t*-butylperoxy radical are compared in Table 5. These rate constants are presented as a linear free energy correlation in Fig. 3 with the

TABLE 5. A comparison of the reactivity of vinyl compounds and their hydrogenated analogues towards *t*-butylperoxy radicals

Vinyl compound	$k_{add}^{Bu^tOO}$ ($M^{-1}\,s^{-1}$)	Saturated analogue	$k_p^{Bu^tOO}$/H ($M^{-1}\,s^{-1}$)
Isopropenyl acetate (1)	0.01	Isopropyl acetate	0.0024

Hydrogen Atom Recombination on Glass Surfaces

L. W. BADER

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

AND

H. D. GESSER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received November 17, 1971

The adsorption and recombination of H atoms at temperatures between 77 and 110 °K have been studied on various silicate glass surfaces consisting of fused silica, porous Vycor with surface adsorbed water, and porous Vycor with chemically altered surfaces achieved by replacement of the surface functional hydroxyl group by chlorine, fluorine, and methoxy substituents.

The concentration of adsorbed H atoms was determined by a measurement of the e.s.r. signal and the kinetics of the disappearance of the hydrogen atoms were observed to be second order in mobile atoms, consistent with a diffusion controlled recombination process.

The results require that there be at least two types of surface adsorbed atoms, namely, weakly physically adsorbed atoms that are mobile and immobile. Identification of these adsorbed atom types with a particular surface functional feature leading to the adsorption is proposed.

The activation energy for the second order decay of hydrogen atoms at the surface was found to vary from 1.0 to 2.3 kcal/mol, depending upon the chemical nature of the surface. A correlation between this activation energy and an electronegativity function of the surface group is presented.

L'adsorption et la recombinaison des atomes H, à des températures entre 77 et 110 °K, ont été étudiées sur diverses surfaces de verre au silicate, constituées soit par de la silice fondue, soit par du Vycor poreux ayant adsorbé de l'eau, soit par du Vycor poreux avec des surfaces modifiées chimiquement où les groupes fonctionnels hydroxyles ont été remplacés par du chlore, du fluor et par le groupe méthoxy. La concentration des atomes H adsorbés est déterminée par la mesure du signal RPE, les cinétiques de disparition des atomes d'hydrogène sont du second ordre en atomes mobiles, compatibles avec un processus de recombinaison contrôlé par la diffusion. Ces résultats impliquent l'existence d'au moins deux types d'atomes adsorbés à savoir ceux qui sont physiquement adsorbés de façon faible, mobiles et immobiles. L'identification de ces types d'atomes adsorbés sur une surface fonctionnelle particulière, est proposée.

L'énergie d'activation pour la disparition du 2ième ordre des atomes d'hydrogène de la surface varie de 1.0 à 2.3 kcal/mol, dépendant de la nature chimique de la surface. Une corrélation entre l'énergie d'activation et l'électronégativité de la fonction sur la surface, est présentée.

Canadian Journal of Chemistry, **50**, 2305 (1972)

Introduction

Since the early observations of Wood (1) of the surface catalyzed recombination of hydrogen atoms, and the effect of surface "poisons" on the recombination, the phenomenon has been observed and studied in many atom systems ... H (2), O (3, 4), Cl (5), N (6) ... to list only a few. In particular, the recombination of hydrogen atoms on glass surfaces has been studied by a number of workers (7–11).

Several common features in the reports of these studies can be noted. There is unanimity in the acceptance of the fact that the recombination proceeds via surface adsorbed atoms, S–H.

The Rideal mechanism

[1] $$S + H(g) \rightarrow S{-}H$$

[2] $$S{-}H + H(g) \rightarrow S + H_2$$

is considered to predominate at moderate (−100 to 200 °C) temperatures. The observed activation energy and the observed first order gas phase atom dependence of the reaction result if reaction 2 is the rate determining step.

The Hinshelwood mechanism

[1] $$S + H(g) \rightarrow S{-}H$$

[3] $$2S{-}H \rightarrow 2S + H_2$$

which requires either close proximity or mobility of the adsorbed atoms, would be most evident at extremes of low temperatures (high S—H concentration) and again at high temperatures (greater S—H mobility).

For the Hinshelwood mechanism to be operative at low temperatures with relatively low S—H concentration would require rather weakly adsorbed H atoms as opposed to the strongly adsorbed atoms which only achieve mobility at elevated temperatures.

TABLE 1. Glasses, pretreatment of porous Vycor: 300 mm O_2, 500 °C, 2 h

Glass	Treatment	Area (m^2/g)
PV-OH	Evacuate, 800 °C, 4-6 h	145
PV-Cl	PV-OH + 100 mm CCl_4, 450 °C, 4-6 h	115
PV-F	PV-OH + 300 mm CF_4, 650 °C, 4-6 h	120
PV-OCH_3	PV-OH + 100 mm $B(OCH_3)_3$, 25 °C, 30 min	100
PV-H_2O	PV-OH + adsorbed H_2O monolayer coverage	130*
Fused silica	Quartz sample tube, evacuate, 800 °C, 2 h	2 cm^2 in cavity

*Inconsistent area determinations, average quoted.

These two types of adsorbed atoms are used by Wood and Wise (11) in qualitative calculations over a wide range of temperatures.

The existence of these two types of atoms is substantiated by Johnson (7) and, most notably, by Hickmott (10) who assigns adsorptive bond strengths of 25 and 6.6 kcal/mol for the strongly, chemisorbed atoms and the weakly, physically adsorbed atoms, respectively.

A further common feature of the experimental studies to date is that all have been conducted by observation of gas phase phenomena ... pressure changes on adsorption or desorption (7, 8, 10) and gas phase atom decay in flow systems (9, 11). No studies have been conducted by observation of the surface adsorbed state or of the surface itself.

This work undertakes such a study under conditions where the low temperature Hinshelwood mechanism may be observed. The study of the surface adsorbed atoms and their reactions is made possible by their definitive unpaired electron which allows observation by electron spin resonance.

Experimental

Porous Vycor glass (Corning Code #7930) and fused silica were used as the adsorptive surfaces. The surface of the porous Vycor was chemically altered, with resulting changes in specific surface area as outlined in Table 1. Hydrogen atoms were generated for the fused silica study by a 2450 MHz electrodeless discharge in purified H_2 directly in the sample tube. The discharge was maintained about 10 cm above the sample region which was immersed in liquid nitrogen. The H atoms diffused down the tube and were adsorbed on the cold walls.

For the study of porous Vycor the atoms were produced by the ultraviolet photolysis of hydrogen iodide adsorbed on the Vycor samples. The photolyzing radiation was passed through a 2 mm Vycor glass filter and focused on the sample in a 3 mm i.d. quartz sample tube. The photolysis was conducted with the sample immersed in liquid nitrogen in an unsilvered quartz Dewar. The sample tube also contained 10 to 20 Torr pressure of He to prevent desorption of the HI upon cooling in liquid nitrogen and to conduct the photolysis heat away.

The treatment and i.r. absorption of porous Vycor surfaces has recently been reviewed by Hair (13). Table 1 summarizes the experimental procedures followed in preparing the glass surfaces together with pertinent information regarding surface area. The complete replacement of the surface hydroxyl groups was established by the infrared absorption spectra of the porous Vycor samples (13). Surface areas were determined from a B.E.T. adsorption isotherm for N_2 at 77 °K. The porous Vycor samples were prepared and treated on a mercury-free vacuum system and could be connected to the system while in the e.s.r. cavity.

The e.s.r. observations were conducted with a Varian E-3, electron spin resonance spectrometer, with an auxiliary 5 in. strip chart recorder.

Optimum machine parameters for observation of the H atom signal were established at the beginning of the study and, other than amplifier gain, remained constant throughout. The microwave power used, generally 2 mW, was about 80% of the observed signal saturation power, and the modulation amplitude was set at 250 mG (approximately half the observed line-width). The automatic repetitive scan facility of the spectrometer was utilized to record the time variation of the spectrum on the strip chart recorder. The spectrum was scanned through ± 5 G about the high-field line of the H atom doublet. Spectra could be simultaneously recorded on the flat-bed recorder of the instrument for peak-height/area correlations.

Kinetic studies were conducted using liquid nitrogen (-196 °C.), liquid argon (-185° C), and liquid methane (-161 °C) successively in the same e.s.r. cavity Dewar, progressively decaying a given H atom generation at higher and higher temperatures.

Results and Discussion

The observed e.s.r. spectrum (Fig. 1) consisted of two absorption peaks centered about $g = 2.0130$ and separated by 507.5 ± 0.5 G, derivative peak-to-peak line-width $= 475 \pm 50$ mG. These observations are consistent with the spectrum for a relatively unperturbed, ground state H atom and have been noted previously (14, 15). The central, $g = 2$ region of the spectra consisted of several peaks attributable to paramagnetic impurities and glass damage centers in the Dewar and sample system, and other paramagnetic fragments from the HI photolysis. Interest was directed to the high-field peak of the H atom doublet and little attention paid to the central region, except to note that the $g = 2$ spectrum varied from surface to surface.

When observed for an extended period, under stable operating conditions, the H atom

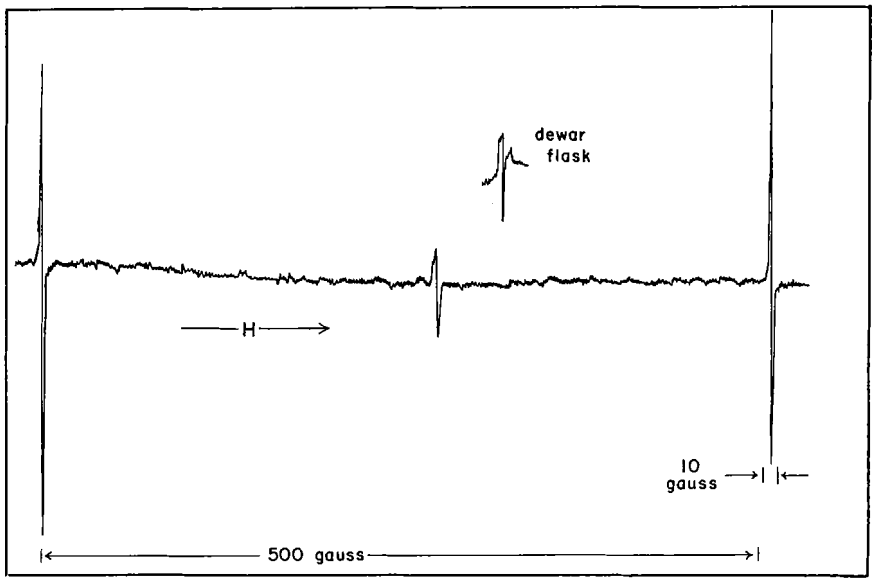

FIG. 1. Electron spin resonance spectrum of H atoms adsorbed on fused silica at 77 °K.

signal was found to decay even at liquid nitrogen temperatures, in direct conflict with the report of Pariiskii and Kazanskii (14). Figure 2 presents a plot of the H atom signal decay at the three temperatures used in this study.

In Fig. 2 it can be seen that in each case the signal does not disappear completely, but rather decays to some finite "steady state" value. (The terminology "steady state" is not meant to imply that there exists a simultaneous atom decay and production. Rather it refers to a constant concentration of non-decayable atoms.) Both the decay rate and the steady state achieved can be seen to be temperature dependent. A study of the atom decay must then be a study of the decayable atoms calculable from $S - H_{ss}$, where S is the total e.s.r. signal and H_{ss} (obtained by extrapolation) is the portion of S attributed to H_{ss} atoms which do not decay at the specified temperatures.

Order determinations showed the decay to be second order in decayable atoms as is evidenced by the second order plot of Fig. 3. The value of the rate constant, k_{obs}, from such plots is in arbitrary chart scale units which are, nonetheless, internally consistent and allow calculation of activation energies.

In the Arrhenius plot of Fig. 4, the k_{obs} data, still in arbitrary units, has been normalized to account for differences in the peak-height/area ratios and differences in scan speeds at the various temperatures. The activation energies thus obtained for the various surfaces are summarized in Table 2 as E_a.

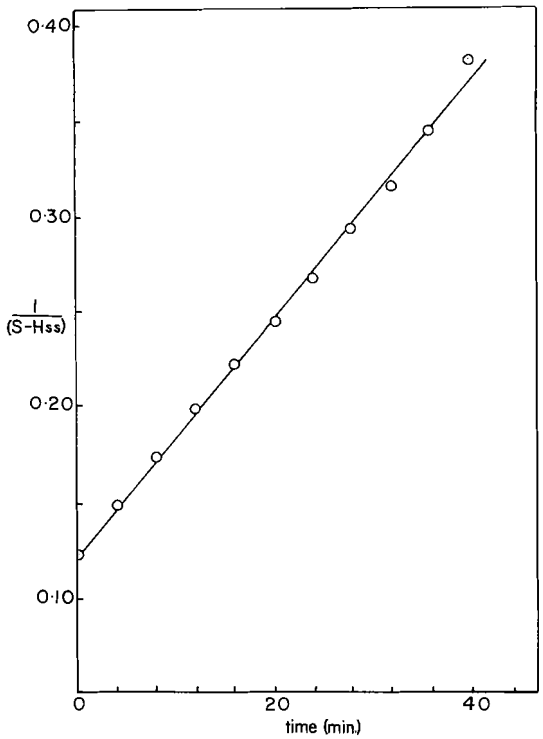

FIG. 3. Second order kinetic plot of decayable adsorbed H atoms (−185 °C decay of Fig. 2).

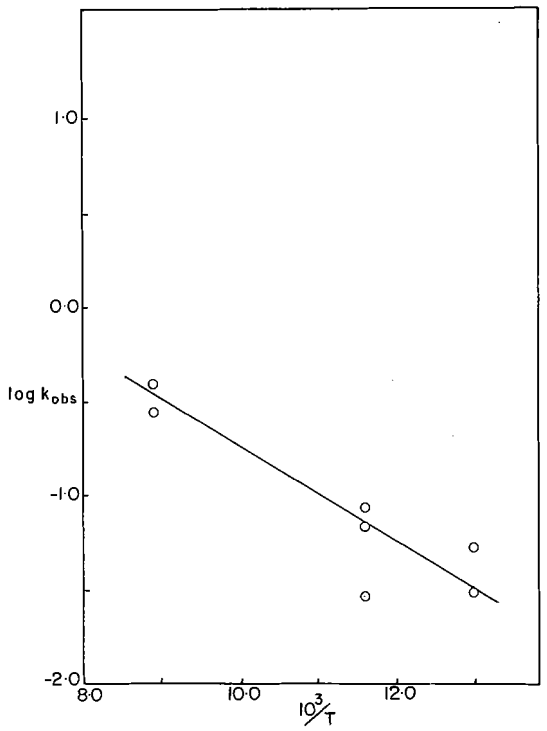

FIG. 4. Arrhenius plot of H atom decay on hydroxylated porous Vycor, PV_{OH}.

The observed temperature dependence of H_{ss} can be related to the decreased adsorption of H_{ss} atoms at successively higher temperatures. A plot of log H_{ss} against $1/T$ is presented in Fig. 5, from which it is possible to determine the heat of adsorption relative to the mobile, decayable atoms. This heat of adsorption data is presented in Table 2 as E_{ss}.

In the course of this study it was noted that the addition of O_2 to the surface adsorbed H atom systems resulted in an increase in the H atom e.s.r. signal. This was previously reported by Pariiskii and Kazanskii (14) who attributed the signal increase to the removal of signal saturation by paramagnetic O_2. Similar enhancement of e.s.r. signals by O_2 addition has been reported (16, 17). More recently (18), it has been shown that the H atom yield from irradiated 1 $M H_2SO_4$ at 77 °K is considerably higher when the matrix is prepared from O_2 saturated solutions than when N_2 saturated. This has been explained by an effective decrease in the relaxation time of the H atom by paramagnetic oxygen.

With an excess of O_2 present the H atom e.s.r. lines were broadened (to about 900 mG) as would be expected for a random perturbation of the resonant magnetic field by a paramagnetic species. The similar addition of He, Ar, N_2, and NO had no such effect. The absence of line broadening by NO or change in spin–lattice relaxation of the H atoms may be explained by the formation of dimeric diamagnetic $(NO)_2$ when NO is adsorbed on some surfaces (19, 20).

Upon evacuation and removal of excess O_2, the H atom signal returned to its former (475 mG) line-width and peak-height/area ratio but retained much of its increased peak-height.

With excess O_2 present several lines were observed in various regions of the e.s.r. spectrum. Upon evacuation these all disappeared except for one peak (now much reduced in size) at $g = 1.9742$ which is attributed to a small amount of residual O_2. The concentration of this residual O_2 is insufficient (or its location inappropriate) to significantly perturb the H atom spectrum or its decay but

*Kinetic plots curved.

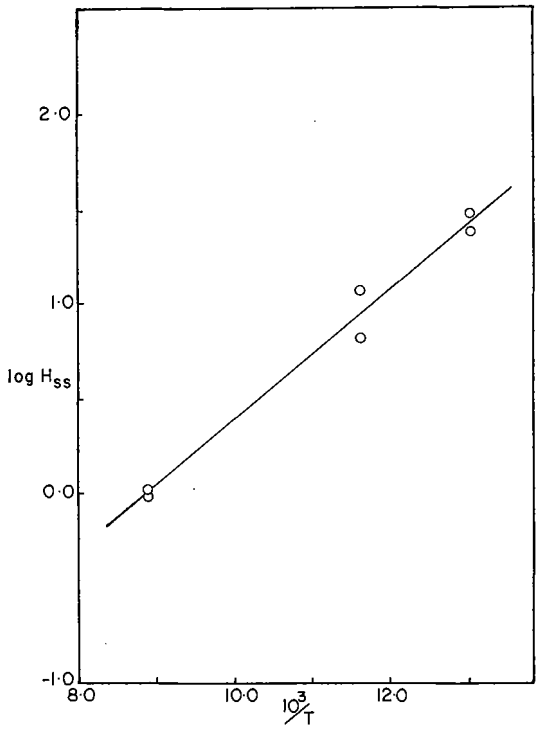

FIG. 5. log H_{ss} against $10^3/T$ for H atoms on PV_{OH}.

is sufficient to affect the relaxation time of the H atom.

The results of this work are consistent with the earlier observations of Johnson (7) and Langmuir (8) and, more recently, that of Hickmott (10) who studied the adsorption and desorption of H atoms. In Hickmott's paper two types of atoms were noted; in his notation these were subscripted "L" for atoms desorbed (pressure recovered) between 77 and 300 °K, and "R" for those desorbed above room temperature. He calculated heats of adsorption of 6.6 and 25 kcal/mol, respectively, consistent with physical and chemical adsorption.

The present study indicates that the weakly bound atoms can be further subdivided as "H" and "H_{ss}" due to adsorption at different physical adsorption sites. E_a, the decay activation energy is variable from glass to glass (Table 2) and would result from adsorption at the chemically altered surface sites. E_{ss}, on the other hand, is constant (± 0.1 kcal/mol) for all the surfaces studied and must result from adsorption at some common surface site.

In the chemical treatment of the porous Vycor all samples started from clean, hydroxylated porous Vycor achieved by evacuation at 800 °C. These conditions not only remove all surface adsorbed contaminants but progressively dehydrate vicinal surface hydroxyl groups, as is evidenced by the narrowing of the infrared adsorption peaks (21). This introduces siloxane bridge structures, $\gtrless$Si—O—Si$\lessgtr$ unaffected by subsequent displacement of the remaining hydroxyl groups. These siloxane bridge sites are thus retained as a common feature of all the glasses (and must also exist at the fused silica surface) and H_{ss} is identified with such sites.

A kinetic scheme can be presented which is consistent with the experimental observations. This is

[4,5] $\quad H \rightleftharpoons H_{ss}$

[6] $\quad H + H \rightarrow H_2$

in which it is to be noted that both H and H_{ss} are surface adsorbed atoms. H is a mobile adsorbed atom. H_{ss} exists as a constant (though temperature dependent) concentration of adsorbed, immobile atoms which are unreactive with H due to their stronger surface adsorptive bond.

E_a is then identifiable with reaction 6 and E_{ss} with reaction 5. Reaction 4, if occurring,

would have a very low activation energy and would proceed unobserved.

The existence of an atom decay even at 77 °K, and the observed second order kinetics are both in conflict with the results of Pariiskii and Kazanskii (14) who report no decay at liquid nitrogen temperatures and first order kinetics at higher temperatures. This is probably due to the different technique and the different surface they used. They calculate an activation energy of 2.1 kcal/mol which is not inconsistent with our $E_{ss} = 1.6$ kcal/mol and which may actually be some combination of our E_{ss} and E_a. A further complication (and one which would enhance their first order decay) is the possible reaction between H atoms and paramagnetic glass defects which are a prominent feature of the $g = 2$ region of their published e.s.r. spectra.

In this study, since the primary atom production process has ceased, only reaction 3, the rate determining step of the Hinshelwood mechanism, can be operative and our results may be compared with the Wood and Wise (11) calculations if the adsorbed atom concentrations are known.

By comparison of the H atom e.s.r. signal to that of a standard diphenyl picryl hydrazil sample under identical operating conditions it was possible to establish that there were of the order of 10^{14} to 10^{15} adsorbed atoms in the e.s.r. cavity. In the case of the fused silica this corresponds to a surface atom concentration of about 10^{14} atoms/cm^2, in good agreement with the figure of 10^{15} atoms/cm^2 as calculated by Johnson (7) and others (8, 10). In the case of the porous Vycor samples, due to the large surface area, the concentration was lower by a factor of 10^4.

Wood and Wise (11), in their table of calculated rates of elementary processes of hydrogen atom recombination on glass, quote a value of 7×10^{15} atoms/cm^2 s for the rate of reaction 6 at 77 °K. If we assume a surface saturated with adsorbed hydrogen atoms (at 10^{15} atoms/cm^2) the second order rate constant, k, can be calculated as 7×10^{-15} cm^2/atom s. Calculation of an equivalent rate constant from our results for fused silica gives $k = 1.3 \times 10^{-17}$ cm^2/atom s or, with a "roughness factor" of 10 (22), $k = 1.3 \times 10^{-15}$ cm^2/atom s. Values of this rate constant for the other surfaces are of the order of 10^{-12} cm^2/atom s as presented in Table 2.

In the Wood and Wise calculations for Pyrex an activation energy of 0.75 kcal/mol is used which compares favorably with our value of 1.0 kcal/mol for hydroxylated porous Vycor which, due to its high surface boron content (21*a*, 23), may be presumed to resemble Pyrex.

The disagreement between the Wood and Wise rate constant and our values for the porous Vycor systems can be ascribed to the physical difference in the surfaces. Wood and Wise's Pyrex and our fused silica (for which the rate constants are comparable) are both essentially smooth surfaces. The porous glass surfaces, on the other hand, are tortuously convoluted and may allow adsorbed atom encounters in the third dimension, normal to the surface. The effective atom concentration available for the recombination reaction is thus larger and would result in the larger rate constant which was calculated assuming only two-dimensional, surface encounters. The magnitude of this effect is incalculable though; in the extreme, it could double the effective atom concentration and the observed rate constant would be larger by a factor of four.

A more likely explanation of the discrepancy is that not all of the surface of the porous Vycor sample was being used. The original HI would adsorb preferentially at the first site encountered ... the outer areas of porous Vycor sample. The interior regions and deep pore would not be covered by HI nor subsequently by H atoms.

These discrepancies or uncertainties cannot, however, greatly affect the activation energies determined for these samples. As can be seen from the data in Tables 1 and 2 there is no correlation between specific surface area and activation energy, nor would any be expected if only some fraction of the surface is utilized. These activation energies should, if our assignment of the H atom adsorption site is correct, correlate with some physical or chemical property of the glass surface such as the electronegativity of the surface adsorption site.

While the electronegativity of atoms in simple molecules can be found in virtually any elementary textbook, the electronegativities of polyatomic, or even simple monatomic functional groups as part of a larger structure are not as easily determined. Sanderson (24)

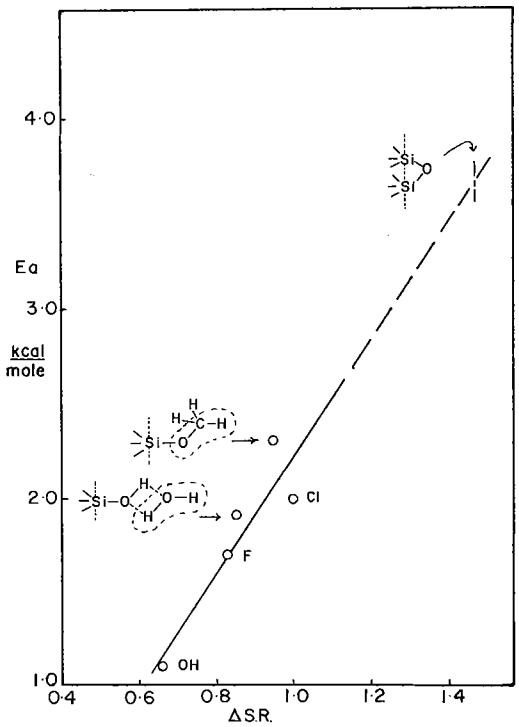

FIG. 6. Plot of the decay activation energy E_a against ΔS.R., the stability ratio difference between the adsorbed H atoms and the surface functional groups.

proposes an electronegativity function, the stability ratio (S.R.) defined as "the ratio of the average electronic density to that of a hypothetical isoelectronic inert element". For atoms and simple molecules there is a linear relationship between Sanderson's S.R. and the more conventional electronegativity scales. In the reference cited Sanderson outlines methods by which the S.R. of molecular fragments may be determined.

Figure 6 presents a plot of the observed activation energies and the S.R. difference ($S.R._H - S.R._{surface}$) for the various glasses studied. The calculation of the S.R. values for $\geq$Si—O—H, $\geq$Si—Cl and $\geq$Si—F are fairly straightforward; however, in the case of $\geq$Si—O—CH_3 and $\geq$Si—OH.H_2O some question exists regarding the exact identity of the effective adsorption site. By judicious choice of a reasonable atomic grouping (outlined in Fig. 6), excellent correlation may be realized.

Also shown in Fig. 6 is the S.R. difference for the siloxane bridge structure, the proposed adsorption site for H_{ss}. Its location would predict an activation energy of 3.6 kcal/mol for a recombination reaction but an activation energy of, very approximately, 1.6 kcal/mol (3.6 − approx. 2.0) for reaction 5. This figure varies slightly from glass to glass but corresponds well to E_{ss} (1.6–1.7 kcal/mol) obtained from the temperature dependence of H_{ss}.

It should be noted too, that the calculated S.R. values are all less than that for the adsorbed H atom, *i.e.*, the H atom is more electronegative than its adsorption site. The increased electron density about the H atom should, therefore be evident from the hyperfine splitting of the H atom doublet in the e.s.r. spectra.

Careful measurement of the splitting showed it to be slightly larger (0.7%) than both the theoretical and the observed splitting for gas phase atoms. The effect was observed for all glasses though no correlation of the magnitude of the effect with glass surface could be observed.

These results substantiate the arguments of Wood and Wise and others regarding the nature of the surface adsorbed species and the relative predominance of the Hinshelwood mechanisms in surface recombination at low temperatures.

The Triplet State of Ketene

JOHN S. E. MCINTOSH[1] AND GERALD B. PORTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received October 28, 1971[2]

Ketene quenches the phosphorescence of both biacetyl and hexafluoroacetone. Although the quenching of hexafluoroacetone emission is nearly collision-controlled, that of biacetyl is much less efficient. The large difference in the rate constants is attributed to endothermic energy transfer from triplet biacetyl to ketene and exothermic energy transfer from triplet HFA to ketene. From the endothermicity, the lowest triplet state of ketene is estimated to be at 61 ± 1 kcal/mol above its ground state. No sensitized photodecomposition of ketene occurs as a result of energy transfer from either biacetyl or hexafluoroacetone.

Le cétène arrête la phosphorescence du biacétyle et de l'hexafluoroacétone. Bien que l'extinction de l'émission de l'hexafluoroacétone est pratiquement contrôlée par la collision celle du biacétyle est nettement moins efficace. La grande différence dans les constantes de vitesse est attribuée au transfert d'énergie endothermique du biacétyle triplet au cétène et au transfert d'énergie exothermique du HFA triplet au cétène. A partir de l'endothermicité, l'état triplet le plus bas pour le cétène est évalué à 61 ± 1 kcal/mol au dessus de son état fondamental. Il n'y a pas de photodécomposition sensibilisée du cétène résultant du transfert d'énergie soit du biacétyle soit de l'hexafluoroacétone.

It is now well established that both singlet and triplet state methylene radicals are produced in the primary photodissociation of ketene (1–5). The fraction of the methylenes formed in the triplet state increases as the wavelength of irradiation is increased (2) and the primary quantum yield decreases, becoming strongly pressure dependent at 366 nm (6).

If the dissociation obeys a spin correlation rule, and there is no reason it should not, the methylenes would arise from the corresponding excited singlet and triplet states of ketene itself (2). However, because no emission has ever been detected from ketene, little is known about the lowest lying singlet and triplet excited states. Dixon and Kirby (7), in a study of the visible and u.v. absorption spectrum of ketene, concluded that two electronic transitions can be seen. They assigned the origin of the *triplet* state as the observed onset of absorption, at *ca.* 61 kcal/mol. In a recent reinvestigation, Laufer and Keller (8) disagreed with Dixon and Kirby and suggested that only one transition is observed, the lowest singlet–singlet absorption. They therefore set an upper limit to the *singlet* state origin as 61 kcal/mol and located the triplet origin at about 55 kcal/mol on the basis of a "normal" singlet–triplet splitting.

The decomposition of ketene can be sensitized by the triplet states of mercury (9) and benzene (10). The fraction of the methylenes then formed in the triplet state is large, which implies that the triplet state of ketene has been formed by energy transfer. In an attempt to locate the triplet state of ketene, Grossman, Semeluk, and Unger (11) tried to sensitize the emission of biacetyl with ketene as donor. Their lack of success can best be interpreted as meaning that the triplet state of ketene is simply too short-lived for such energy transfer to compete with degradation. However, their data do show evidence for energy transfer *from* biacetyl *to* ketene.

We have reinvestigated energy transfer reactions involving ketene, using biacetyl and hexafluoroacetone (HFA) as donors. The results suggest a value for the energy of the ketene triplet state and have important implications about the mechanism of the photochemistry of ketene.

Experimental

Ketene, prepared by the method of Fisher, McLean, and Schnizer (12), was purified by vacuum distillation. Biacetyl (Eastman White Label) was distilled twice and the middle third of each run was retained. Gas chromatographic analysis showed no detectable methane, ethane, or ethylene impurities (less than 1 p.p.m.) in either the biacetyl or the ketene. Both were stored in the dark at -196 °C and were degassed immediately prior to use.

For personal use only.

HFA, supplied by Dupont, was purified and handled as previously described (13). Hexafluoroethane (Matheson) was degassed at −196 °C by distillation, followed by distillation through a LeRoy–Ward still. The fraction collected at −130 °C was retained.

A completely mercury-free vacuum system was used for all of the experiments. Pressures greater than 10 Torr were measured directly with a calibrated glass spiral gauge. Lower pressures were obtained by expansion into calibrated vessels on the vacuum line. Greaseless metal or glass/Teflon stopcocks were used exclusively on the cells, the expansion vessels, and the ketene storage vessel.

Photolyses were carried out in a 5 cm path Pyrex cell with silica windows attached with epoxy resin. A 1 cm square cuvette was used for both lifetime and steady-state emission measurements. Each of the cells was attached to a magnetically driven glass mixing chamber, which allowed gases to be circulated through the irradiated zones of the cells. A 5 min mixing time was found adequate to ensure a completely homogeneous sample at all pressures used. The volumes of the photolysis and emission systems were 94.3 and 124.9 ml, respectively.

For both photolysis and steady-state emission, the excitation source was a PEK 100 W mercury arc with a Bausch & Lomb u.v. grating monochromator (plus a Corning 7-54 filter for excitation below 400 nm). An RCA 935 phototube, calibrated against the ferrioxalate actinometer, was used to monitor the amount of light absorbed. The technique required to detect and record the emission spectra has been described (13).

Phosphorescence lifetime measurements were made with an argon-filled coaxial capillary flash lamp operated at 4–5 kV. This lamp dissipates 16 to 25 J and has a peak rise time of 3 μs and a half-width of 8 μs. The light was focused at the center of the 1 cm cuvette. Phosphorescence decay from the sample was detected at 90° to the pump light beam with an RCA 1P28 photomultiplier fixed to the exit slit of a Bausch & Lomb visible grating monochromator. The photomultiplier output was displayed on a Tetronix 543B oscilloscope. Correction for scattered light was made by condensing the contents of the cell in a side arm or by evacuating the cell completely.

Analyses were done with an Aerograph Hy-Fi gas chromatograph with a flame ionization detector on a 3 m by 3 mm silica gel column at 25 °C. This column could resolve hydrocarbons up to C_4.

The pressures used with ketene–biacetyl mixtures were high enough to be measured directly with the spiral gauge. The components were then condensed into the reaction vessel and mixed.

For lifetime measurements on the ketene–HFA system, it was necessary to prepare mixtures containing only very small amounts of ketene. At the same time it was not possible to condense the two compounds together.[3] The following procedure was used: the cell and an external cold finger were filled with HFA to the desired pressure. Then the HFA was condensed into the cold finger and isolated while ketene was added to the cell using the expansion volumes to attain the necessary low pressures. The HFA in the cold finger was then vaporized completely and expanded into the cell, where the contents were thoroughly mixed. After a lifetime measurement had been completed, either the cell was evacuated for the next run or the contents of the cell were further diluted with HFA (but no more than once) for another measurement. All experiments were carried out at the ambient temperature, 25 ± 1 °C.

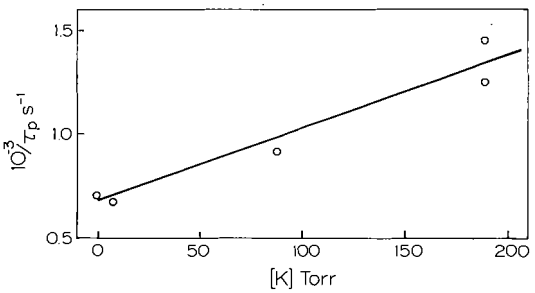

FIG. 1. Lifetime of biacetyl phosphorescence decay in the presence of ketene, with 40 Torr of biacetyl, at 25 °C and excitation at $\lambda > 400$ nm.

Results

Ketene–Biacetyl Mixtures

Lifetime Measurements

For biacetyl excitation, light from the flash lamp was filtered with a Corning 3-75 filter, which is totally absorbing below 370 nm. Therefore only biacetyl was excited directly, and then primarily at wavelengths longer than 400 nm. From the work of Grossman, Semeluk, and Unger (11), it was expected that a relatively high pressure of ketene would be needed to obtain effective quenching. It was first verified, however, that the phosphorescence decay of biacetyl (40 Torr) is unchanged by the addition of 300 Torr of hexafluoroethane as an inert pressurizer.

The effect of ketene on the phosphorescence lifetime of biacetyl is shown in Fig. 1. The quenching rate constant obtained from the least-squares slope is $6.4 \times 10^4\ M^{-1}\ s^{-1}$. This value agrees with that calculated from the data of Grossman *et al.* (11): $k_q = 3$ to $11 \times 10^4\ M^{-1}\ s^{-1}$.

[3]Ketene and HFA have been reported to react in ether solution at −78 °C to form a β-lactone (14). Therefore their compatibility was tested by following the room temperature u.v. absorption spectrum of a mixture of 100 Torr of HFA and 50 Torr of ketene. A slow dark reaction was observed in the gas phase: about 8% of the ketene disappeared over a 2 h period. The reaction was considerably faster when the two were condensed together, presumably occurring during the short interval in which they formed a liquid mixture. At high ketene concentrations, a yellow tar formed in the cold finger where they had been condensed. So long as the two compounds were mixed only in the gas phase and the run times kept short, this reaction between HFA and ketene could be neglected.

Steady-state Measurements

The phosphorescence and fluorescence yields of biacetyl are known to be independent of total pressure above 5 Torr when excitation is at either 436 or 405 nm (15, 16). As an additional check, the relative quantum yields of phosphorescence and of fluorescence were measured at these two wavelengths with and without 300 Torr of hexafluoroethane. No effect on the quantum yields could be found. However, when 300 Torr of ketene was added to 40 Torr of biacetyl, the phosphorescence yield decreased by a factor of 1.6, in agreement with the lifetime decrease. Ketene at this pressure had no measurable effect on the fluorescence yield of biacetyl.

Photolysis

Biacetyl (25 Torr) and biacetyl–ketene mixtures (25 and 200 Torr, respectively) were irradiated at 436 nm ($I_a = 5 \times 10^{-9}$ einstein s^{-1} cm^{-2}). The only products were small amounts of ethane and methane (carbon monoxide was not measured) from the decomposition of biacetyl. That no ethylene could be detected[4] implies that less than 10^{-10} mol of ethylene was produced and that the quantum yield for ethylene formation was less than 4×10^{-5}.

Ketene–HFA Mixtures

Lifetime Measurements

The flash lamp was used without filters because the first absorption bands of ketene and HFA overlap. As only a small quantity of ketene was present in these experiments, direct absorption by ketene was negligible. The effect of ketene on the lifetime of the triplet state of HFA is shown in Fig. 2. The slope of the line is 8.5×10^9 M^{-1} s^{-1}.

Steady-state Measurements

It was established that with 10 to 50 Torr of ketene added to 600 Torr of HFA, and with 313 nm irradiation, the phosphorescence of HFA was completely quenched but the fluorescence was unaffected.

Photolysis

Mixtures containing 100 Torr of HFA and 2 Torr of ketene were irradiated at 334 nm. This exciting wavelength was chosen to minimize the photochemical dissociation of either HFA itself or of ketene as a result of direct absorption of radiation. At this ketene pressure, however, the phosphorescence of HFA is completely quenched. The only hydrocarbon product detected was a trace of ethylene (7.7×10^{-10} mol). Neither CO nor C_2F_6 were measured quantitatively.

In none of these experiments was any luminescence detected that could be attributed to ketene, either with direct excitation or by sensitization.

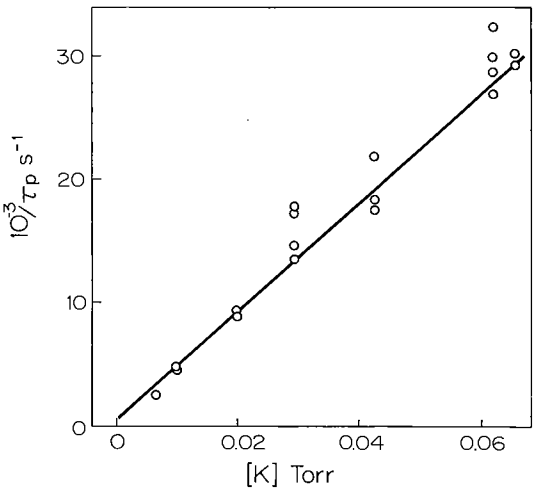

FIG. 2. Lifetime of hexafluoroacetone phosphorescence decay in the presence of ketene, with 100 Torr of HFA, at 25 °C and excitation with unfiltered flash lamp.

Discussion

The quenching data for biacetyl–ketene and HFA–ketene mixtures must be interpreted as the result of energy transfer from an excited state of biacetyl or HFA to one of ketene. Only in this way can the enormous difference in the two rate constants be rationalized. Further, the energy transfer must involve only the triplet states of the two donors because the fluorescence yields of biacetyl and HFA are unaffected by the presence of ketene. By inference then, it is the triplet state of ketene which is populated in the energy transfer. That triplet state is itself too short-lived for either phosphorescence or energy transfer to be important processes in the degradation of excited triplet ketene.

As shown in Figs. 1 and 2, the lifetime data

[4]Biacetyl should have no major effect on the formation of ethylene from sensitized decomposition of the ketene.

fit a Stern–Volmer mechanism in the form

$$[1] \qquad 1/\tau = 1/\tau_0 + k_q[K]$$

The value of k_q for the HFA–ketene system is normal in the sense that it is about one order of magnitude less than the hard sphere collisional rate constant, and is comparable with values found in similar systems (13, 17). That k_q for the biacetyl–ketene system is over five orders of magnitude smaller still can be understood if the energy transfer from biacetyl to ketene is endothermic (18).[5]

On the basis that the triplet state of ketene lies higher than that of biacetyl by an energy ΔE, the ratio of the energy transfer rate constants k_q^B (from biacetyl to ketene) and k_q^K (from ketene to biacetyl) will be given by

$$[2] \qquad k_q^B/k_q^K = \exp(-\Delta E/RT)$$

This equation implies that the triplet state molecules of both ketene and biacetyl become thermodynamically equilibrated with the medium in every sense except that of electronic excitation. For our analysis it is essential that this be so for the biacetyl triplet state, but it need not be so for ketene. At the pressures used here, the lifetime of the triplet state of biacetyl is of the order of 1 ms, while the collision rate is *ca.* 10 ns. Internal equilibration of the biacetyl triplet state molecules is thus assured.

In order to apply eq. 2, it was necessary to have an estimate of k_q^K, which cannot be measured directly. We have therefore assumed that exothermic energy transfer processes in the gas phase will all have about the same rate constants, somewhat less than the hard sphere constant. We use then the value found here for transfer from HFA to ketene: 8.5×10^9 M^{-1} s^{-1}, for k_q^K. Substitution of the two rate constants in eq. 2 gives for ΔE the value 7 kcal/mol. This places the origin of the ketene triplet state at 61 kcal/mol. The estimate of k_q^K can hardly be in error by more than one order of magnitude, therefore ΔE should be reliable to within one kcal/mol.

[5]It is conceivable that the quenching of biacetyl phosphorescence is caused by an impurity in the ketene of low concentration but high efficiency. However, the pyrolysis of acetic anhydride (12) is so clean a reaction that such an impurity is quite unlikely.

We have not attempted to measure the temperature dependence of k_q^B itself. Direct measurements of this kind were reported recently by Jackson and Yarwood (19) for energy transfer processes with activation energies. Even though their data for the 2,3-pentanedione to acrolein energy transfer cover a 45° temperature range, the pre-exponential factor found exceeds the hard sphere bimolecular rate constant by about 10^3. If this difference does represent experimental error, as seems likely, the compensating error in the activation energy is 4.5 kcal/mol.

That E_T is 61 kcal/mol for ketene is in agreement with the conclusions of Dixon and Kirby (7), but not with those of Laufer and Keller (8). The latter have suggested that the spectrum reported by Dixon and Kirby as two overlapping transitions is in fact only one, the lowest singlet–singlet transition, with its origin at 61 kcal/mol. A spectral assignment of this type is, however, notoriously difficult when only diffuse spectra are available. Our data support the conclusion that the bands at the long wavelength end of the absorption spectrum do indeed represent the lowest singlet–triplet transition. The main absorption bands in the near ultraviolet with maximum intensity near 330 nm must be assigned to the lowest singlet–singlet transition simply on the basis of extinction coefficient and position.

A recent determination of the heat of formation of the methylene radical (20) leads to a bond dissociation energy for ketene: $D(CH_2{=}CO) =$ 80 kcal/mol, with triplet (ground) state methylene as one fragment. According to our assignment, the lowest triplet state of ketene lies 19 kcal/mol below the dissociation limit. With so large an energy barrier, triplet state ketene molecules which have been vibrationally equilibrated cannot be responsible for production of triplet methylene. This dissociation must occur from non-equilibrium vibronic levels of the triplet state formed by energy transfer in sensitization or by intersystem crossing in direct photolysis. Thus we find that neither biacetyl nor HFA can cause photodissociation of ketene by energy transfer, yet benzene, with $E_T = 85$ kcal/mol, and mercury, with $E_T = 113$ kcal/mol, both sensitize the dissociation of ketene (9, 10).

Sterically Hindered Aromatic Compounds. IV. Solvolysis of *t*-Butyl-, Phenyl-, and Trialkyl-benzyl Chlorides in Ethanol–Water. Evidence for Steric Acceleration in 2,4,6-Tri-*t*-butylbenzyl Chloride

L. R. C. BARCLAY, H. R. SONAWANE,[1] AND J. C. HUDSON[2]

Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received March 7, 1972

The effect of *o*-, *m*-, and *p*-*t*-butyl and phenyl groups on solvolysis of the benzyl chlorides in 80% by volume ethanol–water was studied through conductometric rates and activation parameters. The rate constants for para- and meta-substituents were correlated by a Brown σ^+ plot indicative of an S_N1-type mechanism. Variations in ΔS^* can be rationalized in terms of differential solvation effects. Solvolysis data for the trialkylbenzyl chlorides-2,4,6-trimethyl-, 2,4,6-tri-*i*-propyl-, 2,4-di-*t*-butyl-6-methyl-, and 2,4,6-tri-*t*-butylbenzyl chloride indicated an unexpected high reactivity for the latter compound. The abrupt increase in ΔS^* for this compound is attributed to steric hindrance to solvation at the reaction site and steric acceleration is offered as an explanation for the unusual reactivity of this compound.

L'influence des groupes *o*, *m*, et *p*-*t*-butyle et phényle sur la solvolyse des chlorures de benzyle, dans un mélange à 80% en volume d'éthanol et d'eau, a été étudiée par les vitesses conductimétriques et par les paramètres d'activation: les constantes de vitesse pour les substituants para et méta ont été correlées par la courbe σ^+ de Brown indiquant un mécanisme de type S_N1. Les variations dans ΔS^* peuvent être expliquées par les effets différentiels de solvatation. Les données pour la solvolyse des chlorures de benzyles trialkylés; triméthyl-2,4,6, tri-isopropyl-2,4,6, di-*t*-butyl-2,4 méthyl-6 et tri-*t*-butyl-2,4,6 chlorure de benzyl, indiquent une grande réactivité inattendue pour le dernier composé. L'accroissement brusque de ΔS^* pour cette molécule est attribué à l'empêchement stérique à la solvatation du site réactionnel et l'accélération stérique est avancée pour expliquer la réactivité inhabituelle dans ce composé.

Canadian Journal of Chemistry, **50**, 2318 (1972)

Introduction

Two ortho *t*-butyl groups are known to exert remarkable *steric hindrance* to reactions of functional derivatives of benzene. In part III of this series, we reported an unexpected high chemical *reactivity* of 2,4,6-tri-*t*-butylbenzyl compounds (1). This included a facile insertion reaction into an ortho *t*-butyl group under acidic conditions. The present investigation was undertaken to explore quantitatively the effect of substituents on the reactivity of benzyl chlorides through measurements of solvolysis rates and activation parameters. The initial study was made on the effect of single bulky substituents-(phenyl and *t*-butyl) at *o*, *m*, and *p* positions on relative rates and activation parameters in ethanol–water solvolyses.

It was thought that kinetic data might lead to some explanation for the origin of the unusual chemical reactivity of 2,4,6-tri-*t*-butylbenzyl chloride. At the same time solvolysis data on this compound, with two bulky *t*-butyls shielding the benzylic carbon, could provide further insight into the phenomenon of specific solvation or solvent sorting in the region of the solute species (2).

With these objectives in mind, a comparative study was undertaken of the solvolytic behavior, including the activation parameters, of a series of 2,4,6-tri-alkylbenzyl chlorides, including 2,4,6-trimethyl-, 2,4,6-triisopropyl-, 2-methyl-4,6-di-*t*-butyl-, and 2,4,6-tri-*t*-butylbenzyl chloride.

Experimental

(a) General Procedures

Most of the substituted benzyl chlorides used are described in the literature. They were usually prepared from the corresponding benzyl alcohols by chlorination with thionyl chloride; either alone or in carbon tetrachloride solution. The excess reagent was distilled and the benzyl chlorides purified by chromatography in petroleum ether solvent on silica gel columns. The compounds were further purified by vacuum distillation or crystallization and vacuum sublimation. The purity of the chlorides was checked by gas chromatography on a F and M-700

programmed-temperature instrument using 20% Apiezon grease on Chromosorb W. The samples were generally at least 99% pure. The n.m.r. spectra were measured on the substituted benzyl chlorides on a Varian A-60 spectrometer using carbon tetrachloride solvent containing tetramethylsilane as internal reference. The compounds showed the expected spectra in all cases and this provided a convenient confirmation of the identity of the chlorides. Melting points were determined by the capillary method on a Thomas Hoover apparatus and are uncorrected. The preparations of the substituted benzyl chlorides are summarized below.

(b) Preparations

Benzyl Chloride

The benzyl chloride used was B.D.H. reagent grade freshly distilled, b.p. 167–168°; n_D^{20} 1.5376.

p-Methylbenzyl Chloride

Methyl *p*-toluate (Eastman Kodak) was reduced with lithium aluminum hydride in ethyl ether to yield *p*-methylbenzyl alcohol (m.p. 56–59°, lit. (3) m.p. 59–60°). The alcohol was chlorinated by treatment with excess thionyl chloride and the *p*-methylbenzyl chloride distilled at 90°/20 mm; n_D^{20} 1.5314 (lit. (4) n_D^{20} 1.5316).

m-t-Butylbenzyl Chloride

m-t-Butylbenzoic acid (K and K Laboratories, New York) was reduced with lithium aluminum hydride in ethyl ether to the corresponding alcohol. The alcohol obtained was chlorinated by treatment with excess thionyl chloride. The *m-t*-butylbenzyl chloride was distilled at 152–153°/7 mm; n_D^{20} 1.5196.

p-t-Butylbenzyl Chloride

p-t-Butylbenzoic acid (K and K Laboratories, New York) was reduced with lithium aluminum hydride to the corresponding benzyl alcohol. The latter was distilled at 132–136°/8 mm; n_D^{25} 1.5135 (lit. (5) n_D^{25} 1.5142). The alcohol was converted to the required chloride by treatment with thionyl chloride. The chloride distilled at 89–90°/3 mm; n_D^{25} 1.5202 (lit. (5) n_D^{25} 1.5196).

2,5-Di-t-butylbenzyl Chloride

The procedure for chloromethylation of *p*-di-*t*-butylbenzene reported by Beets and coworkers (6) yielded the desired chloride, b.p. 120–122°/2 mm; n_D^{20} 1.5195 (lit. (6) n_D^{20} 1.5198).

2,4,6-Trimethylbenzyl Chloride

This chloride was prepared by the method of Vavon and Bolle (7). The compound was distilled at 114–115°/4 mm and crystallized on standing, m.p. 34–36° (lit. (8) m.p. 37°).

2,4,6-Triisopropylbenzyl Chloride

2,4,6-Triisopropylbenzyl chloride was prepared by the method of Beets and coworkers (6). The compound distilled at 129–131°/4 mm and gave n_D^{20} 1.5156 (lit. (6) n_D^{20} 1.5160). Our sample crystallized on standing, m.p. 32–34°.

2-Methyl-4,6-di-t-butylbenzyl and 2,4,6-Tri-t-butylbenzyl Chloride

Syntheses of the above chlorides were given in part III (1).

o-Phenylbenzyl Chloride

o-Phenylbenzoic acid (Aldrich Chemical Co.) was reduced by lithium aluminum hydride to *o*-phenylbenzyl alcohol, b.p. 166–168°/5 mm. The alcohol was reacted with thionyl chloride to yield *o*-phenylbenzyl chloride, b.p. 160–168°/20 mm (lit. (9) b.p. 153–155°/11 mm).

m-Phenylbenzyl Chloride

m-Phenylbenzoic acid was prepared by the Grignard method from 3-bromobiphenyl (K and K Chemicals). The acid (m.p. 159.5–160°) was reduced in ethyl ether solution with lithium aluminum hydride to *m*-phenylbenzyl alcohol. The latter was treated without purification with thionyl chloride to yield *m*-phenylbenzyl chloride, m.p. 41.5–44.5°. Reference to this chloride could not be found in the literature and it appears to be a new compound.

Anal. Calcd. for $C_{13}H_{11}Cl$: C, 77.30; H, 5.48; Cl, 17.52. Found: C, 77.03; H, 5.48; Cl, 17.78.

p-Phenylbenzyl Chloride

p-Phenylbenzyl alcohol (Aldrich Chemical Co., m.p. 102°) was converted by the thionyl chloride method into *p*-phenylbenzyl chloride, m.p. 68–70°. (lit. (10) m.p. 68.4–68.8°).

2,4,6-Triphenylbenzyl Chloride

1,3,5-Triphenylbenzene (Aldrich Chemical Co.) was brominated (11) and the resulting 2,4,6-triphenylbromobenzene (m.p. 130–132°; lit. (12) m.p. 129–130°) converted by means of the Grignard Reaction into 2,4,6-triphenylbenzoic acid, m.p. 252–253° (lit. (12) m.p. 253–255°). The acid was converted by treatment with diazomethane in ethyl ether into its methyl ester, m.p. 88–92° (lit. (12) m.p. 92°) and the latter was reduced by lithium aluminum hydride to yield 2,4,6-triphenylbenzyl alcohol, m.p. 127–129° (lit. (13) m.p. 128°). The latter was chlorinated with thionyl chloride to yield 2,4,6-triphenylbenzyl chloride, m.p. 118–119° (lit. (13) m.p. 118.5–119.5°).

(c) Kinetic Measurements

Kinetic measurements were made on the trialkylbenzyl chlorides using both a titrimetric procedure and a conductance method. In the titrimetric procedure the chloride (1.0 g) was dissolved in 100 ml of 80% ethanol–water, stirred, and thermostated at $25 \pm 0.04°$. At appropriate intervals, 10 ml samples were removed and titrated with 0.025 *N* sodium hydroxide using a methyl red–bromocresol green indicator. The first order rate constants were estimated by the graphical method from the straight line plots of the integrated first order rate equation.

The precision conductance method for temperature dependence studies on solvolyses of trialkylbenzyl chlorides was carried out using the equipment in the laboratory of Dr. R. E. Robertson, National Research Council of Canada, Ottawa, Canada. The procedure has already been published by Robertson and coworkers (14). The other conductivity rate constants were measured by means of a manual conductivity bridge (Tinsley, Type 4896). Four conductivity cells (Queen type, magnetically stirred) were filled with 80% by volume ethanol–water and thermostated in an oil bath at the required temperature, $\pm 0.002°$. Approximately 5 mg of the chloride was dissolved in 10 ml of the same solvent and 0.025 ml of this solution was injected into each cell from a hypodermic syringe.

The Guggenheim method (15) was used to treat the kinetic data. An IBM 1130 computer was used to calculate the rate constants by means of the least squares procedure. The computer program also calculated the ΔE^*, ΔS^* from temperature dependence studies, and estimated the devia-

TABLE 1. Rates and activation parameters of solvolysis of *p*-, *m*-, and *o*-*t*-butyl and phenylbenzyl chlorides in 80% ethanol–water

Substituent	Rate ($k_1 \times 10^5$) (s^{-1})	Temperature (°C)	ΔE^* (*k*cal/mol)	ΔS^* (e.u./mol)
p-*t*-Butyl	0.553	44.89	20.6	−20.1
	2.44	60.09		
m-*t*-Butyl	0.206	44.89	21.9	−17.9
	0.991	60.09		
2,5-Di-*t*-butyl	0.465	44.89	22.4	−14.7
	2.34	60.09

	1.19	60.09		
p-Methyl	0.728	44.89	21.0	−18.2
	3.31	60.09		

tions. The standard deviations in rate constants were generally less than 1%. Deviations in ΔE^* were less than 1 kcal/mol and deviations in ΔS^* less than 1 e.u./mol.

(d) Product Analysis

Larger quantities of each chloride (0.10–0.50 g) were treated with the solvent 80% ethanol–water by stirring at the required temperature. After approximately five half-lives, the reaction was cooled, diluted with ice water, and extracted with ether. The ether extract was washed with water, dried, and the solvent distilled. The crude product was analyzed directly by n.m.r. The ratio of the alkylbenzyl alcohol to corresponding alkylbenzyl ethyl ether product was determined by relative integration of the benzylic protons of the alcohol and ether. In cases where these benzylic proton resonances of alcohol and ether were not well separated at ordinary probe temperature, they were resolved satisfactorily at lower temperature.

Results and Discussion

(a) Effects of o-, m-, and p-t-Butyl and Phenyl Groups on Relative Rates and Activation Parameters of Solvolysis of Benzyl Chlorides

As an introduction to our kinetic study, and preparatory to a kinetic analysis of trialkylbenzyl chlorides, it was desirable to know the relative effects of *o*-, *m*-, and *p*-*t*-butyl and phenyl groups on the solvolysis rates of benzyl chloride in 80% ethanol–water; a solvent system required for solubility reasons. While the effect of ring substituents on solvolyses of benzyl systems has been extensively investigated, the effect of varying the position of a *t*-butyl remained unknown as far as we know. In this preliminary kinetic analysis, we used the readily available 2,5-di-*t*-butylbenzyl chloride as a "model" for *o*-*t*-butylbenzyl chloride. The specific first order rate constants and activation parameters for solvolysis of the above compounds are given in Table 1.

Attempts have often been made in the past to correlate solvolytic reaction rates with structural features of the substrate. In the last decade, more attention has been given to solvation effects on both the reactants and transition states (16). For example, Schubert and coworkers (17) took the view that the effect of para and meta *t*-butyls relative to other alkyls on rates and activation parameters for solvolysis of benzhydryl chlorides can be rationalized in terms of steric hindrance to solvation of electron deficient sites on the benzene ring. A detailed study by Arnett and coworkers (18) draws attention to the importance of solvation of the ground state. Clement and coworkers (5) studied the solvolysis of benzyl-, *p*-methylbenzyl-, and *p*-*t*-butylbenzyl chloride in methanol. They emphasized that differential solvation effects in the ground state as well as the transition state cause ambiguity in the interpretation of relative reactivities in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

terms of the effect of structure on "intrinsic" rates of reaction. Hyne and coworkers (2, 4, 19) developed a "specific solvation hypothesis" to account for the differences in activation parameters for solvolysis of substituted benzyl chlorides. Differences in entropy of activation with varying position of substituents were rationalized in terms of the relative changes in net dipole vector direction, and concomitant solvent reorganization, in the activation process. They even accommodated the lower than expected $-\Delta S^*$ value for *o*-methylbenzyl chloride in terms of steric hindrance to solvent reorganization (19). The analysis of our own results such as in Table 1, are made with the importance of differential solvation effects in mind. The Hyne "hypothesis" (19) for substituted benzyl chlorides is of particular interest in the rationalization of our results for these compounds.

It was desirable to find if these substituted benzyl chlorides could be discussed in terms of a common mechanism (S_N1 or S_N2) before evaluating the results in terms of solvation effects. Hyne and coworkers (4, 19) discussed solvation effects in ethanol–water for substituted benzyl chlorides having both electron-attracting (nitro) and electron-supplying (methyl) groups in terms of a mechanism involving development of positive charge in the activation process (S_N1). However, our solvent system was higher in ethanol content than that used by them and some criterion of mechanism for our conditions seemed desirable. One possible general criterion is the correlation of the rates for the meta- and para-substituted benzyl chlorides in a linear free energy relationship. Brown and Okamoto (20) were able to correlate a set of σ^+ substituent constants for reactions with electron deficient centers in transition states leading to carbonium ions. Correlations of σ^+ constants for solvolysis of benzyl systems are quite well known (21, 22) as are the attempts to draw conclusions about the nature of transition states from such correlations (23). An attempt was first made to correlate the rates for the meta- and para-substituted benzyl chlorides (Table 1) by a Hammett-type plot using the ordinary σ substituent constants. A wide scatter of points results, with no linear correlation. On the other hand, by using a

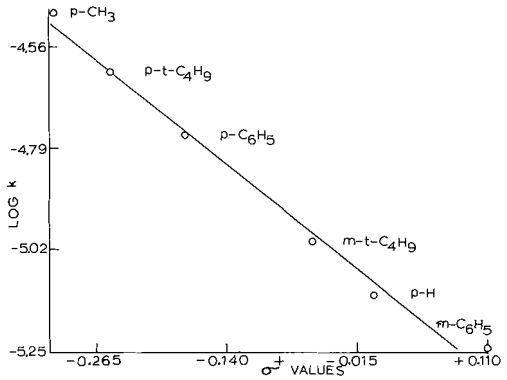

FIG. 1. Brown correlation for solvolysis of substituted benzyl chlorides in 80% ethanol–water at 60°.

Brown correlation of σ^+ substituent constants (21), a good straight line relationship was obtained (Fig. 1) with a $\rho = -1.9$. This may be taken as an indication of a reaction pathway involving a high degree of electron deficiency in the transition state. If this is true, there is some justification in discussing the activation parameters obtained (Table 1) in terms of a common mechanism (S_N1) in this series of compounds.

Similar activation energies were observed for the various *t*-butyl-, phenyl-, and *p*-methylbenzyl chlorides (Table 1). The main notable trend in activation entropy was a decrease in the negative ΔS^* value on going from the meta- to the ortho-substituted derivatives; in both the *t*-butyl- and phenylbenzyl chloride series. This result can be rationalized in terms of steric hindrance to solvent reorganization afforded by the ortho-substituents (19).

It is interesting to note that, while 2,5-di-*t*-butylbenzyl chloride showed a faster solvolysis rate than did *m*-*t*-butylbenzyl chloride, the former compound was actually slower to solvolyze than *p*-*t*-butylbenzyl chloride. That is a single *o*-*t*-butyl group accelerates the rate but comparatively slightly, probably due to the incursion of a steric hindrance factor.

These preliminary results on mono-substituted benzyl chlorides indicated that an S_N1-type mechanism predominated for solvolysis in ethanol–water. Variations in activation entropy (ΔS^*) can be rationalized in terms of solvent reorganization at the transition state or steric hindrance to solvent reorganization, for ortho-

[a]This value was calculated from rate measurements at higher temperatures.

substituents. Because of such variations in solvation effects it was deemed desirable to obtain data on a series of 2,4,6-trialkylbenzyl chlorides as a preliminary to results for 2,4,6-tri-*t*-butylbenzyl chloride.

(b) Solvolysis of Trialkylbenzyl Chlorides and Related Systems

(1) Initial Results on Relative Rates

Initial data on first order rate constants and relative rates for solvolysis of 2,4,6-trialkylbenzyl chlorides obtained by both conductometric and titrimetric techniques are given in Table 2. The ethanol–water solvolysis of 2,4,6-trimethylbenzyl chloride was studied by Charlton and Hughes (24). Their evidence supported a unimolecular mechanism and the rate acceleration was attributed to a "practically pure polar effect". They discounted the idea of steric acceleration for this compound. Our conductometric and titrimetric relative rates for 2,4,6-triisopropyl- and 2,4-di-*t*-butyl-6-methylbenzyl chloride are somewhat less than for trimethylbenzyl chloride. At this point we cannot say whether this is due to some steric retardation or varying polar influences such as differing hyperconjugative and inductive stabilization of the incipient benzyl cation. There could also be a steric effect due to different degrees of steric hindrance to solvation (or to solvent reorganization) of the reaction site. Of most interest is the fact that two *o*-*t*-butyl groups in 2,4,6-tri-*t*-butylbenzyl chloride *accelerated* the reaction rates quite markedly. This is in contrast to the effect of a single *o*-*t*-butyl group (in 2,5-di-*t*-butylbenzyl chloride, Table 1) and it was desirable to explore the nature of this accelerating effect further by means of temperature dependence studies.

(2) Rates and Activation Parameters. Evidence for Steric Acceleration in the Solvolysis of 2,4,6-Tri-t-butylbenzyl Chloride

It was thought that comparative activation parameters for solvolysis of various trialkylbenzyl chlorides might give some insight into the origin of the interesting reactivity of 2,4,6-tri-*t*-butylbenzyl chloride. The results of this study are given in Table 3. The entropy of activation term shows an interesting variation for these trialkyl compounds. The relatively small decrease in the $-\Delta S^*$ terms for the substituents 2,4,6-trimethyl-, 2,4,6-triisopropyl, and 6-methyl-2,4-di-*t*-butyl- can be accounted for in terms of increased steric hindrance to solvent reorganization in the vicinity of the reaction center as the size of the ortho-substituents increases.[3] There was a very abrupt decrease in the $-\Delta S^*$ term for 2,4,6-tri-*t*-butylbenzyl chloride so that the term became approximately zero or slightly positive. This can be attributed to the very much increased steric hindrance to solvent reorganization at the reaction center due to the *two o*-*t*-butyl groups. The fact that the relative rate shows a sizable increase for this compound could be due to steric congestion in the initial state which is relieved in passing to the S_N1-like transition state; that is, due to some steric acceleration. Steric acceleration has been discussed as a factor influencing the solvolytic reactivity of branched tertiary halides (16). Steric acceleration has also been invoked to explain the

[3]2,4,6-Triphenylbenzyl chloride, under these conditions, gave relative rate = 9.02, $\Delta E^* = 21.1$ kcal/mol, and $\Delta S^* = -17.1$ e.u./mol. This compound does not appear to follow the same trend as the trialkylbenzyl chlorides and is still under investigation.

	1.31	45.05			
	3.77	55.01			
2,4,6-Tri-*t*-butyl	2.14	25.27	1618	23.2	+0.3
	7.39	34.76			
	24.3	45.05			

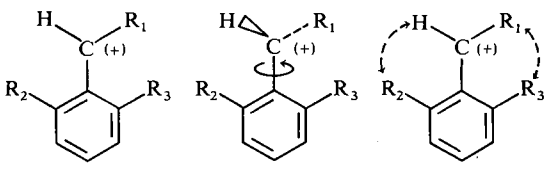
[a]Activation parameters were calculated using the rate constants at 34.76 and 55.01. In the case of 2,4,6-tri-*t*-butyl chloride rates at 25.27 and 45.05° were used.

solvolytic reactivity of various other systems, including derivatives of highly branched alcohols (25), of certain rigid polycyclic systems (26), as well as of a strained polycyclic system (27).

A more detailed analysis of the effect of ortho alkyls on unimolecular solvolysis of benzyl halides becomes ambiguous because of the complex interplay of the steric and electronic effects in such systems. The effects to be considered include the following:

(i) Polar effects. Alkyl groups are well known to facilitate S_N1 solvolysis of benzyl halides by inductive and/or hyperconjugative stabilization of the incipient carbonium ion. The increased solvolysis rate for 2,4,6-trimethylbenzyl chloride has been accounted for by such effects (24).

(ii) Steric inhibition of resonance. Resonance stabilization of the carbonium ion is at a maximum when the benzene ring and the benzylic carbon are coplanar (**1***a*). As reviewed by Eliel (28), steric hindrance to coplanarity occurs with a bulky group at R_1 or when there is a methyl group at R_1 and R_2. This steric interference may twist the carbonium ion away from the plane of the benzene ring (**1***b*) and thus destabilize the ion. This effect could be important in the case of two *o*-*t*-butyl groups and might account for the observed cyclization into the *o*-*t*-butyl groups in acid-catalyzed reactions of tri-*t*-butylbenzyl compounds (1).



1*a* **1***b* **1***c*

(iii) Steric hindrance to solvation. Hyne and Wills (19) emphasized the role of steric hindrance to solvation of the reaction center in the case of ethanol–water solvolysis of *o*-methylbenzyl chloride. Steric hindrance to solvation is expected to be of importance in the trialkylbenzyl chlorides of Table 3.

(iv) Steric acceleration. There does not appear to be a clear-cut precedent for steric acceleration in solvolysis of a benzylic halide. Kleinfelter and Chen observed an increase in rate of solvolysis in 8-substituted (8-methyl- and 8-methoxy-) 1-chloromethylnaphthalenes (29). Their results could be attributed to steric acceleration caused by strong proximity effects of the *peri*-substituents on the—CH_2Cl group.

Charlton and Hughes reported (24) that the solvolysis rate for the secondary halide 2,4,6-trimethyl-α-phenylethyl chloride was not as fast as might be expected (compared to the 2,4-dimethyl homolog) and they attributed this to *steric retardation* due to development of steric pressure between α- and ortho-methyls in the

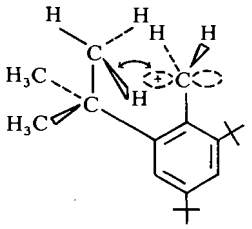
transition state of ionization. On the other hand, Eliel (28) interpreted the acceleration in rate and high entropy of activation for this compound in terms of *steric strain* in the ground state. Considerations of the possible factors involved in the case of 2,4,6-tri-*t*-butylbenzyl chloride become rather involved. In general congestion at the initial state due to steric compression between the two *o*-*t*-butyls and the benzylic —CH_2Cl group might be expected.[4] But if steric compression is present in the benzylic chloride, it would also be expected in the coplanar carbonium ion (**1***c*) and in the corresponding transition state where the angles tend to open up to approximately 120°.

It is true that such steric compression could be relieved by some rotation of the cation (**1***b*) but only at the expense of loss of some resonance stabilization.[5] We suggest that the interplay of these factors has resulted in an overall net steric acceleration to account for the increased reactivity of 2,4,6-tri-*t*-butylbenzyl chloride over the reactivity of other trialkylbenzyl chlorides (Table 3).

(v) Vertical stabilization of the cation. If the tri-*t*-butylbenzyl cation is forced towards the out-of-plane geometry illustrated in **1***b*, this places the empty "p" orbital of the —CH_2^+ in very close proximity to the —C—H bonds of *o*-*t*-butyl groups. There is the possibility of stabilization of this cation through σ–π interaction in a kind of through space "vertical stabilization" (30) afforded by 18 such interations as illustrated in **2**. There is no experimental evidence as yet to permit any decision



2

[4]Evidence will be presented for this in the succeeding paper from n.m.r. chemical shifts.

[5]It has been suggested (16) that a carbonium ion may be twisted rather severely from the plane of an attached benzene ring and still distribute a considerable amount of charge to the ring.

TABLE 4. Product analyses of the solvolysis of trialkylbenzyl chlorides in 80% ethanol–water at 45 °C

Substituted benzyl chloride	$ArCH_2—O—C_2H_5$ (%)	$ArCH_2—OH$ (%)
2,4,6-Trimethyl	66	34

2,4,6-Tri-*t*-butyl	58	42

on the importance (if any) of this effect in the solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride.

(3) Product Analyses

It was necessary to analyze the solvolysis products in order to determine if reactions on the trialkylbenzyl chlorides were in fact only with solvent. There was the possibility of *ortho* group participation which, in the case of 2,4,6-tri-*t*-butylbenzyl chloride, could have accounted for the accelerated rate. This might be expected to give products of rearrangement or insertion as were observed earlier (1) under acid-catalyzed conditions. The results of the product analyses are outlined in Table 4. The trialkylbenzyl chlorides all yielded a mixture of the corresponding benzyl ethers and benzyl alcohols. There was no evidence for complications due to the formation of rearrangement or insertion products.

Financial support of this research provided by the National Research Council of Canada is gratefully acknowledged. Some of the conductometric rate measurements were made by H.R.S. in the laboratory of Dr. R. E. Robertson, National Research Council of Canada, Ottawa, Canada. We thank Dr. Robertson and Mr. S. A. Sugamori of that laboratory for their advice and assistance.

Thermolysis of Δ^3-1,3,4-Oxadiazolin-2-ones

S. L. LEE, A. M. CAMERON, AND J. WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received January 5, 1972

Δ^3-1,3,4-Oxadiazolin-2-ones are decomposed at moderate temperatures, either neat or in solution, by two parallel, first-order processes. One of these results in the formation of the appropriate diazomethane and carbon dioxide while the other leads to ketone, nitrogen, and carbon monoxide. Rates of these competing processes are reported along with some solvent effects and substituent effects on the product ratios.

Les Δ^3 oxadiazoline-1,3,4 ones-2, soit pures soit en solution sont décomposées à des températures modérées selon deux processus parallèles du premier ordre. L'un deux a pour résultat la formation de diazométhane et du gaz carbonique alors que l'autre conduit à la cétone, l'azote et l'oxyde de carbone. Les vitesses de ces réactions compétitives sont rapportées ainsi que quelques effets de solvants et de substituants sur les rapports des produits.

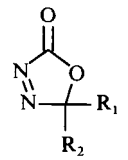
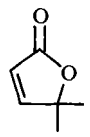
Introduction

Lactones of azocarboxylic acids (**1***a*, *b*) were isolated recently and were found to be remarkably reactive (1). For example, **1***a* was found to decompose to acetone azine with a half-life of about 3 weeks at 3° (1). Both **1***a* and *b* reacted in distilled water at room temperature to yield the appropriate ketone as well as the corresponding azine $(R_1R_2C{=}N{-})_2$. In view of the much greater thermal stability of α,β-unsaturated-γ-lactones (**2**), it was of interest to investigate the mechanism of decomposition of the former. In particular it was important to establish whether decomposition of **1** is strictly unimolecular or whether decomposition is also in some way induced by one of the products. Should dissociation turn out to be unimolecular, it would be of interest to determine the timing, stepwise or concerted, of the bond changes involved. This report is concerned with the first question, the kinetics of the reactions. Scheme 1 outlines possible decomposition pathways, including alternative routes to ketazine.



1



2

a $R_1 = R_2 = CH_3$
b $R_1 = CH_3$; $R_2 = CH_2CH_3$
c $R_1 = CH_3$; $R_2 = C_6H_5$
d $R_1 = R_2 = C_6H_5$

Methods and Results

The two possible mechanisms of ketazine formation should be distinguishable from the kinetics of disappearance of the oxadiazolinone. Reaction of the substrate with one of the products should be detectable in the form of either a deviation from first-order kinetics or a dependence of the apparent first-order rate constant on the substrate concentration. Furthermore the azine:ketone ratio in the product mixture should decrease with time in a given run and its final value should depend on initial oxadiazolinone concentration if induced decomposition of substrate by diazo compound were important. Accordingly, the rate of disappearance of **1***a* and

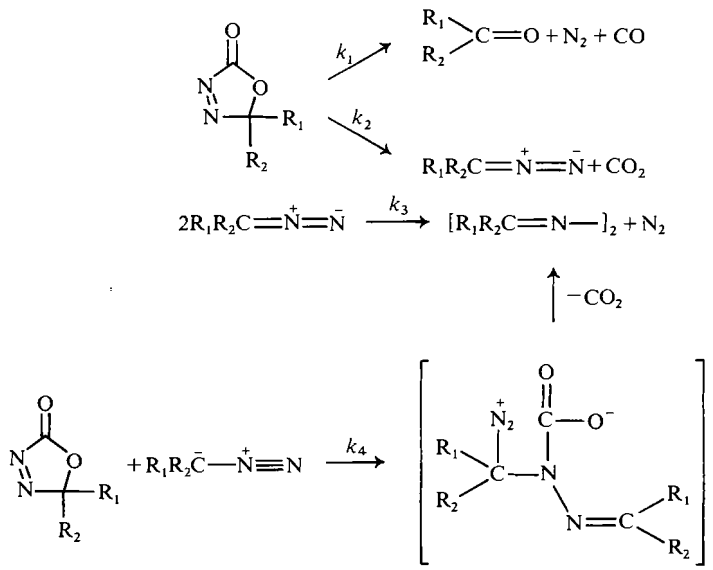
*In CCl_4, unless otherwise indicated. Rate constants are those defined in Scheme 1.
†In CH_3OH.
‡Isopropyl methyl ether, about 13% of the initial 2-propyl groups, was also present. Individual rate constants were calculated from the total first-order rate constant ($k_1 + k_2$) and the product distribution; k_1/k_2 being set equal to the ratio of integrals, ketone/(azine + ether), in which the ether integral was the doublet portion from the isopropyl signal only.



SCHEME 1

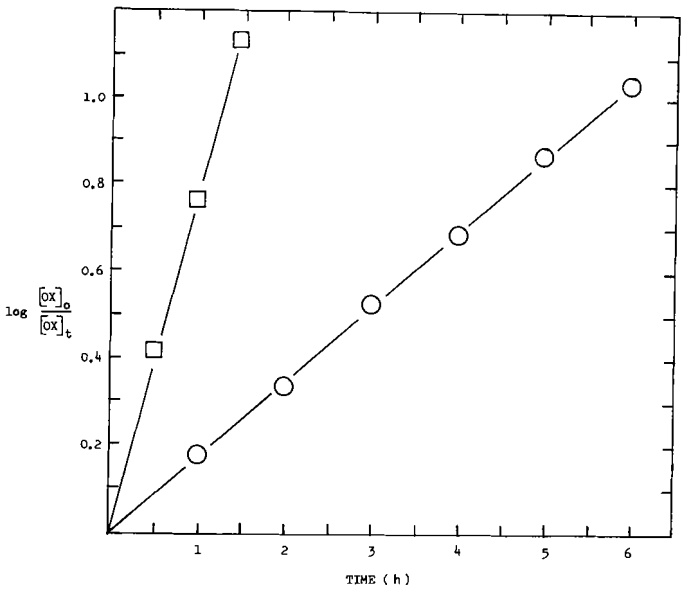


FIG. 1. Decomposition of **1***a* in CCl_4 (circles) and in CH_3OH (squares) at 84°.

the azine:ketone ratio were followed simultaneously by p.m.r. spectroscopy using benzene as internal standard for integration. Results are collected in Table 1 and Fig. 1.

Phenyl-substituted oxadiazolinones **1***c* and *d* are much less stable than **1***a* or *b* and could not be isolated in pure form. Solutions of those compounds in CCl_4 or ether turned red at room temperature and absorbed in the i.r. near 2025 cm^{-1} (2) as a result of decomposition to the appropriate diazo compounds. In CCl_4 at 84°, **1***d* decomposed with a half-life of approximately 30 s, corresponding to an overall rate constant of 2×10^{-2} s^{-1}, assuming first-order decomposition. The major products were diphenyldiazomethane and benzophenone (1653 cm^{-1})

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

with the former predominating. Benzophenone azine (1730 cm^{-1}) was always present in freshly prepared solutions of **1***d* but little, if any, additional azine was formed during the short time required for its decomposition at 84°.

Heating crude **1***c* (neat), at 85° for 25 min, gave acetophenone azine and acetophenone in the ratio 2:1 which corresponds to $k_1/k_2 = 0.25$ (Scheme 1). In solution (CCl_4 or ether) **1***c* also gave much more diazo compound and azine than ketone. Thus phenyl substituents at C-5, relative to methyl groups, enhance the rate of decomposition to CO_2 and diazo compound. Changing the solvent from carbon tetrachloride to methanol also favors decomposition to those products (Table 1).

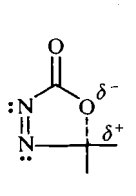
Discussion

The data of Table 1 and Fig. 1 show that **1***a* decomposed with first-order kinetics in carbon tetrachloride and in methanol. That behavior, together with a concentration–independent product ratio (Table 1), points toward unimolecular first steps. Ketazine must therefore arise by a process other than the last reaction of Scheme 1. Presumably the acetone azine is formed in a bimolecular process from two molecules of dimethyldiazomethane. The latter, which is reported to be quite unstable (3), did not accumulate to a level detectable by p.m.r. Applequist and Babad (4) studied the silver- and zinc-iodide-promoted decomposition of dimethyldiazomethane as well as diphenyldiazomethane and suggested that carbenes are not intermediates in those processes. Ketazines were the main products, with only traces of tetramethylethylene and tetraphenylethylene (4). Our results support their conclusion; propylene, from a 1,2-hydrogen shift in dimethylcarbene, was not detectable in the p.m.r. spectra of our product mixtures although formation of olefins from dialkyl carbenes is a facile process (5). Furthermore, decomposition of **1***a* in styrene gave mainly acetone and acetone azine, plus a small amount (<5%) of phenyl-2,2-dimethylcyclopropane. An upper limit is thus set on the amount of dimethylcarbene that could have been formed, for some of the cyclopropane may have come from decomposition of a pyrazoline intermediate.

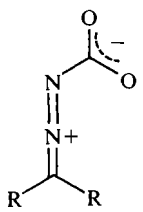
During decomposition of **1***d* the concentration of diphenyldiazomethane builds up to substantial levels, for it is relatively stable at about 80°. Thus there is no reason to assign anything other than a unimolecular mechanism to the decomposition of **1***d*. The same probably applies for **1***c*. In what follows we discuss possible mechanisms of unimolecular decomposition of oxadiazolinones and suggest a reason for their instability, relative to lactones **2**.

The weakest bonds in oxadiazolinones (**1**) should be the N—CR_2 and the O—CR_2 bonds of the ring. Homolytic cleavage of the former is well known azo chemistry and stepwise decomposition is possible in view of the fact that some unsymmetric azo compounds may decompose by breaking N—C bonds one at a time (6). A diradical-like, rather than a dipolar transition state for C—N bond-breaking is in keeping with the small solvent polarity effect on k_1 (Table 1). Alternative processes leading to N_2, CO, and ketone by concerted breaking of two or three bonds could also be relatively insensitive to solvent polarity and cannot be excluded at this time.

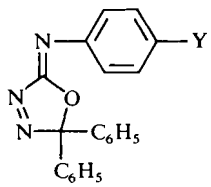
Decomposition to carbon dioxide and diazo compound probably involves a more polar transition state as depicted by structure **3**. The increase in k_2 on changing the solvent from CCl_4 to CH_3OH (Table 1) is consistent with a polar transition state and the substituent effects (CH_3 *vs.* C_6H_5) are accommodated well in such a mechanism. Moreover, in the series of compounds **5**, which also decompose to di-



3



4



5

For personal use only.

phenyldiazomethane, substituents Y which are electron-withdrawing enhance the rate of that decomposition (7), indicating development of negative change at benzylic nitrogen.

At first sight one might expect **2** to be equally suited to heterolytic C—O bond cleavage, as the negative end of the resulting zwitterionic species is again the carboxylate ion whereas the positive end is an allylic cation. However, the π-electrons of **1** and **2** are in an orbital normal to the C—O single bond and can therefore not provide stabilization until substantial C—O bond breaking, and N—CR_2 (or C—CR_2 in the case of **2**) bond rotation have occurred. Probably the most significant structural feature of **1**, which allows C—O bond-breaking to be relatively facile, is the lone pair of electrons at nitrogen, in an orbital coplanar with the stretching C—O bond. Overlap is thus possible and there may be an intermediate (**4**), at least in polar solvents, which rapidly decarboxylates. However, present data do not require a zwitterionic intermediate nor any other intermediate. Decomposition to diazoalkane and carbon dioxide fits the orbital symmetry requirements for fully-concerted bond changes (8). The solvent effect on k_2 (Table 1) is reasonable for either a stepwise mechanism, with formation of **4** rate-determining, or for a concerted mechanism leading to the polar diazoalkane directly. If the mechanism of the general reverse reaction, 1,3-dipolar cycloaddition of diazoalkanes to dipolarophiles, were firmly established, that knowledge could be used to infer the mechanism of decomposition of **1** to diazocompounds and CO_2, even though the reverse of that particular reaction is unknown. Arguments both for (9) and against (10, 11) concerted 1,3-dipolar cycloadditions have been presented and the matter is still not settled. In fact, it is possible that compounds like **1** will provide a solution, for the CO_2 formed from retrograde cycloaddition should be ideal for measurement of the $^{12}C/^{13}C$ kinetic isotope effect. Concerted decomposition must show an isotope effect whereas stepwise decomposition, through **4** or its diradical analog, with the second step fast, would not involve carbon isotope fractionation in the CO_2. We are currently carrying on such experiments.

Experimental

The u.v. and i.r. spectra were obtained with a Cary, Model 14 and a Perkin–Elmer, Model 521 instrument, respectively. The p.m.r. spectra were recorded with Varian A-60 and T-60 spectrometers and are referred to internal TMS as standard. Mass spectra were obtained with a Hitachi RMU-6A spectrometer. Melting points were determined with a Thomas "Unimelt" capillary melting point apparatus and are uncorrected.

2-Imino-Δ^3-1,3,4-oxadiazolines

A typical procedure is the following for preparation of 5-ethyl-5-methyl-2-methylimino-Δ^3-1,3,4-oxadiazoline by oxidative cyclization of the appropriate semicarbazone (12).

Butanone-4-methyl semicarbazone (13.0 g, 0.09 mol) in methylene chloride (100 ml) was added dropwise to a stirred, ice-cooled solution of lead tetraacetate (53.2 g, 0.12 mol) in methylene chloride (250 ml) under nitrogen. When addition was complete, the ice bath was removed and stirring was continued for 30 min. Ice-cold water (200 ml) was then added and the lead compounds were removed by filtering through a bed of Celite. The organic layer was washed with cold water, cold aqueous bicarbonate solution, and again with cold water. Evaporation of the dried ($MgSO_4$) solution at room temperature *in vacuo* gave an oil which appeared to decompose on chromatographic columns of silica gel, deactivated charcoal, or neutral alumina. Purification by g.l.p.c., on SE 30 at 70°, gave 5-ethyl-5-methyl-2-methylimino-Δ^3-1,3,4-oxadiazoline (3 parts) and 5-ethyl-5-methyl-Δ^3-1,3,4-oxadiazolin-2-one (1 part). The combined yield was 71%. Spectra and analyses of 2-imino-Δ^3-1,3,4-oxadiazolines are in Table 2.

5-Ethyl-5-methyl-Δ^3-1,3,4-oxadiazolin-2-one

The following procedure is typical for the hydrolysis of iminooxadiazolines.

To 5-ethyl-5-methyl-2-methylimino-Δ^3-1,3,4-oxadiazoline (200 mg) in methanol (15 ml) at 0° was added ice-cold, aqueous HCl (1 ml, 2.44 *M*). The mixture was stirred for 5 min before it was diluted with water and extracted with ether. Evaporation of ether from the washed (bicarbonate) and dried ($MgSO_4$) solution at room temperature gave the title compound (140 mg, 77%). Data for other oxadiazolinones are listed in Table 3.

Semicarbazones

Unsubstituted semicarbazones were prepared from ketones and semicarbazide hydrochloride according to the procedure of Cheronis and Entriken (13). 4-Methyl semicarbazones were prepared from 4-methyl semicarbazide, which was made by adding hydrazine to methyl isocyanate (14). 4-(β-Phenylethyl) semicarbazones were made by transamination of the appropriate unsubstituted semicarbazones with β-phenylethyl amine, as described below for one member of the series.

Acetone semicarbazone (57.5 g, 0.5 mol) was added all at once to β-phenylethyl amine (84.7 g, 0.7 mol) at 130–140°. The well-stirred mixture was kept at that temperature until evolution of ammonia ceased. The mixture was then poured into aqueous acetic acid (10%) to precipitate the product which was crystallized from aqueous ethanol (82% yield). Data for new semicarbazones are in Table 4.

Ketazines

The azines of acetone, butanone, acetophenone, and benzophenone were prepared according to a published procedure (15).

Thermolysis of 5,5-Dimethyl-Δ^3-1,3,4-oxadiazolinone

Solutions of the oxadiazolinone (concentrations in Table 1) in CCl_4 containing benzene were pumped free of air with several freeze–pump–thaw cycles before they were sealed in n.m.r. tubes. The concentration of benzene was about half that of oxadiazolinone, so that integrals for that reference and the substrate were about equal at 50% reaction of the latter. The p.m.r. spectrum was recorded and integrated before tubes were placed in a bath at 84°, from which they were removed at 1 h intervals for analysis. Reaction was stopped by cooling the tubes quickly in ice water and time outside the bath was not counted. Integrals of p.m.r. signals were normalized with respect to the internal standard. The overall rate constant $(k_1 + k_2)$ for decomposition was obtained from such normalized data from a plot of log $([OX]_0/[OX]_t)$ *vs.* t where [OX] indicates oxadiazoline concentration at the time indicated by the subscript. The slope was set equal to $(k_1 + k_2)/2.303$. Individual rate constants were calculated from the total $(k_1 + k_2)$ and product data; *i.e.* the fraction of oxadiazolinone going to acetone is $k_1/(k_1 + k_2)$.

Product ratios were obtained by comparing averaged integrals, from many sweeps, of the ketazine signals with the ketone signals. In the case of 5,5-diphenyl-Δ^3-1,3,4-oxadiazolinone, where the p.m.r. spectrum is not useful, rate and product data came from measurements of the i.r. absorption bands at 1835 (oxadiazolinone), 2025 (diphenyldiazomethane), and 1730 cm^{-1} (benzophenone azine). Standard solutions of the two latter compounds were used to prepare calibration curves.

Isotope Effect Studies on Elimination Reactions. VIII. The Mechanism of the 1,3-Elimination Reaction of 3-Phenylpropyltrimethylammonium Iodide with Amide Ion in Liquid Ammonia[1]

K. C. WESTAWAY[2] AND A. N. BOURNS

Department of Chemistry, McMaster University, Hamilton, Ontario

Received January 28, 1972

Reaction of 3-phenylpropyltrimethylammonium iodide with potassium amide in liquid ammonia at $-55\,^{\circ}C$ was found to give concurrent 1,3-elimination forming phenylcyclopropane and 1,2-elimination forming 3-phenylpropene and *cis*- and *trans*-1-phenylpropene. Deuterium tracer studies on the salt labelled at C-3 established that neither a carbene nor an ylide are intermediates in the 1,3-elimination process. Isotopic exchange at C-3 was shown to accompany the reaction of the deuterated salt in ordinary ammonia, but it was not detected in the reaction of unlabelled salt in ammonia-d_3. A nitrogen isotope effect, k^{14}/k^{15}, of 1.022 ± 0.001 was found for the 1,3-elimination, while the corresponding hydrogen isotope effect, estimated from the effect of isotopic substitution on the 1,3- and 1,2-elimination ratio, was shown to exceed 20. The hydrogen isotope effect for the disappearance of undeuterated and deuterated salts (elimination and exchange) was approximately 7.4. These observations, as well as the influence of deuterium substitution in both the quaternary salt and the solvent on the relative rates of 1,3- and 1,2-elimination, have been shown to be in accord with an E1cb mechanism in which the rate constants for the conversion of the intermediate 3-carbanion to 1,3-elimination product and for return to reactant by abstraction of a proton from ammonia are of the same order of magnitude.

La réaction de l'amidure de potassium sur l'iodure de phényl-3 propyl triméthylammonium dans l'ammoniac liquide à $-55\,^{\circ}C$ donne lieu à une élimination concurrente de type 1,3 qui conduit au phénylcyclopropane et à une élimination 1,2 conduisant au phényl-3 propène et aux phényl-1 propènes *cis* et *trans*. Les études sur le sel marqué au deutérium au niveau du C-3 montrent que les intermédiaires de l'élimination 1,3 ne sont ni un carbène ni un ylure. Un échange isotopique sur le C-3 accompagne la réaction du sel deutérié dans l'ammoniac ordinaire; cet échange n'a pas été détecté dans la réaction du sel non marqué dans l'ammoniac-d_3. Un effet isotopique sur l'azote $k^{14}/k^{15} = 1.022 \pm 0.001$, a été trouvé pour l'élimination 1,3; l'effet isotopique correspondant sur l'hydrogène, calculé à partir de l'influence de la substitution isotopique sur le rapport de l'élimination 1,3 et 1,2 a été montré supérieur à 20. L'effet isotopique de l'hydrogène sur la disparition des sels non deutériés et deutériés (élimination et échange) est approximativement de 7.4. Ces observations ainsi que l'influence de la substitution par le deutérium (à la fois dans le sel quaternaire et dans le solvant) sur les vitesses relatives de l'élimination 1,3 et 1,2, sont en accord avec un mécanisme de type E1cb dans lequel les constantes de vitesse pour la conversion de l'intermédiaire carbanion-3 en produit d'élimination 1,3 et pour le retour au réactant par arrachement d'un proton de l'ammoniac, sont du même ordre de grandeur.

Canadian Journal of Chemistry, **50**, 2332 (1972)

Introduction

Three-membered ring formation by a 1,3-elimination has been observed with a variety of reactants under widely differing reaction conditions (1). The reaction pathways followed by such reactions have been found to parallel those encountered in 1,2-elimination processes. Thus, the E1 pathway is characteristic of solvolyses involving reactants possessing good leaving groups (2–4), while reaction by either the E2 or E1cb mechanism is favored by the presence of strong base (4–7). A few examples of reaction by way of a carbene intermediate formed in a 1,1-elimination reaction have also been reported (8).

1,3-Elimination competes most effectively with double bond formation in rigid bicyclic systems where the spatial relationship of reacting bonds is favorable for the formation of the three-membered ring (2–6). Base-promoted 1,3-elimination is also found in acyclic systems, but usually, it requires the presence of electron-withdrawing groups (carbonyl (9), sulfonyl (10, 11), nitro (12), cyano (13), and aryl (14–18)) which facilitate the removal of the hydrogen atom. With the more powerful activating groups, there seems little doubt that the reaction proceeds by way of a carbanion intermediate, and

this is one of the accepted mechanisms for the 1,3-elimination process involved in the Favorskii rearrangement (7) (carbonyl activation) and the Ramberg-Backlund reaction (11) (sulfonyl activation). Much less certain, however, is the reaction pathway for eliminations in which activation is provided by the more weakly electron-withdrawing aryl group.

Recently, Baker and Spillett (19) have observed rapid deuterium exchange at the 3-position in the reaction of a series of 2-alkyl-1-methylsulfinyl-3-phenylpropanes with dimethylsulfinyl anion in deuterated dimethylsulfoxide, thus demonstrating that the phenyl group provides sufficient activation to sustain the reversible formation of a carbanion under elimination reaction conditions. This observation, however, does not establish that the 1,3-elimination is proceeding by an E1cb mechanism since, as has been pointed out by Breslow (20) with respect to 1,2-elimination reactions, the carbanion may not be on the elimination-reaction coordinate at all but, instead, reversible carbanion formation and E2 elimination may be entirely separate and concurrent processes.

An extensively studied 1,3-elimination involving aryl activation in an acyclic system has been the conversion of 3-arylpropyl- and 3,3-diarylpropyltrialkylammonium salts to aryl-substituted cyclopropanes by reaction with sodium amide in liquid ammonia (15–17). This reaction was first reported by Bumgardner (15) who suggested (16) that it might proceed either by an E1cb mechanism, eq. 1, or by an E2 process, eq. 2, in which the transition state has considerable carbanion character. Banthorpe (21), on the other hand, has suggested the cyclopropane may be formed by the insertion into the C_3—H bond of a carbene formed in a 1,1-elimination process, eq. 3. A less likely pathway, but one which cannot be excluded *a priori*, is a 1′,3-process, eq. 4, involving an ylide intermediate.

The purpose of the present investigation

was to determine the mechanistic details of the 1,3-elimination reaction of 3-phenylpropyltrimethylammonium ion with amide ion in liquid ammonia. In particular, tests were made for the 1,1- and the 1′,3-elimination mechanisms by examining the deuterium content of the products of the reaction of 3,3-dideutero-3-phenylpropyltrimethylammonium ion, a study was made of the extent of isotopic exchange of the deuterated salt with solvent as a means of detecting the presence of carbanionic species under the reaction conditions, and, finally, measurements were made of the hydrogen isotope effects associated with both substrate and solvent and of the nitrogen isotope effect associated with substrate in order to identify the rate-determining step of the reaction.

Results and Discussion

Product Analysis

The 1,3-elimination reaction of 3-phenylpropyltrimethylammonium iodide was studied at −55 °C in liquid ammonia solution using potassium amide as the base.[3] The hydrocarbon product was quantitatively separated by preparative vapor-phase chromatography into three fractions consisting of (*1*) 3-phenylpropene, (*2*) a mixture of phenylcyclopropane and *trans*-1-phenylpropene, and (*3*) *cis*-1-phenylpropene. These were identified by their v.p.c. retention times and i.r. and n.m.r. spectra. The composition of fraction *2* was determined by u.v. spectroscopy and, in the case of the reaction of 3,3-dideutero-3-phenylpropyltrimethylammonium ion in ordinary ammonia, the analysis was confirmed by v.p.c. and by n.m.r. spectroscopy. The results of the product analysis for the reactions of undeuterated and deuterated salts in ammonia and ammonia-d_3 are reported in Table 1.

3-Phenylpropene is the direct product of 1,2-elimination, while the isomeric 1-phenylpropenes are formed by the base-catalyzed isomerization of this product during the reaction (22). The percentage of 1,2-elimination, therefore, is the sum of the percentages of each of the three olefin products. The absence of 3-phenylpropene in the product of reaction of the deuterated salt in deuterated solvent, in contrast to the approximate 1:1 ratio of this olefin to *trans*-1-phenylpropene in the products of the reactions in ammonia, is accounted for by the longer reaction time with the former. This results in a closer approach to an equilibrium composition of the three olefins in which the *trans*-1-phenylpropene predominates (22). No products of 1,2-elimination could be detected in the reaction of the undeuterated salt in deuterated ammonia. Based on the absence of the reddish-brown coloration characteristics of the carbanion $[C_6H_5CH{=}CH{=}CH_2]^{\ominus}$, it is estimated that the total olefin product formed in this reaction is less than 0.4%.

Test for the 1,1-Elimination (Carbene) Mechanism

This test involved a determination of the number and position of the deuterium atoms in the phenylcyclopropane produced from 3,3-dideutero-3-phenylpropyltrimethylammonium iodide. Elimination by way of a carbene intermediate formed by 1,1-elimination will give a product containing two deuterium atoms per molecule, one on the methine and one on a methylene carbon, eq. 5. Any other reasonable

[3]Bumgardner (15, 16) used the less soluble sodamide resulting in a heterogeneous system unsuitable for kinetic isotope effect studies.

[5] $$C_6H_5CD_2CH_2CH_2\overset{\oplus}{N}(CH_3)_3 + \overset{\ominus}{N}H_2 \longrightarrow C_6H_5CD_2CH_2\dot{C}H\cdot + (CH_3)_3N$$

$$C_6H_5CD_2CH_2\dot{C}H\cdot \longrightarrow C_6H_5C\begin{matrix}CH_2\\ \diagup\\ D\\ \diagdown\\ CHD\end{matrix}$$

mechanism for the reaction will result in the loss of one of the deuterium atoms on C-3 and the formation of 1-deutero-1-phenylcyclopropane.

The *trans*-1-phenylpropene – phenylcyclopropane fraction obtained by v.p.c. separation of the product of the reaction of the deuterated salt gave an n.m.r. spectrum in which the broad multiplet associated with the methine proton of phenylcyclopropane (1.55–2.00 p.p.m.) is absent and the complex multiplet associated with the methylene protons (0.45–1.10 p.p.m.) is reduced to two broad lines (23). These changes are consistent with replacing the methine hydrogen of phenylcyclopropane with deuterium. Furthermore, after subtracting the absorption associated with the phenyl protons of *trans*-1-phenylpropene from the total phenyl-proton absorption of the mixture, the ratio of the residual phenyl-proton absorption to that of the methylene protons of the phenylcyclopropane was found to be 5.0:4.0; precisely that expected if deuterium enrichment did not occur in the methylene groups of the cyclopropane ring.

These results were confirmed by mass spectrometry. The *trans*-1-phenylpropene – phenylcyclopropane fraction was found to be 94.4% monodeuterated, 5.5% undeuterated and 0.1% dideuterated. It can be concluded, therefore, that the 1,3-elimination does not proceed by way of a carbene intermediate.

Test for the 1′,3-Elimination (Ylide) Mechanism

The test for the 1′,3-elimination mechanism, eq. 4, was carried out in the conventional way (24) by determining the deuterium content of the trimethylamine formed from 3,3-dideutero-3-phenylpropyltrimethylammonium iodide. The intermediacy of an ylide would require that a deuterium atom be transferred from the 3-position to the *N*-methyl carbon and result in the formation of trimethylamine-d_1.

The trimethylamine formed in the reaction of the dideuterated salt was separated from ammonia and examined mass spectrometrically using the method of Cope and Mehta (25). The mass spectrum of the amine was identical, within the limits of measurement, to that of trimethylamine of natural isotopic abundance from which it was concluded that trimethylamine-d_1 did not exceed 0.5% of the product.

A complication arises in the application of the test because it was observed that exchange of the *N*-methyl hydrogens of the quaternary salt with solvent is quite rapid in comparison with the rate of 1,3-elimination (50% exchange after only 11% reaction). Consequently, if the conversion of the ylide intermediate to phenylcyclopropane were to occur by way of the 3-carbanion, $[C_6H_5\overset{\ominus}{C}DCH_2CH_2\overset{\oplus}{N}(CH_3)_2CH_2D]$, rather than in a one-step process, this carbanion could react with solvent to regenerate quaternary salt which in turn could lose its *N*-methyl deuterium by exchange before undergoing elimination. Analysis of the isotope effect results reported later in this paper, however, show that if the 3-carbanion is an intermediate in the 1,3-elimination, the ratio of the rate it abstracts a proton from solvent to the rate it loses trimethylamine to give phenylcyclopropane cannot exceed fourteen. It follows, then, that *at least* 7.1% of the *N*-methyl deuterium-labelled 3-carbanions, if formed, must react directly to produce trimethylamine-d_1.

A further complication arises because the 1,3-elimination reaction of the dideuterated salt is accompanied by an almost equal amount of 1,2-elimination which, of course, produces only undeuterated trimethylamine. It follows from these considerations that even if the 1,3-elimination were to proceed entirely by the ylide mechanism, only one-half of 7.1% of the trimethylamine would *necessarily* contain a deuterium atom. Since the limit of detection of trimethylamine-d_1 is at least as good as 0.5%, it follows that the 1′,3-elimination mechanism, if involved at all in the formation of phenylcyclopropane, can only be a minor reaction pathway.

Test for Exchange at C-3

With the carbene and ylide mechanisms eliminated as major reaction pathways for the

1,3-elimination reaction, there remain the E2 and E1cb processes originally proposed by Bumgardner (16). A deuterium exchange test was performed in an effort to detect the carbanion intermediate involved in the two-step process, eq. 1.

3,3-Dideutero-3-phenylpropyltrimethylammonium iodide containing 9.78 ± 0.01 atom % excess deuterium was allowed to react with potassium amide in liquid ammonia to approximately 66% completion. The unreacted quaternary salt was found to contain only 9.26 ± 0.03 atom % excess deuterium. This corresponds to a replacement of approximately 11% of the dideuterated salt by its monodeuterated analog and establishes that 3-carbanions are present in the reaction mixture. The actual extent of exchange must be considerably greater than these results indicate, however, since the large isotope effect associated with the abstraction of the hydrogen on C-3 (*vide infra*) will result in a more rapid rate of disappearance of the exchanged salt by 1,3-elimination than of the deuterium-labelled reactant.

As was pointed out in the Introduction, the observation that 3-carbanions are present in the reaction solution, although consistent with the E1cb mechanism for 1,3-elimination, does not rule out a concerted reaction pathway. It is entirely possible that reversible formation of the carbanion and elimination are entirely separate but concurrent processes (20). Kinetic nitrogen and hydrogen isotope effect studies were next carried out in an effort to distinguish between the E2 and E1cb reaction pathways.

Nitrogen Isotope Effect

Nitrogen isotope effect measurements were made to determine whether carbon–nitrogen bond rupture is involved in a rate-determining step of the elimination reaction (26, 27). Reactions of 3-phenylpropyltrimethylammonium iodide of natural isotopic abundance were carried to extents of completion varying from 53–94% based on quaternary salt and the nitrogen isotope effect was evaluated from the isotopic composition of the nitrogen in the initial reactant and recovered salt using an expression derived by Bigeleisen and Wolfsberg (28), eq. 6,

$$[6] \quad k^{14}/k^{15} = 1.00 + \frac{\log (R_f/R_0)}{\log [(1-f)(1+R_0)/(1+R_f)]}$$

where R_f is the N^{14}/N^{15} mass ratio of the nitrogen in the unreacted salt, R_0 is the N^{14}/N^{15} mass ratio of the nitrogen in the starting material, and f is the mole fraction of salt that has reacted. The results of these experiments are shown in Table 2. Since 96% of the reaction leads to phenylcyclopropane, the observed isotope effect of 2.2% is that associated with the 1,3- elimination process.

It is of value to compare this result with the nitrogen isotope effects previously observed in 1,2-elimination reactions of quaternary ammonium salts. Most measurements of the latter have been made at 60° and it is, therefore, necessary to estimate the magnitude of the isotope effect for the 1,3-elimination at this much higher temperature. This was done in two ways, both of which are very approximate. First, it was assumed that the isotope effect at 60° for the 1,3-elimination will be the same fraction of the theoretical maximum, calculated (29) for reaction at this temperature, as the value of 2.2% is of the theoretical maximum at $-55°$. This suggests a value of 1.4% at 60°. Second, the temperature coefficient for the isotope effect (an increase of 0.6% for each decrease of 10°) observed in a previous study in these laboratories for the reaction of *cis*-2-phenylcyclopentyltrimethylammonium ion with ethoxide ion in ethanol (30), was assumed to apply to the present reaction. This method predicts a value of 1.5% at 60°.

The isotope effect of 1.4–1.5% estimated for the 1,3-elimination reaction using amide ion in liquid ammonia may be compared with the results obtained for a number of 1,2-eliminations using ethoxide ion in ethanol: 2-phenylethyltrimethylammonium ion, 0.9% (27); *cis*-2-phenylcyclopentyltrimethylammonium ion, 1.1% (30); *cis*-2-phenylcyclohexyltrimethylammonium ion, 1.2% (30); and ethyltrimethylammonium ion,

1.7% (27). It can be seen that the isotope effect found in the present study is at least as large as the effects found in 1,2-elimination reactions proceeding by the E2 mechanism with reactants in which there is phenyl activation of the abstracted hydrogen. From this it can be concluded that the 1,3-elimination reaction must be proceeding by a mechanism in which carbon–nitrogen bond rupture is involved in the rate-determining step, that is, either by an E2 process, eq. 2, or an E1cb reaction, eq. 1, in which the rate of return of the carbanion to reactant is at least as large as its rate of decomposition to elimination product (26, 31).

Hydrogen Isotope Effects

If hydrogen exchange with solvent at C-3 does not occur, the isotope effect for 1,3-elimination is given directly by the ratio of 1,3- and 1,2-elimination products from the undeuterated salt divided by this ratio for the products from the 3,3-dideutero-salt, since the rate of 1,2-elimination, except for a small secondary isotope effect, will not be affected by isotopic substitution. The cyclopropane: olefin ratio for the unlabelled reactant was found to be 24 and that for the dideuterated salt 1.2 (see Tables 1 and 3), giving an isotope effect for 1,3-elimination of 20. The elimination reaction, however, is accompanied by exchange resulting in the conversion of a considerable amount of the dideuterated salt to monodeuterated salt which, because of the hydrogen isotope effect, will yield a much higher cyclopropane: olefin ratio than that for the original reactant. This means that the observed value of 20 actually represents a lower limit and that the actual isotope effect for phenylcyclopropane formation must be considerably higher than this. Even for a reaction at $-55°$, this isotope effect is large and suggests the possibility of tunnelling (32).

Of even greater significance with respect to the elucidation of the mechanism of 1,3-elimination is the hydrogen isotope effect associated with the rate of disappearance of the undeuterated and dideuterated quaternary salts. For the undeuterated salt, reaction is by 1,2- and 1,3-elimination only, since isotopic exchange with solvent simply regenerates the original reactant; for the dideuterated salt, reaction involves not only elimination but also exchange giving monodeuterated salt.[4]

This isotope effect was determined by the isotopic competitive method (28). A mixture of undeuterated and dideuterated salts containing 4.75 ± 0.01 atom % excess deuterium was allowed to react until 57.7% of the salt had been converted to elimination products. The recovered quaternary salt was found to contain 8.48 ± 0.02 atom % excess deuterium. The hydrogen isotope effect for the disappearance of dideuterated and undeuterated quaternary salt was then evaluated using eq. 6.

In applying this equation, there is a problem in arriving at an accurate value for R_f, the ratio of undeuterated and dideuterated salt in the recovered reactant, because of the presence of an unknown amount of monodeuterated salt formed by isotopic exchange with solvent. An upper limit to the amount of exchange is the 11% found in the deuterium exchange experiment (*vide ante*) in which 66% of the dideuterated salt had been converted to hydrocarbon compared to the less than 25% conversion of this salt in the present experiment. Assuming this extent of exchange, the composition of the recovered salt is as follows: undeuterated 10.4%, monodeuterated 9.7%, and dideuterated 79.9%.

[4]Further exchange produces undeuterated salt, but this will be small because of the intramolecular isotope effect associated with the abstraction of hydrogen from the monodeuterated compound.

The *total* extent of reaction of the undeuterated and dideuterated salts to produce hydrocarbon and monodeuterated salt becomes 61.8%. These data give an isotope effect of 7.3. On the other hand, if it is assumed that the recovered reactant consists only of undeuterated and dideuterated salt (no monodeuterated salt formed by exchange), its composition would be 15.2% undeuterated and 84.8% dideuterated, the extent of reaction 57.7% (*vide ante*) and the isotope effect 7.5. This close correspondence in the calculated isotope effects using the two extreme limits for the extent of exchange may be fortuitous; the significant fact is that there is a large isotope effect associated with the disappearance of the isotopic reactants.

An isotope effect of this magnitude, of course, is consistent with the 1,3-elimination reaction proceeding by the E2 mechanism, eq. 2. It also can be accommodated by an E1cb process, eq. 1, *provided* that the rate of return of the carbanion intermediate to quaternary salt is not *very large* relative to its rate of decomposition to phenylcyclopropane. The reason for this is that carbanion return in the case of the undeuterated salt reaction generates starting compound whereas return in the dideuterated salt reaction produces a reaction product, namely monodeuterated salt. It follows that the greater the extent of carbanion return the faster the rate of disappearance of dideuterated salt relative to that of the undeuterated salt and the smaller the observed isotope effect. At large rates of return, the isotope effect, so defined, would actually favor the deuterated reactant.

In summary, both the nitrogen and hydrogen isotope effect results are in accord with a concerted mechanism for the 1,3-elimination reaction. They may also be accommodated by a two-step process involving a carbanion intermediate provided that certain restrictions are placed on the relative rates with which this intermediate abstracts a proton from solvent to regenerate quaternary salt and loses trimethylamine to form the cyclopropane product. The nitrogen isotope effect of 2.2% would require that this ratio be greater than unity, whereas the hydrogen isotope effect of approximately 7.4 associated with the disappearance of undeuterated and dideuterated salts would require that this ratio not be large. (This will be discussed in more quantitative terms later in this section.)

Studies in Ammonia-d_3

The reactions of both undeuterated and dideuterated quaternary salts were carried out in ammonia-d_3 in an effort to distinguish between the two reaction pathways accommodated by the isotope effect results.

Although the deuterium exchange found in the reaction of deuterated salt in ordinary ammonia demonstrated the presence of 3-carbanions in solution, it was impossible to even estimate the extent of exchange since the resulting monodeuterated salt undergoes 1,3-elimination much faster than the starting compound. It was reasoned that a better estimate of the amount of exchange could be obtained if the exchange test was performed by reacting undeuterated salt in ammonia-d_3 where the monodeuterated salt would react more slowly than the starting compound and would, therefore, accumulate during reaction.

A reaction of the undeuterated salt in ammonia-d_3 was carried to 11% completion and the recovered salt was examined by both i.r. and n.m.r. spectroscopy. It was found that extensive exchange had occurred at the *N*-methyl carbons (50%) and at C-1 (35%), but deuterium was not detected at either C-2 or -3.

The absence of exchange at the 3-position in this reaction compared to the extensive exchange observed in ordinary ammonia cannot be understood in terms of a concerted elimination process which is accompanied by an irrelevant formation of 3-carbanions. This is because the *relative* rate of carbanion formation and E2 elimination should be approximately the same in the two cases, and if the 3-carbanions are *not* intermediates in the elimination reaction, but only react with solvent to produce exchanged salt, the relative rate of exchange and elimination cannot be significantly different whether a hydrogen is being abstracted from ammonia or a deuterium from ammonia-d_3.

On the other hand, the results of the two exchange reactions can be readily understood in terms of an E1cb process, eq. 1, provided there is a large isotope effect associated with the abstraction of a proton from the solvent by the carbanion. If, for the reaction in ordinary ammonia, the rate with which the carbanion abstracts hydrogen from solvent is not much greater than the rate of its decomposition to phenylcyclopropane, then for the reaction in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

deuterated ammonia, a much slower rate of carbanion return will result in an elimination rate which is much greater than the rate of exchange. Since exchange was extensive in ammonia and not within the limits of detection in ammonia-d_3, the isotope effect for proton abstraction from solvent must be extremely large. This is not surprising, however, since, on the basis of zero point energy consideration (29), the isotope effect associated with the rupture of a N—H bond will undoubtedly be larger than that for a C—H bond (33, 34) and it has already been demonstrated that the isotope effect for the abstraction of the hydrogen from C-3 is greater than 20.

The conclusions based on the results of the exchange experiments find confirmation in the relative amounts of 1,3- and 1,2-elimination in the reactions of deuterated and undeuterated salt in ammonia and ammonia-d_3, see Tables 1 and 3. It is seen that the reaction of the undeuterated salt in deuterated solvent gives a very much higher 1,3- to 1,2-elimination ratio than the reaction of this salt in ordinary ammonia. This is difficult to explain if the 1,3- as well as the 1,2-elimination reactions are concerted, since the secondary and solvent isotope effects associated with a change in the isotopic nature of the base and solvent should be approximately the same for the two elimination reactions. The same would apply for the reaction of the deuterated salt in the two base-solvent systems; yet, again, a much higher 1,3- to 1,2- ratio is found in ammonia-d_3. On the other hand, the results are readily understood in terms of an E1cb mechanism, since the large primary isotope effect associated with the return of the carbanion to reactant would result in a much faster overall rate of 1,3-elimination for the reaction in ammonia-d_3.

Similarly, the increase in the 1,3- to 1,2-elimination ratio from 24:1 to 43:1 in going from the reaction of the undeuterated salt in ammonia to that of the deuterated salt in ammonia-d_3 can only be understood in terms of the E1cb mechanism. If the 1,3-elimination is concerted, the primary hydrogen isotope effect associated with the quaternary salt would strongly decrease the rate of 1,3-elimination, while secondary and solvent isotope effects resulting from a change from ammonia to ammonia-d_3 would be approximately the same for the two processes. The result would be a large decrease in the 1,3- to 1,2-elimination ratio, contrary to observation. On the other hand, these results are fully in accord with an E1cb reaction pathway for phenylcyclopropane formation. The decrease in the rate of 1,3-elimination resulting from the substitution of deuterium for hydrogen on C-3 of the quaternary salt will be compensated by an increase in the rate of this elimination as a consequence of a much smaller tendency for carbanion return in the deuterated solvent. In fact, the primary isotope effect associated with solvent is seen to outweigh the effect associated with the substrate, resulting in an overall increase in the 1,3- to 1,2-elimination rate ratio. Other comparisons of the elimination ratios shown in Table 3 are equally in accord with the E1cb mechanism for the 1,3-elimination.

Relative Rates of Carbanion Return and Elimination

Upper and lower limits can be established for the ratio of the rates of carbanion return and conversion to phenylcyclopropane from the hydrogen isotope effects observed for the disappearance and 1,3-elimination of the undeuterated and dideuterated salts in ordinary ammonia.

It may readily be shown that the rate constant, k^H, for the disappearance of the undeuterated salt is given by eq. 7, where $k_{1,2}$ is the rate

$$[7] \qquad k^H = k_{1,2} + \frac{k_1^H k_e}{k_{-1} + k_e}$$

constant for 1,2-elimination, k_1^H is the rate constant for the formation of the 3-carbanion from undeuterated salt, k_{-1} is the rate constant for carbanion return in ordinary ammonia and includes the concentration of the solvent, and k_e is the rate constant for conversion of the carbanion to phenylcyclopropane (see eq. 1). Also, the rate constant, k^D, for the disappearance of the dideuterated salt by elimination and exchange in ordinary ammonia is given by eq. 8,

$$[8] \qquad k^D = k_{1,2} + k_1^D$$

where k_1^D is the rate constant for carbanion formation from the deuterated salt. (In this treatment, secondary isotope effects are neglected as is the formation of undeuterated salt by a double exchange of the dideuterated reactant.)

Combining eqs. 7 and 8 and substituting the

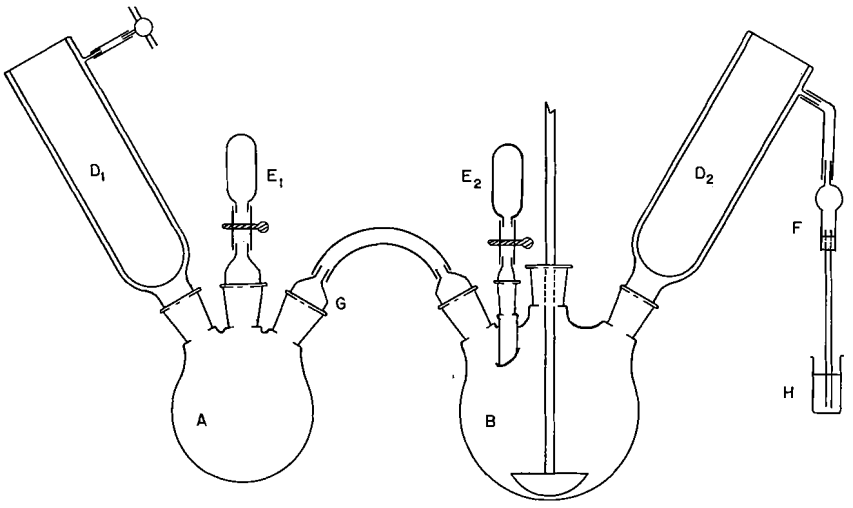

FIG. 1. Apparatus for the reaction of quaternary ammonium salts with potassium amide in liquid ammonia.

observed values of 7.4 for k^H/k^D, the isotope effect for the disappearance of undeuterated and deuterated salts, and 24 for $k_1^H k_e/k_{1,2}(k_{-1} + k_e)$, the ratio of 1,3- and 1,2-elimination from the undeuterated compound (see Table 3), gives eq. 9.

$$[9] \qquad k_{-1}/k_e = 0.099\ k_1^H/k_1^D - 1$$

It has been shown (*vide ante*) that the isotope effect for 1,3-elimination from undeuterated and deuterated quaternary salts is greater than 20. This represents a lower limit for k_1^H/k_1^D, the isotope effect for carbanion formation, and, on substitution into eq. 9, it gives a lower limit of 1.0 for the ratio of k_{-1}/k_e.

An upper limit for this ratio can be established by substituting into eq. 9 the maximum probable value for k_1^H/k_1^D. The largest hydrogen–deuterium isotope effect for a proton transfer reaction has been reported by Lewis and Funderburk (35) who observed a value of 24.8 for the reaction of 2,4,6-trimethylpyridine with 2-nitropropane and 2-nitropropane-2-*d* at 25°. A calculation based on the activation parameters determined by these authors gives a value of approximately 150 for this effect at −55°. Substitution of this value for k_1^H/k_1^D in eq. 9 gives a k_{-1}/k_e ratio of 14.

Neither of these limits represents probable ratios for the rates of carbanion return and elimination. The lower limit of 1.0 has been based on an experimentally observed value for the isotope effect for 1,3-elimination which has not been corrected for the extensive exchange which accompanies the reaction of the deuterated salt; the upper limit of 14 is based on an isotope effect which is undoubtedly much too high for a reaction in which there is relatively little steric hindrance to proton abstraction (35). Although it is not possible to specify narrower limits with any degree of certainty, a range of 3–10 would seem reasonable.

Experimental

Preparation of 3,3-Dideutero-3-phenyltrimethylammonium Iodide

This compound was prepared in four steps from 1,1-dideuterobenzyl chloride (8.6 g, 0.066 mol) which was made by the method of Buncel and Bourns (26). The chloride was converted to the Grignard reagent which was treated with ethylene oxide to give 3,3-dideutero-3-phenylpropanol (36). The alcohol was converted to the tosylate and thence to *N*,*N*-dimethyl-3,3-dideutero-3-phenylpropylamine by reaction with dimethylamine (37). Reaction of the amine with methyl iodide gave the quaternary salt (8.0 g) which was recrystallized from ethanol–ether to a constant m.p. of 178.0–178.5° (uncorrected); lit. m.p. 178.5–180° (37). The product contained 1.96 atoms D/molecule.[5] The undeuterated salt was prepared by the same sequence of reactions.

General Experimental Procedure

The apparatus used for the reaction of the quaternary ammonium salt with potassium amide in liquid ammonia is shown in Fig. 1. Reaction flask A contained a magnetic stirrer and was fitted with a Dry Ice–acetone condenser, D_1, and a vial, E_1, for adding potassium metal. Flask B was

[5]Deuterium analyses were performed by Mr. J. Nemeth, 303 Washington Street, Urbana, Ill.

fitted with an air-tight stirrer, a Dry Ice–acetone condenser, D_2, and a vial, E_2, for addition of ammonium chloride. Condenser, D_1, was connected to nitrogen and ammonia purification trains and D_2 to a barium oxide drying tube, F, whose exit tube passed into a bubbler, H, containing oil. Ferric nitrate nonahydrate (10 mg) was placed in flask A and the quaternary salt (usually 2 g) was added to flask B. Following a thorough flaming of the apparatus and flushing with nitrogen, 200 ml of ammonia was condensed into flask B and 100 ml into flask A. Potassium metal (usually 0.57 g) was added slowly with stirring to A. Thirty minutes after the blue color of the potassium had disappeared, D_1 was replaced by an adapter joined to the nitrogen train, both flasks were cooled to $-55 \pm 1°$ in a Dry Ice–diacetone alcohol bath, flask A was inverted, and the amide solution was pushed by nitrogen through a glass wool filter, G, into B.

The reaction was stopped by adding an excess of ammonium chloride. Ether (200 ml) was added to flask B, which was equipped with a water condenser connected to a gas-wash bottle containing ether, and the ammonia was evaporated slowly. Finally, 100 ml of water was added to B to dissolve the residual salts, the ether layer was separated and the aqueous layer extracted with additional ether. The combined ether solutions contained the hydrocarbon products and the aqueous solution the unreacted quaternary salt.

Product Identification and Analysis

The ether solution was concentrated by distillation using a spinning band column and the residue analyzed by gas chromatography using a 3/8 in. × 20 ft column of 30% SE-30 on 45/60 mesh Chromosorb P at 150°. Three components were separated but only component 2 was recovered in sufficient quantity for identification. Both its n.m.r. and i.r. spectra were identical to those reported for phenylcyclopropane (23, 24).

The minor products were present in much larger amounts in the reaction of the deuterated salt. Component 1 was identified as 3-phenylpropene from its retention time on the gas chromatograph and its i.r. spectrum. Component 2 had the same retention time as phenylcyclopropane and *trans*-1-phenylpropene which is known to be formed by isomerization of 3-phenylpropene (component 1) under the reaction conditions (22). Also, its n.m.r. spectrum corresponded to that expected for a mixture of 1-phenylcyclopropane-1-*d* and *trans*-1-phenylpropene-1-*d*. Identification of component 2 as a mixture of these two hydrocarbons was confirmed by the observation that three different methods of quantitative analysis, each assuming this composition, gave identical results: integration of the n.m.r. spectrum, gas chromatographic analysis using temperature programming on a 1/4 in. × 40 ft column of 5% Ucon Polar,[6] and u.v. spectroscopy at 250 mμ, where the molar extinction coefficient for *trans*-1-phenylpropene was found to be 16 000 and for phenylcyclopropane 153. Finally, component 3 had a retention time which was identical to that of *cis*-1-phenylpropene, which is a minor product of the base-catalyzed isomerization of 3-phenylpropene.

Extent of Reaction

The extent of reaction, required for both hydrogen and nitrogen isotope effect measurements, was determined by quantitative recovery of unreacted quaternary ammonium iodide. The water layer from the reaction mixture was taken nearly to dryness to remove ether and ammonia and the concentrated solution was diluted with water and passed through an anion exchange column (Dowex 1-X8, 100/200 mesh) in the chloride form. The eluant was taken to dryness and the residual chloride salts were thoroughly dried. The salts were shaken for several hours with excess anhydrous acetone and the insoluble potassium and ammonium chlorides were separated by filtration. The quaternary chloride, recovered from the filtrate by removal of acetone, was dissolved in water and the solution was treated with silver oxide and filtered. The filtrate was brought to a p*H* of 5.5 with hydriodic acid, filtered and taken to dryness. Control experiments in which the quaternary iodide was recovered by this procedure from a solution of liquid ammonia containing more than twice the amount of potassium and ammonium chloride and iodide salts that would be present in reaction mixtures showed that the error in the extent of reaction would not exceed 3%.

Test for the Carbene Mechanism

Deuterium analyses were done on the phenylcyclopropane–*trans*-1-phenylpropene product (component 2) from the reaction of the deuterated salt using n.m.r. and mass spectroscopy. For the latter, the ionization voltage was 8.5 eV and the relative intensities of the mass peaks were compared with those for a synthetic sample of undeuterated hydrocarbon of the same composition (71% phenylcyclopropane and 29% *trans*-1-phenylpropene). The percentage of undeuterated, monodeuterated, and dideuterated hydrocarbon in the product was calculated by the method described by Biemann (38).

Test for the Ylide Mechanism

To a solution of 3,3-dideutero-3-phenylpropyltrimethylammonium iodide (0.44 g, 0.0014 mol) in 45 ml of ammonia was added a solution of potassium amide prepared by adding potassium (0.30 g, 0.0077 mol) to 65 ml of ammonia. The reaction was quenched with ammonium chloride after 30 min and 100 ml of ether was added. The ammonia and trimethylamine were distilled into 1 l of stirred ice-cold hydrochloric acid. The hydrochloride salts, recovered by removal of excess acid under reduced pressure, were dried and the trimethylammonium chloride was extracted from the large excess of ammonium chloride by stirring successively with 600 ml of ethanol and two 550 ml portions of chloroform. The salt, recovered by evaporation of the combined solutions, was further purified by a second chloroform extraction. It was then dissolved in ethanol, the solution made basic to phenolphthalein with sodium ethoxide and the resulting trimethylamine purified by gas chromatography using a 10 ft × 3/8 in. column of 20% amine 220 on 60/80 mesh, base-washed Chromosorb W[7] at 55°. Its mass spectrum was compared with that obtained from a purified sample of trimethylamine of natural isotopic abundance.

Test for Isotopic Exchange at C-3 of 3,3-Dideutero-3-phenylpropyltrimethylammonium Iodide in Liquid Ammonia

Two deuterium exchange experiments each using 1.1 g (0.0035 mol) of deuterated salt were carried out as described

[6]This analysis was done by Varian Aerograph, Walnut Creek, California.

[7]The column was obtained from Varian Aerograph, Walnut Creek, California.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

under General Experimental Procedure. The reactions were quenched after 9 min, the unreacted salt was recovered, recrystallized from ethanol–diethyl ether, and analyzed for deuterium.[5] The extent of reaction in each case was 66 ± 2%. A control experiment showed that no deuterium is lost in the recovery and purification procedures.

Hydrogen Isotope Effect Determination by the Competitive Method

A mixture of undeuterated and dideuterated quaternary salts (0.395 g, 0.0013 mol and 0.358 g, 0.0012 mol, respectively) in 300 ml of liquid ammonia was treated with base prepared by adding potassium (0.309 g, 0.0075 mol) to 150 ml of liquid ammonia. The reaction was quenched after 92 s by addition of ammonium chloride and the unreacted salt was recovered, purified, and analyzed[5] for deuterium.

Nitrogen Isotope Effect Determination

The nitrogen isotope effect in the elimination reaction was determined by comparing the N^{14}/N^{15} ratios for the quaternary salt recovered from reactions carried to known extents of completion with this ratio in the initial reactant (28). Samples of salt were decomposed in a Kjeldahl digestion to ammonium sulfate which was then oxidized to molecular nitrogen for mass spectrometric analysis (27). A control experiment showed that there is no isotopic fractionation in the recovery and purification procedures.

Studies in Ammonia-d_3

(a) Reaction of Undeuterated Quaternary Salt

3-Phenylpropyltrimethylammonium (1.11 g, 0.0036 mol) in 100 ml of ammonia-d_3 (Merck, Sharpe and Dohme) was treated with base formed by the addition of potassium (0.114 g, 0.0029 mol) to 75 ml of ammonia-d_3. The reaction mixture was colorless rather than the deep reddish-brown of all other reactions. The reaction was quenched after 45 min with ammonium chloride and the unreacted quaternary salt recovered and purified.

The i.r. spectrum of the recovered salt in a potassium bromide disc showed none of the absorptions associated with the C_3—D bonds while the intensities of the C_3—H absorptions were the same as those for the starting compound. On the other hand, the absorptions associated with the *N*-methyl C—H and C_1—H bonds were much less intense and several new absorptions associated with *N*-methyl C—D and C_1—D bonds were observed. Analysis of the 100 MHz n.m.r. spectrum of the recovered salt in deuterium oxide confirmed that there had been no exchange of C-2 and -3 hydrogens but that 50% of the *N*-methyl hydrogens and 35% of the C-1 hydrogens had been replaced by deuterium.

Gas chromatographic analysis of the hydrocarbon product failed to show the presence of any of the isomeric phenylpropenes. An upper limit of 0.4% phenylpropenes was established by showing that the amount of 3-phenylpropene which would have been formed by this percentage of β-elimination produced a distinct coloration whereas the reaction solution was colorless.

(b) Reaction of Deuterated Quaternary Salt

3,3-Dideutero-3-phenylpropyltrimethylammonium iodide (0.97 g, 0.0032 mol) in 100 ml of ammonia-d_3 was treated with base prepared from potassium (0.35 g, 0.009 mol) in 75 ml of ammonia-d_3. The reaction was quenched with ammonium chloride after 90 min. Neither 3-phenylpropene nor *cis*-1-phenylpropene was detected by gas chromatography while only 2.3% of *trans*-1-phenylpropene, the phenylpropene which predominates in basic solution under equilibrium conditions (22), was shown to be present by u.v. spectroscopy. A control experiment showed that the latter olefin does not undergo significant polymerization under the conditions of the experiment.

The authors are greatly indebted to the National Research Council of Canada for the financial support for this investigation and the Department of University Affairs of the Province of Ontario for scholarships (to K.C.W.).

Sigma and Pi Electron Contributions to Long-range Spin–Spin Coupling Constants in the Methyl Derivatives of the Fluoropyridines

J. B. ROWBOTHAM[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received February 8, 1972

Seven methyl derivatives of the 3- and 4-fluoropyridines are synthesized and their p.m.r. spectra are analyzed. The nuclear spin–spin coupling constants are compared with previous results for the four methyl derivatives of 2-fluoropyridine. A model in which the nitrogen atom polarizes primarily the σ electron system of the ring, leaving the π electron contribution to the coupling mechanism relatively unaffected, qualitatively accounts for the large majority of the coupling constants. For example, the coupling over six bonds between methyl protons and a fluorine nucleus, J_p^{F,CH_3}, is the same whether the fluorine atom or the methyl group is placed ortho to the nitrogen atom and is little different from its value in *p*-fluorotoluene. The model is consistent with significant σ electron contributions to long-range couplings over four and five bonds from methyl protons to fluorine nuclei or ring protons. Evidence is adduced for resonance structures in which fluorine conjugates with nitrogen or with ring carbon atoms. An earlier suggestion, that hyperconjugation of the methyl group with nitrogen is necessary to the interpretation of the observed couplings, is dropped. Instead, a substantial polarization of the σ electron core near C-2 and -6 is invoked but apparently does not extend appreciably beyond these atoms in the ring.

Sept dérivés méthylés des fluoro-3 et 4 pyridines sont synthétisés et leurs spectres r.m.n. analysés. Les constantes de couplage spin–spin sont comparées aux résultats antérieurs obtenus pour les quatre dérivés méthylés de la fluoro-2 pyridine. Un modèle dans lequel l'atome d'azote polarise principalement le système électronique σ du cycle laissant relativement inchangée la contribution électronique π au mécanisme du couplage, explique qualitativement la grande majorité des constantes de couplage. Par exemple, le couplage à travers six liaisons entre les protons du méthyle et le noyau de fluor, J_p^{F,CH_3}, est le même si le fluor ou le méthyle est placé en ortho par rapport à l'azote et diffère peu de la valeur obtenue dans le *p*-fluorotoluène. Le modèle est compatible avec les contributions importantes des électrons σ aux couplages à longue distance à travers quatre et cinq liaisons, à partir des protons du méthyle au noyau du fluor ou au protons du cycle. Une preuve de structures résonantes dans lesquelles le fluor se conjugue à l'azote ou aux atomes de carbone du cycle est apportée. La suggestion première selon laquelle l'hyperconjugaison du groupe méthyle avec l'azote est nécessaire à l'interprétation des couplages observés, n'est pas retenue. A la place, une polarisation substantielle des électrons σ proches du C-2 et du -6 est avancée mais ne s'étend pas apparemment au-delà de ces derniers de façon notable.

Canadian Journal of Chemistry, **50**, 2344 (1972)

Introduction

A model in which σ and π electron contributions to ring proton and to ring proton – fluorine spin–spin coupling constants are distinguished has been successfully applied to the methyl derivatives, **1**–**4**, of 2-fluoropyridines (1, 2). In these compounds the signs and magnitudes of the long-range coupling constants between the methyl protons and the ring protons or the fluorine nucleus support the assumption (3) that the nitrogen atom primarily polarizes the proximate σ bonds, leaving the π electron contribution to the coupling constants mainly unaffected (2). Certain resonance structures of these molecules were invoked in the interpretation of the coupling data (2) apropos of which a referee pointed out the desirability of the examination of the methyl derivatives of the 3- and

4-fluoropyridines. Accordingly the synthesis of a series of these derivatives is reported here, together with the analyses of their p.m.r. spectra. The ensuing spin–spin coupling data are discussed in terms of the earlier model.

Acquaintance with the earlier work (1, 2) is assumed in this final report.

Experimental

(1) Syntheses of Compounds

These were prepared by Schiemann reactions (2) on the respective amines. To prepare **7**, **8**, **9**, and **11** the amine was dissolved in excess 50% aqueous HBF_4 and then treated in the cold with solid $NaNO_2$ over several hours. After heating the solution at 50 °C for 1 h, it was diluted with water, neutralized, and extracted with ether. Distillation of the dried extracts gave poor yields of the methylfluoropyridines.

An improved method (4) was used to prepare **5**, **6** and **10**. The amine was dissolved in the minimum aqueous HBF_4 necessary to maintain fluidity and the cold mixture was treated with excess solid $NaNO_2$ over a period of 0.5 h. The mixture was quickly filtered and the diazonium fluoroborate was covered with pentane (hexane for **5**). The salts decomposed smoothly on heating (**6** and **10** were decomposing on the cool filter but **5** was stable in boiling pentane). A good yield of product was obtained by extraction with dilute HCl, neutralization, steam distillation of the extracts, extraction of the distillate with ether, and distillation under reduced pressure.

Only the amine precursor of **9** was commercially available. The 4-amino-2-picoline, 4-amino-3-picoline, and 4-amino-2,6-lutidine were obtained by nitration and catalytic reduction of the pyridine oxides (5). The 3-amino-2,6-lutidine was prepared via hydrogenation of the commercially available nitro compound in ethanol. 2-Chloro-5-nitro-3-picoline was obtained by nitration, hydrolysis, and treatment with phosphorous oxychloride from 2-amino-3-picoline (6, 7). Hydrogenation over Pd/C in ethanol at 1 atm gave 3-amino-5-picoline. Similarly, 2-amino-4-picoline gave 3-amino-4-picoline. No attempt was made to separate the intermediate isomeric mixtures.

All fluorine compounds had p.m.r. spectra consistent with their structures and all had a mint-like odor. Compounds **5**, **6**, **7**, and **10** have been previously reported (4, 6, 7) while the amine precursors for **8**, **9**, and **11** are known (5, 8).

(2) Proton Magnetic Resonance Measurements

Degassed samples were prepared as 17–30 mol % solutions in carbon disulfide, tetramethylsilane, or benzene-d_6 by the freeze–pump–thaw technique. The choice of solvents, all of low dielectric constant, was dictated by the desire to prevent, as far as possible, the overlap of peaks from different proton groupings.

The peaks belonging to H_2 or H_6 were fairly broad because of incompletely relaxed spin–spin coupling to ^{14}N, but addition of small amounts of trifluoroacetic acid (*1*) did not sharpen these significantly.[2] In consequence the derived coupling constants between fluorine and H_2 or H_6, and between H_2 and H_6, have an uncertainty of about 0.1 Hz.

Proton magnetic resonance spectra were recorded on a Varian DA-60I spectrometer (**10** was measured at 100 MHz on an HA100D spectrometer) in the frequency sweep mode, with internal tetramethylsilane serving as a locking material. The spectra were repeatedly calibrated at intervals of about 5 Hz by reading sweep and manual oscillator frequencies and were measured at a sweep width of 50 Hz at sweep speeds of 0.01 Hz/s. Decoupling as well as weak irradiation experiments (9) employed an HP-4204A audio oscillator and/or a Wavetek 114 sweep generator (10).

For the n.O.e. experiment (11, 12) on **6** in benzene-d_6 solution the spectrometer was locked on internal trifluoroacetic acid. Four scans were made of the H_2 and H_6 regions without strong irradiation of the methyl proton region, followed by four more during which the methyl protons were strongly irradiated. Peak areas were found by weighing and a 10% increase in the area from one set of peaks was taken as indicating that they originated in H_6.

(3) Spectral Analysis

Spectra were analyzed on an IBM 360/65 computer using the program LAME (13) in iterative or noniterative mode; followed by a plotting routine (devised by J.B.R.) which drove a CalComp incremental plotter. The plotting program gave each transition a Lorentzian shape of width $2a$ at half-height, $\Delta\nu_{1/2} = 2a$, retaining this value until the highest point

[2]The splittings of H_6 in **1** were rather larger than those found in the present compounds.

*In p.p.m. to low field of internal TMS; parentheses indicate methyl protons.
†In Hz; when the sign is omitted or is given in parentheses it was not determined. Square brackets indicate ring positions.
‡Solvent and concentration (mol %).
§In **11** one can find only $|J_o^{H,CH_3} + J_p^{H,CH_3}| = 1.08$ Hz because of the symmetrical nature of the spectrum.

on the peak was reached, then changing to a Lorentzian shape with $\Delta\nu_{1/2} = 2b$ for the remainder of the peak. Thus the composite computed peak was determined by two parameters: the width, $a + b$, and the asymmetry, $a/(a + b)$. The asymmetry parameter was generally set at 0.6–0.65 to best simulate the experimental effects of finite sweep times. A total width of about 0.15 Hz generally reproduced the experimental linewidth best but a width of up to 0.8 Hz was used to simulate the broad peaks from H_2 or H_6.

Analysis of the spectra was generally straightforward, particularly when decoupling of specific methyl protons was employed in extracting preliminary spectral parameters for ring protons and fluorine. For **9**, **10**, and **11** all transitions were assigned and all parameters (except, of course, the fluorine shift) were allowed to vary in the final iterations. The transitions associated with H_2 and/or H_6 in the other compounds were not assigned and therefore their chemical shifts as well as their couplings to fluorine and to each other could not be allowed to vary. These were determined by trial and error methods employing the noniterative mode of LAME. The r.m.s. deviations between calculated and observed transitions were always less than 0.023 Hz, standard deviations of the spectral parameters were less than 0.01 Hz and correlation coefficients were less than 0.3 except between the chemical shift of H_5 and $^3J_o^{H^5,H^6}$ in 7, which was 0.8; this is a consequence of the incomplete assignment of transitions to observed peak positions in the H_6 region.

In one or two cases the derived spectral parameters were not immediately assignable to specific protons. For instance, in **10** the protons of the two methyl groups differ only in their chemical shifts and in their coupling to fluorine. They were assigned on the basis that $^6J_p^{F,CH_3}$ is smaller than $^4J_o^{F,CH_3}$, and is almost independent of substituent effects, even of the presence of a heteroatom (2, 14, 15). Again, the ring protons in **9** were assigned on the basis of their relative chemical shifts by analogy with **2** and **4**, measured in the same solvent (2) while the methyl protons were assigned so that the couplings to fluorine agreed with those in **2** and **4** (2).

Results and Discussion

The spectral parameters of **5**–**11** are given in Table 1. Tickling experiments provided the relative signs of the couplings in many cases. When

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

the sign is shown in parentheses it was not determined directly but was assigned on the basis of well-documented previous work (1, 2, 15–18). Attempts at confirming the signs of certain couplings failed, usually because the relevant splittings in the spectrum were not sufficiently well resolved. Thus the sign of $^4J_m^{H_2,H_6}$ is not known from this study but is known to be negative in pyridine itself (17); the sign of $^5J_m^{F,CH_3}$ in **6** is also unknown from the present measurements.

For reasons of space the observed and computed spectra are not displayed here, but show excellent agreement with each other and are certainly not inferior to those portrayed in detail for **1** (1).

(1) The Methyl Proton–Ring Proton Coupling Constants

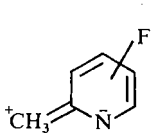
(a) Over Six Bonds, $^6J_p^{H,CH_3}$

In toluene (19) J_p^{H,CH_3} is -0.62 ± 0.02 Hz, the same as in **6**, **8**, **9**, and **10**; confirming the data on **1** and **4** (1, 2) and bearing out the earlier conclusion (2) that, as this coupling constant arises from a π electron mechanism (16, 20, 21), the nitrogen and fluorine atoms are ineffectual in altering the π electron contribution to J_p^{H,CH_3}. The smaller value of -0.55 Hz in **7** is considered as insufficiently different from that in the other compounds to weaken this conclusion.

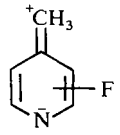
(b) Over Four Bonds, $^4J_o^{H,CH_3}$

In ref. 2 it was argued that, as the negative π electron contribution to J_o^{H,CH_3} is expected to increase as the mobile bond order of the intervening C=C bond increases, the data for **1**, **2**, and **3** were consistent with a contribution from the resonance structure **12**. Extension of the argument to **5**, **6**, and **8** involves **13**, **14**, and **15**, where on *a priori* grounds **12** and **15** may well be favored over **13** or **14** because the strong nitrogen acceptor is placed ortho or para to the fluorine donor in **12** and **15**. In **2** one has $J_o^{H_3,CH_3}$ equal to 0.81 Hz (2), the same as in **8** and indicating **12** and **15** as equally important structures; in accord with quadrupole resonance data (22) and relevant to a referee's comment on ref. 2 concerning the importance of structures of this type. The somewhat smaller magnitudes of this coupling in **5** and **6** suggest that contributions from **13** and **14** are less important than those of **12** and **15**.

The even smaller magnitudes of -0.5 to -0.6 Hz occurring for J_o^{H,CH_3} when a methyl group is situated ortho to the nitrogen atom, as in **4** (2), **7**, **9**, and **10**, were originally (2) attributed either to a structure of the type **16** which decreases the



16



17

mobile bond order between C-5 and -6; or to a decrease in the negative σ electron contribution to J_o^{H,CH_3}, caused by a polarization of the σ core by the nitrogen atom and operating to decrease the σ density near C-6. The former proposal now appears untenable for the following reasons. The methyl group is undoubtedly a weaker π electron donor than a fluorine atom (23). Now because **12** and **15** have here and previously (2) been shown to be fairly important structures in the interpretation of the coupling data, it follows that in **7**, where **15** applies and acts to increase the mobile bond order between C-2 and -3, J_o^{H,CH_3} should have roughly the same magnitude as in **8**. Yet it is 0.3 Hz smaller in magnitude. We think it unlikely that a structure of the type **16** would outweigh one of the type **15**. Again the two different magnitudes of J_o^{H,CH_3} in **2** (2) are in accord with a substantial contribution from **12** but not from **17**.

This conclusion leaves the alternative proposal of σ electron polarization of C-2 or -6 by the nitrogen atom as an explanation of the small magnitude of J_o^{H,CH_3} in those compounds where the methyl group is attached to these carbon atoms. An apparent objection cites the fact that J_o^{H,CH_3} is -0.81 Hz in **8**, involving the ring

proton at C-2, and asks why the decrease in a σ electron contribution to J_o^{H,CH_3} occurs only when the methyl group is attached at C-2. A probable answer cites the possible coupling pathways recently discussed in detail (24, 25). In brief, the exchange integrals involved in the coupling mechanism in a valence bond formulation may be quite different in the two situations (25). Quantitative calculations by a molecular orbital method (26) on propene derivatives predict a marked positive shift in the *cisoid* allylic coupling when substitution occurs at C-2, in agreement with experiment; while the observed change in this coupling on substitution (by fluorine) at C-1 is zero (27). The situation is analogous to our observations, with nitrogen playing the role of the substituent and J_o^{H,CH_3} the role of the *cisoid* allylic coupling, $^4J_c^{H,CH_3}$, in the propene derivatives.

In terms of our model the positive shift in J_o^{H,CH_3}, occurring when the methyl group is bonded to C-2 or -6, is a σ electron effect. Further evidence that it is not a π electron effect can be adduced from two sources. First, a π electron coupling of this kind is proportional to Q_{CCH}, the hyperfine interaction constant of a methyl proton with the π electron system (28–30). In a series of radical anions of the methylpyridine derivatives no marked dependence of this parameter on the position of the methyl group is found (31). Second, a decrease in the Q_{CCH} value at C-2 and -6, which would account for the small magnitudes of the corresponding J_o^{H,CH_3} values, should then also be reflected in a decrease of J_o^{F,CH_3} in **10** relative to its values in **1**, **5**, and **8**. The opposite occurs.

(c) Over Five Bonds, $^5J_m^{H,CH_3}$

In ref. 2 it was reasoned that, as J_m^{H,CH_3} contains a substantial positive σ electron contribution (16, 21), the values of 0.28 Hz in **2** and **4** (0.1 Hz smaller than the 0.4 Hz observed in **1** and **3**) are in agreement with a σ electron polarization at C-2 or -6 by the nitrogen atom. In **2** and **4** these carbon atoms are involved in the coupling path. The couplings of 0.41 Hz in **8** and of 0.27 Hz in **7** are consistent with this assumption.

However, in **5** and **10** the J_m^{H,CH_3} values lie midway between the above extremes of 0.27 and 0.41 Hz but they are expected to lie near 0.27 Hz on the basis of the σ electron picture. There is the possibility that, because in **5** and **10** the fluorine atom is placed para to C-6 and ortho to C-2, resonance structures of the type **13** will enhance the π electron contribution to J_m^{H,CH_3} and thereby partially compensate for the reduction in the σ electron contribution. This is a reasonable proposal insofar as the fluorine is located meta to the nitrogen in **5** and **10**, disallowing its preferred conjugation with the latter; and a structure of type **13** certainly increases the π electron density at C-6, enlarging the relevant Cp_z orbital and thereby enhancing somewhat the hyperconjugative interaction with the methyl group orbitals. A similar argument would follow for position C-4 in **5**.[3]

In any event the contention that the π electron mechanism is relatively unaffected by the presence of the nitrogen atom is nicely supported by the values of (−) 0.17 and (−) 0.21 Hz for $^6J_m^{CH_3,CH_3}$ in **9** and **10**. They compare with a corresponding value of −0.19 Hz in a *m*-xylene derivative (16). As one or both of the methyl groups in **9** and **10** are bonded to C-2 and/or C-6 and as $^6J_m^{CH_3,CH_3}$ is probably accounted for by a π electron mechanism (21), one may strongly infer that the nitrogen atom acts to polarize the σ electron system without affecting the π electron contribution to J_m^{H,CH_3} and also that structures of type **16** are unnecessary in the explanation of the coupling data. Note that $^4J_m^{H_2,H_6}$ in pyridine is −0.13 Hz (17), in benzene it is 1.37 Hz (33) yet $J_m^{CH_3,CH_3}$ in **10** is the same as in a *m*-xylene derivative, a good example of the application of the present model.

One may also conclude that σ electrons play a substantial part in the transmission of spin information in J_o^{H,CH_3} and J_m^{H,CH_3}, this part being proportionately larger in the latter; in agreement with recent molecular orbital calculations on toluene (21) which imply a preponderant σ electron contribution to J_m^{H,CH_3}. If this implication is indeed valid it helps to account for the present observation of a greater sensitivity of J_m^{H,CH_3} than of J_o^{H,CH_3} to the proposed σ core polarization at the carbon atoms proximate to the nitrogen atom.

(2) The Methyl Proton–Fluorine Couplings

In *p*-fluorotoluene J_p^{F,CH_3} is 1.15 Hz (15) while in **3** it is 1.25 Hz (2), the fluorine atom lying ortho to the nitrogen atom. In **10**, where the positions of the fluorine atom and of the methyl

[3]This argument is perhaps an over-refinement of our model and we recognize that it smacks of "enthusiastic yodelling in the blue distance of ... conjecture"(32).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

group have been interchanged, J_p^{F,CH_3} is 1.21 Hz. As it is unlikely that other than a π mechanism is important for this coupling (14, 21) the heteroatom has very little influence on the π contribution to J_p^{F,CH_3} in **3** and **10**, as predicted by the model. The variation in $J_p^{H,F}$ between 1.2 and 2.5 Hz in **1**–**11** can therefore be attributed mainly to a σ electron effect.

Considering now J_o^{F,CH_3} one has 1.45 Hz in **1** (1), 1.71 Hz in **5**, 1.63 Hz in **8**, and 2.1 Hz in a derivative of *o*-fluorotoluene (14), in line (1) with a dominant π electron contribution to J_o^{F,CH_3}; the variation in magnitude being attributable to a variable σ electron contribution to this coupling over four bonds. When the methyl group is bonded to C-2 as in **10**, J_o^{F,CH_3} is 3.03 Hz, representing a substantial positive shift from the magnitudes in the other compounds, and is at least qualitatively in line with the positive shift of the analogous J_o^{H,CH_3} values. Nevertheless the variations are small compared to the corresponding $J_o^{H,F}$ values which range from -3.12 Hz in **4** (2) to $+9.85$ Hz in **7**.

Finally, although $J_m^{H,F}$ varies between -1.02 Hz in **1** (1) and $+10.2$ Hz in **8**, the range of J_m^{F,CH_3} is only from (−) 0.10 Hz in **6** to -0.60 Hz in **4** (2) and does not deviate greatly from its value of -0.4_3 Hz in a derivative of *m*-fluorotoluene (14). On the basis of the model the large changes in $J_m^{H,F}$ arise mainly via the distortion of the σ core by the nitrogen atom.

(3) Ring Proton and Ring Proton–Fluorine Couplings

The data in Table 1 are in accord with the previous detailed discussion (1, 2) of such parameters in **1**–**4** and will not be fully described here. In brief they are consistent with an alternating (3, 34) electronegativity effect of the substituents, acting primarily through the σ electron system. Unfortunately we were unable to determine the sign of $^4J_m^{H_2,H_6}$ in **5**, **6**, and **8**. This coupling is negative in pyridine (17) but for **8** the additivity scheme (2) predicts $+0.1$ Hz.

The value of 10.2 Hz for $J_m^{H_2,F}$ in **8** is the largest known meta proton-fluorine coupling and is larger than all known $J_o^{H,F}$ values in derivatives of fluorobenzene, except that of 10.4 Hz in *o*-difluorobenzene (35).

Conclusions

The majority of the proton–proton and proton–fluorine spin–spin coupling constants in 11 methyl derivatives of the 2-, 3-, and 4-fluoropyridines can be rationalized in terms of a model in which the nitrogen atom polarizes the σ electron core predominantly at C-2 and -6 but does not strongly alter the π electron contribution to the coupling mechanisms. Thus, in these compounds J_p^{H,CH_3} and J_p^{F,CH_3} are little different from their values in toluene and *p*-fluorotoluene. The results also indicate an appreciable σ electron contribution to long-range couplings over four and five bonds from methyl protons to ring protons or fluorine nuclei.

Chemical Shift. VII. The Long-range Shielding Effects of the Cyano Group

J. W. ApSimon, H. Beierbeck, and D. K. Todd[1]

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received March 6, 1972

Using the methods described in parts I–VI of this series, we have examined the long-range shielding effects of the cyano group upon the C-18 and -19 methyl protons in several cyano-steroids and the ring protons in 2-*endo*- and 2-*exo*-cyanonorbornenes.

It was found that the most important shielding mechanism of the cyano group is its electric field effect, with the magnetic anisotropy effect making at most a minor contribution to the screening. However, only in the cases of the cyano-steroids was good agreement obtained between the calculated and the experimental shifts.

En utilisant les méthodes décrites dans les parties I–VI de cette série, nous avons examiné les effets de blindage à longue distance du groupe cyano sur les protons des méthyles 18 et 19 de plusieurs cyano stéroïdes et sur les protons du cycle des *exo* et *endo* cyano-2 norbornènes. Le mécanisme le plus important de l'effet de blindage du groupe cyano se trouve être son effet de champ électrique, l'anisotropie magnétique apportant une contribution mineure à l'effet d'écran. Cependant, seules dans le cas des cyano stéroïdes, les valeurs calculées et expérimentales pour les déplacements chimiques ont été obtenues avec un bon accord.

Introduction

The long-range shielding effects of the nitrile group have been investigated by a number of authors (1–5). Zeil and Buchert (1) and Reddy and Goldstein (2) studied proton chemical shifts in aliphatic nitriles and attributed the observed long-range shielding effects of the cyano group to its magnetic anisotropy, $\Delta\chi$(CN). They obtained values of -34×10^{-30} and -27×10^{-30} cm^3/molecule respectively. Cross and Harrison (3) used the second value to calculate the shifts of the C-19 methyl groups in some 5α and 5β cyano-steroids. The predicted shifts were in the wrong direction, a result which was rationalized in terms of conformational changes in the steroidal A-ring caused by substituent dipole–dipole interactions. Jackman and Sarkis (4) suggested that it might have been the neglect of the electrostatic screening effect of the highly polar cyano group that was responsible for the lack of success. Zürcher (5) had found earlier that only an electric field effect had to be invoked in order to predict the methyl shifts in several cyano-steroids and in ethyl cyanide.

Since new chemical shift data for steroidal nitriles have appeared in the literature, it seemed worthwhile to reappraise the relative importance of the magnetic anisotropy effects and of electrostatic shielding with the methods described in parts I–VI of this series (6–11). In addition to studying the shielding effects in cyano-steroids an attempt was made to predict CN induced shift increments in two isomeric cyano-norbornenes.

[1]Taken in part from the M.Sc. thesis of D. K. Todd, Carleton University, Ottawa, Canada, September 1971.

Results and Discussion

The screening contribution at a given proton due to the magnetic anisotropy of axially symmetric groups (δ^M) is given by McConnell's equation (12):

$$[1] \qquad \delta^M = \Delta\chi(1 - 3\cos^2\theta)/3R^3 = \Delta\chi g^M$$

The shift increment caused by the electric field effect of polar groups (δ^E) is given (13) by eq. 2,[2] where

$$[2] \qquad \delta^E = K(2\cos\theta\cos\phi + \sin\theta\cos\psi)/R^3 = Kg^E$$

$\Delta\chi$ is the magnetic anisotropy and K is a parameter descriptive of the electric field effect. The geometric quantities are defined in Fig. 1. If it is assumed that the complete group C—C≡N can be represented by a single point dipole, the change in chemical shift of a proton upon substitution, somewhere in the molecule, of C—H by C—CN is given by eq. 3. Although it had

$$[3] \quad \delta(\text{calc}) = \delta^M(\text{CN}) + \delta^E(\text{CN}) - \delta^M(\text{CH}) = \Delta\chi(\text{CN})g^M(\text{CN}) + K(\text{CN})g^E(\text{CN}) - \Delta\chi(\text{CH})g^M(\text{CH})$$

[2]See ref. 9, Appendix and ref. 10.

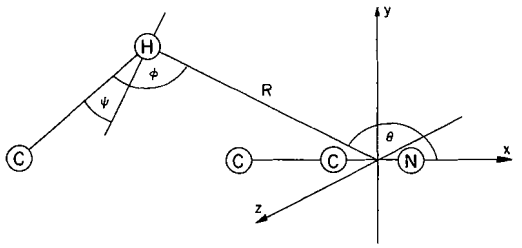

FIG. 1. Definition of geometric quantities. ψ is the angle between the C—H bond and the vector in the plane defined by R and CN and perpendicular to R (see ref. 9, Appendix).

previously been found (10) that the C—H bond anisotropy is small and may safely be neglected, $\Delta\chi$(CH) was included as a variable in one series of calculations to obtain an additional estimate of the magnitude of this parameter. To assess the relative importance of the first two terms was one of the main purposes of this study.

The geometric quantities in eq. 3 for the cyano-steroids were computed from the X-ray data for androsterone (14) (5α,14α-androstane skeleton) and digitoxigenin (15) (15β,14β-androstane ring system). The X-ray data for a *syn*-benzonorbornene derivative (20) were used for the calculations in the cyano-norbornene series. For the derivation of the C—CN (and C—H) bond vectors, tetrahedral valency angles were assumed. The locations of the coincident magnetic and electric point dipoles representing the cyano group, were varied along the bond axes in steps of 0.2 Å. Where the C—H bond anisotropy term was included in the calculations, this dipole was placed 0.8 Å from carbon. In the cyano-steroid series the chemical shifts of the methyl groups were approximated by the averages of the shielding at 72 points around the circle of rotation of the methyl protons, 5° apart (denoted by angle brackets around g^{M}(CN), g^{E}(CN), and g^{M}(CH) in Tables 1 and 2).

In order to assess the relative importance of the magnetic anisotropy effect and the electrostatic shielding of the cyano group, δ(calc) was first equated to δ^{M}(CN), then to δ^{E}(CN), and finally to the sum of the two terms, varying the CN dipole position each time. In addition, as mentioned earlier, the term δ^{M}(CH) was included once.

The results of calculations for both series of compounds, cyano-steroids and cyano-norbornenes, indicate that the electric field effect is the important shielding mechanism of the nitrile group (Table 3), as found by Zürcher (5). The values obtained for K(CN), -13.9 and -13.0×10^{-12} e.s.u. respectively, also agree well with Zürcher's result of -12.2×10^{-12} e.s.u. (5). The standard deviation between experimental and calculated shifts had a minimum near the midpoint of the CN group, 2.1 Å from the ring carbon, and increased only slowly as the dipole location was moved away from this point in either direction. Inclusion of the term δ^{M}(CN) had little effect on the electric field parameter K(CN); $\Delta\chi$(CN) was found to be small and the fit with the experimental shifts did not improve. Inclusion of the anisotropy term for the displaced CH bond, δ^{M}(CH), also had little effect on the other parameters and the calculated shifts. This is further evidence that the CH bond is practically magnetically isotropic.

With a few exceptions the chemical shifts were predicted well in the cyano-steroid series (Table 1). It is somewhat surprising that the predicted shift increment in the case 5β/19 is wrong whereas the calculated shifts in the related cases 2β/19 etc. agree well with experiment. It is likely that the point dipole approximation is inadequate in both situations. Similarly van der Waals interactions might be expected to make comparable contributions in both cases. It is possible that the explanations are in the greater flexibility of the *cis*-fused system which may permit larger conformational changes in the case of the 5β-cyano derivative. It is tempting to ascribe the large error in the case 11β/19 to the fact that the cyano group is virtually sandwiched between the C-18 and -19 methyl groups, although δ(calc) for the case 11β/18 fits rather well. The lack of agreement in the cases 16α/18 and 16β/18 might be due to conformational effects. The nitriles for which shift data were available had an acetyl group in the 17β-position and in some cases a 17α-hydroxyl group as well. As a result of substituent interactions, upon introduction of a nitrile group, either the conformation of the D-ring or the orientation of the highly anisotropic and polar C=O bond of the acetyl group might change. Since calculations with geometric quantities based on X-ray data for steroids with the 16β-bromo, 17α-hydroxy, 17β-acetyl moiety (16, 17) gave essentially the same (incorrect) shifts, the second explanation seems to be more convincing. It is hoped that methyl shifts will

become available for steroids whose only substituent in the D-ring is a nitrile group.[3]

Although the calculations in the cyano-norbornene series gave essentially the same values for the parameter K(CN), the chemical shifts were not predicted as well as in the cyano-steroid series. The disagreement with experiment is especially serious for the predictions of the chemical shifts of protons α to the CN group, in particular in the cases $2n/3n$ and $2n/3x \simeq 2x/3n$, and in the case $2x/7a$. The problem of the 3-protons was also encountered by Zürcher and is extensively discussed in ref. 5. It is possible that the discrepancy in the case $2x/7a$ is also due to a modification of the solute solvent interaction as suggested by Zürcher for the cases $2n/3x$ and $2x/3n$ (5). Rotation of the CH or C—CN bond vectors in the H—C—H plane by up to $\pm 5°$ had little effect on the geometric factors and chemical shifts. Exclusion of these situations from least squares analysis led to almost the same values for the shielding parameters and did not improve the fit with experiment materially for the remaining cases.

Thus it is concluded that it is mainly the electrostatic shielding, assumed to arise from a point dipole at the CN bond center, that is responsible for the long-range shielding effects of the nitrile group. It is interesting that the calculations both for the steroidal and the bicyclic nitriles led to the same conclusions regarding the shielding mechanism, and gave almost the same value for the electric field parameter K(CN), despite the fact that in the cyano-norbornene series the chemical shifts could not be predicted with any accuracy. The magnetic anisotropy effect of the CN group may make minor contributions to the chemical shifts, but in view of the approximations used and the present results, little appears to be gained by including the anisotropy term.

Experimental

All chemical shift values were taken from the literature and converted to Hz and 100 MHz. Solvent was $CDCl_3$ in the case of the cyano-steroids and CCl_4 for the cyano-norbornenes. The calculations were performed on the SIGMA 6 computer at Carleton University. Programs (in FORTRAN) are available on request.

Self Association of Folic Acid in Aqueous Solution by Proton Magnetic Resonance

YUI-FAI LAM AND GEORGE KOTOWYCZ
Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received January 18, 1972

Proton magnetic resonance experiments on the disodium salt of folic acid in aqueous solutions (p*D* 7.1) indicate that the folate ion exists in an unfolded, extended conformation in solution. However, based on a temperature and concentration dependence of the proton chemical shifts, folate ions are involved in intermolecular association consisting of a vertical stacking interaction. A stacking model is proposed for the association with the hydrophilic ends of the molecule alternating in orientation with respect to the hydrophobic portion of the neighboring molecules.

Les expériences de r.m.n. sur le sel dissodique de l'acide folique en solutions aqueuses (p*D* 7.1) indiquent que l'ion folate existe dans une conformation non plissée et étirée. Cependant, les résultats fondés sur l'influence de la température et de la concentration sur les déplacements chimiques du proton montrent que les ions folates sont impliqués dans une association intermoléculaire régie par une interaction due à un empilement vertical. Un modèle pour cet entassement est proposé où les bouts hydrophiliques de la molécule alternent en orientation avec la portion hydrophobique des molécules voisines.

Canadian Journal of Chemistry, **50**, 2357 (1972)

Introduction

Folic (pteroylglutamic) acid (**1**) has been extensively studied and the properties of this water-soluble vitamin have been well described (1–4). Metabolically, a deficiency of folic acid is observed in the failure to make the purines and thymine required for DNA synthesis (2). A component of the above molecule, 2-amino-4-hydroxy-6-substituted pteridine has been implicated (5) in the primary photochemical reduction in photosynthesis.

Following the observation of a large concentration dependence of the folic acid proton chemical shifts in aqueous solution (Fig. 2), the present study was initiated and is concerned with the further study of the self-association properties of this molecule in aqueous solutions. Pastore (6), on the basis of preliminary p.m.r. experiments, has shown that folic acid and several of its derivatives are involved in the formation of complexes, of unknown conformation in solution. However, the molecule may exist either in an unfolded conformation or in a folded conformation with the two rings superimposed over each other. A folded conformation is observed for many coenzymes, examples being the pyridine dinucleotides (7–15) and flavin adenine dinucleotide (FAD) (16–19). Besides these intramolecular interactions, intermolecular association equilibria must be considered. Nucleosides and nucleotides stack in solution (20, 21) whereas benzylpenicillin ions (22) form micelles. Based on a temperature and concentration dependence of the proton chemical shifts, disodium folate exists in solution in an extended, non-folded conformation. The ions stack in solution and a possible model for this stacking interaction is proposed.

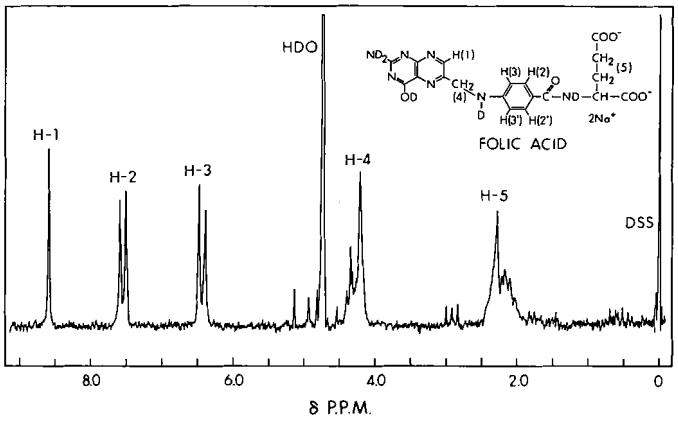

FIG. 1. The 100.0 MHz n.m.r. spectrum of 0.049 *m* disodium folate in D_2O (p*D* 7.1; 30.5 °C). The chemical shifts are with respect to internal DSS.

Angeles, California, was dissolved in a minimal amount of aqueous sodium hydroxide. Further purification was carried out by passing the salt through a cation exchange column and the effluent was freeze-dried. The labile protons were exchanged by dissolving disodium folate in D_2O and freeze-drying the solutions three times. Solutions for the n.m.r. experiments were prepared by weighing out the salt and the internal reference sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) (0.8 mg/g of D_2O) and dissolving them in a weighed amount of D_2O. The p*D* was 7.1 ± 0.1 (meter reading + 0.4) (23). The titration curve for folic acid showed that in solution at a p*D* of 7.1 folic acid exists as the disodium salt. *p*-(Methylamino)benzoic acid, obtained from K & K Laboratories, Inc. and DSS from Merck, Sharp and Dohme of Canada Ltd., were both used without further purification. The solvent D_2O from Columbia Organic Chemical Co. was distilled before use. 2-Amino-4-hydroxy-6-methyl pteridine was a gift from Dr. R. B. Angier of the Lederle Laboratories Division, American Cyanamid Company (24). It only dissolves in an aqueous solution at a p*D* of 12.9.

Instrumentation

The p.m.r. measurements were carried out on the Varian HA-100-15(100.0 MHz) and the Brüker HFX-90(90.0 MHz) NMR spectrometers. For measurements on the Varian spectrometer, tetramethylsilane (TMS) (5%) in deuterated acetone in a co-axial tube was used for the lock signal. The solution temperatures were calibrated within ± 0.5 °C before and after each set of measurements using an ethylene glycol sample obtained from Dr. O. Yamamoto, Government Chemical Industrial Research Laboratories, Tokyo, Japan (25). Measurements on the Bruker spectrometer were carried out using a heteronuclear ^2D lock and the lock signal was derived from the deuterium resonance of the solvent D_2O. The temperature was calibrated using the built-in thermocouple temperature control unit. Several measurements of the chemical shifts were made at various temperatures on both spectrometers and were in agreement within experimental error. All samples remained in the probe for 25 min to reach thermal equilibrium before spectra were obtained. All chemical shifts were calibrated with respect to internal DSS and represent the average of three measurements.

Results

The 100 MHz p.m.r. spectrum of 0.049 *m* disodium folate in D_2O (p*D* 7.1) is shown in Fig. 1 together with the assignment of the resonances. The chemical shifts of protons 1 to 4 were determined using a first order analysis. The singlet at lowest field corresponds to proton H-1 of the pteridine ring. The low-field

doublet with a chemical shift of 7.6 p.p.m. and the high-field doublet at 6.4 p.p.m. were assigned to protons H-2 and -3 of the para-disubstituted benzene moiety of the molecule. These two assignments are based on the proton chemical shifts observed in substituted benzene derivatives (26, 27). The singlet at 4.2 p.p.m. corresponds to proton H-4 whereas the multiplet just to low field of this resonance corresponds to the α-CH proton of the glutamic acid residue of the folate ion. The spectrum of the CH_2—CH_2 (H-5) fragment of the glutamic acid residue was very complex yet remained completely unchanged with a change of temperature or concentration. Hence the position of the most intense line of the multiplet was used as a monitor of the chemical shift of these protons. In fact, calibration of the positions of each of the lines in the multiplet showed them to be independent of temperature and concentration.

A pronounced concentration dependence of the chemical shifts of protons H-1 to -4 was observed for the folate ion in the concentration range from 0.0091 *m* up to the solubility limits of the ion. The results of the measurements at 30.5 °C and p*D* 7.1 are summarized in Fig. 2. A least-squares analysis using the IBM-360/65 computer was applied to the data and the chemical shifts of the protons at infinite dilution were thus determined. These are given in Table 1. The resonances corresponding to protons H-1 to -4 shift to higher field with an increase in solute concentration. This diamagnetic shielding effect is largest for protons H-3 and -4, namely 0.5 p.p.m. over the concentration range of 0.0–0.094 *m*. It is much smaller for protons H-1 and -2 (0.25 p.p.m.) whereas the glutamic acid fragment methylene protons (H-5) are concentration independent. Infinite dilution chemical shifts have also been determined for the H-2 and -3 protons of disodium folate at 60 °C and are 7.68 ± 0.02 and 6.83 ± 0.02 p.p.m., respectively.

Proton chemical shifts for the H-1 to -4 folate ion protons were also studied over a 60° temperature range at two concentrations, namely 0.009 and 0.049 *m*. The temperature measurements are summarized in Fig. 3. The proton chemical shifts for the folate ion at infinite dilution (Table 1) (30.5 °C) are within

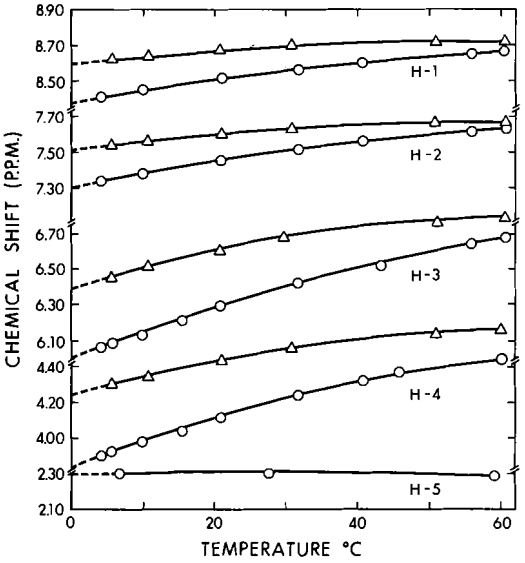

FIG. 3. The temperature dependence of the proton chemical shifts of disodium folate in D_2O (p*D* 7.1). The measurements are carried out at two concentrations, namely: ○ 0.049 *m*; △ 0.009 *m*.

0.05 p.p.m. of the chemical shifts obtained for the 0.009 *m* solution at the highest temperature (Table 2). The H-5 proton chemical shift is completely temperature independent (0.049 *m* solution, Table 2 and Fig. 3) even at the highest concentration (0.094 *m*).

Discussion

Intramolecular interactions of the folate ion may be studied by comparing the chemical shifts of the folate ion protons at infinite dilution, when intermolecular shielding effects are minimized, with the chemical shifts observed for nearly equivalent protons in a model compound. The model compounds chosen were sodium *p*-(methylamino)benzoate and 2-amino-4-hydroxy-6-methyl-pteridine because of their structural similarities with fragments of the folate ion. The proton chemical shifts of sodium *p*-(methylamino)benzoate are concentration and temperature independent and a comparison of the H-2 and -3 proton chemical shifts in the folate ion with those in the model compound at 30.5 °C shows that proton H-3 is shielded by 0.03 p.p.m. whereas proton H-2 is shielded by 0.11 p.p.m. in the folate ion at infinite dilution. These chemical shift differences are much smaller than those arising either from intermolecular or intramolecular diamagnetic ring current shielding in molecules such as flavin adenine dinucleotide (16, 18). Proton H-2 in the folate ion is adjacent to a C(O)—NH-group whereas in *p*-(methylamino)benzoate it is adjacent to a carboxyl group. This will contribute to the 0.11 p.p.m. difference of the H-2 proton chemical shifts. These results indicate that protons H-2 and -3 in the folate ion do not experience a diamagnetic ring-current shielding effect which would arise if the pteridine portion of the molecule was folded over the aromatic benzene ring. Therefore the folate ion exists in an unfolded, extended conformation in solution (Fig. 4).

This result is supported by several other experiments. A similar comparison of the H-2 and -3 proton chemical shifts at infinite dilution at 60 °C, when intramolecular interactions should decrease, again shows small chemical shift differences. Proton H-2 is shielded by 0.09 p.p.m. whereas proton H-3 is deshielded by 0.06 p.p.m. The chemical shift of the H-1 proton of disodium folate can only be compared with the chemical shift of the corresponding proton in the second model compound 2-amino-4-hydroxy-6-methyl-pteridine at a p*D* of 12.9 when the latter compound begins to dissolve. The chemical shifts for this proton at infinite dilution (30.5 °C) are given in Table 1. Proton H-1 experiences a very small deshielding (0.1 p.p.m.) in disodium folate with respect to the model compound. However, the pteridine ring in the two molecules may be ionized to slightly different extents at a p*D* of 12.9 so this comparison should be treated cautiously.

The unfolded, extended conformation for the folate ion in aqueous solution is supported by the temperature studies. From Fig. 3 smooth, monotonic curves are obtained for the temperature dependence of the proton chemical shifts. Sigmoidal curves, characteristic of an equilibrium between folded and unfolded conformers in solution, were not observed. A CPK model of the molecule also indicates that the folded conformation would be highly strained.

In considering intermolecular associations, dilution shifts for aromatic systems are usually of the order of 1 p.p.m. ranging from a pure liquid to the liquid at infinite dilution (28). In organic solvents the dilution shift of azulene in dioxane is 0.1 p.p.m. for the five-membered ring

*The chemical shifts are to low field of internal DSS.
†A positive value of Δ indicates a net shielding of the folate protons at 5.8 °C with respect to 60.0 °C.

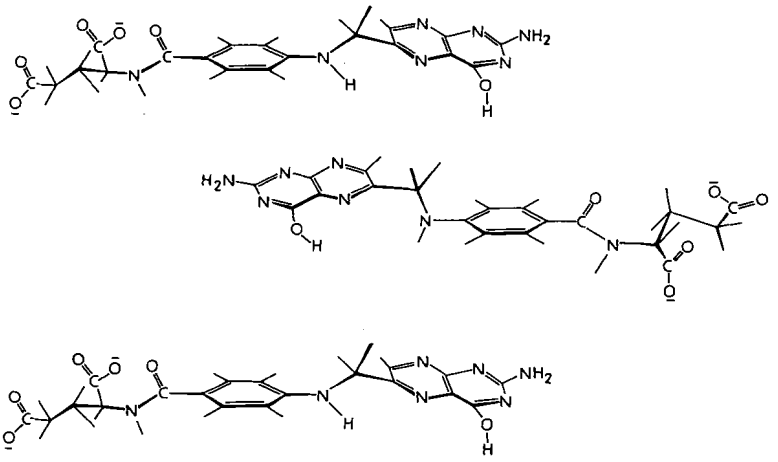

FIG. 4. The proposed, alternating, head-to-tail intermolecular stacking model for folate ions in aqueous solution (pD 7.1).

protons and 0.25 p.p.m. for the seven-membered ring protons in going from a 20 mol % to a 3 mol % solution. However, for aqueous solutions intermolecular association between bases, nucleosides, and nucleotides has been well studied (20). The concentration dependence for protons in purine ranges from 0.69–0.48 p.p.m. over the concentration range 0.0–1.0 m (about 2 mol %) (29). The concentration dependence observed for the folate ion in going from a 0.094 m solution (about 0.2 mol %) to infinite dilution is 0.27, 0.22, 0.47, and 0.52 p.p.m. for protons H-1 to -4 respectively. Hence intermolecular association is proposed for folate ions in aqueous solution.

The large shielding of the aromatic protons with an increase in concentration or a decrease in temperature suggests that intermolecular association consists of a vertical stacking interaction. The data in Table 1 and Fig. 2 indicate that protons H-3 and -4 experience a concentration dependence which is twice as large as that experienced by protons H-1 and -2. The much larger diamagnetic shielding of H-3 and -4 is also observed in the temperature studies. From the data in Table 2 and Fig. 3, for a given temperature interval, the chemical shifts of protons H-3 and -4 vary twice as much as for protons H-1 and -2. This is interesting, especially in view of the fact that both protons H-2 and -3 are part of the same aromatic ring. The glutamic acid fragment methylene protons are temperature and concentration independent.

Intermolecular stacking may occur with the planes of the hydrophobic ends of the molecules stacking one above the other with the hydro-

philic groups all next to each other (head-to-head interaction) or in a vertical stack with the hydrophilic ends of the molecule alternating in orientation with respect to the hydrophobic portion of the neighboring molecules (head-to-tail interaction). For head-to-head intermolecular association, proton H-1 of the pteridine ring would be very closely associated with the pteridine ring of the neighboring molecule. Similarly, protons H-2 and -3 of the para-disubstituted benzene fragment of the folic acid molecule will be closely associated with the neighboring molecule aromatic ring. Hence all three protons would be shielded to the same extent by the magnetic anisotropy of the neighboring ring and would exhibit a similar dependence on concentration. However, this is not observed. In fact, the concentration dependence of protons H-3 and -4 is twice as large as that for protons H-1 and -2 (Table 1). This is surprising also since both protons H-2 and -3 are on the same aromatic ring.

Since protons H-3 and -4 experience the largest diamagnetic shielding, they are most closely associated with the shielding region of a neighboring molecule whereas protons H-1 and -2 are further removed. From a study of molecular models, this is possible only for head-to-tail vertical stacking. A possible intermolecular association model is shown in Fig. 4. From this model it is seen that protons H-3 and -4 are associated with the aromatic ring-current shielding cone of the neighboring molecule pteridine base, protons H-1 and -2 are further removed from a ring-current shielding area whereas the protons of the glutamic acid residue are completely concentration independent and hence removed from any ring-current effects.

Finally, the possibility of micelle formation was investigated. If folate ions should form a spherical micelle with all hydrophobic groups associating together and the hydrophilic, carboxyl groups projecting outwards, protons H-1 to -4 would be expected to exhibit a similar dependence on concentration. This was not observed. Secondly, a mathematical treatment (30) in which the proton chemical shifts are plotted *vs.* the reciprocal of the concentration was carried out. Smooth curves were obtained for all protons and the sharp change in the slope of the curves, corresponding to a critical micelle concentration, was not observed. Therefore it is unlikely that folate ions undergo micelle formation as do the benzylpenicillin ions (22).

Conclusions

The p.m.r. experiments on disodium folate in aqueous solution (p*D* 7.1) indicate that the folate ion exists in an unfolded, extended conformation in solution. Folate ions, however, are involved in intermolecular association consisting of a vertical stacking interaction. A head-to-tail vertical stacking model is proposed with the hydrophilic ends of the molecule alternating in orientation with respect to the hydrophobic portion of the neighboring molecules.

We are grateful to Dr. Kikuko Hayamizu for valuable discussions, to Dr. R. B. Angier for the gift of 2-amino-4-hydroxy-6-methyl-pteridine, and to the National Research Council of Canada for financial support.

Concerning the Discrepancies in the Reported Infrared Spectra of Dibenzo[*a*,*e*]cyclooctatetraene[1]

THEODORE W. CUTSHALL AND PETER W. RABIDEAU[2]

Department of Chemistry, Indiana-Purdue University at Indianapolis, Indianapolis, Indiana 46205

Received February 1, 1972

Controversy has existed concerning the several syntheses of dibenzo[*a*,*e*]cyclooctatetraene. This controversy has resulted from a discrepancy with the i.r. spectrum contained in one of the original preparations with subsequent samples. We have prepared this hydrocarbon, together with 7-methylenedibenzo[*a*,*e*]cycloheptatriene, and have concluded that this discrepancy has arisen from a mixup of spectra (or samples) with this latter hydrocarbon.

Il existait une controverse concernant plusieurs synthèses du dibenzo[*a*,*e*]cyclooctatétraène. Cette controverse résultait d'une différence observée dans le spectre i.r. d'une des préparations originales avec les échantillons subséquents. Nous avons préparé cet hydrocarbure ainsi que le méthylène-7 dibenzo[*a*,*e*]cycloheptatriène et avons conclu que la divergence était due au mélange des divers échantillons (ou spectres) avec ce dernier hydrocarbure.

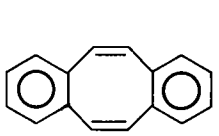
Canadian Journal of Chemistry, **50**, 2364 (1972)

The synthesis of dibenzo[*a*,*e*]cyclooctatetraene (1) was originally reported by Fieser and Pechet (1). In an attempt to provide a more useful preparation of this interesting hydrocarbon, its synthesis was later undertaken by Cope and Fenton (2). These workers prepared samples by a new method and by Fieser's method, and reported them to be identical. In this connection, they published the i.r. spectra of both samples, showing them to be identical. This hydrocarbon has subsequently been prepared by several investigators (3). However, a serious discrepancy exists concerning the integrity of the various preparations. Griffin (3*c*) pointed out that his i.r. spectrum of **1** was identical to the spectrum reported by Wittig (3*a*), but different from that reported by Cope (2). This same observation was later reported by another group of investigators (3*e*, 4). However, Nenitzescu (3*b*) and Schröder (3*d*) have reported their samples of **1** to be identical with that of Fieser (1) (and Cope (2)). We would now like to report our results which provide a solution to this puzzling problem.

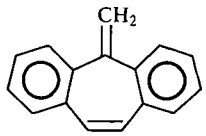
[1]This research was supported in part by grants from the Eli Lilly Company, and the Purdue University Cancer Research Committee.

[2]To whom correspondence should be addressed.

In a paper immediately following the report on **1**, Cope and Fenton also reported the synthesis and i.r. spectrum of **2** (5). We have prepared samples of dibenzo[*a*,*e*]cyclooctatetraene (**1**) and 7-methylenedibenzo[*a*,*e*]cycloheptatriene (**2**), made certain of their identities by their n.m.r. spectra, and recorded the i.r. spectra.



1



2

We have found that our i.r. spectrum of **1** is superimposable with that *reported by Cope for compound* **2**, *and our spectrum of* **2** *is superimposable with that reported by Cope for* **1**. Hence, it appears that all of the synthetic procedures which have appeared in the last 25 years are correct, and the controversy merely resulted from a mixup of spectra (or samples).

Experimental

Dibenzo[a,e]cyclooctatetraene (1)

This was prepared by the photolysis of dibenzobarrelene (3*e*, 4). The i.r. spectrum was identical with that published by Wittig (3*a*) with major absorptions at 12.9 and 13.4 μ.

The n.m.r. δ 7.0 (m, 8H) aromatic and 6.6 (s, 4) vinyl is consistent with the structure of **1**, and identical with that previously reported (4).

7-Methylenedibenzo[a,e]cycloheptatriene (2)

Samples were prepared by two methods: (*a*) by refluxing **1** with an excess of *p*-toluenesulfonic acid hydrate in benzene followed by refluxing the tosylate with sodium hydroxide–ethanol,[3] and (*b*) by reacting dibenzo[*a*,*e*]cycloheptatrienone with methylmagnesium iodide followed by dehydration (2). After recrystallization from aqueous ethanol, the respective samples proved identical, m.p. 117–118° (lit. (6) 118–119°). The i.r. showed major absorptions at 11.0, 12.3, 12.5, and 12.9 μ, and was identical with that published by Cope (2), incorrectly indicated as **1**. The n.m.r. δ 7.35 (m, 8H) aromatic, 6.82 (s, 2) vinyl, and 5.25 (s, 2) *exo*-vinyl is quite consistent with the structure of **2**.

Thermal Rearrangement of Acyl Groups in Anhydronucleosides. A Convenient Synthesis of 5′-*O*-Acetylanhydrouridine[1]

K. K. Ogilvie, J. B. Westmore, G. Taylor, D. Lin, D. Iwacha,[2] H. Wayborn, and G. E. Dunn

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received March 8, 1972

The mass spectra of acylanhydronucleosides suggested that the acyl groups undergo a thermal rearrangement. This was confirmed by studying the melting profiles of these compounds in a differential scanning calorimeter. The results have led to a convenient synthesis of 5′-acetylanhydrouridine.

Les spectres de masse des acylanhydronucléosides laissent penser que les groupes acyle subissent un réarrangement thermique. Ceci a été confirmé par l'étude des profils de fusion de ces composés, dans un calorimètre à balayage différentiel. Les résultats ont conduit à une synthèse commode de l'acétyl-5′ anhydrouridine.

Canadian Journal of Chemistry, **50**, 2365 (1972)

We have recently developed a method for incorporating 2′-anhydronucleosides into nucleotide chains (1). To permit maximum flexibility in this approach we needed acid- and base-labile protecting groups for both the 3′- and 5′-positions. Further, these groups should be sufficiently labile to be removed without opening the anhydro-ring, yet stable during phosphorylation procedures. The monomethoxytrityl (MTr—) and the acetyl (—Ac) groups satisfy these requirements for acid- and base-labile protecting groups respectively. Schemes 1 and 2 (to be discussed later) illustrate the methods by which 3′- and 5′-*O*-acetyl derivatives can be prepared. These multistep procedures are required because acetylating reagents generally have little preference for reaction at the 5′-position *vs.* the 3′-position. 5′-Derivatives in particular are not easy to prepare in high overall yield in just a few reaction steps. For example 5′-*O*-acetylanhydrouridine has been prepared by Todd and co-workers (2) and Verheyden and Moffat (3) both using the same five-step synthesis from uridine giving an overall yield of about 25%. We wish to report a simple synthesis of 5′-*O*-acetyl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (5′-AcAU, **6**) by a method suggested from our mass spectral investigations of 3′,5′-di-*O*-acetyl-2,2′-anhydro-1-β-D-arabino-

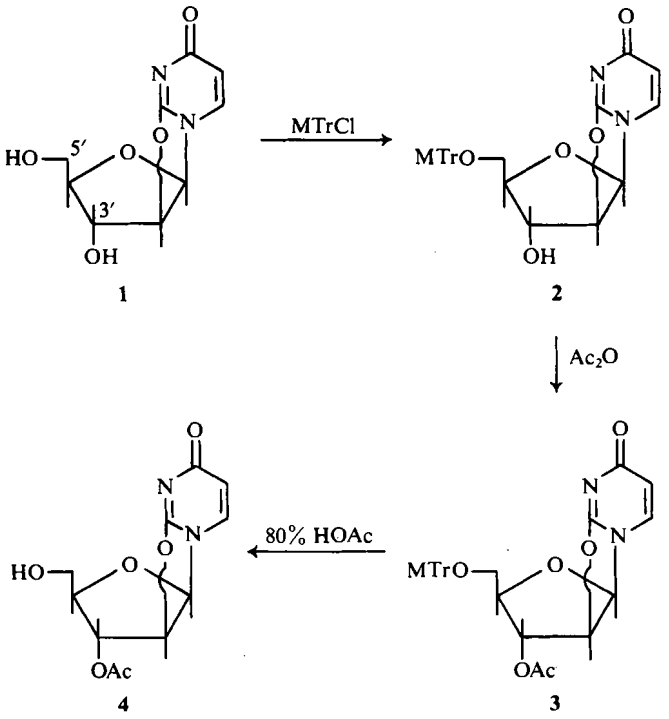

SCHEME 1

furanosyluracil (DiAcAU, **5**) and 3′-*O*-acetyl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (3′-AcAU, **4**).

As part of our investigation of anhydronucleosides we have been carrying out a systematic study of their mass spectra. A sample of 3′-AcAU was prepared by the route shown in Scheme 1. Monomethoxytrityl chloride (MTrCl) reacts with 2,2′-anhydro-1-β-D-arabinofuranosyluracil (AU, **1**) in pyridine to produce 5′-*O*-monomethoxytritylanhydrouridine (**2**) in 60% yield. Acetylation of **2** to produce **3** followed by detritylation using acetic acid at room temperature yields **4**.

In the course of the mass spectral studies we noticed that the mass spectra obtained when **4** and **5** were introduced into the mass spectrometer were similar. In particular, the mass spectrum obtained when **4** had been placed in the mass spectrometer sample probe showed a peak at *m/e* 310 (mw of **5** is 310) as well as at *m/e* 268 (mw of **4**) and at 226 (mw of **1**). Samples of **4** were carefully analyzed by paper chromatography before they were introduced into the mass spectrometer. No diacetylanhydrouridine or anhydrouridine could be detected in these samples under conditions where less than 1% could be detected. However, when the unvaporized residues were removed from the mass spectrometer sample probe (after the spectrum had been recorded) and analyzed by paper chromatography they were always found to contain **1**, **4**, **5**, and a material moving slightly faster (solvent A) than **4**. This unidentified material had an u.v. spectrum characteristic of anhydrouridines and was suspected to be 5′-*O*-acetyl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (**6**).

We synthesized **6** by an alternate route (Scheme 2) for comparison with our unidentified derivative. 5′-Acetyluridine (4) was treated with diphenyl carbonate in dimethylformamide (5) to give **6**. Compounds **1** and **5** were also detected among the products but no **4** was observed. The yield of **6** from this reaction was 45%. We found the synthetic **6** to be identical to our unidentified material from the residue recovered from the mass spectrometer when **4** had been inserted into the sample probe.

The mass spectrum of **6** was similar to that of **4** showing again major peaks at *m/e* 310, 268, and 226. The relative peak heights differed in

AU	6.6	21	23	25

the two cases. The paper chromatographic analyses of the residues recovered from the sample probe are shown in Table 2. Similar mass spectral results were obtained when samples were studied with a Finnigan 1015 quadrupole mass spectrometer.

The mass spectrometric results are not an artifact of electron impact but are evidently thermal in origin. The thermal rearrangement of the anhydro-derivatives was studied further in a differential scanning calorimeter (Perkin–Elmer DSC-1B). Samples of **4** were heated from room temperature to 260 °C at 10°/min in specially designed glass containers (6) sealed at reduced pressure. The results of paper chromatographic analyses are shown in Table 1. These results clearly show that the rearrangement was affected only slightly by reduction in pressure (at atmospheric pressure a small amount of decomposition to a material having a uracil-like u.v. spectrum occurred). The rearrangement was also independent of whether a glass or aluminum sample holder was used. Subsequent experiments were carried out in aluminum pans at atmospheric pressure.

Tables 1 and 2 show that compound **6** undergoes a thermal rearrangement to produce the same kind of products obtained from **4**. The presence of diacetylanhydrouridine in the products clearly indicated that some intermolecular transesterification had occurred. As

a result a mixture of **5** and **1** was heated to 260 °C under controlled conditions in the DSC. The presence of **6** as the major product (Table 2) was encouraging. There was also a significant amount (9%) of decomposition to material having a uracil-like u.v. spectrum (this could result from cleavage of either the anhydro or both the anhydro and glycosidic bonds to give uracil derivatives).

To test the utility of the method as a source of **6** on a preparative scale, 100 mg of a mixture of **5** and **1** (1:1.15 mol ratio) was placed in a small test tube which was suspended in an oil bath maintained at 260 °C (this temperature would ensure rapid melting of the mixture). Complete melting occurred in 55 s and the sample was cooled rapidly to room temperature. The products, isolated by chromatography, contained **6** and **4** in 51 and 12% yields (crystallized from methanol) respectively. Since the monoacetyl derivatives have very similar properties, a combination of thick-layer and paper chromatography was required to separate them. This difficulty is easily avoided by heating the mixtures in the melt for slightly longer periods of time. This results in exclusive formation of the 5′-isomer **6** which is readily isolated and in higher yields by thick-layer chromatography in tetrahydrofuran. The reaction is easily carried out on larger scales in the same manner. The method of heating is not critical and for our own purposes the sample is kept in the melt for 2–3 min using a gas-burner for heat and in all cases only the 5′-isomer is obtained. This represents an exceedingly simple synthesis of **6** from readily available materials.

In the preparative reaction some decomposition had occurred to yield products having a uracil-like spectrum. These products were very numerous and only uracil was positively identified. Most of the other products were probably acetylated uridines or arabinouridines. Samples maintained at 260 °C for longer periods of time gave greater amounts of decomposition products. Uracil was the only identifiable product from a reaction mixture held at 260 °C for 15 min.

In order to check on the generality of this rearrangement, samples of 3′-*O*-pivaloylanhydrouridine (PvAU) and a mixture of 3′,5′-di-*O*-pivaloylanhydrouridine (DiPvAU) and anhydrouridine were heated in the DSC from room temperature to 270 °C at 10°/min. The results, shown in Table 2, confirm that rearrangement had occurred. We have been unable to separate mixtures of 3′-PvAU and 5′-PvAU and as a result only the sum of the two is shown in Table 2.

A similar thermal transfer of acetyl groups in nucleoside derivatives using a fusion method has been described by Michelson *et al.* (7). In their case acetyl groups migrated among secondary hydroxyl groups in protected adenosine derivatives. In our case the migration occurs between secondary and primary hydroxyls with the product being the more stable primary ester.

We also heated samples of **4** and **6** individually in dimethylformamide solutions held at 150 °C and found that rearrangement also occurred in solution. These results are shown in Table 1.

This study has produced a very useful route to 5′-*O*-acetylanhydrouridine. However, it also points out the necessity of exercising care when interpreting the mass spectra of semiesterified molecules of low volatility.

Experimental

General Methods

Thin-layer chromatography was carried out on Eastman Chromagram Sheets 6060 by the ascending technique. Thick-layer chromatography was carried out on glass plates (20 × 20 cm) coated with a 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd.). Paper chromatography was carried out on Whatman 3MM paper by the descending technique. The solvent system employed in paper chromatography was solvent A; *n*-butanol:ethanol:water (4:1:5, v/v/v), the organic phase was used. Nucleosides and their derivatives were detected on paper chromatograms, thin- and thick-layer plates, using an u.v. source (Mineralite, output ≃ 254 nm). Nucleosides were eluted from the paper chromatograms, diluted to volume and their absorbances recorded in the u.v. on a Cary 14 spectrophotometer. The term o.d. unit (8) refers to the extinction of a solution of a nucleoside at neutral p*H* in 1 ml of solution using a 1 cm light path quartz cell.

The i.r. spectra were obtained on a Perkin–Elmer 337 recording instrument using KBr disks for sample preparation. Melting points were determined on a Fisher–Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Labs, Knoxville, Tennessee.

Mass Spectra

Mass spectra were recorded by a Perkin–Elmer Hitachi RMU-6D single-focusing instrument. Samples were introduced to the mass spectrometer in a solid sample probe via a vacuum lock. The electron energy was 50 V. After preliminary experiments the following procedure was used. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ionization chamber temperature and sample heater block were each maintained at 135 °C. The sample probe was inserted into the heater block and spectra were recorded as soon as vaporization started to occur. After the spectra were recorded (total time 15 min) the remains of the samples were withdrawn from the instrument and analyzed by paper chromatography. Results of these experiments are shown in Table 1. Clearly **1**, **4**, **5**, and **6** were obtained when starting with pure samples of either **4** or 6.

Calorimetric Studies

Samples were heated through the melting endotherm (6) in a differential scanning calorimeter (Perkin–Elmer DSC-1B). Typical samples of 2–10 mg and a heating rate of 10°/min were used. After melting, the samples were removed, cooled to room temperature, and analyzed by paper chromatography in solvent A. The results are shown in Table 2. In some cases a product moving slightly faster than DiAcAU (solvent A) was observed. The u.v. spectrum (water) of this material was similar in form to that of uracil with λ_{max} at 260 nm (this compound was most likely an acetylated uridine or arabinouridine resulting from some decomposition of the anhydro-structure).

3′-*O*-Pivaloyl-2,2′-anhydrouridine, 5′-*O*-pivaloyl-2,2′-anhydrouridine, and 3′,5′-di-*O*-pivaloyl-2,2′-anhydrouridine were prepared as described by Wayborn (9). 2,2′-Anhydrouridine was prepared by the method of Hampton and Nichol (5).

5′-O-Monomethoxytrityl-2,2′-anhydrouridine (MTrAU, 2)

Anhydrouridine (4.35 g, 19.2 mmol) and monomethoxytrityl chloride (6 g, 19.5 mmol) were stirred in dry pyridine (100 ml) for 4 days. The solvent was removed at reduced pressure and the residue was dissolved in a mixture (300 ml) of chloroform and water (1:1). The chloroform layer was separated and concentrated to a small volume. White crystals of MTrAU separated and were collected by filtration (5.7 g, 60%), m.p. 154–158 °C. Principal bands in the i.r. spectrum occurred at 6.07, 6.13, 8.05, and 14.2 μ.

Anal. Calcd. for $C_{29}H_{26}O_6N_2$: C, 69.87; H, 5.26; N, 5.62. Found: C, 70.23; H, 5.28; N, 5.53.

5′-O-Monomethoxytrityl-3′-O-acetyl-2,2′-anhydrouridine (MTrAU-Ac, 3)

MTrAU (**2**, 2.5 g, 5 mmol) and acetic anhydride (0.8 ml) were stirred in dry pyridine (15 ml) for 12 h. The solution was poured into ice water (500 ml) and the precipitate was collected, dissolved in chloroform, and dried over sodium sulfate. The chloroform solution was concentrated to a small volume and on addition of hexane a white precipitate formed which was collected by filtration and dried to yield 2.6 g (95%) of MTrAU-Ac (**3**, m.p. 100–107 °C). Principal bands in the i.r. spectrum occurred at 5.7, 6.1, 12.1, 13.3, and 14.2 μ. The u.v. spectrum in ethanol showed λ_{max} of 230 (ε 19 000) and λ_{min} of 223 nm (18 300).

Anal. Calcd. for $C_{31}H_{28}N_2O_7$: C, 68.88; H, 5.22; N, 5.18. Found: C, 68.78; H, 5.14; N, 5.08.

3′-O-Acetyl-2,2′-anhydrouridine (3′-AcAU, 4)

MTrAU-Ac (**3**, 2.2 g, 4 mmol) was dissolved in 80% acetic acid (25 ml) and stirred at room temperature for 3 h. The solvents were removed at reduced pressure and the residue was washed with ether and crystallized from ethanol (0.7 g, 66%), m.p. 204–209 °C. The i.r. spectrum showed principal bands at 5.8, 5.99, 8.2, and 13.1 μ. The u.v. spectrum in ethanol showed λ_{max} 249 (ε 8220), 224 (9600), and λ_{min} 237 nm (ε 7330).

Anal. Calcd. for $C_{11}H_{12}N_2O_6$: C, 49.25; H, 4.51; N, 10.44. Found: C, 49.10; H, 4.50; N, 10.26.

5′-O-Acetyl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (5′-AcAU, 6)

(*A*) 5′-Acetyluridine ((4), 140 mg, 0.5 mmol), diphenyl carbonate (140 mg), and sodium bicarbonate (12 mg) were added to DMF (0.5 ml) and the mixture was heated at 150 °C for 30 min. The solution was cooled to room temperature and applied to two t.l.c. plates which were developed first in ethyl acetate and then three times in tetrahydrofuran. Three anhydronucleoside bands were apparent including diacetylanhydrouridine, anhydrouridine, and a product moving between these two. This latter product was isolated and identified as 5′-AcAU (60 mg, 45%) with m.p. 164–167 °C (lit. m.p. 166–167 °C (2)). R_f values are shown in Table 3.

(*B*) One hundred milligrams of a mixture of DiAcAU and AU (1:1.15, molar ratio) was placed in a small test tube suspended in an oil bath maintained at 260 °C. As soon as the mixture had completely melted (55 s) the sample was removed, cooled to room temperature, and applied to a thick-layer plate which was developed first in tetrahydrofuran (THF). Two nucleoside bands moved up the plate in THF (R_f 0.5, 0.7) and were eluted. Both of these bands contained numerous products (paper chromatography solvent A) all of which had λ_{max} (H_2O) 260 and λ_{min} (H_2O) 231 nm. The total weight of material from the two bands was 20 mg and the only compound positively identified was uracil (4 mg).

The original thick-layer plate was developed in ethanol and another nucleoside band was obtained. This band was eluted and re-applied to another thick-layer plate which was developed five times in THF. Four bands separated with DiAcAU (8 mg, 0.026 mmol) moving fastest and AU (16 mg, 0.071 mmol) moving slowest. In between these were two bands moving very close together. The fastest band contained only 5′-AcAU while the slower band contained a mixture of 5′-AcAU and 3′-AcAU. This mixture was applied to Whatman 3MM paper developed in solvent A and the two materials separated cleanly. The yield of 3′-AcAU was 11 mg (0.041 mmol, 12%) while the total yield of 5′-AcAU (crystallized from ethanol) was 48 mg (0.18 mmol, 51% based on the total mmoles of acetyl groups in the starting materials, m.p. 165–167 °C).

(*C*) A mixture containing 62 mg of DiAcAU and 51 mg of AU was heated as above at 260 °C for 2.5 min. The product was dissolved in ethanol and applied to a single thick-layer plate which was developed four times in THF. Behind the decomposition products (at the solvent front) were three cleanly separated bands which were eluted with ethanol and identified as DiAcAU (3 mg), 5′-AcAU (75 mg, 70%), and AU (10 mg).

When this experiment was repeated, except that the sample was held at 260 °C for longer periods of time, the amount of decomposition increased markedly. In one reaction held at 260 °C for 15 min the only identifiable u.v. absorbing material was uracil.

(*D*) A mixture containing 620 mg of DiAcAU and 504 mg of AU was heated at 260 °C in a 100 ml round-bottom flask for 3 min and cooled to room temperature. The product was dissolved in ethanol and applied to eight thick-layer plates developed as in section *C* above. The yield of 5′-AcAU from this reaction was 720 mg (67%). The same result was obtained when the mixture was melted using a gas-burner for heat (total time in the melt 2–3 min).

Thermal Rearrangement of Acetyl Groups in Dimethylformamide (DMF)

Samples of **4** and **6** were heated separately in DMF at 150 °C for 30 min. The solutions were cooled to room temperature and applied to Whatman 3MM paper developed in solvent A. The results are shown in Table 1.

A Nuclear Magnetic Resonance Study of the Symmetry of the Proton Spins in Ethylene Sulfite in a Nematic Solvent[1]

M. A. RAZA AND L. W. REEVES

The Chemistry Department, University of Waterloo, Waterloo, Ontario

Received February 10, 1972

The proton magnetic resonance spectrum of ethylene sulfite dissolved in the nematic phase *N*(*p*-methoxybenzylidene)-*p*-*n*-butylaniline has been recorded and analyzed. The dipole–dipole coupling constants derived show that the four protons are arranged in an effective plane with C_{2v} symmetry. The spectrum is deceptively similar to that expected for D_{2h} symmetry but errors between the experimental and the optimized computed spectrum are unacceptably large with this assumption. The two vicinal protons *cis* to the extra ring oxygen are closer together than the two *trans* vicinal protons. A comparison is made with the molecule ethylene carbonate studied previously in the same nematic solvent.

Le spectre de résonance magnétique nucléaire du sulfite d'éthylène dissout en phase nématique *N*(*p*-méthoxybenzylidène) *p*-*n*-butylaniline a été enregistré et analysé. Les constantes de couplage dipôle–dipôle montrent que les quatre protons sont dans un arrangement effectif plan selon la symétrie C_{2v}. Le spectre est d'une similitude "décevante" à celui attendu pour la symétrie D_{2h} mais les écarts entre les spectres expérimental et calculé sont trop grands pour retenir une telle hypothèse. Les deux protons vicinaux en *cis* par rapport à l'oxygène sont plus rapprochés que les deux protons vicinaux *trans*. Une comparaison est faite avec la molécule de carbonate d'éthylène précédemment étudiée, dans le même solvant nématique.

Canadian Journal of Chemistry, **50**, 2370 (1972)

Introduction

We have recently reported comparative studies of the proton magnetic resonance (n.m.r.) spectra of a series of ring compounds with four spins dissolved in both lyotropic and thermotropic nematic phases (1–4). Ethylene carbonate (EC) and ethylene monothiocarbonate (EMTC) do not have the same geometry in the two types of nematic phase. Ring puckering motions which

have been a controversial issue in EC (5–7) are much more pronounced in the lyotropic nematic phase. In the present series of studies we have been able to show that provided the spectral quality in terms of resolution is excellent then extremely small changes in geometry represented by the symmetry change D_{2h} to C_{2v} can be readily detected (1–3). β-Propiolactone has 4 protons arranged in C_{2v} symmetry such that a 1° change in the H—C—H angle adjacent to the carbonyl with respect to the other methylene protons is readily detected (2). The number of transitions increases when the symmetry change occurs, though this is complicated by the chemical shift effect not present in an AA′A″A‴ spectrum but present in an AA′BB′ spectrum (8). It is interesting to note that the C_{2v} symmetry of the 5 spins in parachloro- and parabromo-fluorobenzene is not detected in the AA′BB′ subspectra for the protons probably because of lack of quality in the resolution of the spectrum (9). In the present paper we report a study of ethylene sulfite in a thermotropic nematic phase. The expected C_{2v} symmetry of the four proton spins in this molecule is principally related to *cis* vicinal proton distances rather than geminal as in the molecules reported previously (1–3).

Standard methods based on the general analysis of Snyder (10) are used, with the simplifications appropriate to four spins in a plane in C_{2v} or D_{2h} symmetry (11–14). The interproton distance ratios are obtained directly in terms of the dipole–dipole coupling constants by elimination of the motional constants $C_{3z^2-r^2}$ and $C_{x^2-y^2}$.

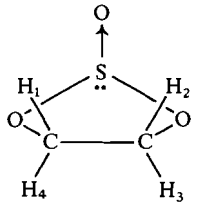
Experimental

The nematic compound *N*(*p*-methoxybenzylidene)-*p*-*n*-butylaniline supplied by the Distillation Products Division of Eastman Organic Chemicals was used as the solvent. The nematic range in the pure state is between +18 and 41 °C. The clearing point of 41 °C is depressed on adding solutes, but in our previous experience it is possible to maintain nematic properties with a standard amount of 5 wt % of solute (2–4). If the sample remains in the magnet for some hour or so the line widths for a non-spinning sample can be reduced to 8 Hz and consequently peak positions are measured to ±0.5 Hz maximum error. Side band modulation techniques described previously with cross checks, and at least five averaged spectra are satisfactory in achieving these small error limits (2, 3).

Ethylene sulfite was supplied by Eastman Organic Chemicals Co., and purified by distillation under 10 mm Hg pressure. Proton magnetic resonance spectra were recorded in the H.R. mode of a Varian HA100 at a probe temperature of 30.5 ± 0.1 °C.

Results

The proton spectrum of ethylene sulfite in the neat isotropic state has been analyzed in this laboratory previously (1). It is a tightly coupled AA′BB′ spectrum which analyzes to give the following parameters; $\delta_1 = \delta_2 = +503.81 \pm 0.02$, $\delta_3 = \delta_4 = +474.76 \pm 0.02$, $J_{14} = J_{23} = -8.47 \pm 0.02$, $J_{12} = J_{34} = 6.74 \pm 0.02$, $J_{13} = J_{24} = 6.52 \pm 0.02$. The chemical shifts are measured with respect to an external tetramethylsilane (TMS) lock signal and refer to Hz at 100 MHz. The spin–spin coupling constants are in Hz. The non-equivalent protons are identified in the structure below as being *cis* or *trans* to the extra ring oxygen. H_1, H_2 are *cis* to the extra ring oxygen and H_3, H_4 are *trans*.



The spectrum of oriented ethylene sulfite is reproduced as Fig. 1. There are twelve observable transitions which could be considered appropriate for the AA′BB′ spectrum with a negligibly small chemical shift δ_{AB} and D_{2h} symmetry. The observed spectrum is very similar in form to that observed for EC (1, 3) and ETTC (4).

The spectrum can be calculated assuming an internal chemical shift $\delta_1 = \delta_2 \neq \delta_3 = \delta_4$ but assuming that the dipolar coupling constants $D_{12} = D_{34}$. Since the cube root of D_{12}/D_{34} is the interproton distance ratio r_{12}/r_{34} then the assumption $D_{12} = D_{34}$ means distances r_{12}, r_{34} are equal. The best fit between the experimental and computed spectrum using the program NMRFIT gives an r.m.s. error for the experimental spectrum for all line positions of 4.9 Hz. This is unacceptably large since the error on the position of proton resonance peaks in this and previous studies is certainly less than 2 Hz even in the thermotropic nematic phase (1, 3). The spectrum was therefore computed on the assumption that $D_{12} \neq D_{34}$. A spectral fit with an r.m.s. error for the difference between frequencies for all computed and experimental lines of 0.8 Hz was achieved. This is in agree-

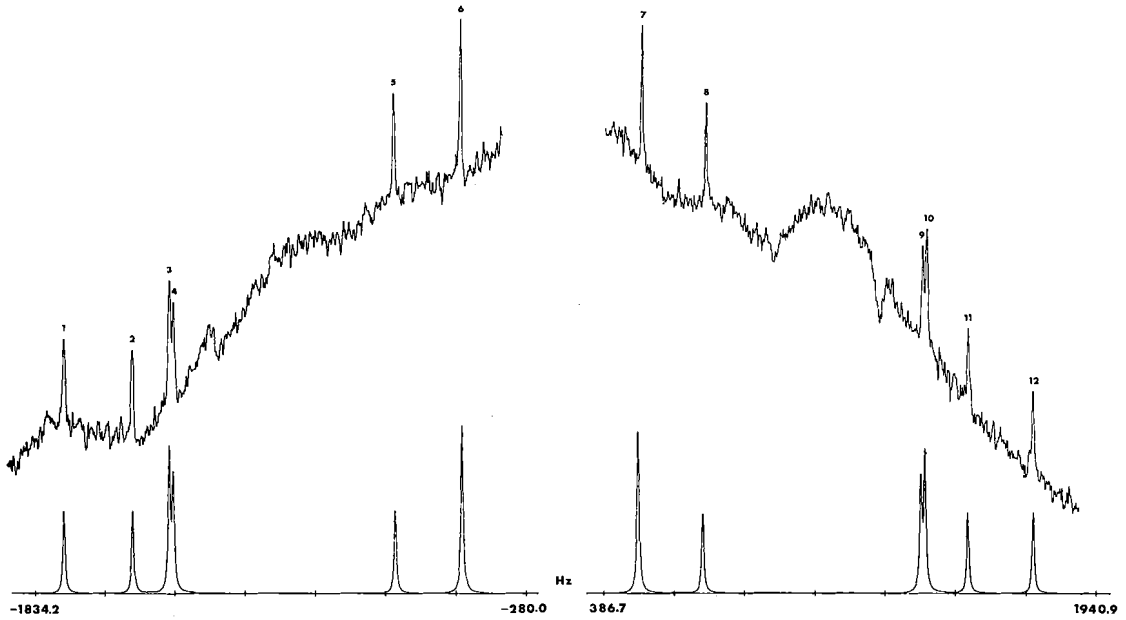


FIG. 1. Spectrum of ethylene sulfite in the nematic phase at 30.5 °C and 5 wt %. Below the experimental spectrum is the simulated spectrum obtained using parameters from Table 1 appropriate to C_{2v} symmetry of the four protons.

TABLE 1. The analyses of the spectrum of ethylene sulphite in the nematic phase assuming C_{2v} and D_{2h} symmetry for the four protons using $\delta_1 = \delta_2$, $\delta_3 = \delta_4$, $\delta_1 - \delta_3 = 68.8$*

Parameter	Value	
	C_{2v} (Assuming $D_{12} \neq D_{34}$)	D_{2h} (Assuming $D_{12} = D_{34}$)
Root-mean-square error	±0.77	±4.90
D_{12}	−763.7	−696.4
$D_{13} = D_{24}$	−140.5	−138.6
$D_{14} = D_{23}$	+1481.7	+1484.1
D_{34}	−630.1	−696.4

*All measurements are quoted in Hz at 100 MHz. Chemical shift convention is that low-field chemical shifts have increasing positive value. The error limits are too large if D_{2h} symmetry is assumed. The dipole–dipole coupling constants are listed for each analysis.

ment with the random error analysis of our experimental peak positions in this paper and is the error we expect from previous and directly comparable studies (2–4). It is extremely important in the present case to use the best resolution and to measure the positions of all peaks as accurately as possible. The parameters for equal and non-equal D_{12}, D_{34} are presented with the r.m.s. errors in Table 1. In β-propiolactone the C_{2v} symmetry of the four proton spins is due to a geminal H—C—H angle change which produces a trapezoidal arrangement where the parallel sides are the shortest ones. Since the dipolar coupling constants depend on r_{ij}^{-3} between protons, this symmetry change has a relatively large effect on the dipolar coupling and the spectrum of β-propiolactone has more transitions (16 peaks observable) with no apparent symmetry in the spectrum (2). In ethylene sulfite, however, the vicinal eclipsed protons are not equidistant along the long parallel sides of trapezoidal arrangement C_{2v}. The relative change in r_{ij}^{-3} is small and hence an extremely careful analysis is required to deter-

*$\frac{1}{2}(r_{34}/r_{14} + r_{12}/r_{14})$.
†A value of 110° for the angle HCC in ethylene sulfite has been reported by an electron-diffraction study (15).

mine the symmetry. The cases of *p*-chloro- and *p*-bromobenzene are similar, but in these molecules the symmetry C_{2v} has not been detected (9).

Discussion

Interproton distance ratios obtained in this study for ethylene sulfite are given in Table 2. These are compared with interproton distance ratios determined previously in the same nematic solvent for EC (3). In thermotropic solvents EC is assumed to be planar and the interproton distance ratios shown in Table 2 are in agreement with a structure; $\angle H—C—H = 111°$, $\angle HCC = 114.6°$, bond length C—H = 1.08 Å, and bond length C—C = 1.52 Å. An error arising from vibrational motions is expected of up to 3% in these comparisons (8) so that the agreement should not be considered as giving an absolute structure (1–4).

Protons 1 and 2 are *cis* to the extra ring oxygen in ethylene sulfite and are closer together than the *trans* protons 3 and 4. This is reflected in the interproton distance ratios r_{34}/r_{14} and r_{12}/r_{14}. An electron diffraction study of ethylene sulfite (15) gives a bond angle 110° for HCC. The measured interproton distance ratios in ethylene sulfite can be calculated using C—H distance = 1.08 Å, C—C distance = 1.52 Å, and $\angle H_4CC = 114.6°$, $\angle H_1—C—C = 110.3°$, and $\angle H_1CH_4 = 103.4°$.

The Self-Reaction of *sec*-Alkylperoxy Radicals: A Kinetic Electron Spin Resonance Study

J. A. HOWARD[1] AND J. E. BENNETT

Shell Research Ltd., Thornton Research Centre, P.O. Box 1, Chester CH1 3SH, England

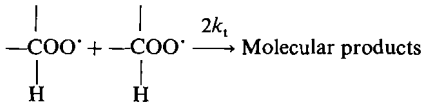
Received May 16, 1972

Absolute rate constants for the self-reaction of cyclopentylperoxy, cyclopentenylperoxy, and *sec*-butylperoxy radicals have been determined over a 125 °C temperature range. Arrhenius plots derived from these rate constants suggest that the mechanism for this reaction is more complex than the currently accepted Russell mechanism.

Les constantes absolues de vitesse pour l'autoréaction des radicaux cyclopentylperoxy, cyclopentènylperoxy et *sec*-butylperoxy, ont été déterminées dans un intervalle de température de 125 °C. Les dérivés des courbes d'Arrhénius, à partir des constantes de vitesse, laissent penser que le mécanisme de la réaction est plus complexe que celui proposé par Russell qui est couramment accepté.

Canadian Journal of Chemistry, **50**, 2374 (1972)

The rate controlling termination reaction for the liquid-phase autoxidation of hydrocarbons with labile primary or secondary hydrogens usually involves the mutual reaction of alkylperoxy



radicals (1) where $2k_t$ is the overall termination rate constant. This reaction is generally believed to proceed through a cyclic transition state (*i.e.*, the Russell mechanism) (2–5)

[1] 
with

$$2k_t = \frac{2k_1k_2k_3}{k_{-1}k_{-2}}$$

The intermediacy of alkoxy radicals and consequently a mechanism analogous to the one generally accepted for the self-reaction of *tert*-alkylperoxy radicals has been discounted (2, 5).

A knowledge of absolute values of $2k_t$ (typically 10^6 to 10^8 M^{-1} s^{-1}) (1) has enabled Ingold and co-workers (6) to conclude from thermochemical calculations that if scheme 1 is the only viable mechanism for the self-reaction of *sec*-alkylperoxy radicals, then the overall activation energy (E_t) should be *negative*. Published values of E_t (1), although they are of low accuracy, are, however, *positive* (0–4 kcal/mol).

We report here accurate measurements of $2k_t$ for cyclopentylperoxy, cyclopentenylperoxy, and *sec*-butylperoxy radicals by kinetic e.s.r. spectroscopy (7) over a temperature range of 125 °C in an attempt to obtain reliable values of E_t. The radicals were generated directly in the cavity of an e.s.r. spectrometer by photolysis of di-*t*-butyl peroxide in the appropriate oxygen saturated hydrocarbon. In the temperature range −16 to −140 °C the peroxy radicals

[1]Visiting scientist, permanent address: Division of Chemistry, National Research Council of Canada, Ottawa K1A OR9, Canada.

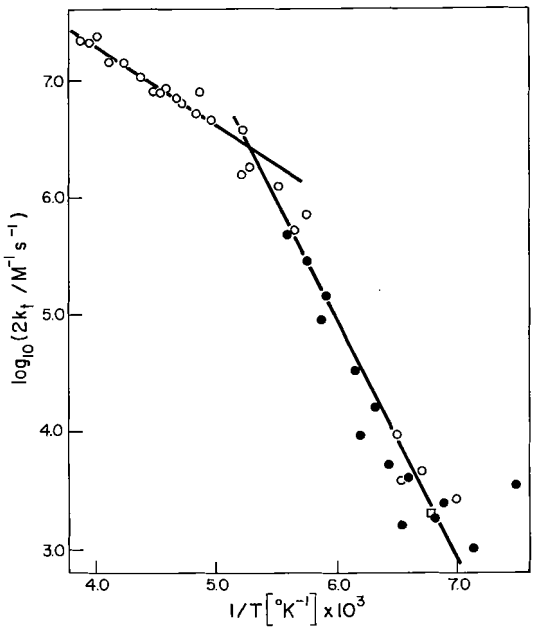


FIG. 1. A plot of log $2k_t$ for the cyclopentylperoxy radical *vs.* the reciprocal of the absolute temperature. Key: ○, 100% cyclopentane; ●, 50% cyclopentane – 50% cyclopropane; □, 25% cyclopentane – 75% cyclopropane.

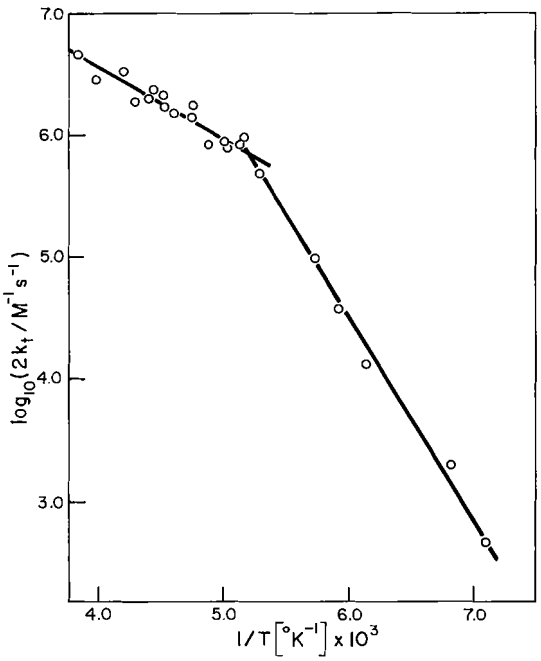

FIG. 2. A plot of log $2k_t$ for the *sec*-butylperoxy radical *vs.* the reciprocal of the absolute temperature.

generally decayed by second order kinetics, *i.e.*, $-d[ROO^{\cdot}]/dt = 2k_t[ROO^{\cdot}]^2$. Figures 1 and 2 show plots of log $2k_t$ against the reciprocal of the absolute temperature for two of the radicals.

Arrhenius parameters for the self-reaction of the *sec*-alkylperoxy radicals above −80 °C are given in Table 1 together with those for *tert*-butylperoxy determined by the same technique. The last two columns in Table 1 compare extrapolated values of $2k_t$ at 30 °C with values determined using either the rotating sector method (1) or the pulse radiolysis technique (8). The rate constants obtained in the present work are slightly larger than those previously reported but these differences are probably caused by the inherent inaccuracies in the various techniques.

Values of A_t for all the radicals listed in Table 1 are similar and consequently the large differences in $2k_t$ between *sec*- and *tert*-alkylperoxy radicals are due primarily to differences in E_t. Thomas and Ingold (9) also came to this conclusion from their kinetic e.s.r. study of the self-reaction of alkylperoxy radicals.

Although the values of E_t for *sec*-alkylperoxy radicals are about 5 kcal/mol lower than the values of E_t for *tert*-alkylperoxy radicals they are still *positive* by several kcal/mol. Thus the present kinetic evidence in conjunction with thermochemical calculations (6) suggests that the self-reaction of *sec*-alkylperoxy radicals (and almost certainly primary alkylperoxy radicals) does not proceed exclusively through a cyclic transition state.

At temperatures below −80 °C values of $2k_t$ for *sec*-butylperoxy and cyclopentylperoxy radicals are described by $2k_t = 10^{15.3} \exp(-8.2/RT)$ M^{-1} s^{-1} and $2k_t = 10^{16.5} \exp(-8.5/RT)$ M^{-1} s^{-1}, respectively, with the activation energies in kcal/mol. Although radical decays below −80 °C were second order, the estimated *A*-factors are much too large for bimolecular reactions. Thus below −80 °C the self-reaction of *sec*-alkylperoxy radicals is not a simple bimolecular reaction but is probably a complex free radical process.

There is e.s.r. evidence from −120 to −160 °C for the formation of a diamagnetic dimer (probably a tetroxide) from two cyclopentylperoxy radicals. Unfortunately the radicals decayed too quickly for reliable estimates to be made for ΔH_1 and ΔS_1 for the equilibrium process.

However, if the values of ΔS_1 and ΔH_1 for *sec*-alkylperoxy radical–tetroxide equilibria are

§Radicals were prepared by photolysis of *t*-butyl hydroperoxide in oxygen free isobutane.

comparable to the values for *tert*-alkylperoxy radical–tetroxide equilibria (10, 11), then only above −80 °C should di-*sec*-alkyl tetroxides be almost completely dissociated. It is therefore tempting to conclude that the dramatic decrease in $2k_t$ for the self-reaction of *sec*-alkylperoxy radicals below −80 °C is associated with the presence of a significant concentration of tetroxide.

The self-reaction of *tert*-alkylperoxy radicals is a complex process that proceeds *via* a tetroxide intermediate (1) with *A*-factors and activation

[2] $\mathrm{ROO^{\cdot} + ROO^{\cdot} \rightleftharpoons RO_4R \rightarrow}$ Molecular products

energies for the overall reaction of about 10^9 $M^{-1}\,s^{-1}$ and 10 kcal/mol (1). This mechanism cannot, however, be invoked to describe the self-reaction of *sec*-alkylperoxy radicals below −80 °C because although the activation energies for the two systems are similar, the *A*-factors differ by about 10^7. It is also improbable that the overall rate of such a process would slow down at −80 °C.

An alternative mechanism is

[3] $\mathrm{RO_4R} \underset{2k_1}{\overset{k_{-1}}{\rightleftharpoons}} \mathrm{2ROO^{\cdot}} \xrightarrow{2k_t}$ Molecular products

and is represented by the potential energy–reaction coordinate curve shown in Fig. 3. The general expression (12) for radical decay by this mechanism is

$$\frac{-\mathrm{d[ROO^{\cdot}]}}{\mathrm{d}t} = \frac{2k_t[\mathrm{ROO^{\cdot}}]^2}{1 + 4k_1[\mathrm{ROO^{\cdot}}]/k_{-1}}$$

At high temperatures (*i.e.*, temperatures at which the tetroxide is completely dissociated)

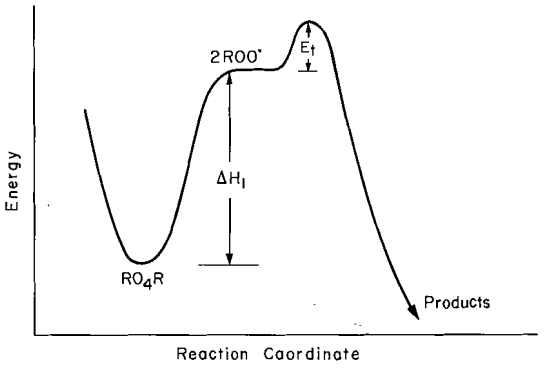

FIG. 3. A possible potential energy curve for the self-reaction of *sec*-alkylperoxy radicals.

$4k_1[\mathrm{ROO^{\cdot}}]/k_{-1} < 1$ and this equation reduces to the usual second order rate expression

$$[4] \qquad \frac{-\mathrm{d[ROO^{\cdot}]}}{\mathrm{d}t} = 2k_t[\mathrm{ROO^{\cdot}}]^2$$

If below −80 °C, $4k_1[\mathrm{ROO^{\cdot}}]/k_{-1} > 1$, then

$$[5] \qquad \frac{-\mathrm{d[ROO^{\cdot}]}}{\mathrm{d}t} = \frac{2k_tk_{-1}[\mathrm{ROO^{\cdot}}]}{4k_1}$$

which could give an overall rate constant $(k_tk_{-1}/2k_1)$ with a higher *A*-factor and activation energy than $2k_t$. However, this expression requires a first-order decay for ROO· at low temperatures whereas our experimental results were generally closer to a second-order process. Further, the equilibrium constant $(2k_1/k_{-1})$ for the tetroxide formation would have to be 10^3 to 10^4 times higher than those for tertiary tetroxides.

Although the present results cannot be described adequately by any of the mechanisms

A Stereospecific Synthesis of Ring A-aromatic Steroids

R. A. DICKINSON, R. KUBELA, G. A. MACALPINE, Z. STOJANAC, AND Z. VALENTA

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received December 21, 1971[1]

A diene synthesis using 2,6-xyloquinone as dienophile and boron trifluoride as catalyst does not follow the normal orientation rules and leads to a facile synthesis of ring A-aromatic steroids. A tetracyclic adduct prepared by a similar reaction and containing the steroidal C_{19}-methyl group is also reported.

Une synthèse de diène utilisant la 2,6-xyloquinone comme diénophile et le trifluorure de bore comme catalyseur ne suit pas les règles d'orientation normales et nous amène à une synthèse facile de stéroïdes cycliques A-aromatiques. On rapporte aussi la synthèse d'un dérivé tétracyclique préparé à l'aide d'une réaction semblable et contenant le groupe stéroïdal méthyle-C_{19}.

Canadian Journal of Chemistry, **50**, 2377 (1972)

We wish to report a steroid synthesis based on an efficient inversion of the usually observed Diels–Alder reaction orientation (1).

Treatment of diene **1** (2) and 2,6-xyloquinone (**2**) with 1.3 mol equiv of boron trifluoride etherate in ether at room temperature gave the desired tetracyclic enedione **3**,[2] m.p. 194–196°, in a 69% yield.[3] A second compound **4**, m.p. 164–167°, obtained in about 14% yield, proved identical with the only product of a thermal reaction of **1** and **2** in boiling benzene. The relative configuration of *d,l*-**3** follows from the expected *endo-cis* course of the diene synthesis (4) and from subsequent transformations. Compound **3** was converted quantitatively to its *trans*-epimer **5**, m.p. 146–148°, on treatment with sodium bicarbonate in refluxing methanol. Lithium aluminum tri-tert-butoxyhydride in tetrahydrofuran at room temperature then reduced one of the carbonyl groups of **5** selectively to give alcohol **6**, m.p. 211–213°, which was converted to the corresponding mesylate **7**. Reduction with zinc (5) in refluxing methanol–benzene followed by treatment with sodium carbonate gave the desired *d,l*-enone **8**, m.p. 174–176°. Hydrogenation with 10% palladium on calcium carbonate in glacial acetic acid gave, after recrystallization from benzene–hexane,

[1]Resubmitted June 20, 1972.

[2]Adduct **3** crystallized from the ether solution within a few minutes and was recrystallized from ethyl acetate.

[3]To our knowledge, such an orientation inversion has not been reported previously. For selected references on catalyzed diene synthesis, see ref. 3.

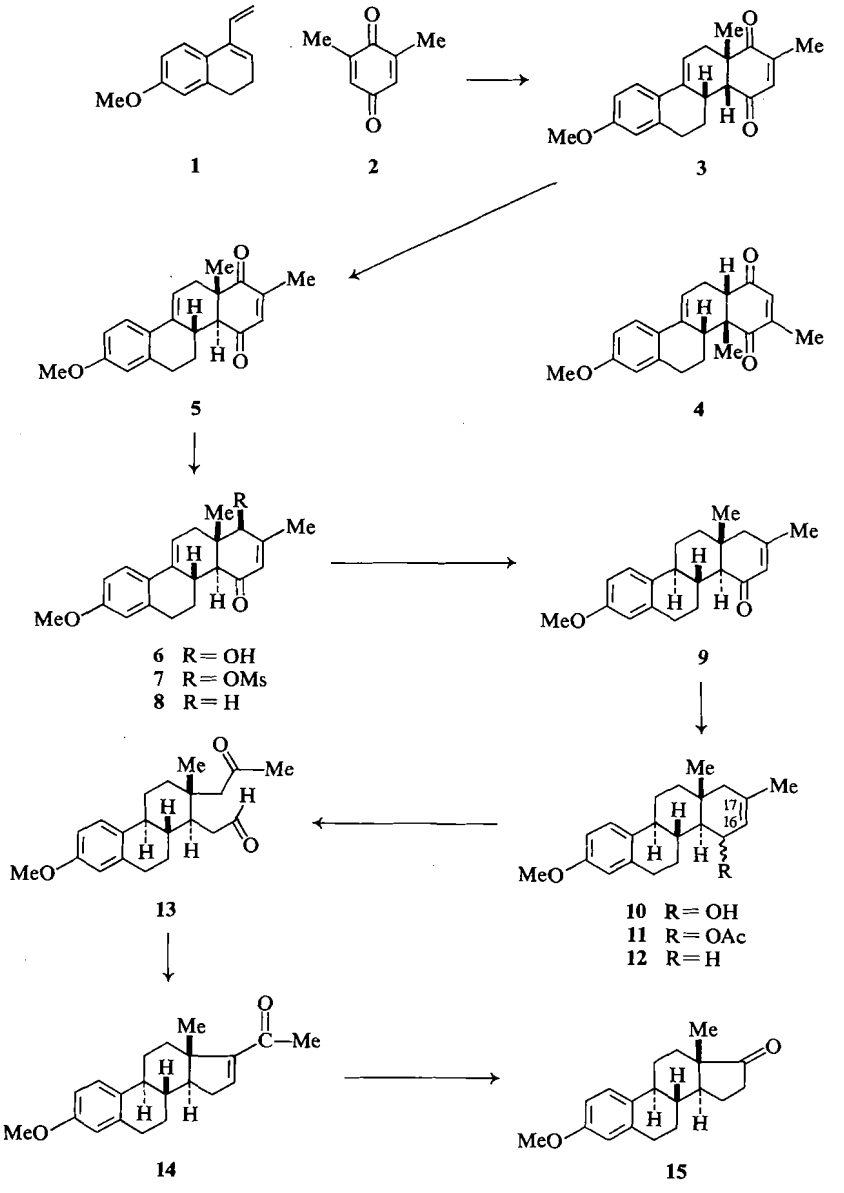
Reduction with zinc (5) in refluxing methanol–benzene followed by treatment with sodium carbonate gave the desired *d,l*-enone **8**, m.p. 174–176°. Hydrogenation with 10% palladium on calcium carbonate in glacial acetic acid gave, after recrystallization from benzene–hexane,

[1]Resubmitted June 20, 1972.

[2]Adduct **3** crystallized from the ether solution within a few minutes and was recrystallized from ethyl acetate.

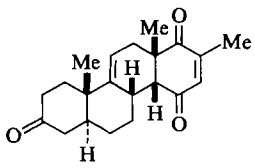
[3]To our knowledge, such an orientation inversion has not been reported previously. For selected references on catalyzed diene synthesis, see ref. 3.



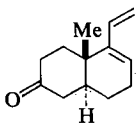
an 85% yield of the desired epimer **9**, m.p. 142–144°. The position of the keto group in **9** follows from the n.m.r. spectrum (C_{16}-H at 4.2 τ, coupled only to the C_{17}-methyl at 8.1 τ).

Reduction of enone **9** with sodium bis(2-methoxyethoxy) aluminum hydride (6) gave a mixture of epimeric alcohols **10**. Conversion of **10** to acetates **11**, followed by reduction of **11** with excess lithium in tetrahydrofuran-refluxing liquid ammonia[4] gave olefin **12** (8) (m.p. 96–97°, 75% yield based on **9** after recrystallization from ether–methanol). Treatment of **12** with osmium tetroxide in pyridine (9) followed by cleavage with lead tetraacetate in tetrahydrofuran at 0° gave oily keto aldehyde

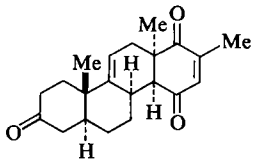
[4]A similar reaction using lithium in ethyl amine has been reported (7).



17



16



18

13 which after reaction with 5% aqueous hydrochloric acid in tetrahydrofuran at 70° for 40 h and recrystallization from benzene–hexane gave enone **14**, m.p. 159–162°, in a 60% yield based on **12**. The overall yield of the conversion **1** + **2** → **14** is 22%.[5]

Enone **14** was converted to *d,l*-estrone methyl ether **15** (40% yield) by the reported Beckmann rearrangement of the corresponding oxime (10). Compound **15**, m.p. 140–141° (11), was found to be identical with the methyl ether of natural estrone in t.l.c., n.m.r., solution i.r., and m.s.

The present sequence does not as yet match in brevity and overall yield some of the efficient synthetic pathways already reported for ring A-aromatic steroids (12). In addition, its elaboration to optically active compounds without recourse to resolution (13) will require an asymmetric induction in the Diels-Alder step itself.

However, it has important advantages. It automatically generates the 9,11-double bond, as well as the 17-acetyl side chain. Furthermore, it promises to be equally effective in the synthetically more challenging saturated steroid series. We now find that a reaction of diene **16** (14) with quinone **2** in the presence of boron trifluoride etherate gives two compounds, **17**, m.p. 187–189° and **18** in a 2:1 ratio.[6] The non-identity of these two adducts with any of the products obtained in a thermal reaction of **16** with **2**, as well as consideration of the *endo* rule (4) and of steric factors (16), strongly favor structure **17** for the major product. Its elaboration into steroids of the progesterone and cortisone type along the lines reported in this Communication is under active study.

[5]This is a minimum yield since recrystallized material was used at several stages of the sequence **3** → **12**, the quoted yield of the conversion **12** → **14** does not include substantial amounts of **14** present in the semi-crystalline mother liquors (n.m.r., t.l.c.) and since no attempt has been made to optimize all individual yields.

[6]Since the precursor to diene **16** has been synthesized under asymmetric induction (15), the diene and its adducts will be readily available in optically active form.

Support of this work by the National Research Council of Canada is gratefully acknowledged.

Juvenile Hormone Mimics in Conifers. I. Isolation of (−)-*cis*-4-[1′(*R*)-5′-Dimethyl-3′-oxohexyl]-cyclohexane-1-carboxylic Acid from Douglas-fir Wood

I. H. ROGERS AND J. F. MANVILLE

Department of the Environment, Canadian Forestry Service, Western Forest Products Laboratory, Vancouver, British Columbia

Received March 9, 1972

The petroleum ether extract from the whole-wood meal of a British Columbia Interior variety of Douglas-fir has yielded a new and potentially useful juvenile hormone mimic, (−)-*cis*-4-[1′(*R*)-5′-dimethyl-3′-oxohexyl]-cyclohexane-1-carboxylic acid (**3***a*). This compound possesses the opposite steric configuration at C-1′ to that of (+)-juvabione (**1***a*), which has been isolated by others from balsam fir. Also, it occurs exclusively as the free acid. Not all Douglas-firs contain this compound and the biological consequences of its formation are being explored.

Une imitation nouvelle et potentiellement utile de l'hormone juvénile, l'acide (−)-*cis*-4-[1′(*R*)-5′-diméthyl-3′-oxohexyl]-cyclohexane-1-carboxylique (**3***a*), a été obtenue de l'extrait d'éther de pétrole de la poudre de bois entier d'une variété de sapin de Douglas, de l'intérieur de la Colombie britannique. Ce composé possède la configuration stérique opposée en C-1′, à celle du (+)-juvabione (**1***a*), que d'autres chercheurs avaient isolé du sapin baumier. On le retrouve seulement sous forme d'acide libre. Il est à remarquer que les sapins de Douglas, ne contiennent pas tous ce composé; nous étudions présentement les conséquences biologiques de sa formation.

Canadian Journal of Chemistry, **50**, 2380 (1972)

The isolation of (+)-juvabione (**1***a*) from the wood of balsam fir (1) (*Abies balsamea* (L.) Miller) of North American origin and the demonstration of its juvenile hormone activity against the hemipteran bug *Pyrrhocoris apterus* L. (2) has evoked wide interest because of the potential for insecticidal application. Subsequently, a second compound, (+)-dehydrojuvabione (**2**), was isolated from balsam fir grown in Czechoslovakia (3) and this also possessed juvenile hormone activity. (+)-Juvabione is the methyl ester of (+)-todomatuic acid ((+)-4(*R*)-[1′(*S*)-5′-dimethyl-3′-oxohexyl]-cyclohex-1-ene-1-carboxylic acid, **1***b*), isolated (4) in 1940 from bisulfite-treated pulp oil of a Japanese fir (*Abies sachalinensis* Schmidt). There is thus reason to expect that active compounds may be widely distributed in the true firs. We report herein the isolation of (−)-*cis*-4-[1′(*R*)-5′-dimethyl-3′-oxohexyl]-cyclohexane-1-carboxylic acid (**3***a*), from the British Columbia Interior variety of Douglas-fir (*Pseudotsuga menziesii* var. *glauca* (Beissn.) Franco) which is not a true fir (*Abies* sp.). In contrast to the true firs, some of which contain (+)-juvabione (*S* configuration at C-1′), compound **3***a* occurs with the opposite configuration (*R*) at C-1′ and is found exclusively as the free acid in certain Douglas-fir trees.

A bolt was cut from the butt log of a 164-year-old Douglas-fir tree growing near Savona, British Columbia. The air-dry wood was milled and the wood meal extracted with petroleum ether in a soxhlet apparatus. A fraction com-

prising a mixture of resin acids and fatty acids was obtained by ion exchange chromatography of the petroleum ether extract on a column of diethylaminoethyl Sephadex (A-25) following the procedure of Zinkel and Rowe (5). The resin acids were removed after selective esterification with sulfuric acid–methanol reagent. Argentative chromatography of the fatty acid ester fraction on a silica column resulted in the isolation of **3***b* and the methyl ester of an unknown acid.[1]

The ester (**3***b*) was a colorless oil $[\alpha]_D^{23}$ 0°, b.p. 150 °C at 0.5 mm, elemental analysis agreed with the empirical formula $C_{16}H_{28}O_3$. The presence of a carbonyl group in a saturated environment was evident from the i.r. spectrum (1710 cm^{-1}). Absence of olefinic double bonds was inferred from the i.r. and n.m.r. spectra and from the behavior of the compound on silver nitrate-impregnated silica thin layers. From the empirical formula, the presence of one degree of unsaturation associated with a ring was evident.

The mass spectral fragmentation pattern of the unknown ester (**3***b*) which contained many metastable ions was most informative. The molecular ion (*m/e* 268) was accompanied by low abundance satellite ions at *m/e* 237 (M − 31) and 209 (M − 59) arising from homolytic cleavages in the carbomethoxy group. Much more significant fragmentations of the molecular ion were associated with cleavage within the side chain giving rise to abundant species at *m/e* 211 (M − 57, *m** 166.1) and 168 (M − 100, *m** 105.4). The latter fragment gave rise to the base peak of the spectrum (*m/e* 108) by elimination of the carbomethoxy function as methyl formate (*m** 69.5). Loss of an eight-carbon side chain containing a carbonyl group from the molecular ion was indicated by the presence of an abundant fragment at *m/e* 127 (*m** 60.3) in which process the charge was carried by the side chain moiety.

Some major species in the fragmentation pattern of juvabione include the molecular ion *m/e* 266 and fragments at *m/e* 207 (M − 59), 177, 167, 166, 127, 85, 79, 59, and 57 as discussed by Sorm and coworkers (3). These were all present in the spectrum of **3***b* with the displacement of the first five species listed by two additional mass units.

The n.m.r. spectrum of **3***b* (Varian HR-220, $CDCl_3$) yielded the following 1st order n.m.r. parameters: τ 6.43 (3 H, singlet, methyl ester), 7.39 (1 H, quintet, $J \simeq 4$ Hz, H_1), 7.59 (1 H, quartet, $J_{2_1,2_2} = 15.8$ Hz, $J_{2_1,1'} = 4.5$ Hz, H_{2_1}), 7.74 (2 H, doublet, $J_{vic} = 6.7$ Hz, H_{4_1} and H_{4_2}), 7.86 (1 H, quartet, $J_{2_2,2_1} = 15.8$, $J_{2_2,1_1} = 9.0$ Hz, H_{2_2}), 7.87 (1 H, multiplet, $H_{5'}$), 8.05 (1 H, multiplet, $H_{1'}$), 8.5 (5 H, broad band, ring protons), 8.8 (4 H, broad band, ring protons), 9.08_6 (3 H, doublet, $J = 6.7$ Hz, $C_{5'}$ methyl), 9.09_1 (3 H, doublet, $J = 6.7$ Hz, $C_{5'}$ methyl), and 9.17 (3 H, doublet, $J = 6.7$ Hz, $C_{1'}$ methyl). The magnitude of the vicinal couplings observed in H_1 indicated that the carboxylic acid methyl ester group was in an axial orientation. It is thus most probable that **3***b* possesses a *cis* configuration with the bulky side chain in the equatorial position.

Gas–liquid chromatographic analysis of hydrogenated (±)-juvabione (3) demonstrated that **3***b* had a retention time identical to that

[1]Structural identification of this related acid is in progress. Initial bioassays, performed at the Pacific Forest Research Centre, Victoria, B.C., against Tenebrio molitor (L.), have shown positive results for both compounds. Further testing is in progress.

of the more volatile component. Epimerization (6) of **3***b* revealed that the compound with the longer retention time must be the *trans* isomer since it was the major component in the epimerized mixture. Thus the minor component, **3***b*, must possess the *cis* configuration.

The o.r.d. spectrum of **3***b* was (*c* 1.0, methanol, 23°) $[\Phi]_{350}$ −107, $[\Phi]_{308}$ −749, $[\Phi]_{292}$ 0, $[\Phi]_{260}$ +1584, and $[\Phi]_{230}$ +780°. With reference to the work of Pawson and coworkers (7), this result establishes the *R* configuration at C-1′ and also that it is the (−)-isomer. This result should allow assessment of the effect of configuration at C-1′ on the juvenile hormone activity of compounds of this structural type.

We wish to thank B. A. Pawson for a sample of (±)-juvabione and W. S. Bowers for a sample of natural (+)-todomatuic acid.

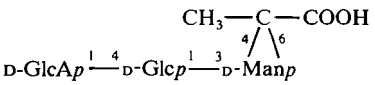
4,6-*O*-(1-Carboxyethylidene)-D-mannose as a Structural Unit in Capsular Polysaccharide of *Klebsiella* K-type 5[1]

G. G. S. Dutton and M. T. Yang

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

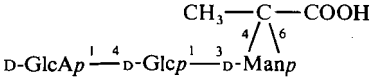
Received April 21, 1972

Methylation, periodate oxidation, and partial hydrolysis techniques have each been used to demonstrate the presence of 4,6-*O*-(1-carboxyethylidene)-D-mannopyranosyl units in the capsular polysaccharide of *Klebsiella* K-type 5. The structure of this polysaccharide differs from those known for other *Klebsiella* capsules by the lack of any carbohydrate side chain. A repeating unit of



(plus one unassigned *O*-acetyl group) is in accord with the experimental data.

Les méthodes de méthylation, oxydation périodique et hydrolyse partielle ont été utilisées pour démontrer la présence de restes de 4,6-*O*-(1-carboxyethylidene)-D-mannopyranose dans le polyoside capsulaire de *Klebsiella* K-type 5. La structure de ce polysaccharide se distingue de toutes les autres connues pour *Klebsiella* par la manque d'une chaîne latérale de sucre. On propose une structure du type



(avec un groupe *O*-acétyle) qui se répète.

Canadian Journal of Chemistry, **50**, 2382 (1972)

The occurrence of pyruvic acid as a covalently linked ketal unit in polysaccharides was first reported by Hirase (1) in a study on agar which contains 4,6-*O*-(1-carboxyethylidene)-D-galactose units. The presence of 4,6-*O*-(1-carboxyethylidene)-D-glucose units was subsequently demonstrated by Sloneker and Orentas (2) in the exocellular polysaccharide from *Xanthomonas campestris*. Since then the presence of this D-galactose ketal has also been shown in the polysaccharides from *Corynebacterium insidiosum* (3), *Klebsiella* K-type 21 (4), and colanic acid (5, 6). Pyruvic acid has been found as well in the M-antigens of *Salmonella* and in *E. coli* linked as 3,4-*O*-(1-carboxyethylidene)-D-galactose (7, 8).

In addition to these ketals of known structure the existence of pyruvic acid has also been demonstrated in other bacteria (*e.g.* 9–12) and in certain cases this acid may be an immunodominant group (11). We now report a new ketal of pyruvic acid namely 4,6-*O*-(1-carboxyethylidene)-D-mannose which is a structural unit in the capsular polysaccharide of *Klebsiella* K-type 5.

The capsular polysaccharide of *Klebsiella* K-5 has been qualitatively analyzed by Nimmich (13) and shown to contain glucose, mannose, and glucuronic acid. A culture of K-5 (E 5051) was obtained from Dr. I. Ørskov, Copenhagen, as an agar slant and was grown on sucrose–yeast extract–agar. Cells were harvested after 3 days, diluted with 5 volumes of water containing 1% phenol and centrifuged at 65 000 g for 1 h. Crude polysaccharide was obtained by freeze drying the supernatant. Pure capsular polysaccharide was obtained by treating a solution of this material with Cetavlon and working-up the precipitate thus formed. The freeze-dried product had $[\alpha]_D^{23}$ −45.2° (*c* 0.4, H_2O). Analysis indicated one *O*-acetyl group and two carboxyl units per three sugar residues. The molecular weight by gel-filtration on Sagavac 6F[2] was about 9×10^5. Hydrolysis of the polysaccharide with 0.5 *M* sulfuric acid at 100° for 8 h showed, by paper chromatography, glucose, mannose, glucuronic acid, and an aldobiouronic acid. The ratio of glucose to mannose was approximately 3:5 (g.l.c. of alditol acetates–ECNSS-M). Hydrolysis of the polysaccharide with 1 *M* hydrochloric acid showed the presence of pyruvic acid by the *o*-phenylenediamine spray (14) and by t.l.c. of the 2,4-dinitrophenylhydrazone.

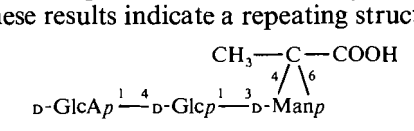
Polysaccharide (400 mg) was methylated by the method of Hakomori (15, 16) followed by three treatments with Purdie's reagents to give a product free of absorption at 3600 cm^{-1} in the i.r. A portion (300 mg) was hydrolyzed with sulfuric acid, neutralized with barium carbonate, and separated by ion-exchange resins into neutral (178 mg) and acidic (60 mg) fractions. Paper chromatography (butanone–water azeotrope) of the neutral fraction showed the presence of only two components with the mobilities expected of a mono- and a trimethylhexose (R_f 0.07 and 0.55). Elution of the appropriate areas of the chromatogram with water and concentration of the extracts gave 2-*O*-methyl-D-mannose (48 mg), m.p. and mixed m.p. 138–140 °C (from ethanol, lit. (17) m.p. 138–139 °C), and 2,3,6-tri-*O*-methyl-D-glucose (32 mg), m.p. and mixed m.p. 116–118 °C (from ethyl ether, lit. (18) m.p. 121–123 °C).

The acidic fraction was treated with methanolic hydrogen chloride, reduced with sodium borohydride, and the product was hydrolyzed with sulfuric acid. Paper chromatography showed, by comparison with authentic samples, the presence of 2,3-di and 2,3,6-tri-*O*-methyl-D-glucose. G.l.c. of the methylated alditol acetates (19) showed the former in greater amount consistent with the acidic fraction being a mixture of methylated D-glucuronic acid and a methylated aldobiouronic acid. The identity of the two methylated glucoses was further confirmed by the mass spectra of their alditol acetates (20).

Isolation of a large amount of 2-*O*-methyl-D-mannose and the absence of a corresponding quantity of end-group means that the mannose cannot represent a branch point. The pyruvic acid cannot be linked as a ketal to the D-glucose or the D-glucuronic acid and must thus be present as 4,6-*O*-(1-carboxyethylidene)-D-mannose. This is confirmed by the following experiment.

A sample of K-5 capsular polysaccharide was autohydrolyzed and the non-dialyzable residue (200 mg) was recovered and methylated. Hydrolysis and examination on paper of the neutral sugars showed a weak response for tetramethylhexose and a strong response for trimethyl hexose with no slower moving compounds. (Butanone-water does not separate 2,3,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose.) Analysis of the neutral fraction as alditol acetates on 3% ECNSS-M programmed from 170° at 1°/min showed peaks corresponding to 2,3,6-tri-*O*-methyl-D-glucose (21.6 min) and 2,4,6-tri-*O*-methyl-D-mannose (18.0 min). The alditol acetate of the latter crystallized spontaneously (4) and had m.p. and mixed m.p. 64–66 °C. There was in addition a small peak at 9 min corresponding to a tetramethyl sugar.

These results indicate a repeating structure as



into which one *O*-acetyl group, at present unassigned, must be accommodated. In support of

[2]An agarose-type gel obtained from Seravac Laboratories, Cape Town, South Africa.

this structure the polysaccharide was found to consume 0.7 mol of periodate per sugar residue. Smith degradation of the polyalcohol gave erythritol and a component with the same mobility as erythritol on paper chromatography in 1-butanol–acetic acid–water (2:1:1). The latter compound, 3-*O*-(4,6-*O*-(1-carboxyethylidene)-D-mannopyranosyl)-D-erythronolactone, gave a positive reaction with the ferric hydroxamic acid spray for lactones (21) and the n.m.r. spectrum in D_2O showed a characteristic singlet for CH_3—C at τ 8.53 (6, 22). Total hydrolysis of this lactone and paper chromatography in ethyl acetate–acetic acid–formic acid–water (18:3:1:4) showed mannose, erythronolactone, and pyruvic acid (R_{Man} 1.0, 2.0, and 4.6). G.l.c. analysis of the acetylated reduced hydrolyzate gave erythritol tetraacetate and D-mannitol hexaacetate, m.p. and mixed m.p. 122–123° (ethanol, lit.(23) m.p. 125 °C).

Further details of the proposed structure and the possible presence of 4,6-*O*-(1-carboxyethylidene)-D-mannose units in other Klebsiella polysaccharides are currently under active investigation.

We are indebted to Dr. I. Ørskov, Copenhagen, for a culture (E 5051) of *Klebsiella* K-5, to Dr. P. J. Salisbury of this department for growing the bacteria, and to Dr. E. G. Gros for an authentic sample of 2-*O*-methyl-D-mannose. The financial support of the National Research Council of Canada, Ottawa, is gratefully acknowledged and we thank Dr. S. C. Churms for the molecular weight determination.

Matrix Infrared and Raman Spectroscopic Evidence for $Pd(N_2)_3$ in Solid Nitrogen

G. A. OZIN,[1] M. MOSKOVITS, P. KÜNDIG, AND H. HUBER

Lash Miller Chemistry Department and Erindale College, University of Toronto, Toronto, Ontario

Received April 28, 1972

Cocondensation of palladium atoms with $^{14}N_2$ at 4.2–10 °K leads to the formation of a binary dinitrogen complex. The complex is detected by matrix isolation infrared and Raman spectroscopy. Isotope studies using equimolar $^{14}N_2/^{15}N_2$ mixtures, together with isotope frequency and integrated absorption intensity calculations, suggest that the species is tris-dinitrogen palladium(0), $Pd(N_2)_3$.

La condensation d'atomes de palladium avec $^{14}N_2$ à 4.2–10 °K permet de former un complexe binaire diagoté. On détecte ce complexe par spectroscopie infrarouge d'isolation de matrice et Raman. Les études isotopiques utilisant des mélanges équimolaires $^{14}N_2/^{15}N_2$, de même que les calculs de fréquence d'isotope et d'intensité d'absorption intégrée, désignent le complexe comme étant le palladium(0) tris-dinitré, ou $Pd(N_2)_3$.

Canadian Journal of Chemistry, **50**, 2385 (1972)

Since the preparation of $[Ru(NH_3)_5N_2]^{2+}$ in 1965 which was the first complex of a transition metal that contained the nitrogen molecule as a neutral ligand (1), many exotic transition metal nitrogen complexes have been reported. For example, di- and trinuclear transition metal complexes are known, in $[(NH_3)_5RuN_2Ru(NH_3)_5]^{4+}$ and $[(NH_3)_5RuN_2Os(NH_3)_4N_2Ru(NH_3)_5]^{6+}$ respectively (2, 3), as well as complexes containing two nitrogen molecules coordinated to a single metal atom, for example, $[Os(NH_3)_4(N_2)_2]^{2+}$ (4).

Recently the cocondensation of metal vapors in their monatomic form with a variety of molecules at cryogenic temperatures has been found to produce a number of new and interesting chemical species and has provided a unique route by which to prepare binary transition metal nitrogen complexes (5).

We have combined the techniques of matrix isolation infrared and laser Raman spectroscopy together with $^{15}N_2$ isotope substitution experiments to study the cocondensation reaction of atomic palladium with molecular nitrogen in nitrogen matrices as well as in dilute nitrogen–argon matrices.

In this preliminary communication we are presenting the data for pure nitrogen matrices in which we have spectroscopic evidence for $Pd(N_2)_3$, the first reported example of a transition metal – nitrogen complex containing more than two neutral dinitrogen molecules coordinated to a single transition metal atom.

Using methods similar to those developed by DeKock (6), Timms (7), Andrews and co-worker (8), Ogden and Darling (9) and Burdett and Turner (5), palladium atoms were cocondensed with molecular nitrogen at 4.2–10 °K, using an Air Products liquid helium transfer system for matrix Raman experiments and a Displex closed cycle helium refrigerator for matrix infrared experiments. The furnace and cryotip arrangements are identical to those previously described (10). The rate of deposition of nitrogen gas was controlled by a fine needle valve and the rate of deposition of palladium atoms was continuously monitored using a quartz crystal microbalance incorporated into the furnace (11). The metal atom concentration was arranged so that the probability of forming a palladium aggregate in the matrix was about 0.1%.

In a number of experiments using pure $^{14}N_2$ as the matrix gas, one strong infrared absorption was observed at 2241 cm^{-1} as well as a very weak band at 2273 cm^{-1} (Fig. 1 *A*). In the analogous matrix Raman experiment one strong polarized line was observed at 2273 cm^{-1}. Matrix Raman depolarization measurements have been described previously (12).

When the matrix infrared experiment was repeated using an approximately equimolar mixture of $^{14}N_2$ and $^{15}N_2$ as matrix gas the spectrum shown in Fig. 1 *B* was observed. The single line observed at 2241 cm^{-1} in pure

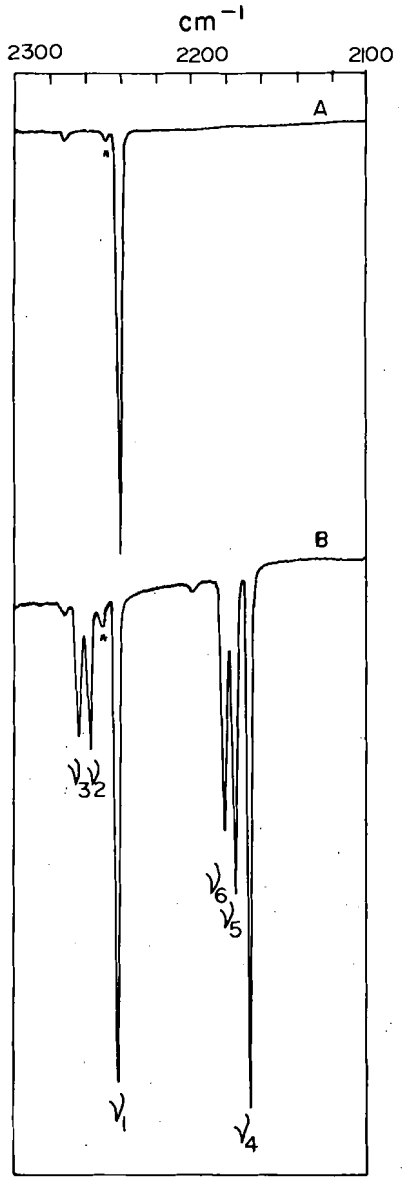

FIG. 1. *A*, the matrix infrared spectrum (2300–2100 cm^{-1}) of the products of the cocondensation reaction of palladium atoms with pure $^{14}N_2$. *B*, the matrix infrared spectrum (2300–2100 cm^{-1}) of the products of the cocondensation reaction of palladium atoms with an approximately equimolar mixture of $^{14}N_2/^{15}N_2$. The asterisks indicate the presence of trace quantities of a palladium species containing more than a single palladium atom.

$^{14}N_2$ was replaced by *two* groups of *three* main lines at 2263.4, 2256.3, 2241.4 cm^{-1} and 2182.5, 2175.6, 2166.9 cm^{-1}, respectively, with two very weak lines observed at 2273 and 2200 cm^{-1}. In a pure $^{15}N_2$ matrix one strong band was observed at 2167 cm^{-1} as well as a very weak band at 2200 cm^{-1}.

TABLE 1. Calculated and observed frequencies for $Pd(^{14}N_2)_n(^{15}N_2)_{3-n}$ where $n = 0$–3

Frequency notation		Calculated	Observed
Infrared	ν_1	2242.8	2241.4
	ν_2	2255.1	2256.3
	ν_3	2264.3	2263.4
	ν_4	2166.8	2166.9
	ν_5	2174.1	2175.6
	ν_6	2182.9	2182.5
Raman	ν_7	2272.0	2273.0

The six line spectrum obtained in the $Pd/^{14}N_2/^{15}N_2$ matrix together with the simplicity of the infrared and Raman spectra for the $Pd/^{14}N_2$ system strongly suggest that the most abundant species in the matrix is $Pd(N_2)_3$, containing three neutral dinitrogen molecules bonded directly to a palladium atom, with either D_{3h} or C_{3v} symmetry.

Following the methods used by Bor (13) and Haas and Sheline (14) for carbonyls we have assigned the six lines in the $Pd/^{14}N_2/^{15}N_2$ spectrum as follows

(E) $Pd(^{14}N_2)_3 + (B_1)Pd(^{14}N_2)_2(^{15}N_2)$	2241.4(ν_1)
(A_1) $Pd(^{14}N_2)_2(^{15}N_2)$	2263.4(ν_3), 2175.6(ν_5)
(A_1) $Pd(^{14}N_2)(^{15}N_2)_2$	2256.3(ν_2), 2182.5(ν_6)
(E) $Pd(^{15}N_2)_3 + (B_2)Pd(^{14}N_2)(^{15}N_2)_2$	2166.9(ν_4)

where the higher of the two A_1 frequencies for the two mixed species are the in-phase modes (13).

A simple calculation assuming the validity of the Cotton–Kraihanzel force field approximation (15) for a D_{3h} molecule indicates that $(\lambda_1\mu_{15}/\lambda_4\mu_{14})$ and $(\lambda_2\lambda_6/\lambda_3\lambda_5)$ should both equal unity, where λ_i is proportional to ν_i^2 and μ_{14} and μ_{15} are, respectively, the inverse reduced masses of $^{14}N_2$ and $^{15}N_2$. Experimentally one finds that $(\lambda_1\mu_{15}/\lambda_4\mu_{14}) = 0.9986$ and $(\lambda_2\lambda_6/\lambda_3\lambda_5) = 1.00004$, in excellent agreement with the predicted values.

A least-squares analysis yielded 20.91 and 0.18 mdyn/Å for the N–N stretch and stretch–stretch interaction force constants, respectively. The calculated frequencies based on these force constants are shown in Table 1.

The integrated absorption intensities of the various bands can also be approximately pre-

dicted using the technique suggested by Haas and Sheline (14). Applying their method one predicts that for an equimolar mixture of $^{14}N_2/^{15}N_2$, $A_3/A_5/A_4$ and $A_2/A_6/A_1$ are in the ratio 1.3:4.6:9.3 and 2.9:3.0:10.0, respectively, where the A_i refer to the absorbances associated with the frequencies ν_i. Experimentally we find that $A_3/A_5/A_4$ is in the ratio 1.85:4.7:8.3 and $A_2/A_6/A_1$ is in the ratio 1.8:3.9:10.

The agreement between the expected and measured band frequencies and integrated absorption intensities provides convincing evidence that the six line spectrum reported in Fig. 1 *B* probably belongs to the pure and mixed species of $Pd(N_2)_3$.

A Regiospecific Construction of α-Haloketones by the Reaction of Enol Borinates with *N*-Bromo- and *N*-Chlorosuccinimide. A Convenient Method for Converting Olefins into α-Haloketones and Esters

John Hooz and John N. Bridson[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 7, 1972

α-Bromo- and α-chloroketones may be synthesized in a regiospecific manner in high yields by treatment of an enol borinate with *N*-bromo- or *N*-chlorosuccinimide. This method preassembles the carbon skeleton of the ketone, and thereby avoids the problems (isomer formation, polyhalogenation) inherent in other methods. α-Haloesters are also easily synthesized by this procedure.

Les α-bromo et α-chlorocétones peuvent être synthétisées de façon régiospécifique, avec de bons rendements, en traitant le borinate d'énol avec le *N*-bromo et *N*-chlorosuccinimide. Cette méthode assemble d'avance le squelette carboné de la cétone et évite de ce fait les problèmes inhérents aux autres méthodes (formation d'isomères, polyhalogénation). Les α-haloesters sont également synthétisés facilement par ce procédé.

Canadian Journal of Chemistry, **50**, 2387 (1972)

α-Haloketones are precursors for several synthetically important processes (such as the Cornforth olefin synthesis (1) Favorskii rearrangement, etc.) yet their preparation is frequently a troublesome operation. According to usual practise an unsymmetrical ketone is halogenated directly; yet, despite the choice of halogenating reagent, or temptation to predict product formation on the basis of kinetic or thermodynamic

*Structures were corroborated by direct comparison with authentic samples or acceptable (±0.30%) compositional analyses and compatible spectral (i.r., n.m.r., mass spectroscopic) data.

†Yields are based on diazoketone using a 1:1 molar ratio of organoborane:diazoketone, and established by v.p.c. analysis. For the preparation of α-bromoketones, a 20% excess of *N*-bromosuccinimide was used at *ca.* 0°, whereas α-chloroketones were synthesized using a ratio of R_3B:NCS = 1:3, at room temperature for *ca.* 1 h. All organoboranes (except triethylborane‡) were prepared by the hydroboration of the appropriate olefin (9).

‡Commercial (Alfa Inorganics, Inc.) triethylborane was employed.

control, low yields and/or difficultly separable mixtures[2] are not an uncommon experimental outcome (eq. 1).

[1] 
Indirect procedures, halogenation of enol derivatives (acetates, ethers, etc), have also been employed. Nonetheless, since enol derivatives are almost invariably constructed from parent ketone, disadvantages similar to those experienced for direct methods accrue, unless rather special circumstances (thermodynamic, steric factors, etc.) predominate (eq. 2) (5).

[2] 
An approach has been developed which obviates these ambiguities: enol borinates react with *N*-bromo- or *N*-chlorosuccinimide[3] to provide the corresponding α-haloketones (eq. 3), *and significantly, in no case was there evidence for formation of the positional isomer.* Since enol borinates are conveniently assembled from readily available materials in an unambiguous fashion, the method allows for the unequivocal synthesis of the more- or less-highly substituted internal α-haloketone.

As a typical example, treatment of the enol borinate (derived from reaction of trihexylborane and diazomethyl isopropyl ketone) with *N*-bromosuccinimide at *ca.* 0° gave (80%) 4-bromo-2-methyl-3-decanone (eq. 4).

This illustrates one general approach in which the requisite intermediate enol borinate is easily generated in high yield upon reaction of an α-diazocarbonyl compound (6) with a trialkylborane (eq. 5). After the evolution of nitrogen is complete, intermediates of this type are employed *in situ*, in accordance with eq. 3, to provide an operationally convenient (one-flask), good yield, regiospecific route to α-haloketones. Bromination is complete in *ca.* 15 min at 0°, whereas chloroketone formation requires ap-

[2]Normally the predominant isomer is the one in which halogen enters the more highly substituted α position (most stable enol). Bromination of 2-pentanone (2), for example, gives a mixture of 3-bromo- (53%) and 1-bromo-2-pentanone (32%). A recent example (which appears somewhat extreme but nonetheless reflects the difficulties) is the chlorination (SO_2Cl_2) of 3-methyl-2-butanone to give (17% yield) 3-chloro-3-methyl-2-butanone (3). Yet chlorination of 2-methylcyclohexanone (SO_2Cl_2) gives an 83–85% yield of 2-chloro-2-methylcyclohexanone (4).

[3]Exploratory experiments by Dr. Hiromichi Kono established that molecular bromine gives a rather complex mixture from which only low yields of α-bromocarbonyl compound can be isolated. Dr. Kono's skillful efforts paved the way for the present developments.

[6] 
[7] 
[8] 
proximately 1 h at room temperature. Due to the hydrolytic sensitivity of enol borinates,[4] anhydrous conditions (nitrogen atmosphere, strictly anhydrous solvent and reagents) are necessary; failure to observe these precautions usually results in *ca.* 10–15% less haloketone with concurrent (and bothersome) formation of ketone by adventitious hydrolysis. Some typical examples are illustrated by the results summarized in Table 1.[5]

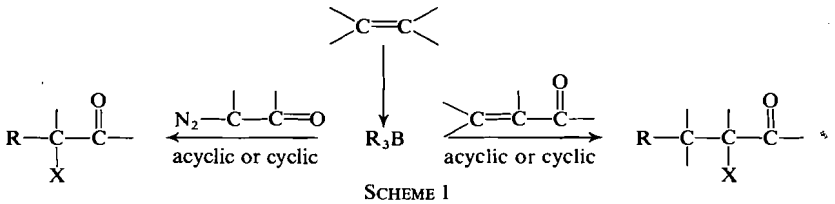
α-Haloesters are also easily prepared by this method. For example, treatment of triethylborane with ethyl diazoacetate followed by reaction with *N*-bromosuccinimide gave (85%) ethyl 2-bromobutyrate (eq. 6).

Moreover, that these developments possess potential for considerably broader scope immediately becomes clear upon recognition that enol borinates are implicated as intermediates in a wide variety of organoborane-based synthetic procedures (among others, the reaction of organoboranes with methyl vinyl ketone (8*a*), acrolein (8*b*), 2-bromo- and 2-methylacrolein (8*c*), cyclic α,β-unsaturated ketones (8*d*, *e*), etc.) (eq. 7).

To illustrate the applicability of this route, we investigated the reaction of triethylborane with methyl vinyl ketone, followed by treatment with NBS. A 70% yield of 3-bromo-2-hexanone was realized (eq. 8).

[4]The *in situ* capture of these intermediates by D_2O provides an unambiguous route to α-deuterioketones and esters (7).

[5]An interesting facet of the R_3B-α-diazocarbonyl reaction is the selective migration of the primary alkyl groups. Although the hydroboration of simple terminal olefins produces approximately 94% primary and 6% secondary boron-bound alkyl groups, no 4-bromo-2,5-dimethyl-2-nonanone was detected (from the reaction of the trialkylboranes obtained from 1-hexene with diazomethyl isopropyl ketone). This fortunate circumstance offers considerable synthetic advantage, since, in general, the products of these reactions appear to be free of any potential isomeric contaminants. Also, we should like to remind potential users that the R_3B-diazo reaction is sensitive to steric factors, and although, in general, yields are excellent for terminal olefins, they fall off with increasing steric hindrance in the organoborane (6).



SCHEME 1

Since there is considerable structural flexibility when choosing among appropriate organoborane, α-diazo substrate, and unsaturated carbonyl component, the simplicity and high yields, combined with the unequivocal regiospecificity of this new alkylation–halogenation method, permits the synthesis of a wide array of useful structures difficult to obtain by present methodology (Scheme 1).

The synthesis of 4-bromo-2-methyl-3-decanone is representative of the standard experimental procedure. A solution of trihexylborane (20 mmol) in 40 ml tetrahydrofuran was prepared by the hydroboration (9) of 1-hexene (60 mmol). To the magnetically-stirred solution was added, dropwise, a solution of 2.24 g (20 mmol) of diazomethyl isopropyl ketone in 20 ml tetrahydrofuran while maintaining the temperature below *ca.* 15° (ice-bath cooling). After stirring at *ca.* 25° for an additional hour, nitrogen evolution was quantitative. The solution was cooled to *ca.* 0°, and *N*-bromosuccinimide (22 mmol) was added at once, while nitrogen was passed over the mixture; an exothermic reaction took place. After stirring at *ca.* 0° an additional 15 min, 20 ml of cold 3 *N* NaOH solution was added. The mixture was stirred vigorously (15 min), then poured into cold saturated brine solution (200 ml), and extracted with pentane (three 50-ml portions). The residue remaining after concentration (rotary evaporator) of the dried (Na_2SO_4) extract was distilled to provide 3.14 g (63%) of 4-bromo-2-methyl-3-decanone, b.p. 92.5–94° (1.9 mm), n_D^{20} 1.4583.

The Far Ultraviolet Photolysis of Alkenes: The Use of Hydrogen Sulfide as a Radical Scavenger

GUY J. COLLIN, PATRICK M. PERRIN, AND CHRISTIAN M. GAUCHER

Département des Sciences Pures et Appliquées, Université du Québec à Chicoutimi, Chicoutimi, Québec

Received January 26, 1972

The far u.v. photolysis of *cis*-2-butene, *n*-1-pentene, and *cis*-2-pentene was carried out in the presence of various quantities of hydrogen sulfide. We showed that in these systems, hydrogen atoms add to the double bond and are not scavenged by 5–10% hydrogen sulfide. On the other hand, alkyl radicals such as methyl, ethyl, *s*-butyl, and *s*-pentyl react with hydrogen sulfide, and the formation of the corresponding alkanes may be used to measure the absolute yields of the radical species. The same holds true for vinyl radicals. We also report some experiments published elsewhere. In particular, in the case of 1,3-butadiene, identification of the principal radicals is possible; however, measurement of absolute yields becomes more difficult.

La photolyse dans l'ultraviolet lointain du *cis*-2-butène, 1-pentène et du *cis*-2-pentène a été faite en présence de diverses quantités d'hydrogène sulfuré. On a montré que dans ces systèmes, les atomes d'hydrogène s'additionnent sur la double liaison et ne sont pratiquement pas interceptés par l'hydrogène sulfuré. Par contre, les radicaux saturés méthyles, éthyles, *s*-butyles et *s*-pentyles réagissent avec l'hydrogène sulfuré et la formation de l'alcane correspondant permet d'obtenir le rendement absolu des espèces radicalaires. Il en est de même des radicaux vinyles. Nous rapportons également des résultats partiels publiés par d'autres auteurs. En particulier, dans le cas du 1,3-butadiène, l'identification des principaux radicaux est possible, bien que la mesure quantitative de leur rendement soit devenue plus difficile.

Canadian Journal of Chemistry, **50**, 2391 (1972)

Introduction

The photo-induced addition of hydrogen sulfide to olefins has been known for many years. In the presence of ultraviolet radiation, it is accepted that this addition occurs via a radical chain mechanism and the products obtained are mercaptan derivatives or disulfides (for a general survey, see for example, ref. 1).

[1] $$H_2S + h\nu \rightarrow HS^{\cdot} + H^{\cdot}$$

[2] $$HS^{\cdot} + RCH{=}CH_2 \rightarrow R\dot{C}H{-}CH_2SH$$

[3] $$R\dot{C}H{-}CH_2SH + H_2S \rightarrow HS^{\cdot} + RCH_2CH_2SH$$

[4] $$2R\dot{C}H{-}CH_2SH \rightarrow HS{-}CH_2{-}\underset{\displaystyle R}{\underset{|}{CH}}{-}\underset{\displaystyle R}{\underset{|}{CH}}{-}CH_2SH$$

In the preceding abstract (1) and in other publications (2–5) high concentrations of hydrogen sulfide were used. In this manner, most of the incident radiation is absorbed by the hydrogen sulfide, thus preventing a photo- or radio-induced decomposition of the olefins. Moreover, high concentrations of hydrogen sulfide increase the importance of reaction 3 compared to reaction 4.

In the u.v. photochemistry of saturated hydrocarbons in the gaseous state, Ausloos and co-workers have shown that hydrogen sulfide in small concentrations (2 to 10%) is an excellent radical scavenger and that it allows one (*a*) to identify the nature of the radicals and (*b*) to measure their absolute yields (6).

In this publication we present the results of our study of olefins in the far u.v. in the presence of low concentrations of hydrogen sulfide and discuss these along with others from the literature (7–8).

Experimental

cis-2-Butene (99.0%), *trans*-2-butene (99.0%) (Matheson of Canada Limited) were purified by chromatography and degassed. Hydrogen sulfide (99.5%) (Matheson of Canada Limited), and 1-pentene and the *cis*-2-pentene (Chem. Sample Co.) were used after being degassed.

All samples were prepared in a mercury-free vacuum system equipped with Teflon stopcocks which were capable of maintaining a vacuum of about 10^{-5} mm Hg. Pressure measurements of samples were made with two metallic membrane manometers (Wallace and Tiernan).

The gaseous samples were irradiated in a 1 l flask sealed to an electrodeless xenon discharge lamp (9) excited by a 125 W microwave generator (Raytheon 2450 Mc unit). This lamp was equipped with a 1.5 mm thick lithium fluoride window and it produced 8.4 eV photons. Isobutene or 1-butene (10) irradiations were carried out to determine the quantum yields. Generally, the intensity was of the order of 7×10^{13} photons s^{-1}. Although we tried to keep the intensity constant, a sulfur deposit slowly accumulated on the window which became increasingly opaque. After approximately 8 h of irradiation, the window was washed with carbon disulfide; the lamp regained its initial intensity after this treatment.

A fraction of the irradiated sample was introduced in the gaseous state into a gas-chromatograph equipped with either a squalane column (25 ft), operated at room temperature, or with an alumina column (10 ft), temperature programmed between 50 and 150 °C. The detector consisted of a double flame ionization system and the calibrations were made by the introduction of known samples. The accuracy of the method of analysis is very good and the experimental error is probably less than 4%.

Discussion and Results

(A) Hydrogen Atoms

In the radiolysis of propane (6), 4.5% hydrogen sulfide is sufficient to scavenge more than 99.5% of thermal hydrogen atoms. In such a system, the rate of abstraction of a hydrogen atom from propane is much slower than from hydrogen sulfide:

[5] $$H^{\cdot} + H_2S \rightarrow H_2 + HS^{\cdot}$$

[6] $$H^{\cdot} + CH_3CH_2CH_3 \rightarrow H_2 + s\text{-}\dot{C}_3H_7$$

The reaction 6 is much slower than reaction 5. In an unsaturated system, the situation is more complex because the hydrogen atoms also add to the double bond:

[7] $$H^{\cdot} + cis\text{-}2\text{-}C_4H_8 \rightarrow s\text{-}\dot{C}_4H_9$$

[8] $$H^{\cdot} + cis\text{-}2\text{-}C_4H_8 \rightarrow H_2 + \dot{C}_4H_7$$

In the literature (11), it was demonstrated that reaction 8 is much slower than reaction 7: $k_8/k_7 = 6.6 \times 10^{-2}$. In the case of *trans*-2-butene, the same ratio k_8/k_7 is close to 11.7×10^{-2}. Thus more than 90% of the hydrogen atoms add to the double bond. In the presence of hydrogen sulfide, the efficiency of reactions 5 and 7 must be compared. It is known that hydrogen atoms add to ethylene at a rate twice that of reaction 5 (12). Also, the addition of hydrogen atoms to *cis*-2-butene (or *trans*-2-butene) occurs at approximately the same rate as that of the addition to ethylene (0.8 and 1.1 times faster respectively) (11):

[9] $$H^{\cdot} + C_2H_4 \rightarrow \dot{C}_2H_5$$

Thus the ratio k_7/k_5 is of the order of 1.6 and since the concentrations of hydrogen sulfide are less than 20%, more than 87% of the thermal hydrogen atoms react with *cis*-2-butene. In the case of *trans*-2-butene, 1-butene, and isobutene, 20% hydrogen sulfide captures less than 9, 5, and 2% of these atoms, respectively. These conclusions were confirmed by the photolysis of hydrogen sulfide in the presence of various alkenes (13).

If reaction 5 is ignored in unsaturated systems as a first approximation, we can consider that the thermal hydrogen atoms are transformed into alkyl (90%) and alkenyl (10%) radicals. Later, we will demonstrate that these radicals probably react with hydrogen sulfide to give an alkane and an alkene, respectively. To summarize, in an unsaturated system, the hydrogen sulfide does not capture the thermal hydrogen atoms. In the case of compounds containing conjugated double bonds, the hydrogen sulfide has no effect on thermal hydrogen atoms because these atoms add more readily to conjugated double bond systems than to simple olefins (14–15).

(B) Photolysis of cis-2-Butene (see Table 1)

Methyl Radical

Ausloos and Lias (6) have demonstrated that in the photolysis of propane, the thermal methyl radicals react with hydrogen sulfide at a rate 2.5×10^5 times greater than with propane in experiments carried out at room temperature. Under these conditions, 0.5% hydrogen sulfide added to propane captures 99.9% of the methyl radicals

[10] $$CH_3^{\cdot} + H_2S \rightarrow CH_4 + HS^{\cdot}$$

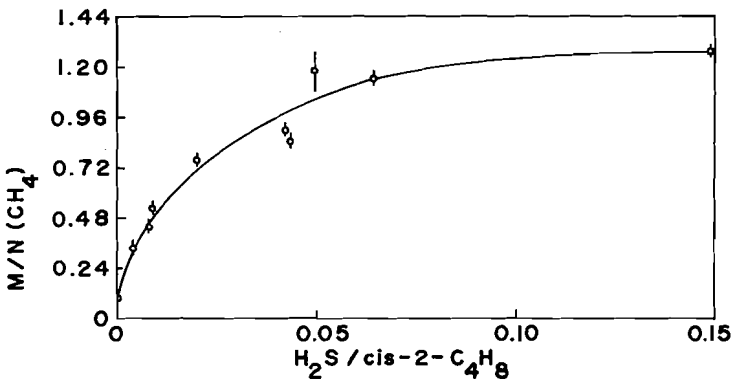

FIG. 1. Yields of methane formed in the photolysis (147.0 nm) of *cis*-2-butene at a pressure of 1.32 Torr and in the presence of varying amounts of hydrogen sulfide: irradiation time 15 min.

The increase in the yields of methane when hydrogen sulfide is added to propane thus allows the determination of the quantum yield of methyl radicals.

In unsaturated systems, the radicals can abstract a hydrogen atom or add to the double bond as in the case of hydrogen atoms

[11] $CH_3^{\cdot} + cis\text{-}2\text{-}C_4H_8 \rightarrow \dot{C}_5H_{11}$

[12] $CH_3^{\cdot} + cis\text{-}2\text{-}C_4H_8 \rightarrow CH_4 + {}^{\cdot}C_4H_7$

The k_{11}/k_{12} ratio is close to unity (14, 16). Moreover, the activation energy of reactions 11 and 12 is of the order of 7.8 ± 0.3 kcal mol^{-1} whereas that of reaction 10 is of the order of 2.6 kcal mol^{-1} (17). From these values, one can estimate that the methyl radicals react about 1000 times faster with hydrogen sulfide than with *cis*-2-butene. Thus in the presence of 5% hydrogen sulfide added to *cis*-2-butene, 99% of the methyl radicals react with the hydrogen sulfide. Therefore, the increase in the yield of methane in the presence of hydrogen sulfide again will permit the evaluation of the quantum yield of methyl radicals. Figure 1 shows that in the presence of 5% hydrogen sulfide, at least $90 \pm 5\%$ of the methyl radicals react according to reaction 10. Reaction between a methylene radical and H_2S produces methane (18). But in the 8.4 eV photolysis, the quantum yield of methylene is 0.02 (19). This yield is negligible and need not be considered here.

Further confirmation that the proposed mechanism is correct is obtained by following the yields of the products that are formed from methyl radicals in the absence of all free radical scavengers. In the case of pure *cis*-2-butene, methyl radicals essentially react with other radicals formed during the photolysis. It is known that in this system the methyl and the *s*-butyl radicals are the most important (8)

[13] $\dot{C}H_3 + \dot{C}H_3 \rightarrow C_2H_6$

[14] $\dot{C}H_3 + s\text{-}\dot{C}_4H_9 \rightarrow (CH_3)_2CHC_2H_5$

Figure 2 shows that the presence of hydrogen sulfide will cause a very rapid decrease in the yields of ethane and isopentane (19). From the increase in methane, the quantum yield of $CH_3^{\cdot}$ is less than or equal to 1.32. In the absence of all radical scavengers, part of the methane is formed by dismutating radical reactions involving the methyl radical and the other part is formed by molecular decomposition of excited *cis*-2-butene molecules. The preceding value must be reduced for the quantity of molecular methane (that is, that formed in the presence of 2% oxygen) which leads to an average value for the quantum yield of $\dot{C}H_3$ of about 1.2 ± 0.1.

In addition, the decrease of the yields of ethane and isopentane allows one to deduce the value of the yield of methyl radicals. Reaction 14 must be corrected for the following dismutation reaction:

[15] $\dot{C}H_3 + s\text{-}\dot{C}_4H_9 \rightarrow CH_4 + C_4H_8$

The ratio k_{15}/k_{14} is not well known: 0.30 or 0.07 (17). If it is assumed that reactions 13–15 are the only reactions involving methyl radicals, then

$$\Phi({}^{\cdot}CH_3) = 2(C_2H_6) + (1 + k_{15}/k_{14})(\text{iso-}C_5H_{12})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

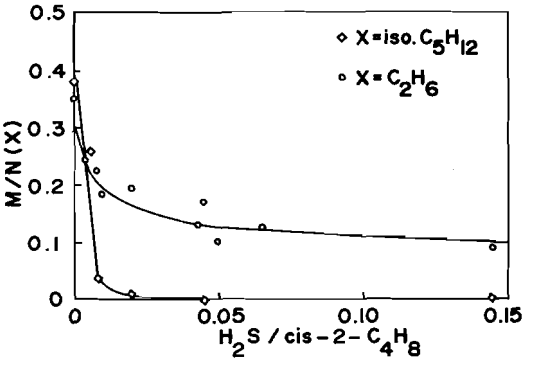

FIG. 2. Yields of ethane and isopentane formed in the photolysis of *cis*-2-butene. The experiments were carried out with conditions similar to those reported in Fig. 1.

These two values lead to quantum yield of $^{\cdot}CH_3$ of about 1.20 or 1.12, respectively. Thus obtained, these two values are minimum values because the methyl radicals also react with other radicals present. However, the methyl and *s*-butyl radicals are really the most important radicals, and if there are any other radicals, they are present in very small quantities. Thus the value of the methyl radical yield is probably close to 1.2.

Of course, the preceding deductions are only valid as long as other reactions do not interfere with the proposed mechanism. In particular, the thiyl radicals ($HS^{\cdot}$) that are formed in reaction 10, as a first approximation, are thought not to interfere with the measurement of methyl radicals, and for various reasons: (*a*) the low intensity used in this work; (*b*) the high degree of reactivity of methyl radicals and other radicals towards hydrogen sulfide; (*c*) the possibility for thiyl radicals to react with themselves or with other radicals that have a high molecular weight; (*d*) finally, in a future publication, we will demonstrate that thiyl radicals react very rapidly with 1,3-butadiene which is formed during the photolytic experiments.

s-Butyl Radicals

As in the case of methyl radicals, one can expect the majority of *s*-butyl radicals to be scavenged by 5% hydrogen sulfide

[16] $$s\text{-}\dot{C}_4H_9 + H_2S \rightarrow n\text{-}C_4H_{10} + HS^{\cdot}$$

In fact, the yield of normal butane was not measured but as was seen before, the variation of the yield of isopentane confirms indirectly this mechanism. The dismutation reactions of *s*-butyl radicals with each other are added to reactions 14 and 15

[17] $$s\text{-}\dot{C}_4H_9 + s\text{-}\dot{C}_4H_9 \rightarrow C_4H_8 + n\text{-}C_4H_{10}$$

[18] $$s\text{-}\dot{C}_4H_9 + s\text{-}\dot{C}_4H_9 \rightarrow C_8H_{18}$$

Even if the yield of normal butane was not measured, the yield of *s*-butyl radicals may be calculated (see note 19, ref. 18) and, depending on the ratio k_{15}/k_{14} (0.07 or 0.30), the value of the yield of $^{\cdot}C_4H_9$ is either 1.1 or 1.3, respectively. The first value seems to be in better agreement with a value obtained by another method in this laboratory (19): $\Phi(s\text{-}C_4H_9) = 1.05 \pm 0.10$. Once again, this calculation disregards other alkyl or thiyl radicals that are present. However, the similarity of the measurements is good and it is probable that the quantum yield of $s\text{-}C_4H_9$ is close to 1.1. Since the *s*-butyl radical is formed by the addition of hydrogen atoms to *cis*-2-butene, the yield of thermal hydrogen atoms is also of the order of 1.15, which is a reasonable value.

Radicals Present in Small Amounts

Ethyl radicals are also present in this system. In the presence of 14.5% hydrogen sulfide, ethane cannot be formed by the addition of two methyl radicals, and since the yield of molecular ethane (that is, the one formed in the presence of oxygen) is 0.004, it is possible to calculate a value of the yield of ethyl radicals. $\Phi(C_2H_5)$ is of the order of 0.08 if we postulate that the ethane in the presence of hydrogen sulfide is formed in the following reaction

[19] $$C_2H_5^{\cdot} + H_2S \rightarrow C_2H_6 + HS^{\cdot}$$

The presence of ethyl radicals in low concentrations is confirmed by the presence of propane that is formed by the addition of methyl and ethyl radicals in the absence of all radical scavengers.

The yield of ethylene also increases in the presence of hydrogen sulfide (Fig. 3). This slight increase can be attributed to the reaction of vinyl radicals with hydrogen sulfide

[20] $$C_2H_3^{\cdot} + H_2S \rightarrow C_2H_4 + HS^{\cdot}$$

This possibility could be questioned because of the manner in which the actinometry is carried out. We have assumed that the yield of allene is constant whatever the operating conditions. In fact it could well be that the yield in allene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

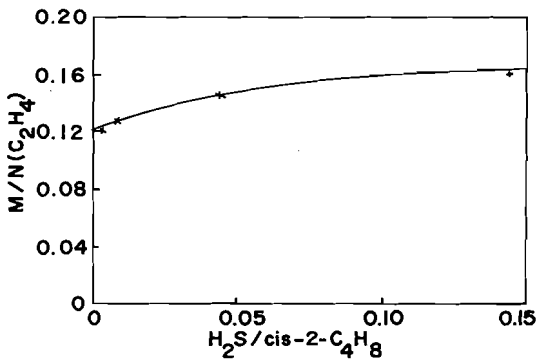

FIG. 3. Variations of the yield of ethylene in the photolysis of *cis*-2-butene (conditions reported under Fig. 1).

decreases slightly in the presence of hydrogen sulfide and is thus responsible for the apparent increase in the yield of ethylene. If the allene is formed by the decomposition of excited *cis*-2-butene molecules, it is improbable that this reaction will be influenced by the presence of hydrogen sulfide. On the other hand, a small part of the allene (30%) may be formed by the decomposition of a C_3H_5 radical. The latter would lead to the formation of propene in the presence of hydrogen sulfide. In the gaseous phase, the C_3H_5 radical, if it is formed, stems from the decomposition of an excited *cis*-2-butene molecule. Considering the energy of the incident photon, the C_3H_5 radical should decompose to allene and to a hydrogen atom well before a molecular collision. Finally, the ratio acetylene/allene is constant whatever the concentration of hydrogen sulfide, showing again that the yield of allene is constant. Thus, the quantum yield of vinyl radicals is of the order of 0.04.

In the irradiation of pure *cis*-2-butene, the absence of isobutane demonstrated without a doubt the absence of *s*-propyl, isobutyl, and *t*-butyl radicals. The absence of these radicals was also confirmed by the absence of propane and isobutane in the experiments that were carried out in the presence of hydrogen sulfide. Nothing can be said about the allyl radicals, if they are present, for the analysis of hydrogen sulfide interferes with the analysis of propene on the chromatographic columns.

(C) Photolysis of 1-Pentene (see Table 2)

In this system, actinometry was not carried out. However, because the yield of allene did not seem to vary, all the given yields are relative to that of allene: $R(C_3H_4) = 100$.

Ethyl Radicals

The most important radicals in the photolysis of 1-pentene are probably ethyl and *s*-pentyl radicals. This assertion is confirmed by the results in Table 2: 7% hydrogen sulfide added to 1-pentene will increase substantially the yields of ethane and normal pentane.

The activation energy of the abstraction of a hydrogen atom by an ethyl radical from olefinic molecules is of the order of 8.0 kcal mol^{-1} and the same reaction with hydrogen sulfide is less than 3 kcal mol^{-1}. Thus the conclusions deduced for the methyl radicals may be applied to the ethyl radicals.

It is rather interesting to attempt to determine the mechanism of formation of these ethyl radicals. *A priori*, two modes of formation can be considered: first of all, by decomposition of excited pent-1-ene molecules

$$[21] \qquad (n\text{-}1\text{-}C_5H_{10})^{**} \rightarrow C_2H_5^{\cdot} + C_3H_4 + H^{\cdot}$$

This decomposition reaction is endothermic by 128 kcal mol^{-1}, which is less than the energy of the incident photons: 194.5 kcal mol^{-1}. Moreover, this reaction is undoubtedly independent of pressure, at least in the region 0.03–100 Torr, and it is similar to the decomposition reactions of excited isobutene (7) and 1-butene (10) molecules. The second possibility for the formation of ethyl radicals stems from the decomposition of excited *s*-pentyl radicals formed by the addition of a hydrogen atom to the 1-pentene molecule

$$[22] \qquad (s\text{-}C_5H_{11})^{*} \rightarrow C_2H_5^{\cdot} + C_3H_6$$

$$[23] \qquad (s\text{-}C_5H_{11})^{*} + M \rightarrow s\text{-}C_5H_{11} + M$$

As shown in reaction 23, the decomposition reaction 22 depends upon the pressure of the system (20). As an example, at 1.32 Torr approximately 75% of the *s*-pentyl radicals are stabilized [23]. Above 100 Torr, reaction 22 does not occur (20). As a result, regardless of the pressure

$$R_1(C_2H_5^{\cdot}) = R(C_2H_6)_{7\%\ H_2S} - R(C_2H_6)_{\text{molecular}}$$

and

$$R_2(C_2H_5^{\cdot}) = R(C_3H_6) - R(C_3H_6)_{\text{molecular}} + R(C_3H_4)$$

$R(C_2H_6)_{molecular}$ is the relative yield of ethane produced in the presence of oxygen; $R(C_3H_6)_{molecular}$ is the relative yield of propane produced at high pressure and in the presence of oxygen; finally $R_1(C_2H_5)$ and $R_2(C_2H_5)$ are the relative yields of ethyl radicals. From Table 2 at 1.32 Torr, $R_1(C_2H_5)$ is equal to 237 and $R_2(C_2H_5)$ is equal to 216. These values are in good agreement and are within the limits of error if it is accepted that each independant measurement is given at $\pm 4\%$.

s-Pentyl Radicals

The high yield of normal pentane formed in the presence of 7% hydrogen sulfide confirms first of all the efficiency of the addition of the hydrogen atoms to the double bond and also, the high reactivity of the hydrogen sulfide with *s*-pentyl radicals. However, we must mention that the addition of a thermal hydrogen atom to the double bond of pentene leads to two types of radicals: primary radicals ($\dot{C}H_3(CH_2)_2\dot{C}H_2$) and secondary radicals ($CH_3(CH_2)_2\dot{C}HCH_3$).

The proportion of the primary radical is probably less than 8% of the total as has already been shown in a similar system (10). An independant measurement of this proportion confirms this value (19). In any case, the primary and secondary radicals probably both lead to the normal pentane in the presence of hydrogen sulfide.

Radicals Present in Small Amounts

Since an increase of 7–15% in the quantity of hydrogen sulfide does not modify the yields of methane and propane, once again we must conclude that 7% hydrogen sulfide is sufficient to scavenge the majority of methyl and propyl radicals *n*-propyl; moreover $R(CH_3) = 30 \pm 10$ and $R(C_3H_7) = 57 \pm 3$.

The absence of isobutane and normal butane in the irradiations carried out in the presence of hydrogen sulfide is an indication of the absence of butyl radicals in this system. In the same manner, the yield of ethylene is constant at constant pressure regardless of the quantity of radical scavengers. The relative yield of vinyl radicals is thus within the limits of error of the measurements, that is, $R(C_2H_3) \leqslant 12$.

(D) Photolysis of cis-2-Pentene

Like the yield of allene in the case of pent-1-ene, the yield of ethylene is also constant regardless of the concentration of hydrogen sulfide. Consequently, the yield of vinyl is low and within the limits of error. As a point of reference, we will use the yield of ethylene: $R(C_2H_4) = 100$. This selection of $R(C_2H_4)$ under all conditions can indeed mask the appearance of C_2H_3 radicals. Figure 4 gives the variation in the yields of methane, ethane, and normal pentane. From these curves, we arrive at the following values: $R(C_5H_{11}) = 480$, $R(CH_3) = 680$, and $R(C_2H_5) = 125$. Once again, these curves demonstrate the efficiency of hydrogen sulfide as a radical scavenger of methyl, ethyl, and pentyl radicals (probably $CH_3\dot{C}HCH_2CH_2CH_3$ and $CH_3CH_2\dot{C}HCH_2$-CH_3).

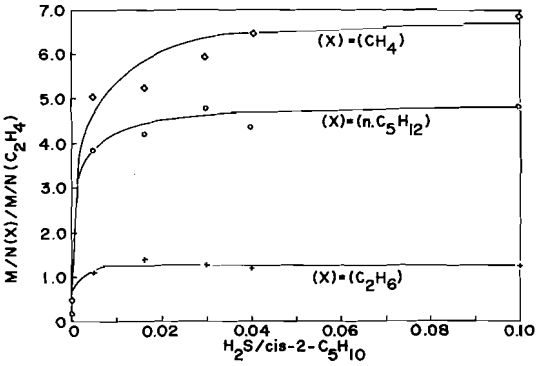

FIG. 4. Relative yields of methane, normal pentane and ethane in the photolysis of *cis*-2-pentene: experimental conditions similar to those reported under Fig. 1.

(E) Other Results Found in the Literature

In the photolysis of isobutene (7) conclusions which are similar to those reported here can be derived. Hydrogen atoms add to the double bond and methyl and butyl radicals (probably for the most part *t*-butyl) react with hydrogen sulfide to give either methane or isobutane. It is interesting to note that in this case, the yield of methyl radicals is close to the yield of C_3 products. In the photolysis of cyclohexane, methyl and cyclohexyl radicals are readily scavenged by 10% hydrogen sulfide (21).

In a more unsaturated system, 1,3-butadiene, hydrogen sulfide was used in order to study the nature of the radicals (8). When 10% hydrogen sulfide was added to 1,3-butadiene, the yield of methane increased by a factor of 10 or more; with higher concentrations of hydrogen sulfide, the yield of methane continued to increase (Fig. 5). The presence of methyl radicals was

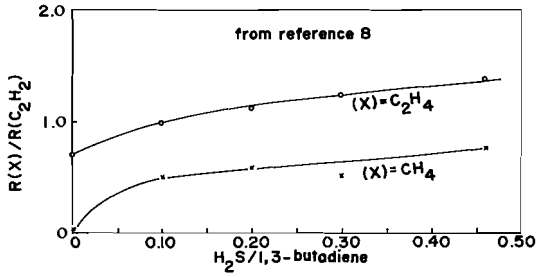

FIG. 5. Variation of relative yield of ethylene and methane (acetylene yield = 100) in the photolysis of 1,3-butadiene: see ref. 8.

proven but it is very difficult to obtain the absolute yield. This is not surprising because it is well known that the addition of methyl radicals to 1,3-butadiene takes place at a speed approximately 300 times faster than to *trans*-2-butene and 75 times faster than to but-1-ene at 65 °C (15). The activation energy of the addition reaction of the methyl radical to 1,3-butadiene is only 4.4 kcal mol^{-1}. This is not much greater than the activation energy of reaction 10. In this system, more than 50% hydrogen sulfide ($H_2S/1,3\text{-}C_4H_6 = 1.0$) is needed to scavenge 95% or more of the methyl radicals.

In the same manner, in the photolysis of 1,3-butadiene at 220.0 nm, the addition of hydrogen sulfide does not increase the yield of ethylene whereas at 147.0 nm, the yield of ethylene increases. The author concludes that at 220.0 nm, there is no formation of vinyl radicals whereas there is formation at 147.0 nm. In Fig. 5, it is possible to see that here again it is difficult to obtain the absolute yield of vinyl radicals.

The high reactivity of 1,3-butadiene toward methyl and vinyl radicals is probably general (15). Consequently, in unsaturated systems with conjugated double bonds, hydrogen sulfide is a poor radical scavenger and it can be used only to indicate the formation of radicals that are formed in appreciable yields, unless very high concentrations of hydrogen sulfide are used at the risk of completely changing the nature of the system studied. Similar observations have been reported in the photochemistry of 1,2-butadiene (22) and of cyclobutene (23).

The authors wish to thank the Université du Québec à Chicoutimi for the subsistence allowance accorded to one of us (P.M.P.), and also the National Research Council of Canada which has partially financed this research.

Photoisomerization of 2-Alkenes in the Presence of Hydrogen Sulfide

GUY J. COLLIN AND PATRICK M. PERRIN

Département des Sciences Pures et Appliquées, Université du Québec à Chicoutimi, Chicoutimi, Québec

Received January 26, 1972

In far u.v. photochemistry, the radicals formed react with hydrogen sulfide to give, amongst others, thiyl radicals (HS·). These radicals initiate the *cis–trans* isomerization of 2-olefins in a chain mechanism. We have tried to demonstrate that the thiyl radicals are also chain carriers. Quantum yields for the isomerization of *cis* to *trans* compound are probably of the order of $6–7 \times 10^3$ and the length of the chain, of the order of 4.7×10^3. We have also studied the radiolysis of these reactions in the liquid phase. The effect of oxygen and of conjugated di-olefins, such as 1,3-butadiene and 1,3-pentadiene is also discussed.

En photochimie de l'ultraviolet lointain, les radicaux formés réagissent avec l'hydrogène sulfuré pour donner entre autres des radicaux thiyles (HS·). Ces derniers initient l'isomérisation *cis-trans* des 2-oléfines dans un mécanisme en chaîne. Nous avons essayé de montrer que ces radicaux thiyles sont aussi les porteurs de chaîne. Les rendements quantiques pour l'isomérisation *cis* vers *trans* sont probablement de l'ordre de $6–7 \times 10^3$ et la longueur de chaîne de l'ordre de 4.7×10^3. Nous avons également étudié la radiolyse de ces systèmes en phase liquide. L'effet de l'oxygène et des di-oléfines conjuguées telles que 1,3-butadiène et 1,3-pentadiène est aussi discuté.

Canadian Journal of Chemistry, **50**, 2400 (1972)

Introduction

In the preceding paper we have studied the efficiency of hydrogen sulfide as a radical scavenger in the far u.v. photolysis of unsaturated compounds (1).

Hydrogen sulfide is a good radical scavenger and its use permits not only the identification of the nature of the radicals, but also the measurement of their absolute yields.

[1] $$R^{\cdot} + H_2S \rightarrow RH + HS^{\cdot}$$

The increase in the yield of the RH compound in the presence of hydrogen sulfide will permit the identification of the nature of the radical $R^{\cdot}$ and the measurement of its quantum yield. However, the chemical activity of the thiyl radical formed in reaction 1 was not considered earlier (1). We had simply stated that the formation of this radical did not intervene in the measurement of the other radicals. Here, we consider the effect of the presence of hydrogen sulfide in low concentrations on the photochemistry and the radiochemistry of 2-olefins.

Experimental

The photolytic techniques in the gaseous phase for the preparation of samples have already been described (1). Helium (Canadian liquid air: 99.995%) was used as received.

Each liquid sample contained 5.8×10^{-3} moles of unsaturated hydrocarbons. The cell was made of a small Pyrex tube equipped with a Pyrex break seal. Its volume was less than double the liquid volume. In this way more than 99.5% of the hydrocarbon was in the liquid phase.

After irradiation, the cell was sealed at the base of a 1 l flask. The liquid vaporized into the evacuated flask immediately after the breakseal was ruptured. Analysis of the irradiated sample was carried out as already described (1).

Irradiation of liquid samples was accomplished in a Gammacell, 220 type; the rate of energy absorption by 2-butene was 1.9×10^{17} eV/mol s.

Discussion and Results

Mechanism

Initiation Steps

The results show that the presence of low concentrations of hydrogen sulfide in the far u.v. photolysis of *cis*-2-butene, *trans*-2-butene, and *cis*-2-pentene isomerizes these compounds into *trans*-2-butene, *cis*-2-butene, and *trans*-2-pentene, respectively (see Table 1, Figs. 1–3). The question then arises as to whether this isomerization is dependent on the absorption of energy by the olefin or by the hydrogen sulfide. Because the absorption coefficient of hydrogen sulfide is not known at the exciting wavelength, it is assumed as a first approximation that this coefficient is at most equal and probably less than that of the olefin. Since the percentage of hydrogen sulfide is, for the most part, less than 15%, more than 85% of the energy is absorbed by the olefin. Generally this percentage is probably greater than 95%. Moreover, since an increase of 2 to 15% of the concentration of hydrogen

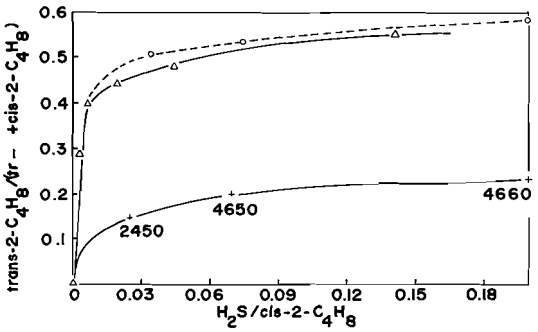

FIG. 1. Photoisomerization of *cis*-2-butene: variation of the *trans*-/(*trans*- + *cis*-2-butene) ratio *vs.* the hydrogen sulfide/*cis*-2-butene ratio: ○, *cis*-2-butene, 1.32 Torr, irradiation time = 2.5 min; △, *cis*-2-butene, 7.92 Torr, irradiation time = 15 min; +, *cis*-2-butene, 1.32 Torr; irradiation time = 0.5 min. Figures are quantum values: Φ (*trans*-2-butene).

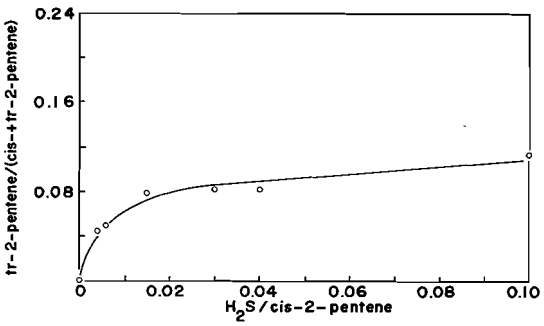

FIG. 2. Photoisomerization of *cis*-2-pentene: variation of the *trans*-/(*trans*- + *cis*-2-pentene) ratio *vs.* the hydrogen sulfide/*cis*-2-pentene ratio: *cis*-2-pentene, 7.92 Torr, irradiation time = 15 min.

sulfide has no, or very little effect on the isomerization yield, the absorption by hydrogen sulfide can be ignored, as far as this last reaction is concerned.

At the wavelength used, the absorption of photons by the olefins does not produce ions. The ionization potential of *cis*-2-butene and *trans*-2-butene is 9.13 eV and that of *cis*-2-pentene is 9.11 eV (2). In fact, absorption of photons leads to the formation of excited neutral molecules that decompose to give hydrogen atoms, radicals, and neutral molecules:

[2] $2\text{-}C_4H_8 + h\nu \rightarrow (C_4H_8)^{**}$

[3] $(C_4H_8)^{**} \rightarrow H^{\cdot}, R^{\cdot}, R_1R_2, \ldots$ etc.

As was recently shown (1), hydrogen atoms react mostly with the double bond by addition; the abstraction reaction of a hydrogen atom is of lesser importance

[4] $H^{\cdot} + 2\text{-}C_4H_8 \xrightarrow{k_4} s\text{-}C_4H_9^{\cdot}$

[5] $H^{\cdot} + 2\text{-}C_2H_8 \xrightarrow{k_5} H_2 + C_4H_7^{\cdot}$

The value of the k_5/k_4 ratio is either 6.6 ×

10^{-2} or 11.7×10^{-2} (3) depending on the *cis*- or *trans*- structure of the 2-butene. The *s*-butyl radical reacts with hydrogen sulfide (reaction 1) to produce the normal butane and the thiyl radical (1). In the same manner, it is probable that the alkenyl radical reacts in the same way to produce 2-butene and a thiyl radical, so that all of the hydrogen atoms indirectly produce thiyl radicals. Of course, the same applies for the majority of other alkyl (methyl, ethyl, etc.) radicals.

Walling and Helmreich have reported the isomerization of 2-butene in a different system (4). Some methanethiol (CH_3SH) was added to a mixture of 2-butene and of azoisobutyronitrile at a temperature of 60 °C. At this temperature, the azoisobutyronitrile was decomposed and formed free radicals. These radicals reacted with methanethiol in the same way as in reaction 1, and the thiyl radical formed is the $CH_3S^{\cdot}$ radical

[6] $$R^{\cdot} + CH_3SH \rightarrow RH + CH_3S^{\cdot}$$

The 2-butenes are rapidly isomerized one into the other and the following mechanism is proposed:

[7] $$HS^{\cdot} + \textit{cis}\text{-}CH_3CH{=}CHCH_3 \underset{k_{-7}}{\overset{k_7}{\rightleftharpoons}} HS{-}\overset{CH_3}{\overset{|}{C}}{-}\overset{CH_3}{\overset{|}{C}}{}^{\cdot}\ (H,H)$$

[8] $$HS{-}\overset{CH_3}{\overset{|}{C}}{-}\overset{CH_3}{\overset{|}{C}}{}^{\cdot}\ (H,H) \underset{k_{-8}}{\overset{k_8}{\rightleftharpoons}} HS{-}\overset{CH_3}{\overset{|}{C}}{-}\overset{H}{\overset{|}{C}}{}^{\cdot}\ (H,CH_3)$$

[9] $$HS{-}\overset{CH_3}{\overset{|}{C}}{-}\overset{H}{\overset{|}{C}}{}^{\cdot}\ (H,CH_3) \underset{k_{-9}}{\overset{k_9}{\rightleftharpoons}} HS^{\cdot} + \textit{trans}\text{-}CH_3CH{=}CHCH_3$$

Naturally, if the concentration in hydrogen sulfide is particularly high, the adduct radical could react with it in a reaction similar to reaction 1. This phenomenon does not seem important with the concentrations of hydrogen sulfide used here since the major part of initial 2-butene seems to have been recovered contrary to results already mentioned in the literature (4–7).

In order to demonstrate that the thiyl radicals cause this isomerization, it is interesting to compare the increase in the methane yield, or the decrease in the yields of ethane and isopentane, with the increase in the yield of isomerization as a function of the concentration of

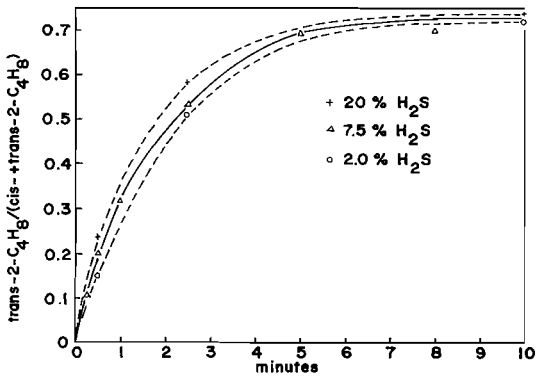

FIG. 3. Influence of irradiation time on the *trans*-/(*trans*- + *cis*-2-butene) ratio in the photoisomerization of *cis*-2-butene: *cis*-2-butene pressure = 1.32 Torr.

hydrogen sulfide between 0.0 and 2%. Moreover, between 2 and 15%, the increase of the hydrogen sulfide concentration has no important effect either on the isomerization yield, or on the methane yield. Therefore there exists a parallel between the effect of the radical scavenger and the isomerization of the olefin.

The relationship that exists between these two phenomena is demonstrated by the effect of the presence of small quantities of oxygen. It is well known that oxygen is an excellent radical scavenger. The activation energy of the reaction between the radicals and oxygen is much lower than that of reaction 1. Thus in the presence of high concentrations of oxygen (5%), the yields of methane, ethane, and isopentane are not affected by the addition of low concentrations of hydrogen sulfide and the quantum yield of isomerization is zero. On the other hand, in the presence of 14% of hydrogen sulfide and of 1% of oxygen some of the radicals react with hydrogen sulfide and the isomerization occurs with a lower yield than in the absence of oxygen. Thus there is no doubt that thiyl radicals are involved in the isomerization(see Table 2).

Despite the above mentioned mechanism, apart from being the initiator of isomerization, the thiyl radical is not demonstrated to be the chain carrier. At this stage, one must report recent work on the photoisomerization of 2-butenes which is initiated by sulfur atoms in the ground state $S(^3P)$ (8). In that study, the isomerization presents approximately the same characteristics as those in the present work. The photostationary ratio *trans*-2-butene/*cis*-2-bu-

tene is the same 2.83 ± 0.06. Oxygen, like 1,3-butadiene, has a very strong negative effect on the yield of isomerization.

A way to reconcile the two mechanisms is to assume that the thiyl radicals react so slowly with either the 2-butene or the hydrogen sulfide that only mutual interactions remain

[10] $$HS^\cdot + HS^\cdot \xrightarrow{k_{10}} H_2S + S^\cdot$$

[11] $$HS^\cdot + HS^\cdot \xrightarrow{k_{11}} H_2 + S_2$$

The k_{11}/k_{10} ratio is either equal to 0.15 (9) or even smaller (10, 11); thus 86% or more of the thiyl radicals are transformed into sulfur atoms. However, this theory can be accepted only with difficulty. First, a reaction (or several) can compete with reaction 10. If the thiyl radicals do not react with 2-butene and hydrogen sulfide, they should at least react with the other radicals. Since this does not seem to be the case, they must react with other species present or formed in the course of irradiation. In particular, thiyl radicals react very readily with conjugated di-olefins. This is well demonstrated by the fact that in the presence of very small amounts of 1,3-pentadiene, the methane yield in the 2-butene/hydrogen sulfide is not greatly affected. The reaction of H_2S or 1,3-butadiene with methyl radicals requires approximately the same activation energy (12, 13). Thus 1,3-pentadiene does not inhibit reaction 1 when the ratio H_2S/1,3-pentadiene is 4. But, on the other hand, the isomerization yield is practically reduced to zero. Other proofs that reaction 10 is not important in this system can be seen from ref. 8. In the photoisomerization of 2-butenes by sulfur atoms, the addition of 12.5% of hydrogen sulfide decreases the isomerization yield by a factor of 2.5, probably because of a reaction between sulfur atoms and hydrogen sulfide. In the present work, an increase of 2 to 15% in the concentration of hydrogen sulfide has no effect.

Alternatively the similarities between the present work and the one involving sulfur atoms (8) could only be accidental. The effect of oxygen leads to a radical mechanism in both systems. The photostationary ratio depends on thermodynamic considerations rather than on the radical involved, and the effect of 1,3-butadiene could be the result of a general reaction between different substituted thiyl radicals ($RS^\cdot$) and conjugated di-olefins.

In these conditions, the reaction mechanism of *cis–trans* isomerization of 2-olefins is a general one that takes place with diverse thiyl substituted radicals ($RS^\cdot$) (see Table 3). In fact, in similar systems, the photo-induced addition of mercaptan alkyls to simple olefins is well known (14*a*, *b*, *c*). It is the case with butyl mercaptan (14*b*), and the $C_4H_9S^\cdot$ radical seems to be the chain carrier although isomerization was not observed.

Termination Steps

Since no study has been undertaken on the effect of the intensity or of the volume of the reactor nothing can be said about the termination reaction(s) of the isomerization mechanism.

However, from the results (see Table 2) one can estimate that the thiyl radical is added to 1,3-pentadiene about 500 times faster than to 2-butenes. This is important, because at the present wavelength, 1,3-butadiene is an important product of the photolysis (15). Moreover, in the presence of hydrogen sulfide, the quantum yield of 1,3-butadiene decreases in an important way, which permits one to foresee a reaction that will make this product disappear. It is thus probable that in such a system, the following reaction is important,

[12] $$HS^{\cdot} + 1,3\text{-}C_4H_6 \rightarrow C_4H_6SH$$

and that the preponderant termination reaction occurs in a homogeneous phase. The C_4H_6SH radical is stabilized by resonance (16) and does not itself decompose, thus removing chain carriers from the system.

Concentration Effects

The addition of helium to the mixture of 2-butene:hydrogen sulfide has no major effect even for a total pressure of the order of 300 Torr. This is in accord with irradiations in the gas phase which are described in the literature under a total pressure of 1800 Torr (7). Even in the liquid phase (see results), the radiolysis of the mixture of 2-butene:hydrogen sulfide (100:3.3) leads to an isomerization which has a very high *G*-value, proving that the isomerization reaction is extremely rapid in the liquid phase. Nevertheless, the radiolysis in the liquid phase is a much more complex system than the photolysis in the gas phase at 147.0 nm. Ionic reactions (with positive or negative ions) not only exist, but also effects of energy concentration around trajectories of energetic particles will have important consequences. Consequently, radiolytic experiments should only be taken as an indication and not as an absolute demonstration. Other current studies will permit the elucidation of mechanisms in the liquid phase.

Quantum Yields

It is now interesting to consider the value of the quantum yield of the *cis–trans* isomerization. Table 1 gives apparent quantum yields between 5600 and 1100 depending on the time of irradiation (or percentage of conversion). This quantum yield decreases with the irradiation time, since the reverse reaction competes rapidly after the accumulation of the *trans*-isomer. For a very short irradiation time, the quantum yield is probably around $6–7 \times 10^3$ (Fig. 4). It is difficult to know the exact length of the chain since the yield of the chain initiator ($HS^{\cdot}$) is not exactly known. However, one can admit that the majority, if not all, of the primary radicals produced in the photolysis, form a thiyl radical (1). From the preceding results, the M/N ($HS^{\cdot}$) value is close to 2.0 ± 0.2. In the far u.v. photolysis, decomposition reactions of each excited neutral hydrocarbon molecule will produce a neutral molecule and two radicals. One hydrogen atom is assimilated to a radical since, as already seen, it is added to the double bond to give the corresponding radical (17–20). This leads to an apparent chain length close to 3500. Since this value is measured from the apparent *trans*-2-butene yield (reaction 9), it must be increased with the yield of the *cis*-2-butene (reaction 7). In admitting that the ratio of the rate of formation of *trans*-2-butene and of *cis*-2-butene is equal to the photostationary ratio, 2.84, the real length of the chain is of the order of 4700.

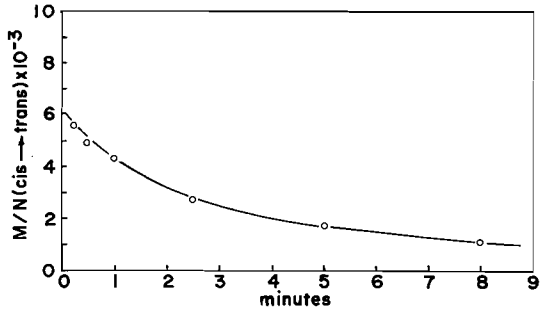

FIG. 4. Variation of M/N (*trans*-2-butene) values *vs.* irradiation time in the photoisomerization of *cis*-2-butene in the presence of hydrogen sulfide: *cis*-2-butene pressure = 1.32 Torr, hydrogen sulfide pressure = 0.09 Torr.

Kinetics and Thermochemistry

Considering only reactions 2 and 1 as initiation steps, reactions 7, −7, 8, −8, 9, and −9 as chain propagating steps and reaction 12 as the only termination step, and admitting that the concentration of the radicals R$^{\cdot}$ and of the *cis* and *trans* forms of the composite radical are constant with irradiation time, the ratio of initial rates of isomerization is (8)

$$\frac{R_{c \rightarrow t}}{R_{t \rightarrow c}} = \frac{k_7 k_8 k_9}{k_{-7} k_{-8} k_{-9}}$$

and this ratio is probably equal to the photo-

stationary state ratio. This does not indicate which is the rate determining step.

It is worthwhile to compare the present results to those obtained from NO_2, NO, and I catalyzed isomerization. With NO_2 the addition step is rate determining (21), and with NO and I (22), bond rotation is rate determining (21). The difference results from the thermochemistry of the addition reaction. With NO_2, the addition reaction is exothermic by 2.8 kcal mol^{-1}, while for NO and I, the addition step is endothermic by 19 and 5 kcal mol^{-1}, respectively. From thermochemical data, the heat of formation of s-C_4H_9S radical was estimated to be 12 ± 3 kcal mol^{-1}, (23), and reaction 7 is exothermic by 10.7 ± 3.0 kcal mol^{-1} and in the $HS^{\cdot}$ catalyzed isomerization, the addition step is probably rate determining.

The authors wish to acknowledge the National Research Council of Canada and l'Université du Québec à Chicoutimi for financial assistance, and le département de Chimie de l'Université Laval for the use of the cobalt bomb.

The Molecular and Crystal Structure of an Oxindole Alkaloid (6-Hydroxy-2′-(2-methylpropyl)-3,3′-spirotetrahydropyrrolidino-oxindole)

M. N. G. James and G. J. B. Williams

Department of Biochemistry, The University of Alberta, Edmonton 7, Alberta

Received January 21, 1972

A previously unknown alkaloid of molecular formula $C_{15}H_{20}O_2N_2$ was isolated from the dried root bark of *Eleagnus Commutata* (Wolf willow or Silverberry). An X-ray analysis was undertaken to complete the structural characterization of the molecule. Columnar crystals obtained from diethyl ether have the unit cell constants, $a = 13.1949(10)$ Å, $b = 9.4525(6)$ Å, $c = 12.1186(6)$ Å, $\beta = 109° 47(1)'$ and belong to space group $P2_1/c$. The structure was solved using an automated symbolic addition procedure and refined by block-diagonal least-squares to weighted and unweighted R factors of 6.25% and 4.30%, respectively. The previous structural studies were shown to be essentially correct except for the incorrect placement of the phenolic hydroxyl on C(5) of the oxindole nucleus. The correct molecular structure is implied by the systematic name given. The —OH group engages in two intermolecular hydrogen bonds with the two nitrogen atoms, but the carbonyl moiety is not involved in any such interactions.

Un alcaloide, inconnu jusqu'à présent, de formule générale $C_{15}H_{20}O_2N_2$, a été isolé à partir d'écorce de racines desséchées de *Eleagnus Commutata*. Une analyse aux rayons-X a été faite pour compléter la caractérisation structurale de la molécule. Les cristaux en forme de colonne, obtenus dans l'éther, possèdent les paramètres suivants pour la maille élémentaire: $a = 13.1949(10)$ Å, $b = 9.4525(6)$ Å, $c = 12.1186(6)$ Å, $\beta = 109° 47(1)'$ et appartiennent au groupe $P2_1/c$. La structure a été résolue par l'utilisation du procédé d'addition symbolique automatique et perfectionnée par la méthode de la diagonalisation de la matrice des moindres carrés appliqués aux facteurs R, pondérés ou non, respectivement de 6.25% et 4.30%. On a montré que les études des précédentes sur la structure sont essentiellement correctes sauf pour la position de l'hydroxyle phénolique sur le C(5) du noyau oxindole. La structure moléculaire correcte est comprise dans le nom systématique cité. Le groupe OH est engagé dans deux liaisons hydrogènes intermoléculaires avec les deux atomes d'azote mais le groupe carbonyle n'est pas impliqué dans de telles interactions.

Canadian Journal of Chemistry, **50**, 2407 (1972)

Introduction

A previously unknown alkaloid of molecular formula $C_{15}H_{20}O_2N_2$ was isolated from the dried root bark of *Eleagnus Commutata* (Wolf willow or Silverberry) by workers at this University (1) during their work on the phytochemistry of this species. Extensive work on the chemical and physical characterization of the compound resulted in the proposed structure shown in Fig. 1 (2). The major point of uncertainty of this structure was the location of the phenolic oxygen atom, although the bonding pattern of the spiran ring and its associated alkyl chain was in some doubt at the time this study was initiated.

Experimental

Columnar crystals of the alkaloid grown from diethyl ether which proved suitable for X-ray diffraction studies were supplied by Locock and Slywka. Preliminary rotation and Weissenberg photographs of a specimen measuring 0.3 × 0.2 × 0.13 mm and rotated about the needle axis revealed $2/m$ diffraction symmetry and the systematic zonal absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$. The space

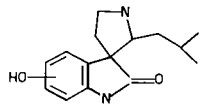

FIG. 1. The proposed molecular structure of the alkaloid.

group was thus uniquely determined as $P2_1/c$ and the c axis shown to be the direction of elongation of the crystals. The unit cell parameters, originally obtained from films, were refined during the initial alignment process on a Picker FACS-1 diffractometer and are $a = 13.1949(10)$ Å, $b = 9.4525(6)$ Å, $c = 12.1186(6)$ Å, $\beta = 109° 47(1)'$. The density calculated for 4 formula units of $C_{15}H_{20}N_2O_2$ (m.w. = 260.34) per unit cell of volume 1422.3 Å^3 is 1.216 g/cm^3. This estimate agrees with that obtained experimentally (1.220(2) g/cm^3) by flotation in a mixture of chlorobenzene and chloroform.

The reflection intensities were collected with Ni filtered CuK_α radiation ($\lambda = 1.54051$ Å) with the diffractometer in the coupled $\theta/2\theta$ scan mode. A total of 2397 unique and space group permissible reflections were collected, within the sphere defined by $2\theta \leqslant 130°$, of these 1915 (80%) had net intensities greater than 3σ and were thus considered observed. Normalized structure factors (E_{hkl}'s) were calculated, and the 221 E's greater than 1.7 were phased using a set of computer programs (3) which automatically select origin defining reflections and apply the symbolic addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

procedure as appropriate to centrosymmetric space groups (4). All non-hydrogen atoms of the molecule except the two methyl carbons were found in a map computed using these phased E's. The remaining two atoms were located in a subsequent electron density difference map and the structure refined using a block-diagonal least-squares procedure. The scattering factors used were derived from the analytical coefficients of Cromer and Mann (5), except for the hydrogen curve which was that of Mason and Robertson (6). The difference Fourier technique was used to find the hydrogen atoms. Block-diagonal least-squares refinement of the model assuming anisotropic vibration for the non-hydrogen atoms and allowing the hydrogens variable isotropic thermal parameters has resulted in final weighted and unweighted R factors $((\sum w||F_o| - |F_c||^2)^{\frac{1}{2}}/(\sum w|F_o|^2)^{\frac{1}{2}}$ and $(\sum||F_o| - |F_c||/\sum|F_o|))$, over the included data, of 6.25% and 4.30%, respectively. Observation weights were calculated according to the expression $\sqrt{w} = 2F_o/[T + (kI)^2 + B]^{\frac{1}{2}}$ (7) at the data reduction stage and were applied during the refinement. In the above equation T is the total peak count, I is the net peak count, B is the background, F_o is the derived structure amplitude, and k is a small constant (0.04 in this case) included to allow for minor instrumental errors. A tabulation of the observed structure amplitudes and the structure factors calculated from the final set of atomic parameters has been lodged with the Depository of Unpublished Data.[1]

*Estimated standard deviations in parentheses.

Results and Discussion

The atomic parameters, and their associated estimated standard deviations, obtained from the final least-squares cycle are given in Tables 1, 2, and 3. Figure 2, which is a diagram of one molecule viewed parallel to the c axis, shows that the compound is a 6-hydroxy derivative of an oxindole nucleus, with a spiro linked secondary alkylamine moiety attached to C(3). Bond distances and interbond angles involving the non-hydrogen atoms are presented in Figs. 3 and 4. Table 4 is a listing of the molecular parameters involving the hydrogen atoms. The numbering scheme for the hydrogen atoms is derived from that used for the non-hydrogen atoms (refer to Fig. 3), *e.g.* H(81′) and H(82′) are bonded to C(8′) and H(6) is bonded to O(6). Interatomic correlations were not considered in the derivations of the estimated standard deviations in these molecular parameters. The bond distances involving those "terminal" atoms of importance were corrected for the effects of thermal motion according to the riding motion model (8) and are: C(2)—O(2) = 1.248(3) Å, C(6)—O(6) = 1.378(3) Å, C(9′)—C(10) = 1.537(4) Å, and C(9′)—C(11) = 1.582(5) Å.

The benzenoid section of the oxindole system is very closely planar with maximum exoplanar displacement of 0.01 Å from the plane with equation $-0.9603x - 0.2424y - 0.1378z + 1.7190 = 0$ (in this context the x, y, and z axes are parallel to the crystallographic a, b, and c^* axes, respectively, and the unit vectors are 1 Å in length). The phenoxy oxygen atom displacement is only −0.043(2) Å from this plane but the phenolic hydrogen is displaced +0.33(3) Å, thus permitting the O—H bond vector to point towards atom N(5′) of another molecule (see Fig. 5). The O—H ---N bond so formed is 2.659(2) Å long and the relevant inter bond angles are C(6)—O(6)—H(6) = 113.7(1.5)°, O(6)—H(6) ---N(5′) = 171.1 (2.4)°, H(6) ---N(5′)—C(4′) = 110.4(0.9)°, H(6) ---N(5′)—C(6′) = 103.9(0.9)°, and H(6) ---N(5′)—H(5′) = 120.4(1.7)°. The (uncorrected) distances involving the hydrogen atoms of this intermolecular bond are O(6)—H(6) = 0.971(25) Å and H(6) ---N(5′) = 1.695(25) Å.

The weighted average of the bond lengths within the benzenoid ring is 1.388 Å with an associated e.s.d. of 0.006 Å. The 0.006 Å discrepancy between this average bond length and the 1.394 Å found in highly accurate work (ref. 9, p. S21s) is not significant and indicates that

*Estimated standard deviations in parentheses.

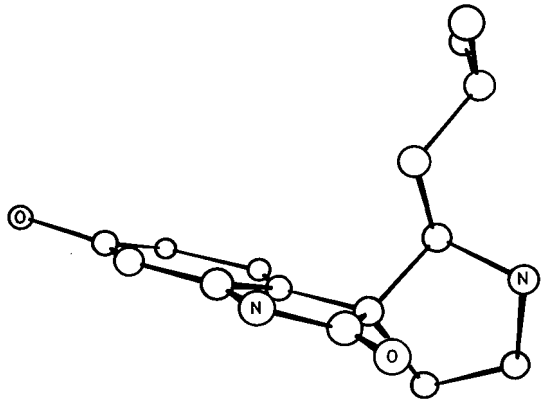

FIG. 2. A perspective view of one molecule as seen parallel to the c axis.

the effects of "rigid body libration" (10) on this molecule in the solid state are small.

The five membered ring of the oxindole nucleus is not planar, the "spiro" atom, C(3), deviates by −0.114(2) Å from the best four-atom least-squares plane which is defined by the four other atoms C(2), N(1), C(8), C(9). This plane has equation $-0.9465x - 0.2723y - 0.1731z + 1.7989 = 0$ and is very nearly parallel to the plane of the benzenoid ring (dihedral angle = 2.8°). None of the four atoms which define the oxindole plane is displaced more than 0.005 Å from it. Interpretation of the geometric details of this ring is complicated by the presence of the delocalized π electrons of the benzenoid system. The —C—NH—CO—C grouping here resembles a *cis* peptide bond and exhibits some of the features associated with this structural unit. All of these 6 atoms are within 0.04 Å from the 5 atom least-squares plane, defined by the non-hydrogen members of this group, with equation $-0.9371x - 0.2572y - 0.2358z +$

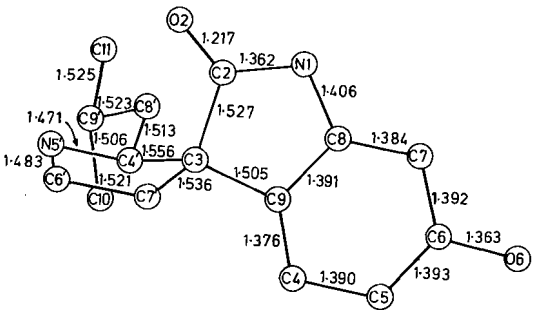

FIG. 3. The intramolecular bond distances in Å. The estimated standard deviations average 0.003 Å overall except for those involving the methyl carbons which are 0.005 Å each. These distances are uncorrected for the effects of thermal motion. Corrected values for the bonds to the four "terminal" atoms may be found in the text.

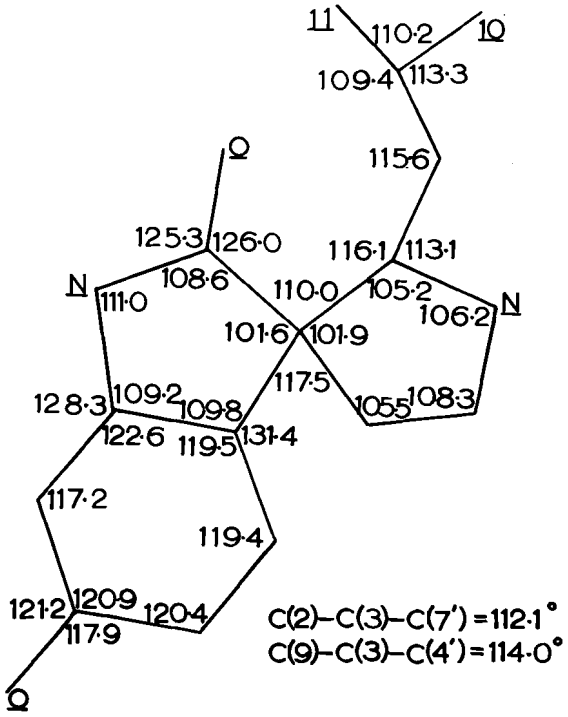

FIG. 4. The interbond angles in deg. The e.s.d.'s average 0.2°.

2.0524 = 0. That the delocalized π electron system of the benzenoid ring extends over the atoms N(1), C(2), and O(2) is indicated by this planarity and also by the lengthening of the C(2)—O(2) bond and the shortening of the N(1)—C(2) linkage. Simple aldehydes and ketones are found to exhibit C=O bond lengths of 1.215(5) Å (ref. 9, p. S21s) the C—N distances for simple tervalent nitrogen compounds are encompassed by 1.472(5) Å (ref. 9, p. S19s). Bond angle distortions forced upon this system by virtue of its cyclic nature probably preclude the most favorable overlap of atomic orbital hybrids and hence the shortening of the OC—N bond here is not as extreme as in more normal peptide bonds where this length is found to be 1.325 Å (11). The nitrogen atom N(1) is engaged in forming the second intermolecular

H(71′)—C(7′)—H(72′)	111(2)	H(113)—C(11)—C(9′)	109(2)

hydrogen bond of this structure to oxygen O(6). This bond is significantly bent, N(1)—H(1)---O(6) = 168.0(1.8)°, and the distance between the donor and acceptor atoms is 2.916(2) Å.

The 1.505 Å bonding distance between atoms C(3) and C(9) appears abnormally short for a C—C single bond length; however, a comparison with documented values (ref. 9, p. S15s) shows that this value is exactly that expected for tetracoordinated carbon bonded to a benzenoid system.

The best 4 atom plane of the saturated spiran ring is that defined by the atoms N(5′), C(6′), C(7′), C(3) and has equation $0.4359x - 0.0076y - 0.9000z + 2.3292 = 0$. The distances of the 5 ring atoms from this plane are: −0.020, 0.527, 0.017, −0.055, and 0.043 Å for C(3), C(4′), N(5′), C(6′), and C(7′), respectively. These distances and the χ^2 value ($\chi^2 = \sum p_i^2/\sigma_{(p_i)}^2$ where p_i is the distance of atom i from the plane and $\sigma_{(p_i)}$ is the e.s.d. in that distance) of 1007.8 imply that this plane has notional existence only and therefore should not be interpreted as an important structural feature.

A more precise description of the conformation of this ring may be given in terms of the relevant torsion angles. If A—B—C—D is a set of atoms connected as shown then the torsion angle about the B—C bond is defined as the dihedral angle between the planes defined by the positions of the atoms A—B—C and B—C—D. A positive angle is one that requires a clockwise

rotation of atom A to achieve superposition of the A—B and C—D bond vectors when viewed in the direction B → C. These angles are: C(7′)—C(3)—C(4′)—N(5′) = −36.2°, C(3)—C(4′)—N(5′)—C(6′) = +32.3°, C(4′)—N(5′)—C(6′)—C(7′) = −15.5°, N(5′)—C(6′)—C(7′)—C(3) = −7.7°, C(6′)—C(7′)—C(3)—C(4′) = +26.1°. An alternative description of this five membered ring, and one that has been proposed for furanose ring forms (12), is in terms of atomic displacements from the plane through those three atoms which are common to both the best and the second best four-atom least-squares plane. In this case these atoms are N(5′), C(6′), and C(7′) and the plane has equation $0.3842x + 0.0724y - 0.9204z + 2.1370 = 0$ and the displacements of C(3) and C(4′) are −0.197 and +0.376 Å, respectively. These two atoms are on opposite sides of the reference plane and so the ring has the "twist" (T) conformation.

The molecular packing is shown in the stereoscopic Fig. 5 which is a projection onto (100). This diagram shows that the molecules form infinite layers with the hydrogen bond network shown being the principal intralayer bonding interactions. Interlayer bonding is the result of nonspecific, nondirectional van der Waals dispersion forces between the isobutyl side chains.

The technique of proton magnetic resonance (p.m.r.) has been developed to the point where it is usually possible to distinguish isomers from one another. The distinction in this case involved deciding whether the phenolic hydroxyl was on C(5) or C(6). A tentative decision in favor of a 5-hydroxy was reached after consideration of the p.m.r. coupling constants between the three benzenoid protons (2). A detailed appraisal of this analysis is out of place here; however, it may be pointed out that the p.m.r. peak assignment, which rests on the supposed shielding and deshielding properties of the phenolic oxygen and the oxindole nitrogen, may be influenced by the possibility of intermolecular hydrogen bonding. Atom N(1) is a donor in its hydrogen bond to O(6) and O(6) is in turn the donor in the intermolecular bond to N(5′). Electronic effects due to this may be lessened in the p.m.r. sample because of the high dielectric constant of the solvent (deuterated DMSO), but this possibility nevertheless exists and its implications may be important.

We thank Drs. Locock and Slywka for the crystalline sample of the alkaloid. Financial support from the Medical Research Council of Canada (grant #MA-3406) is gratefully acknowledged. The set of crystallographic computer programs of F. R. Ahmed *et al.* of N.R.C.C. Ottawa were used throughout this analysis. Miss C. M. Smith and Mr. D. J. Steenkamp were involved in the early stages of this work and we thank them for their help.

La photo-oxydation du Hg(I) par le Ce (IV) en solution aqueuse d'acide perchlorique

A. NUYT ET M. ZADOR

Département de chimie, Université de Montréal, c.p. 6128, Montréal 101, Québec

Reçu le 21 février 1972

La photo-oxydation du Hg(I) par le Ce(IV) a été étudiée à 366 mμ dans des solutions aqueuses d'acide perchlorique. Le rendement quantique varie avec les concentrations en Hg(I) et en Ce(III) et cette variation est différente lorsque l'absorption est faible ou forte. De plus le rendement quantique augmente sensiblement avec l'acidité du milieu. Il est proposé, que ceci est dû au fait que le Ce^{4+} est l'espèce impliquée dans le processus photochimique primaire.

The photo-oxidation of Hg(I) by Ce(IV) has been studied at 366 mμ in aqueous perchloric acid solutions. The quantum yield depends on the concentrations of both Hg(I) and Ce(III). This dependence is different at high and low absorptions. There is a marked increase of the quantum yield with the acid concentration. It is proposed therefore that Ce^{4+} is the species involved in the primary photochemical process.

Introduction

La photo-réduction du Ce(IV) a été étudiée par plusieurs auteurs, aussi bien en solution aqueuse d'acides qu'en présence de divers ions ou molécules (1–6). La première étude quantitative est due à Weiss et Porret (1) qui ont proposé la formation d'un radical OH comme intermédiaire:

[1] $$Ce(IV) + H_2O \xrightarrow{h\nu} Ce(III) + H^+ + OH$$

La formation d'oxygène lors de la photo-réduction de l'eau est expliquée en faisant intervenir ce radical. De plus, la diminution du rendement quantique de la réaction avec l'augmentation de la concentration en Ce(III) s'explique bien à l'aide de l'éq. 2.

[2] $$Ce(III) + OH \longrightarrow Ce(IV) + OH^-$$

Finalement l'oxydation de divers substrats (5, 6) et la formation de radicaux NO_3 et HSO_4 lors de la photolyse éclaire (7), seraient dues aux réactions du radical OH avec les solutés. Ce radical est également proposé comme intermédiaire lors de la radiolyse des solutions du Ce(IV) (8). Récemment la formation directe des radicaux NO_3 à partir d'un complexe Ce(IV)—NO_3 a pu être démontrée à haute concentration en nitrate (9). Toutefois, ce mécanisme ne semble être probable que lorsqu'il y a formation appréciable de complexe avec l'ion cérique, ce qui n'est évidemment pas le cas avec les ions métalliques.

Il est bien établi que le Ce(IV) est hydrolysé partiellement en solution aqueuse (10, 11). La question la moins éclaircie dans la photo-réduction concerne justement l'espèce du Ce(IV) impliquée dans l'acte photo-chimique primaire. Dans diverses publications on trouve Ce^{4+}, sans qu'il soit prouvé que ce soit effectivement la forme réactionnelle (1, 3–6) d'autres proposent un dimère, $CeOCe^{6+}$ (2) ou une forme hydrolysée (ou paire d'ion, $Ce^{4+}\cdot OH^-$ (12), comme responsable de l'éq. 1. On trouve aussi Ce(IV), sans autres indications (7).

L'effet de la paroi a été mis en évidence, ce qui implique qu'une des étapes au moins est hétérogène (3).

L'oxydation thermique du Hg(I) par le Ce(IV) a déjà été étudiée (13), et la réaction est très lente à température ambiante.

Dans ce travail nous nous sommes intéressés à chercher si le Hg(I) pouvait être oxydé par le Ce(IV) par voie photochimique, caractériser cette réaction et, par la suite, d'élucider la nature de l'espèce du Ce(IV) impliquée dans le processus primaire. Nous avons choisi de travailler à une longueur d'onde de 366 mμ pour éviter l'effet de filtre interne des réactifs et produits autres que le Ce(IV) ce qui serait très important à des longueurs d'onde plus courtes utilisées dans d'autres études sur le Ce(IV). On évite aussi la photo-oxydation du Ce(III) en Ce(IV) (14).

*Distance lampe–cellule = 8.7 cm; temps d'irradiation 1 à 6 min; $T = 25 \pm 1$ °C; $[Ce(IV)] = 2\times10^{-3}$ *M*; $[HClO_4] = 0.5$ *M*; force ionique = 2 *M*.
†Force ionique = 0.5 *M*.

solutions ont été préparées avec de l'eau distillée. Le Ce(IV) a été fourni en solution de concentration 0.5 *M* dans l'acide perchlorique 5 *M* par la compagnie G. F. Smith, Ohio, U.S.A. Cette solution contient également une certaine quantité de Ce(III), qui a été déterminée. La solution du Ce(III) a été préparée à partir de perchlorate cereux hydraté et la solution de perchlorate mercureux a été préparée à partir de HgO et Hg en milieu acide perchlorique (15). La solution stock de perchlorate mercureux est maintenue en présence d'un excès de mercure. La solution de $NaClO_4$ a été préparée par neutralisation de $HClO_4$ concentré par la quantité appropriée de NaOH pour éviter les impuretés chlorure présentes dans les sels commerciaux.

Dosages

Les dosages du Ce(IV) et du Ce(III) ont été faits par iodométrie et par gravimétrie (16). Le dosage du $HClO_4$ a été effectué à l'aide d'une solution de NaOH de concentration connue, après précipitation de tout le cérium sous forme d'oxalate cereux. Le dosage de Hg(I) a été effectué suivant une méthode donnée par la littérature (15), par gravimétrie et par spectrophotométrie à 236.5 mμ (17).

En cours de réaction, les dosages ont été effectués par spectrophotométrie du Ce(IV) à 370 mμ en milieu $HClO_4$ 1 *M*. Pour déterminer les rendements quantiques, nous avons mesuré l'intensité lumineuse reçue par la cellule par actinométrie (18). L'actinomètre utilisée est le ferrioxalate de potassium.

Appareillage

Nous avons utilisé une lampe Hanovia medium Pressure Mercury-Vapor 673 A10, ayant une raie intense à 366 mμ, qui a été utilisée pour l'irradiation. Les autres raies ont été éliminées grâces aux filtres Hanovia 6544-001 et 6540-001. Les intensités absorbées étaient de l'ordre de 10^{-5} einstein l^{-1} s^{-1}. Les différents éléments ainsi que la cellule de réaction sont placés sur un banc optique. La cellule est cylindrique avec des parois en quartz optiquement parallèles. Elle est refroidie par circulation forcée d'air. La longueur du chemin optique est de 1 cm.

Procédure

Pour chaque réaction, nous avons préparé 100 ml de mélange réactionnel en prélevant un certain volume des solutions stocks. La force ionique a été maintenue à 2 *M* par du $NaClO_4$. De ce mélange, 20 ml sont placés dans la cellule en quartz et on y fait barboter de l'azote pendant 20 min. Des essais en absence de Ce(IV) ont montré qu'il y a photo-oxydation du Hg(I) en présence d'oxygène. Après un temps d'irradiation donné, on effectue l'analyse. Pour la réaction thermique, une correction est chaque fois effectuée.

Résultats et discussion

La réaction globale est la suivante:

$$[3] \qquad Ce(IV) + Hg(I) \xrightarrow{h\nu} Ce(III) + Hg(II)$$

La stoechiométrie de la réaction est de 1:1, et ceci quelles que soient les conditions expérimentales. Si l'on poursuit la photo-réduction du Ce(IV) après l'oxydation de la totalité du Hg(I), la réaction devient beaucoup plus lente, ce qui implique aussi que la contribution de la photo-oxydation de l'eau par le Ce(IV) est négligeable.

Influence du Hg(I) et du Ce(III)

L'influence de ces ions a été étudiée dans deux conditions expérimentales différentes, soit à absorption faible et à absorption totale.

Absorption faible

A des concentrations en Ce(IV) de l'ordre de 2×10^{-3} *M*, l'absorption, et la réaction, ont lieu dans toute l'épaisseur de la cellule. En effet, à cette concentration la densité optique à 366 mμ est de 0.7. Les rendements quantiques calculés en tenant compte de la fraction de la lumière absorbée par la solution, par la loi de Beer, sont donnés au tableau 1. Ces résultats montrent que le rendement quantique diminue

0.5×10^{-2}	8×10^{-2}	0.077	13.0	16.0
0.25×10^{-2}	8×10^{-2}	0.077	13.0	32.0

*Distance lampe–cellule = 8.7 cm; temps d'irradiation = 20 min; $T = 25 \pm 1$ °C; [Ce(IV)] = 2×10^{-2} M; [$HClO_4$] = 0.5 M; force ionique = 2 M.

avec l'augmentation du rapport Ce(III)/Hg(I), comme c'était le cas dans l'étude de photo-oxydation du Tl(I) et de l'acide formique (6, 7). Le mécanisme, proposé par Sworski, permet d'expliquer les résultats

[4] $Ce(IV)\cdot H_2O \xrightarrow{h\nu} Ce(IV)\cdot H_2O^*$

[5] $Ce(IV)\cdot H_2O^* \longrightarrow Ce(III) + H^+ + OH$

[6] $OH + Ce(III) \xrightarrow{k_1} Ce(IV) + OH^-$

[7] $OH + Hg(I) \xrightarrow{k_2} Hg(II) + OH^-$

L'expression pour le rendement quantique est obtenue en exprimant l'état stationnaire pour le radical OH:

$$[8] \qquad \Phi_{Ce(IV)} = \frac{\Phi_{OH}\cdot k_2[Hg(I)]}{k_2[Hg(I)] + k_1[Ce(III)]}$$

L'inverse de cette expression donne

$$[9] \qquad \frac{1}{\Phi_{Ce(IV)}} = \frac{1}{\Phi_{OH}} + \frac{1}{\Phi_{OH}}\cdot\frac{k_1}{k_2}\frac{[Ce(III)]}{[Hg(I)]}$$

La fig. 1 permet de voir que cette expression est vérifiée dans une grande gamme de concentrations et on obtient pour le rapport k_2/k_1 la valeur de 26. Cette valeur est comparable au rapport des constantes d'étapes analogues dans le cas du Tl(I) dans l'acide sulfurique (5), pour lequel on a rapporté la valeur de 42. La valeur de Φ_{OH} est de 0.19, semblable à celui observé dans d'autres systèmes (4–6).

Absorption totale

A forte concentration en Ce(IV), l'absorption est localisée dans une couche mince près de la paroi de la cellule. Dans ces conditions, les rendements quantiques ne dépendent plus de la concentration en Hg(I) (tableau 2), même à

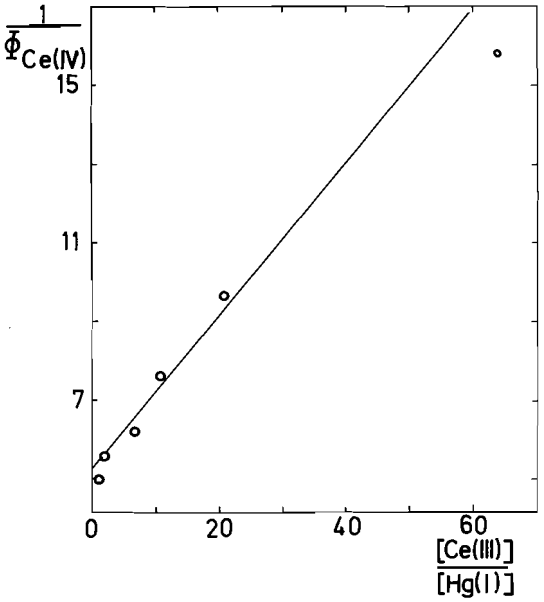

FIG. 1. Graphique de $1/\Phi_{Ce(IV)}$ en fonction du rapport [Ce(III)]/[Hg(I)]. Distance lampe–cellule = 8.7 cm; temps d'irradiation 1 à 6 min; $T = 25 \pm 1$ °C, [Ce(IV)] = 2×10^{-3} M, [$HClO_4$] = 0.5 M; force ionique = 2 M.

For personal use only.

grand excès de ce réactif, ce qui exclut la possibilité d'un appauvrissement local.

Le rendement quantique diminue toutefois avec l'augmentation de la concentration en Ce(III) et on peut obtenir une relation linéaire entre $1/\Phi$ et [Ce(III)].

Ces résultats impliquent qu'il n'y a plus de compétition entre le Hg(I) et le Ce(III) pour l'intermédiaire actif formé dans l'étape primaire (le radical OH).

De plus, le rendement quantique varie de 0.2 à 0.07 avec l'augmentation de la concentration du Ce(IV) de 5×10^{-4} à 5×10^{-2}. Dans la photo-oxydation de l'eau, à forte absorption, l'influence favorable de la paroi a été bien montrée (3).

Une explication plausible dans notre cas serait l'intervention de la paroi comme piège à radicaux, qui serait en compétition pour ceux-ci avec le Ce(III).

[10] $\quad OH + \text{paroi} \rightarrow OH \text{ ads.}$

Toutefois, l'influence de la haute intensité locale est extrêmement difficile à étudier et les conclusions restent fragiles.

Il est à noter que le changement de mécanisme n'influence pas la stoechiométrie qui reste 1:1, ce qui implique que le Hg(I) est finalement oxydé en Hg(II) et que la photo-oxydation de l'eau reste négligeable.

Nous avons voulu vérifier si le même phénomène avait lieu dans le cas de la photo-oxydation du Tl(I), pour lequel on a rapporté, en milieu acide sulfurique, un mécanisme de compétition. A une concentration de 0.02 *M* en Ce(IV) une variation d'un facteur de dix en Tl(I) ne change pas le rendement quantique.

Etant donné que ce mécanisme intervient partiellement à absorption plus faible, la valeur $k_2/k_1 = 26$ doit être considérée comme une valeur limite, la vraie valeur devrait être légèrement supérieure.

Influence de l'acidité

L'influence de l'acidité a été étudiée à basses concentrations en Ce(III) où la réaction 2 peut être négligée.

La nature des espèces en solution aqueuse, ainsi que leur concentration dépend de l'acidité d'après les équations:

[11] $\quad Ce^{4+} + H_2O \underset{}{\overset{K_1}{\rightleftharpoons}} CeOH^{3+} + H^+$

[12] $\quad 2CeOH^{3+} \overset{K_2}{\rightleftharpoons} CeOCe^{6+} + H_2O$

TABLEAU 3. Influence de la concentration en acide perchlorique sur le rendement quantique*

$HClO_4$ (mol l^{-1})	$\frac{1}{[H^+]}$	$\Phi_{Ce(IV)}$	$1/\Phi_{Ce(IV)}$

1.50	0.68	0.149	6.7
1.75	0.57	0.157	6.4
2.00	0.5	0.157	6.4
2.00	0.5	0.149	6.7

*Distance lampe–cellule = 8.7 cm; temps d'irradiation = 20 min; $T = 25 \pm 1$ °C; $[Ce(IV)] = 2 \times 10^{-2}$ *M*; $[Ce(III)] = 6 \times 3510^{-3}$ *M*; $[Hg(I)] = 1 \times 10^{-2}$ *M*; force ionique = 2 *M*.

Il est donc évident que l'influence de l'acidité devrait permettre de décider quelle forme du Ce(IV) est impliquée dans l'acte primaire.

L'étude a été effectuée en absorption totale de lumière et en maintenant les concentrations du Ce(IV), du Hg(I) et du Ce(III) constantes.

Les résultats du tableau 3 montrent que le rendement quantique augmente avec l'augmentation de la concentration en acide perchlorique. Ceci est attribué à l'augmentation de la concentration du Ce^{4+} par le déplacement des éqs. 11 et 12 vers la gauche.

L'énergie absorbée sert à l'excitation d'un électron de la liaison de transfert de charge Ce^{4+}—OH_2 (avec une des molécules d'eau de coordination), [4]. Par après il y a rupture de cette liaison, formation d'un radical OH et de H^+, ainsi que réduction du Ce^{4+} (éq. 5).

Ces résultats sont incompatibles avec les hypothèses voulant que $CeOH^{3+}$ ou $CeOCe^{6+}$ soient responsables de l'acte primaire. La concentration de ces deux espèces diminue quand l'acidité augmente.

Etant donné qu'à la longueur d'onde utilisée les autres réactifs et produits ne contribuent pas à l'absorption de la lumière, on peut exprimer la fraction de lumière absorbée par le Ce^{4+} en tenant compte des éqs. 11 et 12 et des coefficients d'absorption des diverses espèces. Le rendement quantique expérimental, $\Phi_{Ce(IV)}$, est alors donné par l'éq. 13:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$[13] \qquad \Phi_{Ce(IV)} = \Phi_{Ce^{4+}} \frac{\varepsilon_{Ce^{4+}}[Ce^{4+}]}{\varepsilon_{Ce^{4+}}[Ce^{4+}] + \varepsilon_{CeOH^{3+}}[CeOH^{3+}] + \varepsilon_{CeOCe^{6+}}[CeOCe^{6+}]}$$

où $\Phi_{Ce^{4+}}$ est le rendement quantique pour l'espèce Ce^{4+}.

Cette équation contient trop de paramètres pour être vérifiée expérimentalement de manière significative. Elle se simplifie si on néglige la concentration en dimères, ce qui est plausible, surtout à haute acidité.

En faisant le bilan de matière et en utilisant l'éq. 13 on obtient alors:

$$[14] \qquad \Phi_{Ce(IV)} = \Phi_{Ce^{4+}} \frac{\varepsilon_{Ce^{4+}}}{\varepsilon_{Ce^{4+}} + \varepsilon_{CeOH^{3+}} K_1[H^+]}$$

et

$$[15] \qquad \frac{1}{\Phi_{Ce(IV)}} = \frac{1}{\Phi_{Ce^{4+}}} + \frac{\varepsilon_{CeOH^{3+}} K_1}{\Phi_{Ce^{4+}} \varepsilon_{Ce^{4+}}} \cdot \frac{1}{[H^+]}$$

La fig. 2 montre que l'éq. 15 est vérifiée de manière très satisfaisante. L'ordonnée à l'origine permet d'obtenir la valeur de 0.19 pour $\Phi_{Ce^{4+}}$.

En faisant l'approximation que $\varepsilon_{CeOH^{3+}}$ est à peu près égale à $\varepsilon_{Ce^{4+}}$, ce qui est raisonnable étant la faible variation du coefficient d'extinction du Ce(IV) à cette longueur d'onde avec l'acidité, la pente donne la valeur de 0.27 *M* pour K_1. Cette valeur est du même ordre de grandeur que celle obtenue par d'autres méthodes (11).

L'influence de l'acide sulfurique est négligeable dans la photo-oxydation de l'eau (3), mais ces données ne peuvent être comparées à nos résultats étant donné que le Ce(IV) est complexé par l'ion sulfate et l'augmentation de la concentration en acide sulfurique influence les équilibres de formation de ces complexes.

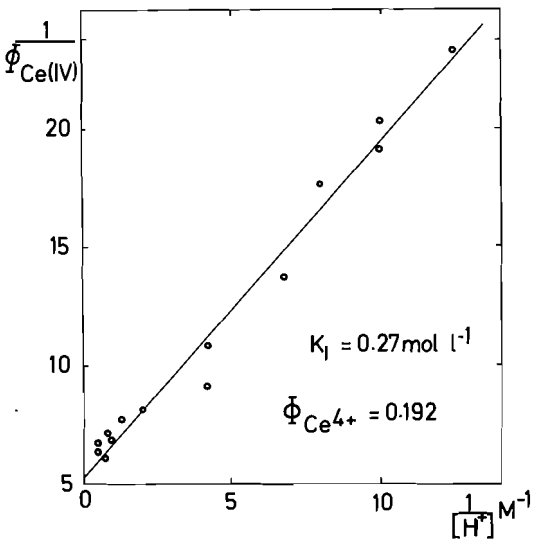

FIG. 2. Variation de $1/\Phi_{Ce(IV)}$ en fonction de $1/[H^+]$ en solution d'acide perchlorique. Distance lampe–cellule = 8.7 cm; temps d'irradiation = 20 min; $T = 25 \pm 1$ °C; [Ce(IV)] = 2×10^{-2} *M*; [Ce(III)] = 6.35×10^{-3} *M*; [Hg(I)] = 1×10^{-2} *M*; force ionique = 2 *M*.

En conclusion, nous proposons que l'espèce responsable de la formation des radicaux OH lors du processus photo-chimique primaire est le Ce^{4+}, non pas $CeOH^{3+}$ ou $CeOCe^{6+}$.

Les réactions ultérieures de ces radicaux dépendent de l'endroit où ils sont formés. Près de la paroi il est probable que la réaction hétérogène, avec adsorption de radicaux soit prépondérante. Par contre, au sein de la solution il y a compétition entre le Ce(III) et le Hg(I) pour ces radicaux de manière analogue aux systèmes étudiés auparavant.

The Relation between Contact Angle and Drop Size for Water at its Boiling Point for a Pressure Range 50–760 Torr

A. B. PONTER
Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

AND

A. P. BOYES
Department of Chemical Engineering, University of Birmingham, Birmingham, England

Received January 10, 1972

Contact angles have been measured using water drops of specified sizes, and in equilibrium with their vapor only, at their boiling point when residing on a copper surface at pressures ranging from 50–760 Torr.

No appreciable change of contact angle with drop diameter was evident for sizes of 0.5 cm or more, but below this value the angles were dependent on the drop diameter, the effect of reducing pressure being to increase the dependency. The phenomenon is qualitatively explained in terms of gravity and surface roughness influences.

Les angles de contact ont été mesurés en utilisant des gouttes d'eau de dimensions déterminées, en équilibre seulement avec leur vapeur et à leur point d'ébullition, lorsque celles-ci sont placées sur une surface de cuivre sous des pressions allant de 50 à 760 Torr.

On n'a pas mis en évidence de changement appréciable d'angle de contact avec le diamètre des gouttes pour des valeurs supérieure ou égale à 0.5 cm mais au-dessous de cette valeur les angles dépendent du diamètre de la goutte. L'influence d'une baisse de la pression étant d'accroître cette dépendance. Le phénomène est expliqué qualitativement en fonction des influences de la gravité et de la rugosité de la surface.

Canadian Journal of Chemistry, **50**, 2419 (1972)

Introduction

Many considerations have been given to the effect of drop size on surface tension, stemming from the initial theory of Gibbs (1) which was later developed extensively by Tolman (2). For drop diameters less than 10^{-6} cm it was concluded that the surface tension decreased appreciably with decreasing drop sizes. Recently in the study of drop size on the attainment of the advancing contact angle of water on polyethylene, poly(methyl methacrylate), and surfactant coated surfaces Hertzberg and Marian (3) suggested that their results demonstrated that the difference in value between minimum and maximum contact angles was a manifestation of hysteresis. In their investigation the final advancing contact angle was determined for a number of drop volumes and it was reported that there was no obvious and consistent change in the contact angle as the drop volume was altered.

The work now described was carried out to ascertain if the contact angle changed with drop size at conditions where the liquid was at its boiling point and in the presence of its own vapor. These conditions were selected because of the practical implication when studying the process of dropwise condensation.

Experimental

The copper specimen used in the experiments was 99.99% pure and was prepared in the following manner. A flat plate 2.54 cm diameter and 0.7 cm in thickness was polished with numbers 220, 330, 400, and 600 silicon carbide paper and then finally polished on a wheel using "Buehler A B Microcloths" impregnated with 6 μ diamond paste. The specimen was then degreased with a mild soap solution and washed with distilled water, absolute ethyl alcohol and distilled water again. The surface roughness (1.01 μin., center line average) of the specimen was measured using a Talysurf meter employing the standard techniques, the result being an average of at least 15 readings. The specimen was prepared as described, before each run.

The glassware was washed with absolute ethanol to remove excess grease then cleaned with a sodium dichromate–sulfuric acid solution, before finally being irrigated several times with distilled water.

The water was triple distilled, each stage incorporated a surface overflow section which continuously removed surface contaminants. Using a Du Nouy Ring Balance the final product was shown to have a surface tension of 72.8 dyn/cm at 20 °C, which is in excellent agreement with reported values.

As the experiments were carried out over a range of pressures a pressure control was required, a Cartesian manostat being selected above all others since it was suitable for the pressure range investigated.

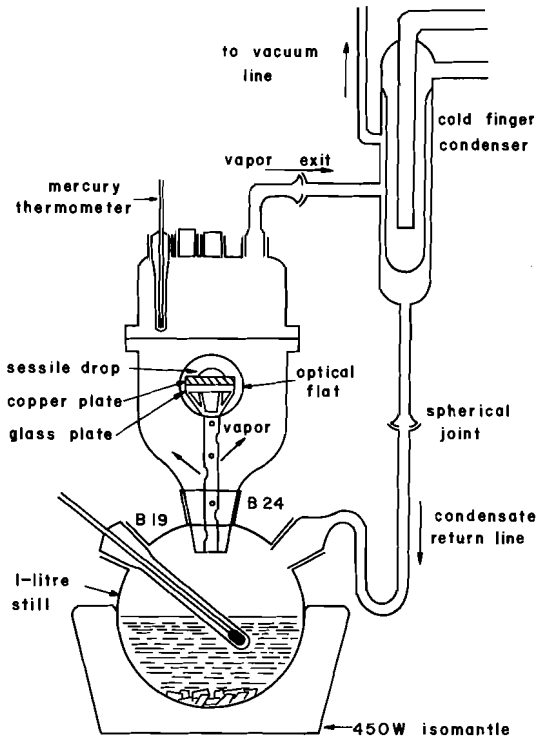

FIG. 1. Equilibrium cell for contact angle measurement.

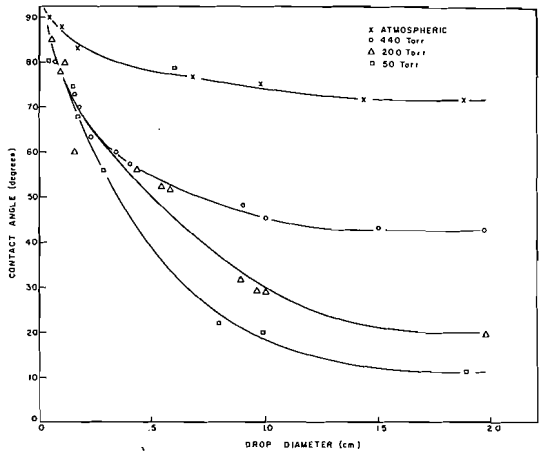

FIG. 2. Contact angle *vs.* drop diameter for the pressure range 50–760 Torr.

All septems used on the apparatus were repeatedly boiled in water which showed no change in surface tension at the end of the operation and all joints on the apparatus were fitted with Tefion sleeves to eliminate contamination from conventional sealants. The "Speedivac" high vacuum oil pump used for the low pressure work was situated some 6 m from the apparatus and had an ice–acetone vapor trap in the glass line between the pump and the apparatus to eliminate any oil contamination in the vapor phase and also to protect the pump.

A diagram of the apparatus used is given in Fig. 1. It consisted of a 1 l flask, a cell in which the contact angles were measured and a cold finger, water-cooled condenser. The 1 l flask was fitted with a thermometer pocket, a condensate return line and was heated by means of a 450 W isomantle fitted with a control. Stainless steel wire guaze was added to the contents of the flask to prevent "bumping". The cylindrical cell (15 cm × 10 cm o.d.), comprised of two sections which were held together with a ring clamp, was fitted with a Teflon gasket. On the bottom section two optical flats were placed on opposite sides of the cell to facilitate readings using transmitted light. A horizontal glass table (3 cm × 3.5 cm) was supported by four legs which were held by a central vapor line. The top section had three B.14 necks, fitted with a thermometer pocket, a vapor exit line to the condenser and a septum to allow the sample to be introduced by means of a syringe fitted with a stainless steel needle. Both sections of the cell were fitted with heaters consisting of coils of resistance wire controlled by a variac. The apparatus was also lagged with asbestos rope to keep heat losses to a minimum.

The glass table was tested to be horizontal by means of a spirit level; once this was achieved the sample plate, prepared and cleaned as described previously, was introduced into the cell and the cell set up as shown in Fig. 1. The copper plate was ensured to be horizontal by aligning one of the cross wires in the microscope with a thin plumb line, then rotating the goniometer eyepiece through 90° and lining up the cross wires with the surface. The contents of the flask were brought to the boil and the heat input to the cell was controlled to keep the temperature of the enclosure slightly above the dew point of the vapor. After equilibrium was reached, which took 2–3 h, a liquid sample was removed from the still, through a side arm fitted with a septum, by means of a syringe fitted with a stainless steel needle. The liquid was then introduced onto the specimen through the central B.14 neck at the top of the cell. The end of the needle was placed just above the plate and the drop was formed slowly. Great care was taken in the removal of the needle from the drop so that no disturbance of the drop ensued. When the sessile drop had come to equilibrium with its vapor the contact angle was measured by direct observation using the travelling microscope fitted with a goniometer eyepiece. The reported values, an average of at least five readings, have standard deviations in the range 0.5–1.0 deg.

Results and Discussion

Plots of contact angle *vs.* drop diameter for pressures ranging from 50–764 Torr for water at its boiling point are given in Fig. 2. Since in practice condensation conditions are usually quoted in terms of the pressure the data have also been presented as contact angle *vs.* pressure curves for given drop diameter in Fig. 3. From Fig. 2 it can be seen that for atmospheric pressure measurements there is a change of less

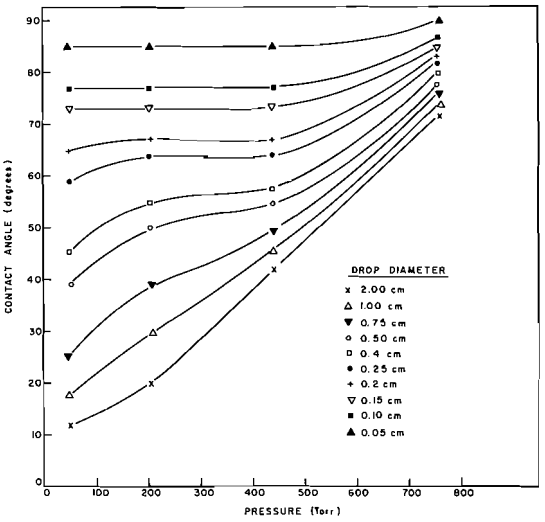

FIG. 3. Contact angle *vs.* pressure for given drop diameters.

than 8% in the contact angle for drop diameters 0.5 cm and upwards which is in agreement with the work of Hertzberg and Marian (3), who showed that there was no appreciable change in contact angle for drop volumes of 5–40 μl which approximate to these drop diameters. However, for drop diameters below 0.5 cm an appreciable increase in contact angle was observed. At the same time for reducing pressures the contact angle becomes more dependent upon drop size. For clarity the effect of pressure and drop diameter on the contact angle is given in Fig. 4.

Considering Young's equation for ideal surfaces

$$[1] \qquad \cos\theta = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}}$$

where θ = intrinsic contact angle, γ = interfacial free energy, and S, V, L refer to solid,

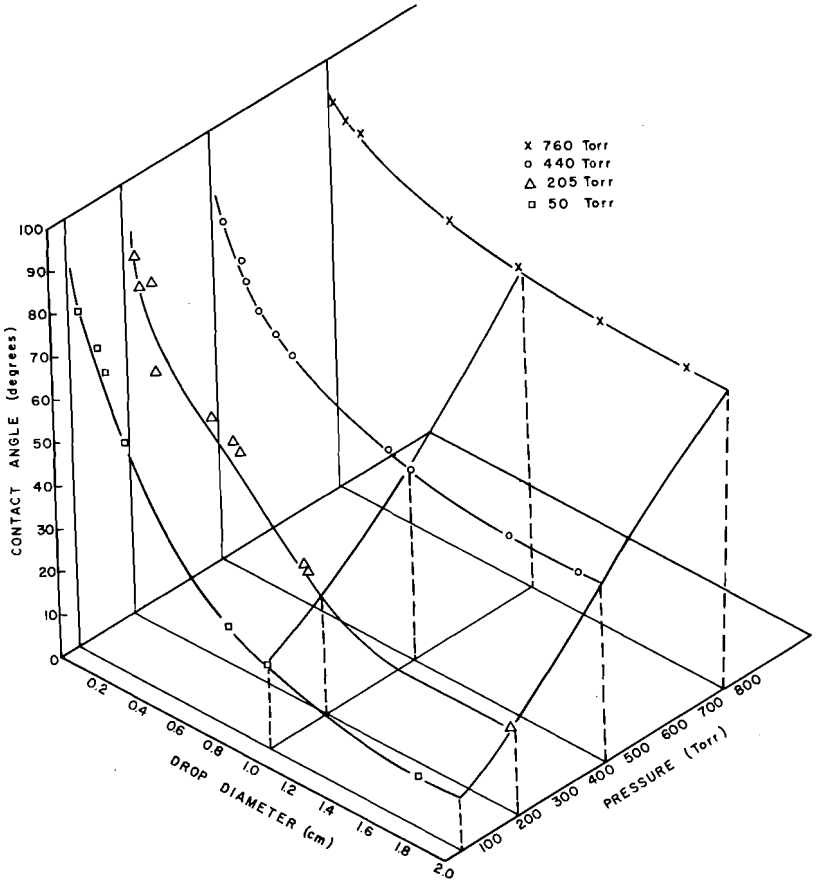

FIG. 4. Contact angle *vs.* drop diameter for a range of pressures.

For personal use only.

vapor, and liquid state, respectively. Then for a given pressure and temperature the contact angle should be independent of drop diameter. The variation of contact angle with drop size for a given pressure cannot be explained in terms of the change in surface tension (1, 2) as this is only significant for drop diameters less than 10^{-6} cm which are several orders of magnitude below our minimum size. It has been discussed in the literature (5, 6) that gravity has a negligible effect on the contact angle, this however was purported for ideal surfaces (*i.e.* uniform, plane, non-deformable). Tovbin and Fal'ko (7) demonstrated that gravity affects the shape of the drop resting on a solid surface and that this distortion could lead to errors in the calculation of θ from drop dimensions. The effect of gravity on the contact angle for non ideal surfaces has however not been clarified.

In these experiments only one surface roughness was considered *i.e.* 1.01 μin. (center line average). It would be expected that for a copper surface exhibiting another roughness that because of Wenzel's (4) relationship

$$\cos \bar{\theta} = r \cos \theta$$

(where $\bar{\theta}$ = observed contact angle and r = surface roughness) for contact angles diverging considerably from 90° the contact angle–drop diameter curve would relocate. At 90°, of course, roughness does not affect the contact angle and hence the pattern of behavior described above will be expected to be similar for a surface of any roughness up to values where air becomes entrapped so producing a composite surface.

Thiohydantoins. IX. Tautomerism of some Methylation Products

J. T. EDWARD AND J. K. LIU
Department of Chemistry, McGill University, Montreal, Quebec

Received October 1, 1969[1]

The methylation product of 5,5-pentamethylene-2-thiohydantoin has been shown by u.v. and i.r. spectral studies to exist predominantly as 2-methylthio-4,4-pentamethylene-2-imidazolin-5-one in chloroform or cyclohexane, and as 2-methylthio-5,5-pentamethylene-2-imidazolin-4-one in water. The tautomerism of the methylation product of 5,5-pentamethylene-2,4-dithiohydantoin exhibits a similar sensitivity to solvent.

Des études dans l'u.v. et dans l'i.r. démontrent que le produit fourni par l'action d'iodure de méthyle sur le pentaméthylène-5,5 thio-2 hydantoïne existe comme méthylthio-2 pentaméthylène-4,4 2-imidazoline-5-one en solution de chloroforme ou de cyclohexane, mais comme méthylthio-2 pentaméthylène-5,5 2-imidazoline-4-one en solution aqueuse. Le produit fourni par la méthylation de pentaméthylène-5,5 dithio-2,4 hydantoïne démontre une tautomerie semblable.

Canadian Journal of Chemistry, **50**, 2423 (1972)

Carrington and Waring (1) obtained a product (**1/2**, X = O) from the methylation of 5,5-pentamethylene-2-thiohydantoin (**3**, X = O) to which they assigned the unconjugated structure **1** (X = O) on the basis of analogies which cannot be considered conclusive. Edward and Martlew (2) pointed out that the u.v. spectral characteristics reported for the compound supported rather the conjugated structure **2** (X = O). Recently it has been shown (3) that the related spiroimidazolone **1/2** (X = O; H in place of SMe) exists practically exclusively as the unconjugated tautomer in chloroform solution. However, in aqueous solution it exists as an approximately 70:30 mixture of the unconjugated:conjugated tautomer, and this proportion should be decreased by the presence of the 2-methylthio group.

In the present work we show that **1/2** (X = O) can exist almost entirely in one tautomeric form or the other depending on its solvent. This has been done by u.v. and i.r. studies making use of **4** and **5** (X = O) as models for **1** and **2** (X = O). The compound **4** (X = O) had already been synthesized by Carrington and Waring (1), and **5** (X = O), hitherto unknown, was prepared by treating 1-methyl-5,5-pentamethylene-2-thiohydantoin (**6**; X = O) with methyl iodide in ether (*cf.* ref. 4),[2] and decomposing the hydriodide thus obtained with aqueous bicarbonate. The structure **5** (X = O) was proved by hydrolyzing the compound with dilute acid to methanethiol and 1-methyl-5,5-pentamethylenehydantoin.

The u.v. spectra of these model compounds (Table 1 and Fig. 1) were similar to those of the simpler compounds **4** and **5** (X = O, H in place of SMe) studied earlier (3), the conjugated compound **5** (X = O) absorbing at longer wavelength than the unconjugated **4** (X = O). The

[1]Revision received March 30, 1972.

[2]Carrington and Waring, in exhaustive studies which furnished every other possible methylation product of 5,5-pentamethylene-2-thiohydantoin, failed to obtain this compound because they treated **6** with methyl iodide in alkaline solution. This has the effect of increasing the amount of *N*-methylation and of causing the hydrolysis of any of the *S*-methyl compound which may be formed to 1-methyl-5,5-pentamethylenehydantoin.

5 R_2 = Me

confusion in the literature over the spectral characteristics of compounds of this class (reviewed in ref. 5), which had prevented a study of their tautomerism, probably arose from a neglect of solvent effects.

The spectra of **4** and **5** (X = O), presented in Fig. 1, show a small dependence on solvent polarity. However, the spectrum of **1/2** (X = O) shows a very large dependence, which is best explained on the assumption that the compound exists predominantly as the tautomer **1** (X = O) in cyclohexane, as **2** (X = O) in water, and as a mixture (very roughly in the proportions 1:2) of **1** and **2** (X = O) in ethanol.

The composition of the tautomeric mixture in water was confirmed by spectrophotometric determination (6) of the ionization constants of **4**, **5**, and **1/2** (X = O). All of these compounds can be expected to be protonated to give an ion of the general structure **7** (7), and it has been shown (8) that the tautomeric constant K_{Tau} (= [**2**, X = O]/[**1**, X = O]) is related to the apparent ionization constant K_{obs} of **1/2** (X = O)[3] and the separate ionization constants K_u of **1** (X = O) and K_c of **2** (X = O) by the relations:

$$[1] \qquad K_{Tau} = K_c/K_u$$

$$[2] \qquad = (K_{obs} - K_u)/K_u$$

$$[3] \qquad = K_c/(K_{obs} - K_c)$$

K_u and K_c are not directly observable, but are approximated by the constants K_u' of **4** (X = O) and K_c' of **5** (X = O), the substitution

[3]This and other ionization constants refer to the ionization of the conjugate acid of the base or bases.

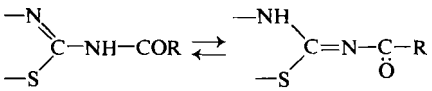
	$CDCl_3$	1720		1580	
	KBr	1730		1585	
5 (X = O)	DMSO	1695	520	1500	260
	$CHCl_3$	1704	560	1494	180
	$CDCl_3$	1704		1495	
	KBr	1705		1505	

of hydrogen by methyl generally having a small effect on the basicity of a compound. The pK values of **1/2**, **4**, and **5** (X = O) are 3.04, 3.78, and 3.00; substituting the appropriate K values into eqs. 1 and 2 gives K_{Tau} of 86:14 and 82:18 respectively. However, it is theoretically impossible for $K_{obs} < K_u$ or K_c, and the fact that $K_{obs} < K_c'$, indicates that the assumption: $K_c = K_c'$, is not strictly valid. For this reason a rational value of K_{Tau} is not obtained by application of eq. 3, but the results would indicate that K_{Tau} is very large. Summing up all the estimates, it would appear the $K_{Tau} \simeq 6:1$, the amount of unconjugated tautomer present in aqueous solution thus being small.

On the other hand, the unconjugated form is the predominant tautomer in chloroform solution, as shown by the i.r. data in Table 2. Comparison of the spectra of **4** and **5** (X = O) shows that the stretching frequencies of C=O and C=N are higher for the former compound, the values for both compounds being close to those for similar compounds already reported (3, 9, 10). In the more polar solvent, dimethyl sulfoxide, peaks indicative of both **1** and **2** (X = O) are present, and examination of the peak intensities (Table 2) indicates that the proportion of **1**:**2** (X = O) is roughly 60:40. The spectrum of the solid in KBr discs indicates that it crystallizes from ethanol mainly in the conjugated form **2** (X = O).

In summary, the proportion of conjugated tautomer present increases with the polarity of the solvent. Peresleni *et al.* (10) observed a similar effect in the tautomerism of 2-acylamino-thiazolines, which also contain the tautomeric system:



and which exhibit similar u.v. and i.r. changes on tautomerization. It consequently became of interest to observe the effect of replacing the C=O group of **1/2** by C=S. Carrington and Waring (1), by methylating 5,5-pentamethylene-2,4-dithiohydantoin (**3**, X = S), had obtained a compound ($\lambda\lambda_{max}$ 330, 297, and 255 nm in methanol) to which they assigned the structure **1** (X = S). However, the model compound **4** (X = S) showed u.v. peaks only at 295 and 250 nm, and it seemed likely that the peak at 330 nm was due to the presence of the tautomer **2** (X = S). This supposition was shown to be correct by preparing the hitherto unknown model compound **5** (X = S) by treatment of 1-methyl-5,5-pentamethylene-2,4-dithiohydantoin (**6**, X = S) with methyl iodide (*vide supra*). The model compound in ethanol had a strong u.v. peak (probably due to a $\pi \rightarrow \pi^*$ transition) at 340 nm, as well as a weak $n \rightarrow \pi^*$ peak at 404 nm[4] and a strong type of IV peak (5) at 263 nm.

Comparison of the spectra of the compound

[4]The $n \rightarrow \pi$ peaks of **4** and **5** (X = S) show a *red* shift when the compounds are protonated to form the ions **7** (R_1 = Me, R_2 = H, X = S, and R_1 = H, R_2 = Me, X = S) (see Table 3). This shift is reasonable, since there is a net flow of electronic charge inwards from sulfur in an $n \rightarrow \pi^*$ transition, and this should be aided by the positive charge spread over the amidine portion of the ring.

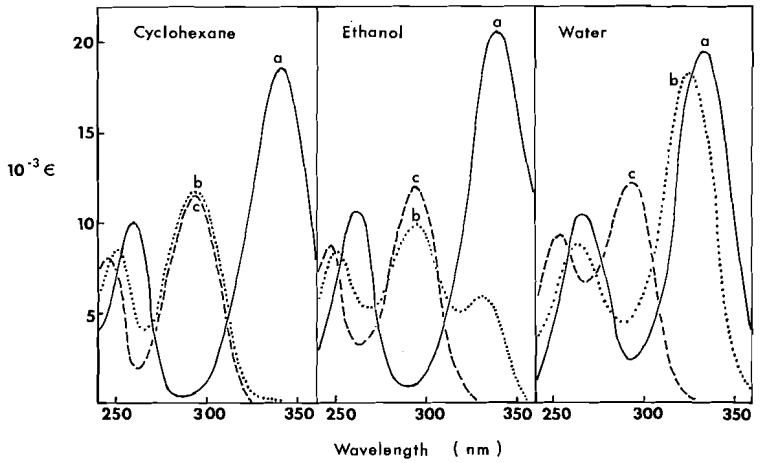

FIG. 2. Ultraviolet absorption spectra in different solvents of **5** (X = S) (*a*), **1/2** (X = S) (*b*), and **4** (X = S) (*c*).

1/2 (X = S) in cyclohexane, ethanol, and water with the spectra of the model compounds **4** and **5** (X = S) (Table 3 and Fig. 2) shows **1/2** (X = S) to be present almost entirely as the unconjugated **1** (X = S) in cyclohexane, as an approximately 4:1 mixture of **1** and **2** (X = S) in ethanol, and as an approximately 1:5 mixture of **1** and **2** (X = S) in water. Application of eqs. 1–3 to the experimental pK values of **1/2**, **4**, and **5** (X = S) (2.40, 3.06, and 2.48 respectively) in water gives K_{Tau} of 79:21, 78:22, and 82:18, which averages to a 1:4 ratio of **1**:**2** (X = S), in fair agreement with the estimate from examination of the u.v. spectra of the aqueous solutions.

In non-polar solvents, **1** (X = S) becomes (like **1** (X = O)) the more stable tautomer. This is shown by the i.r. data in Table 4. The assignments of i.r. spectral bands are based on analogy

with literature values (11) and on comparison of the spectra with those of **4** and **5** (X = O); the latter resemble closely the spectra of **4** and **5** (X = S) except in the C=O and C=S regions. From the positions and intensities of the peaks, it appears that the ratio of **1** (X = S):**2** (X = S) in dimethyl sulfoxide is about 1:1, but that in chloroform it becomes so large, that no **2** (X = S) is discernible.

Experimental

1-Methyl-2-methylthio-5,5-pentamethylene-2-imidazolin-4-one (5, X = O)

A solution of 1-methyl-5,5-pentamethylene-2-thiohydantoin (1.0 g) (1) and methyl iodide (25 ml) in anhydrous ethyl ether (25 ml) was kept in the dark for 48 h. Colorless needles of the hydriodide (0.63 g), m.p. 155–157°, separated, and were removed by filtration and washed with anhydrous ether.

Anal. Calcd. for $C_{10}H_{17}IN_2OS$: C, 35.3; H, 5.0; N, 8.2; O, 4.2; S, 9.4. Found: C, 35.3; H, 5.0; N, 8.1; O, 4.2; S, 9.6.

The hydriodide (0.5 g) in water (25 ml) was treated with sodium bicarbonate (200 mg). After evolution of carbon dioxide, the mixture was evaporated to dryness at room temperature under reduced pressure, and the residue extracted with chloroform (4 × 10 ml). The chloroform solution was dried (Na_2SO_4) and evaporated to give colorless needles of **5** (X = O), m.p. 83–85° (yield 80%). After one crystallization from ethanol the compound melted at 85–86°.

Anal. Calcd. for $C_{10}H_{16}N_2OS$: C, 56.6; H, 7.6; N, 13.2; O, 7.5; S, 15.1. Found: C, 56.4; H, 7.6; N, 13.0; O, 7.7; S, 14.9.

A solution of the compound **5** (X = O) in hydrochloric acid (20%; 5 ml) was heated under reflux for 30 min. Methanethiol was evolved, and the solution on cooling deposited colorless crystals of 1-methyl-5,5-pentamethylenehydantoin, m.p. 173–174° (lit. m.p. 174° (1)).

1-Methyl-2-methylthio-5,5-pentamethylene-2-imidazolin-4-thione (5, X = S)

1-Methyl-5,5-pentamethylene-2,4-dithiohydantoin (3.0 g) (1) was dissolved in methyl iodide (50 ml). On standing at room temperature in the dark for 24 h the solution deposited a brownish solid (3.2 g) which was dissolved in water. A small residue was removed by filtration, and the filtrate was treated with sodium bicarbonate solution until alkaline to litmus paper. Bright yellow crystals of **5** (X = S) separated which after recrystallization from ethanol were obtained in 22% yield, m.p. 149–150°.

Anal. Calcd. for $C_{10}H_{16}N_2S_2$: C, 52.5; H, 7.0; N, 12.2; S, 28.2. Found: C, 52.6; H, 7.0; N, 12.2; S, 28.0.

A solution of **5** (X = S) (0.2 g) in hydrochloric acid (20%; 5 ml) was heated under reflux for 45 min. Methanethiol was evolved, and on cooling a quantitative yield of 1-methyl-5,5-pentamethylene-4-thiohydantoin separated. It crystallized from ethanol as pale yellow needles, m.p. 187–188° (reported m.p. 188° (1)).

Spectral Measurements

The i.r. spectra were obtained with a Perkin–Elmer 337 infracord spectrophotometer, and u.v. spectra with a Unicam SP 800 spectrophotometer. General procedures have been described previously (12). Ionization constants are averaged from values calculated using data for different wavelengths and p*H* values at 25.0°, and have a precision of about ±0.05 units; they have not been corrected for the ionic strength (0.05–0.1) of the buffer solutions used. The compound **5** (X = S) hydrolyzed slowly in 0.4 *M* hydrochloric acid, and spectral measurements were taken at known time intervals and extrapolated back to zero time.

Grateful acknowledgment is made to the National Research Council of Canada for financial support.

Fluorine and Proton Nuclear Magnetic Resonance Spectra of *N*-Dialkylaminosulfur Trifluorides

D. G. IBBOTT AND A. F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 2, 1972

The fluorine and proton n.m.r. spectra of *N*-dimethylaminosulfur trifluoride and *N*-diethylaminosulfur trifluoride have been recorded under anhydrous conditions at −68 and +22°. Chemical shifts and coupling constants of axial and equatorial fluorines are reported.

Les spectres de r.m.n. du fluor et du proton dans le *N*-diméthylaminosoufre trifluorure et dans le *N*-diéthylaminosoufre trifluorure, ont été enregistrés dans des conditions anhydres à −68 et +22°. Les déplacements chimiques et les constantes de couplage du fluor axial et équatorial sont rapportés.

The geometry of tetracoordinate group VI compounds is predicted, on the basis of Gillespie's electron-pair repulsion theory (1), to be trigonal bipyramidal with an electron-pair occupying one of the equatorial sites. In the case of *N*-dialkylaminosulfur trifluorides, $(CH_3)_2NSF_3$ and $(CH_3CH_2)_2NSF_3$, Demitras and MacDiarmid (2) and von Halasz and Glemser (3) have postulated a trigonal bipyramidal structure in which the dialkylamino group also occupies an equatorial site.

Fluorine n.m.r. studies of these compounds have been complicated by fluorine exchange effects and thus Demitras and MacDiarmid observed only a broad signal for $(CH_3)_2NSF_3$ at room temperature and two signals at −100°; von Halasz and Glemser observed a broad signal at room temperature and two signals at −84° for $(CH_3CH_2)_2NSF_3$. However, additional fluorine–fluorine or fluorine–hydrogen spin–spin splitting was apparently not observed.

Fluorine exchange in sulfur fluorides has been explained by intra- and intermolecular mechanisms (4); however, it occurred to us, on the basis of our recent n.m.r. study of the hydrolysis of fluorosilanes (5), that hydrolysis may also be responsible for fluorine exchange in R_2NSF_3. If so, recording the spectra under anhydrous conditions might lead to further understanding of structural and exchange properties of sulfur fluorides.

$(CH_3)_2NSF_3$ and $(CH_3CH_2)_2NSF_3$ were prepared from SF_4 and $R_2NSi(CH_3)_3$ (2, 3) at room temperature in standard n.m.r. tubes which had previously been silylated (with $[(CH_3)_3Si]_2NH$), flamed out and evacuated (at 10^{-4} mm). The tubes were sealed under vacuum and kept at −78° while transferring to the n.m.r. spectrometer, equipped with a variable temperature probe cooled to −68°.

The fluorine n.m.r. spectrum of $(CH_3)_2NSF_3$ at −68° (Fig. 1*a*) shows a doublet ($J_{F^a-S-F^e}$ = 58 Hz) of septets ($J_{F^a-S-N-C-H}$ = 5.0 Hz) at −59.4 p.p.m. assigned to the axial fluorines. A triplet ($J_{F^e-S-F^a}$) of septets ($J_{F^e-S-N-C-H}$ = 8.2 Hz) at −20.2 p.p.m. is assigned to the equatorial fluorine. The proton n.m.r. spectrum at −68° (Fig. 1*b*) shows a doublet ($J_{H-C-N-S-F^e}$ = 8.2 Hz) of triplets ($J_{H-C-N-S-F^a}$ = 5.0 Hz) at −3.06 p.p.m. assigned to the dimethylamino group.

The well resolved multiplets at −68° indicate that fluorine exchange has been significantly slowed down under anhydrous conditions. On warming the sample, the multiplets begin to collapse and fine structure is lost; however, even at +22° two peaks remain which can clearly be identified as a doublet and a triplet, assigned to axial and equatorial fluorines, respectively, as shown in Fig. 2.

The fluorine n.m.r. spectrum of $(CH_3CH_2)_2NSF_3$ at −68° (Fig. 3*a*) shows a doublet ($J_{F^a-S-F^e}$ = 62 Hz) at −54.0 p.p.m. assigned to the axial fluorines. Additional fine structure is apparent and an approximate value for the coupling constant is $J_{F^a-S-N-C-H}$ = 3 Hz.

A triplet ($J_{F^e-S-F^a}$ = 62 Hz) of quintuplets ($J_{F^e-S-N-C-H}$ = 6.1 Hz) at −34.4 p.p.m. is assigned to the equatorial fluorine.

The proton n.m.r. spectrum at −68° (Fig. 3*b*)

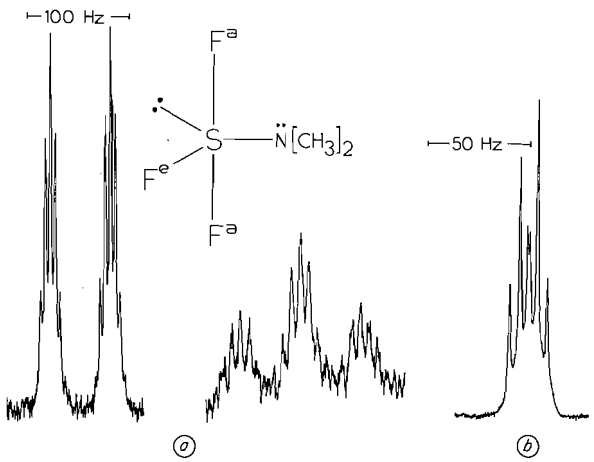

FIG. 1. The n.m.r. spectrum of $(CH_3)_2NSF_3$ at $-68°$ (*a*) fluorine; (*b*) proton.

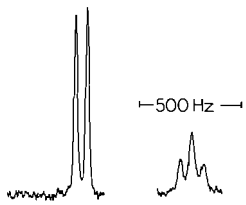

FIG. 2. Fluorine n.m.r. spectrum of $(CH_3)_2NSF_3$ at $+22°$.

shows a multiplet at -3.49 p.p.m. assigned to the CH_2 group. The multiplet may be analyzed as a first order spectrum consisting of a quartet ($J_{H-C-C-H} = 7.0$ Hz) of doublets ($J_{H-C-N-S-F^e} = 6.1$ Hz) of triplets ($J_{H-C-N-S-F^a} = 3$ Hz). The triplet ($J_{H-C-C-H} = 7.0$ Hz) at -1.25 p.p.m., assigned to the CH_3 group, shows no further coupling to fluorines. A summary of chemical shifts and coupling constants is found in Table 1.

During our n.m.r. study of the diethylamine catalyzed hydrolysis of $(CH_3)_3SiF$ (5), it was observed that rapid exchange in a sample containing $(CH_3)_3SiF$, $(C_2H_5)_2NH$, and H_2O could be stopped by adding $(CH_3)_3SiN(C_2H_5)_2$, the latter reagent apparently reacting with HF and H_2O to stop hydrolysis and fluorine exchange. A similar experiment was tried for $(C_2H_5)_2NSF_3$.

Addition of H_2O (5.6×10^{-4} g, 0.031 mmol) to anhydrous $(C_2H_5)_2NSF_3$ (1.0 mmol in 0.5 ml $CFCl_3$) resulted in loss of fine structure and only two broad peaks were observed in the fluorine n.m.r. spectrum. On adding $(CH_3)_3SiN(C_2H_5)_2$ (8.4×10^{-2} g, 0.58 mmol), a well resolved spectrum re-appeared, identical to the anhydrous spectrum of $(C_2H_5)_2NSF_3$ (Fig. 3*a*).

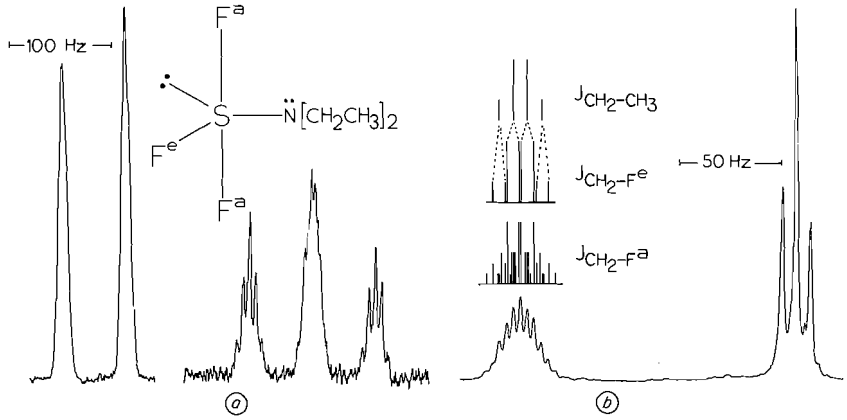

FIG. 3. The n.m.r. spectrum of $(CH_3CH_2)_2NSF_3$ at $-68°$ (*a*) fluorine; (*b*) proton.

TABLE 1. Fluorine and proton n.m.r. data for $(CH_3)_2NSF_3$ and $(CH_3CH_2)_2NSF_3$ at $-68°$. Nuclei are labelled as in Figs. 1*a* and 3*a*

	Fluorine							Proton		
	δ (p.p.m.)		J (Hz)					δ (p.p.m.)		J (Hz)
	F^a	F^e	F^a—F^e	F^a—CH_2	F^e—CH_2	F^a—CH_3	F^e—CH_3	CH_2	CH_3	CH_2—CH_3
$(CH_3)_2NSF_3$	−59.4	−20.2	58	—	—	5.0	8.2	—	−3.06	—
$(CH_3CH_2)_2NSF_3$	−54.0	−34.4	62	3	6.1	0.0	0.0	−3.49	−1.25	7.0

In a separate experiment it was shown that $(CH_3)_3SiN(C_2H_5)_2$ did not react with $(C_2H_5)_2NSF_3$ under the same conditions. These experiments support our hypothesis that hydrolysis is the mechanism of fluorine exchange in *N*-dialkylaminosulfur trifluorides.

If hydrolysis provides the lowest energy pathway for fluorine exchange in *N*-dialkylaminosulfur trifluorides, then it is obvious that the absence of significant exchange at $-68°$ (Figs. 1 and 3) and at $+22°$ (Fig. 2) under anhydrous conditions, suggests a much higher energy barrier to fluorine exchange via alternate intra- or intermolecular exchange mechanisms than has previously been suggested.

Experimental

Sulfur tetrafluoride (Matheson Co.) was handled in a metal vacuum system. Reaction of $(CH_3)_2NSi(CH_3)_3$ and $(CH_3CH_2)_2NSi(CH_3)_3$ (Peninsular ChemResearch) with SF_4 was carried out in a U-tube attached directly to a standard n.m.r. tube in a 1:1 molar ratio on a 2 mmol scale, a modification of the method of Demitras and MacDiarmid (2) and von Halasz and Glemser (3). The n.m.r. tubes were silylated with $[(CH_3)_3Si]_2NH$, flamed out, and evacuated at 10^{-4} mm. After reaction of $R_2NSi(CH_3)_3$ with SF_4, trichlorofluoromethane was condensed in and n.m.r. tubes sealed under vacuum and kept at $-78°$ while transferring to the n.m.r. spectrometer equipped with a variable temperature probe cooled to $-68°$. The n.m.r. spectra were recorded on a Varian A-56/60A spectrometer using 56.4 and 60 MHz for fluorine and proton respectively. Spectra are shown in Figs. 1–3 and coupling constants and chemical shifts are summarized in Table 1. Trimethylfluorosilane was used as internal standard for proton n.m.r. spectra, but chemical shifts are reported relative to internal tetramethylsilane (TMS) using the formula δ p.p.m. ($(CH_3)_3SiF$ internal) − 0.179 p.p.m. = δ p.p.m. (TMS internal). Chemical shifts for fluorine spectra are relative to internal trichlorofluoromethane.

The Barrier to Rotation in Cyclopropylmethyl Cations

ALLISTER BROWN[1] AND GEORGE H. SCHMID
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 16, 1971

The barrier to rotation of a cyclopropyl ring around the planar carbon of a cyclopropylmethyl cation has been estimated from rates of solvolysis to be 14 kcal/mol. This value is obtained by a comparison of the rates of solvolysis of molecules which contain conformationally rigid cyclopropane rings. The results obtained compare favorably with estimates made by other methods.

La barrière de rotation du cycle cyclopropyle autour du carbone plan du cation cyclopropyl méthyle a été évaluée à 14 kcal/mol, à partir des vitesses de solvolyse. Cette valeur a été obtenue en comparant les vitesses de solvolyse des molécules contenant des cycles cyclopropane de conformation rigide. Les résultats obtenus sont tout à fait comparables à ceux calculés à partir des autres méthodes.

The mechanism of solvolysis of cyclopropylmethyl compounds has been the object of numerous investigations (1). It has been observed that their rates of solvolysis are generally much higher than those of model compounds. The solvolysis products often exhibit a high degree of skeletal rearrangement, as well as a degenerate cyclopropylmethyl–cyclopropylmethyl rearrangement (2, 3).

One of the first definitive pieces of information regarding the structure of cyclopropylmethyl cations was presented simultaneously by Pittman and Olah (4), and Deno *et al.* (5). The n.m.r. spectra observed by these workers, for the 2-cyclopropyl-2-propyl cation in SbF_5–SO_2–SOClF, can be explained by assuming that the cyclopropyl cation exists in the bisected conformation, **1**, $R_1 = R_2 = CH_3$

Support for **1** as the structure of the cyclopropylmethyl cation has been derived from the interpretation of the u.v. spectra of several cyclopropyl ketones and esters (6). Electron diffraction data (7) are also consistent with **1** as the structure of the cyclopropylmethyl cation.

Evidence that **1** is an intermediate formed on solvolysis of substituted cyclopropylmethyl compounds has been presented by several authors (1, 8). Schleyer and van Dine (1) showed that the effects of methyl substituents on the rate of solvolysis were consistent with **1** as an intermediate while both Vogel and Roberts (8) and Richey and Richey (9) showed that ionization of optically active 1-cyclopropyl-1-ethyl compounds led to racemization, an observation consistent only with **1**, $R_1 = CH_3$, $R_2 = H$, as intermediate. Brown and Cleveland (10) showed that the intermediate formed on solvolysis of *p*-cyclopropyl-*t*-cumyl chloride (**3**), $R_1 = R_2 = H$ adopts conformation **1**. Introduction of two methyl groups ortho to the cyclopropyl substituent forces the cyclopropyl group to rotate away from the bisected conformation and a decrease in the rate of solvolysis was observed. In a similar study Sharpe and Martin (11) found that the pK_{R^+} of **4** was similarly affected by

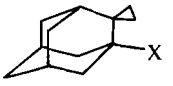
ortho methyl groups. However, the chemical shift difference for the cyclopropyl ring protons in **4** and **5**, $R_1 = R_2 = CH_3$, indicates that charge is still delocalized into the cyclopropyl ring, even though the preferred conformation **1** is not accessible. The slower rate of solvolysis of spiro[cyclopropane-1,2-adamantyl] derivatives (12) **6** than model compounds is significant. In



6

X = Cl or CH_3—C$_6$H$_4$—SO_3—

these compounds the solvolysis intermediate is restricted to conformation **2**. Thus, there appears to be a large net destabilization of cyclopropylmethyl cations when the cyclopropyl group is rotated from the bisected conformation of **1** to that in **2**.

We wish to report experimental results which indicate the magnitude of the torsional barrier for rotation of the cyclopropyl group about the plane of the cationic carbon in secondary cyclopropylmethyl cations. We have obtained such data from a measurement of the rates of solvolysis of *N*-methyl-4-(*cis*- and *trans*-2-bicyclo-[3.1.0]hexanoxy)pyridinium iodides (**7***a* and **8***a*) and *N*-methyl-4-(spiro[2.4]heptan-4-oxy) pyridinium iodide (**9***a*) in 80% aqueous ethanol.

Results and Discussion

cis-2-Bicyclo[3.1.0]hexanol (**7***b*) was prepared by the method of Dauben and Berezin (13). *trans*-2-Bicyclo[3.1.0]hexanol (**8***b*), was obtained by the aluminum isopropoxide equilibration of **7***b*. 4-Spiro[2.4]heptanol (**9***b*), was prepared according to the method of Closson and Kwiatkowski (14). The mixture of **7***b* and **8***b* obtained by equilibration with aluminum isopropoxide could not be separated on a preparative scale using various techniques. The mixture of isomeric compounds also proved inseparable at the various stages in the preparation of the *N*-methyl-4-alkoxypyridinium iodides. However, since **7***a* could be obtained as a single isomer, the solvolysis of a mixture of **7***a* and **8***a* of known composition gave the data required for the solvolysis of **8***a*.

TABLE 1. The rates of solvolysis of *N*-methyl-4-alkoxy pyridinium iodides in 80% aqueous ethanol

Substrate	Temperature (°C)	$10^4 k_{obs}$ (s^{-1})
7*a*	86.4	2.20 ±0.05
8*a*	86.4	1.70 ±0.05
9*a*	39.6	0.498±0.003
"	49.3	2.06 ±0.01
"	59.3	6.41 ±0.01
"	86.4	148

The rates of solvolysis of **7***a* and **8***a* were measured in 80% aqueous ethanol at 86.4°. The rate constant for **9***a* at 86.4° was obtained by extrapolation of the values obtained at lower temperatures. The progress of the reaction was monitored by an acidimetric titration using the ampoule technique. The rate of liberation of acid followed first order kinetics for more than three half-lives in all cases.

The rate constants at 86.4° and the relative rates are presented in Table 1. The value listed for **8***a* was calculated using eq. 1, where k_{obs} is the rate constant observed for the solvolysis of a mixture of 49.5% of **7***a* and 50.5% of **8***a*, X_{8a} being the mole fraction of **8***a* and k_{7a} the independently measured rate constant for solvolysis of **7***a*. Equation 1 is only an approximation and

$$[1] \qquad k_{8a} = \frac{k_{obs} - (1 - X_{8a})k_{7a}}{X_{8a}}$$

is strictly obeyed only in the initial stages of the reaction. However, in the case where the rate constants are similar, as with **7***a* and **8***a*, the deviation from first order behavior is much less than the experimental error.

Vogel and Roberts (8) showed that the intermediate cation formed on solvolysis of *N*-methyl-4-(1-cyclopropyl-ethyl)pyridinium iodide in the rate determining step must have a plane of symmetry. They concluded that **1**, $R_1 = H$, $R_2 = CH_3$, is a reasonable representation of the structure of this intermediate. The mechanism of solvolysis of derivatives of **7**, **8**, and **9**, have been discussed previously (14–18). Compounds **7***a*, **8***a*, and **9***a* all undergo solvolysis reactions that involve the formation of a cyclopropylmethyl cation in the rate determining step. The cationic intermediate formed in the

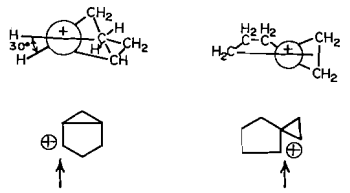


FIG. 1. Structures of the cations obtained by solvolysis of **7***a*, **8***a*, and **9***a*.

rate determining step of the solvolysis of **9***a* has been shown to be symmetrical (15) having the structure shown in Fig. 1. While the solvolysis of **7** and **8** was originally postulated to occur with the homoallylic ions as intermediates (16, 17) it has recently been established (19) that the intermediate formed in the rate determining step in the solvolysis of cyclopropylmethyl compounds retains the structure of the substrate. In the case of **7***a* and **8***a* this intermediate is best represented by a structure which is planar at the cationic carbon, C-2, with the neighboring cyclopropyl group rotated approximately 30° from **1**, as illustrated in Fig. 1. The slight differences in the rates for **7***a* and **8***a* reflect the difference in ground state stabilities, **7***a* being slightly less stable (18). The solvolysis products from either **7***a* or **8***a* consist of the alcohols and corresponding ethyl ethers derived from **7**, **8**, and 3-cyclohexenol (18). The products of the solvolysis of **9***a* were found to be identical to those previously reported (14, 15). These products are consistent with the formation of a cationic intermediate.

Schleyer and van Dine (1) have found that substitution at the α- and β-positions of the cyclopropane ring produces a five-fold and eight- to eleven-fold increase in rate, respectively; over that of the unsubstituted compound. Thus, substitution at the β-position of the cyclopropyl ring is twice as effective as substitution at the α-position. In the absence of any additional gross complications **7***a* and **8***a* would be expected to solvolyze twice as fast as **9***a*. The rate constants in Table 1 reveal that this is not the case.

If it is assumed that the major difference in the rates of solvolysis of **8***a* and **9***a* is caused by the fact that the cyclopropyl ring in **8***a* cannot assume the preferred bisected conformation **1**, an approximation to the torsional barrier for rotation of the cyclopropyl group in **1**, R_1—H, R_2—CH_3, can be calculated. Using eq. 2, the difference in the free energies of activation for **8***a* and **9***a* is found to be approximately 3.5 kcal/mol at 86.4° (3.48 kcal/mol for **7***a* and 3.66 kcal/mol for **8***a*). If it is assumed that the difference in energy between the *cis*- and *trans*-conformers of the 1-cyclopropyl-1-ethyl cation is small compared to the barrier of rotation between the conformers, then the barrier will appear to have two-fold symmetry. The energy, $V(\theta)$, required to rotate a group from the minimum potential energy through an angle, θ, is given by eq. 3 (20), where V_o is the barrier to rotation through $\pi/2$.

[2] $$\Delta\Delta G^{+} = RT \ln (k_{8a}/2k_{9a})$$

[3] $$V(\theta) = V_o/2(1 - \cos 2\theta)$$

The difference in free energy of activation for **8***a* and **9***a* is equal to the energy required to rotate the cyclopropyl group by 30° away from the bisected conformation. In this way the torsional barrier, V_0, can be calculated to be 14 kcal/mol.

There are several assumptions inherent in this calculation. Firstly, the assumption is made that the barrier to rotation of **1**, $R_1 = H$, $R_2 = CH_3$, will have the same angular dependence on energy as the intermediate formed on solvolysis of **7***a* and **8***a*. Secondly, the usual assumption is made that during the rotation of the cyclopropane ring, the entropy changes, as well as $\Delta\Delta S^{+}$, are zero.

Finally it is assumed that rotation of the cyclopropane ring does not alter the α and β substituent effects determined by Schleyer and van Dine (1).

The value of 14 kcal/mol calculated in this study is in good agreement with the value of 13.7 kcal/mol calculated by Kabakoff and Namanworth (22) for **1**, $R_1 = H$, $R_2 = CH_3$, using n.m.r. measurements, as well as other values from *ab initio* calculations (21) (17.5 kcal/mol) and from the solvolysis of **6** (23, 24) (10 kcal/mol).

Our result for the rotational barrier is obtained by using an average value for $\Delta\Delta G^{+}$. If the rotational barrier is calculated from the data of solvolysis of **7***a* and **8***a* values of 13.9 and 14.6 kcal/mol are obtained respectively. This small difference of 0.7 kcal/mol indicates that our third assumption is reasonable.

We would like to conclude from these results, that the major factor which causes the barrier to rotation in cyclopropylmethyl ions must also be a major factor contributing to the stability of cyclopropylmethyl cations. This factor may be "vertical" stabilization as defined by Traylor and co-workers (25), but charge delocalization, as in the allyl cations, can not be great. This view is supported by the hundred-fold greater effectiveness of a methyl group at the C-1 position of a cyclopropane ring in stabilizing the transition state than methyl groups at positions C-2 and -3 (2). Further, the products from solvolysis of **7***a* and **8***a* are derived mainly from solvent capture at C-2, even though considerable strain release would be achieved by solvent capture at C-5, giving 3-cyclohexenyl derivatives (26).

Further support of this conclusion is derived from the contrasting effects of methyl groups on the rotational barriers estimated for allylic and cyclopropylmethyl cations described by Schleyer and co-workers (23). These authors also concluded that the cyclopropylmethyl cation is stabilized in a different manner than the allyl cation.

Experimental

Melting and boiling points are uncorrected. Elemental micro-analyses were carried out by A. B. Gygli of Toronto.

cis-2-Bicyclo [3.1.0]hexanol (7b)

Compound **7***b* was prepared by the procedure of Dauben and Berezin (13) in 60% yield; b.p. 62–65° (9 mm); n_D^{25} 1.4790 (lit. b.p. 78–79.5° (20 mm), n_D^{25} 1.4742 (13); b.p. 76° (17 mm), n_D^{25} 1.4788 (26)).

4-(cis-Bicyclo [3.1.0.]hexyl-2-oxy)pyridine

This compound was prepared according to the method of Schmid and Wolkoff (27) in 76.5% yield. The liquid was sublimed onto a cold finger rather than being distilled. I.r. ν_{max} (CCl_4); 3090, 3050, (cyclopropyl C—H stretch); 2950–2980, 1590, 1560, (pyridyl ring vib.) 1495, 1420, 1366, 1330, 1275, 1210, (pyridyl C—O stretch), 1015 cm^{-1}. N.m.r. ($CDCl_3$); 1.6–1.8, quart., $J_1 = 5$, $J_2 = 1$ Hz, (2H), 2,6-pyridyl protons; 3.0–3.2, quart., (2H), $J_1 = 5$, $J_2 = 1$ Hz, 3,5-pyridyl protons; 4.9–5.2, mult., (1H), methine proton; 7.2–8.9, mult., (6H), cycloalkyl protons; 9.2–9.8, mult., (2H), cyclopropyl methylene protons.

N-Methyl-4-(cis-bicyclo[3.1.0]hexyl-2-oxy)pyridinium Iodide (7a)

Iodide **7***a* was prepared from 4-(*cis*-bicyclo[3.1.0]hexyl-2-oxy)pyridine by the method of Schmid and Wolkoff (27) in 96.5% yield. The solid was recrystallized from methylene chloride and ether as white needles, m.p. 118–119.5°. I.r. ν_{max} ($CHCl_3$); 2930, 1645, 1570, (pyridyl ring vib.), 1340, 1295, 975 cm^{-1}. N.m.r. ($CDCl_3$); 0.7–1.0, doub., $J = 7$ Hz, (2H), 2,6-pyridyl protons; 2.4–2.6, doub., $J = 7$ Hz, (2H), 3,5-pyridyl protons; 4.4–4.8, mult., (1H), methine proton; 5.5, sing., (3H), *N*-methyl protons; 7.5–8.8, mult., (6H), cycloalkyl protons; 9.2–9.6, mult., (2H), cyclopropyl methylene protons.

Anal. Calcd. for $C_{12}H_{16}ONI$: C, 45.58; H, 5.16; N, 4.46; I, 40.23. Found: C, 45.49; H, 5.21; N, 4.43; I, 40.03.

trans-2-Bicyclo [3.1.0]hexanol (8b)

Hexanol **8***b* was prepared by isomerizing **7***b* by the method of Eliel and Ro (28). The fractions obtained by distillation, b.p. 61–65° (11.5 mm) varied in ratio of **7***b* to **8***b* and weighed 4.36 g (44% recovery).

2-Carbomethoxycyclopentanone

Following the method of Pinkney (29), 342.1 g of methyl adipate (1.97 mol) gave 212 g (79% yield) of a clear liquid after distillation under vacuum, b.p. 95–96° (11 mm) (lit. (29) b.p. 83–88° (5 mm); yield, 81%).

4-Spiro [2.4]heptanone

The heptanone was prepared by the method of Mayer (30, 31) from 56 g of 2-carbomethoxycyclopentanone (0.394 mol) in an overall yield of 32%; b.p. 44–46° (10 mm) (lit. (30, 31) b.p. 54–55° (14 mm)).

4-Spiro [2.4]heptanol

The heptanol was prepared by lithium aluminum hydride reduction of 4-spiro[2.4]heptanone in 76% yield; b.p. 59.5–60° (9 mm) (lit. b.p. 68–69° (13–14 mm) (32).

4-Spiro [2.4]heptan-4-oxy)pyridine

The compound was prepared according to the method of Schmid and Wolkoff (27) in 81.5% yield, b.p. 80° (0.075 mm). I.r. ν_{max} (neat); 3010, 2955–2860, 1590, 1565, (pyridyl C=C vib.), 1495, 1280, 1210, (pyridyl C—O stretch), 1080, (alkyl C—O stretch) cm^{-1}. N.m.r. (CCl_4); 1.7–1.8, quart., $J_1 = 5$, $J_2 = 2$ Hz, (2H), 2,6-pyridyl protons; 3.3–3.4, quart., $J_1 = 5$, $J_2 = 2$ Hz, 3,5-pyridyl protons; 5.8–5.9, doub., (1H), methine proton; 7.6–8.8, mult., (6H), cycloalkyl protons; 8.9–9.6, mult., (4H), cyclopropyl protons.

Anal. Calcd. for $C_{12}H_{17}ON$: C, 76.15; H, 7.99; N, 7.40. Found: C, 76.32; H, 8.11; N, 7.41.

N-Methyl-4-(spiro[2.4]heptan-4-oxy)pyridinium Iodide

The iodide was prepared by the method of Schmid and Wolkoff (27) from 4-(spiro[2.4]heptan-4-oxy)pyridine in 97% yield, m.p. 86–88.5°. I.r. ν_{max} ($CHCl_3$); 2930, 1645, 1590, 1510, (pyridyl ring vib.), 1485, 1330, 1305, 1290 (pyridyl C—O stretch), 1080 (alkyl C—O stretch), 1015, 945 cm^{-1}. N.m.r. ($CDCl_3$); 0.6–0.9, doublet; $J = 7$ Hz, (2H), 2,6-pyridyl protons; 2.5–2.7, doublet $J = 7$ Hz, (2H), 3,5-pyridyl protons; 5.4–5.6, multiplet, methine proton; 5.5 singlet, *N*-methyl protons (3H); 7.4–8.7; multiplet, (6H), cycloalkyl protons; 9.0–9.5, multiplet (4H), cyclopropyl protons.

Kinetics

All kinetic runs were carried out in thermostated oil baths, with temperature controlled to maximum deviation of ±0.05°. The rate constants were determined using the general procedure of sealing portions of the reacting solutions in glass ampoules, removing ampoules at chosen intervals from the bath, freezing, and titrating. All samples were titrated automatically to a predetermined p*H* using a Coleman Model 31 p*H* meter and Companion Automatic Titrator. The end point for the titration was determined from a titration curve of *N*-methyl-4-pyridone hydroiodide.

The rate constants were calculated from the volume of base required for neutralization, V_t, in the usual manner (33).

Products

The ratios of products obtained by the solvolysis of **7***a*, **8***a*, and **9***a* were determined using several v.p.c. columns. The ethers and alcohols from **7***a* and **8***a* were isolated as two mixtures and examined by n.m.r. spectroscopy. It was possible to determine the ratio of the three products from the integrated ratios of the three methine resonances as well as from the chromatograms. The n.m.r. product ratio agreed well with that determined by v.p.c.

The products of the solvolysis of **9***a* were isolated by v.p.c. and the structure of each was established by comparing its infrared and n.m.r. spectra with published data (14, 15).

Received February 15, 1972

Carbon-13 Fourier transform n.m.r. spectra of the biopolymer, heparin, are described. The proton-decoupled spectrum corresponds to that of a molecular structure based on 12 carbon atoms, and the observed chemical shifts are shown to be consistent with a previously-proposed alternating sequence consisting of (1 → 4) linked residues of α-L-idopyranosyluronic acid 2-sulfate and 2-deoxy-2-sulfamino-α-D-glucopyranosyl 6-sulfate. Line-broadening of the C-6 signal of the latter residue indicates that spin–spin relaxation of the ^{13}C nucleus of this sulfated primary carbinol group is more effective than for the ^{13}C nuclei of the sugar rings. Among model compounds utilized for assignment of the signals from heparin is a disaccharide, 4-*O*-(α-L-idopyranosyluronic acid 2-sulfate)-2,5-anhydro-D-mannose 6-sulfate, prepared in 65% yield by deaminative degradation of heparin.

Les spectres carbone 13, transformés de Fourier, du biopolymère héparine sont décrits. Le spectre, avec les protons découplés, correspond à celui d'une structure moléculaire contenant douze atomes de carbone; on a montré que les déplacements chimiques observés sont compatibles avec la séquence alternée que nous avons précédemment proposée, consistant des résidus α-L-iodopyranosyluronique acide sulfate-2 et déoxy-2 sulfamino-2-α-D-glucopyranosyl sulfate-6, liés (1 → 4). La largeur de raie du signal C-6 du dernier residu indique que la relaxation spin–spin du noyau ^{13}C de ce groupe carbinol primaire sulfaté est plus facile que celle des noyaux ^{13}C pour les cycles des sucres. Parmi les composés modèles utilisés pour l'attribution des signaux de l'héparine nous signalons que le disaccharide 4-*O*-(α-L-iodopyranosyl uronique acide sulfate-2) anhydro-2,5-D-mannose sulfate-6 a été préparé avec un rendement de 65% par dégradation déaminative de l'héparine.

Canadian Journal of Chemistry, **50**, 2437 (1972)

In conjunction with studies (1–4) on the structure of heparin it became of interest to examine the ^{13}C n.m.r. spectrum of this polymer. However, attempts to obtain the ^{13}C resonance data by the continuous wave technique were unsuccessful; multiple-scanning even for several days failed to yield satisfactory signals. Similarly the use of this technique with another polysaccharide, low molecular weight cellulose acetate has been reported (5) to give a relatively poor spectrum. The current paper describes a high quality spectrum of heparin obtained by Fourier transform (FT) n.m.r. spectroscopy and hence also demonstrates the superior potential of this method for the measurement of ^{13}C spectra of carbohydrate macromolecules.

The FT spectrum of heparin in deuterium oxide has been recorded both with proton-decoupling (Fig. 1A) and without decoupling (Fig. 1B), using a Varian XL-100-15 spectrometer and spectrum accumulation times of 18 and 50 h, respectively. In Fig. 1A, the relative intensities of signals (moving progressively downfield from 134 to 92 p.p.m. from CS_2) are 1.0, 0.9, 4.0, 3.0, 0.8, and 0.9.[3] Together with the signal of 18 p.p.m.,[4] these data correspond to a repeating formula based on a minimum of

[1]Postdoctoral Fellow, 1970–1971 and 1970–1972, respectively.

[2]Present address: Transform Technology Inc., Palo Alto, California.

[3]For a discussion of the accuracy of FT n.m.r. ^{13}C integrated intensities of smaller molecules see ref. 6. Under the conditions used, the acquisition time was estimated to be at least 4–5 times the relaxation time.

[4]The intensity of this signal (carboxyl ^{13}C) cannot be compared satisfactorily with that of the others because carbonyl ^{13}C generally gives weaker signals than H-bearing carbons. Noteworthy, however, is the relative intensity of this signal in 1A as compared with 1B, which illustrates the large improvement in signal-to-noise due to the nuclear Overhauser effect of proton-decoupling.

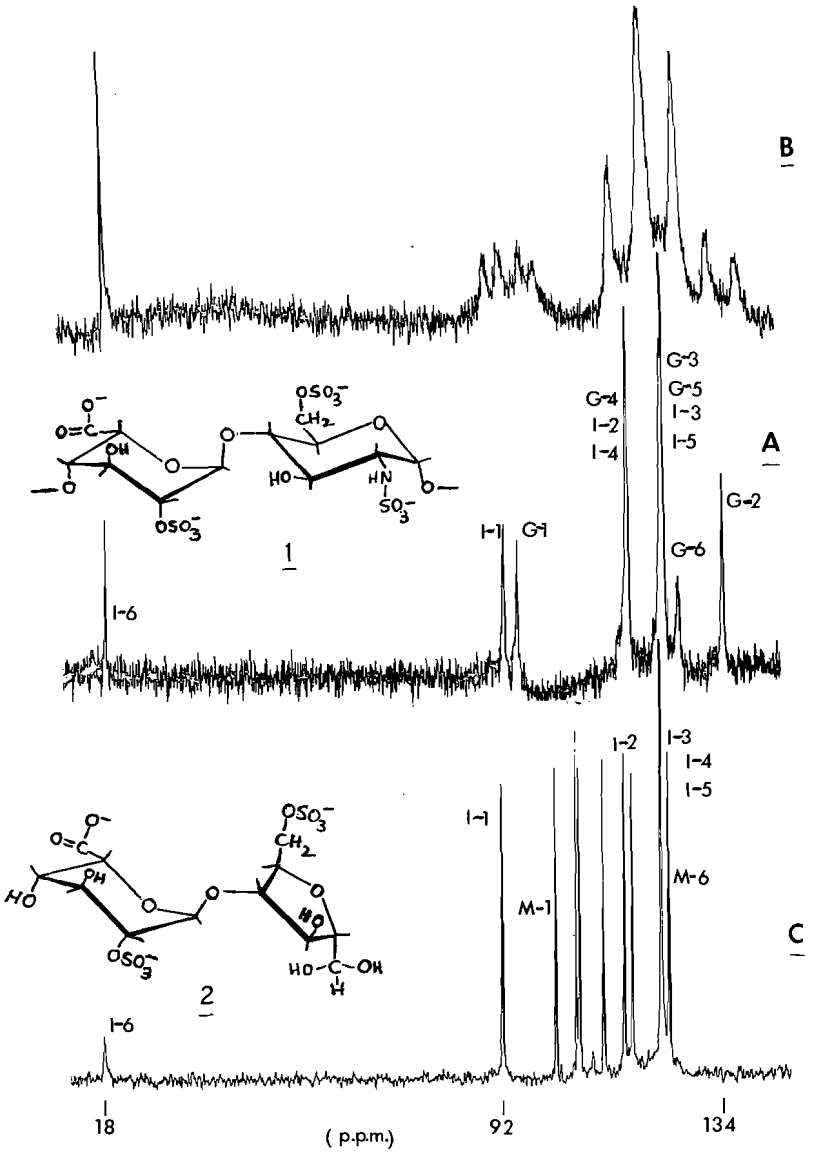

FIG. 1. ^{13}C Fourier transform n.m.r. spectrum of (A) heparin in deuterium oxide, with proton-decoupling (I-signal ascribed to α-L-idosyluronic acid residue, G-signal ascribed to 2-amino-2-deoxy-α-D-glucose residue); (B) heparin in deuterium oxide, without proton-decoupling; (C) disaccharide **2** in deuterium oxide, with proton-decoupling (I-signal ascribed to α-L-idosyluronic acid residue, M-signal ascribed to 2,5-anhydro-D-mannose residue; the unmarked signals also are ascribed to this residue). Chemical shifts (p.p.m.) are relative to downfield carbon disulfide.

12 carbon atoms, such as in the main heparin segment **1** composed of residues of α-L-iduronic acid and 2-amino-2-deoxy-α-D-glucose (2–4, 7–9). The following discussion shows that the observed chemical shifts also are consistent with structure **1**.

The two signals at 92 and 95 p.p.m. are attributable to anomeric carbons, because of their downfield positions (10–13). Also, they show relatively broad C—H coupling: that is, J_{CH} is about 165 Hz in each instance, which is noticeably larger than couplings (130–150 Hz) for the other carbons, as found with α- and β-D-glucose (11). By overlaying traces A and B,

the signal at 125 p.p.m. is found to be that of a CH_2 group, *i.e.* it appears as a triplet in contrast to the doublet structures of the other proton-bearing carbons, and hence is ascribed to C-6 of the hexosamine residue. Relative to the chemical shift (131 p.p.m.) of C-6 of 2-amino-2-deoxy-α- or β-D-glucose hydrochloride, its position corresponds to a downfield displacement of 6 p.p.m. by the 6-*O*-sulfate group of the residue. This assignment is consistent also with the fact that the signal has a greater line-width than do individual signals from the other carbon atoms.[5] The heparin macromolecule must have a relatively long correlation time and correspondingly short relaxation times, T_1 and T_2 (14). Now, T_1 of a given carbon is inversely proportional to the number of attached protons (6). Since T_2 cannot be longer than T_1 (14), the ^{13}C nucleus of the CH_2 group should accordingly experience more effective spin–spin relaxation (shorter T_2) than nuclei of the CH groups, and hence give rise to the relatively greater line-broadening observed.

Assignment of the signal furthest upfield to G-2 is based on the analogous location of C-2 in the spectrum of 2-amino-2-deoxy-α-D-glucose hydrochloride (C-2 of the β-anomer is more deshielded by 3 p.p.m.). Continuing with this comparison, C-3, -4, and -5 of the α-hexosamine resonate of 120–122 p.p.m., *i.e.* close to the chemical shift of the largest group of signals at 122 p.p.m., which leads to the G-3 and -5 designations in Fig. 1A. G-4, however, must be much further downfield because of strong deshielding by an adjacent glycosyl residue linked through O-4. Hence, a shift downward of 7–8 p.p.m. as observed with several oligosaccharides (5, 15), would reasonably place G-4 among the signals resonating at 116 p.p.m.

Reference to the ^{13}C spectrum of sodium methyl α-D-idopyranosiduronate (16), as a possible model for the uronic acid moiety of heparin, shows that signals of C-2 to -5 are closely grouped within the range 121.0–122.5 p.p.m. which again coincides with the broad four-carbon signal at 122 p.p.m. However, since C-4 of uronosyl residues in heparin is glycosidically bonded, it should resonate downfield and, like C-4, is probably one of the signals at 116 p.p.m. Similarly, the signal designated I-2 takes account of the presence of a 2-*O*-sulfate group in heparin; as noted above in relation to G-6 (and this is found also for the effect of an *O*-sulfate group introduced at C-2 of methyl α-D-glucopyranoside) the associated deshielding is expected to place I-2 about 8 p.p.m. downfield of the C-2 signal of methyl α-D-idopyranosiduronic acid.

These various assignments also are in close accord with the ^{13}C spectrum of disaccharide **2** (Fig. 1C),[6] the major product obtained by deaminative degradation of heparin (see below). Thus the three-carbon signal at 122 p.p.m. is coincident with I-3 and -5 of the heparin spectrum, and I-4 of **2** should then account for the remaining signal in this upfield region because O-4 is not engaged in inter-residue bonding as when in the parent polymer. Other signals common to both Figs. 1A and C are those at 93 p.p.m. (which specifically suggests the I-1 designation in 1A), at 111 p.p.m., ascribable in each instance to I-2, and those of the carboxyl ^{13}C at 18 p.p.m.

The high degree of consistency found in comparing appropriate chemical shifts within the series heparin, disaccharide **2**, and methyl α-D-idopyranosiduronic acid, indicates that the conformation of L-iduronic acid residues in heparin is close to that in the smaller molecules. Information available about the methyl glycoside (16) favors a predominance of the C1(D) conformation for it and, accordingly, the L-iduronic acid residues of heparin may be depicted most satisfactorily by the 1C(L) conformation.

Quantitative aspects of ^{13}C FT n.m.r. spectra (6) are of particular interest from the general standpoint of polymer characterization (18). In principle, a reliable measure of the proportion of constituent residues in a mucopolysaccharide, or other polysaccharide, should be afforded by the number and relative intensities

[5]An expanded plot of Fig. 1B shows for example that its line-width is 1.6 times that of the adjacent, upfield, signal. It appears most probable that these line-widths are, in reality, natural line-widths.

[6]Signals of the 2,5-anhydro-D-mannose residue in **2** are seen to be markedly downfield relative to those of the hexosamine residue from which it was derived. This effect is consistent with the fact that most ^{13}C signals of furanose derivatives are more deshielded by 5–10 p.p.m. than are their six-membered ring counterparts (17*a* and *b*).

of the resonance signals in its ^{13}C spectrum. Although many of the signals from heparin coincide in chemical shift, the evidence clearly favors a total of 12 different carbons, and therefore accords with a biose repeating sequence such as represented by **1**. It is noteworthy, nevertheless, that there are no additional, lower intensity signals detected to account for the minor (2, 9) D-glucuronic acid moiety of heparin (7), as found also on examination of its 220 MHz p.m.r. spectrum (3). Presumably, such relatively weak signals in these spectra are obscured through overlap, although insufficient accuracy in the measurement of signal intensities also could be a contributing factor. Despite such limitations, n.m.r. spectroscopy obviously constitutes a valuable adjunct to chemical and enzymic methods for characterizing carbohydrate polymers.

Deaminative Degradation of Heparin[7]

When treated with nitrous acid, heparin is degraded extensively to fragments containing residues of 2,5-anhydro-D-mannose and uronic acid (19, 20). Recent examination of these fragments by Lindahl and Axelsson (9), and now also in this laboratory, shows that the main product is a disaccharide consisting of L-iduronic acid and the anhydromannose. In conformity with sequence **1**, proposed (3, 4) as the major structural feature of the heparin molecule, this disaccharide may be formulated as **2**, *i.e.* 4-*O*-(α-L-idopyranosyluronic acid 2-sulfate)-2,5-anhydro-D-mannose 6-sulfate.

In our study, **2** has been isolated as a chromatographically- and electrophoretically-pure compound[8] in 65% yield by use of column chromatography on Sephadex G-10, and converted to a crystalline brucinium salt. Borohydride-reduced **2** has a specific rotation ($[\alpha]_D$ +2°) of the magnitude expected for a disaccharide composed of 2,5-anhydro-D-mannitol ($[\alpha]_D$ +58° (19)) and α-L-idopyranosyluronic acid (*ca.* $[\alpha]_D$ −70° (16)). As would be expected, acid hydrolysis of the reduced disaccharide yielded 2,5-anhydromannitol and iduronic acid and, following exhaustive borohydride-reduction of the latter, iditol.

As noted above, the ^{13}C spectrum of this disaccharide is commensurate with structure **2**. P.m.r. spectroscopy affords additional supporting evidence. The 100 MHz p.m.r. spectrum of **2** is almost indistinguishable from that of the total deamination product presented in ref. 1, Fig. 1D. At 220 MHz, the superior resolution more clearly shows the doublet (*J* 5.5 Hz) at 5.3 p.p.m. due to H-1 of the hydrated aldehydic group (21) of the anhydromannose residue. Signals ascribable to H-1 and -5 of the L-idosyluronic acid residue, at 4.8 and 5.4 p.p.m., respectively, virtually coincide in shift with the corresponding resonances from heparin (1, 3). Similarly, the narrow spacings (2.0–2.5 Hz) of these signals (which are better resolved as doublets at 220 than at 100 MHz) are consistent with the α-L-*ido* configuration and 1C(L) assignments proposed earlier for the uronic acid residues (3, 4, 16). Aside from a triplet (*J* 5.5 Hz) at 3.9 p.p.m., due to the anhydromannose H-2, all signals of the spectrum appear downfield of 4.0 p.p.m. Since H-2 of methyl α-D-idopyranosyl uronic acid resonates at 3.6 p.p.m., this observation is in accord with the expected strong deshielding of H′-2 of **2** by the *O*-sulfate group. Noteworthy also is the fact that all three signals upfield of 4.0 p.p.m. in the spectrum of heparin (3) have been ascribed to protons of the 2-amino-2-deoxy-D-glucose residues, because corresponding signals are absent from the spectrum from **2**.

The findings of this study based on the isolation of disaccharide **2**, taken in the context of the other evidence available, lead to the conclusion that at least two-thirds to three-quarters (4) of the heparin macromolecule consists of repeating biose residue sequences of structure **1**.

Experimental

Fourier transform ^{13}C n.m.r. spectra of heparin were recorded at 25.2 MHz with a Varian XL-100-15 spectrometer using deuterium oxide as the source of the lock signal. The heparin (sodium salt, Upjohn; *N*-acetyl, trace (2, 3)) (0.23 g in 2.5 ml of D_2O) was contained in a 12 mm tube, the spectrum width was 5000 Hz, acquisition time 0.4 s, and pulse width 75 μs; with concomitant proton-

[7]A preliminary account of this study has been presented by A. S. Perlin and N. M. K. Ng Ying Kin at the ACFAS Conference, Laval University, Quebec, October 17, 1970.

[8]The ^{13}C spectrum of the compound furnishes an additional criterion of its purity: signals from the 12 carbons are clearly accounted for (integration (6) of the expanded spectrum from 90 to 125 p.p.m. confirms that the relative intensities are correct), and the only indication of a possible contaminant is the very weak signal at 115 p.p.m.

For personal use only.

decoupling the total spectrum accumulation time was 18 h, and without decoupling it was extended to 50 h.

Deaminative Degradation of Heparin

To a solution of heparin (sodium salt, Upjohn) (0.63 g) in 1.1 *M* acetic acid (6 ml), sodium nitrite (0.3 g) was added,[9] producing a vigorous effervescence. The solution was stored at 20 °C for 24 h, then concentrated to 1/2 volume, and applied to a column of Sephadex G-10 (2.5 × 105 cm). The column was washed with a buffer consisting of disodium phosphate and citric acid (3.6 and 1.6 g, respectively, per liter), with the eluant being collected at a rate of 30–35 ml/h. Fractions were examined by paper electrophoresis and pooled where appropriate.

Products of the Deamination Reaction

Disaccharide (2)

The major product was recovered by concentrating those eluate fractions comprising 288–310 ml; yield, 0.40 g, $[\alpha]_D$ 0 ± 1° (*c*, 0.5 H_2O). A brucinium salt was prepared, and crystallized from solution in cold aqueous ethanol or aqueous acetone (yield 35%); $[\alpha]_D$ −20° (*c*, 1 H_2O).

Anal. Calcd. for $C_{81}H_{98}O_{29}S_2N_6$: C, 57.8; H, 5.8; S, 3.8; N, 5.0. Found: C, 58.5; H, 5.7; S, 3.9; N, 5.3.

Some preparations of the disaccharide contained sodium sulfate (derived presumably from the original sulfamino group) and, in one experiment, led to co-crystallization of the brucinium salt of **2** with 1 mol of brucinium sulfate.

Anal. Calcd. for $C_{127}H_{152}O_{41}S_3N_{10}$: C, 59.3; H, 5.9; S, 3.7; N, 5.4. Found: C, 59.7; H, 6.3; S, 3.8; N, 5.9.

The product was reduced with sodium borohydride ($[\alpha]_D$ of the neutralized solution, +2° (*c*, 1)), then partially desulfated by treatment with hot methylsulfoxide–pyridine (22), and hydrolyzed with 0.5 *N* sulfuric acid at 95 °C for 3 h. Paper electrophoretic and chromatographic examination of the hydrolysate indicated the presence of iduronic acid and 2,5-anhydromannitol. A second borohydride reduction was carried out, the resulting aldonic acid converted to the methyl ester with diazomethane, and the borohydride reduction repeated. Finally, the products were acetylated with pyridine–acetic anhydride and the acetates examined by g.l.c.: these products corresponded to iditol hexaacetate and 2,5-anhydromannitol tetraacetate in a ratio of about 1:1.

Other Degradation Products

Several minor products that were formed in the deamination reaction emerged from the Sephadex column ahead of disaccharide **2**. Fractions were recovered from eluate volume 80–215 (15 mg), 215–255 (61 mg), and 255–280 ml (81 mg). The latter two fractions gave p.m.r. spectra distinctly different from that of **2**, although each spectrum contained a doublet and triplet (at 4.8 and 3.9 p.p.m., respectively; *J* 5.5 Hz) indicative of the presence of a 2,5-anhydro-D-mannose residue. Presumably, these materials correspond to the higher molecular weight fractions described by Lindahl and Axelsson (9), and have not been further characterized.

[9]The hydrogen-ion concentration of this solution was p*H* 3.5. In other experiments, deaminative degradation was effected with substantially the same results using hydrochloric acid (at this same p*H*) in place of the acetic acid. The latter, however, was more easily removed in the subsequent work-up.

The authors gratefully acknowledge generous support by the National Research Council of Canada and the Pulp and Paper Research Institute of Canada. Heparin was kindly supplied by Dr. E. L. Masson and the Upjohn Company, Don Mills, Ontario.

Rhodium(I) Complexes of 1,2,5-Triphenylphosphole Oxide

D. G. HOLAH, A. N. HUGHES, AND B. C. HUI
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received November 5, 1971

Rhodium trichloride hydrate and rhodium carbonyl chloride react with 1,2,5-triphenylphosphole oxide (TPPO) to produce a rhodium(I) complex $[RhCl(TPPO)]_2$, where the metal is bonded to the ligand through the π system. This complex reacts with $FeCl_3$ to produce $RhCl(TPPO).FeCl_3$ where the iron is bonded through the oxygen of the P=O group. Reactions of $[RhCl(TPPO)]_2$ with other species including nitrogen, phosphorus, and sulfur bases and carbon monoxide are described.

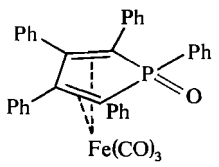
L'hydrate de trichlorure de rhodium et le chlorure de rhodium carbonyle réagissent avec l'oxyde de triphényl-1,2,5 phosphole (OTPP) pour conduire à un complexe de rhodium(I) $[RhCl(OTPP)]_2$, où le métal est lié au ligand par l'intermédiaire du système π. Ce complexe réagit avec $FeCl_3$ et donne $RhCl(OTPP).FeCl_3$ où le fer est lié à l'oxygène du groupe P=O. Les réactions de $[RhCl(OTPP)]_2$ avec d'autres espèces comprenant les bases azotée, phosphorée et sulfurée et l'oxyde de carbone, sont décrites.

Canadian Journal of Chemistry, **50**, 2442 (1972)

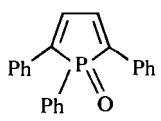
Introduction

In a previous paper (1) we reported some transition metal complexes of 1,2,5-triphenylphosphole (TPP) and its oxide (TPPO), sulfide, and selenide. In all cases, coordination of the ligands to the metal ions (in their normal valence states) occurs through the appropriate donor atom (P, O, S, Se) and not through the π system of the ligand. However, in reactions between metal carbonyls and certain phosphole oxides, π bonded systems have been produced. Thus 1,2,3,4,5-pentaphenylphosphole oxide forms (2) an iron carbonyl complex **1**, while TPPO (**2**) also forms with $Fe(CO)_5$ (3) a π complex similar to **1**. Bonding through the oxygen atom is ruled out because no changes are observed in the P=O stretching frequency (3).

Because of the potential use of metal complexes of cyclic unsaturated phosphines and their derivatives as hydrogenation or hydroformylation catalysts (4), we have extended our previous study to include rhodium, and this paper reports our findings regarding a π-bonded complex obtained from reactions between rhodium(III) chloride and TPPO, together with various reactions of this complex.



1



2 (TPPO)

Results and Discussion

When an ethanolic solution of rhodium trichloride hydrate is heated under reflux with an excess of TPPO, an orange solid of composition RhCl(TPPO) slowly separates. No reaction is observed when either methanol or methylene chloride is used as solvent. The complex can also be obtained by the reaction of TPPO with rhodium carbonyl chloride $Rh_2Cl_2(CO)_4$ in methanol or ethanol solutions.

The complex RhCl(TPPO) is extremely stable, diamagnetic, almost insoluble in ethanol, benzene, and acetonitrile, and slightly soluble in chloroform, methylene chloride, and tetrahydrofuran (THF); it can be recrystallized from THF. The limited solubility of the compound precluded n.m.r. and molecular weight measurements, but infrared data (see Table 1) in the 1200 cm^{-1} region of the spectrum clearly indicate that the TPPO is bonded to the metal by the π system. In TPPO, the P=O stretching frequency occurs as a strong band at 1181 cm^{-1}, and in the complex there are two areas of P=O absorption at 1220 and 1180 cm^{-1}: *i.e.* there is no reduction in the energy of this frequency as occurs with complexes having $>$P=O$\rightarrow$M linkages (1). Other evidence (*vide infra*) suggests that the complex should be formulated as the dimer **3** in which case the complexity of the spectrum in the 1200 cm^{-1} region could be due to the presence of different isomers, the non-equivalence of the ligands because of a puckered bridging structure, or possibly to symmetric and

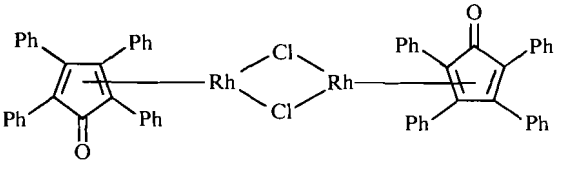
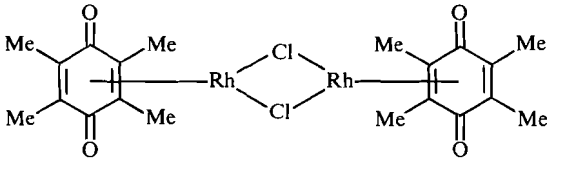
antisymmetric vibrations. Other ligands containing P=O groups but no π-diene system, such as triphenylphosphine oxide and 9-phenyl-9-phosphafluorene-9-oxide (a dibenzophosphole derivative designated here as DBPO) reduce rhodium(III) to rhodium metal, presumably because of the absence of a π-system capable of stabilizing the rhodium(I). The rhodium behaves therefore as a typical class (b) acceptor (5) showing a reluctance to coordinate to the oxygen atom of TPPO, while forming (6) a simple $RhCl_3$.TPP adduct, *via* the phosphorus atom, with 1,2,5-triphenylphosphole.

The infrared spectrum of **3** also shows bands at 295, 240, and 220 cm^{-1} assigned to Rh—Cl stretching frequencies and this too is not inconsistent with a bent bridging structure (7). Similar dimeric π-complexed structures have been postulated for rhodium(I) adducts with other ligands having *cis*-diene π-systems such as 2,3,4,5-tetraphenylcyclopentadienone rhodium(I) chloride (8) **4** and duroquinone rhodium(I) (8, 9) **5**.

The π-complex $[RhCl(TPPO)]_2$ undergoes an extremely wide range of reactions which are summarized in Fig. 1. A particularly interesting reaction occurs with iron(III) chloride, producing a dark-colored solid of composition $RhCl(TPPO).FeCl_3$ from methylene chloride

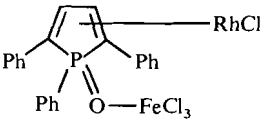


4



5

solutions. The compound is stable in dry air but decomposes when exposed to moisture or alcohol liberating **3**. Its effective magnetic moment (calculation based upon a monomer) is 5.7 B.M. confirming the presence of five unpaired electrons on the iron atom. The infrared spectrum shows a single sharp absorption at 1120 cm^{-1} associated with the P=O group coordinated to the iron *cf.* $FeCl_3.2TPPO$ (1), 1145 cm^{-1}) together with metal–chloride bands at 385 cm^{-1} (Fe—Cl) and at 325, 312 cm^{-1} (Rh—Cl). The most likely structure appears to be as shown in **6**



6

with a chlorine atom from $FeCl_3$ possibly occupying the fourth coordination position about the rhodium. No reaction was observed between **3** and the divalent chlorides of manganese, nickel, and copper, while cobalt(II) partially reacts with **3** to give a crude product having a P=O stretch at 1130 cm^{-1} but which proved impossible to purify. The complex **6** is interesting in that it represents an example of a system in which the ligand is both σ and π bonded to different metal atoms in the same molecule.

$[RhCl(TPPO)]_2$ also reacts with nitrogen donor ligands such as *o*-phenanthroline (*o*-phen) and pyridine (py) in THF and ethanol respectively to give RhCl(TPPO)(*o*-phen) and $RhCl(TPPO)(py)_2$. With phosphorus donor ligands, such as 1,2-bis(diphenylphosphino)ethane(diphos), $RhCl(diphos)_2$ (10) is produced. The reaction of **3** with Ph_3P in 1:1 ratios in MeOH gives $RhCl(TPPO)(Ph_3P)$, but reaction in THF followed by addition of ether produces an impure sample of $RhCl(TPPO)(CO)(Ph_3P)$ in which the CO group has been abstracted from ether (11). The latter compound can also be prepared by the addition of formaldehyde (12) to a solution of $RhCl(TPPO)(Ph_3P)$, prepared *in situ*. With a 6-fold excess of Ph_3P in ethanol solution, $RhCl(Ph_3P)_3$ is produced. The adduct **3** also reacts with dimethyl sulfide (Me_2S) in THF solution to give $RhCl(TPPO)(Me_2S)$, although no reaction was observed with diphenyl sulfide. There is little correlation in Table 1 between the infrared spectra of the above com-

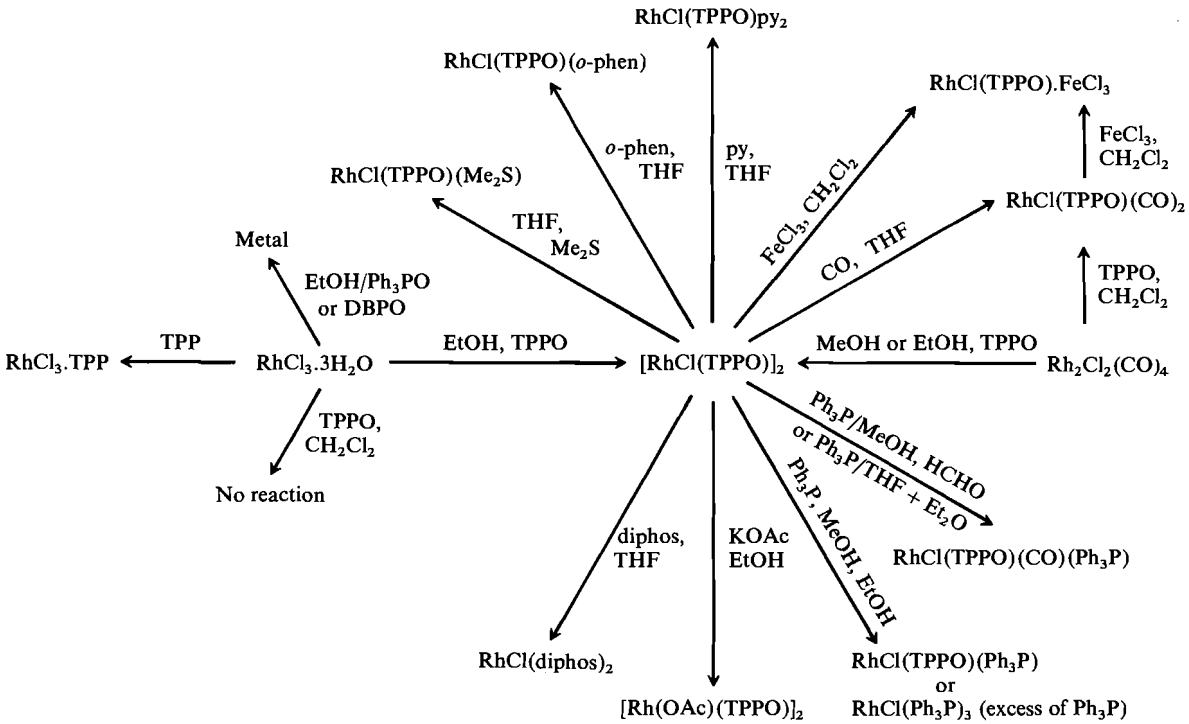

FIG. 1. Summary of some reactions of $[RhCl(TPPO)]_2$.

plexes in either the P=O or the Rh—Cl regions and it is therefore impossible to decide on this basis alone whether the complexes exist as dimers with 6-coordinate rhodium or as monomers with 5-coordinate rhodium (13).

Carbon monoxide reacts with **3** in THF solution under reflux to produce $RhCl(TPPO)(CO)_2$. The same compound is also obtained from the reaction of TPPO with $Rh_2Cl_2(CO)_4$ in methylene chloride at room temperature. The two CO stretching frequencies at 2020 and 2090 cm^{-1} are indicative of *cis* CO groups, possibly with retention of the dimeric structure. The adduct $RhCl(TPPO)(CO)_2$ reacts with $FeCl_3$ in methylene chloride solution to give **6**.

The chloride bridges in **3** can be replaced by acetate groups by treating **3**, in ethanol solution, with an excess of potassium acetate (KOAc). Infrared bands at 1595 and 1410 cm^{-1} in $[Rh(OAc)(TPPO)]_2$ are assigned to the antisymmetric and symmetric stretching frequencies of the $MeCOO^-$ group, indicative of a bridging acetate group (14).

Preliminary results on the catalytic properties of these complexes are encouraging (15).

Thus, in contrast with the other metal systems so far examined (1), the ligand TPPO behaves with rhodium(III) as a reducing diene, forming complexes of comparable stability with other rhodium(I) diene complexes (16).

Experimental

The ligand TPPO was prepared as previously described (17). After isolation, all complexes were dried by pumping under high vacuum (10^{-6} Torr) for prolonged periods at 25–50 °C. Microanalyses and physical measurements were as previously described (1). Chloride was determined potentiometrically (18).

$[RhCl(TPPO)]_2$

$RhCl_3.3H_2O$ (0.52 g) and a 2 molar excess of TPPO (1.4 g) in ethanol (100 ml) were heated under reflux for 12 h producing an orange solid **3** which was recrystallized from THF (yield 70%). An uncharacterized, THF-insoluble, orange phase which could be recrystallized from acetonitrile/ethanol was also obtained.

The same complex was also produced by heating under reflux for 5 h a methanol or ethanol solution of equal molar ratios of $Rh_2Cl_2(CO)_4$ and TPPO (yield 90%).

Subsequent reactions involving the above complex generally involved ~150 mg **3** in 100 ml solvent.

$RhCl(TPPO).FeCl_3$

$FeCl_3.6H_2O$ and either **3** or $RhCl(TPPO)(CO)_2$ in a 1:1 molar ratio were heated under reflux for 12 h in methylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chloride after which the initially orange colored solution had become very dark. The solution was cooled, the excess of iron(III) chloride filtered off and the filtrate reduced in volume by 1/5. The solution was allowed to stand at 0° for 3 days after which a grey solid had precipitated; this was washed with cold methylene chloride and dried under vacuum (yield 80%). ($\chi_M = 14\,800 \times 10^{-6}$ at 27 °C, $\chi_M^{corr} = 14\,500 \times 10^{-6}$).

RhCl(TPPO)(o-phen) and RhCl(diphos)$_2$

o-Phen or diphos and **3** in 3:1 and 5:1 mole ratios respectively, were mixed and warmed in THF solution. Yellow precipitates formed immediately, and were washed with THF (90% yields). RhCl(diphos)$_2$ was recrystallized from methanol/benzene and identified from its analysis, infrared spectrum, and melting point (10).

RhCl(TPPO)(py)$_2$ and RhCl(TPPO)(Me_2S)

An excess of pyridine or dimethyl sulfide was added dropwise to warm solutions of **3** in EtOH and THF, respectively. The solutions were concentrated to small volumes and *n*-hexane and ether added to precipitate the respective products (yields 60%).

RhCl(TPPO)(Ph_3P), RhCl(TPPO)(CO)(Ph_3P), and RhCl(Ph_3P)$_3$

Ph_3P and **3** were mixed (1:1 mole ratios) in MeOH and heated under reflux for 1 h during which time the solution became red. The solution was concentrated to ~1/5 volume and RhCl(TPPO)(Ph_3P) separated as brown crystals (yield 80%).

A mixture of formaldehyde (1 ml, 37%) solution and RhCl(TPPO)(Ph_3P) (0.15 g) in MeOH (40 ml) was heated under reflux for $\frac{1}{2}$ h, the solution was reduced to ~1/5 volume and RhCl(TPPO)(CO)(Ph_3P) separated as a pink solid. Reaction with a 6:1 molar ratio of Ph_3P to **3** in ethanol solution produced RhCl(Ph_3P)$_3$ (19).

RhCl(TPPO)(CO)$_2$

CO was passed into a suspension of **3** (0.2 g) in THF (100 ml) under reflux. The solution became clear red in $\frac{1}{2}$ h and the volume was then reduced by ~1/5. The product was precipitated by addition of ether and was recrystallized from benzene in high yield (80%).

The same product was also obtained by the addition of TPPO to a methylene chloride solution of $Rh_2Cl_2(CO)_4$ (1:1 mole ratios). The solution was stirred for 12 h and *n*-hexane added to precipitate the product (yield 90%).

[Rh(OAc)TPPO]$_2$

A mixture of **3** and potassium acetate (5 fold excess) was heated under reflux for ~12 h in ethanol during which time the solution turned dark brown. The reaction mixture was cooled to room temperature and filtered. The dark colored ethanol filtrate was evaporated to dryness and the product recrystallized twice from EtOH as an ethanol adduct from which the ethanol was removed by pumping under high vacuum at ~50 °C. (Yield 50%).

We acknowledge the assistance of the personnel of the Science Instrumentation laboratory in obtaining micro analytical data.

Complex Fluorides of Tetravalent Cobalt

J. W. QUAIL AND G. A. RIVETT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received December 8, 1971

A new compound, Rb_2CoF_6 has been prepared. Rb_2CoF_6 and Cs_2CoF_6 both have the cubic K_2PtCl_6 structure with $a = 8.460(3)$ Å and $d(Co—F) = 1.65(5)$ Å for Rb_2CoF_6 and $a = 8.914(2)$ Å and $d(Co—F) = 1.73(5)$ Å for Cs_2CoF_6. The temperature dependent magnetic susceptibilities of Rb_2CoF_6 and Cs_2CoF_6 are reported and interpreted. The data are consistent with the Co^{IV} having a $^2T_2$ ground state and both Rb_2CoF_6 and Cs_2CoF_6 exhibiting complex ferromagnetic behavior with a Curie temperature above ambient.

Un nouveau composé, Rb_2CoF_6, a été préparé. Rb_2CoF_6 et Cs_2CoF_6 ont tous deux la structure cubique de K_2PtCl_6 avec $a = 8.460(3)$ Å et $d(Co—F) = 1.65(5)$ Å pour Rb_2CoF_6 et $a = 8.914(2)$ Å et $d(Co—F) = 1.73(5)$ Å pour Cs_2CoF_6. L'influence de la température sur les susceptibilités magnétiques de Rb_2CoF_6 et Cs_2CoF_6 est rapportée et interprétée. Les données concordent avec le fait que Co^{IV} est dans l'état fondamental $^2T_2$ et que Rb_2CoF_6 et Cs_2CoF_6 exhibent tous deux un état ferromagnétique complexe avec une température de Curie au dessus de la température ambiante.

Canadian Journal of Chemistry, **50**, 2447 (1972)

Introduction

The first known complex fluoride of tetravalent cobalt, Cs_2CoF_6, was prepared by Hoppe through treatment of Cs_2CoCl_4 with elemental fluorine at 300 °C in a flow reactor (1). Klemm *et al.* (2) repeated the preparation and studied the magnetic susceptibility of the compound. They found a magnetic moment of 2.53 B.M. at 90 °K and 3.04 B.M. at 294 °K. Cs_2CoF_6 has recently (3) been shown to have a $^2T_2$ ground state. If the spin–orbit coupling constant is taken to be 650 cm^{-1} (4) the magnetic moments would be expected to be 1.9 B.M. at 90 °K and 2.3 B.M. at 300 °K. No satisfactory explanation of this anomalous magnetic behavior has been advanced to date.

We have prepared Cs_2CoF_6 and the previously unknown Rb_2CoF_6. We have measured the reflectance spectra and magnetic susceptibilities of these compounds and have determined their crystal structures from powder diffraction data.

Experimental

Cs_2CoCl_4 and Rb_2CoCl_4 were prepared by the method of Figgis (5). Cs_2CoF_6 and Rb_2CoF_6 were obtained by fluorinating Cs_2CoCl_4 and Rb_2CoCl_4 with elemental fluorine in a flow reactor at a temperature of 250 °C. To improve crystallinity the products were sealed at the reaction temperature under 1 atm of fluorine for periods of time up to 120 h. Both compounds obtained in this way were light gold in color.

Attempts to prepare K_2CoF_6 by similar methods failed.

Analyses were by the tetraphenylboron method for cesium and rubidium (6, 7), the pyridine–thiocyanate method for cobalt (8) and the lead chlorofluoride method for fluorine (8).

Anal. Calcd. for Cs_2CoF_6: Cs, 60.59; Co, 13.43; F, 25.98. Found: Cs, 60.12; Co, 13.61; F, 25.83.

Anal. Calcd. for Rb_2CoF_6: Rb, 49.71; Co, 17.14; F, 33.15. Found: Rb, 49.26; Co, 17.25; F, 33.14.

Powder photographs of the hexafluorocobaltates were taken with FeK_α radiation. Film densities were measured with a Jarrell-Ash Model JA-203 recording microphotometer. 2θ angles were measured on a film illuminator.

The crystal lattice constants and their probable errors were evaluated with the Gvildys least-squares computer program (9). The expected X-ray diffraction pattern was calculated using Smith's computer program (10).

Cs_2CoF_6 f.w. = 438.73

Cubic, $a = 8.914(2)$ Å, $V = 708.3$ Å^3, $\rho_o = 3.93(3)$ g cm^{-3}, $\rho_c = 4.11$ g cm^{-3}, $z = 4$, space group $Fm3m$ (20 °C, FeK_α, $\lambda = 1.9373$ Å).

Rb_2CoF_6 f.w. = 343.87

Cubic, $a = 8.460(3)$ Å, $V = 605.5$ Å^3, $\rho_o = 3.60(3)$ g cm^{-3}, $\rho_c = 3.83$ g cm^{-3}, $z = 4$, space group $Fm3m$ (20 °C, FeK_α, $\lambda = 1.9373$ Å).

The reflectance spectra were obtained on a Cary Model 14 spectrophotometer using a Cary 1411 diffuse reflectance accessory.

Magnetic susceptibilities were measured on a Faraday balance. The design of this instrument was adapted from Hatfield *et al.* (11), while the constant temperature device was as adapted by Clark and O'Brien (12) from Figgis and Nyholm (13). The accuracy of temperature measurements was estimated to be ±0.2 °K. Magnetic susceptibilities were measured as a function of temperature for both compounds and as a function of field for Cs_2CoF_6. The magnetic field was calibrated using $HgCo(SCN)_4$ as a standard (14).

Results and Discussion

Both Cs_2CoF_6 and Rb_2CoF_6 show the K_2PtCl_6 crystal structure, with cobalt ions in

TABLE 1. Interatomic distances for Cs_2CoF_6 and Rb_2CoF_6

Cs_2CoF_6		Rb_2CoF_6	
Bond	Distance (Å)	Bond	Distance (Å)
Cs—F	3.18±0.09	Rb—F	3.02±0.09
Co—F	1.73±0.05	Co—F	1.65±0.05
F—F*	2.46±0.07	F—F*	2.33±0.07
F—F†	3.22±0.09	F—F†	3.06±0.09

*Distance between fluorine atoms in the same octahedron.
†Distance between fluorine atoms in adjacent octahedra.

position *a*, alkali metal ions in position *c*, and fluoride ions in position *e* of the O_h^5 (*Fm3m*) space group. The unit cell is tetramolecular. It is composed of a face centered cube of CoF_6^{2-} octahedra with alkali metal cations in all tetrahedral holes.

The cell edge for the cesium salt was determined to be 8.914(2) Å. Klemm *et al.* (2) reported 8.91 Å. The cell edge for the rubidium salt was found to be 8.460(3) Å. These cell edges are distinctly different from those of Cs_3CoF_6 and Rb_3CoF_6 which are 9.22 and 8.86 Å, respectively. These latter salts differ structurally from the former only in that alkali metal cations are also found in all of the octahedral holes between CoF_6^{2-} ions in the unit cell.

For both Cs_2CoF_6 and Rb_2CoF_6 the only structural parameter not fixed by symmetry is the cobalt–fluorine distance. By comparing observed intensities with intensities calculated for different values of this parameter, a value of 0.195 ± 0.005, in units of cell edges, was determined to give the best fit for both compounds. The observed and calculated spacings and intensities for the X-ray powder diffraction patterns for Cs_2CoF_6 and Rb_2CoF_6 have been placed in the Depository of Unpublished Data.[1] Interatomic distances for both compounds are noted in Table 1.

Attempts to prepare K_2CoF_6 by the fluorination of a molar ratio of $2KCl:CoCl_2.6H_2O$ were unsuccessful. The product was a mixture and only KF could be positively identified.

Cs_2CoF_6 is a stable at 335 °C while Rb_2CoF_6 decomposes at this temperature. Both Cs_2CoF_6 and Rb_2CoF_6 are hygroscopic, reacting with moisture to produce O_2 (identified by mass spectrometry) and O_3 (identified by smell).

[1]Complete set of data may be obtained upon request from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa K1A 0S2, Canada.

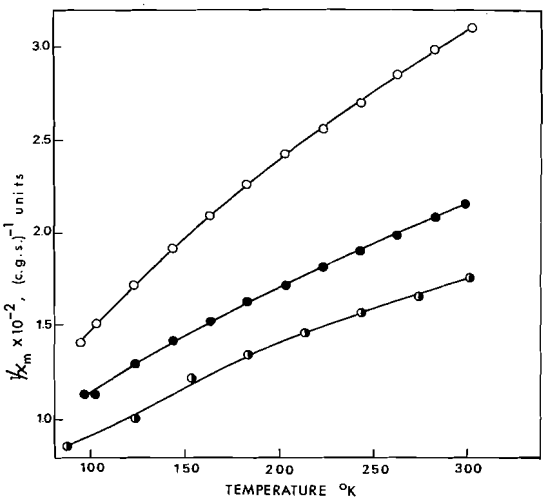

FIG. 1. Variation of the reciprocal of the magnetic susceptibility (corrected for diamagnetism) with temperature: ●, Cs_2CoF_6 for a value of $H \cdot (\delta H/\delta x)$ of 11.26×10^5 G^2 cm^{-1}; ◑, Cs_2CoF_6 for a value of $H \cdot (\delta H/\delta x)$ of 4.37×10^5 G^2 cm^{-1}; ○, Rb_2CoF_6 for a value of $H \cdot (\delta H/\delta x)$ of 11.26×10^5 G^2 cm^{-1}.

The reflectance spectrum for Cs_2CoF_6 has previously been reported by Allen and Warren (3). Our measurements are substantially in agreement with theirs. Our interpretations of the reflectance spectra of Rb_2CoF_6 and Cs_2CoF_6 are both consistent with their interpretation of the reflectance spectrum of Cs_2CoF_6, which indicated that the ground state of Co(IV) in CoF_6^{2-} is the low spin $^2T_2$.

The magnetic susceptibility data have been placed in the Depository of Unpublished Data.[1] A least squares computer program fitted the data for each salt to the Curie–Weiss law. For Cs_2CoF_6 the Weiss constants obtained were -137 and -135 °K for the high and low magnetic field measurements, respectively. The Weiss constant determined for Rb_2CoF_6 was -92 °K. The inverse susceptibilities are plotted *vs.* the absolute temperature in Fig. 1. Magnetic moments were not calculated using the Curie–Weiss law for two reasons. First, the large Weiss constants indicated that application of the Curie–Weiss law might mask temperature dependent behavior of the magnetic properties. Second, the plots of inverse molar susceptibility *vs.* absolute temperature (Fig. 1) are not straight line plots but are curved. Since the value of *H*

*$H\cdot(\delta H/\delta x)$ was 11.26×10^5 G^2 cm^{-1}.
†$H\cdot(\delta H/\delta x)$ was 4.37×10^5 G^2 cm^{-1}.

increases as $H(\delta H/\delta x)$ increases, the susceptibility of Cs_2CoF_6 was shown to be field dependent.

Magnetic moments calculated on the basis of the Curie law are given in Table 2.

The $^2T_2$ ground state would exhibit both spin and orbital contributions to the magnetic moment. The magnitude of the orbital contribution depends on the absolute temperature and the value of the spin–orbit coupling constant, which was taken to be 650 cm^{-1} (4). Magnetic moments including spin–orbit coupling, calculated by the method of Figgis (4) for both the cesium and rubidium hexafluorocobaltate(IV) salts were 2.3 B.M. at 300 °K and 1.9 B.M. at 95 °K. These values are considerably lower than those obtained experimentally. In addition the magnetic susceptibility of Cs_2CoF_6 is field dependent. Thus, contrary to Allen and Warren (3), the anomalously high magnetic moments cannot be attributed to spin–orbit coupling.

Thermal population of the $^6A_1$ state has been suggested (2, 3) as the reason for the anomalously high magnetic moments. The observed magnetic susceptibility in such a case would be a weighted average of the field independent magnetic susceptibilities of the two species and would be essentially field independent. Although the possibility of thermal population of the $^6A_1$ state cannot be eliminated, the observed field dependence of the magnetic susceptibility of Cs_2CoF_6 is not explained by thermal population of the $^6A_1$ state.

On the basis of our data it appears that Cs_2CoF_6 and Rb_2CoF_6 are ferromagnetic and that spin alignment is occurring between neighboring cobalt ions. These neighboring ions are separated by two fluoride ions. The Co—Co distances in Cs_2CoF_6 and Rb_2CoF_6 are less than 6.5 Å. Interaction over 8.5 Å has been reported for the Mn^{2+}—Cl—Cl—Mn^{2+} system (15) and

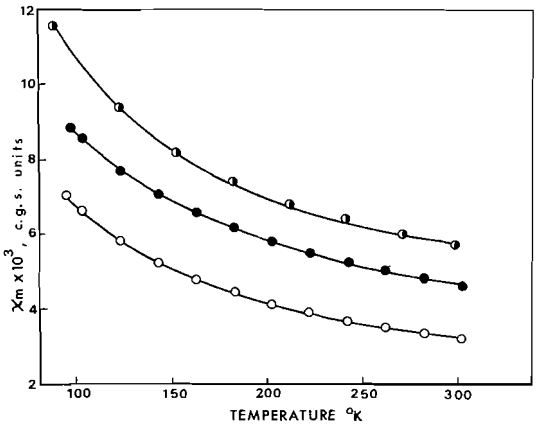

FIG. 2. Variation of magnetic susceptibility (corrected for diamagnetism) with temperature: ●, Cs_2CoF_6 for a value of $H\cdot(\delta H/\delta x)$ of 11.26×10^5 G^2 cm^{-1}; ◑, Cs_2CoF_6 for a value of $H\cdot(\delta H/\delta x)$ of 4.37×10^5 G^2 cm^{-1}; ○, Rb_2CoF_6 for a value of $H\cdot(\delta H/\delta x)$ of 11.26×10^5 G^2 cm^{-1}.

fluorine has been noted as being a powerful agent in providing spin transfer in such superexchange phenomena (16). Ferromagnetism is shown by the susceptibility decrease as magnetic saturation is approached (*i.e.*, as field increases) for Cs_2CoF_6.

Plots of molar susceptibility *vs.* temperature were prepared to determine if the Curie temperature could be ascertained, but no inflection points were noted. The plots of χ_m *vs.* temperature are given in Fig. 2. These plots clearly indicate that Cs_2CoF_6 behaves as a ferromagnetic substance with a Curie temperature above ambient. The Curie temperature for Rb_2CoF_6 is also apparently above ambient.

We wish to thank the National Research Council of Canada for financial support. We also wish to thank Dr. R. G. Cavell of the University of Alberta, Department of Chemistry, for the use of the Faraday balance on which our magnetic susceptibility measurements were made. We wish to express our appreciation to E. D. Day and Dr. R. G. Cavell for guidance and help in the use of the Faraday balance.

Heterogeneous Interactions of Methylamines on porous Adsorbents Part II. Interactions on Silica–Alumina and Silica Gel Surfaces of Di- and Tri-methylamine in the Region of their Boiling Points

W. G. Cook and R. A. Ross
Department of Chemistry, Lakehead University, Thunder Bay 'P', Ontario

Received March 17, 1972

The adsorption of di- and tri-methylamine has been studied at 280 and 276 °K, respectively, on a range of silica gels and on silica–alumina. Adsorption–desorption isotherms and isothermal calorimetric heats of adsorption were measured. Heats of adsorption for di-methylamine on silica gel varied from 29.0 kcal/mol at $\theta = 0.05$ to 12.0 kcal/mol at monolayer completion, while for silica–alumina the heats fell from 31.4 to 9.0 kcal/mol between these same values of surface coverage. For tri-methylamine on silica gel, heats fell from 21.0, $\theta = 0.05$, to 10.3 kcal/mol, $\theta = 1.00$, while heats of 21.4 and 9.9 kcal/mol, respectively, were found at these same surface coverages on silica–alumina. The values of the heats of adsorption are discussed in terms of interactions in the adsorbed layer which are believed to be influenced by the pore sizes in the adsorbent and by the basicity of the amine molecules.

L'absorption de la di- et triméthylamine a été étudiée respectivement à 280 et 276 °K, sur une variété de silicagels et de silica-alumines. Les isothermes d'absorption de désorption et les chaleurs d'absorption isothermales calorimétriques ont été mesurées. Les chaleurs d'absorption de la diméthylamine sur le silicagel, varient de 29.0 kcal/mol pour $\theta = 0.05$ à 12.0 kcal/mol pour la saturation monocouche tandis que pour le silica–alumine, les chaleurs chutent de 31.4 à 9.0 kcal/mol entre les mêmes valeurs pour la surface recouverte. Pour la triméthylamine sur les silicagels, les chaleurs tombent de 21.0 pour $\theta = 0.05$ à 10.3 kcal/mol pour $\theta = 1.00$ tandis qu'on trouve respectivement 21.4 et 9.9 kcal/mol pour le silica–alumine dans les mêmes conditions. Les valeurs des chaleurs d'absorption sont discutées en fonction des interactions dans la couche d'absorption qui, on le pense, dépendent des dimensions des pores de l'absorbant et de la basicité de l'amine.

Canadian Journal of Chemistry, **50**, 2451 (1972)

Introduction

In Part I, studies of the interactions of mono-methylamine vapor, near its boiling point, on silica gel and silica–alumina were reported (1). Adsorption–desorption isotherms and isothermal calorimetric heats of adsorption were measured. The data obtained for the variation of the heat of adsorption of the amine with surface coverage on silica gel were particularly striking in that three heat rises were observed in the regions $\theta = 0.15$, 0.28, and 0.40. These phenomena were related to pore interactions of adsorbing amine molecules with preadsorbed ionic-type species formed by a charge-transfer mechanism in the early stages of adsorption on highly active hydroxyl groups.

The work has now been extended to a study of the adsorption of di- and tri-methylamine on siliceous adsorbents in order to obtain comparative and more extensive information on amine interactions with such surfaces. The possible effects of changes in basicity and molecular size of the amines through the series was of particular interest. Experimental data were obtained mainly by measurement of adsorption–desorption isotherms and isothermal calorimetric heats of adsorption.

Experimental

The sorption balance, calorimeter and techniques of measurement have been described previously (2, 3) and the physical and chemical properties of the adsorbents specified (1, 4). Both di- and tri-methylamine (anhydrous grade, Hopkins and Williams Ltd.) were frozen under vacuum and out-gassed thrice before vacuum distillation over three columns of sodium hydroxide. The middle fraction of the distillate was accepted and again out-gassed three times immediately before use. The final purity was 99.80% v/v for di-methylamine and 99.99% v/v for tri-methylamine, determined by gas-liquid chromatography. The principal impurity detected in di-methylamine was water at 0.11% v/v which concentration is of no significance in these experiments considering the volatility of the component at 280 °K, the large volume of the apparatus (~3 l), the sample mass (~0.75 g) and the pressure range studied.

Results

Di-methylamine and Tri-methylamine Adsorption–Desorption Isotherms and Isosteric Heats of Adsorption

The complete adsorption–desorption iso-

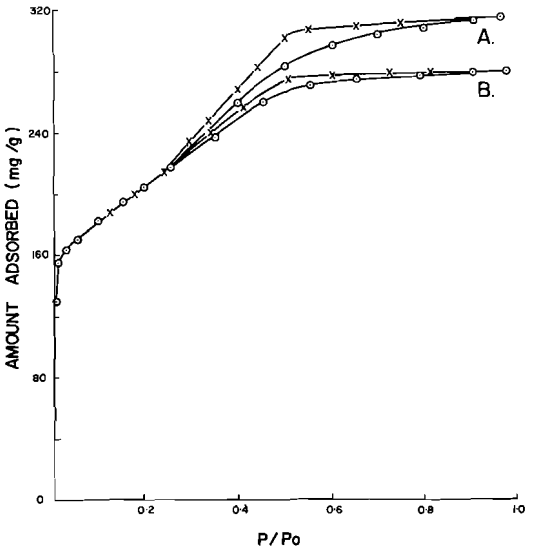

FIG. 1. Adsorption–desorption isotherms for di-methylamine (*A*) at 280 °K and tri-methylamine (*B*) at 276 °K on Davison "923" gel.

therms for di- and tri-methylamine on Davison "923" silica gel at 280 and 276 °K, respectively, are shown in Fig. 1. The gel was activated at 513 °K for 3 h prior to admission of the adsorbates. At low pressures adsorption was very rapid with about 150 to 155 mg/g adsorbed in both cases below $p/p_0 = 0.01$. Equilibrium times were between 5 and 10 min in this pressure region increasing gradually to 60 min above $p/p_0 = 0.90$. At $p/p_0 = 0.97$, 316.0 mg/g dimethylamine was adsorbed and 281.6 mg/g tri-methylamine was adsorbed. Hysteresis was exhibited on desorption of both adsorbates and the monolayer capacities were estimated by the BET method at 164.2 and 165.3 mg/g, respectively, for di- and tri-methylamine. Tests of the reversibility of adsorption (2) were carried out at four points on each isotherm, between 141.0 and 310.0 mg/g adsorbed for di-methylamine and 155.3 and 278.0 mg/g for tri-methylamine. The temperature changes made were between 280 and 360 °K and 276 and 343 °K, respectively, for di- and tri-methylamine. Complete reversibility was found at all points in these temperature cycles.

Isosteric heats of adsorption were determined for the adsorption of both amines on "923" silica gel using the method described previously for mono-methylamine (1). Due to the proximity of the monolayer isotherms, isosteric heats could only be estimated for the surface coverage region $\theta > 0.90$. This fraction of surface coverage lay within the region of proven reversibility. The isosteric heats of adsorption for di-methylamine fell from 10.5 to 9.6 kcal/mol between $\theta = 0.91$ to 1.00 while for tri-methylamine, heats remained constant at 8.6 kcal/mol between these same values of surface coverage.

Adsorption–desorption isotherms for di- and tri-methylamine at 280 and 276 °K, respectively, were also determined on several silica gels with different pore structures and on a silica–alumina, Figs. 2 and 3. Samples were pre-treated in air at 513 °K for 3 h prior to isotherm determination. The principal adsorption characteristics of these adsorbents are summarized in Table 1.

Isothermal Calorimetric Heats of Adsorption

The heat curves for di-methylamine at 280 °K and tri-methylamine at 276 °K were determined on "923" gel and silica–alumina pre-treated as before. Figure 4 shows the di-methylamine heat curves for both adsorbents. The heats for "923" gel decreased from 30.7 kcal/mol at $\theta = 0.04$ to 12.0 kcal/mol at monolayer completion with some intermediate fluctuations. The heat curve for silica-alumina showed no such fluctuations. The main fall in heat, from 33.6 to 14.4 kcal/mol, occurred between $\theta = 0.04$ and 0.20. The heat curves for tri-methylamine adsorption on "923" gel and silica–alumina are shown also in Fig. 4. The general form of the heat curve given by tri-methylamine on "923" gel was similar to that given by di-methylamine. The heat rise of around 1.5 kcal/mol at $\theta = 0.73$ for tri-methylamine on silica–alumina was reproduced with particular care.

Discussion

The very rapid initial adsorption of both amines on Davison "923" silica gel at pressures below those required to complete a monolayer, indicates that adsorption in this region involves forces that are normally associated with chemisorptive interactions. Further, at $p/p_0 = 0.036$ and 0.037 when monolayer completion had been achieved for each of the amines, the gel had adsorbed 164.2 and 165.3 mg/g of di-

and tri-methylamine respectively. Both of these adsorbed amounts were over one-half of the total adsorption capacity of the gel for each amine. Then, for example, after pumping gel samples to 10^{-5} mm at 280 °K for 1 h subsequent to monolayer completion, 103.2 mg/g of di-methylamine remained held by the adsorbent while raising this out-gassing temperature to 360 °K still failed to achieve the removal of all the adsorbate. All of these observations are in accord with previous conclusions made from infrared work (5) on the adsorption of di-methylamine on silica when the adsorption interaction was reported as "unusually strong". While hydrogen bonding was believed to be involved, its nature was discussed then in terms of a "special case" of a charge-transfer interaction.

In general, silanol group protons are believed to be more positive than carbinol protons due to π-bonding between one of the unshared electron pairs on the oxygen of the silanol group and a vacant d orbital of the silicon atom (6). Hence interactions of silanol groups with molecules which have lone pair electrons may be expected to involve stronger forces than those normally associated with the formation of hydrogen bonds between such molecules

and, for example, the carbinol group in alcohols (5). In the particular coverage region $\theta > 0.10$ because of the structural heterogeneity (3) of silica gel the silanol groups involved in the adsorption of the methylamines are those most likely to be capable of taking part in reactions involving proton displacement towards the adsorbed molecule such that charge-transfer adsorbed species could be formed.

The hysteresis loops given by di- and tri-methylamine adsorption of "923" gel are best classified as "type E" (7). The di-methylamine loop is of slightly greater height (8) than for tri-methylamine. This may be explained by the occurrence of a small measure of restricted adsorption of the larger tri-methylamine molecule into the interior pore matrix of the material through narrow pore necks which approach molecular dimensions (4). The molecular cross-sectional area of di-methylamine is slightly smaller at 25 Å^2 than that of tri-methylamine at 30 Å^2. Hence a slightly greater amount of di- than tri-methylamine is likely to be internally adsorbed and subsequently retained longer on

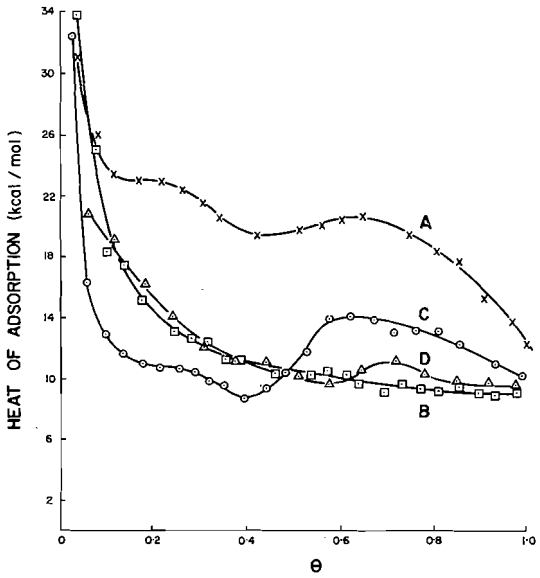

FIG. 4. Variation of isothermal calorimetric heat of adsorption for di-methylamine with surface coverage on (*A*) Davison "923" gel, (*B*) silica–alumina and for tri-methylamine with surface coverage on (*C*) Davison "923" gel, and (*D*) silica–alumina.

desorption. The hysteresis loops determined for di- and tri-methylamine on "high surface area" silica gel and silica–alumina show a similar effect, Figs. 2 and 3.

The adsorption isotherms for di- and tri-methylamine on "microporous" gel, Figs. 2 and 3, are almost Langmuirian in type while both adsorbents exhibit long narrow hysteresis loops. No hysteresis was found for mono-methylamine adsorption on this gel (2) which has a maximum in its pore diameter distribution between 20 and 30 Å. The effects observed for the larger size amines are considered to be brought about possibly by intercalation of small amounts of these adsorbates at high pressures into pores with monomolecular dimensions such that the hysteresis loops open at the saturation pressure in each case and remain open to below $p/p_0 = 0.01$.

The weight of di-methylamine adsorbed at $p/p_0 = 0.95$ on all adsorbents was greater than that of tri-methylamine except for "high surface area" gel. This can be linked simply to the greater total adsorption capacity of the porous materials for the smaller amine molecule. However, the "high surface area" adsorbent gave monolayer coverage values of 172.9 and 212.4 mg/g for di- and tri-methylamine, respectively. This difference of about 40 mg/g was also reflected in the amount adsorbed at $p/p_0 = 0.95$ and can be understood best when the weights adsorbed are expressed in molar quantities. Thus for di- and tri-methylamine the monolayer coverages are equivalent to 4.6 and 4.3 μmol m^{-2}, respectively, so that the difference in weights adsorbed arises from the greater molecular weight of tri-methylamine. Previously it has been shown that mono-methylamine molecules adsorb on a 1:1 basis with hydroxyl groups on silica gel (2) while the mono-methylamine monolayer coverage value of 6.6 μmol m^{-2} for "high surface area" gel indicates an average surface concentration of 4 hydroxyl groups per 100 $Å^2$. Because of steric hindrance effects it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

unlikely that di- or tri-methylamine can achieve a simple 1:1 ratio with silanol groups on adsorption and hence the number of these amine molecules adsorbed per unit area will be less than that for mono-methylamine.

The tendency for di-methylamine to undergo a reaction of the base–acid type with silanol groups would be expected to be greater than that of tri-methylamine since the respective K_b values are 5.12×10^{-4} and 5.27×10^{-5} (9). These values would be expected to reflect on the magnitude of the heats of adsorption. Thus the heat curve for di-methylamine on "923" silica gel lies above that for tri-methylamine, Fig. 4, implying stronger interactions over the whole range of θ.

The initial heats of adsorption for di- and tri-methylamine on "923" gel, Fig. 4, were 29.0 and 21.0 kcal/mol, respectively, at $\theta = 0.05$. These heats are compatible with the strong adsorbate–adsorbent interactions believed to be involved at low surface coverage, $p/p_0 < 0.04$. The heat curves then fall to 19.4 kcal/mol at $\theta = 0.44$ for di-methylamine and to 8.8 kcal/mol at $\theta = 0.40$ for tri-methylamine. In both curves the fall is interrupted by a short plateau, at 23.0 kcal/mol between $\theta = 0.12$ and 0.21 for di-methylamine and at 11.0 kcal/mol between $\theta = 0.20$ and 0.30 for tri-methylamine. These interruptions which occur immediately after the initially high heats, which are believed to be due to the formation of the charged species, could arise from lateral attractive interactions (10–13) between adsorbed molecules. The possibility would be enhanced if the previously adsorbed amine molecules were sited on those hydroxyl groups which exist in dense clusters (14) or are present on the walls of micropores within the gel, particularly at this surface coverage where pores of < 20 Å diameter are filling. The heat curve for di-methylamine rises from 19.4 kcal/mol at $\theta = 0.44$ to 20.6 kcal/mol at $\theta = 0.65$ and for tri-methylamine from 8.8 kcal/mol at $\theta = 0.40$ to 14.1 kcal/mol at $\theta = 0.60$. In this region of monolayer coverage these heat rises are too large to be explained solely by the occurrence of van der Waals' attractive interactions between adsorbed molecules (15), but are likely to include contributions resulting from surface rearrangements of the adsorbed species such as might be caused by interactions among groups of molecules as clusters spread (11) and infringe on their neighbors. The mono-methylamine heat curve on this gel (2) did not show a heat rise in this region. Thus the extent of the interactions seems to be related to the molecular size of the amines and may be a function of an increase in the steric contribution. Towards monolayer coverage the heat curves fall to values of 12.0 and 10.3 kcal/mol for di- and tri-methylamine, respectively, as might be expected since the adsorbed layer covers about 75% of the surface at this point and repulsive interactions between the adsorbed layer and adsorbing molecules should become increasingly significant.

The heat curve for di-methylamine adsorption on silica–alumina, Fig. 4, falls smoothly from 31.4 to 9.0 kcal/mol between $\theta = 0.05$ and 1.00. Its shape is similar to that previously determined for ammonia adsorption on silica–alumina (16). The corresponding heat curve for tri-methylamine falls from 21.4 to 9.0 kcal/mol between these same θ values but exhibits a heat rise of about 1.5 kcal/mol at $\theta = 0.73$. This was the only heat curve determined for silica–alumina with any of the amines to show such a rise and this may be explained in the same fashion as that earlier for silica gel.

The Addition of 4-Chloro- and 2,4-Dinitrobenzenesulfenyl Chloride to *cis*- and *trans*-1-Phenylpropene[1]

GEORGE H. SCHMID, VALERIA M. CSIZMADIA, VINCENT J. NOWLAN, AND DENNIS G. GARRATT

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received January 12, 1972

The *threo-anti*-Markownikoff and *threo*-Markownikoff adducts are the products of addition of 4-chloro- and 2,4-dinitrobenzenesulfenyl chloride to *cis*-1-phenylpropene while only the *erythro* Markownikoff adduct is the product of addition to *trans*-1-phenylpropene. The addition reaction follows second order kinetics, first order in both olefin and arylsulfenyl chloride, with the rate of addition to the *trans*-olefin faster than to the *cis*. These results are consistent with a mechanism involving bridged transition states in both the rate and product determining steps.

Les produits d'addition *thréo-anti*-Markownikoff et *thréo*-Markownikoff sont obtenus par l'action du chlorure de chloro-4 et de dinitro-2,4 benzène sulfènyle sur le phényl-1 propène *cis* tandis que la même réaction sur le composé *trans* conduit uniquement au composé d'addition *erythro*-Markownikoff. La réaction d'addition suit des cinétiques d'ordre deux; l'ordre étant de un à la fois pour l'oléfine et pour le chlorure d'arylsulfènyle, la vitesse de l'addition sur l'oléfine *trans* est plus rapide que pour le *cis*. Ces résultats sont compatibles avec un mécanisme impliquant des états de transition pontés à la fois pour les étapes déterminantes de la cinétique et du produit.

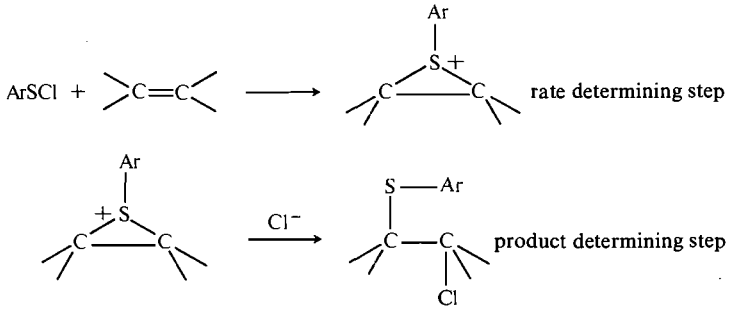
Introduction

The mechanism of the addition of sulfenyl chlorides to olefins has been postulated to involve an episulfonium ion intermediate whose formation is rate determining (Scheme 1) (2, 3). Attack by chloride ion on the intermediate in the product determining step leads to the adduct. In this mechanism both the rate and product determining steps involve bridged transition states. An alternate mechanism which seems to be consistent with the experimental facts involves a bridged transition state in the first step leading to an episulfonium ion intermediate which then opens to a carbonium ion prior to the product determining step (Scheme 2). The *trans* stereospecificity of the reaction is due to the steric hindrance of the adjacent arylthio group which forces the chloride ion to attack from the opposite side. Such a mechanism might be expected in the addition of sulfenyl halides to olefins such as styrene in which the incipient carbonium ion would be of greater stability. We present experimental evidence which has direct bearing upon this question.

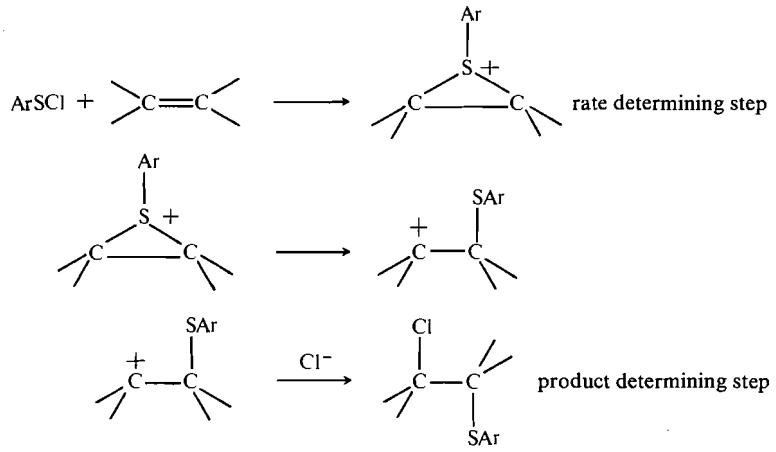
Results

The addition of 4-chlorobenzenesulfenyl chloride to *cis*-1-phenylpropene at 25 °C in



SCHEME 1

[1]Reactions of Sulfenyl Chlorides and their Derivatives. V. For Part IV see ref. 1*a*. For a preliminary communication, see ref. 1*b*.



SCHEME 2

1,1,2,2-tetrachloroethane gives two products, **1** and **2** in 34 and 66% yields respectively, while the addition to *trans*-1-phenylpropene gives initially only compound **3**. After standing for several months at room temperature the formation of a second product, **4**, was observed by n.m.r. No difference in products was observed in the presence of added oxygen or in the presence or absence of light.

It proved possible to obtain a pure sample of each of the four isomers. The pure isomers **2** and **4** were obtained by the slow rearrangement of the corresponding isomers **1** and **3** respectively (4) followed by fractional crystallization. Isomer **1** was obtained by carrying out the addition reaction of the *cis*-olefin in dry formic acid and immediately working-up the product while isomer **3** was the sole product of the addition to the *trans*-olefin at room temperature.

Purification or separation of these adducts by vapor phase chromatography, distillation, or column chromatography proved unsuccessful because of the isomerization tendency of the isomers. The structure and stereochemistry of the four adducts (**1**–**4**) were assigned from their n.m.r. spectra and by chemical means.

The two adducts **1** and **3** were reduced with lithium aluminum hydride to give 1-phenyl-2-(4′-chlorophenylthio)-propane **5** which was prepared by the free radical addition of 4-chlorobenzenethiol to 1-phenylpropene (5) in 1,2-dichloroethane at room temperature (eq. 1).

The two isomers **2** and **4** were treated with boiling potassium *t*-butoxide in *t*-butyl alcohol (6), or 1,5-diazabicyclo[4.3.0]nonene in benzene (7) in the cold (eq. 2). The n.m.r. spectra of the products from both **2** and **4** showed two doublets at δ 2.01 and 1.7 and two quartets at δ 6.38 and 6.16 in CCl_4, indicating that the two olefins, **6** and **7** were formed in the ratio of 4:1. These results are not surprising since elimination of HCl from β-chlorosulfides has been shown to occur non-stereospecifically (8).

On the basis of this evidence compounds **1** and **2** resulting from the addition reaction of the *cis*-olefin were tentatively assigned as the *threo*-Markownikoff (M) and *anti*-Markownikoff (aM) isomers[2] whereas compounds **3** and **4** are

5

[2]The terms *erythro* and *threo* are not strictly applicable where only one group on adjacent carbon atoms are identical. In this work the name *erythro* is given to the isomer formed by the *trans*-addition to the *trans*-olefin. Also in this work, "Markownikoff" orientation indicates adducts with the chlorine on the benzylic (C_α) carbon while "*anti*-Markownikoff" adducts have the chlorine on the β-carbon.

6 **7**

the *erythro*-Markownikoff and *anti*-Markownikoff isomers respectively.

The n.m.r. spectra of the isomers, given in Table 1, are in accord with these structural assignments. From an examination of the n.m.r. spectra of a series of racemic *erythro*- and *threo*-isomers of 1,2-disubstituted 1-arylpropanes, it has been found (9) that the methyl protons of the *erythro*-isomer always appear at lower field than those of the *threo*-isomer. On this basis compounds **1** and **3** resulting from *trans*-Markownikoff addition to *cis*- and *trans*-1-phenylpropene are the *threo*- and *erythro*-isomers respectively whereas compounds **2** and **4** are the *threo*- and *erythro*-isomers respectively of the *anti*-Markownikoff addition. In the two Markownikoff adducts **1** and **3** the peaks of the vicinal hydrogens are well separated and they can easily be identified. The benzylic hydrogen on the carbon bearing the chloride appears at lower field as a doublet, while the hydrogen on the β-carbon, 1 p.p.m. upfield, appears as a "quintet".

The crystalline *anti*-Markownikoff adducts have more complex spectra. The vicinal hydrogens overlap and only the spectrum of the *erythro-anti*-Markownikoff product can be resolved into a doublet and "quintet" by the HA-100 n.m.r. spectrometer. This complexity is due to the fact that in the *anti*-Markownikoff adducts the chlorine is now attached to the carbon bearing the methyl group and consequently both the methyl doublet and hydrogen "quintet" are shifted to lower field, while the benzylic hydrogen doublet shifts to higher field because of the presence of the less electronegative sulfur.

The addition of 2,4-dinitrobenzenesulfenyl chloride to *trans*-1-phenylpropene in 1,2-dichloroethane at 25° yields a single yellow crystalline product **8**. The addition to the *cis*-olefin results in a mixture of two products **9** and **10** in a ratio of 60:40, which can be separated by fractional crystallization. The products are stable and they do not rearrange at room temperature. The stereochemistry of the three adducts **8**, **9**, and **10** was assigned from their n.m.r. spectra, based on the knowledge gained in the addition of 4-chlorobenzenesulfenyl chloride. It is thus concluded that the *trans*-olefin gives only Markownikoff oriented addition product **8** while the *cis*-olefin gives both the Markownikoff **9** and the *anti*-Markownikoff addition product **10**. The n.m.r. spectra of the

pure adducts are very straightforward and easy to analyze. Table 2 summarizes the n.m.r. characteristics of the three adducts.

The rate of the addition of 4-chlorobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene in 1,1,2,2-tetrachloroethane at 25° was followed by the stopped-flow technique using a Durrum–Gibson stopped-flow spectrophotometer. The rate of disappearance of 4-chlorobenzenesulfenyl chloride was followed by measuring the decrease in its absorption at 392.5 nm. The addition was found to exhibit normal second order kinetics, first order in olefin and first order in sulfenyl chloride, to 80% completion of the reaction. The results are given in Tables 3 and 4.

The rate of the addition of 2,4-dinitrobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene in 1,1,2,2-tetrachloroethane at 30° was followed by the usual titration technique (14). Again the reaction was found to exhibit normal second order kinetics; first order in olefin and first order in sulfenyl chloride. The results are given in Table 5.

Discussion

From the results presented in this paper, it is clear that the addition of 4-chloro- and 2,4-dinitrobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene is stereospecifically *trans*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

*M = Markownikoff; aM = *anti*-Markownikoff

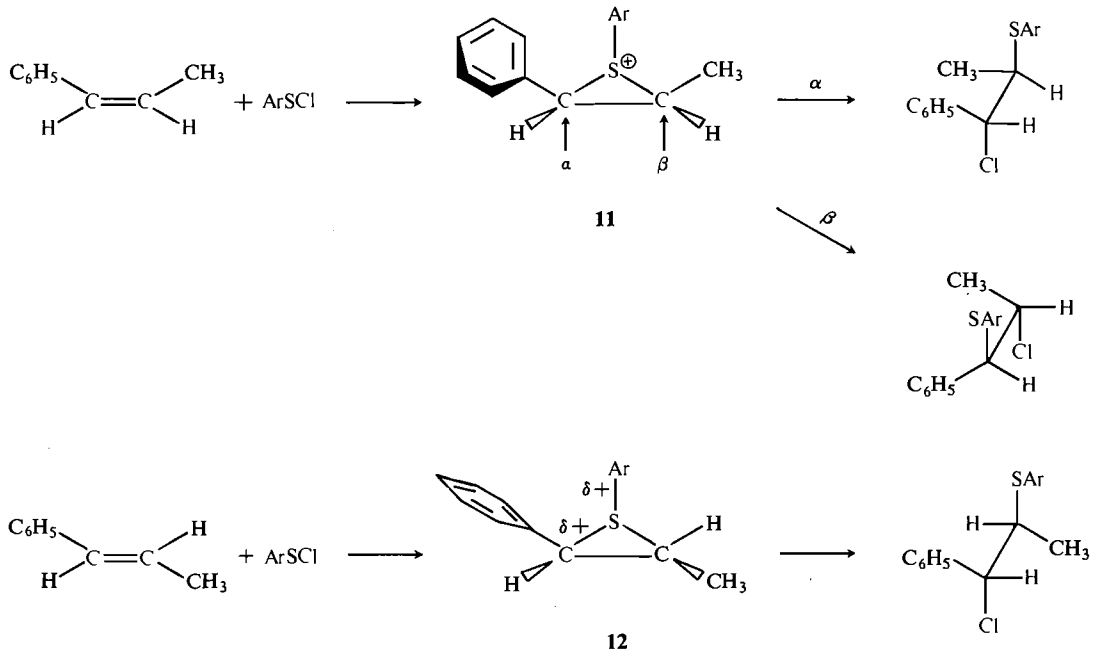
SCHEME 3

within the limits of our n.m.r. analysis. This result as well as the formation of the *anti*-Markownikoff product in the addition to the *cis*-olefin can best be explained by a mechanism involving transition states that resemble the intermediate episulfonium ion in both the rate and product determining steps. This mechanism is illustrated in Scheme 3. These results can be contrasted with other ionic additions to *cis*- and *trans*-1-phenylpropene. The additions of bromine (11) and chlorine (6) are non-stereospecific and are postulated to involve an open benzylic carbonium ion – ion pair mechanism indicating that the benzyl carbonium ion is more stable than the bridged "halonium" ion. Our results show that the episulfonium ion is more stable than a benzylic carbonium ion as an intermediate in the addition of arylsulfenyl chlorides to *cis*- and *trans*-1-phenylpropene. Such a result is consistent with the relative abilities of sulfur, chlorine, and bromine to act as a neighboring group.

It is interesting that the products are analogous for the addition of either 4-chloro or 2,4-dinitrobenzenesulfenyl chloride. Thus the ortho nitro group does not seem to be involved in the product determining step in contrast to its apparent involvement in other reactions (12).

An interesting finding of the work is that the addition to the *trans*-olefin initially yields only the *erythro*-Markownikoff product while the *cis*-isomer yields both the *threo*-Markownikoff and *anti*-Markownikoff products. These results can be accounted for on the basis of the difference in steric crowding in the two intermediate episulfonium ions (see Scheme 4). The steric crowding is more severe in the case of the episulfonium ion intermediate formed by the addition to the *cis* than the *trans* olefin. As a result, these two intermediates have a small but significant difference. The steric crowding in the *cis* episulfonium ion prevents the phenyl ring from assuming a position where it can assist in stabilizing the positive charge on the adjacent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 4

benzylic carbon. As a result, it has a more symmetrical electronic structure **11** than the one from the *trans*-olefin **12**. This difference in the structure of the two episulfonium ions is carried into the product determining transition states. Thus the two transition states for attack of chloride ion at the α and β carbons of **11** are of comparable energy resulting in the formation of products with both Markownikoff and *anti*-Markownikoff orientation. In the case of chloride attack on intermediate **12**, the transition state for attack at the benzylic carbon is of lower energy than the one for attack at the β carbon resulting in the formation of only the Markownikoff product.

If steric crowding in the intermediate episulfonium ions affects the relative energy levels of the product determining transition states, such steric crowding should also be present in the rate determining step leading to these intermediates. The kinetic data are consistent with this idea. Thus in the addition of both 4-chloro- and 2,4-dinitrobenzenesulfenyl chloride to 1-phenylpropene, the *trans*-isomer reacts faster than the *cis* even though the ground state energy of the *trans*-isomer is the lower. This is in contrast to the results of chlorination where *cis*-1-phenylpropene reacts faster than the *trans*-isomer (17). The energy of the rate determining transition state for the addition of arylsulfenyl chloride to the *cis*-isomer must therefore be higher than that of the *trans*-isomer. This is consistent with the formation of a bridged rate determining transition state which shows increased steric interaction over that in the ground state. The difference in the energies between the two transition states must be greater than the 2.8 kcal/mol difference in the starting olefins.

Experimental

All melting points and boiling points are uncorrected. Microanalyses were carried out by A. B. Gygli Microanalysis Laboratory, Toronto.

cis- and trans-1-Phenylpropene

These compounds were obtained commercially from Columbia or Aldrich Chemical Company and their purity was verified by v.p.c. and n.m.r. (b.p. *cis* 160 °C/760 mm, *trans* 98 °C/84 mm).

Bis(2,4-Dinitrophenyl)disulfide

This disulfide was obtained commercially from Eastman Organic Chemicals and used without purification (m.p. 240–280 °C (dec.)).

Bis(4-chlorobenzene)disulfide

In a 2 l Erlenmeyer flask equipped with a magnetic stirrer were placed 1000 ml of distilled water, 86.7 g (0.60 mol) of *p*-chlorothiophenol, and 24.0 g (0.60 mol) of sodium hydroxide. The crystalline *p*-chlorothiophenol dissolved as a fluffy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

precipitate of sodium *p*-chlorothiophenoxide was formed. To the mixture was added 450 ml of 3% hydrogen peroxide at such a rate that the temperature of the reaction mixture did not exceed 30 °C. The light-yellow disulfide precipitated as it was formed. After the addition of the hydrogen peroxide, the reaction mixture was stirred overnight at room temperature. The crystals were filtered and washed with warm tap water and then distilled water until the filtrate was alkaline free. Recrystallization from 95% ethyl alcohol gave a 95% yield of pale-yellow plates, m.p. 73.0–77.5 °C (lit. (2) m.p. 71–71.5 °C).

p-Chlorobenzenesulfenyl Chloride

This compound was prepared by the method of Lawson and Kharasch (13) in 81% yield, b.p. 33–34 °C at 0.22 mm (lit. (13) b.p. 86–90 °C at 5 mm). The purity of the material was determined by the method of Kharasch and Wald (14) and found to be 99.8 ± 1%.

2,4-Dinitrobenzenesulfenyl Chloride

This compound was prepared by the method of Kharasch *et al.* (15) in 85% yield, m.p. 97–98 °C (lit. (15) m.p. 95–95.5 °C).

1,1,2,2-Tetrachloroethane

This compound was purified by washing with concentrated H_2SO_4 until the acid wash remained colorless. The solvent was then washed with water until neutral, dried over K_2CO_3, then distilled from K_2CO_3 through a Vigreux column, b.p. 146° (lit. (16) b.p. 146°).

The Reaction of p-Chlorobenzenesulfenyl Chloride with cis- and trans-1-Phenylpropene

General Procedure

A solution of *p*-chlorobenzenesulfenyl chloride (1.18 g, 0.01 mol) in 20 ml 1,1,2,2-tetrachloroethane (TCE) was added dropwise to a solution containing 1.79 g (0.01 mol) of either *cis*- or *trans*-1-phenylpropene in 20 ml of TCE at room temperature. The reaction mixture was stirred and it immediately became opaque, then a very fine floating precipitate separated. The reaction mixture was allowed to stand in the dark and the precipitate disappeared. After the solvent was evaporated in a stream of nitrogen gas, the residual oil which corresponded to a quantitative yield was analyzed by n.m.r.

I. Preparation of the Pure anti-Markownikoff threo-Adduct (2)

The general procedure given above was followed except that 1,2-dichloroethane was used as solvent and the reaction mixture was refluxed until the n.m.r. spectrum indicated that the equilibrium product ratio was reached. Then the solvent was evaporated and the residual oil was dissolved in *n*-pentane and was allowed to stand in the refrigerator until crystals formed. The solvent was decanted quickly from the crystals, which were then recrystallized repeatedly from *n*-pentane until its n.m.r. indicated that the pure *anti*-Markownikoff product had been obtained. The colorless solid melted at 59–60 °C.

Anal. Calcd. for $C_{15}H_{14}Cl_2S$: C, 60.61; H, 4.74; Cl, 23.85; S, 10.68. Found: C, 60.67; H, 4.68; Cl, 23.88; S, 10.76.

II. Preparation of the Pure threo-Markownikoff Adduct (1)

The *threo*-Markownikoff addition product was prepared by carrying out the addition in dry formic acid, shaking it, then pouring it very quickly into ice water and extracting with chloroform. The chloroform extract was washed with 5% ice-cold $NaHCO_3$ and then dried over $MgSO_4$. After evaporation of the solvent the oily product was found, by n.m.r., to be the Markownikoff product contaminated by disulfide. No purification method was found because of the isomerization tendency of the Markownikoff adduct to the *anti*-Markownikoff adduct. However, the oil was stable for months at −20 °C.

III. Preparation of the Pure erythro-Markownikoff Adduct (3)

The general procedure was followed except that the *trans*-olefin was used and in this case only the *erythro*-Markownikoff addition product was obtained. The n.m.r. was taken directly on the oil because no purification method has been found which did not also cause isomerization.

IV. Preparation of the Pure anti-Markownikoff erythro-Adduct (4)

The *erythro-anti*-Markownikoff product was obtained in low yield by a method analogous to that of the *threo*-isomer except that the *trans*-olefin was used, m.p. 67–68 °C.

Anal. Calcd. for $C_{15}H_{14}Cl_2S$: C, 60.61; H, 4.74; Cl, 23.85; S, 10.78. Found: C, 60.59; H, 4.65; Cl, 23.95; S, 10.69.

Reduction of the threo- and erythro-Markownikoff Addition Products Obtained from cis- and trans-1-Phenylpropene and p-Chlorobenzenesulfenyl Chloride

The addition product, 5.94 g (0.02 mol), was dissolved in 100 ml of dry ether and a solution of $LiAlH_4$ (0.60 g, 0.04 mol) in 100 ml ether was added in small portions while the reaction mixture was stirred with a magnetic stirrer in a three-necked round-bottomed flask, equipped with a reflux condenser. The reaction mixture was left stirring for 1 h at room temperature. The excess $LiAlH_4$ was destroyed by adding ethyl acetate dropwise, followed by aqueous HCl until a clear liquid separated which was decanted. Ether was added, the mixture stirred, and the ether decanted again. The combined ethereal solution was washed three times with aqueous Na_2CO_3 (because of the very strong mercaptan smell it was also washed twice with dilute NaOH solution), then with distilled water, and dried over anhydrous Na_2SO_4. Concentration on the rotary evaporator gave 4.86 g yellowish oil (yield 83%). Chromatography on a 4 × 48 cm silica gel (28–200 mesh) column using petroleum ether, CCl_4, and $CHCl_3$, followed by concentration of appropriate fractions, gave 3.17 (65% yield) of a pale yellow oil.

Anal. Calcd. for $C_{15}H_{15}ClS$: C, 68.55; H, 5.75; Cl, 13.49; S, 12.20. Found: C, 68.26; H, 5.67; Cl, 14.06; S, 12.23.

Addition of p-Chlorothiophenol to trans-1-Phenylpropene

The addition reaction was carried out by the method of Posner (5) affording a yellowish oil which was purified by column chromatography. The purified adduct was characterized by n.m.r. which was identical to that of the $LiAlH_4$ reduced adduct.

Dehydrochlorination of the Markownikoff and anti-Markownikoff Addition Products Obtained from p-Chlorobenzenesulfenyl Chloride and cis- and trans-1-Phenylpropene

Two methods were used: (1) When the reaction was carried out by the technique described by Fahey and Schubert (6) using potassium *t*-butoxide in *t*-butyl alcohol, all four isomers appeared to give the same olefinic product mixture in a ratio of 80:20. (2) When the method of Eiter and Oedinger (7) was used with 1,5-diazabicyclo[4.3.0]nonene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(DBN) in benzene, the Markownikoff adducts did not react, while the *anti*-Markownikoff adducts gave the same olefinic product mixture as with Fahey's method.

The Reaction of 2,4-Dinitrobenzenesulfenyl Chloride with cis- and trans-1-Phenylpropene

In general the addition reaction was carried out as previously described in dry 1,2-dichloroethane and the reaction mixture was analyzed by n.m.r.

I. Preparation of the Pure erythro-Markownikoff Adduct (8)

To a solution of 2.35 g (0.01 mol) of 2,4-dinitrobenzenesulfenyl chloride in 20 ml 1,2-dichloroethane was added slowly 1.18 g (0.01 mol) of *trans*-1-phenylpropene in 20 ml 1,2-dichloroethane while dry nitrogen gas was bubbled through the reaction mixture. The flask was stoppered and was allowed to stand at room temperature in the dark. The end of the reaction was confirmed by the disappearance of the olefinic methyl peak in the n.m.r. spectrum (~16 h).

The solvent from the yellow reaction mixture was removed on a rotary evaporator and the crude oily residue was analyzed by n.m.r. which indicated a single product. The crude product was recrystallized repeatedly from carbon tetrachloride, m.p. 92–93 °C.

Anal. Calcd. for $C_{15}H_{13}O_4N_2ClS$: C, 51.07; H, 3.71; N, 7.94; Cl, 10.05; S, 9.09. Found: C, 51.06; H, 3.70; N, 7.87; Cl, 10.23; S, 9.14.

II. Preparation of the Pure threo-Markownikoff (9) and threo-anti-Markownikoff (10) Adduct

The addition reaction was carried out by the same technique described in section I. The n.m.r. analysis of the crude reaction product indicated the presence of two addition products. The separation of the two adducts by fractional crystallization proved to be the only method.

The crude reaction mixture was dissolved in a mixture of chloroform and *n*-hexane (9:1) at room temperature and the solution was allowed to stand in the refrigerator until a solid separated. After filtration both the solid and the filtrate were analyzed by n.m.r. The solid, which was enriched in the *threo-anti*-Markownikoff adduct, was dissolved again in a mixture of chloroform and *n*-hexane (9:1) and was kept in the refrigerator for crystallization. The filtrate, which was enriched in the *threo*-Markownikoff adduct, was concentrated to a small volume by means of the rotary evaporator and returned to the refrigerator. The process was repeated until n.m.r. analysis indicated that the pure addition products were obtained.

Kinetic Procedure

(a) Stopped-Flow

All kinetic runs were carried out on a Durrum-Gibson stopped-flow spectrophotometer. Prior to any set of kinetic runs the instrument was allowed to stabilize for at least 2 h. A constant temperature bath was maintained at 25.00 ± 0.03°. The instrument was checked out and calibrated prior to each set of runs. Zero and 100% transmittance lines were determined by running pure solvent *vs.* the olefin solution. The time base was accurate to ±1–2% on any time scale. Kinetic runs with each olefin were carried out until a reproducible trace was stored on the oscilloscope. An infinity line was added after an appropriate time lapse. The single run was then recorded on type 107 B & W Polaroid film. Measurements from the film were treated in the usual manner (10).

(b) Titration

An adaptation of the method of Kharasch and Wald (14) was used to follow the decrease in concentration of the sulfenyl chloride. Rate constants were calculated from the slope of the straight line obtained by a least square fit to the second order rate equation.

The Effect of Temperature and Solvent upon the Addition of 4-Chlorobenzenesulfenyl Chloride to *cis*- and *trans*-1-Phenylpropene[1]

GEORGE H. SCHMID AND VALERIA M. CSIZMADIA
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received January 12, 1972

The effect of temperature upon the product composition of the addition of 4-chlorobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene in 1,1,2,2-tetrachloroethane has been studied. The kinetically controlled product in both cases is the adduct with Markownikoff orientation while the thermodynamically controlled product is the one with the *anti*-Markownikoff orientation. Kinetic and thermodynamic parameters have been determined for the isomerization of the *threo* as well as the *erythro* adducts. The effect of different solvents on the product composition has been studied at 25°. The regioselectivity towards Markownikoff product parallels the increasing acidity and anion solvating ability of the solvent.

L'influence de la température sur la composition des produits issus de l'addition du chlorure de chloro-4 benzène sulfènyle au phényl-1 propène *cis* et *trans* dans le tétrachloro-1,1,2,2 éthane, a été étudiée. Le produit cinétique dans les deux cas est le produit d'addition selon l'orientation Markownikoff, tandis que le produit thermodynamique est celui qui suit l'orientation *anti*-Markownikoff. Les paramètres cinétique et thermodynamique ont été déterminés pour l'isomérisation des produits d'addition *thréo* et *erythro*. L'influence des divers solvants sur la composition en produit a été étudiée à 25°. La régiosélectivité pour le produit Markownikoff va de pair avec l'acidité croissante et le pouvoir de solvatation de l'anion du solvant.

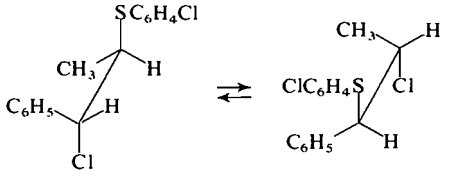
Canadian Journal of Chemistry, **50**, 2465 (1972)

We have found that the relative amounts of Markownikoff and *anti*-Markownikoff adducts formed in the addition of 4-chlorobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene are strongly dependent upon the solvent used and the temperature at which the reaction is carried out.

Table 1 summarizes the results of the influence of the temperature on the initial product distribution in 1,1,2,2-tetrachloroethane. The proportions of Markownikoff and *anti*-Markownikoff adducts were determined by measuring the area of their characteristic methyl peaks (1) in the n.m.r. spectrum of the mixture at room temperature. The values listed are the averages of at least six consecutive integrations.

From the data, it is clear that the addition to *cis*-1-phenylpropene gives an initial product mixture of *threo*-Markownikoff and *anti*-Markownikoff product in a ratio of 79:21 respectively at −42 °C. As the temperature at which the addition is carried out is increased, the percentage of *threo-anti*-Markownikoff adduct also increases. Thus the addition is stereospecific based on analysis of the product by HA-100 n.m.r. spectra. The addition to *trans*-1-phenylpropene gives an initial product of only *erythro*-Markownikoff adduct up to about 50 °C, and even at 146 °C gives mainly *erythro*-Markownikoff adduct (90:10). Again no evidence of *threo*-products could be detected from the HA-100 n.m.r. spectra indicating that the addition is stereospecific.

With time this initial product composition changes until an equilibrium mixture of both the Markownikoff and *anti*-Markownikoff isomers is obtained. These final product distributions are given in Table 1. These results are consistent with isomerization occurring by means of an episulfonium ion (2).



If the final product mixture is allowed to stand for 3 h at 146° leakage between the *threo* and *erythro* adducts occurs. These results are given in Table 2. This leakage can occur by two mechanisms. The first involves the formation of an open carbonium ion which could permit *erythro–threo* isomerization. This means that the activation energy to form the open ion is almost equal to that for formation of the episulfonium

ion. The second possible mechanism is one that involves the reverse of the addition, which regenerates the olefin and 4-chlorobenzenesulfenyl chloride (3). Traces of HCl present in the reaction could cause equilibration of the olefins which would result in the eventual presence of adducts from both the *cis*- and *trans*-olefins, making it appear that the rearrangement is not stereospecific. (see Scheme 1). The latter explanation is preferred since all evidence so far points to a substantial difference in activation energy for formation of the open ion compared to the bridged ion in this system.

The rate of the stereospecific isomerization could be followed by measuring the rate of disappearance of the methyl peak in the n.m.r. spectrum of the Markownikoff adduct as well as the appearance of the methyl peak of the *anti*-Markownikoff adduct. Treating the data obtained from the integrated peak areas according to the method of Frost and Pearson (4) the rate constants given in Table 3 were obtained for this conversion.

	threo-M	aM	*erythro*-M	aM
Parameter	Forward	Reverse	Forward	Reverse
$\Delta H^{\ddagger}$ (kcal/mol)	8.0	8.9	20.4	21.0
$\Delta S^{\ddagger}$ (cal/mol deg)	−53.9	−54.0	−21.1	−19.2
r (correlation coefficient)	0.997	0.997	0.902	0.900

*Measurements were made by n.m.r.-A60.

The thermodynamic parameters for the isomerization were calculated from the data in Table 3 and are listed in Table 4. The quantities ΔH and ΔS are defined as the difference in enthalpy and entropy respectively of the *anti*-Markownikoff and Markownikoff adducts while $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ are defined as the difference in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ respectively for the isomerization of the *anti*-Markownikoff to the Markownikoff adduct.

The data of Table 4 clearly illustrate that the kinetically controlled product is the Markownikoff adduct while the thermodynamically controlled product is the one with the *anti*-Markownikoff orientation.

It should be noted that there is a large difference in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for isomerization of the *threo* and *erythro* adducts. The larger negative value of $\Delta S^{\ddagger}$ for isomerization of the *threo* compared to the *erythro* adduct is consistent with a transition state involving considerable steric crowding with a subsequent loss of entropy. The reason for the large difference in the values of $\Delta H^{\ddagger}$ for the two adducts is not readily apparent. We are hampered by the fact that the relative enthalpies of the *erythro* and *threo* adducts are not known. Further discussion on the mechanistic significance of these quantities must await more experimental data.

The product ratio and stereochemistry of the addition of 4-chlorobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene has been studied in solvents of widely different polarity. The instantaneously formed addition products were analyzed by n.m.r. and are summarized in Table 5.

Both olefins show 100% *trans*-stereospecificity at room temperature independent of solvent polarity. The *trans*-olefin gives 100% solvent

independent regiospecific Markownikoff addition product. The result for the *cis*-isomer is completely different.

The regioselectivity depends on the nature of the solvent, the products ranging from a mixture of Markownikoff and *anti*-Markownikoff adducts to predominantly Markownikoff adduct. The most striking feature is that the regioselectivity toward Markownikoff product parallels the increasing acidity and anion solvating ability of the solvent.

No products due to rotation of an open carbonium ion or solvent incorporation are observed at room temperature in the initial product composition. When the product ratio is plotted as a function of the solvent dielectric constant it fails to give a linear relationship.

During the study of the solvent effect in formic acid, acetic acid, trifluoroacetic acid, and its anhydride, subsequent solvolysis of the adduct occurs.

The result of addition in acetic acid as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

function of time is shown in Table 6. No *anti*-Markownikoff acetate was ever detected. This is strange but the possibility exists that the *anti*-Markownikoff-acetate forms but its n.m.r. peaks are underneath those of an *anti*-Markownikoff-chloride and therefore not easily detectable.

The results clearly establish that isomerization of the Markownikoff and *anti*-Markownikoff adducts occurs more rapidly than does their solvolysis to the acetate. This suggests that isomerization of the adducts occurs by means of tight or intimate ion-pairs (6) while solvolysis occurs by means of solvent separated ion pairs or perhaps even completely dissociated ions. This implies that the stability of the episulfonium ion intermediate is at least as great as that of the norbornyl, cholesteryl, and methoxyphenylethyl ions, all of which show this type of behavior (6).

Experimental

Determination of Product Composition

The reaction was carried out in the dark in a 15 ml, three-neck, round-bottom flask equipped with a thermometer, condenser, drying tube, and magnetic stirrer. The flask was immersed in the appropriate bath containing liquid ammonia, water, or oil. Two stock solutions, one of sulfenyl chloride and the other of the olefin were prepared in 1,1,2,2-tetrachloroethane (TCE) as follows:

(1) 4.476 g 4-chlorobenzenesulfenyl chloride in 25 ml TCE (1 mol/l) and a 4 ml (4.16×10^{-3} mol) portion was used for each experiment.

(2) 2.9540 g *cis*- or *trans*-1-phenylpropene in 10 ml TCE (1 mol/l) and a 1.66 ml (4.16×10^{-3} mol) portion was used in each experiment.

Four milliliters of the sulfenyl chloride solution was placed in the flask which was immersed in the bath at the desired temperature. While this flask was in the constant temperature bath it was cooled about 10° below the temperature of the bath by blowing air on the flask and its immediate surroundings. Then 1.66 ml of the solution, containing the olefin, was introduced dropwise or as quickly as possible into the sulfenyl chloride solution, to keep the temperature as near the bath temperature as possible but at the same time to be able to take out the first sample within the first minute of the reaction. This procedure was adopted because the reaction is extremely rapid and exothermic and an initial increase of 20 °C in the temperature of the reaction is not unusual. At the boiling point of the solvent (TCE) the olefin was added in one portion and the first sample was taken out after 0.4 min. At temperatures below 0 °C the first sample was taken 1–3 min after mixing because the rate of isomerization is slow. The samples were placed in n.m.r. tubes by means of a pipette and were kept in a Dry Ice–acetone bath. All the n.m.r. measurements were then recorded at room temperature with the same setting of the instrument. At least six integrations were made for each measurement.

Isomerization Kinetics

The method used for the determination of the product composition was extended by taking samples at specific time intervals. The method of analysis used was identical.

Hindered Rotation in an *o*-Substituted Acetophenone

VINOD DAVE AND E. W. WARNHOFF

Department of Chemistry, University of Western Ontario, London, Ontario

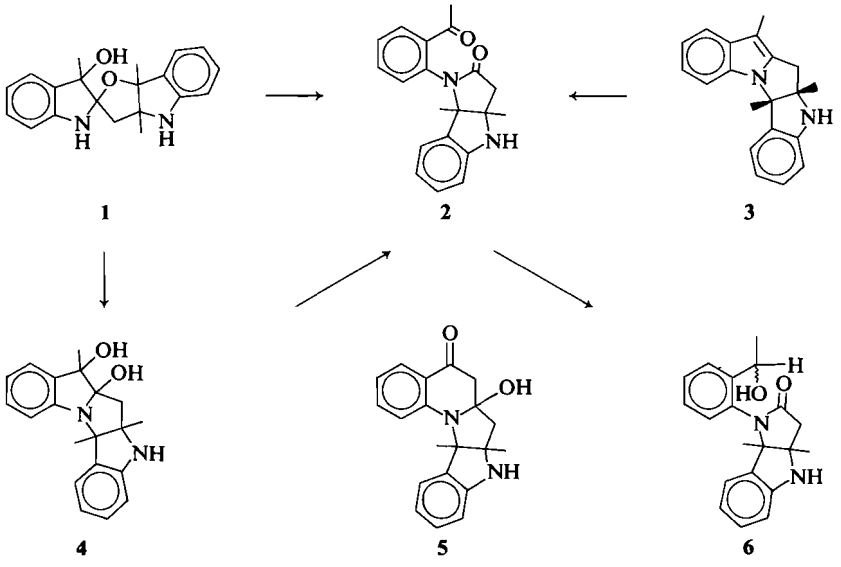
Received February 2, 1972

In the substituted acetophenone **2**, rotation is so restricted that the n.m.r. absorption of the methyl ketone is a broad band in several solvents at room temperature. At 90° this absorption becomes a sharp singlet, while at −60° it separates into two sharp peaks of unequal intensity. At −60° the n.m.r. absorption of the quaternary methyl groups of **2**, **3**, and **11** all show line broadening which is attributed to slowed rotation of these meshed vicinal methyl groups.

Dans l'acétophénone substituée **2**, la rotation est tellement empêchée que l'absorption r.m.n. de la méthylcétone apparaît sous forme d'une bande large dans plusieurs solvants à la température ambiante. A 90° on obtient un singulet fin tandis qu'à −60° ce dernier se sépare en deux pics fins d'intensité inégale. A −60°, l'absorption r.m.n. des groupes méthyles quaternaires de **2**, **3**, et **11**, donne pour tous un signal élargi qui est attribué à une rotation ralentie de ces groupes méthyles vicinaux.

Canadian Journal of Chemistry, **50**, 2470 (1972)

During the study of the rearrangement of the ubiquitous oxidation–dimerization product **1** ($C_{20}H_{22}N_2O_2$) from 2,3-dimethylindole (1), a crystalline compound, $C_{20}H_{20}N_2O_2$, m.p. 217°, was encountered twice. Since its anomalous n.m.r. spectrum, which belied the structure of the compound, has some features of general interest, and since the compound undergoes interesting reactions, further details are reported here and in the accompanying paper. The compound was first obtained on acid treatment of the dimer **1** (Scheme 1), a reaction whose initially obscure nature did not provide enough information for structural assignment, particularly since an oxidation had occurred. The n.m.r. spectrum at both 60 (Fig. 1) and 100 MHz contained eight aromatic protons, one proton exchangeable on addition of D_2O, a two-proton AB pattern, two unsplit quaternary methyl signals, and a broad lump (three protons) centered at δ 2.25. The second appearance of this compound was as the product of the sodium metaperiodate oxidation of both the 1,2-diol **4** and the indole **3** (Scheme 1), reactions which suggested the assignment of structure **2**, at least to the initial product of reaction. Therefore,



SCHEME 1

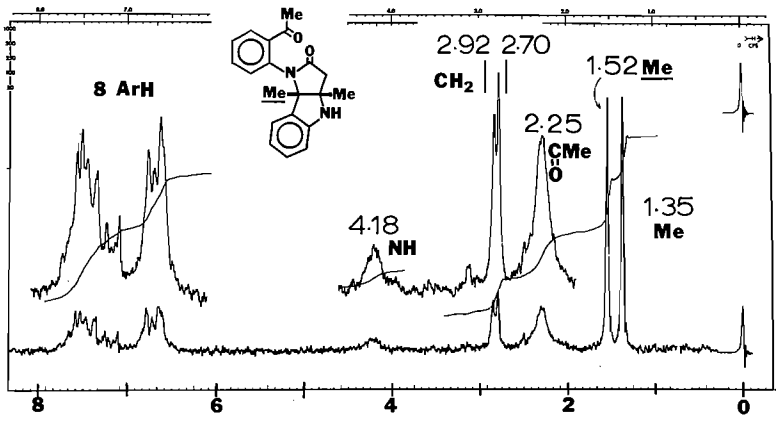

FIG. 1. The n.m.r. spectrum (60 MHz, $CDCl_3$ solution) of keto pyrrolidone **2**.

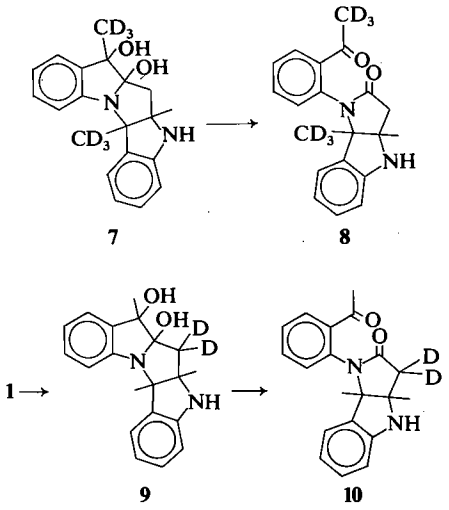
whatever the structure of the compound, the protons responsible for the broad absorption at δ 2.25 were suspected to be derived from the acetyl methyl group of **2**.

The most obvious structural possibility was the aldol **5** in which the hydroxyl and new methylene absorptions might overlap. Or alternatively, **2** and **5** might have been involved in a sufficiently rapid equilibration to result in the observed pattern. Both of these explanations were excluded in several ways. The first possibility requires that there be two exchangeable protons instead of the one found. It also requires that the compound prepared by periodate oxidation of the d_6-diol **7** (Scheme 2) (1) contain at most five D atoms, whereas in fact it still contained six, and also its n.m.r. spectrum was lacking the δ 1.52 methyl peak and the three-proton lump at δ 2.25. The second possibility of a rapid **2**$\rightleftharpoons$**5** equilibration would require that the three protons of the acetyl group of **2** be exchanged rapidly contrary to the retention of all six deuterium atoms during the periodate cleavage of the d_6-diol **7**. The remaining possibility, that the compound was actually **2** in which the environment of the acetyl methyl group was changing relatively slowly, was implicated.



SCHEME 2

Chemical and other spectroscopic evidence was in agreement with this conjecture. In the i.r. spectrum of the compound the NH group was apparent at 3390 cm^{-1} as were the two superimposed carbonyl groups at 1680 cm^{-1} (see footnote 5 in ref. 1*b*). When the oxidative cleavage was carried out on 1,2-diol-d_2 **9**, prepared from dimer **1** in DCl–D_2O–dioxane, the d_2-compound **10** lacked the AB pattern centered at δ 2.81 in its n.m.r. spectrum. An oxime of the methyl ketone of **2** was prepared. Sodium borohydride reduced the methyl ketone to a mixture of stereoisomeric methyl carbinols **6** (Scheme 1) which still retained the 1680 cm^{-1} i.r. absorption of the pyrrolidone carbonyl group.

The n.m.r. spectrum in some other solvents was also consistent with structure **2**. With both pyridine and trifluoroacetic acid solutions the spectrum exhibited *three* singlet methyl peaks. When deuterium oxide was added to the pyridine solution, the low field methyl peak became the familiar broad lump. That no irreversible chem-

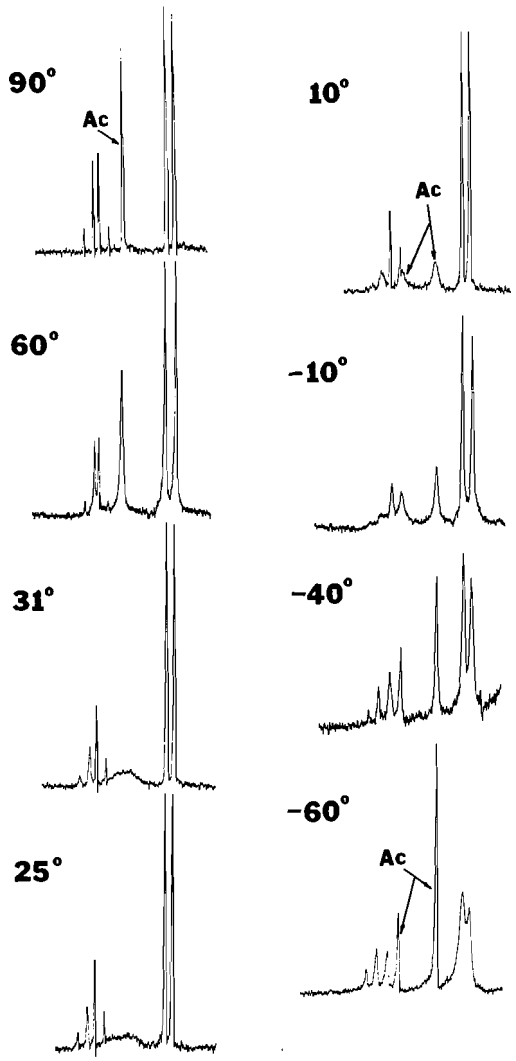

FIG 2. Variable temperature n.m.r. spectra (100 MHz, $CDCl_3$ solution) of the methyl and methylene protons of keto pyrrolidone **2**.

ical change had taken place in trifluoroacetic acid was proved on recovery of the solute; its n.m.r. spectrum in deuteriochloroform was identical with Fig. 1. On the other hand, in perdeuterioacetic acid and acetonitrile there appeared two sharp methyl peaks and the broad lump. To remove any doubts that **2** was indeed the correct structure, a variable temperature study of the spectrum in deuteriochloroform was undertaken.

As the temperature was raised from ambient to 90°, the broad lump gradually became a sharp three-proton singlet at δ 2.28 (Fig. 2) as a well-behaved acetyl methyl group should appear. Moreover, the AB pattern sharpened, and the aromatic pattern was much better resolved (Fig. 3). As the temperature was lowered, the original spectrum reappeared. Below room temperature the broad lump gradually separated at −60° into two sharp signals at δ 2.02 and 2.64 (Fig. 2) in the ratio of 80:20 totalling three protons.[1] These two sharp peaks then corresponded to the acetyl methyl group of two different conformations of the molecule. In deuteriochloroform the coalescence temperature for the acetyl methyl signals of these two conformations is fortuitously near room temperature, more precisely between 25–30° (Fig. 2). Other changes also occurred in the spectrum. At −60° the broad NH signal separated into two sharper peaks at δ 4.20 and 4.48 (Fig. 3) in the ratio of about 20:80, respectively, corresponding to the two "frozen" conformations.

On the other hand, the two narrow high-field peaks from the indolinyl methyl groups gradually *broadened* as the temperature decreased (Fig. 2), and at −60° the broadening was enough to cause the two peaks to merge partially. Although, *a priori*, the line broadening could have been caused by (*a*) lower resolution due to increased viscosity, (*b*) slightly different chemical shifts for the methyl groups in the two conformers, or (*c*) ^{14}N quadrupole-induced relaxation effects, we believe that the line broadening is due instead to slower rotation of these methyl groups, which bear a meshed cogwheel relation to each other, as the temperature is lowered. Decreased resolution is not the explanation since the acetyl methyl signal is relatively narrow ($w_{1/2}$ 3 Hz) at −60°. Moreover, the low temperature spectra of the related compounds **3** and **11** (Fig. 4) show the same broadening of the two indolinyl methyl peaks (albeit to a lesser extent) relative to the indole methyl signal which remains narrow and sharp. If, as seems likely, the broadening has the same cause in all three compounds, then explanation (*b*) is excluded because no conformational changes are possible in the rigid skeletons of **3** and **11**. Explanation (*c*) would have as a corollary that nitrogen quadrupole effects in **11** should be different for the two indolinyl methyl groups. On the contrary, the extent of broad-

[1]After correction is made for the high-field peak of the AB methylene group under the δ 2.64 peak.

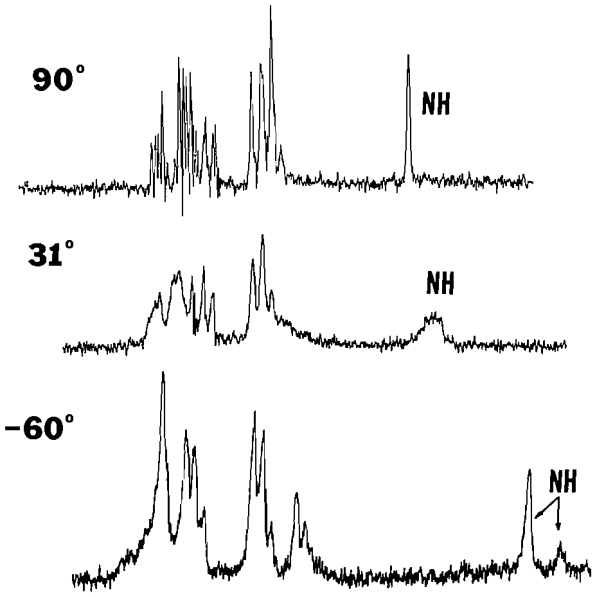

FIG. 3. Variable temperature n.m.r. spectra (100 MHz, $CDCl_3$ solution) of the aromatic and NH protons of keto pyrrolidone **2**.

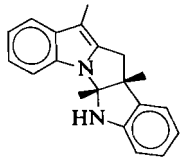
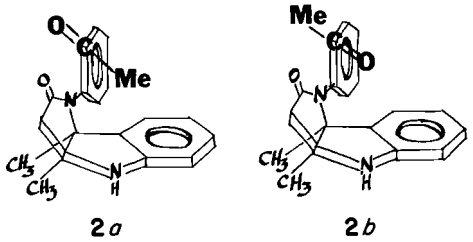
ening of these two methyl groups is the same (Fig. 4). However, this equal extent of broadening of both indolinyl methyl groups in **3** and **11** is required if slower rotation of the meshed groups is responsible for the broadening.



11

From examination of Stuart–Briegleb models the two conformations of **2** which (*a*) maintain the maximum degree of coplanarity of the conjugated ketone and amide with the benzene ring, and yet (*b*) have the fewest repulsive steric interactions are represented in **2***a* and **2***b*. Of the two conformers, **2***a*, in which the oxygen–oxygen dipole repulsion is minimized, should



2*a* **2***b*

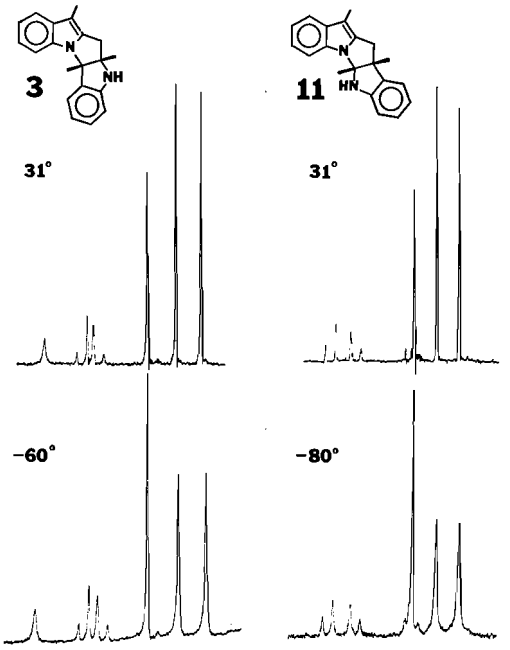


FIG. 4. Variable temperature n.m.r. spectra (100 MHz, CD_2Cl_2 solutions) of the methyl and methylene protons of compounds **3** and **11**.

be of lower energy. Since the acetyl methyl group of **2***a* is directly over the shielding zone of the aromatic ring, this conformer should give rise to the higher field acetyl absorption at δ 2.02

in the $-60°$ spectrum, and this peak is the larger of the two acetyl peaks. The lower field acetyl peak at δ 2.26 is close to the normal range ($\delta \sim$ 2.33–2.59) for acetophenone and *o*-substituted acetophenones (2). Although there are other instances of hindered rotation about the aromatic–carbonyl bond (3), this is the only example of hindered rotation at room temperature involving a methyl ketone group of which we are aware.

Experimental[2]

Preferred Method of Preparation of Keto Pyrrolidone **2**

The following procedure is somewhat more convenient and gives higher yields than the methods reported previously (1*b*).

To a stirred (magnetic bar) solution of dimer **1** (1.00 g, 3.1 mmol) in acetone (25 ml) was added a solution consisting of $NaIO_4$ (1.32 g, 6.2 mmol) in water (10 ml) plus 0.1 *N* HCl (2 ml). Within a few seconds a solid precipitated. After 1 h at room temperature, the reaction mixture was extracted with chloroform. The organic solution was washed with water, dried, and evaporated to leave a brown solid. Two recrystallizations from chloroform – petroleum ether gave 840 mg (84%) of almost colorless **2**,[3] m.p. 212–216°, identical in all respects with previous samples (1*b*).

The oxime was prepared by refluxing a mixture of **2** (150 mg), NaOAc (150 mg), H_2NOH–HCl (150 mg), water (1 ml), and 95% ethanol (8 ml) for 4 days. The crude product was recrystallized from chloroform – petroleum ether to give colorless crystals, m.p. 249–252°; ν_{max} 3570 (NH and OH) and 1670 cm^{-1} (pyrrolidone C=O); *m/e* 335 (molecular ion).

Anal. Calcd. for $C_{20}H_{21}N_3O_2$ (335.4): C, 71.62; H, 6.31. Found: C, 71.77; H, 6.59.

Reduction of Keto Pyrrolidone **2** *with* $NaBH_4$

To a stirred (magnetic bar) solution of **2** (55 mg) in methanol (2 ml) was added at room temperature $NaBH_4$ (100 mg) during 5 min. After 5 h, the reaction mixture was partitioned between water and chloroform. The organic layer was dried and concentrated to leave 57 mg of colorless solid. Two recrystallizations from chloroform – petroleum ether gave 17 mg of crystalline **6**, m.p. 270° (dec., sealed capillary), ν_{max} 3545 (OH), 3390 (NH), and 1675 cm^{-1} (pyrrolidone C=O); *m/e* 322 (molecular ion). The t.l.c. on alumina (PF_{254}, Merck, Germany) in ethyl acetate:methanol (95:5) revealed two spots, one more polar than **2**, and the other less polar than **2**.

Anal. Calcd. for $C_{20}H_{22}N_2O_2$ (322.4): C, 74.51; H, 6.88; N, 8.69. Found: C, 74.70; H, 6.80; N, 8.58.

Preparative thick layer separation of the recrystallization mother liquors on alumina in the same solvent system gave 8 mg of one stereoisomer of **6**, m.p. 248° (dec.); δ 1.16 (Me, d, $J = 6$ Hz), 1.39, (Me, s), 1.67 (Me, s), 2.74 and 2.86 (AB of CH_2, $J = 17$ Hz), 4.08 (1 H, q, $J = 6$ Hz), 4.2 (OH or NH, b.m.), and 6.35–7.60 (8 ArH, m).

Oxidative Cleavage of Diol-d_2 **9**

A solution of dimer **1** (600 mg) in dioxane (5 ml) and 0.1 *N* DCl in D_2O (1.5 ml) was stirred (magnetic bar) at room temperature for 13 h. The solution was diluted with chloroform, washed with water, dried, and concentrated to leave 584 mg of brown oil which was chromatographed on a column of alumina. After elution of rearrangement products (1*b*) by petroleum ether and benzene, deuterated **2** was eluted with chloroform. The pale yellow solid was recrystallized from chloroform – petroleum ether to give 30 mg of **2**-d_2, m.p. 214–216°, whose n.m.r. spectrum was identical with that of **2** except that the AB pattern at δ 2.70 and 2.92 was missing. Deuterium analysis by mass spectroscopy gave 5% d_0, 28% d_1, and 67% d_2.

We would like to thank Mrs. Heather Schroeder for the variable temperature n.m.r. spectra and the National Research Council of Canada for financial support.

A New Indoline Rearrangement

VINOD DAVE, J. B. STOTHERS, AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 2, 1972

The keto pyrrolidone **2** in the presence of acid produces the enamine **3***a* and the rearranged quinolone **4**. Evidence is presented for the mechanism of this new rearrangement, the key step being a remarkably facile opening and reclosure of the indoline ring (**9** ⇌ **10**) which even occurs in acetic acid.

La cétopyrrolidone **2** en présence d'acide donne l'énamine **3***a* et la quinolone réarrangée **4**. Le mécanisme de ce nouveau réarrangement a été mis en évidence; l'étape-clé étant une ouverture et une refermeture, d'une facilité remarquable, du cycle indoline (**9** ⇄ **10**) qui se produit même dans l'acide acétique.

Canadian Journal of Chemistry, **50**, 2475 (1972)

During the structural investigation of the keto pyrrolidone **2** formed from the dimer **1** as described in the preceding paper (1), it was found that in testing the exchangeability of the acetyl protons further reactions occurred. When **2** was refluxed in DOAc-d_3–DCl or HOAc–HCl (or HBr), two isomeric dehydration products were formed. The less polar (t.l.c.) minor compound, m.p. 183°, is assigned the unstrained enamine structure **3***a* formed by addition of the indoline nitrogen atom to the acetyl carbonyl group followed by dehydration. Its n.m.r. spectrum (Fig. 1) contained two 1-H olefinic singlets at δ 5.12 and 5.93 but no NH peak (also absent from its i.r. spectrum). Hydrogenation over palladium (Scheme 1) gave the dihydro deriva-

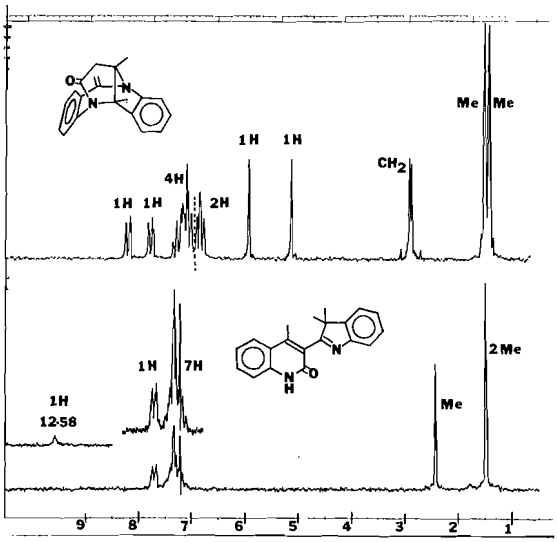

FIG. 1. The n.m.r. spectra (100 MHz, $CDCl_3$ solutions) of the two products, **3***a* and **4**, from treatment of keto pyrrolidone **2** with acid. See Table 1 for peak positions and assignments.

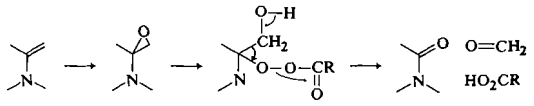

SCHEME 2

tive **3***b* whose n.m.r. spectrum lacked the olefinic protons, but contained a new methyl doublet at δ 1.75 ($J = 7$) and a 1-H quartet from the methine proton at δ 4.67 ($J = 7$). Treatment of the enamine with *m*-chloroperbenzoic acid gave the bis-amide **3***c*, presumably formed by some such process as shown in Scheme 2.

The more polar (t.l.c.) major component, m.p. 321° (dec.), proved to be the product **4** of extensive rearrangement. Its n.m.r. spectrum (Fig. 1) contained a singlet methyl peak, a singlet two-methyl peak and one exchangeable NH peak in addition to the absorption from eight aromatic protons, but lacked the methylene AB pattern of **2**. The u.v. absorption (Fig. 2) contained the readily recognizable 2-quinolone chromophore which must have been formed by condensation of the acetyl carbonyl with the pyrrolidone α-methylene group. Evidence for the presence of the indolenine imine function was provided by several reactions (Scheme 1). Lithium aluminum hydride reduction of **4** furnished the dihydro

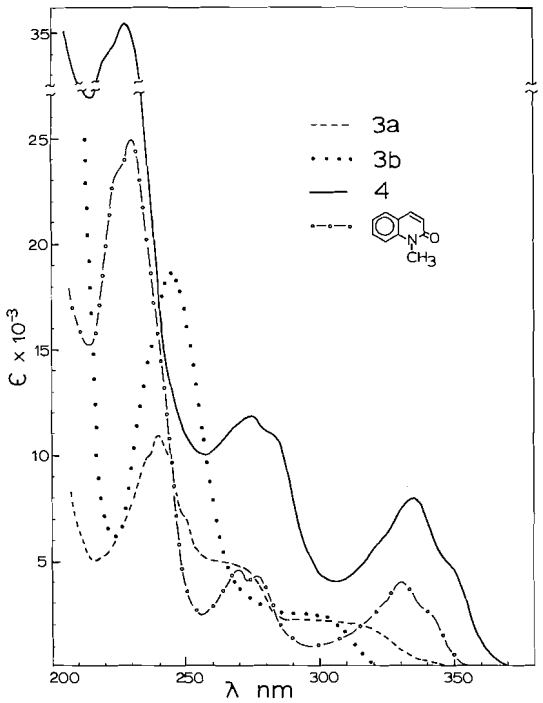

FIG. 2. The u.v. spectra of transformation products of the keto pyrrolidone **2**.

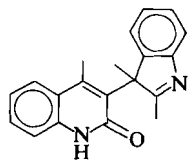
compound **5** whose n.m.r. spectrum contained a singlet at δ 5.58 from the new methine hydrogen. Oxidation of **4** with *m*-chloroperbenzoic acid produced the nitrone **6**[1] from which **4** was regenerated by treatment with phosphorus trichloride (3). Methylation of **4** with methyl iodide gave the *N*,*N*′-dimethyl derivative **7** which was reduced by sodium borohydride to **8** whose n.m.r. spectrum contained a 1-H singlet at δ 4.85 due to the new methine hydrogen in addition to the two *N*-methyl peaks. Of the two possible structures, **4** and **14**, consistent with these structural features, only **4** would have two methyl groups with the same δ 1.47



14

[1]Although an oxazirane may have been the initial oxidation product, the treatment during workup and purification should have caused isomerization to the nitrone (2).

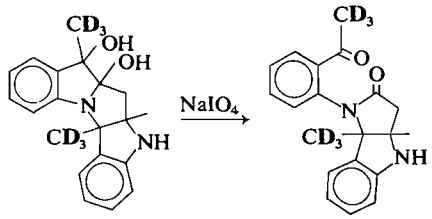
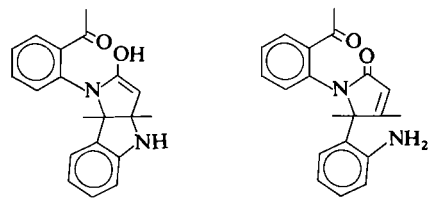
chemical shift, and would give imine reduction products (**5** and **8**) in which the newly introduced methine hydrogen would appear as a singlet in their n.m.r. spectra.

The condensation of the acetyl carbonyl and pyrrolidone α-methylene groups of **2** to form the 2-quinolone is not sterically possible unless the pyrrolidone ring is broken first. Convincing evidence that this ring *is* very easily opened came unexpectedly from the deuterium exchange of **2** in refluxing DOAc-d_3 without any added stronger acid. In this medium ketone **2** is relatively stable, and the rearrangement to **3***a* and **4** was only detectable after several hours. It was found that recovered ketone **2** had incorporated up to 9 D atoms bound to carbon. The n.m.r. spectrum revealed that the acetyl methyl group and one of the other methyl groups were almost completely deuterated.[2] The missing methyl peaks were the same ones missing from the spectrum of the product **16** of periodate cleavage of the d_6-diol **15** prepared earlier (4). Therefore it is the 3-indolinyl methyl group which has been deuterated! Since D-exchange can only occur by cleavage of the benzylic nitrogen bond (**9** → **10**, Scheme 3) and reclosure, this opening and closure of the pyrrolidone ring must be rapid compared to any other reaction of **2**.

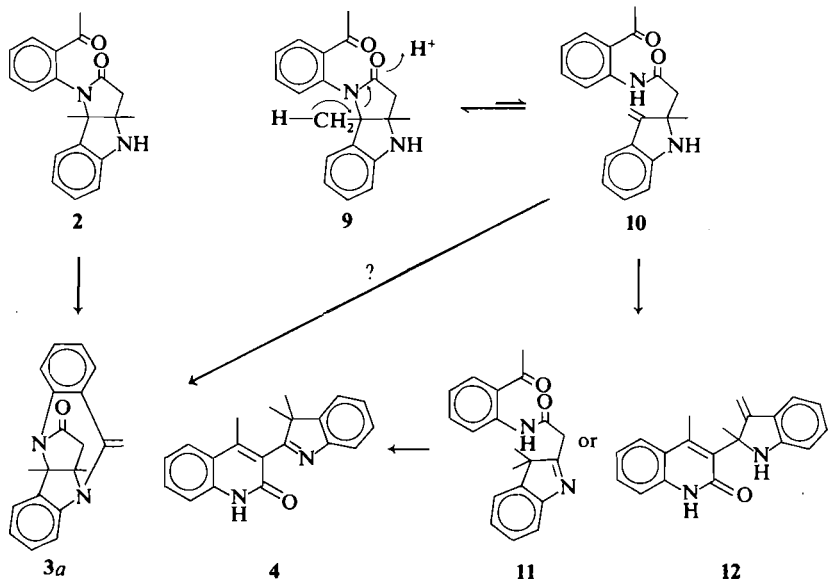


15 **16**

The surprising facility of this cleavage is perhaps best emphasized by the realization that very little (< ~10%) enolization of the pyrrolidone in the direction of its α-methylene group (**2** ⇌ **17**) and no β-elimination of the other nitrogen atom (**2** ⇌ **18**) occurred so far as could be judged by deuterium incorporation into the methylene and third methyl group of **2**. As mentioned previously, some molecules of **2** recovered from DOAc-d_3 did contain up to 9 D

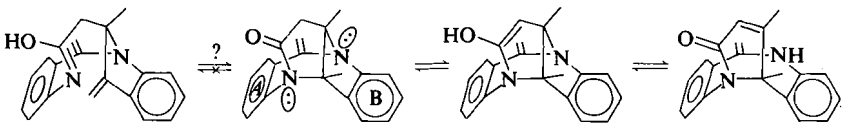


17 **18**



SCHEME 3

[2]The location of the remaining 3 D atoms is discussed further on in this paper.



13 3*a* 19 20

SCHEME 4

atoms (33% d_7, 24–33% d_8, and 3–8% d_9). Although the location of the seventh and eighth D atoms in excess of the six shown in **16** was not definite from proton n.m.r. patterns or integration, comparison of the proton-decoupled ^{13}C-n.m.r. spectra of **2** and deuterated **2** (see Experimental) showed clearly that these two D atoms had entered the indolinyl benzene ring, presumably by electrophilic substitution *o* and *p* to the nitrogen atom. The location of the ninth D atom in one configuration adjacent to the pyrrolidone carbonyl group was suggested by the proton n.m.r. pattern and supported by the deuteration result with **3***a* (see below).

If stronger acid catalyst (*e.g.* HX) is present, reaction rates are increased to the point that formation of **3***a* and rearrangement of the indolinyl portion of **10** by methyl migration (**10** → **4**) become important.[3] When the incorporation of deuterium into these products was examined, the results placed strict limitations on the intermediates and the reversibility of steps as described in the sequel.

It might be expected that formation of the enamine **3***a* from **2**[4] would be reversible and that therefore **3***a* could be rearranged to **4** via hydrolysis to **2**. However, a control reaction with **3***a* gave no indication of the formation of **2** or **4** under the HOAc–H_2O–HCl reaction conditions. This negative result was confirmed in a striking way by comparison of two samples of deuterated **3***a*. The **3***a* isolated from the reaction of **2** with DOAc-d_3 – DCl contained up to 9 D atoms per molecule whose location was apparent from its integrated proton n.m.r. spectrum (see Table 1) and is shown in **3***a*-d_9 (Scheme 5).[5] The **3***a* isolated from the control reaction of undeuterated **3***a* with DOAc-d_3 – DCl contained only up to **4** D atoms per molecule located (see Table 1) as depicted in **3***a*-d_4.[5] Therefore, in **3***a*-d_9 the 2 D atoms in the indoline benzene ring and the 3 D atoms in the second methyl group must have been introduced at some stage before **3***a* was formed. Conversely, once **3***a* is formed it is not re-opened to **2** or else it would have exchanged up to 9 D atoms instead of the 4 D found. The only reactions **3***a* does undergo are reversible enolization of the pyrrolidone carbonyl (**3***a* ⇌ **19**, Scheme 4) and reversible β-elimination of the indolinyl nitrogen atom from the enol (**19** ⇌ **20**) which allows deuteration of the 2-indolinyl methyl group via enolization of **20**.[6] Enolization of **3***a* allows only one methylene hydrogen to be exchanged, presumably because proton loss and capture occur only from the unshielded side of the methylene group.

The unusual behavior of **3***a* is understandable when its geometry is taken into accout (see Scheme 4). It is not a normal *N*-arylenamine because overlap of the nitrogen lone pair orbital with the π-systems of both the double bond and the aromatic ring B is minimal. Hence the failure of the aromatic ring B to undergo *o*- and *p*-electrophilic substitution of deuterium for hydrogen

[3]The probable reason that the alternative migration of the methylene group (→ **14**) is not observed is that its ability to bear positive charge during migration is reduced by the inductive effect of the adjacent carbonyl group. Other apparent examples of inductive inhibition of migration have been encountered in this series of indole derivatives (4).

[4]It is also possible that **3***a* might be formed from **10** via **13** provided that the reaction were irreversible. This path would involve less steric repulsion of the methylene group with the developing sp^3 carbinolamine carbon atom than the direct **2** → **3***a* path, but the probability of having the acetyl group and the indoline nitrogen in close proximity would be lower than for the direct **2** → **3***a* route.

[5]In DOAc-d_3 the enamine β-carbon of **3***a* is undoubtedly deuterated, but the β-deuterium atoms are readily exchanged for hydrogen during workup, and the β-carbon atom is present as $=CH_2$ in the deuterated **3***a* samples. The olefinic proton signals in the n.m.r. spectrum of **3***a* even vanish in a few hours after addition of D_2O to the $CDCl_3$ solution.

[6]The assignments of the two indolinyl methyl peaks in the n.m.r. spectrum of **3***a* are unequivocal. When **2**-d_9 (from **2** + DOAc-d_3) lacking completely the 3-indolinyl methyl peak at δ 1.52 is transformed into **3***a* (in DCl – DOAc-d_3), the n.m.r. peak at δ 1.39 is completely gone; hence this peak must be due to the 3-indolinyl methyl group in **3***a*. Of course, the other methyl peak in the spectrum of **3***a* has also been diminished by exchange involving enolization of **20** after **3***a* has been formed from **2**.

TABLE 1. The n.m.r. data exclusive of most aromatic protons*

Compound	Absorption δ
o-Aminoacetophenone	2.55 (s, Me), 6.30 (s, NH_2)
Keto-pyrrolidone **2**	1.35 (s, Me), 1.52 (s, Me), 2.25 (b.l., COMe), 2.70, and 2.92 (AB of CH_2, $J = 17$), 4.18 (NH), 6.1–7.9 (8 ArH).
" " **2**-d_9	Same as **2** except 1.52 and 2.25 peaks completely missing, ~10% reduction in 2.92 peak, possibly some reduction in intensity of aromatic peaks.
Enamine **3***a*	1.39 (s, 3-indolinyl Me), 1.48 (s, 2-indolinyl Me), 2.77 and 2.97 (AB of CH_2, $J = 16$), 5.12 (s, C=C—H), 5.93 (s, C=C—H), 6.74–6.94 (2 ArH), 6.94–7.42 (4 ArH), 7.79 (dd, 1 ArH, $J = 7, 2$), 8.21 (dd, 1 ArH, $J = 7, 2$).
" **3***a*-d_4	Same as **3***a* except 1.48 peak reduced to ~2H and 2.97 peak missing completely.
" **3***a*-d_9	Same as **3***a* except 1.39 peak missing completely, 1.48 peak reduced to ~2H, 2.97 peak missing, and the 2 ArH absorption at 6.74–6.94 was missing completely.
Dihydroenamine **3***b*	1.35 (s, Me), 1.55 (s, Me), 1.75 (d, Me, $J = 7$), 2.73 and 2.97 (AB of CH_2, $J = 17$), 4.67 (q C*H*—(CH_3), $J = 7$).
Bis-amide **3***c*	1.53 (s, Me), 1.66 (s, Me), 2.83 (s, CH_2).
Quinolone-indolenine **4**	1.47 (s, *gem* di-Me), 2.43 (s, C=C—Me), 7.00–7.58 (7 ArH), 7.71 (b.d., 1 ArH, $J = 7$), and 12.58 (NH).
Quinolone-indolenine **4**-d_5	Same as **4** except that the 2.43 peak was reduced to ~1H intensity, and the 7.00–7.58 ArH absorption was apparently reduced in intensity by ~1H.
" " **4**-d_8	Same as **4** except that the 1.47 peak was reduced to 3H intensity, the 2.43 peak was completely missing, and the 7.00–7.58 ArH absorption was reduced in intensity by ~1H.
Quinolone-indoline **5**	1.14 (s, Me), 1.59 (s, Me), 2.68 (s, C=C—Me), 5.58 (bs, C=C—CH—N), 12.5 (b, NH).
Quinolone-nitrone **6**	1.46 (s, Me), 1.71 (s, Me), 2.41 (s, C=C—Me), 11.7 (b, NH).
N-Methyl methiodide **7**	1.68 (s, Me), 1.80 (s, Me), 2.68 (s, C=C—Me), 3.84 (s, O=C—NMe), 4.20 (s, $^{\oplus}$NMe).
N,*N*′-Dimethyl derivative **8**	1.13 (s, Me), 1.42 (s, Me), 2.59 (s, C=C—Me or NMe), 2.63 (s, N—Me or C=C—Me) 3.59 (O=C—NMe), 4.85 (s, C=C—CH—N).
N-Methylquinolone	3.60 or 3.68 (s, O=C—NMe)†

*Chemical shifts are given in p.p.m. from tetramethylsilane (δ) and coupling constants in Hz for $CDCl_3$ solutions; s = singlet, d = doublet, q = quartet, b = broad, l = lump.
†Values for two different solution concentrations.

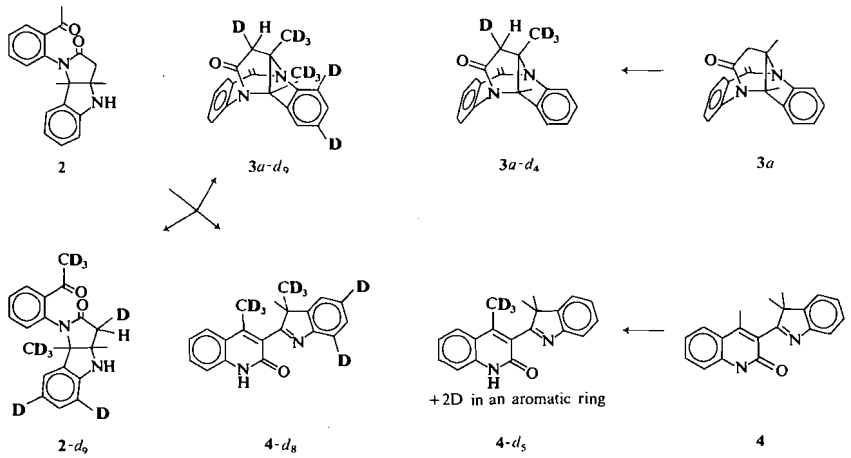
is due to the inability to use the nitrogen lone pair to stabilize the required intermediate cation. Also, the exocyclic methylene group should show diminished enamine character and more normal double bond character in addition reactions. Moreover, addition of water to the double bond in the rigid **3***a* skeleton would cause severe steric interactions with the pyrrolidone α-methylene group.[7] Finally, the failure of **3***a* to exhibit the facile 3-indolinyl–*N*-cleavage (**3***a* → **13**), analogous to the reaction of **2** (**9** → **10**), may be ascribed both to the decreased nitrogen–carbonyl overlap in the pyrrolidone ring of **3***a* and to the geometrical inability of the aromatic ring A to help stabilize the incipient C—N bouble bond in the cleavage to **13**.

As would be expected from the extent of deuterium incorporation into **2**, the quinolone rearrangement product **4** isolated from the DOAc-d_3 – DCl medium or from long reflux in DOAc-d_3 alone contained up to 8 D per molecule as shown in **4**-d_8 (Scheme 5).[8] Most of this deuterium incorporation occurred prior to the

[7]Apparently it is possible to add a proton alone to the exo methylene group and leave the adjacent carbon of the π-system still in its sp^2 state because the olefinic protons can be exchanged on standing with D_2O–$CDCl_3$ in the n.m.r. tube.[5]

[8]The location of the 2 D atoms on the aromatic ring of **4**-d_8 is assumed from their location in **2**-d_9. In one deuteration (**2**-d_9 + DCl + DOAc-d_3) some d_9 molecules were formed, probably by exchange with an aromatic ring of **4**-d_8 after it was formed because under the same conditions **4** incorporated up to 2 D atoms more than the 3 D in the quinolone methyl group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 5

formation of **4** because control experiments showed that only 3 D atoms were introduced into the quinolone methyl group (decrease in δ 2.43 n.m.r. peak) when **4** was refluxed with DOAc-d_3, and a maximum of only 5 D atoms were introduced when **4** was refluxed with DCl–DOAc-d_3. In the two possible routes for the formation of **4**, **10** → **11** → **4** and **10** → **12** → **4**, the steps involving methyl migration, **10** → **11** and **12** → **4**, are not reversible under the conditions used; otherwise the third methyl group of **4** would have been deuterated too. Of the two routes for the formation of **4**, the **10** → **11** → **4** path seems more likely since the methylene group of **11** is then doubly activated for the enolization required for aldol closure of the quinolone ring.

In the previous work on the rearrangement of the dimer **1** (4), the fusion of the indolinyl ring to the adjacent five-membered ring was postulated to remain *cis* (and therefore the *vic* methyl groups also remain *cis*) throughout the rearrangement sequence,[9] although the first step in the rearrangement allows stereochemical change, because the *cis*-fusion of two five-membered rings is more stable than the *trans* in spite of the methyl interactions in the *cis*-arrangement.[10] This assignment is supported by two observations in the present work. First, the opportunity for equilibration provided by the opening and reclosure (**9** ⇌ **10**) of the indoline ring of **2** (formed *after* the first step of the rearrangement sequence[9]) in acetic acid reforms the original stereoisomer, thus proving that the ring fusion in **2** and the rearrangement intermediates[9] really is the more stable *cis* configuration. Second, the intramolecular enamine **3***a* can only form without serious strain if the indolinyl ring fusion is *cis*.

Experimental[11]

Rearrangement of Keto Pyrrolidone **2** *in HOAc–HBr*

A solution of **2** (400 mg), glacial acetic acid (4 ml), and hydrobromic acid (0.4 ml of 47% aqueous acid) was refluxed for 6 h. The cooled solution was diluted with chloroform, washed with aqueous $NaHCO_3$, water, and dried. Evaporation of the organic solution left 371 mg of yellowish solid. Two recrystallizations from chloroform–petroleum ether gave 202 mg (53%) of colorless crystals of the **quinolone-indolenine 4**[12], m.p. 317–321° (dec., sealed capillary); ν_{max} 3400–3100 (broad NH) and 1650 cm^{-1} (quinolone C=O); λ_{max} 228 (35 000), 275 (12 000), and 335 nm (8000); *m/e* 302 (molecular ion).

Anal. Calcd. for $C_{20}H_{18}N_2O$ (302.4): C, 79.44; H, 6.00; N, 9.26. Found: C, 79.36; H, 5.96; N, 8.91.

The mother liquors from the above recrystallizations were chromatographed on two thick plates developed in benzene:ether (50:50). Extraction of a band at R_f 0.87 gave 36 mg of pale yellow liquid ***o*-aminoacetophenone** perhaps containing traces of solvent, ν_{max} 3048 and 3033 (NH), and 1635 cm^{-1} (C=O); λ_{max} 227 (16 000), 258 (5200), and 365 nm (2700); *m/e* 135 molecular ion. Acetylation with acetic

[9]See p. 1923 of ref. 4.

[10]*cis*-Bicyclo[3.3.0]octane is about 6 kcal/mol more stable than the *trans* isomer (5) while the energy difference between *cis*- and *trans*-1,2-dimethyl cyclopentane is only about 1.5 kcal/mol in favor of the *trans* isomer at 130° (6).

[11]For general experimental methods see ref. 7. DOAc-d_3 was supplied by Merck, Sharp, and Dohme of Canada, 99.5 atom % D.

[12]3-(3,3-Dimethyl-3*H*-indol-2-yl)-4-methylcarbostyril.

anhydride–pyridine gave *o*-acetamidoacetophenone (i.r., t.l.c.) (7).

Extraction of a band at R_f 0.69 on the thick plates gave 118 mg (31%) of pale yellow solid. Two recrystallizations from chloroform–petroleum ether gave 73 mg of small colorless granules of **enamine** **3***a*,[13] m.p. 180–183°; ν_{max} 1670 cm^{-1} (pyrrolidone C=O); λ_{max} 240 (11 000), 265 (5000), and 295 nm (2000); *m/e* 302 (molecular ion).

Anal. Calcd. for $C_{20}H_{18}N_2O$ (302.4): C, 79.44; H, 6.00; N, 9.26. Found: C, 79.24; H, 5.86; N, 9.38.

The mother liquors from recrystallization of **3***a* showed the presence of *o*-acetamidoacetophenone (n.m.r., t.l.c.) (7).

The enamine **3***a* was recovered unchanged from attempts to cause it to hydrolyze to **2** and rearrange to **4** under the following conditions: (*a*) refluxing HOAc–H_2O for 60 h, (*b*) refluxing HOAc–HBr–H_2O for 6 h, and (*c*) refluxing CF_3COOH–H_2O for 10 h.

Deuteration of Keto Pyrrolidone **2**

(a) In DOAc-d_3

A solution of **2** (150 mg) in DOAc-d_3 (2 ml) was refluxed for 14 h. The cooled solution was diluted with chloroform, washed with aqueous $NaHCO_3$ and water, and dried. Concentration gave a brown solid which was chromatographed on a thick plate developed in ether. The band at R_f 0.19 gave colorless oily solid **deuterated 2** whose n.m.r. spectrum completely lacked the broad acetyl methyl peak at δ 2.25 and also the methyl peak at δ 1.52. Four recrystallizations from chloroform–petroleum ether gave 26 mg (17%) of colorless crystals of **2**-d_9, m.p. 213–215°. Deuterium analysis by mass spectroscopy gave 0.8% d_3, 3.2% d_4, 11% d_5, 25% d_6, 33% d_7, 24% d_8, and 3.0% d_9.

A second sample of **deuterated 2** prepared in the same way had 1.4% d_4, 6.1% d_5, 18% d_6, 33% d_7, 33% d_8, and 8% d_9. At room temperature after 37 h **2** had 75% d_0, 22% d_1, and only 3% d_2.

(b) In DOAc-d_3

From another experiment similar to (*a*), compounds **4** and **3***a* were also isolated. A solution of **2** (607 mg) in DOAc-d_3 (3 ml) was refluxed for 15 h. The reaction mixture was worked-up as in (*a*) to yield 629 mg of brown solid which was recrystallized twice from chloroform–petroleum ether to give 370 mg of colorless solid. Although t.l.c. on silica gel (chloroform:methanol, 95:5) showed a single spot, t.l.c. on alumina (PF_{254}, Merck, Germany) in the same solvent system revealed two spots, corresponding in R_f to **2** and **4**. The mixture (370 mg) was separated on four thick layer alumina plates developed in chloroform:methanol (97.5:2.5). Extraction of the band at R_f 0.45 gave 193 mg of colorless **deuterated 2**. Two recrystallizations from chloroform–petroleum ether afforded 164 mg of **2**-d_9, m.p. 212–216°, which was used for determination of the ^{13}C-n.m.r. spectrum. D-Analysis by mass spectroscopy gave 3% d_2, 8.5% d_3, 17.5% d_4, 27% d_5, 25% d_6, 13.5% d_7, 5% d_8, and 0.5% d_9.

The proton decoupled ^{13}C-n.m.r. spectrum of **2** (~150 mg/1.5 ml of $CDCl_3$, Varian XL-100-15 with Fourier transform) exhibited the following peaks (p.p.m. from tetramethylsilane): aliphatic carbons: 18.2 (CH_3C=O), 21.5 (CH_3), 28.9 (CH_3), 43.4 (CH_2), 69.2 (**4** °C), 75.5 (**4** °C); aromatic carbons: 109.7, 118.2, 125.0, 128.0, 128.8, 130.1, 131.1, 131.7 (each of the preceding eight carbons bears H), 133.3, 149.7 (neither of preceding two carbons bears H); and 172.6 (amide C=O). Two other peaks from aromatic carbons without hydrogen are hidden behind peaks mentioned above, probably the ones at 128.0 and 128.8 p.p.m. The spectrum was not scanned at low enough field to observe the acetyl carbonyl carbon. The proton-decoupled ^{13}C-n.m.r. spectrum of **2**-d_9 was missing the two highest field aromatic peaks at 109.7 and 118.2 p.p.m. assigned to the *o* and *p* positions of the indoline aromatic ring. Moreover, the two methyl peaks at 18.2 and 28.9 p.p.m. were almost completely obliterated.

Extraction of the alumina band of R_f 0.13 gave 18 mg of colorless crystalline **4**-d_8. D-Analysis by mass spectroscopy gave 1.3% d_0, 3.6% d_1, 7% d_2, 10% d_3, 15% d_4, 19% d_5, 20% d_6, 15% d_7, 7% d_8, and 2% d_9(?).[14]

The n.m.r. spectrum of the mother liquors from the original recrystallization of the 629 mg of crude product showed the presence of the deuterated **enamine** **3***a*. Chromatography on two thick layer plates in benzene:ether (50:50) gave a band at R_f 0.67 from which 43 mg of pale yellow solid was extracted. Two recrystallizations from chloroform–petroleum ether gave 20 mg of **3***a*-d_{10}, m.p. 173–181°. D-Analysis by mass spectroscopy gave 1% d_2, 3% d_3, 6% d_4, 11% d_5, 17% d_6, 23% d_7, 22% d_8, 13% d_9, and 4% d_{10}.[15]

(c) In DOAc-d_3–DCl

A solution of **2** (100 mg) in a mixture of DOAc-d_3 (1.5 ml), $SOCl_2$ (300 mg), and D_2O (0.5 ml) was refluxed for 10 min. The cooled solution was worked up as described in (*a*) to leave 102 mg of almost colorless oily solid. The t.l.c. on alumina (PF_{254}, Merck, Germany) showed the presence of some **3***a* and **4** in the recovered **2**. Thick layer chromatography on two alumina plates developed in chloroform:methanol (95:5) separated the components. Extraction of the band at R_f 0.73 gave 49 mg of colorless **2**. Two recrystallizations from chloroform–petroleum ether gave 38 mg of **2**-d_9, m.p. 212–217°. Deuterium analysis by mass spectroscopy gave 3% d_3, 10% d_4, 25% d_5, 32% d_6, 21% d_7, 7% d_8, and 2% d_9.

Rearrangement of the Keto Pyrrolidone **2** *in DOAc-d_3–DCl*

A solution of **2** (200 mg) in a mixture of DOAc-d_3 (2 ml), $SOCl_2$ (600 mg, 5.1 mmol), and D_2O (1.0 ml, 55 mmol) was refluxed for 6 h. The cooled solution was diluted with chloroform, washed with aqueous $NaHCO_3$, water, and dried. The pale yellow solid left on evaporation of the organic layer was recrystallized from chloroform–petroleum ether to give 42 mg of colorless crystalline **4**-d_8, m.p. 315–320° (dec.). Deuterium analysis by mass spectroscopy gave 2.7% d_3, 8.3% d_4, 25% d_5, 28% d_6, 25% d_7, 9.3% d_8, and 1.8%(?) d_9.[14]

The mother liquors were chromatographed on a thick plate developed with benzene:ether (50:50). Extraction of the band at R_f 0.78 gave 5 mg of ***o*-aminoacetophenone-d_3** ($COCD_3$).

[13]6,13-Dimethyl-12-methylene-6*H*,12*H*-5,6,11-[1]propanyl[3]ylidenedibenzo[*b*,*f*][1,5]diazocin-15-one.

[14]The small amount of d_9 molecules may not be real because D-analysis of **4** by mass spectroscopy must make allowance for the M – 1 peak of **4** which is not completely suppressed even at low ionization voltage.

[15]The tenth D atom in the small amount of d_{10} compound in this one reaction probably replaced the second hydrogen on the pyrrolidone α-methylene group in **3***a*-d_9 either before or after cyclization of **2**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Extraction of the band at R_f 0.66 gave 43 mg (23%) of pale yellow solid. Two recrystallizations from chloroform–methanol–petroleum ether gave 30 mg of pale yellow crystals of **3***a*-d_9, m.p. 175–180°. Deuterium analysis by mass spectroscopy gave 0.4% d_1, 2.8% d_2, 7.5% d_3, 16% d_4, 23% d_5, 25% d_6, 17% d_7, 6.1% d_8, and 1.2% d_9.

Rearrangement of Deuterated Keto Pyrrolidone **2**-d_9 *in DOAc-*d_3*–DCl*

A solution of **2**-d_9 (180 mg from (*b*) above), DOAc-d_3 (2 ml), $SOCl_2$ (300 mg), and D_2O (0.5 ml) was refluxed for 6 h. When the work-up as described for the previous deuterations gave a very low yield, the aqueous washings were further basified with 20% aqueous NaOH and extracted with chloroform. Evaporation of the dried chloroform solution and combination with the original low yield gave 168 mg of brown oily solid. Three recrystallizations from chloroform–petroleum ether gave 50 mg of colorless crystalline quinolone **4**-d_9. D-Analysis by mass spectroscopy gave 4.5% d_5, 14% d_6, 38% d_7, 32% d_8, and 11.5% d_9.[8]

The mother liquors from recrystallization were chromatographed on a thick plate developed in benzene:ether (50:50). Extraction of the band at R_f 0.62 gave 65 mg of pale yellow solid. Recrystallization from chloroform–petroleum ether gave 30 mg of colorless enamine **3***a*-d_{10}. D-Analysis by mass spectroscopy gave 3% d_4, 11.5% d_5, 28% d_6, 33% d_7, 19% d_8, 5% d_9, and 0.5% d_{10}(?).

Reduction of Quinolone-indolenine **4** *with* $LiAlH_4$

To a refluxing solution of **4** (30 mg) in dry tetrahydrofuran (7 ml) was added $LiAlH_4$ (60 mg). After 4 h the cooled reaction mixture was quenched with water and extracted thoroughly with ether. The water-washed and dried ether solution was evaporated, and the residual oily solid was chromatographed on a thick plate developed with chloroform:methanol (97.5:2.5). A band at R_f 0.24 yielded 25 mg (83%) of pale yellow solid. Three recrystallizations from chloroform–petroleum ether gave almost colorless granules of **dihydro compound 5**[16] with a faint yellow tinge, m.p. 240° (dec.); ν_{max} 3400–3000 (broad NH) and 1640 cm^{-1} (quinolone C=O); λ_{max} 230 (28 000), 274 (6300), 283 (6300), and 330 nm (6900); *m/e* 304 (molecular ion).

Anal. Calcd. for $C_{20}H_{20}N_2O$ (304.4): C, 78.92; H, 6.62; N, 9.20. Found: C, 78.04; H, 6.61; N, 8.84.

Methylation and Reduction of Quinolone-indolenine **4**

A solution of **4** (175 mg) and methyl iodide (2.5 ml) in dry tetrahydrofuran–acetonitrile (10 ml of each) was kept in the dark at room temperature for 36 h. The reaction mixture was diluted with chloroform, washed with water, dried, and concentrated to leave an amber oil (**7**), ν_{max} 1765 and 1635 cm^{-1}, λ_{max} 225 (17 000) and 285 nm (4800); λ_{inf} 315 nm (2900). The oil was dissolved in methanol (10 ml) and reduced with $NaBH_4$ (350 mg.) for 3.5 h. The reaction mixture was diluted with chloroform, washed with water, dried, and concentrated to leave 125 mg of pale yellow oil. Chromatography of this oil on a thick plate developed in benzene:ether (37:63) gave a yellow band R_f 0.72 from which was extracted a pale yellow oil which crystallized on trituration with petroleum ether. Three recrystallizations from chloroform–petroleum ether gave pale yellow crystals of **8**,[17] m.p. 138–142°; ν_{max} 1630 cm^{-1} (quinolone C=O); λ_{max} 233 (34 000), 260 (15 000) (broad), and 330 nm^{-1} (7700); *m/e* 332 (molecular ion).

Anal. Calcd. for $C_{22}H_{24}N_2O$ (332.4): C, 79.48; H, 7.28; N, 8.43. Found: C, 79.41; H, 7.43; N, 8.48.

Oxidation of Quinolone-indolenine **4**

To a stirred solution of **4** (50 mg) in chloroform (1 ml) was added a solution of *m*-chloroperbenzoic acid (100 mg) in chloroform (1 ml). After 5 h at room temperature the solution was washed with aqueous Na_2SO_3, aqueous $NaHCO_3$, and water. The dried organic layer was concentrated to leave a white solid. Two recrystallizations from chloroform–methanol–petroleum ether gave 31 mg (59%) of colorless crystalline nitrone **6**,[18] m.p. 337° (dec.) with softening at 275°; ν_{max} 3000–3200 (NH broad) and 1630 cm^{-1} (quinolone C=O); λ_{max} 233 (23 000), 275 (8000), and 340 nm (5000); *m/e* 318 (molecular ion).

Anal. Calcd. for $C_{20}H_{18}N_2O_2$ (318.4): C, 75.45; H, 5.70; N, 8.80. Found: C, 75.52; H, 5.93; N, 8.83.

Reduction of Nitrone **6** *with* PCl_3

The procedure of Sternbach and Reeder (3) was used. A solution of **6** (25 mg) and PCl_3 (0.8 ml) in chloroform (8 ml) was refluxed for 10 h. The cooled solution was washed with aqueous $NaHCO_3$ and water. The dried solution was evaporated to leave 24 mg of colorless solid. Two recrystallizations from chloroform–methanol–petroleum ether gave 14 mg of colorless crystals of **4** identical (m.p., mixed m.p., t.l.c., i.r., n.m.r., mass spectroscopy) with an authentic specimen.

Deuteration of Quinolone-indolenine **4**

(a) In DOAc-d_3

A solution of **4** (25 mg) in DOAc-d_3 (1.0 ml) was refluxed for 9 h. The cooled solution was diluted with chloroform, washed with aqueous $NaHCO_3$ and with water. The dried organic layer was concentrated to leave 25 mg of crystalline solid. Two recrystallizations from chloroform–methanol–petroleum ether gave 12 mg of colorless crystals of **4**-d_3 in whose n.m.r. spectrum the area under the δ 2.43 methyl peak was equivalent to ~1.5H. D-Analysis by mass spectroscopy gave 14% d_0, 42% d_1, 35% d_2, and 9% d_3.

(b) In DOAc-d_3*–DCl*

Part of the partially trideuterated sample from (*a*) (10 mg) was dissolved in DOAc-d_3 (1.0 ml) containing $SOCl_2$ (300 mg) and D_2O (0.5 ml). The mixture was refluxed for 7 h and then worked up as in (*a*). One recrystallization from chloroform–methanol–petroleum ether gave 8 mg of colorless **4**-d_5 whose n.m.r. spectrum did not appear to be different from that in (*a*). D-Analysis by mass spectroscopy gave 8% d_0, 20% d_1, 29% d_2, 22% d_3, 16% d_4, and 5% d_5.

Deuteration of Enamine **3***a in DOAc-*d_3*–DCl*

A solution of **3***a* (30 mg) in a mixture of DOAc-d_3 (1.0 ml), $SOCl_2$ (300 mg), and D_2O (0.5 ml) was refluxed for 6 h. The cooled reaction mixture was partitioned between chloroform and water. The separated organic layer was washed with aqueous $NaHCO_3$ and water, and then dried.

[16]3-(3,3-Dimethyl-2-indolinyl)-4-methylcarbostyril.

[17]1,4-Dimethyl-3-(1,3,3-trimethyl-2-indolinyl)carbostyril.

[18]3-(3,3-Dimethyl-3*H*-indol-2-yl)-4-methylcarbostyril *N*-oxide.

Evaporation of the chloroform left 13 mg of crystalline **3***a*. The original aqueous layer was basified with aqueous NaOH and extracted with chloroform. Evaporation of the dried chloroform layer gave 20 mg more of **3***a*. The combined crude products were recrystallized once from methanol–petroleum ether and once from chloroform–methanol–petroleum ether to afford 20 mg of crystalline **3***a*-d_4, m.p. 175–182°. D-Analysis by mass spectroscopy gave 4% d_0, 21% d_1, 39% d_2, 27% d_3, 8% d_4, and 1% d_5 (?).

Hydrogenation of Enamine 3a

A mixture of **3***a* (60 mg) and 5% Pd/C (45 mg) in methanol (4.5 ml) was stirred under an atmosphere of hydrogen for 1 h. Filtration and evaporation of solvent left a solid which was recrystallized twice from methanol–petroleum ether and twice from chloroform–petroleum ether to give 27 mg (45%) of colorless crystals of **3***b*,[19] m.p. 119–122°. The analytical sample had m.p. 125–129°; ν_{max} 1685 cm^{-1} (pyrrolidone C=O); λ_{max} 243 (18 000) and 295 nm (2400) (broad); *m/e* 304 (molecular ion).

Anal. Calcd. for $C_{20}H_{20}N_2O$ (304.4): C, 78.92; H, 6.62. Found: C, 78.74; H, 6.71.

Peracid Oxidation of Enamine 3a

To a stirred solution of **3***a* (60 mg) in chloroform (2 ml) was added a solution of *m*-chloroperbenzoic acid (120 mg) in chloroform (2 ml). After 12 h at room temperature the solution was washed with aqueous Na_2SO_3, aqueous $NaHCO_3$, and water. The dried organic layer was concentrated to leave an almost colorless solid. Recrystallization from ether–petroleum ether (b.p. 30–60°) gave 21 mg (35%) of colorless crystals of the **bis amide 3***c*,[20] m.p. 147–150°; ν_{max} 1715 and 1650 cm^{-1} (amide C=O); λ_{max} 223 (8000) and 300 nm (3000), λ_{inf} 237 nm (4000); *m/e* 304 (molecular ion).

Anal. Calcd. for $C_{19}H_{16}N_2O_2$ (304.4): C, 74.98; H, 5.30; N, 9.20. Found: C, 75.26; H, 5.59; N, 9.27.

Preparation, Vibrational Spectra, Normal Coordinate Analysis, and Structures of bis-Pyridine and Orthophenanthroline Complexes of Mixed Halogenosilanes

D. H. BOAL AND G. A. OZIN[1]

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario

Received February 17, 1972

The compounds py_2SiCl_3X (where X = H, F, or Br), $py_2SiCl_2X_2$ (where X = F or Br) and the corresponding orthophenanthroline complexes are prepared and the vibrational spectra reported for the first time. Using a combination of the vibrational data and normal coordinate calculations, the stereochemistries may be defined for most of the complexes. Preferences for certain configurations in the series are qualitatively discussed in terms of the spatial requirements of the various atoms and groups within each complex.

Les composés py_2SiCl_3X (où X = H, F, ou Br), $py_2SiCl_2X_2$ (où X = F ou Br) et les complexes orthophénantroline correspondants ont été préparés et leurs spectres de vibration rapportés pour la première fois. En utilisant une combinaison des données vibrationnelles et des calculs des coordonnées normales, les stéréochimies ont pu être établies pour la plupart des complexes. Les préférences pour certaines configurations dans la série sont discutées qualitativement en fonction des exigences spatiales des divers atomes et groupes à l'intérieur de chaque complexe.

Introduction

There has been considerable interest in the molecular structures of pyridine complexes of the main group halides, especially those of group IVB (1). Certain trends have emerged as definitive structural information (usually from X-ray, infrared, and Raman data) has gradually appeared in the literature.

One finds an apparently universal preference for *trans*-octahedral stereochemistries for bis-pyridine adducts; for example, py_2SiF_4 (2), py_2SiCl_4 (3), py_2GeCl_4 (4), py_2SnCl_4, py_2SnBr_4, py_2SeCl_4, and py_2TeCl_4 (5). Monopyridine complexes, such as $pyAlCl_3$ (6) and $pyPCl_5$ (7) have the molecular structures which would be predicted on simple electron-pair repulsion principles. When pyridine is reacted with silicon halides containing SiI bonds, ionization often occurs. This may be illustrated by the unusual compounds py_3SiCl_3I and $py_4SiCl_2I_2$ which were shown to contain the cations $py_3SiCl_3^+$ and $py_4SiCl_2^{2+}$ having C_{2v} and D_{4h} symmetries, respectively (7).

A group of molecules for which stereochemical information has not yet been reported are the bis-pyridine and orthophenanthroline complexes of the mixed halogenosilanes. A combination of infrared and Raman data should allow their stereochemistries to be determined.

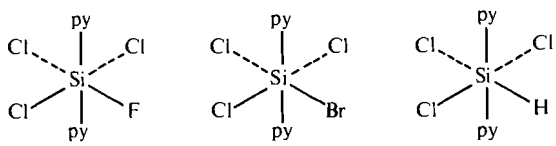
As the parent species py_2SiX_4 (where X = F, Cl, or Br) are all *trans*-octahedral, it is reasonable to assume that all combinations of F, Cl, or Br in the *mixed* halide complexes $py_2SiX_nY_{4-n}$ contain *trans*-pyridine ligands.

Results

bis-Pyridine Complexes

(A) Py_2SiCl_3F, py_2SiCl_3Br, and py_2SiCl_3H

Let us consider the complexes py_2SiCl_3X (where X = F, Br, or H) which would be expected to yield very similar infrared and Raman spectra, characteristic of *trans*-pyridine ligands with a *T*-shaped $SiCl_3$ skeleton (**1** to **3**) shown below



1 (C_{2v}) **2** (C_{2v}) **3** (C_{2v})

The *T*-shaped $SiCl_3$ grouping is easily recognized by a diagnostic pattern of *three* Raman lines, illustrated schematically by their symmetry coordinates below

[1]To whom correspondence should be addressed.

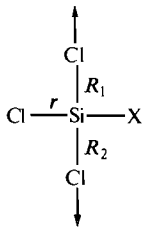
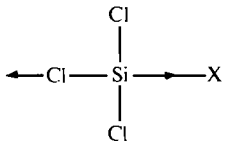
		178w	175vw sh		170vw	
					156vw	
			134s		129s	
		110m	102s	106m		
		73w	65m		83s	

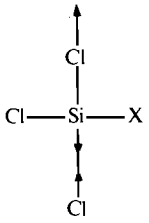
*SiCl and SiBr stretching modes are in italics (see text for description of S_1, S_2, and S_3).



$S_1 = (1/\sqrt{2})(\Delta R_1 + \Delta R_2)$
Very intense (a_1), *low* frequency Raman line (330–270 cm^{-1})



$S_2 = \Delta r$
Medium to low intensity (a_1), *high* frequency Raman line (460–380 cm^{-1})



$S_3 = (1/\sqrt{2})(\Delta R_1 - \Delta R_2)$
Low intensity (b_2), *high* frequency Raman line (500–470 cm^{-1}). Very intense in the infrared

Thus, for py_2SiCl_3X we calculate and observe (Tables 1 and 2) a *low* frequency, totally symmetrical SiCl stretching mode S_1 at 303 cm^{-1} (X = H), 304 cm^{-1} (X = F), and 312 cm^{-1} (X = Br) characteristic of *T*-shaped $SiCl_3$. We note that S_1 occurs at low frequency because the central silicon atom remains stationary during the mode and cannot make a contribution to the respective *G* matrix element. This is not so for S_2 which appears at higher frequencies, 448 cm^{-1} (X = H), 427 cm^{-1} (X = F), and 410 cm^{-1} (X = Br). The monotonical drop to lower frequency parallels the increasing mass of the X grouping *trans* to chlorine and the resulting decreasing motion of the central silicon atom. The asymmetrical SiCl stretching mode S_3 is calculated and observed at *high* frequencies in the range 482–489 cm^{-1} for X = F, Br, and H.

The complex $[py_3SiCl_3^+]I^-$ which has also been assigned a *T*-shaped $SiCl_3$ residue (7) displays a *similar* pattern of $SiCl_3$ stretching modes at 315(S_1), 410(S_2), and 482(S_3) cm^{-1}.

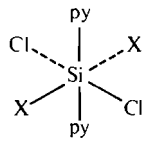
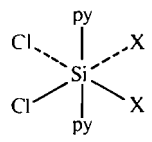
(B) $py_2SiCl_2F_2$ and $py_2SiCl_2Br_2$

Having established the spectral characteristics of a *T*-shaped $SiCl_3$ grouping we will extend the method to the stereochemical problem presented by the complexes $py_2SiCl_2X_2$ (where X = F or Br). Using the *trans*-pyridine approximation described previously, it remains to distinguish the *cis* and *trans* possibilities (**4** and **5**) shown below



4 (D_{2h})



5 (C_{2v})

A mode involving little or no motion of the central silicon atom is expected to appear as an intense, low frequency line in the Raman spectrum of the above complexes.

We find that the Raman spectrum of $py_2SiCl_2Br_2$ displays a *low* frequency SiBr (225 cm^{-1} vs) and *low* frequency SiCl (311 cm^{-1} vs) stretching mode characteristic of *trans*-$SiBr_2$ and *trans*-$SiCl_2$ residues, respectively (configuration **4** and Table 3). Similarly, the Raman spectrum of $py_2SiCl_2F_2$ shows an intense, *low* frequency SiCl stretching mode (279 cm^{-1} vs) which also favors the all *trans* configuration **4**. The characteristic *high* frequency asymmetrical SiCl stretching mode appears in the infrared at 484 and 489 cm^{-1} for $py_2SiCl_2Br_2$ and $py_2SiCl_2F_2$, respectively (Table 3).

Additional evidence for the all *trans* assignment for $py_2SiCl_2F_2$ and $py_2SiCl_2Br_2$ may be obtained by comparing the observed and calculated vibrational spectra for the molecules in the possible conformations, that is, *trans*-pyridines, *trans*-halogens (D_{2h}), and *trans*-pyridines, *cis*-halogens (C_{2v}). The results of the calculations are shown in Table 4 and strongly favor the D_{2h} structure for $py_2SiCl_2X_2$.

Orthophenanthroline Complexes

It is interesting to consider the stereochemical behavior of the silicon–halogen residue when the complexes are locked in a *cis* configuration with the bulky chelate ligand orthophenanthroline. We have prepared the compounds *o*-phen.$SiCl_2X_2$ and *o*-phen.$SiCl_3X$ (where X = F or Br) and will discuss their infrared and Raman spectra using stereochemical arguments similar to those described for the analogous pyridine complexes.

(A) o-phen.$SiCl_2Br_2$ and o-phen.$SiCl_2F_2$

The spectra of the orthophenanthroline adducts are more complex than the corresponding pyridine adducts mainly because of (*a*) the lower molecular symmetries and (*b*) the complexity of the ligand modes in the SiCl stretching region (510–350 cm^{-1}).

Careful examination of the Raman spectrum of *o*-phen.$SiCl_2Br_2$ (Table 5) shows only one intense, *low* frequency SiBr stretching mode

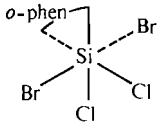
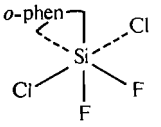
($237\ cm^{-1}$) characteristic of *trans*-bromines shown below (**6**)



6

The absence of a *low* frequency SiCl stretching mode also supports the *cis*-chlorine assignment for o-phen.$SiCl_2Br_2$. Examination of the corresponding data for o-phen.$SiCl_2F_2$ (Table 5) shows an intense, *low* frequency SiCl stretching mode ($298\ cm^{-1}$) characteristic of *trans*-chlorines shown below (**7**)



7

The different stereochemical arrangements for o-phen.$SiCl_2F_2$ and o-phen.$SiCl_2Br_2$ may be rationalized by considering the steric properties of the orthophenanthroline ring and the repulsion between *cis*-halogens. For example, it is

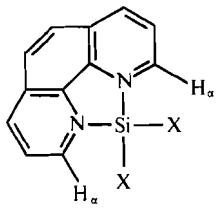
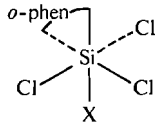
known (8) that $[(o\text{-phen})_2py_2Ru]^{3+}3Cl^-$ will not adopt conformations in which the orthophenanthroline rings are *trans* to one another (*i.e.* it will only adopt optically active *cis* conformations). This would indicate that the hydrogens H_α shown below can interact sterically with atoms occupying the other two positions in the plane about silicon. With this in mind, the con-



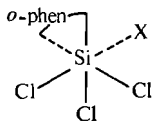
figurations **6** and **7** which we favor for *o*-phen.$SiCl_2Br_2$ and *o*-phen.$SiCl_2F_2$ are those which would have been preferred simply from steric arguments. That is, one would predict that the *larger* halogens would chose positions in the complex such that they were both *out* of the plane of the bulky orthophenanthroline ligand and *as far apart* (*trans*) from each other as possible. In this way the repulsions between (*a*) the hydrogens H_α and the *cis*-halogens in the plane and (*b*) *cis*-halogens are both minimized.

(B) o-phen.$SiCl_3F$ and o-phen.$SiCl_3Br$

In the above complexes containing the $SiCl_3$ residue we do have a stereochemical ambiguity, which was not the case for py_2SiCl_3X. The possible configurations for *o*-phen.$SiCl_3F$ and *o*-phen.$SiCl_3Br$ (**8** and **9**) are shown below



8



9

o-phen.$SiCl_3Br$ shows an exceptionally intense, *high* frequency Raman line at 428 cm^{-1} (Table 6) (its unusually high intensity makes it unlikely to be an orthophenanthroline mode, by comparison with Raman data for many orthophenanthroline complexes), which favors a pyramidal $SiCl_3$ residue as shown in configuration **9**. However, *o*-phen.$SiCl_3F$ shows a characteristic intense, *low* frequency SiCl stretching mode (276 cm^{-1} and for comparison at 273 cm^{-1} in the analogous bipy.$SiCl_3F$) which strongly favors the *T*-shaped $SiCl_3$ residue of configuration **8** (Table 6).

As with *o*-phen.$SiCl_2X_2$ we find that the configurations favored for *o*-phen.$SiCl_3X$ (where X = F or Br) are those which would have been predicted from simple steric arguments. That is, the larger halogen prefers a molecular site in the

complex, such that it is out of the plane occupied by the bulky orthophenanthroline ligand and minimizes *cis*-halogen repulsions.

Conclusion

We may summarize the data for the pyridine and orthophenanthroline complexes of mixed halogenosilanes by stating that interesting structural trends are observed, which appear to be controlled by the spatial requirements of the respective ligands and halogens in the molecule. It appears that electronegativity and π bonding arguments do not have to be invoked in order to explain the data.

Experimental

Trichlorosilane was purchased from Matheson.

The chlorofluorosilanes were prepared using the method of Booth and Swineheart (9) in which a Swarts type reaction was involved. Here, $SiCl_4$ was partially fluorinated using SbF_3, incorporating $SbCl_5$ as a catalyst. The mixed chlorofluorosilanes were initially passed through cold traps, at ice/salt, CO_2/acetone, and liquid nitrogen temperatures, respectively, which thereby achieved a crude separation. Each crude fraction was introduced in turn into a specially designed, double vacuum jacketed, low temperature fractionation column, with a finely controlled take off head. Yields of $SiCl_3F$ and $SiCl_2F_2$ were collected; their vapor pressure/temperature dependence agreed very closely with those quoted by Schumb and Gamble (10). These were separately stored in 5 l bulbs, each having a finger immersed continuously in liquid nitrogen. The latter precaution was to prevent the disproportionation of the gases to SiF_4 and $SiCl_4$. It was found that after a period of three months, on refractionating the gases, no detectable sign of disproportionation was observable. Infrared spectra of the gases $SiCl_3F$ and $SiCl_2F_2$ were taken and were in agreement with those of Stokr and Schneider (11).

The chlorobromosilanes were initially prepared by refluxing $SiBr_4$ and $SbCl_3$ using phosphorus pentoxide guard tubes. The resulting mixture was then fractionated but yielded mainly $SiCl_3Br$. The preparation was repeated, using the method of Forbes and Anderson (12), where a 1:1 mixture of $SiCl_4$ and $SiBr_4$ was sealed off in a thick walled glass bomb which was then heated at 140 °C for 72 h. Again the resulting mixture was fractionated producing $SiCl_3Br$ and $SiCl_2Br_2$ in reasonable yields, b.p. 78 and 103 °C, respectively. The infrared spectra agreed with those of Mlle. Delwaulle (13) where the presence of one fraction in the other was negligible. Pyridine was dried with $SiCl_4$ and then vacuum distilled. Orthophenanthroline and bipyridyl were dried by slow, repeated vacuum sublimation. All solvents were dried with CaH_2 and vacuum distilled. A typical preparation involved the reaction of the appropriate halogenosilane with a slight excess of the ligand in either the pure state or in chloroform solution. The complexes always formed as white precipitates, which remained as white powders after removal of the excess ligand and solvent. All manipulations where possible were carried out in all glass vacuum systems. Raman spectra were recorded for the powdered solids in glass ampoules which had been sealed off directly from the vacuum line preparation. Samples for infrared mull spectra were handled in glove boxes which were continuously purged with dry air. Nujol was dried over molten sodium for 24 h prior to use.

Infrared spectra were recorded on a Beckmann IR 11 spectrometer and Raman spectra on a Spex 1401 spectrometer using krypton or argon ion laser excitation.

Analyses

Analyses were performed by quantitatively hydrolyzing the product and analyzing for halide and py:Si by using argentometric (14) and p*H* titrations, respectively. The preparation of the known compound py_2SiCl_3H was exactly the same as that reported (1). Results of analyses are shown in Table 7.

*Force constants in units of mdyn/Å, mdyn/rad or mdyn Å/rad².
†Force constants for the hypothetical molecule py_2SiH_4.

Normal Coordinate Calculations

Force fields for the parent molecules py_2SiX_4 were derived using methods similar to those described previously for py_2SiCl_4 (1) and $pyPCl_5$ (7). These force constants were transferred directly to the respective mixed halogeno–pyridine complexes. The pyridine ligand was treated as a point mass with a SiN bond stretching constant of about 1.0 mdyn/Å. Force constants not listed in Table 8 for the parent molecules were set equal to zero in the mixed halo species. Table 9 contains the bond lengths used in the calculations.

The calculated spectra for py_2SiCl_3X are shown in Table 2 for a molecular symmetry of C_s. In the case of $py_2SiCl_2X_2$ the spectra were computed for *trans*-pyridines but with both *trans*-halogens (D_{2h}) and *cis*-halogens (C_{2v}). Within the approximations made in the force fields only the D_{2h} $py_2SiCl_2X_2$ calculated frequencies gave a satisfactory fit with the observed spectra.

The computer programs used for the calculation of the vibrational spectra are based on those of Schactschneider's G.MAT, F.MAT, and EIGV. and were run on an IBM 7094 computer system.

We would like to thank the National Research Council of Canada for financial support and an N.R.C.C. scholarship for D.H.B.

Influence des paramètres géométriques sur la résistance d'une cellule électrolytique

J. C. SISI, C. DUBEAU, ET J. P. PÉLISSIER
Département de Génie Chimique, Ecole Polytechnique, Montréal, Québec
ET
L. MITNYAN
Département de Génie Physique, Ecole Polytechnique, Montréal, Québec

Reçu le 18 janvier 1972

Les valeurs de la résistance d'une solution aqueuse de K_2SO_4 à 25 °C dans une cellule électrolytique ont été calculées théoriquement en fonction des paramètres géométriques de la cellule. Les valeurs calculées ont été vérifiées expérimentalement avec une nouvelle méthode utilisant un courant alternatif de 2000 cycles.

The resistance of an aqueous solution of K_2SO_4 in an electrolytic cell has been calculated theoretically as a function of geometric parameters of the cell. The calculated values have been verified with a new experimental method using an alternating current of 2000 cycles.

Canadian Journal of Chemistry, **50**, 2491 (1972)

Introduction

Depuis plusieurs années déjà, l'électrochimie a quitté le modeste rôle de frontière entre la physique et la chimie. Des résultats importants lui sont dus dans des domaines de plus en plus divers et les applications sont de plus en plus nombreuses. Bien que les recherches de pointe en électrochimie soient abondantes, on doit remarquer que beaucoup de résultats plus classiques ou plus anciens mais aussi des résultats récents se limitent souvent à des cas simples. Ceci est dû, en général, aux difficultés mathématiques rencontrées (13).

Une énorme quantité de recherches et d'applications utilisent au moins deux électrodes plongeant dans des cellules diverses (1, 6, 9–11). Il nous a paru intéressant de montrer avec une bonne précision quelle peut être l'influence des facteurs géométriques sur les autres paramètres de ces cellules.

Il semble que les "facteurs géométriques" englobent des concepts variés conduisant chacun à un point de vue d'étude différent: (*i*) forme des électrodes, (*ii*) forme de la cellule, (*iii*) état de surface des électrodes.

Chacun de ces concepts prend plus ou moins d'importance selon que l'on se place en régime hydrostatique ou hydrodynamique. A ce propos, il est bon de rappeler que le régime statique ne peut être employé que si on est sûr que la convection peut être complètement négligée, sinon la convection naturelle peut entraîner des erreurs.

La forme des électrodes est un facteur très important car dans de multiples applications on étudie le comportement d'une électrode particulière en la plaçant vis-à-vis d'une contre-électrode beaucoup plus grande. Il n'est donc pas inutile de vérifier dans quelles mesures cette disposition si fréquente n'entraîne aucune correction et d'essayer d'établir un moyen de mesure précise des corrections à effectuer lorsque c'est nécessaire.

Partie théorique

Problème général

Nous avons limité la majeure partie de notre travail à l'étude de la partie réelle de l'impédance des solutions, c'est-à-dire à la résistance de la cellule.

Nous avons également limité notre étude, quant à la forme des cellules, à un des cas les plus intéressants: des cellules cylindriques dont les deux électrodes sont circulaires, planes et centrées sur l'axe du cylindre. Les calculs et vérifications que nous avons effectués pour ce type de cellule peuvent cependant dans bien des cas être facilement adaptés à des formes différentes.

Evidemment, lorsque les deux électrodes ont le même diamètre, la loi d'Ohm est immédiatement intégrable sous sa forme simple bien connue:

$$\frac{V}{I} = R = \frac{\rho d}{\pi R_i^2} \qquad [1]$$

V, différence de potentiel entre les deux élec-

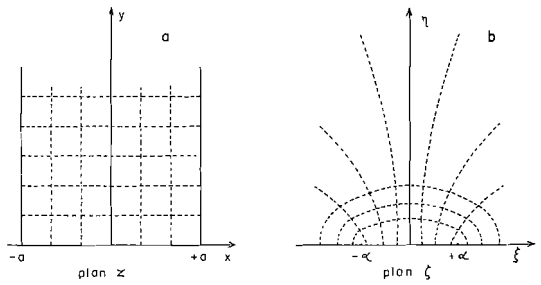

FIG. 1. Transformée de Schwarz simple.

trodes; I, courant passant dans la cellule; R, résistance de la cellule; ρ, résistivité de la solution; d, distance entre les électrodes; R_i, rayon des électrodes.

Par contre, si les rayons des deux électrodes sont différents, la loi d'Ohm n'est plus intégrable directement par une méthode analytique.

C'est essentiellement le problème de cette intégration dont nous allons développer la solution et les vérifications de cette solution.

Etude physique du problème

Les seules transformations mathématiques que l'on puisse faire subir à notre système doivent satisfaire la condition suivante: on doit conserver l'équation fondamentale de Laplace $\nabla^2\varphi = (\partial^2\varphi/\partial x^2) + (\partial^2\varphi/\partial y^2) = 0$, où, dans le cas du potentiel à l'intérieur d'une solution, $\varphi = V = V(\rho, d, R_1, R_2, I)$.

Le groupe des transformations conformes et particulièrement la transformation de Schwarz satisfont cette condition.

D'autre part, on sait que plusieurs auteurs ont appliqué avec succès les transformations de Schwarz à certains problèmes de transport de matière dans les liquides (8, 16).

Transformées de Schwarz simples et doubles

La demi-bande du plan Z (fig. 1*a*) représente le potentiel complexe $\Omega = \varphi + i\varphi$ soumis aux conditions $\varphi(x, 0) = 0$, $-a < x < +a$, $\varphi(-a, y) = -\alpha$, $\varphi(+a, y) = +\alpha$ pour $y > 0$, et $\partial\Omega/\partial Z \to 0$ lorsque $Z \to \infty$.

Cette demi-bande peut être considérée comme étant la surface d'un triangle dégénérée (1) et être transformée dans le demi-plan ξ (fig. 1*b*) par la transformée (1, 3, 16).

$$Z = \frac{2a}{\pi} \arcsin\left(\frac{\zeta}{\alpha}\right)$$

où $\zeta = \xi + i\eta$ et $Z = x + iy$, la transformation inverse étant

$$\zeta = \alpha \sin\left(\frac{\pi Z}{2a}\right)$$

En séparant les parties réelles et imaginaires, on obtient

$$\frac{\xi^2}{\mathrm{ch}^2\left(\frac{\pi y}{2a}\right)} + \frac{\eta^2}{\mathrm{sh}^2\left(\frac{\pi y}{2a}\right)} = \alpha^2$$

qui transforme les ellipses confocales (les foyers aux points $-\alpha$ et $+\alpha$) du plan ζ dans les droites (y = constant) du plan Z, et

$$\frac{\xi^2}{\sin^2\left(\frac{\pi x}{2a}\right)} + \frac{\eta^2}{\cos^2\left(\frac{\pi x}{2a}\right)}$$

qui transforme les hyperboles confocales (les foyers aux points $-\alpha$ et $+\alpha$) du plan ζ dans les droites (x = constant) du plan Z.

D'autre part, l'ensemble géométrique qui représente la distribution des lignes de force à l'intérieur d'une solution comprise entre deux électrodes possède une conformation semblable à celle montrée dans la fig. 2*c*.

Cette conformation peut être obtenue en re-

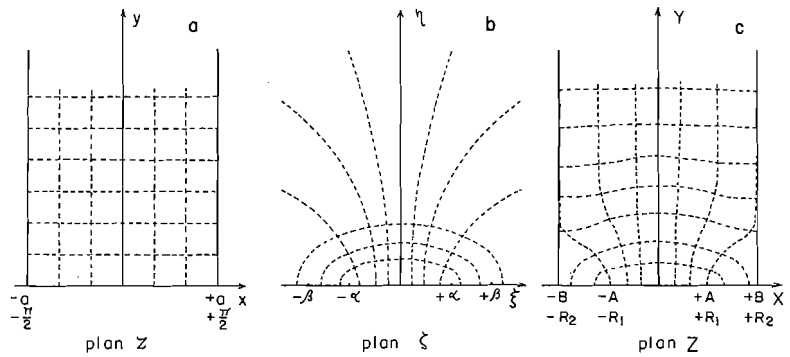

Fig. 2. Transformée de Schwarz double.

pliant de 90° vers le haut l'axe réel du plan ζ aux deux points $-\beta$ et $+\beta$, différents de $-\alpha$ et $+\alpha$ (3, 16).

La série de transformations conformes qui permettent le passage de la fig. 2*a* à la fig. 2*c* à travers la fig. 2*b* sont:

$$Z = \frac{2a}{\pi} \arcsin\left(\frac{\zeta}{\alpha}\right)$$

$$\zeta = \beta \sin\left(\frac{\pi Z}{2B}\right)$$

$$\alpha = \beta \sin\left(\frac{\pi A}{2B}\right)$$

d'où on obtient

$$Z = \frac{2a}{\pi} \arcsin \frac{\sin\left(\frac{\pi Z}{2B}\right)}{\sin\left(\frac{\pi A}{2B}\right)}$$

Si on prend $|a| = \pi/2$, $|B| = R_2$ et $|A| = R_1$

$$Z = \arcsin \frac{\sin\left(\frac{\pi Z}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}$$

Application de la double transformée de Schwarz au calcul de la résistance

Le fait que cette transformation soit conforme nous autorise à calculer la résistance d'une cellule indifféremment dans l'un ou l'autre des espaces associés dans cette transformation.

L'espace Z (fig 2*c*) correspondra à l'espace réel de mesure, l'espace z (fig. 2*a*) sera utilisé pour permettre les calculs.

En coupe, l'électrode de rayon R_1 a pour trace le segment $(-A, +A)$ de l'axe des x, l'électrode de rayon R_2 a pour trace le segment $(-B, +B)$ de la droite $y = d$. La courbe transformée de la 1ère électrode est, comme nous l'avons vu, le segment $(-\pi/2, +\pi/2)$ de l'axe des x. La courbe transformée de la 2ème électrode, est donnée par

$$z_e = \arcsin\left[\frac{\sin\left(\frac{\pi}{2}\frac{X + id}{R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}\right]$$

z_e étant le lieu de la trace de la 2ème électrode dans le plan z, avec X variant entre $-R_2$ et R_2

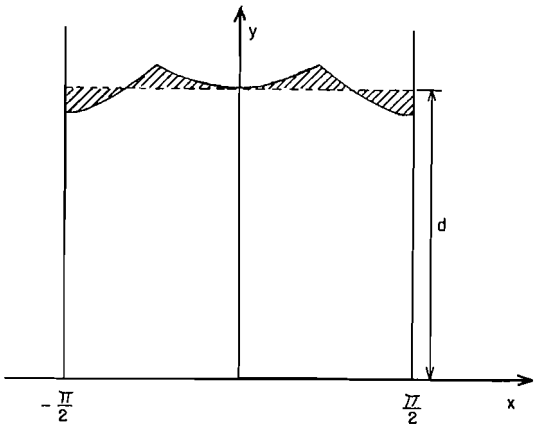

FIG. 3. Tracé de l'électrode no. 1.

$$z_e = \arcsin\,[A + iB]$$

ou en représentation logarithmique

$$z_e = -i \log\,[i(A + iB) \pm \sqrt{1 - (A + iB)^2}]$$

où

$$A = \frac{\operatorname{ch}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)} \sin\left(\frac{\pi X}{2R_2}\right)$$

et

$$B = \frac{\operatorname{sh}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)} \cos\left(\frac{\pi X}{2R_2}\right)$$

D'où

$$x_e = \arcsin\{\tfrac{1}{2}[(A^2 + B^2 + 1) \pm \sqrt{(A^2 + B^2 + 1)^2 - 4A^2}]\}^{1/2}$$

$$y_e = \operatorname{arg\,sh}\{\tfrac{1}{2}[(A^2 + B^2 - 1) \pm \sqrt{(A^2 + B^2 - 1)^2 + 4B^2}]\}^{1/2}$$

Cette courbe, z_e, a l'allure donnée par la fig. 3. On peut montrer par un calcul simple mais long, qu'en général, la surface de la zone hachurée est négligeable.

Dans ce cas, on voit que la résistance peut être calculée à l'aide de la section de cylindre de hauteur d.

On prendra pour valeur de $d = y_e$

$$y_e = \text{partie imaginaire}\left[\text{arc sin}\left(\frac{\sin\left(\frac{\pi i d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}\right)\right]$$

$$= \text{arg sh}\frac{\text{sh}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}$$

La surface de section du cylindre est $\pi^3/4$. La résistance de la cellule est donc

$$R = \rho'\frac{4}{\pi^3}\text{arg sh}\frac{\text{sh}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}$$

où ρ' représente la résistivité dans l'espace transformé. Appliquons cette formule au cas où $R_1 = R_2$.

$$R = \rho\frac{d}{\pi R_2^2} \quad \text{d'où} \quad \rho' = \rho\frac{\pi}{2R_2}$$

où ρ représente la résistivité dans l'espace réel. Donc dans le cas général

$$[2] \qquad R = \rho\frac{2}{\pi^2 R_2}\text{arg sh}\frac{\text{sh}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}$$

Pour plus de commodité par la suite, nous utiliserons le rapport Λ définit ainsi

$$\Lambda = \frac{\text{Résistance de la cellule définie par } (d, R_1, R_2)}{\text{Résistance de la cellule définie par } (d, R_2, R_2)}$$

Si $R_2 > R_1$

$$\Lambda = \frac{2R_2}{\pi d}\text{arg sh}\left(\frac{\text{sh}\left(\frac{\pi d}{2R_2}\right)}{\sin\left(\frac{\pi R_1}{2R_2}\right)}\right)$$

et si nous définissons toutes les dimensions géométriques par rapport à R_2 en posant

$$\frac{\pi d}{2R_2} = L$$

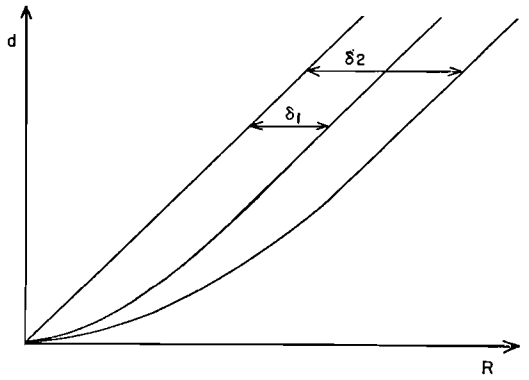

FIG. 4. Résistance *vs.* distance entre les électrodes (relation théorique).

et

$$\frac{\pi R_1}{2R_2} = \Delta$$

$$\Lambda = \frac{1}{L}\text{arg sh}\left(\frac{\text{sh } L}{\sin\Delta}\right)$$

et

$$R = \frac{2\rho}{\pi^2 R_2}\text{arg sh}\left(\frac{\text{sh } L}{\sin\Delta}\right)$$

Quand $L \to \infty$

$$\text{arg sh}\left(\frac{\text{sh } L}{\sin\Delta}\right) \simeq \log\frac{e^L}{\sin\Delta} = L - \log\sin\Delta$$

Donc

$$R_\infty \simeq \frac{2\rho}{\pi^2 R_2}(L - \log\sin\Delta)$$

Or $(2\rho/\pi^2 R_2)\,L$ représente la résistance de la cellule à 2 electrodes de rayons R_2.

Donc la distance δ (fig. 4) est calculée par

$$\delta = \frac{2\rho}{\pi^2 R_2}\log\sin\Delta = K\log\sin\Delta$$

ou

$$[3] \qquad \frac{\delta_1}{\delta_2} = \frac{\log\sin\Delta_1}{\log\sin\Delta_2}$$

Partie expérimentale

Le dispositif de thermostatisation (fig. 5)

L'influence de la température sur la conductivité des cellules électrochimies est grande. De plus les gradients thermiques constituent une source importante de convection naturelle. Pour ces deux raisons il était nécessaire d'effectuer nos mesures à température fixe contrôlée avec une grande précision. Des essais de thermostatisation par immersion de la cellule dans l'eau ont montré que même si la cellule est bien

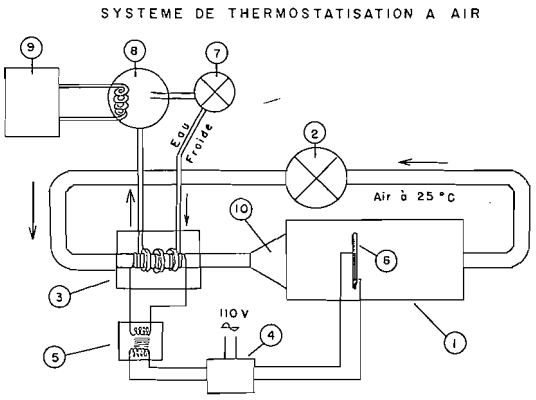

FIG. 5. Système de thermostatisation à air. *1*, Enceinte thermostatisée; *2*, soufflerie; *3*, thermoregulateur; *4*, relais électronique; *5*, autotransfo; *6*, thermomètre à contacts de précision; *7*, pompe de circulation d'eau; *8*, *9*, echangeur de chaleur et système de refroidissement; *10*, diffuseur conique.

isolée, le bain de régulation influence les mesures de façon difficilement contrôlable. C'est pour cette raison que la thermostatisation par air a été choisie en définitive. La température de la salle d'expérience n'ayant aucune fenêtre, il a été facile de régler sa température à 1 °C près.

Le dispositif décrit ci-dessous a permis de fixer la température de la cellule à 25 °C avec une précision supérieure à 1/100° de °C. L'enceinte thermostatisée elle même est en plexiglass à deux épaisseurs séparées par une couche d'air. Des gants permettent d'effectuer des manipulations à l'intérieur mais au cours des mesures les orifices sont fermés par des bouchons en mousse de polystyrène. Outre le thermorégulateur, un thermomètre au 1/100° de degré préalablement étalonné plonge dans cette enceinte.

Les tuyaux de circulation de l'air sont matelassés avec de la laine de verre. Un cône de diffusion percé de trous obturables permet une bonne répartition de la circulation d'air dans l'enceinte.

La cellule de mesure et ses accessoires (fig. 6)

La cellule de mesure elle-même est composée d'un tube de verre cylindrique calibré de 2.992 cm de rayon intérieur et de 8 cm de hauteur, placé verticalement.

Le tube de verre cylindrique s'engage dans la rainure circulaire d'un support en plastique muni d'un trou en son centre. Ce trou est muni d'un tuyau permettant l'arrivée ou le départ du mercure formant l'électrode inférieure (rayon fixe égal au rayon intérieur du tube de verre). Le support en plastique décrit ci-dessus se trouve lui-même monté sur un bâti dont l'horizontalité est contrôlee par deux niveaux à bulle perpendiculaires. La partie supérieure du tube de verre est recouverte par une couronne de plastique munie d'une rainure circulaire, enchassant une électrode plaquée or. Le plastique est percé de deux petits trous permettant l'évacuation de l'électrolyte en cas d'élévation du niveau du mercure. Il existe 6 montures supérieures différentes dont les électrodes mesurent respectivement 1, 3/4, 7/8, 1/2, 1/4, 1/8 de pouce de rayon.

Pour assurer l'étanchéité du système, on a placé sur la monture supérieure une masse assez lourde. Le niveau du

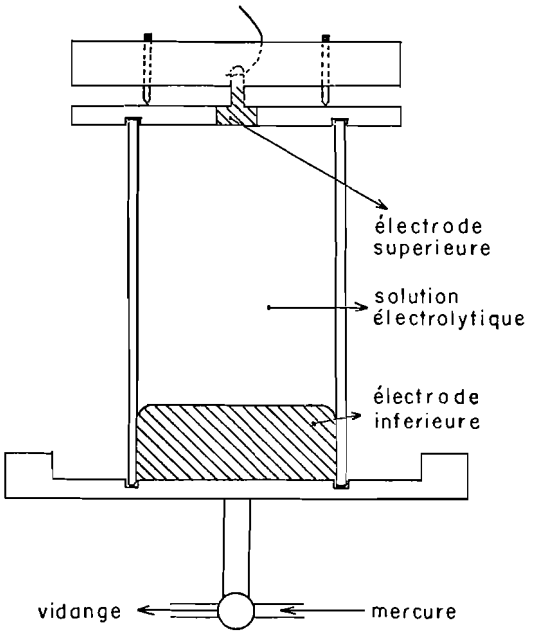

FIG. 6. Schéma de la cellule électrolytique.

mercure dans la cellule est contrôlé par un siphon qui aboutit d'une part à la canalisation sous la cellule et d'autre part à une ampoule à brome fixe sur un support à crémaillère. A la fin de chaque expérience, la cellule est vidée par la canalisation inférieure et le mercure est passé à travers un filtre spécial.

Les appareils de mesure

(a) Mesures géométriques

Le niveau de la surface du mercure (électrode inférieure) et celui de la surface de l'électrode supérieure sont mesurés à l'aide d'un cathétomètre de précision extérieur au montage. Sa verticalité est assurée grâce à des niveaux à bulle.

(b) Mesures électriques

Pour éviter tout phénomène de polarisation, toutes les mesures électriques se font en courant alternatif.

La source de courant est un générateur à fréquence variable utilisant le courant du secteur stabilisé. La tension fournie par ce générateur est appliquée aux bornes d'un point de mesure de type dont tous les éléments de mesures ont été remplacés par des éléments plus précis.

La mesure de l'équilibre du pont s'effectue à l'aide d'un oscilloscope cathodique. On applique respectivement les tensions à mesurer au balayage vertical et horizontal. L'équilibre est obtenu quand l'ellipse correspondant au déséquilibre a pu être réduite à un segment de droite horizontal. Cet équilibre est obtenu en ajustant des résistances et des capacités soigneusement étalonnées au préalable. La mesure de la résistance de la cellule est facilitée par l'existence sur le pont de mesure d'une "terre de Wagner" que l'on ajuste séparément de façon à contrebalancer au mieux la partie capacitive de l'impédance de la cellule.

Choix des conditions expérimentales

Après plusieurs essais, le choix de l'électrolyte a été fixé

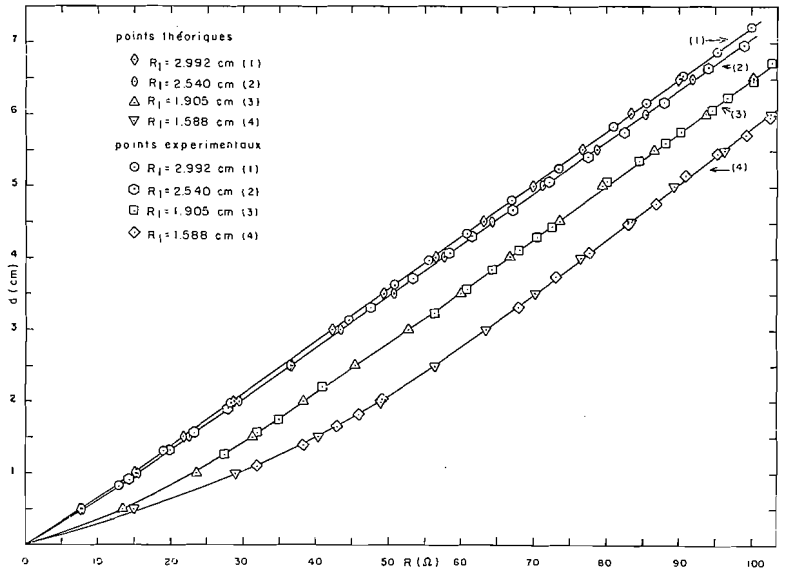

FIG. 7. Résistance *vs.* distance entre les électrodes (relation expérimentale).

sur le sulfate de potassium en solution aqueuse de molalité 10^{-2}, les travaux de Shaw et Remick (15) ayant montré qu'on évite ainsi au maximum les sustensions de toute nature. La fréquence, choisie pour les mêmes raisons entre 500 et 10000 Hz finalement été fixée à 2000 Hz car c'est pour cette valeur que les résultats sont les plus reproductibles.

Résultats expérimentaux

Résultats préliminaires

Un étalonnage minutieux de tous les appareils de mesure (en particulier les résistances d'équilibrage du pont) a permis d'obtenir une précision et une reproductibilité des résultats de $2 \times 10^{-2}\Omega$ pour des résistances comprises entre 1 et 300 Ω.

Résistance de la cellule de mesure (voir fig. 7)

Tous les résultats ont été obtenus à 25 °C ± 0.05 °C avec des solutions de K_2SO_4 de molalité 0.01 ± 0.0001, à une fréquence de 2000 ± 2 Hz.

La distance entre les électrodes est mesurée en centimètres avec une précision de 10^{-3} cm.

Le rayon de l'électrode inférieure (en mercure) est de $R_2 = 2.992$ cm (Tableaux 1, 2).

Etude des écarts

$\delta_1 = 1.80$, $\delta_2 = 10.41$, $\delta_3 = 19.38$ écarts mesurés 1e/2e électrodes, 1e/3e électrodes, 1e/4e électrodes, respectivement.

$\delta_1 = 1.87$, $\delta_2 = 11.31$, $\delta_3 = 19.67$ écarts calculés par la formule $\delta = k \log \sin \Delta$.

Discussion des résultats

On voit que les résultats ci-dessus confirme avec précision l'emploi des formules établies plus haut.

Cependant, des essais avec une électrode de rayon $R_1 = 0.317$ cm ont donné des résultats nettement plus dispersés. Nous avons dû négliger ce résultat car il a été prouvé que l'isolement des flans de cette électrode était défectueux. Cependant, il est certain que pour des distances de moins de 4 cm l'approximation faite sur la fig. 3 ne peut plus être appliquée à une aussi petite électrode.

Extension possible de la recherche

La configuration du système électrolytique étudiée constitue un cas particulier. Nous nous proposons d'étudier d'autres configurations et de vérifier les résultats obtenus par la même méthode expérimentale au moyen de la théorie de la distribution du courant de convection dans une cellule électrolytique.

Le courant d'une cellule électrolytique, comparé au courant limite de diffusion, sera analysé en fonction des paramètres physico-chimiques, tels que la conductivité spécifique de la solution, la forme géométrique des électrodes, l'état de la surface des électrodes, etc.

En appliquant la théorie des distributions nous pouvons considérer le courant électrique, à un instant donné, comme une masse ponctuelle animée d'une vitesse représentée par son vecteur

tangent au point donné. En déterminant le champ des vecteurs-distributions nous obtenons l'intensité du courant de convection comme étant définie par une charge en mouvement. Lorsque l'espace de la cellule électrolytique est orienté, il existe un isomorphisme canonique et les distributions sur l'espace généraliseront les fonctions.

Les distributions se transforment, par changement des variables, comme les fonctions correspondantes et l'intégrale partielle d'une forme différentielle sur la section de l'espace fibré conduira à l'image directe d'un courant de la base.

Cette application de la théorie des distributions, par une transformation de Fourier des courants tempérés sur un espace vectoriel de dimension finie (14), permettra de déterminer les paramètres géométriques de la surface des électrodes.

En expliquant les résultats obtenus avec la théorie des distributions par la géométrie différentielle nous nous proposons d'établir une équation intégrale générale du courant électrolytique dont les constantes pourront être évaluées par l'analyse des courbes expérimentales.

Enfin cette recherche devrait nous conduire à l'établissement d'une relation directe entre le courant électrolytique et les paramètres géométriques moyens de la cellule.

Ce travail a pu être réalisé grâce aux subventions du Conseil National de Recherches du Canada et du Centre de Recherche de l'Hydro-Québec.

The Photolysis of 4-Hydroxybenzil and the Effect of Triethylamine on the Photolysis of Benzil and 4-Hydroxybenzil

DAVID L. BUNBURY[1] AND THERESA MAK CHAN[2]

Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia

Received January 18, 1972

Benzil is photoreduced in neat triethylamine and mixtures of triethylamine and 2-propanol. In neat 2-propanol the principal products are; benzil pinacol, 20%; benzoin benzoate, 19%; benzoin, 18%; and benzoic acid, 12%. When the amine concentration is as low as 0.2 m*M* the benzil pinacol formation is almost completely suppressed. At amine concentrations higher than 0.36 m*M* the principal product is benzoin, 80%. At intermediate amine concentrations benzoin benzoate is important. The rate of benzil disappearance reaches a maximum and then declines as either the benzil concentration in triethylamine is increased or the amine concentration in 2-propanol is increased.

4-Hydroxybenzil is not photoreduced by 2-propanol. It is reduced by triethylamine. The quantum yield of disappearance is 0.04 at a concentration of 47.8 m*M* and in solutions containing at least 0.36 *M* of amine. 4-Hydroxybenzoin is the principal product but at low starting 4-hydroxybenzil concentrations 4,4′-dihydroxybenzil is important. A rate maximum is also observed in this case.

4,4′-Dihydroxybenzil is not photoreduced by 2-propanol. It does undergo photoreaction in neat triethylamine but no products were isolated.

Triethylamine also appears to suppress biacetyl pinacol formation in the photoreaction of biacetyl with 2-propanol.

Le benzile a été photoréduit dans la triéthylamine pure et dans des mélanges de triéthylamine et de propanol-2. Dans le propanol-2 pur les principaux produits sont le benzile pinacol 20%, le benzoate de benzoïne 19%, la benzoïne 18%, et l'acide benzoïque 12%. Pour une concentration en amine aussi basse que 0.2 m*M*, la formation du benzile pinacol est presque complètement supprimée. Pour des concentrations en amine supérieures à 0.36 m*M*, le produit principal est la benzoïne 80%. Pour des concentrations intermédiaires en amine, le benzoate de benzoïne devient important. La vitesse de la disparition du benzile atteint un maximum puis décroît soit par augmentation de la concentration du benzile dans la triéthylamine soit par accroissement de la concentration en amine dans le propanol-2.

L'hydroxy-4 benzile n'est pas photoréduit par le propanol-2, il est réduit par la triéthylamine. Le rendement quantique de la disparition est de 0.04 pour une concentration de 47.8 m*M* et dans des solutions contenant au moins 0.36 *M* d'amine. On obtient principalement l'hydroxy-4 benzoïne mais pour de faibles concentrations initiales en hydroxy-4 benzile, le dihydroxy-4,4′ benzile devient important. Un maximum dans la vitesse a été également observé dans ce cas.

Le dihydroxy-4,4′benzile n'est pas photoréduit par le propanol-2. Il subit une réaction photochimique dans la triéthylamine pure mais on n'a pas isolé de produits. Il apparaît également que la triéthylamine supprime la formation du biacétyle pinacol dans la réaction photochimique du biacétyle sur le propanol-2.

Canadian Journal of Chemistry, **50**, 2499 (1972)

Introduction

There has been much recent work on the photolysis of various benzophenones and of fluorenone using tertiary amines as solvents and hydrogen donors (1–12). This work has shown that those ketones which do not undergo photoreduction in 2-propanol because the lowest lying excited state is unreactive toward hydrogen abstraction, are photoreduced in triethylamine and other tertiary amines. It was thought interesting to see if *p*-hydroxybenzil would show the same behavior relative to benzil that *p*-hydroxybenzophenone shows relative to benzophenone. Since benzil has two carbonyl groups it is conceivable that in *p*-hydroxybenzil the CT state might not necessarily be lowest in energy and that the usual photoreduction takes place. Alternatively the second carbonyl group might perturb the excited carbonyl enough so that intersystem crossing is a facile process even in polar solvents. Cohen *et al.* (10) have shown that *p*-aminobenzophenone is not reduced in 2-propanol due to lack of intersystem crossing.

Experimental

Benzil and benzoin were from Eastman and twice recrys-

tallized from methanol. 4-Hydroxybenzil[3] and 4,4′-dihydroxybenzil were prepared from their corresponding benzoins (Aldrich) by oxidation with cupric sulfate, pyridine, and water (13), then cleaving the methoxy group with pyridine hydrochloride at 190–200° (14). Triethylamine and tri-*n*-butyl amine were from Eastman and distilled immediately before use. 2-Propanol, benzene, and pyridine were Fisher certified reagents and were freshly distilled. Quinuclidine was obtained by dissolving 6.5 g quinuclidine hydrochloride in 4 ml water and adding an excess of potassium hydroxide flakes to the solution. The solution was extracted with petroleum ether which was then evaporated. Pyrene was Aldrich reagent grade. *p*-Hydroxybenzophenone was from Aldrich and recrystallized before use. Biacetyl from Eastman was freshly distilled. Silica gel used in column chromatography was Fisher Certified grade 100–200 mesh. It was dried at 150° for 1 h, then cooled in a desiccator.

All melting points were taken either on a Fisher–Johns or Mel–Temp melting point apparatus. Elemental analyses were done by Organic Microanalyses, Dr. C. Daesslé, 5757 Decelles Ave., Montreal, Quebec. Molecular weights were determined on a Hitachi Perkin–Elmer Model 115 Molecular Weight Apparatus. Gas chromatography was performed on a Burrell Model K-1 with thermal conductivity detector. The column was 1/4 in. i.d. 250 cm long and filled with 20% Dow Corning high vacuum silicone grease on 80–100 mesh chromosorb W. The lights used in irradiation and actinometry have already been described (15). Quantitative t.l.c. was made using a Photovolt Densicord Model 542 Densitometer with a light source of 254 nm. T.l.c. was performed using Eastman Chromagram Sheet 6060 (silica gel with fluorescent indicator). A planimeter was used to measure the areas (because of the drifting baseline the planimeter was found to give better results than the automatic integrator). The R_f for 4-hydroxybenzil, when a solution containing triethyl amine was directly applied to the t.l.c. sheet, was considerably lower (0.25, developing solvent, hexane:ether, 1:1) than when solvents such as 2-propanol THF or chloroform were used to apply the solid (R_f 0.48). The usual R_f was obtained by removing the Et_3N by evaporation and dissolving the residue in some other solvent.

Column chromatography was used to separate the products. The solvent was removed under reduced pressure and the residue redissolved in 50 ml of chloroform. This was shaken with 15 ml saturated sodium bisulfite and after separation washed twice with saturated sodium bicarbonate, twice with 50 ml portions of distilled water, then dried over sodium sulfate. The chloroform was removed under vacuum and the residue redissolved in ether then adsorbed onto silica gel. The silica gel with adsorbed products was placed on top of 300 g silica gel in a previously packed column. The column was eluted with about 6 l of ether–hexane, which varied in concentration from 0–60% ether in the case of benzil and 0–80% in the case of 4-hydroxybenzil. Finally the column was washed with 2.5 l of acetone. Each fraction was examined by t.l.c. Five percent ether brought out benzil, 15% benzoin benzoate, 25% benzoin, 40% 4-hydroxybenzil, 55% 4-hydroxybenzoin, and 75% 4,4′-dihydroxybenzil. The material eluted by acetone could not be separated further and was brownish. There was also a very little material which could not be removed from the column.

Three vessels were used for irradiations. The 70 ml vessel was made of Vycor and used in those runs degassed by the freeze–pump–thaw technique. The 400 ml vessel was Pyrex and the 600 ml vessel Vycor. The volumes of the reaction mixture were 50, 250, and 500 ml respectively. The reaction mixture in the two larger sizes was flushed with nitrogen or helium for 30 min prior to irradiation and during the irradiation.

The products of the reaction were identified and measured as follows. Benzaldehyde: the irradiated solution was directly injected onto the gas chromatograph, and a peak was obtained with the same retention time as authentic benzaldehyde. The solvent was distilled off under reduced pressure and the peak was in the distillate. Benzaldehyde was confirmed by precipitating its 2,4-dinitrophenylhydrazone. It was measured quantitatively by comparing its area on the g.c. with that of a standard solution. Unreacted benzil: after column chromatography it was identified by its i.r. spectrum and melting point. It was measured quantitatively by t.l.c. Benzoic acid: was recovered by acidification of the bicarbonate extract followed by ether extraction. After evaporation of the ether, the residue was identified by its m.p. and i.r. spectrum. It was weighed. Benzoin: was obtained by column chromatography and identified by its i.r. spectrum and m.p. It was measured quantitatively by t.l.c. Benzoin benzoate: was identified by its i.r. spectrum and m.p. It was measured quantitatively by t.l.c. Benzil pinacol: when obtained, was separated from the reaction mixture by filtration and identified by its m.p. and i.r. spectrum. It was measured quantitatively by weighing. Unreacted 4-hydroxybenzil: was obtained by column chromatography and identified by its m.p. and i.r. spectrum. It was measured quantitatively by t.l.c. 4-Hydroxybenzoin: was obtained by column chromatography and after recrystallization had a melting point of 172–175° with some decomposition. Its i.r. and n.m.r. spectra were identical with an authentic sample prepared by sodium borohydride reduction of the 4-hydroxybenzil. The same compound was also prepared by reduction of 4-hydroxybenzil by benzpinacol according to Rubin and Ben Bass (16*a*). The i.r. has a carbonyl band at 1660 cm^{-1}. The n.m.r. spectrum is also consistent with 4-hydroxybenzoin. In DMSO a broad peak at δ 6.06 (2H CH and OH); doublet at 6.85 (2H); multiplet at 7.40 (5H); doublet at 7.98 (2H); broad peak at 9.82 (1H); J for the doublets 8.5 Hz.

Anal. Calcd. for $C_{14}H_{12}O_3$ (mol. wt. 228): C, 73.66; H, 5.30. Found (223): C, 73.89; H, 5.48. 4′-Hydroxybenzoin is reported to melt at 187–189° (16*b*). It was measured quantitatively by t.l.c. 4,4′-Dihydroxybenzil: was obtained by column chromatography and had a melting point and i.r. spectrum identical with an authentic sample. It was measured quantitatively by t.l.c. Polymer: was obtained from triethylamine solutions of benzil in the form of a brown precipitate during irradiation. It was separated by filtration but when it came in contact with air it became oily and very dark colored. Addition of a small amount of water to this oily compound led to the formation of a brown precipitate.

Anal. Found for the last precipitate (mol. wt. >1000): C, 68.69; H, 7.74; N, 2.88.

[3]Both refs. 29 and 30 give the m.p. of 4-hydroxybenzil as 175° based on a report by Weisl (31). Gorvin (32) showed that the true m.p. is 129–130°. Reference 14 also obtains this m.p. as does Friedman *et al.* (33).

Quantum yields: the quantum yield for the disappearance of 4-hydroxybenzil in triethylamine was measured using the actinometer of Hatchard and Parker (17). The light from the medium pressure mercury arc was filtered by a Corning No. 7-39 filter with a peak between 340–380 nm. Both the actinometer solution and the hydroxybenzil solution were stirred by a current of nitrogen during irradiation. The quantum yield for the disappearance of benzil in triethylamine was estimated by comparing it with the rate of disappearance of benzil in 2-propanol (Table 2).

Results and Discussion

Table 1 shows the products of irradiation of benzil in neat triethylamine and the effect of the concentration of benzil on the rate of the reaction. The amount of benzoic acid is much less in the sealed tube run than others, but some was still formed. In a small series of runs where just the acid was measured it was found that if the time between opening the sealed tube and work-up was increased the amount of benzoic acid increased. In comparison with 2-propanol as the solvent it is seen that benzoin is now the major product and no benzil pinacol, benzoin benzoate, or its dimer (15) are produced. These results are somewhat different from those of Gream *et al.* (18) who on an 18 h irradiation of benzil in triethylamine found *N,N*-diethylbenzamide (19%) and a mixture of the two hydrobenzoins (7%). The percentage of the benzil reacting is not mentioned. The hydrobenzoins could arise from photoreduction of first-formed benzoin but explanation of the *N,N*-diethylbenzamide is not immediately apparent.

After formation of the ketyl radical $C_6H_5\dot{C}OHCOC_6H_5$ (**2***a*) Bunbury and Chaung (15) postulated a complex between the ketyl radical and an unexcited benzil molecule leading to the formation of benzil pinacol ($C_6H_5\overset{|}{C}OHCOC_6H_5)_2$ (**6***a*). Based on e.s.r. evidence Schenck *et al.* (19) have proposed that the ketyl radical of benzophenone forms a complex with benzophenone which leads to benzpinacol. If triethylamine is able to coordinate to radicals much better than is benzil or 2-propanol this would explain the lack of benzil pinacol and benzoin benzoate in the products when triethylamine is the solvent. By coordinating more firmly with the ketyl radical, no complex with unreacted benzil can form, and pinacol formation is suppressed. By providing a more easily abstractable hydrogen or by stabilizing the radical against decomposition into benzaldehyde and benzoyl radical, benzoin benzoate is suppressed. Such a stabilized radical would then end up as benzoin, the major product. This is outlined in Scheme 1.

There is another reason possible for benzoin being the principal product. Cohen and Sherman (20) proposed a path, in the photoreduction of aromatic carbonyl compounds in basic solution, that leads to secondary alcohols rather than pinacols. Davidson and coworkers (21) suggested that triethylamine could act the same way in the photoreduction of fluorenone. The same path shown in Scheme 2 for benzil would lead to benzoin.

Stapelfelt and Perone (22), in a study of the photoelectrochemical behavior of benzil, have suggested that in the p*H* range 6.5–10 in aqueous methanol the reaction between the ketyl radical

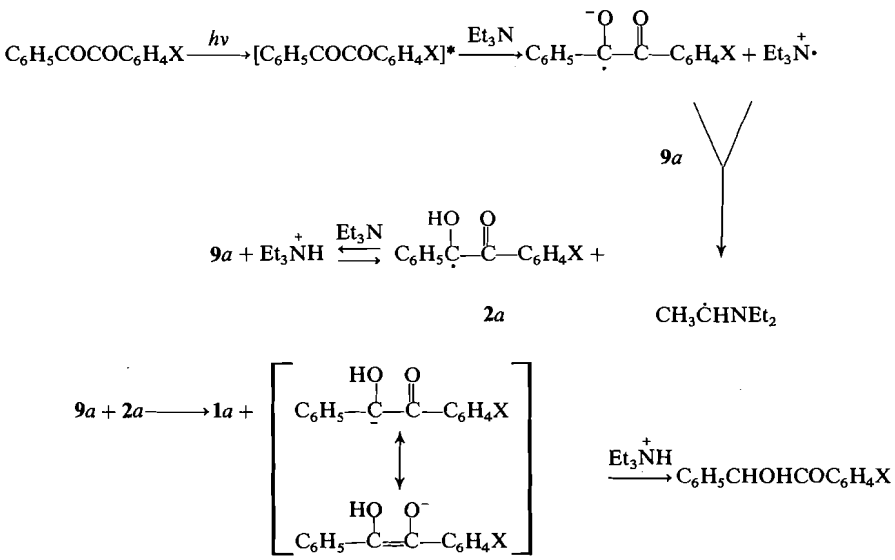

SCHEME 2

and radical anion leading to benzoin is the most important.

To see if it was possibly the geminate amine radical rather then triethylamine itself which was complexing the ketyl radical a series of runs was carried out in which an increasing amount of triethylamine was added to 2-propanol. These results are shown in Table 2.

First, it is seen in run 6 that when the concentration of triethylamine is only 0.2 m*M* that the benzil pinacol is almost completely suppressed. Since 4.9 mmol of benzil were lost, the 2-propanol must have provided the bulk of the hydrogen for the reduction. The conclusion is then that the amine is the species complexing with the ketyl radical **2** and thus preventing benzil pinacol formation. The alternative idea that **2** is being rapidly removed by triethylamine,

as in Scheme 2, thus preventing complex formation with benzil does not seem as likely. The benzil pinacol is almost completely gone but the benzoin yield has not picked up half of the difference. If Scheme 2 were followed the benzoin yield should have gone up more.

Second, as the triethylamine concentration rises, benzoin benzoate is no longer formed. This would appear to be because triethylamine, as suggested by Davidson and Lambeth (4) and Cohen and Baumgarten (23), is a much better hydrogen donor than 2-propanol and the ketyl radicals are removed by their abstracting a hydrogen from the solvent before the dissociation reaction can take place. Also as suggested earlier the triethylamine coordinated radical might have a smaller tendency to dissociate.

Third, there is a marked maximum in the rate of the reaction (quantum yield also since light conditions are constant) with the changing triethylamine concentration. This parallels the results of Cohen and Chao (24) who found that the rate of photoreduction of benzophenone by tertiary amines increased on dilution of the amine with benzene.[4] These authors ascribed the increase to the formation of light absorbing transients in the more concentrated solutions of the amine. It should be noted that there is also a maximum in the rate as the benzil concentration is varied, Table 1.

Three other amines were tried to see if they also caused suppression of benzil pinacol production. The results are shown in Tables 3–5. All three suppress benzil pinacol formation at low concentrations but pyridine requires a concentration of 200–300 times greater than triethylamine, tri-*n*-butyl amine, or quinuclidine. This agrees with the work of Davidson and Wilson (25) who suggest that amines solvate the $Ph_2\dot{C}OH$, and 9-hydroxyfluorenyl radicals. They further suggest that the amount of solvation depends on the basicity of the amine. Triethylamine (p*K* 10.7) is a much stronger base than is pyridine (p*K* 5.2). The tri-*n*-butyl amine and the

[4]The same effect has been noted for fluorenone (8–10).

†Benzaldehyde, benzoic acid, and dimer were not measured.

quinuclidine also cause a rise in the benzoin and a fall off in the benzoin benzoate similar to that caused by triethylamine. The pyridine however, shows no increase in the benzoin nor any fall in the benzoin benzoate. This is exactly what would be expected if the last two changes were due to easier abstraction of hydrogens from tertiary amines, pyridine having no hydrogens that may be easily removed.

If the suppression of benzil pinacol formation was due to Scheme 2 being in operation, even in the case of pyridine a corresponding rise in benzoin should have been noted. (Pyridine would enter at the reaction $\mathbf{2}a + C_5H_5N \rightleftarrows \mathbf{9}a + C_5H_5N^+$ after $\mathbf{2}a$ is formed by reaction with 2-propanol.) Since this was not observed, radical complexing by amines again seems more probable. Further evidence that the amines suppressed benzil pinacol formation by associating with the ketyl radicals was obtained in the following way. It is known that hydrocarbon quenchers are much less efficient in the photoreduction of benzophenone in amines than in alcohols (24, 26).

This lack of efficiency has been attributed (6) to a very fast electron transfer from the amine to the excited ketone as the first step in the photoreduction. The same lack of efficiency appears in benzil photolysis in triethylamine; the results of which are shown in Table 6. If the rate of reaction in run 30, Table 6, is compared with the interpolated value (11.0) between runs 2 and 3, Table 1, it is seen that the reduction caused by the pyrene is not very great. This is also shown if the rate of 31 is compared with the interpolated value (16.8) between runs 35 and 36, Table 7. On the other hand the rate reduction in run 32, where the triethylamine concentration is 0.0036 M in 2-propanol, is the same as the rate reduction in neat 2-propanol: compare run 33, Table 6, with run 5, Table 2.

Since the quenching in run 32 is the same as in neat 2-propanol we can conclude that at this amine concentration the initial chemical step

†Benzaldehyde, benzoic acid, and dimer were not measured.

in the photoreduction is a hydrogen transfer to the excited benzil from the 2-propanol. But the benzil pinacol formation is completely suppressed by that small amount of amine. The amine must then be intervening at the reactions of the ketyl radical.

It was also thought possible that salt formation between the ground state benzil and the triethylamine might be contributing to the fall in rate observed when both the amine concentration and benzil concentration were increased past the value where the maximum occurred. Attempts to obtain u.v. spectra were thwarted by the intense absorption of benzil in the concentration ranges at which the photolyses were carried out. Using *t*-butyl alcohol as a cryoscopic solvent (23) the following results were obtained. Benzil (7.55 mmol) was dissolved in 100 ml of *t*-butyl alcohol and a depression of 0.88° was observed. The calculated value then is 8.38 mmol. Similarly 28.8 mmol of triethylamine gave a depression of 3.00° which solution was calculated to contain 28.5 mmol. The same amounts of benzil and triethylamine were then dissolved together in 100 ml of *t*-butyl alcohol and a depression of 3.20° was observed. This depression corresponds to 30.4 mmol, which is less than 36.9, the sum of the two individual calculations. The conclusion is that there is a fairly strong interaction between benzil and triethylamine at these concentrations.

To see if there is a different effect of varying the benzil concentration when a more dilute amine is used as solvent, three runs were made with benzene diluted triethylamine. These results are shown in Table 7. There is now no decrease in rate with increasing benzil concentration but the effect of transients and/or salt formation are not easily separable.

Comparing runs 5 and 13 in Table 2, it is seen that the quantum yield of disappearance of benzil is almost the same in neat triethylamine as it is in neat 2-propanol. Taking ϕ_{dis} in 2-propanol as 0.11 (15) leads to ϕ_{dis} of 0.10 in triethylamine.

4-Hydroxybenzil Irradiations

4-Hydroxybenzil showed no appreciable photoreduction in 2-propanol, 50% cyclohexane–50% 2-propanol, or in *N*,*N*-dimethylformamide. It was photoreduced in triethylamine and the results are shown in Table 8. As with benzil the quantum yield of photoreduction depends on the initial concentration of 4-hydroxybenzil and shows a maximum around 0.06 *M*. At a concentration of 0.0478 mol in triethylamine and with Corning filter 7-39 the quantum yield of disappearance is 0.04. The principal product is again the corresponding benzoin. As the initial concentration of 4-hydroxybenzil is increased there is a decrease in 4,4′-dihydroxybenzil and benzaldehyde. Both of these products

would have to be formed via dissociation of the ketyl radical, Scheme 1, X = OH. Presumably 4-hydroxybenzoin is the major product for the same reason that benzoin is the major product of benzil photolysis in triethylamine. The decrease in the dissociation of the ketyl radical of 4-hydroxybenzil at higher initial concentrations suggests that the ground state molecule is involved somehow but no dimeric products were isolated.

Since the benzoin isolated is the 4-hydroxy (nearer the carbonyl group) rather than the 4′- it could be argued that reduction takes place on the carbonyl not conjugated with the 4-hydroxy group. However since both thermal reductions also give the 4-hydroxybenzoin it may just be the more stable isomer.

Since there is not enough benzaldehyde corresponding to the 4,4′-dihydroxybenzil there must be another product derived from benzaldehyde but we were unable to find it. Possibly some appears as benzoic acid although this product is formed under all conditions.

When the triethylamine was diluted with 2-propanol the rate increased and passed through a maximum as seen in Table 9. This is qualitatively similar to what is seen with benzil but the concentration of amine at which the maximum occurs is ten times as high. This again could be due to a combination of solvent effects and/or different concentrations of light absorbing transients at different initial concentrations. It is interesting that in run 51 where the molar ratio of 2-propanol to triethylamine was as high as 34, that the reduction proceeded at a rate greater than half that in neat triethylamine. Presumably the polarity of the solvent is about that of neat 2-propanol and that reduction still takes place argues for close association between the amine and the 2-hydroxybenzil. The effect of triethylamine on the photoreduction of 4-hydroxybenzil cannot then be just due to the changing polarity of the solvent. Using the same cryoscopic method as with benzil, 10.03 mmol of 4-hydroxybenzil gave a depression corresponding to 9.98 mmol. 4-Hydroxybenzil (10.03 mmol) and triethylamine (28.8 mmol) were dissolved together and the depression corresponded to 25.7 mmol. There is obviously a great degree of association.

Because such small amounts of triethylamine had such a marked effect on the photoreaction of 4-hydroxybenzil a few runs were made with 4-hydroxybenzophenone to see if the same effect could be observed. *p*-Hydroxybenzophenone in a solution of neat 2-propanol gave a rate of disappearance of 2.88 mmol/h for a 250 ml solution. Comparing this with run 5, Table 2, where the rate of disappearance of benzil is 12.8 mmol/h and the quantum yield of benzil disappearance is 0.11 (15), the calculated quantum yield of 4-hydroxybenzophenone is 0.013. This is fairly close to the 0.02 reported by Beckett and Porter (27) considering all the uncertainties in the present calculation.

It was found that as little as 0.1% triethylamine in the 2-propanol (mole ratio $1:1.82 \times 10^{-3}$) increased the rate of disappearance to 3.8 mmol/h, a 30% increase. Five percent added triethylamine increased the rate to 5.78 mmol/h. In neat 2-propanol there are two products as shown by t.l.c. The principal one is the corresponding pinacol. Enough of the minor could not be isolated for identification. Whenever there is triethylamine present there are three products besides the pinacol, one of them being the coupling product between the amine derived radical and the ketyl radical of the *p*-hydroxybenzophenone. Coupling in the presence of amines has been pointed out by Cohen *et al.* (5).

4,4′-Dihydroxybenzil Irradiations

Solutions of 4,4′-dihydroxybenzil in 2-propanol, 1:1 (v/v) cyclohexane:2-propanol, cyclohexane, and dimethylformamide were irradiated for 3 h. No significant changes were observed by the use of t.l.c. No reaction was found after a 2 h irradiation in a 1:1 (v/v) 2-propanol:triethylamine solution. Reaction occurred in a mixed solvent of cyclohexane:2-propanol, 5:1, and in neat triethylamine. In both of these solvents, however, the solubility was so low (approximately 2 m*M*) that product isolation was not attempted.

In two benzils studied, small amounts of triethylamine have a marked effect on the kinds of products and their relative amounts. Association between the amine and benzil seems to play an important but not well defined role. In the case of benzil itself the amine definitely complexes the intermediate ketyl radical.

To see if the same effect could be observed

57	0.5	1.08×10	0.150	13.9	7.9
58	1.0	2.15×10	0.150	7.0	1.4
59	10.0	2.15×10	0.150	0.7	0.0

*The volume was 500 ml 2-propanol in 55 and 300 in the rest. All solutions were 0.5 *M* biacetyl in 2-propanol with the amine added after. All runs were inert gas flushed. Temperature was 34–36°.

in a non-benzil system a few runs were carried out using biacetyl. These results are shown in Table 10.[5] All measurements were made by visual comparison of the intensity of the t.l.c. spots with those of standard solutions of biacetyl-pinacol at different concentrations and are therefore very approximate.[6] It appears that small amounts of triethylamine also cause a marked suppression of the production of biacetyl pinacol. This result is apparently opposite to that of Turro and Engel (28) who isolated biacetyl pinacol as a major product in the photolysis of biacetyl in tri-*n*-propyl amine. These results would indicate that the ketyl radical from biacetyl is also being complexed by triethylamine, preventing formation of the pinacol. This would be true whether the biacetyl pinacol is formed from dimerization of two ketyl radicals or some other mechanism involving the ketyl radicals. The reaction was carried to disappearance of the yellow color of biacetyl and therefore was not simply quenching of the reaction by the triethylamine.

Possible association in the ground state was checked in the same way as with the benzils. Triethylamine (0.359 mmol) was added to *t*-butyl alcohol and 0.332 mmol calculated from the freezing point depression. Biacetyl added: 0.575. Calculated: 0.725 mmol. Amine (0.359 mmol) and biacetyl (0.575 mmol) were added together for a total of 0.934 mmol. A value of 1.09 mmol was calculated from the freezing point depression which is very close to the sum of the individual calculated values. It was concluded that unlike the benzils there is no association in the ground state. Davidson and Wilson (25) suggest that the association of triethylamine with the ketyl radical of benzophenone and of fluorenone involves the hydroxy group of the radical so the apparent association with the radical but not biacetyl itself is consistent with this.

[5]These runs were made by Miss Mary Carol Losier.

[6]The spots were visualized with a diphenylpicrylhydrazyl spray and the densitometer could not be used.

The authors are pleased to acknowledge support by the National Research Council of Canada for this work and by the St. Francis Xavier University Council for Research for partial summer support of Miss Losier.

Reaction of *N*-Methyl-4-(2′-octoxy)pyridinium Iodide with Silver Oxide. Evidence for a Mechanism Involving a Pseudobase Intermediate

G. H. SCHMID AND A. W. WOLKOFF[1]

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 9, 1972

The reaction of optically active *N*-methyl-4-(2′-octoxy)pyridinium iodide with silver oxide results in the formation of optically active 2-octanol with 91% retention of configuration. A mechanism involving a pseudobase intermediate is consistent with this result.

La réaction de l'iodure de *N*-méthyl (octoxy-2′)-4-pyridinium optiquement actif avec l'oxyde d'argent a pour résultat la formation d'octanol-2 optiquement actif avec 91% de rétention de configuration. Un mécanisme faisant intervenir un intermédiaire pseudo-base est compatible avec ce résultat.

Canadian Journal of Chemistry, **50**, 2511 (1972)

In connection with a study of the mechanism of the thermal elimination reaction of *N*-methyl 4-alkoxypyridinium iodides (1, 2), we wanted to prepare the corresponding hydroxides. An attempt was made to prepare *N*-methyl-4-(2′-octoxy)pyridinium hydroxide (**1***b*) by treatment of the methiodide (**1***a*) with silver oxide in water, in much the same manner (3) that alkyltrimethylammonium iodides are converted to quaternary alkyltrimethylammonium hydroxides. This procedure did not yield the expected hydroxide but instead gave 2-octanol, indicating cleavage of the heteroaromatic ether.

This alcohol can arise by any (or a combination) of the three mechanisms shown in Scheme 1. Pathway 1 involves solvolysis of the substrate via a carbonium ion (S_N1), a route that was proposed by Vogel and Roberts (4) for the solvolysis of cyclopropylcarbinyl derivatives in ethanol. Nucleophilic attack by hydroxide ion (S_N2) at the secondary carbon (pathway 2) leads directly to 2-octanol. A third possibility involves attack of hydroxide ion on the pyridine ring (S_NAr) leading to intermediate **2**, which can then subsequently decompose to give 2-octanol. A mechanism involving nucleophilic displacement by iodide ion on the alkyl group is ruled out by the results of pyrolysis of *N*-methyl-4-alkoxypyridinium iodides (1, 2).

In order to determine which route was operative, the *N*-methyl-4-alkoxypyridinium iodide derived from optically active 2-octanol was synthesized. In Scheme 1, pathway 1 should lead to largely racemized alcohol. Pathway 2 should result in 2-octanol of inverted configuration, while pathway 3 should lead to an alcohol with retained configuration.

We wish to report that treatment of optically active methiodide (**1***a*) with silver oxide in cold water gave a 17% yield of optically active 2-octanol with 91% retention of configuration. Since the reaction proceeds with a high reten-

2

SCHEME 1. Possible mechanisms for cleavage of *N*-methyl-4-(2′-octoxy)pyridinium iodide.

tion of configuration, it may be concluded that little or no C_α—O bond breaking occurs, implying that pathway 3 is the major route for the formation of alcohol.

The reactions of aromatic nitro compounds with base have been shown (5) to involve Meisenheimer complexes. *N*-Alkyl derivatives would be expected to form similar complexes since the *N*-alkyl aza group and a nitro substituent both withdraw electrons from the ring by an inductive and conjugative mechanism. Evidence in support of such intermediates has been summarized by Illuminati (6). Recently Bunting and Meathrel (7) have presented evidence of the formation of pseudobases by the *N*-methyl cations of diazanaphthalenes. Our results are in accord with such a mechanism and indicate that this is the major route to the formation of 2-octanol in the hydroxide ion cleavage of *N*-methyl-4-(2′-octoxy)pyridinium iodide.

Experimental

Optical rotations were determined by means of a Perkin–Elmer 141 Polarimeter. Optically active 2-octanol was prepared by the method of Vogel (8). Elemental analyses were carried out by M. B. Gygli of Toronto, Ontario.

4-(d-2′-Octoxy)pyridine

This compound was prepared by a slight modification (2) of the method of Vogel and Roberts (4) to give 0.72 (76% yield) of the 4-alkoxypyridine, b.p. 98° (0.140 mm).

Anal. Calcd. for $C_{13}H_{21}ON$: C, 75.32; H, 10.21; N, 6.76. Found: C, 75.39; H, 10.29; N, 6.92.

Reaction of N-Methyl-4-(d-2′-octoxy)pyridinium Iodide with Ag_2O

To 0.72 g (3.48 mmol) of 4-(*d*-2′-octoxy)pyridine was added excess methyl iodide (3 ml; 48.1 mmol). After standing overnight, the excess methyl iodide was removed under vacuum to give 1.40 g of an orange oil. Previous work (2) with this material showed that the oil could not be induced to crystallize and so the material was used without further purification. To this oil was added 10 ml of water and 1.86 g (8.05 mmol) of silver oxide. The solution was allowed to stir for 4 h in an ice bath and then filtered. Distillation of the filtrate gave two layers. The distillate was extracted with ether, and the combined ether extracts dried over anhydrous magnesium sulfate. The ether was removed under vacuum to give 79 mg of 2-octanol, $[\alpha]_D^{23}$ 7.94 (*c* 4.0, EtOH), corresponding to 91% retention of configuration. No further purification of the material was attempted, meaning that 91% is a lower limit on the percent retention of configuration.

Continued support by the National Research Council of Canada is gratefully acknowledged.

The Thermolytic Generation of Benzofuran from *o*-Hydroxyacetophenone

O. A. MAMER

The Mass Spectrometry Unit, Royal Victoria Hospital, Department of Experimental Medicine, McGill University, Montreal, Quebec

Received April 4, 1972

The flash thermolysis of *o*-hydroxyacetophenone in a low pressure inert carrier occurs with an apparent rearrangement and subsequent elimination of water to yield benzofuran. A competing minor thermolytic pathway involves the elimination of the elements of acetaldehyde to yield cyclopentadienylidenecarbonyl. There appears to be little similarity between the mechanisms of the thermal and electron impact fragmentations.

La thermolyse flash de l'*o*-hydroxyacétophénone, dans un gaz vecteur inerte à basse pression, se produit avec un réarrangement apparent et une élimination subséquente d'eau pour conduire au benzofurane. Une voie thermolytique mineure et compétitive fait intervenir l'élimination de la portion acétaldéhyde avec obtention du cyclopentadiénylidéne carbonyle. De petites similitudes apparaissent entre les mécanismes de fragmentation thermique et ceux issus de l'impact électronique.

Canadian Journal of Chemistry, **50**, 2513 (1972)

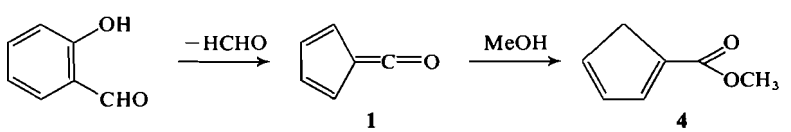
Cyclopentadienylidenecarbonyl (**1**) has been shown (1) to be the major thermolytic fragment of salicylaldehyde (Scheme 1). It was therefore anticipated that *o*-hydroxyacetophenone (**2**) might thermally fragment by a route analogous to Scheme 1.

An unexpected rearrangement and subsequent elimination of water represent the major pathway for the thermolysis of **2** in the interval 400–1100° and form the substance of this brief report.

Thermolyses of **2** were conducted in two modes, both previously described in detail (1). The first was in a low pressure helium flow in a quartz reactor attached through a helium separator to the ion source of a mass spectrometer. Slow scans at low ionizing energy (12 eV) of the furnace effluent permitted the detection of molecular ions of thermal fragments. Figure 1 shows the variation of the intensities of significant masses with furnace temperature.

The second thermolytic mode was semi-preparative in nature and involved the thermolysis of **2** in a low pressure argon carrier in a hot filament reactor. The reactor effluent was rapidly quenched by bubbling through methanol at −78°. The methanol solution was then analyzed by coupled gas chromatography–mass spectrometry (Fig. 2). Individual thermolytic runs were conducted over a series of filament temperatures from 600° (onset of incandescence) to the filament limit of approximately 1100°. Figure 2 represents the product analysis for a filament temperature of approximately 800°. With increasing wire temperature, the ratio of **3** to **2** and the proportion of hydrocarbon products both increase.

The consistently reproducible initial increase in the apparent intensity of *m/e* 136 (Fig. 1) with increasing furnace temperature suggests that **2** begins to rearrange above 400° to an intermediate having an increased ionization efficiency at 12 eV that subsequently decomposes above 700°. The rearrangement may involve acetyl group enolization and cyclization prior to the elimination of water. As *m/e* 136 decomposes, a fragment with *m/e* 118 is produced corresponding to the molecular ion of benzofuran (**3**) detected in the semi-preparative experiment. Relatively smaller increases in *m/e* 92



1 **4**

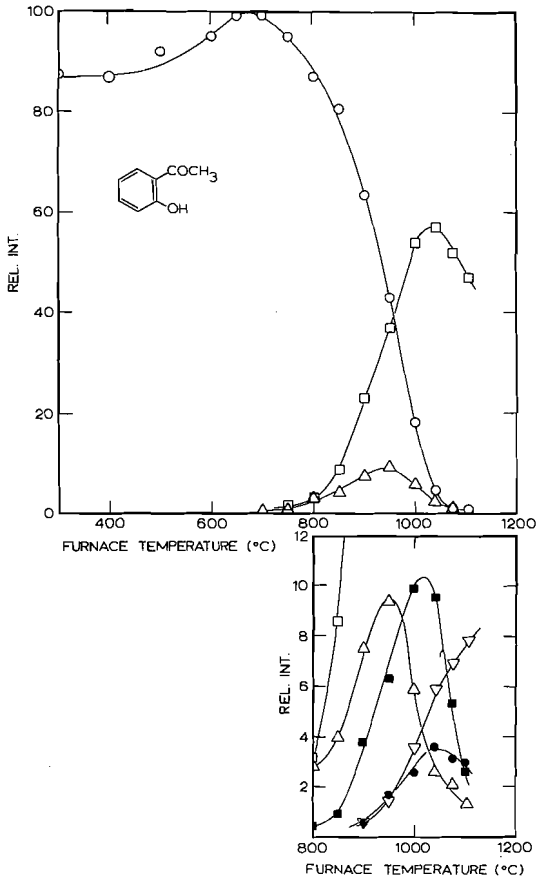

FIG. 1. Relative intensity of apparent molecular ions at 12 eV in furnace effluent *vs.* furnace temperature: ○, *m/e* 136, **2**; □, *m/e* 118, **3**; △, *m/e* 92, **1**; ■, *m/e* 130, $C_{10}H_{10}$; ●, *m/e* 64, **5**; ▽, *m/e* 66 and 128 coinciding, cyclopentadiene and naphthalene, respectively.

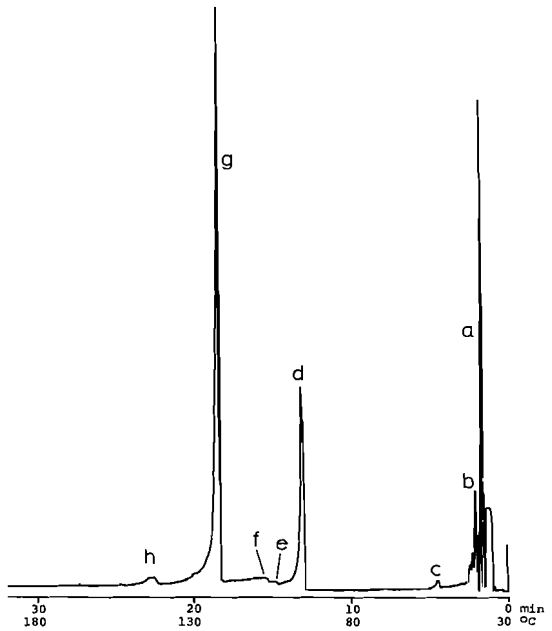

FIG. 2. Gas chromatographic record of the analysis by coupled g.c.–m.s. (LKB 9000) of the preparative scale methanol-trapped thermolysate of **2**. Analytical conditions: column, 72 × 0.25 in. glass, 3% OV-1 on chromosorb W, temperature programmed from 30 + 5°/min; injector and separator 280°; helium flow 35 ml/min; ion source, 290°, 70 eV at 60 μA. Peak assignments, confirmed by direct comparisons with authentic compounds: *a*, methanol tail; *b*, benzene; *c*, toluene; *d*, benzofuran (**3**); *e*, phenol; *f*, carboxymethylcyclopentadiene (**4**); *g*, *o*-hydroxyacetophenone (**2**); *h*, 1- and 2-methylnaphthalene. Peak *d* accounts for 73% of the integrated voltatile components in the preparative thermolysate (methanol and **2** excluded).

and the detection of a small yield of carboxymethylcyclopentadiene (**4**, the methanol adduct of **1**) confirm a minor thermolytic pathway of **2** via **1** and probably acetaldehyde.

In a manner similar to that reported in the thermolysis of salicylaldehyde (1), an increase in *m/e* 64 at the expense of *m/e* 92 supports the proposal of DeJongh and Brent (2) that at elevated temperatures **1** decarbonylates to yield cyclopentadienylidene (**5**). This same decarbonylation reaction has been noted in the electron-impact fragmentation of *o*-nitrobenzamide and *o*-nitroanisole (3).

Coincident with the rise of *m/e* 66, an ion at *m/e* 128 is probably naphthalene produced by the rearrangement of fulvalene (**6**), the dimer of **5**. In addition, the rise and fall of *m/e* 130 ($C_{10}H_{10}$ by % M + 1 and % M + 2 measurements) suggests that **6** may suffer addition of 1 mol of hydrogen and further thermolyze. At the upper limit of the furnace *m/e* 132 and 136 corresponding to $C_{10}H_{12}$ and $C_{10}H_{16}$ also show increases, further providing for the removal of *m/e* 130 by further hydrogenation.

Scheme 2, consistent with the experimental data, is proposed to account for the thermolysis of **2**. 2,3-Dihydrobenzofuran-3-ol (**7**) may be a transient species formed by a thermally induced intra-molecular addition of the phenolic hydroxyl moiety to the enolic unsaturation. If **7** plays an intermediate role in the formation of **3** from **2**, it probably would not survive the high

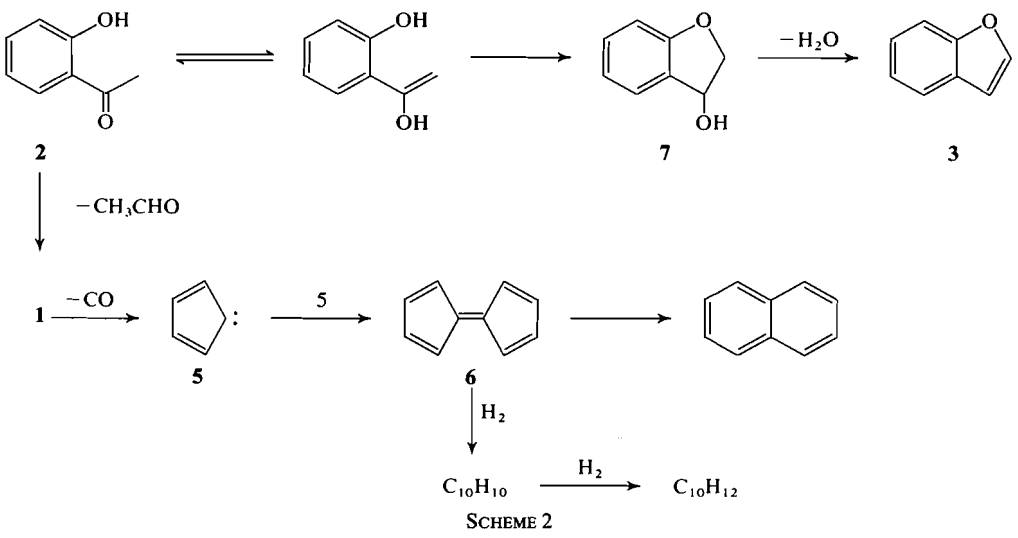
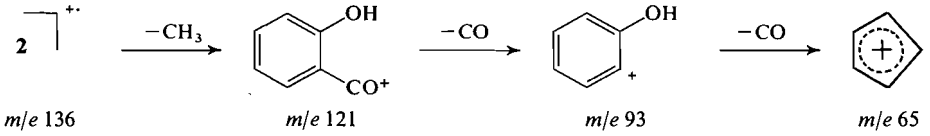


SCHEME 2



SCHEME 3

temperatures of the gas chromatographic inlet system in the analysis of the preparative thermolysate. Attempted distillation of **7** is reported (4) to result in the formation of **3** via water loss.

Scheme 3 outlines the metastable confirmed principal fragmentation route for radical cation **2** (mass spectrum, Fig. 3) and bears relatively little similarity to the thermal route for neutral **2**, particularly in the major initial processes.

There is an interesting parallel, however, between the neutral sequence:

$$136 \rightarrow 92 + CH_3CHO$$
$$92 \rightarrow 64 + CO$$

and the cationic sequence:

$$136^+ \rightarrow 121^+ + CH_3$$
$$121^+ \rightarrow 93^+ + CO$$
$$93^+ \rightarrow 65^+ + CO$$

Masses 93 and 65 might be considered to be protonated (and therefore cationic) 92 and 64, respectively. In the neutral fragmentation, however, there is no corresponding apparent accumulation of mass 120 (*i.e.* the deprotonated *m/e* 121 which is the 70 eV base peak of **2**). On the other hand there appears to be no cationic analogy to the thermal rearrangement and elimination of water. This fragmentation reac-

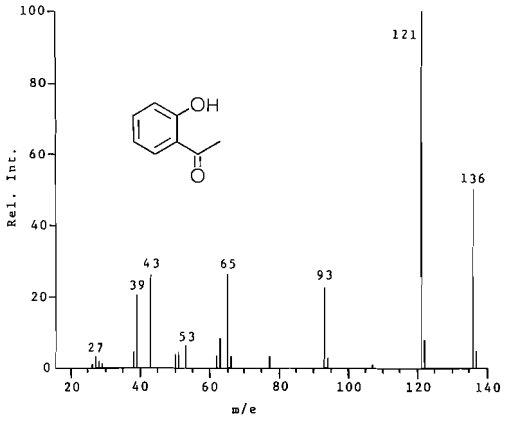


FIG. 3. Mass spectrum of *o*-hydroxyacetophenone at 70 eV. Relative intensities are insensitive to ion source temperature in the interval 150–310°.

Collisional Deactivation Rates of Electronically Excited Molecular Ions. III. O_2^+ ($b^4\Sigma_g^-$)

G. I. MACKAY, J. P. ANGLESEY, AND R. E. MARCH
Department of Chemistry, Trent University, Peterborough, Ontario

Received March 21, 1972

Electron beam excitation of oxygen was utilized to produce ions in the $b^4\Sigma_g^-$ state. Rate constants for the deactivation of $O_2^+(b^4\Sigma_g^-)$ for each of O_2 and N_2 were determined. Charge transfer is a possible mode of deactivation.

L'excitation de l'oxygène par un faisceau d'électrons a été utilisé pour produire des ions dans l'état $b^4\Sigma_g^-$. Les constantes de vitesse pour la désactivation de $O_2^+(b^4\Sigma_g^-)$ pour chaque O_2 et N_2 ont été déterminées. Le transfert de charge est un mode de désactivation possible.

Canadian Journal of Chemistry, **50**, 2516 (1972)

Thermal energy positive ion–neutral deactivation rate constants have been determined for electronically excited molecular oxygen ions, produced in a high energy electron beam. The apparatus has been described previously (1). Deactivation rate constants are presented for the O_2^+ ($b^4\Sigma_g^-$) ion deactivated by oxygen and nitrogen.

There are three known excited state transitions of O_2^+. The Hopfield system ($c^4\Sigma_u^- \rightarrow b^4\Sigma_g^-$) was not observed in our apparatus above 2000 Å. The first negative (1N) system ($b^4\Sigma_g^- \rightarrow a^4\Pi_u$) occurred strongly and the second negative (2N) system ($A^2\Pi_u \rightarrow X^2\Pi_g$) was observed also. It has been shown previously (2) that deactivation of some diatomic molecular ions possessing a single vibrational quantum appears to proceed at a rate which is slower by a factor of 2–3 in comparison to the respective rates for ions possessing zero or two such quanta. In order to avoid this effect with O_2^+, should it exist, the $\Delta v = -2$ band of the 1N system was selected for deactivation studies. The data, which are shown in Fig. 1, were treated as before, but were obtained with a slight modification. Whereas the signal intensity was previously taken as the integrated areas as recorded, in these experiments the signal was fed to a counter and the time to attain a given total count was recorded. This time is inversely proportional to the intensity.

The deactivation rate constant for parent molecules is obtained as a product with the radiative lifetime of the excited ion. Early determinations (3) of the lifetimes of the $v' = 0$, 1, and 2 levels were quite long and of the order of 1.2 μs. More recent work (4) suggests that these were lifetimes of cascade components and that the true lifetime of the $b^4\Sigma_g^-$ state is 170 ± 20 ns for $0 \leqslant v \leqslant 7$, while that of the $c^4\Sigma_u^-$ state is inferred to be 1.2 ± 0.2 μs.

On the basis of this latter value for the lifetime of the $b^4\Sigma_g^-$ state, the deactivation rate constant for parent molecules, k_1 was found to

The apparatus has been described previously (1). Deactivation rate constants are presented for the O_2^+ ($b^4\Sigma_g^-$) ion deactivated by oxygen and nitrogen.

There are three known excited state transitions of O_2^+. The Hopfield system ($c^4\Sigma_u^- \rightarrow b^4\Sigma_g^-$) was not observed in our apparatus above 2000 Å. The first negative (1N) system ($b^4\Sigma_g^- \rightarrow a^4\Pi_u$) occurred strongly and the second negative (2N) system ($A^2\Pi_u \rightarrow X^2\Pi_g$) was observed also. It has been shown previously (2) that deactivation of some diatomic molecular ions possessing a single vibrational quantum appears to proceed at a rate which is slower by a factor of 2–3 in comparison to the respective rates for ions possessing zero or two such quanta. In order to avoid this effect with O_2^+, should it exist, the $\Delta v = -2$ band of the 1N system was selected for deactivation studies. The data, which are shown in Fig. 1, were treated as before, but were obtained with a slight modification. Whereas the signal intensity was previously taken as the integrated areas as recorded, in these experiments the signal was fed to a counter and the time to attain a given total count was recorded. This time is inversely proportional to the intensity.

The deactivation rate constant for parent molecules is obtained as a product with the radiative lifetime of the excited ion. Early determinations (3) of the lifetimes of the $v' = 0$, 1, and 2 levels were quite long and of the order of 1.2 μs. More recent work (4) suggests that these were lifetimes of cascade components and that the true lifetime of the $b^4\Sigma_g^-$ state is 170 ± 20 ns for $0 \leqslant v \leqslant 7$, while that of the $c^4\Sigma_u^-$ state is inferred to be 1.2 ± 0.2 μs.

On the basis of this latter value for the lifetime of the $b^4\Sigma_g^-$ state, the deactivation rate constant for parent molecules, k_1 was found to

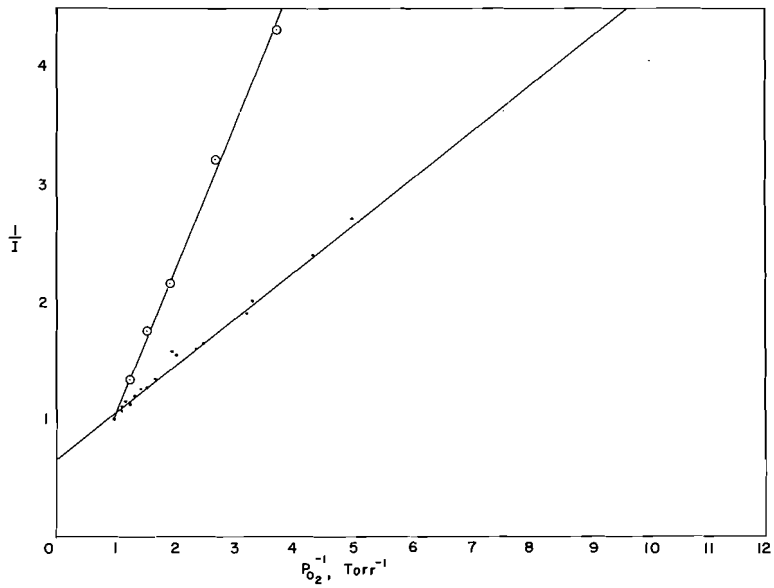

FIG. 1. Plot of the reciprocal intensity (arbitrary units) of the $\Delta v = -2$ band of the O_2 1N system *vs.* reciprocal oxygen pressure: dots, pure oxygen; circled dots, oxygen plus nitrogen, total pressure = 1 Torr.

be $18 \pm 6 \times 10^{10}$ l mol^{-1} s^{-1}. However, no attempt was made to determine the nature of the products. Therefore on the basis of the evidence available it was not possible to distinguish between various plausible contributing modes of deactivation, for example charge transfer.

$$[1a] \qquad O_2^+(b^4\Sigma_g^-)_{v' \geq 2} + O_2 \rightarrow O_2 + O_2^+(X) \qquad k_{1a}$$

or collision induced radiationless transitions, such as

$$[1b] \qquad O_2^+(b^4\Sigma_g^-) + O_2 \rightarrow O_2^+ A^2\Pi_u + O_2 \qquad k_{1b}$$

$$[1c] \qquad \rightarrow O_2^+ a^4\Pi_u + O_2 \qquad k_{1c}$$

Similarly for deactivation of the $b^4\Sigma_g^-$ state with nitrogen, it was not possible to distinguish between charge transfer,

$$[2a] \qquad O_2^+(b^4\Sigma_g^-) + N_2 \rightarrow N_2^+(X) + O_2 \qquad k_{2a}$$

collision induced radiationless transitions, such as

$$[2b] \qquad O_2^+(b^4\Sigma_g^-) + N_2 \rightarrow O_2^+ A^2\Pi_u + N_2 \qquad k_{2b}$$

$$[2c] \qquad \rightarrow O_2^+ a^4\Pi_u + N_2 \qquad k_{2c}$$

or atom exchange

$$[2d] \qquad O_2^+(b^4\Sigma_g^-) + N_2 \rightarrow NO^+(X) + NO \qquad k_{2d}$$

Reactions 2*a* and 2*d* are both exoergic to the extent of some 2.8 and 2.4 eV, respectively, for $b^4\Sigma_g^-$ state ion in the $v' = 2$ vibrational level. The total deactivation rate constant, k_2, was found to be $24 \pm 8 \times 10^{10}$ l mol^{-1} s^{-1}.

The total deactivation rate constants obtained are in fair numerical agreement with the theoretical values of the collision rate constant $k_c = 2\pi e(\alpha/\mu)^{1/2}$ where α is the polarizability of the neutral molecule and μ is the reactant reduced mass. For reaction 1, $k_c = 44 \times 10^{10}$ l mol^{-1} s^{-1} while for reaction 2, $k_c = 47 \times 10^{10}$ l mol^{-1} s^{-1}. It should be emphasized that although there is no clear reason for assuming that either rate constant should be equal to k_c, it is gratifying to note that k_c is not substantially exceeded.

The Structure of $Na_4P_2O_7$ at 22 °C

K. Y. LEUNG AND C. CALVO

Department of Physics, McMaster University, Hamilton, Ontario

Received January 5, 1972

At room temperature $Na_4P_2O_7$ crystallizes in the orthorhombic space group $P2_12_12_1$ with $a = 9.367(5)$, $b = 5.390(2)$, $c = 13.480(8)$ Å, and $z = 4$. The structure was refined by full-matrix least-squares using 1337 reflections measured with a Syntex Automatic diffractometer. The final R value is 0.022. The anion has nearly an eclipsed configuration with a P—O—P angle of 127.5(1)°. The two bridging P—O bond lengths are 1.631(2) and 1.642(2) Å with terminal P—O bond lengths averages of 1.512 and 1.514 Å on either side of the anion. Two of the four Na^+ ions are coordinated to five oxygen atoms while the remainder are coordinated to six oxygen atoms. The structure contains chains of cations with four nearly collinear Na^+ per cell paralleling the c axis. These are surrounded by six anions with the bridging oxygen atoms lying approximately at the corners of an octahedron with the P—P vector of the anion also paralleling the c axis. Adjacent anions along the c axis are separated by a pair of Na^+ ions.

A la température de la pièce, $Na_4P_2O_7$ cristallise sous la forme du groupe spatial $P2_12_12_1$ orthorhombique, où $a = 9.367(5)$, $b = 5.390(2)$, $c = 13.480(8)$ Å et $z = 4$. Nous avons raffiné la structure par la méthode de la matrice pleine par moindres carrés, au moyen de 1337 réflexions mesurées par un diffractomètre syntex automatique. La valeur finale de R est 0.022. L'anion possède une configuration quasi-éclipsée, l'angle P—O—P étant de 127.5(1)°. La longueur des deux liaisons P—O pontées est de 1.631(2) et 1.642(2) Å et la moyenne des liaisons P—O terminales est de 1.512 et 1.514 Å, d'un côté ou l'autre de l'anion. Deux parmi les quatre ions Na^+ sont coordonnés à cinq atomes d'oxygène tandis que les autres sont coordonnés à six atomes d'oxygène. La structure contient des chaînes de cations où quatre Na^+ par maille sont presque colinéaires et parallèles à l'axe c. Ils sont entourés de six anions et les atomes d'oxygène servant de pont sont situés approximativement aux coins d'un octaèdre, où le vecteur P—P de l'anion est aussi parallèle à l'axe c. Les anions adjacents le long de l'axe c sont séparés par des paires d'ions Na^+.

Canadian Journal of Chemistry, **50**, 2519 (1972)

Introduction

Although a large number of crystallographic studies have been devoted toward elucidating the phases and phase transformations of $M_2X_2O_7$ and MX_2O_7 systems, where X ions are tetrahedrally coordinated, the $M_4X_2O_7$ system has largely been ignored. Various members of this series show phase transformations, for example $Li_4P_2O_7$ (1), $Li_4As_2O_7$ (2), and $Na_4As_2O_7$ (3). However, $Na_4P_2O_7$ with four transformations, as determined by differential thermal analysis (4), thermal expansion (5) and recent crystallographic studies (6) seem to be the most complex.

Crystal Data for $Na_4P_2O_7$ at 22 °C:

$Na_4P_2O_7$ molecular weight = 265.91

Space group, $P2_12_12_1$; orthorhombic, $a = 9.367(5)$, $b = 5.390(2)$, $c = 13.480(8)$ Å;[1] $V = 680.58$ Å^3, $z = 4$, $\rho_c = 2.595$ g/cm^3, $\rho_m = 2.53$ g/cm^3.

Experiments

Crystals of $Na_4P_2O_7$ were grown from a melt prepared from $Na_4P_2O_7 \cdot 10H_2O$. The crystals varied from colorless to pale blue-green depending upon the run, and often occurred in the form of flakes.

The structure was determined with 493 unique data points obtained from integrated precession photographs taken with MoKα radiation. The trial structure was determined by direct methods using the procedures of Karle and Hauptman (7). This model was refined by weighted full-

[1]Determined from a least-squares fit of fifteen 2θ values measured with the Syntex Automatic diffractometer using MoKα radiation ($\lambda = 0.71069$ Å).

matrix least-squares to a final R value of 0.109 with individual isotropic temperature factors.

A second data set, consisting of 1337 symmetry independent reflections, was recorded utilizing a Syntex automatic diffractometer and graphite monochromatized MoKα radiation. The crystal used was ground to a sphere of radius 0.25 mm. The peaks were scanned in a θ–2θ mode at a variable rate, from 2 to 24° per min depending upon the peak intensity. Data were recorded up to a sin θ/λ of 0.77 $Å^{-1}$. Backgrounds were measured at either side of the peak for the same period of time as the peak scan. Reflections whose intensity, corrected for background, exceeded 3σ were considered observed. The remaining reflections were assigned a maximum possible value of 3σ, with those whose apparent intensity was negative inserted only in the very last few cycles. The data were corrected for absorption, Lorentz and polorization effects. The final coordinates obtained with the film data were used as initial parameters and were refined by full matrix least-squares using a program written by Stephens for the CDC 6400. Atomic scattering factors curves for Na^+, P^{3+}, and O^- were taken from the International Tables for Crystallography (8). Unit weights were chosen since there seemed to be no systematic variation in $|F_o - F_c|$ with F_o. When a minimum had been obtained with isotropic temperature factors the refinement was completed with individual anisotropic thermal parameters. The final R value, determined when the maximum shift was less then 0.2σ, was 0.022 ($R\omega = \{\Sigma\,\omega(|F_o|-|F_c|)^2/\Sigma\,\omega F_o^2\}^{1/2} = 0.027$). The final atomic parameters are found in Table 1. Table 2 contains the calculated and observed structure factors.[2] Sixteen reflections too strong to be measured with the diffractometer are included in Table 2, but excluded from the refinement, with their film measured values. A final difference electron density map showed no residual peaks larger than 0.1 of an oxygen atom peak.

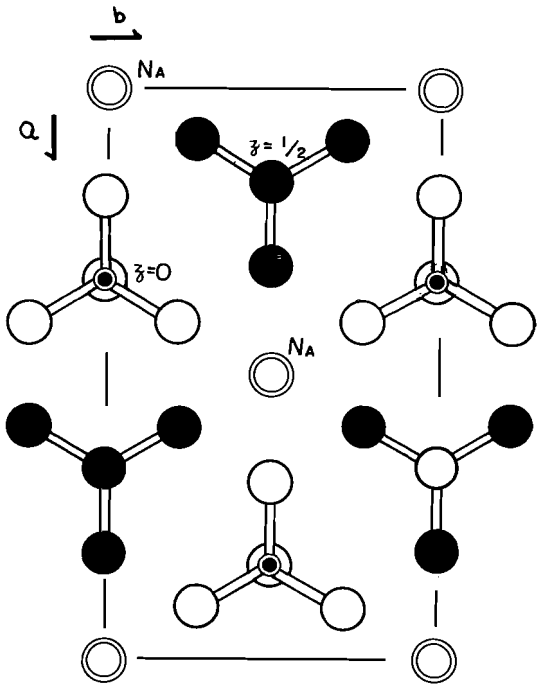

FIG. 1. The idealized structure of $Na_4P_2O_7$ projected onto the *ab* plane. The large circles represent oxygen atoms with the pyrophosphate anion in an eclipsed configuration. The large circles are oxygen atoms. Those bonded to the anion with the bridging oxygen atom at $z = 1/2$ are indicated by filled circles while those attached to the pyrogroup at $z = 0$ are shown as open circles. The small filled circles represent two superimposed phosphorus atoms. The Na ions collinear with these pyrogroups are not indicated.

Description of the Structure

The structure of anhydrous sodium pyrophosphate can be described as a deviant from a simple idealized structure shown in Fig. 1. This ideal structure consists of diphosphate ions formed by a pair of PO_4^{3-} groups sharing a bridging oxygen atom with a P—O—P angle of 180°. The oxygen atoms of the anion are in an eclipsed configuration as viewed down the P—P vector, with this vector paralleling the c axis. These anions lie in layers such that the bridging oxygen atoms lie at the corners of an octahedron elongated parallel to the c axis with adjacent layers related by a 6_3 axis. Chains of Na^+ ions coincide with the 6_3 axis with Na(1) coplanar with the bridging oxygen atoms and Na(2) lying in an octahedral site between layers formed by the terminal oxygen atoms of six separate anions. The terminal oxygen atoms are coplanar with the plane containing the anion and the chain of cations. Two additional Na^+ ions per formula units, Na(3) and Na(4), are collinear with the P—P vectors separating pyrogroups in adjacent cells along the c axis.

Na(1) in this idealized structure has a coordination number of nine as a result of sharing the bridging oxygen atom and one terminal oxygen atom from each end of three pyrogroups. This configuration, with the bridging oxygen atom lying $b/\sqrt{3}$ Å from three Na(1) ions, is unstable towards a bent anion where the Na(1) ion forms a strong bond with only one bridging oxygen atom. It is of interest that an infinite number of configurations are possible for an infinite layer where the only constraint is that each Na(1) is bonded to one and only one bridging oxygen atom, and visa versa. If

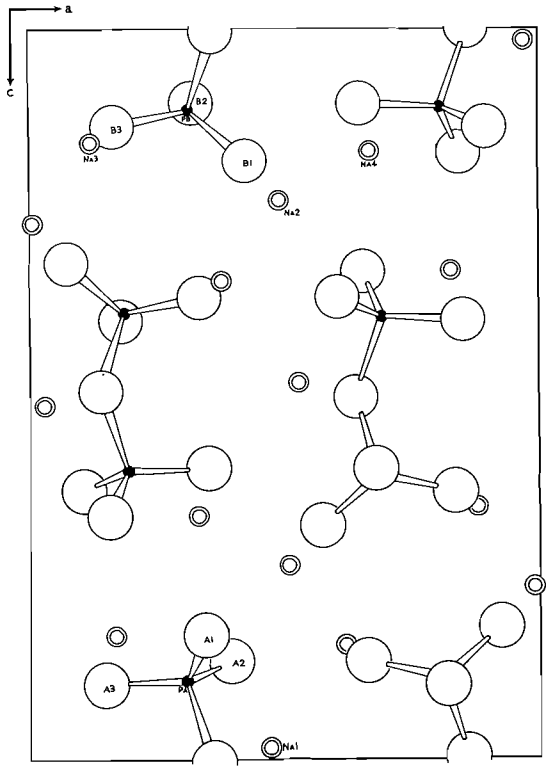

FIG. 4. The structure of $Na_4P_2O_7$ projected onto the *ac* plane. The details are the same as for Fig. 3.

the further constraints of translational periodicity corresponding to the determined *a* and *b* axes are imposed three configurations are possible. The arrangement shown in Fig. 2(*a*) is found in the present structure while that in Fig. 2(*b*) is found in the structure at 400 °C. The configuration seen in Fig. 2(*c*) consistent with either a 2_1 axis or a centering in the layer has not been found as yet.

Since the diphosphate ion bends at the bridging oxygen atom the plane of the terminal oxygen atoms no longer coincides with the *ab* plane. In addition, the two ends of the anion twist slightly destroying the eclipsed configuration and the anion rotates as a whole so that the P—P vector is no longer collinear with the *c* axis. However, as can be seen in Fig. 3, the gross features of the idealized model remain in the present structure. These distortions lead to coordination numbers of five for Na(3) and Na(4) rather than three as expected from the idealized model. See Fig. 4.

Na(1) shares two oxygen atoms with three pyrophosphate ions and shows bond lengths ranging from 2.313(2) to 2.777(2) Å. See Table 3. As predicted this ion shares oxygen atoms from either end of two anions and shares an edge with one of the tetrahedra of a third anion. One of the oxygen atoms in this edge is a bridging oxygen atom. The second cation, Na(2), lies at the center of a distorted octahedron formed by six oxygen atoms arising from six separate anions. The bond lengths range from 2.347(2) to 2.687(2) Å. The environment of Na(3) consists of a very irregular arrangement of five oxygen atoms contributed by four separate anions. Here the bond lengths range from 2.272(2) to 2.441(2) Å for the four shorter Na—O bonds and 2.888(2) Å for Na(3)–O(A1*b*). The five neighbouring oxygen atoms to Na(4) also arise from four separate anions but with the tighter range 2.333(2) to 2.580(2) Å.

The P—O bridging bond lengths at 1.631(2) Å for side A and 1.642(2) Å for side B are significantly longer than the terminal P—O bond lengths which all lie between 1.512 and 1.514 Å. The individual terminal P—O bond lengths are insignificantly different. The P—O—P bond angle, at 127.5(1)°, is the smallest reported for a diphosphate ion. As commonly found for this anion the O—P—O bond angles involving the bridging oxygen atom are less than the ideal tetrahedral value in every case while those involving only terminal oxygen atoms are all larger than the ideal.

Discussion

It is of some interest to compare the geometries of the $P_2O_7^{4-}$ ion in the three sodium pyrophosphates studied to date. In $Na_4P_2O_7 \cdot 10H_2O$(9) the anion has a nearly staggered configuration with crystallographic two-fold axis through the bridging oxygen atom. The P—O—P bond angle is 130.2° while the O—P—O angles involving the bridging oxygen atom range from 101.8 to 108.9° The O—P—O angles among only terminal oxygen atoms range from 111.1 to 115.0°. The average terminal P—O bond length is 1.513 Å while the P—O(—P) bond is 1.612(5) Å long. The two unique Na^+ ions are coordinated to six oxygen atoms but only one is bonded directly to the anion; involving O(2) and O(4). These

*Transformations: $a = x, y, z$; $b = 1/2 + x, 1/2 - y, -z$; $c = x, -y, 1/2 + z$; $d = 1/2 - x, 1/2 + y, 1/2 - z$. Calculated from diagonal elements of least squares matrix and including e.s.d.'s in unit cell parameters.
†Includes all interactions less than 3.0 Å except a PA—Na(4) interaction of 2.998 Å.

P—O bonds are the longer of the three at 1.510 and 1.526 Å, respectively, although they do not differ significantly from the remaining terminal P—O bond length of 1.503 Å.

In $Na_2H_2P_2O_7 \cdot 6H_2O$(10) the anion again contains a crystallographic two-fold axis and has a nearly staggered configuration. The P—O—P bond angle is 136.1° with O(bridge)—P—O angles ranging from 103.4 to 108.8°. The remaining O—P—O angles of the PO_4 group range from 109.9 to 117.7°. The terminal P—O(—H) bond is 1.569(2) Å long while the remaining terminal P—O bond lengths are within 0.002 of 1.493 Å. These two oxygen atoms are bonded to the sodium ion which is coordinated to a total of six oxygen atoms. In this case the P—O(—P) bond is shortened to 1.598(1) Å.

*Reference 9.
†Reference 10.

In Table 4 the results for these two structures and $Na_4P_2O_7$ are compared with the predictions of Baur (11). In no case have thermal corrections been made. It is clear that these predictions are, except with a few glaring exceptions, not far off the mark. In particular, the predicted value for the P—O(A1) bond length in $Na_4P_2O_7$ results from including the two rather long Na—O bonds in the counting. It is clear that weighting the contribution to the electrostatic bond strength by some function inversely related to the atomic separation would improve the agreement. The P—O—P bond angle is small in $Na_4P_2O_7$ probably because the bridging oxygen atom is coordinated to Na^+. A similar effect has been noted in comparing the $Zn_2V_2O_7$ structure (12) to those of $Mg_2V_2O_7$(12) and $Co_2V_2O_7$(13). This effect can be rationalized in the sense that Baur's (11) relationship would predict a lengthened P—O(—P) bond while Cruickshank's considerations (14) suggest that as the ratio of P—O(—P) to P—O increases, the P—O—P angle must contract.

In Table 5 are found data on the principle axes of vibration of the atoms in the $Na_4P_2O_7$ structure. The major components of vibration for P(A), P(B), and O(CE) are in the *ab* plane as would be expected either from the nature of the bonding or if some errors occur in the directions of the bending of the anion relative to the idealized structure. The fact that Na(1) vibrates nearly isotropically and with an

amplitude comparable to the remaining cations suggests that the structure has very little residual configurational disorder at room temperature. The thermal motions of the oxygen atoms are significantly anisotropic with the largest component nearly perpendicular to the P—O bond.

A plurality of phases can be generated by the manner in which bent pyrophosphate ions correlate in a layer and how adjacent layers correlate along the *c* axis. A number of these phases have been identified and the one found at the highest temperature is a disordered structure with an average structure corresponding to that of the "ideal" $Na_4P_2O_7$ (6). Details concerning these phases and phase transformations will be treated elsewhere.

CN Emission in Active Nitrogen. II. The Role of Energy Transfer and Atom Transfer Reactions in $CN(X^2\Sigma^+)$ Excitation

G. M. PROVENCHER AND D. J. MCKENNEY

Department of Chemistry, University of Windsor, Windsor, Ontario

Received July 27, 1971[1]

A simplified mechanism is presented for excitation of ground state $CN(X^2\Sigma^+)$ formed from carbonaceous impurity in flowing N_2 subjected to a microwave discharge.

Analysis of absolute intensity data from spectrometer recordings of $CN(B^2\Sigma^+ \rightarrow X^2\Sigma^+)$ violet band emission enabled order of magnitude estimates of rate constants for $CN(X^2\Sigma^+)$ excitation by energy transfer from vibrationally excited ground state nitrogen, N_2^*

[5] $$N_2^* + CN(X^2\Sigma^+) \rightarrow CN^*(B^2\Sigma^+) + N_2 \qquad k_5 = 10^{13}\ \text{cm}^3/\text{mol s}$$

and formation of electronically excited NCN* in a three body reaction

[8] $$N + CN + M \rightarrow NCN^* + M \qquad k_8 = 10^{16}\ \text{cm}^6/\text{mol}^2\ \text{s}$$

Energy transfer from $N_2(A^3\Sigma_u^+)$ is shown to be a minor source of excitation of CN to radiative levels. $N_2(A)$ is a source of vibrationally excited ground state nitrogen, N_2^*, which in turn excites CN. Vibrational population profiles under all conditions in this work are shown to be primarily a function of $[N_2^*]$. Evidence for the participation of the $A^2\Pi$ state of CN is shown in the population maxima at $v = 4$ and 10 of the $B^2\Sigma^+$ state.

Un mécanisme simplifié est donné pour l'excitation de l'état fondamental $CN(X^2\Sigma^+)$ formé à partir d'impureté carbonée dans un flux d'azote, soumis à une décharge microonde.

L'analyse des données sur l'intensité absolue à partir des enregistrements du spectromètre de la bande d'émission violette de $CN(B^2\Sigma^+ \rightarrow X^2\Sigma^+)$, rend possible des estimations sur l'ordre de grandeur des constantes de vitesse pour l'excitation de $CN(X^2\Sigma^+)$ par une énergie de transfert de l'état fondamental de l'azote, vibrationnellement excité N_2^*

[5] $$N_2^* + CN(X^2\Sigma^+) \rightarrow CN^*(B^2\Sigma^+) + N_2 \qquad k_5 = 10^{13}\ \text{cm}^3/\text{mol s}$$

et la formation de NCN* électroniquement excité, dans une réaction à trois constituents

[8] $$N + CN + M \rightarrow NCN^* + M \qquad k_8 = 10^{16}\ \text{cm}^6/\text{mol}^2\ \text{s}$$

On montre que l'énergie de transfert à partir de $N_2(A^3\Sigma_u^+)$ est une source mineure dans l'excitation de CN aux niveaux radiatifs. $N_2(A)$ est une source pour l'état fondamental de l'azote, vibrationnellement excité, N_2^* qui à son tour excite CN. On montre que les profils de population vibrationnelle, dans toutes les conditions de ce travail, sont principalement une fonction de $[N_2^*]$. La preuve d'une participation de l'état $A^2\Pi$ du CN est montrée par le maximum de population à $v = 4$ et 10 dans l'état $B^2\Sigma^+$.

Canadian Journal of Chemistry, **50**, 2527 (1972)

Introduction

In the past decade several investigators (1–5) have advanced a variety of explanations to account for CN radical emission generated in "active" nitrogen systems. The mechanism is known to be complex and appears to be a function of "fuel", pressure, and relative concentration of reactants (5). These parameters can be characterized by specific vibrational population profiles in the upper states of the two observed band systems. Bayes (4) labeled the distributions P_1 and P_2 for the CN red $(A^2\Pi \rightarrow X^2\Sigma^+)$ system and subsequently Setser and Thrush (1) used designations P_1' and P_2' to identify the corresponding profiles in the violet $(B^2\Sigma^+ \rightarrow X^2\Sigma^+)$ bands. More recently Iwai *et al.* (5) found still a third distribution which they called P_3 and P_3' for the red and violet

systems, respectively. This latter profile known as the "blue flame" distribution does not depend on the nature of the fuel but occurs at low fuel concentrations (less than 0.05%) and higher (above 1 Torr) pressures.

The blue flame features enhanced intensity of the violet emission relative to the red, maxima in vibrational populations of the A state at $v = 7$, for the B state of CN at $v = 7$ and the appearance of a well developed tail band system ($5 \leqslant v \leqslant 15$) in the ($B^2\Sigma^+ \rightarrow X^2\Sigma^+$) emission. Evidence collected by all groups indicates the involvement of at least two distinct processes responsible for excitation of CN to appropriate radiative levels. Boden and Thrush (2) postulated excitation of ground state CN by a combination of steps involving the metastable $N_2(A^3\Sigma_u^+)$ and ground state $N_2(X^1\Sigma_g^+)$ in high vibrational levels. Meyer and Setser (6) have proposed, however, that A state nitrogen is not a major energy transfer agent in CN excitation. Our earlier results (7) and evidence presented in this paper suggest blue flame emission arises as a result of energy transfer to $CN(X)$ by vibrationally excited ground state nitrogen, $N_2^{\neq}$, and through a transfer reaction involving the free radical NCN. Vibrational population profiles obtained suggest that excitation of $CN(B^2\Sigma^+)$ levels is significantly dependent on transfer from the $CN(A^2\Pi)$ state in agreement with Radford and Broida (8) and Brown and Broida (9).

Experimental

The flow system consisted of a reactor, illustrated previously (7), attached to an ancillary glass system evacuable to 1 μTorr pressure. Flow was maintained by a fast (425 l/min) mechanical pump and controlled with a large stopcock. Inlet flows were adjusted and monitored by means of calibrated, capillary flow meters and Matheson needle valves. Pressure measurement was accomplished with an H_2SO_4 manometer. Total pressures were typically 1.5 Torr for "low pressure" work and 5.0–10 Torr for data referred to as "high pressure". Nitrogen flow rate through the discharge was 110 μmol s^{-1} for all experiments while added gases were admixed at 0–10 μmol s^{-1}. Linear flow rates ranged from 3 to 19 cm s^{-1} in the large reactor. Both linear and bulk flow rates were calculated assuming ideal gas conditions.

The spectrometer system was a 0.3 m McPherson scanning monochromator positioned to observe the afterglow emission down the long axis of the reactor. The monochromator exit slit was covered by an RCA 1 P28 photomultiplier tube mounted in a Pacific Photometric housing. The signal from the tube was fed to a Keithley model 417 picoammeter for amplification and subsequent display on a Keithley model 370 strip chart recorder. Survey spectra were frequently recorded over the interval 2000 Å $\leqslant \lambda \leqslant$ 6500 Å to insure detection of pertinent features and possible impurity (*e.g.* NO emission). All kinetic data presented were obtained by scanning the $\Delta v = 0$ sequence of the CN violet bands and then switching rapidly to the region 5000–5900 Å for the signal intensity at 5074 Å ($Hg(6^3P_0 \rightarrow 6^1S_0)$ second order) and/or that at 5804 Å (N_2, $B^3\Pi_g \rightarrow A^3\Sigma_u^+$ (11, 7) transition). For all but high resolution studies a 100 μ entrance and exit slit width was employed. High resolution spectra were taken with the slits adjusted to 10 μ. Matheson "certified" (g.c. analysis furnished) nitrogen was passed over 450 °C copper turnings, through a column packed with P_2O_5 and then through two successive refrigerated (77 °K) traps, the first packed with glass wool covered with apiezon grease – silica gel, the second filled with glass wool. The absence of detectable NO emission under all kinetic conditions indicated an estimated upper limit of $\sim 10^{11}$ atoms/cm^3 for O atoms. NO and CH_4 added to the afterglow were first passed through a P_2O_5 column and then subjected to several freeze, thaw, pump cycles at reduced pressure. Nitrogen (Matheson "high purity") added at the inlet jet was used without further purification. (In experiments using mercury the nitrogen carrier was first saturated with mercury at ambient temperature before admixture.)

The discharge–afterglow was established using a "Microtron 200" (Electro Medical Supplies) microwave generator which coupled 2450 MHz power to the flowing gas by means of a foreshortened quarter-wave coaxial cavity. This type of cavity is known (10) to show less than 1% reflected power over the full range of experimental parameters encountered in this work.

Conversion of raw intensity data to rate constants or concentrations was accomplished by comparison with NO emission developed in this reactor of appropriate wavelength regions of the spectra of interest according to an extension of the method of Fontijn *et al.* (11) by Gross and Cohen (12). The CN violet $\Delta v = +1$ sequence and the NO β (0,10) band were compared over the interval 3570 Å $\leqslant \lambda \leqslant$ 3600 Å. The partial rate constant for the chosen NO band as reported in ref. 12 was adjusted to account for the fact that only 80% of the total emission intensity of this band was used in the comparison.

Intensity maxima of selected bands were monitored as a function of various parameters. Bands were chosen so as to minimize the effect of overlap and while it is recognized that changes in rotational temperature due to rotational perturbations and relaxation could lead to some error in the calculation of relative population of vibrational levels from band head intensities, it is felt that the magnitude of such error would be small at the pressures used in this work.[2]

Intensities were converted to relative populations through the use of the expression derived from Nicholls (14).

$$\frac{N_{v'}}{N_0} = \frac{I_{(v',v'')}}{I_{(0,0)}} \frac{\nu^4_{(0,0)}}{\nu^4_{(v',v'')}} \frac{q_{(0,0)}}{q_{(v',v'')}}$$

where N_i are populations (relative to $N_0 = 10$); I_i are intensities; ν_i are frequencies of spectral lines; q_i are the

[2]Comparison of our high resolution spectra with those of Evenson and Broida (13) at lower pressure shows that at the relatively high pressures employed in this work, significant rotational relaxation has occurred.

Franck Condon factors for $v' \rightarrow v''$ transitions, taken from ref. 15.

To avoid calibration of spectrometer response, relative populations were calculated using the above equation and the bands of the $\Delta v = 0$ sequence whenever possible. In those cases where sequences other than $\Delta v = 0$ were used, population was normalized by assigning the value calculated for a given level from the $\Delta v = 0$ sequences to that same upper level for bands in the $\Delta v \neq 0$ sequence.

Results and Discussion

In this system $CN(B^2\Sigma^+ \rightarrow X^2\Sigma^+)$ violet band emission appeared to be a function of $[N]^2$ at low (1.0–5.0 Torr) pressures. Work above 5.0 Torr discussed in ref. 7, showed the CN violet emission intensity, Φ_{CN}, to be a complex function of experimental variables related to the concentration of vibrationally excited ground state nitrogen, N_2^*. Two band heads of the $\Delta v = 0$ sequence were chosen as observables in kinetic experiments because of their relatively high intensities and freedom from overlap. These were the strong (0,0) head at 3883 Å and the (4,4) head at 3850 Å. The 3850 Å head was chosen with the further consideration that it could possibly reflect the behavior of the (5,5) emission in this same system, the upper level of which is in near resonance to $v = 17$ of the $CN(A^2\Pi)$ state. Hereinafter Φ_{CN} will refer to the total relative emission intensity of the violet system while Φ_λ indicates maximum intensity in arbitrary units for emission at wavelength λ.

It is convenient to discuss the experimental data in terms of the following simplified mechanism,

[1] $2N + M \longrightarrow N_2^* + M$

[2] $2N + M \longrightarrow N_2^{\ddagger} + M$

[3] $N_2^{\ddagger} \xrightarrow{\text{wall}} N_2$

[4] $N_2^{*} \xrightarrow{\text{wall}} N_2$

[5] $N_2^{\ddagger} + CN \longrightarrow CN^* + N_2$

[6] $N_2^{\ddagger} + M \longrightarrow N_2 + M$

[7] $CN^* \longrightarrow CN + h\nu$

[8] $N + CN + M \longrightarrow NCN + M$

[9] $N + NCN \longrightarrow N_2 + CN^*$

[10] $N + N_2^{*} \longrightarrow N_2^{\ddagger} + N$

where $N_2^{\ddagger}$ indicates vibrationally excited ground state nitrogen, N_2^* designates $N_2(A^3\Sigma_u^+)$ and CN* refers to $CN(B^2\Sigma^+)$.

This scheme does not preclude excitation through the $CN(A^2\Pi)$ state, as will be discussed below.

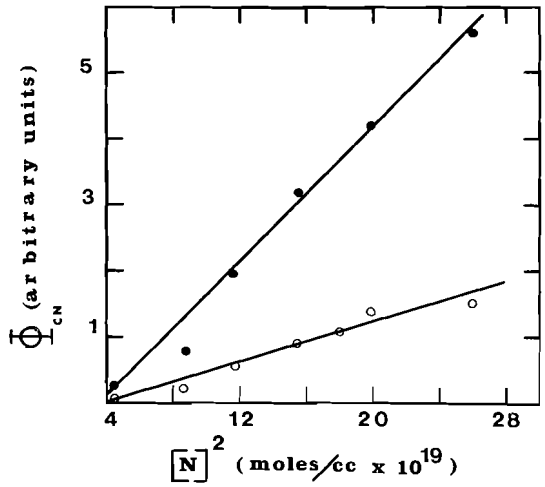

FIG. 1. CN violet band head intensities (●, (0,0) head at 3883 Å; ○, (4,4) head at 3850 Å) as a function of $[N]^2$. Pressure 1.5 Torr at 298 °K.

Application of the usual steady state assumptions yields

[11] $$\Phi_{CN} = k_5[CN]\left[\frac{k_1[N]^2[M] + \dfrac{k_{10}k_2[N]^3[M]}{k_4 + k_{10}[N]}}{k_3 + k_5[CN] + k_6[M]}\right] + k_8[N][CN][M]$$

and at suitably high [N] and [M]

[12] $$\frac{\Phi_{CN}}{[N]^2} = \frac{k_5}{k_6}(k_1 + k_2)[CN] + \frac{k_8[CN][M]}{[N]}$$

Figure 1 illustrates the predicted second order dependence of Φ_{3883} and Φ_{3850} on N atoms. Figure 1 is typical of the results obtained under all conditions, *i.e.*, total pressures ranging from 1.5 to 5.0 Torr and [N] ranging from 10^{-10} to 10^{-9} mol/cm^3. It may be noted that the rates of population of two levels $v = 4$ and $v = 0$ of the B state of CN are different at these lower pressures, perhaps indicative of a lower concentration of suitable activators for level $v = 4$ or alternately reflective of relatively inefficient deactivation from $v = 5$, should resonance crossing at this latter level be the predominant mode of population for $v = 5$ of the $B^2\Sigma^+$ state.

Figure 2 is a representation of $\Phi_{CN}/[N]^2$ plotted against pressure with constant but

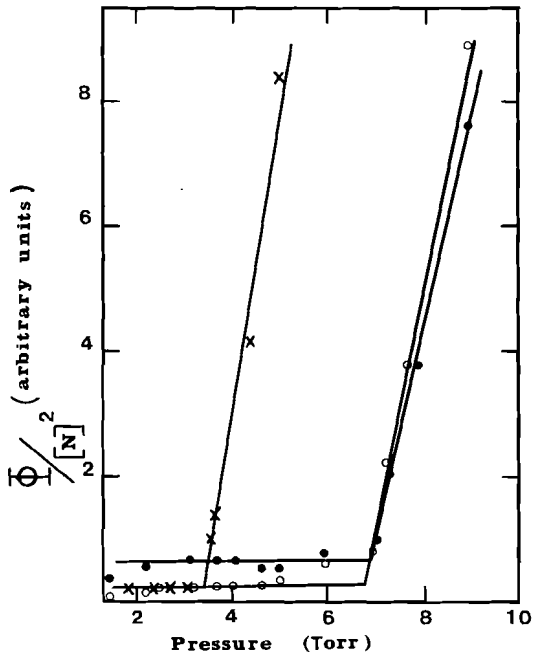

FIG. 2. $\Phi_{CN}/[N]^2$ *vs.* pressure. ●, (0,0) transition; ○, (4,4) transition of CN($B^2\Sigma^+ \rightarrow X^2\Sigma^+$), $[N] = 6 \times 10^{-9}$ mol/cc, $\Phi_{CN}/[N]^2 = 10^8$ cm^3/mol s at 7 Torr. ×, (0,0) transition of CN violet, $[N] = 2 \times 10^{-10}$ mol/cc, $\Phi_{CN}/[N]^2 = 10^7$ cm^3/mol s at 3.5 Torr. Temperature 298 °K.

varied [N]. The data demonstrate the pressure dependence predicted in eq. 12 when the second term on the right of that expression becomes dominant. It may also be noted from the same data that the indicated inverse dependence of the function $\Phi_{CN}/[N]^2$ on [N] is also substantiated. The break in these plots should occur when

$$[13] \quad \frac{k_8[CN][M]}{[N]} = \frac{k_5}{k_6}(k_1 + k_2)[CN] = \tfrac{1}{2}\frac{\Phi_{CN}}{[N]^2}$$

Campbell and Thrush (16) estimated $[CN]/[N] \simeq 10^{-2}$ in reasonable agreement with a value calculated from the data of Iwai *et al.* (3) for $[CN]/[M] \simeq 10^{-6}$ since the Campbell and Thrush work was done at $[N]/[M] \simeq 10^{-3}$. The larger reactor used in this work and the similar atom to molecule ratio for nitrogen suggested use of $[CN]/[N] \simeq 10^{-3}$.

Use of this estimate and conversion to absolute intensity values by the method of Fontijn *et al.* (11) enabled calculation of order of magnitude estimates of $k_8 \simeq 10^{16}$ cm^6/mol^2 s or the ratio $k_5/k_6 \simeq 10^5$, $k_1 \simeq k_2 \simeq 10^{14}$ cm^6/mol^2 s (16).

It is possible to roughly estimate k_6 from data tabulated by Stevens (17), restricting evaluation of that constant to those vibrational levels of ground state N_2 sufficiently highly excited to participate in reaction 5, *i.e.* $N_2^{\ddagger}$ ($v > 15$). It may be shown from Stevens (17) that

$$[14] \quad k_6 = \sum_{i>15}^{v} v_i/15\tau n$$

where v_i denotes the vibrational level of $N_2(X^1\Sigma_g^+)$, τ represents the relaxation time for vibrators in level $v = 1$ to level $v = 0$ and n is the concentration of ground state molecules. The vibrational levels selected were so chosen as to insure a minimum energy of ~4.0 eV (sufficient to excite ground state CN to $B^2\Sigma^+_{v=0}$ or $A^2\Pi_{v=10}$). In addition, that relatively low portion of the $N_2(X^1\Sigma_g^+)$ potential well is still a reasonable approximation of harmonic oscillator form.

Taking $\Sigma \simeq 100$, $\tau \simeq 1$ s at 300 °K (17) and $n \simeq 10^{-7}$ mol/cm^3, $k_6 \simeq 10^8$ cm^3/mol s was calculated leading to an estimate of $k_5 \simeq 10^{13}$ cm^3/mol s.

Boden and Thrush (2) found third order dependence of Φ_{CN} on [N] at concentrations nearly identical to those used in this study. These authors also report a change to second order dependence on [N] in "narrow" tubing in their system.

Expression 11 predicts such behavior. When $k_4 \gg k_{10}[N]$ third order dependence on [N] should dominate. The polymer film and intensity gradient reported in ref. 2 suggest the above inequality holds in the large (i.d.) portion of the reactor. In the narrow tubing

$$k_1[N]^2[M] \gg \frac{k_{10}k_2[N]^3[M]}{k_4}$$

if wall deactivation of $N_2(A^3\Sigma_u^+)$ is efficient. The apparent discrepancy between data presented in this paper and those in ref. 2 may be resolved by noting that neither the polymer nor intensity gradient was observed in this reactor (larger i.d.) and additionally data accumulated near 5.0 Torr have shown Φ_{CN} to be a complex function of power input (7). This is consistent with the mechanism [1]–[10] if wall deactivation of $N_2^{\ddagger}$ is assumed to be negligible and if it is further

assumed that the experimental system is a source of relatively high concentrations of N_2^+ at low power and high pressure. That N_2^+ is present in relatively high concentration in microwave discharged nitrogen under these conditions has been demonstrated in many studies (ref. 7 cites some examples) and at high pressures wall deactivation is minimal. Investigations are presently in progress which should further elucidate the behavior of N_2^+ in this system. Evidence cited earlier from the Meyer and Setser work (6) and observations from this work indicate that $N_2(A)$ must play a minor role in excitation of CN by direct energy transfer. Figure 3 shows the behavior of $N_2(A)$ in our system as indicated by the mercury (5074 Å) signal due to the rapid reaction

$$N_2(A^3\Sigma_u^+) + Hg(^1S_0) \rightarrow Hg(^3P_1) + N_2(X^1\Sigma_g^+)$$

Additionally, a hypothetical "rate constant" for direct excitation of CN by $N_2(A)$ using absolute intensity data can be calculated. It is first necessary to estimate the concentration of $N_2(A)$ using an expression and rate constants from Thrush (18). Accordingly, $[N_2(A)] \simeq 10^{-15}$ mol/cm^3 and with $[CN]/[N] = 10^{-3}$, again using the method presented in ref. 11 for the reaction

$$[15] \qquad N_2(A^3\Sigma_u^+) + CN \rightarrow N_2(X^1\Sigma_g^+) + CN^*$$

$k_{15} \simeq 10^{16}$ cm^3/mol s. This is clearly an unacceptable value since it is orders of magnitude greater than the collisional frequency. The validity of the above results rests on the assumption concerning [CN] (*i.e.* $[CN]/[N] \simeq 10^{-3}$). To test this premise methane was added to the flowing gas, both before the discharge and in the afterglow region. In all cases the additive gas quenched the emission. The lowest concentration of added CH_4 was 10^{-11} mol/cm^3 and since this gas is known to serve as a quenching agent above optimum ratios of $[CH_4]/[N_2] \simeq 10^{-3}$ (19), the results are indicative of the fact that the concentration of CN produced from impurity in the N_2 is less than the additive methane concentration.

It may be shown

$$[16] \qquad \frac{\Phi_{CN}}{\Phi_{NO_2}} = \frac{G(\lambda)}{G'(\lambda)} \frac{\tau_{CN}}{\tau_{NO_2}} \frac{[CN^*]}{[NO_2^*]}$$

where Φ_i represents the absolute intensity of

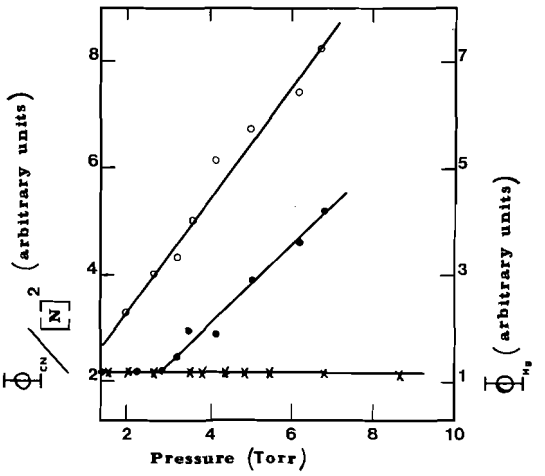

FIG. 3. $\Phi_{CN}/[N]^2$ (left hand ordinate) and mercury 5074 Å emission intensity (right ordinate) as a function of pressure. ○, 5074 Å Hg line intensity, ●, (0,0) head of $CN(B^2\Sigma^+ \rightarrow X^2\Sigma^+)$, $[N] = 1 \times 10^{-10}$ mol/cc. ×, (0,0) CN violet band head intensity, $[N] = 4 \times 10^{-9}$ mol/cc. Flow rate of inletted Hg = 3×10^{-10} mol/s. All data at 298 °K.

emission by molecule i over a given wavelength interval, $G(\lambda)$ and $G'(\lambda)$ are combined geometric and instrument functions over the appropriate spectral intervals. τ_i represents the radiative lifetime of molecule i and the asterisks denote molecules undergoing radiative transitions. Using $\tau_{CN} \simeq 10^{-8}$ s (20), $\tau_{NO_2} \simeq 10^{-6}$ s (21), a rate constant for formation of NO_2^* of $\sim 10^7$ cm^3/mol s and a quantum efficiency (defined as the fraction of NO_2^* formed which undergoes radiation) of 10^{-9} (21) and a ratio of $\Phi_{CN}/\Phi_{NO_2} \simeq 10^{-1}$, it is possible to calculate a value of $[CN^*] \simeq 10^{-19}$ mol/cm^3 from eq. 16. This result is in reasonable accord with a value of $[CN^*] = 5 \times 10^{-19}$ mol/cm^3 computed by Iwai *et al.* (3) for the $v = 0$ level of the $CN(B)$ state.

The ratio $\Phi_{CN}/\Phi_{NO_2} \simeq 10^{-1}$ is an experimentally determined value which reflects the different efficiencies of the spectrometer for detection of 3600 and 7800 Å photons. Calibration of the spectrometer system was effected by comparing a photon density value determined by using spectral data accumulated in this work and rate constants from ref. 12 to determine Φ_{CN} in the region 3570–3600 Å. This value was then compared with a similar computation for determination of Φ_{NO_2} from experimental data according to the method described in ref. 11.

species in the excitation of CN which must be produced independently of the N atom recombination steps [1] and [2]. The data can be explained by including [8] and [9] in the mechanism. Inclusion of these reactions produces a term in [12] with the needed pressure dependence to account for the data in Figs. 2 and 3. NCN has been previously detected in active nitrogen (22) and some spectroscopic work has been carried out on this radical (23, 24). Setser and Thrush (1) note that production of NCN should be favored in systems where [N]/[N_2] is low. A careful search of the u.v. near the quartz cutoff under such conditions resulted in observation of a weak "continuum" with maxima at 3050 and 2650 Å (see Fig. 4). The most prominent feature of the "usual" NCN spectrum at 3290 Å was not detected but may have been obscured by strong CN violet tail band emission. Milligan *et al.* (24) refer to an allowed transition in absorption which terminates on a non-linear excited state configuration of NCN, one possible source of the observed feature in this system. As noted in ref. 1 a second possibility for formation of such a non-linear configuration would be excitation of ground state NCN by collision rather than direct formation as in reaction 8. It is not possible to choose between these two explanations on the basis of the present experimental evidence.

Excitation of CN by reactions 8 and 9 has been suggested earlier (4) but Setser and Thrush (1) have argued against reaction 9 on the basis of accumulated evidence which indicates that excitation of products of transfer reactions usually occurs in the newly formed bond. Reaction 9 involving ground state NCN is suggested to be $\sim$125 kcal/mol exothermic (1) and thus provides sufficient energy for excitation of CN to electronically excited radiative states. Excitation to levels requiring more than 125 kcal could be explained if NCN was itself vibrationally or electronically excited. Arrington *et al.* (25) suggest reaction 9 produces $N_2(A^3\Sigma_u^+)$, requiring that NCN is in fact vibrationally hot, since formation of $N_2(A^3\Sigma_u^+)$ requires 149 kcal/mol. If reaction 9 produces $N_2(A^3\Sigma_u^+)$ the simultaneous excitation of CN to the B state would be precluded on energetic grounds. It is possible, however, that a significant fraction of reaction 9 leads to CN excitation since such an event is not spin forbidden and others (1) have noted that such excitation is probable should NCN be non-linear. Reactions 8 and 9 are included in the mechanism largely on the basis of the pressure and atom dependence and behavior of the observed continuum. The calculated rate constant k_8 also appears to be reasonable by comparison with a value of formation of ground state NCN from Arrington *et al.* ($1 \times 10^{18} < k_{NCN} < 8 \times 10^{18}$).

Excitation of CN(X) through energy transfer by collision with other metastable states of nitrogen cannot be definitely excluded. The $N_2(W^3\Delta_u)_{v=0}$ state is probably long-lived in active nitrogen (26) and could be involved. It is not known, however, how this state behaves with respect to pressure and atom concentration changes. The $N_2(a'^1\Sigma_u^-)$ and the $N_2(a^1\Pi_g)$ states have been reported (27) to show dependence on pressure and [N] which would not be compatible with our observations. This is also the case with the N(^2P) atomic state which has been detected in flowing discharged nitrogen (28, 29) through observation of the 3466 Å "line" of the N($^2P \rightarrow {}^4S$) transition. A moderately high concentration of N(^2P) atoms is therefore indicated because of the long ($\tau = 12$ s) radiative lifetime (29) of the transition. The N(^2D) state ($\tau = 26$ h) (30) has not been detected.

The vibrational profile of the $B^2\Sigma^+$ state of CN appears to be sensitive to several factors over a comparatively narrow range of parametric variation. As illustrated in Fig. 5, low pressure (1.5 Torr) limits the emission to those levels in the B state below $v = 6$. A fourfold increase in pressure results in a change to emission from levels in this state up to $v = 15$. The population maxima at $v = 0$, 4, 10, evident at 6 Torr pressure provides strong evidence for the involvement of the CN($A^2\Pi$) state in the overall mechanism of CN excitation–emission since the above levels are quite likely populated through resonance transfer from levels $v = 10$, 17, and 24 of the CN(A) state. In this connection, high resolution spectra of the rotational structure of the (0,0) band (3883 Å), CN($B^2\Sigma^+$) $\rightarrow$ CN($X^2\Sigma^+$), taken at 7 Torr, show perturbations at $K' = 4$, 7, 11, and the "extra" lines reported by Radford and Broida (8). Figure 5 also illustrates the effect of N atom concentration on the profiles. Increase in [N] at low pressure produced a monotonic increase in population of all observed levels while a similar

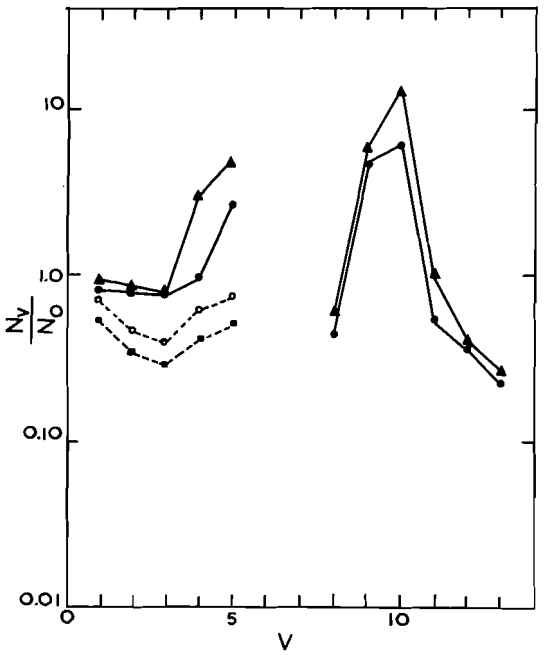

FIG. 5. Relative populations of vibrational levels in the $CN(B^2\Sigma^+)$ state: ■, Pressure = 1.5 Torr, [N] = 6.2×10^{-10} mol/cc; ○, Pressure = 1.5 Torr, [N] = 1.5×10^{-9} mol/cc; ▲, Pressure = 6.0 Torr, [N] = 3.0×10^{-10} mol/cc; ●, Pressure = 6.0 Torr, [N] = 2.3×10^{-9} mol/cc. All data collected at 298 °K. Missing levels (6 and 7) were not listed because of severe overlap. Emission to $v = 15$ was detected.

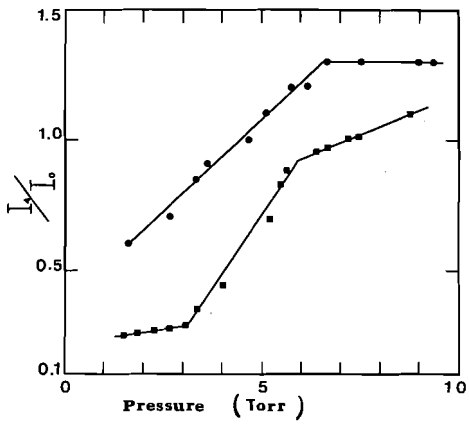

FIG. 6. Relative intensity of the (4,4) band of $CN(B_2\Sigma^+ \rightarrow X^2\Sigma^+)$ to that of the (0,0)-band of the same transition as a function of pressure: ■, [N] = 3.0×10^{-9} mol/cc; ●, [N] = 2.2×10^{-10} mol/cc.

atom concentration increase at higher pressures (>6 Torr) produced the reverse effect. These observations are consistent with the mechanism presented above.

The essential feature of the mechanism is that CN excitation occurs predominantly through energy transfer from vibrationally excited nitrogen. This conclusion is supported by Taieb and Legay (31) who explained excitation of CN to emitting levels in the $CO–N_2$ laser by energy transfer from vibrationally excited nitrogen. At relatively high microwave power the concentration of N_2^* is governed by homogeneous recombination of N atoms and by deactivation of $N_2(A)$ by N atoms. Deactivation by ground state nitrogen is very slow (17). Consequently, the concentration of $N_2(A)$ increases with pressure and decreases with increasing [N].

Equation 11 predicts the observed increase in intensity with [N] at low pressure ($k_3 + k_5[CN] \gg k_6[M]$) and the decrease of $N_2(A)$ by increasing [N] at high pressure (second term in the numerator). The removal of $N_2(A)$ by ground state atoms can produce either ^2P atoms or vibrationally hot ground state N_2. The latter will be formed in levels near $v = 25$ of $X^1\Sigma_g^+$ state of N_2 unless the product atom $N(^4S)$ carries off a large quantity of translational energy. Formation of these hot vibrators, favored at high pressure and high [N], would be expected to change the vibrational profile of the excited CN and produce the higher vibrational level populations responsible for tail band emission.

Figure 6 offers evidence for the participation of two processes in population of the B state. The ratio I_4/I_0 (proportional to N_4/N_0), where I_i stands for the intensity of a transition originating in level i of the B state of CN and N_i represents the population of that same vibrational level, is observed to increase sharply over a small threefold change in pressure. Because of the short radiative lifetime of the B state ($\tau \sim 10^{-8}$ s) (20) vibrational relaxation cannot be important and the effect must be on the precursor. Since the process populating the level $v = 4$ is seen to be favored by pressure increase and retarded by increasing atom concentration, it would appear to be a process involving $N_2(A^3\Sigma_u^+)$. To further test the premise concerning $N_2(A)$, mercury was added to the reactor in the afterglow region. Mercury is known to react rapidly with $N_2(A)$ (32–34).

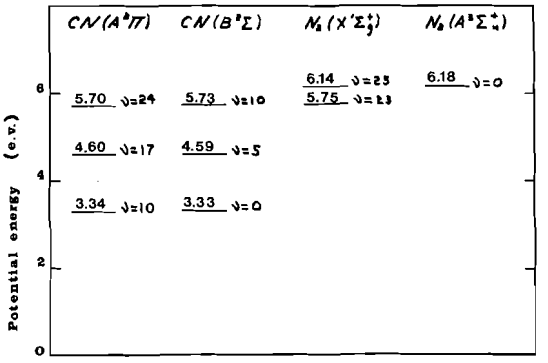

FIG. 7. Partial potential energy scheme for pertinent vibrational levels of molecules discussed in this paper. Energies and levels are indicated under appropriate electronic states. Data for $N_2(X'\Sigma_g^+)$ and $N_2(A^3\Sigma_u^+)$ from Gilmore (35). Energies for $CN(A^2\Pi)$ and $CN(B^2\Sigma^+)$ calculated from data tabulated by Herzberg (36).

The effect of mercury addition was discussed in ref. 7 and provided strong evidence that $N_2(A)$ is not responsible for direct excitation of $CN(B^2\Sigma^+)$ in agreement with Meyer and Setser (6). All of these observations are consistent with the postulated mechanism. The excitation of $CN(B^2\Sigma^+)$ to levels as high as $v = 15$ requires a minimum of 6.49 eV. Excitation to $CN(B)_{v=10}$ requires 5.73 eV. Figure 7 shows the pertinent energies for the species involved. The reaction of $N(^4S)$ with $N_2(A)_{v=1,0}$ will produce either

$$N(^4S) + N_2(A^3\Sigma_u^+) \rightarrow N_2(X^1\Sigma_g^+)_{v<10} + N(^2P)$$

(both products are incapable of exciting CN to $v = 10$ of the B state from $v = 0$ of $CN(X^2\Sigma^+)$), or

$$N(^4S) + N_2(A^3\Sigma_u^+) \rightarrow N_2(X^1\Sigma_g^+)_{v=25} + N(^4S)$$

A large fraction of the $N_2^\ddagger$ produced in this case will be formed at 6.2 eV of the $X^1\Sigma_g^+$ state unless the atom carries off some of the energy in translation, or the $N_2(A^3\Sigma_u^+)$ is itself vibrationally excited. Thus, when the concentration of $N_2(A^3\Sigma_u^+)$ is sufficiently large, it could become a significant source of $N_2^\ddagger$ which could account for the enhancement of tail band emission at high pressures.

Under conditions where NCN is thought to be involved the vibrational profiles were similar to "high pressure" profiles in Fig. 5. Increasing pressure increases intensities from all levels. A decision regarding the relative importance of direct and/or indirect population of CN(B) via the NCN reaction is not possible at this time.

The authors are grateful to the National Research Council of Canada for financial support.

Surface Studies of Heat-treated γ-Aluminas in the Adsorption of Sulfur Dioxide below Monolayer Coverage

R. W. GLASS AND R. A. ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received February 10, 1972

Calorimetric heats of adsorption of sulfur dioxide at surface coverages from 0.1 to 3.5 μmol m^{-2} have been measured on a series of γ-aluminas heat-treated at 500, 700, and 900 °C. Essential features of the structures of the adsorbents have been characterized by analysis of nitrogen adsorption/desorption isotherms and by both direct and indirect electron microscopy.

Heats of adsorption of 423 °K for adsorbed amounts of 0.1 μmol m^{-2} were 48.0, 59.0, and 85.0 kcal mol^{-1} for the 500, 700 and 900 °C samples, respectively. The values for the 500 and 700 °C samples fell rapidly with increasing coverage to around 19.0 kcal mol^{-1} at 3.2 to 3.3 μmol m^{-2}, while the values for the 900 °C sample decreased slowly to 15.0 kcal mol^{-1} at the same coverage.

The pores had circular cross sections and mean diameters of 25, 35, and 40 Å were observed for the 500, 700, and 900 °C samples, respectively. Examination of carbon/platinum replicas of the surface showed the presence of agglomerates of spherical particles approximately 400 Å in diameter.

It is proposed that the high initial heats on the 500 and 700 °C samples are due to the formation of a sulfate-like species on the surface and at higher coverage extensive hydrogen bonding is present. The very high heats obtained on the 900 °C sample are believed to be due to interactions with high-energy defect centers in the oxide which were created by heat treatment.

Les chaleurs calorimétriques de l'adsorption de l'anhydride sulfureux sur des surfaces recouvertes de 0.1 à 3.5 μmol m^{-2}, ont été mesurées pour une série d'alumine γ traitées par la chaleur à 500, 700, et 900 °C. Les caractéristiques essentielles sur les structures des adsorbants ont été obtenues par l'analyse des isothermes d'adsorption et de désorption de l'azote et par la microscopie électronique directe et indirecte.

Les chaleurs d'adsorption à 423 °K pour des quantités adsorbées de 0.1 μmol m^{-2} sont respectivement de 48.0, 59.0, et 85.0 kcal mol^{-1} pour les échantillons à 500, 700, et 900 °C. Les valeurs à 500 et 700 °C chutent rapidement jusqu'à 19.0 kcal mol^{-1} pour 3.2 à 3.3 μmol m^{-2} lorsque la surface d'adsorption croît, tandis que les valeurs à 900 °C décroissent lentement jusqu'à 15.0 kcal mol^{-1} pour la même surface.

Les pores sont de 25, 35, et 40 Å respectivement pour les échantillons à 500, 700, et 900 °C. L'examen des reproductions en carbone–platine de la surface montre la présence d'agglomérats de particules sphériques dans les diamètres qui sont de l'ordre de 400 Å.

On a suggéré que les hautes chaleurs initiales pour les échantillons à 500 et 700 °C sont dues à la formation sur la surface d'espèce de type sulfate, pour des surfaces d'adsorption plus grande, il y a présence très forte de liaison hydrogène. On pense que les très hautes chaleurs obtenues sur l'échantillon à 900 °C sont dues aux interactions entre les défauts de haute énergie dans l'oxyde, créés par la chaleur.

Canadian Journal of Chemistry, **50**, 2537 (1972)

Introduction

Studies have been reported recently of the adsorption of sulfur dioxide up to one-twentieth monolayer coverage on silica gels (1) and on transition metal oxides supported on silica gel (2). Calorimetric heats of adsorption and adsorption isotherms were determined at 423 °K and the adsorbents characterized by measurement of surface areas, pore size distributions, and hydroxyl group concentrations. These data were used to interpret the nature of the adsorbate–adsorbent interactions (1, 2) and now the work has been extended to include a systematic study of the adsorption of sulfur dioxide on heat-treated γ-aluminas.

Although there have been several studies of the adsorption of sulfur dioxide on doped aluminas (3, 4), little work has been reported on pure alumina and little or no heat of adsorption data are available for the sulfur dioxide/alumina system. However, it has been suggested (5) from infrared studies of the adsorption of sulfur dioxide on γ-alumina that both chemisorption and hydrogen-bonding between the oxygen of the sulfur dioxide molecule and hydroxyl groups on the oxide surface takes place.

Experimental

Materials

γ-Alumina was prepared by heating boehmite in air at 500 °C or above for 20 h. The boehmite was prepared by an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

adaptation of a previous method (6) as follows. A 4.5 *M* aluminum sulfate solution was prepared at 60–65 °C and maintained at this temperature. Ammonium hydroxide (4.5 *M*) was then run in slowly, with vigorous stirring over a period of about 1 h. Throughout this period a continuous stream of ammonia vapor was bubbled into the solution to maintain p*H* 9. The precipitate was allowed to stand for 20 h. After washing the gel with ammoniated water until free of sulfate ions it was dried at 150 °C for 20 h. "AnalaR" grade reagents were used throughout.

X-Ray powder diffraction photographs showed that the product was boehmite (7). Samples of this material were heat-treated in air at 500, 700, and 900 °C for 20 h and X-ray powder diffraction photographs showed that γ-alumina had been formed at all three temperatures although the diffraction lines obtained for the 900 °C sample were much sharper than those for the others.

Immediately after heat-treatment, samples were cooled over phosphorous pentoxide, transferred to the appropriate apparatus and then out-gassed at 150 °C overnight at $< 10^{-4}$ mm.

High-purity nitrogen (>99.99%; Canadian Liquid Air Ltd.) was used in the determination of the low-temperature nitrogen adsorption isotherms. Sulfur dioxide (Matheson Co.) was anhydrous quality and was drawn directly from the cylinder after line-flushing to a tray attached to the apparatus. It was then out-gassed at 10^{-4} mm and vacuum distilled over trays of phosphorous pentoxide. Middle portions only were used and g.l.c. analysis showed these to be >99.99% pure.

Apparatus

Heats of adsorption were determined calorimetrically in a similar apparatus to that described earlier (2). Nitrogen adsorption–desorption isotherms (77 °K) were measured in a standard apparatus (8) and pore size distributions (9) calculated with the aid of an IBM 360/50 computer. Mercury "lump" densities were measured as described previously (10).

Hydroxyl group/water "concentrations" were determined gravimetrically (11) to constant weight at 1200 °C in a static air atmosphere using a recording thermobalance (Stanton–Redcroft Model HT5A).

Electron micrographs were taken with a Philips EM 300G instrument operated at 100 kV. Pore structures were examined by the technique of direct transmission electron microscopy since replica techniques (12) have poor replicating resolution (>50 Å). Specimens were crushed in an agate mortar and suspended in *n*-butyl alcohol. Drops of the suspension were placed on the carbon support film on the microscope grids and the alcohol subsequently removed by evaporation at $< 10^{-5}$ mm. Samples were examined also by the single-stage replication technique (13). The oxides were crushed and suspended as before and drops of the suspension placed on a glass coverslip prior to removal of the alcohol by evacuation. A carbon film was deposited onto the slowly rotating sample in a vacuum evaporator. The entire coverslip fragment was floated on 24% v/v HF for 3 h to dissolve the coverslip and the alumina sample. The replica was then transferred to distilled water and a portion picked up on 200 mesh copper grids before shadowing with platinum at an angle of 35°. The specimen was examined at an accelerating voltage of 80 kV. Instrumental magnification errors were ±2%.

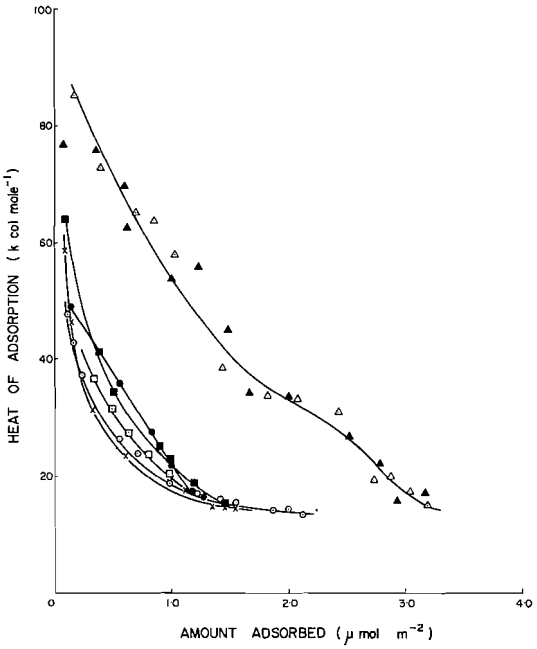

FIG. 1. Heat curves for the adsorption of sulfur dioxide at 423 °K on various heat-treated aluminas. Heat treatment at ○, 500 °C; ×, 700 °C; and △ (run 1), ■ (run 2), ● (run 3), □ (run 4), 900 °C; ▲, 900 °C duplicate sample freshly prepared from boehmite.

Results

Heats of Adsorption and Adsorption Isotherms for Sulfur Dioxide on γ-Alumina

Heats were determined at 423 °K for surface coverages from 0.1 to 2.0 μmol m^{-2} for the 500 and 700 °C samples and between 0.1 and 3.2 μmol m^{-2} for the 900 °C sample. At 423 °K, 7.0 μmol m^{-2} is approximately equivalent to monolayer coverage (2).

All adsorbents exhibited high heats at the lowest coverage, Fig. 1. The heat curves obtained for the 500 and 700 °C samples were almost identical, but differed significantly from that for the 900 °C sample. After a rapid fall between 0.1 and 1.3 μmol m^{-2} the heat curves of the 500 and 700 °C samples levelled out between 13 and 14 kcal mol^{-1} at a surface coverage of 1.5 to 2.0 μmol m^{-2}. In contrast, the curve for the 900 °C sample showed an almost linear decrease in the heat values from 85.0 kcal mol^{-1} at 0.1 μmol m^{-2} to 15.0 kcal mol^{-1} at 3.2 μmol m^{-2}.

The adsorption isotherms for sulfur dioxide at 423 °K are shown in Fig. 2. The shape of the

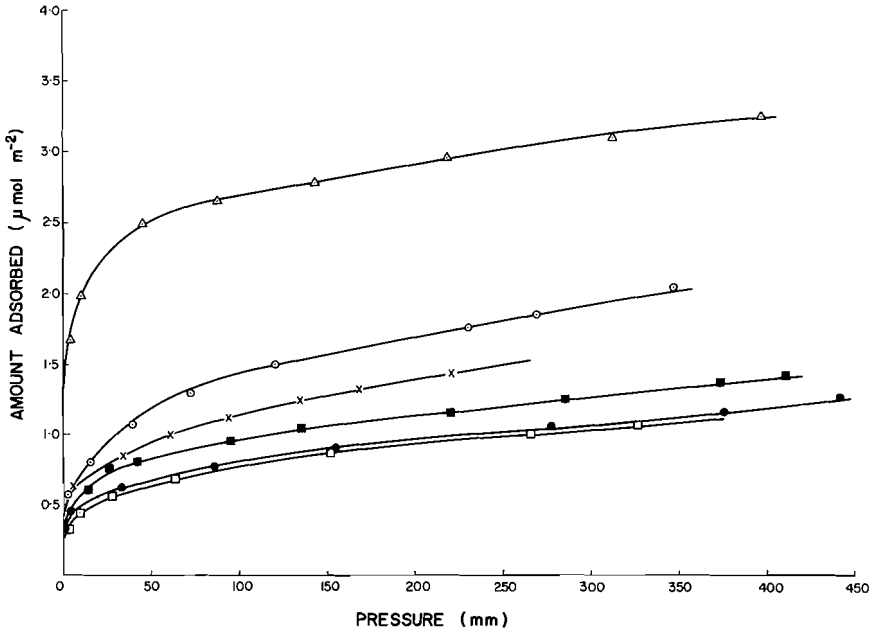

FIG. 2. Adsorption isotherms for sulfur dioxide at 423 °K on heat-treated aluminas. Heat treatment at ○, 500 °C; ×, 700 °C; and △ (run 1), ■ (run 2), ● (run 3), □ (run 4), 900 °C.

isotherms is similar for all samples. A large amount of sulfur dioxide was adsorbed at pressures up to 50 mm followed by a much smaller amount at pressures up to 400 mm. It should be observed that while the amount adsorbed on the 700 °C sample was smaller than that on the 500 °C sample, as might be expected, the amount adsorbed on the 900 °C sample was considerably more than that on the 500 °C sample over the whole pressure range examined.

Additional experiments were carried out with the 900 °C sample to test the possibility of regenerating the "original" surface. The heat curve was measured up to a coverage of 3.2 μmol m^{-2}, the maximum that could be obtained experimentally, corresponding to a maximum pressure of 400 mm. The alumina was then out-gassed overnight at 423 °K at $< 10^{-4}$ mm and samples of the desorbed gas analyzed with a Beckman IR-12 infrared spectrophotometer. No water or any other impurity could be detected. After this procedure, sulfur dioxide was readmitted to the sample and the heat curve determined. The entire experiment was repeated thrice. The heat curves are shown in Fig. 1. No change in the surface area of the alumina was observed after measurement at the end of the fourth run.

The heat curves for the second, third, and fourth runs are close together but at any given coverage, the heat value is only around half of that determined in the first run. The curves for the second, third, and fourth runs appear to begin to level out at about 1.2 μmol m^{-2} to a value approaching 15.0 kcal mol^{-1}, (*cf.* 500 and 700 °C samples, Fig. 1). The amount of sulfur dioxide adsorbed at a given pressure in the second, third, and fourth runs was considerably reduced when compared with that adsorbed during the first run, Fig. 2, and with each succeeding run the adsorption isotherms came closer together.

Nitrogen Adsorption/Desorption Measurements

The nitrogen adsorption/desorption isotherms have the same general shape (Type II) while the amount of nitrogen adsorbed decreases with increase in temperature of heat treatment of the alumina, Fig. 3.

Some differences in the pattern of the desorption isotherms are apparent. The hysteresis loop for the 500 °C sample extended from $p/p_0 = 0.90$ to $p/p_0 = 0.45$, with the loop closing almost vertically. The 700 °C sample had a hysteresis loop extending from $p/p_0 = 0.93$ to 0.58; again the loop closed almost vertically

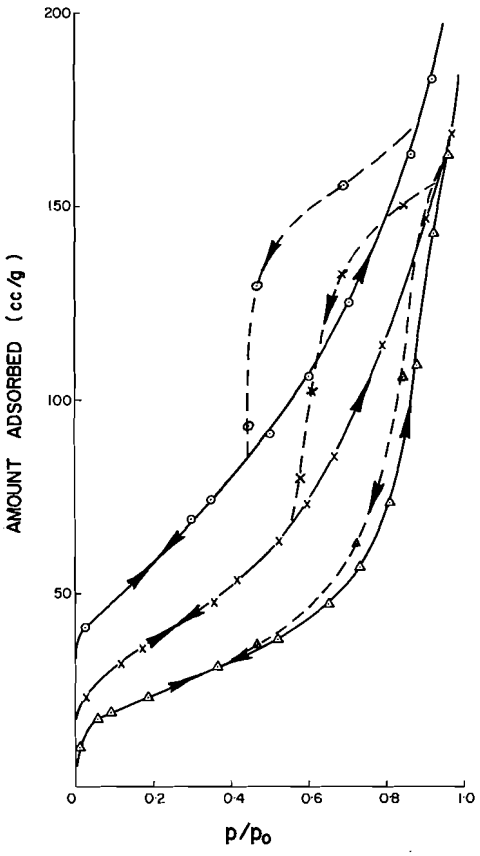

FIG. 3. Nitrogen adsorption/desorption isotherms at 77 °K on heat-treated aluminas. Heat treatment at ○, 500 °C; ×, 700 °C; △, 900 °C.

with its width smaller than that for the 500 °C sample. The 900 °C sample exhibited a hysteresis loop of completely different shape. It was very narrow, extended from $p/p_0 = 0.95$ to 0.50 and closed slowly and smoothly into the path followed by the adsorption isotherm.

The pore size distributions, calculated from the desorption leg of the isotherm on a differential basis, are shown in Fig. 4. The 500 °C sample exhibited two maxima, one at 38 Å and a smaller one at 55 Å. The pore diameter range extended from 28 to 130 Å. The 700 °C sample also showed two maxima, the principal one at 55 Å and the other at 38 Å. The pore diameter range for this sample extended from 23 to 155 Å. The 900 °C sample exhibited at least four maxima at 55, 70, 100, and 145 Å with a pore diameter range from 48 to 220 Å. Figure 4 shows that the percentage of pores larger than 60 Å was greatest for the 900 °C sample.

Table 1 summarizes the data obtained for surface areas (B.E.T. plots), water "concentrations", mercury densities, and the mean pore diameter for each alumina.

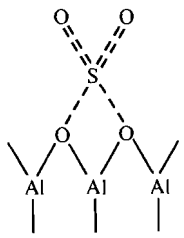
Electron Microscope Examinations

The direct transmission micrographs of the three samples (total magnification × 825 000; microscope magnification × 125 000) were very similar. The mean pore diameters of the samples determined from these micrographs are given in Table 1.

A reproduction of the negative of a single-stage replica (total magnification × 125 000; microscope magnification × 25 000) of a 500 °C alumina sample is shown in Fig. 5. The alumina particles consist of globules which appear to have coalesced, each globule being approximately 400 Å diameter. The fine structure which can be observed in the globules is due to the replicating procedure and should not be interpreted as indicating the presence of fine pores. The large white areas are simply due to shadowing effects.

Discussion

The heat curves for the 500 and 700 °C samples are identical, apart from the values measured at the lowest coverage (0.1 μmol m^{-2}), 48.0 and 58.0 kcal mol^{-1} for the 500 and 700 °C samples, respectively. Heats of this order of magnitude clearly indicate that chemisorption has occurred (14). This conclusion is supported by infrared data (5) which suggest that a chemisorbed sulfur dioxide species is present on γ-alumina at 473 °K. One interpretation (5) of the infrared results is that a "sulfate-like" structure may be formed:



Chemical analysis of the residues in the present experiments did not show the presence of sulfate ions.

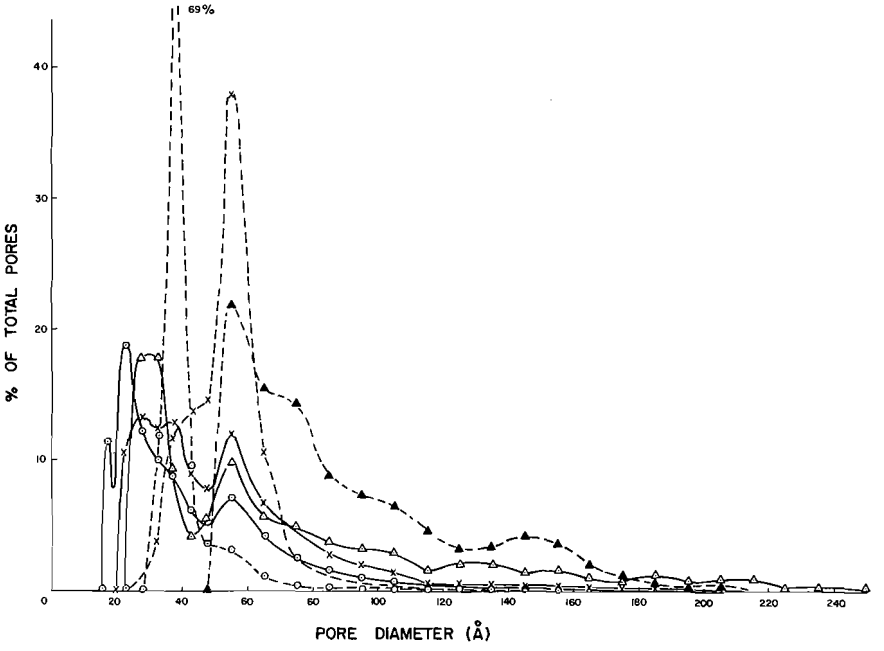

FIG. 4. Pore size distributions based on nitrogen adsorption (—) and desorption (---) isotherms. Alumina heat-treated at ○, 500 °C; ×, 700 °C; △, 900 °C.

TABLE 1. Surface areas, water "concentrations", mercury densities, and mean pore diameters for the heat-treated aluminas

Temperature of heat-treatment (°C)	Surface area ($m^2\ g^{-1}$)	Water "concentration" ($\mu mol\ m^{-2}$)	Mercury density ($g\ cc^{-1}$)	Mean pore diameter (Å)
500	230	19.8	0.6812	25
700	160	18.6	0.6864	35
900	90	7.3	0.6915	40

An approximate value of 10.4 $\mu mol\ m^{-2}$ for a monolayer coverage of water molecules on γ-alumina can be calculated assuming one water molecule is adsorbed (as two OH^- ions) on 16 $Å^2$ in the (100) plane of the oxide (15). Although the present samples are unlikely to be preferentially oriented, this coverage value does give an indication that bulk water is most probably present in the 500 and 700 °C samples. The high concentration of hydroxyl groups and/or water likely to be present on the surface (Table 1), together with the magnitude of the heat of adsorption (16) above a sulfur dioxide coverage of 1.0 $\mu mol\ m^{-2}$, strongly supports the suggestion (5) that bridge-type hydrogen bonds may be formed between the hydroxyl hydrogens and the oxygen atoms of the sulfur dioxide molecule. This is a similar complex to that proposed for the adsorption of sulfur dioxide on silica gel (2).

Peri (15) has made a computerized simulation of the dehydration of spinel-type aluminas and although valid criticisms of his assumptions have been stated (7), the model is still useful. For example, if a spinel-type alumina exposes only (100) planes on the surface then below a surface hydroxyl ion coverage of about 10%, no more adjacent hydroxyl ion pairs are present; and it can be shown (15) that further dehydration is only possible through migration of surface ions. The 900 °C sample has apparently a much higher total hydroxyl group content than 10% (Table 1) but no distinction can be made between surface and bulk water

FIG. 5. Single stage carbon/platinum replica of alumina after heat-treatment at 500 °C (total magnification × 125 000; microscope magnification × 25 000).

molecules with the present gravimetric method; hence these results are inconclusive in this context.

Above 800 °C protons migrate readily on the surface of alumina (7) while the gradual loss of surface area and slow formation of high temperature forms indicate that both oxide and aluminum ion migration occur (7). Thus the number of surface defects and active acidic sites (17) is likely to increase considerably with the 900 °C sample. The presence of these centers and sites will considerably increase the heterogeneous nature of the 900 °C sample surface when compared with those surfaces prepared at lower temperatures. Normally, it is to be expected that heats of adsorption increase with increase in surface heterogeneity (7) and the results of Fig. 1 are clearly in accord with this concept.

Earlier (1) it was shown that the total amount of sulfur dioxide adsorbed on heat-treated silica gels at 423 °K was closely related to the surface hydroxyl group concentration. Although precise data concerning the surface hydroxyl group concentration cannot be obtained for γ-alumina samples for the reasons outlined, it is likely that the adsorption of sulfur dioxide on the 500 and 700 °C samples follows a similar trend. However, the trend is unlikely to be followed by the 900 °C sample when the interaction between sulfur dioxide molecules and defect centers may be expected to be stronger than that for a bridge-type hydrogen bond interaction.

The data in Figs. 1 and 2 are not in conflict with the concept of the presence of these highly active adsorption centers on the 900 °C sample. In Fig. 1, the heats observed on the second run are only about half the magnitude of those of the first at a given coverage and in each succeeding run the heats become lower still. This pattern would be expected with a heterogeneous surface if after the first run most high energy centers were "neutralized" with fewer high energy sites remaining available for adsorption in succeeding runs. Evidence in favor of this view is found in the observation that 1.05 μmol m^{-2} of sulfur dioxide remained adsorbed following desorption after the first run and this value increased only marginally to 1.10 μmol m^{-2} after the fourth run. Further, if adsorption proceeds principally by interactions with high energy centers and these centers are not regenerated on evacuation, then the amount of sulfur dioxide adsorbed at a given equilibrium pressure should be reduced with each succeeding run as is clearly shown in Fig. 2.

The shapes of the nitrogen adsorption/desorption isotherms are very similar to those found previously (18) for samples of heat-treated boehmite. The hysteresis loops are best described as type "E" for the 500 and 700 °C aluminas and approximately type "A" for the 900 °C sample. Type "E" hysteresis loops can be attributed to tubular pores of some effective diameter which have widened parts of varying diameter (18). This feature is clearly shown in the pore size distributions of the 500 and 700 °C samples in which the effective diameters lie at 30 and 55 Å, respectively. Type "A" hysteresis loops can be related to (*i*) open-ended tubular pores with various forms of cross section with only slightly or no widened parts or to (*ii*) "ink bottle" types of pores with wide or very short necks (18). Either of these possibilities suggests that a wider range of diameters would be observed from the pore size distribution data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These data show that with increase in the temperature of heat treatment the maximum in the distribution shifts to pores of wider diameters. At 900 °C sintering of the small pores has probably occurred thus creating an almost random distribution of pores larger than the parents.

The transmission electron micrographs show that the average pore diameter increased with increase in the temperature of heat treatment (Table 1), which supports the trend shown by the pore size distribution data, Fig. 4. However, the average pore diameter for a given sample does not coincide with the pore diameter corresponding to the maximum in the pore size distribution although the average diameter of the pores in the 500 °C sample compares well with other electron micrograph results (19) on γ-alumina.

The apparent discrepancy between the values obtained by the two methods could possibly be explained by the use of the Cranston and Inkley (20) method to determine the pore size distribution. This method was computed for cylindrically-shaped pores closed at one end, whereas the pores of alumina are expected to be slit-shaped (21). However, neither the shapes of the nitrogen adsorption/desorption isotherms nor the electron micrographs confirm the presence of slit-shaped pores and if the pore size distribution is determined from the adsorption leg of the nitrogen isotherm then the maxima correspond more closely with the electron microscope results (Fig. 5).

Various structures have been described (22, 23) for γ-alumina which depend on the conditions of its preparation. For example, agglomerates of (*i*) spherical particles, (*ii*) fibrils, and (*iii*) plate-like layers have all been reported. Clearly, the present preparative method yields agglomerates of spherical particles.

Synthesis and Reactions of 1-Alkyl-3-(*o*-carbalkoxyphenyl)-triazenes

RAYMOND J. LEBLANC AND KEITH VAUGHAN[1]

Department of Chemistry, St. Mary's University, Halifax, Nova Scotia

Received December 23, 1971

The reaction of diazotized anthranilate esters with primary aliphatic amines has been reinvestigated, giving rise to a new series of comparatively unstable 1-alkyl-3-(*o*-carbalkoxyphenyl)-triazenes (**3**). The structures of the products have been confirmed by spectroscopic analysis, molecular ion mass measurements, and from the results of chemical degradation. The spectroscopic properties indicate a preference for the tautomer in which the azo-group is non-conjugated with the benzene ring, Ar·NH·N=N·R; this hypothesis is partly supported by the chemical degradation. In general, the triazenes (**3**) break down by fragmentation of the triazene moiety to give anthranilic acid derivatives, or undergo cyclization to 3-alkyltriazinones (**1**). The alkyltriazinones are also obtained directly in the coupling reaction of the diazonium salt with the amine in the presence of a sodium acetate buffer. The cyclization is quantitative when catalyzed by activity V alumina; a wide variation in the product distribution obtained by reaction with different types of alumina has been observed, and the correlation of these results with the known surface structure of alumina is discussed. Finally, an explanation is offered for the difference between the results of the present work and previous reports.

La réaction des esters anthraniliques diazotés sur les amines primaires aliphatiques a été réexaminée, donnant lieu à une nouvelle série d'alkyl-1 (*o*-carbalkoxyphenyl)-3 triazènes (**3**) relativement instables. Les structures des produits ont été confirmées par analyse spectroscopique, mesure de masse des ions moléculaires et à partir des résultats de la dégradation chimique. Les propriétés spectroscopiques indiquent une préférence pour le tantomère dans lequel le groupe azo n'est pas conjugué au cycle benzènique ArNH·N=N·R; cette hypothèse est en partie confirmée par dégradation chimique. En général les triazènes (**3**) se décomposent par fragmentation du reste triazène qui conduit aux dérivés de l'acide anthranilique, ou subissent une cyclisation en alkyl-3 triazinones (**1**). Les alkyltriazinones sont également obtenues par couplage direct du sel de diazonium avec l'amine en présence du tampon acétate de sodium. La cyclisation est quantitative par catalyse sur alumine d'activité V; une grande variété dans la distribution du produit obtenue par réaction avec divers types d'alumine, a été observée; une corrélation de ces résultats avec la surface d'une structure connue d'alumine est discutée. Finalement, une explication est donnée pour la différence entre les résultats de ce travail et ceux rapportés jusqu'ici.

Canadian Journal of Chemistry, **50**, 2544 (1972)

Generally, the reaction of a diazonium salt with a primary aliphatic amine results in substitution of both amino hydrogen atoms, yielding a 3-alkylpentaz-1,4-diene, Ar·N=N·NR·N=N·Ar, and the intermediate diazoamino compound, Ar·N=N·NHR, is not usually isolated (1). In contrast, 1,3-diaryltriazenes, Ar·N=N·NH·Ar, are readily obtained in high yield from the coupling reaction of the diazonium salt with a primary aromatic amine (2). A much used method of synthesis of 3-aryl-1,2,3-benzotriazin-4-ones (**1**, R = aryl) involves diazotization of an alkyl anthranilate (**2**, R′ = Me or Et), coupling of the diazonium salt solution with a primary aromatic amine, $ArNH_2$, and cyclization of the resulting *o*-carbalkoxyphenyltriazene (**3**, R = aryl, R′ = alkyl) in boiling aqueous ethanol (3). On the other hand, the reaction of diazotized anthranilate esters with primary aliphatic amines has been reported (4–6) to afford directly the 3-alkyl-1,2,3-benzotriazinone (**1**, R = alkyl), although often in low yield. 1-Alkyl-3-(*o*-carbalkoxyphenyl)-triazenes (**3**, R and R′ = alkyl) have been postulated (4, 6) as intermediates in the latter reaction, but in no previously reported case has the intermediate been isolated.

We report a reinvestigation of the reaction of diazotized anthranilate esters with primary aliphatic amines, affording a series of 1-alkyl-3-(*o*-carbalkoxyphenyl)-triazenes (**3**) in good to excellent yields, and an extensive study of the properties and reactions of these compounds.

For example, treatment of a solution of *o*-carbethoxybenzene diazonium salt with excess of methylamine affords an 84% yield of 1-methyl-3-(*o*-carbethoxyphenyl)-triazene (**3***a*); the product must be isolated from the reaction

mixture immediately after addition of the amine. 3-Methyl-1,2,3-benzotriazin-4-one (**1***a*) is obtained in excellent yield if the reaction mixture is stirred for a while after the addition of methylamine. Evidently, under the strongly basic conditions employed, the intermediate triazene (**3***a*) is sufficiently stable to be isolated, but undergoes a slow cyclization when left in the reaction mixture. The cyclization is apparently acid-catalyzed since the methyltriazinone (**1***a*) is formed rapidly, when the coupling reaction of the diazonium salt with methylamine is carried out in the presence of a sodium acetate buffer (weak acid). In fact, as described later, the methyltriazinone (**1***a*) is one of the products of acid hydrolysis of the triazene (**3***a*).

5

The reaction of diazotized anthranilate esters with primary aliphatic amines to give triazenes is not entirely general. 1-Alkyl-3-(*o*-carbalkoxyphenyl)-triazenes (**3***a*–*g*) were obtained in 40–100% yields by diazotization of the alkyl anthranilate (**2**), followed by rapid treatment of the cold diazonium salt solution with an excess of the amine, RNH_2. In the case of reaction of ethylamine with diazotized ethyl anthranilate, a minor yield of the ethyltriazinone (**1***b*) was also obtained. In one reaction, that of *iso*-propylamine with the diazonium salt, the intermediate triazene was not isolated, but in that instance an 80% yield of the *iso*-propyltriazinone (**1***d*) was obtained. This anomaly does not seem to be a function of the nature of the alkyl group, since reaction of the closely similar cyclohexylamine proceeds normally. In two instances, the reactions of *n*- and *iso*-butylamine, neither the expected triazenes nor the cyclization products were isolated; in both cases a quantitative recovery of the anthranilate ester results.

The triazenes (**3***a*–*g*) were frequently obtained contaminated with anthranilate ester if, in the coupling reaction, the amine was added slowly to the diazonium salt solution or if the temperature of the reaction mixture was not maintained at or close to 0°. van Heyningen (4) also observed anthranilate ester regeneration in these reactions. Since it is unlikely that the amine could be formed directly from the diazonium salt (1), it appears that triazene formation does take place in these reactions and that the regeneration of anthranilate ester arises from a fragmentation of the triazene (see later discussion).

The 1-alkyl-3-(*o*-carbalkoxyphenyl)-triazenes (**3**) (Table 1) are unstable, low melting solids or viscous oils, which decompose on standing, in some instances completely within 48 h, affording the corresponding 3-alkyltriazinone (**1**). The solid triazenes are also prone to decomposition when recrystallization is attempted, in some cases precluding further purification. Attempted distillation of the oils resulted in decomposition at approximately 130°. Attempted purification by column chromatography (alumina or silica) results in rapid decomposition on the column with gas evolution. All efforts to separate mixtures of triazene and anthranilate, obtained in the coupling reactions described above, failed due to decomposition of the triazene. Consequently, some of the physical and spectroscopic data in Table 1 relate to unpurified products, but these data show that the triazenes are obtained quite pure directly from the reaction mixture.

*Due to the unstable nature of these compounds, satisfactory elemental analyses could not be obtained.
†From aqueous ethanol.
‡From ethanol.
§Decompose upon recrystallization.
‖A satisfactory n.m.r. spectrum could not be obtained due to rapid decomposition in solution.

[1] 
The i.r. spectra of all the triazenes (**3***a–g*) display N—H absorption at 3300 cm^{-1}, carbonyl absorption at 1690 cm^{-1}, and a strong band at 1495 cm^{-1}, assigned to the azo group, N=N, stretching vibration. The N=N stretching frequency of 1-aryl-3,3-dialkyl triazenes (**4**) has been identified with absorption at 1410–1415 cm^{-1} in the i.r. (7); absorption in the region 1400–1420 cm^{-1} is either very weak or non-existent in the i.r. spectra of the triazenes (**3**). The high frequency of N=N absorption in the triazenes (**3**) suggests non-conjugation of the azo and phenyl groups, indicating a preference for tautomer **3***ii* over **3***i*. The n.m.r. chemical shifts and splitting patterns are consistent with the assigned structures (**3**), and also favor tautomer *ii*. The amino (NH) proton signal is broad in the range 11.87–12.02 p.p.m., compared with 10.95 p.p.m. for compounds of the type ArNH·N=C< (8). Molecular formulae are supported by high resolution molecular ion mass measurement.

The chemical properties of the triazenes (**3**) are also in accord with the assigned structures. Thus, refluxing the triazenes (**3***a*, *e* and *g*) in aqueous ethanol gave the corresponding 3-alkyltriazinones (**1***a* or *e*) in 65–92% yields. Similar treatment of the *n*-propyltriazene (**3***c*) gave a mixture of the *n*-propyltriazinone (**1***c*) and ethyl anthranilate, and of triazenes (**3***b* and *d*) gave only ethyl anthranilate. The formation of the triazines in these reactions compares with analogous cyclizations of 1-aryl-3-(*o*-carbalkoxyphenyl)-triazenes (**3**, R = aryl, R′ = alkyl) (3), but the formation of ethyl anthranilate has not been observed in the reactions of the aryl series. The overall yield of alkyltriazinone (**1**) in these reactions, based on alkyl anthranilate as starting material, is as high as 60%, and is raised to over 80% when the alumina-catalyzed method of cyclization, described below, is employed, representing a substantial improvement over the 20–30% yields reported previously (4). Alkaline hydrolysis of the methyltriazene (**3***a*) gave a high yield of anthranilic acid (**2**, R′ = H), whereas the major product of acid hydrolysis is ethyl anthranilate, with a minor yield of the methyltriazinone (**1***a*).

The formation of anthranilate esters in the degradation reactions of the triazenes (**3**) is best described as an example of general acid–base catalysis. In the case of acid catalysis, either mineral or very weak acid such as water or ethanol, the reaction probably proceeds by protonation of tautomer *ii*, followed by a fragmentation similar to that observed in the diazoamino → aminoazobenzene rearrangement (7) eq. 1.

In the case of alkaline hydrolysis, the equilibrium *i* ⇌ *ii* may be facilitated to the right, leading eventually to exclusive formation of anthranilic acid (**2**, R′ = H), after hydrolysis of the ester group. An alternative route to anthranilic acid in an alkaline medium involves nucleophilic displacement at the azo-nitrogen atom in tautomer *ii*, resulting in replacement of the arylamino group by hydroxide ion eq. 2. There is no evidence in the literature to support

*Activity I alumina was baked out at the given temperature for an overnight period immediately prior to use.
†Activity II and V alumina were obtained from the commercial activity I alumina by addition of the quantity of water specified by the manufacturer.

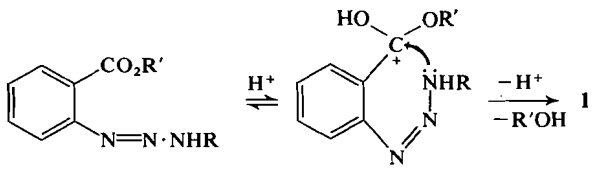
this latter postulation, although van Heyningen (4) made a similar proposal to account for reformation of anthranilate ester in the coupling reaction described previously.

The observation that the triazenes (**3**) undergo cyclization to the triazinones (**1**) under acidic conditions, frequently accompanied by fragmentation to anthranilate ester, suggests that protonation at the carbonyl-oxygen competes successfully with protonation at the amino-nitrogen, catalyzing the cyclization reaction, thus [3].

The alumina-catalyzed decomposition of 1-methyl-3-(*o*-carbethoxyphenyl)-triazene (**3***a*) in anhydrous benzene has been extensively studied. Two modes of reaction are evident: (*a*) cyclization to the methyltriazinone (**1***a*); (*b*) triazene cleavage to ethyl anthranilate, with concomitant evolution of nitrogen gas. The proportion of the two products varies a great deal with the nature of the alumina, and the product distributions obtained with various types of alumina are shown in Table 2.

The compositions of mixtures of ester and triazinone obtained in these reactions, and also in the acid hydrolysis of **3***a*, have been determined by a quantitative i.r. method, which permits rapid analysis and does not require separation of the components. The method thus eliminates any inaccuracies that might be introduced if the mixtures were separated by distillation or chromatography. The method derives from the fact that ethyl anthranilate absorbs strongly at 3500 cm^{-1} (NH stretch) in the i.r., whereas the triazinone (**1***a*) is essentially transparent above 3000 cm^{-1}, but absorbs strongly at 960 cm^{-1} (assigned to N—N stretch). Ethyl anthranilate is almost transparent between 900 and 1000 cm^{-1}. Measurement of the relative intensities of the 3500 and

[3]



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

960 cm^{-1} peaks in the i.r. spectrum of an unknown mixture, and comparison with a series of mixtures of known composition, allowed determination of the composition of the unknown without separation.

Several general trends are evident from the data in Table 2. The yield of triazinone increases as the activity of the alumina is lowered, and is quantitative for activity V alumina, whether acid, neutral, or basic. (This reaction represents the most efficient way of synthesizing the methyltriazinone (**1***a*) from the triazene.) For a particular activity, the ratio of the yields, triazinone:ester, is greatest for basic alumina, least for acid alumina, and intermediate for neutral alumina. The yield of triazinone is also increased markedly by baking out the alumina at 120° prior to reaction, but this effect is lessened somewhat by baking out at higher temperatures.

The product distributions in the acid alumina-catalyzed reactions are almost identical to the distribution of products obtained in the reaction of the triazene (**3***a*) with mineral acid. The acidic sites on the surface of alumina can be either Bronsted or Lewis acid sites, the latter probably being due to the exposure of Al^{3+} ions at the surface (9, 10), so it seems likely that the acid alumina-catalyzed reaction proceeds according to eqs. 1 and 3, or by similar routes involving Al^{3+} ion instead of H^+. The action of acid alumina is completely changed by addition of a small amount of water (activity V), triazinone formation taking over completely, suggesting that adsorbed water molecules cover the previously exposed Lewis acid sites.

The reaction of the triazene (**3***a*) with basic alumina, giving triazinone formation almost exclusively, is very different from the reaction with aqueous alkali. The mechanisms represented by eqs. 1 and 2 are seemingly not applicable in this instance. An alternative course for triazinone formation, involving base catalysis, is proton abstraction from the amino nitrogen, followed by nucleophilic addition at the ester carbonyl group (eq. 4). There does not appear to be a reasonable explanation for the fact that cyclization does not take place in aqueous alkali.

The effect of baking out the alumina before use is more pronounced for basic than for acid alumina, resulting in preference for triazinone formation. de Boer (11) has shown that surface water in alumina is removed easily at 120°, exposing a greater number of active sites. In the case of basic alumina, this might result in a greater facility to catalyze the cyclization by a mechanism such as [4]. At higher temperatures, adjacent ^-OH groups are expelled as water molecules, leaving behind exposed Al^{3+} ions and thus increasing the proportion of acid sites on the surface (10). The observation that the triazinone yield drops in favor of anthranilate formation if the alumina is baked out at a higher temperature, 300 or 600°, is in accordance with these postulations.

Conclusion

The results presented in this paper provide an explanation for the fact that previous workers did not isolate the intermediate triazenes (**3**). The use of a sodium acetate buffer in the coupling reaction is very common, but the present work shows that the 1-alkyl-3-aryltriazenes cannot be isolated when the coupling reaction is buffered. This is in contrast to the reaction of diazonium salts with aromatic primary amines, in which case the yield of diazoamino compound is increased by the use of a buffer (2, 3). van Heyningen (4) used a direct coupling reaction with the aliphatic amine without a buffer, but yet did not isolate the intermediates. Indeed, the conditions of reaction in the present work are virtually identical with those employed by van Heyningen; the difference must be in the method of work-up.

van Heyningen purified his products by distillation under reduced pressure, obtaining low yields of triazinone (**1**) and a high recovery of the starting material, alkyl anthranilate. We have shown here that the coupling reaction of diazonium salts with aliphatic primary amines

[4]

sometimes affords a mixture of the intermediate triazene and *regenerated* alkyl anthranilate, that the intermediates are extremely unstable, resisting all attempts at separation from mixtures, and further that the decomposition of the triazenes (**3**) frequently gives rise to a mixture of triazinone and alkyl anthranilate. Thus, it seems very likely that van Heyningen did in fact isolate the triazenes, either pure or as mixtures with anthranilate, but also equally likely that they decomposed on distillation. Therefore, there is little contradiction between the present work and previously reported results; simply a slight modification of conditions and work-up that results in the isolation of previously unobserved reaction intermediates.

Experimental

Melting points were obtained on a Fisher–Johns apparatus and are corrected. The i.r. spectra were recorded with liquid paraffin mulls on a Perkin–Elmer Infracord spectrophotometer. N.m.r. spectra were obtained with a Varian A-60A spectrometer using tetramethylsilane as the internal standard, and mass spectra with a Dupont/C.E.C. model 21-110B high resolution spectrometer. Molecular ion mass measurements were done by the peak-matching method using electrical detection. Merck grade alumina was obtained from Brinkmann Instruments (Canada) Limited.

*1-Alkyl-3-(o-carbalkoxyphenyl)-triazenes (**3***a–g*)*

Methyl or ethyl anthranilate (0.006 mol) was added to 2 *M* hydrochloric acid (9.0 ml) and diluted with water (20 ml) to dissolve the precipitated salt. The resulting solution was cooled to 0°, diazotized with sodium nitrite (0.45 g) in a minimum volume of water, and stirred at 0° until a clear solution was obtained (up to 1 h). An aqueous solution of the appropriate amine (0.036 mol) was added to the cold diazonium salt solution in one portion, and the solid which separated was isolated immediately by filtration and crystallized from ethanol or aqueous ethanol to afford the *1-alkyl-3-(o-carbalkoxyphenyl)-triazenes* (**3**) as colorless or pale yellow prisms (Table 1). Some of the products separated from the reaction mixture as oils; these were isolated by extraction with ether and evaporation of the washed and dried (Na_2SO_4) ether extract. Attempted purification of the oils by distillation or chromatography resulted in decomposition.

In the reaction of diazotized ethyl anthranilate with ethylamine, affording the triazene (**3***b*), the aqueous mother liquor gave a precipitate on standing, identified as 3-ethyl-1,2,3-benzotriazin-4-one (**1***b*) (11%), m.p. 68.5–70° (lit. (4) 70–71°), ν_{max} 1675 cm^{-1}.

The reaction of diazotized methyl anthranilate with *n*-butylamine or *iso*-butylamine resulted in quantitative recovery of methyl anthranilate.

*3-Methyl-1,2,3-benzotriazin-4-one (**1a**)*

(*a*) 1-Methyl-3-(*o*-carbethoxyphenyl)-triazene (**3***a*) (1.0 g) was refluxed in 70% aqueous ethanol (30 ml) for 4 h. The solution was concentrated *in vacuo* and the precipitated solid was filtered to yield 3-methyl-1,2,3-benzotriazin-4-one (**1***a*) (0.5 g, 65%), m.p. 121–122 °C (ethanol), ν_{max} 1670 cm^{-1} (C=O), which was identical with an authentic sample (i.r. spectrum and mixed m.p. 122–122.5 °C) prepared by diazotization of *N*-methylanthranilamide (**5**, R = Me) (12).

Similar treatment of 1-methyl-3-(*o*-carbomethoxyphenyl)-triazene (**3***g*) gave an identical product (yield 92%).

(*b*) A cold solution of ethyl anthranilate (1.0 g) in concentrated hydrochloric acid (1.75 ml) and water (30 ml) was diazotized with aqueous sodium nitrite (0.45 g in a minimum volume of water). The resulting diazonium salt solution was treated with 40% aqueous methylamine dropwise with constant agitation, at such a rate that the temperature did not rise above 0 °C, until the solution was strongly alkaline ($pH > 11$). A precipitate appeared at this stage, but was not separated. The mixture was allowed to warm to room temperature slowly with stirring, and after stirring overnight the precipitate was collected to yield the methyltriazinone (**1***a*) (0.8 g, 82%), m.p. 120 °C, identical with a sample prepared above.

(*c*) Ethyl anthranilate (1.0 g) was dissolved in 2 *M* hydrochloric acid (9 ml) and water (20 ml) and the solution cooled to 0 °C. The cold solution was diazotized with sodium nitrite to starch–iodide end-point and then made neutral by the addition of a solution of sodium acetate (17.2 g) in water. 40% aqueous methylamine (3.5 ml) was added quickly in one portion, forming a yellow precipitate which was filtered immediately to yield the methyltriazinone (**1***a*) (0.8 g, 82%), identical with a sample prepared above.

(*d*) 1-Methyl-3-(*o*-carbethoxyphenyl)-triazene (**3***a*) (0.5 g) was dissolved in anhydrous benzene (50 ml) and activity V alumina (6.0 g) was added. The resulting slurry was stirred for 12 h at room temperature and filtered. The residual alumina was washed several times with aliquots (10 ml) of anhydrous benzene and the combined filtrate and washings evaporated to dryness *in vacuo* to yield the methyltriazinone (**1***a*) (yield quantitative) identical with a sample prepared above.

*3-Benzyl-1,2,3-benzotriazin-4-one (**1e**)*

Refluxing 1-benzyl-3-(*o*-carbethoxyphenyl)-triazene (**3***e*) in aqueous ethanol, as under procedure *a* above, gave the benzyltriazinone (**1***e*), in 70% yield, m.p. 120–121.5 °C (lit. (5) 122–123 °C), ν_{max} 1670 cm^{-1}.

*3-(n-Propyl)-1,2,3-benzotriazin-4 one (**1c**)*

1-(*n*-Propyl)-3-(*o*-carbethoxyphenyl)-triazene (**3***c*) (0.5 g) was refluxed in 70% aqueous ethanol (15 ml) for 2 h. The solution was concentrated *in vacuo* to remove ethanol and the aqueous residue was extracted with chloroform. Evaporation of the dried (Na_2SO_4) extract yielded a yellow oil which partly solidified on standing. Filtration of the mixture yielded, from the solid phase, the *n*-propyltriazinone (**1***c*) (0.11 g, 27.5%), m.p. 56–56.5 °C (aqueous ethanol) (lit. (13) 61–62°), ν_{max} 1675 cm^{-1}. The oily filtrate was identified as ethyl anthranilate (0.23 g, 66%) by comparison with an authentic sample (Eastman).

Similar treatment of 1-ethyl-3-(*o*-carbethoxyphenyl)-triazene (**3***b*) or of 1-cyclohexyl-3-(*o*-carbethoxyphenyl)-triazene (**3***d*) gave only ethyl anthranilate (yields 78 and 67% respectively).

*3-(i-Propyl)-1,2,3-benzotriazin-4-one (**1d**)*

A solution of methyl anthranilate (1.0 g) in 2 *M* hydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chloric acid (9.9 ml) and water (20 ml) was cooled below 5 °C and diazotized with sodium nitrite (0.45 g) in water. 40% aqueous *iso*-propylamine (6.4 ml) was added slowly, giving a strongly alkaline solution (no precipitate was evident at this stage), which was stirred at room temperature for 5 days. The precipitated solid was filtered to afford the *iso*-propyltriazinone (**1***d*) (1.0 g, 80%), m.p. 55.5–56.0° (lit. (5) 60–61°), ν_{max} 1680 cm^{-1}.

*Alkaline Hydrolysis of 1-Methyl-3-(o-carbethoxyphenyl)-triazene (**3***a*)

1-Methyl-3-(*o*-carbethoxyphenyl)-triazene (0.75 g) was refluxed in 2 *M* sodium hydroxide (25 ml) for 1 h. The resulting yellow solution was cooled, acidified to p*H* 5.5 by the addition of glacial acetic acid (6.8 ml) and extracted with chloroform. Evaporation of the dried (Na_2SO_4) chloroform extracts afforded anthranilic acid (0.45 g, 90%), identical (m.p. and mixed m.p. 143–144°, i.r. spectrum) with an authentic sample (Eastman).

*Acidic Hydrolysis of 1-Methyl-3-(o-carbethoxyphenyl)-triazene (**3***a*)

The triazene (**3***a*) (0.5 g) was added to cold 1 *M* sulfuric acid (10 ml), whereupon a vigorous effervescence took place and a clear pink solution resulted immediately. The solution was basified at once with concentrated ammonia (2.0 ml) and extracted with chloroform, yielding an orange oil (0.35 g). Analysis of the residue by quantitative i.r. measurements showed that it was a mixture of ethyl anthranilate (75% yield) and 3-methyl-1,2,3-benzotriazin-4-one (**1***a*) (14% yield).

*Alumina-catalyzed Decomposition of 1-Methyl-3-(o-carbethoxyphenyl)-triazene (**3***a*)

General Procedure

The triazene (**3***a*) (1.0 g) was dissolved in anhydrous benzene (100 ml) and alumina (12 g) was added in one portion. The slurry was stirred at room temperature for 35 min or 12 h, dependent on the activity of the alumina (see Table 1). The alumina was removed by filtration and washed with 5 × 10 ml aliquots of anhydrous benzene; in some cases Soxhlet extraction was necessary to desorb all organic material from the catalyst. The combined benzene washings and extracts were evaporated to dryness *in vacuo*. At this stage, the residue was either a solid or an oil. In the former case, the solid was invariably identified as 3-methyl-1,2,3-benzotriazin-4-one (**1***a*) by comparison (m.p., mixed m.p., and i.r. spectrum) with an authentic sample (12). The oils were shown to be mixtures of the triazine (**1***a*) and ethyl anthranilate, and the composition was determined by quantitative i.r. measurements of the relative intensities of the absorption peaks at 3500 (NH stretch, anthranilate) and 960 cm^{-1} (N—N stretch, triazine) (see Discussion). The results of this analysis for reactions with various types of alumina are shown in Table 2.

Etude des oxyphosphoranes en tant qu'intermédiaires lors de la réduction de l'ozonide du styrène par les phosphites

J. CARLES ET S. FLISZÁR

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 17 février 1972

L'étude cinétique de la réduction de l'ozonide du styrène par une série de phosphites suggère la formation d'un intermédiaire oxyphosphorane. Une réévaluation du mécanisme d'ozonolyse des oxyphosphoranes comportant une double liaison C—C est présentée.

The kinetic study of the reduction of styrene ozonide by various phosphites suggests the formation of an oxyphosphorane intermediate. A reevaluation of the mechanism of ozonolysis of selected oxyphosphoranes having a C—C double bond is presented.

Depuis leurs premières synthèses par Kukhtin (1) en 1958, les oxyphosphoranes ont fait l'objet de nombreuses études tant du point de vue de leurs propriétés que de leur structure (2). Ces composés sont normalement produits par condensation de composés α-dicarbonylés avec des phosphites trisubstitués (3). De plus, Denney et Jones (4) ont trouvé que les phosphites peuvent réagir avec certains composés peroxydiques pour engendrer des oxyphosphoranes. Parallèlement il est également apparu récemment que des oxyphosphoranes instables à six chaînons peuvent être des intermédiaires se décomposant selon des processus bien définis, lors de réactions entre les composés phosphorés trivalents et des peroxydes présentant une autre fonction oxygénée, tels que les β-peroxylactones (5) et les ozonides (6, 7).

Des études antérieures (6, 7) sur la réduction des ozonides par la triphénylphosphine ont permis de déterminer l'influence des substituants du cycle ozonidique et de conclure au caractère nucléophile de l'attaque de la triphénylphosphine.

Le présent travail a pour objet l'étude de l'influence de la nature du composé phosphoré trivalent sur la cinétique de la réduction d'un ozonide donné. Une telle étude permettra, d'une part, de corroborer les résultats antérieurs (6) concernant le rôle des substituants du cycle ozonidique et, d'autre part, de détecter l'intervention éventuelle d'un composé intermédiaire instable du type oxyphosphorane pour divers composés phosphorés trivalents. Ces derniers forment une série de phosphites $P(RO)_3$ avec $R = CH_3$, C_2H_5, $i\text{-}C_3H_7$, $t\text{-}C_4H_9$, C_6H_5. L'ozonide utilisé est le phényl-2 trioxa-1,3,4 cyclopentane (ozonide du styrène).

Partie expérimentale

La réduction de l'ozonide du styrène a été étudiée à température contrôlée, en solution dans le chloroforme, en déterminant la formation du benzaldéhyde en fonction du temps. Celle-ci a été suivie en spectroscopie i.r. par l'évolution de la bande d'absorption à 1710.4 cm^{-1} due à la vibration du groupement carbonylé.

La stoechiométrie de la réaction a été vérifiée par des analyses des mélanges réactionnels. Après un temps de réaction de 7 jours, à 25 °C, la réduction de l'ozonide du styrène (0.1 *M*) par un phosphite $(RO)_3P$ (0.1 *M*) est pratiquement quantitative (>99%) d'après l'analyse du benzaldéhyde et du phosphate formés. Ainsi, par exemple, lors de quatre expériences indépendantes de réduction de 1 mmol d'ozonide par 1 mmol de triméthylphosphite, il a été obtenu après 7 jours à 25°: 0.995, 0.999, 0.998, 0.996 mmol d'aldéhyde benzoïque et 0.997, 0.995, 1.00, et 0.995 mmol de $(CH_3O)_3PO$. Le formaldéhyde qui est également produit lors de la réaction n'a pas pu être dosé en raison de sa volatilité.

Il a été montré antérieurement (6) que si la réduction de l'ozonide est du deuxième ordre, soit du premier ordre par rapport à chacun des réactifs, la constante de vitesse k peut être déterminée d'après l'éq. 1, où D représente la densité

$$[1] \qquad 1/D = 1/D_\infty + (1/akD_\infty)(1/t)$$

optique du benzaldéhyde au temps t, D_∞ est la valeur de D pour $t = t_\infty$, et a = concentration initiale en ozonide = concentration initiale en phosphite.

Les résultats obtenus permettent de tracer la droite $1/D$ en fonction de $1/t$. Dans tous les cas il a été obtenu une droite satisfaisant l'éq. 1, dont la pente permet le calcul de la constante de vitesse k. L'ordonnée à l'origine ($1/t \to 0$) permet le calcul de D_∞. La valeur de D_∞ calculée à partir des données cinétiques peut être facilement contrôlée par la mesure directe de D_∞ obtenue soit par sa détermination après un temps de réaction suffisamment long, soit par la comparaison avec une solution d'aldéhyde de concentration

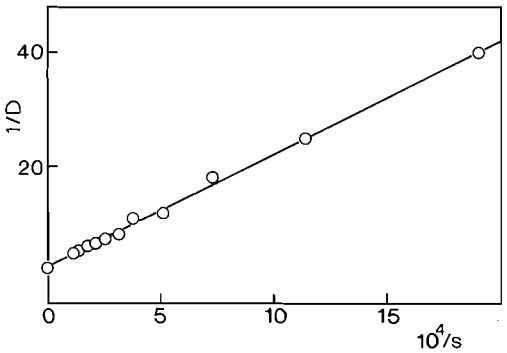

FIG. 1. Vérification de l'éq. 1 pour la réduction de l'ozonide du styrène par le triméthylphosphite dans le méthanol à 25°.

TABLEAU 1. Réduction de l'ozonide du styrène par le triméthylphosphite, dans le chloroforme à 25 °C

a (M)*	$t_{1/2}$ (s)	$10^3\,k$ (1 mol^{-1} s^{-1})
0.1	9250	1.06
0.2	4640	1.08
0.4	2270	1.10
1.0	924	1.06

*a = concentration initiale en ozonide et en phosphite.

égale à a. La méthode est illustrée par la fig. 1, pour la réduction par le triméthylphosphite dans le méthanol absolu à 25°.

La constante de vitesse peut être également calculée directement à partir de l'éq. 1, en y insérant les valeurs de D observées pour différents t. Les équations cinétiques utilisées ont été également vérifiées dans le cas de la réduction de l'ozonide du styrène par le triméthylphosphite, à 25° dans le chloroforme, par des mesures des temps de demi-réaction $t_{1/2}$ effectuées au moyen de solutions de différentes concentrations initiales (a) en ozonide et en phosphite. Les résultats rapportés au tableau 1 montrent bien la constance des valeurs de k ainsi calculées ($k = 1/at_{1/2}$).

D'ultérieures précisions expérimentales sont indiquées dans la réf. 6.

Résultats et discussion

Les constantes de vitesse de réduction, à 25°, de l'ozonide du styrène dans le chloroforme par divers phosphites sont indiquées dans le tableau 2.

Afin d'étudier l'ordre de grandeur des énergies d'activation de la réduction par les phosphites, la dépendance de k en fonction de la température a été étudiée pour le triméthylphosphite. Dans le chloroforme, les valeurs de k (1 mol^{-1} s^{-1}) suivantes ont été obtenues: 1.06×10^{-3} (25°), 2.25×10^{-3} (35°), 4.51×10^{-3} (45°). La loi d'Arrhenius est bien suivie et conduit à une énergie d'activation de 13.6 kcal/mol. Cette valeur est donc assez semblable à celle obtenue précédemment (6) (12.7 kcal/mol) pour la réduction de l'ozonide du styrène par la triphénylphosphine.

TABLEAU 2. Constantes de vitesse de réduction de l'ozonide du styrène par les phosphites $(RO)_3P$, dans le chloroforme, à 25 ± 0.1 °C

R	k (1 mol^{-1} s^{-1})
CH_3	1.06×10^{-3}
C_2H_5	2.15×10^{-3}
i-C_3H_7	2.71×10^{-3}
t-C_4H_9	2.80×10^{-3}
C_6H_5	4.33×10^{-5}

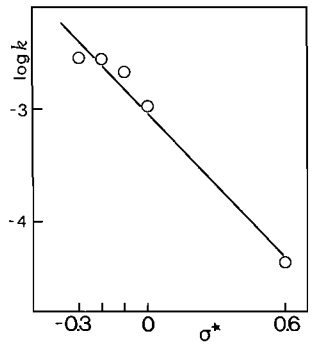

FIG. 2. Vérification de l'éq. de Taft [2] par les résultats du tableau 2.

L'examen des résultats du tableau 2 permet l'étude de l'influence du substituant R de l'agent réducteur sur la constante de vitesse. Il ressort notamment que l'équation de Taft (éq. 2) est

$$[2] \qquad \log k/k_0 = \rho^*\sigma^*$$

bien vérifiée, ainsi que l'illustre la fig. 2.

La pente négative de la droite de Taft indique que les phosphites possédant un substituant donneur d'électrons réduisent plus rapidement l'ozonide du styrène que ceux possédant un substituant attracteur d'électrons. Les phosphites sont donc des agents nucléophiles lors de la réduction des ozonides. Ces résultats sont à rapprocher des études précédentes (6, 7) avec la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

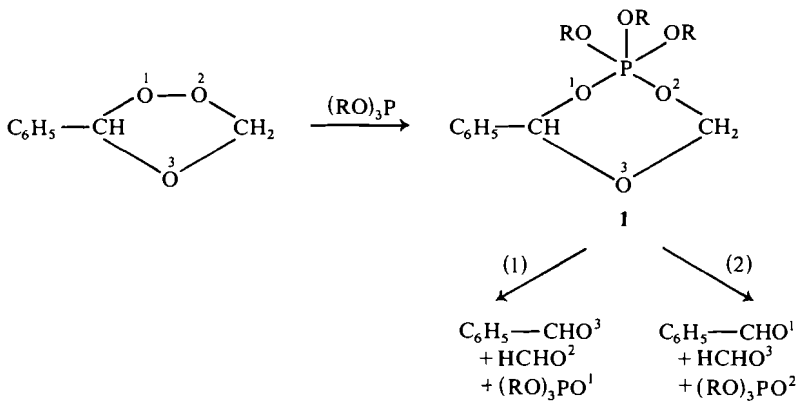

SCHÉMA 1

triphénylphosphine montrant que cette dernière agit en tant qu'agent nucléophile vis-à-vis des ozonides. Le caractère nucléophile des composés phosphorés trivalents est clairement illustré par la comparaison des constantes de vitesse pour la réduction de l'ozonide du styrène par la triphénylphosphine (6.64×10^{-2}) et par le triphénylphosphite (4.33×10^{-5} l mol^{-1} s^{-1}) à 25°.

Comme cela avait été considéré dans le cas de la réduction des ozonides par la triphénylphosphine, il y a lieu d'envisager deux modes d'attaque (schémas 1 et 2).

L'attaque du phosphite pourrait s'effectuer par un processus unique, par une étape où les deux atomes d'oxygène peroxydiques sont simultanément mis en jeu, cette étape contrôlant la cinétique (schéma 1).

Le processus impliqué pourrait alors correspondre à la formation d'un produit d'addition intermédiaire instable, semblable à l'oxyphosphorane suggéré par Adam *et al.* (5) pour la réduction des β-peroxylactones par les composés phosphorés trivalents.

L'intermédiaire (**1**) se décomposerait ensuite très rapidement selon les deux voies possibles: la voie *1* conduisant à l'incorporation de l'oxygène O-3 dans le benzaldéhyde et la voie *2* où l'oxygène O-3 est incorporé dans l'aldéhyde formique. Un tel mécanisme est en accord avec les équations cinétiques utilisées et vérifiées expérimentalement.

Une autre hypothèse consiste à envisager que la réduction des ozonides peut avoir lieu par le truchement de deux mécanismes parallèles (schéma 2), l'un d'entre eux s'effectuant par une attaque sur l'oxygène O-1 et l'autre ayant lieu par une attaque sur l'oxygène O-2.

La comparaison des étapes cinétiques proposées pour les mécanismes 1 et 2 indique que l'intermédiaire intervenant dans le mécanisme 2 possède un caractère nettement plus polaire que celui postulé pour le mécanisme 1. Dès lors, l'étude de l'effet de solvant sur les constantes de

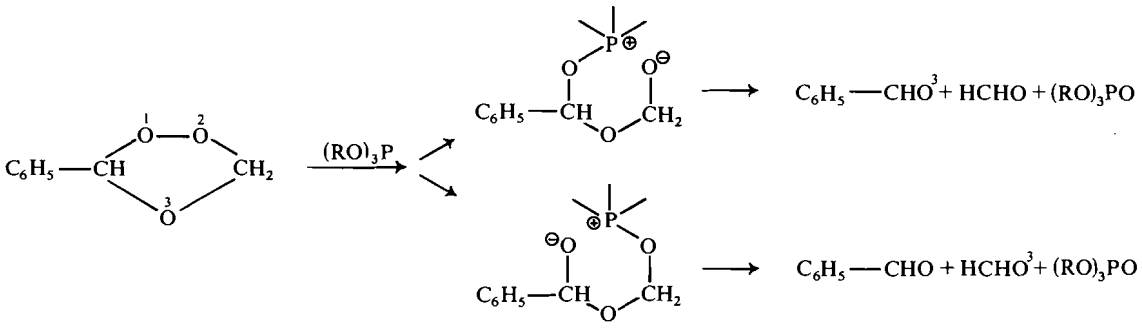

SCHÉMA 2

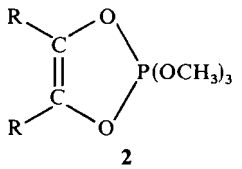
4 3

TABLEAU 3. Effet du solvant sur la réduction de l'ozonide du styrène par le triméthylphosphite à 25 °C

Solvant	Constante diélectrique	$10^3 k$ ($l\ mol^{-1}\ s^{-1}$)
CCl_4	2.228	1.20
$CHCl_3$	4.718	1.06
$C_2H_4Cl_2$	10.36	1.23
CH_3OH	32.63	1.26

vitesse peut permettre une distinction entre les deux mécanismes. Les résultats du tableau 3 indiquent que les constantes de vitesse de réaction dépendent très peu des solvants utilisés, ce qui semble être en faveur du mécanisme 1 qui implique un oxyphosphorane **1**.

L'intervention d'un intermédiaire oxyphosphorane *instable* du type **1** permet d'expliquer de nombreux résultats ayant trait à l'ozonation d'oxyphosphoranes stables **2** comportant une double liaison.



2

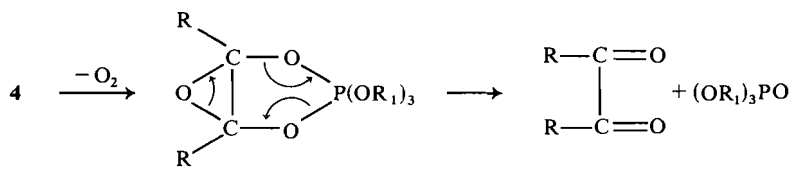
Ramirez *et al.* (8) ont notamment trouvé que l'ozonation d'oxyphosphoranes du type **2** engendre, outre le diacétyle et l'anhydride acétique, le peroxyde d'acétyle **3**. L'explication suggérée par Ramirez *et al.* postule la formation de l'ozonide primaire (1,2,3-trioxolane) de **2** qui, lors de son clivage, conduit à une attaque de l'atome de phosphore par l'oxygène terminal zwittérionique (8).

La grande facilité avec laquelle se forment, en général (9), les ozonides à partir de doubles liaisons C—C comprises dans un anneau à cinq atomes suggère qu'il semble raisonable de considérer la formation d'une proportion importante d'ozonide **4**, dérivé de **2**.

De par sa structure, l'ozonide **4** est voisin à l'intermédiaire **1** postulé précédemment. La décomposition de l'ozonide intermédiaire **4**, en suivant la même voie de décomposition que l'intermédiaire **1**, conduirait alors au peroxyde d'acétyle **3**.

L'éventuelle participation de l'ozonide intermédiaire **4** peut également rendre compte de la formation des autres produits observés lors de l'ozonolyse de **2**. Ainsi, une élimination d'oxygène moléculaire via une rupture hétérolytique du pont peroxyde, semblable à celle rencontrée en spectrométrie de masse des ozonides (10), pourrait rendre compte de la formation de dicétone. Une telle élimination d'oxygène moléculaire est en accord avec les observations de Ramirez *et al.* (8) et s'explique ainsi sans l'intervention d'un hypothétique perozonide, postulé par ces auteurs.

Il est entendu qu'à ce stade toute interprétation des résultats d'ozonolyse des oxyphosphoranes **2**, tant par les mécanismes suggérés par Ramirez *et al.* que par la voie esquisée ci-haut, ne saurait être que spéculative. Cependant, la vraisemblance de la participation d'oxyphosphoranes **1** très instables lors de la réduction des ozonides par les phosphites suggère une instabilité comparable pour les



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ozonides **4** pouvant être attendus lors de l'ozonolyse d'oxyphosphoranes du type **2**. Dès lors, la *possibilité* d'une interprétation des résultats d'ozonolyse des oxyphosphoranes **2** via **4** semble pouvoir être temporairement retenue, dans l'attente de résultats pouvant trancher définitivement entre les mécanismes 1 et 2.

Nous remercions le Conseil National de Recherches du Canada pour un octroi qui a permis le présent travail, et une bourse d'études à J. C.

Adducts of Piperidine, Piperazine, Methylpiperazine, and Morpholine with Bis(β-Ketoenolates) of Nickel(II)

G. MARCOTRIGIANO,[1] R. BATTISTUZZI, AND G. C. PELLACANI

Istituto di Chimica Generale, Università di Modena, Via G. Campi 183, 41100 Modena, Italy

Received January 4, 1972

The bis(β-ketoenolates)nickel(II) adducts of piperidine, piperazine, methylpiperazine, and morpholine are isolated in the solid state and investigated by magnetic measurements and electronic and i.r. spectra. Magnetic measurements and electronic spectra give evidence of *trans*-octahedral configuration while i.r. spectra show that the amines are coordinated to the nickel atom towards the nitrogen atom. The new band found in the range 385–300 cm^{-1} for all complexes can be assigned to Ni—N vibration. In the $Ni(DBM)_2 \cdot 4B$ (B = methylpiperazine and morpholine) the two additional bases are not coordinated to the metal atom.

Les composés d'addition du nickel(II) bis(β-cétoénolates) avec la pipéridine, pipérazine, méthylpipérazine, et morpholine, ont isolés à l'état solide et étudiés par des mesures magnétiques et des spectres i.r. et électroniques. Les mesures magnétiques et les spectres électroniques prouvent la configuration *trans*-octaédrale tandis que les spectres i.r. indiquent que les amines sont coordinées à l'atome de nickel par l'intermédiaire de l'atome d'azote. La bande nouvelle, située dans la région 385–300 cm^{-1}, trouvée pour tous ces complexes peut être assignée à la vibration Ni—N. Dans $Ni(DBM)_2 \cdot 4B$ (B = méthylpipérazine et morpholine) les deux bases supplémentaires ne sont pas coordinées à l'atome de métal.

Canadian Journal of Chemistry, **50**, 2557 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It is known that, on account of the tendency of bis(β-ketoenolates)nickel(II) to be six-coordinate, it easily gives adducts of the type NiL_2B_2 (B = monodentate ligand, L = β-ketoenolate) together with monodentate ligands.

A wide variety of base-adducts of the type NiL_2B_2 have been reported with B as nitrogen-donor ligands (1–6).

X-Ray and spectrophotometric measurements (3, 5) have established, for several of these base-adducts, a *trans*-octahedral configuration, while i.r. measurements show a marked shift to lower frequencies of ν(C—O), ν(C—C), and ν(M—O) of the bis(acetylacetonate)nickel(II) on coordination (4, 6).

Since bis(β-ketoenolate)nickel(II) adducts with aliphatic etherocyclic amines having one or two donor sites (nitrogen for piperidine, nitrogen–nitrogen for piperazine and methylpiperazine, and nitrogen–oxygen for morpholine) are not known, except for the adducts of piperidine with nickel(II)dipivaloylmethanate (7), we have investigated the coordination ability of these amines.

In this work, we have prepared some new adducts of $Ni(AcAc)_2$, $Ni(BA)_2$, and $Ni(DBM)_2$ (AcAc = acetylacetonate; BA = benzoylacetonate; DBM = dibenzoylmethanate) with piperidine, piperazine, methylpiperazine, and morpholine characterized by i.r., near-i.r., visible spectroscopy, and magnetic measurements.

Experimental

Preparations

Bis(β-ketoenolates)nickel(II) was prepared by adding a stoichiometric amount of the corresponding β-diketone in methanolic solution (4×10^{-2} mol in 10–80 ml) to aqueous solutions of the $NiCl_2 \cdot 6H_2O$ (2×10^{-2} mol in 20 ml of water) while stirring at 50–60 °C.

The crystalline products were filtered, washed with water, methanol, and ether, and vacuum-dried.

The adducts with piperidine, methylpiperazine, and morpholine were prepared by crystallization of the bis(β-ketoenolates)nickel(II) from these amines. The adduct $Ni(AcAc)_2 \cdot$piperazine was obtained by mixing a methanolic solution of $Ni(AcAc)_2 \cdot 2H_2O$ with an excess of piperazine in the same solvent at 40–50 °C.

The adducts of the $Ni(AcAc)_2$ and $Ni(BA)_2$ were collected by filtration, washed with benzene or ether, and dried at atmospheric pressure, while $Ni(DBM)_2 \cdot 4$(morpholine) and $Ni(DBM)_2 \cdot 4$(methylpiperazine) were dried in the folds of a filter paper. The latter complexes lose the amines and $Ni(DBM)_2 \cdot 2$(methylpiperazine) was obtained by crystallization of $Ni(DBM)_2 \cdot 4$(methylpiperazine) from benzene.

The analytical data and physical properties for the crystalline solids are given in Table 1.

Analyses

Nickel was determined by complexometric titration with EDTA and nitrogen by the Kjeldhal method.

Physical Measurements

The i.r. spectra were recorded in potassium bromide

discs over the 4000–500 cm^{-1} region and in Nujol mulls supported between thin polyethylene sheets over the range 600–250 cm^{-1} using a Perkin–Elmer 521 spectrophotometer.

Solid-state electronic spectra were recorded in Nujol mulls on filter paper as support using a Beckman DK2 spectrophotometer (1500–500 mμ).

Magnetic susceptibilities were taken on the solid complexes at room temperature by the Gouy method, using $Nien_3S_2O_3$ as calibrant (8).

Results and Discussion

Infrared Spectra

The more important i.r. bands are reported in Table 2. The formation of coordinate bonds in the bis(β-ketoenolates)nickel(II) adducts is immediately apparent from the considerable shifts to lower frequencies (200–100 cm^{-1}) of ν(N—H) that occur in the case of coordinated but not of uncoordinated ligands. These shifts show that piperazine, methylpiperazine, and morpholine are coordinated to metal by means of the nitrogen atom of their N—H group (9, 10). In the morpholine adducts, the positive shift of C—O—C stretching vibration at 1109 cm^{-1} in acetylacetonate, 1105 cm^{-1} in benzoylacetonate, and 1100 cm^{-1} in dibenzoylmethanate adducts, with respect to free morpholine (1095 cm^{-1}), excludes a possible oxygen-to-metal coordination (10). Although for piperidine adducts we have found a small shift to lower frequencies (25–20 cm^{-1}) of ν(NH), nevertheless the great change in the H—N—C deformation region (870–860 cm^{-1}) (11) affords evidence of the coordination of the N-atom of piperidine.

The coordination of the amines also results in corresponding shifts of the C=O, C=C, and Ni—O absorption bands (4, 6).

The assignments of ν(C—O) and ν(C—C) in the range of 1600–1500 cm^{-1} are made on the

basis of previously suggested assignments for acetylacetonates (14, 15) and for phenyl substituted β-ketoenolate nickel complexes (13).

The bands in the region 600–400 cm^{-1} assigned to Ni—O modes (6, 12, 13, 16) shift to lower frequencies by 10–60 cm^{-1} in the adducts, while the bands assigned to ν(C—O) and ν(C—C) shift only slightly in comparison with the corresponding bis(β-ketoenolates)nickel(II) (4, 6).

Moreover, the absence of coordinated water bands in the spectra suggests that the compounds are hexa-coordinated. In addition, in the far i.r., strong bands are observed in the range 390–300 cm^{-1} for all complexes. This band is most probably the (Ni—N) mode due to coordinated amines because such a band is not observed in the spectra of ligands and of bis(β-ketoenolates)nickel(II) and it is in good agreement with the values reported for Ni—N modes by Ahuja (9) for the nickel morpholine sulfate complexes.

The assignment of these bands to metal–nitrogen modes seems reasonable as absorptions in this region have been allocated to M—N modes in most other metal ammonia complexes (500–420 cm^{-1}) and metal–aniline complexes (430–350 cm^{-1}) (17). The set of bands in the range 600–400 cm^{-1}, assignable to coupled metal–oxygen stretching modes (6) (two bands well localized for our acetylacetonate and only one for our phenyl-substituted acetylacetonate adducts), are shifted to lower frequencies in our adducts than in the pyridine adducts. This shift affords evidence that the heterocyclic saturated amines are stronger ligands than pyridine (6, 12). Therefore we could suggest that the third Ni—O absorption band found at 270 cm^{-1} for $Ni(AcAc)_2 \cdot (pyridine)_2$ (12) in our adducts falls at lower energy and within the range of the instrument (250 cm^{-1}).

The nickel–nitrogen stretching frequencies provide a measure of the relative metal–ligand bond strengths in piperazine, methylpiperazine, morpholine, and piperidine, in that order.

Magnetism and Electronic Spectra

The electronic spectra and magnetic moments at room temperature of our adducts have been measured using solid samples. μ_{eff} is calculated from the expression

$$\mu_{eff} = 2.83(\chi_M^C T)^{1/2}$$

where χ_M^C is the molar susceptibility corrected by diamagnetic contribution, using Pascal's constants (18) and by TIP contribution (19).

TABLE 3. Magnetic moments and solid-state electronic spectra

Compound	μ_{eff} (BM)	Absorption maxima (cm^{-1})	
$Ni(AcAc)_2 \cdot (Pipd)_2$	3.16	10400	17000

*Loses morpholine.

The obtained magnetic moments (Table 3) agree well with the spin-free experimental moments for octahedral nickel complexes (2.90–3.30 BM) (20) with a triplet ground-state, $^3A_{2g}$.

The electronic spectra (Table 3) of all adducts show two d–d bands in the explored range 6 000–20 000 cm^{-1}, at 10 000 and 17 000 cm^{-1}, which may be assigned to the $^3A_{2g} \rightarrow {}^3T_{2g}$ ($= 10\,Dq$) and $\rightarrow {}^3T_{1g}(F)$ transitions, respectively, in O_h symmetry.

In the complex $(Ni(AcAc)_2 \cdot piperazine)_n$ the *trans*-octahedral arrangement could have arisen owing to the formation of linear polymeric chains with piperazine "bridging" two metal atoms.

The i.r. spectra of this complex, in which only one N—H band is found, and its insolubility in methanol (unlike all the other complexes) are in agreement with the above assignment. The tendency of piperazine to give "bridge-complexes" is not unusual as it has been found for $CdCl_2 \cdot C_4H_{10}N_2$ (21). This complex and also our adduct, contain long chains of piperazine molecules in the "chair" configuration, "bridging" metal ions (21).

$Ni(DBM)_2 \cdot 2H_2O$ and methylpiperazine in benzene solution give the $Ni(DBM)_2 \cdot (methylpiperazine)_2$ adduct, while $Ni(DBM)_2 \cdot 4B$ (B =

methylpiperazine, morpholine) is prepared by dissolving $Ni(DBM)_2 \cdot 2H_2O$ in the respective base. The identical magnetic and spectral properties of $Ni(DBM)_2 \cdot (methylpiperazine)_2$ and $Ni(DBM)_2 \cdot 4B$ support the hypothesis that the additional base in $Ni(DBM)_2 \cdot 4B$ is accommodated in the crystal lattice, and not coordinated to the metal atom (5).

Novel Rearrangement During Alkaline Hydrolysis of 1,1,1-Trichloro-2-alken-4-ones

EBERHARD KIEHLMANN, B. C. MENON, AND J. I. WELLS

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received October 25, 1971

The action of a five-fold excess of potassium hydroxide in methanol on 1,1,1-trichloro-2-penten-4-one (**1**), 1,1,1-trichloro-6-methyl-2-hepten-4-one (**5**), and 1,1,1-trichloro-6,6-dimethyl-2-hepten-4-one (**9**) gives rise to the potassium salt of 5-chloro-2,4-pentadienoic acid (**2**), the potassium salt and methyl ester of 5-chloro-6-methyl-2,4-heptadienoic acid (**7**), and the methyl ester of 5-chloro-6,6-dimethyl-2,4-heptadienoic acid (**10**), respectively.

When the same reaction is performed with an equimolar amount of base, **1** is converted into methyl 5-chloro-2,4-pentadienoate (**3**) as well as 1,1,1-trichloro-2-methoxy-4-pentanone (**4**); the latter compound (**4**) is shown to be a true intermediate in the formation of **3**.

Neither 1,1,1-trichloro-5-methyl-2-hexen-4-one (**11**) nor 1,1,1-trichloro-5-ethyl-2-hepten-4-one (**14**) yields the expected dienoic acid or ester when treated with an equimolar amount of potassium hydroxide. Instead, alkaline methanolysis of **11** leads to the formation of a mixture of 1,1,1-trichloro-2-methoxy-5-methyl-4-hexanone (**12**) and 1,1-dichloro-2,5-dimethoxy-5-methyl-4-hexanone (**13**), whereas **14** gives predominantly 1,1,1-trichloro-2-methoxy-5-ethyl-4-heptanone (**15**) and traces of 1,1-dichloro-2,5-dimethoxy-5-ethyl-4-heptanone (**16**).

On the basis of these observations, a mechanism is proposed for the formation of **2**, **7**, and **10** which requires the presence of two geminal α-hydrogen atoms in the olefinic starting material.

L'action de la potasse dans le méthanol, en excès de cinq fois sur la trichloro-1,1,1 pentène-2 one-4 (**1**), la trichloro-1,1,1 méthyl-6 heptène-2 one-4 (**5**), et la trichloro-1,1,1 diméthyl-6,6 heptène-2 one-4 (**9**) conduit respectivement au sel de potassium de l'acide chloro-5 pentadiène-2,4 oïque (**2**), au sel de potassium et à l'ester méthylique de l'acide chloro-5 méthyl-6 heptadiène-2,4 oïque (**7**) et à l'ester méthylique de l'acide chloro-5 diméthyl-6,6 heptadiène-2,4 oïque.

Quand la même réaction est effectuée avec une quantité équimolaire de base, **1** est converti en chloro-5 pentadiène-2,4 date de méthyle (**3**) ainsi qu'en trichloro-1,1,1 méthoxy-2 pentanone-4 (**4**); le dernier composé (**4**) étant le véritable intermédiaire dans la formation de (**3**).

Le traitement par une quantité équimolaire de potasse de la trichloro-1,1,1 méthyl-5 hexène-2 one-4 (**11**) et de la trichloro-1,1,1 éthyl-5 heptène-2 one-4 (**14**) ne conduit ni à l'acide diénoïque attendu, ni à l'ester. A la place, la méthanolyse alcaline de **11** conduit à un mélange de trichloro-1,1,1 méthoxy-2 méthyl-5 hexanone-4 (**12**) et de dichloro-1,1 diméthoxy-2,5 méthyl-5 hexanone-4 (**13**) tandis que **14** donne de façon prédominante la trichloro-1,1,1 méthoxy-2 éthyl-5 heptanone-4 (**15**) accompagnée de traces de dichloro-1,1 diméthoxy-2,5 éthyl-5 heptanone-4 (**16**).

Sur la base de ces observations, un mécanisme est proposé pour la formation de **2**, **7** et **10** qui nécessite la présence de deux atomes d'hydrogène géminal en α dans l'oléfine de départ.

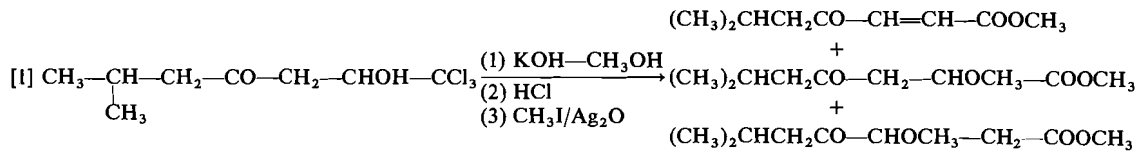
Canadian Journal of Chemistry, **50**, 2561 (1972)

Introduction

The acetate-catalyzed reaction of chloral with alkyl methyl ketones in glacial acetic acid leads to the formation of 1,1,1-trichloro-2-hydroxy-4-alkanones by a crossed aldol condensation (1, 2). Although these β-ketols resist dehydration under the preparative reaction conditions, they are quite reactive when heated in the presence of acidic or basic catalysts. Thus, treatment with silica or strong mineral acid at elevated temperatures leads to dehydration and rearrangement (3).

The literature on the base-catalyzed reactions of these compounds is confusing. Uschakov (4) and Salkind (5) obtained a carboxylic acid, $C_5H_5ClO_2$, by treatment of 1,1,1-trichloro-2-hydroxy-4-pentanone with cold aqueous or alcoholic potassium hydroxide. Caujolle and coworkers (6) found that certain 1,1,1-trichloro-2-hydroxy-4-alkanones react with 4 equiv of sodium hydroxide per mole of starting material to form 3 mol of sodium chloride, and postulated β-ketoaldehydes and sodium formates as the major organic reaction products. However, they were not successful in isolating and identifying these compounds. Kiehlmann (7), on the other hand, reported that the reaction of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



methanolic potassium hydroxide at 50° gives a mixture of three esters (eq. 1).

In view of the diverse nature of the literature on this subject we decided to investigate this reaction by subjecting the dehydration products $RCOCH{=}CHCCl_3$ (assumed to be the first intermediates in the reaction of the corresponding β-ketols with base) of several 1,1,1-trichloro-2-hydroxy-4-alkanones to the action of methanolic bases and by examining the resulting reaction products.

Results and Discussion

Slow addition of a five-fold excess of methanolic potassium hydroxide to a stirred solution of 1,1,1-trichloro-2-penten-4-one (**1**) in methanol at low temperature followed by acidification of the reaction mixture and standard work-up gave a white, crystalline acid $C_5H_5ClO_2$ which was identified as 5-chloro-2,4-pentadienoic acid (**2**) (eq. 2). Compound **2** was found to be identical to the acid $C_5H_5ClO_2$ obtained by Uschakov (4) and Salkind (5) in low yield by treatment of 1,1,1-trichloro-2-hydroxy-4-pentanone with cold aqueous or alcoholic potassium hydroxide. Uschakov and Salkind had proposed $CH_3{-}CCl{=}C{=}CH{-}COOH$ or $CH_2{=}CCl{-}CH{=}CH{-}COOH$ as the most probable structural formula for this compound.

Primarily on the basis of spectral data we have now been able to rule out both of these structures in favor of **2**. Acid **2** exhibits typical olefinic and carbonyl stretching bands (1626 and 1675 cm^{-1}, respectively) in its i.r. spectrum. The high-intensity u.v. absorption maximum (in EtOH) at 255 nm (ε 27 700) is characteristic of highly conjugated carbonyl compounds (8–10). The n.m.r. spectrum (Fig. 1) clearly reveals the compound to be 5-chloro-2,4-pentadienoic acid. Esterification of **2** with diazomethane shifts the carbonyl band to 1720 cm^{-1} in the methyl ester (**3**).

Since reaction 2 was accompanied by the formation of appreciable quantities of unidentified byproducts when a large excess of potassium hydroxide was used as hydrolyzing agent, we carried out a systematic study of the reaction of **1** with several bases in methanolic solution under less severe conditions in order to improve the yield of **2** and to isolate any intermediate that might be present in the reaction mixture. Thus, when equimolar quantities of **1** and sodium carbonate in methanol were heated at 50° for 15 h, the resulting product mixture was found to consist of 25% methyl 5-chloro-2,4-pentadienoate (**3**) and 75% 1,1,1-trichloro-2-methoxy-4-pentanone (**4**) with only trace amounts of other components present, while an identical reactant mixture kept at 100° for 8 h gave a product mixture containing approximately 55% of **3** and 45% of **4** (eq. 3).

Equimolar quantities of **1** and potassium hydroxide in methanol at 0–25° ($2\frac{1}{2}$ h) gave a product mixture which was estimated to contain 24% of ester **3** and 76% of the addition product **4** with traces of **2** also present. That **4** is a true intermediate in these reactions was revealed when equimolar quantities of this compound and potassium hydroxide in methanol at 0–25° ($2\frac{1}{2}$ h) were found to give 38% of ester **3** and 62% of unreacted starting material (eq. 3); neither

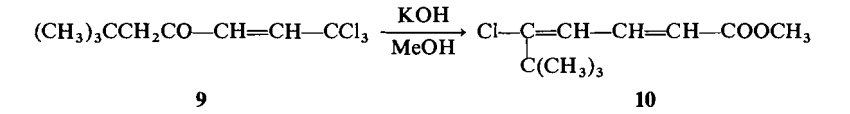
[4] $(CH_3)_2CHCH_2COCH{=}CH{-}CCl_3$ (**5**) + $(CH_3)_2CHCHCl{-}CO{-}CH_2{-}CH{=}CCl_2$ (**6**) $\xrightarrow[MeOH]{KOH}$ $Cl{-}C(CH(CH_3)_2){=}CH{-}CH{=}CHCOO^{\ominus}\,K^{\oplus}$ ($K^{\oplus}$ salt of **7**) + $Cl{-}C(CH(CH_3)_2){=}CH{-}CH{=}CH{-}COOCH_3$ (**8**)



[5] $(CH_3)_3CCH_2CO{-}CH{=}CH{-}CCl_3$ (**9**) $\xrightarrow[MeOH]{KOH}$ $Cl{-}C(C(CH_3)_3){=}CH{-}CH{=}CH{-}COOCH_3$ (**10**)

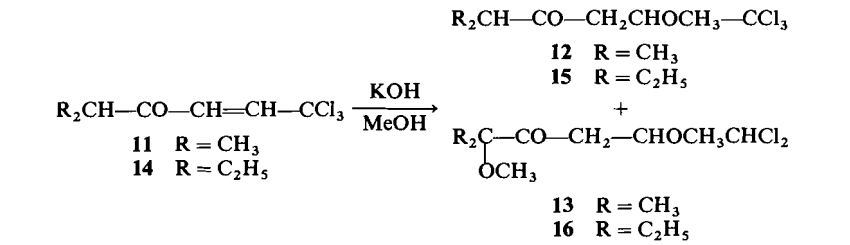
1 nor **2** was detected in the crude product mixture, suggesting that the base-catalyzed addition of methanol to **1** (eq. 3) is irreversible.

The formation of homologous dienoic acids and/or their methyl esters has also been observed in the cases of other 1,1,1-trichloro-2-alken-4-ones which contain a minimum of two geminal α-hydrogen atoms. Thus, treatment of a mixture[1] containing 52% 1,1,1-trichloro-6-methyl-2-hepten-4-one (**5**) and 42% 1,1,5-trichloro-6-methyl-1-hepten-4-one (**6**) with a solution of potassium hydroxide in methanol gave 5-chloro-6-methyl-2,4-heptadienoic acid (**7**) and its methyl ester (**8**) which were identified by molecular weight determination, i.r. and n.m.r. spectroscopy (eq. 4).

The 100 MHz n.m.r. spectrum of **7** in C_6D_6 exhibited absorption peaks at τ 4.13 (α-H, unsymmetrical doublet, $J_{\alpha\beta} = 13.0$ Hz), 3.45 (β-H, quartet, $J_{\alpha\beta} = 13.0$, $J_{\beta\gamma} = 12.0$ Hz), 3.06 (γ-H, unsymmetrical doublet, $J_{\beta\gamma} = 12.0$ Hz), 7.35 ($(CH_3)_2CH$—, multiplet), 8.88 (6 protons, CH_3—, doublet, $J = 6.8$ Hz), and −2.45 (—COOH, singlet) which are consistent only with a 5,5-disubstituted 2,4-pentadienoic acid. Under similar reaction conditions 1,1,1-trichloro-6,6-dimethyl-2-hepten-4-one (**9**) formed the methyl ester of 5-chloro-6,6-dimethyl-2,4-heptadienoic acid (**10**) (eq. 5).

When the methanolysis reaction was extended to 1,1,1-trichloro-2-alken-4-ones containing less than two geminal α-hydrogen atoms, neither the expected dienoic acid nor its methyl ester was formed. Thus, when 1,1,1-trichloro-5-methyl-2-hexen-4-one (**11**) was treated with methanolic potassium hydroxide, v.p.c., i.r., and n.m.r. analysis of the product mixture revealed the presence of 1,1,1-trichloro-2-methoxy-5-methyl-4-hexanone (**12**) and 1,1-dichloro-2,5-dimethoxy-5-methyl-4-hexanone (**13**) in the approximate molar ratio 3:2 and the complete absence of pentadienoic acid derivatives similar to **2** or **5**; and 1,1,1-trichloro-5-ethyl-2-hexen-4-one (**14**) was converted into a mixture containing predominantly 1,1,1-trichloro-2-methoxy-5-ethyl-4-heptanone (**15**) and traces of 1,1-dichloro-2,5-dimethoxy-5-ethyl-4-heptanone (**16**) (eq. 6).

We conclude from this difference in the behavior of **1**, **5**, and **9**, on the one hand, and **11** and **14**, on the other, towards methanolic potassium hydroxide that a minimum of two geminal α-hydrogens are necessary for the formation of the dienoic acid/ester. On the basis of these



[6] $R_2CH{-}CO{-}CH{=}CH{-}CCl_3$ (**11** R = CH_3; **14** R = C_2H_5) $\xrightarrow[MeOH]{KOH}$ $R_2CH{-}CO{-}CH_2CHOCH_3{-}CCl_3$ (**12** R = CH_3; **15** R = C_2H_5) + $R_2C(OCH_3){-}CO{-}CH_2{-}CHOCH_3CHCl_2$ (**13** R = CH_3; **16** R = C_2H_5)

[1]Component 6 was subsequently shown to be an intermediate in reaction 4 (see Scheme 1). For details, see Experimental.

observations, the mechanism shown in Scheme 1 is proposed for reactions 3, 4, and 5.

Base-catalyzed enolization of the enone–methanol addition product (**9**, R = H) is followed by migration of chlorine to form a 1,1,5-trichloro-1-alken-4-one (**3**). A prototropic shift leads to the formation of the more stable enolate ion of an α,β-unsaturated ketone and is similar to the proton migration reported by Takeda and Tsuboi (11) for the reaction of 1,1,3-trichloro-1-penten-4-one with triethylamine. Subsequent ring closure is postulated to give a substituted 2-cyclopentenone intermediate[2] which is cleaved by the nucleophilic attack of methoxide or hydroxide ion at the carbonyl carbon and elimination of chloride ion. Relief of angle strain and resonance stabilization of the highly conjugated product (**2**, **3**, **7**, **8**, and **10**) are believed to be the major driving forces for this final step which is completely identical to the previously reported (12) ring opening of perchloro-2-cyclopentenone by methoxide ion to form methyl pentachloropentadienoate.

The mechanism postulated in Scheme 1 also explains suitably the formation of 1,1-dichloro-2,5-dimethoxy-5-methyl-4-hexanone (**13**) from 1,1,1-trichloro-5-methyl-2-hexen-4-one (**11**), and 1,1-dichloro-2,5-dimethoxy-5-ethyl-4-heptanone (**16**) from 1,1,1-trichloro-5-ethyl-2-hepten-4-one (**14**) with methanolic potassium hydroxide. Due to the lack of a second α-hydrogen, the formation of a cyclopentenone derivative is prevented in this case and, consequently, the intermediates (**17** and **18**) undergo methanolysis (13) and methoxide addition to the double bond to form **13** and **16**, respectively (eq. 7).

Finally, it is noteworthy that although an α-chloroketone is shown to be an intermediate in the mechanistic pathway (Scheme 1), no Favorskii reaction products have been detected in any of the above reactions. A likely explanation is that the developing negative charge on the unsubstituted α-carbon of intermediate **19** is part of an allylic system and hence is not available for the formation of the cyclopropanone intermediate of the Favorskii reaction (14).

Experimental

Elemental analyses were performed by A. Bernhardt, Microanalytical Laboratory, Elbach, Germany. The n.m.r. spectra were recorded on Varian A 56/60 and HA-100 instruments with TMS as internal standard. The u.v. spectra were run on a Unicam SP-200 and the i.r. spectra on a Perkin–Elmer 457 spectrometer. The v.p.c. analyses were carried out on a Varian Aerograph Model 1200-1 HY-F1 111 gas chromatograph using 5 ft × 1/8 in. columns, nitrogen as carrier gas and the specified stationary phases on Aeropak 30. All quantitative estimates of the composition of product mixtures by v.p.c. analysis were obtained by integration of the peak areas of the components using a disc chart integrator.

5-Chloro-2,4-pentadienoic Acid (2)

A solution of 56.0 g (1.0 mol) of potassium hydroxide in 240 ml of methanol was added dropwise (75 min) and with cooling (0–15°) into a solution of 37.5 g (0.2 mol) of **1** (3) in 60 ml of methanol. The mixture was stirred for another 30 min and the potassium chloride (27.14 g) was filtered off. Filtrate and washings were concentrated to 150 ml, extracted with ether to remove neutral products, acidified (concentrated HCl), and again extracted with ether. The ether layer was dried ($MgSO_4$) and evaporated to give 20.6 g (76% crude yield) of a brown solid. Recrystallization from carbon tetrachloride followed by sublimation gave white **2**, m.p. 168–169° (lit. (4, 5) 171–172°).

Anal. Calcd. for $C_5H_5ClO_2$: C, 45.30; H, 3.80; Cl, 26.74. Found: C, 45.16; H, 3.98; Cl, 26.61.

N.m.r. (CD_3COCD_3, 100 MHz) τ 4.98 (2d, α-H, $J_{\alpha\beta}$ = 15.2, $J_{\alpha\gamma}$ = 0.9 Hz), 3.72 (4d, β-H, $J_{\alpha\beta}$ = 15.2, $J_{\beta\gamma}$ = 11.3, $J_{\beta\delta}$ = 0.8 Hz), 4.25 (q, γ-H, $J_{\beta\gamma}$ = 11.3, $J_{\gamma\delta}$ = 13.1 Hz), and 4.08 (2d, δ-H, $J_{\beta\delta}$ = 0.8, $J_{\gamma\delta}$ = 13.1 Hz); n.m.r. (CF_3COOD, 100 MHz, Fig. 1) τ 4.01 (d, α-H, $J_{\alpha\beta}$ = 15.1 Hz), 2.52 (4d, β-H, $J_{\alpha\beta}$ = 15.1, $J_{\beta\gamma}$ = 11.4, $J_{\beta\delta}$ = 0.9 Hz), 3.33 (q, γ-H, $J_{\beta\gamma}$ = 11.4, $J_{\gamma\delta}$ = 13.2 Hz), and 3.20 (d, δ-H, $J_{\gamma\delta}$ = 13.2 Hz); i.r. and u.v.: see Results and Discussion.

Methyl 5-Chloro-2,4-pentadienoate (3)

Esterification of **2** with diazomethane was carried out by the standard procedure (15).

Anal. Calcd. for $C_6H_7ClO_2$: C, 49.17; H, 4.81; Cl, 24.19. Found: C, 49.37; H, 4.92; Cl, 24.09.

N.m.r. ($CDCl_3$, 60 MHz) τ 4.16 (d, α-H, $J_{\alpha\beta}$ = 14.8 Hz), 2.84 (4d, β-H, $J_{\alpha\beta}$ = 14.8, $J_{\beta\gamma}$ = 7.4, $J_{\beta\delta}$ = 3.5 Hz), 3.47 (m, γ-H and δ-H), and 6.32 (s, 3H, OCH_3). Mass spectrum (80 eV): *m/e* 146 (M) and 148 (M+2), ratio 100:35.

Reaction of 1 with Base (Molar Ratio 1:1)

(*a*) A solution of 5.0 g (0.027 mol) of **1** and 2.86 g (0.027

[7] $R_2C(Cl)—CO—CH=CH—CHCl_2 \xrightarrow[-Cl^{\ominus}]{CH_3OH/CH_3O^{\ominus}} R_2C(OCH_3)—CO—CH_2—CH(OCH_3)—CHCl_2$

17 R = CH_3; **18** R = C_2H_5 — **13** R = CH_3; **16** R = C_2H_5

[2]We were not successful in isolating or trapping cyclopentenone intermediates.

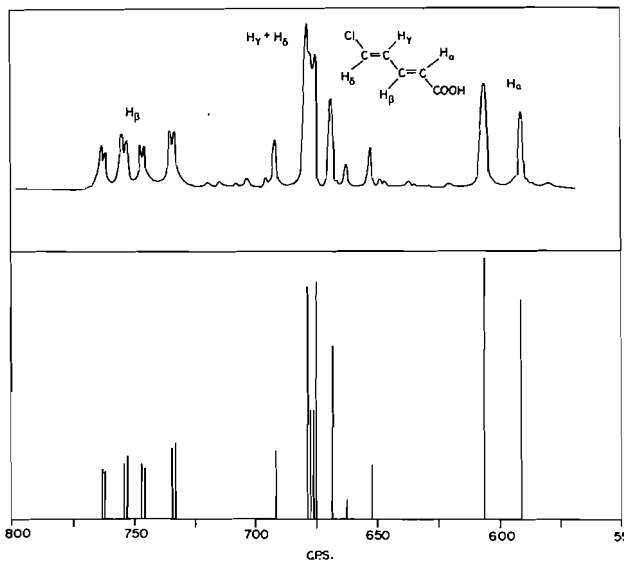

FIG. 1. Experimental n.m.r. spectrum (100 MHz, CF_3COOD as solvent) of 5-chloro-2,4-pentadienoic acid (**2**) (top) as compared to the computer-generated line spectrum (bottom) using LAOCOON (17) program.

mol) of sodium carbonate in 40 ml of methanol was heated at 50° for 15 h and worked-up as described above for the preparation of **2**. The neutral fraction (4.6 g) was shown by v.p.c. (SE-52, 120°) and n.m.r. analysis to contain only **3** (25%) and **4** (75%), the acid fraction (<0.1 g) contained mainly **2**.

(*b*) Heating an identical reactant mixture (see section *a*) at 100° for 8 h gave 4.4 g of neutral fraction (55% of **3** and 45% of **4**) and less than 0.1 g of acid fraction.

(*c*) A solution of 5.0 g (0.027 mol) of **1** in 20 ml of methanol and 1.58 g (0.027 mol) of potassium hydroxide in 20 ml of methanol, obtained by the dropwise addition of the latter to the former, was kept at 0–25° for $2\frac{1}{2}$ h (work-up as described before) to yield 4.3 g of neutral fraction (24% of **3** and 76% of **4**) and 0.1 g of **2** (acid fraction).

1,1,1-Trichloro-2-methoxy-4-pentanone (4)

This compound was separated from **3** (see above) by partition chromatography on silicic acid (Mallinckrodt AR 100 Mesh) using hexane–chloroform (1:1 by volume) as eluent; n.m.r. ($CDCl_3$, 60 MHz) τ 7.89 (s, 3H, CH_3CO), 7.05 (m, 2H, CH_2CO), 6.31 (s, 3H, OCH_3), 5.67 (m, 1H, $CHOCH_3$); i.r. (neat) 1720 (CO), and 1100 cm^{-1} (C—O—C); mass spectrum (80 eV): *m/e* 182 and 184 (ratio 100:65, 2 Cl, probably M-HCl), 101 (100%, $CH_3COCH_2^{\oplus}$ $CHOCH_3$), M not observable.

Reaction of 4 with KOH

A solution of 0.35 g (5.0 mmol) of potassium hydroxide in 5.0 ml of methanol was added dropwise to 1.0 g (5.0 mmol) of **4** in 5.0 ml of methanol and stirred at 25° for 2 h. Evaporation of methanol, addition of 10 ml of water, extraction with ether, drying ($MgSO_4$), and removal of solvent gave 0.63 g of a mixture of 38% **3** and 62% **4**. The aqueous layer contained traces of **2**.

5-Chloro-6-methyl-2,4-heptadienoic Acid (7) and its Methyl Ester (8)

1,1,1-Trichloro-6-methyl-2-hepten-4-one (**5**) was prepared by acid-catalyzed dehydration of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (3). Since this reaction was accompanied by rearrangement of **5** to 1,1,5-trichloro-6-methyl-1-hepten-4-one (**6**), and large-scale separation of these two isomers to obtain pure **5** proved to be difficult, a mixture of **5** and **6** (10.0 g, 0.043 mol) was treated with potassium hydroxide (11.2 g, 0.2 mol) and methanol (65 ml) as described above for the preparation of **2**. The aqueous layer, on acidification, gave 3.5 g (46%) of a brown solid which was sublimed and recrystallized from carbon tetrachloride to give pale yellow **7**, m.p. 112–113°.

Anal. Calcd. for $C_8H_{11}ClO_2$: C, 55.02; H, 6.35; Cl, 20.30. Found: C, 54.85; H, 6.22; Cl, 20.37.

Mol. wt. calcd. for $C_8H_{11}{}^{37}ClO_2$: 176.0418. Found (mass spectrum): 176.0424.

U.v. (EtOH) max 260 nm (23 900); i.r. and n.m.r.: see Results and Discussion. The ether layer was dried ($MgSO_4$) and evaporated to give 7.3 g of a brown liquid. From this a sample of pure **8** was obtained by column chromatography on silicic acid using hexane–chloroform (1:1) as eluent; n.m.r. ($CDCl_3$, 60 MHz) τ 3.0–3.8 (m, 3H, olefinic), 6.29 (s, 3H, $COOCH_3$), 7.0 (septet, 1H, $(CH_3)_2CH$), and 8.80 (d, 6H, $(CH_3)_2CH$).

Repetition of the above experiment with pure **6** (1.2 g, 5.2 mmol) and KOH (1.45 g, 26 mmol) also gave **8** (see footnote 1) as identified by n.m.r.

Methyl 5-Chloro-6,6-dimethyl-2,4-heptadienoate (10)

The reaction of 10.0 g (0.041 mol) of **9** (3) with 11.2 g (0.20 mol) of potassium hydroxide in 65 ml of methanol and usual work-up yielded a brown oil (6.0 g) which was chromatographed on silicic acid (using hexane–chloroform as

eluent) to give pure **10**: n.m.r. ($CDCl_3$, 60 MHz) τ 3.2–4.1 (m, 3H, olefinic), 6.22 (s, 3H, $COOCH_3$), and 8.87 (s, 9H, $(CH_3)_3C$); mass spectrum (80 eV): *m/e* 202 (M), 143 (M-$COOCH_3$); u.v. (EtOH) max 242 nm (20 000). No carboxylic acid (corresponding to **10**) was detected in the aqueous layer.

1,1,1-Trichloro-5-methyl-2-hexen-4-one (11)

Following a previously reported procedure (3), 40.5 g (0.172 mol) of 1,1,1-trichloro-2-hydroxy-5-methyl-4-hexanone, 70.2 g (0.69 mol) of acetic anhydride and 3.0 g of anhydrous sodium acetate were heated at 100° for 90 min. Standard work-up and vacuum distillation of the crude product gave 22.4 g (60% yield) of **11** (90% pure), b.p. 67°/0.5 mm: i.r. (neat) 1700 (CO) and 1650 cm^{-1} (C=C); n.m.r. ($CDCl_3$, 60 MHz) τ 2.87 (d, 1H, C=CHCCl$_3$, J = 15.0 Hz), 3.27 (d, 1H, CO—CH=C, J = 15.0 Hz), 7.14 (septet, 1H, $(CH_3)_2CH$, J = 7.0 Hz), and 8.82 (d, 6H, CH_3, J = 7.0 Hz).

Reaction of 11 with KOH

Treatment of **11** (5.0 g, 2.3 mmol) with 2.4 mmol potassium hydroxide (see reaction of **1** with base, section *c*) yielded 4.95 g of a neutral fraction which was found by n.m.r. and v.p.c. (SE-52, 120°) analysis to contain only 1,1,1-trichloro-2-methoxy-5-methyl-4-hexanone (**12**) (60%) and 1,1-dichloro-2,5-dimethoxy-4-hexanone (**13**) (40%). Pure samples of **12** and **13** were obtained by chromatography on silicic acid using hexane–chloroform as eluent.

Anal. Calcd. for $C_8H_{13}Cl_3O_2$ (**12**): C, 38.82; H, 5.29; Cl, 42.96. Found: C, 39.00; H, 5.17; Cl, 43.12.

I.r. (neat) 1720 cm^{-1} (CO); n.m.r. ($CDCl_3$, 60 MHz) τ 8.87 (d, 6H, $(CH_3)_2C$), 7.40 (septet, 1H, $CH(CH_3)_2$), 7.0 (m, 2H, $COCH_2$), 6.34 (s, 3H, OCH_3), and 5.65 (m, 1H, $CHOCH_3$).

Anal. Calcd. for $C_9H_{16}Cl_2O_3$ (**13**): C, 44.46; H, 6.63; Cl, 29.16. Found: C, 44.66; H, 6.51; Cl, 29.31.

N.m.r. ($CDCl_3$, 60 MHz) τ 8.70 (s, 6H, $(CH_3)_2C$), 6.77 (s, 3H, $(CH_3)_2C$—OCH_3), 6.97 (m, 2H, $COCH_2$), 6.50 (s, 3H, $CHOCH_3$), 5.88 (m, 1H, $CHOCH_3$), and 4.10 (d, 1H, $CHCl_2$, J = 3.7 Hz); mass spectrum (80 eV): *m/e* 73 (100%, $(CH_3)_2C^{\oplus}$—OCH_3) and other fragments characteristic of keto ethers (16).

1,1,1-Trichloro-5-ethyl-2-hepten-4-one (14)

According to a previously reported procedure (3), 17.0 g (0.0654 mol) of 1,1,1-trichloro-2-hydroxy-5-ethyl-4-heptanone, 26.5 g (0.26 mol) of acetic anhydride, and 2.0 g of anhydrous sodium acetate were heated at 100° for 90 min. Work-up and vacuum distillation of the crude product gave 8.1 g (51%) of **14** (99% pure), b.p. 83–87°/0.5 mm; i.r. (neat) 1700 (C=O) and 1660 cm^{-1} (C=C); n.m.r. ($CDCl_3$, 60 MHz) τ 2.88 (d, 1H, $CHCCl_3$, J = 15.0 Hz), 3.35 (d, 1H, CO—CH=C<, J = 15.0 Hz), 7.45 (quintet, 1H, Et_2CH, J = 7.0 Hz), 8.34 (m, 4H, $(CH_3CH_2)_2CH$), and 9.15 (t, 6H, $(CH_3CH_2)_2CH$, J = 7.0 Hz).

Reaction of 14 with KOH

Treatment of 2.0 g (8.2 mmol) of **14** with 0.46 g (8.2 mmol) of potassium hydroxide in 20.0 ml of methanol and work-up (procedure as before) yielded 1.72 g of an oil which was shown by v.p.c. to contain 95% of **15** and a small amount of **16**. N.m.r. of **15** ($CDCl_3$, 60 MHz) τ 5.6 (m, 1H, $CHOCH_3$), 6.28 (s, 3H, OCH_3), 7.0 (m, 2H, CH_2CO), 7.65 (quintet, 1H, $(CH_3CH_2)_2CH$), 8.35 (m, 4H, $(CH_3CH_2)_2C$), 9.1 (t, 6H, $(CH_3CH_2)_2C$). Spectral identification of **16**: n.m.r. ($CDCl_3$, 60 MHz) τ 4.05 (d, 1H, $CHCl_2$, J = 3.5 Hz), 5.87 (m, 1H, $CHOCH_3$), 6.48 (s, 3H, CH_3OCH), 6.8 (s, 3H, $(CH_3CH_2)_2C$—OCH_3), 7.0 (m, 2H, CH_2CO), 7.65 (q, 4H, $(CH_3CH_2)_2C$, J = 6.0 Hz), 9.12 (t, 6H, $(CH_3CH_2)_2C$, J = 6.0 Hz); mass spectrum (80 eV): *m/e* 101 (100%, $(CH_3CH_2)_2C^{\oplus}$—OCH_3).

The authors wish to express their sincere thanks to Miss E. G. Kayser of the Advanced Chemistry Division, U.S. Naval Ordinance Laboratory, White Oak, Maryland for running the 100 MHz n.m.r. spectra, to Dr. W. Reeve of the Chemistry Department, University of Maryland, College Park, Maryland, for many helpful comments on the interpretation of these spectra, to Morris Pudek for technical assistance, and to the National Research Council of Canada, Ottawa, Canada, for financial support.

The Reaction of some Isothiazolium Salts with Sulfur in Pyridine

G. E. BACHERS, D. M. MCKINNON, AND J. M. BUCHSHRIBER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received March 21, 1972

A variety of *N*-methyl and *N*-phenylisothiazolium salts has been synthesized and treated with sulfur in boiling pyridine. The products have been examined by chromatography and their structures determined. While 5-unsubstituted isothiazolium salts appear to give the corresponding isothiazoline-5-thiones, 3-unsubstituted salts give either the corresponding isothiazoline-3-thiones if the nitrogen is alkyl substituted, or 1,2-dithiole-3-imines if the nitrogen is aryl substituted. *N*-Alkyl compounds also give dealkylated products, and dithiolethiones are also found. The initial stages in the reaction appear to involve deprotonation of the isothiazolium salt.

Une série de sels de *N*-méthyl et *N*-phénylisothiazolium ont été synthétisés et traités par du soufre dans la pyridine à ébullition. Les produits ont été examinés en chromatographie et leurs structures déterminées. Tandis que les sels d'isothiazolium non substitués en 5 donnent des isothiazolinethiones-5 correspondantes, les sels non substitués en 3 donnent soit des isothiazolinethiones-3 si l'azote est substitué par un alkyle, ou des dithiole-1,2 imines-3 si l'azote est substitué par un aryle. Les composés *N*-alkyles donnent également des produits déalkylés et des dithiolethiones. Les étapes initiales dans la réaction semblent faire intervenir la déprotonation du sel isothiazolium.

Canadian Journal of Chemistry, **50**, 2568 (1972)

In a previous paper the reaction of two isothiazolium salts, 2-methyl-5-phenylisothiazolium perchlorate (**1***a*) and 2,5-diphenylisothiazolium perchlorate (**1***b*) with sulfur in boiling pyridine was examined (1). It was suggested that the products of the reactions were the corresponding isothiazoline-3-thiones, **2***a* and *b* respectively. The structure of one of these was later confirmed by an alternate synthesis and by ^{15}N n.m.r. and by chemical tests (2, 3). Later work, however, (4) indicated that the product of the other of these reactions was not 2,5-diphenylisothiazoline-3-thione (**2***b*) but was in fact the isomeric 5-phenyl-3-phenylimino-1,2-

9

dithiole (**3***a*), arising from a molecular rearrangement. It therefore seemed desirable to investigate such reactions further to determine the products and the reactions leading to them.

A representative variety of isothiazolium salts was chosen for this investigation, containing *N*-phenyl-, **1***b*, *d*, *f*, *h*, and *i*, and *N*-methyl, **1***a*, *c*, *e*, and *g* substituents. The latter were available by methylation of isothiazoles, formed by treatment of suitable 1,2-dithiolium salts with ammonia (5). One of these isothiazoles **5***a* is previously unreported, although an attempted synthesis (6) appears to have met with failure. The former salts, **1***b*, *d*, and *f*, were prepared according to established methods (1) by oxidative cyclization of 3-anilinopropenethiones, which are available by treatment of certain 1,2-dithiolium salts with aniline (1, 7).

The synthesis of the two other compounds **1***h* and *i* presented more difficulty, since the methods used for the others are inapplicable to the direct synthesis of these. A modified approach was successful. The 3-alkylthio-1,2-dithiolium salt **4***a* treated with aniline gave the acyclic methyl 2-phenyl-3-anilinopropenedithioate (**6***a*) (8) which oxidized by iodine to form the isothiazolium salt **1***j* as its triiodide. Conversion of this to the perchlorate and demethylation by pyridine gave the thione **7***a* which was converted by hydrogen peroxide in acetic acid to the isothiazolium salt **1***h*. This method appears to represent a new synthesis of isothiazolium salts. Similar oxidations are reported for 1,2- and 1,3-dithiolethiones, (9–12) and for thiopyran-2-thiones (13). The thione **7***a* was more conveniently prepared by treatment of 4-phenyl-1,2-dithiole-3-thione (**8***a*) with bromine, followed by aniline. This reaction of 5-unsubstituted-4-aryl-1,2-dithiole-3-thiones, **8**, had been previously reported (14) to give 1,2-dithiole-3-imines, **3**, by nucleophilic attack of aniline at the 3-position of the initially formed 3-bromothiodithiolium bromide, **4***b*, but it now appears more likely that the products formed are in fact the isomeric isothiazoline-5-thiones, **7**, arising by nucleophilic attack at the unsubstituted 5-position. This is what would have been expected on steric grounds and in accordance with the position of nucleophilic attack on 5-unsubstituted-3-alkylthiodithiolium salts (**8**). Similar considerations may be used to explain the nucleophilic ring-opening of cyclopentenodithiolium salts (15). The structure of the isothiazoline-5-thione was further confirmed by its reaction with dimethyl acety-

lenedicarboxylate. The adduct **9** was formed. Had the compound been the isomeric 1,2-dithiole-3-imine, a thioacylmethylenethiazole would have been obtained (16). This, being a thial, would have been unstable and rapidly reacted further in a fashion similar to related thioacylmethylene-1,3-dithioles (17).

However, when 5-phenyl-1,2-dithiole-3-thione (**8***b*) was treated with bromine, followed by aniline, the product obtained was the imine, **3***a*, with greater or lesser amounts of the thione **8***b*, *vide infra*. In this case the steric bulk of the phenyl group blocks attack at the 5-position, and attack at the less hindered 3-position provides imine or thione.

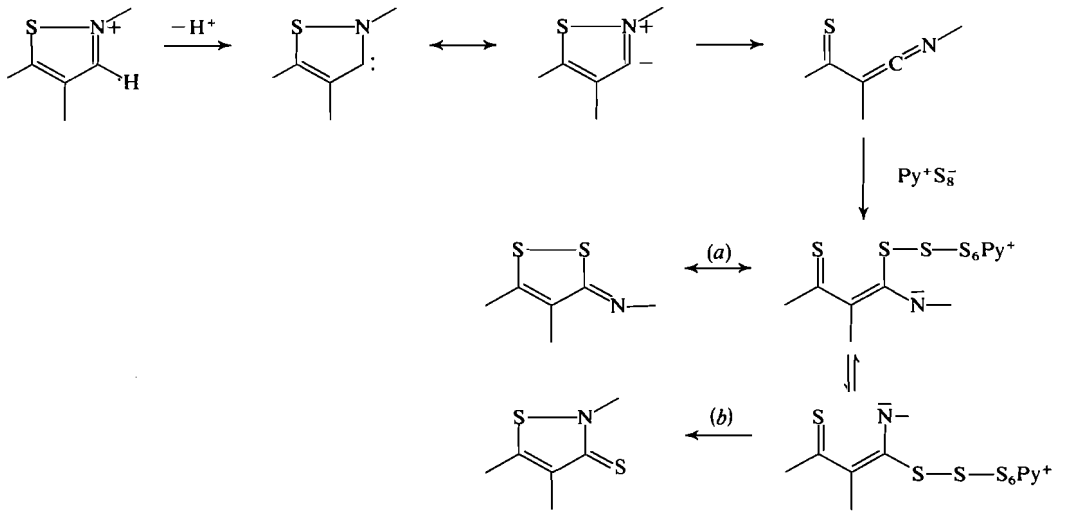
A similar scheme via an aminodithioenoate was used to prepare **7***b*. 3-Ethylthio-5-phenyl-1,2-dithiolium iodide (**4***c*) reacted with aniline in acetic acid to provide as a main product the imine, **3***a* (8, 18). A minor product was the dithioester **6***b*, which was readily separated from the imine. Similar results have been obtained in the reaction of alkylthio-1,2-dithiolium salts with aliphatic amines (19). The dithioester oxidized satisfactorily to the isothiazolium salt **1***k*, and dealkylation of this with pyridine afforded the thione **7***b*. This was oxidized by hydrogen peroxide in acetic acid to the isothiazolium salt **1***i*. Attempted conversion of the 5-alkylthioisothiazolium salts **1***j* and *k* to the thiones **7***a* and *b*, respectively, by treatment with sodium hydrosulfide failed. Instead the dithioesters, **6***a* and *b*, were obtained. It appears that in this case ring cleavage is the dominant reaction, possibly by initial nucleophilic attack at ring nitrogen or sulfur. Traces of the corresponding 1,2-dithiole-3-thiones **8***a* and *b* were also found.

An attempted preparation of the thione **2***b* by treatment of thione **8***b* with bromine, followed by aniline gave only thione **8***b* and imine **3***a*. These are both formed by nucleophilic attack on the initially formed dithiolium salt **4***d* since this salt can be isolated satisfactorily from the reaction. Treatment of the salt **1***b* with sulfur in boiling pyridine afforded the imine **3***a* and traces of thione **8***b*, and treatment of the salt **1***d* afforded the imine **3***b* only. These results indicate that the reaction is proceeding in these cases by ring opening and recyclization. The most likely scheme would involve deprotonation by base to form a carbene or zwitterionic species which would undergo ring fission to a thioketimine, similarly to known reactions of isoxazolium salts (20). This intermediate could then react with a polysulfide or chain (21, 22) formed by reaction of pyridine with sulfur to form the imine (Scheme 1*a*). Direct attack by polysulfide ion on the salt is considered unlikely since the salt **1***f*, which has no reactive hydrogens at 3- or 5-position, was completely unaffected by treatment with sulfur in pyridine. Despite the steric bulk of the phenyl groups, ring opening would have been likely had polysulfide attack been the initial stage.

The thione **8***b* detected in the first of these reactions was not formed from the imine **3***a* since prolonged treatment of the imine under the reaction conditions did not produce any thione. Only prolonged fusion of the imine at 180° gave some thione, along with numerous other products. It thus appears that thione is formed from an acyclic precursor. No thione **8***c* was detected in the reaction of the salt **1***d* with sulfur. Possibly conjugative or steric effects are important, although some thione was detected in the reaction of **1***c*.

Compounds **1***h* and *i* gave thiones **7***a* and *b* respectively on reaction. While **1***i* has only one reactive hydrogen (the 5-position) available and can only give the 5-thione, compound **1***h* has two available, one adjacent to nitrogen and one adjacent to sulfur. That only the product derived from the abstraction of a proton adjacent to sulfur is found, is likely a consequence of the greater ability of sulfur over nitrogen to stabilize an adjacent carbanion by d-orbital participation. Supporting data are available from other isothiazolium salt reactions (23). Since nucleophilic attack at the 3-position is favored by inductive and coulombic considerations, the isolation of products derived from attack at the 5-position is further evidence for deprotonation as the first stage in the reaction. Small amounts of the corresponding dithiolethiones **8***a* and *b* were also obtained in these reactions.

Of course, the detection of isothiazoline-5-thione products rather than dithioleimines does not allow differentiation between a mechanism involving ring opening comparable to Scheme 1 or one involving direct sulfurization of initially formed carbene or zwitterion, as was earlier suggested (1), but the detection of dithiolethione products suggests that there is ring fission to an acyclic precursor of both types of thiones **7** and **8**.



SCHEME 1

When the *N*-alkyl compound **1***e* was treated under these conditions, only the isothiazole **5***b* was obtained, corresponding to a simple demethylation reaction. Treatment of **1***a* under these conditions had been reported (1) to give the isothiazoline-3-thione, **2***a*, but chromatography of the product indicated three fractions, 5-phenylisothiazole **8***c*, the thione **8***b*, and the isothiazoline-3-thione **2***a*, whose structure has been conclusively demonstrated (2). Similarly the salt **1***c* gave the isothiazole **5***d*, the isothiazoline-3-thione **2***c*, and a trace of the dithiolethione **8***c*.

Reaction of the salt **1***g* gave only two products, the isothiazole **5***d* and the thione **8***a*. The lack of any isothiazolinethione or dithioleimine product obtained is probably a consequence of the instability of intermediates. Deprotonation of salt adjacent to sulfur would provide an iminothione. Lacking an aromatic substituent on nitrogen this would be expected to decompose more readily than the intermediate from the reaction of **1***h* with sulfur in pyridine. Deprotonation adjacent to nitrogen, although more unlikely, would give a ketiminothial, which would likewise be unstable.

That the *N*-aryl compounds, **1***b* and *d*, give dithioleimines, and the *N*-alkyl compounds, **1***a* and *c*, give isothiazoline-3-thiones by such treatment may be explained by alternate modes of cyclization of the intermediate in the reaction (Scheme 1*a* or 1*b*), with Scheme 1*a* being favored when the substituent on nitrogen is aryl, and Scheme 1*b* being favored when the substituent is alkyl. Inductive effects appear to be important. Similar differences in products obtained by reaction of 3-alkylthio-1,2-dithiolium salts with aromatic and aliphatic amines have been noted (2) and are probably due to similar causes.

Experimental

The n.m.r. spectra were obtained on a Varian model 56/60A spectrometer in deuterochloroform using tetramethylsilane as an internal standard. Mass spectra were obtained on a Finnegan 1015 quadrupole mass spectrometer. Chromatography (t.l.c.) was performed on "Camag" silica gel type D.S.F.5 supplied by Mondray Ltd. and column chromatography on alumina 504-c, also supplied by Mondray. Elution of both, unless otherwise stated, was by benzene. Melting points (m.p.) were obtained on a precalibrated Fisher–Johns apparatus.

4,5-Diphenylisothiazole (5a)

3,4-Diphenyl-1,2-dithiolium perchlorate (3.55 g, 10 mmol) (1) was slowly added to a boiling solution of ammonium acetate (20 g) in acetic acid (30 ml). The mixture became brown and was boiled 10 min. Dilution with water and extraction with benzene gave a brown solution which was washed once with saturated sodium bicarbonate and once with water. Evaporation gave a brown oil which was extracted with petroleum ether b.p. 60–80° to give a reddish oil. Column chromatography gave three bands. The first (yellow) gave ~0.5 g of an oil which could not be crystallized. The second (red) gave 4,5-diphenyl-1,2-dithiole-3-thione (0.3 g). The third (yellow) gave 4,5-diphenyliso-

thiazole. The product was further recrystallized from ethanol. Pale yellow needles, m.p. 92°, were obtained (23%).

Anal. Calcd. for $C_{15}H_{11}NS$: C, 75.94; H, 4.64; N, 5.92; S, 13.51. Found: C, 76.11; H, 4.72; N, 5.92; S, 13.39.

The n.m.r. spectrum: τ 2.83–2.76 (10H, two closely spaced singlets, the aromatic protons), 1.71 (1H singlet, the heterocyclic proton). The mass spectrum: M^+ 237; calcd. 237.

2-Methyl-4,5-diphenylisothiazolium Perchlorate (1c)

4,5-Diphenylisothiazole (1 g) was heated with an excess of dimethyl sulfate at 100° for 1 h. Dilution with ether precipitated a salt which was converted to the perchlorate in acetic acid containing perchloric acid, and recrystallized from the same solvent as yellow needles, m.p. 99° (80%).

Anal. Calcd. for $C_{16}H_{14}NSClO_4$: C, 54.70; H, 3.99; N, 3.99; S, 9.12; Cl, 9.97. Found: C, 54.62; H, 3.80; N, 3.98; S, 9.00; Cl, 9.95.

2-Methyl-4-phenylisothiazolium Perchlorate (1g)

4-Phenylisothiazole (7) was heated with excess dimethyl sulfate and worked-up as in the previous preparation. Pale brown needles, m.p. 102°, were obtained (85%).

Anal. Calcd. for $C_{10}H_{10}NSClO_4$: C, 43.45; H, 3.64; N, 5.09; S, 11.64; Cl, 12.91. Found: C, 43.15; H, 3.99; N, 5.25; S, 11.51; Cl, 12.70.

2,4-Diphenyl-5-methylthioisothiazolium Perchlorate (1i)

Methyl 2-phenyl-3-anilinopropenedithioate (1 g) (8) was dissolved in the minimum quantity of ethanol, and slowly titrated with a saturated ethanolic iodine solution until precipitation was complete. The buff precipitate of triiodide was converted to the perchlorate in acetone, and precipitated by dilution with ether. Recrystallization from acetic acid containing perchloric acid gave the perchlorate as yellow needles, m.p. 158° (34%).

Anal. Calcd. for $C_{16}H_{15}NS_2ClO_4$: C, 49.10; H, 3.81; N, 3.65; S, 16.62; Cl, 9.26. Found: C, 50.10; H, 3.76; N, 3.72; S, 16.57; Cl, 9.33.

2,4-Diphenylisothiazoline-5-thione (7a)

(*a*) 2,4-Diphenyl-5-methylthioisothiazolium perchlorate (384 mg, 1 mmol), pyridine (1 ml), and benzene (20 ml) were refluxed for 16 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with dilute hydrochloric acid, dried, and evaporated to give a yellow oil which was examined by t.l.c. Three bands were obtained, but only the third eluted gave other than traces of product. The compound was recrystallized from petroleum ether, b.p. 60–80°, as orange prisms, m.p. 168°, (9%).

Anal. Calcd. for $C_{15}H_{11}NS_2$: C, 67.01; H, 4.09; N, 5.20; S, 23.78. Found: C, 66.91; H, 3.94; N, 3.56; S, 23.82.

The i.r. spectrum: 1146 cm^{-1} (tentatively C=S str.). The mass spectrum: M^+ 269, calcd. 269.

(*b*) 4-Phenyl-1,2-dithiole-3-thione (2.10 g, 10 mmol) (24), in carbon tetrachloride (50 ml) was slowly treated with a solution of bromine (1.76 g, 11 mmol) in carbon tetrachloride (20 ml) with stirring. A tan solid formed and was collected and washed with carbon tetrachloride. The solid was added portionwise to aniline (10 ml) with stirring, and the mixture stirred 1 h. Dilution with ether gave a solid which was heated with water (20 ml) for 10 min. The mixture was extracted with benzene. The benzene solution was treated with decolorizing charcoal and evaporated to a small volume. Dilution with petroleum ether gave the product as orange prisms, m.p. 168° (82%). These were identical with that obtained above.

Reaction of 5-Phenyl-1,2-dithiole-3-thione with Bromine, followed by Aniline

5-Phenyl-1,2-dithiole-3-thione (2.10 g, 10 mmol) (10) in carbon tetrachloride (50 ml) was treated with bromine as above. A tan solid was obtained which was added to aniline (10 ml) with stirring. Addition of ether precipitated a solid which was found to be aniline salts. The ether solution was washed with water and shaken with dilute hydrochloric acid (25%). A yellow solid which separated was filtered off. Evaporation of the ether solution gave the thione **8***b* (19%). Treatment of the yellow solid with dilute sodium hydroxide gave the imine (**3***a*) (40%).

Reaction of 3-Ethylthio-5-phenyl-1,2-dithiolium Iodide with Aniline, Ethyl 3-Anilinodithiocinnamate (6b)

The iodide (14.6 g, 0.04 mol) (25) in acetic acid (100 ml) was heated to boiling and aniline (10 ml) added. The mixture was heated until homogeneous (~5 min) then diluted with water, and extracted with a chloroform:carbon tetrachloride 1:1 mixture (200 ml). The extract was shaken with 25% hydrochloric acid (100 ml) and filtered. The yellow precipitate gave the imine (**3***a*) on basification. The filtrate was separated and on evaporation gave a red oil which was examined by column chromatography. The first red band eluted gave a dark red oil which crystallized on trituration under ethanol. The product was recrystallized from ethanol as orange-red needles, m.p. 91° (14%).

Anal. Calcd. for $C_{17}H_{17}NS_2$: C, 68.20; H, 5.68; N, 4.68; S, 21.40. Found: C, 68.12; H, 5.75; N, 4.51; S, 21.37.

The mass spectrum: M^+ 299, calcd. 299. The n.m.r. spectrum: τ 8.69 (3H triplet, $J = 3.6$ Hz, CH_3 group) 6.33 (2H quartet, $J = 3.6$ Hz, CH_2), 3.81 (1H singlet, vinyl proton), 3.40–2.85 (5H multiplet, anilino protons), 2.74 (5H singlet, protons on other phenyl group), −3.09 (1H singlet, proton on nitrogen, hydrogen bonded to sulfur).

2,3-Diphenyl-3-ethylthioisothiazolium Perchlorate (1k)

Ethyl 3-anilinodithiocinnamate (1.50 g, 0.05 mol) in ethanol (20 ml) was slowly titrated with a saturated ethanolic solution until separation of buff-colored needles was complete. The product was filtered off and recrystallized from acetone as dark red needles, m.p. 139°. The triiodide was dissolved in acetone (10 ml) and 70% perchloric acid (1 ml) added. The mixture was carefully refluxed 10 min, then cooled, and diluted with ether. The product was filtered off and recrystallized from acetic acid containing perchloric acid as yellow needles, m.p. 142–144° (70%).

Anal. Calcd. for $C_{17}H_{16}NS_2ClO_4$: C, 51.41; H, 4.03; N, 3.53; S, 16.14; Cl, 8.94. Found: C, 51.25; H, 4.18; N, 3.45; S, 16.24; Cl, 8.88.

2,3-Diphenylisothiazoline-5-thione (7b)

2,3-Diphenyl-3-ethylthioisothiazolium perchlorate (408 mg, 1 mmol) in pyridine (10 ml) was refluxed for 5 min. The orange solution was poured into water, and ether extracted. The extract was washed with dilute hydrochloric acid, dried, and evaporated to give an orange oil which crystallized on standing. The product was recrystallized from ethanol as orange needles, m.p. 117° (28%).

Anal. Calcd. for $C_{15}H_{11}NS_2$: C, 67.01; H, 4.09; N, 5.20; S, 23.78. Found: C, 67.83; H, 4.12; N, 5.31; S, 23.98.

The mass spectrum: M^+ 269, calcd. 269.

2,3-Diphenylisothiazolium Perchlorate (1i)

2,3-Diphenylisothiazoline-5-thione (108 mg, 0.4 mmol) in acetic acid (5 ml) was treated with 30% hydrogen peroxide solution (0.13 g), and the solution allowed to stand 1 h. To the mixture was added 70% perchloric acid (0.2 ml), and the whole diluted with ether. Yellow needles separated. These were collected and recrystallized from acetone containing perchloric acid as yellow needles, m.p. 188–189° (67%).

Anal. Calcd. for $C_{15}H_{12}NSClO_4$: C, 53.28; H, 3.56; N, 4.15; S, 9.48; Cl, 10.51. Found: C, 53.14; H, 3.52; N, 4.05; S, 9.53; Cl, 10.56.

2,4-Diphenylisothiazolium Perchlorate (1h)

To 2,4-diphenylisothiazoline-5-thione (1.08 g, 0.04 mol) in acetic acid (20 ml) was added hydrogen peroxide (1.36 g, 25 mmol). The mixture became warmer as the thione dissolved. Temperature was maintained at 30° for 1 h, then the solution was filtered, 70% perchloric acid (1 ml) added, and the mixture diluted with ether. The precipitated solid was recrystallized from acetic acid containing perchloric acid as yellow needles, m.p. 198–199° (72%).

Anal. Calcd. for $C_{15}H_{12}NSClO_4$: C, 53.28; H, 3.56; N, 4.15; S, 9.48; Cl, 10.51. Found: C, 53.23; H, 3.60; N, 4.11; S, 9.28; Cl, 10.45.

Reactions of Isothiazolium Salts with Sulfur in Pyridine

General Method

The isothiazolium salts were added portionwise to saturated solutions of sulfur in refluxing pyridine, and the mixtures refluxed for 30 min. Lesser times were used for **1***h* and *i* since products from these appeared to be rather less stable in boiling pyridine. The mixtures were diluted with water and ether extracted. The ether extracts were washed with dilute hydrochloric acid (5%) dried, and on evaporation gave pasty solids which were examined by t.l.c. using benzene with increasing proportions of chloroform as an eluant.

The types and yields of the various products are summarized in Table 1.

Reaction of 2,4-Diphenyl-5-methylthioisothiazolium Perchlorate (1j) with Sodium Hydrosulfide

To the salt (0.5 g) in ethanol (3 ml) was added saturated ethanolic sodium hydrosulfide solution. The mixture became red and was warmed until homogeneous. The mixture was poured into water, ether extracted and evaporated. The red oil obtained was identified by its i.r. spectrum as methyl 2-phenyl-3-anilinopropenedithioate (**6***a*) (8).

Reaction of 2,5-Diphenyl-3-ethylthioisothiazolium Perchlorate (1k) with Sodium Hydrosulfide

This experiment was carried out as above. The oil obtained was chromatographed on alumina in benzene. Three bands were obtained. The first eluted was ethyl 3-anilinodithiocinnamate (**6***b*) (75%). The second was the thione **8***b* (7%) and the third was the imine **3***a* (9%).

Reaction of 2,4-Diphenylisothiazoline-5-thione with Dimethyl Acetylenedicarboxylate

The thione (0.538 g, 2 mmol) and the ester (0.284 g, 2 mmol) in benzene (30 ml) were refluxed 4 h. Evaporation gave a red oil which crystallized on trituration under methanol. The product was recrystallized from methanol as yellow prisms, m.p. 117° (91%).

Anal. Calcd. for $C_{21}H_{17}NS_2O_4$: C, 61.31; H, 4.13; N, 3.41; S, 15.59. Found: C, 61.47; H, 3.95; N, 3.28; S, 15.77.

The n.m.r. spectrum: τ 7.19, 7.10 (two 3H singlets, methyl protons), 3.92–3.56 (5H bands, phenyliminoprotons), 3.54 (5H singlet, phenyl protons), 1.80 (1H singlet, aldimine proton).

The i.r. spectrum: 1712, 1732 (C=O str.); 1588 cm^{-1} (C=N str.). The mass spectrum: M^+ 411, calcd. 411.

The authors wish to thank the National Research Council of Canada for financial support of this research. We also wish to thank Mr. M. Arneson for preparation of mass spectra and Mr. R. Dickinson for the preparation of n.m.r. spectra.

Long-range Spin–Spin Coupling Constants from Amino Protons and ^{15}N to Ring Protons in Aniline-^{15}N and Some Derivatives. INDO Molecular Orbital Calculations

R. WASYLISHEN,[1] J. B. ROWBOTHAM,[2] L. ERNST,[2] AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 1, 1972

A complete analysis (8-spins) is given of the p.m.r. spectrum of aniline-^{15}N, of the spectra of some haloanilines-^{15}N and of 2-aminoacetophenone-^{15}N. Intermolecular exchange of the amino protons is slow enough for observation of their spin–spin coupling to the ring protons. The magnitudes of the coupling constants between amino protons and ^{15}N or ring protons are a measure of the geometry of the amino group. This is not true of the couplings between ^{15}N and the ring protons. Long-range couplings computed in the CNDO/2 and INDO approximations of molecular orbital theory show points of agreement with experiment. For example, their signs and magnitudes are consistent with a nonplanar but not with a planar conformation of aniline. Couplings from ^{15}N to ring protons are also computed for nitrobenzene.

L'analyse complète (8 spins) du spectre de r.m.n. est donnée pour l'aniline ^{15}N, quelques haloanilines ^{15}N et pour l'amino-2 acétophénone ^{15}N. L'échange intermoléculaire des protons de l'amino est suffisamment lente pour pouvoir observer leur couplage spin–spin avec les protons du cycle. Les amplitudes des constantes de couplage entre les protons de l'amino et ^{15}N ou les protons du cycle donnent une mesure de la géométrie du groupe amino. Cela n'est plus vrai pour les couplages entre ^{15}N et les protons du cycle. Les couplages à longue distance calculés avec les approximations du CNDO/2 et INDO de la théorie des orbitales moléculaires sont en accord avec les valeurs expérimentales. Par exemple, les signes et les amplitudes des couplages ne sont compatibles qu'avec la conformation non plane de l'aniline. Les couplages entre ^{15}N et les protons du cycle ont été également calculés pour le nitrobenzène.

Introduction

The one-bond ^{15}N—H spin–spin coupling constants in aniline-^{15}N and many of its derivatives have been discussed in detail (1–4). Ring substituents which diminish electron density on the nitrogen atom cause an increase in the magnitude of these coupling constants, apparently implying an alteration in the geometry of the amino group and describable as a change in hybridization of the nitrogen atom. The chemical shifts of the amino protons (5–8) and of ^{15}N are interpreted in a similar manner (1).

Long-range coupling constants between ring protons and protons of sidechain functions such as methyl (9–13), formyl (14–17), hydroxyl (18, 19), and amino (20, 21) groups are stereospecific. Such couplings for the amino protons therefore offer another approach to the study of the geometry of this moiety. The couplings are less than 1 Hz in magnitude and this approach has until recently (22–24) been hampered by the facile intermolecular exchange of the amino protons in solutions of aniline and its derivatives. The mean lifetime before exchange must be increased to the order of seconds before these long-range couplings become observable in a slow-passage experiment. In this paper these parameters are described for aniline-^{15}N itself and also for some of its derivatives.

The spin–spin interactions between ^{15}N and the ring protons are also measured. Other workers have observed their magnitudes only for protons situated ortho to the amino group (1).

In addition, the long-range coupling constants involving the $^{15}NH_2$ fragment are calculated by the finite perturbation technique (25) in the INDO molecular orbital approximation (26). A comparison of calculated with observed couplings leads to inferences about the conformation of the amino group in aniline.

Experimental

(1) Preparation of Compounds

Acetanilide-^{15}N was prepared by the addition of 5.3 ml of acetic anhydride to a solution of 4.2 g of aniline-^{15}N (96.5 at. % ^{15}N from Azote et Produits Chimiques, Toulouse,

[1]NRCC Scholarship, 1971–72.

France) in 2.4 ml of acetic acid. After the mixture solidified, 50 ml of water were added and the product was filtered off and dried at 60 °C/0.01 Torr for 3 h, m.p. 114–116 °C. The mass spectrum was consistent with that expected on the basis of the mass spectrum from a commercial sample of acetanilide.

To prepare 2-aminoacetophenone-^{15}N, a solution of 5.00 g of acetanilide-^{15}N in 120 ml of absolute ethanol was irradiated for 18 h at 254 nm while bubbling dry nitrogen through the solution. Steam distillation and extraction of the distillate gave 0.12 g of a mixture of 2-aminoacetophenone-^{15}N and acetanilide-^{15}N. This mixture was submitted to dry column chromatography: silica gel, column length 80 cm, diameter 2.5 cm, eluant ethyl acetate/cyclohexane 95:5, v:v. The yield[3] of pure 2-aminoacetophenone-^{15}N was 0.10 g, 2%. Extraction of the residue from the steam distillation yielded 4.4 g (88%) of starting material.

A 3:2 mixture of 4-bromo-2-chloroaniline-^{15}N and 2-chloro-4,6-dibromoaniline-^{15}N was obtained by the addition of bromine to 0.2 g of 2-chloroaniline-^{15}N (96.47 at. % ^{15}N from Merck, Sharp, and Dohme of Canada) in 5 ml of acetic acid. When a slight color remained, 10 ml of water were added and the precipitate was collected. An analogous bromination of aniline-^{15}N yielded a 2:1 mixture of 2,4-dibromoaniline-^{15}N and 2,4,6-tribromoaniline-^{15}N.

(2) Preparation of Samples for Spectral Work

All samples (solvents and concentrations given in Table 1) were degassed by the freeze–pump–thaw technique. Internal tetramethylsilane was added as reference material. Intermolecular exchange of the amino protons was retarded by adding basic alumina to the sample tubes before sealing and some of the solutions were stored over NaOH pellets for several hours.

The reaction of equimolar quantities of aniline-^{15}N and D_2O yielded a mixture containing the ^{15}NHD group among others. The mixture was dried over NaOH pellets and was transferred to a sample tube containing basic alumina and sufficient toluene-d_8 to yield a 15 mol % solution of nonexchanging amine. The sample was degassed and the p.m.r. spectrum indicated equimolar amounts of the $^{15}NH_2$ and ^{15}NHD moieties.

(3) Proton Magnetic Resonance Spectra

Spectra were recorded in the frequency sweep mode on an HA100-D spectrometer at sweep rates of 0.01 and 0.02 Hz/s at sweep widths of 1 Hz/cm. They were calibrated by reading sweep and manual oscillator frequencies at intervals of a few Hz, and double and triple resonance experiments (28) yielded the signs of the coupling constants.

Results and Discussion

(1) Spectral Analysis

(a) Aniline-^{15}N

Two samples were subjected to spectral analysis. In one (17% in benzene-d_6) the rate of intermolecular proton exchange was low enough to allow the observation of the long-range coupling constants between ring and amino protons. In the other (30 mol % in benzene-d_6) the rate of proton exchange was high enough to eliminate the effects of these coupling constants from the observed high resolution spectrum.

Each of the 165 peaks observed in the nonexchanging solution was calibrated at 0.01 Hz/s. The spectrum was analyzed as an 8-spin system by means of the computer program LACX (29). Because so many of the 640 calculated transitions were nearly degenerate it was not sensible to assign more than 380 to observed peaks (348 of the 512 calculated ring proton transitions were assigned). The results given in Tables 1 and 2 were obtained when all parameters were allowed to vary in the final iterative stages. The r.m.s. error was 0.015 Hz and the probable error of all parameters was equal to or less than 0.003 Hz, except that the probable error in $^1J(^{15}N,H)$ was 0.006 Hz. The observed ring proton spectrum, together with the calculated spectrum, is shown in Fig. 1. The widths at half-height of nondegenerate peaks in the experimental spectrum are less than 0.11 Hz.

In the spectrum for the exchanging solution, 127 of the 130 transitions of significant intensity calculated by the computer program LAME (30) were assigned to observed peaks. The r.m.s. error was 0.021 Hz in the final iteration and the probable error was less than or equal to 0.008 Hz. Agreement between observed and calculated spectra was excellent. Because all of the coupling constants obtained in this analysis are the same to within 0.01 Hz as those obtained for the nonexchanging sample, the spectra are not reproduced here and the spectral parameters are omitted from the tables.

Only the amino proton resonance peaks were studied for the sample containing $^{15}ND_2$, ^{15}NHD, and $^{15}NH_2$ groups. At 31 °C the (isotope) shift in the ^{15}NHD group was 0.0235 ± 0.0020 p.p.m. to high field of the $^{15}NH_2$ proton shift, compared to 0.0255 ± 0.0020 p.p.m. in 2-chloroaniline-^{15}N (23). At this temperature the line-widths of the ^{15}NHD and $^{15}NH_2$ proton resonance peaks were 1.35 and 0.85 Hz, respectively. In line with the experiments described for 2-chloroaniline-^{15}N (23), we esti-

[3]Elad (27) obtained a 20% yield of 2-aminoacetophenone by using a high pressure mercury vapor lamp.

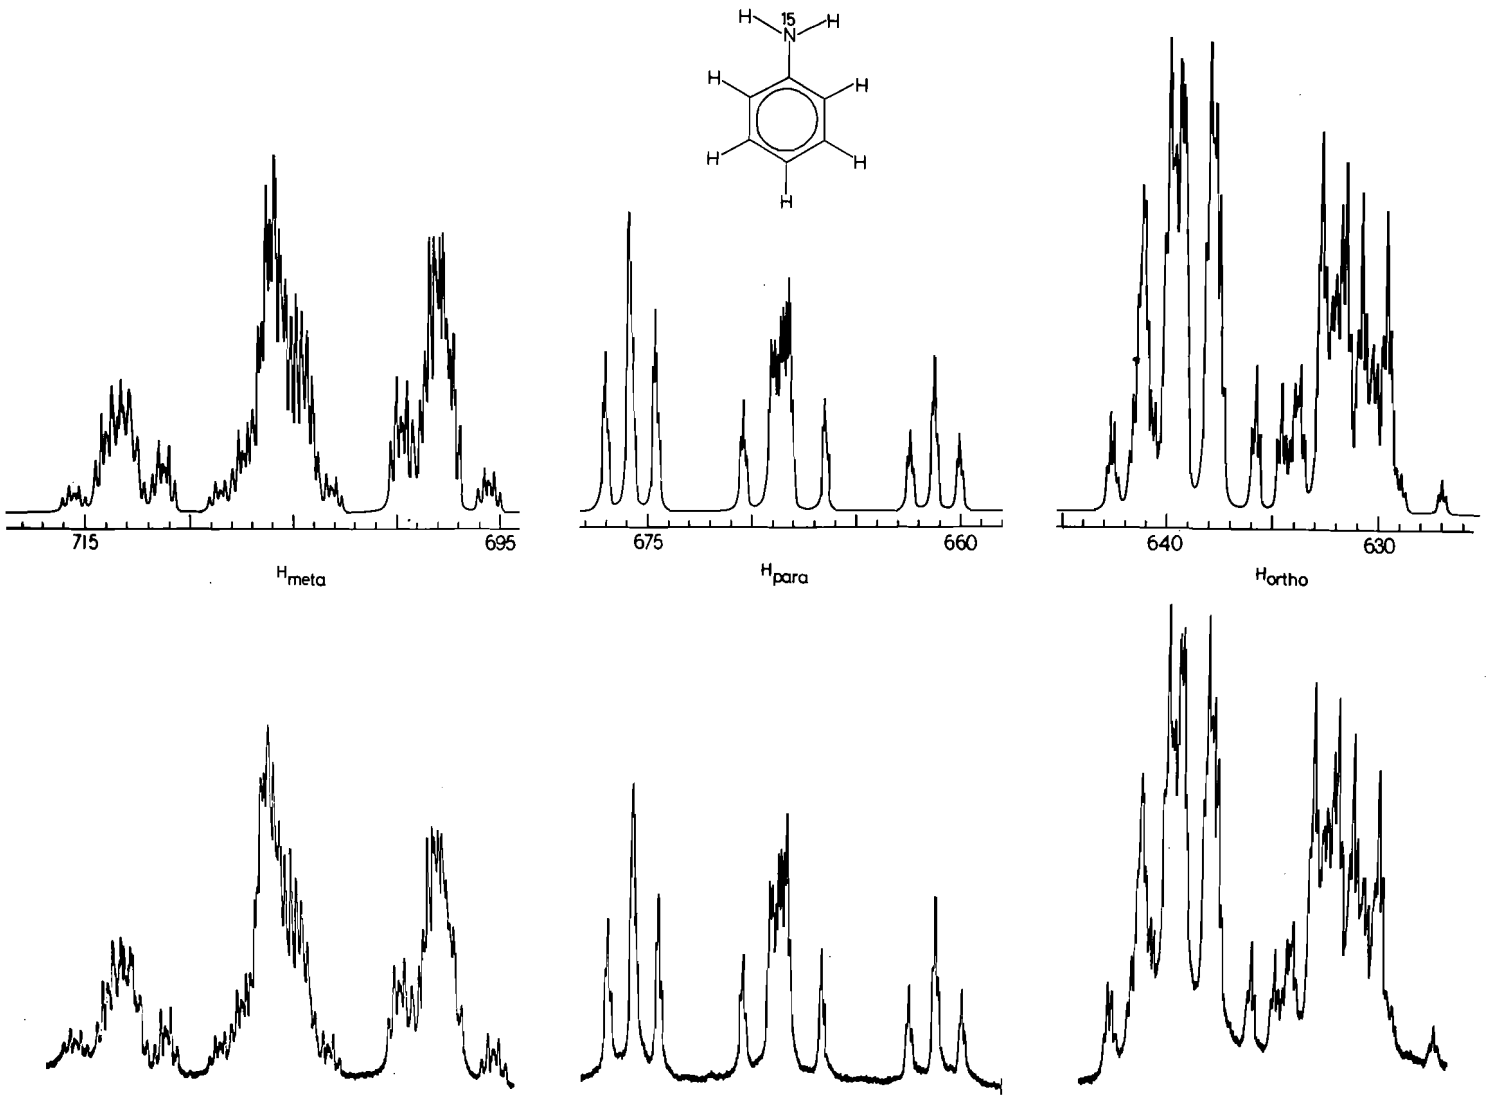

FIG. 1. The lower part shows the ring proton magnetic resonance spectrum of aniline-^{15}N as a 17 mol % solution in benzene-d_6 under conditions where long-range coupling between amino and ring protons is clearly observable. In the upper part of the figure the calculated spectrum employs the parameters given in Tables 1 and 2. In the observed spectrum linewidths at half-height of nondegenerate peaks were less than 0.11 Hz.

mate the magnitude of the geminal proton coupling in the amino group, $^2J_g^{HNH}$, as 1.6 ± 0.6 Hz.

(b) 2-Aminoacetophenone-^{14}N and -^{15}N

The derived coupling parameters for the two isotopomers are in close agreement and only those for the sample containing the nonexchanging ^{15}N compound are given in the tables. The methyl protons are coupled to H_6 (ortho to the acetyl group) by ± 0.187 Hz.[4] On assigning all of the 264 calculated ring proton transitions to observed peaks the results given in Tables 1 and 2 are obtained. The r.m.s. error was 0.024 Hz and all probable errors were less than or equal to 0.006 Hz.

(c) Acetanilide-^{15}ND

Because of its low solubility in benzene, the p.m.r. spectrum of an 11 mol % solution in acetone-d_6 was calibrated and analyzed using the program LACX. When freshly prepared, the amino proton resonance was observable as a doublet. Its disappearance after several weeks is attributed to slow exchange of the amino protons with deuterium in the solvent molecules. The rough analysis gave the results in Tables 1 and 2 and the probable errors were less than or equal to 0.021 Hz but a reasonable error estimate probably lies near 0.04 Hz.

(d) Halogenated Derivatives of Aniline-^{15}N

These were studied as dilute solutions in benzene-d_6. The two bromine derivatives were present as a mixture, as were the two bromochloro derivatives. The peaks originating in each compound in the two mixtures were readily distinguishable. All observed peaks, including those of the amino protons, were assigned in the analysis by LAME. The derived parameters, given in Tables 1 and 2, had probable errors of less than 0.013 Hz and the r.m.s. error varied between 0.015 and 0.023 Hz. The amino proton – ring proton couplings had probable errors lying between 0.003 and 0.006 Hz (one value).

(2) Molecular Orbital Calculations

The coupling constants appearing in Tables 3 and 4 were calculated by the finite perturbation technique (25) in the INDO approximation (26) on an IBM 360/65 computer. Our convergence criteria have been previously described (17, 31). As many as 100 cycles in the SCF procedure were necessary to obtain convergence to 0.01 Hz. The parameterization is available only for first-row elements. Therefore computations were done only for aniline, 2-aminoacetophenone, acetanilide, and nitrobenzene. Standard geometries (26, 32) were employed to calculate the atomic coordinates in the benzene ring.

For aniline the geometry of the amino group was taken from the microwave results of Lister and Tyler (33). Another calculation on aniline assumed complete planarity of the molecule with C—N and N—H bond lengths equal to those given (33) for the nonplanar molecule. Standard geometries were used in a planar (apart from the methyl protons) model of 2-aminoacetophenone and also for nitrobenzene. The geometry of the sidechain in acetanilide was found in the literature (34–36).

According to INDO the nonplanar form of aniline is 11.3 kcal/mol more stable than the planar form. Lister and Tyler (33) suggest an inversion barrier of less than 0.3 kcal/mol. An optimization of the geometry of the amino group at each successive stage of its inversion might well improve the computed value.

The calculated (observed) dipole moments in Debyes are: aniline 1.46 (1.56); planar aniline 1.105; acetanilide 4.10 (3.88 to 4.02); nitrobenzene 5.22 (3.93); 2-aminoacetophenone 1.85 (2.05). Experimental dipole moments are cited from the compilation of McClellan (37).

(3) The Coupling between ^{15}N and Amino Protons

(a) Experimental Data

Three different linear relationships between the one-bond ^{15}N—H coupling and the percent s character of the nitrogen bond orbitals have been proposed (2, 3, 23). Two (2, 3) are based mainly on the observation for $^1J(^{15}N,H)$ of about -75 Hz in ammonium ion (sp^3 hybridization), -90 Hz in amides (sp^2), and about -136 Hz in protonated nitriles (sp). The third (23) uses anilinium ion and the geometry of aniline in the gas phase as calibration points. The latter writes $\%\,s = -0.59\,^1J(^{15}N,H) - 17.5$ and yields 29% s character in aniline and 52% in sp systems. The former two give 46 and 52% for sp hybridization and 27 and 28% s character for aniline. Clearly, only semiquantitative predic-

[4]The value of ± 0.187 Hz is obtained by a complete analysis of the spectrum using LAME and does not represent the observed splitting in the methyl proton resonance.

$^5J(^{15}N,H_p)$	0.18	−0.33	−0.62	−0.82

*The nonplanar geometry for aniline and planar geometries for the other compounds were employed as described in the text. Planar geometries assume an HNH angle of 120°.
†For an amino group coplanar with the aromatic ring one finds $^1J(^{15}N,H)$ = −92.20 Hz.
‡CNDO/2 finds −43.0 Hz.
§This is the average of $^3J(^{15}N,H_2)$ = −3.461 and $^3J(^{15}N,H_6)$ = −4.267.

tions of the geometry of the amino group in aniline derivatives are possible by these methods. Furthermore, the coupling is solvent dependent (1, 4, 38) and the effective nuclear charge (39) is probably rather different in some of the compounds used for calibration, adding to the uncertainty in the reference points.

Nevertheless, in aniline derivatives containing meta and para substituents (1, 4), electron withdrawing substituents cause an increase in the magnitude of $^1J(^{15}N—H)$: interpretable as a decrease in π electron density, a flattening of the pyramid and therefore as a change in hybridization, at nitrogen. In Table 1, the ring-substituted anilines all contain one or two groups ortho to the amino group. The observed magnitudes of $^1J(^{15}N,H)$ in these compounds are compatible with such an interpretation.

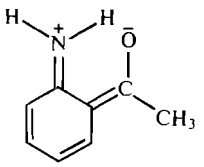
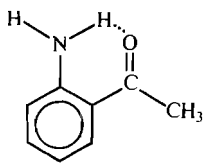
However, in the presence of ortho substituents intramolecular hydrogen bonding is an additional factor which may lead to a flattening of the nitrogen pyramid. Evidence for such bonds comes from X-ray diffraction data (40), the amino proton chemical shifts (5–8), as well as from N—H stretching frequencies (41, 42). The relatively large magnitude of 88.6 Hz for $^1J(^{15}N,H)$ in 2-aminoacetophenone in toluene solution, compared to 86.4 Hz for 4-nitroaniline in chloroform solution (1), can therefore be regarded as arising from a composite effect: electron withdrawal by the acetyl group, described by **1**, together with hydrogen bonding between the N—H and C=O bonds as in **2**.



1



2

Both structures favor an HNH angle larger than the 114° in aniline (33). The linear relationship above yields 35% s character at nitrogen and an HNH angle of 122° in 2-aminoacetophenone (using $\cos\theta/\cos\theta - 1 =$ fractional s character), perhaps somewhat large[5] but rather smaller than the 133° deduced from i.r. data (41).

In an attempt to provide another measure of the degree of intramolecular hydrogen bonding in aniline derivatives Axenrod and Wieder (43) argue that the difference between the magnitudes of $^1J(^{15}N,H)$ in dimethylsulfoxide solution, where a strong tendency to intermolecular N—H hydrogen bonds to solvent molecules exists, and in chloroform solution, where intramolecular hydrogen bonds are preferred, is a measure of the hydrogen bonding abilities of the ortho substituent. These are deduced as $NO_2 > C{=}O > Br$, in reasonable agreement with *a priori* expectations. The data in Table 1 imply similar hydrogen bonding tendencies for Cl and Br substituents if due allowance is made for their electron withdrawing abilities, also indicated (1) as nearly the same by the $^1J(^{15}N,H)$ magnitudes in the meta and para haloanilines.

(b) Computed Data

For ammonia the computed $^1J(^{15}N,H)$ is −42.6 Hz (26, 44) while the experimental value is ±65.1 Hz (45). A similar ratio of the two quantities, −59.5 and −78.9 Hz, is found for aniline in Tables 1 and 4. However, when a planar form is assumed for aniline the computed is larger than the observed magnitude. In this sense the INDO results are in qualitative agreement with the nonplanar geometry of aniline.

For 2-aminoacetophenone one observes −88.6 Hz for $^1J(^{15}N,H)$ whereas the average computed value for a planar 2-aminoacetophenone is −93.5 Hz, not strikingly different from the −92.2 Hz calculated for a planar aniline. The relatively good agreement between observed and calculated values is consistent with an almost planar 2-aminoacetophenone but unfortunately cannot be treated as confirmation of this conformation.[6]

Qualitatively the calculated one-bond ^{15}N—H couplings are in accord with the observed trend towards larger magnitudes as the nitrogen pyramid becomes more shallow in ring-substituted anilines.

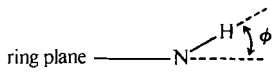
(4) Long-range Couplings from Amino to Ring Protons

(a) Experimental Data

By means of our earlier calibration procedure (22) $^6J_p^{H,NH}$ was estimated (22) as −0.14 Hz in aniline. Because of problems with intermolecular proton exchange, this parameter was not observable at that time (22) but the prediction is now borne out by the observed value of −0.137 Hz (Table 1). The prediction assumes the geometry of the aniline molecule in the gas phase (33), having an angle ϕ of 20° between the ring plane and the plane defined by the nuclei in the C—N—H fragment (see

[5]For acetanilide, $^1J(^{15}N,H)$ attains −91.3 Hz in DMSO solution (Table 1) but in view of the known solvent effects (1, 38) it could well be equal to $^1J(^{15}N,H)$ in 2-aminoacetophenone if both compounds were measurable in toluene solution. Planarity of the geometry about the nitrogen atom in 2-aminoacetophenone is therefore not ruled out by this difference in $^1J(^{15}N,H)$.

[6]There is a much larger difference between calculated and observed values when the acetyl group is bonded directly to the nitrogen atom, as in acetanilide (Tables 1 and 4). However, it should be noted that in the latter case the calculations were carried out assuming that the planar acetamido group was twisted 38° out of the benzene ring plane (36).



3

3). From the value of -0.108 Hz for $^6J_p^{H,NH}$ in 2-chloroaniline an average ϕ of 17.5° follows. $J_p^{H,NH}$ is not observable in 2-aminoacetophenone (Table 1) but an upper limit of 0.06 Hz for this coupling then yields a maximum angle ϕ of 12°. The observed coupling in 2-aminoacetophenone is of course also compatible with $\phi = 0°$ and is an illustration of the unfortunate insensitivity of $J_p^{H,NH}$ to small angles ϕ, a consequence of its proportionality to $\sin^2 \phi$ in the assumed coupling mechanism (22).

Our assumption (22) that $J_p^{H,NH}$ originates in a hyperconjugative overlap between the N—H bonds and the π electron system of the ring, analogous to the mechanism described for methyl proton interactions in toluene (31, 46), is consistent with its observed values in Table 1. Alternatively, it might have been argued that a decrease in ϕ implies an increase in the conjugation of the nitrogen atom with the π system of the ring. A π electron mechanism operating via the nitrogen atom, *i.e.*, via the partially double C⋯N bond, would then serve to enhance the magnitude of $J_p^{H,NH}$ in 2-aminoacetophenone relative to aniline. In fact the opposite occurs, in agreement with the hyperconjugative model. The application of the model to the conformational problem also assumed the absence of an intrinsic, as distinct from a steric, effect on $J_p^{H,NH}$; in line with similar assumptions for other sidechains (17, 31, 46).[7]

Such an effect is harder to exclude for $^4J_o^{H,NH}$, other four-bond couplings in unsaturated systems being subject to intrinsic substituent effects, (17, 47), but its behavior in Table 1 is roughly parallel to that of $J_p^{H,NH}$. An intrinsic effect on $^5J_m^{H,NH}$ is found for the aniline derivatives in Table 1. For example, $J_m^{H_5,NH}$ is 0.1 Hz smaller than $J_m^{H_3,NH}$ in 2-aminoacetophenone. This behavior is reproduced by the molecular orbital calculations.

(b) Computed Data

In Table 3 the computed couplings between the amino and ring protons are given for the nonplanar conformation of aniline as well as for the planar forms of aniline and of 2-aminoacetophenone. Their high stereospecificity is of conformational interest. As the experimental values in Table 1 are measured for molecules in which rapid rotation occurs about the C—N bond, they should be compared with the average calculated couplings (indicated by angular brackets) in Table 3.

Inasmuch as INDO considers one-center exchange integrals it includes the π electron contribution to the coupling constants (26). Thus, INDO finds their correct signs for the nonplanar form of aniline, whereas CNDO/2 calculates positive values for $^4J_o^{H,NH}$ and $^6J_p^{H,NH}$. On the other hand, INDO tends to overestimate the negative π electron contribution to these two couplings as well as the positive π contribution to $^6J_m^{H,NH}$ (reminiscent of a similar situation in benzaldehyde derivatives (17)). CNDO/2 agrees quantitatively with experiment for $^5J_m^{H,NH}$, suggesting a dominance of the σ electron contribution to this coupling; and furthermore finds $^6J_p^{H,NH} = 0.01$ Hz, thereby supporting our assumption that this parameter originates in π electron effects.

The signs of $^4J_o^{H,NH}$ and $^6J_p^{H,NH}$ calculated by INDO for the planar form of aniline are opposite to the observed sign. Although their magnitudes are probably again exaggerated, the implied conformational dependence qualitatively confirms the empirical use of the observed couplings in conformational deductions.

For a planar 2-aminoacetophenone the INDO results reproduce the substituent dependence of the two $^5J_m^{H,NH}$ values but again appear to overestimate the magnitudes of $^4J_o^{H,NH}$ and $^6J_p^{H,NH}$. The average coupling between the methyl protons and ring proton H_3 (configuration of the methyl group as given in Table 3) is computed as 0.20 Hz, compared to the observed value of ± 0.19 Hz. Couplings of this kind occur when the protons are in close proximity (often called "through-space" couplings) and the comparison indicates that INDO can cope with such interactions (49, 50).

(5) Coupling of ^{15}N to Ring Protons

The observed couplings in Table 1 are apparently not closely related to the geometry of the amino group although substituent effects on their magnitudes are present, particularly

[7]Even when the "substituent" atom forms part of the aromatic ring, as in pyridine, its intrinsic effect on couplings over six bonds is relatively minor (48).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for $^4J(^{15}N,H_m)$. In Table 4 the computed couplings are rather larger than, but roughly in the proportion of, the measured parameters. The computed couplings in nitrobenzene are not strikingly different from those in aniline derivatives. In nitrobenzene, $^3J(^{15}N,H_o)$ is calculated as -3.75 Hz, which may be compared to an observed value of ± 2.5 Hz in 1-nitronaphthalene (51).

(6) Coupling between Amino Protons

CNDO/2 finds $^2J_g^{HNH}$ equal to 1.60 Hz in ammonia and INDO finds -6.37 Hz (26). Similar behavior is found for aniline in Table 3, CNDO/2 computing 5.70 Hz for this coupling whereas INDO calculates -0.04 Hz. For a planar aniline model the INDO estimate rises to 8.23 Hz. The INDO results are consistent with a nonplanar aniline form because the observed value is ± 1 to ± 2 Hz.

INDO computes 7.61 Hz in a planar 2-aminoacetophenone. In this respect and also from the viewpoint of the other computed couplings in Table 3, it would be of interest to analyze the spectrum of this compound under conditions where rapid rotation about C—N bond does not occur.

Conclusions

The magnitudes of the coupling constants between amino protons and ^{15}N or ring protons in aniline and some of its derivatives constitute a measure of the degree of flattening at the nitrogen pyramid. In contrast, the coupling constants between ^{15}N and the ring protons are sensitive to the presence of substituents but are not simply related to the geometry of the amino group. The long-range coupling constants computed by molecular orbital theory in the CNDO/2 and INDO approximations are sensitive to the stereochemistry and are in agreement with a nonplanar conformation of aniline.

Temperature and Pressure Dependence of ^{209}Bi Nuclear Quadrupole Resonance in $BiCl_3$

G. C. GILLIES AND R. J. C. BROWN

Department of Chemistry, Queen's University, Kingston, Ontario

Received February 24, 1972

The temperature and pressure dependence of the ^{209}Bi nuclear quadrupole coupling constant and asymmetry parameter in solid $BiCl_3$ have been measured near room temperature. It is not possible to account for the results on the basis of the conventional theory in which the field gradient parameters depend only on the crystal volume.

L'influence de la température et de la pression sur la constante de couplage nucléaire quadrupole du ^{209}Bi et sur le paramètre d'asymétrie du $BiCl_3$ solide, a été mesurée à une température proche de la température ambiante. Il n'a pas été possible d'expliquer les résultats à partir de la théorie classique dans laquelle les paramètres du gradient de champ dépendent seulement du volume du cristal.

Introduction

Nuclear quadrupole resonance frequencies are dependent upon both volume and temperature, and in order to compare theory with experiment properly it is necessary to separate the explicit volume effects from the frequency measurements made at atmospheric pressure (1). A number of studies of the shift of n.q.r. frequencies under hydrostatic compression have been reported which allows this separation to be made; in addition to the temperature and pressure coefficients of the n.q.r. frequency, the thermal expansion and compressibility coefficients must be known, and in many cases the latter information is not available.

The observed n.q.r. frequencies are determined by two parameters of the effective Hamiltonian, the quadrupole coupling constant (eqQ) and the asymmetry parameter (η). For the common case of a nuclear spin of 3/2, η cannot be determined reliably without measurements of the Zeeman splitting of the resonance in a single crystal which can be re-oriented readily, and so in most high pressure n.q.r. experiments on nuclei of spin 3/2, the asymmetry parameter has been ignored; this assumption is logically consistent since the resonant frequency is almost independent of η except for very large values:

$$\nu_Q = \tfrac{1}{2}eqQ(1 + \eta^2/3)^{1/2}$$

Hence in order to obtain information on the temperature and pressure dependence of the asymmetry parameter, it is advantageous to deal with spins other than 3/2. The temperature dependence of the asymmetry parameter has not been measured for many crystals, even though in suitable cases it provides information which is complementary to that obtained from the coupling constant itself.

Bismuth trichloride provides an interesting case for study. The ^{209}Bi resonances have been measured at 299 and 83 K (2), and fall in a convenient frequency range; there are four resonances and η is large enough that two of the resonances lie close together, so the same high pressure bomb may be used to measure both resonance frequencies. Measurement of two of the four resonances suffices to determine the values of eqQ and η using the analysis of the spin 9/2 quadrupolar Hamiltonian given by Cohen (3). The crystal structure (4) and Raman spectrum (5) of solid $BiCl_3$ have been reported. The thermal expansion coefficient has been reported (6) but not the compressibility, and as a result the analysis of the quadrupole spectrum is limited.

The Pure Quadrupole Spectrum for Spin 9/2

There are five energy levels, whose energies may be written in the form (3)

$$[1] \qquad E = x(\eta)(eqQ)/24$$

where $x(\eta)$ are the roots of the equation $f(x, \eta) = 0$.

$$[2] \quad f(x,\eta) = x^5 - 11(3+\eta^2)x^3 - 44(1-\eta^2)x^2 + \tfrac{44}{3}(3+\eta^2)^2x + 48(3+\eta^2)(1-\eta^2)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The frequencies of the transitions between adjacent energy levels can therefore be written

$$[3] \qquad \nu_i = r_i(\eta)(eqQ)/24h$$

where $r_i(\eta)$ is the difference between two adjacent roots of eq. 2. In the following, $i = 1$ refers to the $\pm 1/2 \leftrightarrow \pm 3/2$ transition and $i = 2$ refers to the $\pm 3/2 \leftrightarrow \pm 5/2$ transition; in $BiCl_3$ these transitions occur near 31.8 and 25.1 MHz, respectively (2), and are the transitions which were measured as a function of temperature and pressure. The frequencies were found to be linear functions of the temperature and pressure over the ranges investigated, and the subsequent analysis was therefore carried out in terms of the derivatives $(\partial\nu_i/\partial T)_P$ and $(\partial\nu_i/\partial P)_T$. Using eq. 3 these derivatives can be written

$$[4] \qquad \left(\frac{\partial \nu_i}{\partial T}\right)_P = \frac{r_i(\eta)}{24h}\left(\frac{\partial eqQ}{\partial T}\right)_P + \frac{dr_i}{d\eta}\left(\frac{\partial \eta}{\partial T}\right)_P \frac{eqQ}{24h}$$

$$[5] \qquad \left(\frac{\partial \nu_i}{\partial P}\right)_T = \frac{r_i(\eta)}{24h}\left(\frac{\partial eqQ}{\partial P}\right)_T + \frac{dr_i}{d\eta}\left(\frac{\partial \eta}{\partial P}\right)_T \frac{eqQ}{24h}$$

The derivatives $dr_i/d\eta$ are calculated from differences of the derivatives $dx/d\eta$, which are obtained from setting the total derivative of $f(x, \eta)$ equal to zero.

$$[6] \qquad \frac{dx}{d\eta} = -\left(\frac{\partial f}{\partial \eta}\right)\Big/\left(\frac{\partial f}{\partial x}\right)$$

In evaluating r_i and its derivatives, the value of η at room temperature was used. When $(\partial\nu_i/\partial T)_P$ is known for two resonances, eq. 4 may be solved simultaneously for $(\partial eqQ/\partial T)_P$ and $(\partial\eta/\partial T)_P$, and similarly for the pressure derivatives. It is advantageous to measure the $\pm 1/2 \rightarrow \pm 3/2$ transition no matter which of the other three transitions is measured, for the frequency of this transition varies strongly with the value of η; the frequencies of the other transitions are less sensitive to the value of η and reflect changes in the coupling constant more directly.

Experimental

Spectra were recorded with a self-quenched superregenerative spectrometer similar to that described by Dean (7); for frequency measurements it was found advantageous to remove the coherence feedback control function in order to allow quick manual change in the quench conditions. Frequency modulation and lock-in detection were used to record the resonances on a chart recorder; the shape of the resonances recorded was complex but was not affected by changes of temperature or pressure so that shifts in the resonance frequency could be measured consistently.

Frequency measurement was performed as follows. The unquenched, unmodulated oscillator was driven slowly in frequency by a synchronous motor, and its frequency as measured by a frequency counter was recorded regularly on the chart record; as the frequency of the oscillator approached the resonance the quench and modulation were switched on, and the resonance was recorded. After the resonance had been passed, further frequency measurements on the unquenched, unmodulated oscillator were recorded. The recorded frequency was fitted to a least squares parabolic function of displacement along the record, and the resonance frequency calculated from this function. A correction for the shift in oscillator frequency with grid time constant was applied by also recording the zero beat of the quenched modulated oscillator with an appropriate harmonic of 100 kHz derived from the frequency counter, either before or after the resonance was recorded; the correction was generally less than 10 kHz. Individual frequency measurements made by this technique appear to be repeatable to within several kHz.

The bomb used for the high pressure measurements was of conventional design, with an O-ring seal which was satisfactory up to a pressure of about 275 MNm^{-2}. The coned electrical seal was insulated with epoxy resin. The pressure coefficients of the resonances were large enough that it was not necessary to carry the measurements to very high pressures, the highest pressure used being about 140 MNm^{-2}; vacuum pump oil was used as a hydraulic medium. The powdered sample was mixed with oil and placed inside a short section of drinking straw with the ends sealed with wax, in order to prevent contact with the stainless steel bomb. The coil of the oscillator was a close fit around the sample. The bomb was thermally insulated, and its temperature was recorded; some temperature drift occurred during the measurements and the frequencies were corrected to 25.0 °C later using the measured temperature dependence.

The temperature dependence was measured using a sample sealed under vacuum. The temperature was varied between 0 and 50 °C using a refrigerated thermostat; the temperature was measured with a mercury thermometer which was compared with a calibrated thermometer in a separate experiment.

Bismuth trichloride from the Matheson, Coleman and Bell Company was dried *in vacuo* at 100 °C over phosphorus pentoxide, before being sealed in an evacuated sample tube, or mixed with oil in a dry atmosphere.

Results and Discussion

The frequencies of both resonances varied linearly with both pressure and temperature over the restricted ranges investigated, with the following coefficients. For the 31.8 MHz resonance,

$$\left(\frac{\partial \nu_1}{\partial T}\right)_P = -10.42 \pm 0.06 \text{ kHz K}^{-1}$$

$$\left(\frac{\partial \nu_1}{\partial P}\right)_T = +1.36 \pm 0.02 \text{ kHz (MN m}^{-2})^{-1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and for the 25.1 MHz resonance

$$\left(\frac{\partial \nu_2}{\partial T}\right)_P = -4.46 \pm 0.03 \text{ kHz K}^{-1}$$

$$\left(\frac{\partial \nu_2}{\partial P}\right)_T = -1.720 \pm 0.008 \text{ kHz (MN m}^{-2})^{-1}$$

The pressure coefficients refer to a temperature of 25 °C. The extrapolated zero pressure frequencies measured for the sample in the high pressure bomb were 31 878.3 ± 1.1 and 25 137.3 ± 0.7 kHz, respectively, while the measurements on the larger sample *in vacuo* at the same temperature (25 °C) were 31 893.8 ± 2.0 and 25 136.6 ± 0.9 kHz, respectively; the value of η derived from these measurements is 0.5544 ± 0.0002, and the quadrupole coupling constant is 318.70 ± 0.15 MHz. The two measurements of the lower frequency resonance are in good agreement, but there is a discrepancy of about 15 kHz in the results for the higher frequency; the latter line was weaker than the former, and the assignment of the central point of the resonance pattern for the sample in the bomb may have been in error, without affecting the value of the derivatives. Substituting these values into eqs. 4 and 5 and solving, the temperature and pressure derivatives of the coupling constant and asymmetry parameter are found to be

$$\frac{1}{h}\left(\frac{\partial eqQ}{\partial T}\right)_P = -40.6 \pm 0.7 \text{ kHz K}^{-1}$$

$$\frac{1}{h}\left(\frac{\partial eqQ}{\partial P}\right)_T = -33.6 \pm 0.2 \text{ kHz (MN m}^{-2})^{-1}$$

$$\left(\frac{\partial \eta}{\partial T}\right)_P = -(1.54 \pm 0.03) \times 10^{-4} \text{ K}^{-1}$$

$$\left(\frac{\partial \eta}{\partial P}\right)_T = +(1.15 \pm 0.07) \times 10^{-4} \text{ (MN m}^{-2})^{-1}$$

These results may be combined in an analysis following the method of Kushida *et al.* (1); the parameters q and η of the electric field gradient tensor are assumed to depend explicitly upon the volume V of a fixed amount of solid, as well as the temperature:

$$[7] \qquad q = q(T, V)$$

$$\eta = \eta(T, V)$$

These are fairly drastic assumptions, for it is implied that the effects of thermal expansion and hydrostatic pressure upon the electric field gradient tensor are functions of a single variable, the volume; in a rigorous analysis of a complex crystal, changes of shape and atomic positions within the unit cell must be included as well as the volume, but it is not practical to carry out such an analysis at present. Within the approximations implied by eq. 7, it is found that

$$[8] \qquad \left(\frac{\partial q}{\partial T}\right)_P = -\frac{\alpha}{\beta}\left(\frac{\partial q}{\partial P}\right)_T + \left(\frac{\partial q}{\partial T}\right)_V$$

$$[9] \qquad \left(\frac{\partial \eta}{\partial T}\right)_P = -\frac{\alpha}{\beta}\left(\frac{\partial \eta}{\partial P}\right)_T + \left(\frac{\partial \eta}{\partial T}\right)_V$$

where $\alpha = (1/V)(\partial V/\partial T)_P$ is the coefficient of bulk thermal expansion, and $\beta = -(1/V)(\partial V/\partial P)_T$ is the isothermal compressibility. The value of α has been reported (6) as 2.8×10^{-4} K^{-1}, but the compressibility does not appear to have been measured, and so an approximate value of α/β based upon the Gruneisen–Mie equation of state for solids (8) will be used

$$[10] \qquad \alpha/\beta = \gamma \bar{C}_V/\bar{V}$$

where γ is the Gruneisen constant, generally between 1 and 2, $\bar{C}_V$ is the molar specific heat at constant volume, and $\bar{V}$ is the molar volume. Since $\bar{C}_V$ is not available experimentally, $\bar{C}_p$ may be used together with $\gamma = 2$ to calculate an estimated upper limit for α/β. For $BiCl_3$, $\bar{C}_p = 109$ J K^{-1} mol^{-1} (9) and $\bar{V} = 66 \times 10^{-6}$ m^3 (4), yielding a value $\alpha/\beta \lesssim 3.3$ MNm^{-2} K^{-1}. The compressibility derived from this estimate and the measured value of the thermal expansion coefficient is $\beta \gtrsim 0.8 \times 10^{-4}$ (MNm^{-2})$^{-1}$.

The temperature derivatives of the electric field gradient parameters at constant volume can now be estimated from eqs. 8 and 9

$$\frac{1}{h}\left(\frac{\partial eqQ}{\partial T}\right)_V \cong -150 \text{ kHz K}^{-1}$$

$$\left(\frac{\partial \eta}{\partial T}\right)_V \cong +2 \times 10^{-4} \text{ K}^{-1}$$

The value of $(\partial \eta/\partial T)_V$ is very uncertain, since two terms of opposite sign and comparable magnitude are added together and the uncertainty in the value of α/β is consequently magnified; no further quantitative analysis of the data on the asymmetry parameter is justified.

The large value of η is probably due to the chlorine atoms in the face-bridging positions, and is likely to be very sensitive to the bismuth—chlorine distance, leading to a positive value of $(\partial\eta/\partial P)_T$, as observed. Chihara and co-workers (10) reported the temperature dependence of η for the Sb nucleus in $SbCl_3$ at constant pressure, obtaining a value $(\partial\eta/\partial T)_P$ of about $-1.1 \times 10^{-4}\,K^{-1}$ near 120°K, which is comparable with the value observed for $BiCl_3$; the attempt to interpret the temperature dependence of η and eqQ/h was not successful, and the present results suggest that the effects of thermal expansion should have been taken into account.

The analysis of the coupling constant data is consistent with these conclusions; the contribution of thermal expansion to the temperature dependence of eqQ/h at constant pressure is considerable, for it cancels out about two-thirds of the Bayer term $(\partial eqQ/\partial T)_V$. It may be concluded that the bridging chlorine atoms reduce the bismuth quadrupole coupling constant appreciably, and are the cause of the negative value of $(\partial eqQ/\partial P)_T$; in other words, the coupling constant is reduced when the intermolecular distances are reduced by hydrostatic pressure.

The interpretation of $(\partial eqQ/\partial T)_V$ in terms of the theory of torsional oscillations (11) is not very satisfactory. If θ_x and θ_y are the angles of rotation about the x and y principal axes of the electric field gradient tensor, q_0 is the coupling constant and η_0 the asymmetry parameter for the solid in the absence of torsional oscillations, then the averaged value of the major component of the electric field gradient tensor is given by eq. 11

$$[11]\quad q = q_0[1 - \tfrac{3}{2}(\langle\theta_x^2\rangle + \langle\theta_y^2\rangle) - \tfrac{1}{2}\eta_0(\langle\theta_x^2\rangle - \langle\theta_y^2\rangle)]$$

The quantities q_0 and η_0 are not accessible experimentally because of zero point vibrations; but for the present purposes, sufficiently accurate values may be obtained by extrapolating q and η measured at room temperature to absolute zero using the measured temperature derivatives

$$(eq_0Q)/h \cong 331\ \text{MHz}$$

$$\eta_0 \cong 0.60$$

Equation 11 may be differentiated at constant volume, treating q_0 and η_0 as constants:

$$[12]\quad \frac{1}{q_0}\left(\frac{\partial q}{\partial T}\right)_V = -1.80\left(\frac{\partial\langle\theta_x^2\rangle}{\partial T}\right)_V - 1.20\left(\frac{\partial\langle\theta_y^2\rangle}{\partial T}\right)_V$$

The left hand side of this equation has the approximate value $-4.5 \times 10^{-4}\,K^{-1}$. In the limit of high temperatures, the temperature coefficient of the mean square amplitude of a torsional oscillator is

$$[13]\quad \left(\frac{\partial\langle\theta^2\rangle}{\partial T}\right)_V = k/4\pi^2\nu^2 I$$

where k is Boltzmann's constant, ν is the frequency of the oscillator and I is the moment of inertia associated with the oscillator. Bismuth trichloride in the solid state contains well-defined $BiCl_3$ groups in a distorted trigonal pyramid; if the distortion is ignored, bond angles taken as 90° and the bond lengths as 0.25 nm, the moment of inertia of this group about an axis perpendicular to the trigonal axis is calculated to be approximately 6×10^{-45} kg m^2. For the lowest frequency line reported in the Raman spectrum of solid $BiCl_3$ (5), namely 37 cm^{-1}, eq. 13 yields

$$\left(\frac{\partial\langle\theta^2\rangle}{\partial T}\right)_V = 0.47 \times 10^{-4}\,K^{-1}$$

and for other, higher frequency, vibrations a smaller value will be obtained. It is therefore not possible to fit the observed value of $(1/q_0)(\partial q/\partial T)_V$ using the Raman spectrum data and eqs. 12 and 13. Although the oscillation which is primarily responsible for the temperature dependence of q may lie at a lower frequency than any reported, a more likely reason for the discrepancy is the restriction placed upon the analysis by the assumptions involved in eq. 7.

Biosynthesis of Lycopodine. Pelletierine as an Obligatory Intermediate

J.-C. BRAEKMAN,[1] R. N. GUPTA, D. B. MACLEAN, AND I. D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario

Received March 23, 1972

The distribution of ^{14}C within lycopodine derived from [1,5-^{14}C]-cadaverine and from [2-^{14}C]-Δ^1-piperideine is profoundly affected by the addition of inactive pelletierine. This finding is interpreted as showing that pelletierine is an obligatory intermediate on the pathway from cadaverine and Δ^1-piperideine into lycopodine.

La distribution du ^{14}C dans la lycopodine dérivée de la cadavérine [^{14}C-1,5] et de la Δ^1-pipéridéine [^{14}C-2] est profondément affectée par l'addition de la pelletiérine inactive. Ce résultat est interprété comme suit: le passage de la cadavérine et de la Δ^1-pipéridéine à la lycopodine se fait obligatoirement par l'intermédiaire pelletiérine.

The structural features of pelletierine (**2**) can be discerned within the skeletons of a variety of alkaloids (Schemes 1–3) of which *N*-methylpelletierine (**3**), sedridine (**1**), ψ-pelletierine (**5**), and anaferine (**4**) are the simplest. Attention has been drawn to the possible biogenetic relationship of pelletierine with these and with more complex structures such as the Lythraceae alkaloids (*e.g.*, decodine (**6**)) (1, 2), and the Lycopodium alkaloids of the luciduline (**8**) (3), the cernuine (**9**) (4), the lycodine-obscurine (**10**) (4), and the lycopodine (**11**) (4) type. The structural relationship of the alkaloid dioscorine (**7**) to pelletierine (Scheme 4) has not hitherto been pointed out.

The biosynthesis of several of these alkaloids has been investigated by tracer methods. Activity from labelled pelletierine (**2**) was incorporated non-randomly into anaferine (**4**) (5), cernuine (**9**) (6, 7), and lycopodine (**11**) (8, 9); and activity from *N*-methylpelletierine (**3**) entered ψ-pelletierine (**5**) in a non-random manner (5).

If pelletierine is indeed a normal intermediate in the biosynthesis of these alkaloids, then precursors of pelletierine must also be incorporated in a predictable manner. It is therefore relevant to summarize current knowledge of the origin of pelletierine.

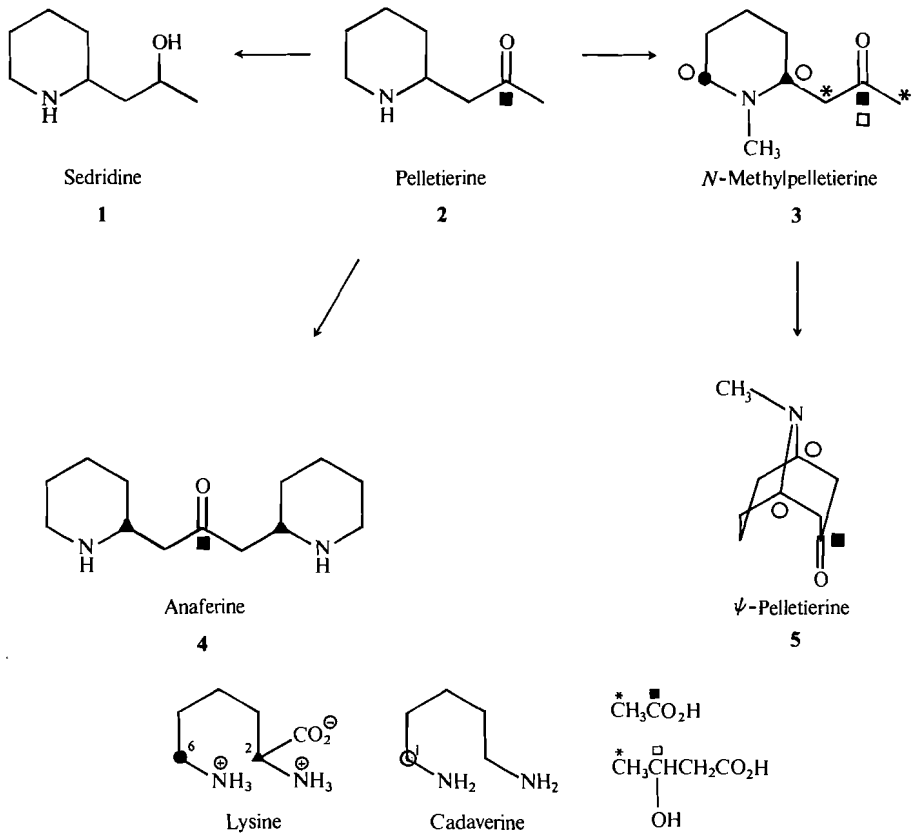
The biosynthesis of *N*-methylpelletierine (**3**) has been studied in *Sedum sarmentosum* (10, 11) and in *Punica granatum* (5, 12, 13). Methionine supplies the *N*-methyl group (12). The sidechain of *N*-methylpelletierine (5, 11–13) as well as that of pelletierine (5) has been shown to arise from acetate. The piperidine nucleus of *N*-methylpelletierine is generated from a C_5N unit which is derived from L-lysine (but not from D-lysine (14)) by loss of the carboxyl and the α-amino group (5, 10, 11), with retention of the hydrogen atoms at C-2 and -6 (14). The same C_5N unit is derived also from cadaverine in a stereospecific manner, with retention of the pro-R and loss of the pro-s hydrogen[2] at C-1 (14).

It is likely that enzyme-bound cadaverine, formed by decarboxylation of lysine, serves as an intermediate in the biosynthesis of the piperidine nucleus of *N*-methylpelletierine and related alkaloids, and that it is the magnitude of the dissociation constant of this cadaverine-enzyme complex which determines whether incorporation of label from lysine into the nucleus of these alkaloids takes place in a non-symmetrical or a symmetrical manner (14). Oxidation of the enzyme-bound cadaverine yields Δ^1-piperideine, the immediate precursor of the piperidine nucleus, which reacts with the acetate-derived precursor of the sidechain. This pathway is summarized in Scheme 5.

The entry of pelletierine-precursors into some of the alkaloids which bear a structural relationship to pelletierine has been examined. The mode of incorporation of label from acetate into anaferine (**4**) (5), ψ-pelletierine (**5**) (5), dioscorine (**7**) (16), and lycopodine (**11**) (4); from lysine into anaferine (**4**) (5) (non-symmetrical incorporation) and into decodine (**6**)

[1]Chargé de Recherche du Fonds National de la Recherche Scientifique de Belgique.

[2]These assignments are based on the assumption that the enzyme-catalyzed decarboxylation of L-lysine by the L-lysine decarboxylase of *Bacillus subtilis* takes place with retention of configuration (*c.f.* ref. 15).



SCHEME 1. Simple alkaloids related to pelletierine. Incorporation of label from lysine, cadaverine, acetate, and β-hydroxybutyrate.

(2), cernuine (**9**) (6, 7), and lycopodine (**11**) (4, 17) (symmetrical incorporation); from cadaverine into ψ-pelletierine (**5**) (12), decodine (**6**) (18), cernuine (**9**) (7), and lycopodine (**11**) (4); and from Δ^1-piperideine into decodine (**6**) (18), cernuine (**9**) (7), and lycopodine (**11**) (9), is consistent in every case with the pelletierine hypothesis of the origin of these alkaloids.
