En présence d'un acide, le *N*-nitrosopiperidine photoexcité réagit avec les 1,3-diènes acycliques conjugués pour donner lieu aux dérivés-1,4 comme produits principaux, de même qu'aux dérivés-1,2. Durant la photoaddition aux 1,3-pentadiènes, on a aussi observé la formation des dérivés-4,1 et 4,3. Ces résultats suggèrent qu'un complexe singulet photoexcité de *N*-nitrosopipéridine et d'acide se dissocie rapidement en radical pipéridinium qui attaque de façon irréversible les diènes d'abord, pour ensuite entreprendre une courte étape de propagation ou de terminaison pour donner les composés *C*-nitroso. Les composés *C*-nitroso sont rapidement éliminés par tautomérisation irréversible pour donner les oximes, qui sont les produits finaux. La réactivité du radical pipéridinium pour les doubles liaisons conjuguées se manifeste dans l'ordre décroissant suivant: $RCH{=}CH_2$ > *cis*-RCH=CHR > *trans*-RCH=CHR. Ce mécanisme est en accord avec les résultats stéréochimiques suivants. Premièrement, la double liaison nouvellement formée dans le dérivé-1,4 (ou le dérivé d'orientation opposée) est orienté exclusivement de manière *trans*. Deuxièmement, les autres doubles liaisons des dérivés-1,2 conservent leur stéréochimie originale.

On a déterminé par r.m.n., la stéréochimie des photodérivés oximes **1**–**11** énone. A partir de la corrélation des déplacements chimiques r.m.n. de ces oximes énone, on a pu démontrer que: (*i*) le proton α-oléfinique résonne généralement à champ plus faible que le proton β-oléfinique (à une exception près) et que (*ii*) si l'on passe du solvant $CDCl_3$ à un solvant aromatique, le proton α-oléfinique et les protons α-alkyl sont déblindés de 0.3–0.05 p.p.m. alors que le proton β-oléfinique est déplacé très légèrement soit à champ plus fort ou à champ plus faible. On observe que l'ordre des déplacements chimiques des protons oléfiniques et les effets de solvant aromatique sur les déplacements chimiques dans le cas de ces oximes énone sont tous deux opposés à ceux qu'on observe dans le cas des systèmes énone.

Canadian Journal of Chemistry, **50**, 1065 (1972)

Introduction

As mentioned in the previous paper (1) there are several features associated with the photoaddition of nitrosamine to an olefinic linkage. It is well-known that conjugated dienes are good electronic energy acceptors from excited states of carbonyl and other types of compounds (2–5). In view of this efficient quenching action it is generally regarded that other photochemical processes of an excited molecule with a diene, for example photocycloaddition of ketones, are unimportant (6). Nevertheless, we have observed an efficient photoaddition of *N*-nitrosopiperidine to butadiene as well as to some

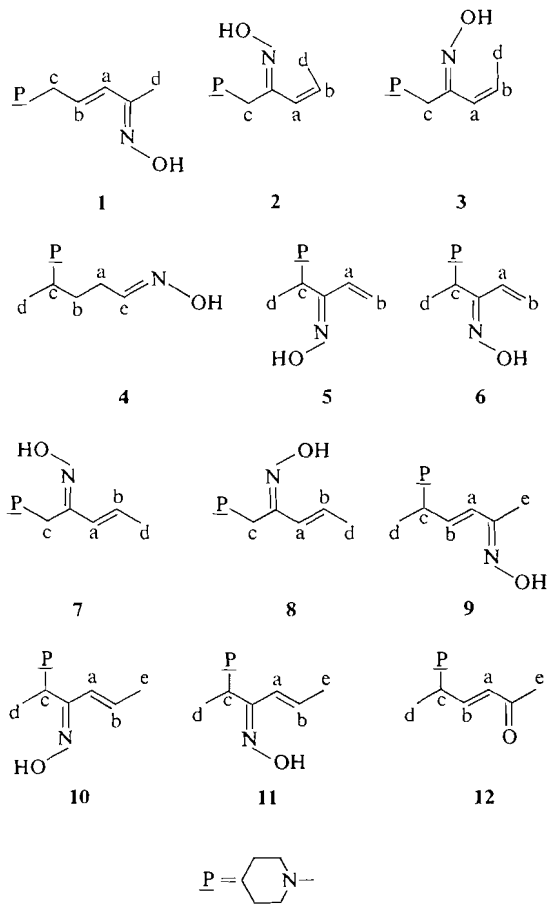
cyclic dienes (7). In this photoaddition, a number of questions arise regarding photoprocesses and addition processes (8). They are, for example, (*i*) the reactive species responsible for the addition, (*ii*) quenching of photoexcited states of *N*-nitrosopiperidine, if any, and the mechanism, (*iii*) the reactivity of the dienes, and finally (*iv*) the stereochemical course of the addition. In this report these questions are discussed in the light of the results obtained in photoadditions to a series of acyclic dienes.

The photoadditions of *N*-nitrosopiperidine to various acyclic dienes, *cis*- and *trans*-1,3-pentadienes and *cis,trans*- and *trans,trans*-2,4-hexadienes, were carried out with the same apparatus and under the same conditions as those used in the photoaddition to cyclic dienes reported in the previous publications (9, 10). The major product, the 1,4-adduct, was crystallized readily from the basic fraction of the crude product. The isolations of the minor products, the 1,2-adducts and the reverse adduct (4,1-adduct),[2] however, have to depend on careful column chromatography. The structures of the photoadducts were derived from the n.m.r., i.r., and mass spectral data; the n.m.r. spectroscopy was the most powerful tool in the present study. The discussion is based on the structure and stereochemistry displayed in **1**–**12**; the pertinent spectral data are given in the Experimental.



Photoaddition Products

The photoaddition to *cis*-1,3-pentadiene afforded the 1,4-adduct, *anti,trans*-5-piperidino-3-pentene-2-one oxime (**1**),[3] as the major product in addition to the 1,2-adducts, *syn,cis*-1-piperidino-3-penten-2-one oxime (**2**) and *anti, cis*-1-piperidino-3-penten-2-one oxime (**3**), all of which are isolated in pure form as demonstrated by t.l.c. Careful chromatography of the photolysate afforded, in addition, three compounds isolated in semi-pure state; they are the 4,1-adducts, *anti,trans*-4-piperidino-2-pentenal oxime (**4**), and 4,3-adducts, *syn*-**5** and *anti*-4-piperidino-1-penten-3-one oxime (**6**).

The photoaddition to *trans*-1,3-pentadiene gave the same 1,4-adducts, **1**, and the 4,1-adduct, **4**, as that obtained in the addition to *cis*-pentadiene though both in lesser yields. The 1,2-adducts, *syn,trans*-**7** and *anti,trans*-1-piperidino-3-pentene-2-one oxime (**8**), however, were isolated in higher percentage than their counterparts in the addition to *cis*-pentadiene. In addition, trace amounts of the reverse 4,3-adducts **5** and **6** were also detected by t.l.c. analysis.

The photoaddition to *cis,trans*-2,4-hexadiene gave the 1,4-adduct, *anti,trans*-5-piperidino-3-hexen-2-one oxime (**9**), and the 1,2-adducts, *syn,trans*-**10** and *anti,trans*-2-piperidino-4-hexen-3-one oxime (**11**). In addition a small amount of ketone derived, presumably, from the hydrolysis of **9**, *trans*-5-piperidino-3-hexen-2-one (**12**), was also isolated. The photoaddition to *trans,trans*-2,4-hexadiene gave the same 1,4- and 1,2-adducts but the latter adducts (**10** and **11**) were

[2]For convenience, the reverse addition products are referred to as 4,1-adducts or 4,3-adducts in this report.

[3]The *syn–anti* notation is used to express configuration of the oxime group and *trans–cis* notation for the configuration of the double bond. The definition of *syn–anti* configuration follows the convention adapted in our previous publication (ref. 7).

TABLE 1. Yields of nitrosopiperidine photoadditions to dienes

†4,3-*syn*- and 4,3-*anti*-adducts were detected in trace amount.
‡The 1,4-adduct to butadiene was mixture of *syn*- and *anti*-isomer. The 1,4-adducts to other dienes are *anti*-isomer.
§The 4,1-adduct was *anti*-isomer.
‖5-Piperidino-3-hexen-2-one was isolated in 2% yield.

obtained in only very small quantity (*ca.* 5% in total). For a comparison the percentage yields of these adducts are tabulated in Table 1.

The adducts exhibited typical i.r. absorptions for common linkages possessed by them (11), *i.e.*, the Bohlmann bands in the 2800–2600 cm^{-1} region, weak but distinct C=C and C=N stretching vibrations in the 1550–1690 cm^{-1} region and the multiple peaks of N—O stretching absorption near 900–1000 cm^{-1}. The stereochemistry of these adducts is readily interpreted from the n.m.r. spectra. Moreover, since we have also observed good correlation between chemical shifts and the nature of solvent, we will, therefore, discuss the n.m.r. results separately in the following section.

Nuclear Magnetic Resonance Data and the Structure

The n.m.r. study of the enone oximes obtained from photoaddition to cyclic dienes (7) has played an important role in clarifying the configuration and conformation of those adducts. The adducts derived from photoaddition to acyclic dienes exhibited well-defined signals in most cases and provided a good deal of information with regard to the structure and stereochemistry. Taking together the data available from our previous (7, 11) and present studies we have arrived at a few general rules that facilitate a decision on enone oxime structure.

First of all, *syn,anti*-isomerism of the oxime group is determined by the comparison of the chemical shifts of α- and/or α′-protons (with respect to the oxime group) in which the α-proton oriented at the same side of the OH group generally resonates at a lower field in comparison to that oriented at the opposite side. This relation holds true for other types of oximes, for an intramolecular comparison and for an intermolecular comparison where *syn–anti* pairs are available (7, 12, 13). Secondly, the *cis–trans* isomerism of the double bond is decided by well-known spin coupling constant correlations (14) in which coupling constants for *trans*-protons (11–17 Hz) are larger than that of *cis*-protons (6–12 Hz). Thirdly, the chemical shift of the α-olefinic proton of an enone oxime generally appears at a lower field than that of the β-olefinic proton (Table 2). Since the α- and β-olefinic protons could be accurately assigned on the basis of their coupling patterns with allylic protons where the spectra were well resolved, this relation could be obtained directly from Table 2 with the exception of **10**.

Where an isomeric pair exists, the *syn*- and *anti*-configurations are readily decided by the chemical shifts of the α- and α′-protons vicinal to the oximino group, for example **2–3**, **5–6**, **7–8**, and **10–11**. This correlation is also supported by some n.m.r. data on *syn* and *anti* enone oximes in the literature (12, 13). For the sole 1,4-adduct (**1** and **9**) obtained in the photoaddition, the *anti*-configuration was assigned on steric grounds (11); the *syn*-configuration would cause strong crowding of the OH group with the olefinic protons (either in *s-cis* or *s-trans* arrangement) due to coplanarity within the conjugated system (10). The *anti*-configuration of the 4,1-adduct **4** is indicated by the chemical shift of the aldoxime proton (H_e, τ 2.3) which is correlated better to the corresponding proton of *anti*-4-piperidino-2-butenal oxime (**14**, τ 2.28) than to that of the *syn*-isomer (**13**, τ 2.90) (7).

In deuteriochloroform solution these enone oximes generally show the appropriate proton signals for the assigned structures except that,

†Compound **25** is *anti*-4-piperidino-2-cyclohexenone oxime and compound **26** *syn*-2-piperidino-5-cyclohexenone oxime (see ref. 7).

‡C, deuteriochloroform; P, pyridine; D, hexadeuteriobenzene; B, benzene.

§The alkyl proton refers to the α-proton opposite to the olefinic proton or the aldehydic proton.

in most cases, the olefinic and the allylic protons are extensively coupled with second order interactions. The olefinic protons reveal themselves as narrow unresolved signals because the shift difference of α- and β-olefinic protons ($\Delta\nu$) is nearly equal to the coupling constant (J). The presence of virtual coupling in these cases is also indicated by the splitting pattern of the allylic protons (15). In pyridine or benzene solution the α-proton of the enone oximes is shifted downfield while the β-olefinic proton remains virtually unchanged. The separation of the olefinic proton signals caused by aromatic solvents apparently is sufficient to generate a first order coupling pattern (AMX_n) from which the estimated coupling constant of the olefinic protons is utilized to define the *cis–trans* configuration of the olefinic linkage.

The order of chemical shifts of α- and β-olefinic protons manifested by cyclic and acyclic enone oximes is just opposite to that of the corresponding protons of enones (16) and provides an interesting comparison. Taking the average chemical shifts for α- and β-olefinic protons of acyclic and six-membered enones as τ 4.00 and 3.10, respectively, (16, 17) it can be seen that in enone oximes, while the β-proton is more shielded by *ca.* 1 p.p.m., the α-proton emerges approximately in the same region with respect to the corresponding protons of enones (Table 2, comparisons in $CDCl_3$ solution). It is instructive to compare these data with those of ketone **12** in which α- and β-olefinic protons resonate at the expected chemical shifts for an enone. The apparent exception to the correlation is found in **11** which will be commented on later. The reversal of the order of the chemical shifts in enone oximes indicates that the contribution of the polar resonance form (16) in enone oximes is not as extensive as that involved in enones, or that the anisotropic effects of the oxime group are drastically different from those of the carbonyl group.

Aromatic solvent effects on chemical shifts of various protons in enone systems have been reported (17) and are explained by *s-cis* and *s-trans* conformation models. In the present case, on passing from $CDCl_3$ to pyridine solution, the β-olefinic proton is generally only slightly affected (either shielded or deshielded) but α-olefinic protons and α′-alkyl protons are deshielded by an average of 0.3 p.p.m. and 0.10–0.05 p.p.m., respectively. In every respect these trends are just the opposite to that observed in enones in which the β-olefinic proton and α′-alkyl protons are shielded and the α-olefinic proton is only slightly shielded or deshielded (17). This indicates the orientation of a collision complex between an enone oxime and an aromatic ring is markedly different from that involved in the enone itself.

The n.m.r. data on oximes **10** and **11** are found to be anomalous in several accounts with respect to the conclusion obtained so far. In oxime **10**, the chemical shift of the β-olefinic proton apparently resonates at a lower field than does that of

13 14 15

SCHEME 1

the α-olefinic proton, since the former is significantly coupled with the methyl group ($J = 6$ Hz) and the latter is only a slightly broadened doublet. Although the chemical shifts of the olefinic protons of oxime **11** cannot be located precisely due to a second order coupling, the same chemical shift pattern as that of **10** is suspected. A careful inspection of the data in Table 2 shows that on changing from $CDCl_3$ to pyridine solution, in oximes **10** and **11**, the β-olefinic proton is deshielded much more than the α-olefinic proton in contrast to other cases. The anisotropic effect of an oxime group and the related aromatic solvent effect are intimately connected to the molecular geometry. The observed anomalies of oximes **10** and **11** are attributed to a stereochemical variation of these two molecules from other enone oximes. A better understanding of these situations requires investigation of simpler model enone oxime systems and is being undertaken.

Stereochemical Course of the Photoaddition

As the structures of the product are firmly proved, the stereochemical course of photoaddition can be summarized as follows. First of all, the 1,4-addition to a conjugated diene (or reverse 4,1-addition) leads to the formation of the new *trans* double bond (such as **1**, **4**, and **9**). Secondly, the 1,2-addition to a diene retains the stereochemical integrity of the remaining 3,4-double bond (such as shown in **2**, **3**, **7**, **8**, **10**, and **11**). Thirdly, if a choice is available internally, a *cis*-double bond is attacked preferentially to a *trans*-double bond. Finally, the reverse addition (4,1-addition) is more prone to take place with *cis*-1,3-pentadiene than the *trans*-diene (**5** and **6**). These conclusions are confirmed by some quantitative experiments described below.

It has been demonstrated that photoaddition of *N*-nitrosopiperidine to butadiene gives a mixture of *syn*-**13** and *anti*-isomer **14**, of *trans*-4-piperidino-2-butenal oxime (7) as the major product. That oximes **13** and **14** are the *syn–anti* isomeric pair but not *cis–trans* isomers has been indicated by the n.m.r. data in the previous report and placed on a firmer basis now by facile Beckmann dehydration reaction. Decomposition of the tosylate of **14** or of a mixture of **13** and **14** gives quantitative yields of *trans*-4-piperidinocrotononitrile (**15**) (Scheme 1) as indicated by the clean n.m.r. spectra of the crude products (Fig. 1). A *cis–trans* mixture of 4-piperidinocrotononitrile was synthesized from a commercial crotononitrile (*cis–trans* mixture) by standard procedures. In order to find out if a trace amount of the *cis*-isomer corresponding to **13** (and/or **14**) is formed in the photoaddition to butadiene, a crude basic product was subjected to Beckmann dehydration to give a crude basic dehydration product. The n.m.r. spectrum of this latter basic product shows clean signals for **15** but no trace of the corresponding *cis*-isomer. In the photoadditions to *cis*- and *trans*-1,3-pentadienes, the n.m.r. spectra of each chromatographic fraction were carefully scrutinized but showed no signals expected for other 1,4-adducts.

In order to prove the second conclusion, advantage was taken that these 1,2-adducts undergo a facile Beckmann cleavage reaction aided by the lone pair electron of the piperidine ring as shown in **16** (Scheme 2) (18, 19). The cleavage of the tosylates **7**, **8**, **10**, or **11** under mild conditions gave only *trans*-crotononitrile as shown by v.p.c. analysis. Similarly, the tosylates of **2** and **3** gave only *cis*-crotononitrile.[4] Crude 1,2-adducts from the photoaddition to each diene were treated under the same conditions and the neutral ethereal extracts were examined by v.p.c. analysis. In the case of photoaddition to *cis*-1,3-pentadiene, the v.p.c. analysis of the ether extract indicated that only *cis*-crotononitrile (**18**) was obtained, that to *trans*-1,3-pentadiene only *trans*-crotononitrile, and that to

[4]A stronger base apparently isomerizes the crotononitriles since a treatment of the tosylate of **8** with 2 *N* sodium hydroxide solution gives *cis*- and *trans*-crotononitrile in the ratio of 20:80.

SCHEME 2

cis,*trans*-2,4-hexadiene, *trans*- and *cis*-crotononitrile were obtained in the ratio of 97:3. The last result also substantiates conclusion three and suggests that the *cis*-disubstituted double bond is more reactive than the *trans*-disubstituted bond. The fourth conclusion is related to the third one and explains the higher percentage yield of the reverse adducts in the photoaddition to *cis*-1,3-pentadiene than that to the *trans*-diene. The higher overall yields of the normal adducts (1,2- and 1,4-addition) in this case also indicates that the monosubstituted double bond is more reactive toward the aminium radical (*vide infra*) than the *cis*-disubstituted double bond which is, in turn, more reactive than the *trans*-disubstituted one.

In the presence of both *cis*,*trans*- and *trans*, *trans*-2,4-hexadienes in 1:1 ratio, however photoaddition to the dienes takes place indiscriminately; thus after the half-completion of the photoaddition, v.p.c. analysis of the residue indicated a 1:1 ratio of the two dienes. The same situation was also observed with a mixture of *cis*- and *trans*-1,3-pentadiene. The latter result is not unexpected since the monosubstituted double bond common to both pentadienes is more reactive than *cis*- and *trans*-disubstituted double bonds by a wide margin. The reactivities of *cis*,*trans*- and *trans*,*trans*-hexadienes toward the photoaddition are different but not significant enough to cause a discriminative attack on the double bonds.

TABLE 3. The quantum yields of the disappearance of *N*-nitrosopiperidine in methanolic HCl solutions*

Olefin	0.5 *N* HCl solution [Olefin] (mol/l)	Φ	0.06 *N* HCl solution [Olefin] (mol/l)	Φ
None	—	2.46	—	2.56
Cyclohexene	2.0×10^{-3}	2.74	2.6×10^{-3}	2.66
1,3-Pentadiene	2.0×10^{-3}	3.06	3.2×10^{-3}	3.02
trans,trans-2,4-Hexadiene	2.1×10^{-3}	3.05	2.4×10^{-3}	3.23
cis,trans-2,4-Hexadiene	2.3×10^{-3}	2.95	2.2×10^{-3}	3.31

*In both determinations the concentration of *N*-nitrosopiperidine is 2.05×10^{-3} mol/l. The solution was irradiated for 20 min during which about 25% of the nitrosamine disappeared. A commercial mixture of 1,3-pentadienes was used in which the ratio of *cis* to *trans* isomer was 40:60.

[1] 
[2] 
19 **20**

[3] 
21 **22**

[4] 
The conservation of the configuration of the disubstituted double bond in the 1,2-adducts resulting from these photoadditions indicates that the dienes are not isomerized during the irradiation. In theory various pathways for isomerization of the dienes are available and the possibility of the diene isomerization has to be checked independently. In particular, since the lowest triplet state energy of *N*-nitrosopiperidine (59 kcal/mol) (20) is nearly the same as those of the dienes (61 ~ 57 kcal/mol), isomerization of the dienes by triplet–triplet energy transfer is a good possibility. The recovered diene in each photoaddition was monitored with v.p.c. analysis and was found to contain no other diene than the starting one. The dienes are therefore not isomerized during the photoaddition.

Mechanism of Photoaddition

We have established that nitrosamine photoaddition is a stepwise process in which the aminium radical is the initial attacking species (20, 21). Further, it has been shown that the aminium radical is generated from the singlet excited state of a nitrosamine–acid association complex (20). The photoaddition mechanism therefore can be divided into two parts for the convenience of discussion, *i.e.*, the photoprocess that generates piperidinium radical, and the addition reaction initiated by the piperidinium radical.

The lack of isomerization of dienes, the high quantum yields of disappearance of nitrosamine (shown in Table 3), as well as the excellent yields of the adducts, suggest that virtually every collision of a diene with the piperidinium radical leads to the irreversible formation of the intermediate cation radical **19** or **20**. Although the piperidinium radical is an electrophilic species it must undergo free radical addition for the reason described previously (1, 21). It is significant that an abstraction of allylic protons, the typical reaction of the aminium radical as exemplified by the Hofmann–Löffler–Frytag

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

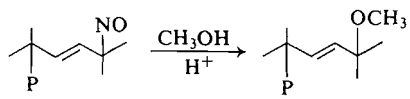
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction (22), is not observed. It is concluded that an aminium radical is an extremely reactive species toward electrophilic addition, as may be expected from its cationic charge. An additional feature worthy of mentioning is that an aminium radical does not attack the remaining double bond of the hydrochloride of the adducts **1**–**12** owing to repulsion of the positive charges.

The addition products **21** and **22** are formed by two independent steps as shown in [3] and [4]. Step 3 is the propagation step corresponding to the short chain process as implied by the observed quantum yield of $3 \sim 4$. In view of the fact that the clean photoaddition occurs, this figure probably represents the chain length of the free radical processes. The termination step 4 enters into the picture quickly and may suggest that nitric oxide is located in the vicinity of the reaction site. The stereochemistry of the adducts is also decided by these two steps. The conservation of the remaining double bond in the 1,2-adduct indicates that steps 3 and 4 occur rapidly before the intermediate **19** (or **20**) has time to undergo rotation. The retention of the configuration of an allyl radical through rapid reaction of the radical has been demonstrated (25). If steps 3 and 4 are indeed rapid, an explanation is required for the failure to form *cis*-1,4-adduct along with the isolated *trans*-1,4-adducts (**13** and **14**) since under ordinary conditions 5% of the butadiene is in an *s-cis* conformation. It may be assumed that the activation energy required to form the *trans*-1,4-adduct is far smaller than that required for the *cis*-1,4-adduct. Steric controls over tautomerization of **21** and **22** to give the *syn*- and *anti*-oximes (**1**–**14**) has been discussed previously (11).

We have shown through kinetic studies by flash photolysis (20) that the piperidinium radical adds to cyclohexene faster than it abstracts hydrogen from methanol, by a factor of 5000. From a similar study, piperidinium radical is shown to add to 1,3-pentadienes with a bimolecular rate constant of $4.5 \times 10^7\ M^{-1}\ s^{-1}$; this is about 1.8 times faster than the rate constant of the addition to cyclohexene ($2.54 \times 10^7\ M^{-1}\ s^{-1}$). The rate constants explain explicitly why, during irradiation of a nitrosopiperidine–diene mixture in methanol solution, the photodecomposition of nitrosopiperidine (23) is not observed and affords the photoaddition product exclusively in a high yield. The same observation has been made previously in the photoaddition to unhindered olefins (such as 1-hexene and cyclohexene) (10, 24).



23 **24**

SCHEME 3

Investigation into the stereochemical course of an addition to a diene is often frustrated by reversible processes in [2], [3], and [4] and/or by an ionization of **21** and **22**. In the present case, fortunately, such processes are prevented since the *C*-nitroso compounds **21** and **22** are rapidly removed by tautomerization to the oximes, due to facile migration of the labile allylic proton (9). If *C*-nitroso compounds **21** and **22** are not removed rapidly, other side reactions involving **21** and **22** may set in as has been experienced in the low temperature photoaddition to cyclopentadiene (7). In particular, the photoaddition of nitrosopiperidine to 2,5-dimethyl-2,4-hexadiene under ordinary conditions appears to accumulate the adducts corresponding to **21** and **22** as witnessed by the deep blue color, which disappears on standing. Since the tautomeric pathway is not available for the 1,4-adduct corresponding to **22**, the labile nitroso group is presumably displaced by a methoxy group through an ionic pathway **23** → **24** (Scheme 3). The crude product, which could not be purified owing to its instability, exhibited strong n.m.r. signals for methoxy groups, thus supporting our hypothesis.

Generally speaking, though photoadditions to olefins are frequently encountered phenomena (26, 27), the direct addition of a photoexcited species to a diene is not a commonly observed process due to the fact that an electronically excited species preferentially transfers energy to the diene instead of physically attacking the diene (6). On the other hand, many examples of addition reactions of dienes by photosensitization are reported in the literature (27, 28). In the present case, it is not likely that the photoexcited nitrosopiperidine transfers its energy to a diene which initiates the addition process. This is further confirmed by the failure to sensitize the addition to 1,3-pentadienes using naphthalene as a sensitizer; an efficient

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

energy transfer from singlet excited state naphthalene to pentadienes has been demonstrated by Hammond and co-workers (3, 29).

The failure of singlet excited state nitrosopiperidine to isomerize dienes has further implications. First of all, the singlet energy transfer to dienes (30, 31) apparently does not take place. Secondly, the reverse process of the piperidinium radical attack [2], similar in concept to the Schenck mechanism (32, 33), does not occur significantly (*vide supra*). This is readily understandable since the reverse process entails the generation of a high energy species, the piperidinium radical. The first implication reflects the short singlet state lifetime of nitrosopiperidine, owing probably to a rapid decay to piperidinium radical. This is significant since even if the classical energy transfer fails to operate efficiently, quenching by an exciplex mechanism is possible at $0.5 \sim 0.3$ *M* concentration of a diene (3). In this regard it should be pointed out that nitrosoamine does form collision complexes with π-electron cloud of aromatic rings in the ground state (34) which should be a factor in favor of an exciplex formation. The total failure of an excited state nitrosamine to act as a sensitizer implies that the dissociation to an aminium radical is extremely facile.

Experimental

Unless specified otherwise the following experimental conditions prevail. The n.m.r. spectra were recorded with a Varian A56/60 spectrometer in $CDCl_3$ solution using TMS as the internal standard. Some n.m.r. spectra were taken with a Varian HA-100 spectrometer through kind assistance of Dr. K. R. Kopecky, the University of Alberta, Edmonton, Alberta. The coupling patterns of n.m.r. signals were presented as d for doublet, t for triplet, q for quartet, b for broad signals, and m for multiplet. A Perkin–Elmer RMU-6E mass spectrometer was used to record mass spectra with the chamber voltage at 80 eV. The i.r. spectra were recorded with a Perkin–Elmer 457 spectrophotometer in Nujol mull or liquid film. An Unicam SP-800 UV–Visible spectrophotometer was used to follow the progress of the reaction.

Material and General Photolysis Conditions

The commercial samples of *trans*-1,3-pentadiene (Aldrich Chemical Co.) and 2,4-hexadienes (Chemical Samples Co., Columbus, Ohio) were distilled and the purity checked by v.p.c. analysis. A pure *cis*-1,3-pentadiene (99%+) was prepared according to the procedure of Craig (35) from a mixture of *cis*- and *trans*-1,3-pentadienes.

In general the photoaddition was carried out according to the conditions described previously (9, 10) for the photoaddition to simple olefins. The t.l.c. was developed with chloroform containing a few percent of methanol and was used to monitor the purity of each fraction from column chromatography and to aid the identification of the *syn*- and *anti*-configuration of the oximes.

Photoaddition of N-Nitrosopiperidine to cis-1,3-Pentadiene

The nitrosamine (5.70 g, 0.05 mol), *cis*-1,3-pentadiene (4.0 g, 0.06 mol), and concentrated hydrochloric acid (5 ml, 0.06 mol) were dissolved in methanol (200 ml). This solution was irradiated with 450 W Hanovia lamp for 70 min. The solvent was removed under vacuum. The usual work-up gave a neutral ether extract which contained *N*-nitrosopiperidine (116 mg) as shown by i.r. and n.m.r. analysis. The basic fraction was extracted with $CHCl_3$ (50 ml × 3) to give a mixture of crystals and oil (9.7 g). To this mixture was added some ether and the mixture was cooled. Filtration of the mixture gave white crystals (3.73 g): m.p. 132–136°. These crystals were recrystallized from a mixture of benzene–Skellysolve B three times to afford *anti,trans*-5-piperidino-3-penten-2-one oxime (**1**); m.p. 141–142°; i.r. 3200, 1620, 1091, 1010–895 (multiple peaks), 763 cm^{-1}; n.m.r. τ 0.0 (b, OH), 3.82 (m, H_a and H_b), 6.92 (m with virtual coupling, H_c), 7.59 (m, 4H), 8.05 (s, H_d), 8.50 (m, 6H); n.m.r. (pyridine) τ 3.38 (dt H_a, $J = 16$ and 0.5 Hz), 3.93 (dt, H_b, $J = 16$ and 6 Hz), 6.96 (d, H_c, $J = 6$ Hz), 7.66 (m, 4H), 7.87 (s, H_d), 8.58 (m, 6H).

Anal. Calcd. for $C_{10}H_{18}N_2O$: C, 65.90; H, 9.95; N, 15.37. Found: C, 65.62; H, 9.85; N, 15.68.

The mother liquor was evaporated to dryness to give a mixture of crystals and oil (5.95 g). This mixture was chromatographed on silicic acid (60 g). The first six fractions eluted with 0–3% methanol in $CHCl_3$ (600 ml) gave fraction A as an oil (360 mg). Next six fractions eluted with 4% methanol in $CHCl_3$ gave fraction B (580 mg). With 8% methanol in $CHCl_3$ an oil (442 mg) was eluted as fraction D.

Fraction A showed one predominant spot at R_f 0.3 and two smaller spots at R_f 0.6 on the t.l.c. plate. The oil was rechromatographed on silicic acid (5 g) giving an oil (109 mg) as the first fraction eluted with $CHCl_3$. The n.m.r. spectrum showed this oil to be mostly *N*-nitrosopiperidine and another compound. This oil was then distilled (110°/0.1 mm Hg) to remove the more volatile nitrosamine giving a colorless resinous liquid (30 mg) of *syn*-4-piperidino-1-penten-3-one oxime (**5**); i.r. 3300, 1660, 1280, 1260, 1100, 995, 940 cm^{-1}; n.m.r. τ 3.74 (dd, H_a, $J = 17$ and 11 Hz), 4.65 (dd, H_b, $J = 17$ and 1 Hz), 4.8 (d, H_b, $J = 11$ Hz), 6.68 (q, H_c, $J = 7$ Hz), 8.72 (d, H_d, $J = 7$ Hz); mass spectrum *m/e* (relative intensity) 182 (6.2), 112 (88), 98 (90), 84 (100), 41 (92). The third fraction from this chromatograph gave an oil (27 mg) which showed single spot on a t.l.c. plate. This oil was distilled (100°/0.1 mm Hg) to afford a colorless oil identified as *syn,cis*-1-piperidino-3-penten-2-one oxime (**2**); i.r. 3300, 1640, 1110, 1000–900 cm^{-1} (multiple peaks); n.m.r. (pyridine) τ 3.69 (dq, H_a, $J = 12.5$ and 1 Hz), 4.2 (dq, H_b, $J = 12.5$ and 7 Hz), 6.41 (s, H_c), 7.54 (m, 4H), 7.91 (dd, H_d, $J = 7$ and 1 Hz); mass spectrum *m/e* (relative intensity) 182 (M^+, 3), 98 (100).

Fraction B consisted predominantly of a new compound as shown by t.l.c., and was rechromatographed on silicic acid (10 g). On eluting with 1% methanol in $CHCl_3$, an oil (230 mg, t.l.c. single spot) was obtained which was distilled in a small scale (90°/0.2 mm Hg) to give *anti,cis*-1-piperidino-3-penten-2-one oxime (**3**); i.r. 3350, 1643, 1459, 1370, 1300, 1270, 1110, 1008, 985, 940, 860, 760 cm^{-1}; n.m.r. τ 0.9 (b,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

OH), 3.97 (d, H_a, $J = 12$ Hz), 4.21 (dq, H_b, $J = 12$ and 5.5 Hz), 6.85 (s, H_c), 7.61 (m, 4H), 8.23 (d, H_d, $J = 5.5$ Hz), 8.53 (m, 6H); n.m.r. (pyridine) τ 3.48 (dq, H_a, $J = 12$ and 1 Hz), 4.17 (dq, H_b, $J = 12$ and 7 Hz), 6.70 (s, H_c), 7.61 (m, 4H), 7.12 (dd, H_d, $J = 7$ Hz), 7.64 (m, 6H); mass spectrum at (20 eV) *m/e* (relative intensity) 182 (2), 164 (26), 98 (100).

Fraction C showed one predominant spot on t.l.c. analysis which corresponded to the 1,4-adduct **1**; n.m.r. τ 3.9 (m, 2H), 6.9 (m, 2H), 7.6 (m, 4H), 8.0 (s, 2H), 8.5 (m, 6H). In addition another minor spot could be detected in the t.l.c. plate which ran slightly ahead but superimposed on the spot of **1**. This spot contributed signals at τ 3.55 (dd, H_a, $J = 16$ and 7 Hz), 4.1 (m, H_b), 8.7 (d, $J = 6$ Hz) to the n.m.r. spectrum of the mixture. This minor compound is probably *anti*-4-piperidino-1-penten-3-one oxime (**6**).

Fraction D consisted of a mixture of **1** and another compounds as shown on the t.l.c. plate by an additional spot beside the spot of **1**. The n.m.r. of this mixture showed, in addition to the signals typical of **1**, signals at τ 2.3 (d, H_c, $J = 9$ Hz), 3.75 ~ 3.9 (m, superimposed with the olefinic proton signals of **1**), and 8.78 (d, H_d, $J = 7$ Hz). The ratio of the integration for the signals at τ 8.03 and τ 8.78 was 15:38, respectively, which indicated that this compound is about 70% of the total mixture. This fraction was recrystallized from 2-propanol to give a semi-pure compound of *anti,trans*-4-piperidino-2-pentenal oxime (**4**); n.m.r. (C_6D_6) τ 2.13 (d, H_c, $J = 9$ Hz), 3.45 (dd, H_a, $J = 16$ and 9 Hz), 3.95 (dd, H_b, $J = 16$ and 7 Hz), and 8.93 (d, H_d, $J = 7$ Hz). The percent yield of compound **4** was estimated by n.m.r. analysis to be 12%.

Photoaddition of N-Nitrosopiperidine to trans-1,3-Pentadiene

A solution of *N*-nitrosopiperidine (5.7 g, 0.05 mol), *trans*-1,3-pentadiene (3.74 g, 0.055 mol), and concentrated hydrochloric acid (5 ml) in methanol (200 ml) was photolyzed as previously described. The reaction was worked-up in the usual manner. The acidic ether extract gave a crude oil (36 mg) which was not investigated further. The basic extract was obtained by extracting with $CHCl_3$ (50 ml × 3) which, upon evaporation of the solvent, gave a resin (9.3 g). This resin was treated with ether to give crystals (3.6 g); superimposable i.r. and n.m.r. with those of **1**. The mother liquor was evaporated down to give a resin (5.29 g) which was chromatographed on silicic acid (60 g). The first compound eluted with $CHCl_3$ (100 ml) was a solid (670 mg) which showed a single spot by t.l.c. analysis and was recrystallized from cyclohexane to give *syn,trans*-1-piperidino-3-penten-2-one oxime (**7**); m.p. 96–97.5°; i.r. 3180, 1650, 1009, 1005–900 (multiple peaks) 863, 790 cm^{-1}; n.m.r. τ −0.9 (b, OH), 3.8 ~ 4.2 (m, H_a and H_b), 6.65 (s, H_c), 7.60 (m, 4H), 8.25, (d, H_d, $J = 5$ Hz), 8.54 (m, 6H); n.m.r. (benzene-d_6) τ 3.63 (d, H_a, $J = 16$ Hz), 4.0 (dq, H_b, $J = 16$ and 6 Hz), 6.74 (s, H_c), 8.38 (d, H_d, $J = 6$ Hz).

Anal. Calcd. for $C_{10}H_{18}N_2O$: C, 65.90; H, 9.95; N, 15.37. Found: C, 65.90; H, 9.73; N, 15.19.

The next fraction eluted with 2% methanol in $CHCl_3$ was an oil (1.4 g) which could be crystallized from petroleum ether to give white crystals (350 mg, t.l.c. single spot). They were sublimed (70°/0.2 mm Hg) to give *anti,trans*-1-piperidino-3-penten-2-one oxime **8**; m.p. 72–73.5°; i.r. 3250, 1640, 1113, 1118, 1000–940 (multiple peaks), 760 cm^{-1}; n.m.r. τ 0.9 (b, OH), 3.36 (m, H_a and H_b), 6.87 (s, H_c), 7.65 (m, 4H), 8.18 (d with virtual coupling, H_d, $J = 6$ Hz), 8.57 (m, 6H); n.m.r. (benzene-d_6) τ 3.0 (dq, H_a, $J = 16$ and 1 Hz), 3.5 (dq, H_b, $J = 16$ and 6 H), 6.82 (s, H_c), 8.42 (dq, H_d, $J = 6$ and 1 Hz). The mother liquors from the recrystallizations were combined to give a residue. This residue was slightly contaminated by **7** showing signals at τ 3.8 and 6.6. This residue was subjected to the amino group assisted Beckmann cleavage reaction (*vide infra*).

Continued elution with 2% methanol in $CHCl_3$ gave 1,4-adduct **1** (1.3 g); i.r. 3200, 1620, 1010–895 cm^{-1}; n.m.r. τ 3.82 (m, 2H), 6.92 (m, 2H), 7.59 (m, 4H), 8.05 (s, 3H), 8.50 (m, 6H). In the last fraction from this chromatography, 4,1-adduct **4** admixed with compound **1** was obtained as shown by the doublet at τ 2.34 and 8.78; the rest of the n.m.r. signals were superimposed with those of **1**.

Photoaddition of N-Nitrosopiperidine to cis,trans-2,4-Hexadiene

The photoaddition was carried out in the same manner as described above. The $CHCl_3$ extract (50 ml × 3) of the basic aqueous solution afforded a quantitative yield of crude adducts as a light yellow oil (10.0 g) which was chromatographed on silicic acid (60 g).

The first fraction A eluted with $CHCl_3$ was an oil (516 mg) and, on a t.l.c. plate, showed two predominant spots with R_f values of 0.42 and 0.29. Continued elution with $CHCl_3$ gave fraction B which was a mixture of two compounds showing spots on the R_f 0.16 and 0.08. The remaining fraction C (6.48 g) was eluted with 1 ~ 20% methanol in $CHCl_3$ to give predominantly the last compound showing R_f of 0.08 on t.l.c. analysis.

Fraction A was rechromatographed on silicic acid (15 g). Elution with $CHCl_3$ gave four consecutive fractions which showed a single spot on a t.l.c. plate. These fractions were combined (200 mg) and distilled to give a colorless oil (170 mg) of *syn,trans*-2-piperidino-4-hexen-3-one oxime (**10**); i.r. 3350, 1660, 1620, 1590, 1390, 1340, 1150, 1110, 990, 940 cm^{-1}; n.m.r. τ − 1.25 (b, OH), 3.7–4.1 (m, H_a and H_b), 6.57 (q, H_c, $J = 7$ Hz), 7.5 (m, 4H), 8.18 (d with virtual coupling, H_c, $J = 5$ Hz), 8.47 (m, 6H), 8.67 (d, H_d, $J = 7$ Hz); n.m.r. (pyridine) τ 3.3 (dq, H_b, $J = 16$ and 6 Hz), 3.74 (d, H_a, $J = 16$ Hz), 5.88 (q, H_c, $J = 7$ Hz), 8.23 (d, H_c, $J = 6$ Hz), 8.75 (d, H_d, $J = 7$ Hz); mass spectrum *m/e* (relative intensity) 196 (1), 111 (32), 84 (53), 41 (100). Continued elution with 1% methanol in $CHCl_3$ gave a fraction which on a t.l.c. plate showed a single spot. This oil was distilled on a small scale (100°/0.2 mm Hg) to give a colorless sample (40 mg) of *trans*-5-piperidino-3-hexen-2-one (**12**); i.r. 2950, 2800, 1678, 1630, 1450, 1360, 1258, 1110, 990 cm^{-1}; n.m.r. τ 3.18 (dd, H_b, $J = 17$ and 7 Hz), 3.94 (d, H_a, $J = 17$ Hz), 6.82 (quintet, H_c, $J = 7$ Hz), 7.5 (m, 4H), 7.71 (s, H_c), 8.46 (m, 6H), 8.76 (d, H_d, $J = 7$ Hz); mass spectrum (at 20 eV), *m/e* (relative intensity) 181 (4), 111 (46), 84 (100).

Fraction B was rechromatographed on silicic acid (15 g). Eluting with up to 1% methanol in $CHCl_3$ gave four fractions which were predominantly a new compound contaminated slightly by **11**. Continued elution with 2% methanol in $CHCl_3$ gave an oil (28 mg) which showed a single spot on a t.l.c. plate. This oil was distilled to afford an analytical sample of *anti,trans*-2-piperidino-4-hexen-3-one oxime (**11**); i.r. 3350, 2995, 1650, 1638, 1458, 1383, 1120, 963, 940 cm^{-1}; n.m.r. τ 0.9 (b, OH), 3.0 ~ 3.7 (m, H_a and H_b), 6.67 (q, H_c, $J = 7$ Hz), 7.50 (m, 4H), 8.12 (d with virtual coupling, H_c, $J = 6$ Hz), 8.50 (m, 6H), 8.73 (d, H_d, $J = 7$ Hz); mass spectrum *m/e* (relative intensity) 196 (1.8), 179 (5.4), 84 (8), 41 (100).

Anal. Calcd. for $C_{11}H_{20}N_2O$: C, 67.31; H, 10.27; N, 14.27. Found: C, 67.20; H, 10.26; N, 14.47.

One of the fractions from fraction C (single spot on t.l.c., 300 mg) was crystallized from petroleum ether: m.p. 83–85°. These crystals were recrystallized three times from petroleum ether and then sublimed (90°/0.2 mm Hg) to give white crystals of *anti,trans*-5-piperidino-3-hexen-2-one oxime (**9**); m.p. 88–89°; i.r. 3000, 1630, 1145, 1110, 1060, 980–900 (multiple peaks), 870, 840, 780, 675 cm^{-1}; n.m.r. τ −1.00 (b, OH), 3.2 ~ 4.0 (m, H_a and H_b), 6.95 (m, H_c), 7.52 (m, 4H), 8.01 (s, H_e), 8.52 (m, 6H), 8.78 (d, H_d, J = 6.5 Hz); n.m.r. (pyridine) τ 3.5 (d, H_a, J = 16 Hz), 3.98 (dd, J = 16 and 7 Hz), 7.78 (s, H_e), 6.92 (quintet, H_c, J = 7 Hz), 8.84 (d, H_d, J = 7 Hz).

Anal. Calcd. for $C_{11}H_{20}N_2O$; C, 67.31; 10.27; N, 14.27. Found: C, 67.25; H, 10.14; N, 14.40.

Beckmann Reaction of trans-4-Piperidino-2-butenal Oximes

A sample of the *anti,trans*-oxime **14** (m.p. 100–103°, 1.1 g) and *p*-toluenesulfonyl chloride (2.9 g) were added to cold triethylamine (50 ml). The mixture was stored in an ice box overnight and was flash evaporated under vacuum to remove triethylamine. The residue was stirred with aqueous sodium carbonate solution (10%) for 1 h and was extracted with ether (30 ml × 3). The ether solution was extracted with 2 *N* hydrochloric acid. The acid solution was basified and extracted with methylene chloride to give a crude basic product (1.02 g); i.r. 2790, 2820, 2240, 1640, 990, 960 cm^{-1}. The crude product was chromatographed on an alumina column (30 g) and eluted with benzene to give *trans*-4-piperidinocrotononitrile (**15**); i.r. 2800, 2780, 2220, 1638, 1345, 1150, 1120, 1035, 990, 960 cm^{-1}; n.m.r. τ 3.33 (dt, 1H, J = 16 and 5.5 Hz), 4.42 (dt, 1H, J = 16 and 1.8 Hz), 6.95 (dd, 2H, J = 5.5 and 1.8 Hz).

The picrate of **15** was recrystallized from a mixture of ethanol–benzene to give orange crystals; m.p. 155.5–156.5.

Anal. Calcd. for $C_{15}H_{17}N_5O_7$: C, 47.55; H, 4.52; N, 18.56. Found: C, 47.57; H, 4.63, N, 18.46.

A crude resin (1.59 g) obtained from the photoaddition of *N*-nitrosopiperidine to butadiene was, without further purification, dissolved in pyridine (30 ml). To this solution was added *p*-toluenesulfonyl chloride (3.0 g, 0.015 mol) as a finely ground powder. The solution was stirred at room temperature for 24 h. At this time, the pyridine was removed under vacuum leaving a dark black oil. This oil was treated with saturated K_2CO_3 solution and stirred for 1 h at room temperature. This solution was worked-up as shown above to afford a brown-black oil (860 mg). The oil was then distilled by bulb distillation at a vacuum of 0.2 mm Hg. The forerun collected distilled at a chamber temperature of 70–76° and the main distillate was collected at a temperature range of 76–88°. Both the forerun and the main fraction showed n.m.r. and i.r. spectra superimposable with that of *trans*-4-piperidinocrotononitrile (**15**).

Beckmann Reaction of cis-1-Piperidino-3-penten-2-one Oximes (2 and 3)

In a round bottom flask (50 ml) equipped with a condenser, pure oxime of **3** (244 mg, 0.0013 mol) was dissolved in pyridine (10 ml). The top of the condenser was closed with a stopper. To the solution was added *p*-toluenesulfonyl chloride (600 mg, 0.003 mol) and the resulting solution was stirred for 18 h. It was then treated with ether. The ether layer was washed with 2 *N* hydrochloric acid solution (30 ml × 3), and then with a saturated K_2CO_3 solution and lastly with water. The ether extract was then dried ($MgSO_4$) and filtered. The ether solution was distilled to a small volume (10 ml) in a distillation apparatus equipped with a Vigreux column (50 mm). This residual ether (10 ml) was examined by v.p.c. and n.m.r. The v.p.c. analysis (20 ft × 3/8 in., 30% SE–30, chromosorb, 100 ml of He/min, 120°) showed that no *trans*-crotononitrile was present. The n.m.r. showed signals at τ 3.5 (dq, 1H, J = 11 and 7 Hz), 4.66 (dq, 1H, J = 11 and 1.5 Hz), 8.0 (dd, 3H, J = 7 and 1.5 Hz).

The crude adduct obtained from the addition of *N*-nitrosopiperidine to *cis*-1,3-pentadiene was recrystallized to remove 1,4-adduct **1**. The mother liquor was evaporated to give a crude mixture. This crude material (1.73 g, 0.0095 mol) was dissolved in pyridine and cooled in an ice bath to 3° with constant stirring. To this solution was added finely powdered *p*-toluenesulfonyl chloride (3.8 g, 0.02 mol) and the resulting solution was stirred overnight. The temperature rose gradually to 22° after stirring for 18 h. The solution was diluted with ether (50 ml). The ether solution was worked-up as described above. The n.m.r. and v.p.c. analysis in the same manner (135 ml/min, 100°) showed only *cis*-crotononitrile.

Beckmann Reaction of trans-1-Piperidino-3-penten-2-one Oximes (7 and 8)

Pure oxime **8** (300 mg, 0.0016 mol) as finely ground crystals was dissolved in pyridine (15 ml). *p*-Toluenesulfonyl chloride (960 mg, 0.002 mol) was added and this solution was stirred for 16 h. The reaction was worked-up as previously described. A v.p.c. analysis (150 ml of He/min, 123°) and n.m.r. spectrum of the concentrated ether solution showed it to contain only *trans*-crotononitrile.

An analogous reaction was carried out in an aqueous 2% KOH solution. The recovered crotononitrile was analyzed to contain about 20% *cis* and 80% *trans* isomer by v.p.c. analysis (125 ml of He/min, 85°). The commercially available *cis*- and *trans*-crotononitrile mixture was stirred for 20 h in an aqueous 2% KOH solution. The *cis* to *trans* ratio was found to be unchanged.

The basic crude mixture obtained from a photoaddition *N*-nitrosopiperidine to *trans*-1,3-pentadiene was chromatographed on silicic acid (60 g). All the fractions that showed the presence of the minor components (other than **1**) by t.l.c. analysis were combined (2.124 g, 0.0118 mol). The oil was treated with *p*-toluenesulfonyl chloride (4.85 g, 0.025 mol) in pyridine (20 ml) for 16 h. The solution was then worked-up in the usual manner. The concentrated ether extract was examined by v.p.c. (120 ml of He/min, 126°) and n.m.r. and was shown to contain only *trans*-crotononitrile.

Beckmann Reaction of a Crude Mixture of trans-2-Piperidino-4-hexen-3-one Oximes (10 and 11)

The basic fraction obtained from the photoaddition of *N*-nitrosopiperidine to *cis,trans*-2,4-hexadiene was chromatographed and all the fractions that showed the presence of minor components (other than **9**) were combined to give a crude mixture (560 mg, 0.0029 mol). This crude mixture was treated with *p*-toluenesulfonyl chloride (1.3 g, 0.0065 mol) in pyridine (20 ml) for 22 h at room temperature and the solution was worked-up in the usual way. The ether extract was examined by v.p.c. analysis (30% SE–30 on chrom. W, 150 ml of He/min, 80°) and was shown to contain *cis*- and *trans*-crotononitrile in a ratio of 3:97 by mixed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

injection. The retention times for the *trans*-crotononitrile was 8 min and for the *cis* isomer 9.5 min.

Attempts of Sensitized Isomerization of 1,3-Pentadienes

(*1*) *N*-Nitrosopiperidine (4.0 g, 0.035 mol) and a mixture of *cis*- and *trans*-1,3-pentadiene (40:60) in cyclohexane (360 ml) was irradiated for 18 h with a 200 *W* Hanovia lamp. At intervals the photolysis solution was analyzed by v.p.c. (20 ft × 3/8 in., 30% SE–30, chromosorb W, 86 ml of He/min, 85°). The 0 h sample showed the *trans:cis* ratio of 60:40; after 1 h irradiation 58.5:41.5; after 3 h, 59.5:40.5; after 18 h, 59.5:40.5. The retention time for *trans*-1,3-pentadiene was 16.5 min and for the *cis*-1,3-pentadiene 17.5 min under the conditions employed.

(*2*) *N*-Nitrosopiperidine (2.3 g, 0.02 mol) *cis*-1,3-pentadiene (2.2 g, 0.032 mol) and concentrated hydrochloric acid (2 ml, 0.024 mol) in methanol (1.4 l) were irradiated with a RPR 3500 Å lamp to about 80% completion (4 h). To this solution was added water (50 ml) followed by sodium bicarbonate (p*H* 7–8). The photolysate solution was partially distilled to collect 25 ml of distillate (b.p. 64–65°) while the receiver was cooled with an acetone–Dry Ice mixture. This distillate was examined by v.p.c. to show the peak for *cis*-1,3-pentadiene with a retention time 13.4 min. No peak having a retention time of *trans*-1,3-pentadiene (11.2 min) was present in the v.p.c. analysis.

(*3*) *N*-Nitrosopiperidine (3.42 g, 0.03 mol), *trans*-1,3-pentadiene (3.40 g, 0.05 mol), and concentrated hydrochloric acid (3 ml, 0.036 mol) in methanol (360 ml) was photolyzed for 5 h with a RPR 3500 Å lamp to completion. The remaining diene was examined by v.p.c. in the usual manner to show the peak of *trans*-1,3-pentadiene at 13 min but no peak at 14.2 min for *cis*-1,3-pentadiene.

Photolysis of N-Nitrosopiperidine in the Presence of cis- and trans-1,3-Pentadienes

A solution of *N*-nitrosopiperidine (2.3 g, 0.02 mol), concentrated hydrochloric acid (2 ml, 0.024 mol), and a (60:40) *cis* and *trans* mixture of 1,3-pentadiene (2.72 g, 0.04 mol) in methanol (380 ml) was irradiated for 5 h and was worked-up in the usual manner to afford the forerun (20 ml). The forerun was examined by v.p.c. (60 ml of He/min, 70°) to show that the *cis:trans* ratio of the 1,3-pentadiene was 60:40, having identical ratio as the 0 h sample. Under the conditions employed *trans*-1,3-pentadiene had a retention time of 19 min, the *cis* isomer 20.4 min.

Photolysis of N-Nitrosopiperidine in the Presence of cis,trans- and trans,trans-2,4-Hexadiene

A solution of *N*-nitrosopiperidine (2.51 g, 0.022 mol), concentrated hydrochloric acid (3 ml, 0.036 mol), *cis,trans*-2,4-hexadiene (1.64 g, 0.02 mol), and *trans,trans*-2,4-hexadiene (1.64 g, 0.02 mol) in methanol (200 ml) was irradiated as described above for 7 h. The photolysate was analyzed by v.p.c. (20 ft × 3/8 in., 30% SE–30, chromosorb W, 120 ml of He/min, 90°). This *cis,trans* isomer had a retention time of 16 min and the *trans,trans* isomer of 18.2 min. At 0 h the ratio of *cis,trans* to *trans,trans* isomer was 1:1 and at the end of photolysis the corresponding ratio was also 1:1.

Synthesis of 4-Piperidinocrotononitrile

A mixture of *N*-bromosuccinimide (17.8 g, 0.11 mol) and a *cis-trans* mixture of crotononitrile (10 g, 40:60 ratio) were refluxed in CCl_4 for 15 h. At this time, the succinimide had crystallized as top layer in the CCl_4 solution and was filtered. To the CCl_4 filtrate was then added piperidine (20 g, 0.24 mol). Upon standing at room temperature piperidine hydrobromide (15.5 g, 0.095 mol) precipitated and was filtered. The filtrate was then refluxed for 1 h. The CCl_4 was then removed under vacuum to give a brown oil which was dissolved in ether and the ether solution washed with water (50 ml × 3), dried ($MgSO_4$), and evaporated to give a crude oil (11.4 g): i.r. 2225, 1640, 1108. This oil was distilled to give a mixture of *trans*- and *cis*-4-piperidinocrotononitrile (76–82°/1.5 mm Hg); i.r. 2225, 1640, 1108 cm^{-1}; n.m.r. see Fig. 1.

Quantum Yield Determination for the Disappearance of N-Nitrosopiperidine

The quantum yield was determined by using a home-made merry-go-round apparatus (36) and in methanol solution containing a suitable concentration of unsaturated compounds at two hydrochloric acid concentrations (0.5 and 0.06 *N*). The solution was degassed by three cycles of freeze–pump–thaw processes. The light source was a PEK #202 high pressure mercury arc lamp and was filtered through a Corning CS-5-60 filter. In each run the duration or irradiation was 20 min. The decrease of *N*-nitrosopiperidine was monitored at the absorption peak at 350 nm. The chemical actinometry described by Hatchard and Parker (37) was used for the photon count which was determined to be $\sim 3 \times 10^{11}$ quanta/s/tube. The quantum yields listed in Table 3 were shown to be reproducible.

We thank the National Research Council of Canada and the President's Research Fund of Simon Fraser University for generous financial support of this work.

The Stereochemistry of the Addition of Two Diazoalkanephosphonates to Norbornene and Norbornadiene; Photolysis of the Adducts. An Entry into the Dimethyl Tricyclo[2.1.1.$0^{2,4}$]octyl Phosphonate System

HENRY J. CALLOT[1] AND CLAUDE BENEZRA

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received July 15, 1971

Dimethyl phenyldiazomethyl- and methyldiazomethylphosphonates were treated with norbornene and norbornadiene and the configuration of the Δ^1-pyrazolines obtained (**3**–**8**) was deduced from n.m.r. by using the dihedral angular dependence relationship of vicinal $^{31}P,^1H$ couplings. The adducts were photolyzed under sensitized and non-sensitized conditions. The resulting cyclopropyl derivatives (**9**–**12** and **14**–**17**) were assigned configuration by using n.m.r. data. The results are discussed in terms of steric and electronic factors. The n.m.r. and mass spectral data are also discussed.

La réaction des phényldiazométhyl- et méthyldiazométhylphosphonates de diméthyle avec le norbornène et le norbornadiène a été étudiée et la configuration des Δ^1-pyrazolines obtenues (**3**–**8**) a été déduite par r.m.n. en utilisant la dépendance angulaire du couplage vicinal $^{31}P,^1H$. Les produits d'addition ont été photolysés dans des conditions sensibilisées et non sensibilisées. La configuration des dérivés cyclopropaniques formés (**9** à **12** et **14** à **17**) a été déterminée en utilisant les données de r.m.n. Les résultats sont discutés en termes de facteurs stériques et électroniques. Les données de r.m.n. et de masse sont également discutées.

Canadian Journal of Chemistry, **50**, 1078 (1972)

1,3-Dipolar cycloadditions are well documented by a large amount of studies, mostly stimulated by the important contribution of Huisgen and co-workers (1) in the field. Some controversy arose recently concerning the mechanism of the addition (2) but the "no-mechanism" concerted pathway originally proposed by Huisgen (3) seems to be generally accepted. The nature of the orientation (when either the dipole or the dipolarophile is unsymmetrical) is still obscure (3) and orbital symmetry considerations (4) do not permit predictions (5).

When the dipole contains a carbon bearing two different substituents, two stereoisomers can be obtained with a symmetrical olefin. This aspect of the stereochemistry of the cycloaddition has apparently received little attention although some examples of the formation of epimeric mixtures (6) and separation and determination of the configuration of epimers have been described recently (7). Strained olefins such as norbornene (**1**) and norbornadiene (**2**) are very reactive toward cycloadditions (1) and should provide an excellent model to study the "tertiary" aspects of the stereochemistry of the cycloadditions.[2] Our interest in phosphonates prompted us to study the cycloaddition of diazoalkanephosphonates $RC(N_2)P(O)(OCH_3)_2$ made readily available through the recent work of Regitz and co-workers (9, 10) and Marmor and Seyferth (11) to those strained olefins. Although the carbenoid-type behavior of those diazo compounds have been studied recently (generation of $R\ddot{C}P(O)(OCH_3)_2$ either by copper-catalyzed decomposition (11) or by photolysis), much less attention has been devoted to their potential as 1,3-dipolar reagents and the stereochemistry of the cycloaddition.

It was hoped to get some insight into the steric and electronic requirements of the cycloadditions and an entry into strained tricyclic systems containing the $P(O)(OCH_3)_2$ moiety through the decomposition of the intermediate Δ^1-pyrazolines expected. This work describes the reaction of dimethyl phenyldiazomethyl- ($R = C_6H_5$) and methyldiazomethyl ($R = CH_3$) phosphonates with norbornene and norbornadiene and the photolysis of the adducts.

[1]On leave of absence from C.N.R.S. (France). Present address: Institut de chimie, 1 Rue Blaise Pascal, Strasbourg, France.

[2]The "primary" aspects being the exclusive *cis* addition (1,3) (except for one case (8) recorded in the literature), the "secondary" aspects the exclusive *exo* addition to norbornene and norbornadiene systems (1), the "tertiary" aspects would be the formation of epimers (possible when the dipole bears two unlike substituents).

Results

Cycloadditions

Cycloaddition of diazoalkanephosphonates $RC(N_2)P(O)(OCH_3)_2$ to norbornene **1** and norbornadiene **2** proceeds smoothly when a mixture containing the olefin, the diazo compound and methylene chloride is warmed at temperatures not exceeding 50 °C.

Interesting to note is the steric course of the addition: with norbornene, for instance, and dimethyl phenyldiazomethylphosphonate (R = Ph), only one pyrazoline, **3**, was formed. However when dimethyl methyldiazomethylphosphonate ($R = CH_3$) was treated with norbornene, two pyrazolines, **4** and **5** (ratio 4:1), epimeric at C-3 were obtained.

Assignment of the configuration of the pyrazolines follows from the examination of their 100 MHz n.m.r. spectra. *exo*-Junction of the pyrazoline ring to the bicyclo[2.2.1]heptyl moiety is shown by the absence of any H_9,H_7 or H_{10},H_4 couplings,[3] such absence of coupling being characteristic of an *endo* proton (12). Configuration at C-3 can be assigned from the different $^3J_{PH_{10}}$ couplings. In compounds **3** and **4** the 17.4 and 18.8 Hz couplings respectively are only compatible with a near-zero P,H dihedral angle (13), while the small 6.0 Hz P,H coupling in **5** can be ascribed to a near 120° dihedral angle.[4]

Similar results were obtained with norbornadiene: pyrazolines **6**–**8** were obtained and assigned stereochemistry based on the same considerations. Results for cycloadditions are summarized in Table 1.

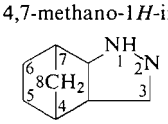
Decomposition of the Pyrazolines

Thermal decomposition of Δ^1-pyrazolines generally results in the formation of olefins or cyclopropanes while photochemical decomposition leads mainly to cyclopropane derivatives (14, 15).

Photolyses of the above pyrazolines **3**–**8** were conducted in a Srinivasan–Griffith reactor. The pyrazolines were in benzene solutions and reacted in Vycor vessel.

Non-sensitized photodecomposition[5] of pyrazoline **3** was a clean reaction with complete stereoselectivity: only one compound, to which we assign structure **9** on the basis of the n.m.r.

[3]The numbering used for the pyrazolines **3**–**8** is based on the nomenclature of Chemical Abstracts (for example Chem.Abstr., subject index, **72**, 2338s, June 1970) for the 5,5,5-ring system of 4,7-methano-1*H*-indazole.



[4]One referee has questioned the validity of our assignments concerning the configurations of the pyrazoline, arguing that these were based on a given conformation of the pyrazoline ring. According to his comments, the large vicinal P,H_{10} coupling could also be ascribed a 180° P,H_{10} dihedral couple and the small P,H_{10} coupling to a 60°angle. When one builds Dreiding models of compound **3**–**8** it becomes clear that the pyrazoline ring is planar due to: (*1*) its attachment to the rigid bicyclo[2.2.1]heptyl moiety and (*2*) to the presence of the *N*=*N* bond. Only 120 and 0° dihedral vicinal angle arrangements between proton H-10 and groups at C-3 are thus possible.

[5]"Non-sensitized" photolyses were conducted at 3500 Å using a Pyrex filter while "sensitized" photolyses were performed at 2537 Å in the presence of benzophenone (see Experimental).

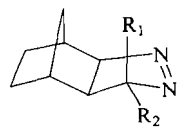
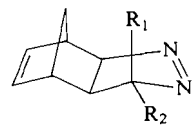
TABLE 1. Cycloadditions



3, 4, and 5



6, 7, and 8

Olefin	Diazoalkane phosphonate $RC(N)_2P(O)(OCH_3)_2$	Total yield* (%)	R_1	R_2		Pyrazolines† (%)	
Norbornene **1**	$R = C_6H_5$	92	C_6H_5	$P(O)(OCH_3)_2$	*anti*	(**3**)	100
			$P(O)(OCH_3)_2$	C_6H_5	*syn*		0
Norbornene **1**	$R = CH_3$	86‡	CH_3	$P(O)(OCH_3)_2$	*anti*	(**4**)	81
			$P(O)(OCH_3)_2$	CH_3	*syn*	(**5**)	19
Norbornadiene **2**	$R = C_6H_5$	90§	C_6H_5	$P(O)(OCH_3)_2$	*anti*	(**6**)	100
			$P(O)(OCH_3)_2$	C_6H_5	*syn*		0
Norbornadiene **2**	$R = CH_3$	84‡	CH_3	$P(O)(OCH_3)_2$	*anti*	(**7**)	78
			$P(O)(OCH_3)_2$	CH_3	*syn*	(**8**)	22

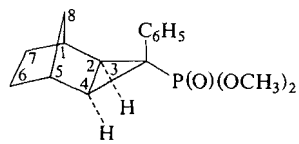
*Relative to the starting diazocompound.

†Relative yield of each epimeric pyrazoline: $\%anti + \%syn = 100$; the words *anti* and *syn* refer to the position of the dimethyl phosphono group relative to the C-8 bridge.

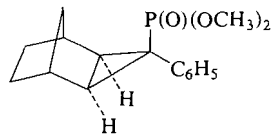
‡The *syn*/*anti* mixture was separated on column chromatography (weight of silica gel = 30 times weight of the mixture; eluent ether and ether–ethyl acetate mixtures).

§In another experiment on larger scale, the total yield was raised to 94 and 4% of the epimeric **6***a* pyrazoline (see theoretical part) was isolated along with 90% of the major isomer, **6**.

data, was formed. Sensitized photolysis of the pyrazoline[5] **3** resulted in complete loss of stereoselectivity: a 1:1 mixture of two epimers **9** and **10** was formed. Structures **9** and **10** were deduced from n.m.r. spectra: the large P,H_2 coupling (15.5 Hz) was assigned to compound **9** where the P,H_2 dihedral angle is near 0° (13) while the low 4.2 Hz P,H_2 coupling was consistent with structure **10**.



9

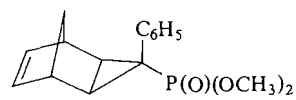


10

Thermal decomposition of pyrazoline **3** in boiling xylene for 40 h resulted in the formation of an intractable mixture in which n.m.r. showed the presence of ~35% of the cyclopropane **9** along with the unreacted pyrazoline **3** (*ca.* 25%) and unidentified products. Pyrolysis like photolysis led to the product with retention of configuration at C-3. No trace of the epimer **10** could be detected in the n.m.r. of the thermolytic mixture.

Although non-sensitized photolytic decomposition of the unsaturated analog, compound **6**, was less clean (the yield in cyclopropanes was lower, see Table 2) it was still highly stereoselective and only isomer **11** could be detected. The photolysis performed under sensitized conditions led to a mixture containing the cyclopropyl derivative **11**, its epimer at C-3, compound **12**, and isomeric unidentified compounds **13** in a 1.2:1:1.2 ratio.

Photolytic behavior of the methyl pyrazolines



11

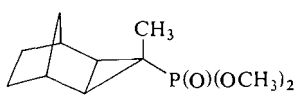
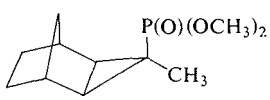
*In % cyclopropane derivatives relative to the starting pyrazoline.
†Relative yield of each epimeric cyclopropane: % *anti* + % *syn* = 100; the words *anti* and *syn* refer to the position of the phosphorus relative to the C-8 bridge.

4 and **5** was of greater interest since epimers **4** and **5**, **7** and **8** were available. Photolyses were conducted under non-sensitized conditions.

Pyrazoline **4** led exclusively to the cyclopropane derivative **14** (96% yield). In turn, pyrazoline **5** with the dimethylphosphono group *syn* to the C-8 bridge led to a 1:4 mixture of cyclopropanes **14** and **15**. The corresponding

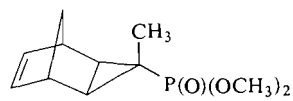


14

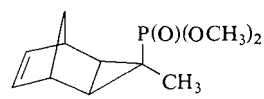


15

norbornadiene pyrazolines **7** and **8** gave comparable results. Configurations at C-3 in compounds **14** and **15** follow from a large (15.0 Hz in **14**) compared to a small (3.6 Hz in **15**) $^3J_{PH_2}$ coupling. In the norbornadiene series



16



17

comparable results were obtained, and compounds **16** and **17** were isolated. Results for photolytic decomposition are summarized in Table 2.

Discussion

Steric Course of the Cycloaddition

On purely steric grounds, the results of the cycloaddition are unexpected. If one compares the Van der Walls radii of the phenyl group (half-thickness 1.7 Å) to that of the methyl group (2 Å) (16) the decreasing size order of the three substituents would be $P(O)(OMe)_2 >$

phenyl > methyl.[6] One would have expected then more steric discrimination in the case of the methyl derivative (CH_3 being much less bulky than the phosphono moiety). The reverse is observed.

Electronic factors probably play an important role since the phenyl group stabilizes the diazo-compound relative to its methyl analog. Since the dimethyl methyldiazomethylphosphonate is more reactive, less discrimination is observed in this case and a mixture of pyrazolines **4** and **5** is obtained.[7]

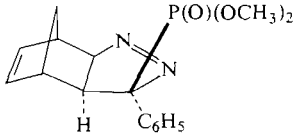
Photolyses

Stereoselectivity of direct photolysis of pyrazolines compared to the absence of stereoselectivity in the photosensitized decomposition can be explained on the basis of different intermediate diradicals. Direct photolysis is believed to proceed through the intermediacy of a short-lived singlet species: time is therefore not sufficient to allow rotation about the C_{10}—C_3 bond and epimerization at C-3. In turn, photosensitized decomposition of pyrazolines occurs through a triplet (18), long lived enough to allow such bond rotation. Recent work confirms this general result concerning stereoselectivity (7).

In agreement with this is the finding that non-sensitized photodecomposition of pyrazolines **3**, **4**, **6**, and **7** was completely stereoselective while sensitized decomposition of pyrazolines **3** and **6** led to mixtures of cyclopropanes (see Table 2).

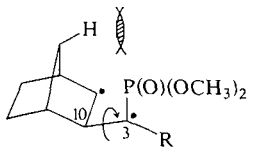
[6]No definite value for the size of the dimethylphosphono group is known; however, from X-ray data (17) it may be inferred that $P(O)(OMe)_2$ occupies as much space as a tert-butyl group although the length of the P—C bond (1.85 Å) compared to that of the C—C bond should make the dimethylphosphono group less bulky than $(CH_3)_3C$. Work to determine the *A* value for the phosphono group is in progress in this laboratory.

[7]In agreement with this hypothesis, is our recent finding that 4% of the epimeric pyrazoline **6***a* was isolated from the cycloaddition of $PhC(N_2)P(O)(OCH_3)_2$ to norbornadiene. Since norbornadiene is more reactive than norbornene (due to the presence of a second double bond), less discrimination is observed for the former.



6*a*

There is a striking difference between the photolytic behavior of pyrazolines **4** and **7** on one hand and that of the epimeric pyrazolines **5** and **8** on the other hand. Complete stereoselectivity is found in the first case while in the second case, where the bulky dimethylphosphono group is *syn* to the C-8 bridge, there are 20% of the cyclopropanes **14** and **16** found with inversion of configuration at C-3. We propose as a possible explanation that the bulkiness of the dimethylphosphono group[6] results in such a steric compression in the intermediate **18** ($R = CH_3$) with the P *syn* to the C-8 bridge that even with a very short-lived singlet, rotation of C_3—C_{10} occurs, thus relieving some of the strain. Such a steric compression when the $P(O)(OCH_3)_2$ group is *syn* to the C-8 bridge is also reflected in the n.m.r. of the compounds (see below).



18

Nuclear Magnetic Resonance Spectra

The data on n.m.r. are summarized in Tables 3 and 4; some general features are worth comment.

In the pyrazolines, the chemical shift of the protons near C-3 strongly depends on the configuration at this center. This is very clear in the methyl series. For instance, the chemical shift of the methyl group in the *anti* compounds **4** and **7**[8] is 1.66 and 1.67 p.p.m. while in the *syn* derivatives **5** and **8** they are 1.31 and 1.33 respectively. There is also a large difference between the chemical shifts of H_{10} in the epimers: H_{10} resonates at higher field in the *syn* derivatives **5** and **8**.

Concerning the couplings, most of our assignments are based on the vicinal P,H_{10} couplings. For a near 120° dihedral angle, this coupling is equal to 6.0–6.2 Hz while a 0° angle results in a high 17.4–19.0 Hz coupling. These results are consistent with a Karplus-type variation of the vicinal P,H coupling (19). Another $^3J_{PH}$ coupling is of interest: the *P*—C—*CH*$_3$ coupling is sensi-

[8]The words *syn* and *anti* refer to the position of the phosphorus group relative to the C-8 bridge.

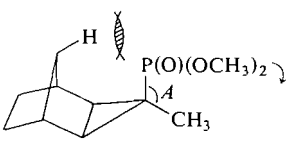
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tive to the configuration at C-3. It is equal to 17.2 and 17.6 Hz in the *syn* compounds **4** and **7** while it drops to 15.2–15.3 in the *anti* derivatives **5** and **8**. It is probable that due to the bulkiness of the dimethylphosphono group some steric compression with the H_8 *syn* to the phosphono occurs, causing a deformation of the P—C—CH_3 angle. Such a compression is more severe in the cyclopropyl derivatives and is reflected by a larger drop in $^3J_{PCH_3}$ (see below).

Some long range P,H couplings can be noted: P,H_9 coupling varies from 3.6 to 6.2 Hz and is the largest when the phosphono group is *syn* to the C-8 bridge.

Almost the same features described above apply to the photo-products **9** to **17**. Interesting to note is the difference in the chemical shift of the H_8 protons depending on the C-3 configuration. In the phenyl derivatives (**9** to **12**) two general features can be described. A phenyl *syn* to the C-8 bridge results in shielding of the H_8 protons: (0.27 to 0.67 p.p.m.) while the effect of the dimethyl-phosphono group seems to be an enhancement of the chemical non-equivalence of the two hydrogens (about 1.0 p.p.m. $\Delta\delta$). The results are less clear-cut in the methyl series (**14** to **17**) but the same type of comment can be made.

Concerning the vicinal coupling, the dihedral dependence of $^3J_{PCH_3}$ allows the assignment of configuration of the cyclopropyl derivatives. As



in the case of the pyrazolines, the *P*—C—*CH*$_3$ splitting strongly depends on the orientation of the bulky dimethylphosphono group. When this is *syn* to the C-8 bridge a substantial drop of this coupling occurs (from $\sim$ 15 to 11 Hz). This is unexpected since steric compression (between P and H_{8syn}) should cause the decrease of the P—C—C(H_3) bond angle *A* and result in the *increase* of the vicinal coupling (20). Other factors such as rehybridization of phosphorus in the *syn* derivatives could play a role.

Mass Spectra

Spectral data are summarized in Tables 5 and 7. Some salient features are worth comment.

Pyrazolines show no parent ion but instead an $M^+ - 28$ (loss of nitrogen) peak. In the norbornadiene series (compounds **6** and **7**) the major fragmentation is the retro-Diels–Alder path (loss of C_5H_6 after nitrogen has been eliminated) where the charge is carried by the moiety containing the phosphorus group. Loss of the elements of dimethyl phosphonate ($HP(O)(OCH_3)_2$($M^+ - 28$)-110 is an important process in both series as was shown for other phosphonates (21). In the unsaturated methyl derivatives **7** and **8**, it is interesting to note that the fragmentation pattern of those epimers seems to depend strongly on the configuration at C-3. When the $P(O)(OCH_3)_2$ group is *syn* to the C-8 bridge the retro-Diels–Alder process becomes minor and the prominent ion is the one corresponding to the loss of [$HP(O)(OCH_3)_2$]. The steric compression existing in the *syn* derivatives seems to be reflected also in the mass spectra.

Cyclopropyl derivatives exhibit spectra which are almost identical with those of the corresponding pyrazolines. It is possible that a common intermediate is involved, once nitrogen has been lost; the parent ion is more intense than the corresponding ($M^+ - 28$) peak of pyrazoline. In the saturated series (**9**, **10**, **14**, and **15**) one of the major fragmentation processes corresponds to the loss of 110 mass units ($C_2H_7O_3P$); note that in compounds **9** and **10** the base peak is the parent ion. In the unsaturated series (**11**, **12**, **16**, and **17**) two major fragmentation patterns are observed: the retro-Diels–Alder process (loss of C_5H_6) and the loss of 110 mass units. Here again the influence of the configuration at C-3 is determinant: when the phosphorus moiety is *syn* to the C-8 bridge (causing severe steric compression), the major process by far is the loss of the elements of dimethyl phosphonate.

Experimental

The i.r. spectra were recorded on a Beckman 20 i.r. Spectrometer either in chloroform solutions when the compound was a solid or as neat liquids. The n.m.r. spectra were run on a HA-100 Varian Spectrometer in deuterochloroform solutions, chemical shifts are given in δ p.p.m. values with TMS as internal reference. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6D Spectrometer at 70 eV. Analyses were performed in Organic Microanalyses laboratories (Dr. C. Daesslé) Montréal. Norbornene and norbornadiene were purchased from Aldrich company, and used without further purification. The silica gel used was purchased from Brinkman instru-

ments Canada: Merck silica gel 0.05–0.20 mm. Dimethyl phenyldiazomethylphosphonate: $C_6H_5C(N_2)P(O)(OCH_3)_2$ and dimethyl methyldiazomethylphosphonate $CH_3C(N_2)P(O)(OCH_3)_2$ were prepared according to Seyferth (11).

Cycloadditions

The general procedure was the following: mixtures of the diazo compound, the hydrocarbon (norbornene or norbornadiene) and methylene chloride were heated until complete disappearance of the yellow color of the diazo compound. The proportions used were as follows: (*1*) R = phenyl: *n* mmol of diazo, 10*n* mmol hydrocarbon, and *n* ml CH_2Cl_2, the mixtures were refluxed 3–4 days; (*2*) R = methyl: *n* mmol diazo, 60*n* mmol hydrocarbon, 4*n* ml CH_2Cl_2, about the 20 h reflux.

The adducts **3** and **6** were isolated by removal of the solvent and excess olefin by distillation. Compounds **4** and **5**, **7**, and **8** were separated by column chromatography. Yields are indicated in Table 1, physical constants and spectral data in Table 5.

Photolyses

Photolyses were conducted in a Srinivasan–Griffith reactor in benzene solutions using Vycor vessels, under nitrogen. There were two types of conditions: (*a*) "non-sensitized" photolyses were performed with a 3500 Å lamp using a Pyrex filter. (*b*) "sensitized" photolyses were performed with a 2537 Å lamp in the presence of benzophenone.

Experimental conditions are given in Table 6. Physical constants (m.p. and mass spectra) are given in Table 7. The duration of photolyses varied from 4 to 6 h, depending on the pyrazoline.

Anal. Calcd. for **9** and **10** (1:1 mixture): C, 65.60; H, 7.12; P, 10.36. Found: C, 65.74; H, 7.24; P, 10.10.

Anal. Calcd. for **16**: C, 57.89; H, 7.51; P, 13.57. Found: C, 58.14; H, 7.41; P, 13.32.

Compounds **11**, **12**, and **14** were correlated by hydrogenating the norbornadiene derivative into the norbornene derivative. Hydrogenations were carried out in a Parr hydrogenation apparatus for 2 h in methanol solutions in the presence of Pd/C at 2.7 atm. The yield was quantitative in each case and only one product was obtained.

Thus hydrogenation of compound **11** led to compound **9**, that of compound **12** to compound **10**, and finally compound **16** was transformed into compound **14**. Compounds **15**

NOTES

An Upper Bound to the Mole Fraction of Unbonded H_2O in Liquid Water at 25 °C

FABIO LENZI

Département de Génie Chimique, École Polytechnique, Université de Montréal, Montréal, Québec

Received October 19, 1971

Liquid water at 25 °C has been treated as a semi-ideal solution of relatively very volatile unbonded monomer dissolved in non-volatile hydrogen-bonded solvent. A mole fraction of less than 0.0016 has been found for unbonded water, in agreement with Stevenson's conclusion.

La notion que l'eau à l'état liquide à 25 °C peut être assimilée à une solution semi-idéale de monomère d'eau relativement très volatil dissout dans des fractions d'espèces liées (par liaisons d'hydrogène) et non-volatiles donne une limite supérieure de 0.0016 à la fraction molaire d'eau monomérique. Ceci est en accord avec les conclusions de Stevenson.

Canadian Journal of Chemistry, **50**, 1088 (1972)

Various estimates of the fraction of non-hydrogen-bonded (or less hydrogen-bonded species in two-state models not invoking monomeric water as such) species in liquid water have been listed (1–6). These range from values over 0.5 to 0.06 (4) to the very low values of monomer mole fraction contended by Stevenson (5). Levine and Perram (6) have calculated the mole fraction of monomeric water, x, between 273 and 373 °K according to different statistical-mechanical postulates. Their values of x at 273 °K lie between 0.054 and 0.0008.

It is assumed that monomeric or non-hydrogen-bonded water, if it could exist independently of other more hydrogen-bonded water species, would exert a vapor pressure p_0^* at least as large as that of liquid H_2S at the same temperature. At 25 °C the vapor pressure of H_2S is 15×10^3 Torr (7); whence the virtual or hypothetical vapor pressure of unbonded H_2O, p_0^*, would be at least 15×10^3 Torr and probably appreciably higher, since H_2O is lighter than H_2S, and liquid H_2S may itself be hydrogen-bonded to some extent.

Consider liquid water to be a semi-ideal solution[1] in the Dolezalek–Scatchard sense comprised of a relatively very volatile unbonded water fraction, x, dissolved in a relatively involatile hydrogen-bonded water solvent. Then at a given temperature the observed solution vapor pressure, p, mainly due to unbonded water, will be given by

$$p = p_0^* x$$

with p_0^* evaluated at the same temperature. Hence at 25 °C,

$$23.8 = (15 \times 10^3) x_{max}$$

where x_{max} is the maximum possible value of x since p_0^* is higher than the minimum 15×10^3 Torr assumed, and some of the observed 23.8 Torr may be due to H_2O molecules with some little hydrogen-bonding. Thus $x_{max} = 0.0016$.

This low figure for the fraction of completely unbonded H_2O molecules in liquid water at 25 °C supports Stevenson's conclusions (5) and some of Levine and Perram's models (6).

[1]Stokes and Robinson (8, 9) have successfully treated concentrated water–sucrose solutions semi-ideally; Crisci and Lenzi (10) have also interpreted kinetic data in aqueous H_2SO_4 and $HClO_4$ solutions up to 6 M in similar fashion.

Synthesis and Kinetic Behavior of Some *trans*-Diacidotetraamminerhodium(III) Complexes

A. J. POË[1] AND M. V. TWIGG

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received June 10, 1971

A greatly improved preparation of *trans*-dichlorotetraamminerhodium(III) chloride has been devised that makes use of *trans*-hydridoaquotetraamminerhodium(III) as an intermediate. The new complexes *trans*-$[Rh(NH_3)_4Br_2]Br$ and *trans*-$[Rh(NH_3)_4I_2]I$ have also been prepared. The kinetics of some reactions of the dichlorocomplex have been studied over a range of temperatures, and the rate parameters are compared with those for the reactions of the analogous *bis*ethylenediamine complex.

La préparation du chlorure du *trans*-dichlorotétraamminerhodium(III) a été très nettement améliorée par l'utilisation du *trans*-hydridoaquotétraamminerhodium(III) comme intermédiaire. Deux nouveaux complexes, le *trans*-$[Rh(NH_3)_4Br_2]Br$ et le *trans*-$[Rh(NH_3)_4I_2]I$ ont également été préparés. Les cinétiques de quelques réactions avec les complexes dichloro ont été étudiées sur une échelle de température et les paramètres de vitesse ont été comparés avec ceux pour les réactions de complexes analogues du *bis*éthylènediamine.

Canadian Journal of Chemistry, **50**, 1089 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The *trans*-diacido*bis*ethylenediaminerhodium(III) complexes can be prepared from $RhCl_3(H_2O)_3$ in moderately good yields by fairly straightforward methods (1, 2) and their kinetic and thermodynamic behavior has received detailed study (3, 4). By contrast, similar methods lead to yields as low as 7% when applied to the tetraammine analogues and very little is known of their behavior (2, 3).

Convenient reactions, involving hydride catalysis (5), lead to the production of *trans*-$[RhL_4Cl_2]^+$ in high yields when L = pyridine or substituted pyridines ($pK_a = ca.\ 5$), but this method does not work when L is a more basic ligand such as ammonia ($pK_a = 9$) because unreactive "rhodium hydroxide" is precipitated. However, salts of $[Rh(NH_3)_5H]^{2+}$ have recently been isolated (6) and, while they are stable in ammoniacal solution, the strong *trans*- labilizing effect of the hydride ion is demonstrated by the existence of the equilibrium

$$[Rh(NH_3)_5H]^{2+} + H_2O \rightleftharpoons [Rh(NH_3)_4(OH_2)H]^{2+} + NH_3$$

In this note we describe the use of $[Rh(NH_3)_5H]^{2+}$ as an intermediate in the preparation, in high yield, of the *trans*-dichlorotetraamminerhodium(III) complex as the chloride or perchlorate salt. This complex is a convenient starting point for the preparation of a wide variety of new *trans*-tetraamminerhodium(III) complexes. We have used it to prepare the new bromo and iodo analogues, and have also studied the temperature dependence of the kinetics of some of its reactions in order to compare its behavior with the corresponding *bis*ethylenediamine complex.

Experimental

A solution of the hydridopentaamminerhodium(III) complex was prepared by treating a suspension of $[Rh(NH_3)_5Cl]Cl_2$ (Johnson Matthey and Co. Ltd.) (0.92 g) in aqueous ammonia (2.3 ml concentrated ammonia in 3.0 ml water) with zinc dust (0.8 g) for 3.5 min at 50°. After removal of the excess of zinc and a little precipitated rhodium metal by filtration through sintered glass, the very pale yellow solution of hydridopentaammine was chilled in ice and made slightly acid (pH 6–7) by cautious addition of concentrated hydrochloric acid. This solution was warmed at 35° for 1 min, when a small amount of a dark precipitate formed. After chilling in ice and adding potassium chloride (1 g), the solution was made strongly acid ($pH \leq 1$) with concentrated hydrochloric acid. Hydrogen peroxide (0.5 ml 30%) was quickly added and a small amount of a yellow precipitate formed. The mixture was transferred to a beaker and boiled for 30 min with dilute hydrochloric acid (30 ml, 5 *M*) and filtered. A golden yellow precipitate formed and was collected and washed with ice cold water on a filter, the product being dried over 'Drierite'. Yield 0.66 g (76%).

solution darkened from yellow to orange whereupon another portion of sodium bromide (1 g) was added and the solution boiled for a further 4 h. On standing, the cooled solution (20 ml) deposited orange crystals of *trans*-$[Rh(NH_3)_4Br_2]Br$ and this was filtered on a sinter, washed with a little ice cold water, and dried over 'Drierite'. Yield, 0.22 g (65%).

Anal. Calcd. for $[Rh(NH_3)_4Br_2]Br$: N, 13.6; Br, 58.4. Found: N, 13.7; Br, 58.2.

trans-Diiodotetraamminerhodium(III) Iodide

(*a*) The procedure used for preparing the dibromo complex was followed exactly but with sodium iodide replacing sodium bromide. A dark red precipitate formed after the first period of boiling and increased in amount during the longer period of boiling. It did not dissolve after boiling the diluted reaction mixture (300 ml for 30 min) and it was collected on a sinter, washed well with water, and air dried. Analysis showed it to be $Rh(NH_3)_3I_3$. Yield, 0.13 g (28.8%).

Anal. Calcd. for $Rh(NH_3)_3I_3$: N, 7.86; I, 71.2. Found: N, 8.02; I, 71.1.

The filtrate was concentrated to *ca.* 25 ml and the red-brown crystals of *trans*-$[Rh(NH_3)_4I_2]I$ filtered off, washed with a little ice cold water, and dried over 'Drierite'. Yield, 0.21 g (71.1%).

Anal. Calcd. for $[Rh(NH_3)_4I_2]I$: N, 10.2; I, 69.0. Found: N, 10.4; I, 68.8.

(*b*) A solution of *trans*-$[Rh(NH_3)_4Cl_2]Cl$ (0.046 g) and sodium iodide (0.4 g) in water (8 ml) was heated to 90° in a foil-wrapped test tube for 3.5 h. The crystals of $[Rh(NH_3)_4I_2]I$ that formed on cooling were filtered off, recrystallized from a dilute solution of sodium iodide, and finally washed with ice cold water and dried over 'Drierite'. Yield, 0.065 g (71%). All of the product was soluble in water and the electronic absorption spectrum was identical with the analyzed product formed in (*a*) above.

Electronic Absorption Spectra

Spectra were measured with Cary 16 and Perkin–Elmer 402 spectrophotometers and the main features are reported in Table 1, together with previously reported spectra for the analogous ethylenediamine complexes.

Kinetics of Reactions of trans-$[Rh(NH_3)_4Cl_2]^+$

The reactions with bromide and iodide were followed spectrophotometrically, by means of a Perkin–Elmer 402 spectrophotometer, at 270 and 344 nm, respectively, absorbance changes of *ca.* one unit being observed during the course of the reactions. When the reaction with bromide was followed by scanning the complete spectrum repeatedly, isosbestic points at 417 and 376 nm were observed. The ionic strength was controlled by the concentration of sodium bromide or iodide used.

Results are shown in Table 2 together with activation parameters calculated by a least squares procedure in which all rate constants, including those from ref. 3, were assumed to have the same % of uncertainty. The uncertainties quoted are standard deviations after appropriate allowance for the number of degrees of freedom so that 95% confidence limits can be obtained by doubling the standard deviations. Corresponding parameters for the reactions of the analogous ethylenediamine complex were similarly estimated by combining the results in refs. 3 and 7 (Table 2).

Discussion

The preparation of the dichlorotetraammine-rhodium(III) complex depends on the formation of *trans*-$[Rh(NH_3)_4(H_2O)H]^{2+}$ on careful warming of a neutral or very slightly acid solution of $[Rh(NH_3)_5H]^{2+}$. Simple addition of chloride to aqueous solutions of $[Rh(NH_3)_5H]^{2+}$ leads to some reduction to metallic rhodium (8) and we find that addition of chloride to the hydridoaquo complex leads to extensive reduction. However, if acid peroxide solution is added quickly to a fresh solution of hydridoaquo complex, reduction does not occur and good yields of the dichloro substitution product are obtained. It seems possible that the substitution

[c]Reference 7.

process occurs via reduction to an unstable $[Rh(NH_3)_4]^+$ intermediate which undergoes rapid *trans* oxidative addition by chlorine from the strongly oxidizing $HCl–H_2O_2$ mixture.

Reaction of the *trans*-dichloro complex with bromide presumably occurs via a simple aquation process, and this is confirmed by the kinetic behavior (*vide infra*). Reaction with iodide in the light produces the neutral complex $Rh(NH_3)_3I_3$ in addition to the *trans*-diiodo complex, but this does not occur in the dark. Reactions of diacido*bis*ethylenediaminerhodium(III) complexes are known to be light catalyzed (9) and it has recently been shown (10) that irradiation of $Rh(NH_3)_5I^{2+}$ produces aquated iodoamminerhodium(III) complexes. Normal laboratory light is evidently inducing similar photochemical replacement of ammonia in our systems.

The electronic spectra of aqueous solutions of the $[Rh(NH_3)_4X_2]^+$ complexes (X = Cl, Br, I) are very similar to those of the known *trans*-$[Rh(en)_2X_2]^+$ analogues, and this confirms our assignment of a *trans*-configuration to the tetraammine complexes. In each case the position of the lowest energy transition in the visible or near u.v. region of the spectrum indicates, as expected (11), that the rhodium in the ethylenediamine complexes experiences a slightly larger ligand field than that in the corresponding ammine complex.

As with its *bis*ethylenediamine analogue (1, 7) the rates of reaction of the *trans*-dichlorotetraammine complex are unaffected by the nature or concentration of the ligand which eventually replaces the coordinated chloride, or by the ionic strength to the extent that that was varied. No intermediate mixed complexes are seen, and there is no sign of any *trans* → *cis* isomerization.

The rate of aquation of the *trans*-$[Rh(NH_3)_4Cl_2]^+$ is about twice that of *trans*-$[Rh(en)_2Cl_2]^+$ at all the temperatures used. Similar behavior has been found for analogous cobalt(III) complexes where rates decrease with increasing numbers of chelate rings. This is consistent with smaller hydration energies of more highly chelated complexes, and a consequent smaller gain in hydration energies during the charge separation as the chloride leaves the complex. It is also consistent with the greater loss of ligand field stabilization energy expected for complexes containing more highly alkylated amines (12). However, $[Rh(NH_3)_5OH_2]^{3+}$ undergoes anation by chloride almost twice as slowly as does *trans*-$[Rh(en)_2(NH_3)OH_2]^{3+}$ under similar conditions (4). Since the effect of L.F.S.E. should be the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

same for anation and aquation reactions this suggests that solvation is the more important factor, there being a *decrease* in solvation on forming the transition state in anation reactions. $\Delta H^{\ddagger}$ for *trans*-$[Rh(en)_2Cl_2]^+$ should, therefore, be higher than $\Delta H^{\ddagger}$ for *trans*-$[Rh(NH_3)_4Cl_2]^+$. The observed difference of 0.70 ± 0.69 kcal mol^{-1} allows this although the precision is unfortunately not sufficient to confirm it.

Epimerization of Monosaccharides in Acetic Acid and Acetic Anhydride. Synthesis of D-Altrose

WALTER SOWA
Department of Organic Chemistry, Ontario Research Foundation, Sheridan Park, Ontario

Received November 25, 1971

Acetolysis of 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose occurred with inversion at C-2 in a medium composed of acetic acid, acetic anhydride, and sulfuric acid. D-Altrose was isolated in 45% yield by deacetylation and chromatographic separation of the mixture of products. Unsubstituted D-allose did not epimerize under the same reaction conditions.

L'acétolyse du 1,2;5,6-di-*O*-isopropylidène-α-D-allofuranose se produit avec une inversion en C-2 dans un milieu composé d'acide et d'anhydride acétiques et d'acide sulfurique. On isole le D-altrose avec un rendement de 45% par la désacétylation et la séparation chromatographique du mélange de produits. Le D-allose non-substitué ne s'est pas épimérisé dans les mêmes conditions de réaction.

Canadian Journal of Chemistry, **50**, 1092 (1972)

There are a number of routes to the altrose configuration of carbohydrates (1). The most practical preparation of D-altrose currently employed involves the reaction sequence methyl 4,6-*O*-benzylidene-α-D-glucopyranoside, methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolysulfonyl-α-D-glucopyranoside, methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, methyl 4,6-*O*-benzylidene-α-D-altropyranoside, α-D-altropyranose pentaacetate, β-D-altrose (2). The present report describes a simple procedure for the preparation of D-altrose on a small scale. It consists of acetolysis of 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose, deacetylation of the reaction mixture, and chromatographic separation of the products, D-allose and D-altrose. The isomerization bears some resemblance to the neolactose synthesis of Hudson and co-workers (*cf.* 1) in which the D-glucose moiety of lactose octaacetate is converted to D-altrose under the influence of aluminum trichloride and phosphorus pentachloride in chloroform. The synthesis from 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose is based on

same for anation and aquation reactions this suggests that solvation is the more important factor, there being a *decrease* in solvation on forming the transition state in anation reactions. $\Delta H^{\ddagger}$ for *trans*-$[Rh(en)_2Cl_2]^+$ should, therefore, be higher than $\Delta H^{\ddagger}$ for *trans*-$[Rh(NH_3)_4Cl_2]^+$. The observed difference of 0.70 ± 0.69 kcal mol^{-1} allows this although the precision is unfortunately not sufficient to confirm it.

The authors are grateful to the National Research Council of Canada for partial support of this work.

Epimerization of Monosaccharides in Acetic Acid and Acetic Anhydride. Synthesis of D-Altrose

WALTER SOWA

Department of Organic Chemistry, Ontario Research Foundation, Sheridan Park, Ontario

Received November 25, 1971

Acetolysis of 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose occurred with inversion at C-2 in a medium composed of acetic acid, acetic anhydride, and sulfuric acid. D-Altrose was isolated in 45% yield by deacetylation and chromatographic separation of the mixture of products. Unsubstituted D-allose did not epimerize under the same reaction conditions.

L'acétolyse du 1,2;5,6-di-*O*-isopropylidène-α-D-allofuranose se produit avec une inversion en C-2 dans un milieu composé d'acide et d'anhydride acétiques et d'acide sulfurique. On isole le D-altrose avec un rendement de 45% par la désacétylation et la séparation chromatographique du mélange de produits. Le D-allose non-substitué ne s'est pas épimérisé dans les mêmes conditions de réaction.

Canadian Journal of Chemistry, **50**, 1092 (1972)

There are a number of routes to the altrose configuration of carbohydrates (1). The most practical preparation of D-altrose currently employed involves the reaction sequence methyl 4,6-*O*-benzylidene-α-D-glucopyranoside, methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolysulfonyl-α-D-glucopyranoside, methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, methyl 4,6-*O*-benzylidene-α-D-altropyranoside, α-D-altropyranose pentaacetate, β-D-altrose (2). The present report describes a simple procedure for the preparation of D-altrose on a small scale. It consists of acetolysis of 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose, deacetylation of the reaction mixture, and chromatographic separation of the products, D-allose and D-altrose. The isomerization bears some resemblance to the neolactose synthesis of Hudson and co-workers (*cf.* 1) in which the D-glucose moiety of lactose octaacetate is converted to D-altrose under the influence of aluminum trichloride and phosphorus pentachloride in chloroform. The synthesis from 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose is based on

the observation that monosaccharides with a *cis*-configuration at C-2 and -3 generally form a mixture of C-2 epimers in an acetolysis medium containing a high concentration of acetic acid (*ca.* 90%) (3). This *cis* to *trans* conversion was first noted by Jerkeman with D-mannofuranose derivatives (4).

1,2;5,6-Di-*O*-isopropylidene-α-D-allofuranose is readily available by oxidation of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose with dimethyl sulfoxide–acetic anhydride (5) followed by borohydride reduction of the intermediate keto-sugar (6). The D-allose derivative was treated at room temperature with an approximately 9:1 mixture of acetic acid and acetic anhydride containing sulfuric acid. After the reaction had proceeded for 24 h, the mixture was worked-up, deacetylated with triethylamine, and chromatographed on paper to obtain D-altrose in 45% yield. The ratio of D-altrose to D-allose, as estimated by preparative paper chromatography, was 1.4 to 1. With a longer reaction time of 89 h, the results were virtually unchanged; the yield of D-altrose was 41% and the D-altrose to D-allose ratio was 1.3 to 1. The high conversion of 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose to D-altrose supports the suggestion that the acetolysis-inversion reaction occurs via the furanose form of a monosaccharide in which a *cis*-orientation of groups is capable of assuming a *trans*-orientation through acetoxonium ion intermediates (3, 4).

Previous work has demonstrated that some unsubstituted pyranose sugars are transformed into their C-2 epimers by the "epimerization" mixture. Thus D-mannose gave D-glucose and D-mannose in 0.3 to 1 ratio while D-ribose yielded a 0.85 to 1 mixture of D-arabinose and D-ribose (3). When D-allose was treated in the same manner, only a trace amount of D-altrose was detected by paper chromatography. It is possible that the lack of reactivity shown by free D-allose is due to acetylation of the sugar in the pyranose form before significant tautomerization to the furanose form can occur.

Experimental

General

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were obtained with a Carl Zeiss photoelectric polarimeter Model 0.005° equipped with a sodium spectral light source. Chromatographic mobilities are quoted relative to D-glucose (R_G). Visualization reagents for paper chromatography were *p*-anisidine hydrochloride (7) and silver nitrate – sodium hydroxide (8).

Acetolysis of 1,2;5,6-Di-O-isopropylidene-α-D-allofuranose

1,2;5,6-Di-*O*-isopropylidene-α-D-allofuranose was prepared from 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose by the dimethyl sulfoxide – acetic anhydride and borohydride route described previously (5) except that the intermediate 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-3-hexulofuranose was crystallized as the hydrate (6, 9) to avoid chromatographic isolation of the product. Sulfuric acid (1.5 ml) was added to a stirred and cooled solution of the di-*O*-isopropylidene-D-allose (1.4 g) in acetic acid (30 ml) and acetic anhydride (4 ml). After 24 h at room temperature, the reaction mixture was poured into ice and water and the solution was extracted with chloroform. The chloroform extract was washed with saturated sodium bicarbonate solution and water, dried (Na_2SO_4), and evaporated to a syrup. This was deacetylated overnight in a mixture of methanol (20 ml), water (2.5 ml), and triethylamine (2.5 ml). The resulting mixture was evaporated to a syrup (0.945 g), one-half of which was separated on a sheet of Whatman 3MM paper (46 × 57 cm) in ethyl acetate – pyridine – water (8:2:1 v/v) to obtain D-allose (153 mg), $[\alpha]_D^{24}$ + 16.3° (*c* 4.6 in water), and D-altrose (216 mg), $[\alpha]_D^{24}$ +32.8° (*c* 3.5 in water). Reported specific rotations for D-allose and D-altrose are $[\alpha]_D^{20}$ +14° (*c* 1.3 in water) (10) and $[\alpha]_D^{20}$ +33° (*c* 4 in water) (2), respectively. The respective R_G values on Whatman No. 4 paper were 1.3 and 2.3. The D-altrose was characterized as its dibenzyl dithioacetal. The syrup (125 mg) was treated with trifluoroacetic acid (1.25 ml) and toluenethiol (0.125 ml) at room temperature for 5 h, the reaction mixture was evaporated to dryness, and the residue recrystallized from ethyl acetate and petroleum ether. The thioacetal had m.p. 119–120° and $[\alpha]_D^{24}$ + 39.8° (*c* 1.75 in pyridine). Literature values are m.p. 121–122° and $[\alpha]_D^{20}$ +39° (*c* 3 in pyridine) (2).

The recovered D-allose was characterized as the *p*-bromophenylhydrazone, m.p. 145–146°, reported value 145–147° (10). Another useful derivative of D-allose is the dibenzyl dithioacetal, prepared as above and crystallized from ethyl acetate. It has m.p. 108–109° and $[\alpha]_D^{24}$ −37.8° (*c* 0.4 in methanol).

Anal. Calcd. for $C_{20}H_{26}O_5S_2$: C, 58.51; H, 6.38; S, 15.63. Found: C, 58.44; H, 6.25; S, 15.41.

An acetolysis of 1,2;5,6-di-*O*-isopropylidene-α-D-allose was carried out for 89 h with other conditions unchanged. The dark-colored solution, after work-up, showed the presence of only D-allose and D-altrose by chromatographic examination. Preparative paper chromatography as before gave D-altrose in 41% yield and a 1.3 to 1 ratio of D-altrose to D-allose.

A sample of free D-allose (syrup, 500 mg) was treated with a mixture of acetic acid – acetic anhydride – sulfuric acid (15:2:0.75 v/v) for 24 h. After work-up of the reaction mixture in the usual manner, only a trace of D-altrose was detectable chromatographically.

The author is grateful to Mrs. Brigitte Licht for valuable technical assistance. The work was made possible by funds received from the Province of Ontario through the Department of Trade and Development.

Isothermal Compressibilities of Aqueous Solutions of Tetraalkylammonium Bromides

J. E. DESNOYERS AND P. R. PHILIP
Department of Chemistry, Université de Sherbrooke, Sherbrooke, Quebec

Received November 3, 1971

The standard isothermal apparent molal compressibilities, ϕ_K^0, of tetraalkylammonium bromides in water at 25° were calculated from known standard apparent molal adiabatic compressibilities, ϕ_{Ks}^0, expansitivites, ϕ_E^0, and heat capacities, ϕ_c^0. ϕ_K^0 is significantly different from ϕ_{Ks}^0 and depends mostly on the extrapolation procedure used to obtain ϕ_{Ks}^0 and on the precision of ϕ_E^0.

Les compressibilités isothermes apparentes molaires à l'état standard, ϕ_K^0, des bromures de tétraalkoylammonium dans l'eau à 25 °C ont été calculées à partir des valeurs apparentes molaires standards des compressibilités adiabatiques, ϕ_{Ks}^0, des expansitivités, ϕ_E^0, et des capacités calorifiques, ϕ_c^0. ϕ_K^0 diffère de façon appréciable de ϕ_{Ks}^0 et depend principalement de l'incertitude sur ϕ_E^0 et de la méthode d'extrapolation pour obtenir ϕ_{Ks}^0.

Canadian Journal of Chemistry, **50**, 1094 (1972)

The apparent molal volume ϕ_V of solutes is a useful function to characterize solute–solvent (1) and solute–solute interactions (2), especially with structured solvents like water. However, any interpretation of ϕ_V^0, the standard apparent molal volume at infinite dilution, must rely on some semi-empirical estimate of the intrinsic volume (1). In this respect, the study of the standard apparent molal expansitivities ϕ_E^0 or compressibilities ϕ_K^0 are most useful: if the ions are considered incompressible spheres, ϕ_E^0 and ϕ_K^0 depend only on ion–solvent interactions. For this reason, many recent studies (3–7) have been made on the compressibility of aqueous solutions.

It is not always easy to measure directly isothermal compressibilities β from which ϕ_K can be derived. Precise adiabatic compressibilities β_s are, on the other hand, easily accessible from sound velocity measurements (3), and they can be converted to isothermal compressibilities (in bars^{-1}) with the relation

$$[1] \qquad \delta = \beta - \beta_s = \frac{\alpha^2 T}{\sigma}$$

where α is the coefficient of thermal expansion (K^{-1}) and σ is the volumetric specific heat ($JK^{-1}\ cm^{-3}$). Unfortunately, α and σ are not always available as a function of concentration and the difference δ is often ignored in the interpretation of aqueous solutions. With alkali halides, δ is in fact small ($\sim 1\%$ of β), but this is not so with large organic salts like tetrabutylammonium bromide where Garnsey *et al.* (6) have shown that δ leads to differences between the isothermal and adiabatic apparent molal compressibilities, $\phi_K - \phi_{Ks}$, that are far from being negligible.

Precise heat capacity measurements of aqueous tetraalkylammonium bromides are now

Me_4NBr	0.111	109	−7.1	4.1	0.12	−3.1
Et_4NBr	0.132	388	−8.2	4.9	0.44	−3.7
n-Pr_4NBr	0.173	789	−11.8	6.4	0.89	−6.3
n-Bu_4NBr	0.255	1210	−23.3	9.5	1.37	−15.2
Ref.	9, 10	8	5			

available (8). Therefore, in view of the importance of these salts in the understanding of structural hydration effects, we have attempted to calculate the standard ϕ_K^0 from the available ϕ_{Ks}^0 (5, 6).

A simple relation between ϕ_K and ϕ_{Ks} can be derived if eq. 1 is combined with the basic apparent molal quantities (3)

$$[2] \qquad \phi_V = \frac{1000}{cd_0}(d_0 - d) + \frac{M}{d_0}$$

$$[3] \qquad \phi_E = \frac{1000}{c}(\alpha - \alpha_0) + \alpha_0\phi_V$$

$$[4] \qquad \phi_K = \frac{1000}{c}(\beta - \beta_0) + \beta_0\phi_V$$

$$[5] \qquad \phi_{Ks} = \frac{1000}{c}(\beta_s - \beta_{so}) + \beta_{so}\phi_V$$

$$[6] \qquad \phi_c = \frac{1000}{c}(\sigma - \sigma_0) + \sigma_0\phi_V$$

where c, d, and ϕ_c are the solution molarity, density, and apparent molal heat capacity respectively, and as usual the subscripts refer to the pure solvent. The difference $\phi_K - \phi_{Ks}$ is thus given by

$$[7] \qquad \phi_K - \phi_{Ks} = \frac{\delta}{\alpha}\left(1 + \frac{\alpha_0}{\alpha}\right)\phi_E - \frac{\delta_0}{\sigma}\phi_c + \left(\delta_0 - \frac{\delta\alpha_0}{\alpha}\right)\phi_V$$

At infinite dilution, eq. 7 reduces to

$$[8] \qquad \phi_K^0 - \phi_{Ks}^0 = \delta_0\left(\frac{2\phi_E^0}{\alpha_0} - \frac{\phi_c^0}{\sigma_0}\right)$$

This equation is equivalent to those of Harned and Owen (3), and of Garnsey *et al.* (6) (which has unfortunately been misprinted) but is much simpler in form.

The three parameters δ_0 (4.726×10^7 $bars^{-1}$), α_0 ($2.55 \times 10^{-4}\ K^{-1}$), and σ_0 ($4.1720 JK^{-1}\ cm^{-3}$) are known for pure water at 25 °C (4). The standard ϕ_c^0 are available for the tetraalkylammonium bromides (8) and are given in Table 1. The expansitivities ϕ_E^0 have been measured for the corresponding chlorides (9), but can be converted to the bromides, using the difference ϕ_E^0 (KBr) − ϕ_E^0 (KCl) = 0.032 $cm^3\ K^{-1}\ mol^{-1}$ derived from the data of Dunn (10), and these again are given in Table 1. It should be noted that the uncertainty on ϕ_E^0 is of the order of 10 to 20% with the tetraalkylammonium halides (9). Two sets of data exist for ϕ_{Ks}^0. Conway and Verrall (5) have plotted ϕ_{Ks} against $c^{1/2}$ and extrapolated to infinite dilution. This procedure implies that ϕ_{Ks} obeys Debye–Hückel's law which is true only at very low concentrations and may lead to some uncertainty in the extrapolated ϕ_{Ks}^0. On the other hand, Garnsey *et al.* (6) have estimated ϕ_{Ks}^0 directly from the variation of the sound velocity with concentration at low concentrations. This procedure in principle assumes that at low concentrations the solution is ideal and obeys Henry's law (no solute–solute interactions), which is certainly not the case in the concentration range studied. Even if they did use a correction term in $c^{3/2}$, this method of measuring ϕ_{Ks}^0 necessarily leads to an average value of ϕ_K at low concentrations. Since ϕ_{Ks}^0 is negative and $d\phi_{Ks}/dc^{1/2}$ is positive, the values of ϕ_{Ks}^0 of Garnsey *et al.* are all too positive; of course, this source of error is independent of the accuracy of the experimental data (not given), which may be superior to that of Conway and Verrall. In view of the better extrapolation procedure, the ϕ_{Ks}^0 of Conway and Verrall are taken as the most reliable and are given in Table 1.

As can be seen from Table 1, the main correction to ϕ_{Ks}^0 comes from the term in ϕ_E^0 and not in ϕ_c^0. Therefore, contrary to what is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

usually believed, accurate expansitivities and approximate heat capacities are needed to convert ϕ_{Ks}^0 to ϕ_K^0. In the present case, the error on ϕ_c^0 is negligible but that on ϕ_K^0 appreciable (10 to 20%) and this leads to a corresponding uncertainty on ϕ_K^0.

The present calculations confirm the observation of Garnsey *et al.* (6) that ϕ_K^0 and ϕ_{Ks}^0 are significantly different and this difference should not be overlooked when discussing properties of organic molecules in aqueous solutions. There is no reason why reliable methods (dilatometers for example) could not be developed to measure accurate expansitivities. Expansitivities, compressibilities and heat capacities are closely related properties (all related to the second derivative of the chemical potential) and should, whenever possible, be studied together.

It is also obvious that better extrapolation procedures should be devised; the limiting Debye–Hückel slope A_K should be estimated, either in terms of ϕ_K or ϕ_{Ks}, so that the data could be fitted with an equation of the type

$$[9] \qquad \phi_K = \phi_K^0 + A_K c^{1/2} + B_K c$$

where B_K would be an adjustable parameter related to deviations of the Debye–Hückel theory, like in the case of apparent molal volumes (2) and heat capacities (8).

We are grateful to the Defence Research Board of Canada for financial assistance.

Electron Spin Resonance of γ-Irradiated Acetylacetone in Adamantane Matrix

W. H. WOLODARSKY AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received November 15, 1971

Electron spin resonance spectrum is observed when samples of solid adamantane doped with acetylacetone are γ-irradiated at room temperature. The spectrum is interpreted due to an enolized allylic radical $CH_3COCHC(OH)CH_2$.

On observe un spectre de résonance paramagnétique électronique lorsque des échantillons d'adamantane solide contenant de l'acétylacétone sont irradiés avec des rayons-γ à la température de la pièce. On interprète le spectre à cause de la présence d'un radical allylique énolisé: $CH_3COCHC(OH)\dot{C}H_2$.

Canadian Journal of Chemistry, **50**, 1096 (1972)

Introduction

At room temperature liquid acetylacetone is known to exist largely (about (80%) in the enolized form $CH_3COCHC(OH)CH_3$ (1). Such enolization would be expected to influence the reactivity of acetylacetone. Thus Rutbi (2) has suggested the primary radical processes in the γ-radiolysis of acetylacetone in both the keto and enol forms:

$$[1] \qquad CH_3COCH_2COCH_3 \rightsquigarrow CH_3\dot{C}O + \dot{C}H_2COCH_3$$

$$[2] \qquad CH_3COCHC(OH)CH_3 \rightsquigarrow \dot{C}H_3 + CH_3C(OH)CH\dot{C}O$$

$$[3] \qquad CH_3COCH_2COCH_3 \rightsquigarrow H + \dot{C}H_2COCH_2COCH_3$$

However, on secondary reactions involving

usually believed, accurate expansitivities and approximate heat capacities are needed to convert ϕ_{Ks}^0 to ϕ_K^0. In the present case, the error on ϕ_c^0 is negligible but that on ϕ_K^0 appreciable (10 to 20%) and this leads to a corresponding uncertainty on ϕ_K^0.

The present calculations confirm the observation of Garnsey *et al.* (6) that ϕ_K^0 and ϕ_{Ks}^0 are significantly different and this difference should not be overlooked when discussing properties of organic molecules in aqueous solutions. There is no reason why reliable methods (dilatometers for example) could not be developed to measure accurate expansitivities. Expansitivities, compressibilities and heat capacities are closely related properties (all related to the second derivative of the chemical potential) and should, whenever possible, be studied together.

It is also obvious that better extrapolation procedures should be devised; the limiting Debye–Hückel slope A_K should be estimated, either in terms of ϕ_K or ϕ_{Ks}, so that the data could be fitted with an equation of the type

$$[9] \qquad \phi_K = \phi_K^0 + A_K c^{1/2} + B_K c$$

where B_K would be an adjustable parameter related to deviations of the Debye–Hückel theory, like in the case of apparent molal volumes (2) and heat capacities (8).

We are grateful to the Defence Research Board of Canada for financial assistance.

radicals abstracting H atom from acetylacetonate, Rutbi considered only the abstraction from the methyl group of the substrate in the keto form. On the other hand, Cadogen *et al.* (3) have concluded that the abstraction reactions involving the keto and the enol forms of acetylacetone are quite different:

[4] $(CH_3)_3C\dot{O} + CH_3COCH_2COCH_3 \rightarrow CH_3CO\dot{C}HCOCH_3$

[5] $(CH_3)_3C\dot{O} + CH_3COCHC(OH)CH_3 \rightarrow CH_3COCHC(OH)\dot{C}H_2$ *or* $\dot{C}H_2COCHC(OH)CH_3$

The exact configurations of the enol radicals have not been elucidated.

The present investigation reports the e.s.r. evidence that when a H atom is removed from acetylacetone during the γ-radiolysis in an adamantane matrix, the predominant radical resulting is the enol radical with a specific configuration of $CH_3COCHC(OH)\dot{C}H_2$.

Experimental

Acetylacetone (PCR Inc.) and adamantane (Aldrich *puriss* grade) were used as supplied. Further purification proved to be unnecessary. Small quantities of acetylacetone were introduced into the adamantane matrix by recrystallization of the solid from acetylacetone. Samples were filtered, dried, and irradiated in air at room temperature in a 19 000 Ci source of ^{60}Co γ-rays. The dose rate was approximately 1 Mrad/h and the total dose was 0.1 to 0.2 Mrad. Electron spin resonance spectra were obtained with an X-band Varian V4502 spectrometer using 100 kc modulation and auxiliary equipment. Microwave power and modulation amplitude were adjusted to avoid saturation.

Results and Discussion

The general usefulness of using adamantane as the trapping matrix (cavity–molecule isolation) in radiolysis systems to improve the resolution of e.s.r. spectra has been amply demonstrated (see, for example, ref. 4).

A typical room temperature e.s.r. spectrum recorded when samples of the acetylacetone doped adamantane were γ-irradiated is given in Fig. 1. The g-value of this radical measured with reference to DPPH ($g = 2.0036$) was $2.0039 \pm .0001$. The hyperfine pattern of the spectrum leads to the conclusion that there are two "equivalent" protons of splitting 14.5 ± 0.2 G and one proton of splitting 9.5 ± 0.2 G.

There are several possibilities that may account for the observed e.s.r. spectrum, but the

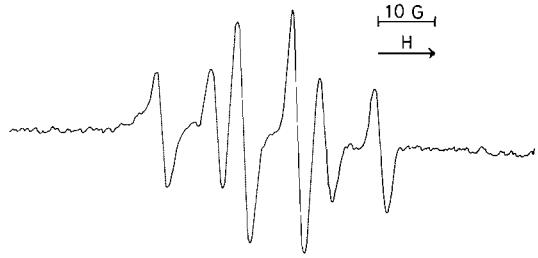

FIG. 1. The e.s.r. spectrum at room temperature from radicals trapped in an irradiated adamantane matrix containing acetylacetone.

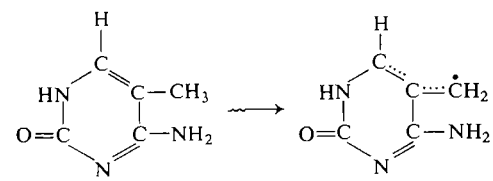
radicals $\cdot CH_2COCH_3$ and $\cdot CH_2CHO$ could be immediately disregarded on the basis of their reported splitting constants and hyperfine pattern (5, 6). The possibility was thus narrowed to one of the three radicals, $CH_3CO\dot{C}HCOCH_3$ (I), $CH_3COCHC(OH)\dot{C}H_2$(II), and $CH_3C(OH)$-$CHCOCH_2$(III). Radical I with six "equivalent" methyl protons was considered unlikely to be responsible for the observed spectrum. Of radicals II and III, the former would be more stable with an allyl type structure (7). Also radical II would be expected to have a relatively large splitting of the methyne proton due to the π-electron delocalization through the allyl type structure. Recently, Hutterman *et al.* (8) have observed e.s.r. spectra of a similar allyl-type radical during the γ-radiolysis of single crystals of 5-methylcytosine:

[6]



Their assignments of the two methylene protons ($a_H = 16.6$ G) and the methyne proton ($a_H = 7.7$ G) are consistent with an allyl-type radical as well as the radical II in the present system. Therefore, it is reasonable to assume that radical II is responsible for the observed e.s.r. spectrum.

The radical II was considered to be planar (9) and the small splitting of the hydroxy proton is not resolved experimentally. However, the reasons why the splitting from the methyl protons are not being observed can be better understood by considering other well-known

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

carbonyl-containing radicals such as the acetonyl $CH_3C\dot{O}CH_2$ (5) and the $HC\dot{O}CH_2$ (6) radical. With an allylic structure, radical II is expected to have appreciable spin density on the methyne carbon atom. Thus one can qualitatively consider radical II as a substituted acetonyl radical. Since the experimental hyperfine splitting for the methyl protons in the acetonyl radical is only 0.27 G (5), similar splittings in the radical II will be too small to be resolved in the present matrix study.

In conclusion, we interpreted the observed e.s.r. spectrum during the radiolysis of acetylacetone doped adamantane due to an enolized allyl radical $CH_3COCHC(OH)\dot{C}H_2$. The result suggests a specific and preferred site for the removal of a H atom from the predominant enol form of acetylacetone.

A Total Synthesis of *dl*-Occidol

TSE-LOK HO
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received October 6, 1971

dl-Occidol has been synthesized from 3,6-dimethylphthalic anhydride.

On a synthétisé le *dl*-occidol à partir de l'anhydride 3,6-diméthyl-phtalique.

Canadian Journal of Chemistry, **50**, 1098 (1972)

The major sesquiterpene alcohol found in the essential oil of *Thuja occidentalis* L. is *d*-occidol. The structure depicted as in **1** (without stereochemical implication) was elucidated by Hirose and Nakatsuka (1), and the absolute configuration (*R*) of the chiral center at C-7 was established by correlation with *l*-santonin (2).

The biogenetically unusual features of occidol have aroused our interests in its synthetic endeavors. *dl*-Occidol has been previously synthesized by Hirose and Nakatsuka, starting from 5,8-dimethyl-1-tetralone in six steps (3). Unaware of the details of this work, the present author sometime ago also completed a shorter synthesis from the same intermediate (4).

In this publication, a totally different synthetic approach is disclosed. Examination of the sesquiterpene framework clearly indicates that occidol is symmetrical except for the single chiral center (C-7). This structural characteristic offers great advantages in synthetic design and facilitates execution thereof.

In this context, one may envisage that the substituted *o*-quinodimethane **A** is the ideal intermediate for our purpose. It is also anticipated that **A** would be adequately reactive toward olefins in participating a Diels–Alder type reaction. Specifically, an acrylic ester serving as the reaction partner fits perfectly well in elaborating the desired bicyclic skeleton.

3,6-Dimethylphthalic anhydride (5) was reduced to the diol **2***a* with lithium aluminum hydride. Treatment of this diol with phosphorus tribromide and pyridine gave the dibromide **2***b*.

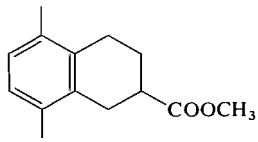
a X = OH
b X = Br



3

Generation of **A** from **2***b* was readily accomplished by reaction with activated zinc dust. In view of the expected reactivity of **A**, it was trapped *in situ* by methyl acrylate placed in the reaction vessel.

Alder and Fremery have reported cycloadditions between unsubstituted *o*-quinodimethane and a number of activated alkenes (6) to produce tetralin derivatives. The reaction may involve a [4 + 2] or an [8 + 2] process, both of which are thermally allowed on the basis of molecular orbital symmetry selection rules (7). A clear-cut case of [8 + 2] cycloaddition has appeared in the recent literature (8).

For the sake of convenience in isolating the ester **3**, the crude reaction mixture was saponified and the acidic material was re-esterified with diazomethane. Exposure of **3** to methyllithium in ether readily afforded *dl*-occidol. The synthetic compound is identical with natural *d*-occidol (kindly supplied by Dr. E. von Rudloff, Saskatoon) with respect to i.r., n.m.r., and t.l.c. properties.

Experimental

α^2,α^3-Dihydroxyprehnetene (2a)

To a stirred suspension of lithium aluminum hydride (1.80 g) in anhydrous ether (60 ml) was added a solution of 3,6-dimethylphthalic anhydride (2.50 g) in dry tetrahydrofuran (40 ml). It was heated under reflux for 18 h, cooled, and the excess hydride was cautiously destroyed by adding a saturated aqueous sodium sulfate solution. The granular suspension was filtered and the filter cake was leached with additional portions of tetrahydrofuran. Evaporation of the dried ($MgSO_4$) organic solution yielded the diol **2***a* (1.66 g, 70%); m.p. 62–64° (ether – petroleum ether); i.r. ($CHCl_3$) ν 3600, 3400 cm^{-1}; n.m.r. ($CDCl_3$) τ 7.60 (6H, s), 6.72 (2H, br.s), 5.20 (4H, s), 2.86 (2H, s).

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.30; H, 8.43. Found: C, 72.53; H, 8.38.

α^2,α^3-Dibromoprehnetene (2b)

To a solution of the diol **2***a* (390 mg) and pyridine (0.4 ml) in ether (15 ml) was added dropwise 0.5 ml of phosphorus tribromide. After stirring at room temperature for 18 h, the reaction mixture was poured into ice water and extracted with ether. Removal of the solvent from the dried ($MgSO_4$) extracts gave the dibromide **2***b* as colorless crystals (540 mg, 79%); m.p. 97–98° (petroleum ether); i.r. ($CHCl_3$) no OH absorption; n.m.r. (CCl_4) τ 7.63 (6H, s), 5.36 (4H, s), 2.95 (2H, s).

Anal. Calcd. for $C_{10}H_{12}Br_2$: C, 41.10; H, 4.11. Found: C, 41.37; H, 4.28.

Methyl-ester 3

A stirred mixture of the dibromide **2***b* (200 mg), methyl acrylate (2.0 ml), and $CuSO_4$–activated zinc dust (2.0 g) in dimethoxyethane (40 ml) was refluxed for 15 h. It was concentrated *in vacuo*, and digested with benzene and water. The gummy substance obtained from the benzene layer was directly saponified with sodium hydroxide (1.0 g) in 50% aqueous methanol (30 ml) for 2 h at reflux. The hydrolysate was diluted with water (50 ml), washed with benzene, acidified, and extracted with chloroform (3 × 25 ml). The combined extracts were dried ($MgSO_4$), treated with ethereal diazomethane, and evaporated to dryness. Chromatography over neutral alumina (5 g) yielded the ester **3** (31 mg, 20%) on elution with benzene and benzene–ether mixture (9:1). This product was identical with a specimen prepared by another route (4), b.p. 125–130° (0.8 mm Hg); i.r. ($CHCl_3$) ν 1730 cm^{-1}; n.m.r. ($CDCl_3$) τ 7.79 (6H, s), 6.25 (3H, s), 3.05 (2H, s).

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.06; H, 8.25. Found: C, 76.82; H, 8.38.

dl-Occidol (1)

A solution of ester **3** (1.1 g, 5.1 mmol) in ether (15 ml) was added slowly to methyllithium (20 ml, 1.2 *M* in ether) at room temperature and the reaction was allowed to proceed for 4.5 h before being poured into aqueous ammonium chloride. Extraction of the resulting mixture with ether (3 × 50 ml) and concentration *in vacuo* furnished a solid (1.1 g). Recrystallization of the product from petroleum ether yielded *dl*-occidol (668 mg, 60%); m.p. 99–100° (lit. (3) m.p. 101–102°); i.r. (CCl_4) ν 3620 cm^{-1}; n.m.r. (CCl_4) τ 8.78 (6H, s), 7.82 (6H, br,s), 3.13 (2H, s).

Introduction

Anhydronucleosides are important modifications of natural nucleosides. They are easily converted into either the natural ribo or sugar modified nucleosides (1, 2) and have also provided alternate synthetic routes to nucleotides (3–5). More recently a thioanhydropurine nucleoside has been used in studies of enzyme specificity (6).

While pyrimidine anhydronucleosides have received a great deal of attention (1), adenosine is the only purine nucleoside for which 8,2′- and 8,3′-anhydro derivatives have been extensively developed (2). Neither the *O* nor *S* 8,2′(8,3′)-anhydro derivatives of guanosine has been reported, although the 3′-methanesulfonate of 8,2′-*O*-anhydroguanosine has been described (7). We wish to report the synthesis of 8,2′-thioanhydroguanosine (**6**) which is readily converted to 2′-deoxyguanosine (7).

Results and Discussion

The synthesis of 8,2′-thioanhydroguanosine is outlined in Scheme 1. The 2-NH_2 group of 8-bromoguanosine (8) was protected with the dimethylaminomethylene group (9). The reaction between 8-bromoguanosine (**1**) and excess dimethylformamide dimethyl acetal gives 8-bromo-N^2-dimethylaminomethyleneguanosine (**2**) in 95% yield. Compound **2** was quantitatively converted to the 5′-monomethoxytrityl derivative **3**.

The essential step in the scheme is the introduction of a good leaving group on the 2′-position. Once this is achieved the 8,2′-thio bridge can be introduced in a single step (10).

The monomethoxytrityl group on the 5′-position screens the 3′-hydroxyl much more than it does the 2′-hydroxyl. As a result large sulfonating agents or triphenylmethyl chlorides react preferentially or exclusively at the 2′-position (10, 11).

For the above reasons we chose to react **3** with mesitylenesulfonyl chloride (MSCl). MSCl is a bulky sulfonating agent but one that does react with hydroxyl groups at a reasonable rate (12, 13). MSCl reacted with **3** in dry pyridine at room temperature for 2 days to produce **4***a* in 42% yield. Starting material **3** was also recovered (34%) from the reaction mixture. While others (10) using more basic conditions have detected small amounts of 3′-isomers from such reactions, we were unable to detect any **4***b*.[2] The structure of our product was confirmed as **4***a* by the subsequent steps which converted it into the 8,2′-thioanhydronucleoside **6** and 2′-deoxyguanosine (**7**).

Because we anticipated that N^2- and $O^{5'}$-protecting groups would be at least partially hydrolyzed during the step to form the anhydro-linkage, we decided to remove them completely before this step. The dimethylaminomethylene group was quantitatively removed from **4***a* using either a hydrazine hydrate solution (hydrazine hydrate : acetic acid : pyridine, 1 : 6 : 24) or ammonium hydroxide solution at room temperature. The monomethoxytrityl group was then removed using 80% acetic acid at room temperature for 3 h to produce 2′-mesitylenesulfonyl-8-bromoguanosine (**5**) in 77% overall yield from **4***a*.

To form the 8,2′-thioanhydro link, **5** was

[1]NRCC Scholarship Holder 1970–1971.

[2]Generally a 3′-substituted nucleoside moves more slowly than the 2′-isomer on silica gel t.l.c. (10, 14).

*Solvents described in General Methods (Experimental).

treated with sodium hydrogen sulfide in *N*,*N*-dimethylformamide. Using a six-fold excess of sodium mercaptan and a temperature of 70 °C for 20 h, a 16% yield of **6** was obtained. By increasing the temperature to 100 °C and using an 11-fold excess of sodium mercaptan the yield was increased to 40%.

Compound **6** was identified as 8,2′-thioanhydroguanosine (Table 1). Elemental analysis and the mass spectrum[3] of the tetrasilyl derivative (*m/e* 585) agreed with the assigned structure. Compound **6** was converted to 2′-deoxyguanosine (**7**) using Raney nickel. The synthetic 2′-deoxyguanosine was identical to authentic material (17) and is readily distinguished from 3′-deoxyguanosine (18, 19) by paper chromatography (Table 1).

Compound **7** was further characterized by acidic hydrolysis (20) to 2-deoxyribose which gave positive tests with Dische reagent (21) and cysteine – sulfuric acid reagent (22).

Experimental

General Methods

Descending paper chromatography was carried out on Whatman 3MM paper. The solvent systems employed were: solvent A, isopropyl alcohol – concentrated ammonium hydroxide – water (7:1:2); solvent B, ethanol–water (7:3). The solvents were prepared on a volume basis. Thin layer chromatography was carried out employing the ascending technique. All thin-layer chromatography was run on Eastman Chromagram Sheets 6060 (silica gel with fluorescent indicator) on strips 10 × 2 cm. Thick-layer chromatography was carried out on glass plates (20 × 20 cm) coated with a 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd). Nucleosides and their derivatives were detected on paper chromatograms, thin and thick-layer sheets, using an u.v. source (Mineralite output 254 nm). Compounds containing *p*-monomethoxytrityl groups were detected on chromatography by spraying with 10% perchloric acid solution and drying them in a stream of warm air.

The i.r. spectra were obtained on a Perkin–Elmer 337 recording spectrophotometer using KBr disks for sample preparation. The u.v. spectra were obtained on a Cary Model 14 recording spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6D instrument. Melting points were determined on a Fisher-Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tenn. Samples submitted to them were prepared by crystallization, lyophilization, or precipitation from tetrahydrofuran with hexane followed by heating in a drying apparatus over P_2O_5.

Reagent grade pyridine was distilled from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over Linde Molecular Sieve. Reagent grade *N*,*N*-dimethylformamide (DMF) was dried by distillation from calcium hydride and stored over Linde Molecular Sieve. 8-Bromoguanosine (m.p. 191–194 °C) was prepared by the method of Shapiro and Agarwal (8).

*N^2-Dimethylaminomethylene-8-bromoguanosine(**2**)*

8-Bromoguanosine (3.63 g, 10 mmol) and *N*,*N*-dimethylformamide dimethyl acetal (5 ml, 50 mmol) were dissolved in DMF (50 ml) and stirred at room temperature for 12 h. The solvents were removed at reduced pressure and the residue was crystallized from water to yield 3.99 g (96%) of **2** (m.p. 216–218 °C, R_f 0.19 (THF)). Principal bands in the i.r. spectrum occurred at 5.85, 8.95, 11.95, and 12.85 μ.

Anal. Calcd. for $C_{13}H_{17}N_6O_5Br$: C, 37.42; H, 4.11; Br, 19.15. Found: C, 37.69; H, 4.20; Br, 19.08.

*5′-O-Monomethoxytrityl-N^2-dimethylaminomethylene-8-bromoguanosine (**3**)*

Compound **2** (3.78 g, 9.1 mmol) and monomethoxytrityl chloride (3.16 g, 10.2 mmol) were dissolved in pyridine (15 ml) and the solution was stirred at room temperature for 24 h. The solution was then poured into ice water with vigorous stirring. A precipitate formed which was collected by filtration, washed with water, and reprecipitated from

[3]A detailed mass spectral analysis of thioanhydropyrimidines will be reported shortly (15). See also Ikehara and co-workers (16).

tetrahydrofuran using hexane. The resulting white solid (m.p. 158° (dec.)) was collected by filtration (6.17 g, 99%) and identified as compound **3**. The thin-layer chromatographic properties of the material were: R_f 0.05 (ethyl acetate) and 0.41 (tetrahydrofuran). Principal bands in the i.r. spectrum occurred at 5.9, 8.55, and 14.3 μ.

Anal. Calcd. for $C_{33}H_{33}N_6O_6Br$: C, 57.48; H, 4.82; Br, 11.59. Found: C, 57.60; H, 4.95; Br, 11.84.

*5′-O-Monomethoxytrityl-2′-O-mesitylenesulfonyl-N^2-dimethylaminomethylene 8-bromoguanosine (**4a**)*

Compound **3** (1.0 g, 1.45 mmol) and mesitylenesulfonyl chloride (0.63 g, 2.9 mmol) were dissolved in pyridine (5 ml) and the solution was stirred at room temperature for 48 h. The solution was poured into ice water and the precipitate was collected by filtration and dissolved in chloroform (100 ml). The chloroform solution was dried over sodium sulfate, concentrated to a small volume, and applied to five thick-layer plates. These plates were developed twice in ether followed by one development in tetrahydrofuran. Three nucleoside bands were present at R_f 0.72, 0.48, and 0.20. The band at R_f 0.20 was eluted from the plates with ethanol and upon evaporation of the ethanol 55 mg of compound **2** were obtained. The band at R_f 0.48 was eluted with tetrahydrofuran and upon evaporation of the solvent 340 mg of compound **3** were obtained. The band at R_f 0.72 was also eluted with tetrahydrofuran and yielded 530 mg (42%) of compound **4a** (m.p. 148–150 °C). The thin-layer chromatographic properties of **4a** were: R_f 0.19 (ethyl acetate) and 0.68 (tetrahydrofuran). Principal bands in the i.r. spectrum occurred at 5.9, 8.48, 8.55, and 14.2 μ.

Anal. Calcd. for $C_{42}H_{43}N_6O_8Br$: C, 57.86; H, 4.97. Found: C, 58.50; H, 5.04.

5′-O-Monomethoxytrityl-2′-O-mesitylenesulfonyl-8-bromoguanosine

Method A. Compound **4a** (200 mg, 0.23 mmol) was dissolved in 3 ml of a solution containing 85% hydrazine hydrate – acetic acid – pyridine (1:6:24) and the solution was stirred at room temperature for 24 h. The solution was poured into ice water and the precipitate was collected by filtration to yield after drying 181 mg (96%) of 5′-*O*-monomethoxytrityl-2′-*O*-mesitylenesulfonyl-8-bromoguanosine (m.p. 162 °C (dec.)). Thin-layer chromatography showed R_f values of 0.18 (ethyl acetate) and 0.60 (tetrahydrofuran). Principal bands in the i.r. spectrum occurred at 5.85, 8.40, 8.50, and 14.2 μ.

Anal. Calcd. for $C_{39}H_{38}N_5O_8Br$: C, 57.35; H, 4.69; Br, 9.78. Found: C, 57.73; H, 4.62; Br, 11.11.

Method B. The dimethylaminomethylene group could be removed in 98% yield by stirring **4a** in concentrated ammonium hydroxide for 24 h.

*2′-O-Mesitylenesulfonyl-8-bromoguanosine (**5**)*

5′-*O*-Monomethoxytrityl-2′-*O*-mesitylenesulfonyl-8-bromoguanosine (500 mg, 0.61 mmol) was stirred in 80% acetic acid (10 ml) for 3 h at room temperature. The solvents were removed at reduced pressure and the residue was dissolved in tetrahydrofuran (3 ml) and applied to three thick-layer plates which were developed in tetrahydrofuran. A nucleoside band appeared at R_f 0.40 and was eluted with tetrahydrofuran. The product was collected by precipitation with hexane followed by filtration to yield 274 mg (80%) of **5** (m.p. 183° (dec.)). Principal bands in the i.r. spectrum occurred at 5.85, 8.40, and 8.50 μ.

Anal. Calcd. for $C_{19}H_{22}N_5O_7Br$: C, 41.92; H, 4.07; Br, 14.68. Found: C, 42.20; H, 4.27; Br, 14.59.

*8,2′-Thioanhydroguanosine (**6**)*

Method A. Compound **5** (50 mg, 0.093 mmol) and 0.2 ml of a 40% solution of NaSH (1.25 mmol) and water were added to DMF (3 ml) and the solution was heated at 100 °C for 18 h. The solution was cooled and applied to Whatman 3MM paper developed in solvent A. Two nucleoside bands appeared at R_f 0.73 and 0.19. The band at R_f 0.73 was eluted with water which was lyophilized to yield 24 mg of **5**. The band at R_f 0.19 was also eluted with water and the aqueous solution was lyophilized to yield 11 mg (39%) of **6** (m.p. 268 °C (dec.)). The mass spectrum of the tetrasilyl derivative showed a parent peak at *m/e* 585. Principal bands in the i.r. spectrum occurred at 5.9, 6.55, and 12.0 μ.

Anal. Calcd. for $C_{10}H_{11}N_5O_4S$: C, 40.40; H, 3.73; N, 23.56. Found: C, 40.34; H, 3.99; N, 23.05.

Method B. The above procedure was repeated using a six-fold excess of NaSH and a temperature of 70° for 18 h. The yield of **6** was 16%.

*2′-Deoxyguanosine (**7**)*

Compound **6** (10 mg, 0.034 mmol) was dissolved in water (1 ml) and the solution was heated at reflux with Raney nickel for 3 h. The product, 2′-deoxyguanosine (m.p. 215 °C (dec.)) was isolated by paper chromatography in solvent A and was identical in all respects to an authentic sample (17).

The product was hydrolyzed (20) to 2-deoxyribose which gave positive tests with Dische reagent (21) and cysteine – sulfuric acid reagent (22).

A Convenient Synthesis of Propargylic Esters and γ-Keto Esters. The Reaction of Trialkynylboranes with Ethyl Diazoacetate, and the Unidirectional Hydration of Propargylic Esters

JOHN HOOZ AND ROBERT B. LAYTON[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 7, 1972

Trialkynylboranes react with ethyl diazoacetate to provide propargylic esters. The process occurs under mild conditions (−20°) and in good yields. Propargylic esters undergo unidirectional mercuric ion-promoted hydration to afford good yields of γ-ketoesters.

Les trialcynylboranes réagissent avec le diazoacétate d'éthyle pour conduire aux esters propargyliques. La réaction se fait dans des conditions douces (−20°) et avec de bons rendements. Les esters propargyliques subissent une hydration unique, provoquée par les ions mercuriques, pour conduire aux esters γ-cétoniques avec de bons rendements.

Canadian Journal of Chemistry, **50**, 1105 (1972)

Although exploration of the synthetic applications of trialkylboranes is an area of active burgeoning development (1), the chemistry of their triacetylenic analogs, in marked contrast, has been almost completely unexplored. Studies directed toward elucidating the organochemical synthetic potential of these interesting derivatives have understandably been hampered by their intrinsic instability. Since they decompose above *ca.* −30°, trialkynylboranes[2] are usually synthesized as (stabilized) amine complexes (eq. 1).

$$[1]\quad 3RC{\equiv}CNa + BF_3\cdot Py \xrightarrow{\text{Pyridine}} (RC{\equiv}C)_3B\cdot Py$$

We have prepared solutions of triacetylenic boranes *in the absence of amine donors*, and utilized these reagents for a convenient mild synthesis of propargylic esters. The requisite organoborane is easily obtained by treating a lithium acetylide (from a terminal alkyne and *n*-butyllithium) with boron trifluoride etherate in tetrahydrofuran solvent[3] at −20° (eq. 2). Subsequent reaction with ethyl diazoacetate

$$[2]\quad 3RC{\equiv}CLi + BF_3\cdot OEt_2 \xrightarrow[-20^\circ]{\text{THF}} (RC{\equiv}C)_3B$$

provides good yields of the corresponding propargylic ester after hydrolysis (eq. 3). The

$$[3]\quad (RC{\equiv}C)_3B + N_2CHCOOC_2H_5 \xrightarrow[-N_2]{\text{THF, }-20^\circ} \xrightarrow{H_2O} RC{\equiv}CCH_2COOC_2H_5$$

reaction proceeds readily at −20°, and organoborane decomposition does not seriously interfere, as indicated by the results summarized[4] by eqs. 4–7.

$$[4]\quad (n\text{-}C_4H_9C{\equiv}C)_3B \xrightarrow[(88\%)]{100\%} n\text{-}C_4H_9C{\equiv}CCH_2COOC_2H_5$$

$$[5]\quad (C_6H_5C{\equiv}C)_3B \xrightarrow[(92\%)]{100\%} C_6H_5C{\equiv}CCH_2COOC_2H_5$$

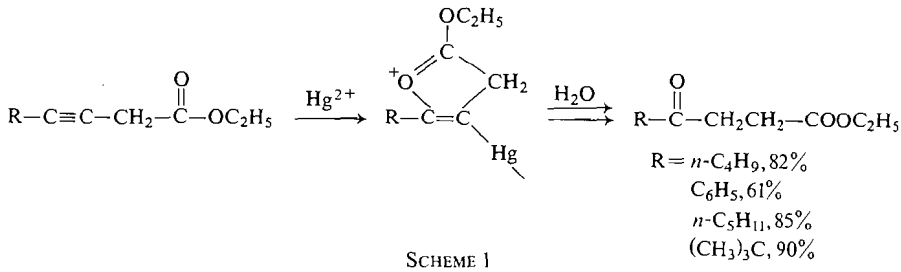
$$[6]\quad (n\text{-}C_5H_{11}C{\equiv}C)_3B \xrightarrow[(87\%)]{97\%} n\text{-}C_5H_{11}C{\equiv}CCH_2COOC_2H_5$$

[1]Holder of a 1967 Science Scholarship.

[2]Evidence for their existence has been obtained at −60°, but attempts at isolation, under a variety of conditions, have led only to polymeric products (2). Reviews on unsaturated organoboron compounds are available (3, 4).

[3]In view of the fact that tris(phenylethynyl)borane forms a complex with tetrahydrofuran (5), the trialkynylboranes described herein may exist as THF complexes. No studies have been made of this matter, and these species are depicted as if uncomplexed merely for convenience and simplification.

[4]Numbers above and below the arrows represent g.l.p.c. and (unoptimized) isolated yields, respectively. The molar ratio of organoborane: diazoacetic ester varied from 1:1.3 to 1:2.



SCHEME 1

[7] $((CH_3)_3C—C\equiv C)_3B \xrightarrow[(63\%)]{83\%} (CH_3)_3C—C\equiv CCH_2COOC_2H_5$

Since propargylic esters are usually prepared by a multi-step sequence (6), this method offers a convenient, high-yield, abbreviated approach to these intermediates.

Moreover, mercuric ion-promoted hydration of β,γ-acetylenic esters occurs in a directionally-specific manner to produce γ-ketoesters. No β-ketoester formation could be detected. Although mechanistic studies have not as yet been undertaken, this regiospecific hydration may be

$$R—C\overset{Hg^{2+}}{\equiv}C—CH_2—COOC_2H_5$$

A

the ultimate outcome of an initial alkyne-Hg^{++} complex (**A**) leading to the more stable γ-carbonium ion as a consequence of the inductive (or field effect) exerted by carboethoxy.

Alternatively, regiospecificity may be the manifestation of carbonyl oxygen participation which results in formation of the more geometrically favorable five-membered ring.[5] Scheme 1 depicts this view, as well as isolated yields.

It is clear, however, that irrespective of which factor prevails, the present development provides a unique uncomplicated route to this class of compounds.[6]

However, in this propargylic ester synthesis, as in other organoborane-diazo reactions (9), only one organic moiety is utilized. In an attempt to circumvent this inherent difficulty, we briefly explored the reaction of dibutylheptynylborane[7] with ethyl diazoacetate in the hope of achieving selective migration of the alkynyl group. Surprisingly, the only ester product formed was ethyl hexanoate. This represents an interesting contrast to the behavior of the congeneric alanes, $R_2AlC\equiv CR$, which, in a variety of reactions, selectively transfer the ligand possessing the highest degree of *s*-character (11). We are continuing to explore the ramifications of these developments.

The experimental procedure is illustrated for the methylenecarbethoxylation of 1-heptyne, and the hydration of ethyl 3-nonynoate. To a solution of lithium 1-heptyne (from 1-heptyne (30 mmol) in 26 ml tetrahydrofuran and *n*-butyllithium[8] (30 mmol)) held at *ca.* $-20°$ was added, gradually, a solution of boron trifluoride etherate (40 mmol). The resulting solution was stirred an additional 0.5 h at *ca.* $-20°$, and a solution of ethyl diazoacetate (1.46 g, 12.8 mmol) was slowly added. After stirring for 1.5 h, water was added, the mixture stirred (*ca.* 20 min), then poured into ice water (200 ml). The aqueous phase was extracted with ether (three 30-ml portions) and the combined organic extract was dried (Na_2SO_4). The g.l.p.c. analysis indicated a 97% yield of ethyl 3-nonynoate. Solvent was removed *in vacuo* (rotary evaporator), and the crude residue was distilled to afford 1.44 g (87%) of ethyl 3-nonynoate, b.p. 90–91° (2.5 mm); n_D^{22} 1.4440; i.r. (liquid film) 1735 cm^{-1}; n.m.r. (τ, $CDCl_3$) 5.75 (2H, q, OCH_2CH_3), 6.70 (2H, t, $CH_2C{=}O$), 7.80 (2H, m, $CH_2CH_2C\equiv C$), 8.30–8.80 (6H, m, $(CH_2)_3$), 8.69 (3H, t, CH_3CH_2O), 9.09 (3H, t, $CH_3(CH_2)_3$); mass spectrum (70 eV) M^+ 182.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95. Found: C, 72.52; H, 9.76.

A mixture of ethyl 3-nonynoate (5.6 mmol),

[5]This possibility is analogous to proposals advanced to account for the unidirectional hydration of γ-ketoacetylenes (7).

[6]A variety of other approaches has been summarized (8).

[7]Prepared by reaction of dibutylboron bromide (10) with lithium 1-heptyne.

[8]A solution of *n*-butyllithium in hexane, obtained from Alfa Inorganics, Inc., was employed.

Densities, Excess Volumes, Surface Tensions, Viscosities, and Dielectric Constants of the Systems: Methanol–Cyclohexane, Acetone–Methanol, Acetone–Cyclohexane, and Methanol–Cyclohexane–Acetone

A. N. CAMPBELL AND S. C. ANAND

Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received October 7, 1971

The density, dielectric constant, change of volume on mixing, refractive index, surface tension, and viscosity of the methanol–cyclohexane system have been investigated experimentally at temperatures ranging from 25° to 50°. The same properties of the binary systems acetone–methanol and acetone–cyclohexane, as well as of the ternary system methanol–cyclohexane–acetone were determined experimentally at 25°. The critical region of the partially miscible system methanol–cyclohexane has been investigated by determining the above physical properties at temperatures above and below the critical solution temperature. A similar investigation of the ternary system has been made, isothermally at 25°, by investigating solutions lying in the neighborhood of the plait point.

The surface tension or a derived function of it, *viz.* the molecular surface energy, does not show a horizontal portion of the isotherm in the methanol–cyclohexane system, but the ternary system does show such a constant surface tension, probably fortuitously, all along the tangential line. The viscosity exhibits anomaly.

All the systems show azeotropic behavior. The methanol–cyclohexane and acetone–cyclohexane systems show marked deviations in molar polarization from linearity and this agrees with the thermodynamic data, which indicate larger than unity values for the activity coefficients of the components' behavior (1). The viscosity isotherms of all these systems give no indication of the formation of any stable compound.

On a étudié expérimentalement la densité, la constante diélectrique, le changement de volume au cours du mélange, l'indice de réfraction, la tension superficielle et la viscosité du système méthanol–cyclohexane à des températures allant de 25° à 50°. On a déterminé expérimentalement à 25° les mêmes propriétés des systèmes binaires: acétone–méthanol et acétone-cyclohexane, de même que celles des systèmes ternaires méthanol–cyclohexane–acétone. La région critique du système partiellement nuisible: méthanol–cyclohexane a été étudiée en déterminant les propriétés physiques citées plus haut, au-dessus et en bas de la température critique de la solution. Une enquête similaire sur les systèmes ternaires a aussi été faite, isothermiquement à 25°, en étudiant des solutions se trouvant au voisinage du point d'inflexion.

La tension superficielle ou une fonction dérivée, l'énergie moléculaire superficielle ne montre pas de partie horizontale de l'isotherme du système méthanol–cyclohexane, mais le système ternaire montre une tension superficielle constante, probablement fortuitement, le long de la ligne tangentielle. La viscosité est anormale.

Tous les systèmes ont un comportement azéotropique. Les systèmes méthanol–cyclohexane et acétone–cyclohexane démontrent des déviations marquées de polarisation molaire de la linéarité et ceci condorde avec les données thermodynamiques, qui indiquent des valeurs plus grandes de coefficients d'activité des composés (1). Les isothermes de viscosité de tous les systèmes ne donnent aucune indication sur la formation d'un composé stable.

Canadian Journal of Chemistry, **50**, 1109 (1972)

Introduction

The general purpose of a series of papers of which the present makes one is to investigate physical properties in the immediate neighborhood of the critical states, $L \rightleftarrows V$, and $L_1 \rightleftarrows L_2$. Homogeneity can be attained in both the above types by working at a temperature slightly above (or occasionally, slightly below) the critical temperature or the critical solution temperature, respectively. The region is of interest because the structure is colloidal or semi-colloidal, as is obvious from the scattering of light. Thermo-

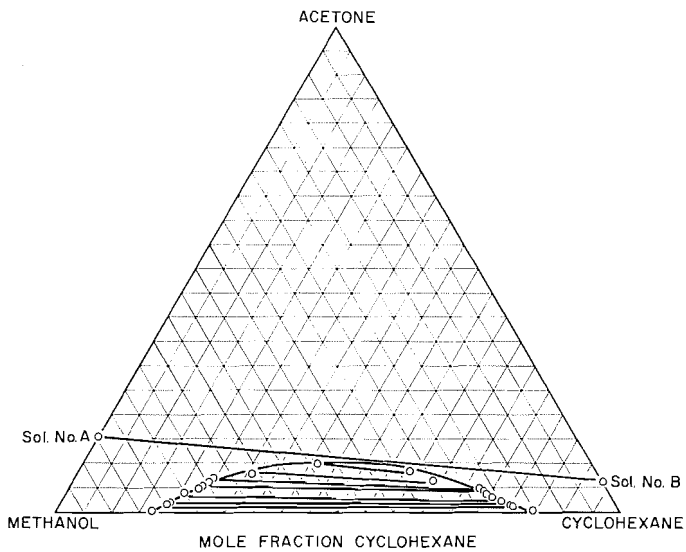

FIG. 1. Binodal curve data for the ternary system: methanol–cyclohexane–acetone at 25 °C.

dynamics requires that certain properties of consolute solutions be identical. The question arises of whether solutions of the same composition retain this identity slightly above the critical temperature. It has been suggested that this identity, *e.g.* of vapor pressure, is thermodynamically necessary for a range of temperature above the critical point, but this view now seems to be more or less abandoned. In fact, we have shown that for various systems, though identity is hard to prove, close similarity does persist above the critical temperature.

In the case of the equilibrium $L_1 \rightleftarrows L_2$, it is possible to study the physical properties isothermally by adding sufficient of a third component to render the system homogeneous. For this purpose we have invariably used acetone. In all the systems we have studied, a very little acetone was sufficient to produce homogeneity. Nevertheless, the two-component system has now become a three-component system and it becomes necessary to study not only the three-component system as such, but also the three binary systems of which it is composed. For obvious reasons, the partially miscible binary system merits attention, but so do the two binary systems involving acetone, since these may or may not be ideal. Only after this work has been completed is it possible to proceed to the investigation of the pseudo-binary system represented by solutions lying on the straight line tangential to the binodal curve (Fig. 1).

In a previous paper (1) we have dealt with the most important thermodynamic properties, *viz.* vapor pressure and heat of mixing. The properties now studied were taken more or less at random and in accordance with apparatus at our disposal. Some are rate processes and there is no *a priori* reason to suppose that any of them should be identical for different concentrations, even in the heterogeneous region. Thus, for example, it is not thermodynamically necessary that the surface tensions of two layers in equilibrium should be identical. It is, however, experimentally true in the majority of cases, that these physical properties change only slowly over the range of composition corresponding to the miscibility gap (at room temperature). Our numerical data for density, surface tension, viscosity, refractive indices, and dielectric constant, of the pure liquids, of the binary systems, and of the ternary system, are all to be found in the Depository of Unpublished Data, but for precise details of our experimental methods, reference should be made to ref. 3 and to previous publications (1, 2).[1]

Discussion of Results

Pure Liquids

Density and Surface Tension

For cyclohexane the average value of the temperature coefficient of density, dd/dt, is 0.0009 per deg, between 25° and 50°. For what it is worth, the parachor value is 240.61 ± 0.26, as against a calculated value (from atomic parachors) of 240.10. For methanol, the average value of the temperature coefficient of density, dd/dt is 0.00094 per deg, between 25° and 50°. The parachor value of methanol is 88.25 ± 0.18, as against a calculated value of 93.20 (or 92.0, depending on the values assigned to the atomic parachors). If any faith is to be placed in the parachor, the results indicate that cyclohexane is practically an inert solvent and methanol highly associated (4). The parachor value of methanol increases slightly with rising temperature, indicating a decrease in the degree of association with rising temperature.

Viscosity

Of numerous viscosity–temperature relations that we tested for cyclohexane, that of deGuzman (5) was found to be the best. The equation is

$$\eta = A.e^{E/RT}$$

where E is a positive constant, called the viscous heat. The average values of the constants A and E are 5.408×10^{-3} and 3024.5, respectively. The calculated viscosities obtained from this equation agree with the experimental values with an accuracy of 0.75%. DeGuzman's equation, however, fails entirely to apply to methanol: it is said that deGuzman's equation does not apply to polar liquids (6, 7).

An equation proposed by Bingham (8) was found the best for reproducing the experimental values for methanol:

$$T = A/\eta + C - B\eta$$

where η is the viscosity, T is the temperature in absolute degrees, and A, B, and C are constants. The average values of the constants A, B, and C are 31.414, 10.944, and 246.401, respectively. By means of this equation, the experimental values are reproduced with an accuracy of $\pm 0.50\%$,

Pelofsky (9) has related viscosity to surface tension (λ) by the following equation:

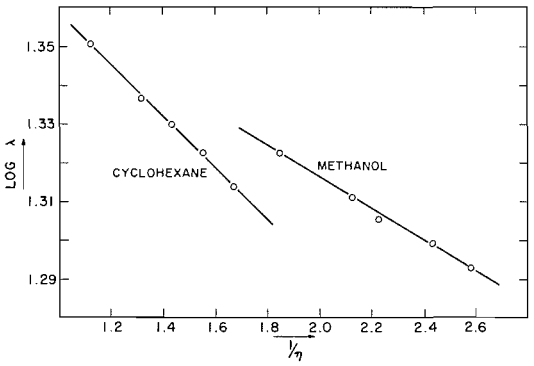

FIG. 2. Plot of logarithm of surface tension *vs.* reciprocal of viscosity for cyclohexane and methanol at different temperatures.

$$\lambda = A \exp B/\eta$$

where A and B are dimensionless constants. Plots of $\log \lambda$ *vs.* $1/\eta$ at 25°, 35°, 40°, and 50°, do indeed give straight lines, as the above equation requires, for cyclohexane and methanol (Fig. 2).

Binary and Ternary Systems

Excess Volumes

The excess volume is positive for all systems, except acetone–methanol, where it is slightly negative; in other words, for all systems except acetone–methanol there is an expansion on mixing the constituents. With acetone–methanol there is a very slight contraction. The expansion is greatest for the acetone–cyclohexane system. It is easy to explain the expansion as due to depolymerization of an associated liquid, but the slight contraction with acetone–methanol is not so easy to account for: contractions are usually associated with complex formation.

Viscosity and Dielectric Constant

There is neither maximum nor minimum on the viscosity isotherms of the binary systems, at 25°. According to Bamelis *et al.* (10) and Liler and Kosabovic (11), such viscosity isotherms are characteristic of those systems in which no addition compounds or compounds of low stability only are formed. The main factor, however, producing a viscosity isotherm of this shape is probably the disruption of the structure of polar liquids, such as methanol and acetone by the addition of cyclohexane.

The molar polarization, P' is defined by

$$P' = \frac{X_1M_1 + X_2M_2}{d_{\text{mixt}}} \cdot \frac{E-1}{E+2}$$

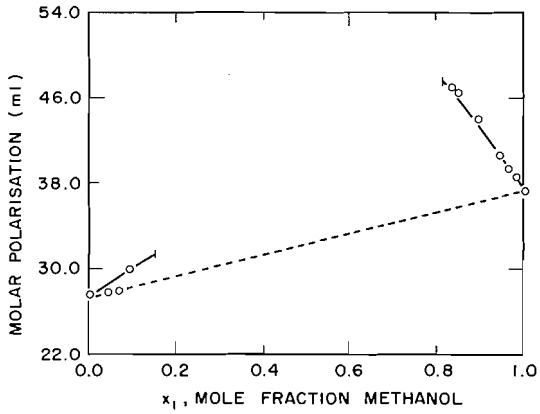

FIG. 3. Molar polarization of the methanol–cyclohexane system at 25 °C.

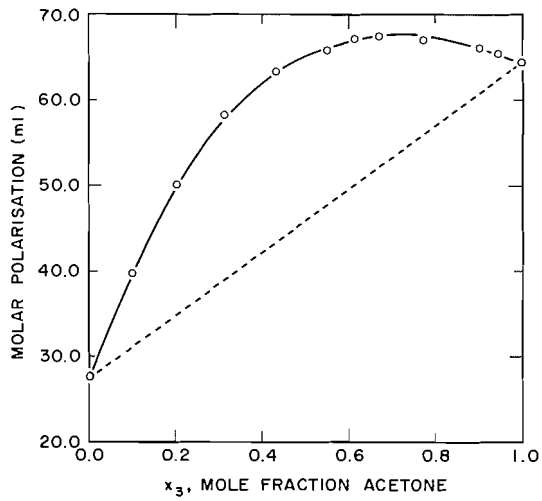

FIG. 4. Molar polarization of the acetone–cyclohexane system at 25 °C.

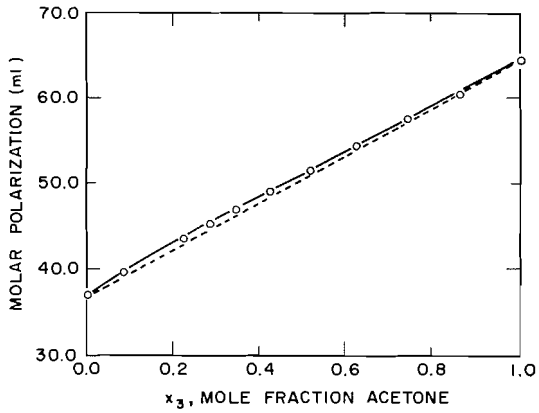

FIG. 5. Molar polarization of the acetone–methanol system at 25 °C.

where E is the dielectric constant and d the density of the mixture.

The distortion polarization is given by

$$P_d = \frac{n^2 - 1}{n^2 + 2} \cdot \frac{X_1 M_1 + X_2 M_2}{d_{mixt}}$$

where n is the refractive index.

Syrkin (12) proposed the following formula for orientation polarization,

$$P_i = \frac{P' - X_1 R_1 - X_2 R_2}{1 - \left(\frac{E-1}{E+2}\right)^2}$$

where P' is the molar polarization and R_1 and R_2 are the molar refractions of the pure components. The molar polarizations are represented graphically in Figs. 3, 4, and 5. All the graphs show positive deviation from linearity, that of methanol–cyclohexane being the greatest, followed by that of acetone–cyclohexane and again by that of acetone–methanol, where the deviation is very slight. This agrees with the observation of Campbell and Kartzmark (13, 14) that strong positive deviation from additivity in molar polarization is an indication of tendency towards formation of a miscibility gap. The statement of Campbell and Kartzmark received further support from the thermodynamic data as the activity coefficients of these systems show similar behavior (1).

When the Syrkin orientation polarization is plotted *vs.* mole fraction, a straight line is said to be obtained in the ideal case. Positive deviation indicates the existence of hydrogen bonding between the components. Negative deviation indicates dipole association, dipole-induced dipole interactions or there is a decrease in hydrogen bonding with dilution. The acetone–cyclohexane system shows negative deviation from additivity. The methanol–cyclohexane and acetone–methanol systems show both positive and negative deviations from additivity. The acetone–methanol system shows positive deviation at concentrations less than 0.52 mole fraction acetone and negative deviation at concentrations greater than 0.52. Thus, at higher concentrations of methanol some interaction may take place between methanol and acetone, while at higher concentrations of acetone, the methanol dissociates. As mentioned above, the

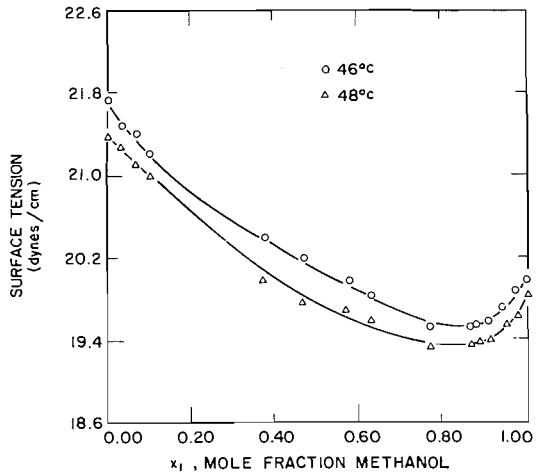

FIG. 6. Surface tension of the methanol–cyclohexane system near the critical solution temperature.

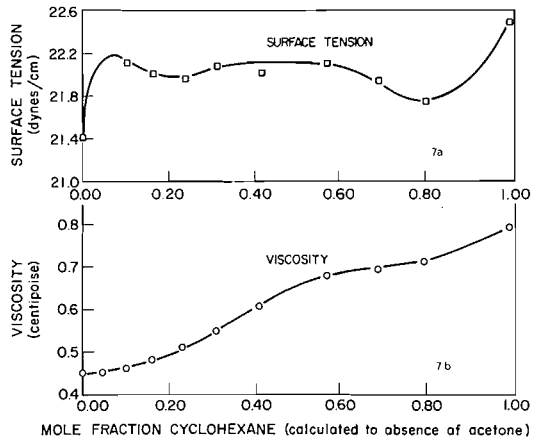

FIG. 7. Viscosities (*b*) and surface tensions (*a*) of such compositions of the ternary system: methanol–cyclohexane–acetone as lie on the tangential line AB (as shown in Fig. 1), and calculated to absence of acetone.

viscosity isotherm gives no indication of the formation of a stable addition compound.

Properties in the Neighborhood of the Critical Solution Temperature

Surface Tension for the Methanol–Cyclohexane System

The results are expressed graphically in Fig. 6 at two temperatures just above the critical solution temperature. For this system there is no temperature for which an isotherm has a range of constant surface tension, neither does thermodynamics require that this should be so. According to Hildebrand and Scott (15), systems showing large positive deviations from Raoult's law give rise to a minimum on the surface tension diagram. This is exemplified by the methanol–cyclohexane diagram which shows large positive deviations from Raoult's law, as well as partial miscibility. The molecular surface energy of cyclohexane is higher than that of methanol. This may indicate that the intermolecular forces between cyclohexane molecules are greater than those between methanol molecules.

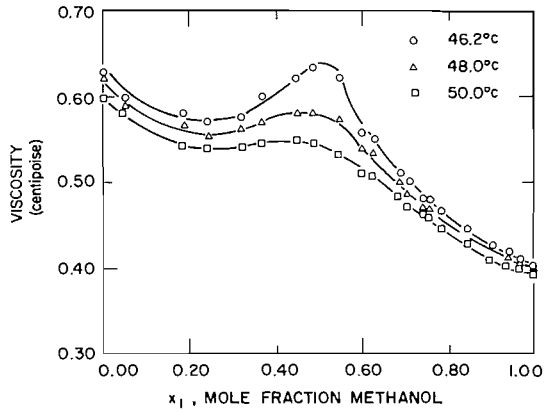

FIG. 8. Viscosity of the methanol–cyclohexane system near the critical solution temperature.

The isothermal (25°) data for such compositions of the ternary system: methanol–cyclohexane–acetone, as lie on the tangential line AB of Fig. 1, are plotted in Fig. 7*a*. The data are calculated to absence of acetone.

The graph indicates that over the critical range of composition and within the limits of experimental error, the surface tension may well be constant. This, however, may be accidental since the surface tensions of the parent solutions A and B differ but little.

Viscosity

As shown in Fig. 8 the anomalous increase in viscosity above the critical solution temperature extends over a considerable range of concentration, *viz.* 0.32 to 0.62 mole fraction methanol, in the methanol–cyclohexane system. This region agrees with the coexistence data of Campbell and Kartzmark (16). The magnitude of the anomalous increase in viscosity is of the order of 15 to 25%, near the critical solution temperature and critical composition. Various theories of viscosity near the critical solution temperature (17–20) explain this anomalous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

increase in viscosity as due to the colloidal structure of the mixture near the critical solution temperature and this colloidal solution is idealized as a continuous medium, in which composition, density, and local viscosity all vary from point to point and are also time dependent.

Figure 7*b* shows the viscosity behavior of the ternary solutions in the neighborhood of the plait point. The viscosity varies more or less continuously with cyclohexane content, except that a small region of anomalous viscosity may be said to exist between 35 and 75 mol% cyclohexane.

The general conclusions of this part are: (*1*) the rule of Campbell and Kartzmark, *viz.* that systems showing strong positive deviation from additivity in molar polarization, exhibit partial miscibility, either at room temperature or some other temperature is confirmed. (*2*) In the pseudo-binary section of the ternary system, the surface tension is constant over the critical range, although there is no apparent reason for this. (*3*) The viscosity plot is, as always, anomalous over the critical range.

Kinetics of the Mercury-Photosensitized Decomposition of Neopentane. Part I. The Overall Mechanism

E. FURIMSKY and K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa K1N 6N5, Canada

The mercury-photosensitized decomposition of neopentane was investigated from 230 to 335 °C, and at pressures from 3 to 280 Torr. The following were identified as primary products and their initial rates of formation measured over a range of conditions: H_2, CH_4, C_2H_6, i-C_4H_8, neohexane and dineopentyl. The results are explained in terms of a mechanism in which the primary step involves the split of neopentane (Nptn) into the neopentyl radical (Nptl) and H; Nptl then undergoes further reactions including a split into i-C_4H_8 + CH_3. Estimates are made of the free-radical concentrations at various temperatures and pressures. A simplified steady-state treatment is worked out and is shown to explain the pressure dependence of the rates of formation of the various primary products.

On a étudié la décomposition photosensibilisée au mercure du néopentane de 230 à 335 °C, à des pressions de 3 à 280 Torr. Les composés suivants ont été identifiés comme étant des produits primaires et leurs vitesses initiales de formation ont été mesurées dans un domaine de conditions: H_2, CH_4, C_2H_6, i-C_4H_8, néohexane, et dinéopentyl. On a expliqué les résultats en termes d'un mécanisme dans lequel l'étape primaire implique la dissociation du néopentane (Nptn) en radical néopentyl (Nptl) et H; Nptl réagit encore, notamment il se dissocie en i-C_4H_8 + CH_3. On a fait l'estimé des concentrations en radical libre à différentes températures et pressions. On a aussi développé un calcul d'état stationnaire et on a montré qu'il explique l'influence de la pression sur les vitesses de formation des différents produits primaires.

Introduction

The method of photosensitization provides a valuable means of generating free radicals and of studying their subsequent reactions. Recent investigations in this laboratory have been concerned with the mercury-photosensitized decompositions of ethane (1), dimethyl ether (2–5), and propane (6, 7), the object being to obtain reliable kinetic parameters for the decompositions of the radicals produced, and to study the behavior over a range of pressures.

The present investigation is concerned with the mercury-photosensitized decomposition of neopentane. The present paper (Part I) is concerned with the experimental methods and results, and with an interpretation of the overall behavior as far as primary products are concerned. Conclusions about the kinetics of reactions of the neopentyl and methyl radicals, especially relative to pressure dependence, are described in the following paper (Part II). Part III is concerned with the kinetics and mechanisms of formation of the secondary products.

Several previous investigations have been concerned with the mercury-photosensitization of neopentane. In an early study Darwent and Steacie (8) established the main course of the reaction, but their measurements were necessarily made at fairly high conversions, so that there were complications due to secondary reactions. In addition, since their mercury saturator was at 20 °C, it is likely that the work was done under conditions of light inhomogeneity; the problems arising from this have been stressed by Loucks and Laidler (2). Their work indicated a very small quantum yield for H_2 production (*e.g.* 0.004 at 25 °C), and they concluded that an important initial step is the transfer of energy to a C_5H_{12} molecule. This, however, violates the spin-conservation rule (9), and is inconsistent with the most recent studies on the paraffins. It is now clear that an important factor leading to a low quantum yield in these experiments is the reaction of H atoms with *neo*-C_5H_{11} radicals, a process that is favored by the light inhomogeneity which leads to high concentrations of H and *neo*-C_5H_{11} at one side of the reaction vessel. Another possible reason for the apparent low quantum yield is the presence of olefin impurities in the *neo*-C_5H_{12}. A more recent investigation by Holroyd and Klein (10) indicated a much higher quantum yield than determined by Steacie and Darwent.

Norstrom, Strausz, and Gunning (11) have reinvestigated the quantum yield for the process, taking care to eliminate olefin impurities from the *neo*-C_5H_{12}. The values were much higher, and suggest that the true primary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

quantum yield is unity, the main initial process thus being

$$Hg(^3P_1) + neo\text{-}C_5H_{12} \rightarrow neo\text{-}C_5H_{11} + H + Hg(^1S_0)$$

On the other hand, an investigation by Sato and Tsunashima (12) has led to a low quantum yield: however, an examination of their results suggests that there was considerable light inhomogeneity, and that there was confusion between primary and secondary products. Our own experiments confirm the conclusions of Gunning and co-workers (11) that the main initial step is the production of $neo\text{-}C_5H_{11} + H$.

Studies have also been made of the vacuum ultraviolet photolysis (13) and pyrolysis (14–17) of neopentane.

Experimental

Apparatus

The reaction was carried out in a static system. A cylindrical quartz reaction vessel was used; it had plane parallel windows at both sides, was about 9 cm in length and 5 cm in diameter, and its volume was 170 cc. It was wrapped in asbestos, and placed in a cylindrical copper collar 14 cm in length. This collar was well insulated and heated electrically, the heating being regulated by a thermo electric temperature controller activated by means of a thermocouple placed in the wall of the collar and reaching the middle of the reaction vessel. The temperature of the reaction vessel was measured at three positions by means of chromel–alumel thermocouples.

The lamp was a low-pressure lamp emitting the characteristic line spectrum of mercury vapor, with peak emission at 2537 Å. It was supported at 25 cm from the window of the reaction vessel and operated at room temperature; before each experiment it was warmed up for 20 min. The 1849 Å line was eliminated by use of a Corning filter C.S. No. 9–54.

The concentration of mercury in the reaction vessel was controlled by the temperature of a spiral trap in the head of the reaction vessel. The temperature of the trap was −15.3 °C.

Materials

The neopentane used was obtained from Phillips Petroleum Company with stated research grade purity of 99.92%; it was further purified, after thorough degassing by distillation from methylene chloride slush (−97 °C), to *n*-pentane slush (−132 °C). Only the middle fraction was used in the investigation. Gas chromatographic analysis of this sample showed no impurities in front of the neopentane peak; a very small peak (probably C_5) was observed on the tail of the neopentane peak; this peak changed very little after one hour's irradiation at 335 °C.

Dineopentyl(2,2,5,5-tetramethylhexane) and 2,2,4,4-tetramethylpentane were obtained from the American Petroleum Institute as API Standard Samples, and 2,2,3,3-tetramethylbutane was obtained from the Matheson-Coleman Co. These compounds were used for calibration without further purification. Neohexane (2,2-dimethylbutane) was obtained from the Aldrich Chemical Co. and was purified by distillation before being used for calibrations.

Procedure

Before each experiment the apparatus was evacuated to 10^{-5} Torr. Neopentane was saturated with mercury vapor by passing it over mercury at 0 °C and was then passed through a spiral trap containing mercury at −15.3 °C; it was then admitted to the reaction vessel. Special attention was paid to the mercury vapor pressure; at all times when the experiments were not being done the mercury saturator was kept at −196 °C (liquid N_2) in order to condense mercury remaining in the reaction vessel, and so to avoid an excess of mercury during the experiments.

The reaction was started by the removal of a shutter and was stopped by switching off the lamp. The reaction products and the remaining neopentane were trapped in a U-tube immersed in liquid N_2, and then underwent analysis.

Analysis

The reaction products were separated into three fractions: (*1*) non-condensables, (*2*) condensables at −196 °C (liquid N_2); (*3*) condensables at −97 °C (methylene chloride slush). In order to prevent loss of C_2 hydrocarbons, a solid N_2 trap (at −210 °C) was used in series with the liquid N_2 trap. Non-condensable products (H_2 and CH_4) were collected by Toepler pumping for 30 min. The type *2* condensables comprised C_2H_6, $i\text{-}C_4H_8$, and neohexane (primary products) and C_2H_4, C_3H_6, C_3H_8, and $i\text{-}C_4H_{10}$ (secondary products). Type *3* condensables comprised 2,2,5,5-tetramethylhexane (primary) and 2,2,3,3-tetramethylbutane and 2,2,4,4-tetramethylpentane (secondary products).

The volume of the non-condensables was first measured in the gas burette; they were then analyzed chromatographically using a 6 m column filled with 80–100 mesh Porapak Q at 0 °C. Fraction *2* was analyzed on an 8.5 column of 30% Squalane on 60–80 mesh Chromosorb P operating at 30 °C; this gave a very good separation of $i\text{-}C_4H_8$ and $i\text{-}C_4H_{10}$. Peak heights were found to be satisfactory except with *neo*-hexane, for which the area was measured. Fraction *3* was analyzed on a 0.5 m column of 30% Squalane on 60–80 mesh Chromosorb P; peak areas were measured because the accuracy of the yield measurements was limited when peak heights were measured. All columns used were 1/4 in. in diameter.

The gas chromatograph used was assembled from commercially available units. The detector used was of a thermistor type and was maintained at 30 °C. The detector was supplied from 6 batteries of 1.5 V (Mallory – M 900) connected in series. The output used was 8 V d.c. and the current through the filament of the detector was 200 mA. The signal from the detector was put through a 10 mV Leeds and Northrup Speedomax Type G recorder. A good baseline was obtained by installing Edwards pressure controllers in both the reference flow and the sensing flow. Greatest sensitivity is obtained when the carrier and the sample have widely differing conductivities; most products have low conductivities, and therefore helium, having a high conductivity, was used in all cases.

Reaction Conditions

A compromise had to be made between the temperature of the mercury saturator and the light homogeneity in the reaction vessel at a given reactant pressure. It was originally intended that the temperature of the saturator should be

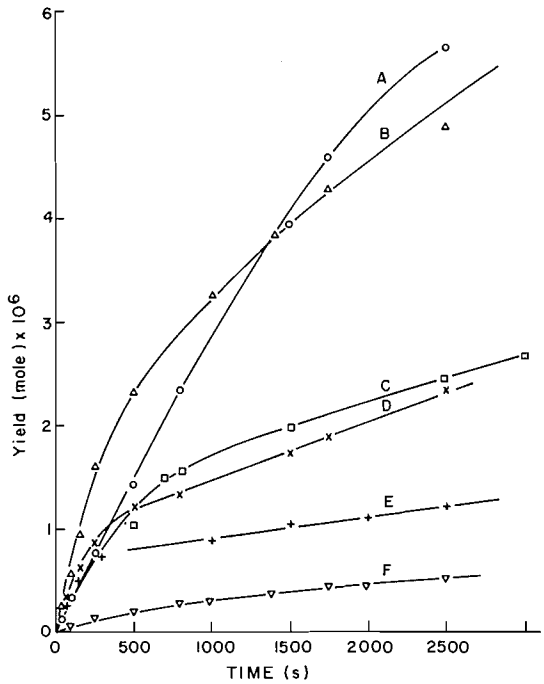

FIG. 1. Yield–time curves for primary products at a temperature of 286 °C and at pressure of 112 mm Hg. *A*, methane; *B*, *i*-C_4H_8; *C*, dineopentyl (at temperature of 256 °C); *D*, hydrogen; *E*, neohexane; *F*, ethane.

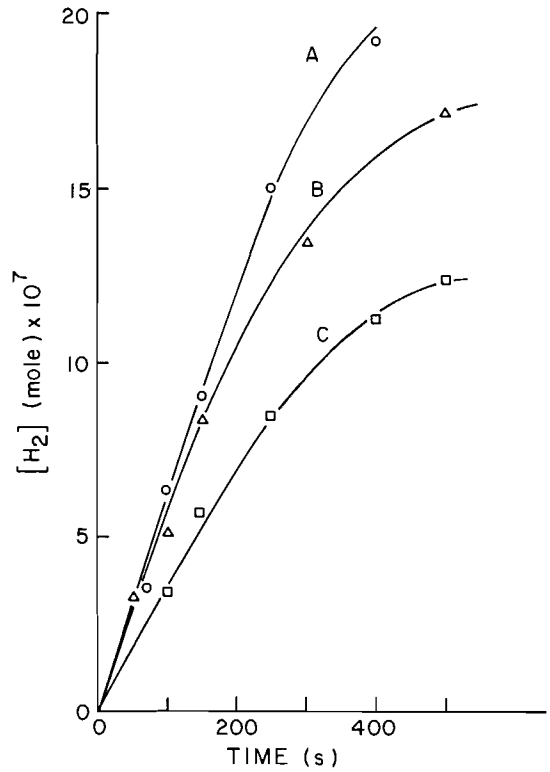

FIG. 2. Yield–time curves for production of hydrogen at 256 °C and at different pressures. *A*, 225; *B*, 110; and *C*, 27 mm Hg.

−32 °C, but the highest reactant pressure that could then be used was 108 mm. At 0 °C it was possible to use a reactant pressure of 530 Torr; however, the region of light inhomogeneity was approached. As a compromise the work was done at a saturator temperature of −15.3 °C, at which the vapor pressure of neopentane is 280 Torr.

Several runs were done to find the maximum temperature of the reaction system at which the rate became independent of pressure; this was found to be 310 °C. It was originally intended that this should be the highest temperature used in the study, but it was later found necessary to work up to 335 °C. At 230 °C, the lowest temperature employed, no measurable amount of ethane was formed; at 256 °C an accurate rate of ethane formation could be measured only at higher pressures. In order to obtain more complete information concerning the combination of CH_3 radicals, and to obtain some parameters for the H abstraction by CH_3 radicals, the experiments were also carried out at 335 °C. Unfortunately, at this temperature the region of constant rate of methane production was not reached.

The highest pressure used was 280 Torr, the vapor pressure of neopentane at the mercury saturator temperature (−15.3 °C). The accuracy of the analysis was limited in the low-pressure region. At 230 and 256 °C reliable rates could not be obtained below 16 and 10 Torr, respectively. At higher temperatures sufficient amounts of CH_4, C_2H_6, and *i*-C_4H_8 were produced at lower pressures, and accurate analyses could be made. Hydrogen also could not be analyzed satisfactorily at the lowest pressures.

Results and Interpretations

As primary products were analyzed: H_2, CH_4, C_2H_6, *i*-C_4H_8, neohexane (2,2-dimethylbutane), and dineopentyl (2,2,5,5-tetramethylhexane). The amounts of H_2, CH_4, *i*-C_4H_8, and neohexane were measured over the entire temperature range (230–335 °C). At 230 °C no measurable amounts of C_2H_6 were obtained. Dineopentyl was observed only at 230 and 256 °C, and at the lower temperature only an approximate rate of production could be obtained; at 286 °C it was detected only in small amounts at high conversions.

Figure 1 shows the yield–time curves at 286 °C for all primary products except dineopentyl, which was studied at 256 °C. The curves are linear only at very low conversions; the effect of secondary reactions on methane formation is evident at later stages.

Hydrogen Production

Typical yield–time curves for H_2 are shown in Fig. 2. The length of the linear region decreases

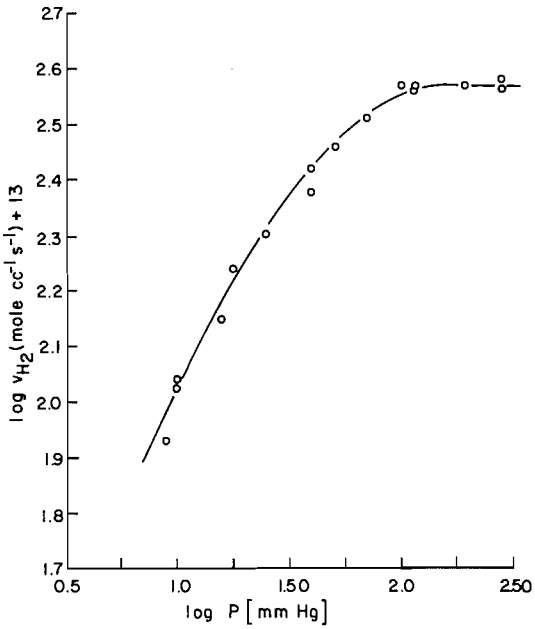

FIG. 3. Order plot for hydrogen production.

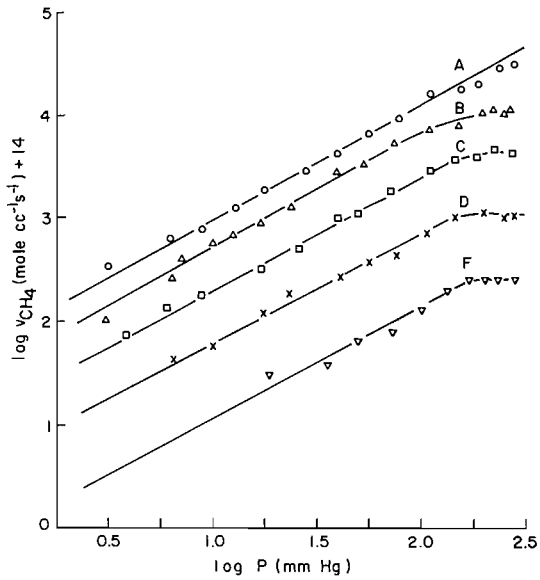

FIG. 4. Order plots for methane at different temperatures: *A*, 335; *B*, 310; *C*, 286; *D*, 256; and *E*, 230 °C.

with increase of temperature, owing to increase in i-C_4H_8 concentration with increase of temperature. Initial rates were obtained from the slopes in the linear region, and Fig. 3 shows a double logarithmic plot of the initial rate of H_2 production against the pressure; the order changes from 1.0 at low pressures to zero at higher pressures. Within the experimental error the rate of H_2 production shows no temperature dependence.

Methane Production

The methane yield–time curves were linear (*cf.* Fig. 1); secondary reactions are only important at very high conversions. Order plots of initial rates are shown in Fig. 4; the order varies from 1.0 at low pressures to zero at high pressures. An Arrhenius plot is shown in Fig. 5, for rates at 280 Torr; the activation energy is 28.8 kcal per mole.

Ethane Production

The ethane yield–time curves are initially linear and later show deviations from linearity. Order plots are shown in Fig. 6; the order changes from 1.0 at low pressures to zero at high pressures. An Arrhenius plot leads to an activation energy of 28.8 ± 0.5 kcal per mole.

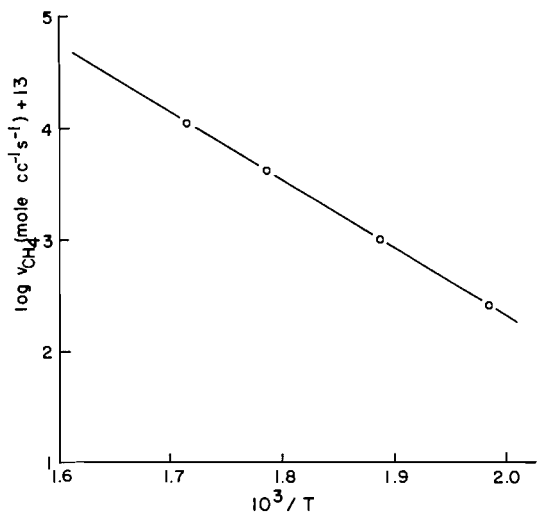

FIG. 5. Logarithm of the rate of methane production (at 280 mm Hg) against the reciprocal of the temperature.

Isobutene Production

The isobutene yield–time plots are also linear only at low conversions. The order plot (Fig. 7) leads to an order of 0.5 at low pressures and of zero at high pressures. The activation energy is 27.5 ± 0.5 kcal per mole.

Neohexane Production

The neohexane results were similar to those

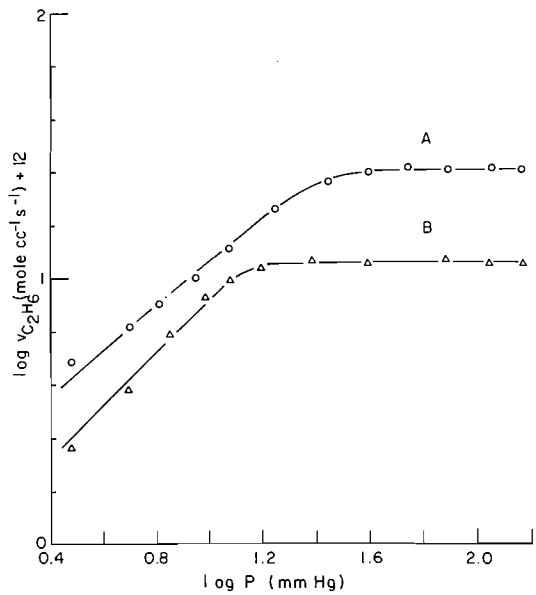

FIG. 6. Order plots for ethane: *A*, 335 and *B*, 310 °C.

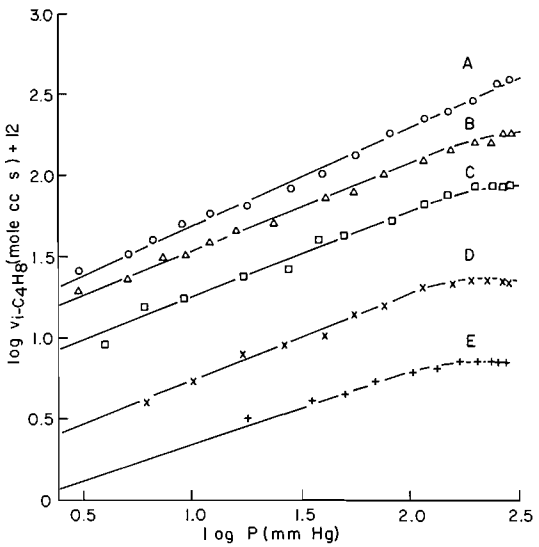

FIG. 7. Order plots of i-C_4H_8: *A*, 335; *B*, 310; *C*, 286; *D*, 256; and *E*, 230 °C.

for other primary products, but reliable rates could not be obtained at the low pressures. With increase of temperature the rate increased until 310 °C was reached, and then remained constant.

Dineopentyl Production

Because of the high boiling point of this product (140 °C) there are difficulties in measuring its yield; approximate rates could be measured only at 230 °C. Pressure was found to have little effect on the initial rates.

Secondary Products

Certain products, C_2H_4, C_3H_6, C_3H_8, i-C_4H_{10}, 2,2,3,3-tetramethylbutane, and 2,2,4,4-tetramethylpentane, were found to have an induction period, and are therefore formed in secondary reactions. The results for these products, and the nature of the secondary reactions, are considered in Part III.

Discussion

The results are consistent with the following reaction scheme, in which Nptn has been written for neopentane and Nptl for the *neo*-pentyl radical:

[1] $Hg + h\nu \rightarrow Hg^*$

[2] $Hg^* + Nptn \rightarrow Nptl + H + Hg$

[3] $Nptn + H \rightarrow Nptl + H_2$

[4] $Nptn + CH_3 \rightarrow Nptl + CH_4$

[5] $CH_3 + H \rightarrow CH_4$

[6] $Nptl \rightarrow i\text{-}C_4H_8 + CH_3$

[7] $Nptl + CH_3 \rightarrow C_6H_{14}$ (2,2′-dimethylbutane)

[8] $2CH_3 \rightarrow C_2H_6$

[9] $2Nptl \rightarrow C_{10}H_{22}$ (2,2,5,5-tetramethylhexane)

[10] $Nptl + H \rightarrow CH_3 + t\text{-}C_4H_9$

[11] $Nptl + H \rightarrow Nptn$

[12] $i\text{-}C_4H_8 + H \rightarrow C_4H_9$

It has been seen that the yield–time relations for all primary products except methane are linear only at low conversions; the deviations from linearity that are observed at later times are due to secondary reactions which have their origin in reaction 12. The secondary reactions are considered in Part III.

In the scheme proposed, H atoms are produced in the initial quenching reaction 2, which is believed to be the only source of H atoms. Most of the H atoms will undergo reaction 3, and reaction of H with Nptl (reactions 10 and 11) also probably occurs.

Nptl radicals are formed in the initial quenching reaction 2 and also in reactions 3 and 4; they can combine in reaction 9 to form dineopentyl and also combine with CH_3 to give neohexane (reaction 7). At higher temperatures (286 °C and higher) most of the Nptl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

radicals decompose into i-C_4H_8 and CH_3 by reaction 6. At low pressures reaction 10 will predominate over 11, whereas 11 will be more important at higher pressures.

The main origin of CH_3 is reaction 6, but at lower pressures there will be some atomic cracking. With increase of temperature and pressure the removal of CH_3 by reaction 4 will become relatively more important with respect to 7 and 8.

Simplified Steady-State Treatment

Reactions 5 and 12 will not be included in the steady-state treatment. The steady-state equation for H then leads to

$$[13] \quad [H] = \frac{I_a\phi}{k_3[\text{Nptn}] + (k_{10} + k_{11})[\text{Nptl}]}$$

where I_a is the intensity of light and ϕ the quantum yield of H_2. The steady-state equation for CH_3, with reaction 8 omitted (since the yield of C_2H_6 is very low), leads to

$$[14] \quad [CH_3] = \frac{k_6[\text{Nptl}] + k_{10}[H][\text{Nptl}]}{k_4[\text{Nptn}] + k_7[\text{Nptl}]}$$

The sum of the steady-state equations for CH_3 and Nptl, with reaction 11 neglected, leads to

$$[15] \quad [\text{Nptl}] = \tfrac{1}{2}\left\{\left(\frac{k_7}{k_9}\right)^2 [CH_3]^2 + \frac{2I_a\phi}{k_9} + \frac{2k_3}{k_9}[H][\text{Nptn}]\right\}^{1/2} - \frac{k_7}{2k_9}[CH_3]$$

At higher temperatures dineopentyl was not detected, so that reaction 9 can be neglected; under these circumstances the Nptl concentration takes a simpler form:

$$[16] \quad [\text{Nptl}] = \frac{[\text{Nptn}](2k_3[H] + k_4[CH_3])}{k_6 + k_7[CH_3]}$$

Estimates of the steady-state concentrations of H, CH_3, and Nptl at different temperatures and pressures are given in Table 1. The concentrations of H atoms were obtained from

$$[17] \quad [H] = \frac{v_{H_2}}{k_3[\text{Nptn}]}$$

with k_3 calculated using $E_3 = 9.7$ kcal per mole and $A_3 = 10^{14}$ cc mol^{-1} s^{-1}. The concentrations of CH_3 were calculated from

$$[18] \quad [CH_3] = \frac{v_{CH_4}}{k_4[\text{Nptn}]}$$

using k_4 values obtained in the present study (*cf.* Part II). The Nptl concentrations were calculated using

$$[19] \quad [\text{Nptl}] = \frac{v_{i\text{-}C_4H_8}}{k_6}$$

using k_6 values obtained in the present work (*cf.* Part II).

The expressions for the rates as functions of the various reaction products are rather complicated; however, a simplified treatment, similar to that of Papic and Laidler (6), leads to a satisfactory interpretation of the behavior. Only a very brief account can be given; further details are to be found elsewhere (18). The arguments are based on the steady-state equations, and the estimated concentrations of free radicals (Table 1).

Hydrogen is formed mainly in reaction 3. Since the production of H atoms by reaction 2 is temperature independent, that of H_2 is expected to be also, in agreement with experiment. The reaction order for H_2 production varies from 1.0 at low pressures to zero at high pressures (Fig. 3). The steady-state rate of H_2 production is

$$[20] \quad v_{H_2} = v_3 = \frac{I_a\phi}{1 + \dfrac{(k_{10} + k_{11})[\text{Nptl}]}{k_3[\text{Nptn}]}}$$

At higher pressures v_{H_2} is thus $I_a\phi$, and is independent of [Nptn]. At low pressures v_{H_2} is proportional to $k_3[\text{Nptn}]/[\text{Nptl}]$. Reference to Table 1 shows that [Nptl] changes only slightly with pressure, so that the hydrogen production is approximately first order in Nptn.

At low pressures $v_{C_2H_6} = v_8$ predominates over $v_{CH_4} = v_4$. The ratio $v_{C_2H_6}/v_{CH_4}$ is equal to $k_8[CH_3]/k_4[\text{Nptn}]$, and use of the values in Table 1, and k_4 and k_8, shows that this ratio at about 10 Torr should be 1–2 depending on temperature, in agreement with experiment. The reaction order for CH_4 production varies from 1.0 at low pressures to zero at high pressures. The steady-state equation is

TABLE 1. The approximate concentrations (in mol/cc) of neopentane (Nptn) and of H atoms, CH_3 and neopentyl (Nptl) radicals

115	310	3.14×10^{-6}	8.44×10^{-13}	1.85×10^{-12}	4.06×10^{-16}
9.5	310	2.61×10^{-7}	9.72×10^{-13}	2.22×10^{-12}	—
280	286	8.03×10^{-6}	3.22×10^{-13}	2.40×10^{-12}	1.10×10^{-16}
112	286	3.21×10^{-6}	4.91×10^{-13}	2.21×10^{-12}	2.14×10^{-16}
9.0	286	2.58×10^{-7}	4.86×10^{-13}	3.00×10^{-12}	6.80×10^{-16}
275	256	8.33×10^{-6}	1.47×10^{-13}	3.41×10^{-12}	3.48×10^{-16}
110	256	3.32×10^{-6}	2.39×10^{-13}	2.97×10^{-12}	8.41×10^{-16}
10	256	3.02×10^{-7}	2.21×10^{-13}	2.79×10^{-12}	27.60×10^{-16}
280	230	8.93×10^{-6}	6.10×10^{-14}	3.12×10^{-12}	5.46×10^{-16}
104	230	3.31×10^{-6}	7.40×10^{-14}	3.0×10^{-12}	14.5×10^{-16}
18	230	5.1×10^{-7}	5.8×10^{-14}	4.11×10^{-12}	45.0×10^{-16}

[21] $$v_{CH_4} = \frac{[\text{Nptl}](k_6 + k_{10}[\text{H}])}{1 + \dfrac{k_7[\text{Nptl}]}{k_4[\text{Nptn}]}}$$

At low pressures

[22] $$v_{CH_4} = \frac{k_4}{k_7}[\text{Nptn}](k_6 + k_{10}[\text{H}])$$

[H] varies much less than [Nptn] as the pressure changes from 10 to 110 Torr (Table 1), so that approximate first-order kinetics is expected. At high pressures reaction 10 is relatively unimportant and v_{CH_4} is now approximately k_6[Nptl]; since [Nptl] varies only slightly with pressure the kinetics are zero order.

Ethane production shows the same variation with pressure as methane production, and a similar explanation applies. Further aspects of the combination of methyl radicals are considered in Part II (following paper).

The order for i-C_4H_8 production is 0.5 at low pressures and zero at higher pressures (Fig. 7). The steady-state expression for the formation of this product is

[23] $$v_{i\text{-}C_4H_8} = v_6 = \frac{k_6}{2}\left\{\left(\frac{k_7}{k_9}\right)^2[\text{CH}_3]^2 + \frac{2I_a\phi}{k_9} + \frac{2k_3}{k_9}[\text{H}][\text{Nptn}]\right\}^{1/2} - \frac{k_6k_7[\text{CH}_3]}{2k_9}$$

At low pressures the predominant term is $2k_3$[H][Nptn]$/k_9$, and [H] is more or less independent of pressure; the dependence of $v_{i\text{-}C_4H_8}$ on [Nptn]$^{1/2}$ can therefore be understood on this basis. At higher pressures [H] becomes inversely proportional to [Nptn], and [CH_3] is fairly constant; the kinetics of formation of i-C_4H_8 is therefore zero order.

Kinetics of the Mercury-Photosensitized Decomposition of Neopentane. Part II. Reactions of the Methyl and Neopentyl Radicals

E. FURIMSKY AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, K1N 6N5, Canada

Received September 2, 1971

The results of Part I are further analyzed with reference to certain of the elementary free-radical processes occurring. A fall-off in the methyl radical combination is observed at low pressures. Comparison of this process with the CH_3 + neopentane abstraction yields for the latter an activation energy of 11.5 kcal/mol and a frequency factor of 4.9×10^{11} cc mol^{-1} s^{-1}. The relative importance of CH_3 + neopentyl and neopentyl + neopentyl is compared. The decomposition of the neopentyl radical into i-C_4H_8 + CH_3 shows a fall-off at low pressures; the limiting activation energy at high pressures is 29.0 kcal/mol, while that at low pressure is 17.1 kcal/mol. The former value leads to 6.7 kcal/mol for the heat of formation of the neopentyl radical at 25 °C, to 21.3 kcal/mol for the heat of its dissociation into i-C_4H_8 + CH_3, and to 98.5 kcal/mol for the heat of dissociation of neopentane into neopentyl + H. Entropy values are also calculated in an approximate manner.

Les résultats de la partie I sont analysés plus en détails, en se référant à certains des procédés radicalaires élémentaires qui se produisent. On observe une chute brusque de la combinaison du radical méthyle à basses pressions. La comparaison de ce procédé avec l'abstraction de CH_3 + néopentane donne pour ce dernier une énergie d'activation de 11.5 kcal/mol et un facteur de fréquence de 4.9×10^{11} cc mol^{-1} s^{-1}. On compare l'importance relative de CH_3 + néopentyl et de néopentyl + néopentyl. La décomposition du radical néopentyl en i-C_4H_8 + CH_3 subit une brusque diminution à basses pressions; l'énergie d'activation limitante à hautes pressions est de 29.0 kcal/mol, tandis qu'à basses pressions elle est de 17.1 kcal/mol. La valeur précédente nous conduit à une chaleur de formation du radical néopentyl à 25 °C de 6.7 kcal/mol, une chaleur de dissociation en i-C_4H_8 + CH_3 de 21.3 kcal/mol et une chaleur de dissociation du néopentane en néopentyl + H de 98.5 kcal/mol. On calcule aussi approximativement les valeurs d'entropie.

Introduction

The present paper is concerned with the detailed kinetics of certain reactions that occur in the mercury-photosensitized decomposition of neopentane, namely the combination and abstraction reaction of methyl radicals and the combination and decomposition reactions of the neopentyl radical.

Results and Discussion

Combination of Methyl Radicals

Several workers have studied the rate of the reaction[1]

$$CH_3 + CH_3 \xrightarrow{8} C_2H_6$$

under a variety of conditions; a matter of particular interest is the variation of the kinetics with pressure. Kistiakowsky and Roberts (1) and Dodd and Steacie (2) made a study of the photolysis of gaseous acetone at temperatures from 150 to 250 °C, and found the expected change of kinetics (from second to third order behavior) at pressures below 10 Torr. Toby and Weiss (3) studied the combination of CH_3 radicals in the photolysis of azomethane at pressures from 3 to 60 Torr, and in the temperature range of 25 to 180 °C. They observed a significant fall-off of the rate coefficient below 10 Torr. Loucks (4) examined the reaction from 200 to 300 °C and observed the beginning of fall-off at a pressure of 100 Torr.

Grotewold and co-workers (5, 6) photolyzed mixtures of azomethane and azoethane, and of azomethane and azopropane. They used the cross-combination of CH_3 radicals with higher radicals to characterize the effect of pressure, the assumption being that the combinations of CH_3 radicals with higher radicals will be pressure independent over the range of the experiments. Their conclusion was that the pressure fall-off at 15, 60, and 100 °C was at pressures about 100 times lower than would be expected from the previous studies.

The pressure dependence of the combination of CH_3 radicals as given by the present study is shown in Fig. 1. It is seen that a significant de-

[1]Reactions are numbered as in Part I (preceding paper).

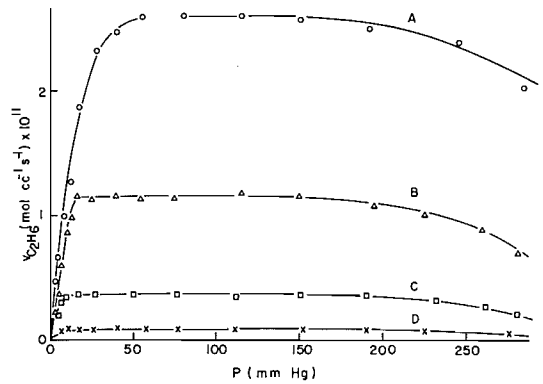

FIG. 1. Rates of ethane production plotted against pressure: *A*, 335; *B*, 310; *C*, 286; *D*, 256 °C.

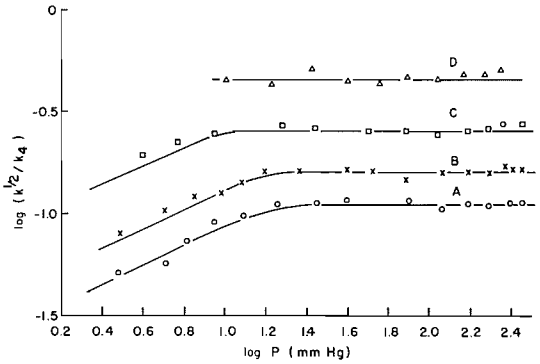

FIG. 2. log–log plots of $k_8^{1/2}/k_4$ against pressure: *A*, 335; *B*, 310; *C*, 286; *D*, 256 °C.

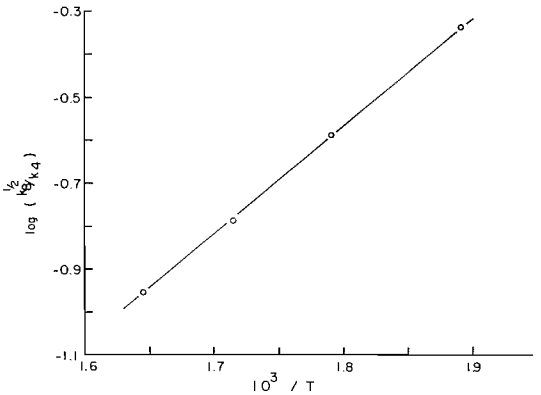

FIG. 3. Plot of logarithm of $k_8^{1/2}/k_4$ against reciprocal of temperature.

crease of the rate of C_2H_6 production occurs at 335 °C at pressures less than 35 Torr. At 310 °C the decrease is observed below about 15 Torr, and at 286 °C below 10 Torr. The conclusion can be drawn that an increase of temperature of about 25 °C results in about a twofold increase in the pressure at which the rate of ethane formation begins to decrease.

It is seen in Fig. 1 that the rate at first increases with increase in pressure and then reaches a constant value, after which there is a decrease in rate. Two explanations are possible:

(*1*) The combination reaction is suppressed by increase in pressure, which favors abstraction by CH_3 radicals.

(*2*) There is a second source of CH_3 radicals, such as the atom cracking reaction

$$H + Nptl \xrightarrow{10} CH_3 + t\text{-}C_4H_9$$

This will occur via an excited Nptn molecule, which is either quenched

$$Nptn^* + Nptn \rightarrow 2Nptn$$

or splits off CH_3

$$Nptn^* \rightarrow CH_3 + t\text{-}C_4H_9$$

The first explanation predominates at higher pressures, so that an increase in pressure suppresses this additional source of CH_3.

The present results can be analyzed by relating the combination reaction with the hydrogen abstraction reaction

$$CH_3 + Nptn \rightarrow Nptl + CH_4$$

which will show no pressure effect. The rates of abstraction and combination are

$$v_{CH_4} = v_4 = k_4[CH_3][Nptn]$$

$$v_{C_2H_6} = v_8 = k_8[CH_3]^2$$

whence

$$\frac{k_8^{1/2}}{k_4} = \frac{v_{C_2H_6}^{1/2}}{v_{CH_4}}[Nptn]$$

A double logarithmic plot of $k_8^{1/2}/k_4$, determined in this way, is shown in Fig. 2. The slope is seen to change from zero at high pressures to 0.5 at low pressures, indicating a change to third order as the pressure is lowered.

Figure 3 shows an Arrhenius plot of the $k_8^{1/2}/k_4$ values in the high pressure region. The effective activation energy is -11.5 kcal/mol, so that

$$E_8^{1/2} - E_4 = -11.5 \text{ kcal/mol}$$

If $E_8 = 0$, $E_4 = 11.5$ kcal/mol.

286	230	35.7	41.20	26.6	80.3	0.96

A value of 10.4 kcal/mol has previously been tabulated as an average value for this reaction (7). Kerr and Timlin (8) compared this value with the activation energy for H abstraction by CH_3 radicals from $(CH_3)_4Si$, and they concluded that it is probably too low. Their own work gave 12.0 kcal/mol for E_4, in good agreement with the value obtained from Polanyi's theoretical equation $E = 0.49\ (D_{CH} - 74.3)$ with $D_{C-H} = 99$ kcal/mol. The value obtained in the present work supports the higher value preferred by these authors.

From the intercept in Fig. 3, and using $A_8 = 2.2 \times 10^{13}$ cc mol^{-1} s^{-1} (9), the frequency factor for the abstraction reaction is

$$A_4 = 4.9 \times 10^{11} \text{ cc mol}^{-1} \text{ s}^{-1}$$

Combination Reactions of Neopentyl Radicals

Neopentyl radicals combine mainly with methyl radicals

$$\text{Nptl} + \text{CH}_3 \xrightarrow{7} \text{C}_6\text{H}_{14}\ (2,2'\text{-dimethylbutane})$$

and with other neopentyl radicals,

$$2\text{Nptl} \xrightarrow{9} \text{C}_{10}\text{H}_{22}\ (2,2,5,5\text{-tetramethylhexane, dineopentyl})$$

Dineopentyl was found only at 230 and 256 °C (and at 286 °C in high conversion experiments), and only at 230 °C was it possible to obtain an approximate initial rate. However, some information about the amounts of Nptl radicals disappearing in reaction 9 can be obtained on the basis of the material balance. With the unimportant reactions 10 and 11 neglected,

$$2v_3 + v_4 = 2v_9 + v_6 + v_7$$

so that the ratio

$$\frac{2v_9 + v_6 + v_7}{2v_3 + v_4}$$

should be unity. The ratio

$$\frac{v_6 + v_7}{2v_3 + v_4} = \frac{v_{i\text{-}C_4H_8} + v_{C_6H_{14}}}{2v_{H_2} + v_{CH_4}}$$

will therefore express the fraction of Nptl radicals removed by reactions 6 and 7; the remainder will be removed by reaction 9. Results are given in Table 1. It is concluded that at 230 °C approximately 85% of the Nptl radicals are removed by reaction 9, and at 256 °C about 55%. At 286 °C the ratio is close to unity indicating that the combination reaction 9 is relatively unimportant.

Reactions 7 and 9 show a striking difference in temperature dependence. The rate of formation of neohexane increases with increase of temperature until 310 °C is reached, but there is a decrease at 335 °C; over the same range there is a decrease of dineopentyl production. Similar effects were found by Sato and Tsunashima (10). The observation can be explained on the basis of different thermal stabilities of dineopentyl and neohexane, the former being much less stable.

It is seen from Table 1 of Part I that the concentration of CH_3 increases strongly with increase of temperature, whereas that of Nptl slightly decreases. This effect favors the combination of CH_3 with Nptl with respect to combination of two Nptl radicals.

Decomposition of Neopentyl Radicals

Few previous studies have been concerned with the decomposition of the Nptl radical,

$$\text{Nptl} \xrightarrow{6} i\text{-}C_4H_8 + CH_3$$

230	240	2.47	—	4.5	6.93	1.00
256	110	6.6	0.895	11.5	20.2	1.06
256	225	10.7	0.67	11.5	22.4	0.95
286	150	36.5	3.71	26.6	75.0	1.05
286	230	41.2	3.24	26.6	80.1	1.06
310	115	68.6	11.5	33.9	120.4	0.96
310	232	11.50	10.1	33.9	163.0	0.97
335	115	158.6	26.5	33.8	237.0	0.99
335	245	272.7	24.4	33.8	353.0	1.00

Anderson and Benson (11) investigated the process in a study of the pyrolysis of Nptn in the presence of HCl. For the rate constant at 742 °K they obtained $10^{3.3\pm0.3}$ with the following kinetic parameters:

$$\log A_6 = 13 \pm 1 \text{ s}^{-1} \qquad E_6 = 34 \pm 3.5 \text{ kcal/mol}$$

Sato and Tsunashima (10) studied the mercury-photosensitized decomposition of Nptn, and from the initial rates of i-C_4H_8 and CH_4 production they obtained $E_6 = 17.0 \pm 2$ kcal/mol. This value is much too low for a high-pressure value, and is to be compared with the low-pressure limiting value E_6^0 obtained in the present study.

It is expected that reaction 6 will be the only source of i-C_4H_8, and this can be checked through the material balance. The steady-state equation for CH_3 is

$$v_6 = v_4 + v_7 + 2v_8$$

so that the ratio

$$\frac{v_{i\text{-}C_4H_8}}{v_{CH_4} + v_{C_6H_{14}} + 2v_{C_2H_6}}$$

should be unity. This is confirmed by the values shown in Table 2.

The rate constant for reaction 6 can be obtained by considering the rates of reactions 4, 6, and 7, whence

$$\frac{v_4 v_6}{v_7} = \frac{k_4 k_6}{k_7}[\text{Nptn}]$$

Thus

$$\frac{k_4 k_6}{k_7} = \frac{v_{CH_4} v_{i\text{-}C_4H_8}}{v_{C_6H_{14}}[\text{Nptn}]}$$

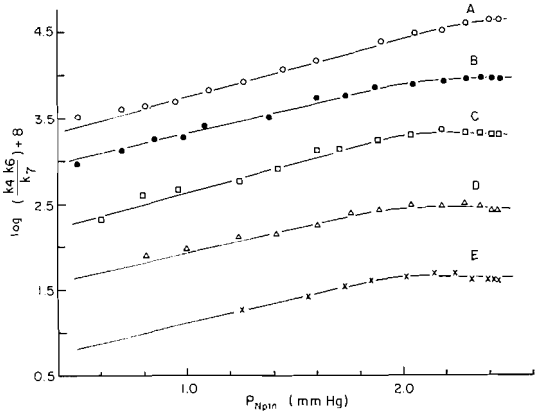

FIG. 4. A double logarithmic plot of k_4k_6/k_7 against the pressure of neopentane: *A*, 335; *B*, 310; *C*, 286; *D*, 256; and *E*, 230 °C.

A double-logarithmic plot of this function against [Nptn] is shown in Fig. 4. Reactions 4 and 7 are assumed to be pressure independent (*cf.* Rabinovitch and Setser (12) for evidence regarding the combination of CH_3 with larger radicals) so that the pressure dependence shown in Fig. 4 can be attributed to the behavior of reaction 6. Average values of k_6 at different temperatures and pressures are listed in Table 3; these values were calculated with $k_7 = 2.2 \times 10^{13}$ cc mol^{-1} s^{-1} and with the k_4 values obtained in the present study (*cf.* above).

Evaluation of the limiting high- and low-pressure rate constants was done by use of a plot of k^{-1} against $[\text{Nptn}]^{-1/2}$, as proposed by Schlag and Rabinovitch (13); such a plot is shown in Fig. 5 for a temperature of 310 °C. From the intercept the value of $k_7/k_4k_6^\infty$ is obtained, while from the slope of the linear part of the curve

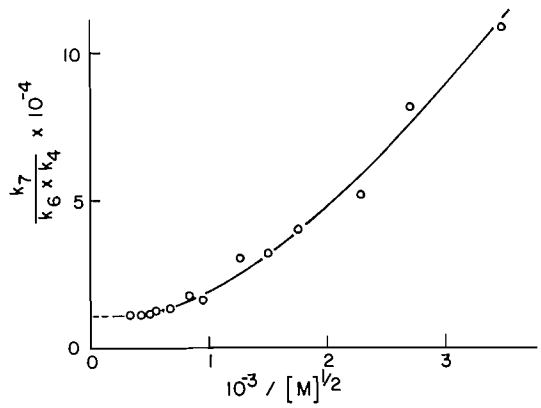

FIG. 5. A plot of k_7/k_4k_6 against $1/[\text{Nptn}]^{1/2}$ at 310 °C.

$k_7/k_4k_6^0$ is obtained. The Arrhenius plots lead to

$$E_6^\infty + E_4 - E_7 = 40.5 \text{ kcal/mol}$$

With $E_7 = 0$, and $E_4 = 11.5$ kcal/mol as obtained in the present study, it follows that the high-pressure activation energy E_6^∞ is 29.0 ± 0.5 kcal/mol. Use of $A_7 = 10^{13.34}$ cc mol^{-1} s^{-1} and $A_4 = 10^{11.7}$ cc mol^{-1} leads to a high-pressure preexponential factor A_6^∞ of 2.5×10^{13}. Thus

$$k_6^\infty = 2.5 \times 10^{13} \exp(-29.0/RT)\ s^{-1}$$

The entropy of activation $\Delta S_6^\ddagger$ is -0.5 cal deg^{-1} mol^{-1} (standard state 1 mol cc^{-1}).

A similar treatment for the limiting low-pressure rate constant leads to

$$k_6^0 = 5.8 \times 10^{10} \exp(-17.1/RT) \text{ cc mol}^{-1}\ s^{-1}$$

The activation energies for this radical decomposition are subject to an estimated error of ± 0.5 kcal/mol. The activation energy difference $E^\infty - E^0$ corresponds to about 12 effective degrees of freedom in the molecule; this is to be compared with a total of 42 degrees of freedom for the neopentyl radical.

Thermochemistry

Knowledge of E_6^∞ (29.0 kcal/mol) and of the activation energy E_{-6} for the reverse addition of CH_3 to i-C_4H_8 permits a calculation of the heat of formation of Nptl radicals. The activation energy for the addition of CH_3 to i-C_4H_8 has been given (14) as 6.9 kcal/mol; this includes addition to both terminal and non-terminal carbon atoms. We have taken, for non-terminal addition, a value of 8.3 kcal/mol, but this is admittedly a guess. These activation energies are related to ΔH_6 for the process

$$\text{Nptl} \rightarrow CH_3 + i\text{-}C_4H_8$$

by the expression

$$\Delta H_6(T) = E_6 - E_{-6} + \Delta nRT$$

where $\Delta n = 1$ in the present case. Enthalpy changes at other temperatures can be obtained from the relationship

$$\Delta H_6(T) = \Delta H_6(0\ ^\circ\text{K}) + \int_0^T \Delta C_p\, dT$$

There are difficulties with this procedure because of lack of heat capacities as a function of temperature. Another possibility is to use heat contents for Nptl, CH_3, and i-C_4H_8. Heat contents for Nptl are not available, but in the present work values for the analogous Nptn were used as giving a reliable estimate. Values of the integral obtained in this way are included in Table 4. The enthalpy change obtained from the experimental results is considered to refer to 550 °K, the middle of the temperature range employed. The heat contents at 550 °K for Nptn, CH_3, and i-C_4H_8 were obtained by extrapolation of the data of Rossini *et al.* (15).

The enthalpy change for the reaction at 0 °K is obtained from the expression

$$\Delta H_6\ (0\ ^\circ\text{K}) = E_6 - E_{-6} + RT - \int_0^T \Delta C_p\, dT$$

This leads to $\Delta H_6\ (0\ ^\circ\text{K}) = 19.0$ kcal/mol. From $\Delta H_6(T)$ it is then possible to calculate at various

TABLE 4. Thermodynamic quantities at different temperatures

T (°K)	$\Delta C_p dT$ (kcal/mol)	ΔH_6 (kcal/mol)	ΔH_f(Nptl) (kcal/mol)	D(Nptl—H) (kcal/mol)
0	0	19.0	14.7	97.6
298.2	2.3	21.3	6.7	98.5
550	2.8	21.8	2.2	98.9

temperatures the heat of formation of the Nptl radical, using the relationship

$$\Delta H_f(\text{Nptl}) = \Delta H_f(CH_3) + \Delta H_f(i\text{-}C_4H_8) - \Delta H_6$$

The resulting heats of formation of Nptl are listed in the fourth column of Table 4. In the literature (16) there is listed the heat of formation of Nptl only at 298.29; the value is exactly the same as that obtained in the present study.

The last column of Table 4 gives the enthalpy change for the process

$$\text{Nptn} \rightarrow \text{Nptl} + \text{H}$$

These values were calculated using the expression

$$D(\text{Nptl—H}) = \Delta H_f(\text{Nptl}) - \Delta H(\text{Nptn}) + \Delta H_f(\text{H})$$

A previous value of the C—H bond dissociation energy of Nptn at 298.2 °K is 100.0 kcal/mol (16), in good agreement with the present value.

The overall standard entropy change for the dissociation of Nptl into $CH_3 + i\text{-}C_4H_8$ is calculated from the present results to be

$$\Delta S_6 = 8.8 \text{ cal deg}^{-1} \text{ mol}^{-1}$$

for the standard state of 1 mol cc^{-1}, or 28.0 cal deg^{-1} mol^{-1} for the standard state of 1 atm. By use of this value and the entropies of CH_3 and $i\text{-}C_4H_8$ (15) the standard entropy of Nptl is calculated to be

$$S(\text{Nptl}) = 109.5 \text{ cal deg}^{-1} \text{ mol}^{-1} \text{ at } 550 \text{ °K}$$

(standard state 1 atm)

This is a very approximate value.

Kinetics of the Mercury-Photosensitized Decomposition of Neopentane. Part III. The Secondary Reactions

E. FURIMSKY AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, K1N 6N5, Canada

Received September 2, 1971

The following were identified as secondary products of the mercury-photosensitized decomposition of neopentane, and their maximal rates measured over a range of conditions: C_2H_4, C_3H_6, C_3H_8, i-C_4H_{10}, 2,2,3,3-tetramethylbutane, and 2,2,4,4-tetramethylpentane. A mechanism is proposed which explains the kinetics of formation of these products. It involves the reaction of H atom with i-C_4H_8 formed as a primary product; this leads to the formation of C_4H_9 which reacts further; one of its products is C_3H_6 which also reacts with H atoms.

On a identifié les produits secondaires suivants venant de la décomposition par photosensibilisation au mercure du néopentane, de même que leurs vitesses maximales mesurées dans un domaine de conditions: C_2H_4, C_3H_6, C_3H_8, i-C_4H_{10}, 2,2,3,3-tétraméthylbutane, et 2,2,4,4-tétraméthylpentane. On propose un mécanisme qui explique la cinétique de formation de ces produits. Il implique la réaction de l'atome de H avec i-C_4H_8 formé comme produit primaire; ceci amène à la formation de C_4H_9 qui réagit encore; un de ces produits est C_3H_6 qui réagit lui aussi avec les atomes de H.

Canadian Journal of Chemistry, **50**, 1129 (1972)

Introduction

The present investigation had necessarily to be carried out up to higher conversions than was the case with propane (1, 2), and as a result secondary products are observed; their yield–time curves show an induction period. The secondary products are i-C_4H_{10}, 2,2,3,3-tetramethylbutane (2,2,3,3-TMB), and 2,2,4,4-tetramethylpentane (2,2,4,4-TMP), and in smaller yields ethylene, propylene, and propane. Because of the relatively small number of primary products it was possible to analyse these secondary products and to obtain information about their origin. Table 1 summarizes the main results. The present paper is concerned with this problem.

Because of the very high quenching cross section of H_2 for $Hg(^3P_1)$ atoms (3) it is expected that H_2 formed in the early stages of the experiments will quench the mercury atoms with production of H atoms. These react with olefins (4–6), and there will therefore be reaction with i-C_4H_8, an important primary product, with the formation of a hot radical. Such hot radicals may decompose by C—C or C—H bond rupture, or may be deactivated by collision; they may then undergo their usual combination, disproportionation, and H-abstraction reactions.

In an early study on the photosensitized hydrogenation of i-C_4H_8 at 23 °C (7) the following products were observed: i-C_4H_{10} (52%), CH_4 (15%), 2,2,3,3-TMB (12%), neopentane (11.7%); C_2H_4, C_2H_6, C_3H_6, and C_3H_8 were observed as minor products. It was concluded that the sole products of the addition of H atom to i-C_4H_8 are t-C_4H_9 radicals, and that i-C_4H_9 radicals are either not formed at all or they

TABLE I. The yields of secondary products

decompose or isomerize before reacting. At 300 °C a small amount of 2,4,4-trimethylpentene-1 was detected. A later study (8) of the reaction was concerned with the object of studying the disproportion–combination ratio for t-C_4H_9 radicals, a value of 2.2 ± 0.3 being obtained.

An extensive study on the addition of H atoms to olefins has recently been made by Falconer and Sunder (9). They investigated the relative rates of terminal and non-terminal addition of H atoms to i-C_4H_8 at room temperature, obtaining this from the amounts of products resulting from combination and disproportionation reactions of i-C_4H_9 radicals; at this temperature most of the i-C_4H_9 radicals were stabilized by collisions. The percentage of non-terminal addition was found to be 0.48, and the activation energy difference for non-terminal and terminal addition of H atoms to i-C_4H_8 was found to be 3.2 kcal/mol.

Results and Discussion

Mechanism

The secondary products obtained in the present investigation can be explained in terms of the following partial mechanism:

[1] $H + i\text{-}C_4H_8 \rightarrow t\text{-}C_4H_9^*$

[2] $H + i\text{-}C_4H_8 \rightarrow i\text{-}C_4H_9^*$

[3] $t\text{-}C_4H_9^* + M \rightarrow t\text{-}C_4H_9 + M$

[4] $i\text{-}C_4H_9^* + M \rightarrow i\text{-}C_4H_9 + M$

[5] $t\text{-}C_4H_9^* \rightarrow i\text{-}C_4H_8 + H$

[6] $t\text{-}C_4H_9^* \rightarrow C_3H_6 + CH_3$

[7] $i\text{-}C_4H_9^* \rightarrow i\text{-}C_4H_8 + H$

[8] $i\text{-}C_4H_9^* \rightarrow C_3H_6 + CH_3$

It is assumed that both t-$C_4H_9^*$ and i-$C_4H_9^*$ are produced by addition of H to i-C_4H_8. The former decomposes mainly by C—H bond rupture, into i-C_4H_8 and H (*i.e.* reaction 5 is more important than reaction 6), while i-$C_4H_9^*$ decomposes mainly by C—C rupture into $C_3H_6 + CH_3$ (reaction 8 is more important than reaction 7). The most recent evidence (10–13) is against isomerization of C_3 or C_4 alkyl radicals. It is expected that the decomposition of i-$C_4H_9^*$ will be much faster than that of t-$C_4H_9^*$, so that there is a much greater possibility for t-$C_4H_9^*$ to be stabilized as compared with i-$C_4H_9^*$; most of the i-$C_4H_9^*$ radicals will decompose before being stabilized by collision.

The following reactions, involving stabilized radicals, are also postulated to explain the observed products:

[9] $2t\text{-}C_4H_9 \rightarrow C_8H_{18}$(2,2,3,3-TMB)

[10] $2t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_8 + i\text{-}C_4H_{10}$

[11] $t\text{-}C_4H_9 + \text{Nptn} \rightarrow i\text{-}C_4H_{10} + \text{Nptl}$

[12] $t\text{-}C_4H_9 + \text{Nptl} \rightarrow C_9H_{20}$(2,2,4,4-TMP)

[13] $t\text{-}C_4H_9 + CH_3 \rightarrow \text{Nptn}$

[14] $t\text{-}C_4H_9 + CH_3 \rightarrow CH_4 + i\text{-}C_4H_8$

There will also be some reaction of H with t-C_4H_9.

The propylene produced in reaction 8 will further react with H to give hot propyl radicals; according to Bradley *et al.* (14), more than 93% of this process leads to i-C_3H_7, which decomposes primarily into $C_3H_6 + H$. Addition of H to C_3H_6 leading to n-C_3H_7 is suggested by the fact that C_2H_4 is formed; this is not formed to an appreciable extent from i-C_3H_7. The following scheme of reactions must therefore be added:

[15] $H + C_3H_6 \rightarrow i\text{-}C_3H_7^*$

[16] $H + C_3H_6 \rightarrow n\text{-}C_3H_7^*$

[17] $i\text{-}C_3H_7^* \rightarrow C_3H_6 + H$

[18] $n\text{-}C_3H_7^* \rightarrow C_2H_4 + CH_3$

[19] $i\text{-}C_3H_7^* + M \rightarrow i\text{-}C_3H_7 + M$

[20] $n\text{-}C_3H_7^* + M \rightarrow n\text{-}C_3H_7 + M$

[21] $2C_3H_7 \rightarrow C_3H_6 + C_3H_8$

[22] $2C_3H_7 \rightarrow C_6H_{14}$

[23] $C_3H_7 + \text{Nptn} \rightarrow C_3H_8 + \text{Nptl}$

It is assumed, on the basis of previous evidence, that i-$C_3H_7^*$ does not isomerize to n-$C_3H_7^*$. The amount of ethylene produced accounted for about 10% of all C_2 and C_3 secondary products analyzed, so that there is substantial addition of H to C_3H_6 leading to the n-C_3H_7 radical.

It is possible to arrive at approximate information about the relative ratio of addition of H to i-C_4H_8 with the formation of i-$C_4H_9^*$ and t-$C_4H_9^*$ radicals. All of the C_2H_4, C_3H_6, and C_3H_8 have their origin in i-$C_4H_9^*$ radicals, and it is seen in Table 1 that those products account for about 3% of all the C_4H_9 radicals removed in secondary reactions at 310 °C. This result is approximate, however, since two opposing factors are also involved; (*1*) some of the C_3H_7 radicals are removed in combination reactions and (*2*) some of the t-C_4H_9 radicals are removed in reactions 13 and 14.

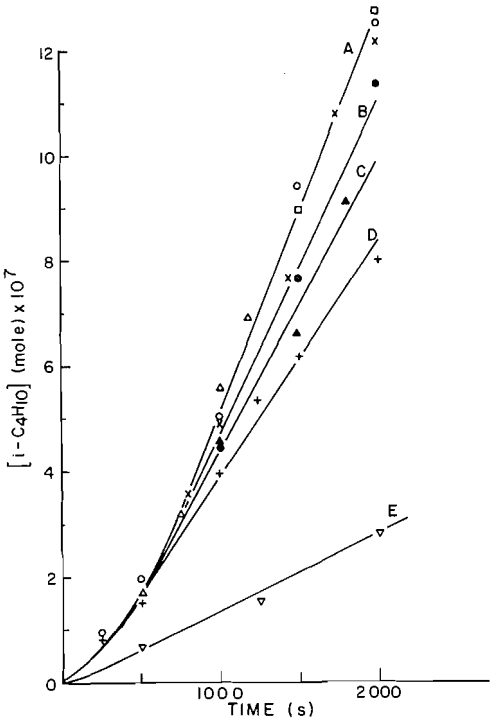

FIG. 1. Yield–time plot for isobutane production at 310 °C and at different pressures: *A*, higher than 54; *B*, 40; *C*, 24; *D*, 16; and *E*, 7 Torr.

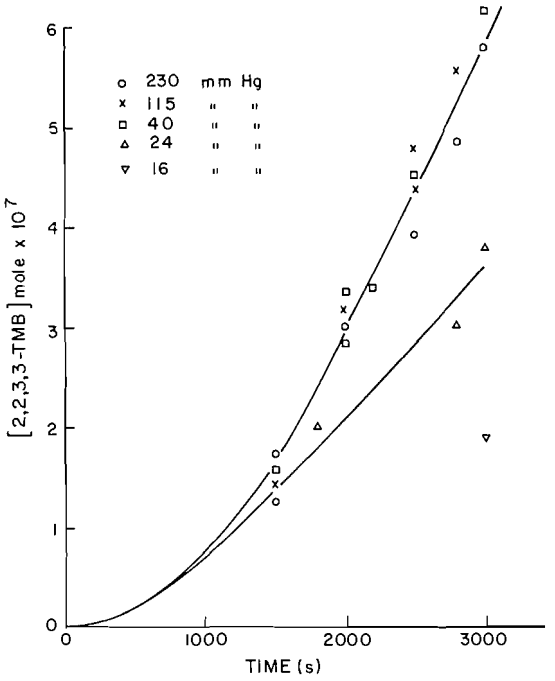

FIG. 2. Yield–time plot of 2,2,3,3-TMB production at different pressures and at 310 °C.

The present results were obtained at much higher temperature than that used by Falconer and Sunder (9). Because no products resulting from combination reactions of i-C_4H_9 radicals were detected, it is believed that in the present study the region of stabilization of i-C_4H_9 radicals was not reached and so most of the radicals decomposed. In view of the higher activation energy for non-terminal addition compared to terminal addition, as found by these authors, the increase of temperature will increase the percentage of non-terminal addition. On this basis one can explain the different results obtained in our investigation.

Production of Isobutane and 2,2,3,3-TMB

Typical yield–time plots for i-C_4H_{10} are shown in Fig. 1. Such plots show an induction period which decreases with increase in temperature. The maximal rates of i-C_4H_{10} production, obtained from the slopes in the linear region, are constant at pressures above 54 Torr at 310 °C. The pressure dependence at lower pressures is attributed to decrease of deactivation of the t-C_4H_9 radicals; an increasing fraction of the t-$C_4H_9^*$ radicals will decompose as the pressure is lowered. The activation energy is 3.6 ± 0.5 kcal/mol.

Typical yield–time plots for 2,2,3,3-TMB are shown in Fig. 2. The induction periods are longer than for i-C_4H_{10}, and increase with decrease of temperature. The activation energy is 2.8 ± 0.5 kcal/mol.

Both of these activation energies are comparable with those for the addition of H atoms to olefins.

The maximal rates for i-C_4H_{10} and 2,2,3,3-TMB production provide some information about the disproportion–combination ratio for t-C_4H_9 radicals:

$$\frac{k_d}{k_c} = \frac{v_{i\text{-}C_4H_{10}}}{v_{2,2,3,3\text{-TMB}}}$$

The ratios for different temperatures are summarized in Table 2. These values are subject to some error because of (*1*) the possibility of H abstraction by t-C_4H_9 radicals and (*2*) a limited accuracy in the analysis of 2,2,3,3-TMB. Listed values for k_d/k_c in the literature (15) vary from

TABLE 2. The maximal rates of i-C_4H_{10} and 2,2,3,3-TMB production, and the k_d/k_c ratio at different temperature

Temperature (°C)	Maximum rate (mol cc^{-1} s^{-1} × 10^{12})		k_d/k_c
	i-C_4H_{10}	2,2,3,3-TMB	
230	2.82	1.2	2.4
256	3.31	1.3	2.5
286	4.15	1.6	2.6
310	4.45	1.7	2.6

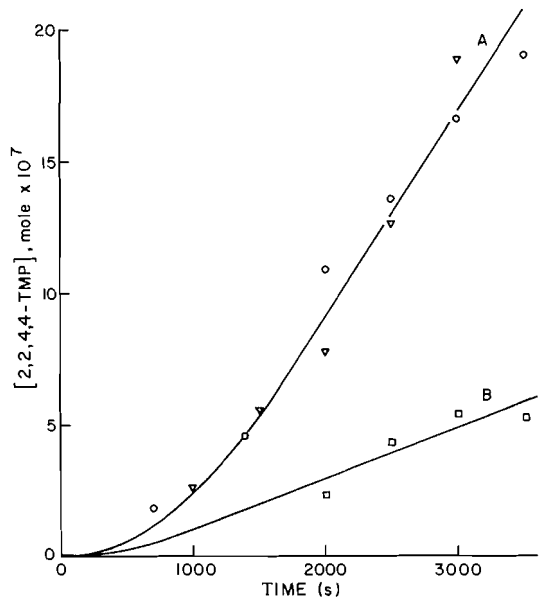

FIG. 3. Yield–time plot of 2,2,4,4-tetramethyl pentane production at different pressures and temperatures: *A*, 230 °C; ○, 54; ▽, 110; and *B*, 286 °C.

2 to 7.4; the present results support the lower values.

Production of 2,2,4,4-TMP

Typical yield–time curves for the production of 2,2,4,4-TMP are shown in Fig. 3. The yield decreases with temperature; little 2,2,4,4-TMP was found at 286 °C and none at 310 °C.

Production of Ethylene, Propylene, and Propane

Typical yield–time plots for these products are shown in Figs. 4, 5 and 6. The plot for C_3H_6 is S-shaped, owing to the fact that C_3H_6 is first formed in a secondary reaction and later is removed by addition of H atoms.

In high conversion experiments several very small peaks were observed for C_5 and C_6 hydrocarbons, but reliable analysis was not possible.

The Crystal Structure of Potassium Hydrogeniodate (V), $KIO_3.HIO_3$

G. KEMPER AND AAFJE VOS

Laboratorium voor Structuurchemie, Universiteit Groningen, Zernikelaan, Paddepoel, Groningen, The Netherlands

AND

H. M. RIETVELD

Reactor Centrum Nederland, Petten (N.H.), The Netherlands

Received August 9, 1971

The crystal structure of $KIO_3.HIO_3$ has been determined by three-dimensional single crystal X-ray diffraction and by neutron powder diffraction. The crystallographic data are $a = 7.025(2)$, $b = 8.206(2)$, $c = 21.839(5)$ Å, $\beta = 97.98(2)°$, space group $P2_1/c$, $Z = 8$ units $KIO_3.HIO_3$. The residual $R = [\Sigma|\Delta F|^2/\Sigma|F_0|^2]^{1/2}$ was 0.048 for 7516 independent X-ray reflections measured on a three-circle diffractometer with Zr-filtered Mo radiation. The results of the present study show good qualitative agreement with the structure recently determined by Chan and Einstein (7). The HIO_3 and IO_3^- groups are pyramidal, the I—O(H) bonds vary from 1.898 to 1.939(4) Å and the I—O bonds from 1.786 to 1.827(4) Å, these lengths are not corrected for the effects of thermal motion. Strong O—I . . . O interactions and electrostatic attractions between K^+ and $O^{\delta-}$ give slabs of thickness $\frac{1}{2}c \sin\beta \approx 10$ Å. The slabs are connected by hydrogen bonds of 2.710 and 2.694 Å.

On a déterminé la structure cristalline de $KIO_3.HIO_3$ par diffraction de rayons-X de cristaux uniques à trois dimensions et par diffraction de neutron de poudres. Les données cristallographiques sont $a = 7.025(2)$, $b = 8.206(2)$, $c = 21.839(5)$ Å, $\beta = 97.98(2)°$, le groupe spatial est $P2_1/c$, $Z = 8$ unités $KIO_3.HIO_3$. La valeur de $R = [\Sigma|\Delta F|^2/\Sigma|F_o|^2]^{1/2}$ résiduelle était de 0.048 pour 7516 réflexions de rayons-X indépendantes mesurées sur un diffractomètre tri-circulaire, au moyen d'une radiation de Mo filtrée par Zr. Les résultats de la présente étude sont en accord qualitatif avec la structure récemment déterminée par Chan et Einstein (7). Les groupes HIO_3 et IO_3^- sont pyramidaux, la longueur de lien I—O(H) varie de 1.898 à 1.939 Å et celle des liens I—O de 1.786 à 1.827 (4) Å, ces longueurs n'étant pas corrigées pour les effets de mouvement thermique. A cause des fortes interactions O—I . . . O et des attractions électrostatiques entre K^+ et $O^{\delta-}$, on obtient des plaques d'épaisseur $\frac{1}{2}c \sin\beta \approx 10$ Å. Les plaques sont reliées entre elles par des ponts hydrogènes de 2.710 et 2.694 Å.

Canadian Journal of Chemistry, **50**, 1134 (1972)

Introduction

The crystal structures of the oxygen acids and salts of iodine have aroused considerable interest because of the presence of short O—I...O distances indicative of strong O—I...O interactions.

For the iodates this strong interaction was observed first in $NaIO_3$ by MacGillavry and Panthaleon van Eck (1). In addition to the three oxygen atoms of the IO_3 group, each iodine atom in $NaIO_3$ is surrounded at short distances by three oxygen atoms of neighboring IO_3 groups in such a way that an irregular octahedron is formed. Similar surroundings of the iodine atoms occur in $Ce(IO_3)_4$ and in $LiIO_3$, giving rise in all cases to the formation of a three-dimensional network (2, 3).

In HIO_3 and in HI_3O_8 (in which HIO_3 and I_2O_5 groups can be distinguished) hydrogen bonds take part in the formation of the three-dimensional network (4–6) in addition to O—I...O interactions. In HI_3O_8 the iodine atom of the HIO_3 group is surrounded by seven oxygen atoms, whereas the remaining iodine atoms have six coordination (6).

To check the role of the hydrogen bonds in an acid iodate and to study the configuration of the different IO_3 groups, we have determined the crystal structure of $KIO_3.HIO_3$ by single crystal X-ray diffraction and by neutron powder diffraction. While our work was in progress an X-ray diffraction study of $KIO_3.HIO_3$ performed with fewer and less accurate reflection data, was published by Chan and Einstein (7). In the present paper our experimental work will be described and some additional information concerning the structure will be given.

Experimental

Crystal Data

$KIO_3.HIO_3$ f.w. = 390

Monoclinic, space group $P2_1/c$ with $a = 7.025(2)$, $b = 8.206(2)$, $c = 21.839(5)$ Å, $\beta = 97.98(2)°$, $V = 1246.7$ Å^3, $D_o = 4.0 \pm 0.5$ g/cm^3, $Z = 8$, $D_c = 4.16$ g/cm^3 (20 °C, $\lambda(CuK\alpha_1) = 1.54051$, $\lambda(CuK\alpha_2) = 1.54433$ Å).

The crystals were grown at room temperature by com-

plete evaporation of a solution of equimolar amounts of KIO_3 and HIO_3 in H_2O, the solution being placed over concentrated H_2SO_4 in a desiccator. The composition of the crystals was checked by chemical analysis. Form {001} is predominant and the crystals are slightly elongated along [010]. The cell dimensions were determined from zero layer line Weissenberg photographs calibrated with NaCl reflection spots. A least-squares program was used to calculate a, b, c, and β from the $\sin^2\theta/\lambda^2$ values of 64 reflections $0kl$ and 54 reflections $h0l$ with $45° < \theta < 80°$. The standard deviations estimated by the least-squares program are given in parentheses. The observed cell dimensions are not significantly different from the values reported by Chan and Einstein. The corresponding axial ratios and the angle β ($a:b:c = 0.856:1:2.661$, $\beta = 97.98°$) show reasonable agreement with the values given in Gmelin's Handbuch (8) for the monoclinic γ modification ($a:b:c = 0.857:1:2.590$, $\beta = 98.45$ after doubling the value given for c).

As reported by Chan and Einstein the systematic extinctions and the symmetry relations between the reflections indicate the space group to be $P2_1/c$. Initially we hesitated to adopt this space group as a large crystal of $KIO_3.HIO_3$ appeared to exhibit a strong piezoelectric effect (9). Later this effect was ascribed to a layer of KIO_3 which was shown to be present on the surface of the crystal by a zero layer line Weissenberg photograph of the crystal used for the piezoelectric test (10). The refinement of the structure described below shows that no difficulties are encountered in describing the structure in space group $P2_1/c$. It seems reasonable to assume that the strong second harmonic effect (11) reported at the end of ref. 7 is also caused by KIO_3 (or HIO_3) deposits.

X-Ray Diffraction Intensities

All intensities were obtained from a crystal with dimensions of 0.2, 0.25, and 0.1 mm along a, b, and c^*, respectively. The measurements were done on an automatic Nonius three-circle single crystal diffractometer with Zr-filtered Mo radiation, the b axis was mounted parallel to ϕ. The θ–2θ scan method was used with scan width $(0.7 + 0.5 \text{ tg } \theta)°$ and scan speed 1.2°/min. At each of the scan limits background measurements were done for half the scan time. All 10 827 independent reflections hkl with $\sin\theta/\lambda < 0.995$ Å^{-1} were considered. Due to the presence of a range selector integrated intensity and background measurements were carried out only for the 7516 reflections having a peak intensity above the level (just above zero) set by the range selector. Every 50 reflections one of the three chosen reference reflections was measured. The deviations of the intensities of these reflections from the respective average values appeared to be smaller than 5%. Corrections were made for the Lorentz and polarization effects, for the variations in the intensities of the reference reflections and for absorption ($\mu = 108$ cm^{-1}). The latter corrections were calculated according to the Busing and Levy (12) scheme; $6 \times 6 \times 6$ volume fragments and 6 bounding planes were considered.

Neutron Diffraction Data

In order to obtain additional information on the hydrogen positions, a neutron diffraction study was undertaken. Because no suitably large crystals for single crystal measurements were available, only powder samples were used. The high background scatter inevitable from powdered samples containing hydrogen was strongly reduced by deuterating the sample. This was done by dissolving I_2O_5 and KIO_3 in hot D_2O and crystallizing the $KIO_3.DIO_3$ by cooling.

The neutron diffraction data were collected on the powder diffractometer installed at the High Flux Reactor of the Reactor Centrum Nederland at Petten. The neutron wavelength was 2.5796(4) Å, obtained from the (111) plane of a copper crystal. As a second-order filter a piece of pyrolytic graphite with a thickness of 10 cm was employed (13). A Soller slit with a horizontal angular divergence of 30′ was placed between the reactor and the monochromator. A second slit of 10′ was placed in front of the BF_3 counter. The sample was contained in a cylindrical vanadium sample holder with a diameter of 2 cm. Powder diagrams from both the deuterated and undeuterated compound were obtained at room temperature and at liquid helium temperature.

Determination of the Structure

Determination of the Structure from the X-Ray Data

A rough model of the arrangement of the iodine atoms could be obtained from a three-dimensional Patterson synthesis. The positions of the K and O atoms were found by the heavy atom technique. The parameters of K, I, and O were refined on a TR4 computer with a least-squares program using the block diagonal approximation (14). All atoms (ions) were given anisotropic temperature factors and scattering factors corresponding with neutral atoms. The scattering factors were taken from Doyle and Turner (15), anomalous effects were not taken into account. All 7516 measured reflections were considered. In the final stages of the refinement the weighting scheme

$$w(hkl) = [\{w_c(hkl)\}^{-1} + p|F_o(hkl)|^2]^{-1}$$

was introduced in which $w_c(hkl)$ is the weight based on counting statistics, for the constant p the value 1.8×10^{-4} was chosen. Corrections for extinction were made according to Zachariasen (16). For the strongest reflection $12\bar{3}$ the extinction appeared to be as high as 26% in F. The residual $R = [\Sigma|\Delta F|^2/\Sigma|F_o|^2]^{1/2}$ and the weighted residual $R_w = [\Sigma w|\Delta F|^2/\Sigma w|F_o|^2]^{1/2}$ decreased to 0.048 and 0.043, respectively for the 7516 reflections used in the refinement. No systematic variations of $\langle w|\Delta F|^2\rangle$ with $|F|$ or with $\sin\theta/\lambda$ were observed. Typical deviations from the mean value found for the different groups are 15 and 25% for the former and latter case, respectively. A difference Fourier map showed no peaks greater than 2.0 e/Å^3 or lower than -1.8 e/Å^3 (standard deviation 0.5 e/Å^3).

are listed in Table 1. In Table 3 the observed and calculated structure factors (hydrogen atoms not included) are compared.[1] An analysis of the thermal parameters showed that these parameters can be described in terms of rigid body motions of independently vibrating IO_3 groups. Although not too much physical significance should be attached to this model because of the strong intermolecular interactions occur-

[1]Tabular data are available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

ring in the structure, libration corrections have been calculated for the I—O bonds. In Table 2*a* the corrected bond lengths are given in addition to the uncorrected values. The further discussion of the structure is based on the uncorrected coordinates given in Table 1.

Determination of the Hydrogen Positions

As the information content of a powder diagram is inherently low compared with single crystal measurements, it was decided to refine the hydrogen positions (and isotropic temperature factors) only and to keep the parameters of the other atoms fixed at the values determined by X-ray diffraction. The refinement was performed by the profile refinement method described by Rietveld (17). This method determines the estimates of the various parameters by finding a least-squares fit between the observed and calculated profile intensities y_i by minimizing the quantity $X_v^2 = \Sigma_i w_i[y_i(\text{obs}) - y_i(\text{calc})]^2/v$, where $y_i(\text{obs})$ and $y_i(\text{calc})$ are the observed and calculated values of the profile intensity measured at diffraction angle $2\theta_i$, w_i is the statistical weight, and v represents the number of degrees of freedom. The coherent scattering lengths used are: $b_H = -3.26 \times 10^{-13}$ cm, $b_D = 6.21 \times 10^{-13}$ cm, $b_K = 3.7 \times 10^{-13}$ cm, $b_I = 5.2 \times 10^{-13}$ cm, $b_O = 5.77 \times 10^{-13}$ cm. No significantly different hydrogen positions were found for the deuterated and undeuterated samples at room temperature and liquid helium temperature. The statistically most reliable results were obtained from the deuterated sample at room temperature. These have been given in Table 1*a* (for deuterium a B value of -0.5 (s.d. 1.2) Å^2 was obtained). The observed and calculated diffractometer profiles of $KIO_3.DIO_3$ are shown in Fig. 1.

During the refinement of the various samples it was found that the deuterated sample easily replaced its deuterium by hydrogen on contact with the atmosphere. The reversed exchange also took place, with the sample in a D_2O saturated atmosphere. No satisfactory explanation for this phenomenon has yet been found.

Structure Description and Discussion

The Three-dimensional Network

The structure reported and the description given in ref. 7 are essentially correct. The positions assumed by Chan and Einstein for the hydrogen atoms from the values obtained for I—O and O...O are confirmed by the present neutron diffraction study. Figure 2 is copied from ref. 7 except for the fact that in the present paper the atoms numbered in the figure correspond with those given in Table 1, moreover the hydrogen atoms have been added. Table 2, in which the atomic distances and valence angles are listed, are directly comparable with Table 2 of ref. 7.[2]

Some additional remarks can be made.

1. The surroundings of the K^+ ions are depicted in Fig. 3. For each of the K^+ ions all oxygen atoms have been projected unto the "best" plane through K^+ and five of its eight coordinating oxygen atoms. According to Chan and Einstein the coordination polyhedra can be best described as distorted square antiprisms. The squares around K(1) involve O(21)—O(22)—O(23)′—O(41) and O(13)—O(13)′—O(23)—O(43), respectively, for K(2) the squares are O(31)—O(42)—O(32)—O(41) and O(11)—O(33)—O(12)—O(21) (for the symmetry relations of these atoms to those in Fig. 2, see Table 2*b*).[3] Especially O(11) lies far from the idealized position.

2. From Fig. 2 it is seen that strong O—I...O interactions and electrostatic attractions between K^+ and $O^{\delta-}$ give slabs lying between $z = \frac{1}{4}$ and $z = \frac{3}{4}$ (and between $z = \frac{3}{4}$ and $z = 1\frac{1}{4}$ etc.) with a thickness of $\frac{1}{2}c \sin \beta \simeq 10$ Å. Successive slabs are connected by hydrogen bonds of 2.710 and 2.694 Å. The one independent O—I...O "bond" which crosses the plane $z = \frac{1}{4}$ (or $z = \frac{3}{4}$) is relatively weak, the relevant I...O distance [I(1)...O(33)] being the largest among those given in Table 2*b* and only 0.13 Å shorter than the accepted van der Waals distance of 3.55 Å (18). The layer-like structure explains the formation of crystals with form {001} predominant.

3. Comparison of the three I...O distances around the iodine atom I(1) of the $I(1)O_3^-$ group in $KIO_3.HIO_3$ (average value 3.16 Å) with the three I...O distances around the IO_3^- groups in $LiIO_3$ (average value 2.89 Å) shows that the I...O distances can vary appreciably,

[2] In ref. 7 the values of some of the interionic distances and angles are incorrect, errors occurring in the numbering of atoms and in the symmetry operations.

[3] We thank Dr. Einstein for sending us details of his description.

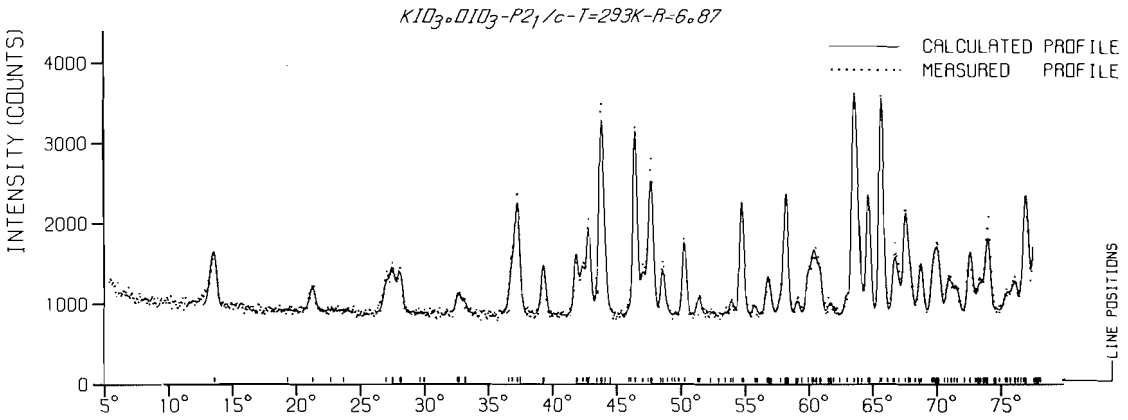

FIG. 1. Observed and calculated neutron diffraction profiles of $KIO_3.DIO_3$ at room temperature.

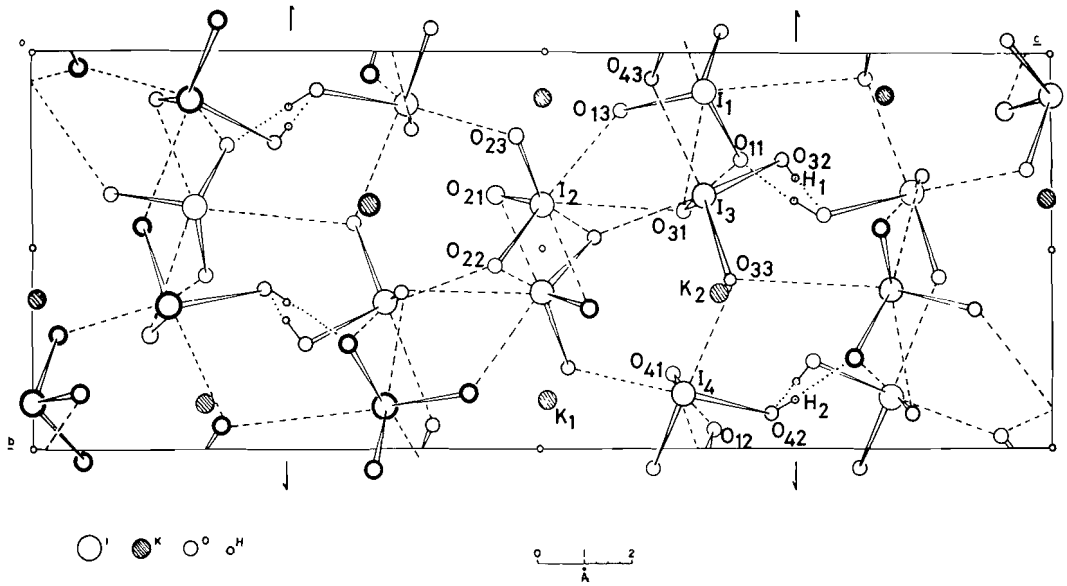

FIG. 2. Crystal structure of $KIO_3.HIO_3$ projected along the *a* axis. (Dotted lines indicate hydrogen bonds; dashed lines weak I...O interactions.)

even when the charge of the IO_3 group does not change. We think it possible that the I...O distances are influenced more by the packing in the crystal than by the charge of the IO_3 groups.

The Covalent I—O Bonds

As the present structure is more accurate than that described in ref. 7 a more detailed discussion of the I—O bonds can be given. The bond lengths and angles are listed in Table 2. The standard deviations calculated from the standard deviations in the coordinates (Table 1*a*) are 0.004 Å for the bond lengths and 0.2° for the angles.

Individual HIO_3 and IO_3^- groups can be described as $(HO)I^{2+}(O^-)_2$ and $I^{2+}(O^-)_3$, respectively, if no d orbitals are taken into account and as

$$HO—I\begin{matrix}O\\O\end{matrix} \quad \text{and} \quad {}^-O—I\begin{matrix}O\\O\end{matrix}$$

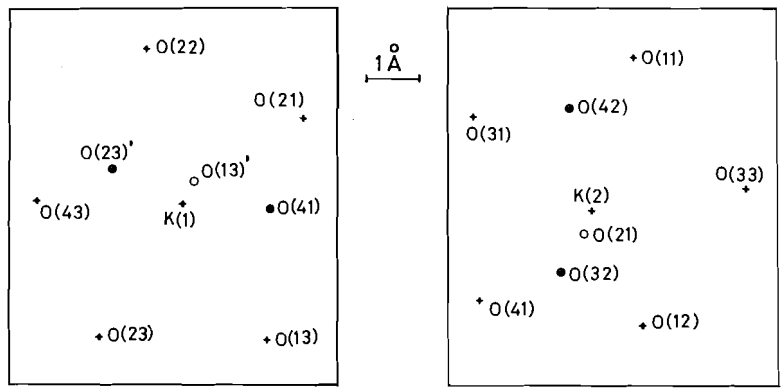

FIG. 3. Projection of K(1) and K(2) with their coordinating oxygen atoms on their respective "best" planes. Atoms within 0.4 Å from the "best" plane are marked +, those about 2.5 Å above or below the plane are marked ● or ○, respectively. O(13)′ = O(13;2*a*), O(23)′ = O(23;2), see Table 2*b*. The equations of the "best" planes are (*X*, *Y*, *Z* in Å along directions *a**, *b*, and *c*) $0.83742X - 0.11913Y + 0.53341Z = 6.07763$ (K_1) and $0.39309X - 0.08077Y + 0.91595Z = 13.90882$ (K_2).
The distances of the atoms to the respective planes of projection (in Å) are: K(1), 0.3; O(23), 0.1; O(43), −0.4; O(22), 0.4; O(21), −0.4; O(13), 0.0; O(23)′, 2.7; O(13)′, −2.5; O(41), 2.6; K(2), 0.2; O(41), −0.1; O(31), −0.2; O(11), 0.2; O(33), −0.3; O(12), 0.1; O(42), 2.5; O(21), −2.6; O(32), 2.6.

(plus appropriate resonance structures) with the use of d orbitals.[4] In view of this description three types of bonds with decreasing bond orders can be distinguished: (*a*) I—O in HIO_3, (*b*) I—O in IO_3^-, and (*c*) I—OH in HIO_3. The observed bond lengths in Table 2*a* show that in groups (*b*) and (*c*) the lengths of the bonds show significant variations. The bonds of type (*c*) are significantly longer than those of types (*a*) and (*b*). The difference between the latter two types, which is evidently small, is obscured by the observed variations. The small difference between bonds of type (*a*) and (*b*) will be due to the I—OH bond having partial double bond character (see below). We tentatively ascribe the observed variations of the I—O bond lengths in group (*b*) to the intermolecular interaction occurring in $KIO_3.HIO_3$, although we have not been able to detect a systematic correlation between the observed variations and the surroundings of the I—O bonds. The average value of I—O in IO_3^- (1.810 Å; group *b*) is in excellent agreement with the I—O bond lengths of 1.809 Å in $LiIO_3$(3).

The length of the I—OH bond I(3)—O(32) = 1.898 Å agrees with the value of 1.90 Å observed for the I—OH bonds in HIO_3 and in HI_3O_8(6). The bond I(4)—O(42) = 1.939 Å is significantly longer, probably due to the fact that O(42) acts both as a hydrogen donor and acceptor whereas O(32) acts as a hydrogen donor alone. The further interactions with the surroundings are approximately the same for the two I—OH bonds. The I—OH bonds can also be compared with the I—O—(I) bonds of the I_2O_5 groups in HI_3O_8 which are 1.96 ± 0.01 Å (6) and with those in I_2O_5 where lengths of 1.93 ± 0.02 Å have been observed (19). All these I—O bonds are shorter than the value 1.99 Å predicted by Schomaker–Stevenson's rule (20) and are thus likely to have a partial double bond character (for a further discussion see ref. 19).

[4]This description corresponds with the formal bond orders used by Chan and Einstein. Their description in terms of I^{5+} surrounded by O^{2-} is not reasonable.

We thank Dr. W. G. Perdok for the piezoelectric measurements. The calculations were done at the Computing Centre of the University of Groningen.

Constantes de stabilité de cyano-complexes d'argent et produit de solubilité de AgCN

A. O. GÜBELI ET P. A. CÔTÉ

Département de Chimie, Université Laval, Québec, Québec

Reçu le 9 septembre 1971

On a appliqué la méthode des pentes à la détermination des constantes de formation cumulatives de $Ag(CN)_2^-$ et $Ag(OH)CN^-$ et à la mesure du produit de solubilité de AgCN, dans $NaClO_4$ 1 *M*, à 25 °C.

The slope method has been applied to the determination of the cumulative formation constants of $Ag(CN)_2^-$ and $Ag(OH)CN^-$ and to the measure of the solubility product of AgCN, in 1 *M* $NaClO_4$, at 25 °C.

Canadian Journal of Chemistry, **50**, 1144 (1972)

Introduction

La méthode des pentes, telle que proposée par Ste-Marie (1), était basée sur la basse solubilité des complexes, $[M]_{tot}$, comparée à la concentration totale de ligand (autre que OH^-) en solution, $[L]_{tot}$. Cette méthode a d'ailleurs été appliquée à l'étude de complexes de métaux en présence de NH_3 (2), H_2S (3), H_2Se (4), et H_2SeO_3 (5) entre autres.

Nous nous proposons de démontrer que, même si le rapport $[L]_{tot}/[M]_{tot}$ tend vers l'unité, la méthode des pentes peut s'appliquer à l'étude de solutions saturées de cyanure d'argent.

Traitement mathématique

Quand on précipite l'argent par un excès de cyanure, un ensemble d'équilibres simultanés s'établit en solution saturée,

$$H_2O \rightleftarrows H^+ + OH^-$$

$$HCN \rightleftarrows H^+ + CN^-$$

$$AgCN(s) \rightleftarrows Ag^+ + CN^-$$

et

$$Ag^+ + xOH^- + yCN^- \rightleftarrows Ag(OH)_x(CN)_y^{1-x-y}$$

dont les constantes respectives, K_e, k_1, K_{s0} et β_{xy}, sont représentées par les éqs. 1 à 4:

$$[1] \qquad K_e = a_H a_{OH}$$

$$[2] \qquad k_1 = \frac{a_H[CN^-]}{[HCN]}$$

$$[3] \qquad K_{s0} = [Ag^+][CN^-]$$

et

$$[4] \qquad \beta_{xy} = \frac{[Ag(OH)_x(CN)_y^{1-x-y}]}{[Ag^+]a_{OH}^x[CN^-]^y}$$

où a_H et a_{OH} représentent les activités de H^+ et OH^-, alors que [ ] indique la concentration de toute autre espèce.

Si nous posons que, dans une région du pH et pour un intervalle de concentration du ligand, un seul complexe mononucléaire[1] est prédominant en solution, on peut écrire

$$[5] \qquad [Ag]_{tot} = [Ag(OH)_x(CN)_y^{1-x-y}]$$

et

$$[6] \qquad [CN]_{tot} = [HCN] + [CN^-] + [CN]_{lié}$$

où

$$[7] \qquad [CN]_{lié} = y[Ag]_{tot}$$

A. Basse solubilité

Lorsque $[Ag(OH)_x(CN)_y^{1-x-y}]$ est très faible comparativement à la concentration totale du ligand en solution, il s'ensuit que

$$[8] \qquad [CN]_{tot} = [CN^-](F_cH)$$

où

$$[9] \qquad (F_cH) = ((a_H/k_1) + 1)$$

Substituant dans l'éq. 5, les éqs. 1, 3, 4, et 8, on obtient la relation

$$[10] \qquad [Ag]_{tot} = \beta_{xy}K_{s0}K_e^x[CN]_{tot}^{y-1}(F_cH)^{1-y}a_H^{-x}$$

dont les dérivées partielles sont les pentes caractéristiques de l'espèce métallique prédominante en solution

$$[11] \qquad \left(\frac{\partial pAg_{tot}}{\partial pH}\right)_{pCN_{tot}} = 1 - x - y$$

si $pH < pk_1 - 1$

[1]Limitation inhérente à la méthode de solubilité ((6), chapitre sur la solubilité).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[12] $$\left(\frac{\partial \mathrm{pAg_{tot}}}{\partial \mathrm{p}H}\right)_{\mathrm{pCN_{tot}}} = -x \qquad \text{si } \mathrm{p}H > \mathrm{p}k_1 + 1$$

et

[13] $$\left(\frac{\partial \mathrm{pAg_{tot}}}{\partial \mathrm{pCN_{tot}}}\right)_{\mathrm{p}H} = y - 1 \qquad \text{à tout p}H$$

Si on vérifie expérimentalement le comportement de Ag^+ en présence de cyanure d'argent, c'est-à-dire quand ($x = y = 0$) et pAg_{tot} est remplacé par pAg^+ dans les éqs. 11 à 13, on peut calculer le produit de solubilité de AgCN dans l'éq. 10, à condition que k_1 soit connu. La valeur de la constante de dissociation de HCN est, sur l'échelle de pH, le point où la pente de pAg^+ en fonction du pH passe de (+1) à (0). Il est, par la suite, possible d'identifier toute espèce prédominante par les pentes de la courbe de solubilité et d'en calculer la constante de formation cumulative, β_{xy}, dans l'éq. 10.

B. Haute solubilité

Si la concentration de $Ag(OH)_x(CN)_y^{1-x-y}$ est beaucoup plus élevée que la somme ($[HCN] + [CN^-]$), l'éq. 6 devient

[14] $$[CN]_{tot} = y[Ag]_{tot}$$

En y introduisant les éqs. 1 et 3 à 5, on tire

[15] $$[CN]_{tot} = y\beta_{xy}K_{s0}^{y}K_c^{x}[Ag^+]^{1-y}a_H^{-x}$$

dont les dérivées partielles sont caractéristiques de l'espèce prédominante en solution à tout pH, quand ($y > 1$):

[16] $$\left(\frac{\partial \mathrm{pAg}^+}{\partial \mathrm{p}H}\right)_{\mathrm{pCN_{tot}}} = x/(1-y)$$

et

[17] $$\left(\frac{\partial \mathrm{pAg}^+}{\partial \mathrm{pCN_{tot}}}\right)_{\mathrm{p}H} = 1/(1-y)$$

Dans un domaine de haute solubilité, on peut identifier une espèce prédominante, très stable, par les pentes des éqs. 16 et 17, si celle-ci contient plus d'un groupement cyanure lié au métal. Si un mono-cyano-complexe simple ou mixte devient prépondérant en solution, les pentes des éqs. 16 et 17 ne sont plus valables.

Puisque k_1 n'intervient pas dans l'éq. 15, on ne peut, dans une telle région, en déterminer la valeur de façon graphique.

Méthode expérimentale

Des réactifs de pureté garantie et de l'eau bidistillée ont servi à la préparation de toutes les solutions. Nous avons précipité le cyanure d'argent à partir de $AgClO_4$ et d'un excès de cyanure de sodium tel que AgCN(s) était toujours en équilibre avec la solution. La solution de $AgClO_4$ contenait un faible pourcentage de ^{110}Ag utilisé comme traceur radioactif. Le pH de chacune des solutions a été ajusté avec $HClO_4$ ou NaOH selon le cas et la molarité de $NaClO_4$ a été maintenue à l'unité. Les solutions saturées ont été agitées durant les premiers jours et laissées au repos pendant quatre semaines.

Une fois l'équilibre vérifié par échantillonnage périodique, nous avons procédé à la mesure de la solubilité totale de l'argent au moyen d'un compteur à scintillations de marque Philips et à la détermination de la concentration totale de cyanure par une méthode spectrophotométrique à l'aide du réactif *p*-phénylènediamine (7). Le pH a été mesuré au moyen d'un couple d'électrodes verre-calomel(sat.) reliées entre elles par un pont d'agar-agar. L'électrode de verre de marque Corning (No 476022), pouvant opérer entre pH = 0 et 14, a été étalonnée à l'aide de tampons Clark and Lubs et de solutions de HCl et NaOH. Ainsi, on a attribué à NaOH 0.1 et 1.0 M des pH de 12.88 et 13.83, étant donnés les $\gamma_\pm$ correspondants, 0.764 et 0.677 (8). On a apporté une correction due à la réponse de l'électrode aux ions Na^+ (toujours <0.04 unité de pH) (9). La concentration des ions Ag^+ a été obtenue en substituant à l'électrode de verre une électrode d'argent dans le couple décrit précédemment. Celle-ci a été étalonnée préalablement par rapport au produit de solubilité apparent de l'oxyde d'argent que nous avons déterminé radiométriquement dans $NaClO_4$ 1 M, à 25 °C. Cet étalonnage est basé sur l'équation de Nernst et sur l'identification par la méthode des pentes des espèces prédominantes Ag^+, AgOH et $Ag(OH)_2^-$ en équilibre avec Ag_2O(s). Le produit de solubilité apparent déterminé ($pK_{s0} = 7.82$) est en accord avec la valeur rapportée par Biedermann et Sillén (10).

Résultats

D'après la fig. 1, puisque la valeur de R ($R = pAg_{tot} - pCN_{tot}$) indique que le rapport $[CN]_{tot}/[Ag]_{tot}$ est grand pour p$H < 4$, on peut traiter les résultats de cette région (I) par l'hypothèse de basse solubilité. Cependant, pour $4 <$ p$H <$ 13, la solubilité totale de l'argent est comparable à celle du cyanure. Les résultats de ce domaine (II) correspondent à une région de haute solubilité. Puisque, pour p$H \geqslant 13$, R tend vers 0, cette partie de la courbe (III) est traitée séparément, car "y" tend vers l'unité.

Puisque la région de haute solubilité (II) cache la valeur de pk_1 (9.21, à dilution infinie et à 25 °C (11)), nous en avons effectué la détermination dans $NaClO_4$ 1 M, par titrage potentiométrique, selon une méthode analogue à celle d'Anderegg (12). Trois mesures pour des solutions de NaCN de concentrations variables nous ont donné comme valeur la plus probable de cette constante apparente, $pk_1 = 8.95$.

Les résultats des régions I et II ont pu être interprétés à l'aide de la méthode des moindres

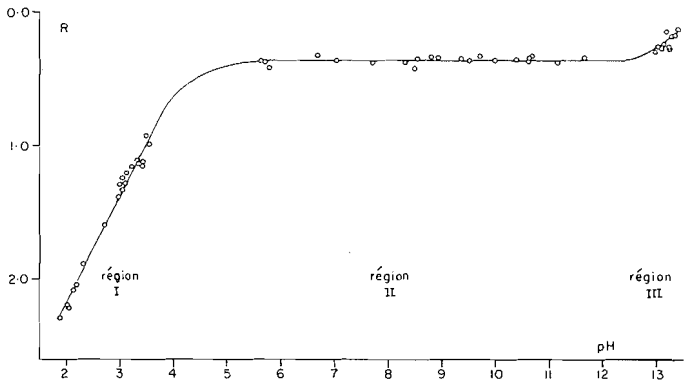

FIG. 1. Influence du pH sur R ($R = pAg_{tot} - pCN_{tot}$).

TABLEAU 1. Solubilité totale (pAg_{tot}) et cationique (pAg^+) de l'argent pour des valeurs variables de pCN_{tot}, $pH < 4$

pH	pCN_{tot}	pAg_{tot}	pAg^+
1.85	2.72	5.02	5.73
2.02	2.70	4.90	5.97
2.05	2.57	4.77	6.14
2.12	2.66	4.75	6.01
2.20	2.51	4.55	6.22
2.32	2.59	4.47	6.33
2.72	2.26	3.85	7.10
2.95	2.67	4.06	6.88
3.00	2.83	4.13	6.79
3.05	2.61	3.86	7.10
3.05	2.34	3.67	7.31
3.10	2.72	4.01	6.97
3.12	2.28	3.49	7.50
3.22	2.20	3.36	7.56
3.22	2.21	3.37	7.58
3.35	2.49	3.63	7.31
3.35	2.80	3.92	7.04
3.42	2.65	3.77	7.20
3.42	2.64	3.70	7.51
3.50	2.31	3.23	7.78
3.55	2.20	3.19	7.99

carrés appliquée à l'équation générale d'un plan, $Z = f(X,Y) = \alpha + \beta X + \gamma Y$. Ceci nous a permis d'évaluer des coefficients α, β, et γ qui ont orienté l'interprétation des données de solubilité totale et cationique.

Région I

Les résultats du tableau 1 permettent d'obtenir l'équation

$$[18] \quad pAg^+ = f(pH,pCN_{tot}) = 7.0 + 0.95pH - 1.1pCN_{tot}$$

qui confirme le comportement de Ag^+ selon les pentes des éqs. 11 et 13.

La valeur la plus probable du produit de solubilité apparent du cyanure d'argent peut être calculée d'après l'éq. 10

$$pK_{s0} = 15.54 \ (\sigma = \pm 0.06)$$

De plus, l'équation

$$[19] \quad pAg_{tot} = f(pH,pCN_{tot}) = 3.7 - 0.81pH + 1.0pCN_{tot}$$

montre la prédominance de $Ag(CN)_2^-$ en solution d'après les pentes des éqs. 11 et 13.

La valeur la plus probable de sa constante de formation cumulative apparente est

$$\log \beta_{02} = 20.14 \ (\sigma = \pm 0.05)$$

De ces constantes, on peut calculer

$$\log K_s = \log (\beta_{02} K_{s0}^2) = -10.94 = \log [Ag(CN)_2^-][Ag^+]$$

Région II

Les résultats groupés au tableau 2 permettent de confirmer que $[Ag]_{tot} = [Ag(CN)_2^-]$ d'après l'équation

$$[20] \quad pAg^+ = f(pH,pCN_{tot}) = 11 + 0.02pH - 1.1pCN_{tot}$$

car β et γ correspondent aux pentes des éqs. 16 et 17 quand $(x = 0)$ et $(y = 2)$. D'ailleurs, la valeur de α dans l'équation

$$[21] \quad pAg_{tot} = f(pH,pCN_{tot}) = 0.34 + 0.00pH + 1.0pCN_{tot}$$

TABLEAU 2. Solubilité totale (pAg_{tot}) et cationique (pAg^+) de l'argent pour des valeurs variables de pCN_{tot}, $4 < pH < 13$

pH	pCN_{tot}	pAg_{tot}	pAg^+
5.63	2.45	2.81	8.18
5.70	2.47	2.84	8.09
5.80	2.93	3.34	7.71
6.70	2.40	2.72	8.13
7.05	2.93	3.29	7.53
7.72	2.30	2.67	8.20
8.33	2.47	2.84	8.05
8.50	2.42	2.84	8.08
8.57	2.33	2.67	8.24
8.82	2.48	2.81	8.12
8.95	2.42	2.76	8.18
9.37	2.35	2.69	8.13
9.52	2.33	2.68	8.20
9.72	2.51	2.84	7.93
10.00	2.34	2.70	8.18
10.40	2.46	2.81	8.09
10.62	2.32	2.68	8.24
10.65	2.48	2.82	7.95
10.70	2.50	2.83	7.91
11.17	2.36	2.73	8.18
11.67	2.34	2.68	8.24

fournit une valeur approchée de ($\log y$), d'après l'éq. 14.

On vérifie de plus cette identification par le calcul de

$$\log K_s = -(pAg_{tot} + pAg^+)$$
$$= -10.89\ (\sigma = \pm 0.05)$$

Région III

Puisque, d'après le tableau 3, on observe que

$$1 < [CN]_{tot}/[Ag]_{tot} < 2$$

on peut écrire

[22] $$[Ag]^f_{tot} = [Ag]_{tot} - [Ag^+] - [Ag(CN)_2^-]$$
$$= [Ag(OH)_x(CN)^{-x}]$$

La constante K_s permet d'évaluer $[Ag]^f_{tot}$ et nous pouvons développer l'éq. 22

[23] $$[Ag]^f_{tot} = \beta_{x1} K_{s0} K_e^x a_H^{-x}$$

La dérivée totale, $(dpAg^f_{tot}/dpH)$, fournit la valeur numérique de x. Un tel graphique donne une pente de (-1) identifiant ainsi l'espèce $Ag(OH)CN^-$, dont nous avons calculé, à l'aide de $pK_e = 14.0$, la constante de formation cumulative apparente

$$\log \beta_{11} = 12.80\ (\sigma = \pm 0.08)$$

TABLEAU 3. Solubilité totale (pAg_{tot}), cationique (pAg^+) et différentielle (pAg^f_{tot}) de l'argent pour des valeurs variables de pCN_{tot}, $pH \geqslant 13$

pH	pCN_{tot}	pAg_{tot}	pAg^+	pAg^f_{tot}
13.00	2.49	2.79	8.06	3.74
13.05	2.65	2.90	7.92	3.69
13.10	2.76	3.02	7.80	3.65
13.15	2.80	3.04	7.74	3.67

13.25	2.59	2.85	7.92	3.46
13.27	2.66	2.93	7.84	3.51
13.30	2.96	3.14	7.50	3.45
13.35	2.99	3.16	7.35	3.38
13.40	3.05	3.18	7.30	3.37

Discussion

Le traitement mathématique proposé explique le comportement de l'argent en présence de cyanure, en milieu hétérogène. Les valeurs mesurées du produit de solubilité de AgCN et des constantes de formation cumulatives de $Ag(CN)_2^-$ et $Ag(OH)CN^-$ s'approchent de celles compilées par Sillén et Martell (13), si l'on tient compte des corrections à apporter à chacune d'elles pour les ramener à dilution infinie. Il est à noter que l'imprécision sur la mesure du pH en milieu très alcalin a pu affecter la valeur de β_{11}.

Dans l'intervalle de pH et de pCN_{tot} étudié, l'absence des espèces prédominantes $Ag(CN)_3^{2-}$ et $Ag(CN)_4^{3-}$ est en accord avec les résultats d'Ammar, Darwish et Rizk (14), et de Jones et Penneman (15) entre autres. En effet, puisque nous avons observé expérimentalement que

$$[CN^-] = \frac{K_{s0}}{[Ag^+]} \ll 1$$

il s'ensuit que, si AgCN(s) est en équilibre avec la solution,

$$\frac{[Ag(CN)_3^{2-}]}{[Ag(CN)_2^-]} = K_3[CN^-] \ll 1$$

et

$$\frac{[Ag(CN)_4^{3-}]}{[Ag(CN)_2^-]} = K_3 K_4 [CN^-]^2 \ll 1$$

où les valeurs de K_3 et K_4 ($\log K_3 = 0.70$ et $\log K_4 = -1.13$) sont tirées de la réf. 15.

Quant à l'espèce neutre, AgCN, sa solubilité, indépendante du pH et du pCN_{tot} en présence de AgCN(s), est reliée au produit de solubilité

par la relation

$$[AgCN] = \beta_{01} K_{s0} = K_{s1}$$

Etant donné la solubilité minimale observée (tableau 1), [AgCN] est nécessairement inférieure à 10^{-5}. Ceci est en accord avec la valeur estimée, $K_{s1} = 10^{-7}$, rapportée par Butler (16).

Nous tenons à remercier le Conseil National de Recherches du Canada pour son aide financière qui a permis la réalisation de ce travail et le Centreau de l'Université Laval pour l'instrumentation supplémentaire.

Microwave Spectrum, Dipole Moment, and Intramolecular Hydrogen Bond of 2-Methoxyethanol

PAUL BUCKLEY AND MIREILLE BROCHU

Département de Chimie et Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec

Received September 23, 1971

The minimum energy conformation of 2-methoxyethanol ($CH_3OCH_2CH_2OH$) has been determined from an analysis of its microwave spectrum. The rotational constants of the normal species are: $A = 12982.35$, $B = 2742.48$, and $C = 2468.10$ MHz; the dipole moment components are $\mu_a = 2.03$, $\mu_b = 1.15$, $\mu_c \simeq 0.25$, and $\mu = 2.36 \pm 0.03$ D. For the $CH_3OCH_2CH_2OD$ species: $A = 12385.71$, $B = 2724.74$, and $C = 2431.42$ MHz. The conformation consistent with this data is *gauche* about each of the C—C, C—O(H) and C—O(ether) bonds, having dihedral angles of $57 \pm 3°$, $45 \pm 5°$, and $8 \pm 3°$, respectively. This distorted conformation is one in which the hydroxyl hydrogen atom is approximately aligned with the nearest sp^3 lone pair electrons of the ether oxygen atom. Transitions in three excited torsional states have also been observed but no other rotational isomer was detected.

L'analyse du spectre de micro-ondes du méthoxy-2-ethanol ($CH_3OCH_2CH_2OH$) a permis d'en déterminer la conformation la plus stable. Les constantes rotationnelles de la molécule sont: $A = 12982.35$, $B = 2842.48$, et $C = 2468.10$ MHz; les composantes du moment dipolaire sont $\mu_a = 2.03$, $\mu_b = 1.15$, $\mu_c \simeq 0.25$, et $\mu = 2.36 \pm 0.03$ D. Pour l'espèce deutériée ($CH_3OCH_2CH_2OD$): $A = 12385.71$, $B = 2724.74$, et $C = 2431.42$ MHz. Ces données correspondent à une conformation *gauche* autour des liaisons C—C, C—O(H), et C—O(éther), les angles dièdres étant respectivement $57 \pm 3°$, $45 \pm 5°$, et $8 \pm 3°$. Dans cette conformation déformée, l'hydrogène hydroxylique est approximativement aligné avec l'un des doublets libres sp^3 de l'atome d'oxygène du groupement éther. Des transitions de trois états excités de torsion ont également été observées, mais aucun autre isomère rotationnel n'a été détecté.

Introduction

The intramolecular hydrogen bond in 2-substituted ethanols is thought to be a weaker variety among hydrogen bonds, yet it appears to be the predominant factor determining the relative stability of molecular conformations. Extensive studies of the 2-substituted ethanols have shown that the minimum energy conformation is one in which an intramolecular hydrogen bond is favorable and that there are definite structural effects associated with its occurrence. Microwave spectroscopy has recently been used to determine the structure of four such molecules: fluoroethanol (1); chloro and bromoethanol (2) and aminoethanol (3). The OH···O interaction is an important example since the analogous OH···O intermolecular hydrogen bonds are among the strongest. The only intramolecular OH···O bond studied by microwave spectroscopy is glycolaldehyde (4) which presumably involves sp^2 hybridized lone pair electrons. 2-methoxyethanol, with sp^3 lone pairs on the ether oxygen atom and with four internal rotation axes, is an interesting case. Very little relevant structural data on this molecule exists. Infrared (5) and n.m.r. (6) spectra of 2-methoxyethanol in dilute solutions were interpreted in terms of a more stable *gauche* conformation about the C—C bond and a small population of a less stable *trans* isomer. The authors of the n.m.r. study suggested that the stability of the *gauche* isomer was not due to an intramolecular hydrogen bond since the acetyl derivative apparently also had a preferred *gauche* conformation.

Experimental

2-Methoxyethanol ($CH_3OCH_2CH_2OH$) was obtained from Anachemia Chemicals and used without further purification. The hydroxyl deuterated species ($CH_2OCH_2CH_2OD$) was prepared by esterifying the alcohol with boric acid and adding D_2O to the ester as required.

Microwave spectra were obtained at about -40 °C on a standard Stark modulation spectrometer, operating at 100 kHz, constructed in this laboratory. All frequency measurements were made with the oscillator phase locked to harmonics of voltage tunable 15 MHz crystal oscillators by means of a Microwave Systems MOS V stabilizer. The reference frequency was counted directly, markers being derived from the electronic counter. The frequencies are accurate to 50 kHz.

Results and Discussion

Ground State Spectra

The spectrum is characteristic of a prolate

asymmetric rotor with transitions resulting from μ_a and μ_b components of the dipole moment. The μ_a R-, and μ_b Q-type transitions were readily identified by their characteristic patterns. Transitions were assigned by means of their resolvable Stark effect, line strengths, and by least-squares fitting of the frequencies. μ_b R-type transition frequencies were then predicted and measured. Some 38 lines of the ground state were measured in the range 8 to 26.5 GHz. Their frequencies are listed in Table 1 along with differences between the calculated and the observed values using the rotational constants listed in Table 4. Some of the higher J and K transitions show small deviations which are probably due to centrifugal distortion but an analysis was not performed. The rotational constants were derived from low J, K transitions showing negligible distortion effects. The constants were used to predict μ_c transition frequencies and a search was made, but no such transitions were found. The spectrum of the hydroxyl deuterated species is similar to that of the normal species and was assigned on the same basis. The observed transitions are listed in Table 2 and the rotational constants in Table 4. These constants and those of the normal species were used to determine the coordinates of the hydroxyl hydrogen atom in the principal inertial axis system; these are included in Table 4. The c coordinate turned out to be imaginary indicating that the hydrogen is near the a–b principal plane. Therefore a value close to zero is assumed for the c coordinate.

Stark Effect and Dipole Moment

Stark effect measurements were performed on nine $\Delta M = 0$ transitions of five lines. The electric field was calibrated before and after measurements using the $2 \leftarrow 1$ transition of OCS with μ(OCS) taken as 0.71521 D (7). The second order Stark coefficients observed are listed in Table 5 along with the calculated values and the derived dipole moment components. The μ_a and μ_b dipole components are well determined from the measured lines but the μ_c component is not. Transitions more sensitive to this component were sought but no reasonably measurable lines were found. The measurements, however, restrict the value of μ_c to between 0 and 0.5 D, with a probable value not exceeding 0.25 D, since no μ_c transitions were observed. The total dipole moment determined is 2.36 ± 0.03 D, slightly higher than the two values, 2.0 (8) and 2.2 D (9), obtained from dielectric constant measurements in solution.

Spectra of Excited Torsional States

The ground state lines are accompanied by several weaker ones due to molecules in vibrationally excited states. These satellites exhibit the same Stark effects as the nearby ground state lines. This observation as well as the typical satellite pattern permitted the assignments listed in Table 3. Two series of lines have an intensity of about 0.5 with respect to the ground state. One series consists of doublets having an average spacing of 450 kHz for the perpendicular transitions and singlets for the parallel transitions. Each member of the doublet could be fit by rigid rotor theory; the average of the two close sets of constants is listed in Table 4. These lines are probably due to the first excited state of the CH_3 torsion about the CH_3—O bond and are labelled as v_{t1} (CH_3). Since the molecular structure is not well determined and the measured transitions are relatively insensitive, the barrier height was not calculated. The small splittings in the first torsional state imply that the barrier is greater than 2.5 kcal/mol, a value of the same order of magnitude as that observed for dimethyl ether (10) and methyl ethyl ether (11).

The other series is accompanied by a third having an intensity factor of approximately 0.3. In the absence of any low frequency infrared assignment it is difficult to positively identify the two states involved. The two remaining lowest frequency vibrations are the torsions about the C—C and C—O (ether) bonds. The relative intensities and the nearly linear changes in rotational constants suggest that the two series are due to the first and second excited states of one of these torsions. The states are labelled $v_{t2} = 1$ and $v_{t2} = 2$ in Table 4.

Conformation of 2-Methoxyethanol

The relatively simple rigid rotor spectrum observed indicates that one molecular conformation is predominant. This conformation can be identified and its three characteristic dihedral angles approximately determined from the

present data. Six possible stable conformations due to internal rotation about the C—C and C—O(H) bonds are shown in Fig. 1; not shown are those resulting from rotation of the methyl group as a whole about the C—O(ether) bond. Bond lengths and bond angles for the preliminary model were those determined from the extensive microwave spectra reported for dimethyl ether (10) and the 2-haloethanols (1, 2). With the methyl group fixed in its *trans* position making the COCC chain coplanar, the internal rotation angles about the C—C and C—O(H) bonds were varied and the nine parameters obtainable from the experimental data computed. The main results are summarized in Table 6 and in Figs. 2 and 3. Comparison of the observed and calculated parameters reveals that the minimum energy conformation must be *gauche–gauche* (*G–g*) about the C—C and C—O(H) bonds. In this minimum the hydroxyl hydrogen atom is directed toward the ether oxygen atom. The calculated principal axis coordinates of the hydrogen atom alone show this clearly. Although only relative values of calculated dipole moment components are significant, they do confirm this isomer since the others would give rise to quite different spectra than the one observed.

The initial model with *G–g* dihedral angles of 60° and a *trans* CH_3 group does not, however, reproduce the *A* and *B* rotational constants and the hydrogen coordinates sufficiently well; the differences are large enough to justify further refinement even though the problem is severely underdetermined. For instance, moving the CH_3 group out of the plane several degrees toward the OH group makes *A* and *B* simultaneously

‡Based on the assumed valence structure and the variation of the dihedral angles within the indicated limits.

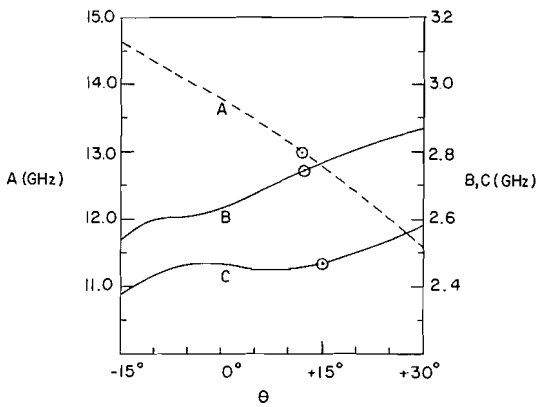

FIG. 4. Variation of rotational constants with COC/CCO dihedral angle (θ) $\theta = 0°$ COCC coplanar; $\theta = (+)$ CH_3 toward OH; $\theta = (-)$ CH_3 away from OH. Circles are observed values.

converge toward the experimental values (Fig. 4) but does not significantly affect the hydrogen coordinates. Decreasing the COH/CCO dihedral angle to about 45° has only a small effect on the rotational constants but brings the hydrogen c coordinate close to zero and improves the a and b coordinates. No combination of reasonable changes in the assumed valence structure alone, *e.g.*, varying the heavy atom lengths and angles or the OH lengths and COH angle, was found which could produce a similar convergence. A consistent fit to the nine parameters occurs for dihedral angles of $8 \pm 3°$, $45 \pm 5°$, and $57 \pm 3°$ about the C—O(ether), C—O(H), and C—C bonds, respectively (Table 7). The error limits quoted are somewhat arbitrary but probably exceed those resulting from changes in the valence structure; they apply for the assumed structure. Modifications of the valence structure and the dihedral angles simultaneously refer to an ultimate refinement which, of course, can only be determined by further isotopic substitution. Improvement of the hydrogen coordinates will depend mainly on the valence structure, particularly the OH length and the COH and CCO(H) angles. It seems clear that, whatever the final structure may be, the conformation responsible for the ground state spectrum is *gauche* about the three internal rotation axes, involving a rather closed COH/CCO dihedral angle and a methyl group oriented about 8° toward the hydroxyl group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

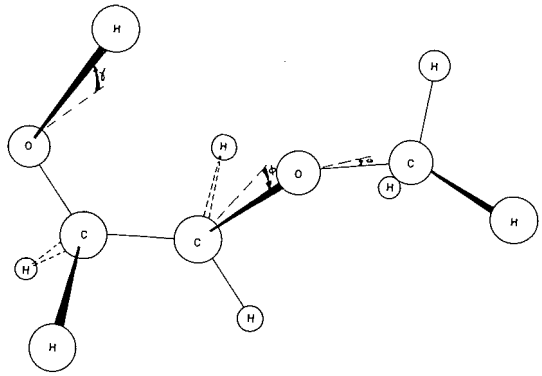

FIG. 5. Representation of the all-gauche conformation of 2-methoxyethanol. $\phi \simeq 57°$; $\gamma \simeq 45°$; $\theta \simeq 8°$.

(Fig. 5). The orientation of the methyl group about its axis is unknown but is presumably staggered with respect to the nearest methylene hydrogen atoms.

The vibrational satellites analyzed are due to molecules in the all-*gauche* conformation. Other weaker lines are present and while they have not been fully analyzed, they are probably due to other excited states of the same conformation. As mentioned previously the spectra of other molecular conformations would be quite different from that observed. Dipole moment calculations show that these would have been observable if an appreciable population existed; if another conformation was within 1 kcal/mol of the ground state.

The absence of any identifiable lines due to a *trans* (C—C) isomer is compatible with an enthalpy difference of 1.8 kcal/mol between the *gauche* and the *trans* isomers determined from infrared intensity measurements of dilute solutions (5). The infrared spectrum of the vapor obtained recently in this laboratory[1] shows only one band for each of the OH stretching and torsional vibrations at frequencies consistent with the all-*gauche* isomer (3635 and 360 cm^{-1}).

The Intramolecular Hydrogen Bond

The all-*gauche* conformation adopted by the molecule is one in which the hydroxyl hydrogen atom is approximately aligned with the nearest, tetrahedrally directed, sp^3 lone pair electrons of the ether oxygen atom. This alignment involves distortion of the usual staggered positions found in similar molecules. Despite the highly electronegative oxygen atoms, the dihedral angle about the C—C bond is the same or slightly smaller than in ethane, and is significantly smaller than in dichloroethane (70°) and the 2-haloethanols (63°). For this angle, however, the O···O nonbonded distance is approximately equal to the sum of the van der Waals radii, as observed in the 2-haloethanols. The hydroxyl hydrogen atom, some 15° away from the staggered minimum toward the unstable *cis* position eclipsing the C—C bond, is nearly as close as possible to the ether oxygen atom, the H···O distance being about 0.3 Å less than the sum of the van der Waals radii. In the haloethanols, the corresponding angle is 55°, making the OH and CX bonds parallel. It is difficult to predict the location of the methyl group about the C—O (ether) axis, but a *trans* methyl group would make all bonds staggered and the methyl and methylene hydrogens as far apart as possible. Small deviations from this geometry may not be significant in themselves, but it is significant that the methyl group is oriented out of the COCC plane *toward* the hydroxyl group: the immediate environment of the methyl group is the same on either side of that plane. In this position the lone pair orbital axis and the hydrogen atom are in the same plane. This would also occur for a COH/CCO dihedral angle of 60° if the CH_3 group was 30° out of the plane or, for a COH/CCO dihedral angle of 25–30° and a *trans* CH_3 group, but these are more distorted configurations. The other lone pair could become directed toward the hydrogen atom only if the methyl group turned 120° into an improbable, sterically unfavorable position.

The actual conformation is evidently a compromise between the intramolecular OH···O interaction and the opposing barrier forces. One can infer that in 2-methoxyethanol the compromise favors the intramolecular hydrogen bond and that the bond involves lone pair electrons. This is the same result as in 2-aminoethanol where the dihedral angles about the C—O (30°) and C—N (40°) bonds permit maximum interaction between the hydrogen atom and the nitrogen sp^3 lone pair electrons (3).

It is a pleasure to acknowledge the expert technical assistance of Marcel Rouillard, Jean-Paul Langlois, and Gaétan Genest during the construction of the microwave

Etude par spectrométrie de vibration des composés d'addition formés entre le chlorure ou le bromure d'aluminium et le dimethylsulfoxyde

J. MEUNIER ET M. T. FOREL

Laboratoire de Spectrométrie de Vibration, associé au C.N.R.S., Université de Bordeaux I, 33-Talence, France

Reçu 9 novembre 1971

Les composés d'addition formés entre le chlorure ou le bromure d'aluminium et le diméthylsulfoxyde ou le diméthylsulfoxyde-d_6 ont été synthétisés. Deux composés solides différents $AlX_3.(dmso)_{1.5}$ et $AlX_3.(dmso)_6$ ont été isolés. L'analyse spectroscopique montre qu'ils sont ioniques et correspondent aux formules $[Al(dmso)_6]^{3+}.3AlX_4^-$ (I) ou $[Al(dmso)_6]^{3+}.3X^-$ (II). Une interpretation complète des spectres est effectuée. Les résultats concernant le cation $[Al(dmso)_6]^{3+}$ sont compatibles avec une symétrie D_{3d} pour les dérivés (I) et C_{2h} pour les dérivés (II). Ils montrent en outre une intéraction importante entre les ions X^- et les cations de la forme (II).

La constante de force de la liaison AlO a été déterminée; elle est proche de 1.8×10^5 dynes cm^{-1}.

Coordination compounds between $AlCl_3$ or $AlBr_3$ and $(CH_3)_2SO$ or $(CD_3)_2SO$ have been prepared. Two different solid compounds $(AlX_3).(dmso)_{1.5}$ and $AlX_3.(dmso)_6$ have been characterized. The vibration spectra show that they are ionic, $[Al(dmso)_6]^{3+}.3AlX_4^-$ (I) and $[Al(dmso)_6]^{3+}.3X^-$ (II). A complete assignment is proposed. Results are in good agreement with a D_{3d} symmetry for the cation of compound (I) and C_{2h} for the cation of compound (II). Strong interaction between the X^- ions and the methyl groups of the form (II) exist.

The (Al—O) bond force constant is close to 1.8×10^5 dynes cm^{-1}.

Canadian Journal of Chemistry, **50**, 1157 (1972)

Introduction

Les réactions de polymérisation du type Ziegler–Natta sont catalysées par des mélanges ternaires contenant un métal de transition, une base de Lewis et un dérivé de l'aluminium (*1*, 2).

Afin d'essayer de comprendre le rôle joué par les différents composants, nous avons étudié, grâce aux travaux déjà effectués au laboratoire, les composés d'addition susceptibles de se former entre les trihalogénures d'aluminium et le diméthylsulfoxyde (dmso).

Le composé d'addition $AlCl_3$.6dmso a été signalé par plusieurs auteurs (3 à 7) et certains ont suggéré l'existence du cation $[Al(dmso)_6]^{3+}$. Cet ion a d'ailleurs été mis en évidence par r.m.n. dans le complexe $Al(ClO_4)_3$.6dmso (8). Le dérivé $AlBr_3$.6dmso est également connu (7). Aucun spectre complet de ces composés n'a été publié et les travaux précédents ne citent que les fréquences des élongations ν(AlO) et ν(SO).

Conditions expérimentales

Les halogénures d'aluminium et le diméthylsulfoxyde proviennent de la maison Fluka A. G. Buchs. Le chlorure et le bromure d'aluminium sont sublimés sous vide, le dmso est distillé sur hydrure de calcium sous pression réduite. Le diméthylsulfoxyde deutérié (dmso-d_6) fabriqué par le C.E.A. est utilisé tel quel; son enrichissement isotopique est de 99.5%. L'éther éthylique est distillé sur sodium. Tous les produits sont manipulés sous atmosphère anhydre.

(a) Synthèse des composés d'addition

La méthode utilisée est celle décrite par Selbin et coll. (5): nous avons dissous dans l'éther éthylique une quantité connue d'halogénure d'aluminium puis ajouté un volume déterminé de dmso. Le précipité formé est recueilli sur un verre fritté et lavé à l'éther pour éliminer l'halogénure en excès. Différents solides ont été isolés en prenant des rapports $\rho = [dmso]/[AlX_3]$ compris entre 0.1 et 10.

(b) Spectres infrarouges et Raman

Les spectres d'absorption entre 4000 et 250 cm^{-1} sont enregistrés avec un appareil Perkin–Elmer 521. La région spectrale comprise entre 400 et 30 cm^{-1} est explorée à l'aide d'un spectromètre interférentiel R.I.I.C.

Les échantillons sont examinés en suspension dans le Nujol ou l'hexachlorobutadiène entre des faces de KRS 5 ou de polythène. Nous avons vérifié qu'elles ne sont pas dégradées au contact des produits.

Les spectres de diffusion sont obtenus à l'aide d'un spectromètre Coderg PH1 utilisant comme source un laser hélium–néon ($\lambda = 6328.17$ Å). En raison de la forte diffusion des poudres, certaines fréquences n'ont pu être déterminées.

Mise en évidence des différentes structures

Quand le rapport $\rho = [dmso]/[AlCl_3]$ augmente jusqu'à 1.5, les spectres infrarouges des précipités restent identiques. Ils correspondent à un composé bien défini de formule $AlCl_3.(dmso)_{1.5}$.

Pour des valeurs supérieures, de nouvelles bandes qui ne sont pas celles du dmso libre (9, 10) se juxtaposent aux précédentes. Ces absorptions augmentent en intensité avec ρ

†Référence 11.

alors que les autres diminuent; elles subsistent seules quand $\rho = 6$. On est alors en présence d'un autre composé de formule $AlCl_3.(dmso)_6$.

Pour ρ supérieur à 6, les bandes du dmso libre apparaissent.

Les mêmes résultats sont obtenus avec le bromure d'aluminium.

Les stoechiométries des composés (I) $AlX_3.(dmso)_{1.5}$ et (II) $AlX_3.(dmso)_6$ avec X = Cl ou Br, ont été vérifiées pondéralement, par un dosage Charpentier–Vohlard de l'halogène et une microanalyse du carbone.

Pour les valeurs de ρ comprises entre 1.5 et 6 les précipités isolés correspondent à des mélanges des composés I et II dont les proportions sont définies par la réaction

$$AlX_3.(dmso)_{1.5} + 4.5\ dmso \rightarrow AlX_3.(dmso)_6$$

Nous avons effectué les spectres Debye–Scherrer des dérivés chlorés (formes I et II); ils ne sont pas identiques, ce qui confirme l'existence de deux structures différentes (tableau 1). Bien que le petit nombre de taches ne nous ait pas permis de déterminer le groupe d'espace, il semble que $AlCl_3.(dmso)_6$ soit isotype de $ScBr_3(dmso)_6$ (11) (tableau 1).

Les spectres infrarouges et Raman des composés de forme I présentent des bandes qui n'ont pas d'effet isotopique du deutérium et sont fortement déplacées par le changement d'halogène (figs. 1 et 2). Leurs fréquences correspondent à celles des ions AlX_4^- (12–14); les exclusions infrarouges–Raman sont celles du groupe de symétrie T_d (tableau 2).

La stœchiométrie et la présence des ions AlX_4^- suggèrent pour les composés de forme I la formule développée $[Al(dmso)_6]^{3+}.3AlX_4^-$.

La très grande similitude des spectres des dérivés de forme II, $AlCl_3(dmso)_6$ et $AlBr_3(dmso)_6$, montre qu'aucune bande ne peut être attribuée à une liaison Al—X (figs. 2 et 3); la même analogie est retrouvée pour les composés deutériés. En raison de la stœchiométrie, on doit être en présence de composés ioniques de formule $[Al(dmso)_6]^{3+}.3X^-$.

Des composés d'addition analogues, entre le chlorure de gallium et le diméthylsulfoxyde, ont été mis en évidence par Carty et Patel (15): $Ga(dmso)_6^{3+}.3GaCl_4^-$ et $Ga(dmso)_6^{3+}.3Cl^-$.

Discussion du spectre de vibration de l'ion $Al(dmso)_6^{3+}$

L'ion $Al(dmso)_6^{3+}$ possède au maximum la symétrie D_{3d} si l'on admet, comme le font tous les auteurs (3–7), que la liaison de coordination met en jeu l'atome d'oxygène. Nous avons dénombré dans cette hypothèse les vibrations d'un modèle $Al(OSC_2)_6$ (tableau 3). L'analyse des spectres repose sur l'examen de l'effet isotopique du deutérium et sur la comparaison avec le dmso libre (9) et le groupe AlO_6(16). Comme le changement d'halogène déplace les fréquences de 5 cm^{-1} au maximum, nous ne discuterons que les résultats relatifs aux dérivés bromés dont les spectres Raman sont les plus complets.

Dérivés $[Al(dmso)_6]^{3+}.3AlX_4^-$

(1) Vibrations du groupe AlO_6

Les fréquences de vibration du groupe AlO_6 ont été peu étudiées et les résultats de la littérature ne sont pas cohérents (16–19).

Entre 450 et 600 cm^{-1}, région où aucune fréquence de vibration du dmso n'est attendue, on observe pour le dérivé $[Al(dmso)_6]^{3+}.3AlBr_4^-$ deux bandes de diffusion à 492 et 461 cm^{-1} et une absorption à 539 cm^{-1} (Fig. 1); nous les attribuons aux mouvements ν(AlO). L'exclusion infrarouge–Raman suggère l'existence d'un centre de symétrie dans l'ion $Al(dmso)_6^{3+}$ et une symétrie locale O_h; elle est compatible avec le groupe D_{3d} si l'on admet que les niveaux A_{2u} et

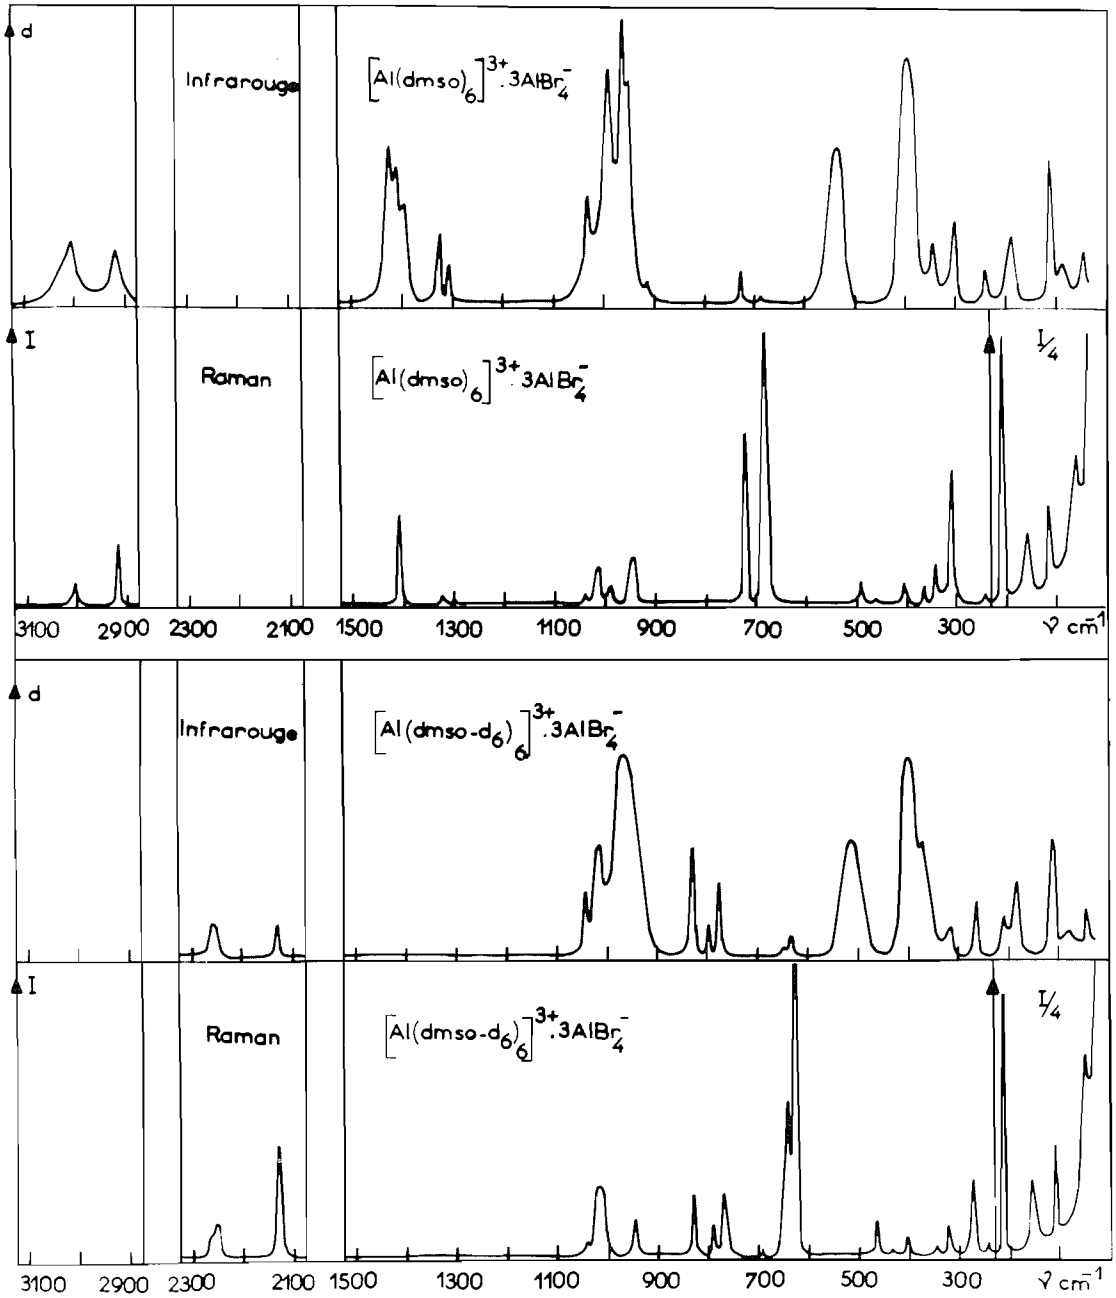

FIG. 1. Spectres infrarouges et Raman des composés bromés de forme I.

E_u ne sont pas séparés (tableau 3). La comparaison avec l'étude récente de l'ion $Al(H_2O)_6^{3+}$ (16) conduit à faire correspondre la raie Raman de plus haute fréquence à la vibration de symétrie A_{1g} (tableau 4). L'important effet isotopique du deutérium sur les élongations ν(AlO) montre qu'elles sont couplées avec les mouvements des ligandes.

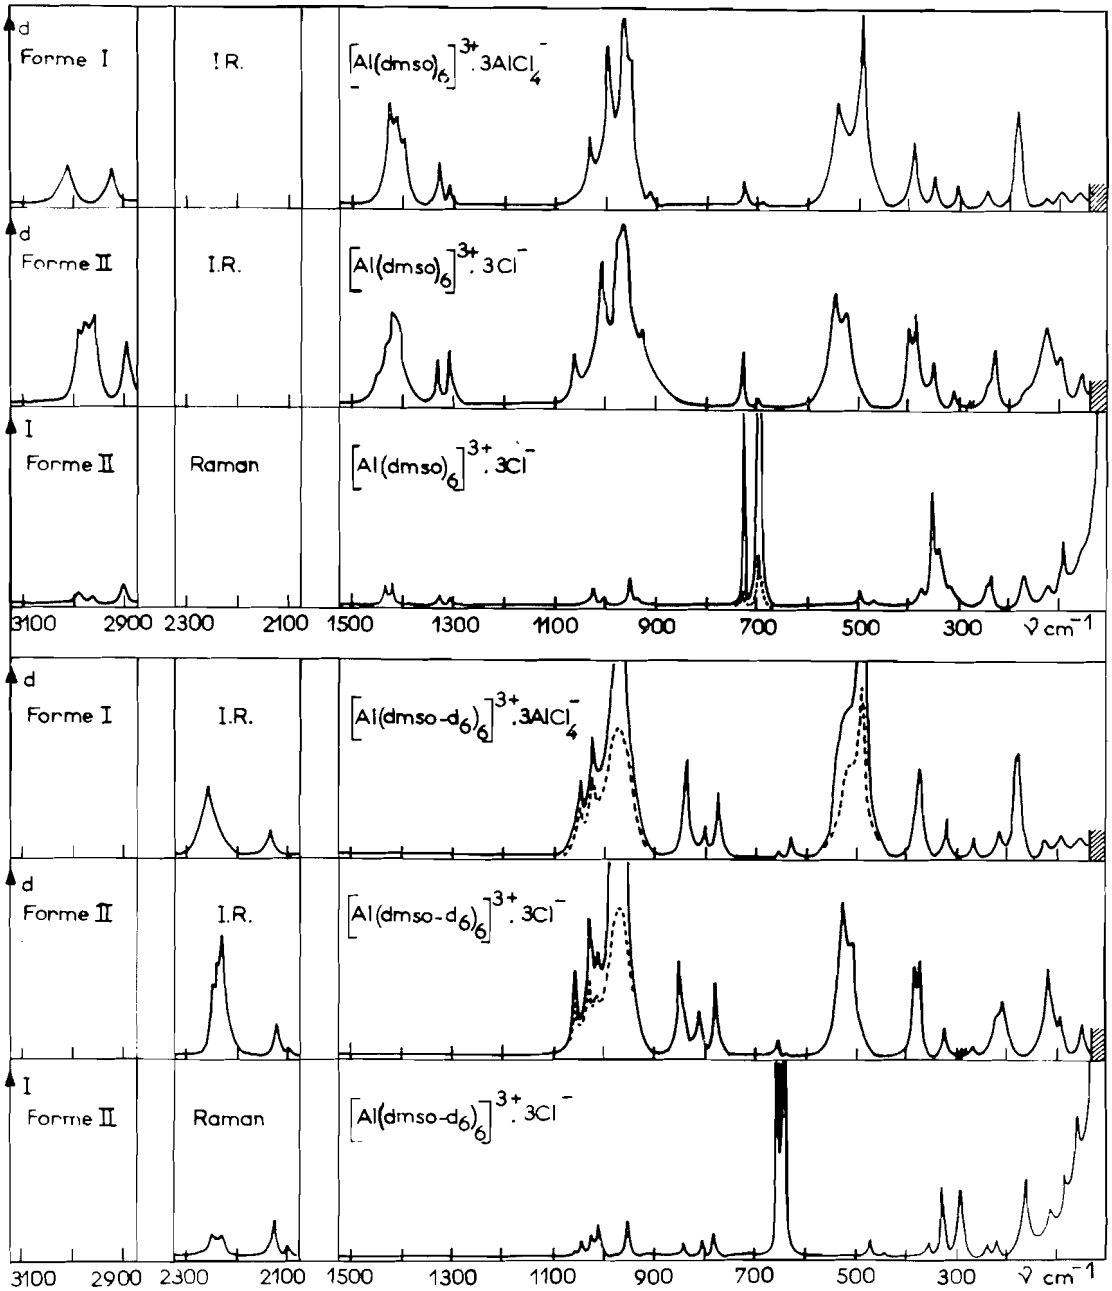

FIG. 2. Spectres infrarouges et Raman des composés chlorés.

Les déformations δ(OAlO) sont observées vers 300 cm^{-1} sur les spectres de l'hexahydrate d'aluminium (16); en raison de la masse du dmso elles sont attendues à des fréquences plus faibles dans l'ion $Al(dmso)_6^{3+}$. Nous les faisons correspondre à la raie à 161 cm^{-1} et à l'absorption à 188 cm^{-1}, car elles ne sont pas modifiées par la deutériation.

Tous les spectres présentent entre 210 et 250 cm^{-1} une bande qui n'a pas d'effet iso-

topique en diffusion alors qu'elle s'abaisse de 31 cm^{-1} en infrarouge. En raison de cette différence de comportement, nous pensons qu'il ne s'agit pas du même mode de vibration et proposons d'attribuer la raie Raman à une déformation δ(OAlO) et la bande infrarouge à un mouvement du dmso.

(2) Vibrations des groupes dmso

Au-dessus de 600 cm^{-1}, les spectres de vibration du dmso libre et de l'ion $Al(dmso)_6^{3+}$ présentent le même nombre de bandes; les six dmso sont donc liée à l'aluminium de façon identique. Sauf dans la région 900–1100 cm^{-1} les fréquences infrarouges et Raman sont très voisines, ce qui indique un couplage très faible entre les groupes dmso.

Les fréquences des vibrations $\nu(CH_3)$, $\nu(CD_3)$, $\delta(CH_3)$, et ν(CSC) augmentent de 5 à 20 cm^{-1} par complexation.

Région 1100–750 cm^{-1}

Les nombres d'ondes infrarouges et Raman des mouvements $\delta(CD_3)$ et $r(CD_3)$ du dérivé $Al(dmso\text{-}d_6)_6.3AlBr_4$ coincident; ils sont en outre proches de ceux du dmso-d_6 libre; nous conservons la même attribution (tableau 4). L'absorption intense à 965 cm^{-1} provient alors de l'élongation ν(SO), la raie Raman correspondante est située à 948 cm^{-1}; il y a donc exclusion.

L'analyse des spectres de l'ion $Al(dmso)_6^{3+}$ montre que la vibration ν(SO) se retrouve à 945 cm^{-1} en Raman et à 960 cm^{-1} en infrarouge. Cet écart de fréquence indique un fort couplage entre les élongations des liaisons SO. La comparaison avec le dmso libre conduit à situer les balancements $r(CH_3)$ à 1031, 990, 950, et 909 cm^{-1}. La raie Raman à 1016 cm^{-1}, qui n'a pas d'homologue en absorption, provient peut-être d'un autre mode ν(SO). Dans ce cas la bande située à 1018 cm^{-1} dans le composé deutérié pourrait être due à la fois à ν(SO) et à un mouvement $\delta(CD_3)$, ce qui expliquerait sa forte intensité.

Ces résultats montrent que les six ligandes ont, autour de l'aluminium, une disposition centrosymétrique compatible avec la symétrie D_{3h} que nous avons proposée.

L'abaissement des fréquences ν(SO) par complexation et l'exclusion infrarouge–Raman confirment que la liaison de coordination s'effectue grâce à l'oxygène.

Région 750–200 cm^{-1}

Les bandes situées à 376, 321, et 266 cm^{-1} sur le spectre infrarouge de l'ion$[Al(dmso\text{-}d_6)_6]^{3+}$ se trouvent à des fréquences supérieures pour l'ion hydrogéné (tableau 4). Elles proviennent des mouvements de déformation δ(SO), γ(SO) et δ(CSC) attendus dans cette région spectrale.

Une seule de ces trois bandes a la même fréquence (321 cm^{-1}) en infrarouge et Raman. Nous l'attribuons à δ(CSC) car c'est le vibrateur qui peut le moins se coupler avec les mouvements de l'octaèdre.

Les déformations γ(SO) sont orthogonales aux élongations des liaisons AlO adjacentes, par contre, elles peuvent se coupler avec les mouvements δ(OAlO). Ces derniers étant situés vers 180 cm^{-1}, les vibrations de groupe γ(SO) sont déplacées vers les hautes fréquences: nous les faisons correspondre aux bandes infrarouges et Raman observées respectivement à 376 et 348 cm^{-1} (tableau 4).

L'absorption de plus basse fréquence, 266 cm^{-1}, est alors attribuée à δ(SO) abaissée par couplage avec ν(AlO); il lui correspond la raie Raman à 271 cm^{-1}.

Seule l'absorption à 212 cm^{-1} n'a pas été interprétée. Elle ne peut pas provenir d'une torsion des groupes CD_3 car le rapport iso-

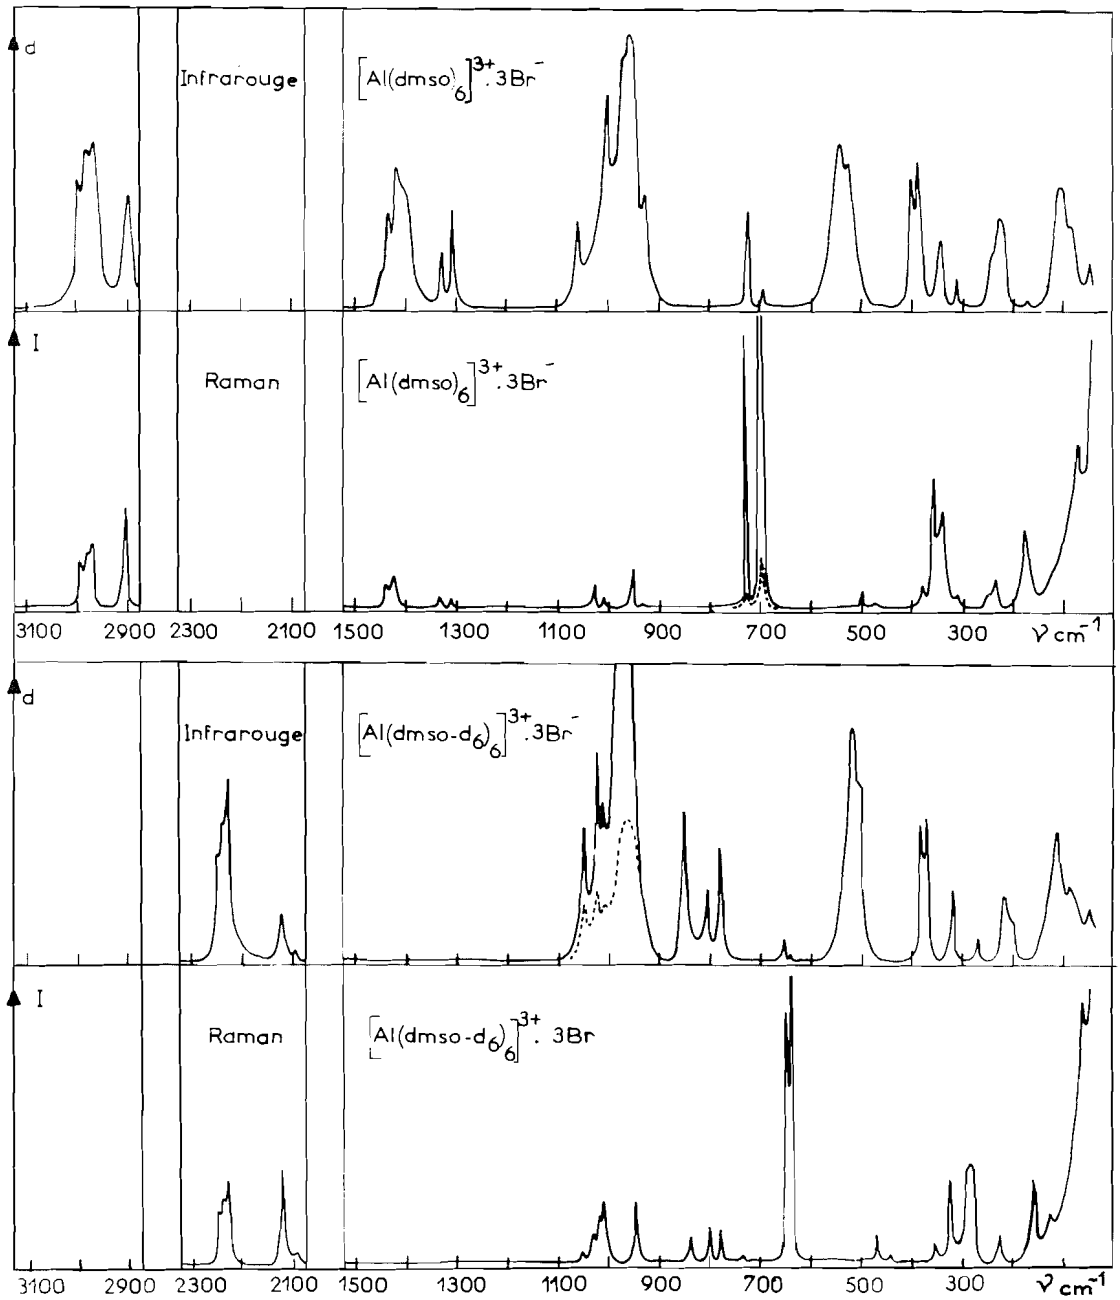

FIG. 3. Spectres infrarouges et Raman des composés bromés de forme II.

topique est trop faible ($\rho_{exp} = 1.14$ et $\rho_{th} \simeq 1.37$). Nous proposons de l'affecter à un mode mettant surtout en jeu δ(SO).

La formation de la liaison de coordination par l'intermédiaire de l'atome d'oxygène modifie donc l'ordre des fréquences δ(SO), γ(SO), et δ(CSC) par rapport à la molécule libre, contrairement à ce qui a été proposé par Berney et coll. (20) pour différents ions $[M(dmso)_6]^{n+}$.

(3) Région inférieure à 200 cm^{-1}

L'absorption à 90 cm^{-1} qui est fortement abaissée par la deutériation doit provenir d'une déformation complexe de l'ion $[Al(dmso)_6]^{3+}$; le rapport isotopique est en effet très différent de ceux que l'on prévoit pour les vibrations de groupe non encore attribuées.

La fréquence de la bande située à 50 cm^{-1} est modifiée par la substitution du deutérium à l'hydrogène et du brome au chlore; nous la faisons correspondre à une vibration de réseau.

Dérivés $[Al(dmso)_6]^{3+}.3X^-$

Les bandes que nous venons d'attribuer aux vibrations de l'ion $[Al(dmso)_6]^{3+}$ des composés de forme I se retrouvent sur les spectres des composés de forme II; nous conserverons donc la même interprétation. Quelques modifications de fréquences et d'intensités sont cependant observées: nous allons les discuter.

(1) Vibrations des groupes méthyles

Les massifs attribués aux mouvements $\nu(CH_3)$ ou $\nu(CD_3)$ et $\delta(CH_3)$ présentent un plus grand nombre de maximums. Nous pensons que cette multiplicité provient de l'existence de groupes méthyles non identiques. En effet, ce phénomène est également observé pour les composés $[(CH_3)_2SO]_2PdX_2$ solides et dans ce cas les dilutions isotopiques montrent qu'il n'est pas dû à un effet de corrélation (21).

Les fréquences des élongations $\nu(CH_3)$ diminuent quand on passe de la forme I à la forme II alors que celles des déformations $\delta(CH_3)$ et des balancements $r(CH_3)$ augmentent (tableaux 4 et 5). Il en est de même pour les vibrations des groupes CD_3. Il y a donc intéraction spécifique entre les anions et les groupes méthyles. Celle-ci est d'autant plus forte que l'anion est plus petit, par contre Cl^- et Br^- ont des actions comparables. Ce résultat est en accord avec les travaux de Roche concernant l'influence des anions sur le méthyl de l'acétonitrile (22).

(2) Vibrations $\delta(SO)$ et $\gamma(SO)$

Les nombres d'ondes des mouvements δ(SO) augmentent et l'écart de fréquence entre les modes actifs en Raman et en infrarouge croît (tableau 5). La raie de diffusion vers 285 cm^{-1} du dérivé $[Al(dmso\text{-}d_6)_6]^{3+}.3Br^-$ est dédoublée mais ceci ne prove pas que le squelette $Al(OSC_2)_6$ ait une symétrie inférieure à D_{3d} puisque deux vibrations δ(SO) sont attendues en Raman pour ce groupe de symétrie (tableau 3). Les raies relevées vers 310 cm^{-1} sur les spectres des composés hydrogénés proviennent sans doute de vibrations de combinaison mettant en jeu les modes de réseau car le déplacement de fréquence par changement d'halogène est très supérieur à ceux relevés pour les autres mouvements de déformation de l'ion $[Al(dmso)_6]^{3+}$.

Les nombres d'onde des vibrations γ(SO) sont également augmentés; en outre, l'absorption infrarouge correspondante présente deux maximums séparés d'une douzaine de cm^{-1}. Un tel éclatement peut provenir d'un effet de corrélation dans le cristal, mais la simplicité du reste du spectre suggère qu'il s'agit plutôt de deux modes différents provenant d'une symétrie de site inférieure à D_{3d}: S_6 ou C_{2h} (tableau 3).

(3) Vibrations du groupe AlO_6

Les élongations ν(AlO) sont peu modifiées,

*Non observée.

mais l'absorption centrée vers 530 cm^{-1} présente deux maximums séparés de 17 cm^{-1} environ, la largeur du massif à la demi-intensité restant du même ordre de grandeur.

Les déformations δ(OAlO) sont plus perturbées: la fréquence infrarouge est augmentée, la bande Raman vers 170 cm^{-1} présente un effet isotopique du deutérium de 8 cm^{-1} alors qu'elle ne varie pas dans les composés de forme I. Ceci suggère une modification des angles OAlO de l'ion $[Al(dmso)_6]^{3+}$.

Le doublet situé vers 230–250 cm^{-1} sur les spectres de diffusion peut correspondre à la raie à 243 cm^{-1} des dérivés de forme I. Dans ces conditions, trois mouvements δ(OAlO) sont actifs en Raman, ce qui est compatible avec une symétrie C_{2h}.

Evaluation de la constante de force de la liaison AlO

Nous avons effectué un calcul des modes normaux de vibration du squelette $Al(OSC_2)_6$ par la méthode de Wilson (23). Les paramètres géométriques sont égaux à ceux de l'ion $[Al(H_2O)_6]^{3+}$ (24) ou $[Fe(dmso)_4Cl_2]^+$ (25) pour les groupes AlO_6 et OSC_2 respectivement. L'angle AlOS a été posé égal à 120°. Les coordonnées de symétrie du groupe AlO_6 ont été écrites dans l'hypothèse d'une symétrie D_{3d}, par contre les six modèles C_2SO ont été considérés séparément.

Un champ de force approché a été obtenu en envisageant successivement les vibrations de AlO_6 et celles de C_2SO. Il conduit à une description assez satisfaisante des spectres de vibration et met en évidence les résultats suivants: (*1*) la constante de force des liaisons AlO est voisine de 1.8×10^5 dynes cm^{-1}, valeur proche de celles obtenus pour $(CH_3)_2OAlX_3$ (26). (*2*) les modes mettant surtout en jeu les coordonnées γ(SO) contiennent une forte participation de δ(OAlO); leurs fréquences sont supérieures à celles des mouvements δ(CSC) et δ(SO). (*3*) les six vibrations δ(CSC) sont calculées à la même fréquence. Pour les mouvements δ(SO), γ(SO), δ(OAlO), ν(AlO), et ν(SO) on attend par contre des éclatements assez importants entre les niveaux de symétries différentes.

Nous remercions Monsieur le Professeur Lascombe pour ses nombreux conseils, et Messieurs les Professeurs Gay et Maurin pour la détermination des spectres R.X.

Received June 15, 1971

Reactions of *N*-chloroazacyclooctane and *N*-chloroazacyclononane are described which give good yields of bicyclic amines. These are: (*a*) short chain homolytic reactions involving *neutral* nitrogen radicals initiated by ferrous ion or metallic silver; (*b*) apparent homogeneous reactions involving silver ion and bases; (*c*) reactions using silver oxide suspension which also require added bases.

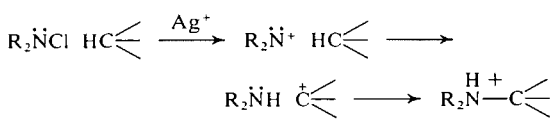
Both rate and product composition for (*b*) and (*c*) are sensitive to oxygen indicating that they are homolytic processes, probably initiated by traces of silver metal. No evidence for involvement of discrete nitrenium ions was found. However, reaction of *N*-chloroisoquinuclidine with silver ions has the character of a heterolytic process, giving products completely distinct from those from its homolytic decomposition. The addition of *neutral* piperidino radicals to styrene is described.

On décrit les réactions du *N*-chloroazacycloactane et du *N*-chloroazacyclononane, qui donnent de bons rendements en amines bicycliques. Ce sont: (*a*) les réactions homolytiques de courtes chaînes impliquant des radicaux azote *neutres* initiés par l'ion ferreux ou l'argent métallique; (*b*) des réactions homogènes apparentes impliquant l'ion argent et des bases; (*c*) des réactions utilisant une suspension d'oxyde d'argent impliquant aussi l'addition de bases.

La vitesse et la composition du produit, dans les cas (*b*) et (*c*) sont sensibles à l'oxygène, indiquant que ce sont des procédés homolytiques, initiés probablement par des traces d'argent métalliques. On n'a pu prouver l'implication dans ces réactions des ions nitrénium. Toutefois, la réaction du *N*-chloroisoquinuclidine avec les ions argent possède le caractère d'un procédé hétérolytique, donnant des produits complètement distincts de ceux provenant de sa décomposition homolytique. L'addition de radicaux *neutres* pipéridino au styrène est aussi décrite.

Canadian Journal of Chemistry, **50**, 1167 (1972)

Substitution of nitrogen on saturated unactivated carbon has been achieved using protonated nitrogen radicals derived from chloramines (1) (Hofmann–Löffler–Freytag reaction), nitrogen radicals from chloramides (2*a*) and chlorolactams (2*b*), by chemically and photochemically generated alkoxycarbonyl nitrenes (3) and acyl nitrenes (4), and by nitrenium ions derived from oximes (5). Some time ago we reported transannular substitution of saturated carbon using electron-deficient nitrogen species derived from chloramines (6). We considered the reactive species to be nitrenium ions, $R_2N:^+$ as illustrated:



We now present evidence that the medium ring reactions are homolytic processes and that simple aliphatic nitrenium ions are not readily produced from chloramines by silver ions.

Attempted Generation of Nitrenium Ions

In our efforts to generate and observe reaction of nitrenium ions we studied medium ring amines. The efficient transannular hydride transfer to medium ring carbonium ions (7) encouraged us to expect similar reaction of any discrete or developing nitrenium ions. We first re-examined the early work of Fischer (8) on the deamination of 1,1-dialkylhydrazines. However, in agreement with his findings, the major reaction of *N*-aminoazacyclononane was frag-

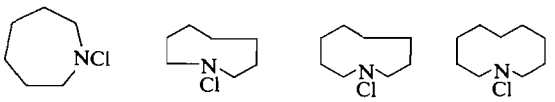
[1] 
mentation to give N_2O and azacyclononane (eq. 1). A second alternative was hence attempted, the silver ion-promoted ionization of medium ring chloramines (eq. 2). The sub-

[2] $R_2NCl + Ag^+ \longrightarrow R_2N{:}^+ + AgCl$

strates chosen were *N*-chloroazacycloheptane (**1**), *N*-chloroazacyclooctane (**2**), *N*-chloroazacyclononane (**3**), and *N*-chloroazacyclodecane (**4**). In our early experiments (6) a rapid reaction



1 **2** **3** **4**

was observed for the eight- to ten-membered ring chloramines in several solvents, leading to bicyclic tertiary amines. However, in attempting to duplicate and extend these experiments it was discovered that medium ring chloramines and simple aliphatic chloramines that were *completely free of amine* were inert at room temperature to silver ions in aqueous dioxane, tetrahydrofuran, or acetonitrile. The other salient observations are:

(*1*) The addition of 0.1 to 0.2 *M* equiv of the corresponding amine to solutions of the silver perchlorate and the medium-ring chloramine initiated moderately rapid reaction in a nitrogen atmosphere. In aqueous dioxane (1 h[4]) the addition of the amine resulted in precipitation of silver oxide, but in aqueous acetonitrile (6 h[4]) the basic solution remained colorless[5] and only silver chloride precipitated.

(*2*) Fresh silver oxide, washed several times with water, induced rapid (*ca.* 2 h[4]) decomposition of medium ring chloramines under nitrogen. If the washing was much more thorough the initial reaction became very much slower, but was autocatalytic. Addition of 10 mol % of amine or ammonia or a trace of hydroxide ion eliminated the induction period. However, over 10 mol % of sodium hydroxide suppressed reaction.

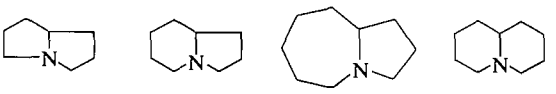
(*3*) A large excess of silver ammonium ions gave moderately rapid decomposition of the chloramines but much metallic silver was produced by oxidation of products.

(*4*) The "homogeneous" reactions in aqueous acetonitrile were dramatically slowed if the nitrogen atmosphere was replaced by air. In addition negligible amounts of bicyclic amines were produced. The effect on the silver oxide-initiated reactions was less dramatic but qualitatively the same.

(*5*) In agreement with the observations of Gassman and Fox (10) *N*-chloroisoquinuclidine reacted slowly with silver nitrate in methanol at room temperature, but was rapidly decomposed at reflux temperature. It reacted very slowly (time for complete reaction greater than 45 h), with silver oxide at room temperature.

(*6*) *N*-Chloropiperidine was inert to a sample of silver oxide which rapidly reacted with *N*-chloroazacyclononane, and inert to the combination of silver perchlorate and 10 mol % of piperidine in 90% acetonitrile – 10% water.

The bicyclic product from *N*-chloroazacyclooctane was pyrrolizidine (**5**), and that from *N*-chloroazacyclononane was indolizidine (**6**). *N*-



5 **6** **7** **8**

Chloroazacycloheptane gave negligible amounts of bicyclic products. It is interesting that *N*-chloroazacyclodecane gave 1-azabicyclo[5.3.0]-decane (**7**) as the major bicyclic product in reaction with Ag(I) although quinolizidine (**8**) was also produced. A summary of yields is presented in Table 1.

A second group of products from the silver ion or silver oxide reactions were aminoaldehydes. If the reaction products from *N*-chloroazacyclononane were directly converted to

[4]Mean time for complete reaction of *N*-chloroazacyclononane.

[5]Presumably both amine and acetonitrile (9) are acting as ligands, because hydroxide ion precipitates silver oxide from this solvent mixture.

hydrochlorides and isolated, the aldehyde group could be detected by a band at 1720 cm^{-1}. Alternatively if the products were acetylated, a neutral *N*-acetyl aldehyde (ν_{max} ($CHCl_3$) 1725 cm^{-1}) was obtained mixed with *N*-acetyl azacyclononane. However, when the free bases were isolated the aldehyde was converted to polymer.

A third type-product was the parent secondary amine. Only traces of azacyclononane were formed in reactions of *N*-chloroazacyclononane with silver oxide or in the silver ion – amine – chloramine reactions in aqueous dioxane, but up to 15% appeared in the products from "homogeneous" reaction in aqueous acetonitrile.

Since very little secondary base was formed, and the bicyclic products were readily separated from the amino aldehyde produced, the reaction using silver oxide provided convenient and mild routes to indolizidine and pyrrolizidine. We hope to extend the reactions to synthesis of natural products containing these ring systems.

As reported by Gassman and Fox (10) *N*-chloroisoquinuclidine gave a nearly quantitative yield of methoxy base **9** in the reaction with silver nitrate in methanol. However, the sluggish reaction of the chloramine with silver oxide only gave 6% of **9**. The major product was isoquinuclidine (**10**).

Metallic Silver-Initiated Reactions

As soon as it was recognized that amines were necessary to induce reaction between silver ions and chloramines, and the inevitable formation of silver oxide was noted in aqueous dioxane, we considered that metallic silver might play an important role in the reactions. Work in these laboratories had shown that fresh silver oxide rapidly oxidized some amines to carbinolamines (11, 12) while being reduced to metallic silver. Indeed small amounts of silver were detectable at the end of some of the present reactions. We hence examined the action of silver metal on medium ring and other chloramines.

The first attempts at inducing a silver catalyzed chloramine decomposition were made using a catalyst with a high specific surface developed for ethylene oxidation (13). Reaction was slow with this initiator or colloidal silver (14). However Tollens' silver (formaldehyde reduction of Tollens' solution) proved to be an effective and reproducible reagent when used in 2.5–3 *M* ratio. The amount of silver chloride produced was 20–40 mol %. The products from the medium ring chloramines were parent secondary amines, bicyclic amines, aldimines (appearing as polymer on work-up), and their hydrochlorides. Attack on solvent dioxane or tetrahydrofuran also took place. The reactions seem best formulated as homolytic processes giving *C*-chloro bases as primary products (see Discussion). However, no direct evidence for the formation of the *C*-chloro base in the silver catalyzed reaction was found. When the bases at the end of the reaction were converted to hydrochlorides, the resulting salt contained only a small excess of chlorine over that required for the hydrochlorides.

In order to further test the conception that homolytic initiation could lead to the above products, the chloramines were treated with fractional molar ratios of the one-electron reducing agents titanous and ferrous chlorides. Again short chain reactions resulted with the medium-ring chloramines (apparent chain length up to 10). The bicyclic bases were formed in comparable yields to those from the metallic silver-initiated reactions.

In marked contrast to the silver ion-promoted reaction (10) described above, *N*-chloroisoquinuclidine reacted with Tollens' silver in methanol to give a mixture of aldimine **11** and isoquinuclidine (eq. 3), but no trace of 2-methoxy-1-azabicyclo[3.2.1]octane (**9**). In the case of the reaction of both *N*-chloroisoquinuclidine and *N*-chloropiperidine with Tollens' silver, nearly 1 mol of silver chloride was produced, hence no chain reaction was involved (see Discussion).

We had earlier observed attack on tetrahydrofuran in the course of the reaction of silver ion with *N*-chloropiperidine (6), and had attributed this to hydride ion abstraction by nitrenium ions. However, since it now appears that nitrenium ions are not involved, the reaction was probably homolytic. We hence examined the decomposition of *N*-chloropiperidine in tetrahydrofuran brought about by metallic silver. As expected γ-hydroxybutyraldehyde was formed (see Scheme 2). Higher boiling neutral products with the spectroscopic characteristics of tetrahydrofuran dimer and polymer were also observed (Scheme 2).

In an attempt to produce further evidence for the homolytic character of the reactions, the reaction of *N*-chloropiperidine with silver was run in the presence of styrene. A moderate yield of a mixture of tertiary amines containing phenylethyl and piperidine units was obtained.

Discussion

The lowest energy reaction pathways for the N—Cl bond of chloramines are either homolytic fission, or heterolytic in the direction $N^- \cdots Cl^+$ in the presence of electron donors. However, heterolysis in the opposite sense can be forced in a E2 process such as the Ruschig reaction (15) (eq. 4). Another situation formally analogous to a retro-Prins reaction (16) in which chloride ion is liberated is illustrated as eq. 5. More unusual cases are the cyclization reported by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[4] 
[5] 
Adam and Schreiber (17) (eq. 6) and the rearrangement discovered by Benezra and Lusinchi (18) (eq. 7). The base in the latter two cases probably plays a secondary role following homolytic chlorination or thermal ionic rearrangement, respectively.

The present work demonstrates that the ionization of chloramine to nitrenium ions involves high activation energy, and in simple aliphatic cases silver ion pull on the halogen is not sufficient to effect this at room temperature. The work of Loeppky and Rotman (19) shows that the same is true of *N*-chloroketimines, silver assisted ionization only occurring synchronous with bond migration to nitrogen. Similarly most of the recent work of Gassman and coworkers, of Rautenstrauch, and of Horwell and Rees, can be accounted for without invoking discrete nitrenium ions. Their reactions can be considered as cases of σ-bond participation (10, 20) or π-electron participation (21, 22) in the ionization of the N—Cl bonds. The elevated temperature takes the place of silver ion pull in the pure solvolytic examples. The possible intrusion of homolytic reactions and acid catalyzed electrophilic chlorinations add uncertainty to mechanistic interpretation.

Our observations confirm that the reaction of *N*-chloroisoquinuclidine with silver nitrate in methanol is heterolytic in character since the products are strikingly distinct from those produced in the homolytic decomposition. The reaction probably involves σ-bond participation in the silver ion assisted ionization of the N—Cl bond.

The silver ion catalyzed rearrangements of azabicycloheptanes (23), the surprisingly rapid internal reaction of primary chloramines with olefinic double bonds discovered by Nagata and coworkers (24) and the silver ion catalyzed cycloaddition of unsaturated secondary chloramines described by Hobson and Riddell (25) present mechanistic problems that merit further study.

Much of the evidence suggested that our transannular reactions with Ag(I) species were push–pull heterolytic processes involving added base. This mechanism is illustrated for *N*-chloro-

[8] 
azacyclononane in eq. 8. The facts which appeared to support this were:

(*1*) Only traces of silver were formed when azacyclononane, indolizidine, or mixtures of these with aldimine (amino aldehyde) were left for 4 h under nitrogen in aqueous acetonitrile containing silver perchlorate. Hence the chance that a large amount of the product in the "homogeneous" reactions would arise in a silver-initiated homolytic process seemed small.

(*2*) The "homogeneous" reaction of the eight- and nine-membered ring chloramines with silver ion and base were much faster than those

[6]

of *N*-chloroazacycloheptane and *N*-chloroazacyclodecane. *N*-Chloropiperidine was almost inert under these conditions. This is consistent with the unique possibility for the colinear arrangement Cl—N···C—H with close approach of the nitrogen and transannular carbon in the eight- and nine-membered rings.

(*3*) The complete or near absence of the parent secondary amine, which is the most characteristic homolytic product, in the reactions with silver oxide argues against a homolytic mechanism (yield of secondary amine in the metallic silver reactions up to 37%). The yield of bicyclic products in the silver oxide reactions was up to 20% greater than in the silver metal reactions (Table 1). In addition the probable heterolytic rearrangement of *N*-chloroisoquinuclidine described above encourages an interpretation of the medium ring reactions in heterolytic terms.

(*4*) The ratio of 1-azabicyclo[5,3,0]decane (**7**) to quinolizidine (**8**) from *N*-chloroazacyclodecane in the silver perchlorate promoted reactions (60:40) was reversed (40:60) in the homolytic reactions initiated by silver metal.

(*5*) Hydroxide ion or ammonia eliminated the induction period in the silver oxide initiated reactions. Neither seems likely to give metallic silver, hence a heterolytic process seemed likely, at least until products accumulated.

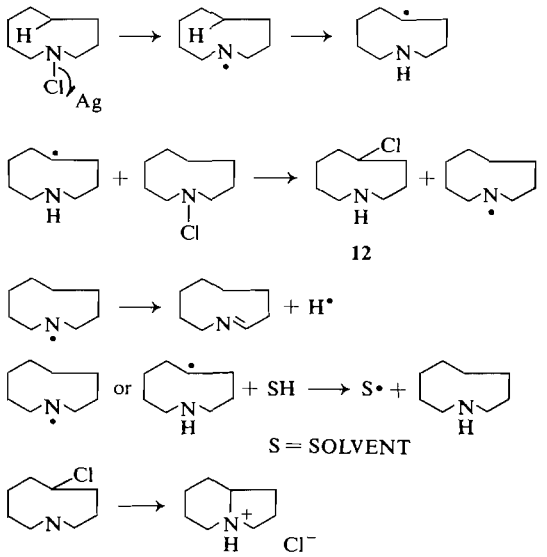
However, three observations are inconsistent with a heterolytic process.

(*a*) Radical trapping reactions showed that amine radicals were present in the "homogeneous" silver ion-initiated reactions in aqueous acetonitrile (26).

(*b*) The secondary amine produced (up to 15%) in these "homogeneous" reactions certainly arises by a homolytic process.

(*c*) The reaction of *N*-chloroazacyclooctane and *N*-chloroazacyclononane with silver perchlorate and parent amines in aqueous acetonitrile was almost stopped by the use of an air instead of a nitrogen atmosphere. In addition the yield of bicyclic products dropped sharply and very water-soluble products resulted.

As a consequence we are forced to conclude that the "homogeneous" reactions are homolytic chain reactions initiated by traces of silver, which are readily stopped by the good radical scavenger oxygen. The postulated reactions are outlined in Scheme 1.



SCHEME 1

The aldimines produced could arise by hydrogen atom expulsion from the amine radical,[6] dismutation of the amine radicals, α-hydrogen abstraction from amines, or a Ruschig-type heterolytic process promoted by silver ion and base.

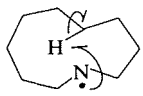
The generation of radicals using silver as a reducing agent has precedence in the preparation of triphenylmethyl radicals from triphenylmethyl chloride (27). Neutral alkylamino radicals have been generated previously by photolysis of amines (28) or decomposition (thermal, photochemical, or radical initiated) of tetrazenes (29) and chloramines (30). They have been shown to abstract hydrogen from carbon α to nitrogen (or eliminate a hydrogen atom from this carbon), producing dimers or imines (28). They are reported to have little tendency to add to carbon–carbon double bonds (29*b*) (see however, ref. 30).

Several cases of transannular hydrogen abstraction by carbon radicals are on record. Ourisson and coworkers discovered examples in the homolytic addition of carbon tetrachloride, etc. to longifolene and a medium ring analogue (31) and Traynham and Couvillon (32) described a similar reaction of cyclooctene (eq. 9). Hence there is good precedent for our postulated transannular radical reactions.

[6]Hydrogen has been identified as a reaction product (26).

[9] 
We conclude that the present work provides a new and convenient method of preparing *neutral* nitrogen radicals in solution and demonstrates their transannular attack on unactivated C—H bonds.

The dominant ring size for the reaction of *N*-chloroazacyclodecane with Ag(I) agrees with the favored six-membered cyclic transition state for hydrogen abstraction by oxygen radicals (33) and protonated nitrogen radicals (34) (see **13**).



13

As indicated in point 3 above, the silver oxide initiated reactions (and the very comparable silver ion – chloramine – amine reactions in aqueous dioxane) are remarkable in that only very low yield of secondary amines are produced. This contrasts with the 17–38% of secondary amine in the Ag^0-initiated reactions in the same solvent. It was tempting to think that the absence of secondary amine ruled out a homolytic process, and that hence a special role of silver oxide surface (with adsorbed base) favored a heterolytic push–pull mechanism resembling eq. 8. Again however, the effect of air in slowing the reaction and the resulting sharp drop in yield of the bicyclic amines seems only consistent with a homolytic process. An explanation of the high efficiency of the transannular hydrogen atom abstraction in these cases could be that most of nitrogen radicals are formed on the silver oxide surface and adsorbed long enough that the carbon radicals are formed before the radicals have contact with other hydrogen sources. This also requires that the carbon radicals react very much more efficiently to abstract chlorine from chloramine molecules than to abstract hydrogen from solvent or other sources.

In the case of the isoquinuclidinyl radical, where no transannular hydrogen is accessible the dominant reaction is attack on the hydrogens α to the nitrogen of other radicals (dismutation) or elimination of a hydrogen atom. Attack on solvent methanol seems a less favored process. Since a full molar equivalent of silver chloride was formed, no chain reaction was involved. *N*-Chloropiperidine behaved similarly. However, the nitrogen radicals did attack solvent dioxane and tetrahydrofuran (see Scheme 2).

The reaction of *N*-chloropiperidine with silver in the presence of styrene in acetonitrile produced a roughly 38% yield of products arising from addition of the piperidine to styrene. Since the bases were tertiary (inert to hot acetic anhydride), the nitrogen radicals had added, rather than carbon radicals derived from them. This agrees with the work of Minisci and Galli (30), but not with the observations of Mackay and Waters (29*b*). Since 77% of the theoretical amount of silver chloride was formed, the intermediate benzyl radicals were inefficient abstractors of chlorine from *N*-chloropiperidine, and very few radical chains were initiated.

The minor importance of chain reactions in the homolytic decomposition of *N*-chloropiperidine and *N*-chloroisoquinuclidine is consistent with the statement of Minisci and coworkers (35) that neutral nitrogen radicals cannot sustain a chain reaction. Thus the chain reactions observed with the medium ring chloroamines are special cases and are probably a consequence of the transfer of the radical center to carbon (Scheme 1).

One surprising feature in the present work was the rapidity with which the *C*-chloro bases

cyclized. However we subsequently found that even the *C*-chlorolactams corresponding to **12** cyclized spontaneously at room temperature (*2b*).

In an attempt to examine the possibility that initial radical formation might be followed by oxidation to nitrenium ions by silver ion (eq. 10), a methanol solution of *N*-chloroisoquinuclidine was treated at 5° with a mixture of Tollens'

$$[10] \qquad R_2NCl + Ag^0 \rightarrow R_2N\cdot + AgCl$$
$$R_2N\cdot + Ag^+ \rightarrow R_2N^+ + Ag^0$$

silver and silver perchlorate. The products were isoquinuclidine, methoxy base **9**, and imine **11**. This mixture could result from concurrent homolytic and ionic reactions, so we failed to demonstrate whether the radical oxidation takes place.

Summary

(*1*) Nitrenium ions *are not* generated from simple secondary chloramines in the presence of silver ions at room temperature.

(*2*) Secondary amino radicals can be generated from secondary chloramine by the action of silver metal. These efficiently abstract hydrogen from unactivated CH bonds. The transannular CH abstraction in medium rings leads to good yields of bicyclic amines. These reactions of *neutral* amine radicals may have synthetic utility where the strongly acid conditions of Hofmann–Löffler–Freytag reaction cannot be used.

(*3*) Neutral amine radicals add to styrene and induce polymerization.

Experimental

The i.r. spectra were obtained on a Perkin–Elmer model 257 grating spectrometer, and n.m.r. spectra on a Varian A-60A spectrometer. The g.l.c. was performed on the following columns: A, 6 ft × 1/4 in. SF-96 (fluorinated silicone) on fluoropak; B, 6 ft × 1/4 in. SE-30 (silicone gum rubber) on silanized Chromosorb W; C, 6 ft × 1/4 in. polyphenyl ether on Chromosorb W.

The yields of bicyclic products are minimum figures, since with the relatively small quantities used, losses were possible on isolation and distillation.

Chloramine determinations were done using 0.5 ml samples which were added to *ca.* 1 g of potassium iodide in 5 ml of methanol, 1 ml of water, and 1 ml of acetic acid. The iodine liberated was titrated with 0.1 *N* sodium thiosulfate.

Chloramine Preparation

In our earlier experiments either *N*-chlorosuccinimide or dichloramine-T in methylene chloride were used to convert the secondary amines to chloramines. However, the use of sodium hypochlorite proved much more convenient. The preparation is illustrated for azacyclononane.

A solution of 1 g of azacyclononane hydrochloride in 2 ml of water was added to 35 ml of a rapidly stirred cold 10–14% solution of sodium hypochlorite in water (strongly alkaline). The mixture was stirred for 1 h at room temperature, then extracted three times with 15 ml portions of pure pentane. The pentane layers were washed successively with water, very dilute sulfuric acid, water, then sodium carbonate solution. The dried solution (Na_2SO_4) was evaporated on a rotating evaporator under reduced pressure in a bath at 20 °C until the volume reached a few milliliters. The evaporation was then continued outside the bath until a thick oil remained. This was dissolved in the appropriate solvent and a 0.5 ml aliquot titrated iodimetrically (see general directions). The yield in all cases was over 90%.

Base Derivatives

The bases used were prepared by reduction of the corresponding lactams using lithium aluminum hydride in refluxing dioxane, followed by isolation as hydrochlorides.

Azacyclooctane hydrochloride, m.p. 178° (lit. m.p. 177° (36)); azacyclononane hydrochloride, m.p. 165° (lit. m.p. 164° (36)); azacyclodecane hydrochloride, laths from ethyl acetate, m.p. 119°, picrate, m.p. 193° (lit. m.p. 192° (37)); isoquinuclidine hydrochloride crystallized as thin plates from methanol – ethyl acetate, m.p. 302° dec. when immersed at 290° (lit. m.p. >300° (38)).

Pyrrolizidine picrate, m.p. 258–260°; mixed m.p. with an authentic sample (m.p. 256–258° (39)) was 258–260°.

Indolizidine picrate, m.p. 230°; mixed m.p. with an authentic sample (m.p. 230° (39)) was not depressed.

Azabicyclo[5.3.0]decane picrate, m.p. 212–216° was shown by g.l.c. of the base to contain *ca.* 15% of quinolizidine picrate. It gave a mixed m.p. of 210–214° with an authentic sample (m.p. 210–213° (40)) which was also shown by g.l.c. of the base to contain *ca.* 15% of quinolizidine picrate.

Tollens' Silver

Freshly washed silver oxide from 2 g of silver nitrate was suspended in 15 ml of water, and the minimum amount of concentrated ammonia added to effect solution. Aqueous formaldehyde was then added dropwise with stirring and cooling. The precipitated silver and mirror scraped from the walls was washed with water by decantation, then on a Hirsch funnel. It was kept moist, and used as soon as possible after preparation.

N-Chloroazacyclononane

The faintly yellow oil could be distilled over a short path using a bath at 65° under 8 mm pressure. It had λ_{max} 287 mμ, ε 390, and pK_a 1.2 in 95% ethanol. The protons α to the nitrogen resonated at δ 3.2 in deuterochloroform. It was stable in solution in pentane, aqueous acetonitrile, and aqueous dioxane in diffuse light. It was stable over a period of 7 h in a stirred mixture of 2 ml of dioxane and 11 mg of sodium hydroxide in 0.12 ml of water. It was also inert to a 3.5% solution (w/v) of azacyclononane in aqueous dioxane.

Solutions of the chloramine and silver perchlorate in aqueous acetonitrile or aqueous dioxane showed less than 10% drop in chloramine concentration in 20 h at room temperature in diffuse light.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

N-Chloroazacyclooctane and N-Chloroazacyclodecane

These were obtained as nearly colorless oils from pentane solution. They were stable for at least 8 h in aqueous dioxane and aqueous acetonitrile, and in solutions of silver perchlorate in these solvents.

N-Chloropiperidine

The nearly colorless oil could be distilled over a short path at 45° under 10 mm pressure. It had ν_{max} 269 mμ, ε 380, and pK_a of 1.0 in 95% ethanol. The methylene groups α to the nitrogen gave a triplet with $J = 5.5$ Hz at δ 3.20 in deuterochloroform. It reacted to the extent of 9% in 19 h at room temperature in 80% dioxane – 20% water containing 4% (w/v) of silver perchlorate.

N-Chloroisoquinuclidine

This was recovered from pentane solution as a waxy white solid. An attempt to distill a sample over a short path at bath temperatures up to 80° under 8 mm pressure led to extensive decomposition. It gave n.m.r. signals in deuterochloroform at δ 3.12 (1H) and 3.50 (2H).

N-Nitrosoazacyclononane

Azacyclononane hydrochloride (2.34 g) in a mixture of water (20 ml) and concentrated hydrochloric acid (14 ml) was cooled to 0° and an aqueous solution of sodium nitrite at 0° (3.0 g in 10 ml) was added. The mixture was stirred for 1 h, ether extracted, and washed well with water. Drying and evaporation yielded *N*-nitrosoazacyclononane (2.5 g), b.p. 90–92°/10^{-3} mm; ν_{max} (film) 1630 cm^{-1} (—N=O).

Anal. Calcd. for $C_8H_{16}N_2O$: C, 61.51; H, 10.32; N, 17.93. Found: C, 61.21; H, 10.22; N, 17.51.

N-Aminoazacyclononane

N-Nitrosoazacyclononane (2.5 g) in dry ether (30 ml) was added to a vigorously stirred solution of lithium aluminum hydride (1 g) in ether (20 ml) and the mixture was stirred overnight at room temperature. Decomposition of the excess lithium aluminum hydride with saturated aqueous Rochelle salt, followed by ether extraction, drying, and evaporation yielded the substituted hydrazine (2.1 g), b.p. 75–80° (10^{-3} mm); ν_{max} 3300, 1600 cm^{-1} (—NH_2).

This compound could not be obtained completely pure for analysis but treatment of an ethyl acetate solution (50 mg in 5 ml) with methyl iodide gave an immediate precipitate of the corresponding methiodide (60 mg) which recrystallized as needles from methanol – ethyl acetate, m.p. 216–218°.

Anal. Calcd. for $C_{11}H_{25}N_2I$: N, 8.98; I, 40.70. Found: N, 8.63; I, 39.3.

Deamination of N-Aminoazacyclononane

N-Aminoazacyclononane (650 mg) was dissolved in 2 *N* HCl (20 ml) and cooled to 0°. Excess saturated aqueous sodium nitrite (*ca.* 1.2 g $NaNO_2$) was added and the mixture stirred at 0° for 1 h then ether was added. The ether layer after washing and drying was evaporated to yield an unstable neutral fraction (*ca.* 200 mg) which was not examined further.

The aqueous layer was basified (5% NaOH) and continuously extracted with ether overnight (caution! the base fraction is fairly soluble in water) which after careful removal of the ether at room temperature under vacuum yielded the basic fraction (270 mg). The g.l.c. (Perkin–Elmer model 154, Fluoropak QF 1 on Chromosorb 60–80) indicated over 95% of one component with retention time identical to azacyclononane. Treatment of the base fraction with HCl gas yielded the corresponding hydrochloride (m.p. and mixed m.p. 164°) and with methyl iodide in ethyl acetate the methiodide (m.p. and mixed m.p. 237–238°) was obtained.

The only other constituent of much longer retention time could not be obtained pure (preparative g.l.c. fractional crystallization of derivatives, column chromatography, t.l.c.) but was probably dimeric material (no N—H in i.r. or n.m.r., yet n.m.r. indicated an azacyclononane-type structure).

Reactions with Ag(I) Species

(A) N-Chloroazacyclononane

(1) With Silver Perchlorate and Azacyclononane in Dioxane–Water

A solution of 830 mg (5.13 mmol) of the chloramine and 90 mg (14 mol % relative to chloramine) of azacyclononane in 14.5 ml of 80% dioxane – 20% water (v/v) was prepared. The flask was flushed with nitrogen, then 1.5 g of silver perchlorate added with stirring. A light brown precipitate formed. The mixture was stirred under nitrogen in a water bath at 22 °C for 40 min, when no chloramine remained. The solution was acidified with hydrochloric acid (p*H* 3) and any remaining silver ion precipitated using aqueous sodium chloride solution. After filtration the solution was taken to dryness under reduced pressure. The base was liberated with sodium hydroxide, and extracted into ether. After removal of the ether it was distilled under 15 mm pressure (bath at 70°), yielding 504 mg of oil. This consisted of indolizidine and azacyclononane in the ratio 4.7:1 (g.l.c. on column B at 125 °C). The yield of indolizidine (correcting for samples removed for titration) was 68%.

A comparable run using 29 mol % of azacyclononane relative to chloramine gave a 56% yield of indolizidine.

(2) With Silver Perchlorate and Trimethylamine in Acetonitrile–Water

A mixture of 4.48 mmol of the chloramine, 0.42 mmol of trimethylamine, and 1.50 g (7.2 mmol) of silver perchlorate in 30 ml of 90% acetonitrile – 10% water gave an opalescent solution and a small white precipitate. The flask was flushed with nitrogen. Titration showed the following reaction rate: 1 h, 7%; 2 h, 28%; 3 h, 56%; 4 h, 83%; 5 h, 95%; 5.5 h, 97.5%. The remaining 27.5 ml was left overnight under nitrogen, then taken to p*H* 5 using dilute hydrochloric acid. The rest of the silver ion was precipitated using sodium chloride. The filtered solution was evaporated to *ca.* 1 ml under reduced pressure. Acetic anhydride (5 ml) and 1 g of anhydrous sodium acetate were added and the solution heated on the steam bath for 1 h. Methanol was then added and the solution refluxed for 0.5 h to destroy excess anhydride. The methanol and methyl acetate were removed under reduced pressure. The acetic acid was neutralized and the bases liberated using solutions of first sodium carbonate then sodium hydroxide. The crystalline mush was extracted thoroughly with ether (4 × 20 ml). Fifty milliliters of the ether was concentrated to 5 ml, then a saturated solution of picric acid in ether was added. The 401 mg of crystalline picrate was recrystallized from methanol, giving 316 mg, m.p. 230°, identical to indolizidine picrate. This corresponded to a 58% yield of indolizidine.

The remaining 30 ml of ether was extracted with dilute sulfuric acid, then water, dried, and concentrated. The 62 mg

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of yellow amide showed i.r. bands in CH_2Cl_2 for amide (ν_{max} 1630 and 1670 cm^{-1}) and enol ester (ν_{max} 1780 cm^{-1}). Gentle hydrolysis using sodium carbonate in hot aqueous methanol converted the enol ester to amide aldehyde (ν_{max} ($CHCl_2$) 1722, 1665 cm^{-1}). The estimated amount of this was 10%. An attempt to obtain a crystalline derivative of the aldehyde(s) was unsuccessful.

(3) With Silver Perchlorate and Azacyclononane in Acetonitrile–Water

Fifty-three milligrams (0.42 mmol) of azacyclononane was added to a solution of 3.12 mmol of chloramine in 20 ml of 90% acetonitrile – 10% water (v/v). The p*H* of the solution was 10. After addition of 1.68 g (8.1 mmol) of silver perchlorate the p*H* dropped to 9. The reaction mixture was left under nitrogen at room temperature. The reaction was followed by iodimetric titration. The consumption of chloramine was: 35 min, 31%; 95 min, 63%; 4 h, 89%; 6 h, 96%. The reaction mixture (17.5 ml) was left overnight under nitrogen, then the base isolated as in run A1. The 240 mg of distilled base contained 62% indolizidine and 38% azacyclononane. The indolizidine yield based on chloramine used was 42%.

(4) With Silver Perchlorate and Indolizidine in Acetonitrile–Water

A parallel run to A3 but using indolizidine as base gave practically identical kinetics. The yield of indolizidine (isolated as picrate after removal of azacyclononane as *N*-acetyl derivative as in A2) was 40%.

(5) With Silver Ammonium Ions in Aqueous Acetonitrile

A solution of 335 mg (1.45 mmol) of silver oxide was prepared in 8 ml of acetonitrile and 4 ml of 28% aqueous ammonia. This was added to a solution of 2.0 mmol of the chloramine in 9.5 ml of 90% acetonitrile – 10% water (v/v). A dark precipitate formed at once. The rate of disappearance of chloramine was: 70 min, 40%; 130 min, 55%; 190 min, 64%. A solution of 340 mg of silver oxide in 2 ml of 28% ammonia was added. After a further 1 h the reaction was 90% complete. The solution (17.5 mol) was acidified with hydrochloric acid, filtered, and evaporated to small volume. The product contained approximately 10 mg of ether-soluble amide (ν_{max} (CH_2Cl_2) 1670 cm^{-1}). The base was recovered as in A1 (some tar produced) and distilled. It consisted of indolizidine (22% yield) and azacyclononane (22% yield). Hence, the bulk of the chloramine must have been converted to aminoaldehydes and/or amino acids. Metallic silver was present at the end of the reaction.

(6) With Silver Oxide in Aqueous Acetonitrile

A mixture of 1.14 g of moist well-washed freshly prepared silver oxide and 19.5 ml of a solution of 2.3 mmol of the chloramine in 90% acetonitrile – 10% water (v/v) was stirred under nitrogen at room temperature. The chloramine consumption was: 30 min, 32%; 1 h, 65%; 1.5 h, 87%; 2 h, 98%. The distilled base, recovered as in the above runs was pure indolizidine in 42% yield.

(7) With Silver Oxide in Aqueous Dioxane

An identical run to A6, using 80% dioxane – 20% water as solvent but identical silver oxide, showed a marked induction period. The rate was: 30 min, 7%; 1 h, 51%; 2 h, 86%; 3 h, 94%; 5 h, 100%. The distilled basic product had a composition 98.5% indolizidine and 1.5% azacyclononane. The indolizidine yield was 51%.

In another run which showed an even more pronounced induction period (5% reaction in 2 h; total time 8 h) the yield of indolizidine was 60%.

In a run with 21% reaction in 4 h, addition of 4 mol % of sodium hydroxide relative to chloramine, accelerated the reaction dramatically (complete in one more hour). A 52% yield of pure indolizidine was recovered.

In a run where presumably the silver oxide was not as thoroughly washed free of hydroxide ion, the reaction was complete in 1.5 h. The yield of pure indolizidine was 58%.

(8) With Silver Oxide and 10 Mol % Ammonia

A solution of 574 mg (4.5 mmol) of *N*-chloroazacyclononane in 25 ml of 80% dioxane – 20% water (v/v) was prepared. Silver oxide was prepared from 2.26 g (13 mmol) of silver nitrate then washed free of alkali. To 10 ml of the chloramine solution under nitrogen was added 40% of the silver oxide and the mixture stirred. The extent of reaction was: 1 h, 4%; 2 h, 58%; 3 h, 91.5%; 4 h, 100%. The recovered distilled base was pure indolizidine.

To the remaining 15 ml of chloramine solution was added 3.9 mg (0.23 mmol) of ammonia in water (0.14 ml) and the remaining silver oxide. The mixture was stirred under nitrogen. The rate of chloramine reaction was: 1 h, 66%; 2 h, 96%; 3 h, 100%. The product after distillation was pure indolizidine in a yield of 55% (picrate, m.p. 229–230° without recrystallization; mixed m.p. with authentic indolizidine picrate 230° dec.). The distillation residue, and the polymer produced on the isolation weighed 69 mg.

(B) N-Chloroazacyclooctane

(1) With Silver Oxide in 90% Acetonitrile – 10% Water (v/v)

To a solution of 2.98 mmol of the chloramine in 15 ml of solvent was added well-washed silver oxide from 2.44 g (14 mmol) of silver nitrate. The solution was stirred under nitrogen. The rate of chloramine reaction was: 1 h, 62%; 2 h, 93%; 3 h, 98%. After one extra hour the 18 ml of reaction mixture was acidified using hydrochloric acid, filtered, and the filtrate taken to a syrup under reduced pressure. The base was liberated using sodium hydroxide then extracted into ether. The recovered base was distilled, giving 213 mg (72% yield) of pyrrolizidine containing a trace of azacyclooctane.

(2) With Silver Oxide in Aqueous Dioxane

Well-washed silver oxide from 2.54 g (15 mmol) of silver nitrate was added to a solution of 3.1 mmol of the chloramine in 15 ml of 80% dioxane – 20% water, then the mixture stirred under nitrogen. The reaction was autocatalytic with the following percentage of chloramine reacted: 1 h, 18%; 2 h, 51%; 3 h, 78.5%; 5 h, 100%. The product, worked-up as in B1 gave a 66% yield of pyrrolizidine picrate, m.p. 258°.

(3) With Silver Perchlorate and Azacyclooctane in 90% Acetonitrile

A solution of 4.4×10^{-3} mol of *N*-chloroazacyclooctane and 9.5×10^{-4} mol of azacyclooctane was prepared in 40 ml of 90% acetonitrile – 10% water. This was split for parallel reactions in air and under nitrogen.

(*a*) Under nitrogen: The solution (25 ml) was stirred under nitrogen, then 1.58 g (7.6 mmol) of silver perchlorate added. The extent of reaction was 11% in 2 h, 72.5% in 9.5 h, and 98% in 21 h. The yield of pyrrolizidine was 50% and of azacyclooctane 13%. The silver chloride precipitate contained approximately 5 mg of silver metal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*b*) In air: Silver perchlorate (1.07 g, 5.16 mmol) was added to 15 ml of the solution, which was then stirred in air. The extent of reaction was 10% in 9.5 h, 35% in 21 h, and 84% in 68 h. The reaction was pushed to completion by addition of 20 mg of amine and stirring for a further 24 h. The product on work-up contained no pyrrolizidine, but gave azacyclooctane in 50% yield.

(C) N-Chloroazacycloheptane

(1) With Silver Perchlorate and Azacycloheptane in Aqueous Dioxane

Silver perchlorate (4.18 g, 20 mmol) was added to 30 ml of 80% dioxane – 20% water (v/v) containing 130 mg (1.3 mmol) of azacycloheptane and 11.46 mmol of *N*-chloroazacycloheptane. An autocatalytic reaction ensued. The rate of disappearance of chloramine was: 1 h, 10%; 2 h, 21%; 4 h, 58%; 6 h, 100%. The reaction mixture was worked-up as in run A2 giving an ether-insoluble tar, a small amount of oily tertiary amine picrate, and a 56% yield of *N*-acetylazacycloheptane.

(2) With Silver Oxide

Identical runs using the same silver oxide were made in two solvents. A solution of 5.9 mmol of chloramine in 25 ml of solvent, and silver oxide from 2.57 g (15 mmol) of silver nitrate was stirred under nitrogen at room temperature. The reaction in 90% acetonitrile – 10% water (36% in 5 h) was somewhat faster than that in 80% dioxane – 20% water (7% in 5 h) but was much slower than reactions of the larger-ring chloramines. The reaction in acetonitrile was complete after 22 h, but the one in dioxane was only 91% complete in that time. The base hydrochlorides were obtained as gums as in run 1. They were triturated with ether to remove neutral products. Chloroform solutions of the remaining hydrochlorides showed strong bands at 1655 cm^{-1} and weaker bands at 1722 cm^{-1} attributable to immonium ion and corresponding aldehyde, respectively. The bases were isolated using successively sodium carbonate and ether and sodium hydroxide and ether. A major product with much longer retention time than azacycloheptane (22 and 5 min respectively, column B at 110°) was present, presumably amino aldehyde. However, only *N*-acetylazacycloheptane was recovered after acetylation of the bases.

(D) N-Chloroazacyclodecane

(1) With Silver Oxide

The chloramine was inert to well-washed silver oxide in aqueous dioxane under nitrogen, but in one case striking autocatalysis was observed. The reaction was accelerated by addition of catalytic amounts of ammonia, trimethylamine, or azacyclodecane. In each case the main products isolated were a polymer (*ca.* 80% yield) and azacyclodecane (5–10% yield).

(2) With Silver Perchlorate and Azacyclodecane in Aqueous Dioxane

A solution of 3.78×10^{-3} mol of *N*-chloroazacyclodecane, 4.6×10^{-4} mol of azacyclodecane, and 1.28 g (6.2 mmol) of silver perchlorate in 20 ml of 80% aqueous dioxane was stirred under nitrogen. The extent of reaction was: 1 h, 25%; 3 h, 60%; 5 h, 73%. The remaining 17.5 ml of mixture was then stirred overnight to ensure complete reaction, acidified with hydrochloric acid, and the base recovered as in run A1. The ether and pentane-soluble base gave 208 mg of picrate. The g.l.c. (column B at 150°) showed it to contain an approximate 2% yield of each of 1-azabicyclo[5,3,0]decane and quinolizidine, and 11% of azacyclodecane (the amount added). The ether-insoluble polymeric base weighed 380 mg (83% yield). Thus the major product as in all other runs was aldimine. In a comparable run in air less than 10% of the chloramine reacted in 24 h.

Homolytic Medium Ring Reactions

(E) N-Chloroazacyclononane

(1) With Tollens' Silver in Aqueous Dioxane

A solution of 4.24 mmol of the chloramine (by iodimetry) in 20 ml of 80% dioxane – 20% water was prepared. Tollens' silver corresponding to 1.19 g (7 mmol) of silver nitrate was added to 15 ml of this solution and the mixture stirred under nitrogen. The amount of chloramine reacted was: 1 h, 71%; 2 h, 89%; 3 h, 93%. Fresh Tollens' silver was added, driving the reaction rapidly to completion. The solid was removed by filtration. By ammonia extraction and reprecipitation of the silver chloride, it was found to contain 156 mg of silver chloride. This represents approximately 40% of the chloramine reacted. The filtrate was titrated using dilute hydrochloric acid. The free base corresponded to 41% of the chloramine. When the base was liberated from the hydrochloride (NaOH) and extracted into ether some dark tar was formed. The composition of the ether-soluble base was 63% indolizidine and 37% azacyclononane by g.l.c. analysis on column B. The yield of indolizidine was 48%.

A sample of the total hydrochloride from the reaction contained 22.84% chlorine. Calculated for indolizidine hydrochloride, 21.8%.

(2) With Tollens' Silver in Aqueous Acetonitrile

A solution of 3.27 mmol of the chloramine in 25 ml of 84% acetonitrile – 16% water (v/v) was prepared. To 20 ml of this solution was added Tollens' silver from 0.72 g (4.25 mmol) of silver nitrate. The mixture was stirred under nitrogen. The chloramine reacted was: 1 h, 64%; 2 h, 75%. Tollens' silver from 0.39 g (2.3 mmol) of silver nitrate was added and stirring continued. After two more hours no chloramine remained. The silver chloride produced was 32% of theoretical and the free base present was 43% of theoretical. The liberated ether-soluble base (tar formed) contained 61% indolizidine and 39% azacyclononane. The yield of indolizidine was approximately 40%. The total base hydrochloride contained 23.25% halogen (calculated for indolizidine hydrochloride, 21.8%). Its i.r. spectrum contained no carbonyl or immonium ion bands.

In another run using 3.18 mmol of chloramine in 25 ml of 84% acetonitrile – 16% water, and silver from 1.42 g (8.35 mmol) of silver nitrate, the reaction was 97% complete in 1 h and complete in 2 h. The basic product was acetylated. The tertiary base gave a picrate, m.p. 230° dec., identical to indolizidine picrate. The *N*-acetyl derivative was mainly *N*-acetyl azacyclononane, but contained 4.25% chlorine. (Calculated for *N*-acetyl chloroazacyclononane, 17.42%.) The silver chloride produced corresponded to 33% of the reacted chloramine.

(3) With Ferrous Chloride in Aqueous Dioxane

Ferrous chloride tetrahydrate (66 mg, 0.33 mmol) was added to a solution of 530 mg (3.3 mmol) of the chloramine in 10 ml of 80% dioxane – 20% water (v/v). The mixture was stirred in the dark under nitrogen. Aliquots were removed at intervals, diluted with ether, the iron salts removed by a sodium carbonate wash, then the residual chloramine determined by iodimetry. The reaction was complete in 4 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The basic product was recovered as hydrochloride, then acetylated as in run A2. The tertiary base gave 561 mg of picrate, which after one recrystallization from methanol had m.p. 230–231° and proved identical to indolizidine picrate. The yield of indolizidine in this and other runs averaged near 50%.

(F) N-Chloroazacyclooctane

(1) With Tollens' Silver in Aqueous Dioxane

Tollens' silver from 2.05 g (12 mmol) of silver nitrate was added to 20 ml of a solution of *N*-chloroazacyclooctane (560 mg, 3.8×10^{-3} mol) in 80% dioxane – 20% water (v/v) under a nitrogen atmosphere. After 1 h, 80% of the chloramine had reacted; after 1.5 h, 96%, and 3.5 h, 97.5%. The 18 ml of mixture was filtered and the filtrate acidified to Congo red with hydrochloric acid. The solution was evaporated to a volume of a few milliliters on a rotating evaporator in a bath at 50°. The base was recovered by exhaustive extraction of the solution after basification with sodium carbonate, then sodium hydroxide. Some tar formed. The ether-soluble base was distilled (bath 70°, 15 mm), leaving a small residue. The distilled base (254 mg) was estimated by g.l.c. on column B to contain 195 mg of pyrrolizidine, the remainder being azacyclooctane. The yield of pyrrolizidine corrected for samples removed for titration was 50%.

The amount of silver chloride (99 mg) produced corresponded to a chain length of approximately five molecules of chloramine for each atom of silver converted.

(2) With Ferrous Chloride in Aqueous Dioxane

In two runs using 10 mol % of ferrous chloride tetrahydrate in 80% dioxane – 20% water, following the conditions in section E1, the reaction was complete in 4 h. Work-up as in E1 gave an average of 26% yield of picrate, m.p. 258–260°, undepressed with pyrrolizidine picrate.

(G) N-Chloroazacyclodecane

(1) With Ferrous Chloride in Aqueous Dioxane

The reaction was run as for *N*-chloroazacyclononane (see E3). The average yield of tertiary base estimated by removal of secondary base by acetylation was 39%. It gave a picrate, m.p. 220–221° after recrystallization from methanol. A mixture with authentic 1-azabicyclo[5.3.0]decane picrate (m.p. 210–221°) (40) melted at 210–221°. A g.l.c. examination of the base from these samples showed it to be a mixture of 86% 1-azabicyclo[5.3.0]decane and 14% quinolizidine. Similarly, g.l.c. of the base recovered from the total tertiary amine picrate showed it to contain approximately 45% of quinolizidine and 55% of azabicyclo[5.3.0]decane.

(2) With Silver in Acetonitrile and Acetic Anhydride

Tollens' silver from 3.0 g (17.6 mmol) of silver nitrate was added under nitrogen to a solution of 3.08×10^{-3} mol of *N*-chloroazacyclodecane in a mixture of 18 ml of dry acetonitrile and 2 ml of acetic anhydride. The extent of reaction was: 1 h, 35%; 3 h, 60%; 5.5 h, 75%; 21 h, 97%. The yield of tertiary base was 16% consisting of azabicyclo-[5.3.0]decane and quinolizidine in the ratio of 1 : 1.17.

N-Chloroisoquinuclidine Reactions

(a) With Silver Nitrate

A solution of 314 mg of the chloramine and 400 mg of silver nitrate powder was dissolved in 10 ml of reagent methanol. The solution was refluxed gently. After 1 h only 7% of the chloramine remained. Excess silver nitrate was then added, after which half an hour reflux completed the reaction. The excess silver ion was precipitated using sodium chloride solution, the solid removed by filtration, and the filtrate evaporated to near dryness under reduced pressure at 25 °C. Sodium hydroxide solution was added, and the base extracted into pure ether. The 224 mg of residue after evaporation of the ether gave only one peak (column A, 124°). Its n.m.r. spectrum contained a poorly defined one-hydrogen doublet centered at δ 3.80 and a methoxyl signal at δ 3.41, and was completely consistent with the product being the methoxy base **6**.

(b) With Silver Oxide

To a solution of 3.18×10^{-3} mol of chloramine in 15 ml of reagent methanol was added silver oxide (thoroughly washed with water, then methanol) from 0.5 g (2.9 mmol) of silver nitrate. The mixture was stirred under nitrogen. After reaction of 14% of the chloramine in the first hour the decomposition became very slow. After 21 h, 43% had reacted. Silver oxide from 1.55 g (9.1 mmol) of silver nitrate was added and the stirring continued. After a further 21 h, 78% had reacted. The basic solution was filtered and the filtrate taken to p*H* 3 with dilute hydrochloric acid in methanol. The solution was then taken to a volume of *ca.* 1 ml under reduced pressure and the residue extracted with pentane to remove any unchanged chloramine. After addition of 1 ml of saturated sodium carbonate solution followed by thorough extraction by ether, sodium hydroxide was added to the solution. It was again thoroughly extracted with ether. The combined ether solutions were distilled to give an oil. The g.l.c. on column B at 120° showed the volatile product to be almost pure isoquinuclidine, with only a few percent of the methoxy base **6**.

An experiment using 2.4×10^{-3} mol of chloramine and silver oxide from 423 mg (2.5 mmol) of silver nitrate in 15 ml of methanol was extremely slow at room temperature (18% in 20 h). However, refluxing for 3.5 h drove the reaction to completion. Again the volatile product was mainly isoquinuclidine with 14% of methoxy base **6**.

(c) With Metallic Silver

To a solution of 4.1 mmol of the chloramine in 19 ml of reagent methanol was added Tollens' silver from 1 g (5.9 mmol) of silver nitrate. The suspension was stirred under nitrogen. After 1 h, 72% of the chloramine had reacted; after 1.5 h, 87% reacted. Tollens' silver from 0.6 g of silver nitrate was added. After a further 4 h of stirring only 5% of the chloramine remained. The 17 ml of mixture was filtered and the basic solution (p*H* 10.7) titrated with 0.1 *N* hydrochloric acid (28 ml required, theory after subtracting the amounts removed by titration is 35 ml). The solution was taken to dryness under reduced pressure. The base was recovered by basifying with sodium carbonate (to avoid destroying the imine) extracting with ether, then basifying with sodium hydroxide and re-extracting with ether. The 360 mg of oil recovered from the ether showed two g.l.c. peaks corresponding to a new compound and isoquinuclidine in the approximate ratio of 1.75:1 (column A, 124°, 10 min, and 8 min, respectively). An ether solution of the mixture slowly deposited a white polymer, while a corresponding drop in intensity of the g.l.c. peak for the new compound occurred. Reduction of the mixture by sodium borohydride in methanol converted the new compound to isoquinuclidine (single g.l.c. peak).

In other runs the new compound was found to give an i.r. peak in ether at 1665 cm^{-1} and a —CH=N— signal at δ 9.7 in its n.m.r. spectrum. It was never obtained pure, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

this evidence is consistent with it being dehydroisoquinuclidine **7**. The silver chloride was extracted from the mixture with silver using ammonia. It was then reprecipitated and weighed. In each case it exceeded 94% of theoretical for one molar equivalent.

(d) With Metallic Silver and Silver Nitrate

The chloramine reacted very slowly with silver nitrate in methanol at 5 °C (5% in 2 h). Tollens' silver from 0.75 g of silver nitrate, and 716 mg of powdered silver nitrate were added to a solution of 550 mg of the chloramine in 15 ml of methanol at 5 °C. After 1 h, 41% of the chloramine had reacted. Tollens' silver from 0.75 g of silver nitrate was added and stirring continued. After one more hour at 5°, 59% had reacted. After a further 4 h at 15° the reaction was 91% complete. The reaction was allowed to run to completion overnight, then filtered. The solution was titrated using 0.1 *N* hydrochloric acid (13 ml required) to p*H* 4.5, then the silver ions in solution completely precipitated using sodium chloride. After filtration the solution was taken to dryness under reduced pressure. The liberated base showed the presence of imine (ν_{max} 1665 cm^{-1}; n.m.r. signal at δ 9.7; g.l.c. peak after 16.5 min, column C at 115°) methoxy base 6 (g.l.c. retention time 6.8 min, column C, 115°) and isoquinuclidine (g.l.c. retention time 4.5 min), in the ratio of 1:1.5:2.7. Sodium borohydride reduction of the mixture in methanol removed the 16.5 min g.l.c. peak.

N-Chloropiperidine

(1) With Tollens' Silver in Tetrahydrofuran

Tollens' silver from 2.1 g (12.3 mmol) of silver nitrate was added to a solution of 1.25 g (11.4 mmol) of the chloramine in 30 ml of 80% tetrahydrofuran – 20% water (v/v). The mixture was stirred under nitrogen at room temperature in diffuse light. The rate of chloramine reaction was: 50 min, 16%; 95 min, 41%; 7 h, 89%. The reaction was pushed to near completion by addition of more silver. After removal of the solid by filtration from the remaining 27 ml of the reaction mixture it was acidified using hydrochloric acid (7.8 mmol required, theoretical for no chain reaction, 10.5 mmol).

Forty percent of the solution was taken to near dryness under reduced pressure. The residue was extracted with ether, giving 14 mg of ether-soluble oil. This contained at least four components. Its n.m.r. spectrum (signal between δ 1.1 and 2.6 and broad signals centered at δ 3.4 and 3.9) resembled that expected for polymers of tetrahydrofuran. The base recovered from the salts was shown by g.l.c. on column B at 130° to be mainly piperidine with 6% of each of two amines with longer retention time.

To the remaining 60% of the solution was added 1 g of dinitrophenylhydrazine as its hydrochloride in methanol. After 1 h at room temperature the solution was evaporated to small volume under reduced pressure at 60°. The residue was distributed between dilute hydrochloric acid and chloroform. The chloroform-soluble fraction was a crystalline solid (150 mg). It was recrystallized twice from methanol–water, giving crystals with m.p. 115°.

Anal. Calcd. for $C_{10}H_{12}N_5O_4$: C, 44.78; H, 4.51; N, 20.89. Found: C, 44.69; H, 4.63; N, 21.11.

Its m.p. (lit. (41) m.p. 118°) and n.m.r. spectrum in $CDCl_3$ (δ 1.62, 2H singlet, absent when D_2O added; 1.8–2.9, 4H multiplets; 2H triplet centered at 3.88 with $J_1 = J_2 = 6$ Hz; 1H doublet centered at 9.2, $J = 2.5$ Hz) in addition to the aromatic hydrogens, were consistent with the compound being the 2,4-dinitrophenylhydrazone of γ-hydroxybutyraldehyde.

(2) With Tollens' Silver and Styrene in Acetonitrile

Freshly distilled acetonitrile and styrene (50°, 8 mm) were used. A solution was prepared of 1.25 g of the chloramine (10.4 mmol) and 1.0 g (9.6 mmol) of styrene in 19 ml of acetonitrile. This was flushed with nitrogen. While stirring under nitrogen, Tollens' silver from 1.13 g (6.6 mmol) of silver nitrate was added to the solution. After 0.5 h a second identical quantity of silver was added. The extent of chloramine reaction was: 2 h, 16%; 4 h, 23%. At this time, silver from 3 g (17.5 mmol) of silver oxide was added, and the stirring continued under nitrogen. In the total reaction time of 6 h, 45% had reacted; 9 h, 76%; 10.3 h, 87%.

The yellow solution was filtered and the precipitate washed with acetonitrile. Addition of 0.6 ml of glacial acetic acid reduced the p*H* to approximately 5. The solution was then evaporated to a volume of *ca.* 3 ml on a rotating evaporator in a bath at 45°. The residue was taken up in methylene chloride, extracted twice with 10 ml of 1 *N* sulfuric acid, then washed with sodium carbonate solution. The neutral product after heating under 0.5 mm pressure on the steam bath weighed 90 mg.

The base was recovered from the acid solution using methylene chloride as solvent. After removal of the methylene chloride the base was taken up in ether and the ether solution filtered from a small amount of solid. The ether yielded 675 mg of orange oil after warming to 40° under water pump vacuum. In an attempt to distill the oil in a chain of bulbs only a small quantity of crystalline solid came over at a bath temperature of 65° under 8 mm pressure. Under 0.5 mm at 80°, 54 mg of oil distilled, and a second fraction of 81 mg distilled at 115–120°. Some tar formed, and the ether-soluble part of the undistilled material weighed 391 mg. By comparison of the n.m.r. signals for aromatic hydrogens to the signals between σ 1.1 and 1.8 (isolated CH_2 groups) the ratio of piperidine groups to phenylethyl groups in the fractions was: 80°, 2.3:1; 120°, 2:1; and the residue, 1.3:1. All three fractions were inert to acetic anhydride at 90° (0.5 h) and the n.m.r. spectra of the recovered bases were unchanged. The chlorine content of the non-volatile base was 1.44%.

The amount of silver chloride produced in the reaction (1.03 g) was roughly 86% of 1 mol (compensated for incomplete reaction and aliquots removed).

We are grateful to M. G. Reinecke and N. J. Leonard for reference samples of bicyclic amines. We thank Mr. H. Seguin for analyses, Mrs. Joyce Lemke and Mr. M. Lesage for technical assistance, and Dr. G. Bernath for preparation of isoquinuclidine. We thank the Abbot Laboratories for financial support.

The Formation of Alkenes by the Thermal Elimination Reaction of *N*-Methyl-4-Alkoxypyridinium Iodides. I. Scope of the Reaction

GEORGE H. SCHMID AND AARON W. WOLKOFF[1]

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received September 28, 1971

Twenty-one 4-alkoxypyridines and their corresponding *N*-methyl-4-alkoxypyridinium iodides have been prepared and the latter pyrolyzed at temperatures ranging from room temperature to 185° to give the olefins derived from the alkyl moiety in high yields.

On a préparé 21 alkoxypyridines-4 différents de même que les iodures correspondants *N*-méthyl-alkoxypyridinium-4; ces derniers produits ont été pyrolysés à des températures variant de la température de la pièce à 185°. Nous avons obtenu de cette façon les oléfines dérivées du groupe alkyl avec de bons rendements.

Canadian Journal of Chemistry, **50**, 1181 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In the course of an investigation of the solvolysis of a series of *N*-methyl-4-alkoxypyridinium iodides it proved impossible to prepare *N*-methyl-4-(Δ^2-cyclopentenoxy)pyridinium iodide and *N*-methyl-4-(1′-indanoxy)pyridinium iodide (1). Attempts to prepare these compounds by the treatment of neat 4-(Δ^2-cyclopentenoxy)-pyridine (**1**) and 4-(1′-indanoxy)pyridine (**2**) with methyl iodide led to the spontaneous formation of cyclopentadiene and indene respectively (Scheme 1). This elimination reaction is unusual since ethers are not generally prone to undergo this kind of elimination under these relatively mild conditions. The purpose of this paper is to report the generality of this thermal elimination reaction of *N*-methyl-4-alkoxypyridinium iodides.

Results and Discussion

The 4-alkoxypyridines used in this study were prepared by the reaction of an alkoxide with 4-chloropyridine (Scheme 2). The properties of the 4-alkoxypyridines, together with the yields and elemental analyses are given in Table 1. The

[a]Analytical samples were prepared by gas chromatography as described for the preparation of the cyclohexyl derivative (Experimental).
[b]Literature (1) b.p. 61–65° (0.075 mm).
[c]On attempting to prepare an analytical sample by gas chromatography (SE-30 column at 200°; flow rate of 200 ml He/min), the compound decomposed to give a product whose n.m.r. spectrum was consistent with that for 1,3-cyclohexadiene.
[d]Analyzed as methiodide derivative.
[e]Material partially solidified.
[f]Melting point 45–45.6°.
[g]An analytical sample was prepared by repeated recrystallization from pentane.
[h]Melting point 75.5–76.5°.
[i]Corrected for recovered starting alcohol; yields were not improved using the extraction procedure described in the Experimental.

preparation of 4-alkoxypyridines derived from tertiary alcohols (*e.g.* 1-methylcyclohexanol, *t*-amyl alcohol, and *t*-butyl alcohol) proved impossible undoubtedly due to the steric bulk of the alkyl groups. Attempts to separate *cis*- and *trans*-2-methylcyclohexanol by preparative g.l.c. failed, consequently, it was decided to use known *cis–trans* mixtures of the alcohol; one obtained commercially (45.1 + 1% *cis*) and another enriched in the *cis* isomer (66.9 ± 0.8% *cis*) by a spinning band distillation. Similarly pure *cis*-2-methylcyclopentanol could not be prepared in sufficient quantity to form the corresponding 4-alkoxypyridine. Again a *cis–trans* mixture was used whose composition was known.

The *N*-methyl-4-alkoxypyridinium iodides were prepared by the reaction of the 4-alkoxypyridines with methyl iodide, either neat or in ether. The properties of the *N*-methyl-4-alkoxypyridinium iodides, together with the yields and elemental analyses (where possible) are given in Table 2. In some cases where the methiodides were oils, yields were not determined and the elimination reaction was carried out directly on the oils.

The results of the elimination reactions are shown in Table 3. In most cases the product compositions are accurate within ±0.5%. In some cases where the component was present in small amounts (*ca.* 5%), the results are good to within ±1%.

Since pure *cis*-2-methylcyclohexanol could not be obtained, the result for the pyrolysis of *cis*-*N*-methyl-4-(2′-methylcyclohexoxy)pyridinium iodide was obtained by the extrapolation of the results from three *cis–trans* mixtures (including the pure *trans*-*N*-methyl-4-(2′-methylcyclohexoxy)pyridinium iodide). The result for the pyrolysis of *cis*-*N*-methyl-4-(2′-methylcyclopentoxy)pyridinium iodide was also obtained by extrapolation.

The decomposition temperatures given in Table 3 are the lowest temperatures at which the reactions could conveniently be studied. In some cases, methyl iodide was isolated along with the reaction products, making exact determination of the yields difficult. In all compounds studied the elimination did in fact take place, although for a few compounds, higher temperatures (>165°) were needed.

The elimination reaction occurs so that Saytzev orientation is observed; that is the more stable olefins are the major products. Geometrical orientation is heavily in favor of the *trans* olefin. A lack of stereospecificity is indicated by the fact that the *cis*- and *trans*-methiodides give similar (but not identical) product mixtures. Products arising from rearrangement can be seen in the case of the *n*-octyl and 2-methylcyclohexyl compounds. Compounds that are capable of forming stable carbonium ions (*e.g.* 1-*p*-methoxyphenyl-1-propanol and Δ^2-cyclohexenol) decompose spontaneously at room temperature to give the corresponding olefin.

The olefin products do not seem to have been formed under conditions of thermodynamic control. While an acid is generated, the experimental procedure involves distilling off the olefins as they are formed and consequently the olefins are in contact with the acid for only a short time. Furthermore, product composition of the pyrolysis carried out in dimethyl formamide as solvent is identical to that obtained by distilling off the olefin. In a solvent, equilibration of the olefins should be facilitated yet it is not observed. Therefore, it is concluded that isomerization of the products does not occur and since the reaction is irreversible, the products are the result of kinetic control.

Experimental

All m.p. and b.p. are uncorrected. Elemental analyses were carried out by A. B. Gygli of Toronto, Ontario.

Many of the alcohols used in this study were commercially available and were purified by distillation before use. Others were available as the corresponding ketones which were then reduced with lithium aluminum hydride to the required alcohol.

trans-2-Methylcyclohexanol, b.p. 87° (33 mm), was prepared in 38% yield by the hydroboration of 1-methylcyclohexene (3).

trans-2-Methylcyclopentanol, b.p. 144–148°, was prepared in 34% yield by the hydroboration of 1-methylcyclopentene (3).

2,2-Dimethylcyclohexanone, b.p. 49–50° (11 mm), was prepared in 42% yield by the method of Meinwald and Ouderkirk (4).

2,2-Dimethylcyclohexanol, b.p. 65° (11 mm) (lit. (5) b.p. 72° (13 mm)) was prepared in 75% yield by the lithium aluminum hydride reduction of 2,2-dimethylcyclohexanone.

(−)-Isoborneol was prepared in 50% yield according to the method of Toivonen (6), $[\alpha]_D^{22}$ −32.78° (94.7% optically pure). Gas chromatographic analysis showed the product to contain 5.8% borneol.

l-Menthone: Oxidation (7) of *l*-menthol by chromic acid, gave *l*-menthone, b.p. 85–92° (15 mm), $[\alpha]_D^{26}$ −28.4° (neat, 1 dm) (lit. (7) b.p. 66–67° (4 mm); $[\alpha]_D$ −29.9°) in 84% yield.

l-Menthol and d-Neomenthol: A mixture of these two alco-

[a]See text for explanation.
[b]Products were determined by gas chromatography and/or n.m.r. (unless otherwise stated); for experimental limits, see text.
[c]Reactions were studied over a period of 3 h (unless otherwise stated).
[d]Methiodide was an oil, so reaction done *in situ* and yields calculated on basis of weight of starting 4-alkoxypyridine.
[e]Product determined to be *cis* isomer by i.r. spectroscopy (2) (absorption at 11.2 and 13.3 μ; no absorption at 11.8 and 12.6 μ).
[f]1% unknown product; shown not to be methylenecyclopentane.
[g]Some methyl iodide produced, making yield over 100%; yields could not be determined exactly but were generally quite high (see text).
[h]Extrapolated graphically and normalized to 100%.
[i]Decomposed spontaneously on addition of methyl iodide.
[j]Yield not determined.
[k]When done at a lower temperature, relatively little product was obtained (37%).
[l]No further analysis attempted.
[m]Values corrected for 1.2% menthol in starting alcohol.
[n]Temperature accidently rose to 250° for 1/2 h.
[o]Decomposition complete after 10 min.
[p]Compound actually decomposed at a much lower temperature.
[q]Values corrected for 5.8% borneol in starting alcohol.
[r]Values corrected for 2.7% isoborneol in starting alcohol.

hols was prepared in 98% yield by aluminum isopropoxide reduction of *l*-menthone (8).

d-Neomenthol was isolated from the mixture of *l*-menthol and *d*-neomenthol by making use of the fact that *p*-nitrobenzoyl chloride reacts 16.3 times as fast with *l*-menthol as with *d*-neomenthol (9). In this way a 72% yield of *d*-neomenthol was prepared; b.p. 85° (10 mm) $[\alpha]_D^{16}$ 17.80° (homog: 1 dm). The specific rotation of the prepared neomenthol corresponds to a mixture of 98.8% *d*-neomenthol and 1.2% *l*-menthol.

1-p-Methylphenyl-1-propanol, b.p. 105° (12 mm) (lit. (10) b.p. 115–116° (13 mm)), was prepared by reaction of ethyl magnesium bromide with *p*-tolualdehyde.

Δ^2-*Cyclohexenol*, b.p. 61–64° (11 mm) (lit. (11) 164–166°), was prepared from cyclohexene according to the method of Alder and Flock (11).

4-Chloropyridine was prepared by neutralization of commercially available (Aldrich Chemical Co.) 4-chloropyridine hydrochloride. The hydrochloride salt (30 g; 0.20 mol) was dissolved in approximately 200 ml of water and cooled in an ice bath during dropwise addition of 120 ml of 10% sodium hydroxide. During the addition the solution turned dark brown. The solution was then extracted with three 200 ml portions of pentane. The combined pentane extracts were dried over anhydrous magnesium sulfate and filtered. After stripping off the solvent under vacuum (20 mm), the material was distilled at room temperature under high vacuum (0.050 mm) into a Dry Ice–acetone trap, to give 19.4 g (86% yield) of 4-chloropyridine. Care was taken not to warm the material since it dimerizes slowly at room temperature (and rapidly on heating) to a red water soluble solid which is thought to be *N*-(4′-pyridyl)-4-chloropyridinium chloride (12). The n.m.r. spectrum of 4-chloropyridine appears as a typical AA′XX′ with quartets centered at δ 7.3 and 8.6.

General Procedure for the Preparation of 4-Alkoxypyridines

A typical procedure is the preparation of 4-cyclohexoxypyridine.

In a dry 50 ml Erlenmeyer flask protected by a calcium chloride drying tube was placed 0.77 g (32.1 mmol) of sodium hydride which had been previously washed with dry hexane in a sintered glass filtering funnel to remove the mineral oil used as a dispersing agent. (In some cases, the sodium hydride dispersion was weighed directly into the reaction flask and stirred with about 25 ml of hexane and the hexane then removed by means of a pipette.) To this was added 10 ml dimethylsulfoxide (previously dried overnight over Linde Molecular Sieves, type 5A). The mixture was allowed to stir for one-half hour before 3.20 g (32.0 mmol) of cyclohexanol was added dropwise. (In those preparations where the alcohol was a solid, a concentrated solution of the alcohol in dimethylsulfoxide was employed.) Considerable foaming occurred and the solution turned dark brown. After the alcohol had been added, 3.63 g (32.0 mmol) of 4-chloropyridine was added and the solution allowed to stir overnight at room temperature. In later preparations a 15% excess of 4-chloropyridine was usually employed. The solution was filtered and the precipitate (sodium chloride) was washed with about 10 ml of hot benzene. The filtrate was concentrated on a rotary evaporator and then distilled under vacuum giving dimethylsulfoxide, b.p. 23° (0.050 mm) and 3.76 g (67% yield) of 4-cyclohexoxypyridine, b.p. 88–92° (0.050 mm). (It was found that an alternative work-up of extracting the product out of dimethylsulfoxide into pentane was equally satisfactory and did not significantly decrease the yields. For example, in the preparation of the 2-octyl derivative, the filtrate was divided into two parts, half being distilled directly and half worked-up using the extraction procedure, the yields were 70% and 64% respectively.)

Analytical samples of the 4-alkoxypyridines were prepared by gas chromatography on an SE-30 column (20 ft × 3/8 in. o.d.) at 200° using a flow rate of about 200 ml He/min.

General Procedure for the Preparation of N-Methyl-4-Alkoxypyridinium Iodides

All *N*-methyl-4-alkoxypyridinium iodides were prepared in essentially the same manner. In a typical procedure, 1.64 g (9.29 mmol) of 4-cyclohexoxypyridine was placed in a tightly stopped test tube. This was cooled in an ice bath while 2 ml (32.1 mmol) of methyl iodide was added. After allowing the solution to stand at 6° overnight, the excess methyl iodide was removed by means of a rotary evaporator. In this case, an oil resulted, but it was found that after keeping this oil under vacuum for a few hours, a red solid resulted. The solid was then recrystallized by dissolving it in acetone and adding ether until precipitation of the methiodide occurred. The solution was then filtered to give 2.70 g (91% yield) of *N*-methyl-4-cyclohexoxypyridinium iodide, m.p. 120°.

In some cases a solid was obtained immediately on removal of the excess methyl iodide or by allowing the oil to stand for a few days or by prolonged concentration on a rotary evaporation. For some compounds, crystallization was induced by dissolving the oil in acetone and adding ether just to the point of cloudiness. The solution was then allowed to stand overnight and then filtered to give crystals of the methiodide. Some of the methiodides failed to crystallize using these procedures and these were pyrolyzed directly without being fully characterized.

Product Studies

The pyrolysis reactions were done in the same general manner. In a typical procedure, 1.56 g (4.89 mmol) of *N*-methyl-4-cyclohexoxypyridinium iodide was placed in a 25 ml round bottom flask. To this was attached a short path distillation column. A tared test tube, fitted with a ground glass joint, was attached to the distillation column and cooled in a Dry Ice–acetone bath. The system was placed under vacuum (10 mm) and slowly heated by means of an oil bath. The solid melted at about 120° and at approximately 165°, the melt was observed to be boiling. Heating was continued until the boiling had ceased (about 3 h), leaving a red solid in the reaction flask. The product (cyclohexene in this case) was analyzed by gas chromatography and n.m.r. The yield of cyclohexene was 0.36 g (90%).

Those methiodides which gave pyrolysis products which were solids (isobornyl and bornyl derivatives) were pyrolyzed by means of a sublimation apparatus. The methiodide was placed in the bottom of the apparatus and heated while a vacuum was applied. The products were then trapped out on the walls of the cold finger.

Those methiodides which were oils were not actually isolated prior to elimination. A known weight of the 4-alkoxypyridine was placed in a flask and an excess of methyl iodide was added. After allowing the solution to stand over-

night, the excess methyl iodide was removed under vacuum and the resulting oil was then pyrolyzed directly. Yields were calculated on the basis of the weight of the starting 4-alkoxypyridine.

Continued financial support from the National Research Council of Canada is gratefully acknowledged.

The Formation of Alkenes by the Thermal Elimination Reaction of *N*-Methyl-4-alkoxypyridinium Iodides. II. An Investigation of the Mechanism

GEORGE H. SCHMID AND AARON W. WOLKOFF[1]

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 13, 1971

A comparison of the products from elimination reactions of a number of compounds containing various leaving groups with those containing the *N*-methyl oxypyridinium leaving group suggests that the elimination is not occurring by means of a simple E1 mechanism. Changing the anion of the salt from iodide to methylsulphate and tetrafluoroborate affects the product composition indicating that the anion is taking part in the reaction. The mechanism of this reaction appears to be on the E1-E2 borderline.

Une comparaison des produits de réactions d'élimination de certains composés contenant une variété de groupes labiles avec ceux contenant le groupe labile *N*-méthyl oxypyridinium suggère que l'élimination ne s'explique pas par un mécanisme simple de type E1. Lorsqu'on change l'anion du sel, soit le sulfate de méthyl ou le tétrafluoroborate à la place de l'iodure, la composition du produit est affectée, ce qui indique que l'anion prend part à la réaction. Le mécanisme de cette réaction semble être le résultat d'une contribution des deux mécanismes E1 et E2.

We have found that *N*-methyl-4-alkoxypyridinium iodides decompose upon heating to give olefins and the hydroiodide of *N*-methyl-γ-pyridone (1). The olefins obtained from this reaction are not stereospecific and there is evidence that rearrangement occurs during the pyrolysis. These results suggest that the elimination is occurring by means of an E1 mechanism. A comparison of our results with elimination reactions carried out by other workers on 2-methylcyclohexyl and menthyl neomenthyl derivations (3–8) indicates that the mechanism is more complicated. In general, elimination reactions which are believed to occur by an E1 mechanism give almost identical product ratios from either the *cis* or *trans* starting material. Results obtained in this work for the pyrolysis of the oxypyridinium iodides show that the menthyl, neomenthyl, and 2-methylcyclohexyl derivatives give products which resemble those formed under E1 conditions. Still there are significant differences in the products from *cis* and *trans* isomers. The question arises as to whether or not the iodide ion does actually play a part in the reaction. Hence, additional product studies were attempted wherein modifications were made in the leaving group. Specifically, the counter-ion was changed from iodide to methylsulfate and tetrafluoroborate.

[1]Holder of NRCC Scholarship, 1967–1971.

The results for the pyrolysis of the *N*-methyl-4-(2′-octoxy)pyridinium salts are shown in Table 1. These results clearly show that the counter-ion affects the stereochemistry and regiospecificity of the products. The fact that the addition of 2,6-lutidine, a non-nucleophilic base, has little effect on the product ratios indicates that no isomerization of the initially formed olefins occurs.

These results can be compared with the dehydration of 2-octanol with phosphoric acid at 120–130° which gives *trans*/*cis* and 2-/1-olefin ratios of 1.06 and 4.71 respectively. These ratios are closer to those from the pyrolysis of the tetrafluoroborate salt than to those from the iodide salt. Since the dehydration proceeds by way of a carbonium ion, this indicates that the reaction of the tetrafluoroborate salt proceeds through a transition state resembling a carbonium ion (E1) while the iodide salt must react through a transition state that has some E2 character.

The results of the pyrolysis of optically active *N*-methyl-4-isobornoxypyridinium salts with varying counter ions are given in Table 2. All compounds upon pyrolysis gave 97–99% camphene and 1–3% tricyclene. Bornylene could not be detected as a product in any of the reactions. A significant drop in retention of optical activity of the camphene is observed on changing from the iodide and methyl sulfate salts to the

tetrafluoroborate salt. As in the 2-octyl case, it is clear that the counter ion must be involved in some way.

The results of the reactions of the isobornyl and 2-octyl derivatives are strikingly similar. It seems that the percent retention of optical activity in the isobornyl system is related to that fraction of the reaction in which the counter-ion participates in removal of a proton. Similarly, in the 2-octyl case, the *trans*/*cis* olefin ratio, as well as the 2-/1-octene ratio, reflect that fraction of the reaction proceeding by a concerted pathway. A comparison of the results for the isobornyl and 2-octyl derivatives is shown in Table 3 and Fig. 1.

These results can be explained by means of the Theory of the Variable Transition State (9). According to this theory, in a series of bimolecular elimination reactions, as the base is made weaker the position of the transition state shifts towards the paenecarbonium extreme with a consequent decrease in the *trans*/*cis* and

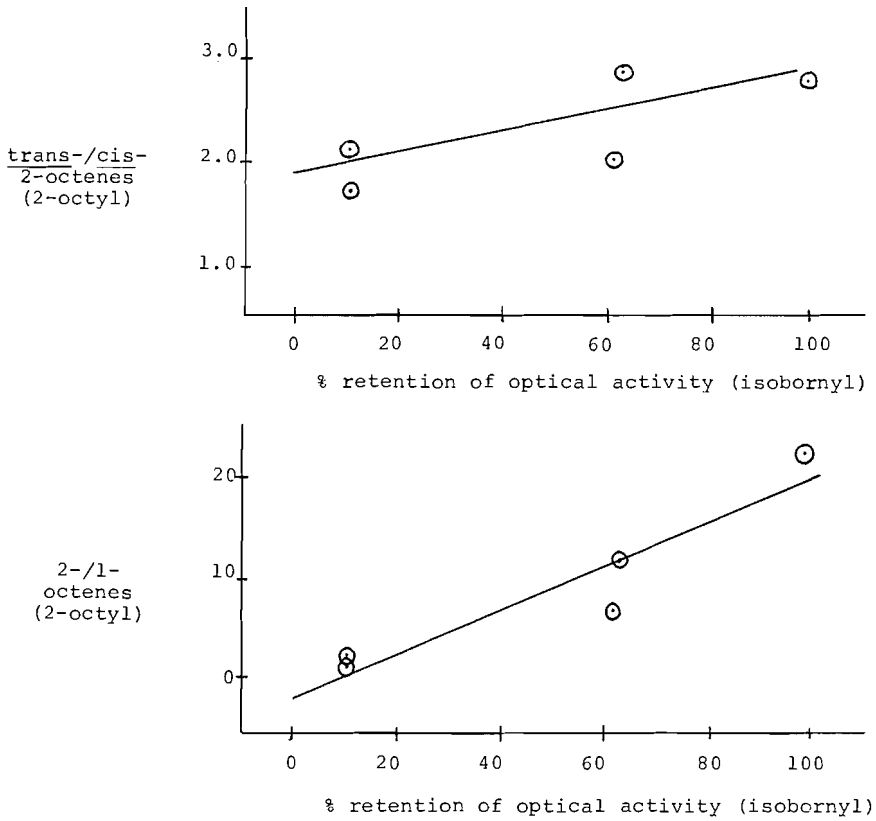

FIG. 1. Plot of the products of pyrolysis of *N*-methyl-4-(2′-octoxy)pyridinium iodide *vs.* the percent retention of optical activity of the products of pyrolysis of *N*-methyl-4-isobornoxypyridinium oxide.

2-/1-olefin ratios. This presumes, of course, that all the reactions are proceeding via transition states that are along the continuum between the paenecarbonium extreme and central regions.

In bimolecular elimination reactions there is a gap in the continuum between the E1 and the paenecarbonium extreme of the E2 mechanism. The reason for this is that there is a loss of entropy due to the inclusion of a base in the E2 transition state. The elimination of *N*-methyl-4-alkoxypyridinium iodides may represent reactions where this gap is bridged. In these reactions, the base is the counter-ion and is therefore present in the transition state for both the E1 and E2 component of the mechanism, leading to small entropy differences between the E1 and E2 transition states. Hence, one can visualize a continuum between E1 and E2 mechanisms for these reactions. Thus in the elimination reaction involving the tetrafluoroborate anion, which is a conjugate base of a very strong acid, little or no abstraction of a proton would be expected in the transition state and the mechanism would approach the E1 end of the continuum. With iodide as the anion the mechanism would approach the paenecarbonium extreme of the E2 mechanism. The results in Table 1, are in accord with this view. As the counter-ion becomes a weaker base, the ratio of 2-octenes/1-octene decreases to a value near that found in the acid-catalyzed dehydration of 2-octanol.

The results definitely indicate some participation of the counter-ion. In the 2-octyl and other acyclic systems as well as the monocyclic systems, the reaction probably proceeds via a concerted mechanism in which the transition state is very near to the E1 extreme. Because ionization of the C_2—O bond is facile in the isobornyl system the role of the iodide and

methylsulfate counter-ion is probably to aid in the loss of a proton from the initially formed carbonium ion.

Alternatively these results may be explained by a dual mechanism in which part of the reaction proceeds through an E1 transition state and in part through a transition state which is close to the paenecarbonium extreme of the E2 mechanism (10).

Experimental

All melting and boiling points are uncorrected. Elemental analyses were carried out by A. B. Gygli of Toronto, Ontario.

4-(−)-Isobornoxypyridine

The compound was prepared according to the procedure previously reported (1) in 44% yield, b.p. 115° (0.050 mm).

4-(2′-Octoxy)pyridine

The compound was prepared according to the procedure previously reported (1) in 70% yield, b.p. 99–100° (0.10 mm).

N-Methyl-4-(−)-isobornoxypyridinium Methylsulfate

To a solution of 1.2 g (5.19 mmol) of 4-(−)-isobornoxypyridine in about 15 ml of ether was added 1.5 ml (15.8 mmol) of dimethylsulfate. After about 2 min, a white precipitate formed. After allowing the mixture to stand overnight, it was filtered to give a white solid. Recrystallization of this solid from acetone gave 1.65 g (95% yield) of *N*-methyl-4-(−)-isobornoxypyridinium methylsulfate, m.p. 158–159°.

Anal. Calcd. For $C_{17}H_{27}SO_5N$: C, 57.12; H, 7.61; N, 3.92. Found: C, 57.23; H, 7.43; N, 4.06.

The n.m.r. δ ($CDCl_3$): multiplet at 0.8–2.3 (16H, methyl and ring protons); sharp singlet at 3.73 (3H, H—C—OSO_3^-); multiplet at 4.3–4.6 (methine α to oxypyridinium group) overlapping a singlet (*N*-methyl protons) at 4.37 (4H total); distorted doublet at 7.37 (2H, 3,5-pyridyl, $J = 7$ Hz); doublet at 8.90 (2H, 2,6-pyridyl, $J = 7$ Hz).

N-Methyl-4-(−)-isobornoxypyridinium Iodide

The compound was prepared according to the method previously reported (1) in 90% yield m.p. 152–153.5°.

N-Methyl-4-(−)-isobornoxypyridinium Tetrafluoroborate

To a solution of 1.00 g (2.68 mmol) of *N*-methyl-4-(−)-isobornoxypyridinium iodide in 15 ml of absolute ethanol, was added a solution containing 0.7 g of silver tetrafluoroborate in 23 ml of absolute ethanol until no further precipitation occurred (20 ml). The mixture was then filtered and the filtrate concentrated under vacuum to give white crystals. The material was recrystallized from water (to remove any excess silver tetrafluoroborate) to give 0.59 g (66% yield) of *N*-methyl-4-(−)-isobornoxypyridinium tetrafluoroborate, m.p. 127–129°. An analytical sample was prepared by a further recrystallization from water and then repeated recrystallizations from acetone–ether (as previously described (2), m.p. 132–132.5°.

Anal. Calcd. for $C_{16}H_{24}ONBF_4$: C, 57.58; H, 7.26; N, 4.20. Found: C, 57.68; H, 7.23; N, 4.29.

The n.m.r. δ ($CDCl_3$): multiplet at 0.7–2.0 (16H, methyl and cycloalkyl ring protons); multiplet at 4.1–4.6 (α-methine proton) overlapping a singlet (*N*-methyl) at 4.33 (4H total); doublet at 7.30 (2H, 3,5,-pyridyl, $J = 7.5$ Hz); doublet at 8.60 (2H, 2,6-pyridyl, $J = 7.5$ Hz). The i.r. λ_{max} ($CHCl_3$): 6.06, 6.60, 7.50, 9.54, (strong, BF_4) 10.77 μ.

Acid-catalyzed Dehydration of 2-Octanol

Treatment of 2-octanol with concentrated phosphoric acid at 120–130° gave a mixture consisting of 17.5% 1-octene, 40.0% *cis*-2-octene, and 42.5% *trans*-2-octene.

N-Methyl-4-(2′-octoxy)pyridinium Methylsulfate

To 1.0 g (4.83) of 4-(2′-octoxy)pyridine was added 1.5 ml (15.8 mmol) of dimethylsulfate. The mixture was allowed to stand for 48 h and then placed under vacuum overnight to remove any excess dimethylsulfate. The oily product was pyrolyzed directly at 135–150° to give 0.70 g (129% yield; contained some methylsulfate) of a mixture of olefins. Analysis by gas chromatography showed the mixture to contain 12.8 ± 0.8% 1-octene, 58.4 ± 1.3% *trans*-2-octene, and 28.8 ± 2.1% *cis*-2-octene.

N-Methyl-4-(2′-octoxy)pyridinium Iodide

The compound was prepared according to the method reported (1).

N-Methyl-4-(2′-octoxy)pyridinium Tetrafluoroborate

To a solution of 1.75 g (5.01 mmol) of *N*-methyl-4-(2′-octoxy)pyridinium iodide in 20 ml of absolute ethanol, was added a solution of 1.50 g (7.69 mmol) of silver tetrafluoroborate in 20 ml of ethanol until precipitation was complete. The mixture was filtered to remove the silver iodide, and the filtrate concentrated to give 1.45 g (91% yield) of an oil. The oil was pyrolyzed to give 0.55 g (99% overall yield) of a mixture of olefins. This mixture was analyzed by gas chromatography using a 13 ft × 1/4 in. o.d. column packed with dimethylsulfolane on Chromosorb G with a flow rate of 37 ml He/min at 35°. The mixture was found to be composed of 4.9% of an unknown compound, 35.7% 1-octene, 37.7% *trans*-2-octene, and 21.7% *cis*-2-octene.

Photoamidation of 3,4,6-Tri-*O*-acetyl-1,2-dideoxy-D-*arabino*-hex-1-enopyranose

ALEX ROSENTHAL AND A. ZANLUNGO

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received November 10, 1971

The acetone-initiated photochemical addition of formamide to 3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-*arabino*-hex-1-enopyranose (**1**) afforded 3,4,6-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptonamide (**2**), 3,4,6-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptonamide (**3**), and 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**) in a combined yield of about 75% (the ratio of yields of **2**, **3**, and **4** was approximately 2:2:3). In addition, trace quantities of the epimeric *manno* branched-chain adduct of **4**, and acetone adducts of **1** were formed. Lithium aluminum hydride reduction of **4** yielded a branched-chain aminopolyol, isolated as its *N*-acetyl derivative.

L'addition photochimique initiée par l'acétone de formamide au 3,4,6-tri-*O*-acétyl-1,2-didéoxy-D-*arabino*-hex-1-énopyranose (**1**) nous a conduit au 3,4,6-tri-*O*-acétyl-2,6-anhydro-3-déoxy-D-*gluco*-heptanomide (**2**), au 3,4,6-tri-*O*-acétyl-2,6-anhydro-3-déoxy-D-*manno*-heptonamide (**3**), et au 3,4,6-tri-*O*-acétyl-1,5-anhydro-2-*C*-carbamoyl-1,2-didéoxy-D-*gluco*-hexitol (**4**), dans un rendement global de 75% (le rapport des rendements de **2**, **3**, et **4** étant approximativement 2:2:3). De plus, des traces du dérivé épimérique branché *manno* de **4** et les dérivés acétone de **1** ont été formées. La réduction de **4** avec l'hydrure d'aluminium et de lithium a donné un aminopolyol branché, qu'on a isolé sous forme de dérivé *N*-acétyl.

Canadian Journal of Chemistry, **50**, 1192 (1972)

During work on the synthesis of homologues of puromycin we have investigated new routes for the preparation of amino sugars in which the amino-group is located in the branching residue. Branched-chain amino sugars have been synthesized by Overend and coworkers (1) by application of the nitromethane synthesis (2) to a methyl glycopyranosidulose. Similar application of the nitromethane synthesis to 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose, followed by a deoxygenation reaction, enabled Albrecht and Moffatt (3) to prepare a a 3-deoxy-3-*C*-aminomethyl branched-chain amino sugar which was subsequently converted into a homologue of the aminonucleoside moiety of puromycin. Other workers (4, 5) have also synthesized branched-chain amino deoxy sugars by application of the nitromethane synthesis and the Wittig reaction to ketoses (6). In this paper we report a new route for the synthesis of deoxy branched-chain amino sugars, namely, by photochemical amidation of unsaturated carbohydrates. Although the photochemical amidation of olefins has been studied in considerable detail (6), the reaction has hitherto not been applied to the unsaturated carbohydrates. Of particular relevance to our investigation was the fact that Elad and Rokach (7) found that the reaction was stereospecific when applied to norbornene.

When an acetone solution of 3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-*arabino*-hex-1-enopyranose (**1**) containing formamide and *t*-butyl alcohol was irradiated with u.v. light in a water-cooled apparatus (see Scheme 1) all of the starting material was consumed in 26 h, as

evidenced by monitoring the reaction mixture by t.l.c. As shown in Table 1 gradient column chromatography of the photolysis products on silica gel using benzene – ethyl acetate – ethanol as eluent afforded a partial separation of the three major carbamoyl components **2**, **3**, and **4** (combined yield about 75%) from the acetone adducts which were formed in trace quantities. The major components were clearly distinguishable and separable by t.l.c. However, a more efficacious procedure for separating large quantities of each component was by fraction crystallization. Thus crystallization of fractions E and F from ethyl acetate afforded pure crystalline 3,4,6-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptonamide (**2**). The acetylated *manno*-epimer (**3**) could only be obtained in pure crystalline form by first deacetylating an aliquot of fractions E and F followed by cellulose column chromatography of the deacetylated products using *n*-butanol–ethanol–water as developer. This procedure afforded the pure deacetylated *gluco* and *manno*-epimers, **5** and **6**. Acetylation of the manno epimer **6** with acetic anhydride and pyridine afforded, after silica gel chromatographic purification, crystalline 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptonamide (**3**).

Although 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**) was clearly distinguishable from compounds **2** and **3** by t.l.c., attempts to prepare crystalline **4** by preparative t.l.c. were unsuccessful. On the other hand, when fractions F and G were deacetylated with methanolic sodium methoxide the deacetylated product readily afforded, on fractional crystallization from methanol, pure crystalline 2,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**7**) in 74% yield (based on fractions F and G only). The overall yield of **4** was approximately 30%. Acetylation of **7** in the usual way readily afforded crystalline 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**).

The principal remaining fraction H showed chromatographic evidence of the presence of **4**, and in addition, a fourth carbamoyl product in less than 5% yield. Attempts to isolate this fourth component in pure crystalline form were unsuccessful.

The complete structures of the photoamidation products **2**, **3**, and **4** and of the corresponding deacetylated products **5**, **6**, and **7** obtained from 3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-*arabino*-hex-1-enopyranose (**1**) were readily deduced from their p.m.r. spectra. Carboxamidation at C-1 of **1** would give compounds **5** and **6** (after deacetylation), both possessing two C-3 methylene protons which would be expected to resonate at high field (about τ 8). On the other

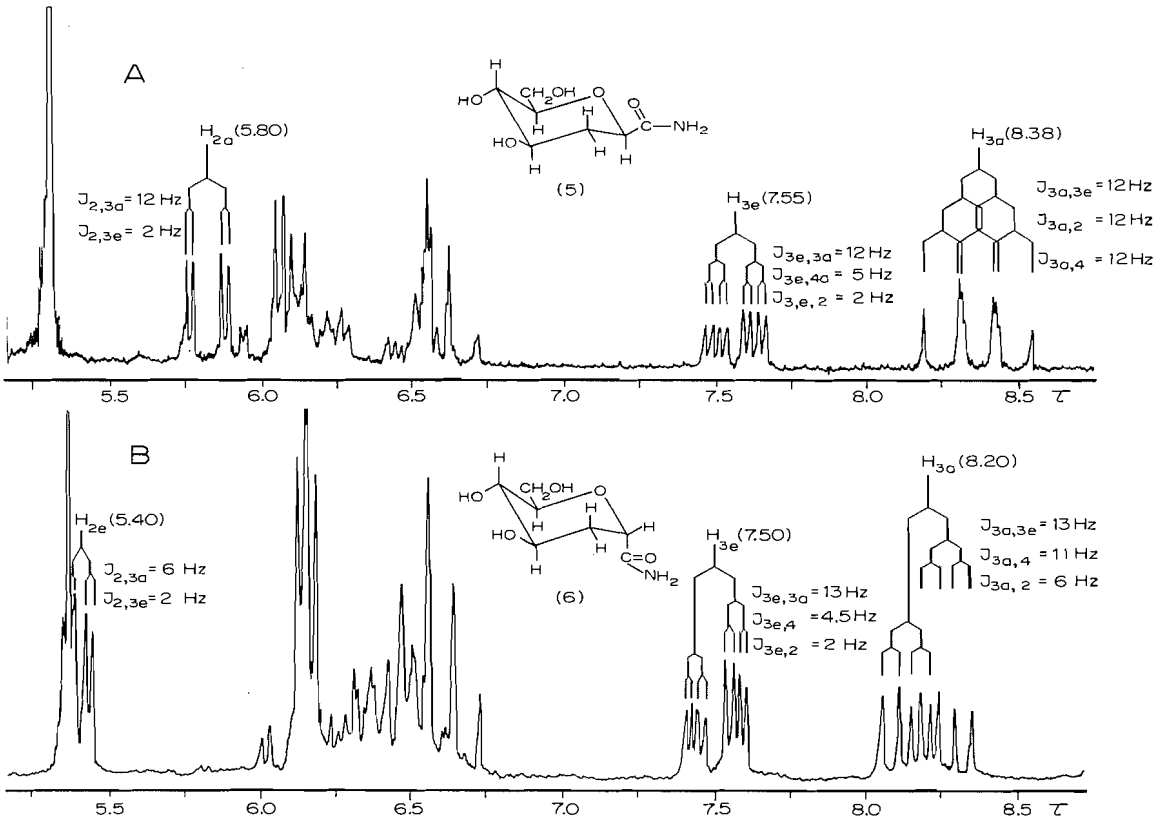

FIG. 1. Partial 100 MHz p.m.r. spectrum of (A), 2,6-anhydro-3-deoxy-D-*gluco*-heptonamide (**5**) and (B), 2,6-anhydro-3-deoxy-D-*manno*-heptonamide (**6**) in D_2O solution.

hand, were carboxamidation to occur at C-2 of the glycal, the resulting, branched-chain carbohydrate would have only one methine hydrogen atom, which would give rise to a high-field signal. It was possible to distinguish readily between the normal chain and branched-chain structures merely from a consideration of the resonance positions and relative intensities of the proton signals observed in the n.m.r. spectra (Figs. 1 and 2) of the unsubstituted compounds **5**, **6**, and **7**, or of their acetate derivatives **2**, **3**, and **4**. The spectra of **5** and **6**, measured in deuterium oxide solution, exhibited two octets at τ 7.5–8.4 equal to two hydrogens which clearly arise from the C-3 methylene protons. Hence both **5** and **6** are clearly normal-chain 2,6-anhydro-3-deoxy-heptonamides. The assignment of configuration at C-2 of both compounds was readily made from the multiplicities of the C-3 equatorial and axial hydrogen signals which occur at τ 7.5–8.2 or from the coupling constants of the C-2 hydrogen which resonates in the lowest-field region (τ 5.4–5.8). The p.m.r. spectrum of **5** (see Fig. 1A) clearly shows two quartets at τ 7.55 which were assigned to the C-3 equatorial hydrogen atom and an octet (two overlapping quartets) at τ 8.38 assigned to the C-3 axial hydrogen atom. On the basis of the observations of Lemieux and coworkers (8), the spin–spin coupling between the two C-3 methylene hydrogen atoms would be expected to be large, of the order of 12 Hz; additional coupling of each proton with neighboring protons on C-2 and -4 would also be large were a diaxial relationship to exist; otherwise it would be small. The observed splitting of H-3e into two quartets, showed indeed, the anticipated, large coupling (12 Hz) with the geminal H-3a. The orientation of the C-2 hydrogen was deduced from the width of the higher-field H-3a signal (36 Hz), this being practically equal to the sum of the three coupling constants ($J_{3a,3e}$,

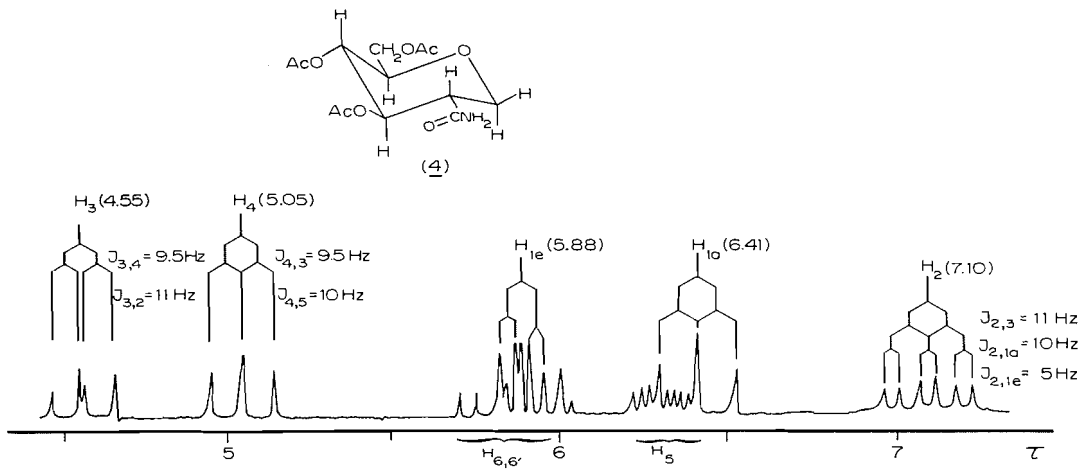

FIG. 2. Partial 100 MHz p.m.r. spectrum of 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**) in $(CD_3)_2$ C=O solution.

$J_{3a,2a}$, and $J_{3a,4a}$) with which the axial C-3 hydrogen atom was coupled to the equatorial C-3 hydrogen and to the two neighboring hydrogen atoms on C-2 and -4. Thus, as $J_{3a,3e}$ was 12 Hz, and $J_{3a,4a}$ must be about 12 Hz (H_{4a} is known to be axial), then $H_{3a,2a}$ must be 12 Hz; this large value could only be rationalized if H-2 and -3a are both axial. The two equatorial–axial interactions of H-3e with H-2 and -4 were assigned J values of 2 and 5 Hz respectively, to account for the observed octet of the lower-field group at τ 7.55. Corroboration of this assignment is readily seen by an analysis of the C-2 hydrogen signal at τ 5.80. Here one clearly sees two doublets having $J_{2a,3a} = 12$ and $J_{2a,3e} = 2$ Hz. The large J value can only arise if the C-2 hydrogen is in an axial orientation. In contrast, the *manno*-epimer **6** gave a spectrum (Fig. 2B) in which the C-2 hydrogen signal occurs at the expected lower field (τ 5.40) for an equatorial hydrogen and it also exhibits the lower J values of 6 and 2 Hz which would be expected to result from the coupling of the C-2 equatorial hydrogen to the C-3 axial and C-3 equatorial hydrogens. First order analysis of the p.m.r. spectra of the heptonamide acetate derivatives **2** and **3** in $CDCl_3$ solution gave the same structural assignments (see Experimental). In the spectrum of **2**, irradiation of the C-3 equatorial methylene hydrogen collapsed the C-2 axial hydrogen signals to a doublet, thus confirming the assignment of the low field pair of doublets to the C-2 hydrogen. Interestingly, the two epimeric 2,6-anhydro-3-deoxy-D-*gluco* (and D-*manno*) heptonamides **5** and **6**, respectively, exhibited p.m.r. spectra which were remarkably similar to the spectra of the two epimeric 2,6-anhydro-3-deoxy-D-*gluco* (and D-*manno*) heptitols obtained by hydroxymethylation (followed by deacetylation) of 3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-*arabino*-hex-1-enopyranose (9). The complete structures of the latter compounds were rigorously proved by chemical means as well as by X-ray studies.

A similar first order analysis of the p.m.r. spectrum of the acetate of compound **4** in $CDCl_3$ solution (Fig. 2) readily showed that carboxamidation had occurred on C-2 of **1**. In this spectrum the lone high-field multiplet at τ 7.10 is equivalent to one hydrogen and therefore must be attributed to the C-2 methine hydrogen. Confirmation of this assignment and in addition, the orientation of the carboxamide group, was provided by double irradiation experiments (see Experimental). The magnitude of $J_{2,1a} = 10$ Hz, clearly indicates that H-2 must be axial and therefore compound **4** must be 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol. A parallel analysis of the p.m.r. parameters of the fourth acetylated carbamoyl carbohydrate (see Experimental) reveals a much narrower high-field multiplet positioned at τ 6.90–7.02 which must be due to the C-2 equatorial hydrogen. It is tentatively suggested, therefore, that the fourth carbamoyl carbo-

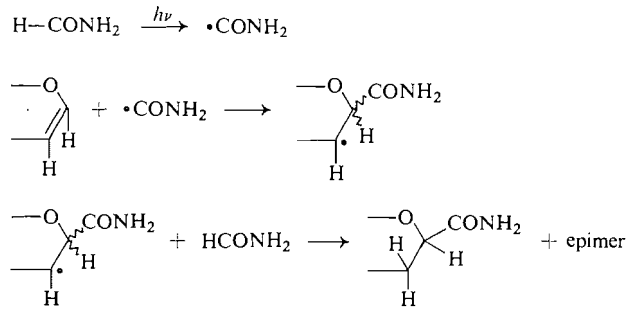

SCHEME 2

hydrate might be the expected epimeric *manno* C-2 branched-chain carbohydrate. Because this component occurred in very small amounts and could not be crystallized, no further definitive structural work was done.

Trace quantities of acetone adducts of **1** were also isolated from fraction B. Because these adducts could not be crystallized further work on them was abandoned.

Lithium aluminum hydride reduction of 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**) in tetrahydrofuran, followed by reacetylation of the product, yielded the branched-chain amino carbohydrate 2-*C*-acetamidomethyl-3,4,6-tri-*O*-acetyl-1,5-anhydro-1,2-dideoxy-D-*gluco*-hexitol.

The course of the reaction for the photochemical synthesis of 1:1 adducts of formamide and the unsaturated carbohydrate **1** may be illustrated by Scheme 2.

Although there was no stereospecificity in the addition of the carbamoyl free radical to C-1 of the glycal there was virtually exclusive stereospecificity in the attack of the same group on C-2 to afford the *gluco* branched-chain adduct **4** (equatorial product) and only a trace of the epimeric *manno* branched-chain adduct (axial product). In contrast to our findings it is interesting to note that Igarashi and Honma (10) found that in the free radical addition of thiolacetic acid to D-glucal triacetate the $CH_3\overset{O}{\overset{\|}{C}}—S\cdot$ free radical added exclusively to C-2 giving a preponderance of the axial product. It would therefore appear that no simplified explanation for the addition of carbamoyl free radicals to the unsaturated carbohydrate can be offered. Steric factors (7) undoubtedly play a role.

Experimental

Irradiations were made with a 450 W Hanovia medium pressure mercury vapor lamp with Corex filter under oxygen-free nitrogen. The reaction mixture was cooled internally with running water. Agitation of the reaction mixture was achieved with magnetic stirring. Purified nitrogen was bubbled for 2 h through the reaction mixture before irradiation. The progress of reactions and purity of products were checked by t.l.c. on silica gel G (benzene – ethyl acetate – ethanol, 5:5:1 v/v). Grace silica gel and Woelm neutral alumina were used for column chromatography. The i.r. spectra were recorded in Nujol with a Perkin–Elmer Model 337 spectrometer, and n.m.r. spectra were determined in deuteriochloroform solution with TMS as the internal standard using a Varian HA-100 spectrometer. The n.m.r. spectra of the deacetylated products were determined in deuterium oxide solution. Mass spectroscopy was obtained with a HMS-9 spectrometer. Optical rotations were measured at room temperature with a Perkin–Elmer automatic polarimeter Model 141. Chemical analyses were performed by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

*Photolysis of 3,4,6-Tri-O-acetyl-1,2-dideoxy-*D*-arabino-hex-1-enopyranose (**1**) in the Presence of Formamide and Acetone*

A mixture of 3,4,6-tri-*O*-acetyl-1,2-dideoxy-D-arabino-hex-1-enopyranose (**1**) (2.0 g), formamide (160 ml), *t*-butyl alcohol (30 ml), and acetone (10 ml) was irradiated for 30 min. A solution of (**1**) (2.20 g), *t*-butyl alcohol (10 ml), acetone (20 ml), and formamide (30 ml) was then added dropwise during 1 h and irradiation was continued for another 26 h (or until all starting material had disappeared as evidenced by t.l.c.). Alteration in the reaction conditions led to the formation of a more complex mixture of products. After the solution was concentrated to remove *t*-butyl alcohol and acetone by evaporation (30 mm pressure at 50°), the resulting solution was diluted with saturated aqueous sodium chloride solution (900 ml). The resulting solution was then extracted with dichloromethane (10 × 200 ml). The combined dichloromethane solution was washed with saturated aqueous sodium chloride solution (100 ml), dried over sodium sulfate, filtered, and concentrated under reduced pressure to yield a syrup (7.05 g). This syrup was applied to a silica gel column (520 g) and eluted by gradient elution chromatography using benzene – ethyl acetate – ethanol as developer as shown in Table 1.

Fraction A was mainly unreacted starting material **1**.

Fraction B was purified by preparative t.l.c. on silica gel G (benzene–ethanol, 97:3). The main zone, homogeneous by t.l.c., was twice distilled in high vacuum at 230° but could not be crystallized. Its i.r. in CCl_4 showed the absence of hydroxyl and ketone carbonyl group; m^+ 332; τ $(CD_3)_2CO$ 8.52 ($(CH_3)_2$), 8.05 (three acetyl groups).

Anal. Calcd. for $C_{15}H_{24}O_8$: C, 54.21; H, 7.28. Found: C, 53.95; H, 6.50.

Fraction C could not be purified by t.l.c.

Fraction D consisted of four compounds. High vacuum distillation of D at 200° removed non-carbohydrate material and left 0.46 g of a mixture of carboxamides **2** and **3**.

*3,4,6-Tri-O-acetyl-2,6-anhydro-3-deoxy-*D*-gluco-heptonamide (**2**) and 2,6-Anhydro-3-deoxy-*D*-gluco-heptonamide (**5**)*

Fractions E and F were crystallized from ethyl acetate to yield 0.23 g of **2**, m.p. 220°, $[\alpha]_D^{23}$ +31° (*c* 1.4, chloroform); i.r. (CCl_4), 3520 cm^{-1} (N—H); τ $CDCl_3$, 8.32 (two overlapping quartets, H-3a, $J_{3a,4}$ = 13.5, $J_{3a,2}$ = 13.5, $J_{3a,3e}$ = 13 Hz), 7.98, 7.96, 7.90 (acetyl), 7.36 (two quartets centered at 7.28 and 7.42 each peak separated by about 2.5 Hz, $J_{3e,3a}$ = 13 Hz), 6.32 (m, H-6), 5.96 (pair of doublets, H-2a, $J_{2a,3a}$ = 12.5, $J_{2a,3e}$ = 2.5 Hz doublets, H-2), 5.84 and 5.68 (m, 2H, H-7 and -7′), 5.05 (*t*, H-5), 4.88 (m, H-4, $J_{4a,3a}$ = 10, $J_{4a,5a}$ = 10 Hz), 4.22 and 3.55 (NH_2). Irradiation of H-3a and -3e collapsed H-2a to doublets; irradiation of H-2a affected H-3a and -3e.

Anal. of **2** Calcd. for $C_{13}H_{19}NO_8$: C, 49.21; H, 6.03; N, 4.41. Found: C, 49.21; H, 6.13; N, 4.36.

Compound **2** was deacetylated with 1 *M* methanolic sodium methoxide and the product deionized with IR-120 (H^+) resin in the usual way to yield, after crystallization from isopropyl alcohol, 2,6-anhydro-3-deoxy-D-glucoheptonamide (**5**), m.p. 194–196°; $[\alpha]_D^{22}$ +56° (*c* 2, water); c.d. $\Delta\varepsilon$ + 1.12 (λ_{max} 208 nm, water), $[\theta]_{208}^{30°}$ + 3636; $\Delta\varepsilon$ + 1.04 (λ_{max} 212 nm, methanol), $[\theta]_{212}^{30°}$ + 3432 (methanol); o.r.d. $[M]_{589}^{23}$ +98, $[M]_{220}^{23°}$ +858; i.r. (Nujol) 1670 (C=O), 1580 cm^{-1} (NH_2).

Anal. of **5** Calcd. for $C_7H_{13}NO_5$: C, 43.97; H, 6.83; N, 7.33. Found: C, 44.02; H, 7.09; N, 7.37.

Compound **5** was also obtained by deacetylating fractions E and F with sodium methoxide followed by cellulose column (60 cm × 3.2 cm) chromatography of the product (0.6 g) using *n*-butanol–ethanol–water (10:1:2) as developer. The fastest moving zone was compound **5**.

*2,6-Anhydro-3-deoxy-*D*-manno-heptonamide (**6**) and 4,5,7-Tri-O-acetyl-2,6-anhydro-3-deoxy-*D*-manno-heptonamide (**3**)*

The second zone (0.290 g, 9.3%) of the above cellulose chromatography was homogeneous by paper chromatography but could not be crystallized; $[\alpha]_D^{23}$ +39° (*c* 0.73, water), c.d. (water) $\Delta\varepsilon$ +0.614 $mol^{-1}cm^2$ (λ_{max} 228 nm), $[\theta]_{228}^{30}$ +2026; o.r.d. (water): $[M]_{589}^{23}$ +72; $[M]_{238}^{23}$ +730; $[M]_{211}^{23}$ −522; i.r. (Nujol) 1670 (C=O), 1585 cm^{-1} (NH_2).

Anal. of **6** Calcd. for $C_7H_{13}NO_5$: C, 43.97; H, 6.85; N, 7.33. Found: C, 43.55; H, 6.92; N, 6.87.

An aliquot of compound **6** (0.060 g) was acetylated with acetic anhydride and pyridine in the usual way. The syrupy acetate was purified by chromatography on silica gel column (10 cm × 1.3 cm) using benzene – ethyl acetate – ethanol (60:40:3) as developer. The main fraction was crystallized from ethyl acetate – *n*-hexane to yield 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptonamide (**3**), m.p. 205–207°; $[\alpha]_D^{24}$ +16° (*c* 1, chloroform); i.r. (chloroform); 3520 and 3400 cm^{-1} (NH); τ $CDCl_3$ 7.97, 7.93 (acetyl), 7.95 (m, H-3a, $J_{3a,2}$ = 5.5 Hz), 7.50 (m, H-3e, $J_{3e,2}$ = 6, $J_{3e,3a}$ = 14, $J_{3e,4}$ = 5 Hz), 5.97 (m, H-6), 5.86 (m, H-7′), 5.61 (m, H-7), 5.55 (t, H-2, $J_{2,3e}$ = 5.5, $J_{2,3a}$ = 5.5 Hz), 5.12 (t, H-5, $J_{5,4}$ = 6.5, $J_{5,6}$ = 6.5 Hz), 4.88 (m, H-4, $J_{4,3a}$ = 8, $J_{4,5}$ = 8, $J_{4,3e}$ = 4.5 Hz). Irradiation at τ 4.88 changed H-3e signals into a pair of doublets, $J_{3a,3e}$ = 14, $J_{3e,2}$ = 5 Hz. Irradiation at 7.50 (H-3e) changed the H-4 signals into a pair of doublets.

Anal. of **3** Calcd. for $C_{13}H_{19}NO_8$: C, 49.21; H, 6.03; N, 4.41. Found: C, 48.77; H, 6.35; N, 4.70.

*1,5-Anhydro-2-C-carbamoyl-1,2-dideoxy-*D*-gluco-hexitol (**7**) and 3,4,6-tri-O-acetyl-1,5-anhydro-2-C-carbamoyl-1,2-dideoxy-*D*-gluco-hexitol (**4**)*

Attempts to prepare a pure crystalline sample of **4** by preparative t.l.c. of fractions F or G were unsuccessful. As a consequence fractions F and G (total 1.65 g) were combined and deacetylated in the usual way with methanolic sodium methoxide for 1 h. The resulting solution was deionized with Amberlite IR 120 (H^+) and the product **7** recrystallized several times from methanol (0.730 g), m.p. 214–215°, $[\alpha]_D^{22}$ +41° (*c* 2, water), c.d. $\Delta\varepsilon$ = 0.0563 $mol^{-1}cm^2$ (λ_{max} 225, water), $[\theta]_{225}^{30}$ − 186; $\Delta\varepsilon$ = +0.090 mol^{-1} cm^2 (λ_{max} 206, water), $[\theta]_{206}^{30}$ +297; o.r.d. $[M]_{310}^{23}$ +323, $[M]_{214}^{23}$ +648; i.r. (Nujol): 1660, amide I band; 1608 cm^{-1}, amide II band; τ D_2O 7.26 (H-2, two overlapping quartets, $J_{2,1e}$ = 5, $J_{2,1a}$ = 11, and $J_{2,3}$ = 11 Hz).

Anal. of **7** Calcd. for $C_7H_{13}NO_5$: C, 43.97; H, 6.85; N, 7.33. Found: C, 43.73; H, 6.74; N, 7.48.

Compound 7 (0.080 g) was acetylated with acetic anhydride and pyridine in the usual way to afford after crystallization from methanol – *n*-hexane 0.110 g (61%) of 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (**4**), m.p. 126–127°, $[\alpha]_D^{21}$ +73° (*c* 2.5, chloroform), i.r. (CCl_4), 3520 and 3400 cm^{-1} (NH); τ ($(CD_3)_2$-C=O) 3.73 (NH_2), 7.90, 7.95, and 7.96 (acetyl), remaining peaks shown in Fig. 2. Irradiation at τ 4.55 changed the triplet at τ 5.05 to a doublet, $J_{4,5}$ = 10 Hz and changed the multiplet at τ 7.10 into a pair of doublets, $J_{2,1e}$ = 5 and $J_{2,1a}$ = 10 Hz. Irradiation at τ 7.10 collapsed the signals at τ 4.55 into a doublet, $J_{3,4}$ = 10 Hz and also affected the multiplets at τ 5.88 and 6.41.

Anal. of **4** Calcd. for $C_{13}H_{19}NO_8$: C, 49.21; H, 6.03; N, 4.41. Found: C, 49.22; H, 5.96; N, 4.27.

*3,4,6-Tri-O-acetyl-1,5-anhydro-2-C-carbamoyl-1,2-dideoxy-*D*-manno-hexitol*

Fraction H was fractionated by preparative t.l.c. to give **4** and a slightly contaminated syrupy product in low yield which is tentatively assigned to be 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*manno*-hexitol on the basis of its n.m.r. spectrum, τ ($CDCl_3$) 6.90–7.02 (overlapping m, H-2), 6.23–6.5 (H-1a, H-5, two doublets at 6.25 and 6.40, H-1a, $J_{1a,2}$ = 3, $J_{1a,1e}$ = 13 Hz, H-5 signals overlapped H-1a signals), 5.6–6.0 (two doublets of H-1e overlapping H-6,6′ signals), 4.85 and 4.95 (H-3, two doublets, $J_{3,2}$ = 6, $J_{3,4}$ = 9 Hz), 4.6 (t, $J_{4,3}$ = 9, $J_{4,5}$ = 9 Hz), 3.5 and 4.2 (NH).

*2-C-Acetamidomethyl-3,4,6-tri-O-acetyl-1,5-anhydro-1,2-dideoxy-*D*-gluco-hexitol*

To a slurry of lithium aluminum hydride (0.160 g) in anhydrous tetrahydrofuran (10 ml) was added dropwise with magnetic stirring a solution of 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-*C*-carbamoyl-1,2-dideoxy-D-*gluco*-hexitol (0.200

g) in 1.0 ml of tetrahydrofuran. After addition of 10 ml of tetrahydrofuran the reaction mixture was heated under reflux for 32 h. The reaction mixture was then cooled to 0° and excess lithium aluminum hydride was decomposed by dropwise addition of water. The solids were removed by filtration and washed with a 1:1 methanol–ethanol mixture (2 × 15 ml). The combined filtrates were evaporated under reduced pressure to yield a syrup which was then extracted with 20 ml of boiling methanol. The resulting filtrate was evaporated under reduced pressure to give 0.105 g of a syrup which gave a positive ninhydrin test. This syrup was acetylated with a 1:1 mixture of acetic anhydride and pyridine (1 ml) at room temperature for 24 h. After evaporation of the acetylating mixture under reduced pressure the product (0.154 g) was chromatographed on silica gel (13.5 × 1.3 cm) using 230 ml of 97:3 benzene–ethanol followed by 100 ml of 93:7 benzene–ethanol as eluent. The latter eluent on evaporation afforded a crystalline product which was recrystallized from ether and then ethyl acetate in benzene to give the title compound, yield 0.052 g (23%), m.p. 112–113°, $[\alpha]_D^{26}$ + 137° (*c* 2, chloroform), i.r. ($CHCl_3$) 3425 (NH), 1675 cm^{-1} (amide); τ $CDCl_3$, 8.04 ($CH_3\overset{O}{\overset{\|}{C}}-N$), 7.98, 7.95, and 7.94 (acetyl), 7.8–8 (m, overlapping acetyl peaks), 7.14 (m, 1H), 6.73 (t, H-1a, $J_{1a,2} = 12$, $J_{1a,1e} = 12$ Hz), 6.45 (m, 2H), 5.7–6.05 (overlapping peaks, 3H), 5.03 (m, H-3 and -4), 3.96 (NH). Irradiation at τ 8 altered the signals at τ 5.03.

Anal. Calcd. for $C_{15}H_{23}NO_7$: C, 52.20; H, 6.66; N, 4.06. Found: C, 52.31; H, 6.95; N, 4.12.

Etude de l'association du 2,6-di-ter-butylparacrésol avec la cyclohexanone

C. BOURDÉRON

Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 13 août 1971

Nous avons étudié, par spectroscopie i.r., jusqu'à la température de l'azote liquide l'association du 2,6-di-ter-butylparacrésol avec la cyclohexanone en solution. Dans un certain domaine de concentration nous avons pu mettre en évidence des complexes 1:1 et 1:2 (cyclohexanone–2,6-di-ter-butylparacrésol) et nous avons pu préciser la nature de ces complexes. Nous avons observé un phénomène d'induction de liaisons hydrogène par un solvant bromé.

The association between 2,6-di-tert-butylparacresol and cyclohexanone has been investigated in solutions down to liquid nitrogen temperature through the measurement of i.r. spectra. The presence of 1:1 and 1:2 complexes in a certain range of concentration was ascertained and the nature of these complexes was established. We observed solvent induced hydrogen bond formation in a bromine containing solvent.

Introduction

L'emploi de basses températures est un avantage certain lorsqu'on étudie la liaison hydrogène et la mise au point dans ce laboratoire de verres résistant jusqu'à une température de -190 °C nous a permis d'envisager l'étude de complexes donneurs–accepteurs de proton jusqu'à cette température; la grande gamme de température utilisée nous permettant alors de calculer d'une manière précise les enthalpies de formation des divers complexes.

Les résultats obtenus par Asselin (1) montrent qu'à basse température des systèmes tels que: phénol–acétone, isopropanol–cyclohexanone dans des solvants neutres évoluent en fonction de la température. Dès -80 °C l'isopropanol se polymérise et l'accepteur de proton ne joue plus aucun rôle sur la polymérisation. Il faut donc choisir pour l'étude envisagée un alcool ou un phénol qui ne polymérise pratiquement pas même à basse température. Nous avons choisi le 2,6-di-ter-butylparacrésol (DTBPC).

Un certain nombre de résultats ont été publiés sur ce phénol et nous citerons les travaux de Wren et Lenthen (2) qui mesurant la constante d'association du système DTBPC–dioxanne pour deux températures (20 et 50 °C), trouvent dans les deux cas la même constante $K_c = 0.12$ et par un calcul d'erreur en déduisent que l'enthalpie de formation de la liaison hydrogène est inférieure à 1100 cal/mol. Ces auteurs étudient d'autres systèmes DTBPC – accepteurs de proton et ils montrent qu'il se forme souvent des complexes comportant plus de deux molécules ou des complexes bimoléculaires dans lesquels l'axe de la liaison O—H est soit dans le plan soit hors du plan du cycle benzènique.

Sakano *et al.* (3) montrent qu'il se forme préférentiellement des complexes de type 1:1 entre le 2,6-di-ter-butylphénol (molécule dont l'encombrement stérique du groupement OH est semblable à celui du DTBPC) et l'acétone, la *N,N*-diméthylacétamide et la pyridine.

Enfin, Ingold (4) dans une étude sur les 2,6-di-ter-butylphénols substitués en position 4 montre que l'axe du groupement OH est situé dans le plan du cycle benzènique.

Nous avons donc associé le DTBPC à différents accepteurs de proton dans différents solvants; suivant ces bases et ces solvants nous avons obtenu divers types de complexes. Le cas qui nous semble le plus intéressant est celui de l'association du DTBPC et de la cyclohexanone. Nous nous proposons d'étudier ce cas ici.

Partie expérimentale

Les solvants employés sont des mélanges dans des proportions 1:1 du CCl_3F (F11) et du méthylcyclopentane (MCP), du CCl_3F et du $C_2F_4Br_2$ (F114B2); tous ces composés ont été distillés sur anhydride phosphorique et conservés sur ce même produit.

Le 2,6-di-ter-butylparacrésol a été sublimé et la cyclohexanone distillée et conservée sur tamis moléculaire.

Les spectres ont été enregistrés sur un spectrophotomètre Perkin–Elmer, modèle 621.

Analyse des résultats spectraux

Lorsque l'on associe le DTBPC avec la cyclohexanone, on voit apparaître deux bandes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

associées, l'une de haute fréquence: 3550 cm^{-1} environ, l'autre de basse fréquence: 3350 cm^{-1} environ. Ceci nous montre que plusieurs espèces associées coexistent, ou qu'un complexe comportant plusieurs molécules de DTBPC se forme. En utilisant comme solvant le mélange F11 + MCP, les deux bandes associées observées sont d'intensité croissante lorsque la température s'abaisse; d'autre part un effet de variation des concentrations nous montre que le rapport des intensités des deux bandes associées pour une température donnée varie avec les concentrations initiales, ce qui élimine l'hypothèse d'un seul complexe. Pour la même raison un équilibre du type suivant est à rejeter:

$$D + A \rightleftharpoons DA$$
$$D + A \rightleftharpoons (DA)'$$

équilibre, dans lequel DA et (DA)′ seraient des complexes qui se différentieraient par l'orientation respective de A et D. Nous pensons donc que les bandes observées indiquent la présence de plusieurs espèces associées: la bande de haute fréquence indique la présence d'un groupement O—H engagé dans une liaison hydrogène faible, celle de basse fréquence à un groupement O—H engagé dans une liaison hydrogène moyenne. Nous supposerons qu'il se forme deux types de complexes: des complexes cyclohexanone–DTBPC 1:1 et 1:2. Nous verrons à posteriori que cette supposition est confirmée.

L'équilibre envisagé se présentera sous la forme:

$$A + D \rightleftharpoons AD \qquad K_1 = c/a.d$$
$$AD + D \rightleftharpoons AD_2 \qquad K_2 = e/c.d$$

A, D, AD, et AD_2 représentent l'accepteur et le donneur de proton et les deux complexes formés; a, d, c, e les concentrations respectives à l'équilibre; a_0 et d_0 les concentrations initiales de l'accepteur et du donneur de proton.

Nous nous proposons de calculer les enthalpies de formation ΔH_1^0 et ΔH_2^0 des complexes AD et AD_2. Pour ce calcul il faut connaître les constantes K_1 et K_2 à plusieurs températures et ce serait facile si on pouvait connaître simultanément les concentrations a et d mais l'absorption des solvants empêche une telle détermination.

La calcul de d, concentration du DTBPC à l'équilibre se fera d'une manière classique; nous mesurerons le coefficient apparent d'extinction moléculaire ε_T de la bande OH libre nous en déduirons la concentration d à chaque température. Cependant si pour une petite gamme de température on peut considérer ε_T comme constant, dans la gamme que nous avons employée il n'en est pas de même. Avec différentes solutions de DTBPC de concentration connue, dans le mélange F11 + MCP nous avons établi la relation:

$$\varepsilon_T = 256 - 0.900\,(t - 25)$$

(Nous avons effectué les corrections dues à la concentration de volume.)

Un certain nombre de méthodes itératives existent pour calculer K_1 et K_2 (5, 6, 7) mais, en général, elles ne permettent pas de calculer ΔH_2^0.

Nous avons donc essayé d'adapter une méthode permettant le calcul des enthalpies de formation des différents complexes.

Des équilibres précédents on tire les relations:

$$d_0 = d + c + 2e$$
$$a_0 = a + c + e$$

ou:

$$d_0 - 2a_0 = d - 2a - c$$

en remplaçant c par $K_1.a.d$ on a

$$a = \frac{2a_0 + d - d_0}{2 + K_1 d}$$

$$K_2 = \frac{e}{c.d} = \frac{a_0 - a - K_1 da}{K_1 d^2 a}$$

Nous fixerons une valeur arbitraire de K_1 à 298 °K et de ΔH_1^0 puis par l'intégration de l'équation de Van't Hoff, nous déterminerons K_1 à diverses températures:

$$K_T = \exp\left[\log K_{(298\,^\circ K)} - \frac{\Delta H^0}{R}\cdot\left(\frac{1}{T} - \frac{1}{298}\right)\right]$$

Nous calculerons alors les K_2 correspondant et ΔH_2^0. Nous répéterons ces calculs pour une série de concentrations initiales a_0 et d_0 différentes. Il suffit ensuite de faire varier K_1 et ΔH_1^0 de façon à obtenir des valeurs pratiquement constantes de ΔH_2^0 et de K_2(298 °K) quelles que soient les concentrations initiales utilisées.

Les erreurs minimales sur ΔH_2^0 et K_2(298 °K) sont obtenues pour des valeurs légèrement différentes de K_1(298 °K) mais nous choisirons

TABLEAU 1. Calcul des constantes d'équilibre K_1 et K_2 et des concentrations des complexes AD et AD_2.* Concentration initiale en DTBPC: 0.065 M, en cyclohexanone: 0.0260 M; $-\Delta H_2^0$: 2.10 kcal/mol; coefficient de corrélation: 0.990

comme valeur de K_1(298 °K) celle qui donne les meilleures valeurs de ΔH_2^0 et dans ce cas l'erreur maximum sur ΔH_2^0 sera de 5% (erreur déterminée à partir de la moyenne des différents ΔH_2^0). Nous verrons alors qu'il y a bon accord pour chaque série de mesures entre les constantes calculées à diverses températures et les constantes moyennes correspondantes déterminées à partir de toutes les séries.

Dans tous les cas on pourra alors vérifier que les coefficients de corrélation ont une valeur proche de 1, ce qui montre une bonne linéarité dans la courbe expérimentale $\log K_2 = f(1/RT)$.

Nous avons fait quatre séries de mesures à diverses concentrations en DTBPC et cyclohexanone.

Les calculs ont été effectués sur ordinateur. Après une série d'itérations nous avons obtenu pour ΔH_1^0, K_1(298 °K), ΔH_2^0 moy, K_2(298 °K) moy, les valeurs suivantes: K_1(298 °K) = 0.6, K_2(298 °K) = 1.9; $\Delta H_1^0 = -1.17$ kcal/mol, $\Delta H_2^0 = -2.21$ kcal/mol.

Dans les tableaux 1–4 nous donnons les résultats obtenus pour K_2, c, et e.

L'avantage de cette méthode est qu'elle n'exige pas que le nombre de mesures pour

−90	0.120	0.070	0.266	2.0	21.1	20.2	0.023	0.023
−105	0.123	0.035	0.271	2.7	46.2	34.9	0.025	0.031
−120	0.125	0.025	0.276	3.9	74.6	67.1	0.023	0.038
−135	0.127	0.014	0.280	6.0	177.9	148.8	0.021	0.045
−150	0.129	0.007	0.286	10.1	398.7	400.4	0.017	0.052

chaque série soit le même; de plus les températures employées peuvent différer d'une série à l'autre.

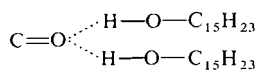
On remarque que généralement l'erreur sur K_2 est grande à 25 °C, mais à cette température $d_0 - d$ est faible et l'erreur sur cette dernière quantité est grande.

Cependant on peut dire que les valeurs de K_2 coïncident pour les quatre séries de mesures et ceci confirme notre hypothèse sur les équilibres successifs avec formation de complexes 1:1 et 1:2.

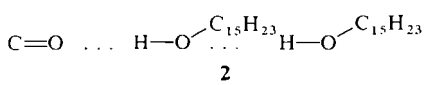
L'examen des quatre tableaux nous montre en outre que bien qu'à la température ambiante la constante K_2 soit plus grande que la constante K_1, la concentration c est plus grande que la concentration e et que c passe ensuite par un maximum vers −100, −120 °C suivant les concentrations, tandis que e croît continuellement.

Discussion

Le complexe 1:2 peut se présenter sous deux formes, **1** et **2**.



1



2

Lascombe (8) signale que pour un grand excès de donneur de proton par rapport à l'accepteur, on détecte des complexes de type **1**. Cependant Murrell (9) montre que les deux doublets libres de l'oxygène du groupement C=O sont différents, le premier est de caractère s très marqué et par conséquent très peu disponible pour former des liaisons hydrogène.

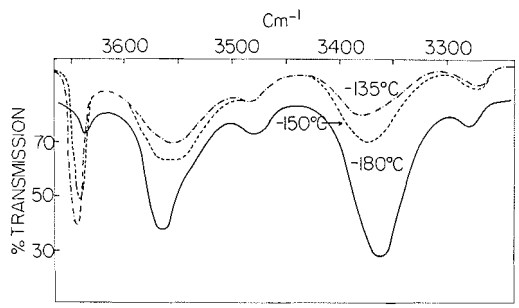


FIG. 1. Spectres du DTBPC (0.096 M) associé à la cyclohexanone (0.055 M) à différentes températures. Epaisseur de la cellule 0.1 mm; solvant F11 + MCP.

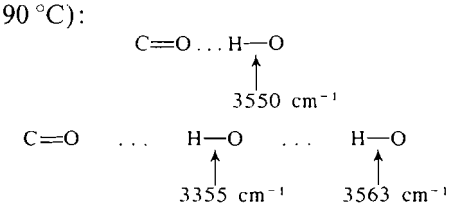
Ce dernier argument nous fait penser qu'en solution une structure de type **2** est plus probable.

L'examen de nos spectres (voir fig. 1) nous montre que nous voyons d'abord croître une bande à 3550 cm^{-1} environ et au fur et à mesure que la température diminue une deuxième bande apparaît à 3565 cm^{-1} environ et croît aussi régulièrement tandis qu'à un certain moment la bande située à 3550 cm^{-1} diminue d'intensité. Ce phénomène est d'autant plus visible que la concentration en cyclohexanone est faible et à condition que le complexe 1:2 se forme en quantité appréciable.

Ceci s'explique très bien lorsqu'on envisage une structure de type **2** et si nous faisons les attributions suivantes (fréquences obtenues à −190 °C):



Nous avons vu par l'étude des constantes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

d'équilibre que la concentration du complexe **1** doit croître jusqu'à -100 °C environ donc que l'intensité de la bande située à 3550 cm^{-1} doit croître elle aussi et ensuite que ce complexe est progressivement remplacé par le complexe 1:2 donc on doit voir la bande à 3550 cm^{-1} diminuer et elle doit être remplacée par la bande à 3565 cm^{-1}. Quant à la bande située à 3355 cm^{-1}, elle croît régulièrement.

Si on admet une relation croissante entre le déplacement de fréquence et l'énergie de formation d'un complexe, on s'aperçoit que le groupement C=O est meilleur accepteur que le complexe (C=O...H—O—$C_{15}H_{23}$), puisque la fréquence du groupement OH du complexe 1:1 est plus basse que celle du groupement OH terminal du complexe 1:2. Ce fait peut peut-être expliquer pourquoi il ne se forme qu'un complexe 1:2 (dans des gammes de concentration et de température importantes) car si on observait l'inverse on pourrait s'attendre à une polymérisation.

Il est à noter que notre attribution correspondant aux fréquences de vibration du groupement central OH du complexe 1:2 et du groupement OH du complexe 1:1 est semblable à celle que l'on ferait pour un dimère et un trimère d'alcool.

Il est difficile de mesurer la demi-largeur exacte des bandes associées du fait que la bande de haute fréquence est une bande double, cependant à -190 °C cette bande est presque simple et a une demi-largeur de 40 cm^{-1} tandis que la deuxième n'a qu'une demi-largeur de 45 cm^{-1} pour une fréquence de 3355 cm^{-1}. Ceci est assez surprenant car on s'attendrait à ce qu'une bande située aussi bas ait une demi-largeur beaucoup plus grande, cependant la fréquence de 3355 cm^{-1} ne correspond qu'à un seul vibrateur associé et non à un polymère. Cet exemple montre quand même que la relation $\Delta\nu_{\frac{1}{2}} = f(\Delta\nu)$ n'est pas générale. Ce fait est lié au degré de désordre qui existe dans le milieu. Il faut remarquer que dans ce cas de liaison hydrogène les groupements OH sont protégés de l'action du solvant par les groupements terbutyl et que ceci est une cause de l'amincissement des bandes OH associées.

Complexes de type 1:n

Le fait d'augmenter la concentration en cyclohexanone conduit graduellement suivant cette concentration à un nouveau phénomène et à un changement de l'équilibre envisagé (pour des concentrations en cyclohexanone de l'ordre de 0.6 *M* et en DTBPC de 0.1 *M*), l'application de notre méthode n'a donné aucun résultat (ce qui est normal du fait que nous avons un équilibre plus complexe). En effet pour des concentrations fortes en cyclohexanone nous voyons la bande associée à 3555 cm^{-1} baisser de fréquence continuellement lorsque la température diminue (il n'y a pas apparition de bande à 3563 cm^{-1} cependant elle peut être masquée par le massif à 3555 cm^{-1}), d'autre part la deuxième bande associée a une fréquence plus basse que précédemment 3320 cm^{-1}; les demi-largeurs pour ces bandes associées sont de 60 cm^{-1} pour la première et d'environ 100 cm^{-1} pour la deuxième (la mesure est assez imprécise du fait de l'absorption de 2ν C=O dans cette région). Pour une concentration initiale de 0.1 *M* en DTBPC et de 0.236 *M* en cyclohexanone on voit à -190 °C dans la région de 3300–3400 cm^{-1} deux bandes, l'une à 3350 cm^{-1}, l'autre à 3320 cm^{-1}, la deuxième devenant plus importante au fur et à mesure que l'on augmente la concentration en cyclohexanone; on passe donc progressivement d'un équilibre à un autre. Il est assez difficile de préciser la nature de ce troisième équilibre; cependant Gramstad et Van Binst (10) ont pu voir que l'on avait dans un certain domaine de concentration des complexes avec une molécule de phénol et deux d'accepteur de proton, ils ont même mesuré l'enthalpie de formation du complexe. Dans notre cas nous avons peut-être des complexes de même type ou des complexes de type 1:3, mais les spectres ne permettent pas de faire une attribution avec certitude.

Lorsqu'on reprend les spectres précédents en utilisant comme solvant le mélange 2F on s'aperçoit que lorsque la température diminue, il apparaît d'abord une bande associée dans la région de 3550 cm^{-1} et une autre dans la région de 3310 cm^{-1}, ensuite les bandes augmentent régulièrement en intensité et à une température voisine de -150 °C la première augmente beaucoup moins rapidement pour finalement diminuer d'intensité ou rester stationnaire suivant les concentrations, tandis que la deuxième devient très importante (fig. 2); dans ce cas la demi-largeur est de 92 cm^{-1} environ. Par comparaison avec les résultats précédents,

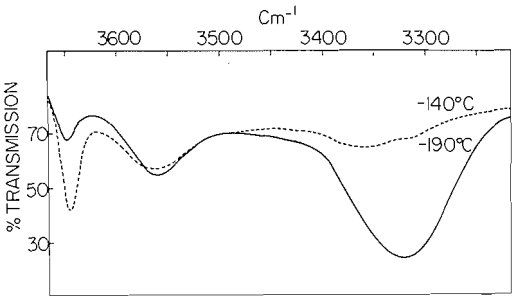


FIG. 2. Spectres du DTBPC (0.100 *M*) associé à la cyclohexanone (0.200 *M*) à deux températures. Epaisseur de la cellule 0.1 mm; solvant 2F.

il est probable que nous ayons obtenu un polymère et que ce polymère ait été induit par le $C_2F_4Br_2$; or dans ce composé seul les atomes de brome peuvent avoir été responsables d'une telle induction. Le mécanisme de l'interaction consiste probablement dans un transfert de charge de l'oxygène au brome.

Conclusion

L'étude du 2,6-di-ter-butylparacrésol nous a montré que ce composé ne forme pratiquement pas d'autoassociation même à la température de l'azote liquide, mais en présence d'accepteur de proton il forme des complexes de type 1:1 et 1:2. Ce résultat est un exemple d'induction de liaison hydrogène par le groupement C=O, cependant il nous est difficile de formuler des explications quant au mécanisme de cette induction. Dans un solvant contenant du brome ($C_2F_4Br_2$) nous avons même des complexes de type $1:n$, et nous avons un exemple d'induction de liaison hydrogène par le solvant.

Dans la gamme de température et de concentration ou le complexe 1:2 existe nous avons calculé son enthalpie de formation et proposé une structure pour ce complexe.

Je remercie tout particulièrement M. C. Sandorfy pour m'avoir aidé de ses conseils et pour avoir relu le manuscrit.

Mechanism of Alcohol to Ester Rearrangement in Phosphorus Compounds[1]

A. F. JANZEN AND T. G. SMYRL
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received October 4, 1971

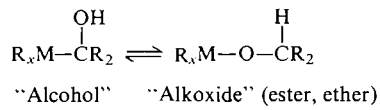
The kinetics of the base-catalyzed rearrangement of dialkyl 2-hydroxy-1,1,1,3,3,3-hexafluoroisopropylphosphonate, $(RO)_2P(O)C(OH)(CF_3)_2$ to 1,1,1,3,3,3-hexafluoroisopropyldialkyl phosphate, $(RO)_2P(O)OCH(CF_3)_2$, where R = methyl, ethyl, *n*-butyl, have been studied. Energies of activation and entropies of activation have been obtained and the base strength of the catalyst has been varied. A mechanism is proposed to account for the results.

Les cinétiques des transpositions baso-catalysées des dialkyl-2 hydroxy-1,1,1,3,3,3-hexafluoroisopropylphosphonates $(RO)_2P(O)C(OH)(CF_3)_2$ en 1,1,1,3,3,3-hexafluoroisopropyldialkyl phosphates, $(RO)_2P(O)OCH(CF_3)_2$ avec R = méthyle, éthyle, *n*-butyle, ont été étudiées. Les énergies d'activation et les entropies d'activation ont été obtenues et la force basique du catalyseur a été modifiée. Un mécanisme est proposé pour rendre compte des résultats.

Canadian Journal of Chemistry, **50**, 1205 (1972)

Introduction

Rearrangements involving isomeric alcohols and alkoxides are potentially useful in synthetic chemistry. Depending on the element M, a straightforward procedure may result in the preparation of one, but not the other, isomer.



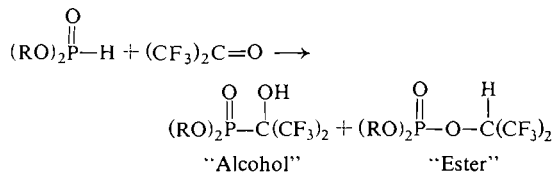
Considering only one example, namely the addition of metalloid–hydrogen bonds across carbonyl bonds, it is well known that B—H (1), Si—H (2), Ge—H, and Sn—H (3) bonds react with ketones to give alkoxides, whereas C—H, N—H, P—H, and As—H (4) bonds react with ketones to give alcohols.

Significant work has been carried out in the area of "alcohol–alkoxide" rearrangements. The Wittig rearrangement (M = C) involves the conversion of ether to alcohol in the presence of a strong base such as alkyllithium (5). The Brook rearrangement (M = Si) involves the conversion of alcohol to alkoxide in the presence of diethylamine (6, 7) whereas the reverse rearrangement, *i.e.* alkoxide to alcohol (M = Si) in the presence of *t*-butyllithium, has recently been reported by West and co-workers (8). Peddle and Ward have reported the alcohol to alkoxide rearrangement for M = Ge (9).

[1]Presented at the 54th Canadian Chemical Conference and Exhibition. Halifax, Nova Scotia, May 31–June 2, 1971.

A number of workers have reported base-catalyzed "alcohol–alkoxide" rearrangements involving phosphorus compounds (10) and a kinetic study, by the refractometric method, of phosphonate to phosphate rearrangement has been reported by Pudovik and co-workers (11).

In 1970 we reported the reaction of dialkyl phosphonates with hexafluoroacetone and found that in each case isomeric products were formed, the relative yield depending on the nature of



R (12). We further observed that rearrangement of alcohol to ester did not take place at room temperature in the absence of basic catalyst, *i.e.* under preparative conditions, and hence a rearrangement was not invoked to explain the relative yield of products.

To investigate this reaction further and determine under what conditions rearrangement does occur and what conditions give maximum yield of either alcohol or ester, a kinetic and mechanistic study was undertaken of the base-catalyzed rearrangement, in which R, base, and temperature were systematically varied.

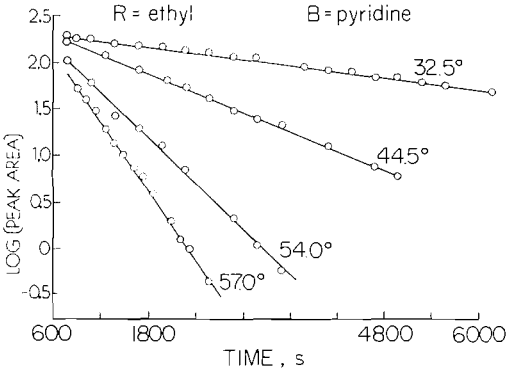

FIG. 2. Plot of log of peak area *vs.* time for rearrangement of $(C_2H_5O)_2P(O)C(OH)(CF_3)_2$ (1.22 M) with pyridine (2.57 M) in dichloromethane at various temperatures.

Kinetic Results

The chemical shifts of trifluoromethyl groups of alcohol and ester differ sufficiently (12) that ^{19}F n.m.r. techniques were suitable for measuring concentrations.

The base catalyst pyridine was added to the alcohol in dichloromethane as solvent and the disappearance of the alcohol doublet was followed as a function of time. Pseudo first order rate constants k_1' were obtained by plotting the logarithm of the peak area against time and the best value of the slope was calculated by the method of least squares. Dividing through by the base catalyst concentration, $k_1'/(\text{base}) = k_2$, gave a second order rate constant k_2 which is independent of initial concentration of alcohol and base, as shown in Table 1.

Alkyl substituents were varied and with the aid of a variable temperature probe on the n.m.r. instrument pseudo first order rate constants were determined at several temperatures for R = methyl (Fig. 1), R = ethyl (Fig. 2), and R = *n*-butyl (Fig. 3). The second order rate constant was obtained as described above and values of k_2 are given in Table 2.

It may be seen from Table 2 that rates of rearrangement decrease in the order R = methyl > ethyl > *n*-butyl, the second order rate constants being 8.03×10^{-4} (45.6°), 1.33×10^{-4} (44.6°), and 1.27×10^{-4} (51.4°) $l\ mol^{-1}\ s^{-1}$, respectively.

Plotting $\log k_2$ *vs.* $1/T$ gave linear plots from which the energy of activation was obtained. The entropy of activation and pre-exponential

TABLE 3. Energy of activation (E_a), entropy of activation ($\Delta S^{\ddagger}$), and logarithm of pre-exponent (log A) for $(RO)_2P(O)C(OH)(CF_3)_2$ rearrangement

R	E_a (k cal/mol)	$\Delta S^{\ddagger}$ (cal/mol degree)	log A
CH_3	14.6	−29.1	6.87
C_2H_5	19.8	−15.9	9.75
n-C_4H_9	24.5	−3.0	14.0

factor were calculated in the usual way (see experimental) and activation parameters are summarized in Table 3.

From the energies of activation it may be seen that the rate of rearrangement is favored in the order methyl > ethyl > *n*-butyl. On the other hand, the entropies of activation partly compensate for this trend since the negative entropies of activation are in the same order.

The effect of the basic catalyst on the rearrangement was also studied. Typical basic catalysts such as pyridine, dimethylsulfoxide, aniline, *N*-methylaniline, *N*,*N*-dimethylaniline, piperidine, and diethylamine, which differ widely in base strength[2] as measured by their pK_b, were added to the alcohol (R = methyl) in dichloromethane and the rearrangement studied at 33°. Rate constants k_1' and k_2 were obtained and, as shown in Table 4, the data indicate that, with the exception of *N*,*N*-dimethylaniline, the stronger the base the greater the rate of rearrangement.

[2]The base strength with respect to the alcohol in dichloromethane solution is not known and pK_b values are an approximation only.

TABLE 4. Effect of base catalyst (1.38 *M*) on rearrangement of $(CH_3O)_2P(O)C(OH)(CF_3)_2$ (1.10 *M*) in dichloromethane at 33 °C

Base	pK_b^*	k_2 (1 mol^{-1} s^{-1})
Dimethylsulfoxide	13	$\sim 7 \times 10^{-6}$
Aniline	9.37	1.11×10^{-4}
N-Methylaniline	9.15	1.47×10^{-4}
N,*N*-Dimethylaniline	8.85	1.02×10^{-4}
Pyridine	8.75	3.00×10^{-4}
Diethylamine	3.51	†
Piperidine	2.88	†

*Value for dimethylsulfoxide taken from Anal. Chem.; all others from "Handbook of chemistry and physics" (see ref. 17).
†Too fast for measurement by n.m.r. techniques.

Mechanism of Rearrangement

A reasonable mechanism for the alcohol to ester rearrangement must be consistent with second order kinetics and the observed activation parameters. If the mechanism was similar to that proposed by Brook, it would suggest that a common mechanism is possible for a variety of elements undergoing the "alcohol–alkoxide" rearrangement. Brook and co-workers (6) found that the base-catalyzed rearrangement of α-silylcarbinol (alcohol) to silyl ether (alkoxide) is first order in alcohol and first order in base and involves processes having low energies of activation but very high negative entropies of activation, and a cyclic three-membered transition state was postulated.

Pudovik and co-workers (11), who studied the thermal isomerization in the absence of solvent, of compounds **3**, **4**, and **5**, postulated a mechanism in which the oxygen atom of the hydroxyl group attacks the phosphorus atom, which then

5

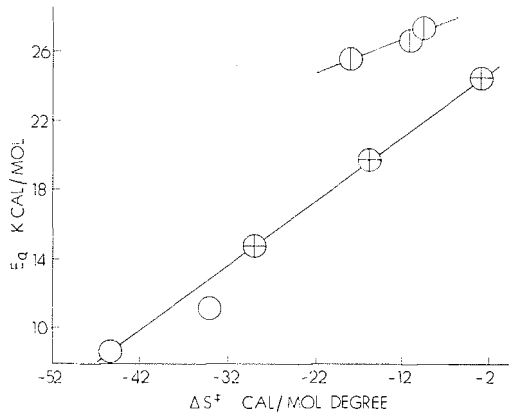

FIG. 4. Plot of E_a *vs.* $\Delta S^{\ddagger}$ for "alcohol to alkoxide" rearrangement: this work, ⊕; Brook *et al.* (6), ○; and Pudovik *et al.* (11), ⊙.

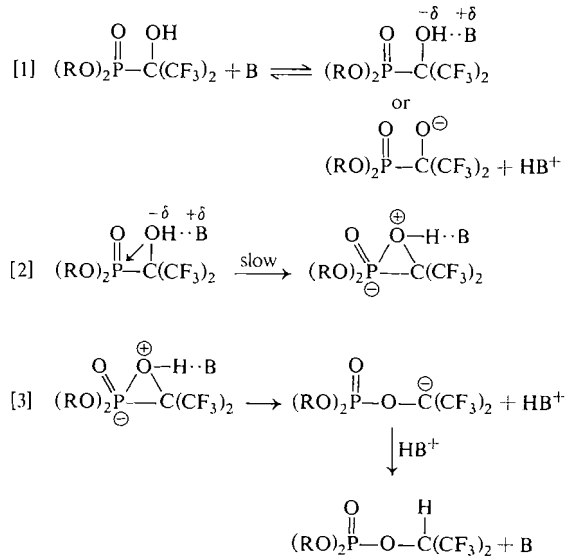
leads to cleavage of O—H and C—P bonds and formation of new C—O—P and C—H bonds.

To test for an isokinetic relationship, the energy of activation was plotted *vs.* the entropy of activation, as described by Leffler (13). As seen from Fig. 4, the results of this work and those of Brook for compounds **1** and **2** give an approximately linear plot, suggesting a common mechanism of rearrangement. On the other hand, the results of Pudovik for compounds **3**, **4**, and **5** are displaced towards higher energies of activation and more negative entropies of activation and since his results were obtained in the absence of solvent and catalyst it is not surprising that a different mechanism is implied by Fig. 4.

A reasonable mechanism that is consistent with the kinetics and activation parameters and, at the same time, is in agreement with the results obtained by Brook, is shown in eqs. 1–3.

Step 1 involves polarization of the hydroxyl oxygen, either through hydrogen bonding, which is expected to be particularly strong for pyridine and perfluoroalcohols (14), or through ionization to give the pyridinium ion. Hydrogen bonding in the starting compound involving phosphoryl oxygen and hydroxyl would probably be of smaller magnitude (15). Step 1 probably involves rapid proton exchange and the effect of increasing base strength of catalyst must be to shift the equilibrium to the right, in the direction of increased ionization.

Step 2 must then represent the rate determining step; in particular, it is postulated that the



slow step is the intramolecular nucleophilic attack of the hydroxyl oxygen on the phosphorus atom, thereby implying that any substituent on the phosphorus atom which releases electron density to the phosphorus atom will increase the energy barrier to the transition state. Since the inductive (electron release) effect of alkyl groups is generally assumed to be in the order butyl > ethyl > methyl the argument is consistent with the trend found for the activation energies.

Step 3 involves collapse to final ester product, either through an intermediate carbanion followed by proton transfer, or directly via simultaneous cleavage of P—C bond and formation of C—H bond.

The negative entropies of activation are consistent with a constrained intermediate, namely a cyclic three-membered complex as postulated by Brook. For R = *n*-butyl the entropy of activation is only −3.0 e.u. and molecular models show that steric interactions are present between rotating *n*-butyl and trifluoromethyl groups. However, these steric interactions are not expected to differ greatly in the ground state and transition state and, in view of an isokinetic relationship, a cyclic three-membered transition state seems most reasonable.

It is interesting to speculate whether eqs. 2 and 3 could, under different conditions, represent equilibrium processes and permit the reverse rearrangement *i.e.* ester to alcohol. Undoubtedly a very strong base would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

required for carbanion formation, and we find that if *n*-butyllithium is added to ester (R = methyl) the characteristic ^{19}F n.m.r. doublet of the ester is replaced by a singlet, as required for the carbanion. Further n.m.r. examination showed that a P—C bond was not formed and we conclude that the reverse reaction did not go past the carbanion stage. What other factors, if any, could drive the equilibrium past the carbanion to the alcohol stage are not known at present, although the relative stabilities of P—C *vs.* P—O and $(RO)_2P(O)C(O^-)(CF_3)_2$ *vs.* $(RO)_2P(O)OC^-(CF_3)_2$ could be important (8).

Experimental

Conventional vacuum line techniques were used for handling volatile materials. Hexafluoroacetone, dialkyl phosphonates, and bases were purified by vacuum distillation or trap-to-trap distillation and their purity checked by i.r. and n.m.r. spectroscopy. Dichloromethane (B.D.H. Chemicals) was used without further purification. The n.m.r. spectra were obtained on a Varian A-56/60A spectrometer using 60 and 56.4 MHz for proton and fluorine, respectively.

Preparation of Dialkyl 2-Hydroxy-1,1,1,3,3,3-hexafluoroisopropylphosphonate, $(RO)_2P(O)C(OH)(CF_3)_2$, in High Yield

The procedure described previously (12) gave low yields for R = methyl and ethyl. Changing reaction conditions as described below substantially increased the yield.

Dimethyl phosphonate (2.40 g, 21.8 mmol) in dichloromethane (10.0 ml) was cooled to −196° and hexafluoroacetone (4.29 g, 25.8 mmol) was added. The reaction tube was sealed under vacuum and placed in a Dry Ice–acetone bath (−78°) which was allowed to evaporate and reach 25° over a period of 24 h. After this time the reaction tube was opened and excess hexafluoroacetone removed. The products were identified as dimethyl-2-hydroxy-1,1,1,3,3,3-hexafluoroisopropylphosphonate ("alcohol"), $(CH_3O)_2P(O)C(OH)(CF_3)_2$ (5.06 g, 84%), and 1,1,1,3,3,3-hexafluoroisopropyldimethyl phosphate ("ester"), $(CH_3O)_2P(O)OCH(CF_3)_2$ (0.96 g, 16%) on the basis of ^1H and ^{19}F n.m.r. and i.r. examination (12).

Diethyl phosphonate (3.01 g, 21.8 mmol) in dichloromethane (10.0 ml) and hexafluoroacetone (4.29 g, 25.8 mmol) were allowed to react as described above to give $(C_2H_5O)_2P(O)C(OH)(CF_3)_2$ (5.83 g, 88%) and $(C_2H_5O)_2P(O)OCH(CF_3)_2$ (0.80 g, 12%).

The compound $(C_4H_9O)_2P(O)C(OH)(CF_3)_2$ was prepared in yields of at least 90%, the remainder being $(C_4H_9O)_2P(O)OCH(CF_3)_2$, using the procedure outlined above or as described previously (12).

No rearrangement occurred when alcohols were kept at room temperature in the absence of basic catalyst. Furthermore, no rearrangement occurred when dialkyl phosphonates were added to the alcohols at room temperature.

One of the esters, namely $(CH_3O)_2P(O)OCH(CF_3)_2$, was found to be unstable in the presence of bases such as pyridine and diethylamine. After an induction period of approximately 30 min, the ester reacted with pyridine to give a new product containing the grouping $CH_3OPOCH(CF_3)_2$, as determined by ^1H and ^{19}F n.m.r. Approximately 50% of the ester had reacted after 24 h, and 66% after 48 h. Since this reaction was too slow to interfere with the kinetic results, it was not investigated further.

Kinetic Measurements

A Varian A-56/60A n.m.r. spectrometer, equipped with a variable temperature probe, was used to determine rate constants. The ^{19}F n.m.r. spectra showed well separated doublets due to trifluoromethyl groups of alcohol and isomeric ester (12).

In a typical kinetic run, a solution of alcohol in dichloromethane, in a standard n.m.r. tube, was allowed to reach thermal equilibrium in the sample probe of the n.m.r. spectrometer. The n.m.r. tube was then withdrawn and a measured amount of base added and the mixture shaken to ensure thorough mixing. The n.m.r. tube was re-inserted and the ^{19}F n.m.r. peaks due to alcohol and ester were recorded at regular intervals of time until at least 90% rearrangement had occurred. During the kinetic runs the integral heights of alcohol and ester were summed to check that sums remained constant *i.e.* to ensure that alcohol was converted only to ester.

Pseudo first order rate constants k_1' were obtained from a plot of the logarithm of alcohol peak area *vs.* the time and the best slope calculated by the method of least squares. Second order rate constants were obtained by dividing the pseudo first order rate constant by the concentration of base *i.e.* $k_2 = k_1'/(\text{base})$.

The Arrhenius energy of activation E_a was obtained by repeating the kinetic runs at several temperatures. An ethylene glycol temperature *vs.* chemical shift chart was used to calibrate the temperature of the n.m.r. probe, and the temperatures are accurate to ±1°. The temperature was checked before and after every run and if the temperature varied that particular run was discarded.

The entropy of activation was calculated from the equation

$$k = e\,\frac{kT}{h}\,e^{\Delta S^{\ddagger}/R}\,e^{-Ea/RT} \quad (16)$$

and A from

$$k = A\,e^{-Ea/RT} \quad \text{(ref. 16, p. 53)}$$

The rearrangement of $(CH_3O)_2P(O)C(OH)(CF_3)_2$ was studied at 33° in dichloromethane as a function of base strength of catalyst. Dimethylsulfoxide, aniline, *N*-methylaniline, *N*,*N*-dimethylaniline, pyridine, piperidine, and diethylamine were used and, in each case, k_1' and k_2 were determined and the results are shown in Table 4.

Synthesis of Oligothymidylates on an Insoluble Polymer Support

K. K. OGILVIE AND K. KROEKER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received August 26, 1971

The synthesis of a succinylated polystyrene polymer is described. The polymer is converted to the acid chloride form and condensed with thymidine derivatives. A number of methods for phosphorylation of polymer bound nucleosides were investigated and the synthesis of tetrathymidine triphosphate (TpTpTpT) is described.

On décrit la synthèse d'un polymère de styrène succinylé. Le polymère est transformé en chlorure d'acide et condensé avec les dérivés de thymidine. On a étudié plusieurs méthodes de phosphorylation des nucléosides attachés au polymère et on décrit la synthèse du dérivé triphosphaté de tétrathymidine (TpTpTpT).

Introduction

The multistep synthesis of oligonucleotides on a polymer support offers a major advantage in that polymer-bound products may be easily separated from excess reagents and soluble by-products at each step. As a result a number of polymers have been investigated as supports for oligonucleotide synthesis. Hayatsu and Khorana (1) and Cramer *et al.* (2) have used soluble polystyrene polymers in which the reactive site was a triphenylmethyl chloride group. Melby and Strobach (3) have used a similar approach except that their polymer was insoluble in organic solvents. Letsinger *et al.* (4*a*) developed a crosslinked polystyrene "popcorn" polymer possessing a benzoyl functional group. Crosslinked polystyrene polymers have also been used by Kusama and Hayatsu (4*b*) and by Blackburn *et al.* (5). While nucleotides have been synthesized on all of these polymers yields are usually low. Further, conditions required to remove the nucleotide from the polymers also hydrolyze protecting groups from the nucleotide units.

We have investigated a succinylated polystyrene polymer as a support in nucleotide synthesis. Nucleosides would be bound to such a polymer via an acyl functional group which would be at a greater distance from the polymer backbone than in the "popcorn" polymer (4*a*). Since completion of our work Yip and Tsou (6) have reported use of an isotactic succinylated polystyrene polymer in ribooligonucleotide synthesis.

Results and Discussion

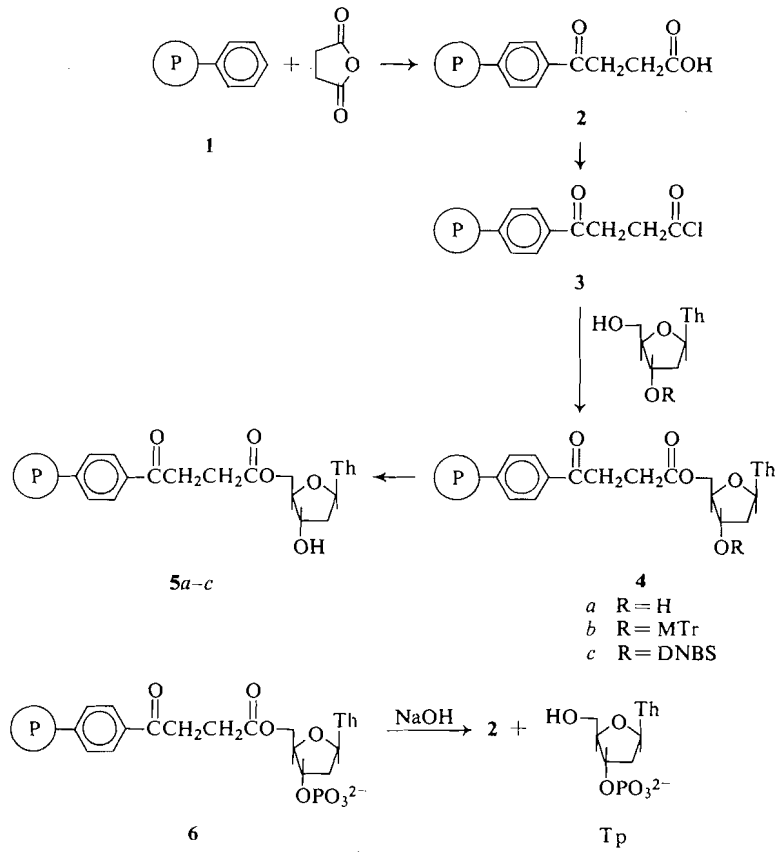
In any general useful synthesis, reagents should be readily available. For this reason we chose Biobeads S-X2, a commercially available (7) porous styrene–divinylbenzene copolymer and acylated it using succinic anhydride (Scheme 1).

When the acylation reaction was carried out at 60 °C using freshly sublimed aluminum chloride in nitrobenzene polymer **2** was obtained. Polymer **2** contained 0.39 mmol of succinyl group per gram of polymer. Polymer **2** was converted to the acid chloride form **3** on reaction with thionyl chloride in benzene with pyridine as catalyst. Polymer **3** reacted readily with thymidine or thymidine derivatives possessing a free 5′-hydroxyl but did not react with thymidine derivatives having only a free 3′-hydroxyl group. The thymidine content of polymer **4** was between 0.08 and 0.13 mmol of thymidine per gram of polymer. In all condensations a thymidine content of 0.11 mmol per gram of polymer was used.

Thymidine could not be removed from **4** using hydrazine solution.[1] Thymidine was easily removed from the polymer using 0.5 *N* NaOH in dioxane:water (1:1).

3′-*O*-Monomethoxytritylthymidine (T-MTr) reacted with **3** to produce **4***b* (R = monometh-

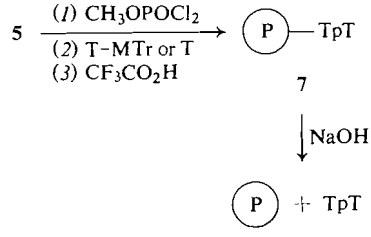
[1]This is in sharp contrast to the isotactic polymer of Yip and Tsou where the hydrazine solution did remove thymidine from the polymer. This must reflect a much greater degree of freedom for the side chain in the isotactic polymer as compared to the cross-linked polymer **4** (6).



SCHEME 1

oxytrityl = MTr). Aqueous acetic acid, even at elevated temperatures, would not completely remove the methoxytrityl group from **4***b*. However, a 0.1% solution of trifluoroacetic acid in benzene completely removed the MTr group at room temperature.

3′-*O*-(2,4-Dinitrobenzenesulfenyl) thymidine also reacted readily with **3** to produce **4***c* (R = 2,4-dinitrobenzenesulfenyl = DNBS). The sulfenyl group was readily removed from **4***c* using thiophenol in pyridine.

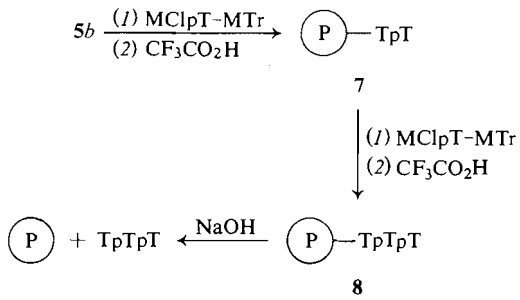


SCHEME 2

For investigation of phosphorylations on the polymer a polymer **5***b* containing 0.11 mmol of thymidine per gram of polymer was used. Using β-cyanoethyl phosphate with mesitylenesulfonyl chloride (MSCl) as condensing agent, 73% of the polymer bound thymidine was converted to thymidine-3′ phosphate (Tp). When dicyclohexylcarbodiimide was used in place of MSCl the yield of Tp was 65%. Methyl dichlorophosphate was the most convenient phosphorylating agent and gave a 75% conversion of thymidine to Tp.

Two different routes (Schemes 2 and 3) were used for the synthesis of nucleotide chains on the polymer (**5**). On the first approach (Scheme 2) polymer **5***b* was phosphorylated with methyl dichlorophosphate and the reactive intermediate was condensed directly with 3′-*O*-monomethoxytritylthymidine. After removal of the methoxytrityl group the nucleotidic material was cleaved from the polymer and a 38% yield of thymidylyl-(3′–5′)-thymidine (TpT) was ob-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 3

tained. The TpT so obtained was completely degraded by both snake venom and spleen enzymes.

This procedure was used with polymer **5***a*, condensing with unblocked thymidine at each step. The conversion of polymer bound thymidine to tetrathymidine triphosphate (TpTpTpT) was 4%.

The alternate route is outlined in Scheme **3**. Polymer **5***b* was condensed with methyl 3′-*O*-monomethoxytritylthymidine-5′ chlorophosphate (MeClpT–MTr) and the polymer was treated with trifluoroacetic acid to yield **7**. Analysis of a sample of **7** revealed a 34% conversion to TpT. Repeating the phosphorylation step with **7**, followed by acid and base hydrolysis gave thymidylyl-(3′–5′)-thymidylyl-(3′–5′)-thymidine (TpTpT) in 10% overall yield. The nucleotides produced by this route were completely degradable by snake venom and spleen enzymes.

These experiments show that the succinylated cross-linked polystyrene polymer can be conveniently used as a support for solid-phase synthesis of oligonucleotides containing entirely the natural 3′–5′ linkage. The yields for this polymer are slightly lower than for the isotactic polymer and this undoubtedly reflects increased steric hindrance at the reactive sites of the cross-linked polymer.

Experimental

General Methods

Paper chromatography was carried out by the descending technique on Whatman 3 mm paper. The solvent systems were: solvent A, 2-propanol – concentrated ammonium hydroxide – water (7:1:2); solvent B, 1-propanol – concentrated ammonium hydroxide – water (55:10:35). The solvents were prepared on a volume basis. Paper electrophoresis was performed using Whatman 3 mm paper in a Savant Flat Plate electrophoretic chamber with a Savant Flat Plate Model HV power supply operated at 2000 V for 1 h; the solution was buffered at p*H* 8.0 with 0.0033 *M* potassium dihydrogen phosphate and 0.063 *M* disodium hydrogen phosphate. Nucleosides and their derivatives were observed on paper strips by fluorescence in u.v. light (Mineralite).

The i.r. spectra were obtained with a Perkin–Elmer 337 recording spectrophotometer. All samples were prepared in KBr disks. The u.v. spectra were obtained on a Cary 14 recording spectrometer. The term OD unit refers to the extinction of the nucleotidic material in 1 ml of neutral solution in a quartz cell with a 1-cm light path.

Reagents and Chemicals

Reagent grade pyridine was distilled from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over Linde Molecular Sieve. Pyridinium mono-β-cyanoethyl phosphate was prepared from the barium salt by passage over a column of Dowex 50WX8 resin (pyridinium form). The clear solution was first concentrated to a small volume and lyophilized to a gum. The gum was dissolved in pyridine and diluted to a known volume and stored in a sealed flask under refrigeration. Nucleotide products were characterized (chromatography and electrophoresis) by comparison to known compounds prepared by the "triester" method (8).

Enzyme Assays

The procedures used for snake venom and spleen phosphodiesterases have been described previously (8).

Methyl 3′-O-Monomethoxytritylthymidine-5′ Chlorophosphate (MClpT–MTr)

This compound was prepared by the method of Smrt and Catlin (9) as a stock solution in pyridine containing 0.11 mmol/ml of MClpT–MTr.

Succinylated Polystyrene (2)

(*a*) SX-2 resin (2 g), freshly sublimed aluminum chloride (2.13 g), and succinic anhydride (0.8 g, 8 mmol) were stirred in nitrobenzene (25 ml) at 60 °C for 1.5 h. The reaction mixture was poured into a beaker containing 25 ml of 6 *N* HCl and stirred for 10 min. The polymer was filtered, washed with water (3 × 25 ml), ethanol (3 × 25 ml), and benzene (3 × 25 ml), and then dried over phosphorus pentoxide. The acid content of the polymer was determined by adding excess standard sodium hydroxide solution (0.01 *M*) to a portion of the polymer and back titrating the excess NaOH with standard HCl (0.014 *M*) using phenolphthalein as indicator. The acid content of the polymer was found to be 0.39 mequiv/g. The i.r. spectrum (KBr disk) showed a broad strong absorption between 3600 and 2600 as well as between 1700 and 1600 cm^{-1}.

(*b*) The above procedure was repeated using reagent grade aluminum chloride directly. After 1.5 h the polymer had 0.10 mequiv of acid/g and at the end of 3 h contained 0.25 mequiv of acid/g.

Acid Chloride Polymer (Polymer 3)

Polymer **2** (100 mg) was added to a solution containing thionyl chloride (5 ml), pyridine (2.5 ml), and benzene (5 ml) and the mixture was heated at reflux for 5 h. The polymer (0.31 mequiv of chloride per gram of polymer by the indirect Volhardt method) was collected by filtration,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

washed with dry benzene, and dried over phosphorus pentoxide. The i.r. spectrum (KBr disk) showed a strong acid chloride absorption at 1830 cm^{-1}.

Addition of Thymidine to Polymer 3

Polymer **3** (100 mg) and thymidine (100 mg, 0.4 mmol) were stirred in pyridine for 48 h at room temperature. The polymer was collected by filtration and washed with pyridine (25 ml), water (3 × 15 ml), and ethanol (3 × 15 ml) and then dried over phosphorus pentoxide. The i.r. spectrum (KBr disk) showed strong absorption between 1750 and 1660 cm^{-1}. The peak at 1830 cm^{-1} present in polymer **3** had disappeared.

Removal of Thymidine From Polymer 4a

(A) Sodium Hydroxide

Polymer **4***a* was treated with NaOH (0.5 N in dioxane: water, 1:1) for 48 h at room temperature. The reaction mixture was filtered and the filtrate neutralized with Dowex 50WX8 (pyridinium form). The filtrate was concentrated and applied to Whatman 3 mm paper which was then developed in solvent A. The nucleoside band (R_F^A 0.68) was eluted with water and the yield determined spectrophotometrically. The yield of thymidine bound to the polymer from several different preparations varied from 0.1 to 0.13 mmol/g of polymer.

(B) Hydrazine Hydrate Solution

Polymer **4***a* was treated with a solution containing hydrazine hydrate: acetic acid: pyridine (1:6:24) for periods up to 48 h. The solutions were separated from the polymer by filtration and applied to Whatman 3 mm paper for chromatography in solvent A. No thymidine was detected from any hydrazine hydrolysis.

Addition of 3′-Protected Thymidines to Polymer 3

In separate experiments 3′-*O*-monomethoxytrityl thymidine (10) and 3′-*O*-(2,4-dinitrobenzenesulfenyl)thymidine (11) were added to polymer **3** in the same manner as described above for thymidine. Analysis of the product polymers **4***b* and *c* by NaOH (method A above) showed the amount of nucleoside bound to the polymer varied from 0.08 to 0.13 mmol/g.

Removal of Protecting Groups From Polymer Bound Nucleosides

(A) Hydrolysis of the Monomethoxytrityl Group

Initially polymer **4***b* was treated with 80% acetic acid in water at room temperature for 24 h. Base hydrolysis (method A) showed that only partial hydrolysis of the monomethoxytrityl group had occurred. The same result was obtained with 80% acetic acid in a steam bath for 3 h. Finally a sample of polymer **4***b* was treated with trifluoroacetic acid (0.1% in chloroform) at room temperature for 6 h. Base hydrolysis (method A) of the polymer showed that the methoxytrityl group had been completely removed from the polymer-bound thymidine.

(B) Hydrolysis of the 2,4-Dinitrobenzenesulfenyl Group

Polymer **4***c* was stirred for 4 h with a pyridine solution containing two drops of thiophenol per ml of pyridine. The polymer was collected by filtration, washed with pyridine (25 ml), ethanol (3 × 15 ml), and water (3 × 15 ml). Base hydrolysis (method A) of the polymer yielded only thymidine, the 2,4-dinitrobenzenesulfenyl group had been completely removed.

Attempted Addition of 5′-Protected Thymidines to Polymer 3

When polymer **3** was treated with either 5′-*O*-monoethoxytritylthymidine (12) or 5′-*O*-(2,4-dinitrobenzenesulfenyl)thymidine (11) using the same conditions as described above for the 3′-protected derivatives, no esterification of the polymer occurred.

General Procedures for Phosphorylation of Nucleosides Bound to the Polymer

(I) Polymer **5***b* (100 mg containing 0.011 mmol of thymidine) and β-cyanoethyl phosphate (0.28 mmol, pyridinium form) were dried by evaporation of pyridine (4 × 1 ml). Mesitylenesulfonyl chloride (120 mg, 0.55 mmol) and pyridine (1.5 ml) were added and the mixture was stirred for 2 days at room temperature. Water (1.5 ml) was added and stirring continued for 24 h. The polymer was separated by filtration, washed with pyridine (25 ml), water (3 × 25 ml), and ethanol (3 × 25 ml), and dried over P_2O_5. A sample (50 mg) of the polymer was hydrolyzed with NaOH (method A) and the products thymidine (T) and thymidine-3′ phosphate (Tp) were separated by paper chromatography in solvent A. The bands were eluted with water to give 69 OD units of Tp (73%, R_F^A 0.09) at 267 nm and 25 OD units of T (R_F^A 0.67) at 267 nm.

(II) The above reaction was repeated except that dicyclohexylcarbodiimide (145 mg, 0.75 mmol) was used in place of mesitylenesulfonyl chloride and the reaction was stirred for 8 days. Analysis of the polymer gave 75 OD_{267} units of Tp (65%) and 40 OD_{267} units of T.

(III) Reaction I was repeated except that methyl dichlorophosphate was used in place of both β-cyanoethyl phosphate and mesitylenesulfonyl chloride. Analysis of the polymer (method A) after 24 h showed a 75% conversion to Tp. The yield was unaffected (71%) when the amount of methyl dichlorophosphate was doubled.

Synthesis of Thymidylyl-(3′–5′)-thymidine on the Polymer

Polymer **5***b* (100 mg containing 0.011 mmol of thymidine) was phosphorylated using method III. At the end of the condensation the polymer was washed thoroughly with dry pyridine (5 × 15 ml). A solution containing 3′-*O*-methoxytritylthymidine (26 ml, 0.05 mmol) in 1 ml of pyridine was added and the mixture was stirred for 4 days. The polymer was collected by filtration, washed with pyridine (3 × 15 ml) and chloroform (3 × 15 ml), and stirred for 6 h with 3 ml of trifluoroacetic acid (0.1% in chloroform). The polymer was collected by filtration, washed successively with chloroform (6 × 15 ml), ethanol (3 × 15 ml), and ether (3 × 15 ml), and a portion hydrolyzed by method A. Analysis of the products showed three products: thymidine (R_F^A 0.68, 29 OD_{267} units); thymidine-3′ phosphate (R_F^A 0.09, 30 OD_{267} units), and thymidylyl-(3′–5′)-thymidine (TpT, R_F^A 0.37, 71 OD_{267} units, 38%). The TpT so produced was completely degraded by both snake venom and spleen enzymes.

Synthesis of Thymidylylthymidylylthymidylylthymidine (TpTpTpT) on the Polymer

Polymer **5***a* (100 mg containing 0.011 mmol of thymidine) was phosphorylated as in method III and condensed with thymidine (0.05 mmol) as in the TpT preparation above. The polymer was washed with pyridine (25 ml), water (3 × 15 ml), ethanol (3 × 15 ml), and tetrahydrofuran (3 × 15 ml) and dried over P_2O_5. The phosphorylation, condensation, and washing steps were repeated twice more and the

TABLE 1. Products of TpTpTpT preparation on the polymer

Product	R_F^B	Identity	OD_{267} Units	% Yield
1	0.76	T	21	
2	0.64	TpT	18	10
3	0.53	TpTpT	10	3.8
4	0.47	TpTp	24	
5	0.43	Tp	34	
6	0.41	TpTpTpT	14	4
7	0.36	TpTpTp	15	

final polymer was hydrolyzed using method A. The products were identified by paper chromatography and electrophoresis by comparison with authentic material (8) and the results are shown in Table 1.

Synthesis of TpT using MClpT–MTr and Polymer 5b

Polymer **5***b* (50 mg, containing 5.5 μmol of thymidine) and 1 ml of the stock solution of MClpT–MTr were stirred together at room temperature for 4 days. The polymer was collected by filtration, washed with pyridine (25 ml), ethanol (3 × 15 ml), and chloroform (3 × 15 ml) and treated with trifluoroacetic acid 13 ml (0.1% in chloroform) for 6 h. The polymer was collected, washed successively with chloroform (6 × 15 ml), ethanol (6 × 15 ml), and tetrahydrofuran (3 × 15 ml), and dried over P_2O_5. Analysis of the product polymer by method A revealed a 38% yield of TpT relative to thymidine. The TpT was completely degraded by both snake venom and spleen enzymes.

Synthesis of Thymidylyl-(3–5′)-thymidylyl-(3′–5′)-thymidine using MClpT–MTr and Polymer 5b

Polymer **5***b* (50 mg, 5.5 μmol of thymidine) was treated exactly as above for the synthesis of TpT. However, after the trifluoroacetic acid treatment the polymer was dried and the condensation procedure using MClpT–MTr was repeated. Analysis of the polymer by method A showed a 10% yield of TpTpT based on the amount of thymidine originally bound to the polymer. The TpTpT so produced was completely degradable by both snake venom and spleen phosphodiesterases.

Reactions of Nitro Sugars. XXVI. Analysis and Separation of Stereoisomers by Nuclear Magnetic Resonance Spectroscopy and Column Chromatography of Benzylidene Derivatives[1]

HANS H. BAER AND WERNER RANK

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received November 18, 1971

Stereoisomeric methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides proved to be distinguishable by the chemical shifts of their benzylidene methine proton signals, and ratios of such isomers in mixtures could be estimated by signal integration. The method was applied to a reinvestigation of the epimeric distributions in which methyl 3-deoxy-3-nitro-α-D-hexopyranosides arise, firstly, in the nitromethane cyclization of 2-*O*-[(*S*)-formyl(methoxy)methyl]-(*R*)-glyceraldehyde and, secondly, in their base-catalyzed configurational equilibration via nitronates. Previous results were essentially confirmed as far as the preferred configurations are concerned but require some revision as to the relative abundance of less favored configurations. By preparative chromatography of benzylidene acetals and subsequent debenzylidenation, some nitrohexopyranosides of the α-D series were isolated for the first time in crystalline condition. Separation of isomers in the β-D series was improved by use of chromatography and by a new method involving differential reactivities of compounds toward alkali.

Les composés méthyl 4,6-*O*-benzylidène-3-déoxy-3-nitrohexopyranosides stéréoisomériques peuvent être différenciés par les déplacements chimiques des signaux du proton méthine benzylidène; de même on peut estimer les proportions de tels isomères dans les mélanges en intégrant le signal. La méthode a été appliquée à une nouvelle étude des distributions épimériques dans lesquelles les composés méthyl 3-déoxy-3-nitro-α-D-hexopyranosides apparaissent, premièrement dans la cyclisation du nitrométhane du 2-*O*-[(*S*)-formyl(méthoxy)méthyl]-(*R*)-glycéraldéhyde, et deuxièmement dans leur équilibre configurationnel catalysé par les bases, via les nitronates. Les résultats précédents ont été essentiellement confirmés en autant que les configurations les plus stables sont concernées, mais il doivent être revisés en ce qui a trait à l'abondance relative des configurations moins favorisées. Par chromatographie préparative des acétals de benzylidène et par la débenzylidénation subséquente, on a isolé quelques nitrohexopyranosides de la série α-D pour la première fois à l'état cristallin. On a amélioré la séparation des isomères dans la série β-D en utilisant la chromatographie et au moyen d'une nouvelle méthode impliquant les réactivités différentielles des composés envers les alcalins.

Canadian Journal of Chemistry, **50**, 1216 (1972)

Introduction

In synthetic work with nitro sugars, as indeed with carbohydrates in general, benzylidene acetals play a paramount role (1, 2). The most recent, extensive use of *O*-benzylidenated nitro sugars was made in syntheses of epoxynitro (3) and halonitro (4) glycosides. Prior publications had recorded the preparation of 4,6-*O*-benzylidene acetals derived from several, but not all, of the known methyl 3-deoxy-3-nitrohexopyranosides. The acetals were obtained, by standard procedures, mostly from pure glycosides and occasionally from non-crystallizable mixtures of stereoisomers (2). In conjunction with various synthetic projects we have now elaborated further the techniques of separating and characterizing nitro glycosides by way of benzylidenation. With n.m.r. spectroscopy as an analytical aid and column chromatography as a preparative tool, some nitro sugar derivatives were isolated for the first time, and the preparation of others was facilitated. Special benefit, however, accrued from benzylidenation when it was applied in studies on the stereochemistry of the sugar dialdehyde – nitromethane cyclization and the epimerization of glycoside nitronates.

Results

A convenient means of differentiating stereoisomeric methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides was found in the sharp n.m.r. singlet given by the methine proton of the benzylidene group. The chemical shifts of these signals proved indicative of sets of isomers (Table 1). Although in chloroform-*d* solution the shifts differed little in compounds having the *gluco* and *galacto* configurations, they permitted differentiation between these and *manno* and

talo isomers. In dimethylsulfoxide-d_6 solution, on the other hand, the *gluco* and *talo* derivatives had similar shifts but could be distinguished from the *manno* and *galacto* derivatives. The variations observed were distinctly larger than those recorded (5) for a number of non-nitro analogs. In fact, the signal separation in certain mixtures of isomers readily allowed quantitative determination of the component ratio by integration (Table 2, mixtures A–D). Thus, in three-component mixtures containing **2**, **3**, and **4** in varying proportions, the percentage of each compound could be measured with an accuracy of $\pm 4\%$ or better. On the other hand, the chemical shift of the methine proton was scarcely influenced by the anomeric configuration. However, anomers may be distinguished by their methoxyl proton resonances (Table 1) which tend to occur at higher field for axial groups than for equatorial ones (6).

Prompted by the feasibility of spectral identification and quantitative assay of certain benzylidene acetals, we decided to reinvestigate the configurational distributions in which stereoisomeric methyl 3-deoxy-3-nitro-α-D-hexopyranosides are formed (7, 8) in the nitromethane cyclization of 2-*O*-[(*S*)-formyl(methoxy)methyl]-(*R*)-glyceraldehyde (**1**, "D-hydroxymethyl-D′-methoxydiglycolaldehyde") and also those in which they exist after thermodynamically controlled epimerization (8). In the earlier work, the nitro glycosides had not been obtained in crystalline form; approximate estimates of product ratios in the amorphous mixtures could be gleaned from the amounts of amino sugars that were isolated, upon catalytic hydrogenation, partly by direct crystallization and partly by chromatographic procedures. Although the configurational preferences in these reactions had thereby been reasonably well established, no great accuracy could be claimed in a quantitative sense. A renewed study using improved techniques therefore appeared worthwhile.

A mixture of nitro glycosides was prepared, essentially as described (8), by the reaction of dialdehyde **1** with nitromethane followed by

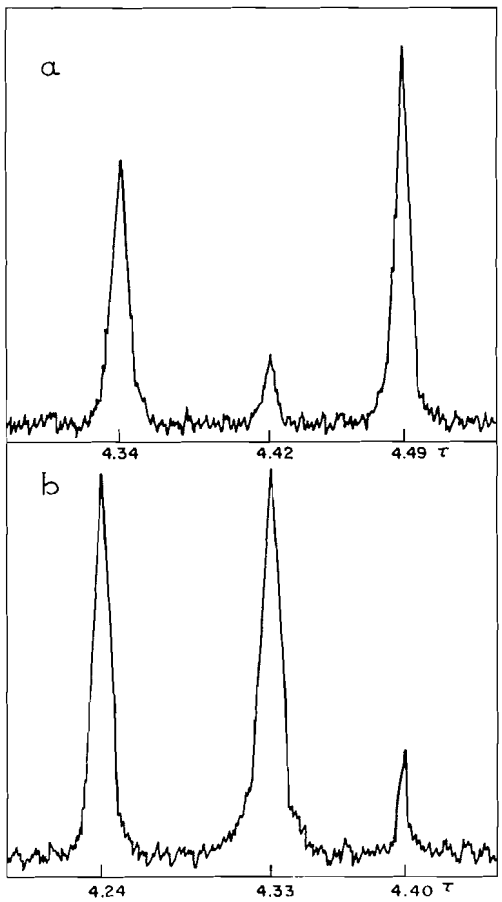

FIG. 1. Methine proton signals, in 100 MHz n.m.r. spectrum with 100 Hz sweep width, of nitromethane cyclization mixture from **1**, after benzylidenation; *a*, in $CDCl_3$; *b*, in DMSO-d_6.

deionization.[2] Exhaustive benzylidenation with benzaldehyde and zinc chloride gave a mixture of 4,6-acetals that showed methine proton signals assignable to the α-D-*manno* (**2**), α-D-*talo* (**3**), α-D-*gluco* (**4**), and α-D-*galacto* (**5**) isomers. In $CDCl_3$, there occurred three signals having an intensity ratio of 37:12:51, corresponding to **2**, **3**, and **4** + **5**. In DMSO-d_6, there occurred three signals with an intensity ratio 42:49:9, corresponding to **2**, **3** + **4**, and **5** (Fig. 1 and Table 2, mixture E). It is concluded from these data that the *manno* and *gluco* compounds, **2** and **4**, were present as main products in similar amounts (about 40% each), whereas the *talo* and *galacto* compounds, **3** and **5**, were minor products present to the extent of about 10% each. The acetal mixture was then chromatographed on silica gel, and substantial amounts of each isomer could be isolated in crystalline form. Complete separation was not achieved, but the proportions of isomers contained in mixed fractions were estimated spectroscopically, and summation of the yields indicated a ratio of 42:8:41:9 for **2**:**3**:**4**:**5**, in good agreement with the ratio found in the mixture prior to chromatography.

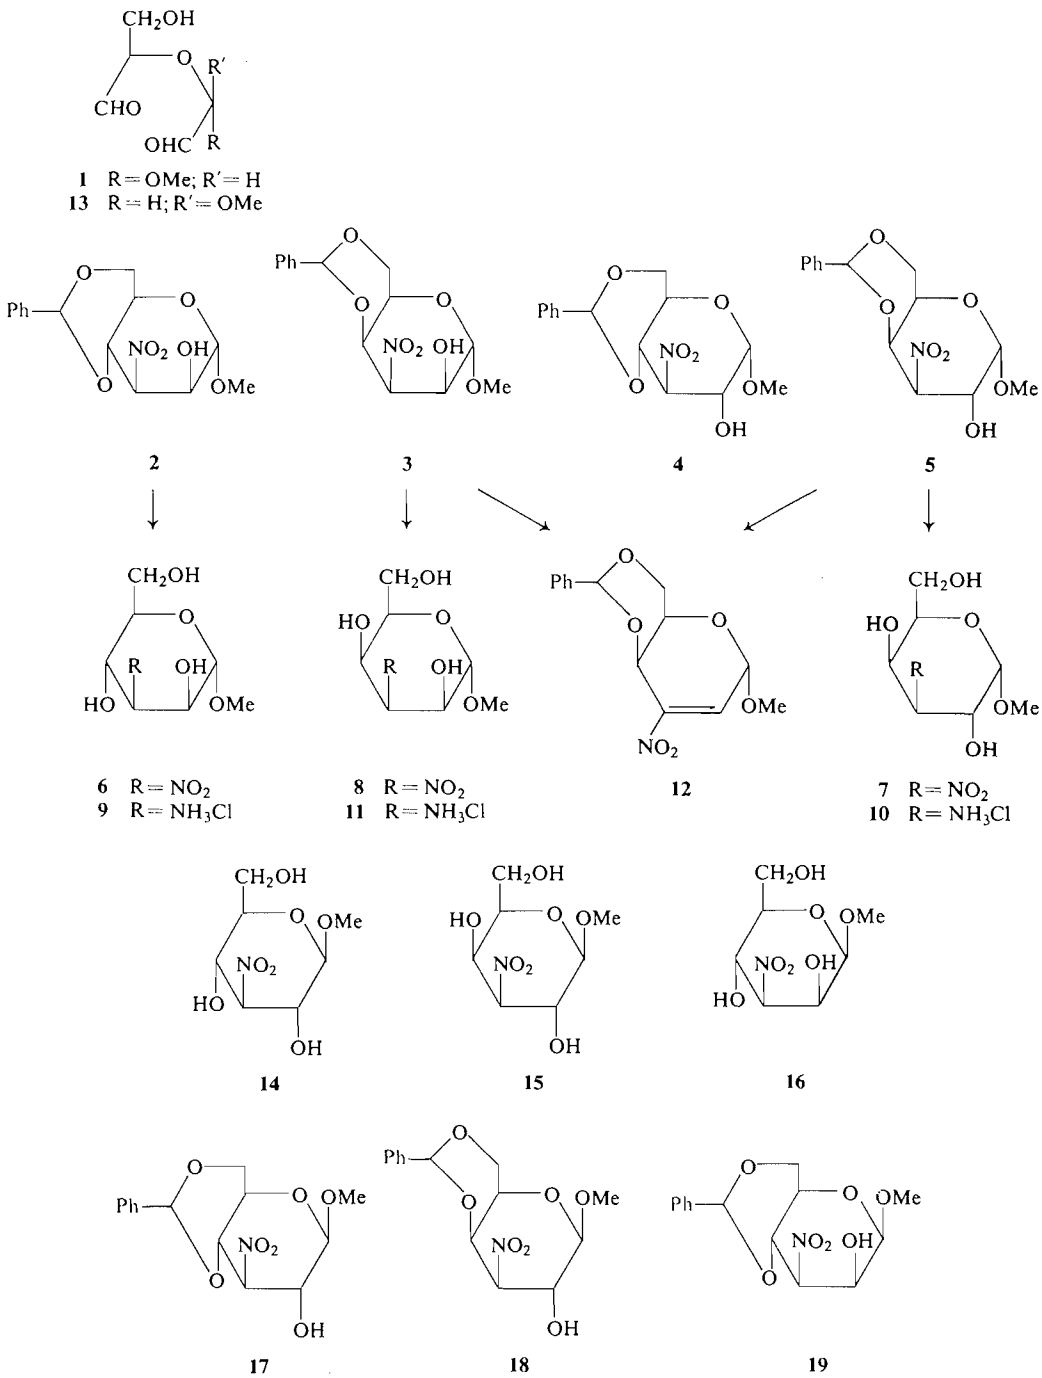
These results established in a more reliable, quantitative way what had been deduced earlier (8) from preparative separation of products on the amine stage, namely, that the *manno* and *gluco* configurations are favored in the nitromethane cyclization of **1** when kinetic control prevails. The results revealed, moreover, that the *talo* and *galacto* configurations are formed to a significant extent; the former had previously been observed to arise in an unspecified, small proportion and the latter had not been detected at all, under similar reaction conditions.[3]

We then proceeded to examine in the same way the isomer ratio that exists after the aforementioned nitro glycosides have been allowed to epimerize in aqueous, alkaline solution to the thermodynamic equilibrium of their nitronates. Equilibration and subsequent deionization of the nitronate mixture was performed as previously described (8), and the product was then benzylidenated. The acetal mixture in $CDCl_3$ solution showed three methine-proton peaks (τ 4.34, 4.415, and 4.49), and their intensity ratios were 15.5:52.5:32 in a 3-day epimerization experiment[4] (Fig. 2 and Table 2, mixture F). The first two signals corresponded to the α-D-

[2]The reaction time allowed for the nitromethane cyclization was 45 min whereas in the previous work (8) it was 25 min.

[3]It may be expected that minor changes in such conditions as reaction time (see footnote 2), temperature, or alkalinity of the medium could produce measurable variations in product ratios, owing to the interplay of kinetic and thermodynamic factors. In the nitromethane cyclization leading to analogous 6-deoxy glycosides, for instance, the *gluco* to *manno* ratio was about 1:1 after a reaction time of 25 min, but about 2:1 after 40 min; *talo* and *galacto* derivatives were minor products in either event (9). See also the discussion on this subject in ref. 10.

[4]In an independent experiment we found almost no difference in spectra from benzylidenations performed after nitronate epimerizations running for 3 and 5 days. This indicated that epimerization was essentially complete within 3 days.



1 R = OMe; R′ = H
13 R = H; R′ = OMe

manno and α-D-*talo* isomers (**2** and **3**), respectively, and the third signal was due to the α-D-*gluco* (**4**) and α-D-*galacto* (**5**) isomers. Column chromatography confirmed this pattern, indicating the presence of **2**, **3**, **4**, and **5** in the ratio 15.5:51.5:20:13.

The direct evidence so obtained confirms the principal statement which was based on con-

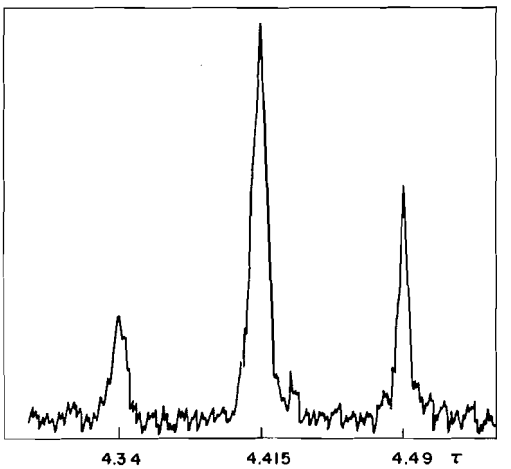

FIG. 2. Methine proton signals, in 100 MHz n.m.r. spectrum with 100 Hz sweep width, of nitromethane cyclization mixture from **1** after *epimerization* and subsequent benzylidenation; solvent, $CDCl_3$.

version into amine derivatives (8), namely that the nitro glycosides produced in the nitromethane cyclization of **1** epimerize, as nitronates, so as to generate chiefly the α-D-*talo* configuration at the expense of the α-D-*manno* and α-D-*gluco* configurations. Clearly, the nitronate of the α-D-*talo* compound is the thermodynamically most stable one. The experiments showed furthermore, that the amount of α-D-*galacto* isomer increases, if only slightly, during the epimerization. However, the relative stabilities of the nitronates of the α-D-*gluco* and α-D-*galacto* isomers have now been revealed to be in fact rather similar whereas, in the earlier work (8), the former had been underrated and the latter overestimated. The present results are for the most part in good harmony with those from a recent study (10) on analogous 6-deoxy glycosides in which, after nitronate equilibration, the *manno*:*talo*:*gluco*:*galacto* ratio was approximately 28:59:7:6.

In the course of the chromatographic separations just mentioned, methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside (**2**) and its α-D-*galacto* isomer (**5**) were isolated for the first time. These acetals as well as the previously described (11) α-D-*talo* isomer (**3**) were debenzylidenated to furnish methyl 3-deoxy-3-nitro-α-D-mannopyranoside (**6**), -α-D-galactopyranoside (**7**), and -α-D-talopyranoside (**8**) as new, crystalline compounds. The structures of **6** and **8** were ascertained by catalytic hydrogenation giving the known, crystalline amino glycoside hydrochlorides **9** and **11**, respectively. Similarly, **7** afforded the corresponding amine hydrochloride (**10**) in crystalline form. In this case, however, further structural proof was needed since the amine had been obtained earlier (8) as a syrup of questionable purity only, and data of comparison were lacking. The α-D-*galacto* configuration was established by dehydration of the acetal **5** with hot acetic anhydride and sodium acetate, which produced known methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*threo*-hex-2-enopyranoside (**12**), *i.e.*, the same nitro olefin that was formed (11) by such dehydration from the α-D-*talo* isomer (**3**). The procedure for preparing **12** was improved in this connection.

Further preparative improvements to be recorded concern the separation of the three β-glycosides which are available (12, 13) by nitromethane cyclization of 2-*O*-[(*R*)-formyl-(methoxy)methyl]-(*R*)-glyceraldehyde (**13**, "D-hydroxymethyl-L′-methoxydiglycolaldehyde"), namely, methyl 3-deoxy-3-nitro-β-D-glucopyranoside (**14**), -β-D-galactopyranoside (**15**), and -β-D-mannopyranoside (**16**). Although preparation of **14** and **15** by direct crystallization is easy enough (14), it may be desirable to augment yields by working-up mother liquors that retain considerable quantities of material. Benzylidenation of such isomer mixtures from mother liquors has served (15) to separate components as their crystalline acetals (**17**–**19**), and in the Experimental we describe improved procedures involving fractional crystallization and column chromatography. Another method of separation was elaborated on the basis of the differential reactivities of **17**–**19** towards alkali; it represents a useful, preparative corollary to a recent communication on this subject (16). Thus, when a mixture of the three acetals (or a mixture of **18** and **19** alone) in chloroform solution was treated briefly with potassium hydroxide, the β-D-*manno* isomer **19** was quantitatively epimerized, and a mixture of **17** and **18** resulted. These two components then proved readily separable due to the fact that, under the conditions employed, the β-D-*galacto* isomer **18** forms a chloroform-insoluble, water-soluble nitronate whereas the β-D-*gluco* isomer **17** does not do so but remains soluble in chloroform and insoluble in water.

Experimental

The n.m.r. data were obtained from 100 MHz spectra taken on a Varian HA-100 instrument, using tetramethylsilane for the lock signal. For analysis of acetal mixtures, spectra were taken from approximately 10% solutions in chloroform-*d* or DMSO-d_6, at 100 Hz sweep width and 500 Hz sweep offset. The component ratios were determined by averaging three integrations of the methine proton signals and expressing each signal intensity in terms of percent of the sum of intensities. In standard mixtures, single integrations of a given signal deviated ± 1–2% from the average value, and the latter deviated ± 1–4% from the expected value.

The t.l.c. was performed on silica gel G (E. Merck AG) with carbon tetrachloride – ethyl acetate (7:3, v/v) as solvent unless specified otherwise. Ceric sulfate – sulfuric acid served as spray reagent. In column chromatography, silica gel refers to the 70-325 mesh ASTM product of E. Merck AG.

Separation of α-Glycosides

(a) Preparation of Nitro Glycoside and Acetal Mixtures

Preparation of the dialdehyde **1**, its cyclization with nitromethane in methanol solution containing sodium methoxide, and deionization of the product to give a mixture (E) of nitro glycosides was performed as previously described (8), with a minor modification.[2] The same applies to the preparation of the mixture (F) of epimerized nitro glycosides (8). Separation of crystalline methyl 3-deoxy-3-nitro-α-D-glucopyranoside by chromatography of mixture E on powdered cellulose has been recorded (15). Benzylidenation of mixtures E and F with benzaldehyde and zinc chloride had previously yielded the crystalline α-D-*gluco* (**4**) (15) and α-D-*talo* (**3**) (11) acetals, respectively. For the present studies, benzylidenated mixtures were prepared as previously described, but the syrups obtained were used for n.m.r. spectroscopy and column chromatography without prior removal of crystallizable components.

(b) Chromatography of Benzylidenated Mixture E

Crude, benzylidenated mixture E, obtained as a syrup (21.5 g) from **1** (0.068 mol, from 13.2 g of methyl α-D-glucopyranoside) was placed on a column (6.5 × 60 cm) containing 800 g of silica gel. Elution was performed with carbon tetrachloride – ethyl acetate mixtures of compositions (v/v) 7:3 (fractions 1–30), 1:1 (fractions 31–39), and 2:3 (fractions 40–80), the fractions being 75 ml in volume. All fractions were inspected by t.l.c., and the residues obtained after appropriate pooling and evaporation were examined by n.m.r. spectroscopy. Fractions 1–15 were free from carbohydrates but contained benzaldehyde (6.76 g). Fractions 16–21 yielded pure **2** (2.22 g). Fractions 22–30, 31–36, 37–39, 40–50, and 51 contained 4.49, 1.46, 0.43, 1.29, and 0.68 g of mixtures of **2**, **3**, and **4**. Fractions 52–63 and 75–80 were blank, and fractions 64–74 gave pure **5** (1.00 g). Thus the total, overall yield of nitro glycoside acetals was 11.57 g (54.7% of the theoretical based on starting methyl α-D-glucopyranoside). Individual yields, calculated by summation of pure fractions and spectroscopically-determined proportions of components in mixed fractions, were the following: **2**, 4.86 g (22.9%); **3**, 0.94 g (4.4%); **4**, 4.77 g (22.5%), and **5**, 1.00 g (4.7%).

When the column chromatography was performed with half the above glycoside load and with carbon tetrachloride – ethyl acetate mixture of constant composition (7:3), a somewhat better separation of the more mobile compounds, **2**, **4**, and **3** took place and parts of each were eluted as pure fractions, in that order, with mixed fractions occurring in between. However, the solvent was unsatisfactory for elution of slow-moving **5**.

(c) Chromatography of Benzylidenated Mixture E

A crude syrup (21.8 g) resulting from benzylidenation of a mixture (F) of epimerized nitro glycosides obtained from **1** was chromatographed. The technique detailed in section *b* was used except that the eluant composition was carbon tetrachloride–ethyl acetate in the ratios 4:3, 1:1, and 2:3 for fractions 1–24, 25–30, and 31–50, respectively. Fractions 1–10 contained benzaldehyde (5.6 g). Fractions 11–15 and 17–18 consisted of mixtures of **2** (1.20 g) and **4** (0.80 g), and of **4** (0.30 g) and **3** (0.55 g), respectively, the product ratios being determined from n.m.r. spectra. Fractions 16, 19–30, and 31–50 yielded virtually pure **4** (0.47 g), **3** (3.48 g), and **5** (1.03 g), respectively. Hence the total yield of nitro glycoside acetals was 7.83 g. Since the ratios of individual acetals were very similar before and after chromatography it appears that recovery was essentially complete. The weight deficit is attributed to benzaldehyde (5.6 g) and residual solvent in the starting syrup.

Characterization of α-D-Glycosides

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside (2)

Compound **2** as obtained from a chromatographic column was recrystallized for analysis from chloroform – petroleum ether; m.p. 138–139°, $[\alpha]_D$ +27.7° (*c*, 0.8 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51; N, 4.50. Found: C, 53.96; H, 5.56; N, 4.59.

Methyl 3-Deoxy-3-nitro-α-D-mannopyranoside (6)

The acetal **2** (300 mg) was debenzylidenated (17) by treatment with 3 ml of 90% trifluoroacetic acid at room temperature for 15 min. Completion of the reaction was ascertained by t.l.c. using ethyl acetate – petroleum ether (2:3). Water was added to the reaction mixture which was then evaporated. The residue was repeatedly evaporated with added water and ethanol, and the remaining syrup was dried *in vacuo* (206 mg, 96%; homogeneous on t.l.c.). Crystallization from tetrahydrofuran–ether furnished **6** (184 mg), m.p. 113–115°, $[\alpha]_D$ +44.5° (*c*, 0.9 in water).

Anal. Calcd. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87; N, 6.28. Found: C, 37.79; H, 5.93; N, 6.35.

A sample of **6** (100 mg) was dissolved in water (8 ml), 0.1 *N* HCl (5 ml), and platinum catalyst (from 50 mg of PtO_2) was added, and the mixture was hydrogenated overnight. Filtration and evaporation of the solution, followed by crystallization of the residue from 95% ethanol at 4° furnished 84 mg (81.5%) of methyl 3-amino-3-deoxy-α-D-mannopyranoside hydrochloride (**9**) in two batches, m.p. 234–236° (dec.) and 232–235° (dec.); $[\alpha]_D$ +57.5° (*c*, 0.3 in water). Reported: $[\alpha]_D$ +60° in water (7, 18), and decomposition at about 205° (7), 221–223° (8), 210–240° (18). Evidently the melting behavior is not very characteristic, it being probably influenced by traces of impurities and the mode of heating. A sample at hand from previous work in this laboratory melted with decomposition at 230–231° and caused no depression when admixed to new **9**. The i.r. spectra were identical.

For personal use only.

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-talopyranoside (3)

Compound **3** collected from the column showed m.p. 177–178°, $[\alpha]_D$ +66.8° (*c*, 1.1 in $CHCl_3$), and its i.r. spectrum was identical with that of an authentic sample. Reported (11): m.p. 175°, $[\alpha]_D$ +68° (in $CHCl_3$).

Methyl 3-Deoxy-3-nitro-α-D-talopyranoside (8)

The acetal **3** (200 mg) was debenzylidenated with trifluoroacetic acid as described for **2**, above. The reaction was complete after 20 min as indicated by t.l.c. with chloroform–acetone (7:3). The syrupy product (117 mg, 82%) was crystallized from chloroform to give **8** (93 mg), m.p. 86–87°; $[\alpha]_D$ +87.5° (*c*, 0.9 in water).

Anal. Calcd. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87; N, 6.28. Found: C, 37.46; H, 6.08; N, 6.12.

A sample of **8** (40 mg) was catalytically hydrogenated for 3 h in water (3 ml) and 0.1 *N* HCl (2 ml), in the presence of platinum catalyst (70 mg of PtO_2). Upon recrystallization of the product from 99% ethanol by slow addition of ethyl acetate, methyl 3-amino-3-deoxy-α-D-talopyranoside hydrochloride (**11**) was obtained in 99% yield; m.p. 187–188° (dec.), $[\alpha]_D$ +88.3° (*c*, 0.3 in water). Reported (8): m.p. 187–188 (dec.), $[\alpha]_D$ +90° (in water). Identity with an authentic sample was established by a mixture melting point (186–188° with dec.), comparison of i.r. spectra, and paper chromatography (8).

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (4)

Compound **4** collected from a column showed m.p. 166–167°, $[\alpha]_D$ +86.5° (*c*, 0.7 in ethanol), and its i.r. spectrum was identical with that of an authentic sample. Reported (15): m.p. 167°, $[\alpha]_D$ +87.2° (in ethanol).

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-galactopyranoside (5)

Compound **5** collected by column chromatography was recrystallized for analysis from ethyl acetate–petroleum ether; m.p. 166–167°, $[\alpha]_D$ +205° (*c*, 0.5 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51; N, 4.50. Found: C, 53.83; H, 5.51; N, 4.41.

Methyl 3-Deoxy-3-nitro-α-D-galactopyranoside (7)

The acetal **5** (94 mg) was debenzylidenated with trifluoroacetic acid as described for **2**, above. The reaction was complete after 30 min as shown by t.l.c. Crystallization of the syrupy product (67 mg) from chloroform afforded **7** (32 mg), m.p. 145–146°, $[\alpha]_D$ +209° (*c*, 0.4 in water). The remainder of **7** (35 mg) was recovered as a syrup.

Anal. Calcd. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87; N, 6.28. Found: C, 37.92; H, 6.02; N, 6.16.

Methyl 3-Amino-3-deoxy-α-D-galactopyranoside Hydrochloride (10)

Syrupy **7** (35 mg) in water (5 ml) and 0.1 *N* HCl (2 ml) was hydrogenated for 3 h in the presence of prereduced PtO_2 (50 mg). Evaporation of the filtrate followed by two coevaporations with ethanol gave crystalline **10** (34 mg) which upon recrystallization from ethanol melted with decomposition at 219–221° and had $[\alpha]_D$ +146.5° (*c*, 0.2 in water).

Anal. Calcd. for $C_7H_{16}ClNO_5$ (229.7): C, 36.61; H, 7.02; Cl, 15.44. Found: C, 36.76; H, 6.79; Cl, 15.71.

In agreement with the earlier observation on amorphous **10**, the mobility of the compound in paper chromatography (8) was lower than that of its isomers **9** and **11**.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-α-D-threo-hex-2-enopyranoside (12)

A mixture of the acetal **5** (100 mg), anhydrous sodium acetate (200 mg), and acetic anhydride (2 ml) was heated on a steam bath for 30 min with continual swirling. The mixture was then poured into ice water (50 ml) which caused a white crystalline material to precipitate. The product, which was collected by filtration, washed well with cold water, and dried *in vacuo*, weighed 86 mg (91%) and melted at 175–177°. Recrystallization from ethyl acetate – petroleum ether raised the m.p. to 182–184°; reported (11), m.p. 185–186°. An i.r. spectrum was identical with that of **12** from the earlier work (11).

In like manner but with a reaction time of 15 min, **12** was obtained in 83% yield starting from the isomeric acetal **3**. Evidently, employment of steam-bath rather than reflux (11) temperature improved the yields in these dehydrations. Moreover, the procedure was more reliable than that formerly employed, which sometimes failed due to decomposition by overheating.

Separation of β-D-Glycoside Acetals

The preparation of dialdehyde **13** and its cyclization with nitromethane to give the nitro β-D-glycosides **14**, **15**, and **16** has been described (12–14*a*) as has the benzylidenation of these glycosides, individually as pure compounds and in mixtures recovered from mother liquors (14*b*, 15).

(a) Fractional Crystallization

Mother liquors that remained when upon nitromethane cyclization of **13** the bulk of crystallizable β-D-glucoside **14** had been collected (13) were evaporated, and the residue was benzylidenated. From the mixture of acetals so produced, the β-D-*galacto* isomer **18** can be obtained by fractional crystallization from ethanol in which it is the least soluble component. However, 6–8 recrystallizations are needed to achieve high purity. A more convenient procedure is to dissolve the mixture in a small amount of acetone and then to add chloroform, which causes precipitation of a material highly enriched in **18**. One subsequent recrystallization of the precipitate from ethanol usually is sufficient to give reasonably pure **18**, m.p. 229–231° (dec.). Reported (15): m.p. 230–231° (dec.). This procedure is probably the most convenient one for the preparation of larger quantities of **18**, as it renders unnecessary the use of isolated, crystalline **15** for benzylidenation.

The acetone–chloroform mother liquor from the above separation procedure is strongly enriched in the β-D-*manno* compound **19**, but purification of the latter by continued fractional crystallization could not be achieved. If pure **19** is desired without having to start with pure **16** and without resorting to chromatography, one may benzylidenate nitromethane cyclization mixtures from which the bulk of both **14** and **15** have been removed (13, 15). However, column chromatography proved advantageous for isolating **19**.

(b) Column Chromatography

The following example describes the separation of an acetal mixture containing mainly **18** and **19** (the latter preponderating) as well as a small proportion of **17**. The mixture (10 g) and a few grams of silica gel were intimately mixed by two coevaporations with acetone in a rotary evaporator, and the dry mass was then placed on a column (4.5 × 65 cm) containing 500 g of silica gel. Elution was performed with chloroform–acetone (7:3, v/v) at a rate of about 17 ml per

10 min. The eluate was inspected at intervals by t.l.c., and the fractions were suitably combined. The first 800 ml (approximately) of effluent was blank (it may be recycled). The following 300 ml contained β-D-*manno* derivative **19** which was obtained by evaporation and was recrystallized from ethanol to give a very pure product (5.23 g), m.p. 202°, $[\alpha]_D$ −112° (*c*, 1.2 in ethanol). Reported (15): m.p. 194–196° and 198–199°, $[\alpha]_D$ −107.5°. The next 60 ml of effluent yielded impure **19** (1.05 g, m.p. 189°) that contained some **17**. Continued elution with about 500 ml of solvent furnished the β-D-*galacto* derivative **18** (3.23 g) which emerged after a few blank fractions (or, in similar runs, with slight overlapping). Upon recrystallization from ethanol it showed m.p. 232°, $[\alpha]_D$ +25° (*c*, 1 in dimethylformamide). Reported (15): $[\alpha]_D$ +24.8°.

(c) Nitronate Formation

A mixture (1 g) containing mainly **18** and **19** along with a small proportion of **17** was dissolved in chloroform (40 ml), and an ethanolic, *N* potassium hydroxide solution (3.5 ml) was added. A voluminous precipitate occurred within 5 min, and t.l.c. of the reaction mixture, performed after 10 min with a neutralized sample, indicated absence of **19** and presence of both **17** and **18**. The reaction mixture was then shaken with 40 ml of water in which the precipitate dissolved. After phase separation the aqueous layer was extracted twice with chloroform which was combined with the organic phase. Excess acetone was then added to the aqueous phase and the solution was at once deionized with an acidic cation exchange resin. The filtrate was concentrated *in vacuo* to remove most of the acetone, whereby the β-D-*galacto* isomer **18** crystallized in chromatographically pure form (131 mg). The aforementioned chloroform phase was washed twice with water, dried over sodium sulfate, and evaporated to give chromatographically pure β-D-*gluco* isomer **17** (710 mg). The products were identified by their i.r. spectra and physical constants.

Support of this work by the National Research Council of Canada is gratefully acknowledged. Miss Ursula Eppenberger is thanked for her skilful technical assistance.

The Effect of Heat on *cis*- and *trans*-Crotonic Acids: Alternatives to Direct *cis–trans* Isomerism[1]

M. B. HOCKING[2]

Research Department,[3] Dow Chemical of Canada Limited, Sarnia, Ontario

Received August 16, 1971

The thermal *cis–trans* equilibration of *cis*- and *trans*-crotonic acids (2-butenoic acids) has been examined at temperatures in the range 100–189°. The *trans* acid has been found to yield a mixture of at least five components, of which 9–11.6% was *cis*-crotonic acid, and 19.4–31.7% was a dimer of *trans*-crotonic acid. Heating *cis*-crotonic acid yielded similar final mixtures, but with an initial component of vinylacetic acid, not seen in the *trans* acid equilibrations. The rates of formation and identities of the components formed in these two sets of experiments, together with data for the thermal tautomerization of vinylacetic acid, are discussed with reference to suggested pathways for these transformations.

L'équilibration thermique *cis–trans* des acides crotoniques *cis* et *trans* (ou acides butène-2 oiques) a été examinée dans l'intervalle de température de 100–189°. L'acide *trans* donne alors un mélange d'au moins cinq composants parmi lesquels 9–11.6% d'acide crotonique *cis* et 19.4–31.7% d'acide crotonique *trans* à l'état de dimère. Le chauffage de l'acide *cis* donne des résultats finals semblables avec en plus un composant initial d'acide vinylacétique inconnu lors des équilibrations sur l'acide *trans*. Les vitesses de formation et les composants identiques formés dans ces deux séries d'expériences ainsi que les données sur la tautomérisation thermique de l'acide vinylacétique, sont discutés par rapport aux processus réactionnels suggérés pour ces transformations.

Canadian Journal of Chemistry, **50**, 1224 (1972)

Introduction

Morrell and Hanson (1), in their early study of the *cis*- and *trans*-crotonic acid equilibrium system, claimed that the equilibrium mixture at 172° consisted of 24% *cis*- and 76% *trans*. This was a sufficiently high proportion of *cis* to make separation of it from an equilibrium mixture produced by thermally isomerizing *trans* seem an attractive route to *cis*-crotonic acid. However, it was felt that temperatures below 172° were likely to be more propitious for *cis* isolation and Morrell and Hanson's data below this temperature were not obtained at equilibrium since their heating times were insufficient. Also their melting-point method of analysis, assuming a binary mixture, aroused a cautious treatment of the results since the possibility of another component being present was mentioned (1). Twenty-five years later, Skau and Saxton (2) confirmed the presence of a large proportion of a third component, a finding which reduced confidence in the values of Morrell and Hanson. Consequently, the equilibration of both *cis*- and *trans*-crotonic acids over a range of temperatures was re-examined with a view to using the results to prepare *cis*-crotonic acid from the *trans*, if the equilibrium was sufficiently favorable. The equilibration results and conclusions which can be drawn from these, are reported here.

Results

Equilibration of trans-Crotonic Acid

Heating *trans*-crotonic acid converted it to a mixture of at least five components (Scheme 1). Those predominating, *trans*- and *cis*-crotonic acids (**1**, **2**) and 3-hydroxybutyric acid *cis*- and *trans*-crotonates (**3***a*, *b*), have been isolated and identified with the aid of n.m.r. (3, 4). The more minor fifth component, the concentration of which was related to that of **3***a* and never rose above 7%, was more difficult to characterize. A combination of mass and proton spectroscopic methods together with quantitative bromination and hydrogenation established its identity as the trimer of crotonic acid, **4** (3). On long term heating at relatively high temperatures small amounts of a tetramer **5** were isolated, and there was evidence for the presence of higher oligomers (3).

The n.m.r. spectra of the pure components

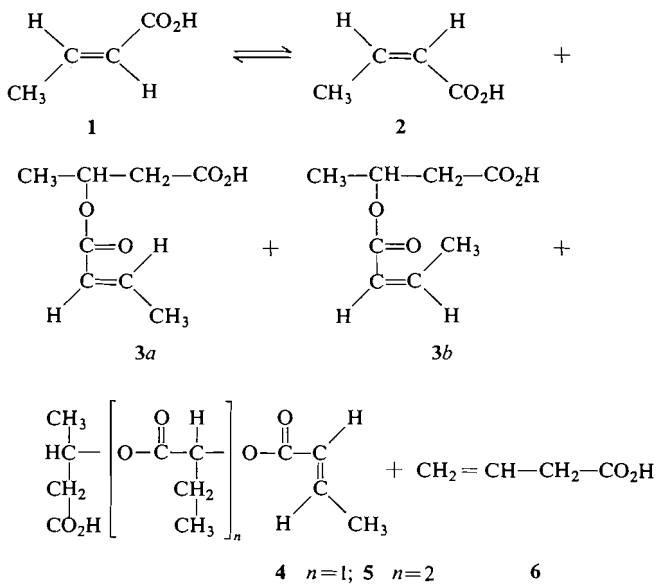

SCHEME 1. Products from crotonic acid on heating.

had been obtained (3, 4). Using these it was possible to determine the proportions of the components present in mixtures merely by integration of the composite n.m.r. spectrum. This was the method by which a series of equilibrations of small samples of *trans*-crotonic acid, each heated at temperatures ranging from 100–189°, was followed. The samples of *trans*-crotonic acid yielded mixtures which reached equilibrium after times ranging from about 8 h for the hottest to more than 250 h for the coolest runs.

The major component in all cases was *trans*-crotonic acid. In the runs in which there was reasonable certainty that equilibrium was reached in less than 250 h (Table 1) the molar concentrations of *trans*-crotonic acid ranged from a low of 51% to a high of 66%. Between 138 and 156° all the equilibrium percentage concentrations of *trans* were in the low or middle fifties (Table 2). However, the runs above 160° showed a 10% increase in the percentage of *trans* present at equilibrium, mostly at the expense of a dimer of crotonic acid, the next most abundant constituent.

The dimer of crotonic acid (3), the formation of which had been previously demonstrated (2), was the next most abundant component. Its concentration in the *trans* equilibrations ranged from around 30% at temperatures below 160° but dropped to around 20% at the higher temperatures (Fig. 1). This lower concentration at higher temperatures can probably be ascribed to an enhanced rate of cracking of the dimer back to crotonic acids (3).

The concentration of *cis*-crotonic acid in the equilibrium mixtures was found to be about 9% below 160° and to rise slightly to 11.5% above this temperature (Fig. 2); it never approached the 24% claimed earlier (1). This rise was proportionate to that of the *trans*-crotonic acid component above 160° and kept the *cis–trans* ratio within the narrow range of 0.16–0.18 (Table 2). For isolation of *cis*-crotonic acid (4), the lowest boiling component, this latter proportion was of importance since none of the dimer entered the distillation column.

Equilibrations of cis-Crotonic Acid

The thermal equilibrations of *cis*-crotonic acid, which were carried out after a quantity had been prepared (4) by successful use of the *trans*-crotonic acid equilibration, were expected to be fairly routine. Unexpectedly, a new component appeared in these, which was not seen in the *trans*-crotonic acid equilibrations. The additional compound was found by isolation and comparison of its physical properties with an authentic sample (5) to be vinylacetic acid (3-butenoic acid, **6**). The rate of change of the

concentration of this compound is given in Table 3. In the first few hours of heating, its concentration rose to as high as 15% but subsequently fell to less than 1% of the total, both of these changes occurring more rapidly with higher temperatures.

The drop in vinylacetic acid concentration coincided with a significant rise in the proportion of *trans*-crotonic acid formed (Fig. 3, Table 3). Then very shortly after the simultaneous build-up of *trans*-crotonic acid and decline of vinylacetic acid, the dimer concentration began to rise very sharply (Table 3). In spite of an initial pronounced lag, the concentration of dimer

any, had isomerized to *trans* and no vinylacetic acid had formed. This indicated that it was much more stable than even recent literature reports would suggest (6).

Equilibration of trans-Crotonic Acid in the Presence of Catalysts

A few substances were tried, which might have had a catalytic effect on equilibrations. *trans*-Crotonic acid, with added alumina, *m*-benzenedisulphonic acid, or caustic, was heated at 138°, a temperature sufficient without catalysis to give easily observable and yet not too fast rates of formation of both *cis* acid and dimer. Alumina had a deleterious effect on the rates of formation

of all three *trans* equilibration products (Table 4), perhaps because of a surface effect, and one equivalent of the strong organic acid accelerated quite markedly the appearance of all three. That the effects of alumina were not primarily the result of its basicity was evident on comparison of these with the results in the presence of caustic. The latter gave the most impressive acceleration of the appearance of dimer (as good as that obtained by heating at 189° without catalysis) but, at the same time, retarded the formation of *cis*-crotonic acid.

Ethyl *trans*-crotonate, with or without crotonic acid present, was found to be stable to geometrical or tautomeric isomerization at temperatures as high as 155° for periods of up to 16 h.

Discussion

The equilibrium concentrations and the approximate rates of geometrical isomerization on heating of either *cis*- or *trans*-crotonic acid at various temperatures was determined. These data indicated that a method of separation of *cis*-crotonic acid from a thermally equilibrated mixture obtained by heating the *trans* was practical. This has been demonstrated (4). In addition to this premeditated data utilization, methods for isolating the dimers **3***a* and *b* (3), and vinylacetic acid (5) have been devised and experimentally carried out. Here, the overall quite complicated crotonic acid equilibrium is discussed.

Direct double bond isomerism is unnecessary to explain the mechanism of formation of *cis* acid from the *trans* or vice versa since the results show alternative routes for either transformation. However, the equilibration runs show that the proportion of direct interconversion between **1** and **2** is not the predominant one at 100–140°, and is probably only as important as interconversions of **1** and **2** through **3** and **6**. Scheme 2 summarizes the overall qualitative picture demonstrated by these equilibrium studies.

Heating *trans*-crotonic acid can give rise to one or more of several products. At 100 and 117°, temperatures effecting relatively slow equilibration where an intermediate could be noticed, dimer **3***a* had formed to a considerable extent before any *cis*-crotonic acid had appeared. Hence, the formation of *cis* directly from the *trans* is improbable or at least very slow at these temperatures. However, for Scheme 2 to satisfy the principle of microscopic-reversibility (7, 8) there must be at least slow direct *cis* formation. The dimers and higher oligomers also arise

primarily from *trans*-crotonic acid because this is the dominant component, and because *trans*-crotonic acid, having a less hindered carboxyl, could add more readily than *cis* to **1** or **2**. Some *cis*-crotonic acid does add to *trans* as evidenced by the appearance of **3***b* on long term heating (3).

cis-Crotonic acid in the room temperature stability test changed very little over a period of 80 days. The minute amount of *trans* formed was more at the expense of the vinylacetic component than of the *cis* (Table 3). In fact, if all the *trans* had arisen from vinylacetic acid with concomitant tautomerization of *cis* to vinylacetic acid, this would explain the observed concentration changes. Stepwise geometrical isomerization of this type is closely analogous to the citraconic, itaconic, mesaconic acid equilibrium (Scheme 3) investigated by Linstead and Mann (9). Their data can be mathematically fitted[4] to a system where k_1 and k_2 are 0.

At 160° in the crotonic acid system however, only 3.1% *trans* acid was formed from vinylacetic acid in the time taken for 20.6% to form from *cis*-crotonic acid (*cf.* Tables 3 and 5). Therefore, at this temperature most of the *trans* must have arisen directly from *cis*-crotonic acid.

[4]E. C. Clarke, Dow Chemical of Canada, Ltd., Sarnia, 1966. Personal communication.

The dimer **3***a* arises from *trans*-crotonic acid since it appeared almost immediately on heating *trans* acid whereas none appeared in the *cis*-crotonic acid equilibrations until well over 30% *trans* had formed (Tables 2, 3). The addition of *cis* to *trans* is the probable mode of formation of dimer **3***b*. No dimer appeared on short term heating of vinylacetic acid (Table 5). The dimers only continue to form an equilibrium concentration with *trans*-crotonic acid (Tables 2, 3). Cracking dimer **3** by heat (3) yields both of the crotonic acids and vinylacetic acid in about equilibrium proportions, as indicated in Scheme 2.

As for the various isomerization pathways open to vinylacetic acid, its neat tautomerization to crotonic acid confirms earlier work carried out in caustic (10). Vinylacetic acid was never seen in aliquots from *trans*-crotonic acid equilibrations; traces could have been present. The minute amounts found during dimer isolation procedures (3) probably arose either by tautomerization of the small amount of *cis* present or from the dimer via heat cracking. Vinylacetic acid obtained on the distillation of *trans*-crotonic acid (4) probably arose via the former route.

Large proportions of vinylacetic acid arose from the *cis*-crotonic acid on heating (Fig. 3)

and virtually none from the *trans*. That the *trans*-crotonic – vinylacetic acid equilibrium must be nearly completely on the side of the former has been demonstrated with initial crotonate salts in strong base (11, 12). However, that either isomer of crotonic acid should form more than a very small amount of vinylacetic acid was unexpected since it involved a double bond moving out of apparent resonance with a carbonyl group. For the *trans*, the apparent is true; hence the lack of a noticeable equilibrium proportion of vinylacetic acid (Table 1). But in α,β-unsaturated *cis*-acids generally, as has been pointed out by Newman (13), there is little carbonyl–olefin π-overlap due to mutual interaction of the *cis* groups twisting the carbonyl out of the plane of the olefinic double bond. Manipulation of a Stuart–Briegleb model of *cis*-crotonic acid confirmed Newman's general statement for this acid in particular and in addition demonstrated considerable steric strain. Therefore, the thermal tautomerization of *cis*-crotonic acid to vinylacetic acid can be explained on the basis of no significant loss of conjugative stabilization and relief of steric strain.

The stability to geometrical isomerization found for ethyl *trans*-crotonate can be attributed to a number of factors. It is unable to form a dimer analogous to **3**, and the olefinic double bond (14) has reduced permanent polarization and polarizability (14). Hence, even in the experiments where ester was heated in the presence of free acid no addition of the acid across ester double bonds and, consequently, no ester *cis–trans* isomerism occurred. Esterification of the ordinarily labile citraconic acid (**8**) has been found to stabilize it (15), but it has been found possible to isomerize and tautomerize esters of olefinic acids at somewhat higher temperatures (16) than used here. The high temperature data were interpreted as favoring a 1,5-prototropic shift as one pathway for interconversion of the *cis* esters (5).

The results support the suggestion that the interconversion of *cis*- and *trans*-crotonic acids is only partly direct; a significant proportion of the interconversion is via the intermediates **3** and **6**, especially at lower temperatures (100–140°). At higher temperatures and for certain of the catalytic experiments more transient intermediates might play a part in the equilibration. Isotopic labelling experiments may give more unequivocal answers.

Experimental

Boiling points are not corrected. The n.m.r. spectra were obtained at room temperature on deuteriochloroform solutions using a Varian A60 instrument and have been reported (3–6).

trans-Crotonic Acid Equilibrations

The thermostats used were as follows: 100°, boiling water; 117, 138, and 189°, stirred polyethylene glycol; 147, 156.5, and 179°, vapor phases of refluxing *sym*-tetrachloroethane, *n*-hexanol, and *o*-dichlorobenzene respectively. The heating media were frequently checked with the same calibrated thermometer and were constant to $\pm 0.5°$ over the periods used, except for the 189° polyethylene glycol bath. Mechanical difficulties caused the latter to cool to the indicated extent during the run. *trans*-Crotonic acid was freshly recrystallized (using decolorizing charcoal) from hexane just before the runs, and samples of about 4 g were placed in stoppered test tubes in each of the thermostats described above. The crotonic acid interface in each case was situated at least 2 in. below the level to which the test tubes were heated. Time for the start of heating at each temperature was staggered 5 min, the same order being observed for the withdrawal of aliquots of about 100 mg. With this aliquot put directly into a cold n.m.r. sample tube the equilibration was effectively quenched. Shortly after the aliquots were removed, deuteriochloroform (about 0.3 ml) and TMS were added to the tubes and, following analysis and integration of n.m.r. spectra, the concentrations were calculated (Table 2).

cis-Crotonic Acid Equilibrations

The equilibration of *cis*-crotonic acid was carried out in a strictly analogous way using 97% *cis* acid as the starting material (Table 3). Room temperature stability was determined on a 300 g sample in a nearly full amber bottle left on a bench top.

Catalyzed Equilibrations

The equilibrations by heat with catalysis of *trans*-crotonic acid were carried out in a way analogous to those without catalysis. Woelm basic alumina (1.2 g; activity 1) was kept well suspended in a melt of 4.2 g of the acid with a micro air-powered stirrer for a surface activity test. For the acid catalysis test a solution of *m*-benzenedisulfonic acid (0.1 g; 12 mol %) in 3.0 g of the *trans* acid was used. Anhydrous caustic (0.6 g; 21 mol %) was dissolved in a melt of 6.0 g of the *trans* acid to give the results in strongly basic media. Table 4 summarizes these results.

Equilibration of Vinylacetic Acid

A 5 g sample of neat vinylacetic acid was heated in a stoppered test tube and the changes in composition determined by n.m.r. (6). The results obtained are given in Table 5 and, for comparison, the changes noted in another system in which the initial presence of a large proportion of *cis*-crotonic acid gave ambiguous conclusions (*cis* → *trans vs. cis* → vinylacetic → *trans*, or mixed) is included.

Ester Equilibrations

A test-tube containing ethyl *trans*-crotonate (2.5 g) and

trans-crotonic acid (50 mg) was heated in a bath at 117° for 65 h and an aliquot was analyzed by n.m.r. No ethyl *cis*-crotonate had formed. One gram of the above solution was sealed into an n.m.r. tube and heated in a 138° bath for 120 h, and again, no *cis* ester formed. A further experiment at 155° using the *trans* ester alone sealed into an n.m.r. tube again showed no *cis* after 16 h heating.

Molar Composition Determination

Molar compositions of the equilibration components were determined from the integrated areas of the resonances of the largest proton groupings in each molecule. The integral for the saturated methylene resonance of vinylacetic acid at 179 and 186 Hz was multiplied by 3/2 to convert its integral to a molar proportion for a three proton resonance. The proportion of *cis*-crotonic acid present was clearly determined from the integral of its methyl resonance. The pair of doublets due to the olefinic methyl of dimer **3***a* inconveniently straddled those of the *trans* acid and likewise, the resonance of trimer **4** straddled the resonance doublet of the saturated methyl of **3**. However, both of these composite integrals were resolved using the ratios of these integrals to the integral of the relatively clear methylene doublet of **3**. The latter ratios were determined using both peak height and peak area ratios on two expanded and integrated spectra of different samples and were found to be consistent. These ratio approximations amounted to multiplying the integral of the methylene doublet of **3** by 3/2 to give the integral equivalent of a methyl of the dimer, which then was subtracted from both the dimer methyl *trans*-crotonic methyl composite integral and the dimer methyl-trimer methyl composite integral. The remainders were the *trans*-crotonic acid integral and the trimer integral respectively. For the dimer, which has twice the molecular weight of the other components, the integral for the methylene doublet was multiplied by three to give a six proton equivalence and this figure was used to calculate its molar proportions.

As a consequence of the approximations required to get meaningful data from the integrated spectra, the absolute values quoted should be treated with some caution though it is estimated that the error introduced should not be larger than $\pm 5\%$ of the value given.

Actual isolation of the components of the mixtures formed was relatively easy for some of them. For instance, *trans*-crotonic acid was recovered when required simply by dissolving the mixture with warming in a small amount of hexane and allowing to cool to room temperature. The isolation of *cis*-crotonic acid has been presented in detail (4), and vinylacetic acid, dimers, and higher oligomers were isolated by essentially distillation procedures (3, 5).

The assistance of H. D. Mak in obtaining most of the n.m.r. spectra is recorded with gratitude. The author thanks a referee for bringing the relevance of reference 16 to his attention.

Aromatic Halogenation with Titanium(IV) Chloride in Presence of Peroxytrifluoroacetic Acid

G. K. CHIP AND J. S. GROSSERT[1]

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received July 2, 1971

Titanium(IV) chloride in the presence of an oxidizing reagent such as peroxytrifluoroacetic acid is shown to chlorinate a variety of aromatic substrates. The substitution orientation patterns suggest that the reaction is an electrophilic substitution process, which possibly involves the intermediacy of hypochlorous acid. Chlorination fails to occur with ring systems bearing strongly deactivating substituents, but it proceeds very cleanly and in high yield with activated rings, *e.g.* phenol. The reaction conditions are mild and are adaptable for bromination or iodination as well as chlorination.

On montre que le chlorure de titanium(IV), en présence d'un agent oxydant tel l'acide péroxytrifluoroacétique, permet d'introduire un chlore sur plusieurs substrats aromatiques. Les modèles d'orientation de la substitution suggèrent que la réaction est un procédé de substitution électrophile, qui implique possiblement l'intermédiaire de l'acide hypochloreux. Il n'y a pas de substitution de chlore sur les noyaux portant des substituants fortement désactivants, mais elle se produit facilement, avec de bons rendements, dans le cas de noyaux activés, tel le phénol. Les conditions de réaction sont douces et peuvent être adaptées pour la bromuration et l'ioduration, aussi bien que pour la chloruration.

Halogenation of aromatic rings is one of the more thoroughly investigated organic reactions, and it has been discussed in a wealth of chemical literature (1). Most reactions of this type fall into four general classes, *viz.* (*1*) reaction of electron-rich aromatic rings with molecular halogen; (*2*) reaction of less-activated rings with molecular halogen in the presence of a catalyst; (*3*) reaction of aromatic compounds with systems which furnish a positively charged halonium ion species (*e.g.* chlorine–silver acetate); and (*4*) direct halogenation of an aromatic molecule with halogen, apparently derived from reduction of a metal halide, but without the addition of any free halogen.

Of these four general approaches, the last-mentioned has been studied relatively little, although the use of iron(III) and antimony(V) chlorides as aromatic chlorinating agents has been known for over 100 years (2). Since that time, those metal halides which have received most attention include antimony(V), copper(II), iron(III), and vanadium(V) chlorides (3). It should be noted that metal halides may effect other transformations in addition to halogenation. Depending on the reaction conditions, nuclear coupling, side-chain attack in alkylbenzenes, disproportionation, and polymerization are known to occur (4, 5). In the nuclear chlorination of aromatic compounds with metal halides, various lines of evidence, including the predominant ortho/para orientation, point to an electrophilic substitution mechanism, although the actual attacking form of the metal halide is uncertain.

Titanium(IV) chloride by itself has never been reported to chlorinate aromatic compounds, but it has been used as a catalyst and as a solvent in the chlorination of aromatic rings by other metal halides (6). Previously, we reported that titanium(IV) chloride, in the presence of peroxytrifluoroacetic acid or *m*-chloroperbenzoic acid, will chlorinate aromatic compounds (7). In the present paper, we report further examples of aromatic chlorination with this system and present evidence for a proposed mechanism of the reaction.

Results and Discussion

In general, the chlorination reactions were performed in methylene chloride solvent at 0–20 °C with aromatic reactant–titanium(IV) chloride–peroxytrifluoroacetic acid in a 1:1:1 molar ratio. Aromatic substrates, which represent a range of different reactivities toward electrophiles, were chlorinated by this reaction; the results are presented in Table 1. The products

were isolated and were identified by comparison with authentic materials or by their spectroscopic properties.

Benzene was converted to chlorobenzene with no detectable formation of dichlorobenzene. Toluene and chlorobenzene were monochlorinated also. Although there is considerable literature on chlorination of these two aromatics (8–10), it appears that the use of titanium(IV) chloride as a catalyst for chlorination with molecular chlorine has not been reported previously. In Table 2, we have included our results on this system, together with relevant literature data for other systems, in order to compare these with the reactions of the titanium(IV) chloride – peroxytrifluoroacetic acid reagent.

In the case of mesitylene, 94% was consumed and the products contained trichloromesitylene (65%) and mesitol (5%). Reaction of mesitylene with peroxytrifluoroacetic acid alone has been

*Shown to be 2,4,6-trichlorophenol.

reported to give mesitol in 45% yield, whereas this was increased to 88% by carrying out the same reaction in the presence of boron trifluoride (11). On the other hand, we have observed that aluminum(III) chloride–peroxytrifluoroacetic acid is a chlorinating system.[2] From these reactions it may be concluded that a Lewis acid will only enhance the reactivity of peroxytrifluoroacetic acid as a source of electrophilic hydroxyl if the Lewis acid itself will not become involved in a reaction to form a species less electrophilic than "HO^+".

Acetanilide gave a mixture of chloroacetanilides, in addition to 2,4,6-trichlorophenol.[3] With *p*-acetotoluidide, 2-chloro-4-methyl-acetanilide and 2,4,6-trichloro-4-methylcyclohexa-2,5-dienone were produced, the structure of this dienone being deduced from its spectral characteristics (see Experimental). On acetylation with acetic anhydride/*p*-toluenesulfonic acid, it rearranged to 3-methyl-2,4,6-trichlorophenyl acetate. This rearrangement rules out the possibility that the dienone might have been 3,4,5-trichloro-4-methylcyclohexa-2,5-dienone which, solely on spectral grounds, could not be unequivocally distinguished from the 2,4,6-trichloro-4-methyl isomer. Similarly, *p*-methoxyacetanilide gave 3-chloro-4-methoxyacetanilide, 2,5-dichloro-4-methoxyacetanilide and 2,4,5-trichloro-4-methoxycyclohexa-2,5-dienone, which proved to be much less stable than the similar dienone from *p*-acetotoluidide. The formation of 3-chloro- instead of 2-chloro-4-methoxyacetanilide is consistent with a dominance in substituent directive power of the methoxyl group over the *N*-acetylamino group (12).

Phenol was cleanly chlorinated with a mixture of titanium(IV) chloride and peroxytrifluoroacetic acid to give chlorophenols in 90% yield. No oxidation products of phenol, such as benzoquinone, could be detected; indeed, the reaction was remarkably smooth. Presumably, phenol first reacts with titanium(IV) chloride to form phenyl titanate (13) which is sufficiently nucleophilic to be chlorinated.

Aniline was chlorinated in 64% yield to *o*-chloroaniline (34%), *p*-chloroaniline (23%), and 2,4-dichloroaniline (43%). These products were identified by conversion to the corresponding chloroacetanilides which were analyzed by v.p.c. It is relevant to note that in this case too, no oxidation products could be detected, whereas the direct chlorination of most primary aromatic amines with free chlorine results in extensive oxidation (14).

Some aromatic compounds failed to undergo chlorination. Benzoic acid and nitrobenzene were too strongly deactivated to react, whereas pyridine and thiophene failed to react because of the nucleophilic heteroatoms which, on complexing with the titanium(IV) chloride, caused the ring to become highly deactivated toward electrophilic substitution (15).

Titanium(IV) chloride also chlorinates aromatic compounds in the presence of other peroxides. For example, acetanilide with titanium(IV) chloride–*m*-chloroperbenzoic acid in a 1:1:1 ratio gave a 56% yield of chloroacetanilides. Reaction with a mixture of titanium(IV) chloride and 90% hydrogen peroxide also gave chlorination products, although generally the yields were much lower than when using peroxytrifluoroacetic acid. Results for this system with three representative aromatic substrates are shown in Table 3.

Some conclusions concerning the mechanism of the chlorination reaction may be drawn at this point. The predominance of ortho/para

[2]G. K. Chip and J. S. Grossert. Unpublished data.

[3]We had previously reported (7) the absence of *o*-chloroacetanilide in this reaction. This was due to the inadequacy of t.l.c. separation techniques, and the presence of the ortho isomer has since been demonstrated unequivocally by the use of v.p.c.

TABLE 4. Chlorination of acetanilide with $TiCl_4$–CF_3CO_3H in the presence of added anions

Added anions (mmol)	Reaction conditions		Overall yield (%)	Products
	Time (h)	Temperature (°C)		
$(C_2H_5)_4N^+Cl^-$ (24)	8	20	97	2,4-Dichloroacetanilide
$(C_2H_5)_4N^+Br^-$ (24)	24	20	98	4-Bromoacetanilide
$(C_2H_5)_4N^+I^-$ (6)	18	40	80	4-Iodoacetanilide
$(C_2H_5)_4N^+F^-$ (9)	48	20	50	2-Chloroacetanilide (25%) 4-Chloroacetanilide (54%) 2,4-Dichloroacetanilide (21%)

substitution and the lack of attack on alkyl side chains point to a reaction which is electrophilic rather than radical in nature. The possibility that the active species is molecular chlorine was considered unlikely on the grounds of the product isomer distribution (*cf.* Table 2), and the fact that the decomposition of titanium(IV) chloride into titanium(II) chloride and chlorine is not known (16). Examination of the substitution pattern for all the substrates investigated pointed to an active species of relatively low specificity (and hence of relatively high reactivity), with a relatively small steric factor (17); we suggest that this is best accounted for by postulating hypochlorous acid, or a titanate ester thereof, as the active chlorinating species. The formation of hypochlorous acid by reaction between a peroxy acid and titanium(IV) chloride may be readily rationalized by eq. 1, and a corresponding reaction with hydrogen peroxide by eq. 2.

We have found two additional pieces of evidence to support eq. 1. Reaction of cyclohexene with titanium(IV) chloride–*m*-chloroperbenzoic acid gave 2-chlorocyclohexanol and *m*-chlorobenzoic acid as the only isolable products, eq. 3. No 2-chlorocyclohexyl *m*-chlorobenzoate or 1,2-dichlorocyclohexane could be isolated, which is in accord with the proposed mechanism.

Results from the addition of an excess of various halide anions to the reaction of acetanilide with titanium(IV) chloride–peroxytrifluoroacetic acid (3mmol of each) are given in Table 4. On addition of an excess of chloride ions, the appearance of a greenish-yellow color in the reaction flask indicated the liberation of chlorine gas. The sole product was 2,4-dichloroacetanilide, formed in 97% yield. With an excess of bromide ions, 4-bromoacetanilide was formed in 98% yield, whereas addition of iodide ions gave 4-iodoacetanilide in 80% yield. Addition of fluoride ions gave no fluorination, but only a mixture of chloroacetanilides. These results are as would be expected for a hypochlorite as the active species (18).

The formation of dienones during chlorination of acetanilides is a novel reaction, although their formation during halogenation of phenols is known (19). We have depicted in Scheme 1 our speculation on how the reaction may convert the amide function into a leaving group.

Titanium(IV) chloride is known to form complexes with acetanilide, although the structure of these is in doubt.[4] However, an adduct of the Vilsmeier–Haack type, analogous to the one proposed in Scheme 1, has been postulated (21)

[4]We have prepared a red titanium(IV) chloride–acetanilide complex, m.p. 160–164° (dec.), from methylene chloride solutions. This does not correspond to complexes reported in the literature (20) and we are investigating its structure.

For R = —H or —CH_3; if R = —OCH_3, then chlorination pattern is changed

SCHEME 1

to decompose by expulsion of acetonitrile. As a result of this postulate, we examined the reaction mixture and did detect acetonitrile by v.p.c. and i.r. spectroscopy. On the basis of Scheme 1, mono- or dichlorinated dienones could have been expected but we have found no evidence of their presence.

We believe that this reaction offers a novel and versatile approach to the synthesis of halogenated aromatic compounds, and it may also have some potential for the synthesis of chlorohydrins. In particular, the reaction is easy to carry out, it occurs under mild, controlled conditions and it is applicable to chlorination of reactive molecules, such as aniline or phenol. We are exploring further its applicability to other systems.

Experimental

All melting points were recorded on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded (in $CHCl_3$) on a Perkin–Elmer Model 237B grating spectrophotometer. Ultraviolet spectra were obtained in 95% ethanol solutions on a Coleman–Hitachi Model 124 spectrophotometer. The n.m.r. spectra were determined in $CDCl_3$ on Varian Associates A-60 or T-60 spectrometers using tetramethylsilane as an internal standard. Mass spectra were taken on a C.E.C. Model 21-104 spectrometer operating at 70 eV. Vapor-phase chromatography was performed on a Hewlett–Packard Model 700 chromatograph, equipped with a flame ionization detector and a 6 ft × 1/8 in. stainless steel column (packed with a 15% DC-200/10% QF-1 mixture on 80–100 mesh acid-washed Chromosorb W) generally at 175°, with a nitrogen flow rate of 45 ml/min. Overall yields were calculated on the basis of consumption of starting aromatic substrate, and isomer ratios reflect the relative composition of the isolated product mixture.

Materials

Titanium tetrachloride (Matheson, Coleman & Bell) was refluxed over copper turnings for 4 h and then distilled, giving a colorless fraction, b.p. 136°. Methylene chloride was reagent grade (Fisher Scientific) and was dried over Linde molecular sieve 4A. Hydrogen peroxide (90%) was from the FMC Corporation, and chromatography was done using appropriate Merck products. Tetraethylammonium chloride was made by the method of Coppens *et al.* (22). All other materials were either reagent grade or were prepared by standard procedures.

Reaction of Acetanilide with Titanium(IV) Chloride and Peroxytrifluoroacetic Acid; General Procedure

An anhydrous solution of peroxytrifluoroacetic acid (11) was prepared by dissolving trifluoroacetic anhydride (0.63 ml, 3.2 mmol) in anhydrous methylene chloride (3 ml). After cooling to 0 °C, 90% hydrogen peroxide (0.09 ml, 3 mmol) was added while maintaining vigorous stirring until a homogeneous solution was obtained (15 min). The peracid solution was then added dropwise, during a 15 min period, to a cooled, well-stirred solution of acetanilide (405 mg, 3 mmol) and titanium(IV) chloride (0.33 ml, 3 mmol) in dry methylene chloride (15 ml), under N_2. After the addition of peracid was complete, the reaction mixture was stirred at room temperature for 4 h, during which time its color changed from dark orange to light yellow. The mixture was then hydrolyzed with cold water (50 ml). The product was extracted with methylene chloride, washed with water, 10% sodium bicarbonate, water again, and then dried over anhydrous sodium sulfate. The extract was concentrated and v.p.c. analysis showed that the product (formed in 76% overall yield) contained a mixture of *o*-chloro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

acetanilide (27%), *p*-chloroacetanilide (48%), 2,4-dichloroacetanilide (15%), and 2,4,6-trichlorophenol (10%). In some other experiments, the products were separated on preparative t.l.c. plates and the individual components were extracted and characterized by their melting points and spectroscopic properties.

Reactions of other aromatic substrates were carried out by a procedure identical with that described above. The reagent quantities, reaction conditions, yields, and isomeric distributions are presented in Table 1.

The aryl chlorides were identified by n.m.r. and v.p.c. techniques and in most cases by comparison of their physical properties with those of authentic samples.

Chlorination with Molecular Chlorine in the Presence of Titanium(IV) Chloride; General Procedure

A solution of chlorine (7 mmol) was prepared by bubbling molecular chlorine into methylene chloride (10 ml). This solution was then added to a mixture of acetanilide (7 mmol, 945 mg) and titanium(IV) chloride (7 mmol, 0.77 ml) in methylene chloride (20 ml). The reaction mixture was allowed to stir at room temperature for 5 h. After aqueous work-up, analysis of the organic fraction by v.p.c. indicated a mixture of ortho- and para-chloroacetanilide in the ratio 32:68 and in a 15% overall yield.

When a large excess of molecular chlorine was used in this reaction, only 2,4-dichloroacetanilide (in 96% yield) could be isolated. Similar reactions were carried out on toluene and on chlorobenzene. The results are reported in Table 2.

Reaction of Acetanilide with Titanium(IV) Chloride

The reaction of acetanilide and titanium(IV) chloride was repeated without the addition of peroxytrifluoroacetic acid. After aqueous work-up, the acetanilide recovery was essentially quantitative. No chloroacetanilides could be detected either by t.l.c. or v.p.c.

Reaction of p-Acetotoluidide with Titanium(IV) Chloride – Peroxytrifluoroacetic Acid

The same general procedure was followed. The crude reaction mixture (570 mg) was chromatographed on a column of neutral alumina, Brockman activity 1, 80–200 mesh. Elution with petroleum ether (b.p. 30–60°) gave a white solid (90 mg, 15%) which crystallized from petroleum ether (b.p. 30–60°), m.p. 89–90°. This was identified as 2,4,6-trichloro-4-methylcyclohexa-2,5-dienone from its spectral data: i.r. 1680, 1630 cm^{-1}, no NH or OH absorption; u.v. (95% EtOH) λ_{max} 251 nm (ε 8600), λ_{min} 288 nm; n.m.r. δ 1.98 (s, 3H), 7.21 p.p.m. (s, 2H); mass spectrum M^+ at 209.9399 a.m.u. (calculated for $C_7H_5OCl_3$, 209.9405 a.m.u.) with the isotopic ratio $M^+ + 2 : M^+ + 4 : M^+ + 6$ indicating three chlorine atoms. Further elution gave 2-chloro-4-methylacetanilide (340 mg, 62%, m.p. 117°, undepressed with an authentic sample) and 4-methylacetanilide (56 mg, 16%).

The cyclohexa-2,5-dienone was converted to its 2,4-dinitrophenylhydrazone by warming with an ethanolic solution of the hydrazine reagent. An orange solid precipitated immediately; water was added until the solution became cloudy, and the solid was extracted with chloroform, which was dried (Na_2SO_4). The solvent was evaporated and the residue was recrystallized from EtOH, giving orange-yellow plates, m.p. 160–161°, M^+ 390 a.m.u.

The dienone was converted to 3-methyl-2,4,6-trichlorophenyl acetate by refluxing with a mixture of acetic anhydride and *p*-toluenesulfonic acid for 20 h. The dark solution was poured into cold water and solid Na_2CO_3 added to neutralize excess acid. The product was extracted with chloroform, washed with water and dried (Na_2SO_4). Evaporation of the solvent gave a brown gum which was purified by column chromatography on silica gel. The product was recrystallized from petroleum ether (b.p. 30–60°) to give colorless prisms, m.p. 94–95°. The i.r. showed a band at 1760 cm^{-1} (ester C=O); n.m.r. showed a singlet at δ 2.3 (3H), a singlet at 2.08 (3H), and a singlet at 7.3 p.p.m. (1H).

Reaction of p-Methoxyacetanilide with Titanium(IV) Chloride – Peroxytrifluoroacetic Acid

The same general procedure was followed with *p*-methoxyacetanilide (495 mg, 3 mmol), titanium(IV) chloride (3 mmol), and peroxytrifluoroacetic acid (3 mmol). The crude reaction mixture (570 mg) was chromatographed on a column of neutral alumina, Brockman Activity 1, 80–200 mesh. Elution with petroleum ether (b.p. 30–60°)/benzene (3:1) gave a white solid (20 mg, 10%), m.p. 63–65°, identified as 2,4,5-trichloro-4-methoxycyclohexa-2,5-dienone by its spectral characteristics: i.r. 1665 and 1610 cm^{-1} (α,β-unsaturated C=O), no NH or OH adsorption; u.v. λ_{max} 235 nm (ε 8400); n.m.r. δ 3.84 (s, 3H, OCH_3), 6.83 (s, 1H), and 6.86 p.p.m. (s, 1H); mass spectrum M^+ 226 a.m.u. with the isotopic ratio indicating the presence of three chlorine atoms. This dienone was unstable and readily decomposed to a brown solid of undetermined composition, but which did appear to contain quinonoidal material.

Further elution gave 2,5-dichloro-4-methoxyacetanilide (153 mg, 31%) recrystallized from 95% ethanol, m.p. 194–195° (lit. (23) 189–190°), n.m.r. δ 2.20 (s, 3H, $-CH_3$), 3.87 (s, 3H, $-OCH_3$), 6.90 (s, 1H), 7.33 (broad s, 1H, NH, exchanged in D_2O), 8.17 p.p.m. (s, 1H); i.r. 3420 (NH), 1690 cm^{-1} (amide C=O), and 3-chloro-4-methoxyacetanilide (225 mg, 59%) recrystallized from ethanol, m.p. 92–93° (lit. (24) 94°).

Reactions with Titanium(IV) Chloride – Hydrogen Peroxide

The general procedure already outlined was followed, except that the appropriate amount of hydrogen peroxide (90%) was used in place of the peroxytrifluoroacetic acid. The two-phase system was stirred vigorously; the results are given in Table 3.

Reactions of Acetanilide with Titanium(IV) Chloride – Peroxytrifluoroacetic Acid in Presence of Added Anions

The same general procedure was followed, except that prior to the addition of the peroxytrifluoroacetic acid, a solution of tetraethylammonium chloride, bromide, or fluoride in methylene chloride was added. The results are presented in Table 4. Tetraethylammonium iodide was insoluble in methylene chloride and hence was added in methanol. At the end of this reaction, the solvent was evaporated, leaving a dark violet mass. This was thoroughly washed with cold water, leaving a violet solid which had m.p. 113° and smelled of iodine. The filtrate was extracted with benzene, and the extract was washed first with sodium thiosulfate, then with water, and dried (Na_2SO_4). Evaporation of the solvent gave *p*-iodoacetanilide, recrystallized from ethanol, m.p. 189–190° (lit. (25) 184°), The n.m.r. spectrum of this compound showed the characteristic AA′BB′ pattern

of a 1,4-disubstituted benzene and the mass spectrum showed the molecular ion at *m/e* 261 (C_8H_8NOI has mol. wt. 261).

Reaction of Cyclohexene with m-Chloroperbenzoic Acid–Titanium(IV) Chloride

Cyclohexene (246 mg, 3 mmol) was added to a stirred solution of *m*-chloroperbenzoic acid (517.5 mg, 3 mmol) and titanium(IV) chloride (0.33 ml, 3 mmol) in methylene chloride (20 ml) under N_2. The reaction was allowed to proceed at room temperature for 4 h. The mixture was hydrolyzed with water and the organic product was extracted with methylene chloride. The extract was washed with water and dried (Na_2SO_4). Evaporation of the solvent gave 493 mg of product which was washed with hot water to dissolve the *m*-chlorobenzoic acid. These washings were extracted with chloroform, which was dried and evaporated to give *m*-chlorobenzoic acid (212 mg, 45%), m.p. 155–156°, identical with an authentic sample.

The above product, having been washed with hot water, was extracted with methylene chloride, which was washed, dried and evaporated to give 2-chlorocyclohexanol (150 mg, 37%), the spectroscopic properties of which were identical to those of an authentic sample.

Identification of Acetonitrile

A reaction with acetanilide, as described in the general procedure, was repeated using 1,1,2,2-tetrachloroethane, b.p. 114°, as solvent. At the end of the reaction, the mixture was fractionated and the distillates were analyzed by v.p.c. and i.r. One fraction showed an absorption band in the i.r. spectrum at 2260 cm^{-1} and on the v.p.c. showed a peak corresponding to the retention time of authentic acetonitrile.

We thank the National Research Council of Canada and Dalhousie University for financial support, and Dr. W. D. Jamieson for the high-resolution mass spectrum.

The Effect of Heat Treatment of Silica Gels on the Calorimetric Heats of Adsorption of Sulfur Dioxide up to One-twentieth Monolayer Coverage at 423 °K

R. W. GLASS AND R. A. ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received November 15, 1971

Calorimetric heats of adsorption of sulfur dioxide have been determined at 423 °K for a series of silica gels heat-treated at 240, 550, 700, 800, and 900 °C. At the lowest surface coverage of 0.01 μmol m^{-2}, heats of 25 to 30 kcal mol^{-1} were observed. These values dropped rapidly with increasing coverage and approached "limiting" values of 6 to 7 and 12 kcal mol^{-1} for dehydroxylated and hydroxylated surfaces, respectively. To explain the results at lowest coverages an adsorbed complex involving multiple hydrogen bonds is proposed while at higher coverages it is suggested that single and dual site adsorbed species predominate for the dehydroxylated and hydroxylated surfaces, respectively. Sulfur dioxide adsorption isotherms on all gels at 423 °K obeyed the Langmuir equation.

Adsorbents were characterized by nitrogen adsorption–desorption isotherms at 77 °K and pore size distribution data were calculated from the desorption branch.

On a déterminé les chaleurs calorimétriques d'adsorption d'anhydride sulfureux à 423 °K pour une série de gels de silice traités à des chaleurs de 240, 550, 700, 800, et 900 °C. Lorsque la plus petite surface est couverte, soit 0.01 μmol m^{-2}, on observe des chaleurs de 25 à 30 kcal mol^{-1}. Ces valeurs diminuent rapidement lorsqu'on augmente la surface couverte et approchent des valeurs limites de 6 à 7 et 12 kcal mol^{-1} pour des surfaces respectivement, déhydroxylées et hydroxylées. Pour expliquer les résultats dans le cas d'une faible portion de surface couverte, on propose l'existence d'un complexe adsorbé qui implique des liaisons hydrogène multiples; pour une grande surface couverte, on suggère que des espèces adsorbées à site simple et double prédominent respectivement pour les surfaces déhydroxylées et hydroxylées. Les isothermes d'adsorption de l'anhydride sulfureux sur tous les gels à 423 °K obéissent à l'équation de Langmuir.

Les adsorbants sont caractérisés par des isothermes d'adsorption–désorption de l'azote à 77 °K et les données de distribution de la grandeur des pores sont calculées en se servant de la branche de désorption.

Canadian Journal of Chemistry, **50**, 1241 (1972)

Introduction

This investigation is an extension of the earlier studies of the adsorption of sulfur dioxide on various catalytic and porous solids (1, 2). Previously, results were described (1) for the adsorption of sulfur dioxide on silica gels in the temperature range 263 to 323 °K when both adsorption–desorption isotherms and isosteric heats for surface coverages above one-tenth of a monolayer were determined. These data showed that physisorption was the dominant process although some chemical interaction with surface hydroxy groups appeared to take place.

In the present work calorimetric heats of adsorption of sulfur dioxide for surface coverages below one-tenth of a monolayer have been determined at 423 °K for a series of silica gels heat-treated at temperatures between 240 and 900 °C. In addition, nitrogen adsorption–desorption isotherms for all gels have been measured at 77 °K and the pore size distributions calculated using the Cranston and Inkley method of analysis (3).

Experimental

Materials

Davison '923' grade silica gel with a particle size range 75–150 μ was used. Samples of this material were heat-treated in air at 240, 550, 700, 800, and 900 °C for 20 h. Immediately prior to making adsorption measurements all adsorbents were activated at 240 °C for 2 h, transferred to the appropriate apparatus, and then outgassed at 150 °C overnight at $<10^{-4}$ mm.

High-purity nitrogen (>99.99%; Canadian Liquid Air Ltd.) was used in the determination of the low-temperature nitrogen adsorption isotherms. Sulfur dioxide (Matheson Co.) was anhydrous quality and was drawn directly from the cylinder after line-flushing to a trap attached to the apparatus. It was then outgassed at 10^{-4} mm and vacuum distilled over trays of phosphorous pentoxide. Middle portions only were used and g.l.c. analyses show these to be >99.99% pure.

Apparatus

Heats of adsorption were determined calorimetrically in an apparatus similar to that described earlier (4), using the modified experimental technique for measurements above 273 °K (2).

Nitrogen adsorption–desorption isotherms at 77 °K were determined in an apparatus similar to that used by Joyner (5), and pore size distributions were calculated with the aid of an IBM 360/50 computer.

Hydroxyl group concentrations were determined (6) with

a thermobalance (Stanton–Redcroft Model HT5A) at 1200 °C until a constant-weight value was recorded in a static air atmosphere.

Results

Heats of adsorption were determined for low surface coverages from 0.02 to 0.25 μmol m^{-2} on all five adsorbents at 423 °K. At this temperature, 0.70 μmol m^{-2} is approximately equivalent to one-tenth of a monolayer (2).

There was a tendency for the heats on all the adsorbents to level out at coverages above 0.12 μmol m^{-2}, following a relatively rapid fall between 0.02 and 0.06 μmol m^{-2}, Fig. 1.

Figure 2 shows the adsorption isotherms for sulfur dioxide at 423 °K. All are essentially linear while their slopes decrease with increase in the temperature of heat treatment of the specimens. Ultimately for gels heat-treated at 700, 800, and 900 °C the slopes are almost identical. Langmuir plots of these isotherm data are presented in Fig. 3.

Nitrogen Adsorption/Desorption Measurements

The nitrogen adsorption–desorption isotherms were very similar in shape while the amount of nitrogen adsorbed decreased with increase in temperature of heat treatment, as could be anticipated (7), Fig. 4. A large amount of nitrogen was adsorbed below $p/p_0 = 0.1$ followed by an almost linear adsorption path to $p/p_0 = 0.6$. Saturation was reached around $p/p_0 = 0.9$. The hysteresis loop extended between 0.4 and 0.7 p/p_0 in almost every case although the height of the hysteresis loop decreased with increasing temperature of heat treatment of the samples.

Pore size distributions calculated on a differential basis are shown in Fig. 5. The pore diam-

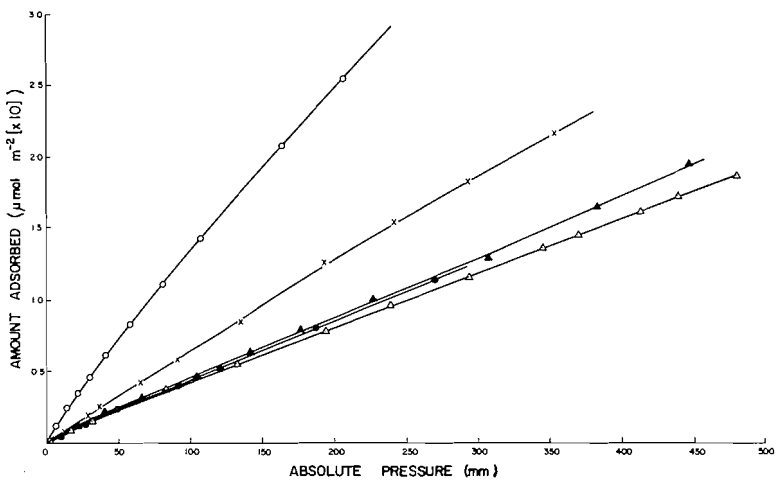

FIG. 2 Adsorption isotherms for sulfur dioxide at 423 °K on heat-treated silica gels. Silica gel heat-treated at: 240 °C, ⊙; 550 °C, ×; 700 °C, ●; 800 °C, △; 900 °C, ▲.

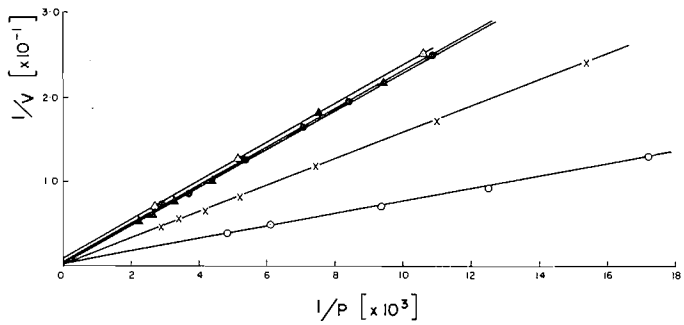

FIG. 3. Langmuir plots for the adsorption of sulfur dioxide at 423 °K on heat-treated silica gels. Silica gel heat-treated at: 240 °C, ⊙; 550 °C, ×; 700 °C, ●; 800 °C, △; 900 °C, ▲.

eter range was from below 20 to 55 Å for silica gels heat-treated at 240, 550, 700, and 800 °C. Maxima occur at about 15, 23, and 38 Å for all of these samples. For the sample heated at 900 °C, the pore diameter range increased to include diameters up to 85 Å, and when compared with the 550 °C sample there were 40% fewer pores of diameter 23 Å and a considerable increase in the numbers of pores <20 Å diameter. Similar results were recorded earlier (7) although the maximum at about 15 Å was not observed.

Table 1 summarizes the data obtained for surface areas (B.E.T. plots), hydroxyl group concentrations and the "limiting heats" of adsorption for sulfur dioxide on each of the heat-treated samples.

Discussion

The high heats of adsorption for sulfur dioxide of 25 to 30 kcal mol^{-1} occur at surface coverages of less than one-hundredth of a monolayer with all samples. These values are too high to be explained by a purely physical adsorption process (8). Earlier it was proposed (2) that in the absence of surface dehydration, adsorption heats of 25 kcal mol^{-1} for sulfur dioxide on silica gel could be explained by the formation of a total of four hydrogen bonds between the oxygen atoms in the sulfur dioxide molecule and adjacent hydroxyl groups on a hydroxylated gel surface. For the interactions at lowest coverages on the heat-treated gels a similar adsorbed complex may occur. While there is infrared evidence (9) that after heat treatment at 800 °C, only isolated hydroxyl groups remain on silica gel surfaces, it is stressed that the bonding arrangement is proposed for extremely low surface hydroxyl group concentrations outside the scope of detection by present infrared techniques. At coverages greater than one-fiftieth of a monolayer, the heats, 6 to 7 kcal mol^{-1}, are more in agreement with infrared studies (9)

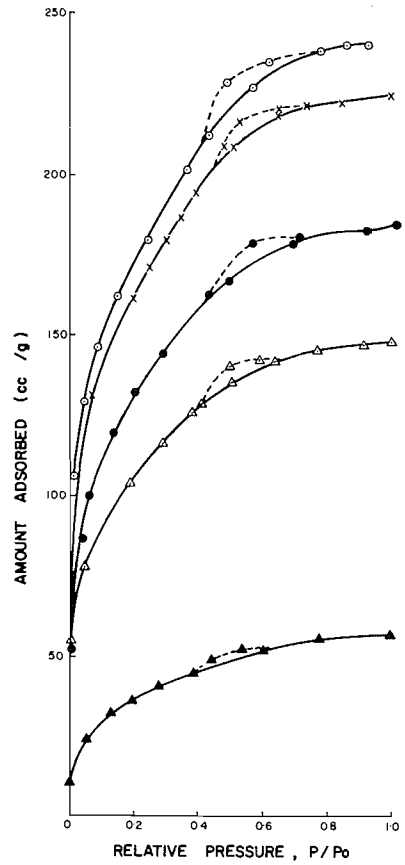

FIG. 4. Nitrogen adsorption–desorption isotherms at 77 °K on heat-treated silica gels. Silica gel heat-treated at: 240 °C, ⊙; 550 °C, ×; 700 °C, ●; 800 °C, △; 900 °C, ▲.

TABLE 1. Surface areas, hydroxyl group concentrations, and "limiting"* heats of adsorption of sulfur dioxide for heat-treated silica gels

Temperature of heat treatment (°C)	Surface area ($m^2\ g^{-1}$)	Hydroxyl group concentration ($\mu mol\ m^{-2}$)	'Limiting' heat of adsorption (kcal mol^{-1})
240	630	7.2	12.0
550	580	2.4	7.5
700	490	1.3	6.6
800	385	1.2	6.6
900	135	1.1	6.5

*The "limiting" heat of adsorption is defined here, for practical convenience, as that value which appears constant over at least the final 30% of the total range of surface coverage measured.

since the formation of a single hydrogen bond of this nature involves between 3 and 6 kcal mol^{-1} of energy (10).

The hydroxyl group concentrations, Table 1, are similar for the samples heat-treated at 700, 800, and 900 °C. Although it has been suggested (11) that the gravimetric method of determining surface hydroxyl group concentrations does not take into account the possibility of bulk water desorption, Uytterhoeven (12) has shown that the total hydroxyl group content of silica xerogels is located at the surface as soon as the material is annealed at a temperature of 600 °C or higher. Thus, the concentrations quoted here give an excellent indication of surface hydroxyl group concentrations. Further, since the surface hydroxyl group concentration for the silica gel heat-treated at 700 °C is very similar to that determined for the samples heat-treated at 800 and 900 °C, it is reasonable to conclude that the chemical structures of the surfaces of these silica gels do not differ much and hence similar sulfur dioxide heat curves would be expected, Fig. 1.

The "limiting" values of the heats at coverages $> 0.2\ \mu mol\ m^{-2}$ may be explained by the adsorption of sulfur dioxide on a largely uniform surface. Previously (1) in studies of the adsorption of sulfur dioxide at 263 °K, boiling point, isosteric heat values of 7 to 7.5 kcal mol^{-1} were observed at around $\theta = 0.8$ for a 240 °C gel. This value was close to that of the heat of liquefaction of sulfur dioxide under these conditions and a physical adsorption process could be envisaged for that region of surface coverage up

For personal use only.

to completion of the monolayer. However, at 473 °K the heat of liquefaction (13) is 1.7 kcal mol^{-1} at a pressure of 68.67 atm and clearly a liquefaction mechanism cannot be used to explain the present results.

The heat curve obtained for the 900 °C gel does not fall as rapidly as those for the 700 and 800 °C samples. At a given coverage the heat of adsorption is 1–2 kcal greater up to a coverage of 0.12 μmol m^{-2} and although the surface hydroxyl group concentrations of the gels are very similar, the pore structure of the 900 °C gel is different from the other two (Fig. 5). More than 25% of the pores have diameters less than 20 Å while the gels heat-treated at 700 and 800 °C have few, if any, pores of these dimensions. This phenomenon is most probably related to the onset of bulk sintering (14) and loss of pore volume above 800 °C which is close to the Tammann temperature for this material (0.5 T_m). The additional 1–2 kcal mol^{-1} of adsorption heat has been detected previously and may be explained by restricted adsorption in pores of diameters approaching molecular dimensions (15).

The 'limiting' heats of 7.5 and 12.0 kcal mol^{-1} for the 550 and 240 °C samples respectively, are in accord with their higher hydroxyl group concentrations and hence with the increased possibility that hydroxyl groups would be more favorably spaced to accommodate more than one OH···O type of linkage with adsorbed sulfur dioxide molecules. Confirmation of this possibility is evident from Fig. 2 which shows that the amount of sulfur dioxide adsorbed depends significantly on the hydroxyl group concentration.

The shapes of the sulfur dioxide isotherms are typical (ref. 16, p. 80) of those which obey the Langmuir equation for low pressures or small adsorptions, especially when capillary condensation or multilayer adsorption phenomena may be excluded (see, for example ref. 16, p. 80). These exclusions are appropriate to the present studies for isotherms determined at 7° below the critical temperature of sulfur dioxide and only up to a maximum coverage of less than 5% of a monolayer. Further, (*i*) the isotherms are linear above surface coverages of 0.08 μmol m^{-2} coincident with the point at which the adsorption heats begin to level out (Fig. 1) and (*ii*) the slopes of the Langmuir plots are proportional to the heats of adsorption (ref. 16, p. 80) (Fig. 3). When all of these factors are combined there results very strong evidence in favor of the Langmuir model of adsorption which allows the additional conclusion that the free energy of adsorption does not vary with the surface coverage (ref. 16, p. 80) above 0.08 μmol m^{-2}.

Hindered Rotation in Styryl Anions[1]

S. BROWNSTEIN AND D. J. WORSFOLD

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received November 26, 1971

Magnetically non-equivalent meta-protons, and occasionally ortho-protons, were observed on the benzene ring in styryl anions. With some cations and solvents it was possible to follow the coalescence of the peaks with increasing temperature and obtain Arrhenius activation energies for rotation of the phenyl group.

On observe des protons-méta magnétiquement non-équivalents et occasionnellement des protons-ortho sur le noyau benzénique dans les anions styryl. Il a été possible, avec quelques cations et solvants, de suivre la coalescence des pics avec l'augmentation de la température et d'obtenir les énergies d'activation d'Arrhénius pour la rotation du groupe phényle.

Introduction

The planar character of benzylic anions has been demonstrated in some of the organometallic compounds formed from styrene and α-methylstyrene by reason of their proton resonance spectra (1, 2). For example when α-methylstyrene is reacted with potassium in tetrahydrofuran solution, it forms a dimer anion, 2,5-diphenyl-2,5-dipotassiohexane (3). The planar character about the benzylic carbon atoms of this molecule is evidenced by the doubling of the n.m.r. absorptions of both the ortho- and meta-protons, and by the sharpness of the single methylene signal. 2,5-Dideutero-2,5-diphenylhexane by comparison no longer has a single peak for the methylene protons, but a quartet, and exists also in two isomeric forms.

Similarly the adducts of *t*-butyllithium with one molecule of either styrene or α-methylstyrene show resonances in two places for both ortho and meta protons at suitable temperatures. In the case of the styryl compound this is below room temperature.

The spectrum of the potassium dimer compound appears to be independent of temperature up to 75 °C. Above this temperature side reactions start to become significant. Both the lithium compounds have spectra which are temperature and solvent dependent. The phenyl group appears to rotate at speeds fast on the n.m.r. time scale at 0° for the styryl compound and 50° for the α-methylstyryl compound. In the former it is the meta-protons which show the greater separation at low temperature, the ortho for the latter. From comparison of exchange broadened spectra of these protons with computer generated curves (5), it is possible to obtain rates of rotation and the Arrhenius activation energy for the rotation process.

Experimental

All preparations were made in an all glass vacuum apparatus, using sublimed tertiary butyllithium, and styrene and α-methylstyrene purified as before (6).

2,5-Diphenyl-2,5-dipotassiohexane (**1**) was prepared in tetrahydrofuran-d_8 by shaking a 5% solution of α-methylstyrene with excess sodium–potassium alloy for 2 days at room temperature. The solution was filtered under vacuum into the n.m.r. sample tube.

2-Lithio-2-phenyl-4,4-dimethylpentane (**2**) was prepared in benzene by reacting equimolar amounts of *t*-butyllithium-d_9 with α-methylstyrene. The product precipitated and was filtered and dissolved in tetrahydrofuran-d_8.

1-Lithio-1-phenyl-3,3-dimethylbutane (**3**) was prepared by adding a solution of styrene in benzene containing 10% tetrahydrofuran to a benzene solution of an equimolar amount of *t*-butyllithium. Tetrahydrofuran was then added to give a 50% tetrahydrofuran–benzene solvent mixture.

All spectra were obtained on a "Varian Associates HA-100" spectrometer. Proton spin decoupling was performed with audio side band modulation in the usual manner. Temperature calibration was done as previously described (5). The data were fitted by least square techniques and the errors quoted are standard deviations.

Results

The generalized formula for the phenyl portion of these compounds is

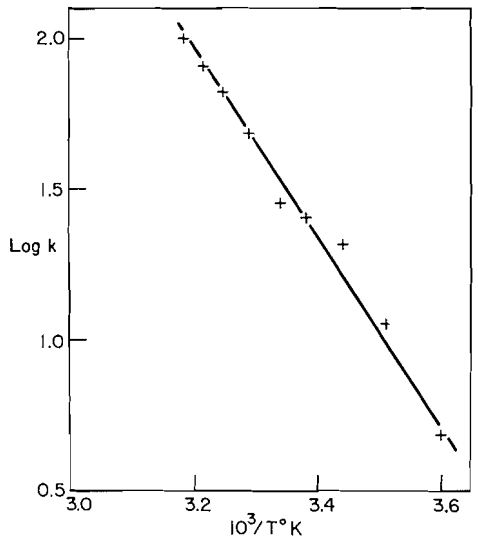

FIG. 1. The rate constants for phenyl rotation in 3 as a function of the temperature; k is in s^{-1}.

The chemical shifts and coupling constants of the aromatic protons in these three compounds are given in Table 1. The assignments were confirmed with the simplified spectra obtained by selective decoupling in double resonance experiments and by comparison of the experimental spectra with theoretical spectra calculated for the appropriate parameters. The chemical shifts of the meta protons of **3** are sensitive to the relative amounts of tetrahydrofuran and benzene. Since **3** has a greater thermal stability the lower the concentration of tetrahydrofuran in solution, a solvent composition was chosen with a minimum of tetrahydrofuran consistent with an adequate separation of the meta-proton signals and a sufficiently low freezing point. The chemical shift and spin coupling constants are consistent with, but of higher precision than, those previously reported (1, 2).

Also given in Table 1 are Arrhenius activation energies for the phenyl rotation in compounds **2** and **3**, derived from the rate constants obtained from spectra taken over a range of temperatures. These results for compound **3** are plotted in Fig. 1 and the spectra shown in Fig. 2. The calculation of the rate constants for rotation about the phenyl–carbon bond are straightforward for compound **2** where each of the well-separated ortho-protons gives a doublet due to spin coupling with the adjacent meta-proton. The meta-proton region of compound **3** is considerably more complex but can be simplified to a four line pattern, in the absence of rotation, by spin decoupling the para-proton. Because of the symmetry of the benzene ring this double irradiation will not affect the transfer of magnetization for the meta-protons.

The hindrance to rotation of the phenyl ring has been ascribed to the delocalization of the charge of the anion away from the α carbon atom, adjacent to the metal atom, to the ring. To delocalize the charge the α carbon atom has to adapt an sp^2 configuration, with the remaining electrons in the residual p orbital which projects above and below the plane of the other carbon bonds (7). The greatest overlap with the π electrons will occur when the phenyl ring and the substituents on the α carbon atom are coplanar. The activation energy for rotation about this bond is then a measure of the electron overlap.

The degree of delocalization of the charge can be measured by estimating the charge on the ring carbons. This is done by comparing the upfield shift of their p.m.r. absorption with the corresponding position in the neutral parent compound. The calculated total charge on the five ring carbons attached to protons is also given in Table 1. Two factors probably affect the degree of delocalization. Firstly, the change from a potassium to lithium as counterion probably concentrates the charge on the α

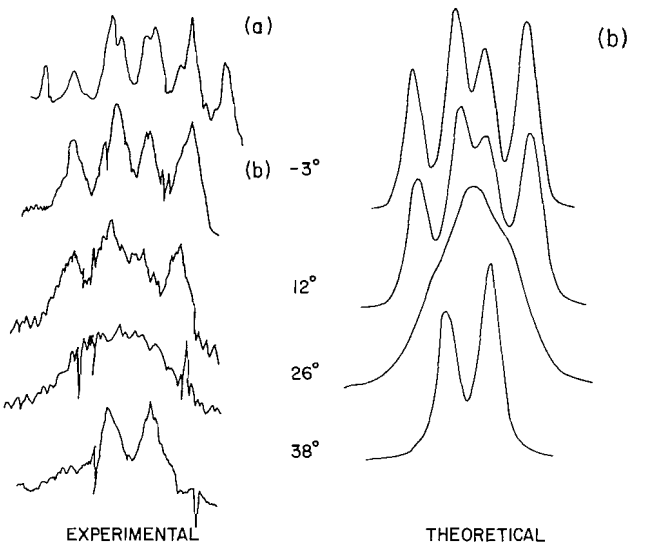

FIG. 2. Experimental and theoretical spectra of the meta-protons of **3**. (*a*) Without decoupling of the para-proton; (*b*) with decoupling of the para-proton.

carbon atom. This is because both are probably contact ion pairs (8) and the carbon lithium interionic distance is smaller. Also on changing from a styryl to an α-methylstyryl compound, the additional methyl substituent on the α carbon appears to increase the charge on the ring.

The compound with the highest delocalization of the charge did not show evidence for rotation, on the n.m.r. time scale, at temperatures below that where decomposition becomes rapid, probably because of high activation energy. The activation energies of the other two compounds are in order of the ring charge, and in general there appears to be a correlation between the degree of delocalization and the activation energy.

Similar barriers to rotation have been found for phenylallyl alkali metal salts (9). The hindrance to rotation occurs in both the allyl group and the bond linking it to the phenyl ring. The activation energy for the latter process was 13.9 kcal/mol when the counterion was lithium and the solvent tetrahydrofuran. This increases somewhat when the counterion is sodium or potassium. In the lithium compound the charge on the ring appears to be near 0.5 e, somewhat lower than the styryl compounds, although the activation energy is high. However, the more extensive conjugation of the phenylallyl system could contribute to the rotation barrier.

Metal–Ammonia Reduction. Part I. The Reduction of α,ω-Diarylalkanes and Triphenylmethanes

D. N. BUTLER AND R. MILBURN

Department of Chemistry, York University, Toronto, Ontario

Received June 4, 1971[1]

The Birch reductions of 15 α,ω-diarylalkanes, **1***a*, *b*, *c* ($n = 1$–5) and of triphenylmethane (**3***a*) and tris-(*p*-methoxyphenyl)methane (**3***b*) are described. In every case reduction proceeds independently in each ring to furnish the products, namely, α,ω-bis(2′,5′-dihydroaryl)alkanes, **2***a*, *b*, *c* ($n = 1$–5), and tris(2′,5′-dihydroaryl)methanes, **4***a*, *b*.

Acid hydrolysis of the enol ethers **2***b*, *c* ($n = 1$–5) and **4***b* affords the corresponding ketones **6** ($n = 1$–5), **7** ($n = 1$–5), and **8**.

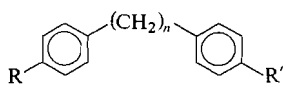
On décrit les réductions de Birch de quinze α,ω-diarylalcanes, **1***a*, *b*, *c* ($n = 1$–5), du triphénylméthane (**3***a*) et du tris(*p*-méthoxyphényl)méthane (**3***b*). Dans chaque cas, la réduction agit indépendamment dans chaque noyau pour conduire aux produits, soient les α,ω-bis(2′,5′-dihydroaryl)alcanes, **2***a*, *b*, *c* ($n = 1$–5), et les tris(2′,5′-dihydroaryl)méthanes, **4***a*, *b*.

L'hydrolyse acide des éthers d'énol **2***b*, *c* ($n = 1$–5) et **4***b* nous amène aux cétones correspondantes **6** ($n = 1$–5), **7** ($n = 1$–5), et **8**.

Canadian Journal of Chemistry, **50**, 1249 (1972)

Relatively few unconjugated diarylalkanes have been subjected to the Birch reduction conditions. Those that have been reported (1*a*–*g*) mostly involve steroid or related systems. Only one triphenylmethane, *viz.* tris(*m*-methoxyphenyl)methane has been reduced (1*g*).

This paper describes the reduction of the α,ω-diphenylalkanes of the type **1** ($n = 1$–5) and the characterization of the products **2** ($n = 1$–5).



1

($n = 1$–5)

The 15 starting materials, **1**, were either known or synthesized by standard methods (see Experimental). The reductions using lithium, *t*-butyl alcohol, tetrahydrofuran, and liquid ammonia at −33° were carried out at much higher dilutions than usually described to keep diarylalkanes in solution (1*a*). The product yields were all better than 90% of theory. The reduction products were characterized by elemental and spectroscopic analysis, and by some chemical reactions described below, and all corresponded to the expected α,ω-bis(2′,5′-dihydroaryl)alkanes **2** ($n = 1$–5).

Compounds **2***a* ($n = 1$–5) were catalytically hydrogenated and all absorbed approximately 4 mol of hydrogen giving rise to the correspond-

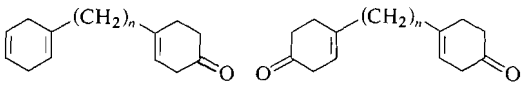
ing α,ω-dicyclohexylalkanes **5** ($n = 1$–5). These liquids **5** ($n = 1$–5) showed characteristic absorptions for saturated C—H bonds in i.r. and p.m.r. spectra, and in all cases produced the predicted intense parent ion in the mass spectra. The reduction products **2***a* ($n = 1$–5) were all easily oxidized back to their aromatic precursors by the action of 2,3-dichloro-5,6-dicyanobenzoquinone.

Gas liquid chromatographic analysis of the reduction products of compounds **1***a* ($n = 1$–5) revealed them all to be mixtures of two components. In each case, the major component (90–95%) was shown by collection and mass spectrometry to be the expected tetraolefin **2***a* ($n = 1$–5) whilst the minor component (5–10%) appeared to be an over-reduced product having a molecular weight two mass units greater than that of the major product. Cyclohexenes (and even cyclohexanes) have been mentioned (2) as minor products of the Birch reduction of benzenes and are proposed to arise via either a base-catalyzed conjugation/re-reduction pathway, or initial 1,2-hydrogen addition competing with the usual 1,4-addition.

Entirely similar chemistry was encountered in the reduction of triphenylmethane to the hexahydro-compound **4***a*. In this case the proportion of over-reduced product increased to nearly 25% of the total reduction material. Again, hydrogenation and oxidation proceeded as expected to afford tricyclohexylmethane and triphenylmethane respectively, as indicated by spectroscopic examination. The structure of the over-reduced product (*m/e* 252) was not further investigated.

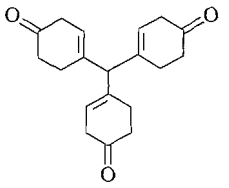
There was no problem with over-reduction of the ten methoxyl-carrying α,ω-diarylalkanes **1***b*, *c* or with tris(*p*-methoxyphenyl)methane, **3***b*. All these reduction products **2***b*, *c* and **4***b* were essentially pure directly from the reaction. However, upon vacuum distillation of the reduction products **2***b*, *c* ($n = 1$–5), it was evident by the appearance of vicinally coupled vinyl protons in the p.m.r. spectra that partial conjugation of the two double bonds in the methoxyl-containing ring or rings was occurring. Thermal conjugation of 2,5-dihydroanisoles has been reported and utilized in obtaining Diels–Alder adducts from these systems (3). No attempt was made to distil **4***b*.

Following the Birch method (4), small quantities of the ten enol ethers **2***b*, *c* ($n = 1$–5) and **4***b* were warmed in tetrahydrofuran with 2 *N* sulfuric acid to produce the ketones **6** ($n = 1$–5), the diketones **7** ($n = 1$–5), and the triketone, **8**.



6 ($n = 1$–5)

7 ($n = 1$–5)



8

In all cases by this treatment, it was observed that the enol ether C=C stretching frequency near 1700 cm^{-1} was replaced by a C=O stretch near 1725 cm^{-1} in the i.r. spectra and the characteristic enol ether vinyl C—H absorption near δ 4.47 p.p.m. in the p.m.r. spectra disappeared along with the methoxyl group absorptions near δ 3.45 p.p.m. Although insufficient quantities of the ketones **6** ($n = 1$–5), **7** ($n = 1$–5), and **8** were available for an evaluation of their melting points or boiling points, these compounds all showed spectral characteristics in their i.r. and p.m.r. spectra consistent with their formulations. They all (except for compound **8**) showed the expected parent ions in their respective mass spectra. For the triketone **8**, the P-28 (loss of CO) at *m/e* 270 was observed as the highest peak. All the ketones were characterized as their 2,4-dinitrophenylhydrazones.

From the preceding results it seems likely that the Birch reduction of compounds containing two or more unconjugated benzenoid rings will take place via the predictable stepwise reduction of the individual rings to furnish the bis- or poly-dihydroaromatic compounds as the major product.

Experimental

All melting points and boiling points are uncorrected. The i.r. spectra were determined on a Unicam SP1000 spectrophotometer as Nujol mulls or in carbon tetrachloride solution. The p.m.r. spectra were recorded on a Varian A-60 instrument in carbon tetrachloride using tetramethylsilane

(TMS) as the internal standard. The g.l.c. separations were made on a Varian Aerograph Series 1700 instrument using a 6 ft × 0.25 in. column packed with 3% Silicone Rubber gum, SE 30 on 100/120 mesh Varaport #30 support. Mass spectra were taken at 70 eV using a Hitachi–Perkin–Elmer RMU-6E instrument. Microanalyses were obtained from A. B. Gygli, Toronto, Ontario.

α,ω-Diarylalkanes, 1a, b, c, and Triphenylmethanes, 3a, b

Compounds **1***a* ($n = 1$), **1***a* ($n = 2$), and **3***a* were purchased from Eastman Chemical Company. The following diarylalkanes are listed with their appropriate reference. **1***a* ($n = 3$) (5), **1***a* ($n = 4$) (6), **1***a* ($n = 5$) (7), **1***b* ($n = 1$) (8), **1***b* ($n = 2$) (9), **1***b* ($n = 3$) (10), **1***c* ($n = 1$) (11), **1***c* ($n = 2$) (12), **1***c* ($n = 3$) (13), **1***c* ($n = 4$) (14), **1***c* ($n = 5$) (15), **3***b* (16).

p-(4-Phenylbutyl)anisole, 1b (n = 4)

A mixture of *p*-(4-phenylbutyryl)anisole (17) (50 g), triethylene glycol (150 ml), and 90% hydrazine hydrate (60 g) was heated under reflux for 15 min. Potassium hydroxide pellets (50 g) were then added and the mixture heated for 30 min at 195–200°, during which time the water that formed was distilled off. The mixture was then diluted with water (600 ml) and extracted with ether (3 × 200 ml). This ether extract was dried (anhydrous Na_2SO_4), filtered, and evaporated. Vacuum distillation of the resulting oil afforded the product **1***b* ($n = 4$) (32 g), b.p. 136–138° (0.06 mm), m.p. 31–33°.

Anal. Calcd. for $C_{17}H_{20}O$: C, 84.96; H, 8.39. Found: C, 85.29; H, 8.53.

p-(5-Phenylpentyl)anisole, 1b (n = 5)

1-*p*-Methoxyphenyl-5-phenylpent-1-en-3-one was prepared from benzylacetone (18) and anisaldehyde according to the method of Pond and Shoffstall (19). This material was first catalytically hydrogenated then the ketone function reduced as for **1***b* ($n = 4$). The product **1***b* ($n = 5$) was a colorless liquid, b.p. 138–140° (0.03 mm).

Anal. Calcd. for $C_{18}H_{22}O$: C, 84.99; H, 8.72. Found: C, 85.19; H, 8.53.

General Metal–Alcohol–Ammonia Reduction Procedure

The reductions were conducted in a three-necked 1 l flask, equipped with an ammonia inlet tube, a Dry Ice/acetone cooled Dewar condenser, and a dropping funnel. Liquid ammonia was transferred directly from the cylinder to the flask and the inlet tube replaced with a stopper. Then the aromatic substance (0.01 mol) was added, followed by excess *t*-butyl alcohol (5 ml) and sufficient tetrahydrofuran to affect solution. The lithium metal (0.1 g atom) was added in small pieces until the reaction was seen to slow down; then the remainder of the lithium was added. The blue reaction mixture was allowed to stand for 2 h and then quenched by the addition of solid ammonium chloride to discharge the blue color. Most of the ammonia was allowed to evaporate; then water and petroleum ether (30–60°) was added. The organic phase was separated, washed with water, dried over anhydrous magnesium sulfate, and then evaporated to give the reduction products in essentially quantitative yield. These products were either vacuum distilled or recrystallized from ethanol or ethanol–water mixtures. In the cases of the enol ether products **2***b*, *c* and **4***b* distillation brought about partial conjugation of the double bonds in the methoxyl-carrying ring or rings as indicated in the p.m.r. spectra of the distillates.

The analytical, physical, and spectroscopic data for all the reduction products have been placed in the Depository of Unpublished Data.[2] Compound **2***b* ($n = 5$) represents a typical example. 1-(2′-5′-Dihydrophenyl)-3-(2″,5″-dihydro-4″-methoxyphenyl)propane, **2***b* ($n = 5$), m.p. 66–68°; i.r. (CCl_4) 1654, 1670, 1702 cm^{-1}; p.m.r. (CCl_4) δ 5.60 (2H, m), 5.30 (2H, m), 4.47 (1H, m), 3.44 (3H, s), 2.61 (8H, m), 1.91 (4H, m), 1.34 (6H, m) p.p.m.; mass spectrum parent ion *m/e* 258, calcd. 258.

Anal. Calcd. for $C_{18}H_{26}O$: C, 83.67; H, 10.14. Found: C, 83.72; H, 9.94.

General Hydrolysis Procedure for the Enol Ethers, 2b, c and 4b

The enol ethers, **2***b*, *c* ($n = 1$–5) and **4***b* (approximately 100 mg) were each warmed on a water bath for 10 min with tetrahydrofuran (5 ml) and 2 *N* H_2SO_4 (2 ml). The reaction mixtures were then diluted with water and extracted with ether. The ether layers were dried over anhydrous Na_2SO_4, filtered, and evaporated giving crude ketones **6** ($n = 1$–5), **7** ($n = 1$–5), and **8**. The i.r., p.m.r., and mass spectra were taken in each case and all were consistent with the assigned structures. No evidence for acid-catalyzed conjugation to α,β-cyclohexenones of the β,γ-cyclohexenone moieties was found in the p.m.r. spectra.

The 2,4-dinitrophenylhydrazones were prepared in the usual way (20). These yellow compounds showed no evidence of conjugation of the incyclic double bond as indicated by the p.m.r. spectra. Their analytical and physical data have been placed in the Depository of Unpublished Data.[2]

Hydrogenations

The hydrocarbons, **2***a* ($n = 1$–5) and **4***a*, were individually reduced in ethyl acetate using 10% palladium-on-charcoal catalyst. When hydrogen uptake ceased, the catalyst was filtered off and the solvent evaporated to leave the product.

Oxidations

The hydrocarbons, **2***a* ($n = 1$–5) and **4***a*, were individually shaken in benzene with excess 2,3-dichloro-5,6-dicyanobenzoquinone for 2 h. The mixture was filtered and the filtrate passed through a short column of alumina (Woelm-activity grade 1). The clear eluate was evaporated and the product shown to be identical to the respective starting materials **1***a* ($n = 1$–5) and **3***a* by direct comparison.

Use of $Eu(fod)_3$ Shift Reagent and Solvent Effects in Structural Elucidation of Novel Isomeric Pyrimidones and Model Methoxylated Pyrimidines[1]

GEORGE A. NEVILLE

Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received July 29, 1971

1-Ethyl-1,6-dihydro-2,4-dimethoxy-5-methyl-6-oxopyrimidine (**1***a*) and 1,5-diethyl-1,6-dihydro-2,4-dimethoxy-6-oxopyrimidine (**2***a*) are shown to be the correct positional isomers, respectively, for the major *O,O*-dimethyl derivatives isolated from the reaction products of 1-ethyl-5-methylbarbituric acid (**1**) and the new 1,5-diethylbarbituric acid (**2**) with excess diazomethane. In addition to the above compounds, the behavior of 2,4-dimethoxypyrimidine (**3**), 4,6-dimethoxypyrimidine (**4**), 2,4,6-trimethoxypyrimidine (**5**), and 6-chloro-2,4-dimethoxypyrimidine (**6**) were studied by p.m.r. spectrometry in various solvents. The relatively new shift reagent, $Eu(fod)_3$ was used in these studies because of its affinity for weak electron donors such as ethers.

On montre que le 1-éthyl-1,6-dihydro-2,4-diméthoxy-5-méthyl-6-oxopyrimidine (**1***a*) et le 1,5-diéthyl-1,6-dihydro-2,4-diméthoxy-6-oxo-pyrimidine (**2***a*) sont les isomères de position corrects, respectivement pour les dérivés principaux *O,O*-diméthyl isolés des produits de réaction de l'acide 1-éthyl-5-méthylbarbiturique (**1**) et du nouvel acide 1,5-diéthylbarbiturique (**2**) avec le diazométhane. En plus des composés précédents, le comportement du 2,4-diméthoxypyrimidine (**3**), du 4,6-diméthoxypyrimidine (**4**), du 2,4,6-triméthoxypyrimidine (**5**), et du 6-chloro-2,4-diméthoxypyrimidine (**6**) a été étudié par spectrométrie r.m.p. dans différents solvants. On a utilisé le relativement nouvel agent de déplacement $Eu(fod)_3$ dans ces études à cause de son affinité pour les donneurs faibles d'électrons tels que les éthers.

Canadian Journal of Chemistry, **50**, 1253 (1972)

Introduction

In an earlier paper (1), where it was shown that *N*-methylation of 5,5-disubstituted barbiturates is predominant with the methylating agent diazomethane, reference was made to the formation of various products with *O*-methyl proton signals from 1,5-dialkylbarbituric acids by the action of excess diazomethane. Although no difficulty was experienced in recognizing the nature of the substituents of these products by p.m.r. spectrometry, the correct positional isomerism could not be established from the usual p.m.r., i.r., and mass spectral data. In addition, the various isomers are not easily and unambiguously obtained by alternative synthesis. It is the purpose of this communication to establish that **1***a* and **2***a* are the correct structures for the crystalline *O,O*-dimethyl derivatives isolated from 1-ethyl-5-methylbarbituric acid (**1**) and 1,5-diethylbarbituric acid (**2**), respectively, by the action of diazomethane. In arriving at these structural assignments, use has been made of the recently reported tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione)-europium(III), $Eu(fod)_3$, as a paramagnetic shift reagent (2) and of solvent effects in p.m.r. spectrometry. The $Eu(fod)_3$ shift reagent appears to be superior to the more common and somewhat older shift reagent, tris-(dipivalomethanato)europium, $Eu(DPM)_3$, recently reviewed by Sanders and Williams (3), because it is more soluble than $Eu(DPM)_3$ in non-alcoholic solvents and has complexing properties such that it will affect weak electron donors such as ethers and esters. For comparison, four model pyrimidines of known structure, 2,4-dimethoxypyrimidine (**3**), 4,6-dimethoxypyrimidine (**4**), 2,4,6-trimethoxypyrimidine (**5**), and 6-chloro-2,4-dimethoxypyrimidine (**6**), were subjected to similar solvent and shift reagent studies. An earlier example of the application of these techniques for structural elucidation of isomeric pyrimidone and uracil derivatives has been reported from these laboratories (4).

[1]Presented in part at the 54th C.I.C. Conference, Halifax, N.S., June 1, 1971.

Results and Discussion

Structural Elucidation of the Pyrimidones

Excluding *O,N*-dimethyl derivatives which are minor products of the action of excess diazomethane in 1-ethyl-5-methylbarbituric acid (**1**) and 1,5-diethylbarbituric acid (**2**), only one of the structures **1***a*, *b*, *c* and **2***a*, *b*, *c*, respectively

can be assigned to the major *O,O*-dimethyl product from each of **1** and **2**.

Using the solvent shift data of Table 1, one can deduce the most likely structure for the positional *O,O*-dimethyl isomer formed from each of **1** and **2**. For ketones and ethers, the magnitude and sign of the proton resonance solvent shifts have been rationalized by means of reference plane rules (5–7). These rules have been generalized (8, 9): protons lying in front of the plane will tend to be deshielded in benzene (relative to an "inert" solvent) while those behind the plane will tend to be shielded in benzene. The shifts ($\Delta = \delta CCl_4 - \delta C_5H_5N$ p.p.m.) observed for pyridine are in general more negative than the corresponding benzene-induced shifts (10). The carbonyl plane "rule" is also applicable to pyridine-induced solvent shifts in some ketones (11), but the reference plane is displaced so that it passes through the α-carbons rather than the carbonyl carbon (10). By these rules one finds that the benzene shifts ($\Delta = \delta CCl_4 - \delta C_6H_6$ p.p.m.) support structures **1***a* and **2***a* best, and similarly, the pyridine shifts support structures **1***a* and **2***a* best.

Some use has been made of the solvent shifts for methoxy-group resonances induced by trifluoroacetic acid (TFA) (12, 13) as an aid to structural elucidation. The downfield shift by

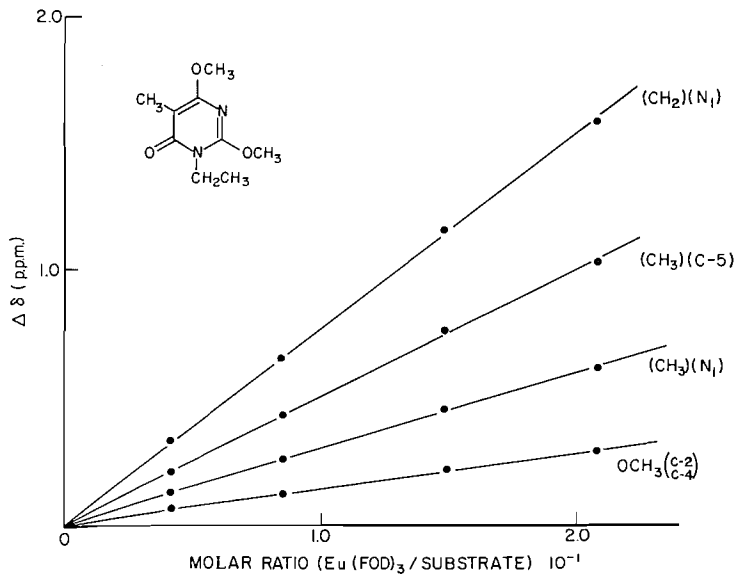

FIG. 1. Normalized Eu(fod)$_3$ induced p.m.r. shifts for 1-ethyl-1,6-dihydro-2,4-dimethoxy-5-methyl-6-oxopyrimidine (**1***a*) in $CDCl_3$ solution.

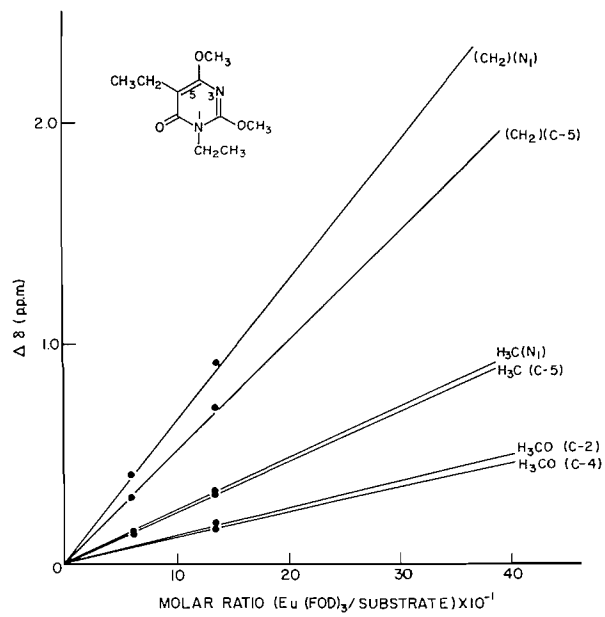

FIG. 2. Normalized Eu(fod)$_3$ induced p.m.r. shifts for 1,5-diethyl-1,6-dihydro-2,4-dimethoxy-6-oxopyrimidine (**2***a*) in $CDCl_3$ solution.

TFA ($\Delta = \delta CCl_4 - \delta TFA$ p.p.m.) for methoxy-group resonances of several methoxybenzenes has been attributed to protonation of the methoxy group (12) whereas with flavones protonation by TFA at both methoxy and carbonyl groups has been proposed (13). The TFA solvent shift data of Table 1 support structures **1***a* and **2***a* best assuming protonation at the carbonyl oxygen only.

The structural assignments for **1***a* and **2***a*, based on solvent studies, were confirmed from chemical shift behavior (Figs. 1 and 2) observed

TABLE 2. Variation of deshielding gradients with functionality

Compound	Functional group	Gradient (p.p.m./mol $Eu(fod)_3$ per mol substrate)	Solvent
1*a*	CH_2 (N-1)	7.5	$CDCl_3$
	CH_3 (C-5)	4.9	
	CH_3 (N-1)	3.0	
	OCH_3 (C-2,3)	1.4	
2*a*	CH_2 (N-1)	6.3	$CDCl_3$
	CH_2 (C-5)	5.1	
	CH_3 (N-1)	2.3	
	CH_3 (C-5)	2.3	
	OCH_3 (C-2)	1.2	
	OCH_3 (C-4)	1.1	
3	OCH_3 (C-2)	7.8	$CDCl_3$
	OCH_3 (C-4)	4.4	
	H (C-5)	3.7	
	H (C-6)	1.5	
4	H (C-5)	5.7	$CDCl_3$
	OCH_3 (C-2,4,6)	4.3	
5	H (C-5)	6.0	CCl_4
	OCH_3 (C-4,6)	4.8	
	OCH_3 (C-2)	4.5	
6	OCH_3 (C-2)	6.3	$CDCl_3$
	OCH_3 (C-4)	3.9	
	H (C-5)	3.7	

with $Eu(fod)_3$, shift reagent. In selecting **1***a* as the correct structure, it was noted that both methoxy resonances are nearly equally affected by the shift reagent and have the same deshielding gradients of 1.4 p.p.m. (Table 2). Although structure **1***b* is best suited by symmetry for this deshielding, assuming complexation at the carbonyl oxygen by the shift reagent, the asymmetrical location of one ring nitrogen would not be expected to alter the chemical shifts greatly. In contrast, the similarly strong deshielding of both the CH_2(Et) protons at N-1 and of the C-5 methyl protons (gradients of 7.5 and 4.9 p.p.m., respectively) by the shift reagent can only be accounted for on the basis of structure **1***a*. Confirmation of structure **2***a* was likewise based on the similarity of deshielding of the methoxy resonances (gradients of 1.1 and 1.2 p.p.m., Table 2) and on the similar but larger deshielding of the CH_2(Et) and CH_3(Et) protons at N-1 and C-5 (gradients of 6.3, 2.3 and 5.1, 2.3 p.p.m., respectively). It is concluded, therefore, that the major products formed by the action of diazomethane on **1** and **2** are 1-ethyl-1,6-dihydro-2,4-dimethoxy-5-methyl-6-oxopyrimidine (**1***a*) and 1,5-diethyl-1,6-dihydro-2,4-dimethoxy-6-oxopyrimidine (**2***a*), respectively.

Solvent and Eu(fod)$_3$ Shift Studies with Some Methoxylated Pyrimidines

The assignment of chemical shifts to methoxylated and methylated pyrimidine rings has been difficult due to very small or negligible differences in these values among structurally similar derivatives. Nishiwaki (14) has reported that the methoxy signal of 2,4-dimethoxy-6-methylpyrimidine appears as a singlet in carbon tetrachloride (3.83 p.p.m.) or in acetic acid (4.00 p.p.m.) while two distinct bands (4.33 and 4.27 p.p.m.) were seen for this pyrimidine in trifluoroacetic acid. The signal at lower field was assumed to be the C-2 methoxy because this signal is likely to be affected more extensively by protonation of the nitrogen atom. Ma and Warnhoff (15) have reported that methoxyl groups show a negligible shift (+0.03 to −0.11 p.p.m.) on changing from deuterochloroform to perdeuteroacetic acid and only a small (−0.08 to −0.37 p.p.m.) further downfield shift in trifluoroacetic acid.

In considering the assignment of the correct structure *a*, *b*, or *c* to compounds **1** and **2**, the known compounds 2,4-dimethoxypyrimidine (**3**), 4,6-dimethoxypyrimidine (**4**), 2,4,6-trimethoxypyrimidine (**5**), and 6-chloro-2,4-dimethoxypyrimidine (**6**) were studied for solvent effects in the hope that frequency assignments made with this series of compounds would aid in the structural elucidation of **1** and **2**. These frequency data (Table 3), however, do not prove helpful by analogy in selecting the correct structure for **1** and **2**. The aromatic solvent shifts indicate that competitive complexation is occurring at different sites with the simpler substrates (**3**–**6**) to produce the range of values observed. Competitive complexation undoubtedly contributes to the character of the solvent shifts recorded for **1** and **2** even though these two compounds possess a carbonyl function which usually exerts a stronger polarizing influence in such solvent effects.

The relative solvent shifts for **3**, **4**, **5**, and **6** in trifluoroacetic acid ($\Delta_{TFA}^{CCl_4}$) (Table 3) show the largest downfield shift for the C-5 proton with

smaller deshielding for the C-2 proton (*e.g.* **4**) or for the methoxyl protons at C-2 (*e.g.* **3**, **5**, **6**). These shifts are in accord with some delocalization of charge through a protonated nitrogen atom; however, the larger downfield shift for the C-5 proton is opposite to what Nishiwaki found for TFA solutions of 4-hydroxy-6-methylpyrimidine and 5-bromo-4-hydroxy-6-methylpyrimidine (14) where the C-2 proton moves downfield more than 1 p.p.m. in TFA relative to chloroform. Similarly, the results of these studies of the effect of TFA on the simpler substrates (**3**–**6**) are of little help in selecting the correct structures for **1** and **2** where protonation of the carbonyl oxygen appears to be more favored than a ring nitrogen.

In studying the effect of Eu(fod)$_3$ on 2,4-dimethoxypyrimidine (**3**), one is surprised to find that it is the C-2 methoxy protons which show the largest deshielding gradient (7.8 p.p.m.) Table 2 and Fig. 3. It would appear that complexation[2] of Eu(fod)$_3$ involves the C-2 methoxy oxygen rather than the C-4 methoxy oxygen atom which might have been expected to have the higher electron density. Reversal of the methoxy assignments shows appreciable non-linearity in graphical representation of the C-4 methoxy proton shifts. It is also interesting to note from Fig. 3 that the deshielding gradient (3.7 p.p.m.) for the C-5 proton of 2,4-di-

[2]A referee has noted that complexation may involve a nitrogen of the pyrimidine ring instead of the oxygen of an *O*-methyl group because of the fact that pyridine is tightly complexed with lanthanide reagents while anisole is not. While this may be the case for some pyrimidine derivatives, complexation does not appear to involve the N-1 site, more favored than N-3 as a Lewis base, of 2,4-dimethoxypyrimidine because H (C-6) shows the smallest deshielding gradient (Fig. 3) of all protons of this molecule.

methoxypyrimidine is significantly greater than that for the C-6 proton which is more proximate to the site of complexation. This reversal in deshielding effect with distance may be due to a dominant ring inductive effect influencing the para-proton more than the meta-proton, or it may arise in this instance by the influence of the angular dependence term $(3 \cos^2 X_i - 1)$ of the McConnell equation (16) applicable to pseudo-contact complexation. Recent mathematical considerations of the geometry in regions of angular dependence for simple model compounds showing an anomalous upfield shift with Eu shift reagents have shown that the

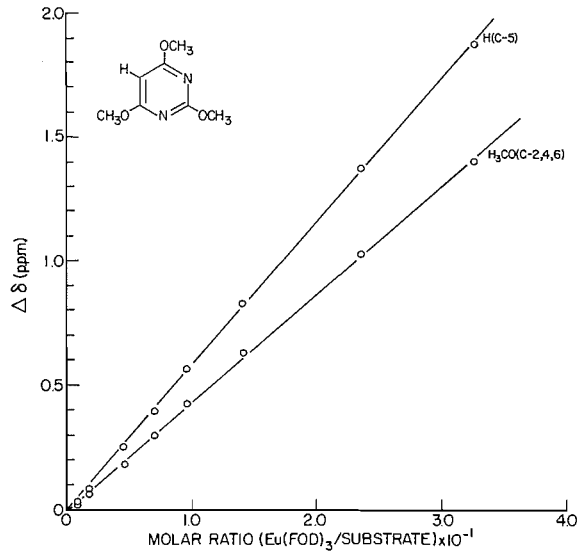

FIG. 5. Normalized Eu(fod)$_3$ induced p.m.r. shifts for 2,4,6-trimethoxypyrimidine in $CDCl_3$ solution.

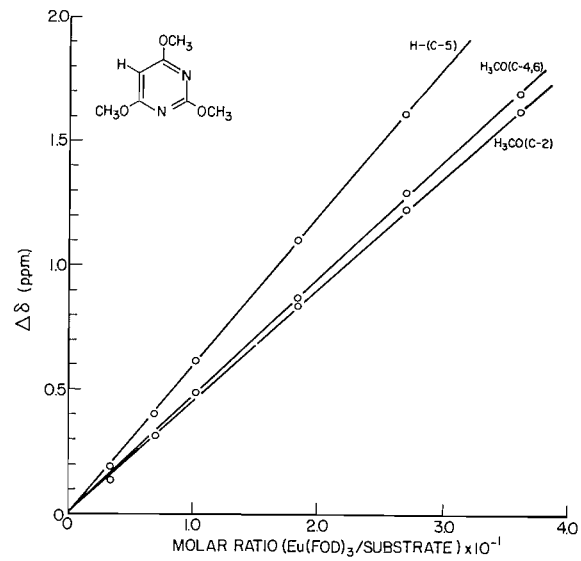

FIG. 6. Normalized Eu(fod)$_3$ induced p.m.r. shifts for 2,4,6-trimethoxypyrimidine in CCl_4 solution.

angular term can override the distance term and result in anomalously small (but not necessarily with reversed sign) deshielding effects (17).

Support for the assignments and complexation model for 2,4-dimethoxypyrimidine was obtained from similar studies of the effect of Eu(fod)$_3$ on 6-chloro-2,4-dimethoxypyrimidine (**6**) (Fig. 4) where the presence of the chloro substituent was not found to alter the electronic character of the pyrimidine ring sufficiently to alter the mode of complexation. The C-2 methoxyl protons of **6** show the largest deshielding gradient (6.4 p.p.m.) (Fig. 4) whose somewhat smaller value than 7.8 p.p.m. for the C-2 methoxyl protons of 2,4-dimethoxypyrimidine cannot be attributed entirely to the electron withdrawing effect of the chloro substituent of **6** because the C-5 proton of both **3** and **6** shows the same gradient of 3.7 p.p.m. (Table 2).

In contrast to the above examples, no dif-

ferentiation is made between the 2 and 4 (or 6) methoxyl protons of 2,4,6-trimethoxypyrimidine (**5**) by $Eu(fod)_3$ in $CDCl_3$ solution (Fig. 5). In addition the C-5 proton of **5** shows a larger deshielding gradient (5.7 p.p.m.) (Table 2) than the methoxyl protons (4.3 p.p.m.) which suggests that a different complexation geometry may be involved with this molecule. In carbon tetrachloride solution Fig. 6, $Eu(fod)_3$ does permit one methoxyl group of *sym*-trimethoxypyrimidine (**5**) to be distinguished from the other two, but this distinction is only possible at higher molar concentrations of $Eu(fod)_3$ shift reagent, i.e. $>0.1\ M$ $Eu(fod)_3$/substrate. In this instance because the peak integrating for three protons consistently occurred upfield from the peak integrating for six protons, the former was assigned to the C-2 methoxyl group and complexation was assumed to involve either the C-4 or -6 methoxyl oxygen atom consistent with the large gradient (6.0 p.p.m.) for the C-5 proton of *sym*-trimethoxypyrimidine in CCl_4 solution.

It is apparent from these studies of the effect of various solvents and of the shift reagent, $Eu(fod)_3$, in model pyrimidines (**3**–**6**) for the novel methoxylated pyrimidones **1** and **2** that very subtle effects are involved which make the choice of model compounds difficult. From these studies, it appears that the structural evidence presented for the pyrimidones **1***a* and **2***a* is best considered on its own merits and internal consistency.

Experimental

Proton Magnetic Resonance Studies

The p.m.r. shifts were measured with a Varian A-60A spectrometer with a probe temperature of 40°. The shifts are believed accurate to ± 0.02 p.p.m.

The $Eu(fod)_3$ shift reagent was obtained from Merck Sharp and Dohme Canada Limited, P.O. Box 898, Pointe Claire–Dorval 700, Quebec.

Syntheses

The conditions for barbiturate synthesis and various physicochemical properties of 1-ethyl-5-methylbarbituric acid (**1**) have been described (18).

*1,5-Diethylbarbituric Acid (**2**)*

Diethyl ethylmalonate (20.0 g, 0.107 mol, n_d^{20} 1.4164, Aldrich) was condensed with ethylurea (9.5 g, 0.110 mol, m.p. 92–94 °C, Aldrich) during 3 h heating under reflux in absolute ethanol (150 ml) containing dissolved sodium (5.0 g, 0.221 mol). The reaction mixture was diluted with water (200 ml), acidified with concentrated hydrochloric acid to Congo red, and left to crystallize overnight in a refrigerator. The crude dry solid (9.2 g, 50%) was recrystallized twice from boiling heptane containing sufficient benzene to maintain miscibility of the oily solute to obtain the analytical sample, m.p. 89.2–91.5° (precision m.p., ref. 19).

Anal. Calcd. for $C_8H_{12}N_2O_3$: C, 52.17; 6.57; N, 15.21. Found: C, 51.96, 52.03; H, 6.45, 6.43; N, 15.37, 15.42.

The p.m.r. spectrum: δ in $CDCl_3$ relative to TMS internal reference: 0.97 (t), CH_3 (C—Et); 1.20 (t), CH_3(N—Et); 2.18 (m) CH_2 (C—Et); 3.45 (t), CH (C-5); 3.93 (q), CH_2(N—Et); 9.32 (broad), NH.

*1-Ethyl-1,6-dihydro-2,4-dimethoxy-5-methyl-6-oxopyrimidine (**1***a*)*

Treatment of a methanolic solution of 1-ethyl-5-methylbarbituric acid (**1**) (m.p. 146.8–147.5 °C) with excess ethereal diazomethane (20) at 0–5 °C and subsequent evaporation gave an oil which crystallized on standing. The crude solid (m.p. 71–80 °C, 15% yield) was recrystallized twice from heptane to obtain an analytical sample of **1***a*, m.p. 80.5–82.2°(corr.) (19).

Anal. Calcd. for $C_9H_{14}N_2O_3$: C, 54.54; H, 7.11; N, 14.13. Found: C, 54.99, 55.29; H, 7.23, 7.30; N, 14.53, 14.51.

*1,5-Diethyl-1,6-dihydro-2,4-dimethoxy-6-oxopyrimidine (**2***a*)*

Similar treatment and handling of a methanolic solution of 1,5-diethylbarbituric acid (**2**) (m.p. 89.2–91.5 °C) gave a crude solid (m.p. 76–81 °C, 28% yield). Two recrystallizations from heptane gave the analytical sample of **2***a* (m.p. 85.6–87.2 °C (corr.) (19).

Anal. Calcd. for $C_{10}H_{16}N_2O_3$: C, 56.59; H, 7.60; N, 13.20. Found: C, 56.32, 56.33; H, 7.54, 7.45; N, 13.25, 13.30.

The p.m.r. spectrometry indicated the mother liquor fractions from both reactions using diazomethane to be complex mixtures of *O*,*N*-dimethyl and *O*,*O*-dimethyl positional isomers.

Methoxylated Pyrimidines

2,4-Dimethoxypyrimidine (**3**) and 6-chloro-2,4-dimethoxypyrimidine (**6**) were used as received from the Aldrich Chemical Co.

*4,6-Dimethoxypyrimidine (**4**)*

A methanolic solution (25 ml) of 4,6-dichloropyrimidine (10.0 g, 0.067 mol, Aldrich) was added in small portions to a freshly prepared methanolic solution of sodium methoxide (4.50 g, 0.20 mol Na/75 ml methanol). The exothermic reaction was allowed to proceed just below the boiling point of the mixture. The reaction mixture was allowed to cool to room temperature before the sodium chloride by-product was removed by filtration. The filtrate was stripped of methanol, and the resulting oil was distilled at reduced pressure to obtain liquid b.p. 36–40°/0.2 mm; lit. b.p. 85°/16 mm (21). The product was verified by p.m.r. spectral analysis (Table 3).

*2,4,6-Trimethoxypyrimidine (**5**)*

A methanolic solution (25 ml) of 2,4,6-trichloropyrimidine (5.0 g, 0.027 mol, Aldrich) was added in small portions to a freshly prepared methanolic solution of sodium methoxide (2.55 g, 0.108 mol Na/50 ml methanol). The reaction proceeded with bubbling and the evolution of heat. The

mixture was allowed to cool to room temperature before the precipitated sodium chloride was removed by filtration. The filtrate was reduced to an oil by rotary evaporation. The oil crystallized on standing. Three recrystallizations of the solid from heptane gave crystals (0.9 g) m.p. 50–52°; lit. m.p. 53° (22). The product was verified by p.m.r. spectral analysis (Table 3).

The author is grateful to Mr. H. W. Avdovich of these laboratories for preparative work and p.m.r. spectra.

A Proton Nuclear Magnetic Resonance Study of the Exchange Reactions of Acetonitrile – Boron Trihalide Adducts with Excess Acetonitrile[1,2]

J. FOGELMAN AND J. M. MILLER[3]

Department of Chemistry, Brock University, St. Catharines, Ontario

Received July 21, 1971

Proton n.m.r. studies of the mechanism for exchange of excess acetonitrile with $CH_3CN{\cdot}BX_3$ (X = F, Cl, Br) adducts show that the rates and activation energy for dissociation are influenced by solvent effects when mixed solvents such as $C_6H_5NO_2/CH_2Cl_2$ or CD_3NO_2/CH_2Cl_2 are used. On extrapolation to inert solvent conditions, first order activation energies are obtained which are in close agreement with previously measured dissociation energies of acetonitrile adducts in solution. The relative rates of dissociation are $CH_3CN{\cdot}BF_3 > CH_3CN{\cdot}BCl_3 > CH_3CN{\cdot}BBr_3$; in agreement with previous experimental evidence that the strength of the donor–acceptor band varies as $CH_3CN{\cdot}BBr_3 > CH_3CN{\cdot}BCl_3 > CH_3CN{\cdot}BF_3$.

Des études par r.m.n. de protons concernant le mécanisme d'échange d'un excès d'acétonitrile avec des dérivés $CH_3CN{\cdot}BX_3$ (X = F, Cl, Br) montrent que les vitesses et l'énergie d'activation de la dissociation sont influencées par les effets de solvants quand des solvants mixtes, tels $C_6H_5NO_2/CH_2Cl_2$ ou CD_3NO_2/CH_2Cl_2 sont utilisés. On obtient, par extrapolation aux conditions de solvant inerte, les énergies d'activation de premier ordre; celles-ci concordent très bien avec les énergies de dissociation de dérivés d'acétonitrile en solution mesurées précédemment. Les vitesses de dissociation relatives sont, dans l'ordre $CH_3CN{\cdot}BF_3 > CH_3CN{\cdot}BCl_3 > CH_3CN{\cdot}BBr_3$; ces résultats sont en accord avec les faits expérimentaux précédents qui montraient que la force de la bande donneur–accepteur varie dans l'ordre $CH_3CN{\cdot}BBr_3 > CH_3CN{\cdot}BCl_3 > CH_3CN{\cdot}BF_3$.

Introduction

It has previously been reported (1) that the downfield chemical shift of acetonitrile–boron trihalide adducts increase in the same order as the acceptor power of the boron trihalides, and also that the exchange with excess acetonitrile proceeded rapidly at room temperature. We now report an n.m.r. kinetic study of the exchange process

$$CH_3CN{\cdot}BX_3 + CH_3CN^* \rightleftarrows CH_3CN + CH_3CN^*{\cdot}BX_3 \qquad (X = F, Cl, Br)$$

De Roos and Oliver (2) have shown that for a first order, dissociation dependent, exchange of the type

$$AB \underset{}{\overset{k_1}{\rightleftharpoons}} A + B \qquad \text{(slow)}$$

$$A + B^* \underset{}{\overset{k_2}{\rightleftharpoons}} AB^* \qquad \text{(fast)}$$

the inverse mean lifetime of adduct species AB, *i.e.* $1/\tau_{AB}$, obtainable from the n.m.r. line widths, is independent of the concentration of either the adduct AB or free base B, *i.e.* $1/\tau_{AB} = k_1$. Similarly, the inverse mean lifetime of the free base has the following concentration dependence, $1/\tau_B = k_1[AB]/[B]$.

For the second order reaction

$$AB + B^* \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B + AB^*$$

the concentration dependence of the mean lifetimes are $1/\tau_{AB} = k_1[B]$ and $1/\tau_B = k_1[AB]$. Thus, from changes in n.m.r. line widths with concentration the order of reaction may be obtained. Such n.m.r. studies have been reviewed recently for organometallic systems (3–5).

Cowley and Mills (6) have shown that for the exchange reaction of $(CH_3)_3N{\cdot}B(CH_3)_3$ with excess acid or base, the rate determining step is dissociation of the adduct. Henold *et al.* (7) have argued that steric hindrance is the explanation for first order rather than second order exchange in Cowley and Mills' work. An additional factor which makes second order displacements at boron less favorable is the increase in activation energy from repulsive terms between groups bonded to boron when the small boron atom must go through a five coordinate transition state. In this work we report on

exchange of acetonitrile with $CH_3CN \cdot BX_3$, where the acetonitrile is certainly much less sterically hindered and serves as a test of Henold's argument.

Experimental

$CH_3CN \cdot BX_3$ adducts were prepared from acetonitrile (dried over molecular sieve followed by vacuum distillation), and freshly distilled boron trihalides as previously described (1). The BF_3 adduct was washed with dry benzene prior to vacuum sublimation (25 °C) while the BCl_3 and BBr_3 adducts were sublimed directly at 85 and 150°, respectively. All manipulations of the adducts were carried out in a nitrogen filled dry box. The n.m.r. samples were prepared using weighed samples of adduct in capped n.m.r. tubes, the solvent and excess acetonitrile being added by syringe in the dry box. Samples were stored at −78 °C prior to use.

The ^1H n.m.r. spectra were recorded on a Varian A-60 equipped with a V-6040 variable temperature unit modified to function over a temperature range of +200 to −150 °C. Temperatures were calibrated using a Varian methanol sample and the corrected calibration curves of Van Geet (8). Spectra were calibrated by audio side bands from a HP4204A decade oscillator monitored by an El Dorado 224 frequency counter.

The A-60 was also equipped with a C-1024 time averaging computer which was used for some measurements on the more dilute samples. Other accessories included a V-6058A homonuclear decoupler and an NMR Specialties HD-60 heteronuclear decoupler operating at 19.25 MHz for ^{11}B decoupling. No coupling to ^{11}B was observed.

Line widths were measured at half height and were approximately corrected for natural line widths by subtracting the width of the TMS reference line, since under the low temperature conditions of our experiments the TMS and pure acetonitrile line widths were approximately the same (0.45 ± 0.05 Hz). The TMS simultaneously provided a monitor of spectrometer resolution. We were unable to measure the line width of the adducts in the absence of exchange so our correction for natural line width is only an approximation. It is probably quite reasonable by analogy with $Me_3N \cdot BX_3$ adducts which we observe to have line widths similar to trimethylamine itself (0.50 and 0.47 Hz, respectively), under conditions of no exchange.

Straight line fits of the kinetic data were computed using a least squares program.

Results and Discussion

(I) Acetonitrile–Boron Tribromide System

This system exhibited the slowest exchange rate of the three described, and could be studied under slow exchange conditions at temperatures not far from ambient (−5 to 25 °C). However, nitrobenzene or nitrobenzene–dichloromethane mixtures had to be used as solvents since the already limited solubility of $CH_3CN \cdot BBr_3$ in dichloromethane decreased rapidly on reducing temperature. Studies were carried out at several temperatures with varied concentration of adduct and free base. Typical results are shown in Table 1.

It can be seen that these data show the

4.13	15.8±1.0	−1.8	10.4
2.99	16.9±1.0	+7.9	15.2

behavior expected for a first order dissociation controlled reaction, namely; (*a*) $1/\tau_{AB}$ is independent of concentration, *i.e.* $1/\tau_{AB} = k_1$; and (*b*) $1/\tau_B$ is concentration dependent, but when multiplied by the ratio of free base to adduct concentrations is constant within experimental error and approximately equal to $1/\tau_{AB}$.

The activation energy for this dissociation process in neat nitrobenzene was determined from a plot of ln $1/\tau$ *vs.* $1/T$ °K. These activation energies were 11.6 ± 0.4 and 12.1 ± 0.4 kcal/mol as determined from the adduct and free base peaks, respectively. These values are low when compared to 19.1 kcal/mol for the dissociation energy of $CH_3CN \cdot BBr_3$ measured by Blackborow and Lockhart (9). A solvent effect was suspected so activation energies and entropies of activation were determined at various concentrations of nitrobenzene in dichloromethane as shown in Table 2.

Since the reaction of nitrobenzene with the boron trihalides is a well known reaction (10), second order interactions with nitrobenzene are possible, namely

$$PhNO_2 + CH_3CN \cdot BX_3 \rightleftarrows CH_3CN + PhNO_2 \cdot BX_3$$

Such a reaction could also affect the concentrations of base and adduct used in the calculations. However, we found that, within experimental error, the ratios of adduct to free base as measured by electronic or planimeter integration of the n.m.r. spectra were the same as the ratios originally added to the n.m.r. tubes, so the free acetonitrile–adduct equilibrium is not seriously disturbed.

Participation of a competitive reaction with the solvent could still greatly affect the n.m.r. line widths. The fact that $1/\tau_{AB}$ is constant with changes in adduct or acetonitrile concentration would still be consistent with a pseudo first order reaction for constant nitrobenzene concentration. Participation of a third species in the exchange is also indicated by the fact that $[B]/\tau_B[AB]$, although constant, is not exactly equal to $1/\tau_{AB}$.

The low activation energy and negative entropy at higher nitrobenzene concentrations is consistent with increasing participation of nitrobenzene in the exchange reactions. If the activation energy is plotted against nitrobenzene concentration, and extrapolated to zero nitrobenzene concentration, *i.e.* pure dichloromethane solvent, the extrapolated activation energy is 18.5 ± 1.0 kcal/mol, in good agreement with the measured dissociation energy in solution, 19.1 kcal/mol (9).

Thus, in the absence of nitrobenzene, dissociation of $CH_3CN \cdot BBr_3$ would be the rate determining step for exchange with excess acetonitrile. A S_N1 mechanism has been reported by Blackborow and Lockhart for the reaction of aromatic amines with $CH_3CN \cdot BBr_3$ adduct (11), although they also report a mechanistic crossover with the BCl_3 adduct reacting via a S_N2 mechanism.

The effect of nitrobenzene concentration on the observed rate constants indicates that in addition to the probable second order attack of nitrobenzene on the acetonitrile adduct, further complicating processes are involved which will be discussed later.

(II) Acetonitrile–Boron Trichloride System

Exchange of excess acetonitrile with the adduct $CH_3CN \cdot BCl_3$ was more rapid than for the corresponding BBr_3 adduct, and thus lower temperatures (−35 to −55 °C) were required for observation of the ^1H n.m.r. spectra of both free base and adduct under conditions of slow exchange. Lower temperatures necessitated using the mixed solvent system, nitrobenzene–dichloromethane. The mechanism of exchange was again elucidated from a study of adduct and free base line widths on varying concentrations of both adduct and free base as shown in Table 3.

For BCl_3 as was the case for the BBr_3 adduct $1/\tau_{AB} = k_1 = [B]/\tau_B[AB]$. Unlike the reaction of aromatic amines with acetonitrile adducts (9) for which there is a crossover from S_N1 to S_N2 mechanism on changing from the bromide to the chloride adduct, we find that both

dissociation energy of $CH_3CN \cdot BCl_3$ (9), and as was the case for the BBr_3 adduct the effect of solvent concentration on activation energy was examined (Table 5).

These results show the same trend as for the BBr_3 adduct, an increase in rate, entropy of activation and energy of activation on decreasing the nitrobenzene concentration. On extrapolation to pure dichloromethane an activation energy of 17.7 ± 1.0 kcal/mol is obtained, in good agreement with the 18.1 kcal/mol dissociation energy for $CH_3CN \cdot BCl_3$ calculated by Blackborow and Lockhart (9). This is further confirmation of a dissociative mechanism, complicated in the mixed solvent system by pseudo

first order reaction with nitrobenzene, and other complications.

Deuteronitromethane was also used as a solvent system for a study of $CH_3CN \cdot BCl_3 + CH_3CN$. Slow exchange conditions were observed at higher temperatures (-35 to -17 °C) than required for the nitrobenzene–dichloromethane mixed solvent system. The results were not as accurate as those discussed above, but all indications were that a similar exchange mechanism was operative in CD_3NO_2 as well.

(III) Acetonitrile–Boron Trifluoride System

$CH_3CN \cdot BF_3$ had the highest solubility of the three adducts studied, but being the most weakly bonded it was not surprising to find that it exchanged most rapidly. It proved impossible to cool this system below the coalescence point (≈ -100 °C) without precipitation of the adduct. A mixed solvent system, CD_3NO_2/CH_2Cl_2 was found to have a low enough freezing point, while maintaining its ability to dissolve the adduct, to permit studies down to about -95 °C, still in the region for fast exchange.

Activation energies were calculated based on the exchange broadening of the single peak observed, typical data being given in Table 6 for a system where adduct and free base concentration were the same.

Again the activation energies were lower than the 12.5 kcal/mol calculated for dissociation of $CH_3CN \cdot BF_3$ in solution (12), so the measurements were performed over a series of solvent concentrations (Table 7).

These values, if extrapolated to pure CH_2Cl_2 solvent correspond to an activation energy of 11.2 ± 0.6 kcal/mol; similar to the value for the dissociation energy of $CH_3CN \cdot BF_3$ in solution. By analogy, therefore, to the trichloride and tribromide adducts, for which the extrapolated activation energy corresponded to the dissociation energy, and which were independently shown by concentration studies to exchange with acetonitrile via a first order dissociative mechanism, we conclude that the $CH_3CN \cdot BF_3$ adduct also exchanges via a dissociative mechanism.

(IV) Other Considerations

As the nitrobenzene concentration was decreased, the rate of exchange increased (Table 8).

4.49	7.09	4.57
4.26	10.4	6.49
2.75	15.2	10.1

For the two competing reactions, [1] and [2],

[1] $CH_3CN \cdot BX_3 \rightarrow CH_3CN + BX_3$

[2] $PhNO_2 + CH_3CN \cdot BX_3 \rightarrow CH_3CN + PhNO_2 \cdot BX_3$

we expect in the first case the adduct peak width $1/\tau_{AB} = k$, and in the second, $1/\tau_{AB} = k[PhNO_2]$, the exact opposite to that shown by the data in Table 8. This slower rate of exchange, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

perhaps part of the negative entropy of activation at high nitrobenzene concentrations might be explained by a solvent cage effect such as that described by Rutenberg *et al.* (13), which can also result in a lower apparent activation energy. A solvent cage effect which would prevent rapid diffusion of the free acid and base after dissociation could be a partial explanation for both the slower reaction rate and negative entropy of activation (indicative of some ordering process) at higher concentrations of nitrobenzene. At low nitrobenzene concentration the positive entropy of activation observed is consistent with the dissociative process.

Solvent viscosity does not appear to be seriously involved since there is no apparent broadening of the TMS reference line with increasing nitrobenzene concentration.

The observed effect of solvent on activation energies may alternatively be approached from an electrostatic point of view. If the donor–acceptor bond is considered as a dipole $\overset{\delta^- \delta^+}{B—N}$ with Coulombic attraction involved, then the energy to separate the charges will be inversely proportional to the dielectric constant of the medium. Higher concentrations of nitrobenzene (dielectric constant = 34; compared to $CH_2Cl_2 = 9$) will increase the dielectric constant of the medium and lower the energy for charge separation, in agreement with the observations reported above.

Schmulback and Ahmed (14) in a conductometric study of the boron trihalides in acetonitrile solution have shown that BBr_3 and BCl_3 exhibit weak electrolytic behavior and that BX_4^- is present in their solutions. Therefore, the possibility of ionic species being involved in the exchange had to be considered. Reactions of type [3] and [4] may be postulated, or alternately, [5] and [6]. However, for all reactions of this type, the n.m.r. line width for the adduct peak, $1/\tau_{AB}$, would be expected to be concentration dependent, in particular, dependent upon adduct concentration. Since it has been shown above that $1/\tau_{AB}$ is independent of concentration we can, therefore, eliminate ionic species as serious participants in the exchange. In addition, an ionic mechanism would promote more rapid reaction in solutions of higher dielectric constant, the exact opposite to that observed. The ^{19}F n.m.r. spectra of the $CH_3CN \cdot BF_3$ system did not show any BF_4^- present.

[3] $$2CH_3CN \cdot BX_3 \overset{k_1}{\rightleftharpoons} \underset{\text{ion pair}}{[(CH_3CN)_2BX_2^+, BX_4^-]} \overset{k_2\ (\text{slow})}{\rightleftharpoons} (CH_3CN)_2BX_2^+ + BX_4^-$$

[4] $$CH_3CN^* + (CH_3CN)_2BX_2^+ \overset{\text{fast}}{\rightleftharpoons} (CH_3CN)(CH_3CN^*)BX_2^+ + CH_3CN$$

[5] $$(CH_3CN)_2BX_2^+ \overset{k_3\ (\text{slow})}{\rightleftharpoons} CH_3CN + CH_3CNBX_2^+$$

[6] $$CH_3CNBX_2^+ + CH_3CN^* \overset{k_4\ (\text{fast})}{\rightleftharpoons} (CH_3CN)(CH_3CN^*)BX_2^+$$

TABLE 9. Comparison of activation energies with heats of dissociation in solution

Adduct	E_A (kcal/mol)	ΔH_{Dissn} (kcal/mol)	Reference
$CH_3CN \cdot BF_3$	11.2±0.6	12.5	12
$CH_3CN \cdot BCl_3$	17.7±1.0	18.1	9
$CH_3CN \cdot BBr_3$	18.5±1.0	19.1	9

In conclusion we can say that the exchange of excess acetonitrile with acetonitrile–boron trihalide adducts proceeds in absence of solvent complications, via a first order dissociative mechanism

$$CH_3CN \cdot BX_3 \overset{\text{slow}}{\rightleftharpoons} CH_3CN + BX_3$$

$$CH_3CN^* + BX_3 \overset{\text{fast}}{\rightleftharpoons} CH_3CN^* \cdot BX_3$$

The rate of dissociation of these adducts is in the order $BF_3 > BCl_3 > BBr_3$ and the extrapolated activation energies for exchange parallel the dissociation energy of the adducts in solution (see Table 9), in agreement with the accepted order of Lewis acidity, $BBr_3 > BCl_3 > BF_3$.

This work also shows that, unlike the gallium adducts, (5) for which first or second order exchange mechanisms may be explained on steric grounds, this is not the case for boron, since the sterically unhindered acetonitrile exchanges via a first order mechanism.

We thank the National Research Council of Canada and the Ontario Department of University Affairs for financial support, and Dr. J. S. Hartman for helpful discussions.

Introduction

The coordination chemistry of copper with tertiary phosphines and arsines has been extensively studied (1, 2) and complexes of these ligands with copper(I) are well known. Copper(II) salts, however, are readily reduced by tertiary phosphines and arsines, and to our knowledge, no copper(II) complexes of phosphines or arsines have been satisfactorily characterized. We have recently reported that the powerful Lewis acid copper(II) hexafluoroacetylacetonate, Cu(hfac)$_2$, forms 1:1 adducts with di-*t*-butyl nitroxide (3) and we now describe reactions of Cu(hfac)$_2$ with tertiary phosphines and related compounds to form five-coordinate 1:1 adducts of the general formula Cu(hfac)$_2$·L. A preliminary report of this work has appeared (4).

Experimental

Anhydrous Cu(hfac)$_2$ was prepared by the method of Bertrand and Kaplan (5) and dried *in vacuo* over sulfuric acid at room temperature. The tertiary phosphines used were purchased from Maybridge Chemical Company, while the compounds $OPPh_3$ (6), $SPPh_3$ (7), $OAsPh_3$ (8), and $SAsPh_3$ (9) were prepared as described in the literature.

Cu(hfac)$_2$·L, L = PPh_3, $PMePh_2$, PMe_2Ph, PEt_3, PBu_3, $AsPh_3$

The complexes were prepared by mixing equimolar amounts of Cu(hfac)$_2$ and the ligand in deaerated, anhydrous cyclohexane under nitrogen. In all cases, the blue Cu(hfac)$_2$ solutions turned deep green. The solvent and any unreacted starting materials (Cu(hfac)$_2$ and the liquid phosphines are volatile) were removed under vacuo at room temperature, leaving a dark green oil of the 1:1 adduct. In the case of PPh_3 and $AsPh_3$, the oil slowly crystallized; the other adducts are liquids at room temperature. The compounds obtained are somewhat unstable, both in the solid state and in solution and could not be purified by recrystallization, sublimation, or distillation. Analytical data are shown in Table 1. The low molecular weight of the arsine adduct suggests that it is largely dissociated in solution.

Cu(hfac)$_2$·L, L = $OPPh_3$, $SPPh_3$, $OAsPh_3$, $SAsPh_3$

The above procedure gave pale green, crystalline 1:1 adducts in all cases except $SPPh_3$, whose adduct was very unstable. Analytical data are shown in Table 1.

Cu(hfac)·2L, L = PPh_3, $AsPh_3$

Addition of PPh_3 to a methanolic solution of Cu(hfac)$_2$ (molar ratio 2.5:1) at room temperature resulted in rapid color changes from light green to dark green to yellow. On concentration of the solution, yellow crystals of the product precipitated in virtually quantitative yield. The same compound was also prepared by heating a 2.5:1 mixture of PPh_3 and Cu(hfac)$_2$ at 90 °C. An extremely malodorous mixture of gases was evolved; n.m.r. and mass spectroscopy showed that the mixture was predominantly hexafluoroacetylacetone, although some unidentified higher weight fluorocarbons were also present.

The orange arsine derivative was obtained in 40% yield by fusing the reactants at 70 °C for 1 h.

Both compounds were recrystallized from methanol. Analytical data are shown in Table 1.

Physical Measurements

Infrared spectra were obtained on Beckman IR-10 and Perkin–Elmer 180 infrared spectrometers, mass spectra on a Jeolco JMS-OISC high resolution mass spectrometer, optical spectra on a Unicam SP820 spectrophotometer, e.s.r. spectra on a Varian V450Z spectrometer with auxiliary equipment, and n.m.r. spectra on a Bruker HX60 spectrometer with internal TMS and hexafluorobenzene lock for proton and fluorine spectra, respectively. Melting points were determined using a Gallenkamp melting point apparatus and are corrected. Molecular weights were determined in deaerated chloroform using a Hewlett–Packard 302B vapor pressure osmometer operating at 37 °C.

Air-sensitive samples were prepared and run under nitrogen as much as possible. Exposure to air, when necessary was kept to a minimum.

Magnetic susceptibilities of the compounds in chloroform solutions were determined by the method of Evans (10). The magnetic moments listed in Table 1 were calculated

TABLE 1. Analytical data

using the equation

$$\mu_{eff} = 2.84[(\chi'_M - N\alpha)T]^{1/2}$$

where χ'_M is the molar susceptibility corrected for the diamagnetic susceptibility of the ligands and $N\alpha$ is the temperature-independent paramagnetism of copper(II).

Results and Discussion

Anhydrous $Cu(hfac)_2$ reacts rapidly with tertiary phosphines to form the deep green 1:1 adducts $Cu(hfac)_2 \cdot PR_3$. Although the compounds cannot be purified using standard techniques, the analytical data in Table 1, especially the molecular weights, and the physical properties of the reaction products are completely consistent with their formulation as 1:1 adducts rather than mixtures of reactants. Their structures are presumably square pyramidal, as are similar systems (11). There was no color change and apparently no reaction, on adding tertiary phosphines to solutions of Cu(acetylacetonate)$_2$. This is in accord with the fact that $Cu(hfac)_2$ is a much better Lewis acid than the non-fluorinated derivative (12).

The presence of copper(II) rather than copper(I) is indicated by the magnetic moments, which are close to the expected spin-only value for one unpaired electron. Some of the magnetic moments are somewhat lower than normal; it is possible that partial reduction of the copper occurred in these cases, especially since the compounds decompose slowly in air, even in the solid state. The $OPPh_3$ and $OAsPh_3$ adducts were prepared for purposes of comparison; the former has been incorrectly reported (13) as being an oil. The phosphine and arsine complexes are definitely different from the corresponding oxide complexes, showing that oxidation of the ligands had not occurred, and that the new compounds do contain copper–phosphorous and copper–arsenic bonds.

The infrared spectra of the copper(II) adducts were essentially superpositions of the spectra of $Cu(hfac)_2$ and the phosphines in the region 4000 cm^{-1} to 300 cm^{-1}, the ligand bands shifting at most only a few cm^{-1}.

Nakamoto *et al.* (14) have assigned a weak band at 415 cm^{-1} in the spectrum of $Cu(hfac)_2$ to a Cu—O stretching mode. We find that this band (which appears at 418 cm^{-1} in the spectra of our samples) has an apparent counterpart in the spectrum of hexafluoroacetylacetone, a weak band appearing at 430 cm^{-1}. A new, strong band does appear, however, in the spectrum of $Cu(hfac)_2$ at 279 cm^{-1}, beyond the region scanned by Nakamoto *et al.* Although the latter band seems rather low for a copper–oxygen stretch, we question the previous assignment.

On forming the monoadduct of triphenylphosphine, medium intensity bands at 358 and 323 cm^{-1} in the spectrum of $Cu(hfac)_2$ shift to 353 and 314 cm^{-1}, and strong bands at 279 and 204 cm^{-1} are replaced by a series of bands at 258, 230, 213, and 182 cm^{-1}. Assignments of these bands are difficult at present but may

involve copper–phosphorous and/or copper–oxygen stretching modes.

The optical spectra of solutions of $Cu(hfac)_2$ in the presence of varying concentrations of triphenyl phosphine are shown in Figs. 1 and 2. The predominant changes are large increases in the intensities of the band envelopes in the regions 370–450 and 550–850 mμ as the phosphine:copper ratio increases to approximately unity. The increase in intensity of the low energy (d–d transition) band envelope is indicative of adduct formation, and similar observations have been reported for the 1:1 adducts of $Cu(hfac)_2$ with nitrogen (15, 16) and oxygen (3, 12, 17)

donors. Funck and Ortolano (18) have recently reported the color changes on adding a series of aryl phosphines to solutions of $Cu(hfac)_2$, although no complexes were isolated and thus no explanation for the spectral changes could be given.

Wavelengths and approximate molar extinction coefficients for the 1:1 adducts studied are listed in Table 2. Since formation of the five-coordinate complexes necessarily causes loss of the inversion center of the molecule, thus relaxing the parity selection rule forbidding d–d transitions, it is reasonable to expect that the increases in the extinction coefficients of the d–d bands are related to the degree of the perturbation of the copper(II) electronic system on formation of the adducts. On this basis, the relative strengths of the interactions would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

appear to be $PPh_3 > PMePh_2 > PBu_3 > PMe_2Ph > PEt_3$. The extinction coefficient of the arsine derivative is probably low because of partial dissociation. There is no correlation of the band intensities with the basicities of these ligands in polar solvents (19, 20).

As is shown in Figs. 1 and 2, the addition of more than one equivalent of triphenylphosphine to a cyclohexane solution of $Cu(hfac)_2$ results in a decrease in the intensity of the absorption bands in the region 600 to 850 mμ. The decrease in color could be caused by a redox reaction yielding the yellow $Cu(hfac)\cdot 2PPh_3$ (as occurs in methanol) or by the formation of a 2:1 adduct, as has been observed for some nitrogen donors (16). The latter suggestion seems more likely, as the decrease in intensity is not observed in the more polar chloroform, in which a redox reaction might be favored. The reduction in the extinction coefficient can be rationalized in terms of formation of a *trans* 2:1 adduct, since the molecule would become centrosymmetric and the parity selection rule forbidding d–d transitions would apply.

The mass spectra of $Cu(hfac)_2\cdot PPh_3$, $Cu(hfac)_2\cdot PEt_3$, and $Cu(hfac)_2\cdot AsPh_3$ at 70 eV did not show the molecular ion lines, although lines attributable to PPh_3^+, PEt_3^+, and $AsPh_3^+$ were observed. In contrast to the relative intensities of the lines in the mass spectrum of $Cu(hfac)_2$ (21, 22), the lines assigned to the ions $[Cu(hfac)_2]^+$, $[Cu(hfac)_2 - CF_3]^+$, $[Cu(hfac)_2 - 2CF_3]^+$, and $[Cu(hfac)_2 - 4CF_3]^+$ were more intense than the lines corresponding to the ions CF_3^+, $hfac - CF_3^+$, and $hfac^+$. Similar results were reported for the $Cu(hfac)_2$ adduct of di-*t*-butylnitroxide (3). It seems likely that the energy of the ionizing electrons was largely dissipated in breaking the copper–phosphorous or –arsenic bond, leaving the rest of the molecule relatively intact.

The major lines in the mass spectrum of $Cu(hfac)\cdot 2PPh_3$ were attributable to the ions $[Cu(hfac)\cdot PPh_3]^+$, $[CuPPh_3]^+$, and PPh_3^+.

The n.m.r. spectra of the copper(II) complexes were in all cases broadened because of the paramagnetism. In those cases where spectra were obtained, the proton chemical shifts were usually in the "normal" regions for chemically similar diamagnetic compounds or were shifted only slightly. The chemical shifts and linewidths are listed in Table 3. The proton linewidths of the phosphine complexes provide further evidence for their formulation as complexes of copper(II), since the linewidths are much greater than those of the diamagnetic copper(I) complexes, and are even significantly greater than the linewidths of the copper(II) complexes of $OPPh_3$, $OAsPh_3$, and $SAsPh_3$, the correct formulation of which is not in doubt. If the phosphine complexes somehow did not have phosphorous bonded to copper(II), the n.m.r. linewidths should be much smaller.

The ^{19}F resonance of $Cu(hfac)_2$ in chloroform is too broad to observe because of the short fluorine spin–lattice relaxation time induced by the unpaired electron. We have previously shown (3) that spin exchange between $Cu(hfac)_2$ and the stable free radical, di-*t*-butylnitroxide, can cause sufficient electron spin relaxation that the ^{19}F spectrum can be observed. It is now seen that coordination of a tertiary phosphine to $Cu(hfac)_2$ can also shorten the fluorine relaxation time, possibly by delocalization of spin density from the copper(II) into the phosphine ligand via d_π–d_π bonding between copper and phosphorous. Thus the spin density on the fluorine atoms, and hence the linewidth, would be decreased. It is perhaps significant that the order of increasing ^{19}F isotropic shifts from the diamagnetic positions ($PPh_3 < PMePh_2 < PBu_3 < PMe_2Ph < PEt_3$) parallels the order of increasing fluorine resonance linewidths (the $AsPh_3$ derivative is omitted from consideration because of dissociation). The $OPPh_3$, $OAsPh_3$, and $SAsPh_3$ derivatives exhibited no ^{19}F spectra, presumably because the resonances were too broad to be observed.

On the basis of ^{19}F resonance positions and linewidths, the interactions of $Cu(hfac)_2$ is strongest with PPh_3 decreasing along the series. The greatest degree of electronic interaction is expected to remove the largest proportion of electron density from the ^{19}F nuclei, leading to a resonance position exhibiting the smallest isotropic shift relative to the diamagnetic position. This series of relative $Cu(hfac)_2$–phosphine interactions parallels the apparent trend established on the basis of the magnitude of the extinction coefficients of the complexes.

Furthermore, the proton resonances of the neutral ligands of the PEt_3, $OPPh_3$, $OAsPh_3$, and $SAsPh_3$ complexes are relatively narrow, suggesting less delocalization of spin density

into these ligands. Calculations suggest (23) that dipolar shifts of the ^{19}F resonances should be negligible in these systems, and thus the isotropic shifts may be expected to be proportional to the spin densities on the fluorine atoms.

The most conclusive evidence for copper–phosphorous bonding was obtained from the e.s.r. spectra of the complexes. The e.s.r. spectrum of $Cu(hfac)_2$ in chloroform solution (g 2.14, $a_{Cu} \sim 71$ G) at room temperature is shown in Fig. 3. The lower field lines are broadened because the tumbling rate does not average out the anisotropies. The spectrum of $Cu(hfac)_2 \cdot PMe_2Ph$ is shown in Fig. 4. The four-line spectrum of copper(II) ($I = 3/2$) is split into eight lines by coupling with the phosphorous ($I = 1/2$). The e.s.r. data for the five phosphine complexes are listed in Table 4. The spectra are all similar, although the overlap of the quartets of the triphenylphosphine adduct is such that a sextet (intensities 1:1:2:2:1:1) is observed. Because of dissociation of the

complex, the spectrum of the triphenylarsine adduct is essentially that of $Cu(hfac)_2$.

The possibility that the observed spectrum is only that of a small amount of a copper(II) impurity can be rejected because the magnetic moments (Table 1) clearly show that the oxidation state of the copper is +2 rather than +1. In addition, the intensities of the lines in the e.s.r. spectra of the phosphine complexes are comparable with the intensities of the lines in the spectrum of $Cu(hfac)_2$, while the g values are quite different.

There have been several recent reports of observations of phosphorous superhyperfine interactions in the e.s.r. spectra of transition metal complexes. Kramolowsky and Schmidt (24) and Cullen and co-workers (25) have studied the e.s.r. spectra of the series of compounds $Fe(NO)_2LX$ (L = tertiary phosphine; X = Cl, Br), observing values of a_p in the region 31–78 G. Henrici-Olivé and Olivé (26), on the other hand, observed phosphorous splittings of 25–36 G for a series of vanadium(IV)–tertiary phosphine complexes. Thus the degree of spin density delocalization from metal-to-phosphorous is somewhat greater in the copper than in the iron and vanadium systems.

Although, as expected, the copper hyperfine splitting is reduced on going from $Cu(hfac)_2$ to the phosphine adducts, there is no correlation between either of these quantities and the isotropic shifts/linewidths of the ^{19}F n.m.r. resonances. Clearly the mechanism of delocalization of spin density from the copper(II) into the ligands is very complicated, and results in the placing of spin density on fluorine, phosphorous, and the organic groups of the coordinated tertiary phosphines.

The mechanism of the reduction of the copper(II) by excess triphenyl phosphine probably involves coordination of a second phosphine to give the unstable, octahedral complex $Cu(hfac)_2 \cdot 2PPh_3$ (Fig. 5, 1). This step could be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

followed by homolytic cleavage of a copper–oxygen σ-bond to form $Cu(hfac)\cdot 2PPh_3$ and the radical **2**. The latter could then abstract a hydrogen atom from, say, a solvent molecule to form hexafluoroacetylacetone. This type of reaction has been suggested by Carty and co-workers (27) as an efficient procedure for the preparation of copper(I) complexes such as $Cu(hfac)\cdot 2PPh_3$.

We thank the International Nickel Company of Canada for a scholarship to R.A.Z. and the National Research Council of Canada for financial assistance. We are also indebted to Dr. J. K. S. Wan for assistance in running the e.s.r. spectra.

The Structures of the Trihydroxyflavans from the Acid-catalyzed Rearrangement and Dimerization of 3-Carene-2,5-dione[1]

I. W. J. Still and D. J. Snodin[2]

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 15, 1971

The structures of the trimethyl ethers of three of the four mechanistically probable trihydroxyflavans derived by acid-catalyzed rearrangement and dimerization of 3-carene-2,5-dione have been assigned on spectroscopic grounds and by analogy with earlier results obtained under conditions which precluded dimerization. Confirmation of these assignments has been obtained by the unambiguous synthesis of two of the isomeric trimethyl ethers from simple aromatic precursors.

Les structures des triméthyl éthers de trois parmi les quatre trihydroxyflavanes possibles quant au mécanisme, et qui dérivent d'une transposition acido-catalysée et d'une dimérisation du carène-3 dione-2,5, ont été attribuées en se fondant sur des données spectroscopiques et par analogie avec des résultats précédents obtenus dans des conditions qui excluent toute dimérisation. La confirmation de ces attributions a été obtenue par une synthèse non ambigüe de deux des triméthyl éthers isomères, à partir de progéniteurs aromatiques simples.

As part of our investigation of the chemistry of the bicyclo[4.1.0]heptane derivative, 3-carene-2,5-dione (**1**) (1–3) we examined the effect of concentrated hydrochloric acid at room temperature. After a very brief interval a pale brown solid precipitated in 77% yield from the initially clear yellow solution. The same product was obtained on similar treatment of **1** with concentrated sulfuric acid, albeit in lower yield. The nature of this solid product, actually a mixture of isomers, is the subject of the present study.

Preliminary i.r. examination of the solid product revealed intense hydrogen-bonded hydroxyl absorption in the range 3600–3100 and a moderately strong band at 1600 cm^{-1} indicative of aromatic character. A bathochromic shift in the u.v. absorption maximum from 295 to 312 nm on addition of potassium hydroxide to a methanolic solution, and the ready solubility in aqueous alkali provided further indications of the presence of a phenolic group or groups in the product, although ferric chloride tests were consistently negative. The mass spectrum of the product showed an apparent molecular weight of 328, with major fragment ions occurring at *m/e* 165 and 164. The n.m.r. spectrum showed two main sets of broad resonances, in the aromatic region at δ 6.5–8.0 and in the region 0.9–3.2 p.p.m. From the complexity of the spectra in general and from the difficulty in obtaining analytical samples of reproducible melting point, we concluded that we were probably dealing with a mixture of at least two components. Furthermore, because of solubility problems we felt that conversion of the dimeric rearrangement product to a more tractable derivative would be rewarding.

Various attempts at esterification of the product were unsuccessful but methylation with excess methyl sulfate under mild conditions produced a viscous yellow oil which contained only traces of unreacted hydroxyl. A preliminary analysis of this oil by t.l.c. indicated that there were at least three major components present. The mass spectrum of the mixture revealed an apparent molecular weight of 370, indicating the presence of three hydroxyl groups in the original product, all presumably phenolic in nature from the ease of methylation. Column chromatography of the methylated product, using a large ratio of adsorbent (Grade I alumina) to substrate, led to the elution in ether–hexane of four isomeric products, referred to subsequently in the order of elution as methylated dimers **A**–**D**. Relative yields of **A**–**D** and details of the n.m.r. and mass spectra appear in Table 1.

The n.m.r. spectra of **A**, **C**, and **D** confirmed in each case the presence of three methoxyl

*These designations refer to the disposition of the hydrogens in the benzo- and phenyl rings, respectively, of the flavan system.
†Only relative intensities > 20% are indicated.
‡This is an estimated yield, based on n.m.r. spectra of **B** contaminated with varying amounts of **A** and **C**.

groups and five methyl groups, three of which are attached to sp^3 carbon atoms. Assuming from the original mass spectral evidence that a mixture of dimers ($C_{20}H_{24}O_4$) had been formed, then the fourth oxygen present in addition to the three hydroxyl groups must be accounted for by an ether functionality. At this point, the results of related experiments which we had conducted on the rearrangement of **1** in acetic anhydride–sulfuric acid mixtures (1) led us to the conclusion that the products obtained in the present investigation might well be trihydroxyflavans produced by the acid-catalyzed dimerization of the *o*-isopropenylphenols, **4** and **5**, arising from acid-catalyzed ring opening of the cyclopropane ring in **1**. The facility of flavan formation in such cases had been demonstrated earlier by Baker and his collaborators (4). The selectivity of the acid-catalyzed opening of the cyclopropane ring in **1**, apparent in our earlier study (1), is not so evident from the distribution of both "symmetrical" (**A** and **D**) and "mixed" (**B** and **C**) products in Table 1. This may be regarded as supporting evidence for our contention that the reaction leading to the formation of the phenolic diacetates described in ref. 1 is actually initiated by acetylium ions rather than by protons, giving rise to the observed selectivity by virtue of the much greater difficulty of electrophilic attack by a bulky ion at the sterically crowded C-2 carbonyl group site. The mechanism proposed for the formation of the trihydroxyflavans in the present reaction appears in Scheme 1. Further evidence in support of our gross structural assignment arises from the presence of major fragment ions in the mass spectra of **A**, **C**, and **D** at *m/e* 192 and 178. This

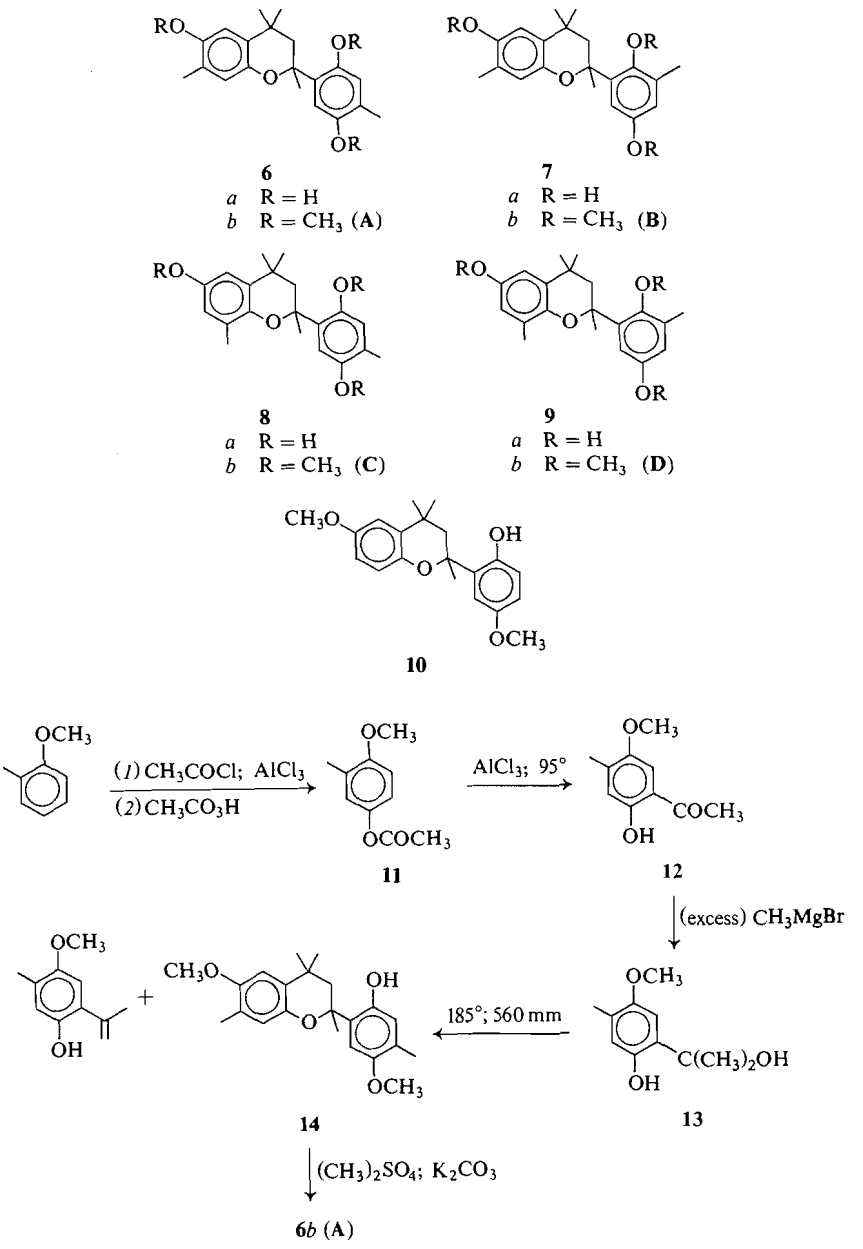

SCHEME 2

is indicative of a *retro*-Diels–Alder type of disintegration, observed previously (5–7) as being characteristic of flavan derivatives.

The individual assignments of structures **6***b*–**9***b* to the methylated products **A**–**D** respectively, and hence of structures **6***a*–**9***a* to the original phenolic products, were made largely on the basis of the n.m.r. spectra and in particular from an inspection of the aromatic region. The spectrum of methylated dimer **A** revealed four singlets of equal intensity between δ 6.48 and 6.83 p.p.m. and thus the *p*,*p*-relationship of the hydrogens in each aromatic ring, as represented in structure **6** was assigned. On the

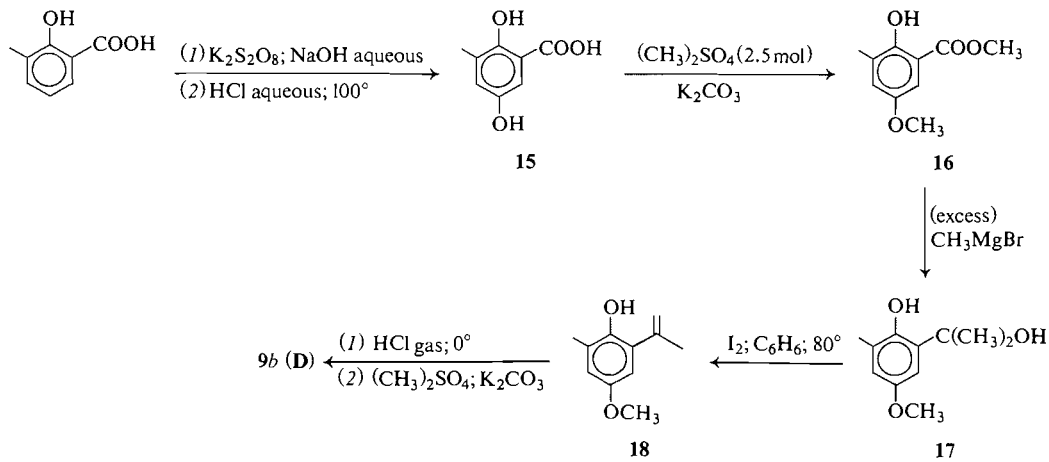

SCHEME 3

other hand, the dimer **D** was assigned structure **9** because its spectrum possessed the most complex aromatic region, δ 6.40–6.55 (m, 3H) and 6.61 (1H, d, $J = 3$ Hz), in accord with expectation for the *m*-orientation of the hydrogens in both aromatic rings. The structural assignments for both **A** and **D** have been confirmed by unambiguous syntheses (see Schemes 2 and 3).

The remaining dimers **B** and **C** resulting from "mixed" coupling of the carbonium ion precursors **2** and **3** with the isopropenylphenols **4** and **5** were more difficult to differentiate. Methylated dimer **C** was assigned structure **8** on the following grounds. Mechanistic analogy to the result obtained in the acetic anhydride – sulfuric acid system (1) and the observed preponderance of **D** over **A** (see Table 1) suggests that formation of carbonium ion **2** would be preferred and thus one might reasonably expect that the *m,p*-mixed dimer would be formed in greater amount than the *p*-, *m*-mixed dimer. The methylated dimer **B** could never be obtained free of contamination with **A** and **C**, and thus analytical, n.m.r., and mass spectral data are not reported for this isomer. The general similarity of its i.r., u.v., and n.m.r. spectra, to those of **A**, **C**, and **D**, however, as well as very similar elution properties lead us very tentatively to assign the remaining mechanistically probable structure **7** to this isomer. One remaining feature of interest in the n.m.r. spectra of **A**, **C**, and **D** is the relatively large chemical shift difference (0.71–0.94 p.p.m.) observed for the two methylene protons in the heterocyclic rings of the flavans. Bowman *et al.* (8) have observed a similar difference (0.70 p.p.m.) and an identical coupling constant ($J = -14$ Hz) for the two methylene protons in the closely related structure **10**.

The synthetic routes to the methylated dimers **A** and **D** from *o*-methylanisole and 2-hydroxy-3-methylbenzoic acid (*o*-cresotic acid), respectively, are illustrated in Schemes 2 and 3, and were generally straightforward, with satisfactory yields being obtained in all steps. In Scheme 2, dehydration of **13** proceeded almost quantitatively, producing a mixture of the monomeric and dimeric dehydration products in a ratio of 1:4. In Scheme 3, the crucial hydroxylation step to produce the dihydroxybenzoic acid derivative **15** with the desired substitution pattern proceeded in 43% yield (9). The iodine-catalyzed dehydration of the tertiary alcohol **17** produced the monomeric *o*-isopropenylphenol **18** almost quantitatively and strong acid catalysis was required to produce dimerization. The presumed intermediate monohydroxy-dimethoxyflavan was not isolated and the synthesis of **9***b* was completed by methylation. The synthetic routes provide additional, indirect support for the mechanistic scheme already described in Scheme 1, in that an *o*-isopropenylphenol derivative is a presumed intermediate in each case.

Experimental

General

The i.r. spectra (cm^{-1}) in CCl_4 solution or as otherwise specified were recorded on a Perkin–Elmer 337 grating spectrophotometer and the u.v. spectra (in methanol) on a

Unicam SP 800 recording instrument. The n.m.r. spectra (δ) were obtained on Varian A-60 and HA-100 instruments in the solvents specified, using tetramethylsilane as the internal standard. Mass spectra were recorded on a Bell and Howell 21-490 spectrometer and the elemental analyses were performed by A. B. Gygli, 329 St. George Street, Toronto and by the Scandinavian Microanalytical Laboratory, Herlev, Denmark. Column chromatography was performed using silica gel (Davison Chemical, Grade 923, 100–200 mesh) or neutral alumina (Fisher Grade I, 80–200 mesh) and Fisher A.C.S. grade solvents. All melting points and boiling points are uncorrected.

*3-Carene-2,5-dione (**1**)*

This compound was synthesized and purified by a previously published procedure (10).

*Reaction of **1** with Concentrated HCl*

3-Carene-2,5-dione (2.0 g) was finely powdered and added rapidly to concentrated HCl (50 ml) with stirring at 25 °C. After 2–3 min a pale brown precipitate appeared and the acid solution was poured into iced water (100 ml). The precipitate was filtered off, washed thoroughly with ice-cold water, 5% sodium hydrogen carbonate solution, and finally again with ice-cold water before drying in a vacuum desiccator for 2 days. The crude product (1.55 g, 77%) was recrystallized from a variety of mixed solvents such as ether–hexane, methylene chloride–petroleum ether (30–60°) but no purified sample with a range of melting of less than 5° could be obtained. (The melting points varied from 160–190° depending on the solvent system used.)

The mass spectrum of this product showed an apparent molecular ion at *m/e* 328, while the n.m.r. spectrum (acetone-d_6) looked exceedingly complex. The i.r. spectrum showed a broad OH band at 3600–3100 and prominent peaks at 1600 and 1485 indicative of aromatic character. The u.v. spectrum showed a prominent maximum at 295 nm (ε, 7000).

Methylation of Mixture of Dimers

The product (1.05 g) obtained as described above was methylated under standard conditions with an excess of methyl sulfate in acetone in the presence of anhydrous potassium carbonate. Examination of the i.r. spectrum of the viscous yellow oil (1.13 g) so obtained revealed almost no residual OH absorption bands. Chromatography of the crude methylation product on alumina (850 g) and examination of the fractions by following changes in the intensity of the 295 nm band in the u.v. led to the isolation of four main fractions designated **A**, **B**, **C**, and **D** in the order of their elution. The product **A** began to elute with 12% ether–hexane and the last traces of **D** were eluted with ether. The four isomers accounted for essentially all of the substrate chromatographed. The i.r. spectra of **A**–**D** showed general similarities with no hydroxyl or carbonyl absorption and peaks characteristic of —OCH_3 at 2830, as well as the aromatic bands at 1600 and 1490. The details of the n.m.r. and mass spectra of **A**, **C**, and **D**, as well as the relative yields of the methylated dimers, appear in Table 1.

Methylated dimer **A**, **6***b* was recrystallized from methanol, m.p. 115–116°.

Anal. Calcd. for $C_{23}H_{30}O_4$: C, 74.56, H; 8.16. Found: C, 74.72, H; 8.09.

Methylated dimer **C**, **8***b* was recrystallized from 60% aqueous ethyl alcohol, m.p. 96.5–97.5°.

Anal. Calcd. for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16. Found: C, 74.71; H, 8.13.

Methylated dimer **D**, **9***b* was recrystallized from 50% aqueous ethyl alcohol, m.p. 94–94.5°.

Anal. Calcd. for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16. Found: C, 74.82; H, 7.96.

*4-Methoxy-3-methylphenyl Acetate (**11**)*

4-Methoxy-3-methylacetophenone (11) was converted to 4-methoxy-3-methylphenyl acetate by the procedure of Bowman *et al.*, (8). The product was obtained as a pale yellow oil (19.2 g, 51%), b.p. 136–138°/20 mm; i.r. 2835, 1770, 1503, 1210; n.m.r. ($CHCl_3$-d_1) 2.24 (3H, s), 2.29 (3H, s), 3.80 (3H, s), and 6.85 (3H, m) p.p.m. The mass spectrum showed the expected molecular ion at *m/e* 180 (17) and major fragment ions at *m/e* 138 (100) and 123 (68).

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71. Found: C, 66.42; H, 6.73.

*2-Hydroxy-5-methoxy-4-methylacetophenone (**12**)*

Fries rearrangement of **11** (18.4 g) was carried out by adding aluminum chloride (15 g) to the ice-cold acetate. A vigorous reaction occurred as the flask warmed up to room temperature. The reaction mixture was then stirred at 90° for 16 h before cooling and adding 2 *N* HCl (80 ml). The resulting yellow solid was extracted with ether and the combined extracts in turn extracted thoroughly with cold 2 *N* NaOH solution. The alkaline solution was strongly acidified with concentrated HCl and the product steam-distilled (a total of 1100 ml was collected). Extraction of the phenol with ether gave, on evaporation of the dried extract, a yellow solid (7.8 g). Recrystallization from aqueous ethyl alcohol afforded **12** as small yellow needles (5.9 g, 38%), m.p. 108–109°. (Some unreacted starting material was recovered from the neutral fraction in the original ethereal extract.) The i.r. 2850, 2830, 1650, 1630 (sh), 1585, 1495; n.m.r. ($CHCl_3$-d_1) 2.22 (3H, s), 2.57 (3H, s), 3.82 (3H, s), 6.78 (1H, s), and 6.99 (1H, s); u.v. λ_{max} 230 (ε, 16 100), 265 (ε, 9900), 352 nm (ε, 5100). The mass spectrum showed the expected molecular ion at *m/e* 180 (63) and further peaks at 165 (100), 147 (11), and 137 (10).

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71. Found: C, 66.64; H, 6.70.

*2-(2-Hydroxy-5-methoxy-4-methylphenyl)-2-propanol (**13**)*

The substituted acetophenone, **12** (2.83 g, 0.016 mol) in ether (15 ml) was added to a refluxing ethereal solution of methylmagnesium bromide, prepared from magnesium (1.13 g, 0.047 g-atom) and excess methyl bromide. After refluxing the reaction mixture for 1 h under N_2, saturated ammonium chloride solution (10 ml) was added dropwise until a clear supernatant ethereal layer was obtained. Separation and drying of the ethereal layer gave on evaporation a white solid. Recrystallization from petroleum ether (b.p. 60–70°) with the aid of charcoal gave the expected tertiary alcohol (2.53 g, 82%); m.p. 70–71°; i.r. 3640, 3420, 2815, 1495; n.m.r. ($CHCl_3$-d_1) 1.63 (6H, s), 2.14 (3H, s), 3.74 (3H, s), 5.13 (1H, s), 6.57 (1H, s), 6.67 (1H, s). (The phenolic proton was not detected.) The mass spectrum showed a molecular ion at *m/e* 196 (20) and major fragment ions at 178 (100) and 163 (76).

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22. Found: C, 67.12; H, 8.11.

Dehydration of ***13****: Formation of 2-(2-Hydroxy-5-methoxy-4-methylphenyl)-6-methoxy-2,4,4,7-tetramethylchroman (****14****)*

The tertiary alcohol **13** (2.75 g) was heated at 185°/580 mm for 1 h and a product (0.37 g, 18%), b.p. 174–176°/11 mm, was collected. This was shown to be the expected *o*-isopropenylphenol derivative (see Scheme 2) arising from simple dehydration; i.r. 3530, 2830, 1620, 1500, and 911; n.m.r. ($CHCl_3$-d_1) 2.11 (3H, s), 2.17 (3H, s), 3.76 (3H, s), 5.13 (1H, bs), 5.31 (1H, bs), 5.52 (1H, bs), 6.60 (1H, s), and 6.70 (1H, s).

The glassy residue in the distilling flask was extracted with hot benzene and the solvent evaporated. Trituration with petrol afforded white crystals of **14**, (2.06 g, 81%) which were recrystallized from petroleum ether (b.p. 60–70°, m.p. 106–107°; i.r. 3420, 2830, 1500; n.m.r. ($CHCl_3$-d_1) 1.13, 1.39, 1.70, 2.12, 2.18, 3.70, 3.77 (each 3H, s) 2.0 (1H, d), and 2.67 (1H, d)($J = -14$ Hz), 6.69 (4H, m), and 7.56 (1H, s). The mass spectrum showed the expected molecular ion at *m/e* 356 (42) and major fragment ions at *m/e* 180 (13), 179 (96), 178 (100), and 163 (16).

Anal. Calcd. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92. Found: C, 74.15; H, 7.89.

*2-(2,5-Dimethoxy-4-methylphenyl)-6-methoxy-2,4,4,7-tetramethylchroman (****6b****)*

Methylation of **14** (0.95 g) using methyl sulfate and anhydrous potassium carbonate in acetone under standard conditions afforded the expected methyl ether, ***6b*** (0.87 g, 88%), m.p. 114–115° on recrystallization from aqueous ethyl alcohol, undepressed on admixture with a pure sample of methylated dimer, **A**. The i.r., n.m.r., and mass spectra of the synthetic sample were identical with those of dimer **A**.

*2,5-Dihydroxy-3-methylbenzoic Acid (****15****)*

A solution of 2-hydroxy-3-methylbenzoic acid (Eastman Kodak) (10 g, 0.067 mol) in 10% NaOH solution (125 ml), was cooled to 10° and a saturated aqueous solution of potassium perdisulfate ($K_2S_2O_8$) (18 g in 350 ml, 0.067 mol) was added with stirring, over a period of 5 h. During this period, the temperature was never allowed to rise above 15°. The reaction was then stirred overnight at 25° before acidifying first with solid CO_2 and then to p*H* 4 with 2 *N* HCl. Extraction with ether and washing the ethereal extract (water, saturated brine) afforded on drying ($MgSO_4$) and evaporation some unreacted starting material (4.6 g); i.r. (Nujol) 3250–2300, 1670, 1605; m.p. 166–167°, undepressed on admixture with 2-hydroxy-3-methylbenzoic acid.

The p*H* of the residual aqueous solution was readjusted to about p*H* 8 with (solid) $NaHCO_3$, and the solution evaporated to dryness at 60°, under vacuum. The brown solid residue was extracted thoroughly on the steam bath with three portions of 90% aqueous ethyl alcohol (500 ml in total) according to the modified procedure of Baker and Brown (9). The residue (6.5 g) obtained on evaporation was then hydrolyzed on the steam bath with 2 *N* HCl for 1 h, in the presence of a layer of ether. Removal of the ethereal layer, washing (brine), and drying ($MgSO_4$) gave the crude dihydroxybenzoic acid derivative (3.9 g) which afforded the expected product (2.65 g, 43%) on recrystallization from 20% aqueous ethyl alcohol; m.p. 222–223° (dec.) (lit (12) m.p. 215° (dec.)); i.r. (Nujol) 3290–2400, 1660, 1605; n.m.r. (DMSO-d_6) 2.18 (3H, s), 6.97 (1H, d, $J = 3.2$ Hz), and 7.14 (1H, d, $J = 3.2$ Hz) p.p.m. (The acidic protons were unobservable.) The mass spectrum showed the expected molecular ion at *m/e* 168 (46) and major fragment ions at 150 (100) and 121 (74).

Anal. Calcd. for $C_8H_8O_4$: C, 57.14; H, 4.80. Found: C, 56.76; H, 4.86.

*Methyl 2-Hydroxy-5-methoxy-3-methylbenzoate (****16****)*

Esterification of the acid **15** was accompanied by concomitant methylation of the unhindered phenolic group when carried out by treating **15** (2.37 g, 14.5 mmol) with methyl sulfate (4.5 g, 36 mmol) and anhydrous potassium carbonate (5.0 g) in anhydrous acetone (20 ml). After refluxing for 2 h and stirring at room temperature overnight, the product was isolated as a semi-solid material (3.5 g). Chromatography on silica gel (80 g) and elution with 10% ether–benzene led to the recovery of pure **16** (1.71 g, 62%), m.p. 78–79° on recrystallization from petroleum ether (b.p. 60–70°); i.r. 3200, 2835, 1685, 1615; n.m.r. (CCl_4) 2.22 (3H, s), 3.68 (3H, s), 3.89 (3H, s), 6.83 and 6.97 (each 1H, d, $J = 3.2$ Hz), 10.44 (1H, s) p.p.m. The mass spectrum showed the expected molecular ion at *m/e* 196 (41), with major fragment ions at 164 (100), 136 (23), and 121 (14).

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17. Found: C, 61.54; H, 6.44.

*2-(2-Hydroxy-5-methoxy-3-methylphenyl)-2-propanol (****17****)*

The ester **16** (1.5 g, 7.5 mmol) in ether (35 ml) was added to a refluxing solution of methylmagnesium bromide, prepared from magnesium (0.65 g, 0.0265 g-atom) and excess methyl bromide in ether (15 ml) over 0.75 h and the reaction mixture refluxed for a further 2 h. Addition of saturated ammonium chloride solution (15 ml), extraction with ether, and evaporation afforded a pale brown solid (1.46 g) which gave a white solid (0.99 g, 66%) on recrystallization from petroleum ether (b.p. 60–70°), m.p. 99–100°; i.r. (Nujol) 3415, 3165, 2850, and 1605; n.m.r. ($CHCl_3$-d_1) 1.60 (6H, s), 2.21 (3H, s), 3.70 (3H, s), 4.73 (1H, s), 6.52 and 6.66 (each 1H, d, $J = 3.0$ Hz) p.p.m. The mass spectrum showed the expected molecular ion at *m/e* 196 (23), and major fragment ions at *m/e* 179 (21), 178 (100), 163 (37), 135 (11), 131 (31), and 119 (14).

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22. Found: C, 67.08; H, 8.02.

*2-(2-Hydroxy-5-methoxy-3-methylphenyl)propene (****18****)*

The tertiary alcohol **17** (490 mg) was refluxed for 5 h in anhydrous benzene (10 ml) containing iodine (5 mg). The cooled reaction mixture was washed successively with 5% sodium hydrogen sulfite solution, water, and saturated brine. Drying ($MgSO_4$) and evaporation afforded a mobile colorless oil (412 mg, 93%). The i.r. spectrum (liquid film) showed peaks at 3520, 2835, 1605, and 910, and the n.m.r. spectrum (CCl_4) 2.05, 2.18, 3.66 (each 3H, s), 5.08 (1H, bs), 5.16 (1H, s), 5.31 (1H, bs), 6.36 (1H, d, $J = 3.2$ Hz), and 6.50 (1H, d, $J = 3.2$ Hz) p.p.m. were in accord with expectation for the simple dehydration product **18**.

*2-(2,5-Dimethoxy-3-methylphenyl)-6-methoxy-2,4,4,8-tetramethylchroman (****9b****)*

Anhydrous hydrogen chloride was bubbled through the

o-isopropenylphenol derivative **18** (380 mg) for 15 min at $-10°$ (*cf.* Baker *et al.* (4)) and the reaction mixture allowed to warm to 25° (1 h). Excess iced water (100 ml) was added and the product extracted with ether. Washing the ethereal extracts (water, $NaHCO_3$ solution, water, and saturated brine), drying ($MgSO_4$), and evaporation afforded a very viscous pale yellow gum (355 mg) which did not crystallize on standing or cooling. Further purification was not attempted and the viscous oil was dissolved in anhydrous acetone (10 ml) containing methyl sulfate (200 mg) and anhydrous potassium carbonate (250 mg). After refluxing the mixture for 2 h and stirring overnight at 25°, the methylation product was isolated as a yellow gum (375 mg). Chromatography on silica gel (80 g) gave, on elution with 7% ether in benzene, a fraction (179 mg) which partly crystallized on standing. Isolation of the solid product (65 mg), m.p. 93–95°, was achieved by adding ice-cold pentane and thorough washing with the same solvent. The melting point of the product on admixture with pure methylated dimer "**D**" was undepressed (91–94°), and the identity of the two materials was further confirmed by comparison of the i.r., n.m.r., and mass spectra.

We thank the National Research Council of Canada for generous support of this work. Preliminary experiments by Mr. R. W. Mulligan and Mr. G. W. Nathan are gratefully acknowledged.

Oligoribonucleotide Synthesis. IV.[1] Approach to Block Synthesis

EVA S. WERSTIUK AND THOMAS NEILSON

Department of Biochemistry, McMaster University, Hamilton, Ontario

Received August 3, 1971

A convenient block synthesis for oligoribonucleotides of predetermined sequence is developed. Preparation and deblocking of protected tetranucleotide, Ph_3COCH_2CO.O-U(Thp)p(Cl_3Et)A^{bz}(Thp)p(Cl_3Et)U(Thp)p-(Cl_3Et)A^{bz}(Thp)-OH (**8**) to give UpApUpA is described. Phosphorylation of HO-U(Thp)-OH derivative (**1**; R = Ph_3COCH_2CO) and subsequent coupling with HO-A^{bz}(Thp)-OH (**4**) gave protected UpA (**5**). Specific removal of triphenylmethoxyacetyl group from **5** is accomplished by dilute methanolic ammonia. 5′-Hydroxyl group of resulting UpA derivative (**7**) is condensed with the 3′-phosphate derivative of **5** to give **8** in good overall yield.

Ease of mild alkaline cleavage, convenient ceric sulfate spray detection and enhancement of solubility, make the triphenylmethoxyacetyl group an excellent choice for 5′-protection of nucleoside derivatives.

Une synthèse commode des oligoribonucléotides de séquence déterminée est développée. La préparation et la déprotection du tétranucléotide (**8**), Ph_3COCH_2CO.O-U(Thp)p(Cl_3Et)A^{bz}(Thp)p(Cl_3Et)UThp)p-(Cl_3Et)A^{bz}(Thp)-OH en UpApUpA est décrite. La phosphorylation du dérivé (**1**) de HO-U(Thp)-OH (où R = Ph_3COCH_2CO) et le couplage ultérieur avec **4** = HO-A^{bz}(Thp)-OH donnant **5** = UpA protégé. L'enlèvement spécifique du groupe triphénylméthoxyacétyle sur **5** est effectué par une solution diluée d'ammoniac dans le méthanol. Le groupe hydroxyl-5′ du dérivé UpA **7** qui en résulte, est condensé sur le groupe phosphate au 3′ de **5** pour donner **8** avec un bon rendement global.

La facilité du clivage alcalin dans des conditions douces, la détection commode par pulvérisation de sulfate cérique et l'accroissement de la solubilité font du groupe triphénylméthoxyacétyle un réactif de choix pour la protection en 5′ de dérivés nucléosides.

Canadian Journal of Chemistry, **50**, 1283 (1972)

Synthesis of "tailor-made" oligoribonucleotides of defined length and sequence to function as model transfer RNAs in various site recognition studies, is an attractive proposition (1). Already some oligoribonucleotide fragments from enzymic digestions on native molecules have shown similar but reduced activities relative to their precursors (2, 3). To determine the exact points of interaction within these fragments, series of oligoribonucleotides with single base changes should be prepared and their binding assayed.

Chemical synthesis of oligoribonucleotides is still in the developmental stage, the literature (1, 4–7) only offers the preparation of trinucleotides. Deoxyoligoribonucleotide synthesis on the other hand, is more advanced because use is made of fragment coupling methods in which short sequences prepared by a stepwise method are linked together to give sequences of greater length. One example of a block synthesis being applied to the preparation of oligoribonucleotide has been reported (8). However, the conditions necessary for coupling protected trinucleotides, caused extensive cleavage to the starting material. Perhaps triisopropylbenzenesulfonyl chloride (TPS) activation of the phosphodiester linkages of these protected trinucleotides promoted undesirable coupling at the diphosphate centers producing unstable phosphotriester intermediates (attachment of three ribofuranosyl residues to one phosphate) which break down on work-up giving mixtures of many different species containing phosphodiester linkages.

Elimination of these undesirable side-reactions should be possible using protected trinucleotides which contain phosphotriester linkages, the "third" ester substituent being the easily removable β,β,β-trichloroethyl. Only the phosphate destined to become the new internucleotidic link should be allowed to be secondary. TPS activation in pyridine should be inert towards phosphotriester centers and reaction restricted to the terminal diphosphate sites ensuring linear sequences and excluding branched species. In a previous communication, a stepwise synthesis for short oligoribonucleotides using phosphotriester intermediates was described (1). However, in order to couple these

short sequences, the 5′-trityl group must be removed specifically so that a new internucleotide link can be created at that 5′-position. Unfortunately, acid hydrolysis necessary for cleavage also deblocks the tetrahydropyranyl groups which protect the hydroxyls at the 2′-positions. A new protecting group to substitute for the terminal 5′-trityl group was sought bearing in mind that its removal conditions must be neutral, but not catalytic, or mildly alkaline.

A 2,4-dinitrobenzenesulfenyl group appeared to be a reasonable choice, its removal being effected by hydrogen sulfide in pyridine. 5′-(2,4-Dinitrobenzenesulfenyl)-2′-*O*-tetrahydropyranyluridine (**1**; R = 2,4-dinitrobenzenesulfenyl) was prepared from 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) using a literature method (10). However, on phosphorylation with *β*,*β*,*β*-trichloroethyl phosphate and TPS in pyridine (11), the dinitrobenzenesulfenyl group was found to be too sensitive and this approach had to be abandoned.

Various substituted acetates were next considered. Sensitivity to alkaline cleavage increases in the series: acetate, methoxyacetate, and phenoxyacetate, the last two being removed by dilute methanolic ammonia in 1–2 h (12). Since ammonolysis of benzamido groups on the heterocyclic bases required 1–2 days under the same conditions, specific de-*O*-acylation should be possible at position 5′. 5′-*O*-Methoxyacetyl-2′-*O*-tetrahydropyranyluridine (**1**; R = $MeOCH_2CO$—) was prepared from 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9). Phosphorylation with *β*,*β*,*β*-trichloroethyl phosphate and TPS (11) was successful but on work-up, the pyridinium salt (**2**; R = $MeOCH_2CO$—) could not be extracted with methylene chloride. Apparently, the molecule is not as lipophilic as the corresponding 5′-trityl analogue (1). Since no other simple isolation procedure was available, this approach also was set aside. To make the 5′-grouping more lipophilic, the corresponding 5′-*O*-phenoxyacetate derivative (**1**; R = $PhOCH_2CO$—) was prepared from 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) in 79% yield. Phosphorylation (11) to give pyridinium salt (**2**; R = $PhOCH_2CO$—) was successful and isolation presented no problems. Coupling with a further mole of 2′-*O*-tetrahydropyranyluridine (**1**; R = H) gave protected UpU (**3**; R = $PhOCH_2CO$—) in 44% yield. Steric interference between the neighboring 2′-*O*-tetrahydropyra-

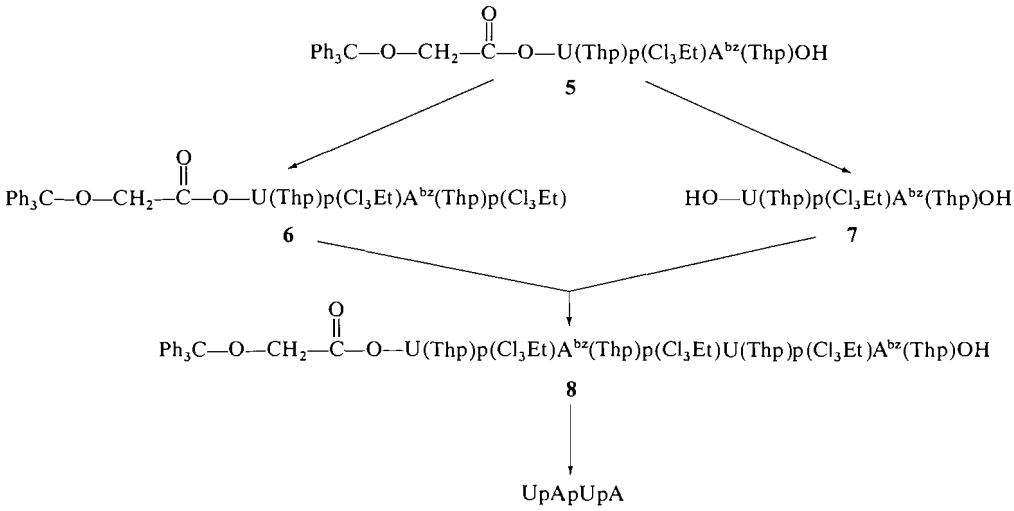
nyl group and the bulky TPS complex, together with the secondary nature of the 3′-hydroxyl group, ensures specific 5′-condensation (1). Removal of the phenoxyacetyl group was accomplished using 0.1 *N* ammonia in methanol for 1 h to give 2′-*O*-tetrahydropyranyluridylyl (3′-β,β,β-trichloroethyl-5′) 2′-*O*-tetrahydropyranyluridine (**4**; R = H) quantitatively. Thus, the 5′-position could be deblocked specifically leaving the rest of the protection intact.

Stepwise synthesis using groups other than trityls at the 5′-position had one inherent disadvantage in that detection of the product during its formation in the actual reaction or during column purification, was unsatisfactory. Compounds containing various trityl groups exhibit distinctive yellow–orange color on development with a ceric sulfate spray (1), whereas, those containing phenoxyacetyl groups give the ubiquitous brown coloration. Combination of trityl and phenoxyacetyl groups led directly to the "evolution" of a triphenylmethoxyacetyl group, compounds containing which, should be detectable by ceric sulfate spray, possess the necessary lipophilicity for extraction as a pyridinium salt, and be deblocked with dilute methanolic ammonia. Since cleavage of the trityloxyacetyl to the corresponding hydroxyacetyl would not be necessary and in fact, would be undesirable, the stable triphenylmethyl derivative was chosen.

Standard tritylation on methyl glycolate was carried out. Deesterification of the product gave sodium triphenylmethoxyacetate which on neutralization yielded the parent acid in good overall yield. The sodium salt was used in further reactions, the parent acid being required for characterization.

2′-*O*-Tetrahydropyranyl-5′-triphenylmethoxyacetyluridine (**1**; R = Ph_3COCH_2CO—) was prepared from 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) in good yield. Phosphorylation using pyridinium β,β,β-trichloroethylphosphate and TPS (11) to give 3′-phosphate derivative (**2**; R = Ph_3COCH_2CO—) was successful and isolation was routine. Coupling with 1 mol of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**4**) (13) gave the protected dinucleotide, 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridylyl (3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**5**)[2] in *ca.* 90% yield over the two steps. Again reaction would be expected to occur specifically at position 5′ of **4**.



SCHEME 2

[2]To condense the huge structural formulae necessary to describe protected oligoribonucleotides shown in the flow sheet, a shorthand method suggested by the IUPAC-IUB commission on Biochemical Nomenclature is adopted (14).

For example, 2′-*O*-tetrahydropyranyl-5′-triphenylmethoxyacetyluridylyl (3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine can be written as Ph_3COCH_2CO.O-U(Thp)p(Cl_3Et)A^{bz}(Thp)OH.

TABLE 1. The p.m.r. comparison of diastereoisomers of 7

Protons	Chemical shifts (δ in p.p.m.) High R_F isomer	Low R_F isomer	Signal J in Hz
2 of A	8.72	8.80	1H-s
8 of A	8.67	8.75	1H-s
o-PhCO and 6 of U	8.00	8.00	3H-m
m- and *p*-PhCO	7.60	7.60	3H-m
1′ of A	6.25	6.20	1H-d (both 6)
1′ of U	6.05	6.00	1H-d (both 8)
C-methylene of Thp	1.50	1.58	12H-broad m

Inspection of the t.l.c. of **5** showed two spots (R_F 0.70 and 0.62) in unequal amounts. An enriched sample of the major component (lower R_F) was isolated (45%) using careful column chromatography, p.m.r. data being obtained only for this component. Existence of isomerization around the tertiary phosphate of **5** could result in a pair of diastereoisomers,[3] the inequality in amounts resulting from the steric restrictions towards the reacting species in the second step of internucleotidic link formation. Complete removal of protection (1) on isomeric mixture **5** gave a single molecular species. Since deblocking will ultimately remove any chirality at phosphotriester centers, further transformations were carried out on the unseparated mixture.

Removal of the trityloxyacetyl group from **5** (both components) was smoothly accomplished in dilute methanolic ammonia to give protected dinucleotide **7** which on t.l.c. was shown to consist of an unequal mixture. Column chromatography on silica gel gave a major component (R_F 0.52) and a minor component (R_F 0.60) in the ratio of 2:1 and in a total yield of 93%. The p.m.r. spectra of these two isomers are summarized in Table 1. Each set of data indicated the correct structure for **7**. The subtle differences in chemical shifts could be explained by the occurrence of a diastereoisomeric pair. Prolonged methanolic ammonia treatment on unresolved **7** only gave debenzoylated materials; no interconversion was detected, the ratio of 2:1 remaining constant. Although the two components of **7** could be isolated, the unseparated mixture was used in further condensations.

Convenient specific removal of the triphenylmethoxyacetyl group from dinucleotide derivative (**5**) to give dinucleotide derivative (**7**) possessing free hydroxyl groups at both its 3′ and 5′ positions, meant that a block synthesis for oligoribonucleotides could now be undertaken. Dinucleotide derivative **5** was phosphorylated using the pyridinium salt of β,β,β-trichloroethylphosphate and TPS in pyridine to give pyridinium salt of 3′-phosphate derivative **6** which was successfully isolated by methylene chloride extraction. Immediate coupling of **6** with 1 mol of **7** gave the protected tetranucleotide **8** in 93% yield over two steps. As mentioned previously, the 5′-hydroxyl of a nucleoside derivative will participate preferentially in the second step of internucleotidic link formation, consequently the 5′-hydroxyl group of dinucleotide derivative **7** might be expected to react likewise to give specific 3′–5′ phosphotriester linkages. The t.l.c. of material **8** gave an extended oval spot as would be anticipated from a mixture of eight components (three chiral centers). The p.m.r. spectrum was too complicated for interpretation. Complete deblocking of **8** using the three step procedure described previously (1) gave the free tetranucleoside triphosphate, UpApUpA, as a single species in 95% yield.

Pancreatic ribonuclease treatment of UpApUpA gave ApUp as well as Up and A in the correct ratio. Combined pancreatic ribonuclease and alkaline phosphatase treatment of UpApUpA gave ApU as well as U and A in the correct ratio. Snake venom diesterase treatment on ApU gave A and pU in the correct ratio. Snake venom diesterase treatment of UpApUpA gave U, pA, and pU in the correct ratio. Complete digestions in each case confirmed the fidelity of the 3′–5′-diphosphate linkages (<1%,

[3]Existence of diastereoisomeric pairs of phosphotriesters has been reported independently (15).

Up	1.00	1.00	1.00	1.00

*Solvents: A, EtOH – 1 *M* NH_4OAc, p*H* 7.5 (7:3, v/v); B, 1-BuOH – glacial HOAc – H_2O (5:3:2, v/v); C, 2-PrOH – concentrated NH_4OH – H_2O (7:1:2, v/v).

2′–5′ linkage). Thus enzymic digestion confirmed the synthesis of tetranucleoside triphosphate (UpApUpA) and characterized ApU which contained the internucleotidic link formed between the two original UpA fragments (Table 2).

Extension to general block synthesis of oligoribonucleotides of predetermined sequence and length is now underway.

Experimental

The p.m.r. spectra were recorded on a Varian T60 or Varian HA-100 spectrometer in 10–15% (w/v) DMSO-d_6 – D_2O solutions, and line positions are reported in p.p.m. from the reference (TMS).

Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were usually developed in 5 or 10% methanol in methylene chloride mixtures. The t.l.c. detection was carried out using a ceric sulfate spray (1 g $H_4Ce(SO_4)_4$ in 10% aqueous sulfuric acid solution) and followed by heating the plates at 300–400 °C. Compounds containing a trityl group develop as yellow spots, while others appear as brown colorations.

Paper chromatography was performed using the descending technique on Whatman No. 1 or 3 MM paper. Analtech pre-coated cellulose plates (Avicel F) were used for t.l.c. of deblocked nucleotides. The solvent system employed for p.c. and t.l.c. on cellulose was ethanol – 1 *M* ammonium acetate, p*H* 7.5 (7:3, v/v). A short wave u.v. lamp was used for detection.

It was essential that moisture be excluded from all coupling reactions. After evaporation *in vacuo* of the pyridine solution, normal pressure was restored with dry nitrogen and *not* atmospheric air. All such evaporations were carried out in the temperature range 30–40 °C.

Emulsion, frequently obtained during methylene chloride extractions of aqueous pyridine solutions, was broken by the addition of a few milliliters of saturated sodium chloride solution.

*5′-O-Phenoxyacetyl-2′-O-tetrahydropyranyluridine (**1**; R = $PhOCH_2CO$)*

Lower R_F diastereoisomer of 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) (110 mg) was added to an anhydrous pyridine solution (5 ml) of phenoxyacetic acid (51 mg) and TPS (101 mg). Reaction proceeded overnight at room temperature and was followed by t.l.c. (R_F 0.25 → 0.55 in 5% CH_3OH–CH_2Cl_2). On the disappearance of starting material, ice (10 g) was added and the mixture extracted with methylene chloride (3 × 25 ml). The combined extracts were washed with water (2 × 25 ml) and evaporated *in vacuo* to an oil, the last traces of pyridine being removed by co-distillation with toluene (2 × 10 ml). The major component was purified using silica gel chromatography with methanol – methylene chloride as solvent to give a solid foam (122 mg, 79%). The p.m.r. data indicated monoesterification, signals (δ TMS) at 7.67 (1H-doublet, $J \simeq$ 8 Hz; 6 proton of U); 7.2 (5H-multiplet; phenyl protons); 5.93 (1H-doublet, $J \simeq 5$ Hz; 1′-anomeric proton); 5.63 (1H-doublet, $J \simeq 8$ Hz; 5 proton of U); 4.80 (2H-singlet; OCH_2CO); 4.70 (1H-singlet; Thp acetal proton); 4.1 (7H-broad multiplet; sugar protons and O—CH_2 of Thp); 1.57 p.p.m. (6H-broad multiplet; C—CH_2's of Thp). Non-reactivity towards trityl chloride confirmed 5′-substitution.

*5′-O-Phenoxyacetyl-2′-O-tetrahydropyranyluridine-3′-β,β,β-trichloroethylphosphate (**2**; R = $PhOCH_2CO$)*

Bis-cyclohexylamine salt (133 mg, 1.25 equiv) of mono-β,β,β-trichloroethylphosphate (11) was dissolved in anhydrous pyridine (10 ml) (warming was necessary) and converted to its corresponding pyridinium salt by repetitive evaporation *in vacuo* and solution in pyridine (4 × 10 ml).

Triisopropylbenzenesulfonyl chloride (TPS) (181 mg, 2.5 equiv) was added to the pyridinium salt in pyridine (10 ml). Thirty minutes later, 5′-*O*-phenoxyacetyl-2′-*O*-tetrahydropyranyluridine (122 mg, 1 equiv; R_F 0.55 in 5% CH_3OH–CH_2Cl_2) was added as a pyridine solution (5 ml). The reaction mixture was sealed under nitrogen and left at room temperature for 1–2 days in the dark. The t.l.c. indicated the phosphorylation was complete (R_F 0.55 → 0.05 in 5% CH_3OH–CH_2Cl_2). Ice (2 g) was added and the quenched reaction left for 30 min, poured into ice-water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

(20 ml), and then extracted with methylene chloride (4 × 20 ml). The combined organic extracts were washed with distilled water (2 × 20 ml). Methylene chloride was removed by evaporation *in vacuo* and replaced by anhydrous pyridine (10 ml). This pyridine solution containing the pyridinium salt (**2**; R = $PhOCH_2CO$) of the desired nucleotide derivative was used immediately to form blocked dinucleotide derivatives.

*5′-O-Phenoxyacetyl-2′-O-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)2′-O-tetrahydropyranyluridine (**3**; R = $PhOCH_2CO$)*

TPS (91 mg, 1.25 equiv) was added to the pyridine solution of blocked uridylate derivative (**2**; R = $PhOCH_2CO$) prepared in the previous experiment and activation was allowed to proceed for 30 min at room temperature. The lower R_F diastereoisomer of 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) (90 mg, 1.1 equiv) dissolved in anhydrous pyridine (5 ml) was added and the sealed reaction mixture was left at room temperature for 1–2 days in the dark. The t.l.c. indicated coupling was complete (R_F 0.05 → 0.50 in 5% CH_3OH–CH_2Cl_2). Ice (2 g) was added and after 30 min the aqueous pyridine solution was poured into ice-water (20 ml) and extracted with methylene chloride (4 × 20 ml) and evaporated *in vacuo* to an oily residue, the last traces of pyridine being removed by co-distillation with toluene (2 × 10 ml). The residue was dissolved in methylene chloride (50 ml) and subjected to column chromatography on silica gel. Elution with 2% CH_3OH–CH_2Cl_2 gave the appropriate fractions which were pooled and evaporated *in vacuo* to give the blocked dinucleotide (**3**; R = $PhOCH_2$-CO) (110 mg, 44%) as a solid foam. The p.m.r. spectrum showed signals (δ TMS) at 7.43 (2H-superimposed doublets, both $J \simeq 8$ Hz; 6 protons of Us); 6.9 (5H-multiplet; phenyl protons); 5.80 (2H-superimposed doublets, $J \simeq 6$ and 7 Hz; 1′-anomeric protons); 5.48 (2H-superimposed doublets, both $J \simeq 8$ Hz; 5 protons of Us); 4.71 (2H-singlet; OCH_2-CO); 4.60 (2H-superimposed singlets; Thp acetal protons); 4.1 (16H-broad multiplet; sugar protons, O—CH_2 of Thps and O—CH_2 of Cl_3CCH_2O); 1.57 p.p.m. (12H-broad multiplet; C—CH_2's of Thps).

*2′-O-Tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)2′-O-tetrahydropyranyluridine (**3**; R = H)*

5′-*O*-Phenoxyacetyl-2′-*O*-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)2′-*O*-tetrahydropyranyluridine (**3**; R = $PhOCH_2CO$) (40 mg) was dissolved in 0.1 *N* methanolic ammonia (5 ml). Reaction was followed by t.l.c. in 10% CH_3OH–CH_2Cl_2 (R_F 0.65 → 0.43) and was complete in 30 min. Evaporation *in vacuo* gave a residue which was extracted with anhydrous ether (6 × 5 ml) to leave a solid foam (22 mg, 81%). The p.m.r. spectrum showed signals (δ TMS) at 7.30 (2H-superimposed doublets, $J \simeq 8$ Hz; 6 protons of Us); 6.00 (2H-superimposed doublets, both $J \simeq 6$ Hz; 1′ anomeric protons); 5.63 (2H-superimposed doublets, both $J \simeq 8$ Hz; 5 protons of Us); 1.53 p.p.m. (12H-broad multiplet C—CH_2's of Thps); no $PhOCH_2CO$ signals.

Methyl Triphenylmethoxyacetate

A mixture of methyl glycolate (5.0 g, 0.055 mol), triphenylchloromethane (18.0 g, 0.065 mol) in anhydrous pyridine (50 ml) was set aside at room temperature in the dark. After 2 days ice (20 g) was added, and stirring continued for a further hour. The reaction mixture was then poured into ice-water (200 ml) and repeatedly extracted with methylene chloride (3 × 50 ml). Combined organic extracts were washed and evaporated to dryness *in vacuo*. Last traces of pyridine were removed by co-distillation with toluene (3 × 30 ml) to give a solid residue (16.2 g) which was used in the next reaction. A pure sample of the methyl ester was obtained by chromatography on silica gel in 20–30% methylene chloride – hexane mixtures. The p.m.r. spectrum of methyl triphenylmethoxyacetate showed signals (δ TMS) at 7.28 (15H-multiplet; trityl aromatic protons); 3.75 (2H-singlet; —OCH_2CO protons); and 3.58 p.p.m. (3H-singlet; OCH_3 protons).

Sodium Triphenylmethoxyacetate

To a suspension of crude methyl triphenylmethoxyacetate (16.2 g) in ethanol (75 ml), 4 *N* sodium hydroxide solution (75 ml) was added, and the reaction mixture stirred at room temperature. After 16 h t.l.c. indicated *ca.* 90% hydrolysis of the ester (R_F 0.95 → 0.0–0.20 in 10% CH_3OH–CH_2Cl_2). The reaction mixture was then poured into ice-water (100 ml) and repeatedly extracted with methylene chloride (4 × 50 ml). Combined organic extracts were evaporated *in vacuo*, and residue (20.0 g) triturated with benzene (2 × 30 ml), then hexane (6 × 30 ml) to give sodium salt of triphenylmethoxyacetic acid (15.10 g, 84% yield over two steps) which was used directly for reactions involving nucleosides described below.

Acid (1.67 g) m.p. 101–103° was obtained by neutralizing a methylene chloride solution of the sodium salt (1.84 g in 40 ml) with Dowex 50W (pyridinium form) and crystallization from petroleum ether (30–60°). The p.m.r. spectrum of triphenylmethoxyacetic acid showed signals (δ TMS) at 8.5 (1H-broad singlet; —COOH proton); 7.35 (15H-multiplet; trityl aromatic protons); and 3.60 p.p.m. (2H-singlet; —OCH_2CO protons).

Anal. Calcd. for $C_{21}H_{18}O_3$ (mol. wt. 318.35): C, 79.22; H, 5.70. Found: C, 79.31; H, 5.60.

The mass spectrum of triphenylmethoxyacetic acid (recorded at 200°) showed a strong M^+ peak at 318 *m/e*; and further peaks at 259 (M-59, corresponding to fragment Ph_3C—O—; and loss of —CH_2—COOH), 243 (M-75, corresponding to fragment Ph_3C—, and loss of —O—CH_2—COOH).

*2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridine (**1**; R = Ph_3COCH_2CO)*

Sodium triphenylmethoxyacetate (2.72 g, 0.008 mol) was evaporated *in vacuo* from anhydrous pyridine (2 × 30 ml) and finally its volume reduced to *ca.* 20 ml. The solution was sealed under nitrogen, TPS (1.34 g, 0.0044 mol) added, and the reaction mixture allowed to stand at room temperature for 2 h. The low R_F diastereoisomer of 2′-*O*-tetrahydropyranyluridine (**1**; R = H) (9) (1.31 g, 0.004 mol; R_F 0.40 in 10% CH_3OH–CH_2Cl_2) was evaporated from anhydrous pyridine (2 × 30 ml) and finally its volume reduced to *ca.* 10 ml. This solution was then added to the triphenylmethoxyacetic acid–TPS complex (prepared above) and the reaction mixture set aside at room temperature for 1–2 days in the dark. A further portion of TPS (0.33 g, 0.0011 mol) was added after 1 day to ensure complete esterification. After 2 days t.l.c. indicated *ca.* 90% conversion into a product of R_F 0.80 in 10% CH_3OH–CH_2Cl_2. Ice (20 g) was then added to the mixture, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

stirring continued for a further hour. The reaction mixture was then poured into ice-water (100 ml) and repeatedly extracted with methylene chloride (6 × 30 ml). The combined organic extracts were washed, and evaporated to dryness *in vacuo*. The yellow glass obtained was purified by chromatography on silica gel (40 g) in methylene chloride. Elution with methylene chloride (400 ml) removed some impurity (R_F 0.78). Elution with 0.5% methanol – methylene chloride mixture yielded some impure product (0.336 g). Pure 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridine (1.32 g, 53%) (R_F 0.82 in 10% CH_3OH–CH_2Cl_2) was obtained by elution with 1.0–1.5% methanol – methylene chloride mixtures (400 + 400 ml). The p.m.r. spectrum showed signals (δ TMS) at 7.38 (16H-multiplet; trityl aromatic protons and 6-proton of U); 5.90 (1H-doublet; $J \simeq 6$ Hz; 1′-anomeric proton); 5.50 (1H-doublet; $J \simeq 8$ Hz; 5-proton of U); 4.75 (1H-singlet; Thp acetal proton); 3.80 (2H-singlet; OCH_2CO); 1.58 p.p.m. (6H-broad multiplet; C—CH_2 of Thp).

Anal. Calcd. for $C_{35}H_{36}N_2O_9$ (mol. wt. 628.658): C, 66.87; H, 5.77; N, 4.46. Found: C, 67.15; H, 5.89; N, 4.21.

The mass spectrum of 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridine (recorded at 370°) showed *no* M^+ peak, but peaks at 385 *m/e* (M-243, loss of Ph_3C—); 355 (M-273, loss of Ph_3C—O—); 326 (M-302; loss of Ph_3C—O—CH_2—CO—); 243 (M-385; loss of —O—CH_2—CO—O—U(Thp)—OH); 241 (M-387; loss of Ph_3C—O—CH_2—CO—, and Thp); 215 (M-413; loss of Ph_3C—O—CH_2—CO—, and uracil base); 112 (M-514; loss of Ph_3C—O—CH_2—CO—, Thp and ribose).

2′-*O*-Tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridine (**1**; R = Ph_3COCH_2CO) (145 mg, R_F 0.82 in 10% CH_3OH–CH_2Cl_2) was suspended in dilute methanolic ammonia (5 ml, prepared by tenfold dilution of saturated (at 0°) methanolic ammonia with methanol) and stirred at room temperature. After 1 h t.l.c. indicated complete regeneration of starting material (**1**; R = H) (R_F 0.43 in 10% CH_3OH–CH_2Cl_2).

2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridine-3′-β,β,β-trichloroethyl Phosphate (2; R = Ph_3COCH_2CO)

Bis-cyclohexylamine salt (2.25 g, 0.005 mol; 2 equiv) of mono-β,β,β-trichloroethyl phosphate (**11**) was dissolved in anhydrous pyridine (50 ml) with warming, and converted to its pyridinium salt by repetitive evaporation *in vacuo* and solution in pyridine (5 × 50 ml). The TPS (3.02 g, 0.01 mol; 4 equiv) was then added to the pyridinium salt in pyridine (50 ml). After 1 h a pyridine solution of 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridine (**1**; R = Ph_3COCH_2CO) (1.5 g, 0.0025 mol; 1 equiv; R_F 0.82 in 10% CH_3OH–CH_2Cl_2) was added to the yellow solution and the reaction mixture sealed under nitrogen and set aside at room temperature in the dark. After 1–2 days t.l.c. indicated complete conversion into a product of R_F 0.0–0.24 in 10% CH_3OH–CH_2Cl_2. Ice (20 g) was added and the quenched reaction left for 30 min, poured into ice-water (250 ml), and repeatedly extracted with methylene chloride (4 × 50 ml). The combined organic extracts were washed with distilled water (4 × 50 ml). Methylene chloride was removed by evaporation *in vacuo* and replaced by anhydrous pyridine (50 ml). This pyridine solution, containing the pyridinium salt of (**2**; R = Ph_3COCH_2CO) was used immediately to form blocked dinucleotide phosphate derivatives.

2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N⁶-benzoyl-2′-O-tetrahydropyranyladenosine (5)

TPS (0.80 g, 0.0027 mol; 1.1 equiv) was added to the blocked uridylate derivative (**2**; R = Ph_3COCH_2CO) and activation allowed to proceed for 30 min at room temperature in the dark. The low R_F diastereoisomer of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**4**) (1.70 g, 0.0037 mol; 1.5 equiv; R_F 0.48 in 10% CH_3OH–CH_2Cl_2) dissolved in anhydrous pyridine (30 ml) was added and the reaction mixture sealed under nitrogen, and set aside at room temperature for 2–3 days in the dark. On the second day a further portion of TPS (0.36 g, 0.55 equiv) was added to ensure complete coupling. After 3 days t.l.c. indicated *ca.* 90% conversion into a product of R_F 0.62–0.70 in 10% CH_3OH–CH_2Cl_2. Ice (20 g) was then added to the mixture, and stirring continued for further 30 min. The reaction mixture was then poured into ice-water (200 ml) and repeatedly extracted with methylene chloride (5 × 50 ml). The combined organic extracts were washed with water (5 × 30 ml) and evaporated *in vacuo*. The last traces of pyridine were removed by co-distillation with toluene (3 × 30 ml). Methylene chloride (30 ml) was then added to the residue, and the precipitated tri-isopropylbenzenesulfonic acid was filtered off. The filtrate was purified by chromatography on silica gel (120 g) in methylene chloride. Elution with 2.5–3.0% methanol – methylene chloride mixtures (1 + 1 l) yielded a *ca.* 4:1 mixture of **5** and **4** (3.2 g, R_F 0.62–0.70; and 0.45 in 10% CH_3OH–CH_2Cl_2). This mixture could *not* be purified further by chromatography, so it was treated with an excess of *p*-anisylchlorodiphenylmethane (0.45 g, 1.5 mmol, *ca.* 1.1 equiv, based on a 4:1 mixture of **5** and **4**) in anhydrous pyridine (30 ml). The reaction mixture was set aside at room temperature in the dark. After 16 h t.l.c. indicated *complete* conversion of **4** into N^6-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyladenosine (R_F 0.84 in 10% CH_3OH–CH_2Cl_2). Ice (20 g) was then added, and stirring continued for further 30 min. The reaction mixture was then poured into ice-water (250 ml), and repeatedly extracted with methylene chloride (5 × 50 ml). The combined organic extracts were washed with water (5 × 50 ml), and evaporated *in vacuo* to give a yellow glass. This mixture was separated by chromatography on silica gel (50 g) in methylene chloride. Washing the column with methylene chloride (200 ml); 0.5–1% methanol – methylene chloride mixtures (200 + 200 ml) removed the trityl alcohol. Elution with 2.0% methanol – methylene chloride mixture (800 ml) yielded the 5′-*O*-*p*-methoxytrityl ether of **4** (0.8 g, R_F 0.83 in 10% CH_3OH–CH_2Cl_2). Continued elution with 2.5% methanol – methylene chloride mixture (800 ml) yielded a mixture of the isomers of **5** (0.262 g, R_F 0.80 and 0.72 in 10% CH_3OH–CH_2Cl_2) of an enriched sample of the lower R_F isomer **5** (1.44 g; 45% yield) was obtained by eluting the column with 3.0% methanol – methylene chloride mixture (400 ml). Further 0.25 g of an impure sample of **5** was isolated on elution with 4% methanol – methylene chloride mixture (400 ml).

The p.m.r. spectrum of the lower R_F isomer showed signals (δ TMS) at 8.65 and 8.60 (2H-singlets: 2- and 8-protons of A) 8.20 (2H-multiplet; *o*-benzoate protons); 7.42 (19H-multiplet; trityl aromatic protons, 6-proton of U; and other benzoate protons); 6.38 (1H-doublet; $J \simeq 4$ Hz; 1′-anomeric proton of A); 6.02 (1H-doublet; $J \simeq 6$ Hz;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1′-anomeric proton of U); 5.65 (1H-doublet; $J \simeq 8$ Hz; 5-proton of U); 3.95 (2H-singlet; OCH_2CO); 1.78 p.p.m. (6H-broad multiplet; C-methylenes of Thp).

Uridylyl(3′–5′)adenosine (UpA)

A solution of 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**5**) (15 mg, R_F 0.62–0.70 in 10% CH_3OH–CH_2Cl_2) in *N*,*N*-dimethylformamide (1.0 ml) was stirred at 50° with Cu–Zn couple (*ca.* 20 mg). After 1 day t.l.c. indicated complete conversion of starting material into a product of R_F origin in 10% CH_3OH–CH_2Cl_2. Half saturated methanolic ammonia (1 ml) was then added, and the reaction mixture stirred at room temperature for 2 days. *N*-Ammonia solution (1 ml) was added, and the Cu–Zn couple filtered off, and washed well with dilute ammonia. The combined filtrate and washings were carefully concentrated *in vacuo* and the solution p*H* brought to 8–10. Dowex 50 W (NH_4^+ form; *ca.* 1 g) was added, and the mixture stirred at room temperature for 15 min. The resin was filtered off and washed well with water. The combined filtrate and washings were concentrated *in vacuo* to *ca.* 20 ml. The p*H* of the solution was then adjusted to 2.0 with 0.1 *N* hydrochloric acid solution, and the reaction mixture stirred at room temperature. After 2 days t.l.c. on cellulose plates indicated that the hydrolysis was complete (R_F 0.76 → 0.32) UpA (144 o.d.$_{260}$ 93%, R_{Up} 1.50) was isolated and purified using preparative paper chromatography.

2′-O-Tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine (7)

2′-*O*-Tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**5**) (0.516 g; 0.004 mol; R_F 0.62–0.70 in 10% CH_3OH–CH_2Cl_2) was suspended in dilute methanolic ammonia (50 ml, prepared by tenfold dilution of a saturated (at 0°) methanolic ammonia with methanol) and stirred at room temperature. After 1 h t.l.c. indicated complete conversion into *two* products of R_F 0.60 and 0.52 in 10% CH_3OH–CH_2Cl_2 in a ratio of *ca.* 1:2. The reaction mixture was then evaporated *in vacuo*, and the mixture separated by chromatography on silica gel (15 g) in methylene chloride. Washing the column with methylene chloride (200 ml) and 0.5–1.0% methanol–methylene chloride mixtures (200 + 200 ml) removed the triphenylmethoxyacetamide. Elution with 2.5% methanol–methylene chloride mixture (400 ml) yielded the pure high R_F isomer (R_F 0.60; 0.073 g). Continued elution with 3.0–4.0% methanol–methylene chloride mixtures (400 + 200 ml) gave a mixture (R_F 0.60 + 0.52; 0.131 g). Finally, pure low R_F isomer was obtained (R_F 0.52, 0.166 g) on elution with 5% methanol–methylene chloride mixture (400 ml) (total yield: 0.370 g, 93%). For the p.m.r. spectra: see Table 1.

2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine-3′-β,β,β-trichloroethyl Phosphate (6)

Bis-cyclohexylamine salt (0.180 g, 0.0004 mol, 2 equiv) of mono-β,β,β-trichloroethyl phosphate was converted into its pyridinium salt as described previously. TPS (0.240 g, 0.0008 mol; 4 equiv) was then added to the pyridinium salt. After 1 h a pyridine solution of **5** (0.260 g, 0.0002 mol; 1 equiv; R_F 0.62–0.70 in 10% CH_3OH–CH_2Cl_2) was added to the yellow solution, and the reaction mixture sealed under nitrogen and set aside at room temperature in the dark. After 2 days t.l.c. indicated complete conversion of starting material into a product of R_F 0.0–0.30 in 10% CH_3OH–CH_2Cl_2. Ice (5 g) was then added followed 30 min later by a similar methylene chloride extraction as described for (**2**; R = Ph_3COCH_2CO). Blocked UpAp **6** was obtained as its pyridinium salt in pyridine and was used immediately in the next step.

2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenylyl(3′-β,β,β-trichloroethyl-5′)-2′-O-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine (8)

TPS (66 mg, 0.22 mmol; 1.1 equiv) was added to the pyridine solution of blocked UpAp **6** pyridinium salt prepared above. After 1 h a mixture of isomers of 2′-*O*-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**7**) (300 mg, 0.30 mmol; 1.5 equiv; R_F 0.60 + 0.52 in 10% CH_3OH–CH_2Cl_2) was added, and the reaction mixture sealed under nitrogen, and set aside at room temperature for 2–4 days in the dark. After 2 days a further portion of TPS (66 mg, 0.22 mmol; 1.1 equiv) was added to ensure complete coupling. After 4 days t.l.c. indicated *ca.* 90% conversion into a product of R_F 0.80–0.88 in 10% CH_3OH–CH_2Cl_2. After a similar work-up described for **5** the product was purified by chromatography on silica gel (20 g) and alumina (5.0 g) in methylene chloride.

Elution with 1% methanol–methylene chloride mixture (200 ml) yielded an impurity (62 mg, R_F 0.94 in 10% CH_3OH–CH_2Cl_2). Elution with 2.0–2.5% methanol–methylene chloride mixtures (200 + 200 ml) gave the faster R_F isomer (32 mg, $R_F \simeq 0.6$ in 10% CH_3OH–CH_2Cl_2). Continued elution with 3.0% methanol–methylene chloride mixture (400 ml) yielded a mixture of the isomers (0.308 g, $R_F \simeq 0.60 + \simeq 0.55$ in 10% CH_3OH–CH_2Cl_2). Finally, the lower R_F isomers (0.316 g, $R_F \simeq 0.55$ in 10% CH_3OH–CH_2Cl_2) were obtained, contaminated with some unreacted starting material **7**. The last impure fraction (0.316 g) was re-chromatographed on silica gel (10 g) and alumina (5.0 g) in methylene chloride. Enriched lower R_F isomers of **8** were obtained (0.133 g, $R_F \simeq 0.55$ in 10% CH_3OH–CH_2Cl_2) on eluting the column with 3.0–3.5% methanol–methylene chloride mixtures (400 + 400 ml). A mixture, containing **8** + **7** (0.092 g, R_F 0.55–0.37 in 10% CH_3OH–CH_2Cl_2) was finally eluted with 4.0–5.0% methanol–methylene chloride mixtures (400 + 200 ml). (Combined yield of enriched isomers of **8**: 0.032 + 0.308 + 0.133 g; 93%.) Since no single isomer could be isolated, no p.m.r. spectrum was recorded.

Uridylyl(3′–5′)adenylyl(3′–5′)uridylyl(3′–5′)adenosine (UpApUpA)

A solution of 2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetyluridylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenylyl(3′-β,β,β-trichloroethyl-5′)-2′-*O*-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)-N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**8**) (15 mg, R_F 0.60–0.55 in 10% CH_3OH–CH_2Cl_2) in *N*,*N*-dimethylformamide (1.0 ml) was stirred at 50° with Cu–Zn couple (*ca.* 20 mg). After 1 day t.l.c. indicated complete conversion of starting material into a product of R_F: origin in 10% CH_3OH–CH_2Cl_2. Half-saturated methanolic ammonia

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(1 ml) was then added, and the reaction mixture stirred at room temperature for 2 days. *N*-Ammonia solution (1 ml) was added, and Cu–Zn couple filtered off and washed well with dilute ammonia. Combined filtrate and washings were carefully concentrated *in vacuo* and the solution p*H* brought to 8–10. Dowex 50 W (NH_4^+ form; *ca* 1 g) was added, and the mixture stirred at room temperature for 15 min. The resin was filtered off and washed well with water. The combined filtrate and washings were concentrated *in vacuo* to *ca.* 20 ml. The p*H* of the solution was then adjusted to 2.0 with 0.1 *N* hydrochloric acid solution, and the reaction mixture stirred at room temperature. After 2 days t.l.c. on cellulose indicated that the hydrolysis was complete. (R_F 0.80 → 0.07) UpApUpA (260 o.d.$_{260}$, 95%; R_{Up} 0.36) was isolated and purified using preparative paper chromatography.

Enzymatic Analysis of UpApUpA

Pancreatic RNase Digestions

A solution of the ammonium salt of UpApUpA (10 o.d.) in 0.2 ml of Tris buffer (0.1 *M*; p*H* 8.0) was digested completely at 37° with 100 λ of Pancreatic Ribonuclease (Calbiochem., Grade A, 1 mg/ml) for 16 h. Paper chromatographic analysis showed the expected products (Up + ApUp + A) of R_{Up} 1.04, 0.74, 1.92 respectively, in the correct ratio. The t.l.c. analysis also showed the expected products (Up + ApUp + A) of R_{Up} 0.93, 0.40, 3.50 respectively in correct ratio.

To the above incubation mixture further 100 λ of Bacterial alkaline phosphatase (Worthington, 0.5 mg/ml) was added. Paper chromatographic analysis showed the expected products (U + ApU + A) of R_{Up} 2.15, 1.30, 1.92 respectively, in the correct ratio. The t.l.c. analysis also showed the expected products (U + ApU + A) of R_{Up} 5.2, 1.65, 3.55 respectively in correct ratio.

Snake Venom Diesterase Digestions

A solution of the ammonium salt of UpApUpA (10 o.d.) in 0.2 ml of Tris buffer (0.1 *M*; p*H* 8.0) was digested completely at 37° with 100 λ of Snake Venom Diesterase (Worthington, 1 mg/ml) for 16 h. Paper chromatographic analysis showed the expected products (U + 2pA + pU) of R_{Up} 2.10, 0.72, 0.93 respectively in correct ratio. The t.l.c. analysis also showed the expected products (U + 2pA + pU) of R_{Up} 5.2, 0.74, 0.64 respectively, in correct ratio.

A solution of the ammonium salt of ApU (18 o.d.) isolated by preparative paper chromatography from PRNase–Alk phosphatase digestion (40 o.d. scale), in 0.2 ml Tris buffer (0.1 *M*; p*H* 8.0) was digested completely at 37° with 100 λ of Snake Venom Diesterase for 16 h. Paper chromatographic analysis showed the expected products (A + pU) of R_{Up} 1.94, 0.92 respectively, in the correct ratio. The t.l.c. analysis also showed the expected products (A + pU) of R_{Up} 3.55, 0.65 respectively, in the correct ratio.

Selective Reduction of Carbohydrate Nitroolefins[1,2]

HANS H. BAER AND WERNER RANK

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received November 18, 1971

Reduction of the four stereoisomeric methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-hex-2-enopyranosides (**1**–**4**) with sodium borohydride gave in 80–90% yield the corresponding saturated nitro glycosides that possess an equatorial nitro group (**5**–**8**). Reduction of **1**–**4** with zinc and acetic acid gave in similar yields the corresponding 2,3-dideoxy-3-oximino glycosides (**9**–**12**). Two of the latter were deoximated to 2,3-dideoxy-3-oxo sugar derivatives.

La réduction des quatre méthyl 4,6-*O*-benzylidène-2,3-didéoxy-3-nitro-hex-2-énopyranosides (**1**–**4**) stéréoisomères par le borohydrure de sodium conduit avec un rendement de 80–90% aux nitro glycosides saturés correspondants qui possèdent un groupe nitro en position équatoriale (**5**–**8**). La réduction de **1**–**4** par le zinc dans l'acide acétique conduit avec un rendement similaire aux 2,3-didéoxy-3-oximino glycosides correspondants (**9**–**12**). Parmi ces derniers, deux ont été soumis à une désoximation pour conduire aux sucres 2,3-didéoxy-3-oxo.

Canadian Journal of Chemistry, **50**, 1292 (1972)

In early work on nitro sugars, which has been comprehensively reviewed by Sowden (1), conversion of polyhydroxy-α-nitroalkenes into saturated nitro alditols was achieved by palladium-catalyzed hydrogenation in ethanolic solution. Use of ethyl acetate as the solvent has been said (1) to diminish the selectivity of this hydrogenation. Nevertheless, in our own previous work, which dealt with glycosides containing an endocyclic α-nitroalkene grouping, facile and selective hydrogenation of the olefinic bond by palladium on charcoal in an ethyl acetate medium has been observed in certain cases. Thus, the methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohex-2-enopyranosides with β-D-*erythro* (**1**) and β-D-*threo* (**2**) configuration gave high yields of the saturated methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*arabino*- and β-D-*lyxo*-hexopyranosides, **5** and **6**, respectively (2, 3). In the corresponding α-anomers, on the other hand, the same procedure was not selective. Thus, the α-D-*erythro* (**3**) and α-D-*threo* (**4**) olefins afforded saturated nitro glycosides (**7** and **8**) in lesser yields, and these were accompanied by substantial proportions (49 and 30%) of oximes, namely the methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-oximino-α-D-*erythro*- and α-D-*threo*-hexopyranosides, **11** and **12**, respectively (4). An explanation for the differential behavior of α- and β-glycosides in these catalytic hydrogenations has been given (4).

We now describe selective chemical reductions by which the four nitroolefins (**1**–**4**) have afforded in 80–90% yields either the saturated nitro compounds (**5**–**8**) or the oximes (**9**–**12**), regardless of configuration. Sodium borohydride in ethanol, first applied to nitroalkenes including one from the carbohydrate series by Shechter and coworkers (5), smoothly gave **5**–**8**. There was no evidence for formation of the corresponding 3-epimers (with axial nitro group) or other reduction products.[3]

Reduction with zinc and acetic acid, a method known to convert nitroalkenes into oximes (7, 8), was then applied to **1**–**4**, and oximino glycosides were produced exclusively. In addition to the known α-glycosides **11** and **12**, their β-anomers **9** and **10** were thus obtained for the first time. Acetylation of **9** and **10** gave the corre-

[1]Part XXVII in a series on reactions of nitro sugars. For Part XXVI see ref. 15.

[2]Presented before the Joint Conference of the Chemical Institute of Canada and the American Chemical Society, Toronto, Ontario, May 25, 1970.

[3]Szarek and coworkers (6) have reported that borohydride reduction of benzyl 2-*O*-benzyl-3,4-dideoxy-4-nitro-α-D-*glycero*-pent-3-enopyranoside produces an axial nitro group, the product having the β-L-*threo* configuration. Furthermore, they have reduced in the same way carbohydrate derivatives containing an exocyclic α-nitroalkene group.

sponding acetoximino derivatives **13** and **14**. The i.r. and n.m.r. spectral data confirmed the structures (see Experimental).

The facile availability of oximino from nitro sugars may provide an attractive avenue to oxo sugars as an alternative to oxidative procedures. Lemieux and coworkers (9) have successfully deoximated 2-oximino glycosides by use of levulinic acid (10). To test this method in the present series it was applied to **11**, giving known methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**15**) (11, 12) in 77% yield. Similar deoximation of **9** quantitatively produced the β-anomer (**16**) of **15**.

Experimental

The methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-hex-2-enopyranosides **1** (2, 13), **2** (13, 14), **3** (4), and **4** (4, 15) were prepared as described in the literature. Special reference is made to improved procedures for preparation of some of the nitro glycoside precursors required (15). Reactions were monitored by t.l.c. on silica gel G plates with mixtures of ethyl acetate and petroleum ether (b.p. 30–60°) as irrigating solvent. The i.r. spectra were taken from Nujol mulls. The n.m.r. data were obtained from 100 MHz spectra taken with a TMS lock signal. Specific rotations were measured in an automatic polarimeter at room temperature and in sample concentrations of 0.5–1.2%.

Reductions with Sodium Borohydride

A solution of sodium borohydride (50 mg) in ethanol (5 ml) was mixed with the solution of a given nitroolefin (100 mg) in ethanol (10 ml), and the reaction mixture was magnetically stirred at room temperature. Reaction times were 3 h for **1**, 2 h for **2**, and **1** h for **3** and **4**. Sodium ion was then removed by cation exchange, the resin was washed well with ethanol, and the combined filtrate and washing solvent was evaporated to dryness. Several portions of methanol were then evaporated from the residue which was finally recrystallized from ethyl acetate–petroleum ether (b.p. 30–60°) to give the pure saturated nitro glycoside. The following results were obtained.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-D-arabino-hexopyranoside (5) from 1

Yield, 87%; m.p. 149–150°; $[\alpha]_D$ −96.1° (in chloroform). Reported (2): m.p. 148–149°, $[\alpha]_D$ −95.5°.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-D-lyxo-hexopyranoside (6) from 2

Yield, 89%; m.p. 177–179°; $[\alpha]_D$ +21.7° (in dimethylformamide). Reported (3): m.p. 176°; $[\alpha]_D$ +15.2°.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-α-D-arabino-hexopyranoside (7) from 3

Yield, 91%; m.p. 108–110°; $[\alpha]_D$ +67.0° (in chloroform). Reported (4): m.p. 112°; $[\alpha]_D$ +67°.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-α-D-lyxo-hexopyranoside (8) from 4

Yield, 81%; m.p. 108–109°; $[\alpha]_D$ +155.5° (in dimethylformamide). Reported (4): m.p. 108°.

Reductions with Zinc and Acetic Acid

To the solution of a given nitroolefin (293 mg, 1 mmol) in ether (30 ml) was added zinc dust (600 mg) and 4 *N* acetic acid (1.5 ml). The mixture was heated under reflux for 1 h, filtered, and evaporated to give a residue from which several portions of added methanol were evaporated. Finally, recrystallization of the residue from ethyl acetate–petroleum ether furnished the pure oximino glycoside.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-oximino-β-D-erythro-hexopyranoside (9) from 1

Yield, 87%; m.p. 233°; $[\alpha]_D$ −16.4° (*c*, 0.8 in chloroform); ν_{max} 3360 (broad; OH) and 1660 cm^{-1} (weak; C=N), no NO_2 band. The n.m.r. data: in $CDCl_3$ containing a small

amount of DMSO-d_6 a 1-proton singlet (=N—OH) that disappeared on adding D_2O occurred at -0.5 τ. Other data refer to DMSO-d_6 solution: τ 2.57 (5-proton narrow multiplet, C_6H_5); 4.28 (1-proton singlet, PhCH); 5.33 (1-proton quartet, H-1, $J_{1,2a} = 8$, $J_{1,2e} = 3$ Hz); 5.60 (1-proton doublet, H-4, $J_{4,5} = 9.5$ Hz); 5.70 (1-proton quartet, H-6e, $J_{6a,6e} = 10$, $J_{5,6e} = 4.5$ Hz); 6.17 (1-proton triplet, H-6a, $J_{6a,6e} = J_{5,6a} = 10$ Hz); 6.45 (1-proton sextet of H-5, partly obscured by overlapping signals due to OCH_3 and H-2e in the 6.6–6.7 τ region); 7.90 (1-proton quartet, H-2a, $J_{2a,2e} = 15$, $J_{1,2a} = 8$ Hz). Compare also the published 60 MHz spectrum (4) of the α-anomer **11**.

Anal. Calcd. for $C_{14}H_{17}NO_5$ (279.3): C, 60.21; H, 6.14; N, 5.02. Found: C, 60.40; H, 6.19; N, 5.07.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-oximino-β-*D*-threo-hexopyranoside (**10**) from **2***

Yield, 81%; m.p. 215–216°; $[\alpha]_D$ −61.5° (in chloroform); ν_{max} 3370 (broad, OH) and 1650 cm^{-1} (very weak, C=N), no NO_2 band. The n.m.r. data: in $CDCl_3$ solution containing a small amount of DMSO-d_6 a 1-proton singlet occurred at τ −0.7 (=NOH); it disappeared on addition of D_2O. Spectrum in DMSO-d_6: τ 2.64 (5-proton narrow multiplet, C_6H_5); 4.32 (1-proton singlet, PhCH); 6.60 (OCH_3 signal). The ring proton signals were poorly resolved.

Anal. Calcd. for $C_{14}H_{17}NO_5$ (279.3): C, 60.21; H, 6.14; N, 5.02. Found: C, 60.12; H, 6.09; N, 4.92.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-oximino-α-*D*-erythro-hexopyranoside (**11**) from **3***

Yield, 88%; m.p. 197–199°; $[\alpha]_D$ +171° (in chloroform). Reported (4): m.p. 203° (dec.), $[\alpha]_D$ +172°.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-oximino-α-*D*-threo-hexopyranoside (**12**) from **4***

Yield, 86%; m.p. 220–221°, $[\alpha]_D$ +248° (in chloroform). Reported: m.p. 219–220° dec. (4, 16), $[\alpha]_D$ +257° (16).

*Methyl 3-Acetoximino-4,6-benzylidene-2,3-dideoxy-β-*D*-erythro-hexopyranoside (**13**)*

Oxime **9** (100 mg) was acetylated overnight at room temperature with acetic anhydride (1 ml) and pyridine (2 ml). The reaction mixture was poured into ice water, which produced a white solid precipitate that was washed with cold water, dried, and recrystallized from ethanol. The acetate **13** (107 mg, 93%) melted at 216° and showed $[\alpha]_D$ −15.6° (in chloroform), ν_{max} 1770 cm^{-1}. The n.m.r. data (in $CDCl_3$): τ 2.55 (multiplet of C_6H_5); 4.36 (1-proton singlet, PhCH); 5.32 (quartet, H-1, $J_{1,2a} = 8$, $J_{1,2e} = 3$ Hz); region about 5.5 and 6.0–6.4 (partly overlapping signals corresponding to 4 protons, H-4, 5, 6, 6′); 6.48 (OCH_3 singlet); 6.51 (quartet partially overlapped by OCH_3 signal, H-2e, $J_{1,2e} = 3$, $J_{2a,2e} = 16$ Hz); 7.60 (quartet, H-2a, $J_{1,2a} = 8$, $J_{2a,2e} = 16$ Hz), 7.81 (3-proton singlet, $OCOCH_3$).

Anal. Calcd. for $C_{16}H_{19}NO_6$ (321.3): C, 59.80; H, 5.92; N, 4.36. Found: C, 59.72; H, 5.99; N, 4.21.

*Methyl 3-Acetoximino-4,6-O-benzylidene-2,3-dideoxy-β-*D*-threo-hexopyranoside (**14**)*

Acetylation of oxime **10**, performed exactly as that of **9**, gave **14** in a yield of 78%; m.p. 163–164°, $[\alpha]_D$ +83.8° (in chloroform), ν_{max} in Nujol, 1770 cm^{-1}. The n.m.r. data (in $CDCl_3$): substituent resonances at τ 2.6 (5-proton multiplet, C_6H_5), 4.38 (1-proton singlet, PhCH), 6.46 (singlet, OCH_3), 7.85 (singlet, $OCOCH_3$). There were poorly resolved signals integrating for 4 protons in the τ 5.3–5.9 region and 2 protons in the τ 6.5–6.7 region. A 1-proton quartet was centered at τ 7.47 (H-2a, $J_{1,2a} = 10$, $J_{2a,2e} = 15$ Hz).

Anal. Calcd. for $C_{16}H_{19}NO_6$ (321.3): C, 59.80; H, 5.92; N, 4.36. Found: C, 59.78; H, 6.08; N, 4.37.

*Methyl 4,6-O-Benzylidene-2-deoxy-α-*D*-erythro-hexopyranosid-3-ulose (**15**)*

To a solution of oxime **11** (200 mg) in ethanol (10 ml) was added levulinic acid (4 ml) and 0.1 *N* hydrochloric acid (1 ml). The mixture was allowed to stand at room temperature for 4 h after which it was diluted with water (25 ml) and concentrated *in vacuo* to remove ethanol. The remaining, largely aqueous, solution was extracted with chloroform (3 × 20 ml) which was then washed with *M* sodium bicarbonate solution (2 × 10 ml) and twice with water (2 × 10 ml). Evaporation of the dried (Na_2SO_4) chloroform solution gave crystalline **15** which was recrystallized from 2-propanol. The yield was 142 mg (77%); m.p. 176–177°, $[\alpha]_D$ +155° (in ethyl acetate). Reported: m.p. 177–178° (11), 174–176° (12), $[\alpha]_D$ +159° (11).

*Methyl 4,6-O-Benzylidene-2-deoxy-β-*D*-erythro-hexopyranosid-3-ulose (**16**)*

The oxime **9** was treated with levulinic acid exactly as described above for **11**. Compound **16** crystallized from the reaction mixture in 99% yield. It melted at 193–195°, and at 194–195° after recrystallization from 2-propanol; $[\alpha]_D$ −51.5° (in chloroform); ν_{max} 1725 cm^{-1} (C=O). The n.m.r. data (in $CDCl_3$): τ 2.56 (multiplet, C_6H_5), 4.41 (singlet, PhCH), 5.22 (quartet, H-1, $J_{1,2e} = 4$, $J_{1,2a} = 8$ Hz), 5.52 (quartet, H-6e, $J_{5,6e} = 4.5$, $J_{6a,6e} = 10$ Hz), 5.65 (doublet, H-4, $J_{4,5} = 11$ Hz), 6.08 (triplet, H-6a, $J_{5,6a} = J_{6a,6e} = 10$ Hz), 6.3–6.5 (multiplet, H-5), 6.46 (singlet, OCH_3), 7.25 (two overlapping quartets, H-2a and -2e).

Anal. Calcd. for $C_{14}H_{16}O_5$ (264.3): C, 63.62; H, 6.10. Found: C, 63.46; H, 6.30.

Studies on the Decomposition of Tetra-alkylammonium Salts in Solution. V. Rates and Activation Parameters of Salts Containing Substituted-benzyl or Other Active Groups

E. C. F. KO AND K. T. LEFFEK

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received July 22, 1971

First order rate constants and activation parameters are reported for the decomposition in chloroform and acetone solvents of a series of 4-substituted-benzylphenyldimethylammonium bromides and iodides and also of a series of tetra-alkylammonium bromides which contain no benzyl group. The results are discussed in terms of general mechanism of these reactions, which are unimolecular "ionic internal" nucleophilic substitutions.

On rapporte les constantes de vitesse du premier ordre et les paramètres d'activation pour la décomposition dans le chloroforme et l'acétone d'une série de bromures et d'iodures de benzylphényldiméthylammonium substitués en position-4 et d'une série de bromures de tétra-alkylammonium ne contenant aucun groupe benzyle. Les résultats sont discutés à la lumière des mécanismes généraux dans ces réactions qui sont des substitutions nucléophiles unimoléculaires "ionique interne".

Canadian Journal of Chemistry, **50**, 1297 (1972)

Introduction

The evidence from earlier studies (1–4) shows that tetra-alkylammonium iodides, which contain a benzyl group, decompose in chloroform solution by a unimolecular reaction of the ammonium ion, probably associated in the form of a triple ion. These decompositions are clean and invariably yield benzyl iodide and a tertiary amine. Structural variations on that portion of the substrate which is transformed to the tertiary amine can be explained, qualitatively, in terms of electronic effects of the substituents (2). Reasonably linear plots for the Hammett ($\rho - \sigma$) correlation, for $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$, and for $\Delta G^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ exist for these compounds, which confirm the direction of movement of electrons during the activation process and the fact that all the decompositions follow the same basic mechanism. Secondary deuterium isotope effects (benzyl-1,1-d_2) on the rate of decomposition of one salt indicated that the benzyl carbon atom had considerable carbonium ion character in the transition state (4).

Hammett correlations for the decomposition of benzylphenyldimethylammonium iodides and bromides, containing para-substituted benzyl groups, were reported (3) and this paper, which concludes the series on this reaction, describes the effect of this structural change on the activation parameters for the same compounds and for seven other tetra-alkylammonium salts containing various active groups other than benzyl.

Results and Discussion

The first order rate constants for the decomposition reactions were obtained by the application of the Guggenheim method to the integrated first order rate equation (5). However, straight line plots were obtained, only when the measured conductance was used rather than the stoichiometric concentration of the salt. Since the salts are known to exist in chloroform solution mainly as ion-pairs (6), this means that the velocity of reaction is proportional to the concentration of single ammonium ion or triple ions (1). The rate constants, collated in Table 1, therefore, are calculated with respect to the concentration of the ammonium ion (or triple ion). All the values quoted are the means of at

ducts, the dimethylaniline and the corresponding alkyl halide.

Rate Constants and Anion Identity

For a simple S_N1-type reaction the rate constant should be independent, not only of the concentration of the nucleophile, but also of its identity. In this case, the anion of the salt is the nucleophile and it may be calculated from Table 1 that the iodides react 5 to 8 times faster in chloroform and 2 to 4 times faster in acetone, than the bromides. This phenomenon is not novel, since it was reported by Hughes, Ingold, and coworkers in their study of S_N1 and E1 reactions in sulfur dioxide solvent (7–11) and was also observed by the same workers for certain reactions of triphenylmethyl chloride in benzene solvent (12, 13). From the evidence available, it is postulated that the phenomenon should appear when unimolecular reactions take place in solvents of low dielectric constant. Hughes, Ingold, and coworkers found that, in nitromethane, dielectric constant about 40, the effect was absent (14, 15). Consistent with this, the present work illustrates that the effect is greater in chloroform, dielectric constant 4.6, than in acetone, dielectric constant 20.7.

The long range electrostatic forces which must be present in solutions of ions or ion-pairs in solvents of low polarity were seen as the source of the deviation from typical S_N1 behavior by Ingold (13), although the details of the explanation were conceived in slightly different terms at different times; first in terms of an intermediate mechanism (9), then as a ubiquitous presence of the nucleophile in the reacting system (12, 13) and then again in terms of intermediate mechanisms (16). The present results seem to fit better the concept of the ubiquitous presence of the nucleophile in the form of ammonium ion-pairs.

On this basis, the least complicated picture of the reaction mechanism is a decomposition of a triple ion containing the anion nucleophile. With most of the substrate present as ion-pairs, the triple-ion concentration will be equal to the stoichiometric concentration of salt, times the degree of ionization of the ion-pairs, and a decomposition involving only a triple-ion will give a reaction order of one-half in the stoichiometric concentration of salt or an order of unity with respect to the conductivity of the solution. We call this a unimolecular reaction because there is one entity, *i.e.* one triple-ion, present in the transition state. Thus, the halide atom in the alkyl halide product comes from within the triple-ion which contains the decomposing ammonium ion. If it came from another ion-pair or another triple-ion a different kinetic order would be observed, and such a reaction would be S_N2. Although our observed mechanism is unimolecular and therefore properly written S_N1, it is not a simple S_N1 reaction and for this reason we have called it an "ionic internal nucleophilic substitution". This terminology is an extension of the unimolecular S_Ni mechanism as found *e.g.* in reactions of alkyl chlorosulfites (17).

With the halide ion present in the triple ion in the transition state, it is possible to explain the rate difference between bromide and iodide as a catalytic effect or in terms of a more specific covalent bonding between the halide and the carbon seat of reaction. To estimate the relative importance of these sources of rate differences the secondary kinetic isotope effects were studied for α-deuterated benzyl compounds (4) and were found to be much larger than the literature values for non-solvolytic S_N2 reactions and almost as large as the values found for typical limiting S_N1 reactions. Thus, the benzyl compound decomposition involves a carbonium ion, but this carbonium ion may, in fact, always be an ion-pair (4) since the halide ion is present in the transition state.

For the compounds shown in section *c* of Table 1, in which there is no benzyl group, the rate of reaction is seen to correlate approximately with the ease with which the reacting alkyl group can accommodate positive charge on the central carbon. Even when the reacting group is a saturated alkyl radical such as isopropyl or ethyl, the reaction goes very slowly and in the case of ethylphenyldimethylammonium ion some methyl cleavage was also observed. All these reactions show the same kinetics. In these circumstances it is reasonable to postulate a similar mechanism for all the reactions. This can be accomplished by postulating some covalent bonding between the halide ion and the methyl carbon in the transition state, which does not alter the S_N1 designation of the reaction. However, such covalent bonding cannot be completely dominating because the methyl and ethyl groups cleave more slowly than the isopropyl

TABLE 3. Purification of some tetra-alkylammonium salts

Alkyl(R)phenyl-dimethyl ammonium bromide	Medium of recrystallization (by volume)	Melting point (°C)
$CH_2{=}CHCH_2$	Ethanol/acetone(1:10)	134–135
$CH_3CH{=}CHCH_2$	Ethanol/acetone(1:25)	143–144

C_2H_5	Ethanol/ether(1:10)	197–198

*The salt is very unstable on heating. The purification was done by dissolving in a minimum amount of ethanol and precipitating with dried ether. This was repeated three times.

group, that is, the alkyl groups are still in the classical order for alkyl halides reacting by a simple S_N1 mechanism rather than the S_N2 relative rate order.

Thus, the general mechanism of the triple-ion decomposition is via a transition state which contains a central carbon atom carrying some positive charge with some covalent bonding to the halide. For benzylic compounds the positive charge is large and covalent bonding quite small, whereas for saturated alkyl group cleavage these two factors must be more evenly balanced.

Activation Parameters

Within the substituted benzyl series of compounds some overall trends may be seen in the activation parameters given in Table 2. Electron releasing para-substituents are associated with smaller enthalpies of activation, a result which is expected if the reaction involves some build-up of positive charge on the benzylic carbon atom in the transition state since this would be stabilized by electron release from this substituent. The entropies of activation are, in general, compensating, with less than $1\frac{1}{2}$ kcal mol^{-1} spread in the free energy of activation. The positive $\Delta S^{\ddagger}$ values are expected for any reaction in which one molecule gives rise to two molecules of product, but the values in Table 2 are rather small and some even negative. Undoubtedly, there is a contribution to $\Delta S^{\ddagger}$ from changes in the solvation shell during reaction but it is not possible to determine the relative sizes of the contributions from the measured $\Delta S^{\ddagger}$ values of the present data.

The activation parameters for the substrate molecules containing no benzyl group in section *c* of Table 2 show much more variation and this probably reflects the differing amounts of carbonium-ion-pair character in the transition states of the different reacting groups.

Experimental

Materials

The preparation and properties of the para-substituted benzylphenyldimethylammonium salts have already been described (3). The other ammonium bromides were prepared similarly, from redistilled dimethylaniline and the corresponding alkyl bromide, purified from commercial materials. The reactions of dimethylaniline with isopropyl bromide and ethyl bromide are extremely slow. The former bromide was heated, without solvent, with the amine at about 120 °C for 125 h and gave a 9% yield and the latter at 50° for 18 h for a 10% yield. The other bromides gave quantitative yields. The methods of purification of these salts are summarized in Table 3.

Kinetics

The rate measurements were carried out as previously described (1).

Product Analyses

The reaction mixtures, after about 10 half-lives, were analyzed by v.p.c. using two columns, a silicon gum rubber SE30 and a 30% Carbowax. The first column separated the anilines and some high boiling alkyl bromides effectively at a column temperature of about 180°, and the latter was used to separate the low boiling alkyl bromides at a column temperature about 140°. The peaks were identified by comparing the retention times with those of authentic samples under identical conditions. All the reactions gave only two products except ethylphenyldimethylammonium bromide (see Results and Discussion).

The Effect of Pressure on the Rate of Acetolysis of a Charge-transfer Complex

R. K. WILLIAMS, J. J. LOVEDAY, AND A. K. COLTER
Department of Chemistry, University of Guelph, Guelph, Ontario

Received December 1, 1971

Rates of acetolysis of the π acceptor 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate, with and without added 9-methylanthracene donor, have been measured at 1, 680, and 1362 atm at 55.2 °C. The volume of activation for acetolysis of uncomplexed ester was -27 cm^3 mol^{-1} while that for acetolysis of the 1:1 complex was -33 cm^3 mol^{-1}, relative to uncomplexed reactants. The mechanistic significance of these results is discussed.

On a mesuré les vitesses d'acétolyse de l'accepteur π 2,4,7-trinitro-9-fluorenyl *p*-toluènesulfonate, avec ou sans donneur 9-méthylanthracène à 1, 680, et 1362 atm, à 55.2 °C. Le volume d'activation pour l'acétolyse de l'ester non-complexé était de -27 cm^3 mol^{-1} tandis que celui de l'acétolyse du complexe 1:1 était de -33 cm^3 mol^{-1}, comparativement aux réactifs non-complexés. On discute de la signification mécanistique des résultats.

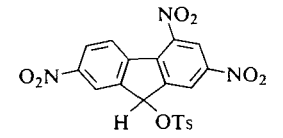
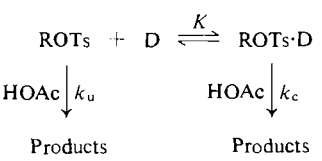
Introduction

Acetolysis of the π acceptor 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate (**1**) is strongly accelerated by a variety of π donors (1). The kinetics of acetolysis in the presence of added donor are consistent with a mechanism involving substrate (ROTs) and donor (D) in equilibrium with 1:1 complex (ROTs·D), with concurrent acetolysis of uncomplexed and complexed substrate (Scheme 1). The greater reactivity of the 1:1 complex (rate constant k_c) is assumed to arise through electron supply from donor to acceptor in an electronically-deficient transition state.



1



SCHEME 1

The influence of pressure on the catalyzed reaction is of particular interest for several reasons. First, the spectroscopic properties of typical π donor–π acceptor complexes are sensitive to pressure, both in solution (2, 3) and in the solid state (4, 5). An increase in pressure is almost invariably accompanied by a bathochromic shift in the charge-transfer absorption maximum and an increase in the intensity of the charge-transfer band. Since the catalytic effectiveness of aromatic donors in acetolysis of **1** also increases with an increase in the wavelength of the charge-transfer maximum (1) the chemical properties of charge-transfer complexes might be expected to be unusually pressure sensitive. The influence of pressure on k_c is of interest with regard to the structure of the complexed transition state, particularly with relation to the charge delocalization in the complex. Volumes of complex formation for a series of π donor and π acceptors in methylcyclohexane and methylene chloride were found by Ewald (3) to range between -2 and -12 cm^3 mol^{-1}.

The present study seeks to estimate the influence of pressure on the uncatalyzed acetolysis of **1** and on the acetolysis catalyzed by 9-methylanthracene donor. A previous investigation (6) has established that 9-methylanthracene is a very effective catalyst, with $K = 6.4$ l mol^{-1} and $k_c/k_u = 4.6 \times 10^2$ at 70°.

Experimental

Materials

9-Methylanthracene (Aldrich) was purified by crystallization from ethanol to m.p. 78–79°. 2,4,7-Trinitro-9-fluorenyl *p*-toluenesulfonate, m.p. 202–204°, was prepared as previously described (7). Anhydrous acetic acid was prepared by refluxing a 0.02 *M* solution of freshly fractionated acetic anhydride in reagent grade glacial acetic acid for 24 h, followed by fractionation to remove excess acetic anhydride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Standard 0.002 *M* sodium acetate in glacial acetic acid was prepared as previously described.

Kinetic Measurements

The kinetic procedures have been described previously (8). First order behavior was observed at all donor concentrations studied and rate constants were obtained by least squares analysis of a plot of residual ester concentration *vs.* time. The pressure vessel and technique for its use were essentially as described by Koskikallio and Whalley (9). The reaction vessel was a 100 ml glass syringe lubricated with silicone grease and placed inside a standard $4\frac{3}{4}$ in. o.d. pressure vessel supplied by the American Instrument Co., Silver Spring, Maryland. The syringe was connected by an 18 gauge steel hypodermic needle to a micro control valve supplied by the High Pressure Equipment Co., Erie, Pennsylvania. Samples of 10 ml volume were extracted at intervals of time without releasing the pressure. White mineral oil was used as pressurizing fluid. The silicone grease used to lubricate the syringe was found to provide an effective barrier between the oil and the reaction solution.

Treatment of Data

The assumed mechanism leads to eq. 1 relating the observed rate constant, k_{obs}, and the stoichiometric donor concentration, $[D]_0$ (8). A plot of $(k_{obs} - k_u)^{-1}$ *vs.* $[D]_0^{-1}$

$$[1] \qquad \frac{1}{k_{obs} - k_u} = \frac{1}{k_c - k_u} + \frac{1}{K(k_c - k_u)[D]_0}$$

leads to a straight line of intercept $(k_c - k_u)^{-1}$ and slope $K(k_c - k_u)^{-1}$ from which both k_c and K can be obtained, provided that values of k_{obs} can be measured to an accuracy of $\pm 1\%$ or better. In the present work we were unable to obtain data of sufficient accuracy to determine the pressure dependence of k_c and K separately. However, $K(k_c - k_u)$, the reciprocal of the slope of the plot according to eq. 1, could be determined to about $\pm 4\%$. Since $k_c \gg k_u$ for 9-methylanthracene, $K(k_c - k_u) \approx k_c K$. The values listed in Table 2 were obtained by a simple least squares analysis of the data according to eq. 1 treating k_{obs} from each rate run as an individual point.

Calculation of the volumes of activation corresponding to the rate constants k_u and $k_c K$ was based on eq. 2 (10). Plots of log k_u and log $(k_c K)$ *vs.* pressure were linear within

$$[2] \qquad \left(\frac{\partial \ln k}{\partial P}\right)_T = -\frac{\Delta V^{\ddagger}}{RT}$$

the experimental error up to 1362 atm (Fig. 2), and values of $\Delta V^{\ddagger}$ were obtained from the least squares slopes of these plots.

Results

The observed first order rate constants obtained in this study are listed in Table 1. Figure 1 shows plots of $(k_{obs} - k_u)^{-1}$ *vs.* $[D]_0^{-1}$ for 1, 680, and 1362 atm. Values of $(k_c - k_u)K$ derived from the slopes of the plots in Fig. 1 are listed in Table 2. Figure 2 shows plots of log (k_p/k_o) *vs.* pressure for the rate constants k_u and $k_c K$, where (k_p/k_o) is the ratio of the rate constant

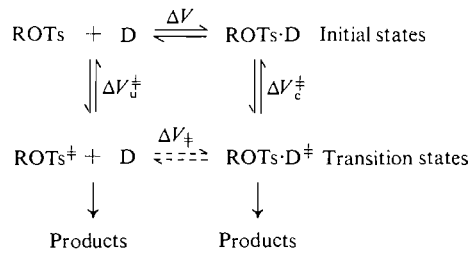
at a given pressure to its value at atmospheric pressure. Table 3 lists values of the volumes of activation, $\Delta V^{\ddagger}$, corresponding to the rate constants k_u and k_cK.

Discussion

The value of $\Delta V^{\ddagger}$ for acetolysis of uncomplexed ester, -27 cm^3 mol^{-1}, is of little diagnostic value with regard to the structure of the uncomplexed transition state. First, there are no published results on *p*-toluenesulfonate acetolyses with which we can compare our results. Secondly, $\Delta V^{\ddagger}$ is likely to be rather insensitive to the extent of solvent nucleophilic participation in the transition state (11). However, a considerable amount of other evidence (12), including the catalysis by aromatic donors, points to a transition state having considerable carbonium ion character and the present results are not inconsistent with this picture.

The significance of the two volumes of activation measured in the present work can be seen by reference to Scheme 2 which is an



SCHEME 2

expansion of the mechanism outlined in Scheme 1 to include equilibrium between initial and transition states (13). The quantity k_cK is simply the rate constant for acetolysis via the 1:1 complex based on uncomplexed reactants. The volume of activation based on k_cK is equal to $\Delta V + \Delta V_c^{\ddagger}$, or $\Delta V_u^{\ddagger} + \Delta V_{\ddagger}$ in Scheme 2. The difference between the two volumes of activation measured in the present work (5 cm^3 mol^{-1}) can therefore be viewed as the volume of the uncomplexed transition state plus donor minus the volume of the complexed transition state, *i.e.*, $-\Delta V_{\ddagger}$. On this basis, $\Delta V_{\ddagger}$ (-5 cm^3 mol^{-1}) is within the range of values observed by Ewald (3) (above) for formation of a variety of π complexes.

Considering: (*a*) the usual magnitude of the variation of the charge-transfer absorption frequency with pressure (2, 3) and, (*b*) the magnitude of the variation of k_c and k_cK with the frequency of the charge-transfer maximum for different donors (1), one might have expected a much larger variation of k_cK with pressure. Such a variation in the chemical properties of the complex with pressure would show up as a negative contribution to $\Delta V^{\ddagger}$ for acetolysis via the 1:1 complex. Using data reported in the literature (1, 3) we have calculated that this contribution could be as large as -10 cm^3 mol^{-1}. Why no such dramatic effect was observed in the present work we cannot yet say. Possibly it may be obscured by the effects of extensive charge delocalization in the complexed transition state. The measured value of $\Delta V_{\ddagger}$ (-5 cm^3 mol^{-1}) is consistent with a contribution of, say, -8 to -10 cm^3 mol^{-1} due to complexation, which is within the range found by Ewald (3), and a contribution of $+3$ to $+5$ cm^3 mol^{-1} due to charge delocalization, which is within the range estimated by le Noble and co-workers (14) for several solvolysis

Received October 6, 1971

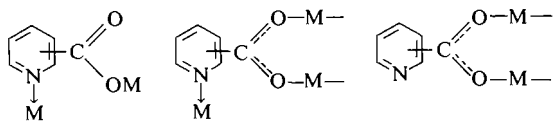
Several pyridine carboxylate complexes of cobalt(II) and nickel(II) have been prepared and their spectral and magnetic properties and X-ray powder patterns used to establish their stereochemistry. The cobalt(II) complex of pyridine-3-carboxylic acid $Co[3\text{-}py(CO_2)]_2 \cdot 4H_2O$, whose crystal structure we have previously reported, was used as a model for a consideration of the structural details of these complexes. Like the latter cobalt(II) derivative, the nickel(II) complex of pyridine-3-carboxylic acid and the cobalt(II) and nickel(II) complexes of pyridine-4-carboxylic acid and pyridine-3-sulfonic acid, isolated as their tetrahydrates, are formulated as non-classical zwitterions. Comparisons are made with the related pyridine carboxylate complexes of silver(II).

On a préparé plusieurs complexes carboxylate de pyridine de cobalt(II) et de nickel(II) et on a utilisé leurs propriétés spectrales et magnétiques et leurs spectres de poudres par rayons-X pour établir leur stéréochimie. Le complexe de cobalt(II) de l'acide pyridine-carboxylique-3 $Co[3\text{-}py(CO_2)]_2 \cdot 4H_2O$, dont la structure cristalline a été rapportée précédemment, a été utilisé comme modèle dans l'étude des détails structuraux de ces complexes. Comme le dérivé du cobalt(II) précédent, le complexe de nickel(II) de l'acide pyridine-3 carboxylique et les complexes de cobalt(II) et de nickel(II) l'acide pyridine-4 carboxylique et de l'acide pyridine-3 sulfonique, isolés sous forme de tétrahydrates, sont formulés comme étant des zwitterions non-classiques. On compare ensuite ces complexes à ceux de l'argent(II), soient les complexes pyridine carboxylate.

Canadian Journal of Chemistry, **50**, 1307 (1972)

Introduction

In our studies of pyridine carboxylates of silver(II) (2–6), we have investigated the structural features of certain of these species in order to provide a basis for the interpretation of their spectral and magnetic properties, and to better understand their chemical reactivity, in particular their role as oxidizing agents. Unlike pyridine-2-carboxylic acid (picolinic acid), the pyridine-3- and -4-carboxylic acids (nicotinic and isonicotinic acids, respectively) cannot act as chelating ligands, although they can conceivably bridge metal atoms in several ways (structures **1**, **2**, or **3**), or act as monodentate



1 **2** **3**

donors. We have previously noted (2) that the temperature range magnetic properties of $Ag[3\text{-}py(CO_2)]_2$, which is not isomorphous with $Cu[3\text{-}py(CO_2)]_2$, could be interpreted in terms of the presence of a pronounced antiferromagnetic interaction, although we have as yet no information on the structural details of this polymeric complex. Accordingly, we decided to investigate the cobalt(II) and nickel(II) complexes of several pyridine carboxylic acids in which $-CO_2H$ groups were present in the 3- and 4- positions. We chose these particular systems since (*i*), the complexes

can generally be isolated in the pure state in nicely crystalline form and should be suitable for single-crystal X-ray studies, and (*ii*), from a study of their magnetic and spectral properties we should be able to establish the gross stereochemistry of the metal atoms fairly readily, and thereby deduce the nature of the pyridine carboxylate coordination. The results of this investigation are now reported.

Experimental Section

The pyridine carboxylic acids were all commercially available (Aldrich, B.D.H., Koch-Light, or Mersey Chemicals Ltd.) and were used without further purification. Pyridine-3-sulfonic acid (Aldrich) was recrystallized twice from water before use. Henceforth, the acids and their anions are abbreviated *N*-py(X) where $X = CO_2^-$, CO_2H, SO_3^-, or SO_3H and *N* denotes the position of X in the pyridine ring, py.

Preparation of the Complexes

Complexes $ML_2 \cdot 4H_2O$ where M = Co or Ni and L = 3-py(CO_2), 4-py(CO_2), or 3-py(SO_3). The ligand (2.2 mol) was dissolved in dilute, aqueous sodium hydroxide and the p*H* of the solution adjusted to *ca.* 6 with dilute nitric acid. The solution was filtered, warmed to *ca.* 60° and added to a warm solution of the metal(II) nitrate hexahydrate (1.0 mol) in a small volume of water. The product precipitated immediately from solution. After the solution had cooled to room temperature, the product was collected, washed with water, ethanol, and ether, and dried *in vacuo* over calcium chloride.

Complexes $M[2,3\text{-}py(CO_2)(CO_2H)]_2 \cdot 2H_2O$ where M = Co or Ni. Pyridine-2,3-dicarboxylic acid (2.2 mol) was dissolved in dilute aqueous sodium hydroxide and the solution adjusted to p*H* 4–5 using dilute nitric acid. The solution was filtered, warmed to *ca.* 60° and added to a warm solution of the metal(II) nitrate hexahydrate (1.0 mol) in a small volume of water. After allowing the solution to stand at 0–5° for a few hours, the complex precipitated and was filtered off, washed with water, ethanol, and ether, and dried *in vacuo* over calcium chloride. The same product was also obtained when a metal to ligand ratio of 1.1:1.0 was used.

Complexes $Co[2,5\text{-}py(CO_2)_2] \cdot 4H_2O$ *and* $Ni[2,5\text{-}py(CO_2)_2] \cdot 5H_2O$. Pyridine-2,5-dicarboxylic acid monohydrate (1.0 mol) was dissolved in dilute aqueous potassium carbonate solution. The solution was brought to p*H ca.* 6 with dilute nitric acid, boiled for a few minutes to expel CO_2, filtered, and added to a warm solution of the metal(II) nitrate hexahydrate (1.1 mol) in a small volume of water. On cooling to room temperature, the product precipitated from solution. After collection the product was washed with water, ethanol, and ether, and dried *in vacuo* over calcium chloride.

Complex $Ni[2,5\text{-}py(CO_2)(CO_2H)]_2 \cdot 3H_2O$. Pyridine-2,5-dicarboxylic acid monohydrate (2.2 mol) was dissolved in a large volume of boiling water. After filtering the hot solution, it was further boiled while a solution of nickel(II) nitrate hexahydrate (1.0 mol) in a small volume of water was added dropwise. The product precipitated immediately and was collected by filtering the hot reaction mixture through a heated Buchner funnel. The product was washed with boiling water, ethanol, and ether, and dried *in vacuo* over calcium chloride.

Attempts to prepare the cobalt analog of this complex by a similar procedure yielded products which analyzed closely for $Co[2,5\text{-}py(CO_2)(CO_2H)]_2 \cdot 1\frac{1}{2}\ H_2O$.

Anal. Calcd. for $C_{14}H_{11}N_2O_{9.5}Co$: C, 40.2; H, 2.7; N, 6.7. Found: C, 39.7; H, 2.6; N, 6.7.

Analyses

Cobalt. The complexes were destroyed by boiling with a 1:1 mixture of concentrated sulfuric and perchloric acids. After dilution the solution was buffered, treated with R-nitroso salt and the cobalt determined spectrophotometrically.

Nickel. The complex was dissolved in concentrated hydrochloric acid and the solution made alkaline with concentrated ammonia solution (28%). The nickel was determined gravimetrically as the dimethylglyoxime complex.

Carbon, Hydrogen, and Nitrogen. These elements were determined in the microanalytical laboratory at the University of Reading and by A. Bernhardt, Germany.

Colors, elemental and thermogravimetric analyses for the complexes are shown in Table 1.

Physical Measurements

Since the complexes were found to be insoluble in polar and non-polar solvents, visible–u.v. spectra were determined by the diffuse reflectance technique on Unicam SP 700 and Cary 14 spectrophotometers. Infrared spectra were recorded as Nujol and hexachlorobutadiene mulls on Perkin–Elmer PE 457 and Beckman IR 10 spectrophotometers. Magnetic susceptibility measurements were made on a Newport Instruments variable temperature Gouy balance system. Mercury tetrathiocyanatocobaltate(II) was used as calibrant and diamagnetic corrections were estimated from Pascal's constants.

Thermogravimetric analyses were made using a Stanton thermogravimetric balance. The X-ray powder patterns were determined on a Philips X-ray diffractometer (PW 1051) using filtered Cu–$K_{\alpha 1}$ radiation ($\lambda = 1.5405$ Å).

Results and Discussion

A series of complexes of cobalt(II) and nickel(II) with pyridine carboxylic acids containing acid groups in the 3-, 4-, 2,3-, and 2,5-positions has been prepared, together with related complexes of pyridine-3-sulfonic acid. Complexes with metal to ligand ratios of 1:2 were obtained for mono-acidic ligands and pyridine-2,3-dicarboxylic acid, while ratios of 1:2 and 1:1 were obtained using pyridine-2,5-dicarboxylic acid. The presence of water of hydration in all the complexes was confirmed by the observation of ν(O—H) bands in the i.r. spectra, and by thermogravimetric analyses (Table 1).

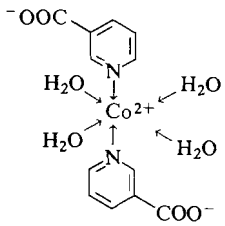
The X-ray powder data (Tables 2–5) for the complexes $M[3\text{-py-}(CO_2)]_2\cdot 4H_2O$, $M[4\text{-py-}(CO_2)]_2\cdot 4H_2O$, $M[3\text{-py}(SO_3)]_2\cdot 4H_2O$ and $M[2,3\text{-py}(CO_2)(CO_2H)]_2\cdot 2H_2O$ (M = Co, Ni) shows that each cobalt complex is isomorphous with its nickel analog and a consideration of the d values and intensities suggests that the complexes are isostructural. The 1:1 complexes of cobalt and nickel with pyridine-2,5-dicarboxylic acid are not isomorphous (Table 6).

As a basis for considering the magnetic and spectral properties of these complexes, we had previously (7) established the structure of crystalline $Co[3\text{-py}(CO_2)]_2\cdot 4H_2O$ from a 3-dimensional single crystal X-ray analysis which revealed a slightly distorted octahedral environment around cobalt, comprising a planar array of aqueous oxygens and two axial nitrogens (structure **4**). This species can clearly be formu-



4

lated as a non-classical zwitterion. The magnetic and electronic spectral properties (Tables 7 and 8) of this complex are as expected typical of a pseudo-octahedral environment (8, 9) and since these properties are similar to those of the cobalt(II) complexes of pyridine-4-carboxylic acid and pyridine-3-sulfonic acid, it is reasonable to conclude that octahedral coordination around the cobalt atom prevails throughout the series. Likewise, the nickel complexes have similar magnetic and electronic spectral properties and these are characteristic (8, 9) of approximate octahedral coordination around the metal ion. The isomorphism of the related cobalt and nickel complexes confirms this conclusion, and so we can envisage similar structures to **4** for $M[4\text{-py}(CO_2)]_2\cdot 4H_2O$ and $M[3\text{-py}(SO_3)]_2\cdot 4H_2O$. Previous work by Sacconi (10) and Kleinstein and Webb (11) is of relevance to these conclusions. In these two earlier studies, room temperature magnetic moments were

recorded for $M[3\text{-py}(CO_2)]_2\cdot 4H_2O$ (M = Co, Ni) and $Ni[4\text{-py}(CO_2)]_2\cdot 4H_2O$ which are in reasonable agreement with our more complete data. However, Kleinstein and Webb (11) concluded from a study of these three complexes, together with the anhydrous salts and several nitrogen base adducts of the type $M[X\text{-py}(CO_2)]_2\cdot nL$, where $n = 4$ for $L = NH_3$ and $n = 2$ for L = pyridine and β- or γ-picoline, that "small differences in the electronic spectra and magnetic moments of the cobalt(II) and nickel(II) complexes produced by the introduction of water or base indicate little change in the structure of the complexes." This clearly is not the case since we have demonstrated that the tetrahydrates are mononuclear species in which the $-COO^-$ groups are not coordinated. On the other hand, dehydration of these derivatives must be accompanied by gross structural changes, with the $-COO^-$ groups now becoming incorporated in the first coordination sphere with the resulting formation of polymeric species. However, it seems possible that a MO_4N_2 (M = Co, Ni) structural unit is preserved since the electronic absorption spectra of the anhydrous complexes (11) are still indicative of a pseudo-octahedral stereochem-

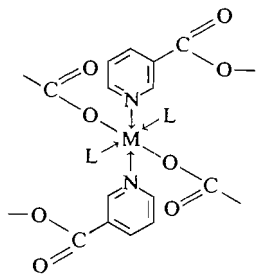
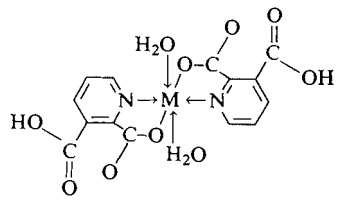
istry. We suggest that the adducts M[X-py-(CO_2)]$_2$·2L (11), may represent an intermediate structural situation, with coordination from the nitrogen atoms of the pyridine carboxylic acid and the nitrogen base L, and an oxygen atom of the —COO^- group (structure **5**).



5

The isomorphous pair of complexes derived from pyridine-2,3-dicarboxylic acid, M[2,3-py-(CO_2)(CO_2H)]$_2$·2H_2O are seen to have magnetic and spectral properties characteristic of pseudo-octahedral species (Tables 7 and 8). These are also reminiscent of the related properties of the corresponding complexes of pyrazine-2,3-dicarboxylic acid, M[2,3-pyz-(CO_2)(CO_2H)]·2H_2O (12). These complexes must contain a MO_4N_2 moiety, and we believe that they have a structure in which the two water molecules are coordinated (structure **6**)[5] rather



6

than the alternative in which the primary coordination sphere is completed by weak "interactions" with the —COOH groups in the 3 positions of *adjacent* M[2,3-py(CO_2)(CO_2H)]$_2$ molecules. This latter possibility is realized in the related silver(II) complex Ag[2,3-py(CO_2)-(CO_2H)]$_2$·2H_2O, in which the stereochemistry about silver approaches square-planar (5, 6). Support for this conclusion comes from our observation that this silver(II) derivative is not

[5]A related stereochemistry has been found for the nickel(II) and zinc(II) complexes of pyridine-2-carboxylic acid, M[2-py(CO_2)]$_2$·4H_2O (13, 14); the remaining two water molecules per formula unit are hydrogen-bonded within the lattice.

isomorphous with the cobalt(II) and nickel(II) complexes considered here.

The final group of complexes which we have investigated are those derived from pyridine-2,5-dicarboxylic acid. Although 1:1 complexes $Co[2,5\text{-}py(CO_2)_2]\cdot 4H_2O$ and $Ni[2,5\text{-}py(CO_2)_2]\cdot 5H_2O$ are not isomorphous, it seems probable that they also possess pseudo-octahedral structures, with some water molecules involved in the first coordination sphere while the remainder are incorporated into the lattice via a complex hydrogen-bonding network. While we have isolated the 1:2 complex $Ni[2,5\text{-}py(CO_2)(CO_2H)]_2\cdot 3H_2O$, a species whose thermal properties have been reported previously (15), we did not isolate the previously reported $Co[2,5\text{-}py(CO_2)(CO_2H)]_2\cdot 4H_2O$ (15). Rather we found that the product from this latter system analyzed as a lower hydrate. However, its infrared spectrum was virtually identical to that of the above nickel(II) complex and its powder pattern, while more complex than that for $Ni[2,5\text{-}py(CO_2)(CO_2H)]_2\cdot 3H_2O$, showed all but two weak lines characteristic of the latter system. The extra lines observed in the powder pattern of the cobalt(II) complex are not due to the presence of $Co[2,5\text{-}py(CO_2)_2]\cdot 4H_2O$ or the free acid. Accordingly, this product may be a mixture of $Co[2,5\text{-}py(CO_2)(CO_2H)]_2\cdot 3H_2O$ and an unidentified impurity.

Infrared mull spectra (4000–600 cm^{-1}) have been recorded for all the complexes described in this investigation. At the present time, we feel that detailed analyses of these spectra are not justified, particularly with regard to any deductions as to the nature of the carboxylate groups. One of the main reasons for this is that the hydrated complexes of these different pyridine carboxylic acids have lattices which are stabilized by different degrees of hydrogen-bonding, in which interactions between $-COO^-$, $-COOH$ and H_2O are clearly extremely important. Consequently, modifications of the $\nu(C{-}O)$ vibrations can arise from strong hydrogen-bonding effects. An inspection of the spectra of these complexes clearly shows that as expected the isomorphous pairs of complexes have virtually identical spectra.[6]

The Crystal and Molecular Structure of Tetrameric Phosphonitrilic Isothiocyanate

J. BRIAN FAUGHT

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received November 4, 1971

The crystal structure of tetrameric phosphonitrilic isothiocyanate, $N_4P_4(NCS)_8$, has been determined by three-dimensional X-ray studies from data collected on a Picker FACS-1 automated diffractometer. The compound crystallizes in the triclinic space group $P\bar{1}$ with $a = 8.098(8)$, $b = 8.018(7)$, $c = 9.937(10)$ Å, $\alpha = 104.08(7)$, $\beta = 99.42(7)$, $\gamma = 95.42(7)°$, and one molecule per unit cell. The structure was solved from 1766 independent non-zero reflections and refined to a conventional R factor of 0.063. Nitrogen atoms of two isothiocyanate groups are bonded to each phosphorus atom of the eight-membered phosphorus–nitrogen ring. The ring has a chair configuration. The average dimensions of the structure are $P—N_{ring} = 1.543 \pm 0.017$, $P—N_{isothiocyanate} = 1.644 \pm 0.011$, $N—C = 1.168 \pm 0.008$, $C—S = 1.535 \pm 0.009$ Å, $P\hat{N}_{ring}P = 140.2 \pm 1.8°$, $N_{ring}\hat{P}N_{ring} = 120.2 \pm 1.3°$, $N_{iso}\hat{P}N_{iso} = 100.1 \pm 1.0°$, $P\hat{N}C = 151.1 \pm 9.0°$, and $N\hat{C}S = 176.6 \pm 1.1°$.

La structure cristalline du tétramère de l'isothiocyanate phosphonitrilique, $N_4P_4(NCS)_8$, a été déterminée par diffraction de rayons-X à partir de données tridimensionnelles obtenues sur un diffractomètre automatique Picker FACS-1.

La maille trichinique de ce composé est monomoléculaire de dimensions: $a = 8.098(8)$, $b = 8.018(7)$, $c = 9.937(10)$ Å, $\alpha = 104.08(7)$, $\beta = 99.42(7)$ et $\gamma = 95.42(7)°$, et appartient au groupe spatial $P\bar{1}$.

La structure a été déterminée à partir de 1766 reflexions uniques observées et affinée jusqu'à une valeur de 0.063 du facteur d'accord R.

A chaque atome de phosphore du cycle à 8 atomes N_4P_4 sont liée deux groupes isothiocyanate par l'intermédiaire de leur atome d'azote. Le cycle a la configuration chaise. Les dimensions moyennes de la structure sont: P—N(cycle) = 1.543(17), P—N(isothiocyanate) = 1.644(11), N—C = 1.168(8), C—S = 1.535(9) Å, ∠PN(cycle)P = 140.2(18)°, ∠N(cycle)PN(cycle) = 120.2(13)°, ∠N(iso)PN(iso) = 100.1(10)°, ∠PNC = 151.1(90)° et ∠NCS = 176.6(11)°.

Canadian Journal of Chemistry, **50**, 1315 (1972)

Introduction

The crystal structures of a number of tetrameric phosphonitrilic halides have been reported, including the fluoride (1) and two forms of the chloride (2, 3). Other tetrameric phosphonitrilic compounds which have eight similar substituents have been studied and these include the $[NP(CH_3)_2]_4$ (4), $[NP(NMe_2)_2]_4$ (5), and $[NP(OCH_3)_2]_4$ (6). This paper reports the X-ray analysis of tetrameric phosphonitrilic isothiocyanate and is the first tetrameric phosphonitrilic pseudohalide studied so far.

Experimental

Crystal Structure Analysis

Tetrameric phosphonitrilic isothiocyanate was prepared according to the method of Audrieth and co-workers (7, 8). Crystals suitable for structural analysis were prepared from a solution of tetrameric phosphonitrilic isothiocyanate in *n*-heptane at room temperature. Crystal data are as follows:

$N_4P_4(NCS)_8$ f.w. = 644.5

Triclinic, $a = 8.098(8)$, $b = 8.018(7)$, $c = 9.937(10)$ Å, $\alpha = 104.08(7)°$, $\beta = 99.42(7)°$, $\gamma = 95.42(7)°$, $V = 611.2$ Å^3, $\rho_{obs} = 1.70 \pm 0.01$ g cc^{-1}, $Z = 1$, $\rho_{calc} = 1.751$ g cc^{-1} (22 °C, MoK_α, $\lambda = 0.7107$ Å).

The unit cell dimensions and their estimated standard deviations were obtained from a least-squares refinement of 12 independent reflections. The possible space groups are $P1$ or $P\bar{1}$.

Intensity data were collected on a Picker FACS-1 automated four-circle diffractometer. The a axis of the crystal (0.044 × 0.056 × 0.028 cm) was mounted parallel to the ϕ axis of the diffractometer. The take-off angle was 2°; β-filtered MoK_α radiation was used. All reflections were measured with a scintillation counter and attenuators were inserted when necessary.

The four octants, hkl, $hk\bar{l}$, $h\bar{k}l$, $h\bar{k}\bar{l}$ were explored in the 2θ range 4–50° using the moving-crystal, moving-counter technique with a 2θ scan rate of 1°/min. The $5\bar{4}0$ reflection was monitored after every 20 measurements, and the maximum variation of the intensity was ±1.5% of the average intensity of the reflection. The linear absorption coefficient for MoK_α radiation $\mu = 9.67$ cm^{-1}. No absorption or extinction corrections were applied.

The results of the E-statistics are given in Table 1. These results suggest that the crystal is centric and therefore, the space group is $P\bar{1}$ (no. 2) (9).

The structure was determined by the application of symbolic addition procedures (10). The programs of Hall and Ahmed were used (11). The sulfur and 2 phosphorus atoms were found readily in the E-map, and with this skeleton, the 6 N and 4 C atoms were located. A structure factor calculation based on these 16 atoms, with the thermal parameter for all atoms except S set to 4.0 Å^2, B for S = 5.0 Å^2, led to an R

TABLE 1. *E*-Statistics for $N_4P_4(NCS)_8$

Parameter	Value		
		Theoretical	
	Observed	Centric	Acentric
Mean $\|E\|$	0.817	0.798	0.886
Mean $\|E\|^2$	1.015	1.000	1.000
Mean $\|E^2 - 1\|$	0.945	0.968	0.736
$\%\|E\| > 3$	0.33	0.30	0.01
$\%\|E\| > 2$	3.96	5.00	1.80
$\%\|E\| > 1$	33.80	32.00	37.00

factor of 0.412 where

$$R = \frac{\Sigma \| F_o | - | F_c \|}{\Sigma | F_o |}$$

The refinement was carried out using a modification of the Busing, Martin, and Levy program ORFLS (12). All observed reflections were assigned unit weights and the quantity minimized was $\Sigma w \| F_o | - | F_c \|^2$. After full matrix least squares refinement of the positional and isotropic thermal parameters, R was reduced to 0.166 and R_2 was 0.162 where

$$R_2 = \left[\frac{\Sigma w (|F_o| - |F_c|)^2}{\Sigma w (F_o)^2} \right]^{1/2}$$

The thermal motion of the atoms was then treated anisotropically. Because of the limitation on the number of parameters that could be refined at one time, the refinement was carried out in sections, each section included the 4 ring atoms and 2 complete isothiocyanate groups. After 12 such cycles of anisotropic refinement, R was reduced to 0.063 and $R_2 = 0.083$. In the final cycles of refinement, the largest ratio of shift to standard deviation was found to be 0.07. Unobserved reflections were not included in the least squares refinements, but the structure factors of all the unobserved reflections were calculated and no inconsistencies were found. A final difference map was calculated, and for the most part, the highest peaks associated with this map were 0.3 e $Å^{-3}$. However, two peaks of intensity 0.6 e $Å^{-3}$ were observed, and each of these was in the region of a phosphorus and two isothiocyanate nitrogen atoms. The refinement was deemed to be complete at this point.

The scattering curves for neutral P, N, C, and S atoms were taken from the compilation of Hanson *et al.* (13). No corrections for $\Delta f'$ and $\Delta f''$ were made for P and S because they are quite small, 0.1 and 0.2 for both P and S (14).

Results and Discussion

A drawing of the molecule of tetrameric phosphonitrilic isothiocyanate viewed perpendicular to the *a*–*b* plane is shown in Fig. 1. The atom notation is indicated in this drawing. The centrosymmetric phosphorus atoms are also labelled.

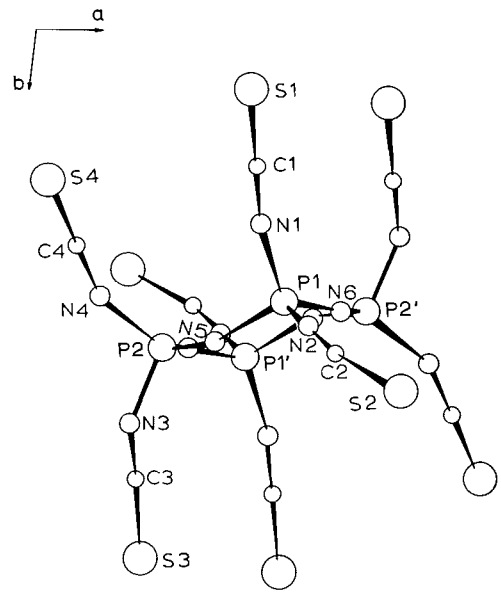

FIG. 1. A view of the molecule $N_4P_4(NCS)_8$ perpendicular to the *a*–*b* plane.

Table 2 contains the list of final fractional coordinates of the atoms and their anisotropic thermal parameters. The final observed and calculated structure factors based on these positional and thermal parameters may be obtained from the Depository of Unpublished Data.[1] Table 3 is a list of the calculated bond lengths and angles with standard deviations.

There are four independent P—N bond lengths in the ring and these vary from 1.523 to 1.565 Å and a root-mean-square (r.m.s.) deviation of 0.017 Å; the standard deviation calculated from least squares for an individual bond length is 0.008 Å. Ansell and Bullen (6) suggest that there is a correlation between the P—N bond length in a tetrameric phosphonitrilic ring and the electronegativity of the exocyclic atom bonded to the phosphorus atom. This does not hold true for this case, and it is evident that the electronegativity of the nitrogen atom is not a good approximation of the electronegativity of the isothiocyanate group. However, the electronegativity suggested by Huheey (15) for the isothiocyanate group, 4.2 on the Pauling scale, also does not fit this correlation well.

		S(4)—C(4)—N(4)	176.8(5)

There are no significant differences on bond angles of a given type and the mean values for the ring are $P\hat{N}P = 140.2 \pm 1.8°$, $N\hat{P}N = 120.2 \pm 1.3°$, and $X\hat{P}X = 100.1 \pm 1.0°$, where X is the exocyclic N atom. These values are compared with other tetrameric phosphonitrilic derivatives in Table 4. Several features stand out from this comparison. The angle at N in the ring is larger than all except that of the fluoride. In partially substituted derivatives only the fluoride derivatives have angles larger than 140°. The other feature is the $X\hat{P}X$ angle, which is comparable to the angle in the fluoride derivative. These angles along with the short P—N bond length seem to indicate that there is a greater inductive effect from the isothiocyanate group than all other substituents except for the fluoride substituent.

The isothiocyanate groups have the following mean values: P—N = 1.644 ± 0.011 Å, N—C = 1.168 ± 0.008 Å, C—S = 1.535 ± 0.009 Å, $P\hat{N}C$ 151.1 ± 9.0°, $N\hat{C}S = 176.6 \pm 1.1°$. The P—N bond length is considerably shorter than the presumed single bond length of 1.77 Å found in the $NaPO_3NH_3$ species (16). The C—S bond length is shorter than that of any other reported isothiocyanate (17). This amounts to more than double bond character. The N—C length indicates a bond order of three.

There is no simple valence bond canonical structure to explain the bond lengths in this isothiocyanate structure, but this is not uncommon (see for example ref. 17). The best simple representation can be made in the following structure:

*Data taken from ref. 20 except for $N_4P_4(NCS)_8$.

Delocalization of the nitrogen lone pair would not only result in a shorter P—$N_{(exo)}$ bond length but also a PN̂C angle greater than 120°. The PN̂C angle is interesting from another aspect. Of the 4 independent angles, three are quite close to 146° while the fourth is 164.5°. This difference is significant, but was also noticed in the structure of trimeric phosphonitrilic isothiocyanate (18). Hazell (19) has suggested that there is a relationship between the MN̂C angle and the N—C and C—S bond lengths. N—C distances generally decrease and C—S distances generally increase with increasing MN̂C angle. M is the atom to which the NĈS group is bonded. In this case, the N—C bond length corresponding to the largest PN̂C angle is 0.02 Å shorter than the average of the other three N—C bond lengths, with a least-squares estimated standard deviation of 0.01 Å on these bond lengths. However, that particular C—S bond length shows no corresponding increase.

Since the molecule occupies a center of symmetry, the ring has the chair configuration. The nitrogen atoms are 0.35 and 0.30 Å out of a plane described by the 2 crystallographically independent phosphorus atoms and the center of symmetry. The equation of this plane is

$$-0.3064\,X' - 0.9459\,Y' - 0.1066\,Z' + 7.5922 = 0$$

where X', Y', and Z' are an orthogonal set of axes, X' along a, Y' in the ab plane, and Z' along c^*. If the phosphonitrilic ring were to exhibit perfect $2/m$ symmetry, the dihedral angles of the bonds P(1)—N(6) would be equal to that of P(1)—N(5) and that of P(2)—N(5) equal to P(2′)—N(6). The dihedral angles of other chair forms of tetrameric phosphonitrilic derivatives are listed in Table 5. The numbering of the atoms has been changed to compare with the present work. Tetrameric phosphonitrilic isothiocyanate has a ring very close to $2/m$ symmetry. The mirror plane is that plane passing through atoms P(1) and P(1′) while the diad axis passes through P(2) and P(2′).

A molecular packing diagram projected on the a–b plane is shown in Fig. 2. The crystal packing appears to be dominated by the isothiocyanate groups, which participate in all of

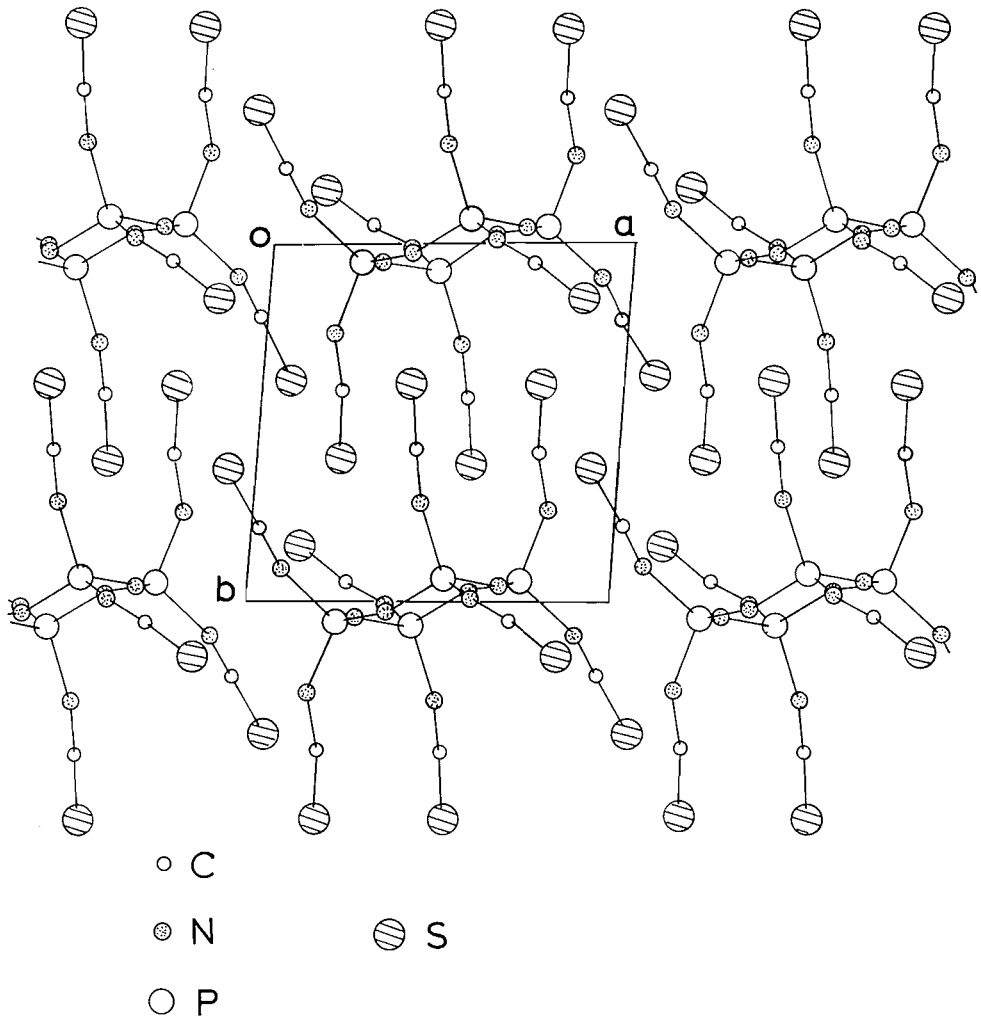

FIG. 2. Packing diagram of tetrameric phosphonitrilic isothiocyanate.

the closest intermolecular contacts. Most of the short intermolecular contacts are between two isothiocyanate groups. The shortest S...S distance is 3.91 Å, while the shortest S...N, N...N, N...C, C...C, and C...S distances are 3.63, 3.38, 3.42, 3.72, and 3.60 Å, respectively. None of these distances are smaller than the sum of the van der Waals radii of the two atoms.

The author wishes to thank Professor Harry Lynton of the University of New Brunswick for the use of the automated diffractometer. He also wishes to thank Mr. Peter S. White for help with computer problems and the National Research Council of Canada for financial support.

All computations were done on the IBM 360/50 and the CDC 6400 of the Dalhousie University Computer Centre.

Desorption of Hydrogen from Palladium and Palladium–Silver Alloys followed by Differential Scanning Calorimetry

D. ARTMAN AND TED B. FLANAGAN

Chemistry Department, University of Vermont, Burlington, Vermont

Received October 18, 1971

Differential scanning calorimetric curves have been obtained corresponding to the desorption of hydrogen from palladium and palladium–silver alloys. There was no evidence for the existence of an exotherm, following the endothermic desorption of hydrogen, which has been previously found and attributed to the relaxation of a metastable, expanded hydrogen-free palladium lattice. Heats of desorption have been evaluated from the areas of the endotherms and these are reasonable in the light of values obtained by other techniques. Comparisons of scanning curves for palladized and unpalladized hydrogen-containing silver–palladium alloys demonstrate that solid-state diffusion cannot be the slow step for the former but may be for the latter.

Nous avons obtenu des courbes de balayage calorimétrique différentiel correspondant à la désorption de l'hydrogène du palladium et des alliages palladium–argent. Nous n'avons pas remarqué l'existence d'un exotherme à la suite de la désorption endothermique de l'hydrogène, tel que trouvé auparavant et attribué à la relaxation d'un réseau du palladium métastable, étendu et exempt d'hydrogène. Nous avons évalué les chaleurs de désorption à partir des surfaces des endothermes et ces valeurs sont raisonnables à la lumière des valeurs obtenues par d'autres techniques. La comparaison entre les courbes de balayage pour des alliages argent–palladium contenant de l'hydrogène, palladiés et non-palladiés, démontre que la diffusion à l'état solide ne peut pas être l'étape lente pour la première, mais peut l'être pour la deuxième.

Canadian Journal of Chemistry, **50**, 1321 (1972)

Palladium and its alloys with high palladium contents have the ability to absorb large amounts of hydrogen (1). If their surfaces are not especially activated by, *e.g.*, palladium black, this hydrogen will remain within the sample in a metastable state, *i.e.*, under conditions where $\mu_H^{metal} > \mu_H^{gas}$. When they are heated, hydrogen is evolved. This suggests that thermoanalytic techniques may be readily applicable to hydrogen-containing samples of palladium and its alloys. No one has, to our knowledge, applied these techniques to hydrogen-containing palladium, save Michel and Michel (2) who followed the loss of hydrogen from a palladium specimen in nitrogen using differential thermal analysis (DTA). The DTA curve obtained by Michel for Pd/H_2 in the β-phase exhibits an endothermic peak with a maximum at 175 °C corresponding to the desorption of hydrogen (2). Subsequently an exothermic peak, which was even larger than the endothermic one, appeared with a maximum at *ca.* 280 °C. This latter peak was attributed to the relaxation of the extended hydrogen-free lattice to its normal lattice spacing. Michel and co-workers (3) have presented ancillary evidence that hydrogen may be removed from palladium without an accompanying relaxation of the lattice. To a limited extent, Gibb *et al.* (4) have supported their finding, *i.e.*, the magnetic susceptibility can remain low despite the fact that a considerable fraction of hydrogen may be removed from a hydrogen-containing palladium sample in the β-phase. Other workers (5) have not supported Michel's suggestion. It is of interest to repeat these early thermoanalytic investigations on samples of high purity in order to reexamine the possibility of the occurrence of the metastable lattice.

An additional motive was to determine if a thermoanalytical approach could provide accurate thermochemical data on these important systems. Considerable thermodynamic data are available for the hydrogen/palladium and the silver/palladium/hydrogen systems (1). Most data are derived from pressure–temperature equilibrium data rather than from calorimetric measurements. Calorimetric measurements on palladium/hydrogen have been limited (1) and there are none available for the interaction of hydrogen with palladium alloys.

The most extensive calorimetric investigation of the palladium/hydrogen system is that of Nace and Aston (6). They found an average value for ΔH of -40.19 kJ/mol H_2 for absorption into the α/β two-phase region (25 °C) which is consistent with the results of earlier workers who found an average of -38 kJ/mol (1). For hydrogen concentrations exceeding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

those corresponding to the two-phase region, H-to-Pd, atomic ratio, = 0.58 (25 °C), calorimetric data are unavailable. It is known that at 1 atm hydrogen pressure absorption ceases at H-to-Pd = 0.69 (1) (25 °C). To attain values of H-to-Pd greater than this, either high pressures of gaseous hydrogen are required (7) or the maintenance of a non-equilibrium concentration of hydrogen atoms such as produced by gaseous discharges or heated tungsten filaments (8). It is of interest to explore the feasibility of thermoanalytic techniques for the determination of enthalpies of desorption at values of $n > 0.69$ because direct calorimetric approaches at these concentrations are fraught with potential experimental difficulties.

Experimental

Palladium and silver–palladium wires (99.99% purity, 0.027 cm diam) were charged with hydrogen employing the technique of spontaneous absorption from solution (9) to H-to-metal values of 0.65 and 0.45, respectively. This method was employed in order to avoid non-homogeneous charging often associated with electrolytic introduction of hydrogen. Contents in excess of H/Pd = 0.65 were obtained by gas phase reaction of hydrogen atoms and palladium (8). Contents were determined by weighing the specimen before and after degassing and also by measurement of the hydrogen evolved following heating of a segment of the sample *in vacuo*.

The samples were cut into many small pieces (~1–6 mg) and then the course of desorption was followed by differential scanning calorimetry (Dupont). The heating rate was generally 15 °C min^{-1} and the purge rate, ~100 cc min^{-1}.

In order to prepare samples with catalytically active surfaces, they were charged electrolytically with hydrogen and then submerged into a palladium chloride solution. Palladium was spontaneously deposited upon the surface of the metal creating a very active surface for the $H_2 \leftrightarrow 2H^*$ reaction (10). The samples were then kept in distilled water until they were transferred to the DSC cell in a wet condition where they were purged with helium in order to remove the water at room temperature before being heated.

The major difficulty in obtaining meaningful results was the accuracy of the calibration. The samples were placed directly onto the sample platforms and were short enough so that their entire lengths were in contact with the sensing element. Calibration based upon the transition In(s) → In(l), where the Indium was placed in an aluminum pan, did not lead to accurate data. The geometry and size of the calibration sample must approximate the hydrogen-containing sample as closely as possible. Measurements of the heat capacity of aluminum wire (diam 0.08 cm, wt ≅ 3–4 mg, ~3 mm long) provided relatively successful calibration. Aluminum wire was chosen over palladium itself because of its considerably larger heat capacity, *i.e.*, 0.949 J g^{-1} deg^{-1} (Al) and 0.250 J g^{-1} deg^{-1} (Pd).

Results and Discussion

A typical differential scanning calorimetric run is shown in Fig. 1 for an unactivated sample of composition $PdH_{0.65}$. Runs were performed in either nitrogen (as Michel and Michel (2)) or in helium in order to avoid reaction of the absorbed hydrogen with oxygen. It can be seen that there is no evidence of an exothermic process following the endothermic desorption of hydrogen (2). Such an exothermic peak was never noted in the numerous runs carried out in this research. For $PdH_{0.65}$, hydrogen commences to be evolved at *ca.* 150 °C and the maximum occurs at approximately 265 °C.

Heats of Desorption

Further support for the finding that the lattice relaxes after desorption of hydrogen can be

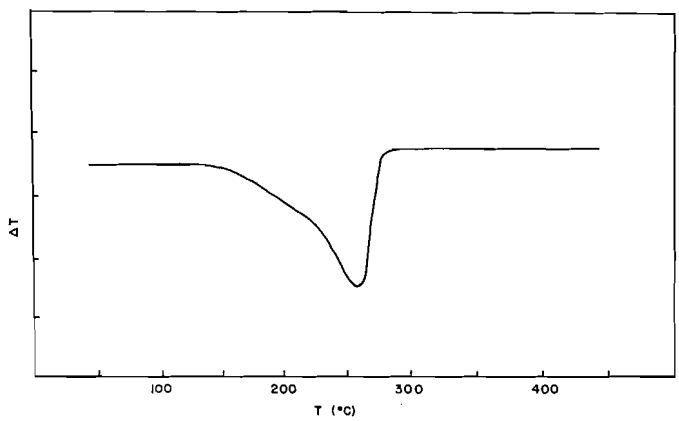

FIG. 1. Typical DSC run for unactivated $PdH_{0.65}$ in the presence of helium.

TABLE 1. Integral heats of desorption of hydrogen from Palladium and Ag(20%)/Pd

Sample type (unpalladized)	Endotherm$_{max}$ (°C)	ΔH (kJ/mol H_2)
$PdH_{0.65}$	265 ± 10	37.8
$PdH_{0.81}$	245	36.6
$PdH_{0.92}$	205	27.2
$Ag(20\%)PdH_{0.45}$	235	38.3

gained from a quantitative evaluation of the endothermic peaks. The value of ΔH_{des} can be determined for the process

$$[1] \qquad \frac{2}{x} PdH_x \rightarrow \frac{2}{x} Pd + H_2$$

Results are given in Table 1 for values of ΔH_{des} corresponding to reaction 1 (integral heats of desorption).

The composition $PdH_{0.65}$ (Table 1) exceeds that of the β-phase boundary (25 °C) only slightly (1), and, therefore, a natural comparison is that between the observed heat of desorption of $PdH_{0.65}$ (reaction 1) and the often determined value corresponding to the $\beta \rightarrow \alpha$ transformation. The error introduced into this comparison by the larger partial molar heat of desorption which obtains for the $PdH_{0.65}$ sample in the range H-to-Pd > 0.58 is only 1% and a comparable error arises from the fact that the desorption product is not α-phase palladium/hydrogen but pure palladium. These errors, however, are well within the present experimental precision. The value reported for the integral heat of desorption per mole of H_2 for $PdH_{0.65}$ (Table 1) is the average of ten determinations with two different DSC cells. The average values found for the two different cells with separate calibration determinations were within 1.2 kJ/mol H_2 of each other.

Values in the literature reported for the $\beta \rightarrow \alpha$ transition are greater than those for the $\alpha \rightarrow \beta$ transition because of the presence of hysteresis (1). Calorimetric values have not been determined for the desorption of hydrogen from β-phase palladium. Wicke and Nernst (11) report 39.9 kJ/mol H_2 for the heat of desorption from −30 to 50 °C. Lewis (1) has collected all available data for the two-phase pressures and, surprisingly, a single Arrhenius straight line can be drawn through these extensive data (−30 to 290 °C) with a value for $\Delta H_{\beta \rightarrow \alpha}$ of 40.9 kJ/mol H_2. The value reported here is within experimental error of these previously reported values. The convenience of this technique makes it quite useful, *e.g.*, it requires only small samples (1–6 mg) and is very rapid.

Wicke and Nernst (11) give an expression for the partial molar heat of desorption of hydrogen from the β-phase of Pd/H_2, *i.e.*, $\Delta \bar{H} = 96.7 - 90.0 \times (H/Pd)$ kJ/mol H_2. This expression can be integrated between values of H-to-Pd of 0.58 and 0.81 and, together with the two-phase heat, an integral heat of desorption of 37.7 kJ/mol H_2 can be calculated to compare with the value shown in Table 1; a similar treatment applied to $PdH_{0.92}$ gives 36.1 kJ/mol H_2. The results for the $PdH_{0.81}$ alloy are not unreasonable, but the calculated heat for the largest hydrogen content alloy is in poor agreement with the experiment (Table 1). It is quite possible that the analytical expression for $\Delta \bar{H}$ (11) is not suitable for H-to-Pd values greater than 0.81. It can be shown from Table 1 that the partial desorption of hydrogen from $PdH_{0.92}$ to $PdH_{0.81}$ is exothermic, yet a distinguishable exothermic peak is not observed when $PdH_{0.92}$ is heated; therefore, there is no tendency for the "exothermic" hydrogen to be desorbed before the rest of the hydrogen.

The differential heat of solution of hydrogen at small hydrogen contents is greater in Ag(20%)/Pd than in pure palladium (12) so that the reported value (Table 1) supports this trend. Further quantitative calorimetric data are needed for the desorption of hydrogen from palladium alloys.

Kinetics of Desorption

Figure 2 shows the differential calorimetric scanning curve for a palladized and a bright, *i.e.*, unpalladized, sample of hydrogen-containing Ag(20%)/Pd. It is of interest to note that the endothermic peak which appears at about 235 °C for the bright sample has shifted to about 80 °C for the palladized sample. This demonstrates that solid state diffusion cannot be the rate-limiting step for desorption from the bright sample; such a slow step may be obtained for the palladized sample. (A comparison of the desorption rates was made with silver/palladium alloys rather than pure palladium in order to avoid complications due to the presence of the two phases.) It is known that a coating of palladium

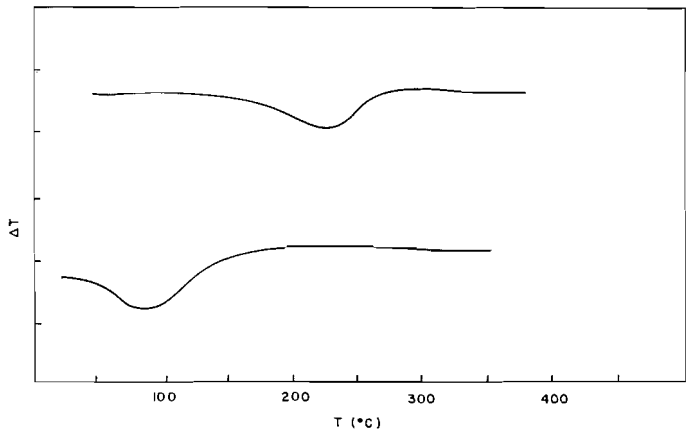

FIG. 2. DSC plots for hydrogen containing Ag(20%)Pd specimens. Upper curve is of a bright sample and lower is of a palladized specimen.

black can sufficiently activate the surface of palladium so that surface steps are not rate-controlling for permeation experiments (13). Palladized samples of hydrogen-containing Ag(35%)/Pd and Ag(45%)/Pd were also subjected to scanning runs. The endothermic peaks for these samples occurred at 140 and 160 °C, respectively. Züchner (14) has recently measured the diffusion coefficients in this system and noted that the diffusion coefficients decline with silver content so that it would be expected for the endothermic peaks to shift to progressively higher temperatures as observed here.

Numerical evaluation of the diffusion coefficients using approximate solutions of the cylindrical diffusion problem with the assumption that the surface concentration during desorption is zero, lead to values of D which are too small. It is quite likely that the assumed boundary condition, $c_{H_2} = 0$ at the surface, is invalid under the experimental conditions. This general approach for the determination of diffusion parameters deserves further attention because of its great convenience.

Complexes de platine avec des dérivés acétyléniques $Pt(R_1R_2C(OH)—C\equiv C—C(OH)R_1R_2)_2$

FERNANDE D. ROCHON[1] ET T. THEOPHANIDES

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 12 août 1971

Les complexes $Pt(ac)_2$ où $ac = R_1R_2C(OH)—C\equiv C—C(OH)R_1R_2$ ont été étudiés. Les composés sont mononucléaires, non ioniques et diamagnétiques. Les résultats expérimentaux semblent indiquer que les ligands ne sont pas réarrangés dans le complexe. L'ordre de la liaison C≡C a été partiellement réduit et il y a probablement une distorsion assez importante de la molécule acétylénique. Une structure où les deux ligands acétyléniques sont liés par des ponts hydrogène est proposée.

La réaction des complexes $Pt(ac)_2$ avec la triphénylphosphine a été étudiée. On a la réaction suivante:

$$Pt(ac)_2 + 2PPh_3 \rightarrow Pt(PPh_3)_2(ac) + ac$$

Complexes of the type $Pt(ac)_2$ where $ac = R_1R_2C(OH)—C\equiv C—C(OH)R_1R_2$ have been studied. The compounds are mononuclear, non ionic, and diamagnetic. The experimental results seem to indicate that the ligands are not rearranged in the complex. The order of the triple bond has been partially reduced and there is an important distortion of the acetylenic molecule. A structure with the two ligands hydrogen bonded is proposed.

The complexes $Pt(ac)_2$ react with triphenylphosphine according to the following equation:

$$Pt(ac)_2 + 2PPh_3 \rightarrow Pt(PPh_3)_2(ac) + ac$$

Canadian Journal of Chemistry, **50**, 1325 (1972)

Dans un article précédent (1), nous avons rapporté la synthèse d'une nouvelle série de complexes de platine avec des dérivés acétyléniques de formule générale $Pt(ac)_2$. Six composés dans la série ont été préparés où $ac = R_1R_2C(OH)—C\equiv C—C(OH)R_1R_2$.

Résultats

Les complexes $Pt(ac)_2$ sont formés comme produits secondaires de la réaction suivante:

$$K_2PtCl_4 + ac \rightarrow K[Pt(ac)Cl_3] + KCl$$

L'analyse élémentaire indique la composition $Pt(ac)_2$ (1). Les composés sont non-ioniques, diamagnétiques et monomères (tableau 1).

Spectres de masse

Le spectre de masse de tous les complexes $Pt(ac)_2$ montrent des pics moléculaires correspondant aux trois isotopes du platine 194, 195, et 196. Ce phénomène est très intéressant puisque les ligands ac n'ont pas montré de pics moléculaires. Le fragment le plus élevé dans le spectre de masse des ligands correspond à la masse $M^+ - 17$ (perte probable d'un groupement hydroxyle). L'intensité relative de ce pic ($M^+ - 17$) est faible, environ 1%. Par contre, tous les complexes $Pt(ac)_2$ possèdent des pics moléculaires. L'intensité relative du pic M^+ varie de 1 à 16%. La stabilité du ligand dans la chambre d'ionisation semble donc plus grande lorsqu'il est coordiné au métal. La première partie du spectre de masse des complexes (fragments ne contenant pas de platine) ressemble beaucoup au spectre de masse du ligand correspondant.

TABLEAU 1. Poids moléculaire

Complexe*	Poids moléculaire Théor.	Sp. de masse (^{195}Pt)	Solution dans l'acétone†
$Pt(ac^1)_2$	535.54	535	562
$Pt(ac^2)_2$	591.69	591	615
$Pt(ac^3)_2$	591.69	591	608
$Pt(ac^4)_2$	703.89	703	673
$Pt(ac^5)_2$	703.89	703	730
$Pt(ac^6)_2$	639.72	639	600

*$ac^1 = (CH_3)(C_2H_5)C(OH)—C\equiv C—C(OH)(CH_3)(C_2H_5)$;
$ac^2 = (C_2H_5)_2C(OH)—C\equiv C—C(OH)(C_2H_5)_2$;
$ac^3 = (CH_3)(C_3H_7)C(OH)—C\equiv C—C(OH)(C_3H_7)(CH_3)$;
$ac^4 = (CH_3)(C_5H_{11})C(OH)—C\equiv C—C(OH)(C_5H_{11})(CH_3)$;
$ac^5 = (C_2H_5)(C_4H_9)C(OH)—C\equiv C—C(OH)(C_4H_9)(C_2H_5)$;
$ac^6 =$  .

†Les complexes étant peu solubles dans l'acétone, ces résultats sont approximatifs.

Résonance magnétique nucléaire

Les spectres de résonance magnétique nucléaire du complexe $Pt(ac^1)_2$ et du ligand cor-

[1]Adresse actuelle: Université du Québec à Montréal, Montréal, Québec.

TABLEAU 2. Spectre de résonance magnétique nucléaire

τ (p.p.m.)				
ac^1				
CCl_4	DMSO-d_6	$Pt(ac^1)_2$ DMSO-d_6	Intensité relative	Attribution
9.01	9.08	9.10	3 (triplet)	CH_3 (de C_2H_5)
8.60	8.68	8.63	3 (singulet)	CH_3
8.42	8.45	8.34	2 (quadruplet)	CH_2
5.88 (conc. 0.30 m/l)	5.06 (conc. 0.15 m/l)	5.29 (conc. 0.037 m/l)	1 (singulet)	OH

respondant ($ac^1 = (CH_3)(C_2H_5)C(OH)—C\equiv C—C(OH)(CH_3)(C_2H_5)$) ont été mesurés dans le diméthylsulfoxyde-d_6 à la température ambiante entre 0 et 30 p.p.m. (τ). Les résultats ont été notés sur le tableau 2. Les spectres n'ont pas été mesurés dans l'acétone-d_6 puisque les complexes ne sont pas suffisamment solubles. Les spectres du diol ac^1 et du complexe $Pt(ac^1)_2$ sont semblables. Les mêmes intensités relatives ont été notées, indiquant la présence de deux groupements hydroxyles par ligand dans le complexe tout comme dans le diol même. On peut donc conclure que l'environnement des groupements hydroxyles du diol et du complexe n'est pas très différent.

Le spectre de résonance magnétique nucléaire des autres composés de la série n'a pas été mesuré, puisque leur solubilité est insuffisante, ou il y a décomposition du complexe en solution. Les complexes en solution se décomposent sous l'effet de la chaleur.

Spectres électroniques

Le spectre électronique des complexes $Pt(ac)_2$, mesuré dans l'acétonitrile, a montré la présence de trois transitions, à 46 700 ($\varepsilon \sim 7\,500$), à 39 200 ($\varepsilon \sim 1\,500$), et à 35 200 cm^{-1} ($\varepsilon \sim 1\,500$) (tableau 3) (DDI).[2]

Les trois transitions observées ont été attribuées à des transferts de charge à cause des grands coefficients d'extinction moléculaire et de l'énergie relativement grande des transitions. En se basant sur les travaux de Denning, Hartley, et Venanzi (3) et sur le fait que dans les complexes de Pt(0) la liaison π semble très importante, on peut attribuer ces transitions à des transferts d'électrons d'une orbitale d du métal à une orbitale π^* (antiliante) du ligand, donc $M \rightarrow L$, $d \rightarrow \pi^*$.

L'absence de transition d–d dans le spectre électronique semble indiquer la configuration électronique d^{10} pour le platine. Par conséquent, les complexes $Pt(ac)_2$ sont probablement des complexes de Pt(0).

Spectres infrarouges

Le spectre infrarouge des ligands ac et des complexes $Pt(ac)_2$ (fig. 1) a été mesuré de 4000 à 200 cm^{-1}. Le tableau 4 montre la position d'absorption des vibrateurs O—H et C≡C.

Les complexes sont complètement insolubles dans les solvants neutres, excepté $Pt(ac^5)_2$ qui est légèrement soluble dans le tétrachlorure de carbone. Trois bandes d'absorption ont été notées, à 3600, 3530 et 3335 cm^{-1} (fig. 2). Il semble donc y avoir une liaison hydrogène intramoléculaire et une liaison hydrogène intermoléculaire.

Une absorption très intense située entre 1880 et 1904 cm^{-1} a été attribuée à la vibration C≡C. Il y a probablement une distorsion assez importante de la molécule acétylénique et la vibration devient active et très forte dans l'infrarouge. Dans la molécule libre, la triple liaison est observée dans le Raman autour de 2230 cm^{-1} (18). La fréquence du vibrateur C≡C est abaissée à cause de l'interaction entre le platine et la triple liaison. La possibilité que cette absorption soit causée par une vibration Pt—H a été écartée, puisque la deutération n'a pas altéré cette absorption (tableau 4). Le vibrateur Pt—H absorbe généralement autour de 2100 cm^{-1} (2, 4). Donc les complexes ne sont pas des hydrures. Les complexes $Pt(ac)_2$ absorbent à une valeur intermédiaire entre les

[2]Dépôt des données inédites. Les photocopies des tableaux 3, 5, et 6 peuvent être obtenues, sur demande adressée aux archives des documents non publiés, à la Bibliothèque scientifique nationale, au Conseil national de recherches du Canada à Ottawa, Canada K1A 0S2.

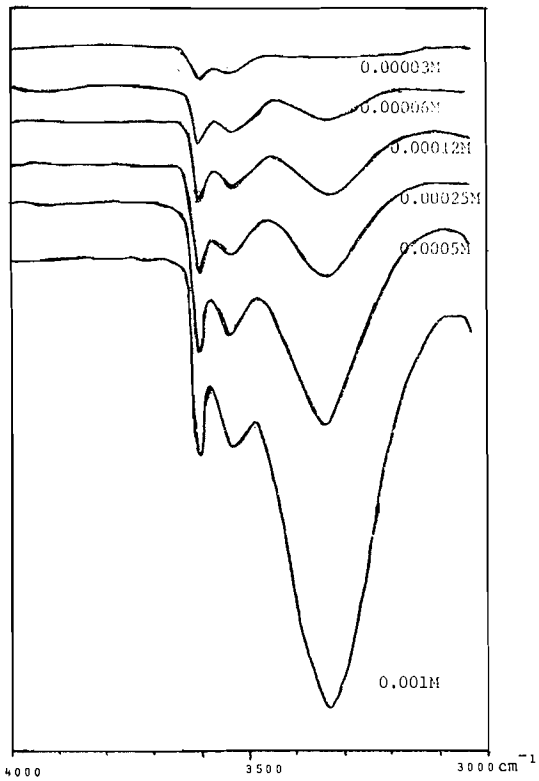

FIG. 2. Spectre infrarouge de $Pt(ac^5)_2$ dans CCl_4.

complexes de platine II (ex. $K[Pt(ac)Cl_3]$ $\nu_{C\equiv C} = 2000\ cm^{-1}$) et les complexes de platine(0) de type $[Pt(PPh_3)_2(ac)]$ ($\nu_{C\equiv C} \simeq 1750\ cm^{-1}$). Plusieurs complexes possédant une absorption similaire ont été décrits dans le passé (2, 4–9). Chatt a signalé l'existence possible de toute une série de complexes de platine variant entre les deux sortes de liaisons ($\nu_{C\equiv C} = 2000$ et $1750\ cm^{-1}$). Collman et Kang (10), en se basant sur leurs résultats de complexes de rhodium et d'iridium avec des composés acétyléniques, ont noté le même phénomène et ont conclu que les deux sortes de liaison correspondaient à des descriptions extrêmes d'une transformation graduelle.

Les spectres infrarouges ($700–200\ cm^{-1}$) des ligands et des complexes ont été mesurés dans le Nujol. Les bandes observées ont été notées dans le tableau 5 (DDI).[2]

Réaction avec la triphénylphosphine

Lorsqu'on ajoute très lentement une solution de triphénylphosphine dans l'hexane à une suspension du complexe $Pt(ac)_2$ dans l'hexane, la réaction suivante a lieu:

$$Pt(ac)_2 + 2PPh_3 \rightarrow Pt(PPh_3)_2(ac) + ac$$

$Pt(PPh_3)_2(ac)$ où (ac) est un dérivé acétylénique a été préparé selon la méthode décrite par Chatt et ses collaborateurs (11) ainsi que par Allen et Cook (12) et comparé au produit final de la réaction de $Pt(ac)_2$ avec PPh_3. L'analyse élémentaire, le point de fusion, le poids moléculaire, la susceptibilité magnétique et le spectre infrarouge des deux composés obtenus par les deux méthodes se sont révélés identiques.

Les complexes $Pt(PPh_3)_2(ac)$ sont diamagnétiques. Les poids moléculaires mesurés dans l'acétone varient de 425 à 465. Ces complexes semblent se décomposer en solution pour donner l'espèce monocoordinée $Pt(PPh_3)$, probablement solvatée. Ugo, Cariati, et La Monica (13) ont observé pour le complexe $Pt(PPh_3)_2$ (*P.M.* théorique = 719) un poids moléculaire de 464 dans le benzène et de 395 dans l'acétone.

Le tableau 6 (DDI)[2] montre la position d'absorption des vibrateurs O—H et C≡C à l'état solide dans l'infrarouge des complexes $Pt(PPh_3)_2(ac)$. L'ordre de la liaison C—C a été réduit puisque le vibrateur absorbe à environ $1750\ cm^{-1}$.

Les spectres de masse des complexes $Pt(PPh_3)_2(ac)$ n'ont pas montré de pics moléculaires ni de fragments contenant du platine. Les fragments sont surtout ceux du glycol acétylénique (ac) correspondant. Il y a probablement la décomposition suivante du complexe $Pt(PPh_3)_2(ac)$

$$Pt(PPh_3)_2(ac) \rightarrow Pt(PPh_3)_2 + (ac)$$

Le glycol acétylénique étant beaucoup plus volatil que le complexe $Pt(PPh_3)_2$, les fragments observés sur le spectre de masse sont surtout ceux du glycol acétylénique.

Discussion

La réaction du $Pt(ac)_2$ avec la triphénylphosphine est particulièrement intéressante pour prouver que le ligand acétylénique est intact dans le complexe. Les deux ligands sont probablement liés au platine par la triple liaison puisqu'ils sont facilement enlevés. Ils sont vraisemblablement liés au platine d'une façon

identique puisqu'une seule vibration C≡C est observée dans le spectre infrarouge.

En se basant sur nos résultats, nous proposons la structure suivante (fig. 3).

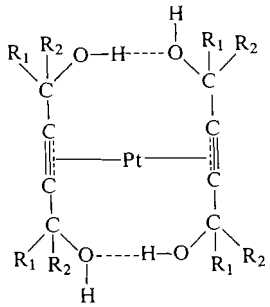

FIG. 3. Structure proposée pour les complexes $Pt(ac)_2$.

Cette structure semble concorder avec tous nos résultats expérimentaux. Les deux triples liaisons ne sont probablement pas parallèles, à l'extrême elles pourraient être perpendiculaires. Il y a une distorsion, probablement cis, assez importante des ligands acétyléniques. Jusqu'à maintenant, toutes les structures déterminées par diffraction des rayons X ont montré des distorsions cis de la molécule acétylénique, vers le côté opposé au platine. Le nombre de coordination du platine est deux et l'hybridation probable dp, puisque dans le complexe $Pt(PPh_3)_2(PhC{\equiv}CPh)$ les orbitales s ne prennent pas part à l'hybridation (14). Il y a des ponts hydrogène entre les groupements hydroxyles des deux ligands acétyléniques.

La stabilité très grande de ces complexes à l'état solide, semble indiquer l'existence d'un excès de charge négative sur le métal zérovalent. Plusieurs auteurs (15, 16) croient que les liens π sont plus forts dans les coordinations linéaires et trigonales que dans les coordinations tétraédriques. Il semble qu'avec une configuration d^{10}, la charge négative sur le métal est plus facilement dispersée sur le ligand (liaison π) lorsque le nombre de coordination est petit. La liaison π (rétro-donation) est donc très importante. Cette interaction est facilitée par la présence sur l'alcyne de groupements électronégatifs (deux groupements hydroxyles) qui diminuent l'énergie des orbitales π^* (antiliantes) du ligand acétylénique permettant un lien π très fort. La donation d'électrons du métal à l'orbitale π^* (antiliante) du ligand est donc un facteur électronique très important dans ce genre de composés.

Partie expérimentale

Les points de fusion ont été déterminés avec un appareil Fisher–Johns et ne sont pas corrigés.

Un appareil Hitachi Perkin–Elmer 115 a été utilisé pour déterminer les poids moléculaires. Les complexes $Pt(ac)_2$ et $Pt(PPh_3)_2(ac)$ ont été analysés dans l'acétone (Fisher A-20) à une température de 37.8 °C. Le benzil (*P.M.* = 210.22) a été utilisé comme standard pour préparer la courbe de calibration.

Les spectres électroniques ont été mesurés avec un spectrophotomètre Cary 14.

Un appareil Perkin–Elmer 621 a été utilisé pour mesurer les spectres infrarouges entre 4000 et 200 cm^{-1}. Le spectromètre était fréquemment vérifié avec un échantillon de polystyrène. Les ajustements standards de l'appareil ont été utilisés. Les spectres des échantillons solides ont été mesurés par la méthode de dispersion dans des pastilles de bromure de potassium ou d'iodure de césium. Des cellules de chlorure de sodium, de bromure de potassium, de KRS-5 et de quartz (région 3500 cm^{-1}) de différentes épaisseurs ont été utilisées pour mesurer les spectres de composés en solution. Un appareil pour sécher l'atmosphère a été utilisé pour les spectres dans l'infrarouge lointain. Un spectrophotomètre Perkin–Elmer 457 a également été utilisé à l'occasion.

Les mesures de conductivité ont été faites avec un conductomètre Radiometer de type CDM 2d et une cellule conductométrique Radiometer de type CDC 104.

La susceptibilité magnétique des complexes a été mesurée à la température ambiante par la méthode de Faraday avec un appareil ALPHA muni d'un électroaimant modèle No 9506. La distance entre les pointes des pôles est de $1\frac{1}{2}$ pouce. Un régulateur de courant ALPHA type 110 a été utilisé ainsi qu'une électrobalance Cahn Rg et un enregistreur Varian G 1000. La contribution diamagnétique du panier en quartz a été soustraite. $HgCo(SCN)_4$ a été utilisé comme standard pour calibrer l'appareil.

Les quatre appareils suivants ont été utilisés pour les spectres de résonance magnétique nucléaire: Varian A 60, Jeol C 60 H, Jeol 100 Mc 4 H et Perkin–Elmer R 12.

Les spectres de masse ont été mesurés avec un appareil Hitachi Perkin–Elmer R.M.U.-6D. L'énergie du faisceau d'électrons ionisants était de 70 eV, la température de la chambre à ionisation étant maintenue à 250 °C.

Préparation des ligands

Diméthyl-3,6 octyne-4 diol-3,6 (ac^1) a été obtenu de Air Reduction Chemical and Carbide Company et recristallisé dans le tétrachlorure de carbone p.f. 49°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 9.01, 3 triplet, CH_3 (de C_2H_5); 8.60, 3 singulet, CH_3; 8.42, 2 quadruplet (?), CH_2; 5.88, 1 singulet, OH.

Diéthyl-3,6 octyne-4 diol-3,6 (ac^2) a été préparé d'après la méthode décrite par Theophanides (17). Le glycol a été recristallisé dans l'hexane p.f. 76°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 9.00, 6 triplet, CH_3; 8.46, 4 multiplet, CH_2, 7.85, 1 singulet, OH).

Diméthyl-4,7 décyne-5 diol-4,7 (ac^3) a été préparé par la même méthode que celle décrite dans la référence (17) en substituant la pentanone-3 par la pentanone-2. Le glycol a été recristallisé dans l'hexane-*n* p.f. 62–63°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 9.05, 3 multiplet, CH_3 (de C_3H_7); 8.61, 3 singulet, CH_3; 8.45, 4 multiplet, CH_2; 7.37, 1 singulet, OH.

Diméthyl-6,9 tétradécyne-7 diol-6,9 (ac^4) a été préparé par la même méthode (17) en utilisant l'heptanone-2. Le ligand a été recristallisé dans l'hexane-*n* p.f. 84–85°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 9.1, 8.6, 14 multiplet, CH_3 (de C_5H_{11}), CH_3 et CH_2; 7.21, 1 singulet, OH.

Diéthyl-5,8 dodécyne-6 diol-5,8 (ac^5) a également été préparé par la même méthode (17). L'heptanone-3 a été utilisé. Le glycol a été recristallisé dans l'hexane-*n* p.f. 71°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 9.0, 6 multiplet, CH_3; 8.5, 8 multiplet, CH_2; 7.3, 1 singulet, OH.

Di(hydroxy-1 cyclohexyl)-1,2 acétylène (ac^6) a été préparé par la même méthode (17). La cyclohexanone a été utilisée. Le glycol acétylénique a été recristallisé dans l'hexane-*n* p.f. 105–106°.

Spectre r.m.n. (CCl_4) (τ (p.p.m.), intensité relative, attribution): 8.40, 10 multiplet, CH_2; 6.60, 1 singulet, OH.

Préparation des complexes $Pt(ac)_2$

0.002 *m* de K_2PtCl_4 est dissous dans 25 ml de solvant. Le solvant est une solution de 40% d'éthanol dans l'eau. La solution de K_2PtCl_4 est filtrée pour enlever les particules insolubles et on ajoute 0.005 *m* de ligand (ac) à la solution. Le mélange est ensuite chauffé sur un bain-marie pendant cinq minutes et laissé au repos pendant au moins 12 h. Un précipité brun se forme lentement. Le précipité est alors filtré et lavé avec de l'hexane-*n*. On obtient alors un produit beige ou brun pâle que l'on cristallise deux fois dans l'acétone. Un produit blanc, cristallisé en forme d'aiguille est finalement obtenu. Les rendements sont bas, de 5 à 18% et varient avec le ligand.

L'analyse élémentaire des complexes $Pt(ac)_2$ a déjà été publiée (1). $Pt(ac^1)_2$: p.f. 164–173° (déc.); $Pt(ac^2)_2$: p.f. 186–192° (déc.); $Pt(ac^3)_2$: p.f. 145°; $Pt(ac^4)_2$: p.f. 148°; $Pt(ac^5)_2$: p.f. 145°; $Pt(ac^6)_2$: p.f. 190–197° (déc.).

Préparation des complexes $Pt(PPh_3)_2(ac)$

(a) Ces complexes ont été préparés selon les méthodes décrites dans la littérature par Chatt et ses collaborateurs (11) et par Allen et Cook (12) afin de comparer ces complexes avec ceux que nous avons isolés comme produits de la réaction des complexes $Pt(ac)_2$ avec la triphénylphosphine.

(b) Ces complexes peuvent également être préparés selon la réaction suivante:

$$Pt(ac)_2 + 2PPh_3 \xrightarrow{\text{hexane-}n} Pt(PPh_3)_2(ac) + ac$$

0.00005 *m* de $Pt(ac)_2$ sont ajoutés à 10 ml d'hexane-*n*. Le mélange est agité avec un agitateur magnétique. 0.0001 *m* de triphénylphosphine est dissous dans 15 ml d'hexane-*n*. Cette dernière solution est ajoutée goutte à goutte très lentement à la suspension contenant le complexe $Pt(ac)_2$. L'addition doit durer environ 8 h et l'agitation doit être continuelle. La réaction est quantitative. Des rendements de 80% sont obtenus. Les complexes ne sont pas recristallisés puisqu'ils se décomposent facilement en solution.

$Pt(PPh_3)_2(ac^1)$ p.f. 125–132° (déc.), $\chi g(c.g.s.) = -0.3 \times 10^{-6}$ et *P.M.* (acétone) = 445 (théoriquement = 889).

Anal. calc.: C, 62.14; H, 5.90; P, 6.97. Trouvé: C, 61.93; H, 5.43; P, 6.74.

$Pt(PPh_3)_2(ac^5)$ p.f. 108–114° (déc.), $\chi g(c.g.s.) = -0.4 \times 10^{-6}$ et *P.M.* (acétone) = 438 (théoriquement = 973).

Anal. calc.: C, 64.18; H, 6.22; P, 6.37. Trouvé: C, 64.24; H, 6.10; P, 6.23.

$Pt(PPh_3)_2(ac^6)$ p.f. 105–135° (déc.), $\chi g(c.g.s.) = -0.4 \times 10^{-6}$ et *P.M.* (acétone) = 435 (théoriquement = 941).

Anal. calc.: C, 63.82; H, 5.57; P, 6.59. Trouvé: C, 63.18; H, 5.49; P, 6.61.

Notre vive appréciation va au Conseil National de Recherches du Canada et à l'Imperial Oil Co. Ltée pour l'aide financière accordée.

Fluorescence and Phosphorescence of 2,3-Pentanedione

A. W. JACKSON AND A. J. YARWOOD
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 9, 1971

The fluorescence and phosphorescence yields on photolysis of 2,3-pentanedione were investigated at various temperatures. The processes involved in the formation and removal of both the singlet and triplet states are considered. The data agree qualitatively and quantitatively with the results of an earlier study of the lifetime of the triplet state. It is shown that delayed fluorescence is not observed in the pentanedione system. A mechanism is proposed that can correlate the temperature variation of both the lifetime and quantum yield data.

On a étudié les rendements de fluorescence et de phosphorescence durant la photolyse du 2,3-pentanedione à différentes températures. On examine les procédés impliqués dans la formation et la disposition des états singulet et triplet. Les résultats que nous obtenons sont en accord qualitatif et quantitatif avec ceux provenant d'une étude précédente sur le temps de demi-vie de l'état triplet. On montre que la fluorescence retardée n'est pas observée dans le système pentanedione. On propose un mécanisme qui peut expliquer la variation de température du temps de demi-vie et des résultats de rendement quantique.

The electronically excited singlet and triplet states of diketones are of low energy. As a result, diketones, particularly biacetyl, have often been used as acceptors in studies of both singlet and triplet energy transfer (1–3). The features required of an acceptor in sensitization studies have been considered by Noyes and Unger (3), and in many respects 2,3-pentanedione fulfils the criteria. An earlier study investigated the radiationless processes involving the triplet state in the photochemistry of 2,3-pentanedione through measurement of the phosphorescence lifetime (4). This investigation considers the photochemical processes involving both the singlet and triplet states of 2,3-pentanedione. The temperature dependence of the fluorescence and phosphorescence yields is studied and the data correlated with the phosphorescence lifetime data.

Experimental

The 2,3-pentanedione was purified in the manner described earlier (4). The equipment used in the emission measurements with wavelength resolution was also described (4). However, in this research the luminescence spectra were corrected for the quantum efficiency of the photomultiplier and the bandwidth and transmission factor of the monochromator. A standard lamp (Electro Optics Associates, Type 101) was used to calibrate the monochromator–photomultiplier arrangement. The quantum yields were determined using quinine sulfate ($\phi = 0.55$) as a standard (5, 6) and the incident light intensities were determined using potassium ferrioxalate actinometry (7).

Measurements were also made of the relative yields of fluorescence and phosphorescence. The excitation source for these studies was a 60 W medium pressure mercury lamp operated from a Gates Omnirange power supply. The light was focussed to produce parallel light which passed through a filter holder. Interference filters supplied by Baird Atomic were used to isolate wavelengths of 313, 365, 405, and 436 nm. A portion of the light passed by the filter was reflected by a quartz plate onto a photocell (GE Type 935). The signal was displayed on a recorder and measured the intensity of the light entering the system. The majority of the light was transmitted by the plate, passed through a cell and was focussed onto a second photocell, and the output measured on an electrometer (Keithley 610C). The cell and thermostatically controlled box were described earlier (4).

Light emitted by the sample through the side window of the cell passed down a tube mounted to reduce the scattered light and restrict the portion of the cell viewed. The emission at 460 and 527 nm was isolated using interference filters (Baird Atomic, bandwidth at half peak transmittance about 10 nm) and measured using a photomultiplier (EMI 6256 cooled to −80 °C) and an electrometer (Keithley 610C).

The relative yield of emission, Q_λ, at 460 or 527 nm was determined in the experiments and is defined by

$$Q_\lambda = \frac{l_\lambda - l_\lambda^0}{g(l_{trans}^0 - l_{trans})}$$

where $(l_\lambda - l_\lambda^0)$ is the difference between the emission readings with and without sample in the cell. $(l_{trans}^0 - l_{trans})$ is the difference between the transmitted photocell readings without and with sample in the cell. For a particular exciting wavelength the electrometer readings were corrected to some arbitrary value of the incident light intensity.

The quantity g is a geometric factor that takes into account that the actual incident light causing emission in the region viewed by the photomultiplier varies as the amount of light absorbed varies. In this case, $g = [\sinh(\varepsilon c\delta/2)]/[\sinh \varepsilon cl/2]$ where α is the natural extinction coefficient, c is the concentration in mol l^{-1}, $\delta = 10$ mm, is the length viewed by the photomultiplier, and $l = 100$ mm, is the length of the cell.

The value of Q was also corrected (8) for reflection effects in the cell. A further correction was necessary for the emission data at 460 nm. This is due to reabsorption of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fluorescence by the sample before its detection by the photomultiplier. The illuminated section of the cell in these experiments had a width $2a$ and the distance between the outer edge of the illuminated area and the cell window was also a (where $a = 13$ mm). The "inner filter" correction factor assumed that the light emitted by a region of thickness dx a distance x from the cell wall that reached the cell wall was $I_x = Ae^{-\alpha cx}.dx$. The total light that reached the wall as a result of illumination in the region between a and $3a$ from the wall was thus $I_{total} = A[e^{-\alpha ca} - e^{-3\alpha ca}]/\alpha c$. In the absence of the "inner filter" effect the light intensity would be $2a$A so the correction factor was $2a\alpha c/[e^{-\alpha ca} - e^{-3\alpha ca}]$. Now $\alpha = 2.303\varepsilon$ where ε is the decadic extinction coefficient and the correction factor was calculated using $\varepsilon = 4.0$ for 460 nm excitation.

In some experiments the narrow band interference filters were not used to select the wavelength viewed by the photomultiplier. Instead, a glass filter (CS 3-72) covered the photomultiplier and restricted the emitted light so that only wavelengths greater than 470 nm were recorded by the photomultiplier (type 1P28 in these experiments). The total emission was recorded, then oxygen added, and the fluorescence intensity recorded. The phosphorescence intensity was taken as the difference between the total and the fluorescence intensities.

Results

The absorption spectrum of 2,3-pentanedione in the gas phase is shown in Fig. 1. The spectrum consists of two systems. The system at shorter wavelengths extends from less than 220 nm to greater than 320 nm with a maximum at 253 nm ($\varepsilon = 31.5\ M^{-1}\ cm^{-1}$). The only structure observed is a shoulder at 280 nm. The longer wavelength system extends from less than 340 nm to greater than 465 nm. Some structure is observed in the system and no absorption is detected at wavelengths longer than 480 nm.

The luminescence spectrum of 2,3-pentanedione was determined by irradiating a sample (15 Torr) in the vapor phase at 24 °C. The emission extends from less than 430 nm to greater than 610 nm. The corrected total emission spectrum is shown in Fig. 2, and the emission profile was identical for excitation at 365, 405, and 436 nm. The emission at longer wavelengths, associated with a long lived species from earlier phosphoroscope experiments, disappeared on addition of 20 Torr of oxygen. The profiles of the emission after addition of oxygen were identical at the three excitation wavelengths used. The corrected spectrum observed in presence of oxygen is also shown in Fig. 2 (note that the figure indicates only the emission profiles and that curve B is not to the same scale as curve A).

The absolute quantum yields of emission were determined with respect to quinine sulfate as a standard and the results are shown in Table 1. A further check of the quantum yield of emission was made using the relative yield apparatus.

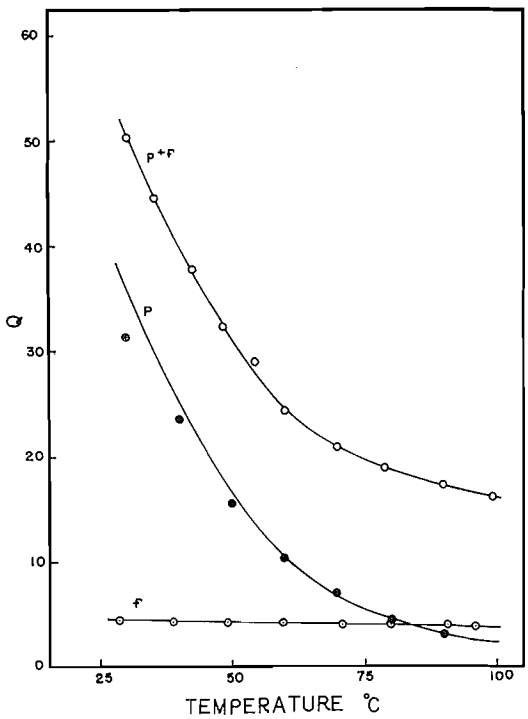

FIG. 3. Variation of total emission, fluorescence and phosphorescence yields with temperature. Pentanedione concentration = 2.2×10^{-4} M. $\lambda_{ex} = 436$ nm. (The total emission (p + f) curve is displaced 10 units vertically.)

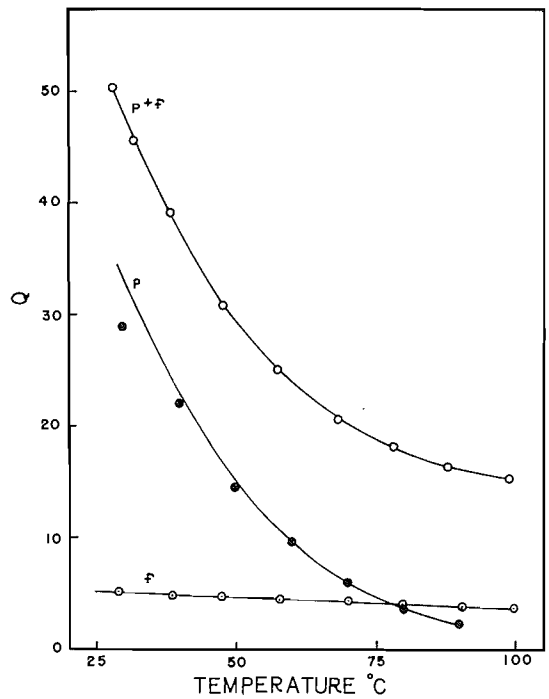

FIG. 4. Variation of total emission, fluorescence and phosphorescence yields with temperature. Pentanedione concentration = 1.2×10^{-3} M. $\lambda_{ex} = 436$ nm. (The total emission curve is displaced vertically by 10 units.)

The emission spectra of 2,3-pentanedione and butanedione are very similar and butanedione (biacetyl) was used as a relative standard ($\phi = 0.18$ (9)). The quantum yield of total emission of 2,3-pentanedione at 14 Torr at 30 °C was found to be 0.022. Initial experiments were conducted using the oxygen quenching technique to monitor the fluorescence. Since the emission filter passed only wavelengths longer than 470 nm, where absorption by the diketone is negligible, the "inner filter" correction was not applied. In these studies, a more extensive temperature range was investigated and various excitation wavelengths were used. The results for a low concentration of pentanedione (2.2×10^{-4} M) excited at 436 nm, are shown in Fig. 3, while the results of excitation at 365 nm are shown in Fig. 4 for 1.2×10^{-3} M pentanedione. Figures 5 and 6 show the data for 6.1×10^{-3} M pentanedione excited at 436 and 365 nm, respectively.

Other relative yield experiments involved excitation at 436 nm and used the filter technique to discriminate between the fluorescence and the phosphorescence. The values of Q_f and Q_p were measured at various pentanedione pressures at 50.0, 70.0, and 90.0 °C. There was no significant variation in Q_f over the concentration range studied. The variation in Q_p is presented in Fig. 7 in the form Q_p^0/Q_p vs. concentration at various temperatures. Q_p^0 is the phosphorescence yield at zero pressure for 436 nm excitation.

In one sequence of experiments, the fluorescence yield of pentanedione (1.4×10^{-3} M) at 40.0 °C was measured as an inert gas (perfluoroethane) was added. No change in Q_f was detected for 436 nm excitation up to a perfluoroethane concentration of 5×10^{-2} M.

Discussion

The visible and ultraviolet absorption spectrum of 2,3-pentanedione in the vapor phase is shown in Fig. 1 and shows clearly the absorptions expected for a diketone in the 260 and 420 nm regions. The long wavelength absorption

of 2,3-pentanedione shows considerable structure and this transition can be classified as $n\pi^*$ by analogy with biacetyl and glyoxal (10, 11). In the short wavelength region, pentanedione in the gas phase has a structureless absorption with a maximum at 255 nm ($\varepsilon \simeq 30\ M^{-1}\ cm^{-1}$) which can be compared with those of biacetyl at 270 nm ($\varepsilon \simeq 12\ M^{-1}\ cm^{-1}$) (8) and chlorobiacetyl at 265 nm ($\varepsilon \simeq 240\ M^{-1}\ cm^{-1}$) (12). The short wavelength absorption of diketones is often considered as the second $n\pi^*$ transition. However, on the basis of solvent effects on the absorption spectra and calculations of the position and intensity of the absorption band this assignment can be questioned (24).

From the absorption spectrum, the natural radiative lifetime of the excited state can be estimated. Although, there are several formulae (13) available, the simple expression $\tau_0^{-1} = 2.88 \times 10^{-9} \nu^{-2} \int \varepsilon\, d\bar{\nu}$ was used to obtain τ_0 as 8.1×10^{-6} s. Although the formula is valid only for atomic absorption with resonance fluorescence, it is useful in comparing the natural radiative lifetime of the $^1n\pi^*$ state with that of biacetyl, 8.5×10^{-6} s (14). This confirms that the long wavelength excitation in 2,3-pentanedione is similar to that of biacetyl.

The corrected luminescence spectrum of 2,3-pentanedione, Fig. 2, shows that excitation in the $n\pi^*$ band leads to emission in the blue and green regions of the spectrum. The stronger

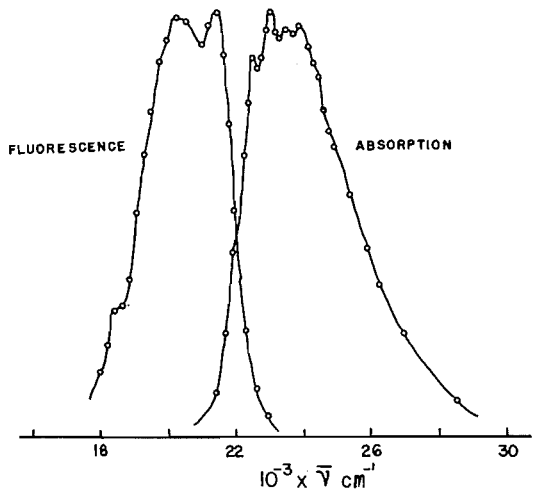

FIG. 8. Relationship between fluorescence and absorption spectrum.

green emission has already been shown to be associated with a long lived species (4) and is the phosphorescence. Figure 2 shows that the green emission is quenched by a low pressure of oxygen and the remaining blue emission is fluorescence.

The absorption and fluorescence spectra can be used to estimate the energy of the 0–0 transition. Figure 8 shows the approximate "mirror image" relationship between the fluorescence and absorption spectra and a value of 63.2 kcal is obtained for the singlet 0–0 transition in pentanedione. Since the onset of the fluorescence and phosphorescence spectra leads to a S_1–T_1 splitting of 9.2 kcal then the T_1–S_0 0–0 energy is 54.0 kcal. This value can be compared with the 54.7 kcal obtained by Hammond and co-workers (15) for 2,3-pentanedione in a 3-methyl pentane matrix at 77 °K. It is also very similar to the energy, 55 to 57 kcal, of the triplet state of biacetyl (16).

The fluorescence and phosphorescence yields are collected in Table 1. For excitation at 405 nm, the phosphorescence is about seventeen times greater than the fluorescence at 23 °C. Thus, the total emission spectrum in Fig. 2 is essentially the phosphorescence spectrum with a small contribution from the fluorescence at about 21 500 cm^{-1}.

A comparison between the triplet lifetime and luminescence yield data can be made from the relative yield data collected using the oxygen quenching technique. The results for excitation at various wavelengths and concentrations are shown in Figs. 3–6. There are two features common to the data. The fluorescence yield varies only slightly with the temperature and the phosphorescence yield varies significantly with the temperature.

The variation in the fluorescence yield is not large, about 10% between 30 and 100 °C. Since the quantum yield of fluorescence is small, then the quantum yield of fluorescence directly measures the ratio of the fluorescence emission and radiationless process rate constants for excitation at long wavelengths. It is likely that the reduction in Q_f with temperature is due to a small increase in the radiationless rate constant from the singlet state.

In contrast to the slight variation in the fluorescence yields with temperature, the phosphorescence variation is dramatic. As the singlet state is the precursor of the triplet state, the contrast in behavior could be due to the destruction of some intermediate between the emitting levels of the singlet and triplet states or to the processes removing the triplet. The phosphorescence lifetime study (4) has already shown that the processes removing the triplet state are strongly temperature dependent so the following mechanism can be considered for the long wavelength photolysis.

[1] $P + h\nu \rightarrow {}^1P^0$

[2] ${}^1P^0 \rightarrow P + h\nu_f$

[3] ${}^1P^0 \rightarrow {}^3P^h$

[4] ${}^3P^h + P \rightarrow {}^3P^0 + P$

[5] ${}^3P^0 \rightarrow P + h\nu_p$

[6] ${}^3P^0 \rightarrow$ radiationless removal

[7] ${}^3P^0 + P \rightarrow$ removal

When k_2 is small compared to k_3 the quantum yield of phosphorescence, ϕ_p, is given by

$$[8] \qquad \phi_p = \frac{k_5}{k_5 + k_6 + k_7(\mathrm{P})} = \tau_p k_5$$

where τ_p is the phosphorescence lifetime. Thus, if the mechanism is correct and k_5 does not vary with the temperature, then the variation of ϕ_p should be described by the variation of τ_p. This is tested in Figs. 3–6 where the continuous curve representing the variation of the phosphorescence yield with temperature is obtained as the

difference between the curves for the total emission yield and the fluorescence yield. The open circles on the total emission and fluorescence curves represent experimental data. The filled circles close to the phosphorescence curve in Figs. 3–6 represent the variation of the phosphorescence lifetime (4) with temperature for a particular pentanedione concentration. The lifetime data are plotted using $Q_p = \text{constant} \times \tau_p$ and the value of the constant was chosen by substitution at a temperature in the middle of the temperature range (a quantitative comparison of the phosphorescence yield and lifetime data is considered later).

The correlation of the lifetime and yield data is good and the mechanism described above is adequate to describe the behavior on long wavelength excitation. The temperature variation due to decomposition of intermediate levels between the vibrationally equilibrated singlet and triplet levels cannot be detected at these concentrations even for 365 nm excitation.

The variation of the fluorescence yield of pentanedione with temperature is similar to that of biacetyl. Groh (17) reports that a reduction of about 30% is observed for the fluorescence yield at 200 °C compared with 30 °C. The variation of the phosphorescence yield with temperature was studied by Coward and Noyes (18) and has been re-investigated by Noyes *et al.* (19). They showed that at low temperature the decomposition of the triplet state occurred by triplet–triplet annihilation and that at high temperature by thermal decomposition. Any thermal decomposition of the triplet state of pentanedione would have to compete with the rapid unimolecular reaction proposed for that triplet state and thermally induced decomposition was not detected.

As discussed above, excitation of pentanedione at 436 nm forms the singlet state with an energy about 3 kcal above the 0–0 level. The quantum yield of formation of vibrationally equilibrated singlet level is effectively unity at this wavelength since spontaneous dissociation is unlikely. This assumption is confirmed by the fact that the fluorescence quantum yield is independent of the pressure of pentanedione for 436 nm excitation at 50.0, 70.0, and 90.0 °C. Again, the data also indicate that there is no bimolecular quenching process involving the excited singlet state that can be detected in the 0–0.01 M concentration range (only processes with rate constants greater than $3 \times 10^9\ M^{-1}\ s^{-1}$ can be detected).

The behavior of pentanedione with respect to the self-quenching of the fluorescence cannot be compared directly to that of biacetyl since the variation of the fluorescence yield of biacetyl excited at 436 nm has not been studied at a variety of temperatures and pressures. However, the photochemical decomposition of biacetyl has been studied under these conditions and the behavior can also be described without including a bimolecular quenching process of the vibrationally equilibrated singlet with the ground state species (20).

A more detailed investigation of the dependence of the phosphorescence yield on pentanedione concentration was undertaken using the relative yield apparatus with interference filters for the selection of the fluorescence and phosphorescence. The results are shown in Fig. 7 in a simple Stern–Volmer plot. This indicates that the self-quenching reaction of the triplet state involves a bimolecular reaction of the vibrationally equilibrated triplet molecule with the molecule of pentanedione in its ground state. This is just the conclusion reached in the phosphorescence lifetime study (4). The phosphorescence yield data can be discussed in terms of eq. 8 which can be rearranged to

$$[9] \qquad \frac{\phi_p^0}{\phi_p} = 1 + k_7\tau_0(\mathrm{P})$$

where τ_0 and ϕ_p^0 are the phosphorescence lifetime and quantum yield extrapolated to zero pentanedione pressure. The variation of τ_0 with temperature is already known (4) and, in conjunction with the values of the slopes in Fig. 7, k_7 can be evaluated from the phosphorescence yield data, on the basis of the above mechanism. The results are shown in Table 2. The agreement is good and supports the mechanism presented above.

The possibility of E-type delayed fluorescence in the pentanedione photolysis was also investigated. The phenomenon has been observed in many systems and is associated with the thermal excitation of the triplet state to the singlet state. It has been detected in molecules characterized

TABLE 2. Comparison of rate constants for self-quenching of triplet state from τ_p and Q_p data

Temperature (°C)	k_7 from τ_p (M^{-1} s^{-1})	k_7 from Q_p (M^{-1} s^{-1})
50.0	5.3×10^5	7.5×10^5
70.0	1.5×10^6	2.5×10^6
90.0	2.5×10^6	2.0×10^6

by a small triplet–singlet energy gap, *e.g.* benzil in solution (21) and biacetyl in the gas phase (22).

The mechanism of the reactivation can be considered as

[10] $$^3P + M \rightarrow {}^3P^v + M$$

[11] $$^3P^v + M \rightarrow {}^3P + M$$

[12] $$^3P^v \rightarrow {}^1P$$

It can be shown from a detailed consideration of the differential equations that describe the mechanism (23) for the pentanedione system that reactivation from the triplet would not affect the lifetime of the triplet. This arises because the major process removing the singlet state is a rapid intersystem crossing to reform the triplet. Thus, triplet lifetime studies could not show the presence of a reactivation process, *i.e.* delayed fluorescence, in the system. The fluorescence yield from pentanedione was measured as a function of the concentration of an added inert gas, perfluoroethane. It was found that the fluorescent yield was constant for pentanedione (concentration of 1.4×10^{-3} M) at 40 °C excited at 436 nm as the perfluoroethane concentration varied up to about 5×10^{-2} M. Delayed fluorescence cannot be detected under those conditions in the pentanedione system. The difference between the pentanedione and biacetyl (22) systems in this regard may be due to the shorter lifetime of the triplet pentanedione, so that more rapid processes are in competition with reactivation in this case.

Emission and Deactivation of the Excited States of 2,3-Pentanedione

A. W. JACKSON AND A. J. YARWOOD
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 9, 1971

Vibrationally excited singlet and triplet states of 2,3-pentanedione are formed by photolysis at 365 nm. The processes removing these excited states in the gas phase are studied by measuring the fluorescence and phosphorescence yields. Fluorescence can occur from the vibrationally excited, as well as the vibrationally equilibrated, singlet state. The fluorescence and phosphorescence data are considered in terms of mechanisms which involve either weak or strong collisions. Although the data cannot distinguish between the alternatives, there are two significant conclusions. The fluorescence data require that emission occur from at least two levels in the singlet manifold. To explain the phosphorescence data, the highest emitting singlet level must not lead to a vibrationally equilibrated triplet state.

Les états excités vibrationnels singulet et triplet du 2,3-pentanedione sont formés par photolyse à 365 nm. On étudie les procédés qui enlèvent ces états excités en phase gazeuse en mesurant les rendements de fluorescence et de phosphorescence. La fluorescence peut provenir de l'état singulet vibrationnel excité aussi bien qu'équilibré. On considère les résultats de phosphorescence et de fluorescence en termes de mécanismes qui impliquent des collisions fortes ou faibles. Quoique les résultats ne permettent pas de distinguer les cas intermédiaires, on arrive à deux conclusions significatives. Les résultats de fluorescence impliquent que l'émission se fait à partir d'au moins deux niveaux à l'état singulet. Pour expliquer les résultats de phosphorescence, le niveau singulet émetteur le plus élevé ne doit pas conduire à un état vibrationnel triplet équilibré.

Canadian Journal of Chemistry, **50**, 1338 (1972)

Introduction

The deactivation of vibrational energy is a topic that is central to the problem of describing the photochemical behavior of molecules excited at short wavelength in the gas phase. The deactivation is particularly clearly shown in the photochemistry of the iodine molecule (1, 2). The resonance fluorescence spectrum observed at very low iodine pressure changes on the addition of an inert gas. The spectrum includes new emission lines, due to the iodine molecules in new vibrational and rotational levels formed by collisional deactivation. The early research on iodine has been consolidated in an extensive series of recent papers, *e.g.* ref. 3.

The photochemistry of polyatomic molecules, particularly carbonyl compounds, has also contributed to an understanding of the deactivation of vibrational energy. The first paper (4) on the photochemistry of hexafluoroacetone included a consideration of vibrational excitation, and the photochemistry of hexafluoroacetone has been a fruitful field of endeavor (5, 6). Much of the discussion has concerned the problem of whether deactivation is by a single strong collision, or by a weak collision mechanism in which vibrational energy is removed in a cascade process (7–11). The problem has also been considered in the photochemistry of chloropentafluoroacetone (12) and biacetyl (13–15).

This paper is concerned with the emission and deactivation of the excited states of 2,3-pentanedione. The results are consistent with fluorescence from the vibrationally excited singlet state, and the problem of vibrational deactivation is investigated through measurement of the fluorescence and phosphorescence yields.

Experimental and Results

The details of the experimental procedure were given earlier (16). The quantum yields of fluorescence (ϕ_f) and phosphorescence (ϕ_p) of 2,3-pentanedione (15 Torr) excited at 436 and 405 nm were reported (16) as 0.0011 and 0.019, respectively; whereas, on excitation at 365 nm ϕ_f was 0.00063 and ϕ_p was 0.010.

The effect of adding a high pressure of an inert gas on the emission yields of pentanedione was investigated. At all excitation wavelengths the emission profiles were unchanged in the presence of 1000 Torr of sulfur hexafluoride. Also, for excitation wavelengths of 436 and 405 nm, the absolute yields are unaffected by the addition of inert gas. However, at 365 nm excitation, the values of the fluorescence and phosphorescence yields increased to 0.0012 and 0.020, *i.e.* to essentially those found when 405 and 436 nm excitation was used.

The enhancement of the emission in the presence of added

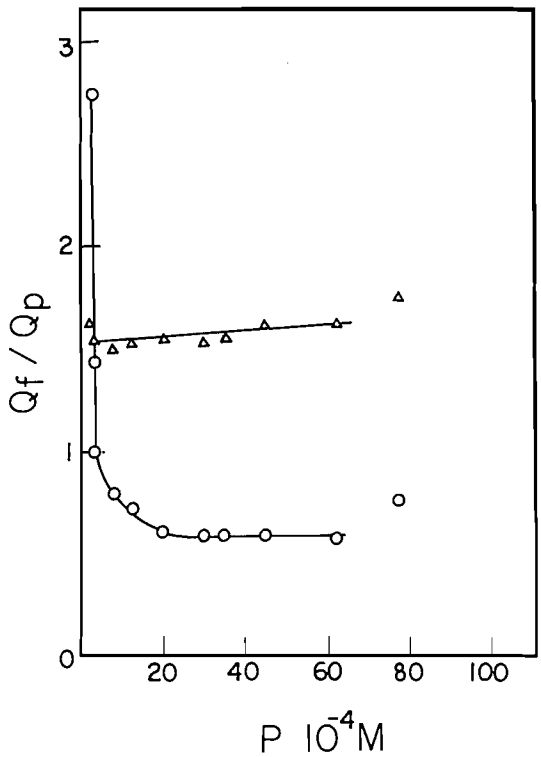

FIG. 1. Ratio of fluorescence to phosphorescence yields as a function of pentanedione concentration at 70 °C. ○, $\lambda_{ex} = 365$ nm. △, $\lambda_{ex} = 405$ nm. The data for $\lambda_{ex} = 405$ nm are displaced one unit vertically.

gas for excitation at 365 nm was further investigated through measurements of the relative fluorescence and phosphorescence yields. In one study the phosphorescence yields were determined from the difference between the total emission yield and the fluorescence yield (which was taken as the emission yield in the presence of oxygen). The ratios of the relative fluorescence and phosphorescence yields at 70 °C as a function of the pentanedione concentration are shown in Fig. 1 for excitation at 405 and 365 nm.

A more detailed investigation of the luminescence behavior at low pressures was carried out using narrow band interference filters to select the fluorescence and phosphorescence. Figure 2 shows the individual fluorescence and phosphorescence yields of pentanedione at 90 °C for 365 nm excitation. The value $Q_{f\infty}$ corresponds to the value of Q_f when 1000 Torr of methyl chloride were added to the sample at a concentration of 1.0×10^{-2} M.

The behavior on 365 nm excitation was also investigated at a lower temperature, 30.0 °C. Due to the low vapor pressure of 2,3-pentanedione at this temperature, the experiment was carried out at a fixed pressure of pentanedione, and various pressures of sulfur hexafluoride were added. The results are shown in Fig. 3, where Q_e, the yield of total emission, *vs.* sulfur hexafluoride pressure is plotted.

Discussion

There is a distinct difference between the luminescence behavior observed on excitation at 405 nm and at 365 nm, since $\phi_f = 0.00063$ for $\lambda_{ex} = 365$ nm compared with $\phi_f = 0.0011$ for $\lambda_{ex} = 405$ nm. The phosphorescence yield is also lower for the shorter wavelength excitation at low pressures. The pressure of the system also has a large influence, since the addition of 1000 Torr of sulfur hexafluoride to 15 Torr of pentanedione changes the emission yields observed on excitation at 365 nm to the values observed on excitation at 405 nm. The differences are shown very clearly in the data taken using the relative yield apparatus. At high concentrations, the ratio of fluorescence to phosphorescence yields (oxygen quenching technique) is approximately the same for 365 and 405 nm excitation at 70 °C, Fig. 1. However, at low concentrations there is a dramatic increase in the ratio for 365 nm excitation which is not detected for 405 nm excitation.

This feature of the system was further investigated using narrow band interference filters to isolate the fluorescence and phosphorescence wavelengths. The results for pentanedione at 90 °C are shown in Fig. 2. Again the excitation wavelength is 365 nm, but in Fig. 2 the individual values of Q_f and Q_p are presented. This shows that as the concentration is decreased, it is the phosphorescence yield that decreases rapidly to zero whereas the fluorescence is finite. Thus, the ratio $Q_f : Q_p$ in Fig. 1 increases at low concentration for 365 nm excitation because the phosphorescence yield has decreased rather than the fluorescent yield increased. This indicates the formation of the emitting level of the triplet depends upon a collisional process.

Another interesting point concerning the data of Fig. 2 is the enhancement of the fluorescence (and phosphorescence) as the concentration increases. Similar fluorescence enhancement has been observed in biacetyl (14, 15), hexafluoroacetone (10), and chloropentafluoroacetone (12) and has been interpreted in terms of a model involving competition between radiation and radiationless processes in the excited singlet state.

The variation of the fluorescence yield with concentration in the low concentration region cannot be reasonably extrapolated to the origin (although this does not show very clearly in Fig. 2). This is a particularly noteworthy aspect of the system and suggests that pentanedione excited at short wavelength at low concentration can emit from vibrationally excited levels of the excited singlet state. Consequently, the mechanisms to be discussed all involve emission from vibrationally excited singlet states.

The following scheme represents an initial kinetic model that considers vibrational deactivation in the singlet state and can account for emission from vibrationally excited singlet levels and collisional dependence of the phosphorescence. The fluorescence behavior is considered first.

Scheme A

[1] $S_0 + h\nu \rightarrow S_1^v$

[2] $S_1^v \rightarrow S_0 + h\nu_f$

[3] $S_1^v \rightarrow$ removal

[4] $S_1^v + M \rightarrow S_1^0 + M$

[5] $S_1^0 \rightarrow S_0 + h\nu_f$

[6] $S_1^0 \rightarrow T_1^v$

Absorption of light [1] can populate a vibrationally excited singlet state S_1^v that can fluoresce $h\nu_f$ [2], be removed in a radiationless process [3], or be vibrationally deactivated in a single collision by a species M [4] to form S_1^0. The vibrationally equilibrated excited singlet level S_1^0 can fluoresce [5] or can intersystem cross [6] to form a vibrationally excited triplet state T_1^v.

Application of the steady state approximation to this system gives for the quantum yield of fluorescence ϕ_f,

$$[7] \quad \phi_f = \frac{k_2}{k_2 + k_3 + k_4(M)} + \frac{k_4 k_5(M)}{(k_5 + k_6)(k_2 + k_3 + k_4(M))}$$

If it is assumed that $k_2 = k_5$, and that $k_2 \ll k_3$ and $k_5 \ll k_6$ (since the fluorescence yield is small) then

$$[8] \quad \phi_f = \frac{k_2}{k_3 + k_4(M)} \left\{ 1 + \frac{k_4(M)}{k_6} \right\}$$

This expression may be rearranged in several ways to yield a functional dependence that can be tested using the data. One method is to recognize the limits of the fluorescence quantum yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at high and low concentrations, ϕ_{f_∞} and ϕ_{f_0}.

$$\text{As (M)} \rightarrow 0, \qquad \phi_f \rightarrow \phi_f^0 = k_2/k_3$$

$$\text{As (M)} \rightarrow \infty, \qquad \phi_f \rightarrow \phi_f^\infty = k_2/k_6$$

Inserting these limits gives

$$[9] \qquad \phi_f - \phi_f^0 = \frac{k_2 k_4(\text{M})(k_3 - k_6)}{k_3 k_6(k_3 + k_4(\text{M}))}$$

$$[10] \qquad \phi_f^\infty - \phi_f = \frac{k_2(k_3 - k_6)}{k_6(k_3 + k_4(\text{M}))}$$

which gives the dimensionless equation

$$[11] \qquad \frac{\phi_f - \phi_f^0}{\phi_f^\infty - \phi_f} = \frac{k_4}{k_3}(\text{M}) = \frac{Q_f - Q_f^0}{Q_f^\infty - Q_f}$$

Equation 11 is tested in Fig. 4 using the fluorescence data of Fig. 2. The value of Q_f^0 was obtained by extrapolating the experimental curve of Fig. 2 to zero concentration and the value of Q_f^∞ was taken as the relative fluorescence yield when about 1000 Torr of methyl chloride were added to the pentanedione. It can be seen from Fig. 4 that the dependence is well described by a straight line passing through the origin. The fit is particularly good since the dimensionless quantity $(Q_f - Q_f^0)/(Q_f^\infty - Q_f)$ contains three experimentally determined quantities and accumulates the experimental errors.

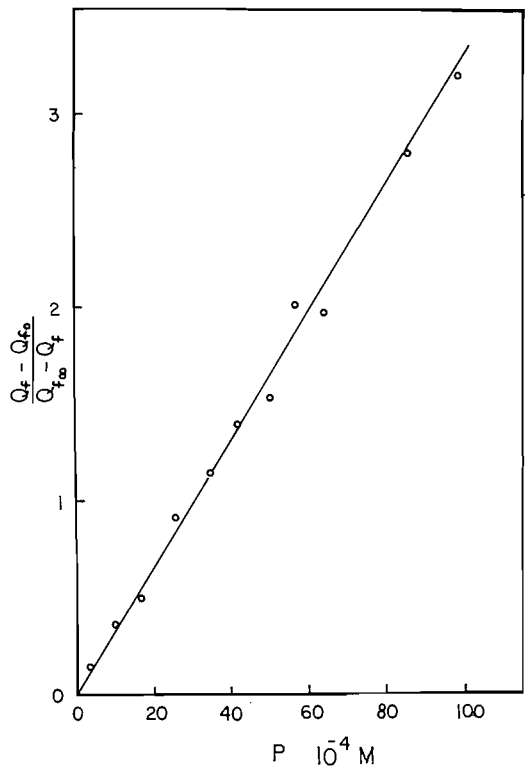

FIG. 4. Dependence of the dimensionless fluorescence function on pentanedione concentration at 90 °C, $\lambda_{ex} = 365$ nm.

The conclusion from this test is that a model in which there are two emitting levels in the singlet manifold that are connected through a strong collision is consistent with the fluorescence data. Although a model in which there is only one emitting singlet level would also predict a linear relation for Fig. 4 it is not consistent with the finite intercept for ϕ_f in Fig. 2. The rate constant k_3 can be estimated from $Q_f^\infty/Q_f^0 = k_3/k_6 = 4.4$. The rate constant k_6 can be estimated as about 2×10^8 s^{-1} (from the natural radiative lifetime and the fluorescence yield) and if it is assumed that the rate constant does not change with temperature then $k_3 \simeq 8.8 \times 10^8$ s^{-1}. The slope of the line in Fig. 4 is given by k_4/k_3 ($= 330 \pm 20\ M^{-1}$) and so $k_4 \simeq 2.9 \times 10^{11}\ M^{-1}$ s^{-1}. This value can be compared with the collision frequency (about $2 \times 10^{11}\ M^{-1}$ s^{-1}) and indicates that within the context of this mechanism every collision successfully deactivates the vibrationally excited singlet species.

Fluorescence is a useful tool in studying collisional deactivation in the gas phase and much work (8, 9, 12) has been carried out to distinguish between strong and weak collisional deactivation mechanisms. Accordingly, a mechanism was constructed for pentanedione involving more than two excited singlet levels to discover how the fluorescence behavior would be modified. This weak collision mechanism is:

Scheme B

$$[12] \qquad S_0^0 + h\nu \xrightarrow{\text{labs}} S_1^v$$

$$[13] \qquad S_1^v \longrightarrow \text{removal}$$

$$[14] \qquad S_1^v \longrightarrow S_0^n + h\nu_f$$

$$[15] \qquad S_1^v + \text{M} \longrightarrow S_1^{v'} + \text{M}$$

$$[16] \qquad S_1^{v'} \longrightarrow \text{removal}$$

$$[17] \qquad S_1^{v'} \longrightarrow S_0^n + h\nu_f$$

$$[18] \qquad S_1^{v'} + \text{M} \longrightarrow S_1^0 + \text{M}$$

$$[19] \qquad S_1^0 \longrightarrow S_0^n + h\nu_f$$

$$[20] \qquad S_1^0 \longrightarrow T_1^v$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This mechanism involves an extra vibrationally excited singlet level $S_1^{v'}$ and the removal steps are radiationless processes. This situation is more complicated than Scheme A but can be treated if simplifying assumptions are made. These assumptions are: (*a*) the spontaneous emission rate constants are the same from the three levels, *i.e.* $k_{14} = k_{17} = k_{19}$; and that in each case the radiative rate constant is small compared to the radiationless rate constants; (*b*) the vibrational quenching efficiency is independent of the level in singlet manifold, *i.e.* $k_{15} = k_{18}$; and, (*c*) the intersystem crossing rate constant is the same from the intermediate level as from the thermally equilibrated level, *i.e.* $k_{16} = k_{20}$.

Under these conditions $\phi_f^0 = k_{14}/k_{13}$, $\phi_f^\infty = k_{14}/k_{20}$, and $(Q_f - Q_f^0)/(Q_f^\infty - Q_f) = k_{15}(M)/k_{13}$; which is the same form as Scheme A. Scheme B, with the same assumptions, is indistinguishable from Scheme A since the $S_1^{v'}$ level has the same processes controlling its fate as the S_1^0 level.

Changes in the mechanism can cause only small changes in fluorescence behavior. This is emphasized by considering Scheme C, which is a modification of Scheme B in which k_{16} is now set equal to k_{13} rather than k_{20}. Under these circumstances, retaining assumptions *a* and *b* above,

$$[21] \quad \phi_f = \frac{k_{14}}{k_{13} + k_{15}(M)} + \frac{k_{14}k_{15}(M)}{(k_{13} + k_{15}(M))^2} + \frac{k_{14}k_{15}^2(M)^2}{k_{20}(k_{13} + k_{15}(M))^2}$$

and this can be rearranged to

$$[22] \quad \frac{1}{\phi_f - \phi_f^0} = \frac{k_{20}k_{13}(k_{13} + k_{15}(M))^2}{k_{15}^2 k_{14}(k_{13} - k_{20})(M)^2}$$

The prediction of this mechanism is tested using eq. 22 in Fig. 5, where $(M)/(Q_f - Q_f^0)^{1/2}$ *vs.* (M) is plotted. A straight line dependence is indeed found and shows that Scheme C is also in accord with the experimental data. Thus, the data do not distinguish between the three models presented above.

An important feature of the above mechanisms is the suggestion that vibrationally excited levels of the excited singlet diketone can fluoresce. This might be expected to cause a shift in the profile of fluorescence as a function of wavelength at low concentrations. No change in the profile was detected in this research, but experiments could only be carried out at pressures greater than 15 Torr. Experiments with more sensitive equipment and much lower pressures would be useful.

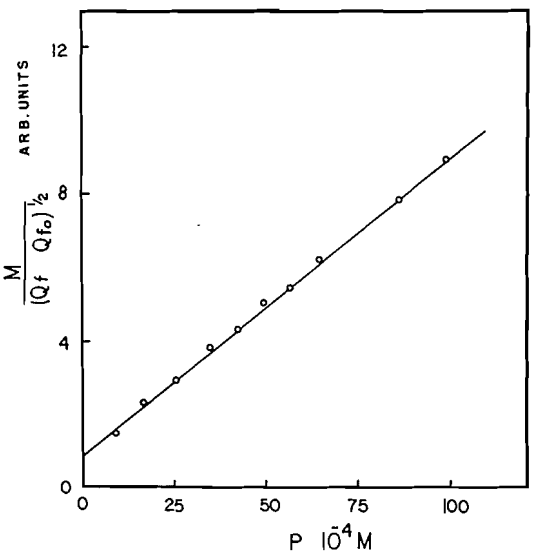

FIG. 5. Test of fluorescence Scheme C at 90 °C, $\lambda_{ex} = 365$ nm.

The phosphorescence behavior expected on the basis of Scheme A can now be considered. If it is assumed that only those molecules which intersystem cross from the S_1^0 level of the singlet manifold give triplet molecules capable of phosphorescence, then the quantum yield of T_1^v is

$$[23] \quad \phi_{T_1}^v = \frac{k_4(M)}{k_2 + k_3 + k_4(M)} \times \frac{k_6}{k_5 + k_6}$$

Since $k_5 \ll k_6$ and $k_2 \ll k_3$ then $\phi_{T_1}^v = k_4(M)/(k_3 + k_4(M))$. Further, if vibrational deactivation occurs without loss of population in the triplet manifold then the quantum yield of triplet in the emitting level is also given by $\phi_{T_1}^0 = k_4(M)/(k_3 + k_4(M))$. The processes removing the triplet state in its vibrationally equilibrated level have been considered earlier (17), and the quantum yield of phosphorescence ϕ_p is given by

$$[24] \quad \phi_p = k_p \tau_p k_4(M)/(k_3 + k_4(M))$$

where k_p is the rate constant for phosphorescence emission and τ_p the phosphorescence lifetime.

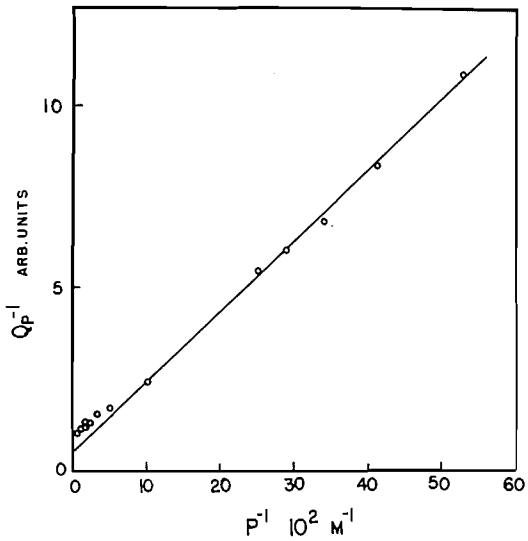

FIG. 6. Variation of the reciprocal of the phosphorescence yield with the reciprocal of the pentanedione concentration at 90 °C, $\lambda_{ex} = 365$ nm.

Equation 24 can be rearranged to

$$[25] \qquad \frac{1}{\phi_p} = \frac{1}{k_p\tau_p}\left\{\frac{k_3}{k_4} \times \frac{1}{(M)} + 1\right\}$$

If one neglects the variation of τ_p with pentanedione concentration, then this predicts that Q_p^{-1} *vs.* $(M)^{-1}$ should be linear. This is tested in Fig. 6, where the data are derived from Fig. 2. The dependence is linear at low concentrations but deviates at high concentrations; the high deviation can be reconciled with self-quenching of the triplet state (17). From the slope of Fig. 6, the ratio k_4/k_3 can be calculated as 250 M^{-1}. This value is sensitive to the extrapolated intercept of Fig. 6 and uses a value of $k_p\tau_0 = 2 \times 10^{-3}$ at 90 °C. It can be compared directly with the value of 330 M^{-1} determined in the fluorescence study. Considering the error involved in determining the intercept of Fig. 6, the agreement between the rate constant ratios determined from the fluorescence and phosphorescence data is very good. This emphasizes the internally consistent nature of Scheme A.

The phosphorescence model assumes that only those triplet molecules which originate from the vibrationally equilibrated level of the singlet state successfully reach the emitting equilibrated level of the triplet state. This implies that the radiationless process [3] does not yield triplet molecules capable of deactivation to the equilibrated level of the triplet. Process [3] could involve decomposition through the singlet manifold or intersystem crossing to a dissociative triplet state. At 90 °C, a rate constant for decomposition of the triplet of greater than 5×10^9 s^{-1} would effectively prevent deactivation to emitting levels of the triplet.

It is interesting to note the approximations necessary in Schemes B and C to provide agreement with the phosphorescence behavior. In both cases, if the S_1^v level is the only level incapable of yielding vibrationally quenchable triplets then the same functional dependence is found as for Scheme A.

Even though a choice cannot be made between the three alternatives, there are two important common features: (*a*) to explain the fluorescence data at least two levels in the singlet manifold must emit; (*b*) to explain the phosphorescence data the highest emitting singlet level must not be capable of giving thermally equilibrated triplet states.

The results of the enhancement experiments at 30.0 °C with sulfur hexafluoride can now be considered. Since the phosphorescence is about seventeen times the intensity of the fluorescence at 30.0 °C, the total emission yield plotted in Fig. 3 is effectively the phosphorescence yield. The deactivation phenomena in a mixture of gases can be discussed within the framework of a strong collision mechanism in the manner recommended by Caro, Grotewold, and Lissi (14). In the following Scheme, M is sulfur hexafluoride and P is the pentanedione.

Scheme A'

[26] $S_0^0 + h\nu \rightarrow S_1^v$

[27] $S_1^v \rightarrow$ radiationless removal

[28] $S_1^v + M \rightarrow S_1^0 + M$

[29] $S_1^v + P \rightarrow S_1^0 + P$

[30] $S_1^0 \rightarrow T_1^0$

[31] $T_1 \rightarrow S_0 + h\nu_p$

[32] $T_1 \rightarrow$ radiationless removal

If $Y = \phi_p^0/\phi_p$ where ϕ_p^0 and ϕ_p are the phosphorescence quantum yields in the absence and presence of M, and if $F = Y/(1 - Y)$, then the steady state approximation in Scheme A' leads to

$$[33] \qquad F = \frac{1}{(M)}\frac{k_{29}(P)^2}{k_{28}} + \frac{k_{29}^2(P)^2}{k_{27}k_{28}} + \frac{k_{29}(P)}{k_{27}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

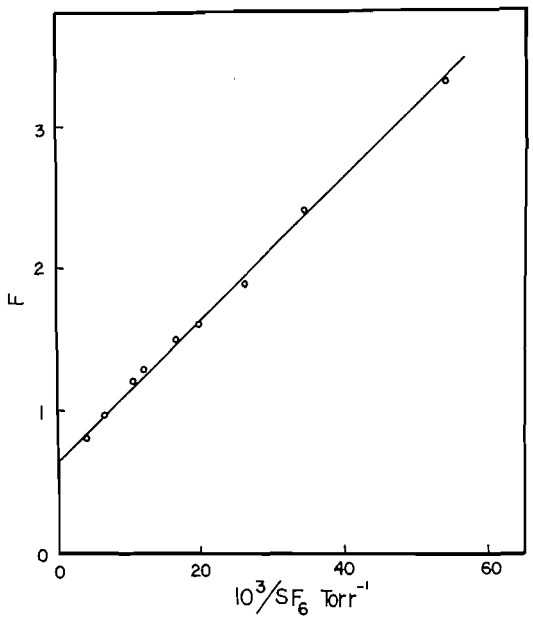

FIG. 7. Variation of F with the reciprocal of the sulfur hexafluoride pressure at 30 °C, $\lambda_{ex} = 365$ nm.

For a particular pentanedione concentration this predicts a linear relation between F and $1/(M)$. Figure 7 shows a plot of F *vs.* the reciprocal of the sulfur hexafluoride pressure for the data of Fig. 3. From the slope and intercept of Fig. 7, the ratios $k_{29}/k_{27} = 1.04 \times 10^3\ M^{-1}$ and $k_{29}/k_{28} = 2.94$ at 30.0 °C can be derived. The sulfur hexafluoride molecule is about one-third as efficient as the pentanedione molecule in deactivating the excited singlet state and this result is in agreement with the data obtained on the deactivation of the excited singlet state of biacetyl (15).

The value of $k_{29}/k_{27} = 1.04 \times 10^3\ M^{-1}$ at 30.0 °C derived from the sulfur hexafluoride experiments can be compared with the value of the similar rate constant ratio (k_4/k_3) derived from the pure pentanedione experiments at 90.0 °C (330 and 250 M^{-1} from the fluorescence and phosphorescence experiments, respectively). The smaller value of the ratio at the higher temperature suggests that process [3] involving radiationless removal has increased at the higher temperature, since the rate constant k_4 is not likely to change greatly.

The research on pentanedione can be compared with that on biacetyl. Phosphorescence behavior of biacetyl on excitation at 365 nm has been reported by several workers (13–15), and was also described by a strong collision mechanism. There is a very recent preliminary study (18) of interference effects on the helium quenching of fluorescence of biacetyl (at 0.05 Torr) on excitation at 405 nm, but excitation at shorter wavelengths was not considered in detail.

In summary, the fluorescence behavior of pentanedione with varying pressure during 365 nm photolysis is consistent with emission from vibrationally excited levels of the singlet state. Examination of the variation with pressure does not distinguish between a strong and weak collision mechanism for deactivation in the singlet manifold. An internally consistent model for the phosphorescence data is proposed in which the highest emitting singlet level is not capable of forming vibrationally equilibrated triplet states.

Theory of Enthalpy of Mixing in Reactive Charge Asymmetrical Molten Salt Systems. Part II. Ternary Solutions

S. N. FLENGAS AND J. M. SKEAFF[1]

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received October 14, 1971

The enthalpies of mixing for a reacting charge asymmetrical ternary molten salt system have been calculated on the basis of an extension of a previously developed model for binary systems. The enthalpy of mixing is considered to consist of a reaction term and a mixing term; the former results from the formation of the tetrahedrally coordinated complex species MCl_4^{2-} and the latter from the mixing of the products of reaction according to quasichemical theory modified to account for charge asymmetry.

The ternary model enables the prediction of the integral enthalpies from a knowledge of the interaction parameters determined for the two charge asymmetrical binary systems. The calculations are compared with experimentally measured integral enthalpies of mixing in the ternary system $MnCl_2$–NaCl–CsCl, and shown to give accurate predictions of the behaviour of the system.

On a calculé les enthalpies de mélange d'un système ternaire de sel fondu à charge réactive assymétrique sur la base d'une extension d'un modèle développé auparavant pour les systèmes binaires. On considère que l'enthalpie de mélange consiste en un terme de réaction et un terme de mélange; le premier terme résulte de la formation d'espèces complexes tétraédriquement coordinées MCl_4^{2-} et le dernier du mélange de produits de réaction selon la théorie quasi-chimique, modifiée pour tenir compte de l'assymétrie de charge.

Le modèle ternaire rend possible la prédiction des enthalpies intégrales, connaissant les paramètres d'interaction déterminés pour les deux systèmes binaires à charge assymétrique. On compare les calculs avec les enthalpies intégrales de mélange, mesurées expérimentalement, dans le système ternaire $MnCl_2$–NaCl–CsCl et on montre qu'ils prédisent de façon précise le comportement du système.

Canadian Journal of Chemistry, **50**, 1345 (1972)

Introduction

In a previous publication (1) from this laboratory the enthalpies of mixing of the charge asymmetrical molten salt systems of the type MCl_2–ACl (where M represented Mn, Fe, Co, Ni, Mg, and Cd, and A represented Li, Na, K, Rb, and Cs) measured elsewhere (2–4) were interpreted on the basis of a quasichemical model in which the mixing process was separated into a reaction and a mixing step. The heat evolved during the reaction step was attributed to the formation of a tetrahedrally coordinated complex MCl_4^{2-}, and that associated with the mixing step was calculated by the application of a regular solution treatment which accounted for charge asymmetry in the liquid. For the latter calculation the coordination number of the solution was taken to be proportional to the concentration average coordination number of the cationic species present.

The adjustable parameters predicted by this treatment were shown to be physically meaningful as they related to the structural properties of the melts.

As indicated previously, the presence of tetrahedrally coordinated complex species in mixtures of mono- and divalent melts is supported by cryoscopic (5*a*) and spectrophotometric evidence (5*b*). According to Papatheodorou and Kleppa (2–4), the exothermic heats of mixing observed in these systems could be attributed to the formation of the MCl_4^{2-} complex species and to dispersion effects. The treatment is semi-qualitative and the various adjustable parameters are assigned arbitrary values.

Pelton and Thompson (6) calculated the concentration dependence of the heats and entropies of mixing in the $MgCl_2$–ACl type binary systems for about 60% of the composition range using a dissociating complex ion model based on the $MgCl_4^{2-}$ species. The model does not account for charge asymmetry or vibrational contributions to the entropies of mixing and also makes the questionable assumption that *pure* $MgCl_2$ consists of "free" Mg^{2+} and complex MCl_4^{2-} species related by a dissociation constant.

Also, recently Østwold (7) developed a model

which is quite similar to that proposed by Pelton and Thompson (6) with the main difference that, although charge asymmetry is accounted for in the calculation of the enthalpy of the solution, it is ignored in the calculation of the entropy.

Experimental data and theoretical interpretations are almost totally lacking for ternary charge asymmetrical fused salt systems. In the present investigation the previously proposed quasichemical model developed for charge asymmetrical binary fused salt systems is extended to ternary systems. The method is applied to the enthalpies of mixing of the system $MnCl_2$–NaCl–CsCl as determined in a previous investigation (8) in this laboratory. The isothermal heats of mixing were measured by means of a high temperature isoperibol solution calorimeter which is also described elsewhere (8). The ternary model enables the prediction of the integral enthalpies of mixing in the ternary system from the knowledge of the interaction parameters of the two binary systems $MnCl_2$–NaCl and $MnCl_2$–CsCl.

Complexes in Fused Salts

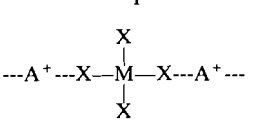
The concept of complexes in fused salts is based upon the following postulates (1):

(*1*) The fused salt is a continuous and highly charged medium, and as a result interlocking anionic and cationic quasi-lattices exist to preserve local electrical neutrality.

(*2*) A non-ionic solvent capable of separating ionic species such as water is not present.

(*3*) The difference between a complexed and a non-complexed state, involving a cation M^{2+} and an anion X^-, is simply defined by a characteristic average "shorter" bond distance M—X for the complexed state as compared to the M—X bond distance for the non-complexed state.

(*4*) Complexed ionic species must still belong to their respective quasi-lattices and not disrupt the continuity of the phase. Hence the ligands X in a complex MX_n interact with the surrounding A^+ cations in the sequence



whereby an anion X is always a cation "bridging" species.

(*5*) Under such restrictions, the complex represents a coordinated configuration of the type MX_n which may be treated as a statistical entity.

(*6*) The formation of a complex is initiated by the presence of foreign cations A^+ which compete poorly with the central cations M^{2+} for the same ligands X^-. Accordingly, the charge density of the cation A^+ is related to its capability of promoting or preventing the formation of complexes.

(*7*) The coordination number of a given monovalent cation is taken to be one-half of that of a divalent cation, with respect to a monovalent anion ligand. The coordination number of a solution containing both mono- and divalent cations is taken to be the ion-fraction average of that of the two cations.

Composition Representation Within a Ternary System

The composition of a ternary system is usually represented by points within an equilateral triangle in which the points of 100% of each component are situated at the corners.

Any composition point P is found by drawing through P, lines parallel to each of the three sides. The complement of the perpendicular distance from each corner to the respective line through P gives the amount of the particular component. If the composition variable is the mole fraction, then the values thereby ascertained must satisfy the relationship

$$[1] \qquad x_1 + x_2 + x_3 = 1$$

where 1, 2, and 3 are the components of the ternary.

A tie-line from 1 to the 2, 3 binary represents compositions for which

$$[2] \qquad t' = \frac{x_3}{x_2} = \text{constant}$$

but since t' goes to infinity as x_2 goes to zero, it is more convenient to define

$$[3] \qquad t = \frac{x_3}{x_2 + x_3}$$

which is seen to be always finite and to lie between 0 and 1.

When x_1 is constant then $1 - (x_2 + x_3)$ is also constant and the parameter, y, is defined as

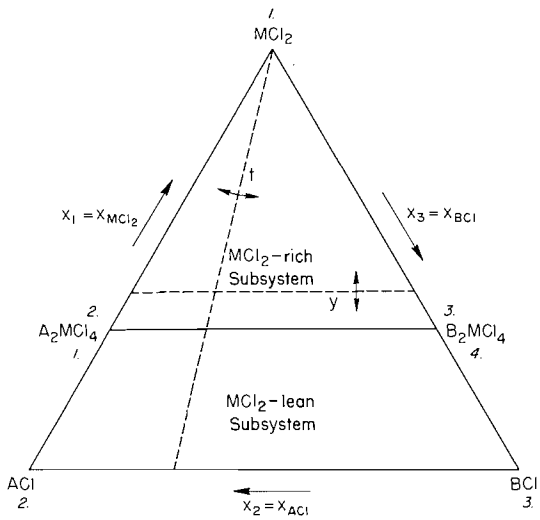

FIG. 1. Division of the ternary system MCl_2–ACl–BCl into two subsystems.

$$y = x_2 + x_3 = 1 - x_1 \quad [4]$$

$t = 0$ in the *1–2* binary, and $t = 1$ in the *1–3* binary; for pure component *1*, $y = 0$ and $y = 1$ for all values of t in the *2–3* binary.

Calculation of the Enthalpies of Mixing in Reactive Charge Asymmetrical Ternary Fused Salt Systems

The concentration dependence of the enthalpy of mixing in reactive charge asymmetrical ternary fused salt systems will be derived on the basis of the complex ion model (1).

The thermodynamic properties of a ternary system of the type MCl_2–ACl–BCl, where M represents a divalent cation and A and B represent two different monovalent metal cations, may be predicted by postulating that the behavior of the ternary system is a function of the constituent binaries. As an extension of the approach to binary systems, the ternary is divided into two composition ranges at $y = 2/3$: a MCl_2-rich three component subsystem, MCl_2–A_2MCl_4–B_2MCl_4 and a four component subsystem A_2MCl_4–ACl–BCl–B_2MCl_4, as shown in Fig. 1.

For both regions the total enthalpy of mixing in the ternary, ΔH_{tot}, is considered to consist in a reaction term ΔH_R, and a mixing term, ΔH_{mix}, *i.e.* $\Delta H_{M,T} = \Delta H_R + \Delta H_M$. In a solution of composition (y,t), the actual mole fractions of the three component reactants are

$$x_{MCl_2} = x_M = 1 - y$$
$$x_{ACl} = (1 - t)y \quad [5]$$
$$x_{BCl} = ty$$

The complex forming reactions are

$$2ACl + MCl_2 \rightarrow A_2MCl_4 \quad [6]$$
$$2BCl + MCl_2 \rightarrow B_2MnCl_4$$

The Subsystem MCl_2–A_2MCl_4–B_2MCl_4

For convenience, the subscripts *1*, *2*, and *3* will refer to the components as they appear in the heading of this section.

The reaction term is comprised of the two following heat effects: (*i*)

$$y(1-t)ACl + \tfrac{1}{2}y(1-t)MCl_2 \rightarrow \tfrac{1}{2}y(1-t)A_2MCl_4 \quad [7]$$

for which the enthalpy is

$$\Delta H_{12} = \tfrac{1}{2}y(1-t)b_{R_{12}} \quad [8]$$

and (*ii*)

$$yt BCl + \tfrac{1}{2}yt MCl_2 \rightarrow \tfrac{1}{2}yt B_2MCl_4 \quad [9]$$

for which the enthalpy is

$$\Delta H_{13} = \tfrac{1}{2}yt b_{R_{13}} \quad [10]$$

where $b_{R_{12}}$ and $b_{R_{13}}$ are the reaction parameters of the binary systems MCl_2–ACl and MCl_2–BCl, respectively. The total "reaction heat" is thus

$$\Delta H_R = \tfrac{1}{2}y[(1-t)b_{R_{12}} + tb_{R_{13}}] \quad [11]$$

After the stoichiometric reaction has taken place, the solution consists of

$$n_1 = (2 - 3y) \text{ moles of unreacted } MCl_2$$
$$n_2 = y(1-t) \text{ moles of } A_2MCl_4 \quad [12]$$
$$n_3 = yt \text{ moles of } B_2MCl_4$$

The mixing reaction to be considered is thus

$$n_1MCl_2 + n_2A_2MCl_4 + n_3B_2MCl_4 \rightarrow [(MCl_2)_{n_1}(A_2MCl_4)_{n_2}(B_2MCl_4)_{n_3}] \quad [13]$$

for which the energy of mixing is

$$\Delta E^{int}_{mix} = E_{soln} - n_1E^0_{MCl_2} - n_2E^0_{A_2MCl_4} - n_3E^0_{B_2MCl_4} \quad [14]$$

In this region, the ionic fractions N are

$$N_{M^{2+}} = \frac{n_1}{\Sigma n_+}, \qquad N_{A^+} = \frac{2n_2}{\Sigma n_+}$$

$$[15] \qquad N_{B^+} = \frac{2n_3}{\Sigma n_+}, \qquad N_{Cl^-} = \frac{2n_1}{\Sigma n_-}$$

$$N_{MCl_4^{2-}} = \frac{n_2 + n_3}{\Sigma n_-} = N_{Cl^*}$$

where $\Sigma n_+ = (n_1 + 2n_2 + 2n_3)$ and $\Sigma n_- = (2n_1 + n_2 + n_3)$. The symbol Cl* refers to chloride bonded within a complex.

The significant interactions in this ternary for the pure components and for the solution are considered to be those involving nearest neighbors only. The coordination number of A^+ or B^+ will be $Z_1/2$ and that of M^{2+} will be Z_1. Thus the average coordination number will be

$$[16] \qquad \bar{Z} = Z_1 N_{M^{2+}} + \tfrac{1}{2} Z_1 N_{A^+} + \tfrac{1}{2} Z_1 N_{B^+}$$

and substitution of the concentration terms for the ionic fraction yields

$$[17] \qquad \bar{Z} = \frac{n_1 + n_2 + n_3}{n_1 + 2n_2 + 2n_3} Z_1$$

The total number of bonds in solution will thus be $(n_1 + n_2 + n_3)NZ_1/2$ which N is now Avogadro's number.

The pure liquid components are characterized by the interactions M–Cl, A–Cl*, and B–Cl*. In addition to these the solution contains the interactions A–Cl, B–Cl, and MCl*.

From eq. 14, following the method which is applicable to regular solutions extended to ternary systems, the expression for the integral internal energy of mixing is given as

$$[18] \quad \Delta E_M = \tfrac{1}{2} NZ_1[(n_1 + n_2 + n_3)(N_{M^{2+}}.N_{Cl^-}\varepsilon_{MCl} + N_{M^{2+}}.N_{Cl^*}\varepsilon_{M-Cl^*} + N_{A^+}.N_{Cl^-}\varepsilon_{A-Cl} + N_{A^+}.N_{Cl^*}\varepsilon_{A-Cl^*} + N_{B^+}.N_{Cl^-}\varepsilon_{B-Cl} + N_{B^+}.N_{Cl^*}\varepsilon_{B-Cl^*}) - (n_1\varepsilon_{M-Cl} + n_2\varepsilon_{A-Cl^*} + n_3\varepsilon_{B-Cl^*})]$$

where nearest neighbor bond energies of the same kind are taken to have the same value in the solution as in the corresponding pure material. With the introduction of the expressions for the ionic fractions, factoring, rearranging and assuming that $P\,dV_{mix} = 0$, we obtain the following expression for the integral enthalpy of mixing

$$[19] \quad \Delta H_{mix} = \frac{NZ_1}{2\Sigma n_+ . \Sigma n_-}\{[n_1^2 n_2(4\varepsilon_{A-Cl} + \varepsilon_{M-Cl^*} - 3\varepsilon_{M-Cl} - 2\varepsilon_{A-Cl^*}) + 2n_1 n_2^2(2\varepsilon_{A-Cl} + \tfrac{1}{2}\varepsilon_{M-Cl^*} - \varepsilon_{M-Cl} - \tfrac{3}{2}\varepsilon_{A-Cl^*}) + n_1^2 n_3(4\varepsilon_{B-Cl} + \varepsilon_{M-Cl^*} - 3\varepsilon_{M-Cl} - 2\varepsilon_{B-Cl^*}) + 2n_1 n_3^2(2\varepsilon_{B-Cl} + \tfrac{1}{2}\varepsilon_{M-Cl^*} - \varepsilon_{M-Cl} - \tfrac{3}{2}\varepsilon_{B-Cl^*}) + n_1 n_2 n_3(2\varepsilon_{M-Cl^*} - 4\varepsilon_{M-Cl} + 4\varepsilon_{A-Cl} - 3\varepsilon_{A-Cl^*} + 4\varepsilon_{B-Cl} - 3\varepsilon_{B-Cl^*})]\}$$

The interaction energies in parentheses may be rearranged to take the form of simple functions of the interaction parameters previously determined for the binary systems MCl_2–ACl and MCl_2–BCl for the MCl_2-rich regions. For example, for the MCl_2–ACl binary these were

$$[20] \qquad \begin{aligned} b_1' &= \tfrac{1}{2} NZ_1(2\varepsilon_{ACl} + 0.5\varepsilon_{MCl^*} - 2\varepsilon_{MCl} - 0.5\varepsilon_{ACl^*}) \\ b_2' &= \tfrac{1}{2} NZ_1(2\varepsilon_{ACl} + 0.5\varepsilon_{MCl^*} - \varepsilon_{MCl} - 1.5\varepsilon_{ACl^*}) \end{aligned}$$

where N is the Avogadro number. The parameters for the MCl_2–BCl system are obtained by substituting all the A's in eq. 20 with B's.

From eqs. 11, 19, and 20 the final expression for the total enthalpy of mixing in terms of the y and t concentration parameters is

$$[21] \quad \Delta H_{mix}^{int} = \frac{y(2-3y)(1-t)}{8(1-y)}\left[\frac{2-3y}{4(2-y)}(b_1')_{1,2} + (b_2')_{1,2}\right] + \frac{(2-3y)yt}{8(1-y)}\left[\frac{2-3y}{4(2-y)}(b_1')_{1,3} + (b_2')_{1,3}\right] + \frac{y}{2}[(1-t)(b_R)_{1,2} + t(b_R)_{1,3}]$$

which is valid for $2/3 > y > 0$ and $0 < t < 1$. It is thus possible to predict the properties of the ternary system from a consideration of the parameters determined for two of the constituent binaries.

The Subsystem A_2MCl_4–ACl–BCl–B_2MCl_4

In the composition range defined by $1 > y > 2/3$ and $1 > t > 0$, the solution consists of n_1 g-mol of A_2MCl_4, n_2 g-mol of ACl, n_3 g-mol of BCl, and n_4 g-mol of B_2MCl_4, and contains the ionic species A^+, B^+, Cl^-, and MCl_4^{2-}. The complex configuration MCl_4^{2-} results from the reaction between MCl_2 and the stoichiometrically required Cl^- anions provided by the ACl and BCl components.

The solution may be considered as being formed from a binary mixture containing ACl and A_2MCl_4 or BCl and B_2MCl_4 to which either BCl or ACl are added, respectively. In the first case, for example, addition of BCl to a ACl–A_2MCl_4 mixture shall affect the thermodynamic stability of the already existing complex configurations and in this case increase their strength to an extent proportional to the concentration average of the two ligand donors. With respect to the bond energy within a complex, a solution containing the nominal A_2MCl_2, and B_2MCl_4 components should be characterized at each ACl/BCl ratio by a single value for the energy of the M–Cl* type interaction.

The reaction part of the enthalpy of mixing is therefore calculated as the concentration average of the contributions of the two complex species A_2MCl_4 and B_2MCl_4.

Although the system A_2MCl_4, ACl, BCl, and B_2MCl_4 appears to be a reciprocal salt mixture which ordinarily would be treated from the point of view of stable pairs determined by an exchange reaction between ACl and B_2MCl_4 or BCl and A_2MCl_4, the concentration dependent thermodynamic stability of the MCl_4 complex configuration enables the treatment of the system in terms of the four nominal components. Hence, exchange reactions of the type

$$2ACl + B_2MCl_4 \rightarrow A_2MCl_4 + 2BCl$$

should not be taken into account.

Considering a solution consisting of X_1 g-mol of MCl_2, X_2 g-mol of ACl, and X_3 g-mol of BCl, the nominal quaternary composition is calculated on the assumption that the gram-moles of A_2MCl_4 and B_2MCl_4 present are proportional to the ratio of ACl/BCl.

From a mass balance based on eq. 6, the quaternary composition is defined as

$$\begin{aligned} n_1 &= X_1(1-t) && \text{g-mol } A_2MCl_4 \\ n_2 &= X_2 - 2X_1(1-t) && \text{g-mol ACl} \\ n_3 &= X_3 - 2X_1 t && \text{g-mol BCl} \\ n_4 &= X_1 t && \text{g-mol } B_2MCl_4 \end{aligned} \quad [22]$$

The reaction part of the enthalpy of mixing is therefore given as

$$\Delta H_R = (1-y)[(1-t)(b_R)_{1,2} + t(b_R)_{1,3}] \quad [23]$$

where $(b_R)_{1,2}$ and $(b_R)_{1,3}$ refer to the reaction parameters in the ACl–MCl_2 and BCl–MCl_2 binary systems.

The mixing part of the total enthalpy of mixing may be calculated by extending the previous treatment to the quaternary concentration range.

For this purpose, only next nearest neighbor type interactions with respect to an alkali cation shall be considered as being significant. Thus, the pure liquid components are characterized by the interactions Cl*ACl*, ClACl, ClBCl, Cl*BCl*. In addition to these the solution contains the interactions Cl*ACl and Cl*BCl.

The number of bonds for the common coordination number Z_1 of the A^+ and B^+ cations is given as $\frac{1}{2}NZ_1(2n_1 + n_2 + n_3 + 2n_4)$. Accordingly, the concentration dependence of the enthalpy of mixing is calculated as:

$$\begin{aligned} \Delta H_M = \tfrac{1}{2}NZ_1\{&[(2n_1 + n_2 + n_3 + 2n_4)[(N^2_{Cl^*}.N_{A^+}\varepsilon_{Cl^*ACl^*}) + (N^2_{Cl^-}.N_{A^+}\varepsilon_{ClACl}) + (N^2_{Cl^-}.N_{B^+}\varepsilon_{ClBCl}) \\ &+ (N^2_{Cl^*}.N_{B^+}\varepsilon_{Cl^*BCl^*}) + (2N_{Cl^*}.N_{A^+}.N_{Cl^-}\varepsilon_{Cl^*ACl}) + (2N_{Cl^*}.N_{B^+}.N_{Cl^-}\varepsilon_{Cl^*BCl})] \\ &- 2n_1\varepsilon_{Cl^*ACl^*} - n_2\varepsilon_{ClACl} - n_3\varepsilon_{ClBCl} - 2n_4\varepsilon_{Cl^*BCl^*}]\} \end{aligned} \quad [24]$$

where

$$N_{Cl^-} = \frac{n_2 + n_3}{\Sigma n_-}, \qquad N_{MCl_4^{2-}} = N_{Cl^*} = \frac{n_1 + n_4}{\Sigma n_-}$$

$$N_{A^+} = \frac{2n_1 + n_2}{\Sigma n_+}, \qquad N_{B^+} = \frac{n_3 + 2n_4}{\Sigma n_+}$$

and

$$\Sigma n_- = n_1 + n_2 + n_3 + n_4, \qquad \Sigma n_+ = 2n_1 + n_2 + n_3 + 2n_4$$

With the introduction of the expressions for the ionic fractions eq. 24 may be rearranged as

$$[25]\quad \Delta H_M = \tfrac{1}{2}NZ_1\Big[\frac{(n_1+n_4)^2}{\Sigma n_-^2}[n_2(\varepsilon_{Cl^*ACl^*} - \varepsilon_{ClACl}) + n_3(\varepsilon_{Cl^*BCl^*} - \varepsilon_{ClBCl})]$$
$$+ \frac{2(n_2+n_3)^2}{\Sigma n_-^2}[n_4(\varepsilon_{ClBCl} - \varepsilon_{Cl^*BCl^*}) + n_1(\varepsilon_{ClACl} - \varepsilon_{Cl^*ACl^*})]$$
$$+ \frac{2(n_1+n_4)(n_2+n_3)}{\Sigma n_-^2}[2n_1(\varepsilon_{ClACl^*} - \varepsilon_{Cl^*ACl^*}) + n_2(\varepsilon_{Cl^*ACl} - \varepsilon_{ClACl})]$$
$$+ n_3(\varepsilon_{Cl^*BCl} - \varepsilon_{ClBCl}) + 2n_4(\varepsilon_{Cl^*BCl} - \varepsilon_{Cl^*BCl^*})\Big]$$

The interaction energies in parentheses may be expressed as simple functions of the interaction parameters previously determined for the binary systems MCl_2–ACl and MCl_2–BCl for the MCl_2-lean regions. For example, for the MCl_2–ACl binary these were (1)

$$[26]\quad b_1 = \tfrac{1}{2}NZ_1(\varepsilon_{Cl^*ACl^*} + \varepsilon_{ClACl} - 2\varepsilon_{Cl^*ACl})$$
$$b_2 = \tfrac{1}{2}NZ_1(4\varepsilon_{ClACl^*} - 3\varepsilon_{Cl^*ACl^*} - \varepsilon_{ClACl})$$

Replacement of A's with B's yields the corresponding parameters in the MCl_2–BCl binary system. Factoring of eq. 25, rearranging in terms of the interaction parameters, and introducing the y and t composition variables, we obtain the following expression for the mixing part of the total enthalpy

$$[27]\quad \Delta H_M = \frac{(1-y)^2(2-3y)}{(2y-1)^2}[(1-t)(2b_1+b_2)_{1,2} + t(2b_1+b_2)_{1,3}]$$
$$+ \frac{2(3y-2)^2(1-y)}{(2y-1)^2}[(1-t)(2b_1+b_2)_{1,2} + t(2b_1+b_2)_{1,3}]$$
$$- \frac{(1-y)(3y-2)^2}{(2y-1)^2}[(1-t)(3b_1+b_2)_{1,2} + t(3b_1+b_2)_{1,3}]$$
$$+ \frac{2(1-y)^2(3y-2)}{(2y-1)^2}[(1-t)(b_1+b_2)_{1,2} + 2t(b_1+b_2)_{1,3}]$$

The total enthalpy of mixing is calculated by adding eqs. 27 and 23. The partial molar enthalpies of mixing are readily obtained by partial differentiation of the corresponding equations for the total enthalpies of mixing.

Application of the Treatment to the Ternary System $MnCl_2$–NaCl–CsCl

The enthalpies of mixing in the binary systems, $MnCl_2$–NaCl and $MnCl_2$–CsCl, and in the ternary system $MnCl_2$–NaCl–CsCl were determined calorimetrically at 820 °C and are reported in a previous publication (8). The interaction parameters b_1, b_2, b_1', b_2', and $(b_R)_{1,2}$, $(b_R)_{1,3}$ for the two binary systems $MnCl_2$–NaCl and $MnCl_2$–CsCl are given in Table 1.

The contributions to the total enthalpy of mixing over the entire composition range from reaction and mixing effects have been calculated from eq. 21 for the MCl_2-rich region and eqs. 23 and 27 for the MCl_2-lean region using the data in Table 1 and are given in Table 2.

It is seen that the mixing effects are significant and cannot be ignored, particularly in the $MnCl_2$-rich regions where the mixing contributions are comparable to the reaction enthalpy. Mixing contributions to the total enthalpy of mixing are also significant in the $MnCl_2$-lean region and amount to about 20% of the total heat.

The calculated total enthalpies of mixing over the entire concentration range are compared with the experimental values in Fig. 2.

Solid lines in this figure are calculated while the points are experimental. It is seen that the agreement is within ±100 cal, which is within the stated uncertainty of the experimental data (8), with the exception of two points at about $y = 0.4$ which appear to deviate more than this amount. It should be noted that the b-values used for the calculations are those determined in this laboratory (8). The enthalpies of mixing of the $MnCl_2$–NaCl and $MnCl_2$–CsCl system measured by Papatheodorou and Kleppa (2) are more negative by about 18% from the former and if used in the present model calculations would predict more negative total enthalpies of mixing. The foregoing binary systems have also been investigated in this laboratory by the e.m.f. method (9) and the electrochemically obtained enthalpies of mixing are close to the calorimetric results (8).

The application of the proposed quasichemical model to the NaCl–CsCl–$MnCl_2$ ternary

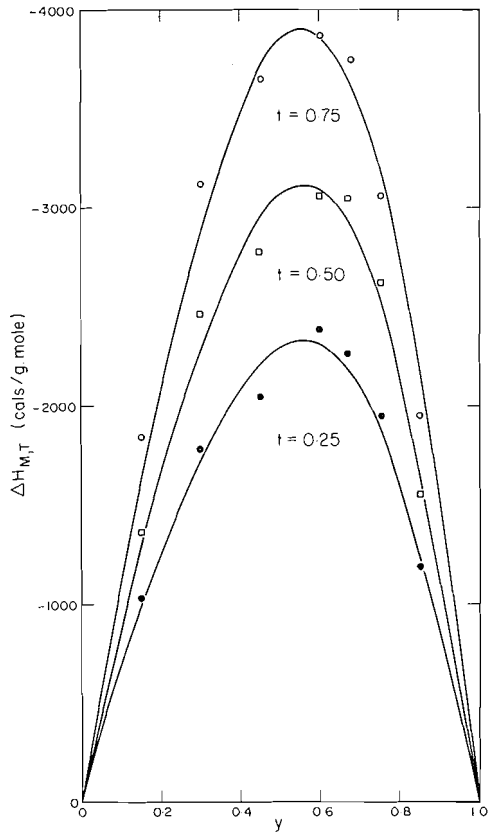

FIG. 2. Total enthalpy of mixing in the ternary system $MnCl_2$–NaCl–CsCl. Solid lines are calculated from theory, points are experimental (8).

system constitutes a severe test of the theory. As indicated the maximum integral enthalpies of mixing in the two constituent binary systems NaCl–$MnCl_2$ and CsCl–$MnCl_2$ occur at about 33 mol% $MnCl_2$, which is the stoichiometric composition for the formation of a tetrahedrally coordinated complex species. In addition, these heats have been found (8) to have the widely different values of 1600 and 4600 cal/g-mol, respectively, and available quasichemical models based on ideality and simple additivity are not expected to be valid.

The Hydrolysis of *t*-Butyl Chloride in Aquo-Organic Mixtures: Heat Capacity of Activation and Solvent Structure[1]

R. E. ROBERTSON[2] AND S. E. SUGAMORI

Division of Chemistry, National Research Council of Canada, Halifax, Nova Scotia and Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received October 19, 1971

The temperature dependence of the rate of solvolysis of *t*-butyl chloride in mixtures of tetrahydrofuran and of acetonitrile in water have been determined. In the high-water range both minor co-solvents lead to a reduction in the value of $\Delta H^{\ddagger}$ similar to that found previously where alcohol was the co-solvent. However, a remarkable difference in the values of $\Delta C_p^{\ddagger}$ across the same concentration range reflected a difference in the effect of these two co-solvents on the structural properties of the several solvent media. Where tetrahydrofuran or alcohols are the minor co-solvent, $\Delta C_p^{\ddagger}$ becomes much more negative until that concentration is reached where the quasi-aqueous structure collapses. Where acetonitrile is the minor co-solvent $\Delta C_p^{\ddagger}$ becomes more positive relative to the value found for hydrolysis in water until a value of about -40 cal deg^{-1} mol^{-1} is reached. The implication of these findings concerning the nature of solvation of weakly polar solutes in such mixtures is discussed.

On a déterminé l'influence de la température sur la solvolyse du chlorure de *t*-butyl dans des mélanges de tétrahydrofuranne et d'acétonitrile dans l'eau. Dans le domaine de haute concentration en eau, les deux co-solvants mineurs mènent à une réduction de la valeur de $\Delta H^{\ddagger}$ semblable à celle qu'on a trouvé précédemment, où l'alcool était le co-solvant. Toutefois, une différence remarquable dans les valeurs de $\Delta C_p^{\ddagger}$ dans le même domaine de concentration reflète une différence de l'effet de ces deux co-solvants sur les propriétés structurales des différents milieux de solvants. Lorsque la tétrahydrofuranne ou les alcools sont le co-solvant mineur, $\Delta C_p^{\ddagger}$ devient beaucoup plus négatif jusqu'à ce qu'on atteigne la concentration où la structure quasi-aqueuse s'effondre. Lorsque l'acétonitrile est le co-solvant mineur, $\Delta C_p^{\ddagger}$ devient plus positif comparativement à la valeur qu'on trouve pour l'hydrolyse dans l'eau, jusqu'à ce qu'on atteigne une valeur d'environ -40 cal deg^{-1} mol^{-1}. On discute de l'implication de ces résultats relativement à la nature de la solvatation des solutés faiblement polaires dans de tels mélanges.

Canadian Journal of Chemistry, **50**, 1353 (1972)

For some time we have been exploring the changes in the temperature coefficient of $\Delta H^{\ddagger}$ ($\Delta C_p^{\ddagger}$) as an indicator of the degree of reorganization of water structure associated with ionogenic reactions in water (1). Recently we have shown that remarkable changes occur in $\Delta C_p^{\ddagger}$ (as well as in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (2)) when this coefficient was determined for the same compound, *t*-butyl chloride, solvolyzing in a series of alcohol–water mixtures. The changes $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ in this study were similar to those reported previously (3). Arnett and co-workers have shown (4–6) that the changes in $\Delta H^{\ddagger}$ obtained from the hydrolysis of *t*-butyl chloride across a series of alcohol–water mixtures in the high-water range are closely equivalent to the corresponding changes in $\Delta \bar{H}_s$ characterizing the transfer of the solute from its pure liquid state to aqueous solution. The effect for non-electrolytes was much larger than for those electrolytes which could be regarded as models for the transition state in the above reaction. From this they concluded that the decrease in $\Delta H^{\ddagger}$ noted above was the consequence of an increase in $\Delta \bar{H}_s$ of the initial state. The corresponding $\Delta C_p^{\ddagger}$ values (2) support this hypothesis and further clarify the effect of temperature on the reorganization of solvents in such systems.

In this paper we determine $\Delta C_p^{\ddagger}$ for the solvolysis of *t*-butyl chloride in a series of tetrahydrofuran mixtures where the structure of the mixture appears to be enhanced over that in water and in acetonitrile–water mixtures where there is evidence of a break-down of water structure over the same concentration range. Attempts to obtain reproducible results in urea–water mixtures based on the assumption that urea would act as a structure-breaker (7) failed to yield data of sufficient accuracy for our purpose. Similar attempts with ethylene glycol as the minor co-solvent were unsuccessful.

Experimental

For all the rate determinations, A.R. *t*-butyl chloride was purified by distillation and passage through Al_2O_3 for absorption, and was shown to be kinetically pure. The stock sample was shielded from light and placed in a desiccator which was opened only for removal of samples.

Solvolyzing Media

Distilled H_2O was passed through an ion exchange column (Rexyn R208-1-300-H-OH) and used without further purification.

Acetonitrile was of spectroscopic grade and used without further purification. Tetrahydrofuran was purified by distillation from sodium carbonate. The adherence of rate data to strict first-order behavior was taken as evidence that no deleterious impurity was present.

All concentrations used throughout this investigation were mixed by volume and then checked by density measurements. Densities of the mixtures were done prior to and at the end of each series. Enough of each solvent mixture was made to complete the series of studies. Incremental amounts were siphoned from a stock bottle provided with a double vapor trap. Value of densities, volume ratios, and mole fractions are given in Tables 1 and 2.

Kinetic Studies

Rates of reaction were determined by a conductance method using Queen-type stirred conductance cells. Temperatures were controlled by a Tronac system (Tronac, Provo, Utah) and measured by means of a platinum resistance thermometer.

Rate data were collected by means of our Auto-Ram (2) save for the highest rates, where the system used previously for the study of hydrolysis of *t*-butyl chloride in water was adopted.

The suitable initial concentration range for kinetic studies on the halide was determined, as in previous studies, by trial and error. At the concentration range $< 10^{-3}$ *M* the *t*-butyl chloride was assumed to exist in true solution; *i.e.* in a condition which led to reproducible, strictly first-order-rate behavior with small random experimental error. Any appreciable increase above that range led to non-linear behavior attributed to incipient micelle formation. When this was observed the initial concentration was reduced by a safe margin. The consistency of results was taken as sufficient justification for this technique, in the absence of some independent method of detection of supersaturation. It is suspected that micelle formation can take place in binary systems at low concentrations more readily than in water even though one component of the binary is a much better solvent for the halide than water. This tendency toward phase separation at low concentrations was more notable where acetonitrile was the co-solvent than for the alcohols (2) or in the presence of tetrahydrofuran, as the minor co-solvent.

Results and Discussion

The rate data[3] for the solvolysis of *t*-butyl chloride over a range of temperatures were fitted to the usual three constant equation $\log k = A/T + B \log T + C$ by the method of least squares. The values so obtained for the indicated concentrations of solvent mixtures are given in Tables 1 and 2. The pseudo-thermodynamic quantities, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ derived from these empirical terms by accepting transition state assumptions and the approximation that $d\Delta C_p^{\ddagger}/dT = 0$, are given in Tables 3 and 4. Calculated rates at 10 °C are included for convenience, though these will not be discussed.

[3]Values of individual rates are available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

It is assumed that under the experimental conditions, *t*-butyl chloride reacts according to the classical S_N1 mechanism (8) as amplified by Winstein and co-workers (9, 10) and generalized by Sneen and Larsen (11). We assume that the solute is first activated to an intermediate indistinguishable from the intimate-ion-pair, stabilized in part by external interaction with the solvent and in part by hyperconjugation (12, 13). It does not seem that this latter stabilizing effect alters significantly over the solvent range investigated here (14, 15), hence we assume that charge development at the transition state is relatively constant across the series of solvent mixtures.

The pattern of change in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values found here across a series of solvent mixtures of tetrahydrofuran–water and acetonitrile–water mixtures are similar to the pattern found for the hydrolysis of *t*-butyl chloride in alcohol–water mixtures (Fig. 1) (2) and about the same as reported earlier by Winstein and Fainberg (3). The latter authors analyzed the factors determining $\Delta H^{\ddagger}$ in a Haber-type cycle but for lack of the necessary initial state data were forced to treat their extensive kinetic data and derived values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ by an empirical classification of little, if any, predictive value. This lack of supplementary calorimetric data was met in part by Arnett and co-workers (4) who, as we have noted above, provided a neat hypothesis to explain the

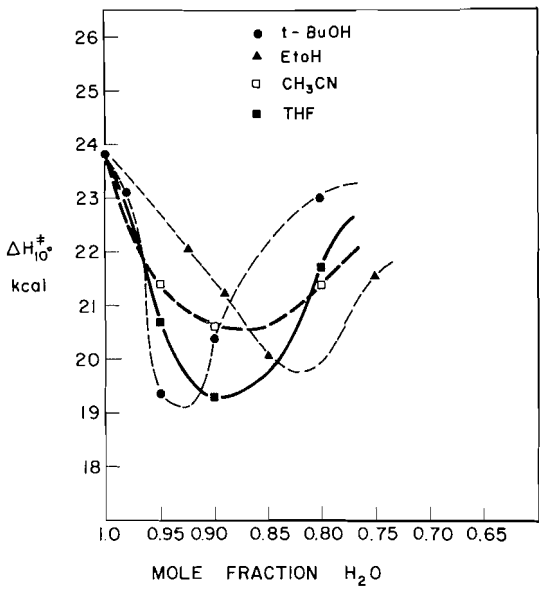

FIG. 1. A correlation of changes in $\Delta H^{\ddagger}$ with changes in the concentration of the organic co-solvent.

changes in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ reported by Winstein and Fainberg (3). In an extensive survey of enthalpy changes for the solution of a wide range of neutral and charged species in aqueous binaries where the mole fraction of the organo-co-solvent was small ($x_2 = 0.2$ mole fraction or less) changes in $\Delta \bar{H}_s$ for neutral molecules were found to bear a striking relationship to corre-

sponding changes in $\Delta H^{\ddagger}$ over the same range of solvent composition.

The changes in $\Delta \bar{H}_s$ were found to be very much less for the solution of tetramethylammonium chloride and trimethylsulfonium chloride than for non-electrolytes in the same series of alcohol–water mixtures. If these salts were accepted as approximate models for the transition state in the hydrolysis of *t*-butyl chloride, the reasonable deduction followed that the reduction in the values in $\Delta H^{\ddagger}$ on the addition of small increments of alcohol to water (Fig. 1) were the consequence of compensating changes in the solvation of the initial state. Specifically Arnett and co-workers claimed that the addition of small increments of alcohol to water produce an increase in structuredness, a view supported by many others (4, 16–18). In the terminology of Nemethy and Scheraga (19) the presence of the non-electrolyte caused a shift in the water–water equilibrium toward a greater degree of hydrogen bonding. This extended quasi-aqueous structure is sensitive to changes in temperature (2, 20) and pressure (21). It is the former characteristic which is of interest here.

The capacity of water to maintain a quasi-aqueous structure presumably through an extension of co-operative hydrogen bonding in the presence of increasing concentrations of weakly polar alkyl groups is distinctly limited, a limit depending in an obvious way on the size of the alkyl groups (2, 20, 22). Any addition of co-solvent beyond that limit leads to a rapid change in the properties of the solvent consistent with a "break-down" in solvent structure. In such cases it is concluded that the hydrogen-bonding maintaining extended co-operative structure is weaker than the thermal agitation tending to disorganize structure.

Solvent Structure in Alcohol–Water Mixtures

It will be recognized that the above observations and deductions are simply an extension of the observations published more than 25 years ago by Frank and Evans (16) in which they introduced the idea that non-electrolytes when dissolved in water caused a shift toward greater structuredness rather than occupying interstitial sites in an ice-like lattice (23). In that paper Frank and Evans made passing reference to what has become known as the "iceberg hypothesis". This graphic term provided an instant if imprecise description of the effect of weakly polar solutes on water structure — sufficiently true to be useful, sufficiently imprecise by implication to be misleading (24). Recently, a common misinterpretation of this hypothesis has been criticized by Grunwald and Ralph (25, 26). Apparently, these authors would de-emphasize the possible structural effect of weakly polar solutes on adjacent water structure and attempt to account for the unique characteristics of such aqueous solutions in terms of London dispersion forces. No one is likely to deny that such forces are present and contribute to the overall effect. We find it equally unlikely that this interpretation will provide an adequate explanation for the extrema observed in the thermodynamic quantities reported by Arnett (4) and Ben-Naim (17) who favor the structural hypothesis. In particular we take exception to likening the iceberg hypothesis to a "suit of armour" for which Grunwald and Ralph would substitute a "form-fitting sweater". The latter light-hearted suggestion is reminiscent of the surface-tension hypothesis of Langmuir while the former is a graphic figure based on the idea that the presence of the weakly polar solute "strengthens" (4) the water structure, an idea which may follow naturally enough from the analogy but which is inconsistent with our kinetic results (2). Thus while we agree with Grunwald and Ralph that the iceberg hypothesis is misleading, we disagree with the alternative they propose. In particular the substitution of solute–solvent interaction (London forces) as the dominant factor does not provide for sudden changes in properties of organo-aqueous mixtures in the high water range (A).[4] We assume, as a working hypothesis, that the changes in such properties as heat of mixing, partial molal volume, velocity of ultrasound (20) are less a function of solvent–solute interaction than of altered solvent–solvent interaction. This assumption is important for it determines the interpretation we attach to the changes in the values of $\Delta C_p^{\ddagger}$ found for ionogenic reactions across a series of such solvent mixtures in range A. Equally important

[4]In range A, some degree of three-dimensional quasi-aqueous structure is maintained. On the addition of sufficient co-solvent (range B) this extended structure can no longer be maintained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

is the observation that non-electrolytes have somewhat larger effects than small ions on the properties of the solvent mixture (4–6). Since solvolytic reactions such as the solvolysis of *t*-butyl chloride involve the transformation of a non-electrolyte to a charged transition state, we assume that the changes in $\Delta C_p^{\ddagger}$ in range A for a series of solvent mixtures reflect mainly changes in the initial state solvation of the reactant. Thus the central idea we have used for the interpretation of the large negative values of $\Delta C_p^{\ddagger}$ found in these reactions in mixed solvents is the same as that for the corresponding values for solvolysis in water (2), *i.e.* the value of this coefficient is mainly determined by the effect of temperature on that component of $\Delta H^{\ddagger}$ required to reorganize the solvent shell adjacent to the reactant from dominant water–water interaction to ion–water interaction. We note (Fig. 1) that the $\Delta H^{\ddagger}$ values obtained from the solvolysis of *t*-butyl chloride in a series of alcohol–water mixtures (range A) decrease as the alcohol concentrations increase. Whatever the detailed description of the solvation shell, each added increment of alcohol appears to move the initial state solvation shell closer to that of the transition state. Proceeding on the assumption that the values of $\Delta C_p^{\ddagger}$ found for solvolysis in such mixtures are dependent on $d\Delta H^{\ddagger}/dT$ and that $d\Delta \bar{H}_s/dT$ is small by comparison, then we note that in range A (Fig. 2) the incremental addition of alcohol has the effect of making $\Delta C_p^{\ddagger}$ more negative, *i.e.*, the quasi-aqueous structure becomes more sensitive to a change in temperature relative to water. Hence we conclude that as the concentration of co-solvent is increased the initial state solvation shell in equilibrium with aqueous mixture becomes *extended* and *weakened*. The ability of the system to maintain a quasi-aqueous structure (*i.e.*, a three-dimensional hydrogen-bonded network or some combination of clusters (27) or cages (28)) is limited, and beyond a critical concentration the quasi-aqueous structure is replaced by a solvent with quite different characteristics as judged by previously noted criteria (20). Here $\Delta C_p^{\ddagger}$ for the above reaction has a value in the range -30 – -40 cal deg^{-1} mol^{-1} and is relatively insensitive to solvent composition (29). From the above we conclude that our $\Delta C_p^{\ddagger}$ values for the solvolysis of *t*-butyl chloride in alcohol–water mixtures serve to underline the weakness in those hypotheses which claim that the addition of a non-electrolyte "strengthens" the adjacent water structure.[5]

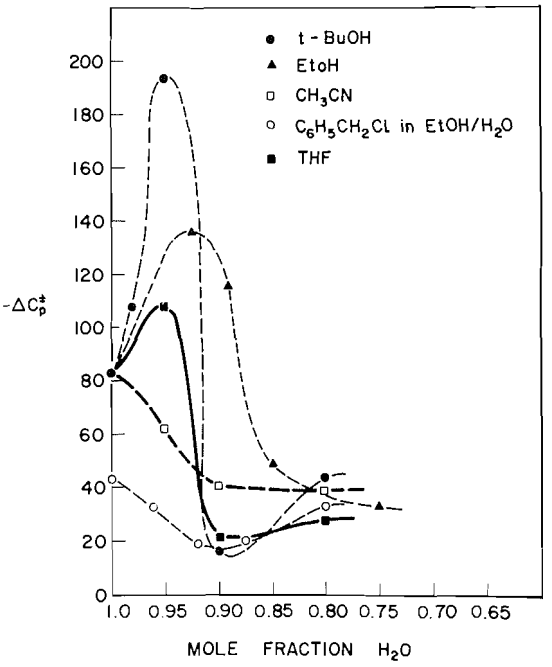

FIG. 2. A correlation of the changes in $\Delta C_p^{\ddagger}$ with changes in the concentration of the organic co-solvent.

Solvolysis in Tetrahydrofuran–Water Mixtures

The trend in values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ found for the solvolysis of *t*-butyl chloride in a range of tetrahydrofuran–water mixtures are similar to the corresponding values in alcohol–water mixtures over the same concentration range. This suggests that the major effect of this co-solvent on water structure (30, 31) is similar to that of the alcohols in agreement with Arnett's generalization with respect to the effect of non-electrolytes on water structure (4).

Tetrahydrofuran is a solvent of low ionizing power (32), hence the major effect of THF on the rate will be a consequence of the modifying effect on water structure. Since $\Delta H^{\ddagger}$ is observed to decrease and $\Delta C_p^{\ddagger}$ becomes more negative

[5]In the case of ethanol being added to water, the implication seems to be that some ethanol strengthens the adjacent water structure; further successive increments strengthen it more until presumably the structure is so strong that it falls apart under the influence of thermal fluctuation. This progression lacks logic. It also underlines the implied fallacy in the iceberg analogy, as frequently interpreted.

through the high water range (A) and the change in both terms is assumed to be related to the structural stability of the initial state solvation shell which is disrupted in the activation process, we are led to the same conclusion as reached with respect to results of solvolytic studies in alcohol–water mixtures: that the co-solvent over the initial range modifies and weakens the quasi-aqueous structure toward reorganization (but see ref. 33). As before, we assume that charge development at the transition state does not alter appreciably over the concentration range (14, 15) and that $d\bar{H}_s/dT \gg dH^{\ddagger}/dT$. Beyond a critical concentration of tetrahydrofuran ($x_2 = 0$–0.05 m) the quasi-aqueous structure undergoes a major collapse, and the value $\Delta C_p^{\ddagger}$ becomes more positive (-30 to -40 cal deg^{-1} mol^{-1}), *i.e.* the system becomes much less sensitive to a change in temperature. Values of $\Delta C_p^{\ddagger}$ in this range (B) are too large to arise from the temperature dependence of the dielectric constant of the bulk-solvent (34) and at the moment are not explained. It seems likely, however, that the assumption $d\bar{H}_s/dT \gg dH^{\ddagger}/dT$ is no longer valid.

Solvolysis in Acetonitrile–Water Mixtures

The effect of acetonitrile on water structure is quite different from that of alcohol or of THF as co-solvents in range A. Thus Blandamer and co-workers (35, 36) found no minimum in the plot of excess partial molal volume *vs.* x_2 for water rich acetonitrile mixtures (in contrast to that found for *t*-butanol–water mixtures). They conclude from a comparison of the enthalpy of mixing and from i.r. spectra that in contrast to the effect of *t*-butanol as a co-solvent, acetonitrile appears to compete successfully with water–water interaction. Such intercomponent interaction leads to endothermic mixing (37) due to the breakdown of water-structure in contrast to the exothermic effect in the *t*-butanol–water binary, and to a lowering of the temperature of maximum density of water (38) in contrast to the effect of alcohol (20). The competition between water–water interaction and water–acetonitrile interaction shifts in favor of the former with decreasing temperature; phase separation occurring at -1 °C. We have found that *t*-butyl chloride or cyclohexyl bromide enhance this tendency giving rise to a separation of two ternary phases at low concentrations. As a result no method was found which permitted a characterization of saturation solubility of these solutes over a series of H_2O–MeCN mixtures as was done for cyclohexyl bromide in *t*-butanol–H_2O mixtures (2). This characteristic imposed the practical limitation that the initial concentration of *t*-butyl chloride in kinetic studies be reduced well below 10^{-3} M in order to ensure uncomplicated kinetics.

That $\Delta H^{\ddagger}$ decreased initially in the three systems (Fig. 1) was taken as prima facie evidence that the initial addition of each co-solvent in some manner weakened the initial state solvation shell. The very different trend in $\Delta C_p^{\ddagger}$ is evidence that this structure modification is different for co-solvents such as alcohols and tetrahydrofuran and for acetonitrile. In the former mixtures, the solvent structure is extended and weakened and thus rendered more sensitive to changes in temperature ($-\Delta C_p^{\ddagger}$ is increased), in the latter the acetonitrile appears to act as a structure breaker. This characteristic will be reflected in the initial state solvation of the *t*-butyl chloride and hence in the temperature dependence of that part of the enthalpy of activation required for solvent reorganization. Rather simply, since the acetonitrile appears to act like small ions and partially melt the water structure (4, 16) less structure remains to be influenced by a change in temperature. Qualitatively, at least, this argument accommodates the opposed differences in the apparent values of $\Delta C_p^{\ddagger}$ in these systems, *i.e.* for the cases where the co-solvent extends and so weakens the initial solvent shell and for the case where the co-solvent is a structure breaker. Both types of structure modification would be expected to show a reduction in the structural component of $\Delta H^{\ddagger}$ with increasing concentration of the co-solvent in range A. The modifying word "apparent" might well be prefixed to $\Delta H^{\ddagger}$ as well as $\Delta C_p^{\ddagger}$. Of necessity the quantities $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ are derived from rates determined over a range of temperatures. Since the solvent is sensitive to a change of temperature, the purist might claim that data from different systems are being compared (39). This argument becomes bothersome only if one insists on absolute values. In the present study the apparent temperature coefficient of $\Delta H^{\ddagger}$ ($\Delta C_p^{\ddagger}$) provides a useful insight into the different effects of certain co-solvents on water structure and so requires no further justification.

Solvent Structure $\Delta H^{\ddagger}$ *and* $\Delta S^{\ddagger}$

Granted the above deductions are consistent with our data we are left with an apparent anomaly. Thus, many authors have concluded (40, 41) that D_2O has more structure than H_2O at comparable temperatures. Certainly it would seem that the higher freezing point, the higher temperature of maximum density, the higher viscosity and the lower the conductance values, the lower rate of self diffusion are physical indicators which are consistent with such a conclusion.[6] Similarly, it is the conclusion of many authors beginning with the classical paper of Frank and Evans (16) that the presence of a weakly polar solute in water leads to an enhancement of structure. Whether that enhancement takes the form of enhanced fluttering cluster formation or of incipient clathrate formation or of some combination involving the occupancy of interstitial sites are questions of detail. Since the initial state solvent shell about a reactant in such a solvent mixture must necessarily be in equilibrium with that mixture, the initial state solvent shell will reflect the co-operative nature of that mixture. The important fact is the claim that the structure is enhanced and/or strengthened.

We have shown that if *t*-butyl chloride is hydrolyzed in H_2O and in D_2O, the $\Delta H^{\ddagger}$ for the reaction is higher in the latter and we have attributed this increase in $\Delta H^{\ddagger}$ to the greater degree of structure which must be reorganized (42) in the activation process. In this and in our previous paper (2) we note that on the addition of alcohol or THF to water, $\Delta H^{\ddagger}$ for the solvolysis of *t*-butyl chloride decreases in range A and the results obtained by Arnett and co-workers show that this decrease probably arises from a change in the nature of the initial state solvation shell. That a nominal increase in structure in D_2O over H_2O and in alcohol–water or THF–water mixtures over water alone as reaction media for the solvolysis of *t*-butyl chloride can be responsible for both an increase and a decrease in $\Delta H^{\ddagger}$ seems improbable unless the word "structure" refers to different types of co-operative interaction. We note further that in the D_2O/H_2O comparison the difference in k_{obs} is determined by the difference reduced by a compensating change in $\Delta S^{\ddagger}$, while in the mixed solvents the decrease in $\Delta H^{\ddagger}$ was more than cancelled by an opposing change in $\Delta S^{\ddagger}$ and the decrease in k_{obs} was far larger. This is hardly surprising in view of the much greater change in solvent. That a structure-maker such as THF and a structure-breaker such as acetonitrile when co-solvents in water should lead to a similar though by no means equal decrease in $\Delta H^{\ddagger}$ is less anomalous when the quite different trends in the accompanying values of $\Delta C_p^{\ddagger}$ are taken into consideration. While the latter factor may have important contributions from sources other than the solvent structure (see above) it is interesting to note that the difference in conductance between K^+ and Cs^+ in ethanol–water mixtures ($x_2 = 0.08$) is twice as great as it is in water, suggesting that the more highly "structured" solvent mixture discriminates better or is more sensitive to the structure-breaking power of ions than water (20). Our results suggest that the addition of alcohol or THF to water both extends and weakens the structure toward reorganization by a charged transition state relative to water. Such structural interpretations if valid are inseparable from the accompanying changes in entropy, and here the picture is not at all clear. The idea that there is more structure in D_2O than in H_2O and hence requires a greater input of energy in the activation process is borne out by the relative value of $d_l\Delta H^{\ddagger}$ and $d_l\Delta S^{\ddagger}$, where the difference in $\Delta H^{\ddagger}$ is dominant (42). In the organo–solvent mixtures $\Delta H^{\ddagger}$ has lower values but the rate is controlled by an opposed shift in $\Delta S^{\ddagger}$ relative to the value in water. It could be argued that in the solvent mixture, the gain in entropy is reduced but this is hardly consistent with the idea advanced to account for the more negative values of $-\Delta C_p^{\ddagger}$ or the idea of a more extended co-operative initial state solvent shell. This lack of consistency between the values of $\Delta C_p^{\ddagger}$ and $\Delta S^{\ddagger}$ has been noted previously (43) but has not been resolved.

[6]Holtzer and Emerson have recently questioned this conclusion and have noted that just the opposite conclusion might be drawn from a consideration of dielectric constant differences (24).

^{13}C Nuclear Magnetic Resonance Studies. XX. ^{13}C Shieldings of Several Allyl Alcohols. Geometric Dependence of ^{13}C Shieldings[1]

H. BROUWER[2] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received October 25, 1971

The ^{13}C spectra of 21 methyl- and halo-substituted 2-propenols have been determined. The shielding data are discussed with particular emphasis on their dependence on the orientation of the 3-halo substituents. Linear regression analyses of the results gave sets of additive parameters which correlate the shieldings with reasonable precision ($\leqslant 1$ p.p.m.). A similar set of parameters has been generated from the published data for acyclic alkenes: these parameter sets are intercompared. The results of complete analysis of the proton spectra of most of the alcohols are also presented.

On a déterminé le spectre au ^{13}C de 21 dérivés méthylés et halogénés du 2-propenol. On discute des données de blindage en insistant particulièrement sur leur effet dans l'orientation des substituants halogénes en position-3. Les analyses de régression linéaire des résultats ont donné des ensembles de paramètres additifs qui nous fournissent les blindages avec une précision raisonnable ($\leqslant 1$ p.p.m.). Un ensemble similaire de paramètres a été tiré des données publiées pour les alcènes acycliques: on compare ces paramètres avec ceux qu'on a obtenus. On présente aussi les résultats de l'analyse complète des spectres de protons de la plupart des alcools.

Introduction

In an earlier part of this series, ^{13}C n.m.r. spectra of several unsaturated aliphatic systems were discussed and the results of an examination of α,β-unsaturated carboxylic acids and esters compared with earlier data (1). These results clearly showed that olefinic ^{13}C shieldings exhibit a marked dependence on the orientation of substituents bonded to the olefinic carbons. Furthermore, these shieldings were correlated by a linear expression entirely analogous to that employed for acyclic saturated hydrocarbons (2),

$$[1] \qquad \delta_C^i = K + \sum_j A_j n_{ij}$$

where δ_C^i, the shielding of the ith olefinic carbon, is given by a summation of specific substituent parameters, A_j; n_{ij}, is the number of such substitutions and K, a constant, corresponds to the shielding in the parent system. Similar correlations, initially proposed by Savitsky and Namikawa (3) and by Grant and Paul for saturated hydrocarbons (2), and methylcyclohexanes (4), have proved to be valuable in the analysis of more complex systems; a good example is the steroid study by Reich *et al.* (5).

In the paper presenting the first results of a systematic study of the ^{13}C spectra of alkenes, Retcofsky and Friedel (6) noted the general trends exhibited by olefinic shieldings upon alkyl substitution but, for practical reasons, these authors did not investigate the shieldings of carbons bonded to the olefinic nuclei. In our previous report, we noted that the carboxyl carbon shieldings of acrylic acids and esters are essentially independent of substituent orientation whereas olefinic methyl carbons exhibit a marked geometrical dependence. As an extension of our study of stereochemical effects on ^{13}C shieldings, we have determined the ^{13}C spectra of a series of substituted allyl alcohols to examine the variation of these shieldings as a function of substitution and substituent geometry. Additive correlations have been found for the olefinic and carbinyl carbon shieldings which may be compared with similar data which have been generated from the published results for acyclic alkenes. In this paper these correlations are discussed and compared with the results for saturated systems. In addition, the proton parameters for most of the allyl alcohols are presented.

Experimental

Materials

All of the alcohols employed in this study are known compounds and were obtained as commercial samples or prepared by published procedures. In all cases, their physical properties agreed well with literature values and the proton

spectra were recorded to insure that the samples employed for ^{13}C spectra were of high purity.

Spectra

For detailed analysis, proton spectra were recorded on a Varian HA-100 spectrometer using 5 mol % solutions in CCl_4. The spectra were analyzed using the LAOCOON III program and the parameters obtained were employed to calculate 60 MHz spectra. As a check on the analysis, the latter were compared with spectra obtained on a Varian HA-60 instrument; for these comparisons, calculated spectra were plotted using the n.m.r. Plot II program, kindly supplied by Dr. S. Castellano. Confirmation of the geometry of several of the examples was obtained by nuclear Overhauser enhancement measurements on samples of the alcohols or the methyl esters from which the alcohols were prepared.

The ^{13}C spectra were determined for 25% (v/v) solutions in *p*-dioxane using a frequency-swept, field-locked spectrometer operating at 15.1 MHz; the proton-decoupled solvent signal served as the lock signal. This instrument was controlled with a Varian 620i computer. In most cases, ^{13}C spectra were obtained from ten, 50-s scans over 250 Hz; the sweep unit was a Wave-Tek III VCO. Proton decoupling was accomplished with a "home-built" decoupler utilizing a Frequency Electronics 60 MHz VCO whose output was amplified to provide up to 6 W of r.f. power at the probe. Frequency modulation with a HP 3722A noise generator provided noise modulation of the decoupler output. A Varian V4336 probe[3] which permitted the use of 12 mm spinning samples was employed. In this instrument, the sample temperature was *ca.* 40°.

The ^{13}C shieldings (δ_C) are given relative to TMS by conversion of the raw data, measured from dioxane, using the value 67.4 p.p.m. for the shielding of dioxane.

Results

The results of analysis of the proton spectra using the LAOCOON III program are listed in Table 1. In general, individual shieldings were initially estimated from first-order analysis and the coupling constants from the observed spacings; these parameters were used to generate a theoretical spectrum and the transitions matched with those observed as the input for iterative convergence on a best fit. As an example the 100 MHz spectra of allyl alcohol, observed and calculated, are illustrated in Fig. 1. It is interesting that the r.m.s. error for fitting all lines is 0.06 if all coupling constants except the geminal ones are assumed to be positive whereas the r.m.s. error is 0.04 if the allylic couplings are negative. Thus the latter assignment is preferred and is in agreement with the earlier results for methyl allyl ether and allyl chloride (8).

The ^{13}C shielding data are collected in Table 2. Assignments for the methyl and carbinyl carbon signals were straightforward since the former appear at higher field, δ_C 12–33, while the latter absorb near 60 p.p.m. For the compounds in which each olefinic carbon is bonded to a single proton the specific carbon signals were identified by the differences in the one-bond coupling constants observed in spectra obtained without proton-decoupling. The J_{CH} values for olefinic carbons bearing polar groups are larger than those exhibited by carbons bonded to sp^3-carbons (9). Confirmation of these assignments was provided by the results for the methyl substituted homologs since the shielding changes produced by replacement of an olefinic hydrogen with a methyl group are well known (1, 6), *i.e.*, the substituted carbon is deshielded while its neighbor is shielded.

Discussion

(a) General Trends

Although significant proton chemical shift differences are found between geometrical isomers, the largest difference is only *ca.* 0.2 p.p.m. In general, the methyl protons are slightly shielded in the *E*-3-halobut-2-en-1-ols and the carbinyl protons are deshielded by up to 0.2 p.p.m. in the *Z*-isomers, both relative to the values for the corresponding analogs. Similarly the carbinyl protons are deshielded and the α-olefinic proton shielded in the *Z*-3-substituted-2-propen-1-ols relative to the *E*-isomers. The somewhat larger vicinal coupling constants for the carbinyl protons in the substituted alcohols compared to the value for the parent compound indicate that the rotamer population is affected by the 3-substituents. The microwave spectrum of allyl alcohol itself (10) indicates that the preferred rotamer is the *gauche* form **1** for which the vicinal coupling will be the average of a *trans* ($\phi = 180°$) and a *gauche* ($\phi = 60°$) interaction or *ca.* $(11.5 + 2.8)/2 = 7.2$ Hz assuming that the vicinal coupling constants for specific dihedral angles are approximately the same as those found for 3-methoxypropene (11). Since J_{vic} for rotamer **2** having an eclipsed hydroxyl is expected to be *ca.* 2.8 Hz, the observed value of 5.04 Hz for allyl alcohol indicates that **1** and **2** are present in approximately equal amounts. It is interesting that the introduction of a *cis*-3-methyl group, as in 3-methyl-2-buten-1-ol, serves to increase J_{vic} substantially, a trend consistent

[3]We wish to thank Varian Associates, Palo Alto, California, for the loan of this probe for these studies.

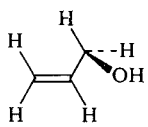
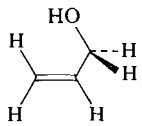
*Relative orientation of substituents indicated by the convention of Blackwood *et al.* (7); *Z*-isomers have highest priority groups on the same side of double bond.

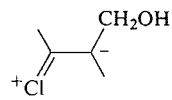
with an appreciable increase in the concentration of forms corresponding to **1** in the rotamer equilibrium. Furthermore, the *E*-isomer for each of the 3-halobutenols exhibits the larger J_{vic} by 1.2–1.4 Hz. Although it is difficult to estimate the effect of the 3-halo substituents on the magnitude of this coupling constant, the differences for J_{vic} between *Z*- and *E*-isomers in the 3-halopropenols are very much smaller (0.05–0.2 Hz) possibly indicating little change in the preferred conformation of the hydroxymethyl group in these alcohols.



1



2



3

Although no regular trend is observed for the allylic proton–proton couplings as a function of geometry the homoallylic interactions ($J_{HCC=CCH}$) are consistently larger for a *transoid* disposition of carbons α to the double bond, 1.35 *vs.* 0.77 Hz. Perhaps this difference would be helpful for stereochemical assignments in related systems but both isomers would be required.

Perhaps the most striking trend exhibited by the ^{13}C shielding data (Table 2) is the upfield shift found for methyl and carbinyl carbons if eclipsed, *i.e.*, in a *cis*-orientation, with respect to another methyl group compared to the shieldings in the corresponding *trans*-isomers. For example, the methyl carbons are equivalent (δ_C 12.9) in *E*-2-methyl-2-buten-1-ol but differ by 9.1 p.p.m. in the *Z*-isomer. In the latter case, the signal at δ_C 21.9 may be assigned to the 2-methyl carbon and the 12.8 p.p.m. peak to the terminal methyl. A similar shielding difference (7.6 p.p.m.) is observed for the carbinyl carbons in these two isomers with that in the former at higher field. The terminal methyls in 3-methyl-2-buten-1-ol also differ appreciably (7.8 p.p.m.). By comparison with the remaining methyl carbon shieldings a consistent pattern emerges such that the more shielded carbon is eclipsed with either a methyl or carbinyl carbon. It is interesting that the carbinyl carbons are much less sensitive to the configuration of the 3-halogens. The differences ($\delta_C^E - \delta_C^Z$) between the *Z*- and *E*-3-halo-2-propen-1-ols are 2.8 (Cl), 1.8 (Br), and −1.0 p.p.m. (I), but, in the corresponding 3-halo-2-buten-1-ols, the *E*-isomers consistently exhibit the more shielded carbinyl carbons (*i.e.*, in those isomers in which the carbinyl and terminal methyl carbons are eclipsed). As noted above the methyl carbons in the latter series are shielded by *ca.* 5 p.p.m. relative to the *Z*-isomers.

(b) Regression Analyses

To test for the existence of an additive rela-

Standard error	±0.7	

*Positive values denote downfield shifts.

tionship for substituent effects on the carbinyl carbon shieldings the results were analyzed using a linear regression program to furnish the parameters, A_j, listed in Table 3. Using these parameters and expression [1] the shieldings of the ith carbinyl carbon in this series of alcohols can be estimated with an overall precision of ±0.7 p.p.m. The constant term K is expected to be close to the value for allyl alcohol itself although, in fact, it differs from the latter by 1.5 p.p.m. It may be noted that two parameters are required for each *cis*-substituent which, as a first approximation, may perhaps be regarded as a subdivision into polar and steric components. If this view is valid, it is apparent that the largest steric effect is that exerted by a *cis*-β-methyl group.

With the exception of the iodo derivatives, the shieldings of the olefinic carbons in these alcohols are much less sensitive to substituent geometry than those of the sp^3-hybridized carbons. Although the C-2 nuclei show a general tendency to absorb at somewhat higher fields in the *Z*-isomers, the C-3 shieldings follow no consistent pattern. In general, the differences between *Z*- and *E*-isomers are <2 p.p.m. for both centers. In the iodo derivatives, however, the *Z*-C-2 nuclei are shielded by *ca.* 5 p.p.m. relative to their *E*-counterparts while the C-3 nuclei show the opposite behavior. While it is clear that iodine exerts pronounced effects on the shieldings of its neighboring carbons, a rationalization of the trends cannot yet be offered. This problem has been discussed in some detail for other olefinic systems (12, 13) but a satisfactory explanation was not presented.

Since the trends observed for the methyl-substituted systems appeared to be similar to those previously reported for the simpler alkenes it seemed reasonable to examine the available data by linear regression analysis to test for a possible additive correlation. In their initial report on olefinic shieldings in alkenes, Retcofsky and Friedel (6) noted the consistent effects of alkyl substitution on these shieldings but did not attempt a detailed analysis of their somewhat limited data. Because of the appearance of additional data (13–16) and the finding that saturated hydrocarbon shieldings may be correlated through expression [1], we have analyzed the alkene data to obtain the parameters listed in the second column of Table 4; these are analogous to those found for the alkanes by Grant and Paul (2). More parameters are required for the alkenes since the effect of an alkyl substituent is transmitted to the olefinic carbons by two pathways (*a*) entirely through σ-bonds or (*b*) through the π-bond. The two factors for each position relative to the olefinic carbons are distinguished by the superscripts, σ and π, respectively. As in the alkanes (2), the shieldings of branched systems relative to those for linear alkenes show that branching attenuates the substituent effects such that additional parameters are required to correlate the data. Substitution on the double bond is accounted for by the *gem* parameters while the effects of branching at the α-, β-, or γ-sp^3-carbons are the *mult* factors. Finally, a factor for the *cis*-disposition of alkyl groups is required to achieve a reasonable correlation. It may be noted that the constant term K of 122.1 p.p.m. is remarkably close to the observed value (16) for ethylene (δ_C 122.8). Even though the majority of the data employed in this analysis was obtained by rapid-passage techniques for which the precision is *ca.* ±0.3 p.p.m. at best, the standard error of 0.9 p.p.m. for the correlation indicates that the parameters should be helpful for estimations in related systems. As a comparison of the effect of a hydroxymethyl group with that of a methyl substituent on the olefinic shieldings, the data for the methyl-substituted allyl alcohols were included in a second analysis to obtain the results listed in the final column of Table 4. Clearly the alkyl effects

are similar in the alcohols since the precision of the individual factors as well as that overall is comparable. It is interesting that the β^{π}-effect of the CH_2OH group (−6.7 ±0.5 p.p.m.) is essentially the same as that of the CH_3 group (−7.1 ±0.4 p.p.m.). Thus, except for its enhanced α-effect, the hydroxymethyl group is comparable to a methyl function.

A regression analysis of the olefinic data for the 3-halo-2-propenols was also carried out with the results listed in Table 5. The constant term, 114.0 p.p.m., compares well with the observed value for the β-carbon in allyl alcohol, 113.7 p.p.m. As a result of the choice of a reference point for the analysis, the β^{π}-factor for the CH_2OH group is given as 0.0 p.p.m. but if the value of this factor from the previous analysis is employed (−6.7 p.p.m.) the constant term becomes 120.7 p.p.m. which is in fair agreement with the ethylene shielding. On the latter basis the α-effect of the CH_2OH group is 18.5 p.p.m. compared with the value of 17.4 p.p.m. found

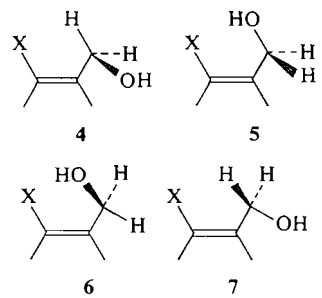
from the preceding analysis. In view of the relatively small number of compounds, the overall standard error of ± 1.1 p.p.m. seems remarkably small, and indicates that an additive relation indeed exists.

(c) Origins of the Trends

Although the existence of additive relations for ^{13}C shieldings has been recognized for several years (17) various attempts to place these on a firm theoretical basis have not been particularly successful; a general review and discussion of the various approaches employed is available (18). For linear saturated hydrocarbons Grant and Paul (2) found that the ^{13}C shieldings can be correlated with five parameters representing the effects of replacing a hydrogen atom by a methyl group at the α, β, γ, δ, and ε position with respect to the carbon of interest. For acyclic systems in general, additional parameters are required to account for the attenuation of these five parameters caused by branching along the main chain. The results of the analysis described in the preceding section are discussed in terms of the alkane parameters in the following.

Only one of the factors for the carbinyl shieldings (Table 3) is operative entirely through σ-bonds, the "α-Me" parameter. Since this factor corresponds to the β-effect of alkyl carbons in alkanes it is expected to be positive, *i.e.*, deshielding, but its magnitude is less than half that found for the saturated hydrocarbons (2). A similar attenuation of the effect is apparent from the data for several acyclic alcohols (19) but the effect in the allyl alcohols is even smaller. Clearly, the hydroxyl group strongly attenuates the "β-effect" of alkyl carbons but it is difficult to comment on the trend because the origin of the β-effect is not yet understood.

The remaining factors in Table 3 are analogous to the γ-effects in alkanes and are of special interest because these appear to arise, at least in part, from steric perturbations between closely-lying atoms. In fact, a simple model has been proposed to account for the observed trends in terms of steric polarization arising from nonbonded interactions between neighboring hydrogens (20). Several examples are available to support this idea, on a qualitative basis, since it is generally found that carbons in sterically hindered environments tend to absorb at higher fields than the corresponding nuclei in electronically similar positions but without close neighbors. For example, in methylcyclohexanes axial methyl groups appear at consistently higher fields than their equatorial counterparts (4). In saturated acyclic systems it seems reasonable to assume that the γ-effect arises primarily from interactions in *gauche* rotamers. By virtue of the double bond in the allyl alcohols, however, the 3-substituents are constrained to either eclipsed or *trans* orientations relative to the carbinyl carbon and, as a first approximation, the effects of the substituents may be subdivided into "polar" and "steric" components; in this manner the "*cis*-X" factors may be taken as the "steric" components for each substituent and the "β-X" factors represent the "polar" component. Implicit in this interpretation and the regression analysis is the assumption that the latter factor is independent of configuration. On this basis, it is apparent that, in general, 3-substituents tend to deshield the γ-carbon. Chlorine is the exception to this trend since the β-Cl effect is -0.6 p.p.m., possibly as a result of some contribution of resonance forms such as **3** which would increase the electron density at C-2. Presumably, delocalization of this sort is less likely with the larger halogens such that their inductive effects dominate the electron distribution along the carbon chain. Although it is apparent that *cis*-3-substituents tend to shield the carbinyl carbon relative to the effects of the *trans*-groups, it is difficult to offer even a semi-quantitative assessment of the trend. It is of interest, however, to examine the internuclear separation between the *cis*-groupings. To this end, the coordinates of the *cis*-isomers were computed, using the COORD program of Baird and Dewar (21), to compare the data for different possible rotamers. For example, the interatomic distances between X and the eclipsed H in **4** were obtained as listed in the first column of



4 **5** **6** **7**

TABLE 6. Interatomic separations of nearest neighbors in *cis*-allyl alcohol rotamers,[a] $XCH{=}CHCH_2OH$ (in Å)

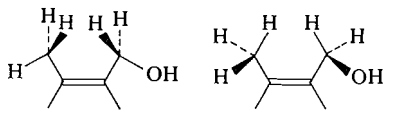
[b]Sum of the van der Waals radii.

Table 6. Although only **1** and **2** were considered in the earlier analysis of rotamer distribution in allyl alcohol, the interatomic distances between nearest neighbors in the corresponding rotamers for the series of allyl alcohols, **4** and **5**, are much smaller than the sum of the van der Waals radii for each pair of neighboring atoms indicating that severe repulsive interactions would occur. The separation between nearest neighbors is markedly increased, however, by rotation to **6** as shown by the data in Table 6. Furthermore, the J_{vic} values for the carbinyl protons in **6** are expected to be similar to those in **1**. As noted above the configuration of the 3-halogen atoms has little effect on the observed J_{vic} couplings but, since each is larger than J_{vic} in allyl alcohol itself, it seems unlikely that **7** is a major contributor. For the crotyl alcohols, the proton data indicate that the carbinyl group is oriented as in **4** (or **6**) but with $X = CH_3$ the interatomic separation of nearest neighbors is less than the sum of the van der Waals radii for all orientations of the methyl group, having a maximum



8 **9**

value of 2.317 Å for **8** and a minimum (1.423 Å) in **9**. Clearly the carbinyl group will experience appreciable nonbonded interactions in each. Of the various "*cis*-X" factors in Table 3 that for the methyl group is largest which may be a consequence of the differences in polarizability of the substituents as well as differences in the rotameric equilibria. Because the interatomic distances listed in Table 6 were computed for normal bond lengths and angles, the individual values are less meaningful than the general trend since a slight increase in, for example, the $C_1—C_2—C_3$ angle would increase the separation between nearest neighbors. Evidence for some splaying of this angle in *Z*-2-butene has been presented (22). In addition, the interatomic separation would be affected by a small rotation of the carbinyl group about the $C_1—C_2$ bond. These possibilities coupled with the lack of hard information on the rotamer populations limit one to a purely qualitative assessment of the trends. It would appear, however, that rotamers such as **6** may be important in the alcohols having elipsed methyl and carbinyl groups.

Turning to the olefinic shielding parameters (Table 4) it is immediately apparent that the factors for σ-bonded networks are qualitatively analogous to those found from the saturated hydrocarbon data although the α-effect is somewhat larger and the β-factors smaller. The most striking difference between the two sets of parameters is the *shielding* β-effect through a π-bond. While hyperconjugation may be suggested as a possible cause of the effect, its magnitude (-7.1 p.p.m.) is remarkably large. In fact, it is comparable, in absolute value, to the β-effect in saturated systems ($+9.4$ p.p.m.) which, as noted above, remains unexplained. A similar reversal of the β-effect is found for Cl and Br which in 1-haloalkanes tend to deshield β-carbons by *ca.* 10 p.p.m. (23) whereas their β^{π}-effects are shielding (Table 5). The parameters in Table 5 may be compared with a similar set generated for α,β-unsaturated carboxylic acids and esters (1) to assess the effect of conjugation on the sensitivity of the olefinic shield-

ings to polar substituents. In general, the "polar" components as represented by the entries for Cl, Br, and I in Table 5 are more negative than the corresponding values for the conjugated carboxyl derivatives, whereas the "*cis*-X" factors are more positive for the allyl alcohols.

In summary, it would appear that the additive parameters generated from the currently available data will be useful for estimating ^{13}C shieldings in closely-related systems although a detailed theoretical interpretation of the trends is not yet available.

We wish to thank the National Research Council of Canada for operating funds to support this project and Varian Associates, Palo Alto, California for the loan of the probe employed in this study.

Rearrangement Studies with ^{14}C. XXXVI. Solvolysis of 1-^{14}C-2-Phenylethyl Tosylate in Aqueous Acetic Acid with or without Added Sodium Azide

C. C. LEE, D. UNGER, AND SHARON VASSIE

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 3, 1971

Solvolyses of 1-^{14}C-2-phenylethyl tosylate (**1**-OTs-1-^{14}C) were carried out in HOAc and H_2O solvent systems with or without added NaN_3. In the absence of added azide ion, the products obtained from a given solvent mixture of HOAc–H_2O, **1**-OAc-^{14}C, and **1**-OH-^{14}C, showed essentially the same extent of rearrangement of the ^{14}C-label from C-1 to -2. In the presence of added azide ion, the rearrangement in the **1**-N_3-^{14}C was less than that found in the **1**-OAc-^{14}C or **1**-OH-^{14}C. The results are interpreted in terms of concurrent direct displacement to give product and product formation from the ethylenephenonium ion.

Les solvolyses du ^{14}C-1 phényl-2 éthyl tosylate (OTs-**1**-^{14}C-1) ont été menées dans des systèmes AcOH–H_2O, avec ou sans addition de NaN_3. En l'absence de l'ion azoture, les produits obtenus à partir d'un mélange donné AcOH–H_2O, c'est-à-dire -OAc-**1** ^{14}C et OH-**1** ^{14}C, montrent essentiellement le même pourcentage de réarrangement du ^{14}C marqué du C-1 au -2. En présence de N_3^-, le réarrangement de N_3-**1** ^{14}C est inférieur à celui trouvé pour OAc-**1** ^{14}C ou OH-**1** ^{14}C. Les résultats sont interprétés par une compétition entre un déplacement direct conduisant au produit et la formation de ce dernier par l'intermédiaire de l'ion éthylène phénonium.

Canadian Journal of Chemistry, **50**, 1371 (1972)

The acetolysis of 1-^{14}C-2-phenylethyl tosylate (**1**-OTs-1-^{14}C) has been extensively investigated (1 and references given therein) and the results have generally been attributed to two competing processes, namely, a direct displacement (solvent assisted or k_s pathway) and reaction via the ethylenephenonium ion (**2**) (anchimerically assisted or k_Δ pathway) (1–3). On the other hand, the work of Sneen and Larsen (4, 5) suggested the possibility that such solvolyses could proceed solely through an ion-pair mechanism. Very recently however, Schleyer and coworkers (6, 7) have utilized the azide ion as a probe for the k_s process and have interpreted their results as in support of the concurrent mechanism. In the present work, solvolyses of **1**-OTs-1-^{14}C in H_2O–HOAc with or without added NaN_3 were carried out, and the isotope position rearrangements in the different products, **1**-OAc-^{14}C, **1**-OH-^{14}C, and **1**-N_3-^{14}C, were ascertained in an attempt to obtain data that might be pertinent in differentiating between the concurrent k_s and k_Δ processes and the single ion-pair mechanism. Moreover, since in all previous solvolytic studies with **1**-OTs-1-^{14}C, only a single product from a given reaction has been analyzed for isotopic scrambling, it is of interest to determine the extents of scrambling in the different products obtained from a solvolysis under conditions that could give rise to more than one product.

The solvolyses of **1**-OTs-1-^{14}C in water and acetic acid solvent systems were carried out by heating under reflux 0.05 mol of the substrate per 100 ml of solvent for 24 h. The products were analyzed and separated by v.p.c. and then oxidized to benzoic acid whose ^{14}C-activity gave the extent of isotope position rearrangement from C-1 to -2. The results are summarized in Table 1. In the case of the solvolysis in pure water, because of the low solubility of the **1**-OTs-1-^{14}C, the reaction mixture was not homogeneous. The unreacted tosylate was recovered and degraded by conversion to **1**-Br-^{14}C followed by oxidation to PhCOOH. It was found that in both runs in water, the recovered tosylate showed only 0.4% rearrangement of the ^{14}C-label from C-1 to -2. Since it is known that ion-pair return is suppressed in a highly ionizing solvent (8), the small amount of rearrangement observed in the recovered tosylate would suggest that ion-pair return in this solvent was not extensive, although the possibility that solvolysis of **1**-OTs-1-^{14}C in H_2O may not involve the symmetrical ethylenephenonium tosylate ion-pair could not be excluded.

The data in Table 1 indicate that when aqueous acetic acid was used as solvent, the resulting **1**-OH-^{14}C and **1**-OAc-^{14}C showed essentially the same amount of isotope position rearrangement. Moreover, the yields of **1**-OH and **1**-OAc were almost directly related to the

relative amounts of H_2O and HOAc in the solvent mixture. These findings thus failed to provide evidence for a difference in k_s contributions by the two components of the solvent mixture. A possible explanation of the identical amounts of rearrangement in the two products might be that the products arose from a single intermediate, such as an ion-pair (4, 5). Alternatively, the nucleophilic characters of H_2O and HOAc might not be sufficiently different to cause any observable difference in the k_s contributions, or the ion-pair might be insensitive to the nucleophilic differences between H_2O and HOAc. Since the azide ion is a strong nucleophile and since it has been used as a mechanistic probe for the k_s process (6, 7), the work was extended to include the solvolyses of **1**-OTs-1-^{14}C in HOAc or 50:50 (by volume) H_2O–HOAc in the presence of added NaN_3. The results, recorded in Table 2, showed that the rearrangement of the ^{14}C-label to C-2 was indeed lower in the **1**-N_3-^{14}C than in the **1**-OAc-^{14}C or **1**-OH-^{14}C, in accord with the anticipation of a greater k_s contribution in the formation of **1**-N_3-^{14}C. However, the variations in the extents of rearrangement, shown in both Tables 1 and 2, require further interpretations.

Utilizing the concurrent mechanism (1, 6, 7), when two or more products are formed in a given solvolysis of **1**-OTs-1-^{14}C, the isotope position rearrangement in each product is the composite result of product formation from the phenonium ion **2** and from the direct displacement involving rearranged starting material that resulted from ion-pair returns. As an illustration, Scheme 1 shows the possible processes involved in the acetolysis of **1**-OTs-1-^{14}C in the presence of added azide ion. Analogous to Scheme 1, if the two nucleophiles were HOAc and H_2O, and if the pseudo-first order rates for the k_s processes in the reaction with HOAc and with H_2O, k_A and k_W, were not significantly different, for a solvolysis in a given H_2O–HOAc mixture, there would be no significant difference in the extents of rearrangement of the label in the two products, **1**-OH-^{14}C and **1**-OAc-^{14}C, as was observed (Table 1). It may also be noted from Table 1 that the amount of rearrangement in the products increases with increasing proportions of HOAc in the solvent. This could be attributable to a greater tendency for ion-pair return when the solvent contains more HOAc. It has been pointed out earlier that for solvolysis of **1**-OTs-1-^{14}C in H_2O the recovered starting material was only 0.4% rearranged. On the other hand, Coke and coworkers (1) have found extensive ion-pair returns in the solvolysis of **1**-OTs-1-^{14}C in unbuffered HOAc; for example, after a reaction time of 22 h at 115°, the recovered tosylate was 26.1% rearranged. The greater extent of ion-pair return would result in a greater overall rearrangement since the k_s process would give rise to more rearranged product besides the rearrangement arising from the Fk_Δ process.

For the solvolyses in the presence of added azide ion, the k_s process involving azide ion, or $k_N[N_3^-]$, apparently could compete with $f_N k_\Delta$

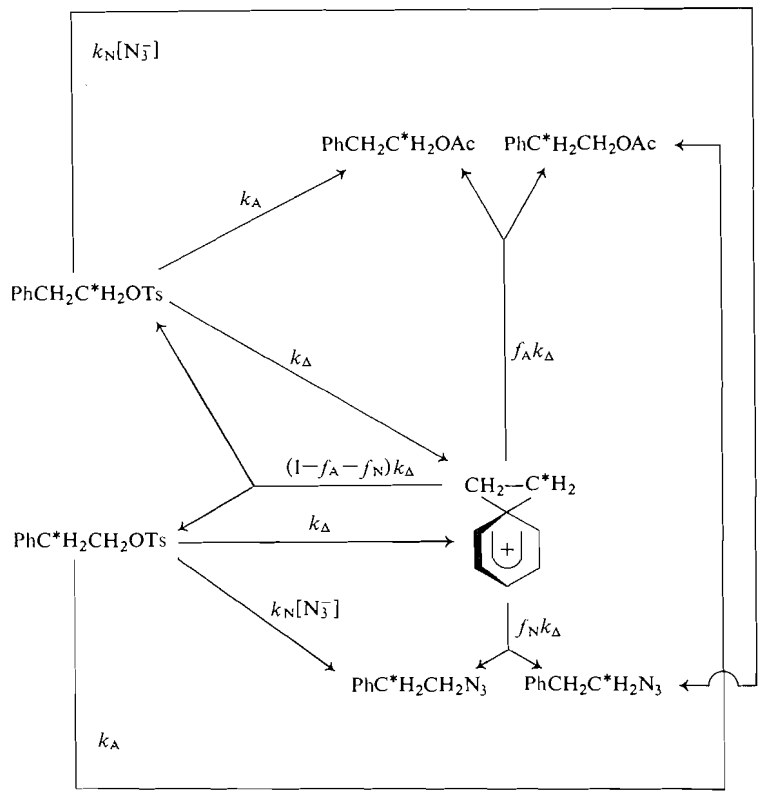
¶Reduced to **1**-NH_2 and then assayed as *N*-phenethyl-*N'*-phenylurea.



SCHEME 1

more effectively than did k_A in competing with f_Ak_Δ (or k_W in competing with f_Wk_Δ), thus resulting in lesser amounts of isotopic scrambling in the 1-N_3-^{14}C than in the 1-OAc-^{14}C or 1-OH-^{14}C (Table 2). It is seen from Table 2 that for the reaction in HOAc with added azide ion, only about 4% of 1-N_3-^{14}C was formed as product, but this product showed nearly 6% rearrangement of the label from C-1 to -2. On the other hand, solvolysis in 50:50 H_2O–HOAc gave more than 20% 1-N_3-^{14}C as product, which, however, showed only about 2% rearrangement of the isotopic label. The greater yield of 1-N_3-^{14}C in H_2O–HOAc could be the result of a greater availability of the azide ion for displacement reactions, possibly because NaN_3 might be more readily ionized in H_2O–HOAc than in HOAc. The greater amount of rearrangement in the 1-N_3-^{14}C obtained from the solvolysis in HOAc is likely due to more ion-pair returns in HOAc than in H_2O–HOAc; thus the formation of 1-N_3-^{14}C would involve reactions with more extensively rearranged 1-OTs-^{14}C in HOAc than in H_2O–HOAc.

Finally, a comparison of the data in Tables 1 and 2 shows that the presence of added azide ion has the effect of decreasing the extent of rearrangement in the products, 1-OAc-^{14}C and 1-OH-^{14}C. Such differences in the amounts of rearrangement are not unexpected since the overall observed rearrangement should be highly dependent on reaction conditions (1). A factor that might have played an important part in decreasing the rearrangement could be that in the presence of added NaN_3, the reaction rate would likely be enhanced (6, 7), and there would be lesser opportunity for the occurrence of many cycles of ion-pair formation and ion-pair return, thus resulting in a lower amount of rearrangement in the reaction product. Thus all the results obtained in the present work could be explained by, and hence lend further support to, the occurrence of competing k_s and k_Δ processes, involving direct displacement to give product as well

as product formation from the phenonium ion, as illustrated in Scheme 1.

Experimental

Solvolyses

The solvolyses were carried out by heating under reflux for 24 h 0.5 *M* solutions of **1**-OTs-1-^{14}C in the appropriate solvent (HOAc or H_2O–HOAc). In the experiments with H_2O as solvent, 0.05 mol of **1**-OTs-1-^{14}C in 100 ml of H_2O was heated, but a homogeneous solution was not obtained and much of the tosylate remained as a molten oil during the period of reflux. When the solvolysis was effected in the presence of added NaN_3, the concentration of NaN_3 was 0.7 *M*. In some preliminary work, 0.5 *M* NaN_3 was utilized, but the higher concentration of 0.7 *M* was chosen in order to raise somewhat the yields of **1**-N_3-^{14}C. The following is a typical experiment carried out with added NaN_3.

A solution of 3.452 g (0.0125 mol) of **1**-OTs-1-^{14}C (9) and 1.134 g (0.0175 mol) of NaN_3 in 25 ml of 50:50 (by volume) H_2O–HOAc was heated under reflux for 24 h. Appropriate amounts of ordinary **1**-N_3 (10), **1**-OAc, and **1**-OH were added as carriers. The mixture was then subjected to vacuum distillation (about 20 mm) to remove most of the solvent. Ice-water was then added, followed by neutralization with 5% NaOH solution. The resulting material was continuously extracted for 24 h with ether. The extract was dried over $MgSO_4$, the ether removed, and the products were recovered by preparative v.p.c., using a Pye Automatic Preparative Chromatograph with a 10-ft, 3/8-in. copper column packed with 20% silicone DC 710 on 60/80 mesh Chromosorb W. Knowing the weights of the carriers and the appropriate specific activities, the yields of the three products were obtained by isotope dilution calculations.

In the solvolyses without added NaN_3, instead of isotopic dilution, the yields were determined by v.p.c. analyses using 1-phenylethanol as an internal standard, a preliminary injection of the product mixture from each solvolysis having shown that 1-phenylethanol was not present as a product. An aerograph 200 Chromatograph with flame ionization detector fitted with a 25-ft, 1/8-in. copper column packed with 20% silicone DC 710 on 60/80 mesh Chromosorb W was utilized for the analyses.

Degradations

Samples of the v.p.c. purified **1**-OH-^{14}C, **1**-OAc-^{14}C, and **1**-N_3-^{14}C, diluted further with carriers if necessary, were converted to appropriate solid derivatives for radioactivity assays. **1**-OH-^{14}C was treated with α-naphthyl isocyanate to give the α-naphthylurethane, m.p. 117–118° (lit. (11), m.p. 119°). The **1**-OAc-^{14}C was hydrolyzed by heating with 10% NaOH to give **1**-OH-^{14}C which was, in turn, converted to the α-naphthylurethane. The **1**-N_3-^{14}C was reduced with $LiAlH_4$ to give **1**-NH_2-^{14}C (12) which was converted, by treatment with phenyl isocyanate, to *N*-phenethyl-*N'*-phenylurea, m.p. 153–154° (lit. (13) m.p. 153.5–154.5°).

The remaining portions of the **1**-OH-^{14}C, **1**-OAc-^{14}C, and **1**-N_3-^{14}C, after the derivative preparations, were oxidized directly with alkaline $KMnO_4$ (9) to give benzoic acid, whose radioactivity measured the ^{14}C content at the C-2 position of these products.

The **1**-OTs-^{14}C recovered from the solvolysis in H_2O was converted to **1**-Br-^{14}C by treatment with LiBr in dry acetone (14). The **1**-Br-^{14}C so obtained was also oxidized to benzoic acid (9) in order to ascertain the extent of rearrangement.

The authors wish to express sincere appreciation to Professor P. v. R. Schleyer for valuable comments and for suggesting the use of NaN_3 in this study. The financial assistance given by the National Research Council of Canada is gratefully acknowledged.

Sur la reduction par les hydrures complexes de benzyl-3 camphres

JEAN-CLAUDE RICHER ET ARMAND ROSSI[1]

Département de Chimie, Université de Montréal, B.P. 6128, Montréal, Québec

Reçu le 22 mars 1971[2]

La synthèse de benzyl-3 camphres et les résultats obtenus lors de leur réduction par les hydrures complexes sont rapportés; les divers benzyl-3 bornéols qui en dérivent, ont été isolés et caractérisés.

Benzyl-3 camphors have been prepared and the stereochemistry of their reduction by complex hydrides is reported; the corresponding benzyl-3 borneols have also been prepared and characterized.

Canadian Journal of Chemistry, **50**, 1376 (1972)

Introduction

Dans le cadre de nos travaux (1, 2) sur les facteurs influençant les quantités relatives d'addition 1:2 *vs.* 1:4, lors de la réduction par les hydrures complexes, de méthylène-3 camphres (**1**), nous avons été amenés à préparer les benzyl-3 camphres **2** et **3**. La stéréochimie de leur réduction a été examinée. La structure et la configuration des produits obtenus ont été établies. Les résultats de cette étude font l'objet de la présente communication.

Partie expérimentale

Les points de fusion sont déterminés sur un "Hot Stage Apparatus" de la compagnie Reichert (Autriche) à l'aide d'un thermomètre calibré. Les indices de rotation sont mesurés à l'aide d'un polarimètre modèle 80 de la compagnie O. C. Rudolph; le benzène est utilisé comme solvant et une moyenne de cinq lectures est effectuée pour chaque mesure. Les spectres i.r. sont pris sur un spectromètre modèle IR-8 de la compagnie Beckman; les spectres des alcools et des cétones sont pris en solution dans le CCl_4. Les spectres u.v. sont mesurés dans l'éthanol à 95% à l'aide d'un appareil Spectronic 505 de la compagnie Bausch et Lomb. Les spectres de masse sont déterminés sur un spectromètre de masse Hitachi, modèle RMU 60, à 70 eV; ces spectres sont rapportés sous forme de schémas dans la thèse de doctorat de M. Armand Rossi. Les spectres r.m.n. sont pris sur des spectromètres Jeol modèle C-60H et 4H-100; à moins d'indications contraires le solvant utilisé est $CDCl_3$ et les déplacements chimiques se réfèrent au TMS utilisé d'une façon interne. Les spectres des produits des différentes séries se ressemblent beaucoup et afin d'éviter de fastidieuses répétitions nous n'avons résumé dans le tableau 1 que les caractéristiques spectrales des dérivés contenant le groupe *p*-méthylphényle. Les analyses par c.p.g. sont effectuées sur un appareil F et M 700 de la compagnie Hewlett Packard. Les colonnes utilisées sont: (A) carbowax 20M 5%, hyprose 2.5%, KOH 2.5% sur chromosorb W 60/80, longueur 16 pd, diamètre 1/8 p; (B) LAC 728 10% sur Diatoport S 80/100, longueur 8 pd, diamètre 1/8 p. Les temps de rétention en minutes de chacun des produits et les conditions expérimentales permettant de faire une analyse complète de tous les produits de chaque série sont résumés dans le tableau 2. Les c.p.g. préparatives sont effectuées sur un appareil Varian du type 90 P. La colonne utilisée de 12 pd de longueur et 1/4 p de diamètre est remplie de chromosorb W 30/60 portant 15% de carbowax 20M, 5% d'hyprose et 5% de KOH.

Benzylidène-3 camphres (1)

Suivant le protocole expérimental suggéré par Haller (3), 5 g de sodium en fil sont ajoutés à une solution de 30 g de camphre dans 300 ml de benzène anhydre; le tout est porté à reflux, sous agitation, pendant 18 h. Après refroidissement de la solution, le sodium n'ayant pas réagi est retiré avec une spatule; 30 g de benzaldéhyde approprié, fraîchement distillé, sont alors ajoutés. Après 4 h d'agitation à la température ambiante, le mélange est versé dans 500 ml d'eau. La solution est extraite au benzène, les fractions benzéniques lavées à l'eau, séchées sur du sulfate de sodium anhydre et évaporées. La recristallisation des benzylidène-3 camphres (**1**) dans l'éthanol absolu conduit aux dérivés désirés avec des rendements variant entre 50 et 70%; leurs caractéristiques physiques et spectrales sont résumées dans le tableau 3.

Benzyl-3 camphres (2 et 3)

D'une manière générale, 3 g de cétone insaturée **1** sont hydrogénés sous pression normale, à la température ambiante, en présence de palladium sur charbon (5%) dans 80 ml d'éthanol absolu. Après avoir éliminé le catalyseur par filtration, l'évaporation du solvant conduit à des mélanges contenant environ 80% de cétone *exo* **2**; ce pourcentage est déterminé en intégrant en r.m.n. le signal du méthyle 8 de l'isomère *exo* par rapport à l'ensemble des méthyles 8, 9 et 10. La chromatographie de 2 g de mélange sur 250 g de gel de silice en utilisant le benzène comme éluant permet d'obtenir la cétone **2***a* à l'état pur; par ailleurs la recristallisation des autres mélanges permet d'isoler les cétones **2***b*, *c*, et *d* à l'état pur; les constantes physiques et les caractéristiques spectrales de ces dérivés sont rapportées dans le tableau 3.

L'équilibration des mélanges d'hydrogénation (ou des

[1]Les résultats rapportés dans cette communication sont extraits en partie de la thèse soumise par M. Armand Rossi en vue de l'obtention du grade de Ph.D., Faculté des Sciences, Université de Montréal, janvier 1971.

identique à celui du dérivé **3***b*. La spectrométrie de masse révèle que le produit est monodeutéré à 87%. Les signaux dus au $-CH_2$ benzylique apparaissent, dans le spectre r.m.n., sous la forme de deux doublets ($J = 14.4$ Hz) à 2.37 et 3.30 p.p.m.

*Benzylidène-3 isobornéols (**5**) et bornéols (**6**)*

D'une manière générale, ces dérivés sont obtenus de la façon suivante: dans un ballon de 100 ml surmonté d'une colonne Vigreux, contenant 2.5 g de cétone **1** dans 60 ml d'alcool isopropylique, sont ajoutés 12 g d'isopropylate d'aluminium. Le mélange est porté à un léger reflux de façon à ce que l'acétone formée puisse distiller au fur et à mesure de sa formation. Lorsqu'il ne se forme plus d'acétone (1 à 4 jours), le mélange réactionnel est jeté dans 300 ml d'une solution de soude à 5%. Les produits sont alors extraits avec des rendements pratiquement quantitatifs. La chromatographie sur gel de silice en utilisant le benzène comme éluant permet d'isoler les alcools insaturés **5** et **6** à l'état pur. Les constantes physiques et les caractéristiques spectrales de ces alcools sont résumées dans le tableau 3.

*Benzyl-3 bornéols (**7**, **8**, **9** et **10**)*

*Benzyl-3 exo isobornéols (**7**)*

Ces alcools sont obtenus par le procédé suivant: 1.5 g de cétone **2** en solution dans 20 ml d'éther anhydre sont ajoutés à une suspension de 1 g de $LiAlH_4$ dans 30 ml d'éther anhydre. Après un reflux de 4 h, l'excès d'hydrure est détruit en ajoutant 50 ml d'une solution de soude à 5%. Les produits extraits à la manière habituelle renferment environ 96% des alcools désirés **7** et 4% de l'épimère **8**. La chromatographie sur gel de silice permet d'isoler les dérivés **7***a*, *b*, et *d* à l'état pur; il suffit de recristalliser dans l'éther de pétrole les produits bruts de la réaction pour récupérer l'acool **7***c* chromatographiquement pur. Les constantes physiques et les caractéristiques spectrales de ces alcools sont résumées dans le tableau 3.

*Benzyl-3 endo isobornéols (**8**) et bornéols (**9**)*

La réduction des benzyl-3 *endo* camphres (**3**) par $LiAlH_4$ suivant le mode opératoire donné précédemment conduit à des mélanges réactionnels contenant environ 67% des alcools **8**, 29% des alcools **9**, et 4% des alcools **7**. La chromatographie de ces mélanges sur colonne de gel de silice, en utilisant le benzène comme éluant, permet d'isoler les alcools **8***a*, **8***d*, **9***a*, et **9***d* à l'état pur. Les alcools **8***b*, **8***c*, **9***b*, et **9***c* à l'état pur sont obtenus par c.p.g. préparative. Les constantes physiques et les caractéristiques spectrales des alcools **8** et **9** sont résumées dans le tableau 3.

*Benzyl-3 exo bornéols (**10**)*

L'hydrogénation de 600 mg de benzylidène-3 bornéols (**6**) (ou isobornéols **5**) à pression normale, à la température ambiante et en présence de palladium à 5% sur charbon dans 40 ml d'éthanol absolu conduit à des mélanges contenant 54% de benzyl-3 *exo* bornéols (**10**) et 46% de benzyl-3 *endo* bornéols (**9**) (ou 85% de benzyl-3 *exo* isobornéols **7** et 15% de benzyl-3 *endo* isobornéols **8**).

La c.p.g. préparative permet de séparer quantitativement les deux isomères et d'isoler les bornéols **10** à l'état pur. Les constantes physiques et les caractéristiques spectrales de ces alcools **10** sont rapportées dans le tableau 3.

*Stéréochimie de la réduction des p-méthylbenzyl-3 exo (**2***b*) et endo (**3***b*) camphres par les hydrures complexes*

Considérations générales. Les techniques opératoires utilisées pour ces réductions ont fait l'objet de nombreuses descriptions. Le tableau 4 résume les résultats obtenus. Les références appropriées à ces techniques y sont rapportées.

Réduction par une solution de L.D.P.A. dans la pyridine

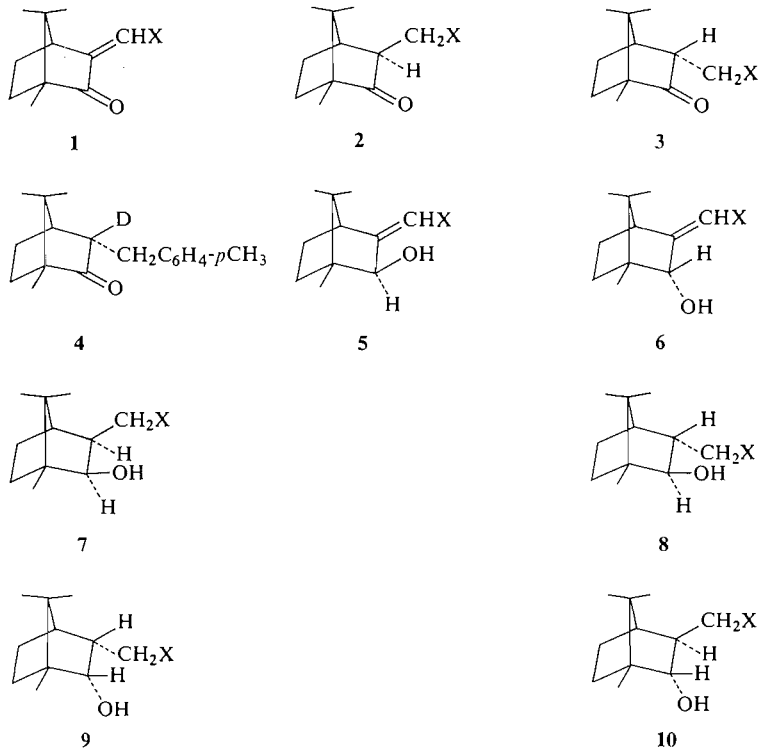
La solution de tétrakis-(*N*-déhydropyridil) aluminate de lithium (L.D.P.A.) est préparée d'après la méthode décrite par Lansbury et Peterson (14) (1 g de $LiAlH_4$/100 ml de pyridine). Dans un flacon fermé hermétiquement par un bouchon de caoutchouc et renfermant 128 mg de cétone à réduire en solution dans 5 ml de pyridine sont introduits, à l'aide d'une seringue, 20 ml de la solution de L.D.P.A. (environ 5 mmol). Le mélange est maintenu à 35 °C pendant 72 h. L'hydrolyse est effectuée avec une solution d'acide chlorhydrique très diluée (2%). L'extraction à l'éther est effectuée à la manière habituelle (rendement 80–90%). Les mélanges réactionnels sont examinés par c.p.g.

Discussion des résultats

Configurations des produits obtenus

Les spectres r.m.n. des benzylidène-3 camphres (**1**) ne présentent qu'un seul signal (7.28–7.10 p.p.m.) correspondant à un proton vinylique. Celui-ci apparaît à des champs relativement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



a X = C_6H_5— *c* X = *p*-$CH_3OC_6H_4$—
b X = *p*-$CH_3C_6H_4$— *d* X = *m*-FC_6H_4—

faibles, dû au déblindage par le groupement carbonyle, confirmant ainsi, en accord avec les travaux de Sotiropoulos (17), la configuration *trans* de ces dérivés.

Il est admis généralement (18) que dans la série du camphre, les composés *endo* sont plus stables que les composés *exo*. Les configurations des benzyl-3 *exo* (**2**) et *endo* (**3**) camphres ont donc été attribuées en se basant sur les résultats obtenus lors de leur mise à l'équilibre en milieu alcalin (*exo*/*endo* = 7/93). En r.m.n., la constante de couplage nulle entre les protons H-3 et -4 confirme l'attribution faite aux dérivés *exo* **2**, en accord avec les valeurs déjà rapportées (19) pour des systèmes comportant un proton *endo* en position 3. Les spectres des cétones *endo* **3** sont plus complexes à analyser, la constante de couplage entre H-3 et -4 n'est plus égale à zéro et il n'est pas exclu que le proton en position 3 soit également couplé avec celui en position 5-*exo* dans un système en W(20). De l'étude des spectres r.m.n. des cétones *exo* **2** et *endo* **3**, il ressort également que les chaînes benzyliques existent dans des conformations privilégiées. En effet, le proton en position 3 et les deux protons benzyliques des benzyl-3 *exo* camphres (**2**) apparaissent sous la forme d'un système ABX qui a été analysé et pour lequel $\delta_A = 2.43$, $\delta_B = 2.03$, et $\delta_X = 3.40$ p.p.m. avec $J_{AB} = 10.0$, $J_{AX} = 13.6$, et $J_{BX} = 3.0$ Hz. Les déplacements chimiques très différents pour les protons H_A et H_X et les constantes de couplage observées seraient compatibles avec l'existence de conformations privilégiées **A** *ou* **B**.

Pour des dérivés de la benzyl-2 hydrindanone, présentant des spectres r.m.n. comparables à ceux de nos produits, Imbach *et al.* propose (21)

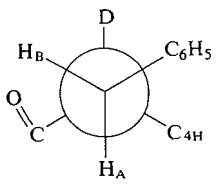
†Voir réf. 28.
‡Voir réf. 29.

la conformation **A**. En considérant le fait que le proton H_X apparaît à un champ plus bas que H_A, nous sommes portés à croire, à la suite de l'interprétation de Mathieson (22) qu'il est plus approprié de suggérer que les benzyl-3 *exo* camphres (**2**) existent sous la conformation **B**. Les protons benzyliques du *p*-méthylbenzyl-3 *endo* camphre-3*d* (**4**) apparaissent respectivement à 2.37 (H_A) et 3.30 p.p.m. (H_B) avec $J_{AB} = 14.4$ Hz; nous pouvons donc considérer que les cétones **3** et **4** existent préférentiellement sous la conformation **C**. Il faut noter que dans chacune de ces confor-



C

mations, considérées comme préférentielles sur la base de la r.m.n., le groupe phényle se trouve toujours dans la position la moins encombrée stériquement, c'est-à-dire entre H-3 (ou D) et C_4H.

Les configurations des benzylidène-3 isobornéols (**5**) et bornéols (**6**) découlent de leur mode de préparation (23), si on considère que dans des conditions de formations équilibrantes les bornéols **6** sont obtenus de façon prépondérante. La stéréochimie de ces composés est confirmée par l'étude en r.m.n. de la position et du type de couplage des protons carbinoliques (C*H*OH). Flautt et Erman (24) ont constaté que le signal dû à un tel proton est localisé à des champs plus forts pour les isomères *exo* (proton *endo*). Les benzylidène-3 isobornéols (**5**) (proton *endo*) et bornéols (**6**) (proton *exo*) donnent respectivement pour le proton en position 2 un signal à 3.95 et 4.31 p.p.m. Les couplages auxquels sont soumis de tels protons caractérisent également l'environnement stéréochimique dans lequel ils se trouvent. Les protons *endo* (H_{2n}) des benzylidènes-3 isobornéols (**5**) sont couplés uniquement avec le proton vinylique (H_v) ($J_{H_{2n}H_v} = 1.6$ Hz) et se présentent sous la forme de doublets, alors que pour les benzylidène-3 bornéols (**6**) les mêmes protons en position *exo* (H_{2x}) sont de plus couplés possiblement à longue distance (couplage en W) (25) avec le proton en position 6 *exo* ($J_{H_{2x}H_v} = 1.6$, $J_{H_{2x}H_{6x}} = 1.6$ Hz) et apparaissent sous forme de triplets assez mal définis.

Enfin, bien que les configurations relatives des quatre benzyl-3 bornéols (**7**–**10**) découlent directement de leur mode de formation, c'est essentiellement la comparaison, en r.m.n., des constantes de couplage entre les protons H-2 et -3 et les valeurs données par Karplus (26) pour les dérivés de l'éthane qui permet d'attribuer une configuration aux diastéréoisomères de bornanes substitués. Les constantes de couplage entre les protons H-2 et -3 de quelques bornéols substitués en position 3 sont résumés dans le tableau 5. Il est intéressant de noter que cette constante de couplage augmente d'une façon plus ou moins prononcée avec l'encombrement du substituant en position 3: —OH, —NH_2, et —$CH_2C_6H_5$. L'introduction du groupe hydroxyle en position 2 *exo* ou benzyle en position 3 *exo*, pour les dérivés étudiés, peut être la cause de certaines distorsions dans la molécule, faisant varier ainsi les valeurs des angles dièdres, par rapport à celles observées dans un bornane non substitué et expliquer les écarts observés pour les constantes de couplage entre les protons H-2 et -3 et les valeurs théoriques attendues (29). Conformément aux remarques faites précédemment pour les benzylidène-3 bornéols (**5** et **6**) le signal relatif au proton 2 *endo* apparaît à des

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

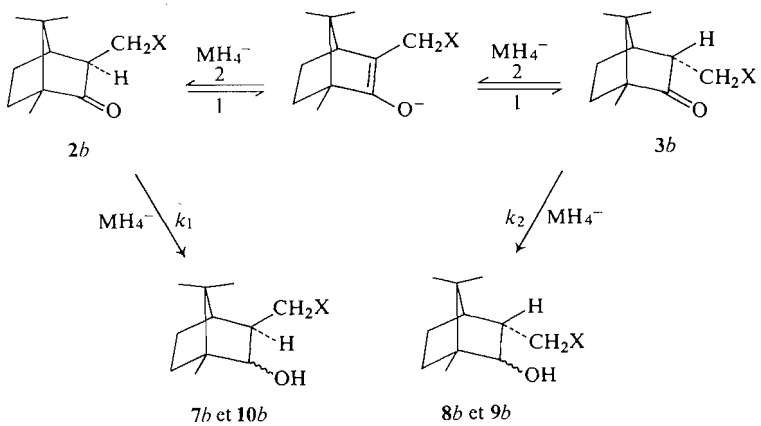


SCHÉMA 1

champs plus forts que celui correspondant au proton 2 *exo*; de plus, des couplages à longue distance entre les protons H(-2 *exo*) et H(-6 *exo*) de l'ordre de 1.5 Hz sont observés pour les dérivés **9** et **10**.

Stéréochimie de la réduction des p-méthylbenzyl-3 camphres (2b et 3b)

Un premier aspect des données rapportées dans le tableau 4 mérite des commentaires. La réduction des cétones **2***b* et **3***b* par le L.D.P.A. ou par $NaBH_4$ conduit à des quantités appréciables de produits provenant d'une réduction de la cétone épimère de celle mise en réaction. Ces résultats sont à rapprocher de ceux d'Erman et Flautt (30) qui observent, au cours de la réduction par $NaBH_4$ dans le méthanol des *p*-anisyl-2 *endo* et *exo* épicamphres, uniquement la formation de *p*-anisyl-2 *endo* épiisobornéol. Cette tendance à l'épimérisation, observée au cours de ces réductions ne semble pas générale pour toutes les cétones bicycliques substituées en α du groupe carbonyle puisqu'elle n'est pas observée lors de la réduction des méthyl-3 norbornanones (31). Les résultats obtenus au cours du présent travail s'accommodent bien avec le schéma 1 qui tient compte des faits suivants: (*a*) le pourcentage relatif des alcools isomères **7***b* *vs.* **10***b* formés au cours des réductions des deux cétones **2***b* et **3***b* reste le même; (*b*) la même remarque est valable pour le pourcentage relatif des alcools isomères **8***b* *vs.* **9***b*; (*c*) la proportion importante d'isomérisation (17.6%) obtenue pour la réduction par $NaBH_4$ dans le propanol-2 du *p*-méthylbenzyl-3 *endo* camphre (**3***b*) comparée au résultat de la mise à l'équilibre des deux cétones isomères **2***b* et **3***b* (*exo*/*endo* = 7/93 suggère que la réduction de l'isomère **2***b*, pour lequel le groupe carbonyle reste facilement accessible par la face *endo* de la molécule complètement dégagée, se fait plus rapidement que celle du dérivé **3***b*, déplaçant l'équilibre entre les deux cétones vers la formation du dérivé *exo* **2***b*.

D'une façon plus générale, la stéréochimie de la réduction de cétones cycliques a fait l'objet de nombreux travaux et est maintenant essentiellement rationalisée en fonction d'une théorie complètement stérique (32) ou de la variante proposée par Cherest et Felkin (33) faisant intervenir des effets de torsions. Appliqués aux dérivés du camphre, ces concepts permettent de prévoir que les réductions conduiront de façon prépondérante aux alcools *exo* (23, 31, 34–37). L'examen des résultats rapportés dans le tableau 6 permet de réaliser que l'introduction du groupe *p*-méthylbenzyle *exo* en position 3 de la cétone **2***b* ne fait qu'augmenter la stéréospécificité de la réaction comparée aux résultats obtenus lors de la réduction du camphre et de l'apocamphre. En accord avec ces théories, l'introduction d'un groupe *p*-méthylbenzyle-3-*endo* dans la cétone **3***b* ralentit l'attaque de l'hydrure s'approchant par la face *endo* du carbonyle en position 2. Le pourcentage de réduction par la face *exo* se trouve

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

ainsi considérablement augmenté, ce qui explique la proportion croissante d'alcool *endo*.

Enfin, les résultats obtenus lors des réductions par le L.D.P.A. ont retenu notre attention. En effet, Lansbury (14) rapporte qu'après avoir laissé le camphre en contact avec une solution de L.D.P.A. pendant 5 jours, 98% de cétone n'ayant pas réagi sont récupérés. La même réaction reprise dans des conditions identiques à celles décrites par ces auteurs nous conduit avec un rendement de 90% à un mélange formé de 62.5% d'isobornéol et 37.5% de bornéol. Cette différence de réactivité reste inexpliquée. Alors qu'il est probable que la présence du groupe *p*-méthylbenzyle en position 3 favorise l'action du L.D.P.A. sur les cétones 2 et 3 conformément aux résultats obtenus pour la réduction de benzophénones dans des conditions identiques (14). Les pourcentages élevés de bornéols (37.5%) et de *p*-méthylbenzyle-3-*endo* bornéol (**9***b*, environ 80%) obtenus respectivement pour les réductions du camphre et du *p*-méthylbenzyle-3-*endo* camphre (**3***b*) s'expliquent si nous admettons à la suite de Lansbury et MacLeay (38) que le L.D.P.A. est moins soumis à l'encombrement stérique des réactifs que les autres hydrures; son comportement serait intermédiaire entre celui de $NaBH_4$ et du produit d'addition du butyllithium sur la pyridine (39).

Les auteurs remercient vivement le Conseil National de Recherches du Canada, le Ministère de l'Education du Québec, et le Conseil des Arts du Canada pour l'aide financière apportée sous forme d'octroi et de bourses.

Nuclear Magnetic Resonance Studies of some Trimethyl Tin Carbamates

A. E. LEMIRE AND J. C. THOMPSON[1]

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received November 24, 1971

The low temperature n.m.r. spectra of some trimethylstannyl esters of *N,N*-dimethylcarbamic acid, *N,N*-dimethyldithiocarbamic acid, and *N,N*-dimethylmonothiocarbamic acid have been examined. Activation parameters for hindered rotation about the C—N bond in the trimethylstannyl ester of *N,N*-dimethylmonothiocarbamic acid have been determined to be: in hexane solution, $E_a = 17.0 \pm 0.5$ kcal/mol, $\Delta H^{\ddagger}_{298.2} = 16.4 \pm 0.5$ kcal/mol, $\Delta G^{\ddagger}_{298.2} = 16.4 \pm 0.4$ kcal/mol, $\Delta S^{\ddagger}_{298.2} = 0.2 \pm 2.0$ e.u.; in chloroform solution, $E_a = 19.9 \pm 0.5$ kcal/mol, $\Delta H^{\ddagger}_{298.2} = 19.3 \pm 0.5$ kcal/mol, $\Delta G^{\ddagger}_{298.2} = 16.6 \pm 0.4$ kcal/mol, $\Delta S^{\ddagger}_{298.2} = 9.1 \pm 2.0$ e.u.

Nous avons examiné les spectres r.m.n. à basse température de quelques esters triméthylstannyl des acides *N,N*-diméthylcarbamique, *N,N*-diméthyldithiocarbamique et *N,N*-diméthylmonothiocarbamique. Nous avons déterminé les paramètres d'activation pour la rotation gênée autour du lien C—N dans l'ester triméthylstannyl de l'acide diméthylmonothiocarbamique: (en solution dans l'hexane) $E_a = 17.0 \pm 0.5$ kcal/mol, $\Delta H^{\ddagger}_{298.2} = 16.4 \pm 0.5$ kcal/mol, $\Delta G^{\ddagger}_{298.2} = 16.4 \pm 0.4$ kcal/mol, $\Delta S^{\ddagger}_{298.2} = 0.2 \pm 2.0$ e.u.; (en solution dans le chloroforme) $E_a = 19.9 \pm 0.5$ kcal/mol, $\Delta H^{\ddagger}_{298.2} = 19.3 \pm 0.5$ kcal/mol, $\Delta G^{\ddagger}_{298.2} = 16.6 \pm 0.4$ kcal/mol, $\Delta S^{\ddagger}_{298.2} = 9.1 \pm 2.0$ e.u.

Canadian Journal of Chemistry, **50**, 1386 (1972)

Introduction

The question of hindered rotation about C—N bonds has long aroused interest, and increasingly, dynamic n.m.r. studies have been made on amide and amide-like systems. While some of the early data appear to be unreliable, the use of total line shape techniques has led to an increasing body of information that will allow systematic comparisons (1) of barriers to rotation both in amides (2–4) and thioamides (4, 5).

Less information is available, however, on carbamate and thiocarbamate systems (1, 6–9). Such systems, while analogous to amides and thioamides, are potentially even more interesting. If one represents them as compounds of the general formula RR′NC(X)YR″, then one sees that one may study the effects of X, Y, R, R′, and R″ functional groups upon the barrier to rotation about the C—N bond.

This paper is one in a series of systematic studies (8, 9) of carbamate and thiocarbamate esters of the group IV elements. By such studies, one may, hopefully, discover not only the effect on hindered rotation of various substituents, but also make comparisons of bonding modes used by different members of the group IV series.

Experimental

(a) Methods

The techniques for obtaining and analyzing n.m.r. spectra have been described previously (8). Temperatures were measured using the methanol and ethylene glycol standards supplied by Varian Associates and employing the equations reported by Van Geet (10, 11). Temperatures are believed to be accurate to ± 0.3 °K when using the glycol method and ± 0.8 °K when using methanol. The solutions were sealed in n.m.r. tubes under vacuum. Values of T_2^* were obtained from the low temperature line width of the *N*-methyl protons and modified by a correction factor obtained from the $-SnMe_3$ or $CHCl_3$ peak, in order to take into account temperature and homogeneity changes. All n.m.r. spectra were obtained from a Varian A56/60D n.m.r. spectrometer.

(b) Preparation of Compounds

The preparations of all compounds used in this study are given in refs. 12–14.

Results

(a) $Me_2NC(O)SSnMe_3$

The *S*-trimethylstannyl ester of *N,N*-dimethylmonothiocarbamic acid was studied in *n*-hexane and chloroform solutions.

In a 10 mol% solution in hexane, the *N*-methyl protons give rise to two resonances with a low temperature equilibrium separation of 13.4 c.p.s. It is interesting to note that, while the collapse seems to be symmetrical over most of the region of exchange, at low temperatures the low field *N*-methyl resonance is slightly broader

than the high field *N*-methyl resonance. Some representative peak widths are given in Table 1. The two peaks collapse to a singlet at 315 °K.

In a 10 mol% solution in chloroform, the *N*-methyl resonances have a low temperature equilibrium separation of 12.7 c.p.s.; they again collapse to a singlet at 315 °K.

In this case, the line widths of the two *N*-methyl peaks are essentially the same at low temperatures as shown in Table 1.

The low field *N*-methyl also shows the greatest shift in benzene and hence, as in amides, is assigned to be the methyl group *trans* to the carbonyl (1).

The peak separation in the absence of exchange showed only a small temperature dependence, increasing slightly with decreasing temperature in the case of hexane solutions and decreasing slightly with decreasing temperature in the chloroform solutions. This effect was taken into account in the calculations by varying $\delta\omega_\infty$ for best fit.

Arrhenius plots yielded the activation parameters in Table 2.

A study of this compound has also been recently made using *o*-dichlorobenzene as a solvent (15).

(b) $Me_2NC(S)SSnMe_3$

This compound exhibits a singlet for the *N*-methyl protons at room temperature both in *n*-hexane and in chloroform solutions.

No splitting of the *N*-methyl signal was noted at temperatures as low as 221.1 °K for a 12 mol% solution in $CHCl_3$ or as low as 227.7 °K for an 8 mol% solution in *n*-hexane.

(c) $Me_2NC(O)OSnMe_3$

The trimethylstannyl ester of *N*,*N*-dimethylcarbamic acid also exhibits a singlet for the *N*-methyl protons at room temperature in chloroform, *n*-hexane, and carbon tetrachloride solutions.

In a 17 mol% solution in chloroform, no splitting of the *N*-methyl signal was observed at temperatures down to 221.1 °K. No splitting was observed at 248.2 °K for a dilute solution in carbon tetrachloride or at 279.3 °K for a dilute solution in *n*-hexane.

Discussion

The activation parameters obtained in this study are summarized in Table 2.

Of the three esters, the trimethylstannyl ester of *N*,*N*-dimethyldithiocarbamic acid is the one which has been most extensively studied in the past.

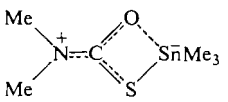
Infrared spectra were not conclusive in determining whether the structure was a non-cyclic monomer or a monomer containing a cyclic SnSCS ring in which the tin atom is 5-coordinated (13, 14).

Sheldrick *et al.* (16, 17) carried out a crystal structure determination and found that in the solid there is indeed some distortion of the tetrahedral coordination of the tin.

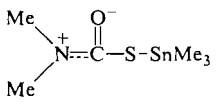
The lack of any splitting of the *N*-methyl resonance at low temperatures found in our study supports a symmetric structure in which tin is 5-coordinated in solution. A very similar situation was found with the trimethylsilyl ester (9).

The trimethylstannyl ester of *N*,*N*-dimethylcarbamic acid has also been studied both by Lappert and co-workers (13) and Dalton and Jones (14). From the i.r. data, both sets of workers conclude that the compound has a polymeric structure. Our n.m.r. data are consistent with this hypothesis since in a polymeric structure the two *N*-methyl environments would be identical. However, a cyclic monomer is also consistent with the n.m.r. data.

The structure of the *S*-trimethylstannyl ester of *N*,*N*-dimethylmonothiocarbamic acid is still ambiguous. While the n.m.r. data show that hindered rotation does occur about the C—N bond, it cannot distinguish between the two possible structures **1***a* or **1***b*, since in each case the two *N*-methyl positions are non-equivalent.



1*a*



1*b*

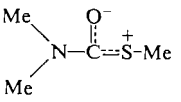
In view, however, of the tendency of tin to 5-coordination (16–18), the first structure is, at least, quite possible.

Our previous studies of analogous methyl and trimethylsilyl esters allow some comparisons to be made (8, 9).

First, the free energy of activation, $\Delta G^{\ddagger}_{298.2}$, is lower in $Me_2NC(O)SSnMe_3$ than in either $Me_2NC(S)OMe$ and $Me_2NC(S)OSiMe_3$.

This is in keeping with the general pattern observed by several workers of the barriers to rotation in amides being lower than in thioamides (3, 4, 6, 8, 9).

The barrier is also higher than in the almost exactly analogous methyl ester, $Me_2NC(O)SMe$. Again, this is to be expected, since the lower barrier in $Me_2NC(O)SMe$ relative to amides has been explained (6) in terms of a resonance contribution of the type:



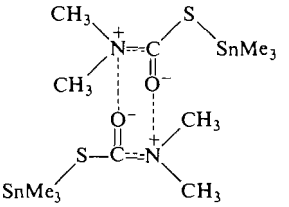
1*c*

In the case of structure **1***b*, this resonance contribution may be reduced by donation of electrons on sulfur into empty tin orbitals; it has however been suggested that tin d orbitals are too diffuse to take part in (p–d)π bonding (19).

Alternatively, formation of a 5-membered ring would also tend to increase the barrier relative to $Me_2NC(O)SMe$, as electron withdrawal from the oxygen into tin acceptor orbitals on forming the ring system should tend to further facilitate the donation of the lone pair on nitrogen into the $N^+{=}C{=}O^-$ system. The bonding in the ring, in this case, might involve either tin d orbitals or a 3-center bond formed from an sp^3 orbital of tin as postulated in compounds such as $(C_6H_5)_3Sn(Ox)$ (19).

The possibility of dimeric and other polymeric species of the trimethylstannyl ester of *N*,*N*-dimethylmonothiocarbamic acid at low temperatures is, of course, not precluded. Indeed formation of dimeric species may be the explanation for the different widths of the *N*-methyl peaks at low temperatures.

If the formation of dimers did occur at low temperatures, then the environment of the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

N-methyl group *cis* to the carbonyl would probably be slightly different in the dimer than in the monomer, and formation and destruction of dimeric species would hence lead to some broadening of its peak.

On the other hand, the difference in environment for the *trans* *N*-methyl group would probably not be substantially different between the monomer and dimer and hence this peak would not be as broadened.

In the more polar solvent chloroform, in which one would expect the molecule to be better solvated and dimerization not so likely to occur, there is indeed no substantial inequality of the line widths at low temperatures.[2]

It should be noted that in some cases other workers have observed unequal line widths for the *N*-methyl peaks in amides. For example, Neuman *et al.* noted this in a study of *N*,*N*-dimethylacetamide (3).

In this latter case, however, the workers attributed the asymmetric *N*-methyl line shapes to the unequal coupling with the *N*-methyl protons of the hydrogens of the other methyl group.

While this explanation seems quite reasonable for the situation in *N*,*N*-dimethylacetamide, the effect noted in the trimethylstannyl ester of *N*,*N*-dimethylmonothiocarbamic acid is unlikely to be due to spin–spin coupling, since the protons of the ester grouping are seven bonds removed from the *N*-methyl protons.

A similar broadening has been reported in the compound $(CH_3)_2ClSn[SSeCN(CH_3)_2]$ (20) and attributed to a coupling of the CH_3 protons *trans* to the selenium atom with the ^{77}Se isotope (natural abundance 7.58%). However, in view of our results, it appears this interpretation is incorrect.

Finally let us consider the results in chloroform solutions: solvation could occur by the formation of a hydrogen bond between the hydrogen on chloroform and the unshared electron pairs either on the carbonyl oxygen or on the ester sulfur.

In either case, this would be expected to raise the barrier to rotation: in the first case, by increasing the polarity of the $\bar{N}$=–C=–$\bar{O}$ system, and in the second case, by reducing the contribution of the resonance form **1***c*. And, indeed, the barrier to rotation in both $Me_2NC(O)SSnMe_3$ and $Me_2NC(O)SMe$ appears to be higher in chloroform solution than in hexane solution.

[2]A referee has suggested that the unequal line widths might be due to unequal quadrupole coupling with the low temperature structure in hexane solution.

Electron Spin Resonance Studies of Thiocarbonyl Anion Radicals

LEON J. AARONS[1] AND F. C. ADAM
Department of Chemistry, University of Calgary, Calgary, Alberta
Received October 25, 1971

The temperature dependence of the e.s.r. spectra of a series of sodium reduced thiones is reported. The thioketyls thiobenzophenone, *p,p'*-dimethoxythiobenzophenone, xanthene-9-thione, thioxanthene-9-thione, and their ketone analogues have been studied. Several show temperature-dependent sodium hyperfine structure near room temperature, but dissociate at lower temperatures to give spectra of thioketyl anions with no sodium coupling and markedly different *g*-values. Ring proton hyperfine splittings are found to be independent of the ion pairing process and independent of temperature. Models of ion pairing are discussed. Comparison is made to uhf–scf–mo calculations.

La variation des spectres r.p.e. en fonction de la température est décrite pour une série de thiones réduites par le sodium. Les thiocétyles (thiobenzophénone, diméthoxy-*p,p'*-thiobenzophénone, xanthène thione-9, thioxanthène thione-9) ainsi que leurs analogues cétoniques ont été étudiés. Pour plusieurs d'entre eux, la structure hyperfine du sodium montre une dépendance avec la température dans une zone voisine de la température ambiante, qui se dissocie aux températures plus basses en donnant les spectres des anions thiocétyles sans couplage avec le sodium et avec des valeurs *g* très différentes. On a trouvé que les multiplicités hyperfines pour les protons du cycle sont indépendantes de la température et du processus d'appariement ionique selon des modèles qui sont discutés. Une comparaison est faite avec les calculs uhf, scf et mo.

Canadian Journal of Chemistry, **50**, 1390 (1972)

Introduction

Although extensive research has been performed on aromatic ketyls (1) little work has been done on the analogous thioketyls, although the preparation and e.s.r. spectra of a few such compounds have been reported (2). The present investigation was undertaken to study the temperature dependence of the hyperfine couplings of this type of molecule and to improve, if possible, the understanding of the formation of ketyl ion pairs.

Since the early studies of Adam and Weissman (3) on the benzophenone ketyl, and of Atherton and Weissman on the sodium naphthalenide system (4), there has been considerable interest in the properties of ion pairs. Although the exact nature of these species is still not fully understood, aromatic ketyl ion pairs have proved to be particularly useful in such studies due to their greater stability and their tendency to form contact ion pairs, presumably because of the localization of negative charge in the carbonyl function. Aromatic hydrocarbons do not generally have such highly localized charge centers and as a result do not show as great a tendency to form tight ion pairs. For instance ketyls exhibit alkali metal couplings in the ethereal solvent dimethoxyethane (DME) while most hydrocarbon anions do not (5). The ketyl solutions in DME require additions of up to 40 volume per cent of a polar solvent such as dimethylformamide before the e.p.r. spectrum of the metal-free anion is obtained (6).

The alkali metal splitting of ketyl ion pairs usually decreases as the temperature is lowered (7). Several mechanisms have been suggested to explain this behavior of which the following two are the most frequently cited (1*c*).

Firstly McClelland (8) has calculated the most stable position of the alkali metal ion to be in the vicinity of the carbonyl group using as a perturbation the electrostatic interaction between the ions. It was proposed (9) that, in fact, the alkali metal ion lies in the nodal plane of the π-electrons at low temperatures but spends a proportionately greater time out of this nodal plane and in regions of higher π-electron spin density as the temperature is raised. This notion is similar in kind to that proposed by Atherton and Weissman for sodium naphthalenide (4), a concept which was later improved upon and put on a more theoretical basis by Aono and Oohashi (10).

The latter authors considered the temperature-dependent metal splittings to arise from configurational mixing between the ionic ground state, characterized by $\psi(Ar^-, Na^+)$, with an

excited charge transfer state ψ(Ar, Na). The amount of mixing was dependent upon the amplitude of the oscillations of the sodium nucleus about a low energy configuration which was characterized by small metal couplings.

While no formal bonding occurs between the aryl anion and the metal cation in the description of Aono, the treatment can be extended to the ketyl system if it is assumed that the sodium nucleus undergoes torsional oscillations about the carbonyl bond. In analogy to the temperature dependence observed in the β-proton coupling constants of simple aliphatic radicals (11), it may be presumed that the coupling is given by an expression of the sort (12)

$$a_M = \rho_c(B_0 + B_2 \cos^2 \theta)$$

wherein ρ_c is the spin density at the π carbon atom while θ is the dihedral angle between this π orbital and the O—M bond as viewed down the C—O axis. In this manner, temperature variations in the hydroxyl splitting of biacetyl semidione radical could be explained as resulting from restricted torsional oscillations whose amplitude increases with temperature. This in turn determines the mean values of $\cos^2\theta$ and hence the magnitude of the coupling constant (13). For the particular case of the hydroxyl proton, the coupling decreases with increasing temperature. This was accounted for by a large negative value of $B_0(-9$ Oe), which included contributions from spin density delocalized onto the oxygen atom.

The rather more ionic nature of the metal to oxygen bond and the consequent lability of the metal ion compared to that of the proton prompted Hirota (7*a*, 14) to propose a second model to explain the temperature dependence of metal hyperfine coupling in ketyls. This model involves rapid equilibration between structurally different ion pairs which owe their difference mostly to the degree of solvation of the metal ion. This particular approach is supported by evidence from conductivity experiments (15) which show that both ion pairs and solvent separated ion pairs exist in solution, and that the relative amounts vary with temperature. The e.p.r. spectra suggest that the metal–ketone systems exhibit two main types of ion pairs which are termed "tight ion pairs", with large alkali metal splittings, and "loose ion pairs" or "solvent separated ion pairs" which have small or zero metal couplings. The temperature dependence of the thermodynamic equilibrium between the two ketyl forms accounts for the variation of the alkali–metal coupling with temperature. Although more than one type of ion pair has been observed in the spectra of hydrocarbon radical ions (16) only contact ion pairs have been detected in ketyl spectra in ethereal solvents. More recently Hirota and coworkers (7*b*) have suggested that there are in fact two kinds of tight ion pairs, with different metal coupling constants, which arise according to whether the cation is found primarily in a low-energy, low (negative) spin density configuration in the plane of the molecule, or in a second out-of-plane position characterized by large (positive) spin densities. As a result, the temperature dependence does not involve the solvent separated forms but only tight ion pairs. Specific solvation of the cation at the in-plane sites may then force the cation to a predominantly out-of-plane position giving rise to an increase in the metal coupling with polarity using mixed solvents. The carbonyl C^{13} and *g*-value shifts which accompany the changes in metal coupling can be predicted by a McClelland-type calculation which considers only the coulombic perturbation of the cationic charge upon the energy levels of the anions (7*c*) although the metal splittings themselves are not given by this procedure.

In this paper we present the experimental results of an e.p.r. study from which a comparison between a variety of sodium ketyls and the analogous sodium thioketyls can be made. The spectra are obtained using pure ethereal solvents. This avoids the complications arising from specific solvation effects in mixed solvents which are alluded to above. Uhf–scf calculations have also been carried out for the same compounds. Neither the experimental evidence nor the computations give results which are entirely consistent with the models described above.

Experimental

Table 1 gives the parent ketones which were studied, and notes the commercial sources from which they were obtained. The thioketones there listed were prepared from their oxygen analogues by heating the molten ketone with neat P_2S_5, or by refluxing a toluene solution of the ketone in the presence of excess P_2S_5 (17). Also included in Table 1 are the uncorrected melting points. Thiobenzophenone is not recorded because of its extreme sensitivity to air and mois-

ture, either of which rapidly convert it back to benzophenone. This particular thioketone was purified by vacuum sublimation and could also be satisfactorily stored under vacuum. Preparations of the compounds so obtained showed no carbonyl stretch in the i.r. spectrum and no trace of the benzophenone ketyl e.s.r. spectrum could be detected when a sample was slightly reduced in DME over a sodium mirror. The purification method was therefore deemed satisfactory for the present study.

The homodyne X-band spectrometer used for the e.s.r. studies is a unit built up from precision components following a design by Buckmaster and Dering (18). It uses a Currie, McLaughlan and Len MOS-1 phase-lock unit for klystron stabilization. This is fed by an A.F.C. circuit which operates at 6 KHz, using a small amount of the reflected carrier signal from the cavity to effect the stabilization. Field modulation was at a nominal 10 KHz. Signal was detected by a balanced pair of L-4164 Philco backward diodes and amplified using a Princeton Applied Research HR-8 lock-in amplifier. Field markers were obtained using a Harvey Wells F-10 gaussometer unit monitored by a Hewlett–Packard 5168-L frequency counter. Klystron frequencies were determined using a combination of the Hewlett–Packard counter to determine the base frequency of the crystal of the MOS-1 (nominally 15 MHz) which controls the klystron, and a Hewlett–Packard wavemeter which gives sufficient resolution (±5 MHz) to determine the particular harmonic of the crystal to which the klystron was locked. Several preliminary studies were carried out using a Varian 4502 spectrometer at the University of Sydney, Sydney, N.S.W., Australia.

The ethereal solvents used were distilled from lithium aluminum hydride and stored over sodium potassium alloy under vacuum. All samples were prepared using standard high vacuum techniques. Low temperature spectra were obtained by passing a stream of cold dry nitrogen gas past the sample in a quartz dewar insert set in the cavity.

Results

(A) Experimental

The hyperfine coupling constants and *g*-values of the radicals studied are given in Table 2. The

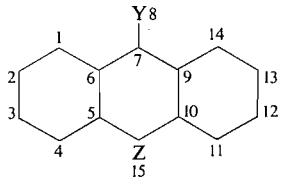
numbering scheme used is as follows:



For benzophenone (B) and thiobenzophenone (BS), Z represents two non-bonded hydrogen atoms while Y = O and S respectively. Xanthone (X) and xanthene-9-thione (XS) have Z = O with Y = O and S respectively; finally thioxanthone (TX) and thioxanthene-9-thione (TXS) have Z = S with Y = O and S respectively. In most cases the coupling constants quoted in Table 2 were checked by comparison of the experimental spectrum with a computor stimulated spectrum based on the measured coupling constants and line widths, assuming Lorentzian line shapes. The spectra were plotted on a Calcomb 565 Digital Incremental Plotter. Representative samples of the spectra with their simulations are shown in Figs. 1–3. The assignments of the coupling constants given in Table 2 were made in the case of the thioketyls by comparison to their oxygen analogues, and from the results of uhf-scf-mo calculations to be described later. The assignments given also conform to those obtained by Sevilla and Vincow (23) for xanthyl radicals deuterated in either the 2 or 3 positions.

As can be seen from the results in Table 2, the spectra of the thioketyls are qualitatively quite similar to the corresponding oxyketyls. The decrease in proton hyperfine splittings at most

ring positions indicates that greater spin density accumulates in the thiocarbonyl moiety than is found in the corresponding carbonyl function. This is evident in all pairs of ketyls of thioketyls studied. The ring proton splittings of the xanthene derivatives were in general larger than the corresponding hyperfine couplings of the unbridged compounds. This can probably be attributed to the nonplanarity of the latter compounds which results from the strong steric repulsion between the ortho protons at positions 5 and 10 (24) whereas the xanthene derivatives are constrained to be planar. As the phenyl groups are twisted out of the plane of the central carbonyl group, the resonance integral for the extracyclic 5–7 and 7–9 bonds decreases with the result that the spin density is withdrawn from the rings and augments that already present in the carbonyl or thiocarbonyl groups (24).

No differences in the ortho proton couplings at sites, 1, 5, 10, and 14 were observed in the spectra of the unbridged thioketyl anions of BS and DMBS. The splittings of the meta sites at 2, 6, 12, and 13 were also found to be equal. Some differences might have been expected on the basis of the mo spin density calculations and because of the observations of Takeshita and Hirota (6) who found only pairwise equivalence between the ortho sites in benzophenone anions at low temperatures. The inherently greater line widths (0.1–0.3 Oe) of these compounds and the more complex hyperfine spectrum of the DMBS anion do not encourage a more detailed study into this effect.

The thioketyls exhibited relatively larger sodium coupling constants of about 4 Oe compared to the 1 Oe splittings (25) commonly obtained for the oxyketyls and in general they show a similar temperature dependence, in that this splitting decreases as the temperature is lowered. Plots of this effect are given in Figs. 4 and 5 for some of the compounds and solvents

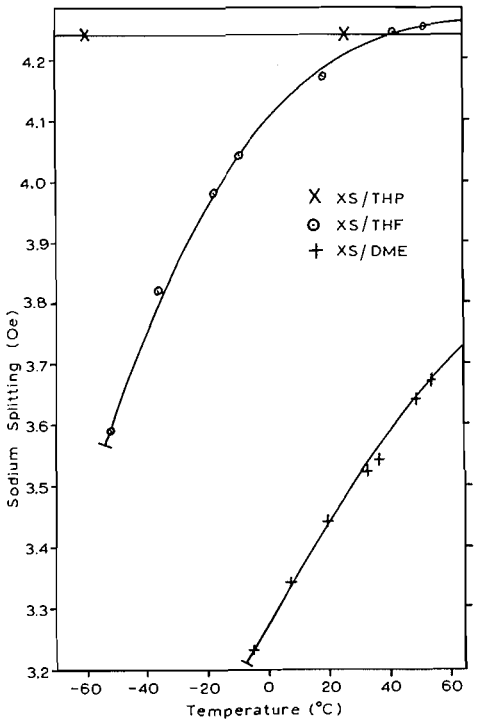

FIG. 5. Plot of the sodium hyperfine coupling constant a_{Na} as a function of temperature for the xanthione ketyl in different ether solvents.

studied. As can be seen the alkali metal splittings show a considerable solvent sensitivity for any particular ketyl. The variation in the coupling constant decreases at higher temperatures and is in fact essentially constant for both Na–TXS and Na–XS in tetrahydropyran (THP).

While the thioketyls do show analogous temperature dependence to the oxygen compounds, they do differ in one extremely important aspect. This behavior is typified by Na–BS in DME which shows a well resolved spectrum in the region +50 to −10 °C with the temperature dependent sodium splittings noted in Fig. 4. Within the accuracy of our measurements the *g*-value (2.0068) and the proton hyperfine splittings are independent of temperature in this range. Below −10 °C a complex and unsymmetrical spectrum was observed to evolve, which appears to be a superposition of the above spectrum upon a second spectrum which accounts for the entire absorption below −40 °C. The low temperature spectrum itself has no metal splitting and a different *g*-value (2.0079). No marked change in the proton coupling constants from the high temperature form is observed. Both the proton splittings and the *g*-value appear unchanged as the temperature is lowered to the gel point of the solvent near −80 °C. The suggestion may be made that the ion pairs observed at elevated temperatures can be considered to be more or less completely dissociated at the lower temperatures. This occurs with a jump, rather than a gradual shift, in the *g*-value, and a loss of, rather than a gradual decrease in the alkali metal splitting. At the same time essentially no change in the ring proton hyperfine splittings is observed. The temperature at which the dissociation occurs is indicated in Figs. 4 and 5 by the termination of the curves.

That the low temperature form is the free ion, and not an isomer of the ion pair in which the sodium ion shifted to a different position of low spin density in the ion pair, is shown by the following experiment. We have taken a preparation of BSNa in DME and added tetra-*n*-butyl ammonium perchlorate. At room temperature a spectrum is obtained with no sodium splittings, proton couplings of 2.43 (4H), 2.82 (2H), and 0.94 Oe (4H) and a *g*-value of 2.0072. These should be compared to the values obtained for the low temperature form for the BS anion in Table 2. Clearly the "free ion" is obtained in this case not because of solvent action, but because the size of the cation precludes the close association required for the formation of the tight ion pair.

A final observation concerning the metal splittings in the thioketyl ion pairs can be seen from Figs. 2 and 3 in that the hyperfine lines corresponding to $M_{Na} = \pm 3/2$ and $M_{Na} = \pm 1/2$ have the same peak-to-peak heights. Thus no selective broadening (1*b*) occurs in these systems to indicate that the sodium ion oscillates rapidly between a bound and an unbound state. If such an oscillation occurs, it must proceed at a frequency much lower than the alkali hyperfine line widths or less than $\sim 10^5$ s^{-1}.

The larger *g*-values of the thioketyls as compared to the oxyketyls result from the heavy atom effect (26) which can mostly be ascribed to the sulfur atom since it has a spin-orbit coupling parameter $\xi_S = -382$ cm^{-1} compared to that of oxygen, $\xi_O = -152$ cm^{-1}, and of carbon, $\xi_C = -28$ cm^{-1}. Shifts of the *g*-value away from

†Spin densities at 1 and 3 assigned on basis of calculated values.

the free electron value $g_e = 2.0023$ can accordingly be related linearly to the spin density on the sulfur atom (*2b*). For those ketyls which dissociate at lower temperatures, the *g*-values are consistently larger than for the ion pairs observed at higher temperatures. This is the expected result since the unpaired electron is completely delocalized onto the sulfur atom of the free ion, while in the covalent limit for the ion pair, the sulfur atom would behave more like a thioether linkage with most of the spin density on the adjacent carbon atom at position 7. There are, however, alternative explanations of this *g*-value jump (*vide infra*), and every reason to believe that the covalently bound ion pair is not a good approximation. However, the relative insensitivity of the *g*-values to changes in solvent, temperature and counterion does support the contention that the low temperature form is in fact the free ion. The relatively small *g*-shifts observed for the ion paired species in different solvents and at various temperatures contrast markedly with the strong dependence exhibited by the metal coupling constants to both these factors. Whatever is happening to cause this variation does not apparently result from appreciable changes in the spin density at the sulfur atom.

(B) Calculations

Spin densities were calculated using the Pariser, Parr, and Pople (PPP) technique, a method which is described thoroughly elsewhere (27, 28). The bridged compounds were regarded as planar (23) while benzophenone and thiobenzophenone anions were assumed to be non-planar with each phenyl ring counter-rotated from the planar configuration by 30° to the carbonyl (thiocarbonyl) group. This was the angle calculated (29) to give the lowest total energy considering both the π-electron delocalization energy and the steric repulsion energies which vary as the rings are rotated (30). The parameters used will be described in more detail in ref. 29. The additional values required in the present calculations are those involving the ether and thioether linkages at position 15. In the notation of ref. 29, the ionization potentials I_O and I_S are taken as -33.9 (39) and -20.0 eV (40) respectively, while the repulsion integrals γ_O and γ_S are 20.0 (41) and 10.84 eV (40) respectively. The resonance integrals β are calculated using Mulliken's approximation (42) with β_{co} ($r = 1.37$ Å) $= -2.16$ eV and β_{cs} ($r = 1.71$ Å) $= -1.6$ eV. (40) The calculated spin densities appear in Table 3 along with the experimental spin densities (ρ_i) for the free ions. The latter were obtained from the measured proton hyperfine coupling constants (a_i) using McConnell's relationship (31)

$$\rho_i = a_i/Q_H$$

with Q_H taken to be -27.0 Oe.

Calculations were also carried out for the

covalently bonded analogues of the ion pairs for X and XS. These are symbolized by XR and XSR in Table 3, and are the compounds which would result if the metal atom were replaced by a non-polar group such as an alkyl group. The atomic parameters used for position 8 in these calculations are the same as those used at position 15 in the free ion computations. The effect of the alkyl group upon the π-bonding was not considered in the ether and thioether analogues. As can be seen, the spin densities at the ring positions do not change very much as a result of this substitution, but the spin density in the central group shifts sharply from the heteroatom in the free ion to the carbon atom at 7 in the "ion pair". This agrees with the experimental observation that the g-value of the free ion is significantly greater than that of the ion pair, if the presumption could be made that the S—M bond has considerable covalent character. While it would have been desirable to carry out the calculations taking the effect of the sodium atom more directly into account, such computations cannot be readily accommodated within the framework of the PPP approximation.

Discussion

While little attempt has been made to vary the atomic parameters of the mo calculations in order to obtain the best fit with the proton hyperfine spectra, it can be seen that in general the agreement with experiment is quite reasonable. The computations reflect the parallel behavior of the oxy and thio compounds with regard to planarity and to the insertion of different bridging elements. Also reproduced is the reduction in spin density observed for the ring positions of the thioketyls as compared to their oxygen analogues. As has been seen, the greatest change in spin densities, comparing the free ion to the covalently bound species XR and XSR, occurs at the central positions 7 and 8 while the changes within the ring are fairly modest, as experimentally observed. XR and XSR represent one extreme case for the association process and it would be expected that when the metal–ketyl bond has a rather more ionic nature, the real situation would lie somewhere between this limit and that given by X or XS free anions. It appears that the jump in g-value that occurs upon dissociation may therefore result from a redistribution of only that spin density found within the thiocarbonyl group, while the spin distribution in more remote parts of the molecule remains nearly the same. In any case it is apparent that the sodium ion is closely associated with the heteroatom in the ion pairs of both the oxy and thioketyl systems. Regardless of their detailed structure, it is clear that the rate of dissociation of these ion pairs to yield the free ions must occur slowly on the time scale of the present measurements; if this were not so the spectra of two distinct species could not be observed in the same solution, and one would expect instead a gradual change in both the averaged g-value and the mean metal splitting between the two extremes representing the bound and unbound ketyl anions. If the sodium ion exchange rate were not extremely rapid then one would expect broadening of the $M_{Na} = \pm 3/2$ lines relative to the $M_{Na} = \pm 1/2$ lines as well. Because of these observations it does not appear as if the original Hirota model can be used to explain the situation represented by the thioketyls. While the variation in sodium couplings may well result from rapid exchange between structurally different contact ion pairs such as proposed in his later models, the process cannot involve the low temperature species observed here.

The plots of a_{Na} *vs.* temperature as seen in Figs. 4 and 5 have the general appearance expected for restricted torsional oscillators with low energy barriers to rotation (32). According to this scheme, both TXS and XS in THP would be regarded as "free rotors" since the metal hyperfine coupling is both large and constant with respect to temperature changes. The g-value shifts are also fairly large in these compounds which indicates that the expression given in the introduction should be modified to take explicit account of the spin density on the sulfur atom. The computations for XSR also suggest that this is an appropriate step since the spin density at position 8 is by no means a negligible quantity. The general features of the situation can be expressed in the relationship

$$a_M = \rho_C(\theta)(B_0 + B_2 \cos^2 \theta) + \rho_S(\theta)B_3$$

in which θ retains its earlier meaning and the angular dependencies of ρ_C and ρ_S result from the fact that these values depend upon the C—S π overlap; as the torsional amplitude increases, ρ_S will decrease and probably ρ_C will increase. This oscillation accounts for the temperature dependence of the metal couplings, but since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ρ_C does not contribute to the g-value shift, it also predicts that the g-value should change with temperature. This is not observed. Nor is it very apparent why the ketyls TXS and XS should behave so differently in three such similar solvents, behaving as free rotors in THP but as restricted rotors in DME. It seems reasonably clear that at least part of the resistance to free rotation about the C—S axis arises from the π character of this bond, yet the computed bond orders are not reduced materially between XS (0.5113) and XSR (0.4408) and in either case represent a much higher barrier to rotation than would be expected for a "free rotor". While a significant reduction in bond order occurs between X (0.6199) and XR (0.2693) it is felt that the more polar nature of the O—M bond would favor the higher value so that the situation is similar for the oxyketyl ion pairs as well. For these reasons it appears as if the torsional oscillator model does not adequately account for the experimental observations.

The effect of solvent in the dissociation process itself follows the qualitative trends outlined by Aten *et al.* (33) in that the energy of solvation increases with increasing dielectric constant and decreasing radii of the ions. In accordance with the negative temperature coefficient of the dielectric constant for the solvents studied here, solvation of the metal ions becomes stronger as the temperature is lowered, and results in the ultimate dissociation. DME has the highest dielectric constant and also the highest dissociation temperatures, while THP has the lowest dielectric constant and does not in fact induce the dissociation of TXS or XS above the freezing point. It appears that there is a strong competition between the solvent and the anion to complete the solvation sheath of the metal ion. This factor may account for some of the observations which have been made for the ion pairs, in that the effect of the solvent probably does not end with the process of association but continues to affect the polarity of the bond which joins the metal to the ketyl ion. Since the g-values suggest there is considerable spin density on the sulfur atom even in the ion pair, it can be presumed that the S—M bond lies in the π-nodal plane of the thiocarbonyl group. The usual description of π-σ interactions in systems of this sort suggests the Q values depend only on the covalent (non-polar) part of the σ bonding description and smaller couplings due to spin polarization effects are expected as the ionic character (polarity) of this bond increases. The couplings also depend on the spin density of the heteroatom, as do the g-values. The temperature dependence of the metal hyperfine couplings in the ion pair could then result from changes in the dielectric behavior of the medium which are reflected in the polarity of the S—Na bond and hence the Q value, while the spin density (and hence g-values) in the π-system remain largely unchanged. Such changes as are observed would be in the direction of the free ion as the dielectric constant of the solvent increases but would not include such specific solvation effects as are observed in mixed solvents (*7b*). The eventual dissociation process must be considered as distinct from these effects although obviously not unrelated. Thus XSK with the more polar S—K bond has a g-value of 2.0058 compared to the value of 2.0057 for XSNa in DME at room temperature. In the three solvents, the TSXNa ion pair has g-values of 2.0064, 2.0065, and 2.0066 in THP, THF, and DME respectively while the sodium couplings are 4.11, 3.85, and 3.33 Oe, in the same order. Similar results obtain for XSNa.

The free ions also show a slight shift with the different solvents but in the reverse direction. This we attribute to solvation effects involving the unshared electron pairs (n-electrons) on the sulfur atom. Since the g-value shifts arise from terms of the sort (34, 35)

$$\Delta g_{xx} = -\frac{2\xi_S \rho_S \langle \sigma | l_x | \pi \rangle \langle \pi | l_x | \sigma \rangle}{\Delta E_{\sigma \to \pi}}$$

and because the resonance denominator is smallest for $n \to \pi$ transitions, the largest contribution will come from molecular excitations involving the non-bonding electrons of the sulfur atom. As is also well known, the $n \to \pi$ transitions are characteristically blue shift bands (36) so that $\Delta E_{n \to \pi}$ increases with the polarity of the solvent. It is for this reason our g-values are much higher for BS in DME (2.0079) than those obtained by Heller in ethanol–water mixtures (2.0054) (*2b*), where the n-electrons are specifically solvated by the protonic solvents. The analogous situation is observed for the radicals RS· in aqueous systems ($g = 2.0105$) (37) compared to similar "dry" radicals in hydrocarbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

glasses which yield mean g-values of about 2.0250 (38). The ionic association process of interest in the present case is different only in kind from the solvation effects recorded above. In fact if one considers the sulfur atoms to be unhybridized in the free ketyl ions in non-polar solvents but to be sp^2 hybrids in the ion pair, one would expect a reduction in the g-shift of about 33% for constant spin density in the $3p_z\pi$ orbital. This presumes the electron pair binding the metal ion does not contribute to the g-value shift at all. Considering the polarity of the S—M bond, this is probably an over-statement of the fact. The actual shifts decrease by only 20% between the free ion and the ion pairs of the thioketyls, and it is not certain whether the observed jump is due to this effect or whether a shift in the spin density away from the sulfur atom has also occurred. Since the latter will be accompanied by an increase in the C^{13} coupling constant of the carbonyl atom, studies are presently under way to investigate further the dissociation phenomenon using isotopically substituted thioketyls.

Finally it should be noted that the model used by Aono and Oohashi can be readily applied to the present study. The magnitude of the sodium couplings requires a spin density of only about 0.01 in the sodium orbitals. Solvation of the metal ion would decrease its electron affinity and hence decrease this spin density, to give the observed temperature dependence. Solvation of the anion produces the opposite effect. The model does not require any particular bonding structure to be ascribed to the ion pair, except to say that the metal ion resides primarily in regions of low potential energy. The only conceptual difficulty which appears to arise is that concerning the actual dissociation process. If this results when the ketyl anion is replaced by a solvent molecule in the ion envelope of the cation, then the model differs little from the one suggested above. Since furthermore this model includes the perturbing effect of the cation on the anionic energy levels, it contains the essential features of the calculation carried out by Takeshita and Hirota (7*c*) and may well be the best approach to take for future computations based on this system.

The technical assistance of Mr. Glenn Smith and financial support of the Defence Research Board of Canada and the Isaac Walton Killam Foundation are gratefully acknowledged.

Kinetics and Mechanism for the Hydrolysis of Chlorothionoformate and Chlorodithioformate Esters in Water and Aqueous Acetone

D. M. McKINNON AND A. QUEEN

Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

Received October 1, 1971

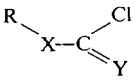
The effects of structural changes on the rates of hydrolysis of a series of chlorothionoformate esters and the analogous chlorodithioformate esters have been studied. For both classes of compound, the reactivity is enhanced by increased electron donation by the hydrocarbon group. These results, the activation parameters for the hydrolyses of the methyl compounds, and the solvent isotope effect are shown to be consistent with the operation of the S_N1 mechanism.

Les effets de modifications structurales sur les vitesses d'hydrolyse d'une série d'esters chlorothionoformates et d'esters chlorodithioformates analogues, ont été étudiés. Pour les deux classes de composés, la réactivité est accrue si l'on augmente le pouvoir donneur d'électrons du groupe hydrocarbure. Ces résultats concernant les paramètres d'activation pour les hydrolyses des composés méthylés et l'effet isotopique du solvant, sont consistants avec l'intervention d'un mécanisme S_N1.

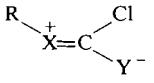
Canadian Journal of Chemistry, **50**, 1401 (1972)

Introduction

Previous studies (1–3) have established that chloroformate esters (**1**; X = Y = O) and chlorothiolformate esters (**1**; X = S, Y = O) hydrolyze much more slowly than other acid chlorides, a feature that is most reasonably attributed to initial state conjugation, **2**. This effect is enhanced by structural changes that increase electron donation by the hydrocarbon group (R) (3, 4) and is diminished in compounds where the hetero-atom (X) has only a limited tendency to use its unshared electrons for π-bond formation. Thus, chloroformates are much less reactive than their thio analogues (3).



1



2

3

4

5

Whereas chloroformates hydrolyze by the addition–elimination mechanism 1 (2), chlorothiolformates and dimethylcarbamyl chloride react unimolecularly with water (mechanism 2) (3). These differences have been explained in the following terms.

(*i*) It is first of all assumed that, irrespective of the mechanism of hydrolysis, the nucleophile is supplied by the solvation shell surrounding the molecule. Hence for a given compound, the operative mechanism is determined by the differences in the transition state energies.

(*ii*) In the series of compounds (**1**; Y = O; X = O, S, NR), the inductive effect of the hetero atom (X) opposes its mesomeric effect, when this can operate. This latter tendency would act to stabilize a forming acylium ion (**4**; Y = O) but would be much reduced in the bimolecular formation of a tetrahedral intermediate (**6**; Y = O).

(*iii*) For the chloroformates, the inductive and mesomeric effects almost cancel so that the

TABLE 2. The effects of temperature on the rates of hydrolysis of methyl chlorothionoformate in water and methyl chlorodithioformate in 70% aqueous acetone

Compound	Solvent	Temperature (°C)	($k \times 10^4$ s^{-1})	Mean temperature (°C)	$\Delta H^{\ddagger}$ (cal/mol)	$\Delta S^{\ddagger}$ (cal/mol deg)
CH_3O—(CS)—Cl	Water	4.438	1.628 ± 0.004	14.6	24767	13.5
		14.960	8.805 ± 0.008			
		24.396	35.34 ± 0.08			
CH_3S—(CS)—Cl	70% aqueous acetone	4.937	1.271 ± 0.004	12.6	20180	−3.7
		12.619	3.524 ± 0.004			
		20.230	8.992 ± 0.006			

S_N1 mechanism is not particularly favored, whereas mechanism 1 is promoted by the electron-withdrawing properties of the hetero atom (X = O).

(*iv*) For the other compounds, the inductive effects of nitrogen and sulfur are much smaller than for oxygen but the corresponding mesomeric effects are either particularly large (X = NR) or still appreciable (X = S) so that significant stabilization of the corresponding acylium ions is possible. However, it has been pointed out (3) that, in the case of the chlorothiolformate esters, the degree of cancellation of the two effects may be such that the observed unimolecular hydrolysis of these compounds reflects the favorable entropy terms for this mechanism rather than significantly reduced activation energies.

In these earlier studies it was not possible to determine the degree to which the carbonyl oxygen influenced reactivity and mechanism. However, its effect is unlikely to be negligible. For example, mesomerism should delocalize the charge in acylium ions (**5**; Y = O). As a logical extension of this work we have measured the rates of hydrolysis of the analogous chlorothionoformates (**1**; X = O, Y = S) and chlorodithioformates (**1**; X = Y = S). No previous kinetic studies of these compounds have been reported.

Results

First order rate constants for the hydrolyses of the chlorothionoformate esters in water at 5 °C are listed in Table 1 where they are compared with values for the corresponding reactions of chloroformates and chlorothiolformates, calculated from previous data (2, 3). The hydrolysis of isopropyl chlorothionoformate in water was too fast to be measured but its reactivity towards 70% aqueous acetone at 20 °C is compared with that of the methyl compound. The alkyl chlorodithioformates were not readily dissolved in water and also reacted too rapidly for convenient kinetic studies. However, they hydrolyze at convenient rates in 70% aqueous acetone and data for 5 °C are given in Table 1.

Table 2 gives rate constants for the hydrolyses of methyl chlorothionoformate and methyl chlorodithioformate at different temperatures in water and 70% aqueous acetone, respectively. Enthalpies and entropies of activation are

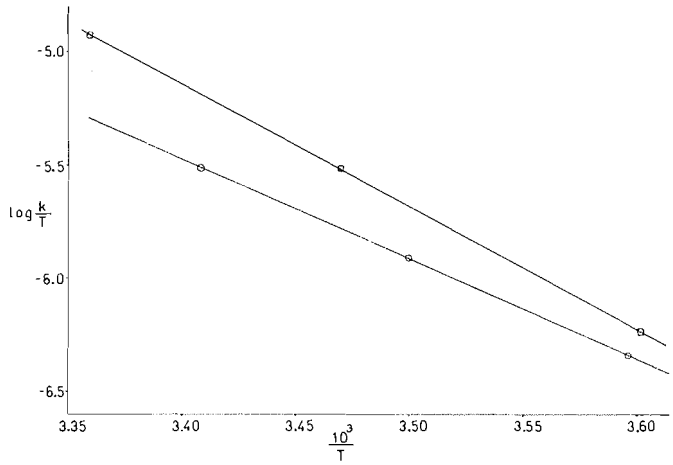

FIG. 1. Plots of $\log k/T$ *vs.* $1/T$ for the hydrolysis of methyl chlorothionoformate in water ⊡ and the hydrolysis of methyl chlorodithioformate in 70% aqueous acetone ⊙.

assumed to be constant over the experimental temperature ranges and evaluated from plots of $\log kT^{-1}$ against T^{-1} (Fig. 1). Close examination of these plots shows that they are slightly curved, consistent with decreases of the standard heat capacities of the systems during the activation processes, as previously reported for many solvolytic reactions (5, 6). At this time we have not attempted to measure heat capacities of activation for any of the reactions now studied. However, because of the indicated variations in the activation parameters, the values in Table 2 are assumed to refer to the averages of the experimental temperatures.

The chlorothionoformates hydrolyze rapidly to yield hydrochloric acid, carbonyl sulfide, and the corresponding alcohol. In agreement with this conclusion, the rate of hydrolysis of the methyl compound at 15.2 °C ($k = 8.82 \times 10^{-4}$ s^{-1}), determined by following the rate of collapse of the absorption peak at 247 mμ (Fig. 2) is in good agreement with the value calculated from the conductometric rate constants given in Table 2.

Methyl trithiocarbonate was the only organic material formed when methyl chlorodithioformate (2 ml) was reacted with 70% aqueous acetone (100 ml) at 20 °C. When a similar experiment was carried out with refluxing solvent, methanethiol and methyl trithiocarbonate were formed. These results indicate that the initial products of hydrolysis of methyl chlorodithioformate are hydrochloric acid, carbonyl sulfide, and methanethiol. This latter product reacts rapidly with methyl chlorodithioformate as it is added to the reaction mixture. However, it seems unlikely that trithiocarbonate esters would be formed in significant amounts when the substrates are in the low concentrations (*ca.* 10^{-4} *M*) used in the kinetic experiments. In agreement with this conclusion, the rate of hydrolysis of methyl chlorodithioformate in 70% aqueous acetone at 15.2 °C ($k = 4.89 \times 10^{-4}$ s^{-1}), determined by following the rate of change of optical density at 325 mμ (Fig. 3), is in good agreement with the value calculated from the data in Table 2. This result shows that methyl trithiocarbonate, which absorbs strongly at this wave-

length, ($\varepsilon = 5700$ l mol^{-1} cm^{-1}), is not formed at low concentrations of the substrate.

Discussion

The relatively low reactivities of the compounds listed in Table 1, when compared to that of acetyl chloride (7), show that initial state conjugation is important for all of them. The smaller mesomeric effect of sulfur than oxygen is consistent with the reactivity relationships:

$$CH_3O—(CO)—Cl < CH_3S—(CO)—Cl$$
$$CH_3O—(CS)—Cl < CH_3S—(CS)—Cl$$

However, the different order of reactivity for the phenyl compounds

$$C_6H_5O—(CO)—Cl \gg C_6H_5S—(CO)—Cl$$
$$C_6H_5O—(CS)—Cl < C_6H_5S—(CS)—Cl$$

indicates that the same mechanistic differences that apply to chloroformates (**1**; X = Y = O) and chlorothiolformates (**1**; X = S, Y = O) cannot apply to chlorothionoformates (**1**; X = O, Y = S) and chlorodithioformates (**1**; X = Y = S). In fact, the differences in the rate sequences between the four classes of compounds show that those containing sulfur must react by different mechanisms to the chloroformates, which follow mechanism 1. By analogy with the chlorothiolformate esters, the increase of reactivity of the chlorothionoformates and chlorodithioformates with increasing electron donation by the group (R) indicates that these compounds also hydrolyze by S_N1 mechanisms 2. In the case of methyl chlorodithioformate, alternative processes involving alkyl–sulfur bond fission have been excluded by identification of methanethiol and methyl trithiocarbonate as products of hydrolysis (see above). Moreover, v.p.c. did not indicate the presence of methanol in the reaction mixture.

It is necessary, however, to consider the possibility that the present reactions may involve conversion of the thiono compounds to the corresponding carbonyl compounds. Presumably, the reaction would involve the formation of tetrahedral intermediates (**7**; X = O or S) as in mechanism 3. In the case of the chlorothionoformates, the initial products would be chloroformates (**8**; X = O) which would hydrolyze bimolecularly (steps *6*, *7*, and *8*). Two experimental facts argue against this possibility. These are that excellent first order rate constants were obtained over at least three half lives and that the reactivities of the chloroformates are much too low to account for the observed rates, if the phenyl compounds are excluded from consideration. Moreover, it is difficult to see why this pathway should be characterized by the observed differences of reactivity. In the case of the chlorodithioformates, the intermediates (**8**; X = S) would be chlorothiolformates which do hydrolyze unimolecularly. However, once again the high reactivities of the dithio compounds and the excellent first order rate constants are not in accord with mechanism 3, steps *1–5* and *9–12*. Unimolecular hydrolysis of the present compounds is therefore indicated.

In accord with these mechanistic assignments, the enthalpies of activation for the hydrolyses of the methyl compounds (Table 2) are much greater than those reported (2) for bimolecular hydrolysis of chloroformates. The positive entropy of activation for the hydrolysis of methyl chlorothionoformate in water is similar to the value reported for the corresponding reactions of *t*-butyl chloride (5, 8) and methyl chlorothiolformate (3), as is the solvent deuterium isotope effect, $k(D_2O)/k(H_2O) = 0.78$ at 4.96 °C. The entropy of activation for the hydrolysis of methyl chlorodithioformate in 70% aqueous acetone is comparable to values reported by Kohnstam (6) for S_N1 solvolyses in this solvent, if due allowance is made for temperature differences. The entropy terms for S_N2 reactions are much more negative.

These results clearly show that replacement of either of the oxygen atoms of a chloroformate by sulfur is sufficient to cause a change from bimolecular hydrolysis (mechanism 1) to unimolecular hydrolysis (mechanism 2). Hence, the combined effects of two strongly electron-withdrawing groups (*e.g.*, the oxygen atoms of the chloroformates) are necessary to dictate bimolecular hydrolysis. It follows that all unsubstituted acyl chlorides should react unimolecularly with water, a conclusion that is supported by data for acetyl halides (7, 9). Trifluoroacetyl chloride should hydrolyze bimolecularly and trifluorothioacetyl chloride unimolecularly, but data to test these conclusions are not available. However, although benzoyl chloride seems to solvolyze by a bimolecular process (10), it has been suggested (11) that thiobenzoyl chlorides may react unimolecularly with methanol.

Experimental

Materials

The chlorothionoformate and chlorodithioformate esters were prepared by established methods (see Table 3) from thiophosgene and the corresponding alcohols and thiols, respectively. The compounds were purified by fractional distillation and shown to contain at least 99.4% of hydrolyzable chlorine.

Water was triply distilled from weakly alkaline potassium permanganate. Analar grade acetone was first distilled from alkaline permanganate and then from hydroquinone using a long fractionating column. 70% aqueous acetone was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

prepared by mixing acetone (70 volumes) and water (30 volumes).

Measurement of Rates

The conductance methods used in these studies have been previously described (2, 12) as have the methods of calculating the rate constants. For the reactions in aqueous acetone, the resistance readings were converted to concentrations by means of large scale calibration curves. These curves were derived from measurements made using the completely reacted solutions of the various substrates, successive dilutions of these solutions being made so as to cover the complete ranges of conductance observed in the kinetic experiments.

Products of Hydrolysis

Methyl chlorothionoformate (4 ml) was shaken for 15 h with water (100 ml) and a sample (20 μl) of the solution examined by means of v.p.c. using a Poropak column. Methanol was identified as a component of the solution.

Methyl chlorodithioformate (2 ml) was added dropwise to 70% aqueous acetone (100 ml) in a flask fitted with a stirrer and a cold trap immersed in an acetone–Dry Ice bath. After 6 h there was no volatile material in the trap. The reaction mixture was evaporated to about a quarter of the original volume under reduced pressure and then extracted with methylene chloride (10 ml). After drying the extract and distilling off the solvent the yellow product was distilled at atmospheric pressure, b.p. 222 °C. The n.m.r. spectrum in deuterochloroform showed a single peak at 7.25 τ while the mass spectrum gave major peaks for masses 138 and 91, a smaller one at mass 76, and minor peaks at masses 47, 45, and 18. These results indicated that the product was methyl trithiocarbonate which is reported to boil at 225 °C (13). A sample of this compound was prepared by reacting methyl chlorodithioformate with methanethiol and shown to have identical properties to the above sample.

A similar experiment was carried out using refluxing 70% aqueous acetone. Methyl trithiocarbonate was again identified as a product but in this case the cold trap contained a volatile substance as well as a large amount of acetone. The volatile contents of the trap were reacted with a solution of 2,4-dinitrofluorobenzene in ethanol as previously described (3) to yield a yellow solid. Part of this solid was soluble in hot ethanol and the solution, on standing, yielded crystals of 2,4-dinitrophenyl methyl sulfide, m.p. and mixed m.p. with an authentic sample 126 °C (lit. 127 °C (14)). The insoluble fraction has not yet been identified.

The authors gratefully acknowledge the award of grants by the National Research Council of Canada. They also thank Miss Julia Queen for her careful measurements of the rates in the mixed solvents.

Steroids and Steroidases. XIV.[1] Studies on the Reactions of 2-Lithio-1,3-dithianes with Steroids Possessing Spiroepoxide Functions at C-3[2]

J. Bryan Jones and Roger Grayshan

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 2, 1971

The scope of the reactions of lithio-dithianes with spiro-epoxides for various stereospecific functionalizations of alicyclic systems has been illustrated by their application to spiro-3α- and -3β-oxiranes of the 5α-cholestane and 5α-androstane series.

La portée des réactions entre les lithio-dithianes et les époxydes spiranniques pour fonctionnaliser de façon stéréospécifique les systèmes cycliques a été illustrée par des applications sur les oxirannes-3α et 3β spiranniques dans les séries 5α-cholestane et 5α-androstane.

The reactions of a 2-lithio-1,3-dithiane anion with appropriate 1,2 epoxides have been demonstrated to provide a versatile, convenient, and flexible method for the stereospecific introduction of substituents into the steroid nucleus (1*a*, *c*). The facility with which such reactions occurred encouraged us to explore the scope of lithio-dithiane-epoxide reactions further and the investigations have now been successfully extended to spiro-epoxides.

The ease with which spiro-epoxides would undergo reaction with dithiane anions, and establishment of the stereochemical integrity of the reactions, were evaluated on the readily available spiro-3α- and -3β-oxiranyl-5α-cholestanes **1** and **4**. The synthetic sequences followed are outlined in Scheme 1.

Treatment of 5α-cholestan-3-one with dimethylsulfonium methylide according to the literature procedure (2) gave a 95% yield of a mixture of **1** and **5** in the ratio 3:2. Although pure samples of **1** and **5** had not been obtained by this method in the previous work (2), it was found that separation of the two epimers could be effected by careful preparative layer chromatography (p.l.c.). The supply of the 3α-oxide **1** was augmented by its preparation in 80% yield from the 5α-cholestan-3-one-dimethylsulfoxonium methylide reaction (2) and in view of the more ready availability of the latter oxide, the initial experiments were carried out on the sequence of reactions involving compounds **1**–**4**.

When the 3α-epoxide **1** was kept with 2-lithio-1,3-dithiane in tetrahydrofuran at 0° for 2 days, the spiro-epoxide ring opened smoothly to give

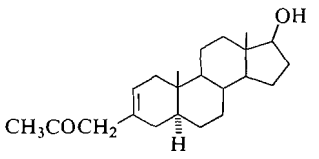
For personal use only.

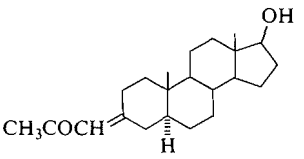
the hydroxydithianyl compound **2** in 85% yield. Although from the mode of formation of **2**, little doubt existed with regard to the stereochemistry at C-3, Raney nickel desulfurization of **2** to the hydroxyethyl derivative **3** (92% yield) was carried out in order to provide a convenient reference compound for which unambiguous assignment of the C-3 geometry could be made. That the C-3 configuration of **3** was as designated was confirmed by its preparation by catalytic hydrogenation of 3β-ethynyl-3α-hydroxy-5α-cholestane (**7**), the stereochemistry of which had been established previously (3).[3]

The corresponding reactions in the 3β-epoxide series proceeded with equal facility and treatment of **4** with 2-lithio-1,3-dithiane as described above yielded **5** in 86% yield. The C-3 configuration of the latter compound was again confirmed by its desulfurization (in 88% yield) to the corresponding hydroxyethyl derivative **6** which was shown to be identical with an authentic sample of 3α-ethyl-3β-hydroxy-5α-cholestane prepared by catalytic hydrogenation of the ethynyl compound **8** of known geometry (3).

The above results confirmed our expectations with regard to the facility of spiro-epoxide-dithiane reactions and their potential for stereospecific exocyclic functionalization of the steroid nucleus. Although all of our studies in this area had up to this time involved conversion of the dithianyl substituents into alkyl groups, several other types of transformations of these versatile intermediates have been well documented (5). Accordingly, attention was turned towards the application of the spiro-epoxide reactions for the introduction of functional groups other than alkyl. The compounds considered first were the βγ- and αβ-unsaturated ketoandrostanes **9** and **10** which were of interest to us as a potential substrate and inhibitor respectively of the Δ^5-3-ketoisomerase of *P. testosteroni*. Furthermore, it was desired to evaluate the biological activities of androstanes possessing C-3 functions of the 2′-oxopropyl type. The reactions carried out are outlined in Scheme 2. A mixture of spiro-3α-(**11**) and spiro-3β-oxiranyl-5α-androstan-17β-ol (**12**) in the proportions of 1:2 was obtained in 90% yield by reaction of 17β-hydroxy-5α-



9



10

androstan-3-one with dimethylsulfonium methylide. The stereochemistry and spectral characteristics of **11** and **12** had been established previously (2) and corroboration of the assigned C-3 geometries was provided by a comparison of the spectral data of **11** and **12** with those determined for the analogous oxiranes of the cholestane series **1** and **4**. The proportions of each of **11** and **12** present were estimated from the areas of the characteristic epoxide CH_2 n.m.r. peaks at δ 2.61 and 2.57 p.p.m. respectively. The individual oxiranes could not be purified by any of the usual chromatographic methods and the subsequent dithiane reactions were therefore carried out on the mixture of the two epoxides.[4] Treatment of the epoxide mixture with 2-lithio-2-methyl-1,3-dithiane in tetrahydrofuran at 0° for 2 days yielded 68% of the corresponding dithianyl addition products **13** and **14**. The n.m.r. spectra of each isomer were quite distinctive, with the main differences being reflected in the positions of the C-19 methyl and dithianyl methyl peaks. For the 3α-hydroxy derivative **13**, these protons resonated at δ 0.75 and 1.77 p.p.m. respectively, while for the 3β-epimer **14**, they appeared at δ 0.85 and 1.80 p.p.m. Correlation of the n.m.r. spectra of **13** and **14** with the correct C-3 configuration was made using the C-19 methyl resonance of the corresponding cholestane analogues **2** and **5**, which occur at δ 0.74 and 0.83 p.p.m. respec-

[3]A 3-ethyl-3-hydroxy-5α-cholestane has been reported previously (4). A comparison of the physical data for this compound with those of the current work shows that this material has the same C-3 configuration as **3**.

[4]Repeated fractional recrystallization of the epoxide mixture has been reported (2) to give low yields of each of the pure epimers. However, in view of the quantities of material required to complete the proposed synthetic schemes, and the ease with which the subsequently obtained dithianyl acetates **15** and **16** could be separated, it was decided to bypass the epoxide separation procedure.

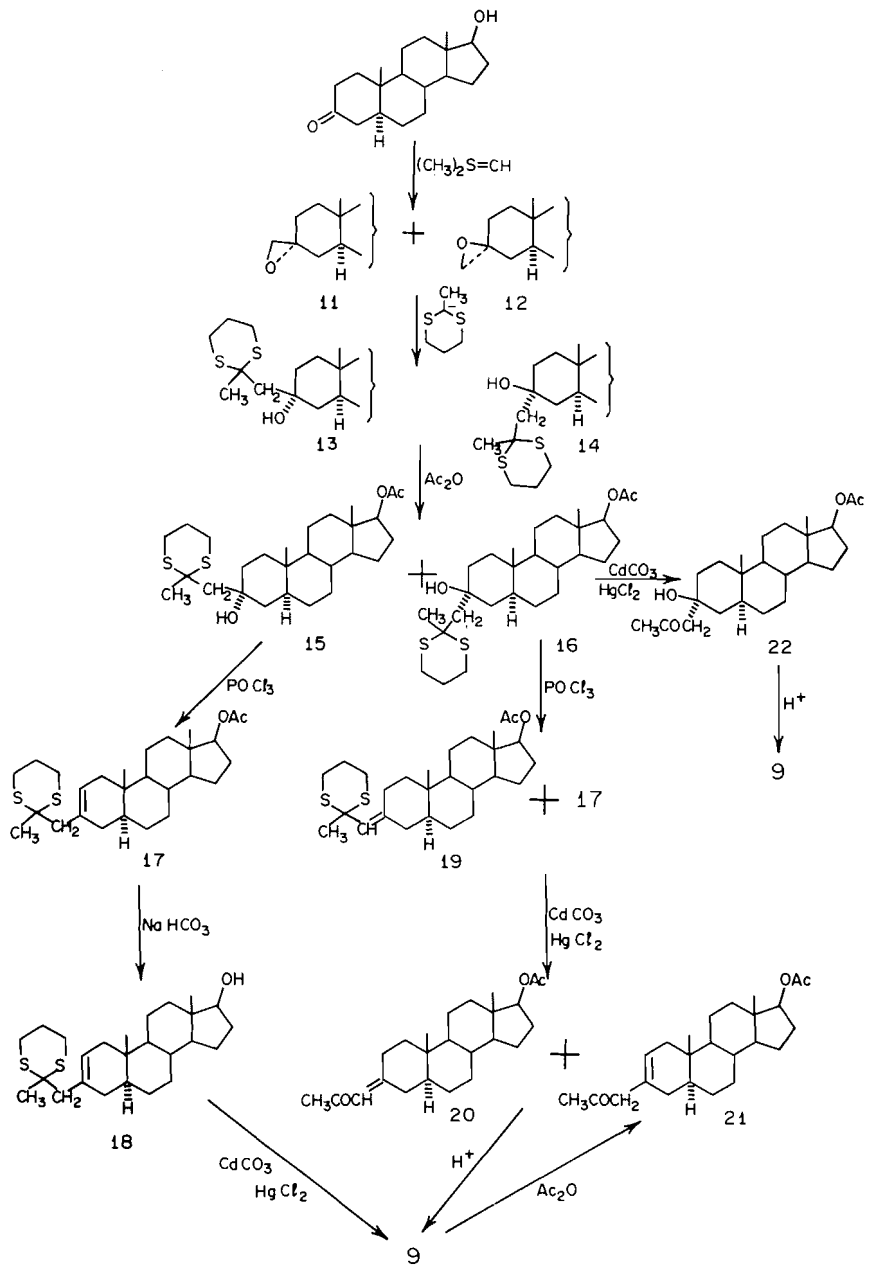

SCHEME 2

tively, for reference. The C-19 chemical shift differences for both pairs of epimers, **2** and **5**, and **13** and **14**, reflect C-19 deshielding by the C-3β hydroxyl groups which does not occur in the 3α-hydroxy compounds.

Since no further experiments could reasonably be carried out unless pure C-3 hydroxydithiane compounds could be obtained, the mixture of **13** and **14** was converted into the corresponding 17β-acetates **15** and **16** with acetic anhydride. Fortunately, the two acetates exhibited small differences in their chromatographic behavior

For personal use only.

and following several fractional p.l.c. separations pure samples of each epimer were obtained.[5] The C-3 configurations of the hydroxydithianyl 17β-acetates were again assigned using the chemical shifts of the C-19 n.m.r. peaks as a basis for the correlation. For the 3α-hydroxyacetate **15**, the C-19 proton resonance occurred at δ 0.76 and for the 3β-hydroxy analogue **16** at δ 0.85 p.p.m.

It was anticipated that of the two desired en-ones **9** and **10**, the non-conjugated $\beta\gamma$-unsaturated isomer **9** would be thermodynamically the less stable,[6] and consequently it was decided to attempt its preparation first by introduction of the Δ^2-double bond prior to ketonization of the dithianyl function. Accordingly, elimination of the axial 3α-hydroxyl groups of **15** was effected with phosphoryl chloride in pyridine to give the Δ^2-compound **17** in 83% yield. The predominant formation of the Δ^2-isomer **17** (C-2 H at δ 5.45 p.p.m.) was expected on thermodynamic grounds. However, some of the less stable Δ^3-isomer was formed as evidenced by the C-4 olefin resonance at 0.28 p.p.m. higher field (6) than that of the C-2 vinyl peak of **17**. No still higher field n.m.r. peak ascribable to an exocyclic olefinic proton was observed. The small amounts of the Δ^3-compound formed during the preparation of **17** did not pose any separation problem since they were readily isomerized to the desired Δ^2-isomer by a trace of acid. Hydrolysis of the 17β-acetate of **17** under conditions which did not affect the dithianyl group was accomplished with sodium bicarbonate in methanol and the 17β-hydroxy product **18** was obtained in quantitative yield. Subsequent ketonization of the dithianyl function with the aqueous cadmium carbonate/mercuric chloride reagent (5) proceeded smoothly to give 49% of 3-(2′-ketopropyl)-5α-androst-2-en-17β-ol (**9**). That the product was the desired $\beta\gamma$-nonconjugated isomer was confirmed by the spectral data.

To our surprise, treatment of **9** with acid or base under a variety of conditions did not effect the expected isomerization to the conjugated isomer **10**. This was the first indication that for **9** and **10** the normal order of the thermodynamic stability of $\beta\gamma$- and $\alpha\beta$-unsaturated ketones was reversed. In order to obtain the desired compounds possessing an exocyclic C-3 double bond, phosphoryl chloride mediated dehydration of the 3β-hydroxydithiane **16** was carried out and the mixture of exocyclic olefinic **19** and Δ^2-dithianyl **17** products expected (7) was formed in 79% yield. However, the desired isomer **19** (identified by the C-19 methyl n.m.r. peak at δ 0.78) was the minor component. Disappointingly, separation of **17** and **19** could not be achieved even by repeated fractional p.l.c. and the mixture was therefore converted directly into the corresponding ketones **21** and **20** by hydrolysis under neutral conditions with aqueous cadmium carbonate/mercuric chloride. The $\beta\gamma$-unsaturated ketoacetate **21** was readily separated by p.l.c. and showed characteristic n.m.r. peaks at δ 0.80 (C-19 CH_3), 5.48 (C-2 H), and 2.99 p.p.m. (C-3 CH_2). This compound was also obtained in 89% yield by acetylation of **9** with acetic anhydride.

The presence in the mixture of the conjugated ketone **20** was established by the positions of the n.m.r. resonances of the C-19 methyl (δ 0.92) and COCH= (δ 5.99 p.p.m.) protons. Unfortunately, a pure sample of the conjugated ketone **20** could not be obtained owing to the facility with which it isomerized to **21** even under the mildest p.l.c. conditions. The attempts to prepare the $\alpha\beta$-unsaturated ketones **20** and **10** were therefore discontinued and the remaining mixture of **20** and **21** was converted directly to the $\beta\gamma$-unsaturated ketone **9** with aqueous methanolic hydrochloric acid.

The ketone **9** was also obtained smoothly *via* treatment of the dithianylacetate **16** with cadmium carbonate/mercuric chloride to give the hydroxy ketone **22** (62%). The subsequent acid-catalyzed hydrolysis and concomitant dehydration of **22** proceeded in 93% yield. Following the delineation of the reactions outlined in Scheme 2, it was found that quantities of **9** could be conveniently accumulated by direct ketonization of the mixture of the 17β-alcohols **11** and **12** (or their 17β-acetates **13** and **14**) obtained from the initial dithian-epoxide reaction.

With the ketone **9** being thermodynamically more preferred than its conjugated isomer **10**, our initial aim of studying its enzymic isomerization could obviously not be realized. It is unusual

[5]Small amounts of the two 3,17-diacetates were also present in the acetylated mixture. However, these were easily separated from the desired 17β-monoacetates **15** and **16** during the p.l.c. purification procedure.

[6]As discussed later, the converse was found to be true.

for a non-conjugated ketone to be the more stable and it is therefore of interest to consider some of the factors which would affect the relative stabilities of **9** and **10**. Spectral analyses of acid- or base-equilibrated mixtures of **9** and **10** indicated that the conjugated isomer is present to the extent of 1–2%. Thus the $\beta\gamma$-unsaturated compound **9** is favored by at least 2–3 kcal/mol (8). The marked propensity in 5α-steroids for a double bond to occupy the Δ^2-position in preference to C-3-exocyclic (9) would be a major component in the overall free energy balance favoring **9**. However, that this factor is not of overriding importance is demonstrated by the fact that for steroids analogous to **9** and **10**, but with $\alpha\beta$-unsaturated aldehyde (4, 10, 11), acid (4, 10), ester, and nitrile (12, 13) functions at C-3, the conjugated isomers are favored in each case. Such apparent contradictions are not restricted to the steroids. For example, similar reversals of isomer stabilities are observed with unsaturated keto- and carboxy-derivatives of cyclohexane (14, 15) and in view of the conflicting data currently available it is evident that a satisfactory rationalization for the relative stability of $\beta\gamma$-unsaturated ketones such as **9** must await further studies.

Experimental

Details of analytical methods, instrumentation, criteria of purity etc. used were as described previously (1). All p.l.c. separations were effected on silica gel G. Final drying of tetrahydrofuran was accomplished by distillation from lithium aluminum hydride. The i.r. and n.m.r. spectra were recorded on CCl_4 and $CDCl_3$ solutions respectively.

Spiro-3α-oxiranyl-5α-cholestane (1) and Spiro-3β-oxiranyl-5α-cholestane (4)

A 95% yield of a mixture of the spiro-oxiranylcholestanes **1** and **4** in the ratio 3:2 (by n.m.r.) was obtained by reaction of 5α-cholestan-3-one with dimethylsulfonium methylide in tetrahydrofuran according to the procedure of Cook *et al.* (2). The epoxides were separated by p.l.c. using benzene–hexane (1:1) as developing solvent. Final recrystallizations from methanol yielded the 3α-epoxide **1**, m.p. 127–128° (lit. (16) m.p. 129–130°) and the 3β-epoxide **4**, m.p. 172–173° (lit. (16) m.p. 175–176°).

3β-(2′-(1,3-Dithianyl))methyl-5α-cholestan-3α-ol (2)

To a solution of 2-lithio-1,3-dithiane (1 g, 8.1 mmol) prepared by the slow addition of *n*-butyl lithium (4.7 ml of a 1.6 *M* hexane solution, 8.1 mmol) to 1,3-dithiane (0.9 g, 8.1 mmol) in freshly dried tetrahydrofuran (21 ml) at −20° under dry nitrogen (5) was added spiro-3α-oxiranyl-5α-cholestane (**1**, 1.08 g, 2.7 mmol) in dry tetrahydrofuran (7 ml), also at −20°. After keeping for 2 days at 0° the mixture was poured into water (500 ml) and extracted with ether (4 × 50 ml). The combined ether extracts were washed with water (2 × 25 ml) and then dried ($MgSO_4$) and evaporated. The residual gum was purified by p.l.c. using ether–benzene (1:50) as developing solvent followed by recrystallization from ether–methanol to give the 3β-dithianyl-methyl-5α-cholestan-3α-ol **2** (1.2 g) m.p. 190°; i.r. 1278 and 914 cm^{-1} (dithianyl); n.m.r. δ 0.64 (C-18 CH_3), 0.74 (C-19 CH_3), 1.90 (2H, d, J = 7 Hz, C-3 CH_2), and 4.29 p.p.m. (1 H, t, J = 7 Hz, HCS_2).

Anal. Calcd. for $C_{32}H_{56}OS_2$: C, 73.8; H, 10.8; S, 12.3. Found: C, 73.9; H, 10.8; S, 12.3.

3β-Ethyl-5α-cholestan-3α-ol (3)

The above 3β-dithianyl-3α-ol **2** (0.15 g, 0.29 mmol) in ethanol (30 ml) was refluxed with freshly prepared Raney nickel (1.5 g) for 4 h. The filtered ethanolic solution was then evaporated to give 3β-ethyl-5α-cholestan-3α-ol (**3**, 0.11 g) which after recrystallization from ether–methanol was identical with an authentic sample, m.p. and mixed m.p. 109–110°.

The authentic sample was prepared in quantitative yield from 3β-ethynyl-5α-cholestan-3α-ol (**7**) m.p. 104–105° (obtained according to the procedure of Giraud *et al.* (3)) by hydrogenation in ethanol over 10% Pd–C; n.m.r. δ 0.66 (C-18 CH_3) and 0.74 p.p.m. (C-19 CH_3).

Anal. Calcd. for $C_{29}H_{52}O$: C, 83.4; H, 12.6. Found: C, 83.5; H, 12.7.

3α-(2′-(1,3-Dithianyl))methyl-5α-cholestan-3β-ol (5)

2-Lithio-1,3-dithiane (0.9 g, 7.1 mmol) in freshly dried tetrahydrofuran (18 ml) at −20° was reacted with spiro-3β-oxiranyl-5α-cholestane (**4**, 0.99 g, 2.5 mmol) in dry tetrahydrofuran (7 ml) as described above for the 3α-hydroxy isomer **2**. The p.l.c. purification with ether–benzene (1:20) as developing solvent gave the 3α-dithianylmethyl-5α-cholestan-3β-ol **5** (1.09 g), m.p. 132°, after recrystallization from ether–methanol; i.r. 1278 and 914 cm^{-1} (dithianyl); n.m.r. δ 0.64 (C-18 CH_3), 0.83 (C-19 CH_3), 2.14 (2H, d, J = 6.5 Hz, C-3 CH_2), and 4.19 p.p.m. (1H, t, J = 6.5 Hz, HCS_2).

Anal. Calcd. for $C_{32}H_{56}OS_2$: C, 73.8; H, 10.8; S, 12.3. Found: C, 73.9; H, 11.1; S, 12.1.

3α-Ethyl-5α-cholestan-3β-ol (6)

The 3α-dithianyl-3β-hydroxycholestane **5** described above (0.21 g, 0.4 mmol) in ethanol (40 ml) was heated under reflux for 4 h with freshly prepared Raney nickel (2 g). Filtration of the mixture followed by evaporation yielded 3α-ethyl-5α-cholestan-3β-ol (**6**, 0.51 g). The material obtained was identical, m.p. and mixed m.p. 138–138.5°, n.m.r. δ 0.66 (C-18 CH_3) and 0.83 p.p.m. (C-19 CH_3), with a sample prepared (quantitative yield) by hydrogenation in ethanol over 10% Pd–C of 3α-ethynyl-5α-cholestan-3β-ol (**8**) m.p. 165–167° (3).

Anal. Calcd. for $C_{29}H_{52}O$: C, 83.4; H, 12.6. Found: C, 83.3; H, 12.6.

The Reactions of 2-Lithio-2-methyl-1,3-dithiane with Spiro-3α-oxiranyl-5α-androstan-17β-ol (11) and Spiro-3β-oxiranyl-5α-androstan-17β-ol (12)

5α-Androstan-17β-ol-3-one and dimethylsulfonium methylide were reacted as described by Cook *et al.* (2) to give, after p.l.c. purification, a 90% yield of a mixture of the spiro-epoxides **11**, n.m.r. δ 0.75 (C-18 CH_3), 0.87 (C-19 CH_3), and 2.62 p.p.m. (2H, broad s, C-3 CH_2), and **12**, n.m.r.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

δ 0.75 (C-18 CH_3), 0.88 (C-19 CH_3), and 2.57 p.p.m. (2H, broad s, C-3 CH_2) in the ratio 1:2.

To a solution of 2-lithio-2-methyl-1,3-dithiane (8.25 g, 60 mmol), prepared by the slow addition of *n*-butyl lithium (3.78 g, 60 mmol, 36.75 ml of a 1.6 *M* in hexane solution) to 2-methyl-1,3-dithiane (7.95 g, 60 mmol) in freshly dried tetrahydrofuran (150 ml) at $-20°$ under nitrogen (5), was added the above mixture of spiro-epoxides **11** and **12** (4.3 g, 14 mmol) dissolved in dry tetrahydrofuran (37 ml) at $-20°$. The mixture was kept for 2 days at 0° and was then worked-up as described previously for the analogous cholestane compounds **2** and **5**. The p.l.c. purification of the gum obtained yielded 4.2 g of an inseparable mixture of the 3α-hydroxydithiane **13**, n.m.r. δ 0.73 (C-18 CH_3), 0.75 (C-19 CH_3), and 1.77 p.p.m. (CH_3CS_2), and the 3β-hydroxy-dithiane **14**, n.m.r. δ 0.73 (C-18 CH_3), 0.85 (C-19 CH_3), and 1.80 p.p.m. (CH_3CS_2).

The above mixture of **13** and **14** (4.2 g) was refluxed with acetic anhydride (20 ml) for 20 min and the cooled reaction mixture was then evaporated. Fractional p.l.c. of the residue (4.8 g) using ethylacetate–hexane (1:4) developments yielded samples of the two 17β-acetates. The 17β-acetoxy-3β-(2′-oxopropyl)-5α-androstan-3α-ol 1,3-propylenethioketal (**15**) was recrystallized from methanol to give 0.46 g of material m.p. 184°; i.r. 908 cm^{-1} (dithianyl); n.m.r. δ 0.76 (C-18 CH_3), 0.78 (C-19 CH_3), 1.78 (3 H, s, CH_3CS_2), 2.03 (3 H, s, 17β-OAc), 2.18 (2 H, s, C-3 CH_2), and 4.59 p.p.m. (1 H, t, $J = 7.5$ Hz, C-17α H).

Anal. Calcd. for $C_{27}H_{44}O_3S_2$: C, 67.5; H, 9.2; S, 13.4. Found: C, 67.5; H, 9.4; S, 13.4.

The 17β-acetoxy-3α-(2′-oxopropyl)-5α-androstan-3β-ol 1,3-propylenethioketal (**16**) fraction was recrystallized from methanol to give 0.8 g of pure material, m.p. 136–137°, i.r. 906 cm^{-1} (dithianyl); n.m.r. δ 0.79 (C-18 CH_3), 0.85 (C-19 CH_3), 1.81 (3H, s, CH_3CS_2), 2.04 (3H, s, 17β-OAc), 2.30 (2H, s, C-3 CH_2), and 4.59 p.p.m. (1H, t, $J = 7.5$ Hz, C-17α H).

Anal. Calcd. for $C_{27}H_{44}O_3S_2$: C, 67.5; H, 9.2; S, 13.4. Found: C, 67.8; H, 9.4; S, 13.5.

*17β-Acetoxy-3-(2′-oxopropyl)-5α-androst-2-ene 1.3-propylenethioketal (**17**)*

Phosphoryl chloride (7 ml) was added dropwise with vigorous stirring at 0° to the dithianyl acetate **15** (0.35 g, 0.73 mmol) in dry pyridine (70 ml). The mixture was stirred overnight at 20° and was then poured into ice-water and extracted with ether (3 × 50 ml). The ether extracts were washed *rapidly* with ice-cold 0.1 *N* aqueous hydrochloric acid (50 ml) and were then dried ($MgSO_4$) and evaporated. The residual solid was purified by p.l.c. using ether–benzene (1:1) as developing solvent followed by recrystallization from ether–methanol to give the 17β-acetoxy-Δ^2-dithiane **17** (0.28 g) m.p. 164–165°; i.r. 908 cm^{-1} (dithianyl); n.m.r. δ 0.77 (C-18 CH_3), 0.79 (C-19 CH_3), 1.67 (3H, s, CH_3CS_2), 2.03 (3H, s, C-17β OAc), 2.58 (2H, s, C-3 CH_2), 4.60 (1H, t, $J = 7$ Hz, C-17α H), and 5.45 p.p.m. (1H, m, C-2 H).

Anal. Calcd. for $C_{27}H_{42}O_2S_2$: C, 70.1; H, 9.2; S, 13.9. Found: C, 70.1; H, 9.2; S, 14.0.

*17β-Hydroxy-3-(2′-oxopropyl)-5α-androst-2-ene 1.3-propylenethioketal (**18**)*

The 17β-acetate **17** (0.22 g) in methanol (40 ml) containing saturated aqueous sodium bicarbonate (2 ml) was refluxed for 12 h and then poured into water (200 ml). Extraction with chloroform (3 × 50 ml) followed by evaporation of the dried ($MgSO_4$) chloroform solution yielded the 17β-hydroxy-Δ^2-dithiane **18** (0.18 g) m.p. 158–159°, i.r. 3460, and 908 cm^{-1} (dithianyl); n.m.r. δ 0.75 (6H, s, C-18 and C-19 CH_3), 1.67 (3H, s, CH_3CS_2), 2.58 (2H, s, C-3 CH_2), 3.65 (1H, t, $J = 7$ Hz, C-17α H), and 5.45 (1H, m, C-2 H).

*Preparation and Attempted Isolation of 17β-Acetoxy-3-(2′-oxopropylidene)-5α-androstane (**20**)*

Phosphoryl chloride (25 ml) was added dropwise with vigorous stirring at 0° to the 3β-hydroxydithianyl acetate **16** (1.1 g, 2.3 mmol) in dry pyridine (250 ml). The mixture was stirred for a further 12 h at 20° and was then worked-up as described above for **17**. The product (0.84 g) was not resolvable by p.l.c. but was shown by n.m.r. analysis to be a mixture of the Δ^2-dithiane **17** isolated previously and 17β-acetoxy-3-(2′-oxopropylidene)-5α-androstane 1,3-propylidenethioketal (**19**), n.m.r. δ 0.78 (C-18 CH_3), 0.88 (C-19 CH_3), 1.83 (3H, s, CH_3CS_2), 2.03 (3H, s, C-17β OAc), and 5.33 p.p.m. (1H, s, COCH=).

The above mixture of **17** and **19** (0.8 g) in acetone–water (80 ml, 20:1) was stirred with mercuric chloride (0.8 g) and cadmium carbonate (0.8 g) at 20° for 1 day and was then filtered and evaporated (5). The residue was extracted with chloroform (100 ml) and the chloroform solution dried ($MgSO_4$) and evaporated. Fractional p.l.c. of the residue (0.56 g) with ether–benzene (1:15) as the developing solvent yielded only the Δ^2-ketone **21** (characterized as described later) in a pure form. The desired exocyclic olefin **20** present in the fractions isomerized progressively during the p.l.c. procedure and isolation of a pure sample by this approach was precluded by its instability.

*17β-Acetoxy-3α-(2′-oxopropyl)-5α-androstan-3β-ol (**22**)*

A solution of the 3β-hydroxydithianylacetate **16** (0.3 g, 0.63 mmol) in acetone–water (30 ml, 20:1) was treated with mercuric chloride (0.3 g) and cadmium carbonate (0.3 g) by the general ketonization procedure detailed in the attempted preparation of **20**. P.l.c. purification with ether–benzene (2:3) as developing solvent, followed by recrystallization from ether–methanol gave 17β-acetoxy-3α-(2′-oxopropyl)-5α-androstan-3β-ol (**22**, 0.15 g), m.p. 164–165°; i.r. 3534 and 1718 cm^{-1} (broad).

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.8; H, 9.7. Found: C, 73.9; H, 9.8.

*17β-Hydroxy-3-(2′-oxopropyl)-5α-androst-2-ene (**9**)*

*(a) From the Pure Dithiane **18***

The dithiane **18** (0.18 g, 0.43 mmol) was dissolved in acetone–water (20 ml, 20:1) and the dithianyl function hydrolyzed in the presence of mercuric chloride (0.2 g) and cadmium carbonate (0.2 g) by the general procedure described for compound **20**. P.l.c. of the crude product with ether–benzene (1:4) as the developing solvent and recrystallization from cold ether afforded 17β-hydroxy-3-(2′-oxopropyl)-5α-androst-2-ene (**9**, 70 mg), m.p. 110–111°; i.r. 1708 cm^{-1}; n.m.r. 0.77 (6H, s, C-18 and C-19 CH_3), 2.13 (3H, s, CH_3CO), 3.01 (2H, s, C-3 CH_2), 3.64 (1H, t, $J = 8$ Hz, C-17α H), and 5.48 p.p.m. (1H, m, C-2 H).

Anal. Calcd. for $C_{22}H_{34}O_2$ (mol. wt. 330.2559): C, 80.0; H, 10.4. Found (330.2553 (mass spectrum)): C, 80.1; H, 10.3.

(b) From Mixtures of ***13*** *and* ***14****, and* ***15*** *and* ***16***

In a typical experiment, a mixture of the 17β-acetates **15** and **16** (2 g) was dissolved in acetone–water (200 ml, 20:1) and treated with mercuric chloride (2 g) and cadmium carbonate (2 g) in the usual way. The gum (1.5 g) obtained was then refluxed for 1 day in methanol (150 ml) containing 10% aqueous hydrochloric acid (10 ml). Purification of the product as in section *a* yielded 1.4 g of **9**, m.p. 110–111°.

When the 17β-hydroxy compounds **13** and **14** were used, the final acid-catalyzed hydrolysis step was omitted.

(c) From a Mixture of ***20*** *and* ***21***

The mixture of the unsaturated ketones **20** and **21** (0.1 g) obtained from **19**, dissolved in methanol (20 ml) containing 0.1 *N* aqueous hydrochloric acid (1 ml), was heated under reflux for 12 h. The usual work-up and purification afforded **9** (80 mg), m.p. 108–110°.

(d) From ***22***

Hydrolysis of the 17β-acetate **22** (0.14 g) as described for section *c* above yielded 0.11 g of **9**, m.p. 110–111°.

Equilibration of **9** by treatment with methanolic hydrochloric acid or methanolic sodium hydroxide did not result in the formation of a detectable amount of the $\alpha\beta$-unsaturated isomer **10**.

*17β-Acetoxy-3-(2′-oxopropyl)-5α-androst-2-ene (****21****)*

The 17β-ol **9** (0.1 g) and acetic anhydride (5 ml) were refluxed for 20 min. The mixture was then evaporated and purified by p.l.c. (developing solvent ether–benzene (1:12)) followed by recrystallization from ether–methanol to give **21** (98 mg), m.p. 123–124°; i.r. 1718 cm^{-1} (broad); n.m.r. δ 0.76 (C-18 CH_3), 0.80 (C-19 CH_3), 2.03 (3H, s, C-17β-OAc), 2.13 (3H, s, CH_3CO), 2.99 (2H, s, C-3 CH_2) and 5.48 p.p.m. (C-2 H).

We express our thanks to the National Research Council of Canada and to the University of Toronto School of Graduate Studies for the award (to R.G.) of a Postdoctoral Fellowship.

Steroids and Steroidases. XV.[1] Investigations of Some 2-Lithio-1,3-dithiane Reactions Directed Towards the Introduction of Corticoid and Related Functions at C-17 of the Steroid Nucleus[2]

J. Bryan Jones and Roger Grayshan

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 2, 1971

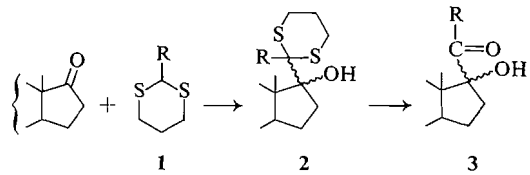
The potential of 2-lithio-1,3-dithiane reactions for the introduction of corticoid and related C-17 functions into the steroid nucleus has been explored. Although attempts to effect the direct addition of the dithiane reagents to C-17 ketones met with limited success, reactions of C-17 spiroepoxides were found to provide a convenient entry into routes to homocorticoid compounds.

La possibilité d'introduire le système corticoide et les fonctions apparentées sur le carbone C-17 du noyau stéroide a été explorée avec les réactions du lithio-2 dithiane-1,3. Bien que les essais d'addition directe entre les réactifs dithiane et les cétones C-17 soient d'un succès limité, on a constaté que les réactions avec les spiroépoxydes C-17 fournissent une voie convenable permettant l'accès aux composés homocorticoides.

Canadian Journal of Chemistry, **50**, 1414 (1972)

As a result of previous studies (1) evaluating the potential of 2-lithio-1,3-dithiane reactions for effecting stereospecific introductions of various functional groups into the steroid nucleus, we became interested in the possible utilization of dithiane reagents for the elaboration of C-17 functions of the corticoid types. Corey and his co-workers had demonstrated that their additions to carbonyl groups were often facile (2) and reaction of an appropriately substituted dithiane with a steroidal C-17 ketone therefore presented itself as an attractive initial step to the desired 17-hydroxy-20-oxo function outlined in Scheme 1. From the literature (3, and references therein) regarding the stereochemistry of addition of nucleophiles to steroid-17-ones, the hydroxydithianyl intermediate **2** was expected to be a mixture of the two C-17 epimers with the 17β-hydroxy compound predominating. However, it was hoped that the proportion of the 17α-hydroxy epimer present would be sufficient to make the route a viable one for the preparation of steroids possessing the general C-17 corticoid pattern represented in partial structure **3**.

The hydroxymethyldithiane, **1**, R = CH_2OH required for the introduction of the characteristic 17,21-dihydroxy-20-oxo corticoid function via the projected reactions of Scheme 1 was not a



1 **2** **3**

Scheme I

known compound and the validity of the approach was evaluated initially using the readily available 2-methyl analogue **1**, R = CH_3. The potential cortexolone precursor androst-4-ene-3,17-dione, with its Δ^4-3-keto moiety protected as the Δ^5-ethylene ketal, was selected for the initial experiments. The ethylene ketal **4** was reacted with 2-methyl-1,3-dithiane anion and the 17β-hydroxy-17α-dithianyl derivative **5** was obtained in 59% yield (see Scheme 2). Disappointingly, t.l.c. and spectral analyses (*e.g.* only one C-18 CH_3 n.m.r. peak at δ 0.99 p.p.m.) did not indicate that any significant amount of the epimer with the desired 17α-hydroxy configuration was formed during the addition reaction. The hydroxydithiane **5** was unstable and at room temperature decomposed with discoloration to give a mixture of much more polar (by t.l.c.) compounds. Accordingly, the dithiane **5** was subjected to the neutral mercuric chloride – cadmium carbonate in aqueous acetone deketalization conditions (2) immediately following its p.l.c. purification. However, in spite of repeated hydrolysis attempts, none of

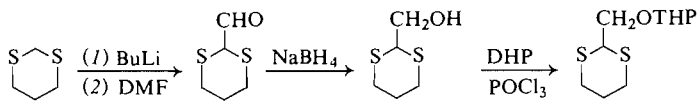
SCHEME 2



7 1, R = CH_2OH 8

SCHEME 3

the 17-hydroxy-20-ketone **6** could be detected in the multiple component reaction mixture. This was not entirely unexpected in view of the predilection of α-ketols to undergo further reactions (4). In order to prevent such complications, protection of the 17-hydroxyl group of **5** as the acetate was considered, but our endeavors to effect 17-acetylation of **5** under a variety of conditions resulted only in the formation of complex reaction mixtures. An alternative attempt to preclude α-ketol and subsequent decompositions by dehydration of **5** with thionyl chloride to the corresponding Δ^{16}-dithiane, for which re-introduction of a hydroxyl function into the required 17α-orientation following the dithiane hydrolysis step was an attractive possibility, was equally unrewarding.

Subsequently, the synthesis of 2-hydroxymethyl-1,3-dithiane (**1**, R = CH_2OH) was achieved as outlined in Scheme 3. A formyl group was introduced at C-2 of 1,3-dithiane by reaction of its anion with dimethylformamide and the unstable 2-formyl-1,3-dithiane (**7**) obtained was reduced directly with sodium borohydride to give the hydroxymethyl compound **1**, R = CH_2OH in 82% yield. Its n.m.r. spectrum in DMSO-d_6-D_2O was a complex one in which the eight-line AB_2 pattern of the C-2 H and hydroxymethylene protons was superimposed on the C-4 and -6 methylene multiplets centered at δ 2.85 p.p.m. Spin decoupling of the C-2 and $CH_2O(D)$ protons resulted in their collapse to singlets at δ 4.07 and 3.68 p.p.m. respectively. Surprisingly, **1**, R = CH_2OH was recovered unchanged when treated with toluene-*p*-sulfonic acid in benzene under conditions effecting dehydration of its substituted analogues (2).[3]

The dithianyl anion of 2-hydroxymethyl-1,3-dithiane required for effecting the C-17 carbonyl addition reaction of Schemes 1 and 2 could not be formed owing to the insolubility of the lithium alkoxide salt formed when **1**, R = CH_2OH was treated with *n*-butyllithium in tetrahydrofuran. Consequently, the hydroxyl group was protected as the tetrahydropyranyl ether with the product **8** being obtained in 83% yield (after p.l.c. purification). On mixing with *n*-butyllithium in tetrahydrofuran in the usual way, the tetrahydropyranyl derivative **8** appeared to form the desired anion. Unfortunately, it proved to be unstable in the basic reaction medium (*cf.* footnote 3 and ref. 5) and could not be trapped even using the standard (2) alkylation with methyl iodide assay. In view of the difficulties encountered with respect to formation of the desired dithianyl anions, and the problems associated with the generation of α-ketol functions from intermediates such as **5**, work on the Scheme 1 approach to cortico-steroids was discontinued.

Attention was then focussed on related routes to homocorticoid derivatives based on dithiane-spiro-epoxide reactions as outlined in Scheme 4. That reactions of dithiane anions with steroidal

[3]This attempt to prepare 2-methylene-1,3-dithiane was prompted by the report of its instability when formed under basic conditions (5).

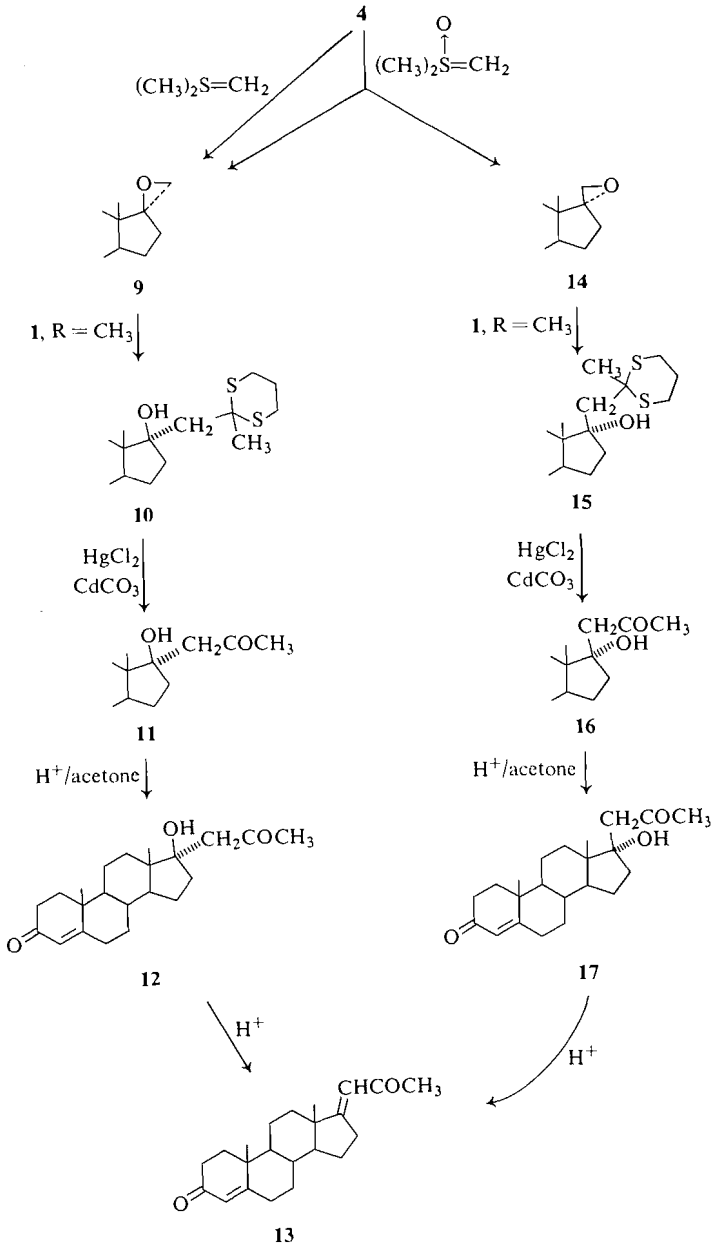

SCHEME 4

C-3 spiro-epoxides occurred smoothly and stereospecifically had been established previously (1*a*) and the corresponding reactions with C-17 spiro-oxiranes have now been shown to be equally facile. As shown in Scheme 4 the feasibility of the reactions contemplated was again explored with the readily available 2-methyl dithiane **1**, R = CH_3. The C-17 epoxides were prepared by reaction of the Δ^5-3-ethyleneketal **4** with dimethylsulfoxonium methylide (6), which gave a 96% yield of an inseparable mixture of the two epimers **9** and **14**, or with sulfonium methylide (6) which yielded the 17β-oxirane **9** exclusively in 97% yield (3). Since of

For personal use only.

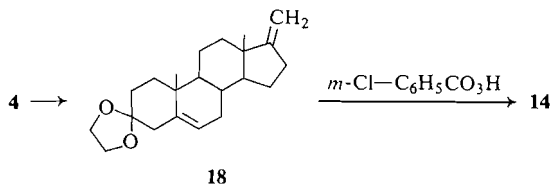
the two epoxides only the latter oxirane **9** was available in a pure form it was used in the initial experiments.

Opening of the epoxide ring of **9** with 2-methyl-1,3-dithianyl anion proceeded smoothly to give the 17β-hydroxydithiane **10** in 69% yield. In contrast to our experience with compound **5**, no difficulties were encountered during the mercuric chloride–cadmium carbonate mediated hydrolysis of the dithianyl group of **10** and the 17β-hydroxyketone **11** was obtained in 94% yield. Removal of the C-3 ethyleneketal function was effected with toluene-*p*-sulfonic acid in acetone to give 17α-acetonyltestosterone **12** (78%). When the acidic reaction conditions were applied for a more prolonged period, dehydration of **12** occurred to give 68% of the $\Delta^{17,20}$-homoprogesterone **13**.

The 17-hydroxy-21-oxo-compound **12** obtained by the above route has a C-17 configuration opposite to that present in naturally occurring cortico-steroids. Accordingly, in order to obtain the corresponding "homocorticoid" compound of the epimeric 17α-hydroxy series, the reactions were repeated using the 17α-oxirane **14**. As mentioned above, the mixture of C-17 epoxides containing **14** obtained by reaction of **4** with dimethylsulfoxonium methylide could not be resolved. The mixture was calculated to contain **9** and **14** in the ratio of ~2:1 by measurement of the relative intensities of the C-18 CH_3 peaks at δ 0.90 and 0.84 p.p.m. respectively and, after p.l.c. purification, it was used directly in the subsequent experiments. On reaction with the anion of **1**, R = CH_3, the corresponding hydroxydithianes **10** and **15** were obtained and p.l.c. separation afforded pure samples of each in 68 and 62% yields respectively from their parent epoxides. The sample of the 17β-hydroxy epimer **10** was identical with the material obtained previously from the pure oxirane **9**. The C-17 epimeric relationship of **10** and **15** was most readily illustrated by the chemical shift differences of the C-18 CH_3 peaks in the n.m.r. spectra (0.87 and 0.69 p.p.m. respectively). Neutral hydrolysis of **15** under the conditions applied to the corresponding 17β-epimer **10** gave 58% of the 17α-hydroxy-21-ketone **16** possessing the desired C-17 homocorticoid configuration and substitution pattern. Subsequent ketonization of the 3-ethyleneketal function of **16** to generate the 17α-hydroxyhomoprogesterone **17**, was again readily effected by acid-catalyzed exchange with acetone. However, owing to the ease with which the 17α-hydroxyl group of **17** underwent acid-catalyzed elimination during the work-up procedure, a significant proportion of the dehydrated product **13** was also formed. This situation contrasts with that in the corresponding 17β-series where the rate of ketonization of **10** was much greater than that of the subsequent elimination reaction.[4]



18

SCHEME 5

The samples of $\Delta^{17,20}$-homoprogesterone **13** obtained from both the 17α- and 17β-routes proved identical in all respects and all the t.l.c. and spectral data indicated that only one of the two $\Delta^{17,20}$-geometrical isomers was present. Assuming that the dehydrations of both **12** and **17** involve a *trans*-antiparallel elimination mechanism, examinations of molecular models suggest that an E configuration (7) 17,20-olefinic bond should be formed preferentially.

Subsequently, a more satisfactory route to the starting 17α-oxirane **14** was developed as outlined in Scheme 5. The C-17 ketone **4** was converted into the 17-methylene compound **18** in 77% yield using the normal Wittig procedure. On treatment of **18** with *m*-chloroperoxybenzoic acid in chloroform the main product was the desired 17α-oxirane **14** with the epimeric epoxide **9** present to a very minor extent. Use of peroxyacetic acid as the epoxidizing reagent afforded a mixture containing both C-17 and C-5,6 epoxides.

With relatively pure 17α-spiroepoxide **14** available, an extension of the reactions of Scheme 4 to the preparation of a "true homocorticoid", such as the C-22-hydroxy derivative of **17**, using the dithianes **1**, R = CH_2OH or **8** was attempted. However, presumably for the reasons discussed earlier in connection with C-17 carbonyl addition, none of the products

[4]The compounds of the 17α-hydroxy series were generally found to be less stable than their 17β-counterparts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

resulting from opening of the epoxide ring in the desired manner could be detected in any of the numerous experiments carried out. A parallel investigation using the 17β-oxirane **9** was equally discouraging.

From the above and previous (1) results it is now apparent that although reactions involving dithiane anions provide a valuable addition to the methods available for the stereospecific introduction of biologically interesting and other functions into the steroid framework, the method is not as generally applicable as had been hoped.

Experimental

If not included below, all general procedures, purification and analytical methods, criteria of purity, spectral analyses, etc. were carried out as detailed previously (1*a*,*c*, 3). Silica gel G was used for all p.l.c. separations.

17α-Acetyl-3,3-ethylenedioxyandrost-5-en-17β-ol 1,3-Propylenethioketal (5)

To a solution of 2-lithio-2-methyl-1,3-dithiane (2.3 g, 16.7 mmol), prepared from *n*-butyllithium (1.05 g, 16.7 mmol, 10.25 ml of a 1.6 *N* hexane solution) and 2-methyl-1,3-dithiane (**1**, R = CH_3, 2.21 g, 16.7 mmol) in freshly dried tetrahydrofuran (50 ml) at −20° under nitrogen (2), was added 3,3-ethylenedioxyandrost-5-en-17-one (**4**, 1.2 g, 3.63 mmol, prepared as described previously (3, 8)) in dry −20° tetrahydrofuran (17 ml). After keeping for 2 days at 0° the reaction mixture was worked-up in the usual (1*a*,*c*) way. The p.l.c. purification using ether–benzene (1:9) development yielded unchanged **4** (0.36 g) and the 17β-hydroxydithiane **5** (0.99 g) as an unstable foamy powder; i.r. ($CHCl_3$) 3497 and 909 cm^{-1} (dithianyl); n.m.r. ($CDCl_3$) δ 0.99 (C-18 CH_3), 1.03 (C-19 CH_3), 2.03 (3H, s, CH_3CS_2), 3.96 (4H, s, OCH_2CH_2O), and 5.29 p.p.m. (1H, m, C-5 H).

Anal. Calcd. for $C_{26}H_{40}O_3S_2$: C, 67.2; H, 8.7; S, 13.8. Found: C, 67.2; H, 8.8; S, 13.8.

2-Hydroxymethyl-1,3-dithiane (1, R = CH_2OH) and its Tetrahydropyranyl Ether (8)

Dimethylformamide (1.28 g, 16.6 mmol) was added quickly with stirring to a −20° solution of 2-lithio-1,3-dithiane (1 g, 8.3 mmol) prepared in a nitrogen atmosphere as described above in dry tetrahydrofuran (20 ml). A white solid precipitated almost immediately and the mixture was then poured into water (100 ml) and acidified with 1 *N* aqueous hydrochloric acid (20 ml). The clear aqueous solution was then extracted with chloroform (3 × 50 ml) and the combined extracts were washed with water until neutral and then dried ($MgSO_4$). Evaporation of the chloroform solution gave 2-formyl-1,3-dithiane as an oily liquid which was immediately redissolved in methanol (100 ml) containing 1 ml of water. Sodium borohydride (0.95 g, 25 mmol) was added and the solution kept at 20° until frothing ceased (30 min). The reaction solution was concentrated, diluted with water (100 ml), and extracted with chloroform (3 × 50 ml). The dried ($MgSO_4$) chloroform extracts were evaporated and the oily product purified by p.l.c. with ether–benzene (1:2) development. 2-Hydroxymethyl-1,3-dithiane (**1**, R = CH_2OH) was obtained as a gum (700 mg), i.r. ($CHCl_3$) 3400 (broad) and 907 cm^{-1} (dithianyl); n.m.r. (d_6-DMSO, and with D_2O added), δ 1.9 (2H, distorted t, J = 8 Hz, C-5 CH_2), 2.85 (6H, t, J = 5 Hz, C-4 and -6 CH_2), 3.6–4.2 (3H, AB_2 m, collapsing to two singlets at 3.68 (line 7) and 4.07 (line 3) on spin decoupling, C-2 H and CH_2O(D)).

Mol. Wt. Calcd. for $C_5H_{10}OS_2$: 150.0173. Found (mass spectrum): 150.0177.

Treatment of the above hydroxymethyldithiane (**1**, R = CH_2OH, 1.34 g, 8.7 mmol) and purified dihydropyran (1.46 g, 17.4 mmol) in purified chloroform (10 ml) at 0° with purified phosphoryl chloride (0.02 ml), followed by p.l.c. (ether–benzene (2:3) development) purification yielded the tetrahydropyranylether **8** (1.76 g) as a gum.

Mol. Wt. Calcd. for $C_{10}H_{18}O_2S_2$: 234.0748. Found (mass spectrum): 234.0748.

3,3-Ethylenedioxy-17β-hydroxy-7α-(2′-oxopropyl)androst-5-ene 1,3-Propylenethioketal (10)

3,3-Ethylenedioxy-spiro-17β-oxiranylandrost-5-ene (**9**) was prepared according to the literature procedure (3).

To a solution of 2-lithio-2-methyl-1,3-dithiane (4.13 g, 30 mmol) under nitrogen in −20° freshly dried tetrahydrofuran (80 ml) was added the spiro-17β-epoxide **9** (1.72 g, 5 mmol) in freshly dried −20° tetrahydrofuran. The reaction mixture was then kept for 2 days at 0° and worked-up in the usual (1*a*,*c*) way. The p.l.c. purification with ether–benzene (1:9) development, followed by recrystallization from ether, gave the 17β-hydroxy dithianyl compound **10** (1.62 g) m.p. 164–165°; i.r. (CCl_4) 3448 and 907 cm^{-1} (dithianyl); n.m.r. ($CDCl_3$) δ 0.87 (C-18 CH_3), 1.04 (C-19 CH_3), and 1.87 p.p.m. (3H, s, CH_3CS_2).

Anal. Calcd. for $C_{27}H_{42}O_3S_2$: C, 67.7; H, 8.8; S, 13.4. Found: C, 67.7; H, 8.6; S, 13.5.

3,3-Ethylenedioxy-17β-hydroxy-17α-(2′-oxopropyl)androst-5-ene (11)

The 17β-hydroxydithiane (**10**, 0.6 g, 1.26 mmol) was dissolved in acetone (60 ml) containing water (2.5 ml) at 20°. Mercuric chloride (0.6 g) and cadmium carbonate (0.6 g) were then added and the mixture was stirred for 24 h (2). A further 0.2 g each of mercuric chloride and cadmium carbonate were then added and stirring continued for another 5 h. The reaction mixture was then filtered and evaporated and purified by p.l.c. (ether–benzene (3:7) development) to give 3,3-ethylenedioxy-17β-hydroxy-17α-(2′-oxopropyl)-androst-5-ene (**11**, 460 mg) m.p. 192–195°; i.r. (CCl_4) 3521 and 1705 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.90 (C-18 CH_3), 1.05 (C-19 CH_3), and 2.21 p.p.m. (3H, s, CH_3CO).

17β-Hydroxy-17α-(2′-oxopropyl)androst-4-en-3-one (12)

The 17β-hydroxy-2′-oxopropyl ketal **11** (460 mg) in acetone (80 ml) containing toluene-*p*-sulfonic acid (10 mg) was stirred at 20° until the t.l.c. monitoring process indicated that C-3 ketonization was almost complete (4 h). The mixture was then poured into water (200 ml) and extracted with ether (3 × 25 ml). The usual (1*a*,*c*) work-up procedure followed by p.l.c. purification (with ether–benzene (7:3) as developing solvent) and recrystallization from ether afforded 17β-hydroxy-17α-(2′-oxopropyl)androst-4-en-3-one (**12**, 320 mg) m.p. 133–134°; i.r. ($CHCl_3$) 3480 and 1701 cm^{-1};

n.m.r. ($CDCl_3$) δ 0.90 (C-18 CH_3), 1.20 (C-19 CH_3), and 2.20 p.p.m. (3H, s, CH_3CO).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.7; H, 9.4. Found: C, 76.9; H, 9.5.

*17-(2′-Oxopropyl)androsta-4,17(20)-diene-3,21-dione (**13**)*

Prolonged (36 h) treatment of 17β-hydroxy-17α-(2′-oxopropyl)androst-4-en-3-one (**12**, 25 mg) with acidic acetone as described above effected dehydration smoothly to give the diene-dione **13**. Purification by p.l.c. (ether–benzene (3:2) development) followed by recrystallization from ether gave 16 mg of the product m.p. 177–178°; i.r. ($CHCl_3$) 1672, 1661, and 1613 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.88 (C-18 CH_3), 1.21 (C-19 CH_3), 2.20 (3H, s, CH_3CO), 5.75 (1H, broad s, C-14 H), and 5.95 p.p.m. (1H, t, $J = 2.5$ Hz, C-20 H).

Anal. Calcd. for $C_{22}H_{30}O_2$: C, 80.9: H, 9.3. Found: C, 80.8; H, 9.2.

*Preparation of a Mixture of the Spiro-17β- and 17α-Oxiranyl Epimers **9** and **14** by Reaction of 3,3-Ethylenedioxyandrost-5-en-17-one (**4**) with Dimethylsulfoxonium Methylide*

A 53.8% suspension of sodium hydride in mineral oil (1.2 g, 30 mmol) was washed with petroleum ether (b.p. 40–60°) by decantation in a nitrogen atmosphere. Trimethylsulfoxonium iodide (7.2 g, 32.7 mmol) was then added and dimethylsulfoxide (20 ml) was allowed to drip slowly into the reaction flask. After the evolution of hydrogen had ceased (20–30 min) 3,3-ethylenedioxyandrost-5-en-17-one (**4**, 3 g, 9.1 mmol) obtained by the standard literature procedure (3, 8) dissolved in *hot* dimethylsulfoxide (75 ml) was added without delay (3, 6, 9). The mixture was stirred for 4 h at 20°, and was then heated at 55° for 3 h during which time the reaction solution became clear. Water (300 ml) was added and the mixture extracted with ether (4 × 75 ml). The ether extracts were washed with water (2 × 50 ml), dried ($MgSO_4$), and evaporated. The product (3 g) was purified by column chromatography on alumina. The mixture obtained contained the 17β- and 17α-epoxides **9** and **14** in the ratio ~2:1 (estimated by n.m.r.) and could not be resolved into its individual component epoxides by p.l.c. or by fractional recrystallization (*cf.* 9, 10). The t.l.c. and n.m.r. characteristics of each epoxide were identical with those observed above for **9** (3) and below for **14**.

*3,3-Ethylenedioxy-17α-hydroxy-17β-(2′-oxopropyl)androst-5-ene 1,3-Propylenethioketal (**15**)*

The above mixture of spiro-17β-(**9**) and spiro-17α-(**14**) oxiranes (3 g, 8.7 mmol) in dry −20° tetrahydrofuran (25 ml) was added to 2-lithio-2-methyl-1,3-dithiane (5.5 g, 40 mmol) prepared in freshly dried tetrahydrofuran (100 ml) at −20° under nitrogen. The mixture was then allowed to stand at 0° for 2 days. The normal work-up procedure (1*a*,*c*) gave 2.6 g of an unstable mixture of the hydroxydithianes **10** and **15** in the ratio of ~2:1 (by n.m.r.). Several fractional p.l.c. purifications with ether–benzene (1:14) developments gave pure samples of the 17β-hydroxy epimer **10** (0.41 g, identical with the material obtained above) and 3,3-ethylenedioxy-17α-hydroxy-17β-(2′-oxopropyl)androst-5-ene 1,3-propylenethioketal (**15**, 0.25 g) as an unstable glassy foam, i.r. ($CHCl_3$) 3410 and 907 cm^{-1} (dithianyl); n.m.r. ($CDCl_3$) δ 0.69 (C-18 CH_3), 1.05 (C-19 CH_3), and 1.78 p.p.m. (3H, s, CH_3CS_2).

Anal. Calcd. for $C_{27}H_{42}O_3S_2$: C, 67.7; H, 8.8; S, 13.4. Found: C, 67.6; H, 8.9; S, 13.3.

*3,3-Ethylenedioxy-17α-hydroxy-17β-(2′-oxopropyl)androst-5-ene (**16**)*

The 17α-hydroxydithiane **15** (0.23 g), 0.48 mmol) was dissolved in acetone (20 ml) containing water (1 ml) and mercuric chloride (0.23 g) and cadmium carbonate (0.23 g) were then added (2). The mixture was stirred at 20° for 8 h after which time t.l.c. analysis indicated that complete reaction had taken place. The filtered reaction solution was evaporated and the residue redissolved in chloroform (50 ml), dried ($MgSO_4$), and evaporated. The p.l.c. purification, with ether–benzene 1:1 developing solvent, and recrystallization from ether yielded the 17α-hydroxy-17β-(2′-oxopropyl) compound **16** (0.11 g) m.p. 163–166°; i.r. (CCl_4) 3535 and 1706 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.69 (C-18 CH_3), 1.04 (C-19 CH_3), and 2.20 p.p.m. (3H, s, CH_3CO).

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.2; H, 9.3. Found: C, 74.4; H, 9.5.

*17α-Hydroxy-17β-(2′-oxopropyl)androst-4-en-3-one (**17**)*

A solution of 3,3-ethylenedioxy-17α-hydroxy-17β-(2′-oxopropyl)androst-5-ene (**16**, 100 mg, 0.26 mmol) in acetone (20 ml) containing toluene-*p*-sulfonic acid (10 mg) was stirred at 20° until t.l.c. analysis indicated C-3 ketonization to be complete (2 h). The solvent was then removed by evaporation (during which process some elimination of the C-17α-OH occurred) and the residue was purified by p.l.c. with ether–benzene (1:1) as the developing solvent. Recrystallization of the two main fractions from ether gave the $\Delta^{17(20)}$ elimination product **13** (30 mg), identical in all respects with the sample obtained previously, and 17α-hydroxy-17β-(2′-oxopropyl)androst-4-en-3-one (**17**, 30 mg) m.p. 125–127°; i.r. ($CHCl_3$) 3520, 1704, 1664, and 1616 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.72 (C-18 CH_3), 1.20, (C-19 CH_3), 2.20 (3H, s, CH_3CO), and 5.63 p.p.m. (1H, s, C-4 H).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.7; H, 9.4. Found: C, 76.8; H, 9.4.

*3,3-Ethylenedioxy-17-methylene-androst-5-ene (**18**)*

3,3-Ethylenedioxyandrost-5-en-3-one (**4**, 7 g, 21.3 mmol) in dry benzene (140 ml) was added dropwise with stirring at 20° to triphenylphosphonium methylide (prepared from methyltriphenylphosphonium bromide (25.2 g, 70 mmol) and potassium *t*-butoxide (14 g, 125 mmol)) in dry dimethyl sulfoxide (125 ml) by the usual Wittig procedure (11). The mixture was kept at 20° until t.l.c. indicated the reaction to be complete (~24 h) and was then poured into water (500 ml) and extracted quickly with ether (4 × 50 ml). The ether solution was washed with water (2 × 50 ml), then dried immediately with $MgSO_4$ and evaporated. The residue was column chromatographed on Florisil (benzene elution) to give 3.2 g of the 17-methylene-3-ketal **18**. A fraction containing its hydrolysis product, 17-methyleneandrost-4-en-3-one, was reketalized with ethylene glycol and toluene-*p*-sulfonic acid in benzene, and p.l.c. purification afforded a further 1.2 g of **18**. Unchanged starting material **4** (1.1 g) was also recovered. Recrystallization from ether–methanol effected final purification of 3,3-ethylenedioxy-17-methyleneandrost-5-ene (**18**) m.p. 157–158°; n.m.r. ($CDCl_3$) δ 0.82 (C-18 CH_3), 1.07 (C-19 CH_3), 4.0 (4H, s, OCH_2CH_2O), 4.69 (2H, s, $=CH_2$), and 5.4 p.p.m. (1H, s, C-4 H).

Anal. Calcd. for $C_{22}H_{32}O_2$: C, 80.4; H, 9.8. Found: C, 80.4; H, 10.0.

*3,3-Ethylenedioxy-spiro-17α-oxiranylandrost-5-ene (**14**)*

m-Chloroperoxybenzoic acid (0.94 g, 5.5 mmol) in pure chloroform (10 ml) was added dropwise with stirring during 10 min to the 17-methyleneketal **18** (1.5 g, 4.6 mmol) in pure chloroform (25 ml) at 0°. After stirring for a further 30 min at 0°, chloroform (100 ml) was added and the solution was washed with 5% aqueous sodium bicarbonate (50 ml) and then with water (50 ml). The chloroform solution was dried immediately ($MgSO_4$) and evaporated. The p.l.c. purification (silica gel G, ether–benzene (1:6) development) gave unchanged starting material (0.4 g) and an oxirane fraction (1.4 g) which was shown by n.m.r. to be predominantly the 17α-epimer **14**. Recrystallization from ether–methanol provided a sample m.p. 163–167°, n.m.r. ($CDCl_3$) δ 0.83 (C-18 CH_3), 1.04 (C-19 CH_3), 2.75 (2H, C-20 CH_2),[5] 4.03 (4H, s, OCH_2CH_2O) and 5.23 p.p.m. (1H, broad s, C-5 H).

This work was carried out during the tenure of a University of Toronto School of Graduate Studies Postdoctoral Fellowship (awarded to R.G.) and was supported by the National Research Council of Canada.

[5]This peak was a broadened singlet in which some signs of the splitting pattern of an AA′ quartet could be detected. *cf.* refs. (3, 12).

The Preparation of 1,2-Dimethylarsinohexafluorocyclopentene, 1,2-Dimethylarsinooctafluorocyclohexene, and Related Mixed Ligands

L. S. CHIA AND W. R. CULLEN

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received December 15, 1971

Dimethylarsine reacts with the compounds $FC{=}CF(CF_2)_{n/2}$ to give the ligands

$$(CH_3)_2AsC{=}C\,As(CH_3)_2(CF_2)_{n/2},$$

$f_n$fars ($n = 4, 6, 8$). The reaction of diphenylphosphine with $(CH_3)_2AsC{=}CF(CF_2)_{n/2}$ results in the mixed ligands

$$(CH_3)_2AsC{=}CP(C_6H_5)_2(CF_2)_{n/2},$$

f_nAsP ($n = 4, 6, 8$).

La diméthylarsine réagit avec les composés $FC{=}CF(CF_2)_{n/2}$ pour donner les ligands

$$(CH_3)_2AsC{=}C\,As(CH_3)_2(CF_2)_{n/2},$$

$f_n$fars ($n = 4, 6, 8$). La réaction de la diphénylphosphine avec $(CH_3)_2AsC{=}CF(CF_2)_{n/2}$ conduit à un mélange de ligands

$$(CH_3)_2AsC{=}CP(C_6H_5)_2(CF_2)_{n/2},$$

f_nAsP ($n = 4, 6, 8$).

Canadian Journal of Chemistry, **50**, 1421 (1972)

Reaction of the ditertiary arsine ligand $f_4$fars,

$$(CH_3)_2AsC{=}CAs(CH_3)_2CF_2CF_2,$$

with metal carbonyl compounds has provided a number of novel compounds. The related ditertiary phosphines $f_n$fos which are prepared by treating the perfluorocycloolefin with diphenylphosphine have also been described (1,

[1] $$2(C_6H_5)_2PH + FC{=}\!\!=\!\!=CF \rightarrow (C_6H_5)_2PC{=}\!\!=\!\!=CP(C_6H_5)_2 + 2HF \quad (n = 4, 6, 8)$$

and references therein). In this note we wish to describe an improved synthesis of $f_4$fars and its elaboration to the isolation of $f_6$fars and $f_8$fars. We also describe the preparation of the mixed ligands f_4AsP and f_8AsP

$$(CH_3)_2AsC{=}CP(C_6H_5)_2(CF_2)_{n/2}$$

($n = 4, 8$) and an improved synthesis of f_6AsP.

Experimental

All reactions were carried out in sealed tubes. Volatile reactants were manipulated in a conventional vacuum system. The preparation of f_4AsP is given as an example. This is also listed in Table 1 together with the conditions used to isolate the other ligands. The analytical data for new compounds are given in Table 2.

Preparation of 1-Diphenylphosphino-2-dimethylarsinotetrafluorocyclobutene (f_4AsP)

1-Dimethylarsinopentafluorocyclobutene was obtained by treating perfluorocyclobutene with dimethylarsine (2). The arsinocyclobutene (35.5 g, 0.143 mol) and diphenylphosphine (26.0 g, 0.140 mol) were sealed under vacuum in a thick-walled Pyrex tube. After shaking for 2 days at 20° the tube was opened. The solid product was dissolved in acetone and the residue was filtered off. The acetone was then removed *in vacuo* and the resulting residue (an orange oil) was dissolved in the minimum amount of methylene chloride and chromatographed on a Florisil column. A 1:1 diethyl ether–petroleum ether mixture eluted a pale yellow band. After removal of the solvent, pale yellow crystals were obtained which were purified by rechromatography and recrystallization from diethyl ether–petroleum ether to give colorless crystals of f_4AsP (43.0 g, 74%); m.p. 39°.

TABLE 1. Reaction conditions for the preparation of new ligands

Reactants	Conditions		Product	Yield (%)

*All compounds are colorless.

Results and Discussion

Previous syntheses of $f_4$fars involved the reaction of dimethylarsine with 1-dimethylarsino-2-chlorotetrafluorocyclobutene (3). This two-step process was undesirable and since the $f_n$fos ligands were best prepared from the perfluorocycloolefins (eq. 1) the corresponding reactions using dimethylarsine were investigated. This has resulted in a convenient single step synthesis of $f_4$fars and the two new ditertiary arsines $f_6$fars and $f_8$fars. Unlike the reaction of

$$[2]\quad 2(CH_3)_2AsH + FC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CF \rightarrow (CH_3)_2AsC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CAs(CH_3)_2 + 2HF \qquad n = 4, 6, 8$$

eq. 1, where only disubstitution occurs, the reaction of eq. 2, can be stopped if required at the monosubstitution stage. This has previously been demonstrated when $n = 4$ and 6 (2) and in the present investigation the monosubstituted compound with $n = 8$ has been isolated. The products of eq. 3 react further with diphenylphosphine to afford the mixed ligands f_nAsP.

$$[3]\quad (CH_3)_2AsH + FC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CF \rightarrow (CH_3)_2AsC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CF + HF \qquad n = 4, 6, 8$$

$$[4]\quad (CH_3)_2AsC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CF + (C_6H_5)_2PH \rightarrow (CH_3)_2AsC{=}^{\ulcorner(CF_2)_{n/2}\urcorner}{=}CP(C_6H_5)_2 + HF \qquad n = 4, 6, 8$$

The synthesis of f_6AsP ($n = 6$) has been described (1) but it has now been found that if the reaction of eq. 4 is carried out at 20° rather than 45°, with a corresponding increase in the reaction time, the yield is considerably increased. Two other mixed ligands f_4AsP and f_8AsP can be obtained by the same method although f_8AsP has been characterized only by its spectroscopic properties.

In general, all these reactions involving perfluorocycloolefins require more forcing conditions as the ring size is increased which is probably a consequence of ring strain (4).

The n.m.r. spectra of all the new compounds

For personal use only.

$f_8$fars, and the mixed ligands f_nAsP. Indeed, because of this, it is difficult to assign this band with any certainty. In the monosubstituted series $(CH_3)_2AsC{=}CF(CF_2)_{n/2}$ the strong ν(C=C) changes very little with ring size, it being 1662, 1661, and 1664 cm^{-1} for $n = 4$, 6, and 8 respectively. In the C—F stretching region, the pattern and position of absorption for the di-substituted compounds ($f_n$fars, f_nAsP, $f_n$fos) with a given ring size is very similar. The ν(C—F) are $1308 \pm 4, \sim 1227, 1154 \pm 5, 1106 \pm 6$ cm^{-1} for $n = 4$; $\sim 1331, 1236 \pm 3, 1187 \pm 3, 1136 \pm 5, 1092 \pm 2, 1000 \pm 7$ cm^{-1} for $n = 6$; and $1344 \pm 1, 1213 \pm 5, 1193 \pm 5, 1177 \pm 2, 1162 \pm 4, 1109 \pm 7, 1038 \pm 3, 980 \pm 8$ cm^{-1} for $n = 8$.

All the derivatives which possess a $(CH_3)_2As$ group show a doublet in the region 565–585 cm^{-1} which is associated with As—CH_3 stretching vibrations and which is fairly insensitive to the nature of the other substituents on the arsenic(III) atom. The values for other compounds not listed in Table 4 are 568, 581, $f_4$fars; 565, 580, $(CH_3)_2AsC{=}CF(CF_2)_2CF_2$; 562, 584 cm^{-1} $(CH_3)_2AsC{=}CFCF_2CF_2$.

Synthesis of 6-*O*-(4-*O*-Methyl-β-D-glucopyranosyl)-D-galactose

J. M. Berry and G. G. S. Dutton
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received December 13, 1971

6-*O*-(4-*O*-Methyl-β-D-glucopyranosyl)-D-galactose has been synthesized by a Koenigs–Knorr reaction. The disaccharide is most readily characterized in the form of the crystalline glycosyl alditol peracetate.

Le 6-*O*-(4-*O*-methyl-β-D-glucopyranosyl)-D-galactose a été synthétisé selon la methode de Koenigs–Knorr. Le disaccharide est plus facilement identifié sous forme du glycosyl alditol peracétate.

Canadian Journal of Chemistry, **50**, 1424 (1972)

In studying the structure of acidic polysaccharides it is often more convenient to carry out fragmentation after the uronic acid function has been reduced, a transformation which is readily achieved with diborane (1) or complex hydrides (2, 3). Similarly, an aldobiouronic acid may more readily be characterized as the derived neutral disaccharide (*e.g.* 4, 5). The aldobiouronic acid 6-*O*-(4-*O*-methyl-β-D-glucopyranosyluronic acid)-D-galactose is found in many plant gums (6–8) and it is thus of interest to prepare 6-*O*-(4-*O*-methyl-β-D-glucopyranosyl)-D-galactose. This note reports the synthesis and characterization of this disaccharide and of the related disaccharide alditol.

4-*O*-Methyl-D-glucose was prepared by Hakomori methylation (9) of 2,3:5,6-di-*O*-isopropylidene-D-glucose dimethyl acetal which was obtained via the diethyl thioacetal and purified through the crystalline *p*-nitrobenzoate (10). This sugar was identified as the osazone (10, 11) and the β-D-tetraacetate (12), both crystalline.

2,3,6-Tri-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl bromide was condensed with 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (13) in chloroform using freshly prepared silver oxide (14). The reaction product was deacetylated with sodium methoxide to give 6-*O*-(4-*O*-methyl-β-D-glucopyranosyl)-1,2:3,4-di-*O*-isopropylidene-D-galactopyranose as a crystalline material in 62% yield. Preliminary experiments showed that the ketal groups could be removed with minimal hydrolysis of the glycosidic linkage by 0.05 *N* sulfuric acid on a steam bath for 40 min. Hydrolysis in this way gave 6-*O*-(4-*O*-methyl-β-D-glucopyranosyl)-D-galactose as a

syrup in 90% yield. Examination by paper chromatography showed a very small amount (<5%) of monosaccharide and pure disaccharide was obtained as a syrup by passage through Dowex 50W X2 (Li^+) (15). The disaccharide had $[\alpha]_D \sim 0°$ in water consistent with the assignment of a β-D-linkage. According to Hudson's rules (16) the calculated values for $[\alpha]_D$ are approximately +93 and −6° for α-D- and β-D-(1→6) links.

The disaccharide consumed 4.9–5.0 mol of periodate and successive borohydride reduction and total hydrolysis gave ethylene glycol and 2-*O*-methyl-D-erythritol identified by g.l.c. of their trimethylsilyl derivatives (17). Methylation (Hakomori) of the disaccharide followed by methanolysis and g.l.c. indicated the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose together with 2,3,4- and 2,3,5-tri-*O*-methyl-D-galactose (18). It is of interest to note that the Hakomori method of methylation, like the Kuhn reagents (19), gives a high proportion of the furanose isomer. The peak areas for the 2,3,4- and 2,3,5-isomers were in the approximate ratio of 3:2. No satisfactory crystalline derivatives were obtained from the disaccharide which was most conveniently characterized as the glycosyl alditol acetate, m.p. 104–106°. The n.m.r. spectrum of the free glycosyl alditol in deuterium oxide showed $J_{1,2}$ 7.5 Hz (τ 5.3) consistent with a β-D-linkage (20).

Experimental

Thin-layer chromatography was carried out using solvent systems A and B on silica gel. Plates were developed by spraying with 50% aqueous sulfuric acid and heating to about 150° for 3–5 min. Paper chromatograms using solvent systems C and D were developed using silver nitrate in acetone for reducing sugars (21) and sodium periodate – benzidine for non-reducing compounds (22). Solvent A, ethyl ether – toluene (2:1); B, butanone–water azeotrope; C, ethyl acetate – pyridine–water (4:1:1); D, ethyl acetate – acetic acid–formic acid – water (18:3:1:4). Gas–liquid chromatography was carried out on a F and M 720 instrument using columns: (*a*) 8 ft × 1/4 in. 20% SF 96 on 80–100 mesh Diatoport S, (*b*) 4 ft × 1/4 in. 5% butanediol succinate on 80–100 mesh Diatoport S, and (*c*) 2 ft × 1/4 in. 20% SE 30 (F and M Division, Hewlett–Packard, Arondale, Pennsylvania). The n.m.r. spectra were recorded on a Varian HA-100 instrument using tetramethylsilane as internal standard except as noted. Optical rotations were measured at 23 ± 1° on a Rudolph polarimeter model 219 and later on a Perkin-Elmer model 141 polarimeter. Melting points are uncorrected. Solvents were removed *in vacuo* at a bath temperature not exceeding 40°.

4-O-Methyl-D-glucose

2,3:5,6-Di-*O*-isopropylidene-D-glucose dimethyl acetal (10 g) (10) was dissolved in dry methyl sulfoxide (100 ml), a solution of methyl sulfinyl anion (0.6 *M*, 120 ml) was added and the solution left 45 min at room temperature (23). Excess methyl iodide was then added while keeping the temperature below 25°. Thin-layer chromatography in solvent A showed the reaction to be complete in 30 min. Petroleum ether (65–110°, 400 ml) and water (200 ml) were added and the water layer extracted with petroleum ether (8 × 100 ml). The combined solvent extracts were washed, dried, and concentrated to give a syrup (9.6 g) which was heated for 4 h at 60° with sulfuric acid (0.05 *N*, 100 ml). Neutralization ($BaCO_3$) and concentration gave crude 4-*O*-methyl-D-glucose (5.7 g), [α] +49° (*c*, 2 in water). A pure sample obtained by sodium methoxide deacetylation of the tetraacetate had [α] +60.0° (*c*, 2.8 in water), lit. (11) $[\alpha]_D$ +61.1° (*c*, 2 in water); $R_{glucose}$ 2.65 (solvent C). Phenylosazone m.p. 158–160°, (lit. (10, 11) m.p. 158–160°).

Crude 4-*O*-methyl-D-glucose (4.5 g) was acetylated with acetic anhydride (32 ml) and anhydrous sodium acetate (2.25 g) to give the tetraacetate, (3.58 g), m.p. 98–100°. 1,2,3,6-Tetra-*O*-acetyl-4-*O*-methyl-β-D-glucopyranose (**1**) was recrystallized from cyclohexane and had m.p. 102–103°, $[\alpha]_D$ −8.1° (*c*, 2.3 in chloroform), (lit. (12) m.p. 98–99°, $[\alpha]_D$ −7° (*c*, 2 in chloroform)), the n.m.r. data ($CDCl_3$) $J_{1,2}$ 8.0 Hz (τ 4.40) (24).

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.70; H, 6.12. Found: C, 49.62; H, 6.05.

2,3,6-Tri-O-acetyl-4-O-methyl-α-D-glucopyranosyl Bromide (**2**)

Tetraacetate (**1**) (1.6 g) was dissolved in cold hydrogen bromide in glacial acetic acid (32%, 28 ml) and the solution allowed to stand at room temperature for 45 min. Chloroform (50 ml) was added and the solution was shaken with water (50 ml). The aqueous layer was extracted with chloroform (3 × 25 ml) and the combined extracts were washed with saturated sodium hydrogen carbonate (2 × 50 ml) and cold water (2 × 25 ml). Evaporation of the dried chloroform gave (2) as a syrup (1.8 g), [α] +190° (*c*, 4.2 in chloroform).

6-O-(4-O-Methyl-β-D-glucopyranosyl)-1,2:3,4-di-O-isopropylidene-D-galactopyranose (3)

1,2:3,4-Di-*O*-isopropylidene-D-galactopyranose (**4**) (600 mg, 2.5 mmol, distilled syrup), freshly prepared silver oxide (2.0 g), and Drierite (2.0 g, finely powdered, preheated to 200° *in vacuo*) were stirred for 1 h in absolute chloroform (15 ml) at room temperature. A solution of the bromide **2** (1.5 g, 3.7 mmol) in absolute chloroform (8 ml) was then added over 2 h with continuous stirring. Thin-layer chromatography (solvent A) showed R_f values as follows: **2**, 0.54; product, 0.44; **4**, 0.33; and a compound, assumed to be a degradation product of **2**, at 0.28. Thin-layer chromatography further showed that the reaction was complete 30 min after the final addition. The mixture was filtered, the solid was washed with chloroform, and the filtrate and washings evaporated to a syrup which was reacted directly with sodium methoxide (0.1 *N*, 30 ml). After 30 min sodium ion was removed with Amberlite IR 120 resin and the methanol evaporated to give a solid product, m.p. 168–170° (680 mg, 62%). Recrystallization from ethanol (4 ml/g)

gave pure **3** m.p. 174–175°, $[\alpha]_D$ −60.5° (*c*, 0.8 in methanol), R_f (t.l.c., solvent B) 0.50.

Anal. Calcd. for $C_{19}H_{32}O_{11}$: C, 51.88; H, 7.35; OMe, 6.93. Found: C, 52.25; H, 7.39; OMe, 7.11.

*6-O-(4-O-Methyl-*D*-glucopyranosyl)-*D*-galactose*

Compound **3** (600 mg) was heated on a steam bath for 40 min in sulfuric acid (0.05 *N*, 30 ml). Passage through Duolite A-4 resin and concentration gave the disaccharide as a syrup (486 mg), $[\alpha]_D$ +4° (*c*, 1 in water); $R_{glucose}$ 0.34 (solvent C); 0.26 (solvent D) on paper chromatography. These conditions of hydrolysis were chosen when 0.5 *N* sulfuric acid and Amberlite IR-120 resin were found to give glycosidic cleavage and 0.01 *N* sulfuric acid required heating for 90 min. Removal of isopropylidene groups was followed by t.l.c. in solvent B and paper chromatography (solvents C and D) was used to check on glycosidic cleavage. Purification of 100 mg of disaccharide on Dowex 50W X2 (Li^+) gave a recovery of 94 mg, $[\alpha]_D$ ~0° (*c*, 1 in water). Solid products were obtained by reaction with phenylhydrazine, aniline (m.p. 145–147°) and *p*-nitrobenzoyl chloride (m.p. 153–156°) none of which gave satisfactory analyses.

The g.l.c. of the per(trimethylsilyl) disaccharide (column c at 260°) gave one peak (~15%) at 7.3 min and two unresolved peaks at 10.7 min (per(trimethylsilyl)sucrose 5.5 min).

Anal. Calcd. for $C_{13}H_{24}O_{11}$: C, 43.82; H, 6.74. Found (after drying over P_2O_5 at 68° for 3 days): C, 43.63; H, 7.09.

Reaction of the pure disaccharide (10.40, 10.50 mg) in duplicate oxidations with sodium metaperiodate (0.015 *M*, 20 ml) at room temperature in the dark showed a rapid uptake of 4 mol with the consumption of periodate becoming constant (4.9, 5.0 mol) in 18 h (25). Iodate and excess periodate were removed by addition of barium acetate and sodium borohydride was added. The polyalcohol, obtained by deionization, distillation with methanol and concentration, was hydrolyzed (1.0 *N* H_2SO_4, 5 ml, 100°, 4h) and the neutralized ($BaCO_3$) hydrolyzate converted to trimethylsilyl derivatives. Injection in hexane, onto column *a* programmed from 120 to 195° at 2°/min, gave peaks identical to authentic standards of the per(trimethylsilyl) derivatives of ethylene glycol (5.3 min) and 2-*O*-methyl-D-erythritol (27.2 min) (4, 26).

Pure disaccharide (28 mg) in dry methyl sulfoxide (2.0 ml) was methylated using methyl sulfinyl anion (1.5 *M*, 1.0 ml) and methyl iodide (6.0 ml). Methanolysis and examination of the methyl glycosides on column *b* programmed from 130 to 190° at 2°/min showed peaks corresponding to methyl 2,3,4,6-tetra-*O*-methyl-D-glucosides (5.1, 7.7 min), methyl 2,3,5-tri-*O*-methyl-D-galactofuranosides (15.9 min), and methyl 2,3,4-tri-*O*-methyl-D-galactopyranosides (21.3 min).

*6-O-(4-O-Methyl-β-*D*-glucopyranosyl)-*D*-galactitol (5)*
*[1-O-(4-O-Methyl-β-*D*-glucopyranosyl)-*L*-galactitol]*

Disaccharide (180 mg) was reduced with sodium borohydride (360 mg) in water (18 ml) for 4 h. Passage through cation exchange resin, concentration and distillation with methanol gave **5** ($R_{glucose}$ 0.34, solvent C; 0.33 solvent D) which was acetylated with acetic anhydride (10 ml) and anhydrous sodium acetate (500 mg). The peracetate of **5** was obtained as a syrup which crystallized on seeding with crystals obtained by g.l.c. Crude yield 346 mg, m.p. 95–100°. Two recrystallizations from ethanol (20 ml/g) gave 6-*O*-(4-*O*-methyl-β-D-glucopyranosyl)-D-galactitol octaacetate m.p. 104–106°, $[\alpha]_D$ −31.3° (*c*, 2.2 in chloroform), R_f 0.35 solvent A). Retention time on column *c* at 275° 8.0 min (sucrose octaacetate 5.1 min). The n.m.r. spectrum of the acetate in $CDCl_3$ did not show clearly the signal for the anomeric proton but the free alditol **5** in D_2O showed $J_{1,2}$ 7.5 Hz (τ 5.53, Me_4Si external) (20).

Anal. Calcd. for $C_{29}H_{42}O_{19}$: C, 50.12; H, 6.10. Found: C, 50.09; H, 6.07.

Conformational Studies of the Benzophenone and Thiobenzophenone Radical Anions

F. C. ADAM AND LEON J. AARONS[1]

Department of Chemistry. University of Calgary. Calgary. Alberta

Received October 25, 1971

A conformational energy map is calculated for the anions of benzophenone and thiobenzophenone, using a Bartell repulsion potential. A low energy configuration is obtained in which the phenyl rings are counterrotated by 30° from the planar form. The energy barrier to concerted rotation is also calculated and found to be in reasonable agreement with the findings of Takeshita and Hirota for the oxyketyl. Spin density distributions are also given.

Un diagramme d'énergie conformationnelle a été calculé pour les anions de la benzophénone et du thiobenzophénone en se servant d'un potentiel de répulsion de Bartell. On obtient une configuration de faible énergie dans laquelle les noyaux phényl effectuent une contre-rotation de 30° relativement à la forme planaire. On calcule aussi la barrière énergétique à la rotation concertée et notre résultat est en accord avec les découvertes de Takeshita et Hirota sur l'oxycétyl. On donne aussi les distributions de densité de spin.

Canadian Journal of Chemistry, **50**, 1427 (1972)

Recent electron spin resonance (e.s.r.) studies by Takeshita and Hirota (1) have shown that at low temperatures the benzophenone radical anion has two sets of non-equivalent ortho protons. These result from the fact that at low temperatures the frequency of rotation of the phenyl rings is low compared to the frequency difference between the hyperfine couplings at the two sites. Adam and Falle (2) have suggested that the phenyl rings in radicals of the diaryl methyl type undergo a concerted rotation; this motion must occur with a minimum loss of delocalization energy but because of the steric repulsion energy between the ortho groups the system goes through a configuration in which only one ring is coplanar with the carbonyl group. The frequency of this rotation increases at higher temperatures until it is much greater than the difference in hyperfine couplings in which case identical couplings are observed from all ortho sites. Because of an interest in the structure of the benzophenone and thiobenzophenone anion radicals and their ion pairs (3), we have undertaken a theoretical study of the conformation of these systems.

The method used is similar to that used by Laidlaw and Flewwelling (4) and involves the minimization of the total energy (E_T) defined by:

$$E_T = E_\pi + E_S$$

[1]Present address: Department of Chemistry, University of Manchester, Manchester, England.

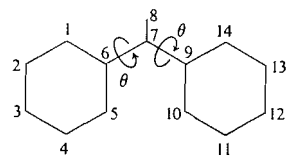

FIG. 1. Geometry of systems studied.

where E_π is the total π-electron energy and E_S is the steric repulsion energy.

E_π was calculated using the Pariser–Parr–Pople (PPP) (5) technique. The numbering system and geometry of the system is shown in Fig. 1. All C—C bonds of the aromatic rings were taken as 1.40 Å and extracyclic C—C bonds (6—7 and 7—9) as 1.48 Å. The C—O and C—S bonds (7—8) were taken as 1.23 and 1.71 Å, respectively (6). The C—H bonds were taken as 1.08 Å. The parameters used in the calculation are listed in Table 1.

E_S was calculated using the formulae of Bartell (10) which are given by eqs. 1, 2, and 3 for C—C, C—H, and H—H nonbonded repulsions respectively with V in eV and r in Å. The total repulsion energy was obtained by summing over all pairs of interacting atoms.

$$[1] \qquad V_{CC}(r) = 12\,800r^{-12} - 1.41 \times 10^3 r^{-6}$$

$$[2] \qquad V_{CH}(r) = [-5.42 + 1.94 \times 10^3 \times \exp(-r/0.490)]r^{-6}$$

$$[3] \qquad V_{HH}(r) = -2.14r^{-6} + 2.86 \times 10^2 \times \exp(-r/0.245)$$

8	0.6540	0.6487	

*Spectra taken by sodium reduction in 1,2-dimethoxyethane (3) at reduced temperature (−50 °C). Experimental spin densities were calculated using McConnell's relation (14), $a_i = Q\rho_i$ where Q is a parameter taken as −27.0 Oe.

The conformations in which each ring has been rotated through equal and opposite angles (θ) were considered to be the low energy configurations as suggested by Adam and Falle (2). The formulae failed to give reasonable results around $\theta = 0°$ but these regions are obviously energetically unfavorable due to ortho proton–proton repulsion so these values were ignored. The conformational energy maps for benzophenone and thiobenzophenone are shown in Fig. 2. Both curves suggested minima in E_T at about 30°.

The results of our calculation suggest that both the benzophenone and thiobenzophenone radical anions are non-planar. The decrease in steric repulsion, which results mainly from the interaction between the ortho groups 5 and 10, compensates for the loss in π delocalization energy. The angle of rotation in the benzophenone radical anions is slightly reduced from that of benzophenone in the crystal (11) (33°) and that calculated by Hoffman and Swenson (12) (38°) for the ground state of benzophenone This is in accord with a suggestion of Rieger and

Fraenkel (13) who noticed that the calculated bond order between the carbonyl carbon atom and the phenyl rings increased from 0.323 in neutral benzophenone to 0.428 in the anion.

The barrier to concerted rotation was calculated as the energy difference between the above conformation with $\theta = 30°$, and that in which one ring is perpendicular to, and the other is coplanar with, the carbonyl group. The result is 0.34 eV, ($\sim$7.5 kcal mol^{-1}), about twice as large as the barrier to rotation of the phenyl rings found experimentally by Takeshita and Hirota (1) *i.e.* about 5 kcal mol^{-1} for the benzophenone radical anion. A value of 0.39 eV was found for thiobenzophenone. Finally the results of the spin density calculations for the benzophenone and thiobenzophenone anions in the planar ($\theta = 0°$) and non-planar ($\theta = 30°$) conformations are given in Table 2. It is evident from the table that the calculated ring proton spin densities are relatively insensitive to twist of the phenyl rings. Hence the comparison of calculated and observed hyperfine splitting constants could prove misleading if used as a basis for configurational studies concerning these compounds. The use of conformational energy maps would appear to be a more satisfactory technique.

Quenching of Fluorescence of Chloropentafluoroacetone by Saturated Hydrocarbons

A. J. Yarwood

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 9, 1971

Saturated hydrocarbons can quench the electronically excited singlet state of a simple ketone in the gas phase. Measurements on the quenching of the fluorescence yield of chloropentafluoroacetone at 23 °C show that different saturated hydrocarbons can deactivate the excited singlet state with varying efficiencies. The quenching rate constants are reported and possible relationships considered.

Les hydrocarbones saturés peuvent réprimer l'état singulet électroniquement excité d'une cétone simple en phase gazeuse. Des mesures de répression du rendement de la fluorescence du chloropentafluoroacétone à 23 °C montrent que certains hydrocarbones saturés peuvent désactiver l'état excité singulet avec une efficacité variable. On rapporte les constantes de vitesse de répression et on considère les relations possibles.

Canadian Journal of Chemistry, **50**, 1429 (1972)

Introduction

$^3P_1$ state of mercury by saturated hydrocarbons. More recent research has shown that the processes involved in the triplet mercury quenching are quite complex (2–7).

The triplet states of not only atoms, but also molecules, can be deactivated by collisions with saturated hydrocarbons. Thus, the photoreduction of aromatic ketones in solution is a well documented reaction (8) and the photoreduction of the triplet state of acetone in *n*-hexane has been reported (9). The first example of a photoreduction in the gas phase was reported by Whittemore and Swarc (10). They found that hexafluorobiacetyl was reduced on photolysis in the vapor and in solution in presence of saturated hydrocarbons. A chemical effect of isobutane was proposed by Kutschke and coworkers (11, 12,) to explain the observed quenching in the photolysis of hexafluoroacetone. Direct measurements (13) of the effect of isobutane on the phosphorescence lifetime of hexafluoroacetone in the gas phase showed clearly that there was an interaction ($k_Q = 1.2 \times 10^8\ M^{-1}\ s^{-1}$) between the isobutane and the triplet state of hexafluoroacetone.

Although the interaction of the triplet state of atoms and molecules with saturated hydrocarbons is now well-illustrated, there is little research reported on the interaction of electronically excited singlet states with saturated hydrocarbons. This paper reports the quenching of the electronically excited singlet state of chloropentafluoroacetone by saturated hydrocarbons in the gas phase.

Experimental

Chloropentafluoroacetone was supplied by Allied Chemical Co. and was purified as described earlier (14). The following hydrocarbons were C.P. grade chemicals supplied by Matheson Co. (all were used after distillation at suitable low temperatures in which large head and tail fractions were discarded): ethane, propane, *n*-butane, 2-methylpropane, and 2,3-dimethylpropane. Philips Research grade 2-methylpropane was also studied. The 2-methylbutane (Philips Pure grade), *n*-pentane (Matheson, Coleman and Bell, spectroquality), and germane (a gift of Dr. T. Birchall) were also used after distillation at low temperature. The cyclopentane and 2,3-dimethylbutane (Chemical Samples Co.) were both greater than 99.9% pure and were used after being deaerated.

The fluorescence equipment used in this study has been described earlier (15). In this investigation similar techniques were used; however, in all cases the ketone and hydrocarbon were mixed using an efficient all-glass pump that was driven magnetically.

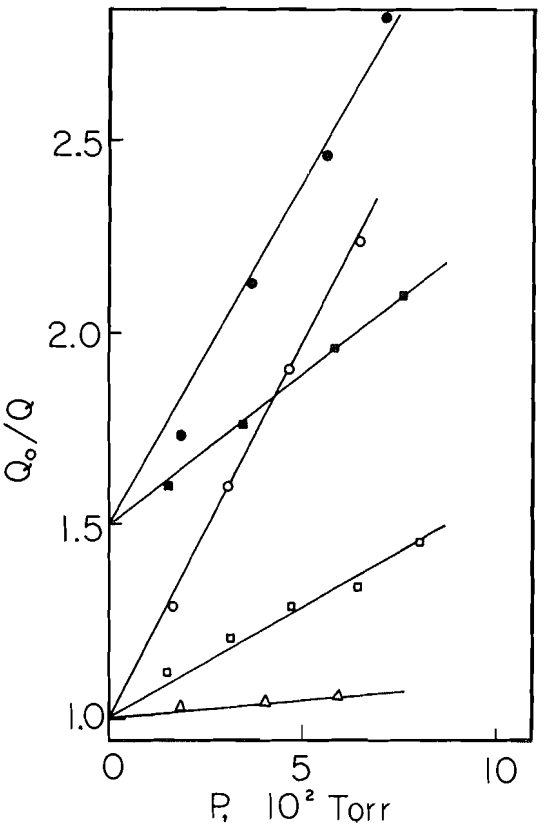

FIG. 1. Quenching of fluorescence of chloropentafluoroacetone. ○, 2-methylpropane; □, 2,2-dimethylpropane; △, ethane; ●, *n*-butane; ■, propane. N.B. The *n*-butane and propane data are displaced vertically in 0.5 units.

Results

The fluorescence of chloropentafluoroacetone (temperature, 23 °C and pressure, 200 ± 5 Torr) was excited at 313 nm and the quenching efficiencies of the hydrocarbons were deduced from the decreased fluorescence intensities when the hydrocarbons were present. Figure 1 shows the results for *n*-butane, propane, 2-methylpropane (Research grade sample), 2,2-dimethylpropane, and ethane. There are good linear relations between Q_0/Q and the pressure of the quencher. Q is the relative fluorescence yield in the presence of the quencher and Q_0 the relative fluorescence yield for the pure ketone. Figure 2 shows the Stern–Volmer plots for 2,3-dimethylbutane and *n*-pentane. Figure 3 includes the data for cyclopentane, germane, and 2-methyl-

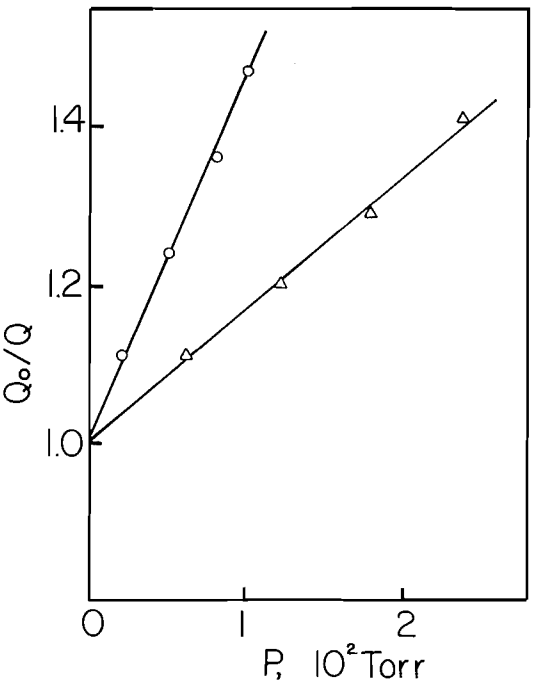

FIG. 2. Quenching of fluorescence of chloropentafluoroacetone. ○, 2,3-dimethylbutane; △, *n*-pentane.

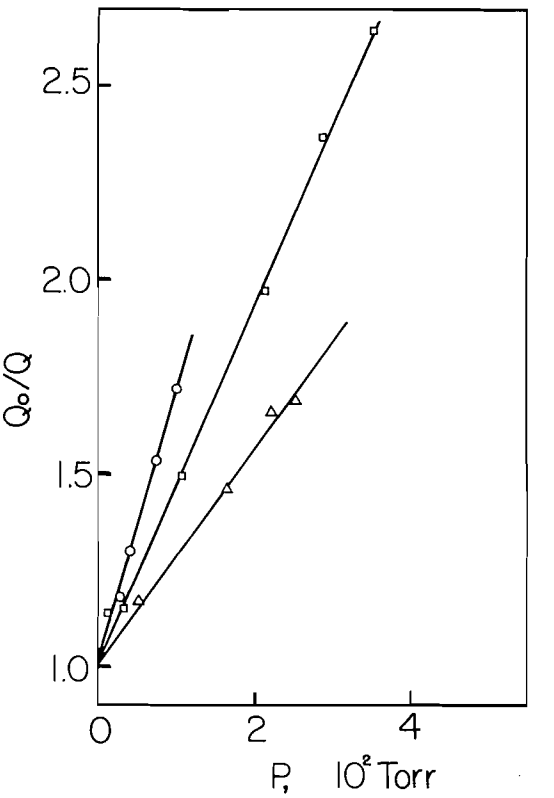

FIG. 3. Quenching of fluorescence of chloropentafluoroacetone. ○, cyclopentane; □, germane; △, 2-methylbutane.

butane. In each case good linear behavior is observed.

Discussion

Only fluorescence is observed when chloropentafluoroacetone is excited in the n,π^* band in the gas phase (14). On excitation at 313 nm, it was found that the relative fluorescence yield Q_0 was independent of the ketone pressure when the pressure was larger than about 150 Torr. Thus, deactivation of the initially populated vibrationally excited singlet levels is expected to be complete at a pressure of 200 Torr. The quenching efficiencies reported are for ketone molecules in low vibrational levels of the electronically excited singlet state.

The plots of Q_0/Q *vs.* pressure of quencher shown in Figs. 1–3 are linear, so the kinetics of the quenching can be explained in terms of a simple bimolecular quenching reaction (rate constant k_Q). The slopes of the lines in the figures are related to $k_Q\tau$ where τ is the actual lifetime of the ketone singlet state in the absence of quencher. τ has been measured (14) as 3.5×10^{-8} s and the quenching rate constants for the hydrocarbons are shown in Table 1.

TABLE 1. Rate constants for quenching of singlet chloropentafluoroacetone

Quencher	$k_Q(M^{-1}\ s^{-1})$
Ethane	5.0×10^7
Propane	4.1×10^8
n-Butane	9.4×10^8
2-Methylpropane	1.0×10^9
n-Pentane	9.0×10^8
2-Methylbutane	1.5×10^9
2,2-Dimethylpropane	3.0×10^8
Cyclopentane	3.7×10^9
2,3-Dimethylbutane	2.5×10^9
Germane	2.5×10^9

Since the saturated hydrocarbons could contain small amounts of olefins as impurities, care was taken in the purification procedure. The first experiments were, in fact, done using a sample of C.P. grade 2-methylpropane supplied

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by Matheson. The results of that experiment are not shown in figures since the quenching rate constant obtained was essentially the same as for the research grade sample studied later, Fig. 1. It is believed that the rate constants shown in Table 1 represent intrinsic quenching by the saturated hydrocarbons. The quenching behavior of saturated hydrocarbons on the excited singlet state of a simple ketone was discovered independently by Kutschke (17) in a study of the fluorescence of hexafluoroacetone.

Recently the quenching by unsaturated hydrocarbons of the singlet state of chloropentafluoroacetone was reported (15) and an intriguing relationship between the rate constants was noted. For olefins that do not contain electron-withdrawing groups, it was found that there was a linear relation between the logarithm of the quenching rate constant and the ionization potential of the quenching molecule. The possibility of a similar relationship in the quenching by saturated hydrocarbons was considered. For many of the molecules, the data were consistent with the notion that a quencher with a high ionization (*e.g.* ethane, $5 \times 10^7\ M^{-1}\ s^{-1}$, 11.5 eV) had a lower quenching rate constant than a quencher with a low ionization potential (*e.g.* 2-methylbutane, $1.5 \times 10^9\ M^{-1}\ s^{-1}$, 10.3 eV). However, the correlation could not encompass all the data since the results for cyclopentane and 2,2-dimethylpropane deviated significantly. The quenching rate constant for 2,2-dimethylpropane is $3.0 \times 10^8\ M^{-1}\ s^{-1}$ and it has an ionization potential of 10.4 eV (16), whereas cyclopentane, with an ionization potential of 10.5 eV, has a quenching rate constant of $3.7 \times 10^9\ M^{-1}\ s^{-1}$. The quenching rate constant observed for 2,2-dimethylpropane is much smaller than might have been anticipated on the basis of a relation with the ionization potential.

When the individual values are considered some interesting aspects of the quenching are noticed. The values of the rate constants for the sequence ethane, propane, 2-methylpropane, 2,2-dimethylpropane suggest that the interaction of the excited singlet state ketone molecule is with the carbon–hydrogen bond. The rate constant for quenching by molecules with tertiary C—H bonds is larger than that for molecules with secondary bonds and this in turn is greater than that for molecules with primary C—H bonds. This suggestion is supported by the data on the substituted butanes. The rate constants increase along the series *n*-butane, 2-methylbutane and 2,3-dimethylbutane; also, the rate constant for 2-methylbutane is larger than that for 2-methylpropane.

The rate constant increases along the series ethane ($5 \times 10^7\ M^{-1}\ s^{-1}$), propane ($4.1 \times 10^8\ M^{-1}\ s^{-1}$) and *n*-butane ($9.4 \times 10^8\ M^{-1}\ s^{-1}$), but the value is smaller for *n*-pentane ($9.0 \times 10^8\ M^{-1}\ s^{-1}$) than for *n*-butane. Therefore, the quenching rate constant cannot be considered as a simple additive function of the number of methylene groups in quenching molecules. It should also be noted that the rate constant of cyclopentane quenching is more than twice that for quenching by *n*-pentane; germane is a surprisingly efficient quenching molecule.

In summary, saturated hydrocarbons can quench the electronically excited singlet state of chloropentafluoroacetone. The rate constants are consistent with the view that the interaction is with the carbon–hydrogen bond. The sequence of quenching ability of carbon–hydrogen bonds is tertiary > secondary > primary.

I thank the National Research Council of Canada for financial support and Dr. K. O. Kutschke for communicating his results prior to publication.

The Cotton Effects of Conjugated Homoannular Dienes. I. The Non-generality of the Rule of Moscowitz[1]

J. LESSARD[2]
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 9, 1971

The non-generality of the diene rule of Moscowitz, relating the helicity of a non-planar conjugated homoannular diene to the sign of its Cotton effect, is discussed. We report the preparation of 3β-bromoacetoxy-16α-ethyl-16²-cyano-16²,21-cyclo-5α-pregna-17,21-diene, the X-ray crystallographic analysis of which confirms, as reported by Ahmed and Pollard, the stereochemistry which we previously assigned to the parent alcohol and acetate. We also report the synthesis of the methyl ketonic analogues of these dienonitriles and show that their sodium borohydride reduction product still has a Cotton effect in contradiction to the diene rule. The implications of these and other experiments are discussed.

On discute la non-généralité de la règle diénique de Moscowitz qui met en relation l'hélicité de dienes homoannulaires conjugués non planaires au signe de leurs effets Cotton. Nous rapportons la préparation du bromoacétoxy-3β éthyl-16α cyano-16² cyclo-16²,21 (5α)pregnadiène-17,21 dont l'analyse cristallographique aux rayons X, rapportée dans une publication parallèle par Ahmed et Pollard, confirme la stéréochimie que nous avons attribuée précédemment aux dérivés 3β-hydroxy et 3β-acétoxy et qui est en opposition avec la règle de Moscowitz. Nous décrivons la synthèse des analogues méthylcétoniques de ces diénonitriles et montrons que la réduction du groupe cétonique ne résulte pas dans une inversion du signe de l'effet Cotton. Nous discutons, ensemble avec d'autres données, les implications de ces expériences.

Canadian Journal of Chemistry, **50**, 1433 (1972)

In previous publications in our series on cyanoethylations and Michael additions, we have shown that the cyanoethylation of certain α,β-unsaturated aldehydes and ketones may take place in the γ-position, with cyclization, leading to allylic cyclohexenols, substituted in the α′-position by a nitrile group, and to derivatives of such products, such as conjugated dienonitriles arising by dehydration of the alcohols (1, 3–7). The experiments had been carried out with a steroid aldehyde (4, 5), an aldehyde of the D-homo steroid series (6), an aldehyde derived from decalin (1, 7), and a steroid ketone (3) (*cf.* partial formula **i**). On the basis of chemical and physical evidence, in particular of n.m.r. analyses, we assigned to the main reaction products of the steroidal carbonyl compounds (with a five-membered D-ring) a β-hydrogen-configuration at the new ring junction, position 16 (*cf.* partial structures **ii** and **iii**) (3, 5, 8). These assignments were, however, in opposition to the diene rule of Moscowitz (9) which relates the sign of the Cotton effect of a non-planar homoannular diene to its helicity (*cf.* 1, 4–8). Since our findings seemed to represent the first exceptions to this rule which has rendered important services in stereochemical structure determinations, it appeared opportune to confirm our conclusions by a crystallographic X-ray analysis.

We therefore prepared the bromoacetate **1***b*

of 16α-ethyl-16²-cyano-16²,21-cyclo-5α-pregna-17,21-dien-3β-ol (**1**), as described in the Experimental. The product which, just as the free alcohol **1** and the acetate **1***a*, exhibits a negative Cotton effect, in opposition to Moscowitz' rule, was subjected by Ahmed and Pollard of the National Research Council of Canada to a crystallographic X-ray analysis which confirmed fully our stereochemical assignments and thus the non-generality of the diene rule. Ahmed and Pollard report their results in a parallel publication (10).

We demonstrated the limitations of the diene rule not only by the "exceptional" Cotton effects of the dienonitriles **1**, **1***a*, and **1***b*, the methyl ketonic analogue **1***c* of dienonitrile **1***a*, and the 16-epimer **2** of dienonitrile **1***a*, but also by those of the conjugated dienones **4** and **4***a*, which we had prepared by a Diels–Alder addition of acrylonitrile to the enol acetate **3** (8) and now also by the reaction of dienonitrile **1***a* with methyllithium (see Experimental).

One could have envisioned that the "exceptional" Cotton effects of these homoannular dienes be related to their conjugation with a nitrile function or a carbonyl function. We therefore reduced dienone **4***a* with sodium borohydride; the resulting product (*cf.* **5**), still showed an "abnormal", negative, Cotton effect which makes such a hypothesis improbable. A referee has kindly drawn to our attention that the sign of the Cotton effect of a steroidal 5α-hydroxy 6α-acetoxy 7,14-diene is opposite to that of the 5,6-unsubstituted product and that conclusions drawn from the Cotton effect of an allylic conjugated dienol are, therefore, subject to caution. We may also refer in this respect to a very recent article by Beecham *et al.* (11), in which the determining influence of allylic oxygen on the Cotton effects of non-planar dienes is demonstrated. However, in these examples, the allylic oxygen is attached directly to a ring and has a fixed geometry, a situation which does not prevail in the case of "aliphatic" allylic alcohols of type **5**. Furthermore, as already reported (6), dienonitrile **6** of the D-homo steroid series, to which, on the grounds of chemical and n.m.r. evidence, we assign a 17β-hydrogen configuration, shows a "normal", positive, Cotton effect, in agreement with Moscowitz' rule, in spite of the conjugation of the diene system with a nitrile group, so that the "anomaly" of the other Cotton effects observed by us can definitely not be rationalized solely on the grounds of the conjugation of the diene system with a nitrile or keto group or, for that matter, on the grounds

of allylic substitution with an aliphatic hydroxy group.

The pertinent optical data of the homoannular dienes discussed in this publication are summarized in Table 1[4] and related to the helicities of the diene systems and to the signs of the Cotton effects expected on the grounds of the diene rule of Moscowitz. We are greatly indebted to Prof. G. Wagnière and Mr. R. Geiger, University of Zurich, Switzerland, for the c.d. measurements, and to Prof. P. Crabbé, Syntex S.A., Mexico, for the o.r.d. curves of dienes **1***a* and **2**, and we also thank sincerely Prof. A. Burgstahler, University of Kansas, Lawrence, Kansas, for having kindly supplied us with the c.d. measurement of dienonitrile **1***b* in another solvent. As already indicated, it is apparent that the D-homo dienonitrile is the only product of this series whose Cotton effect is in agreement with the diene rule of Moscowitz, although one may note that the magnitude of this Cotton effect is lower than that of the Cotton effects of the other dienonitriles under discussion. The relatively low value of the negative o.r.d. extremum of the allylic dienol **5** (which is, actually, a mixture of epimeric alcohols) could point to a potentiating effect of a nitrile group in conjugation with the diene system, if one compares it with the extrema of the dienonitriles of the steroid series with a non-expanded D-ring. However, the consideration of both the sign and the magnitude of the Cotton effect of dienonitrile **6** of the D-homo series clearly indicates how cautious one has to be in attempting to establish such correlations. It seems that at this stage the only reasonably safe conclusion which may be drawn from our results is the assumption that the sign of the long-wavelength Cotton effect of complex homoannular dienes appears to depend to an appreciable extent on the environment of the optically active chromophore. This would become plausible if one accepts the recent suggestion of Burgstahler and Barkhurst (12) that the optical activity of nonplanar dienes were not due primarily to the inherent chirality of the diene system but to asymmetric perturbations of the double bond components. However, it must be pointed out that our results are also in opposition to the "axial allylic diene rule", proposed by Burgstahler and Barkhurst, which rationalizes the observed effects on the grounds of "asymmetric perturbations of the chromophore . . . through excited-state interactions with their allylic axial or pseudo-axial bonds".

On the other hand, our tentative suggestion (1, 3) that the apparently anomalous optical properties of our steroid dienes may be related to the fact that in these compounds one of the double bonds of the diene system is attached to a rigid five-membered ring, must be abandoned, or must at least be regarded as an over-simplification. Indeed, in a recent communication[5] (13),

[4]Copies of the original spectra are available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[5]We sincerely thank Prof. P. Crabbé for sending us the manuscript prior to publication.

Crabbé and Guzmán describe a homoannular diene (B-nor-androsta-2,4-dien-3β-ol), one of the double bonds of which is attached to a rigid five-membered ring and which, in spite of that fact, exhibits a "normal" Cotton effect. Its relatively low magnitude could possibly confirm an influence of the size of the ring to which the diene system is attached but, evidently, other structural features also influence the optical activity of the chromophore.[6] Hence, a more detailed study becomes necessary for the explanation of the particular optical behavior of our pentacyclic steroid dienes. Work in this direction has been initiated in our laboratory.

Experimental[7]

3β-Bromoacetoxy-16α-ethyl-16^2-cyano-16^2,21-cyclo-5α-pregna-17,21-diene (1b)

To a solution of 200 mg of 3β-hydroxy-16α-ethyl-16^2-cyano-16^2,21-cyclo-5α-pregna-17,21-diene (**1**) (5), m.p. 199–200°, in 4 ml of absolute benzene and 0.06 ml of pyridine, 0.048 ml of bromoacetyl bromide was added and the mixture was left at room temperature for 15 h. The precipitate was filtered and washed with absolute benzene, the washings were combined with the filtrate which was then taken to dryness *in vacuo*. The crystalline residue was dried by repeated evaporation with benzene and recrystallized from ether–hexane to give 230 mg (86%) of the bromoacetate **1***b*, m.p. 187–189°. For analysis, a sample was recrystallized twice from ether–hexane; m.p. 191–191.5°; $[\alpha]_D^{25}$ −255.5° (*c*, 1.00 in $CHCl_3$); o.r.d. (*c*, 0.0012 in CH_3OH, 50 mm cell): $[\alpha]_{450}$ −500, $[\alpha]_{400}$ −1080, $[\alpha]_{350}$ −3000, $[\alpha]_{322}$ −6325, $[\alpha]_{314}$ −6670 (min), $[\alpha]_{308}$ −5670, $[\alpha]_{288}$ 0, $[\alpha]_{270}$ +4590, $[\alpha]_{258}$ +5340 (max), $[\alpha]_{244}$ +4840, $[\alpha]_{230}$ +4170° (negative Cotton effect); λ_{max} (EtOH) 296 nm (ε 11 130); ν_{max} (KBr) 3050 (vinylic hydrogens), 2180 (conjugated nitrile), 1740 (acetate), 1658 and 1572 (conjugated double bonds), 1285 (acetate), 1112, 1002, 988, 855, 840, and 680 cm^{-1}; n.m.r.: δ ($CDCl_3$) 1.84 (s) (18- and 19-CH_3), 2.35 (m) (16^1-CH_2), 2.70 (m) (16β-H), 3.78 (s) ($BrCH_2CO$), 4.80 (m) (3α-H), 5.60 (d of d, J = 5.0 and 2.5 Hz) (20-H), and 6.72 (d of d, J = 5.0 and 2.0 Hz) (21-H) (A/B system).

Anal. Calcd. for $C_{26}H_{34}O_2NBr$: C, 66.16; H, 7.26; N, 2.97; Br, 16.93. Found: C, 66.34; H, 7.22; N, 3.03; Br, 16.99.

[6]Crabbé and Guzmán indeed point out significant changes in the magnitude of Cotton effects upon changes of certain substituents (13).

[7]The melting points were taken in evacuated capillaries and the temperatures were corrected. The microanalyses were performed by the microanalytical laboratory of Drs. F. and E. Pascher, Bonn, Germany, to whom we are much obliged. For chromatography non-alkaline aluminum oxide Woelm, activity III, and Davison's silica gel no. 923 were used. The i.r. spectra were recorded on a Beckman model IR-4 spectrophotometer, the u.v. spectra on a Beckman model DK-1A spectrophotometer, the rotatory dispersion curves on a Jasco ORD/UV-5 instrument, and the n.m.r. spectra on a Varian A-60 spectrometer, in deuteriochloroform, tetramethylsilane serving as internal standard.

3β-Acetoxy-16α-ethyl-16^2-acetyl-16^2,21-cyclo-5α-pregna-17,21-diene (4a)

To a solution of 132 mg of 3β-acetoxy-16α-ethyl-16^2-cyano-16^2,21-cyclo-5α-pregna-17,21-diene (**1***a*) (4, 5) in 10 ml of absolute ether, 3.5 ml of a 0.5 *N* ethereal methyllithium solution was added in the course of 4 h. The progress of the reaction was followed by t.l.c. analysis. The formation of the methyl ketones **4** and **4***a* seemed to come to an end when a proportion of 1:2 of the ketones and the starting material was attained. The reaction mixture was poured into ice water and the precipitate was extracted with ether. The ethereal layer was washed with water and dried over sodium sulfate. The solvent was evaporated and the amorphous residue (125 mg) subjected to preparative t.l.c. on silica gel, using a benzene–ether (4:1) system. Two principal fractions were separated. The first one afforded 26 mg of *16α-ethyl-16^2-acetyl-16^2,21-cyclo-5α-pregna-17,21-dien-3β-ol (4)*, m.p. 180–185°, ν_{max} ($CHCl_3$) 3610 and 3450 (hydroxyl), 3010 (vinylic hydrogens), 1662, 1645, and 1575 ($\alpha,\beta,\gamma,\delta$-unsaturated ketone), 1040 cm^{-1} (hydroxyl). The product was acetylated in the usual fashion in 1 ml of pyridine with 0.5 ml of acetic anhydride. The crude reaction product (28 mg), m.p. 162–172°, representing *3β-acetoxy-16α-ethyl-16^2-acetyl-16^2,21-cyclo-5α-pregna-17,21-diene (4a)* was purified by preparative t.l.c. on silica gel, with the system benzene–ether (95:5), to give 18.5 mg of the pure methyl ketone **4***a*, m.p. 182–184°, not depressed upon admixture of a sample prepared from enol acetate **3** (8); $[\alpha]_D$ −204, $[\alpha]_{578}$ −214, $[\alpha]_{546}$ −251, $[\alpha]_{436}$ −609, $[\alpha]_{365}$ −3590° (*c*, 0.1 in dioxane); λ_{max} (EtOH) 318 nm (ε 12 700); ν_{max} ($CHCl_3$) 3005 (vinylic hydrogens), 1748 (acetate), 1662, 1647, and 1575 ($\alpha,\beta,\gamma,\delta$-unsaturated ketone), 1264 and 1248 (acetate), 1026 cm^{-1} (acetate and alcohol); n.m.r.: δ($CDCl_3$) 6.97 (d of d, J = 5.5 and 2.5 Hz) (21-H), 5.67 (d of d, J = 5.5 and 2.0 Hz) (H-20), 4.70 (m) (3α-H), 3.2-2.6 (complex absorption, three protons: 16β-H, 16$^1\alpha$-H, and 16$^1\beta$-H), 2.28 (methyl ketone), 2.02 (acetate), 0.87 (19- and 18-CH_3).

The second main fraction consisted of 33 mg of dienonitrile **1**, m.p. 194–197°, whose i.r. and n.m.r. spectra were identical with those of an authentic sample (5). Acetylation under the usual conditions in 1 ml of pyridine with 0.5 ml of acetic anhydride gave 33 mg of crude *acetoxy dienonitrile 1a* which, upon purification by t.l.c., gave 30 mg of pure product, m.p. 170–172°, ξ_{max} (EtOH) 299 nm (ε 10 100), identified by the determination of a mixture melting point and by the comparison of its infrared spectrum with that of an authentic product (**5**).

Reduction of 3β-Acetoxy-16α-ethyl-16^2-acetyl-16^2,21-cyclo-5α-pregna-17,21-diene (4a)

To a solution of 15 mg of the acetyl diene **4***a* in 3 ml of absolute alcohol containing traces of pyridine (to avoid acidity), 5.5 mg of sodium borohydride was added portionwise, within 2 h. After that period, the reaction mixture did not contain any starting material, as evidenced by thin-layer analysis. The product was poured into ice water and acidified at 0° with 0.1 *N* hydrochloric acid to p*H* 4, the precipitate was extracted at 0° with ether, the ethereal layer was washed with iced sodium bicarbonate solution and with ice water, and was dried over sodium sulfate. Removal of the solvent *in vacuo*, at a bath temperature not exceeding 35°, gave 16 mg of crude, crystalline *3β-acetoxy-16α-ethyl-16^2-(1ξ-hydroxyethyl)-16^2,21-cyclo-5α-pregna-17,21-diene (5)*. Recrystallization from ether–hexane gave a purified product, m.p. 168–172°, showing only minor impurities, by t.l.c. analysis.

A further purification was not possible since the product is extremely labile; λ_{max} (EtOH) 268 nm (ε 7100); ν_{max} ($CHCl_3$) 3600 and 3440 (hydroxyl), 1728 (acetate), 1665 and 1612 (weak bands of the conjugated diene), 1260 (acetate), 1030 cm^{-1} (acetate and alcohol); n.m.r.: δ ($CDCl_3$) 5.90 (21-H), 5.48 (20-H), 4.73 (m) (3α-H), 2.58 (H on OH-substituted carbon), 2.05 (acetate), 1.32 (d, $J = 6.5$ Hz) (CH_3 of side chain), 1.28 (d, $J = 6.5$ Hz) (CH_3 of side chain[8], 0.88 and 0.87 (19- and 18-CH_3); o.r.d. (*c*, 0.013 in dioxane[9]): $[\alpha]_{450}$ −220, $[\alpha]_{325}$ −827, $[\alpha]_{310}$ −1120, $[\alpha]_{300}$ −1430, $[\alpha]_{290}$ −1570 (min), $[\alpha]_{275}$ −675, $[\alpha]_{265}$ 0, $[\alpha]_{255}$ +375 (max), $[\alpha]_{245}$ 0 (negative Cotton effect). The allylic alcohol was too labile to be subjected to an elemental analysis. An attempt to reoxidize it with Jones' reagent (14) resulted primarily in decomposition but a very small quantity of the unsaturated ketone (**4***a*) seemed to have been formed, according to thin-layer analysis.

We sincerely thank Prof. G. Wagnière and Mr. R. Geiger, Zurich, Prof. P. Crabbé, Mexico, and Prof. A. W. Burgstahler, Lawrence, Kansas, for c.d. and o.r.d. measurements and for allowing us to include some details of these measurements in this paper. We are also very grateful to Professors Burgstahler and Crabbé for communicating to us various results prior to publication, as well as for stimulating discussions. Our appreciation is expressed to Mrs. J. Capitaine for her valuable collaboration in some of the experiments, and to Mr. D. Capitaine and Mrs. G. Pelletier for devoted technical assistance. The support of this project by the National Research Council of Canada is gratefully acknowledged.

[8]We rationalize the appearance of two peaks by the assumption that the reduction leads to two epimeric alcohols.

[9]Freshly treated with aluminum oxide, activity I, and twice redistilled.

Search for the N–N_2 Exchange Reaction

RICHARD K. LYON

Corporate Research Laboratories, Esso Research and Engineering Company, Linden, New Jersey 07036

Received August 5, 1971

Since N_3 is a stable molecule, one might expect the N–N_2 exchange reaction to occur readily; however, if the reaction exists, its rate constant is $\leq 8 \times 10^6$ cc/mol s at 1000 °C. An explanation in terms of spin conservation is discussed.

Etant donné que N_3 est une molécule stable, on pourrait prévoir que la réaction d'échange N–N_2 apparaisse aisément; cependant, si la réaction existe, sa constante de vitesse est $\leq 8 \times 10^6$ cc/mol s à 1000 °C. Une explication en termes de conservation de spin est discutée.

Canadian Journal of Chemistry, **50**, 1437 (1972)

The exchange reaction $^{18}O + {}^{32}O_2 \rightarrow {}^{16}O + {}^{34}O_2$ has been demonstrated to be a facile process, occurring with an activation energy of only 1.1 ± 0.4 kcal/mol (1). The generally accepted mechanism is $^{18}O + {}^{32}O_2 \rightarrow {}^{50}O_3^* \rightarrow {}^{16}O + {}^{34}O_2$ where O_3^* is an ozone molecule with enough internal energy to decompose. One might expect that this mechanism would be general, *i.e.*, if ABC is a stable triatomic molecule, and if the reaction A + BC → AB + C is not endothermic, then the reaction should be rapid, occurring with little or no activation energy. Consistent with this expectation, the activation energies for the reactions ^{18}O, $^{18}O + C^{16}O \rightarrow$

A further purification was not possible since the product is extremely labile; λ_{max} (EtOH) 268 nm (ε 7100); ν_{max} ($CHCl_3$) 3600 and 3440 (hydroxyl), 1728 (acetate), 1665 and 1612 (weak bands of the conjugated diene), 1260 (acetate), 1030 cm^{-1} (acetate and alcohol); n.m.r.: δ ($CDCl_3$) 5.90 (21-H), 5.48 (20-H), 4.73 (m) (3α-H), 2.58 (H on OH-substituted carbon), 2.05 (acetate), 1.32 (d, $J = 6.5$ Hz) (CH_3 of side chain), 1.28 (d, $J = 6.5$ Hz) (CH_3 of side chain[8], 0.88 and 0.87 (19- and 18-CH_3); o.r.d. (*c*, 0.013 in dioxane[9]): $[\alpha]_{450}$ −220, $[\alpha]_{325}$ −827, $[\alpha]_{310}$ −1120, $[\alpha]_{300}$ −1430, $[\alpha]_{290}$ −1570 (min), $[\alpha]_{275}$ −675, $[\alpha]_{265}$ 0, $[\alpha]_{255}$ +375 (max), $[\alpha]_{245}$ 0 (negative Cotton effect). The allylic alcohol was too labile to be subjected to an elemental analysis. An attempt to reoxidize it with Jones' reagent (14) resulted primarily in decomposition but a very small quantity of the unsaturated ketone (**4***a*) seemed to have been formed, according to thin-layer analysis.

We sincerely thank Prof. G. Wagnière and Mr. R. Geiger, Zurich, Prof. P. Crabbé, Mexico, and Prof. A. W. Burgstahler, Lawrence, Kansas, for c.d. and o.r.d. measurements and for allowing us to include some details of these measurements in this paper. We are also very grateful to Professors Burgstahler and Crabbé for communicating to us various results prior to publication, as well as for stimulating discussions. Our appreciation is expressed to Mrs. J. Capitaine for her valuable collaboration in some of the experiments, and to Mr. D. Capitaine and Mrs. G. Pelletier for devoted technical assistance. The support of this project by the National Research Council of Canada is gratefully acknowledged.

[8]We rationalize the appearance of two peaks by the assumption that the reduction leads to two epimeric alcohols.

[9]Freshly treated with aluminum oxide, activity I, and twice redistilled.

$C^{18}O + {}^{16}O, N + NO \rightarrow N_2 + O$, and $O + CN \rightarrow CO + N$ have been reported to be 6.9 (1), 0.2 (2), and 2.4 kcal/mol (3), respectively. To the author's knowledge there is only one reported exception to this expectation. Back and Mui (4), in an attempt to observe the reactions $^{15}N + {}^{28}N_2 \rightarrow {}^{29}N_2 + {}^{14}N$ and $^{14}N + {}^{30}N_2 \rightarrow {}^{29}N_2 + {}^{15}N$, injected $^{30}N_2$ into a stream of active nitrogen flowing through a hot tube. No formation of $^{29}N_2$ was observed and the authors estimate an upper limit for the exchange reaction rate constant, k_E, of 4×10^8 cc/mol s at 1000 °C. As pointed out by Benson (5), the great majority of reported A factors for metathesis reactions involving atoms may be represented as $10^{14 \pm 0.5}$ cc/mol s and values less than 10^{13} cc/mol s are theoretically implausible. Hence, the data of Back and Mui imply that the nitrogen atom molecule exchange reaction has an activation energy greater than 25 kcal. Back and Mui very tentatively suggested this might mean that N_3 is an unstable, highly repulsive structure, but subsequently Douglas and Jones (6) proved that N_3 is a stable molecule.

The author decided to investigate the nitrogen atom molecule exchange reaction by a different and more sensitive method. This method is the measurement as a function of temperature of the formation of $^{29}N_2$ during the ^{60}Co gamma irradiation of $^{28}N_2$–$^{30}N_2$ mixtures. Let $G^0_{^{29}N_2}$ be the yield per 100 eV absorbed of $^{29}N_2$ measured at room temperature. Dawes and Back (7) have demonstrated that chain reaction does not occur at room temperature. If at some higher temperature isotopic mixing occurs via a nitrogen atom chain reaction, it can be readily shown that

$$[1] \quad G_{^{29}N_2} - G^0_{^{29}N_2})/G^0_{^{29}N_2} = 2\alpha(1-\alpha)k_E \times [N_2]\tau_N G_N / G^0_{^{29}N_2}$$

where α is the mole fraction of $^{28}N_2$ in the $^{28}N_2$–$^{30}N_2$ mixture (0.671 in the present experiments), $[N_2] = [^{28}N_2] + [^{30}N_2]$, τ_N is the nitrogen atom lifetime and G_N is the yield per 100 eV absorbed of nitrogen atoms. In the above expression, isotope effects are neglected. $G^0_{^{29}N_2}$ depends on α and is $2\alpha(1-\alpha)G_{EX}$ where G_{EX} is the total exchange yield. G_N and G_{EX} have been determined by Dawes and Back (7) and are 8.84 and 7.30. If τ_N may be estimated from literature data, the right side of eq. 1 contains no unknown quantities except k_E. Hence measurement of the formation of $^{29}N_2$, over a temperature range in which chain reaction begins, provides a measurement of k_E.

The experimental procedures used were those which are standard in radiation chemistry. Samples were placed in a small furnace which had provisions for holding ^{60}Co plates in reproducible positions. One hundred hours was a typical irradiation time. The only crucial point relates to the purity of the $^{28}N_2$–$^{30}N_2$ mixtures used. Sample preparation was done on a high vacuum system on which all essential parts were made of quartz and were baked out at 600 °C and 10^{-6} Torr. Lif-O-gen Research grade $^{28}N_2$ and $^{30}N_2$ from Isomet were treated with well-degassed copper at 600 °C for 22 h. The mixture was then transferred by condensation with liquid He into a manifold of 18 quartz capsules, 1.0 cm i.d. and 9 cm long. The capsules were provided with sealoff constrictions. The quartz in the vicinity of the constrictions had been degassed by heating under vacuum with a torch to slightly less than the softening point of quartz. Sealoff was done by rapid application of a small hydrogen oxygen flame. Blank experiments showed that isotopic mixing did not occur during sealoff of the capsules. The sample capsules were then placed inside larger quartz capsules, and the latter were evacuated and sealed off. This double-walled construction prevents atmospheric oxygen from diffusing into the sample (8).

The experimental results are readily summarized (Table 1). Thermal blank experiments up to 1094 °C showed no significant production of $^{29}N_2$ due to either four center gas phase reactions or heterogeneous processes. The change of the $^{29}N_2$ to $^{30}N_2$ ratio per hour of irradiation time is $(1.10 \pm 0.13) \times 10^{-4}$ at room temperature and $(1.10 \pm 0.04) \times 10^{-4}$ at 900–1000 °C. Hence, $(G_{^{29}N_2} - G^0_{^{29}N_2})/G^0_{^{29}N_2}$ is 0 ± 0.2 at 1000 and 900 °C. The mass spectra done for $^{28}N_2$–$^{29}N_2$–$^{30}N_2$ analysis showed no impurities. High sensitivity mass spectral analysis, done after irradiation at 1000 °C with a CEC 21-104 mass spectrometer, showed traces of argon and carbon dioxide to be present. If oxygen was present, it was below the threshold of detectability, estimated to be less than 10^{-4} times the mass 30 peak, or 33 p.p.m. based on total nitrogen.

Again the N–N_2 exchange reaction has escaped detection, and only an upper limit for k_E can be calculated. Using literature data a

*Δt is irradiation time in h.

lower limit for τ_N may be calculated. The only important nitrogen atom removal processes are recombination and reaction with catalytic impurities. Impurities which are consumed by reaction with nitrogen atoms need not be considered, since they will be exhausted shortly after the start of irradiation. Due to the low dose rate (2×10^{13} eV/cc s) used in these experiments, recombination occurs chiefly by diffusion to the walls. D_{N,N_2} is reported to be 0.37 cm^2/s at 300 °K and 760 Torr (9). This implies $D_{N,N_2} = 2.5$ cm^2/s at the 1273 °K and 960 Torr. Using the solution given by Carslaw and Jaeger (10) for the analogues heat conduction problem, one may calculate that the average time for the nitrogen atoms to diffuse to the wall is 0.0122 s. Hence the average lifetime of nitrogen atoms with respect to wall recombination is $\tau_{WR} \geqslant 0.0122$ s. O_2 is the only impurity both likely to be present and known to have a high rate constant for catalytic nitrogen atom removal. The reaction sequence is $N + O_2 \rightarrow NO + O$ and $N + NO \rightarrow N_2 + O$, followed by wall recombination of the oxygen atoms. Wilson (11) has determined k_{N+O_2} to be $1.4 \times 10^{13} \exp(-7900/RT)$ cc/mol s. Hence at 1000 °C and $O_2 \leqslant 33$ p.p.m. the lifetime of nitrogen atoms towards scavenging by oxygen, τ_{O_2}, is $(2k_{N,O_2}[O_2])^{-1}$, *i.e.*, $\geqslant 0.0020$ s. The effective lifetime, τ_N, is $(\tau_{WR}^{-1} + \tau_{O_2}^{-1})^{-1}$ and $\tau_N \geqslant 0.0017$ s.

On this basis, one calculates $k_E \leqslant 8 \times 10^6$ cc/mol s at 1000 °C. If the A factor for the exchange reaction is greater than 10^{13} cc/mol s (the minimum theoretically acceptable value), the activation energy must be greater than 36 kcal. From this example, it would appear that the existence of a bonding intermediate is not a sufficient condition for the occurrence of a facile exchange reaction.

It might be argued that the principal of spin conservation must also be considered, *i.e.*, that facile reaction is to be expected if and only if the triatomic intermediate possesses an energetically accessible electronic state which correlates with reactants and products. The suggestion that a reaction which is overall spin-allowed may be slow because access to the transition state is spin forbidden is not new. It has been previously proposed to explain the slowness of the ion molecules $O^+(^4S) + N_2(^1\Sigma) \rightarrow NO^+(^1\Sigma) + N(^4S)$, which may occur via the $N_2O^+(^1\Sigma)$ ground state only by a slow spin-forbidden step (ref. 12 and references cited therein). The $N-N_2$ exchange reaction is isoelectronic with and involves the same states as this ion–molecule reaction, so the same explanation appears applicable. If one accepts that the rate determining step in the $N-N_2$ exchange is the spin-forbidden step $N(^4S) + N_2(^1\Sigma) \rightarrow N_3^*(^1\Sigma)$, then it may reasonably be compared with another spin-forbidden reaction $O(^3P) + N_2(^1\Sigma) \rightarrow N_2O^*(^1\Sigma)$. The rate constant of the latter reaction may be calculated from the observed rate constant for N_2O unimolecular decomposition in the high pressure limit (13) and the equilibrium constant. One obtains $k_{O+N_2} = 3 \times 10^9$

Non-Steady-State Kinetics for a Double-Intermediate Enzyme Mechanism: The Case of High Enzyme Concentrations

NASRAT H. HIJAZI AND KEITH J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received December 14, 1971

An equation has been derived for the non-steady-state kinetics arising from the mechanism

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EA \xrightarrow[X]{k_2} EA' \xrightarrow{k_3} E + Y$$

in which the concentration of enzyme E is greatly in excess of that of the substrate A; EA and EA′ are two intermediates and X and Y the products. Solutions for the rate of formation of the first product X were given by Kasserra and Laidler. The present work is concerned with the rate of formation of Y. A general equation is derived for the rate of production of Y, and it is shown that under certain simplifying conditions, easily realized in practice, the rate law reduces to $y = a_0(1 - e^{-k_3 t})$; study of the rate of formation of Y therefore leads to a determination of k_3.

Une équation a été obtenue pour les cinétiques en état stationnaire non constant provenant du mécanisme suivant:

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EA \xrightarrow[X]{k_2} EA' \xrightarrow{k_3} E + Y$$

La concentration en enzyme est en large excès par rapport à celle du substrat A; EA et EA′ représentent deux intermédiaires et X et Y deux produits. Les solutions concernant la vitesse de formation du premier produit X ont été données par Kasserra et Laidler. Le présent travail concerne la vitesse de formation de Y. Une équation générale a été obtenue pour la vitesse de formation de Y et il est montré que sous des conditions simplifiées, aisément réalisables en pratique, la loi de vitesse se réduit à $y = a_0(1 - e^{-k_3 t})$; l'étude de la vitesse de formation de Y conduit alors à une détermination de k_3.

Canadian Journal of Chemistry, **50**, 1440 (1972)

A considerable number of enzyme systems follow a mechanism of the type

$$E + A \rightleftharpoons EA \xrightarrow[X]{} EA' \longrightarrow E + Y$$

Here the enzyme E and substrate A form an addition complex which splits off a product X to form a second intermediate EA′ (*e.g.* an acyl enzyme); this gives the enzyme and a second product Y, usually by a solvolytic reaction. Steady-state studies do not yield a satisfactory separation of rate constants, but this can be

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EA \xrightarrow[X]{k_2} EA' \xrightarrow{k_3} E + Y$$

in which the concentration of enzyme E is greatly in excess of that of the substrate A; EA and EA′ are two intermediates and X and Y the products. Solutions for the rate of formation of the first product X were given by Kasserra and Laidler. The present work is concerned with the rate of formation of Y. A general equation is derived for the rate of production of Y, and it is shown that under certain simplifying conditions, easily realized in practice, the rate law reduces to $y = a_0(1 - e^{-k_3 t})$; study of the rate of formation of Y therefore leads to a determination of k_3.

Une équation a été obtenue pour les cinétiques en état stationnaire non constant provenant du mécanisme suivant:

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EA \xrightarrow[X]{k_2} EA' \xrightarrow{k_3} E + Y$$

La concentration en enzyme est en large excès par rapport à celle du substrat A; EA et EA′ représentent deux intermédiaires et X et Y deux produits. Les solutions concernant la vitesse de formation du premier produit X ont été données par Kasserra et Laidler. Le présent travail concerne la vitesse de formation de Y. Une équation générale a été obtenue pour la vitesse de formation de Y et il est montré que sous des conditions simplifiées, aisément réalisables en pratique, la loi de vitesse se réduit à $y = a_0(1 - e^{-k_3 t})$; l'étude de la vitesse de formation de Y conduit alors à une détermination de k_3.

Canadian Journal of Chemistry, **50**, 1440 (1972)

A considerable number of enzyme systems follow a mechanism of the type

$$E + A \rightleftharpoons EA \xrightarrow[X]{} EA' \longrightarrow E + Y$$

Here the enzyme E and substrate A form an addition complex which splits off a product X to form a second intermediate EA′ (*e.g.* an acyl enzyme); this gives the enzyme and a second product Y, usually by a solvolytic reaction. Steady-state studies do not yield a satisfactory separation of rate constants, but this can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

achieved by studies under non-steady-state conditions.

Usually such investigations, using high-speed kinetic techniques, have been carried out under the usual enzyme-kinetic conditions, with the substrate present in great excess of the enzyme. There is then a transient non-steady-state phase prior to the establishment of the steady state, and an analysis of the results in this region in principle leads to some of the rate constants. Solutions of the equations under these conditions have been given by Ouellet and Laidler (1) and by Ouellet and Stewart (2). The equations are, however, rather complex and only become sufficiently simple for application to experimental results if certain conditions are satisfied. One of these is that the substrate is in sufficiently great excess to saturate the enzyme. However, it is sometimes impossible to achieve this.

Non-steady-state studies with the enzyme present in great excess of the substrate offer some advantages in this connection, the resulting kinetic equations being simpler and more directly applicable to the experimental results. Kasserra and Laidler (3) have obtained equations for the kinetics of formation of the first product X under these conditions. They found that there was no establishment of a steady state, the concentration of X rising steadily to a limiting value equal to the initial concentration of A. Under certain conditions, which are easily realized in practice, the rise is an exponential one with a rate constant of k_2. Kasserra and Laidler applied their equations to a trypsin-catalyzed reaction and obtained k_2.

The solution for the formation of Y presents some difficulties which have been overcome in the present work.

Theoretical

The reaction scheme is

$$\begin{array}{ccccccc} \mathrm{E} + \mathrm{A} & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & \mathrm{EA} & \xrightarrow{k_2} & \mathrm{EA'} & \xrightarrow{k_3} & \mathrm{E} + \mathrm{Y} \\ & & & \searrow \mathrm{X} & & & \\ e_0 \quad a_0 - m - n - y & & m & x & n & & e_0 \quad y \end{array}$$

The concentrations of the various species are indicated in small letters. Since E is in great excess the amounts of enzyme tied up in EA and EA′ are insignificant. The differential rate equations are

[1] $\dot{m} = k_1 e_0 (a_0 - m - n - y) - (k_{-1} + k_2)m$

[2] $\dot{n} = k_2 m - k_3 n$

[3] $\dot{x} = k_2 m$

[4] $\dot{y} = k_3 n$

Kasserra and Laidler eliminated n between eqs. 1 and 2 and obtained a differential equation for which a solution was possible. The equation for m was

[5] $$m = M(\mathrm{e}^{-Ft} - \mathrm{e}^{-Gt})$$

where

[6] $$F = \tfrac{1}{2}(P - \sqrt{P^2 - 4Q})$$

[7] $$G = \tfrac{1}{2}(P + \sqrt{P^2 - 4Q})$$

[8] $$M = \frac{k_1 e_0 a_0}{G - F}$$

[9] $$P = k_1 e_0 + k_{-1} + k_2$$

[10] $$Q = k_1 k_2 e_0$$

Equations 3 and 5 lead readily to the following equation for x:

[11] $$x = \frac{k_2 M}{F}(1 - \mathrm{e}^{-Ft}) - \frac{k_2 M}{G}(1 - \mathrm{e}^{-Gt})$$

A comparable procedure in which m is eliminated between eqs. 1 and 2 unfortunately leads to a differential equation in $\ddot{n}$, $\dot{n}$, n and n^2 which cannot be solved. An alternative procedure has therefore been used; the equation for m has been inserted into eq. 2 and the resulting equation solved. Insertion of eq. 5 into eq. 2 gives

[12] $$\dot{n} = k_2 M\,(\mathrm{e}^{-Ft} - \mathrm{e}^{-Gt}) - k_3 n$$

which has to be solved subject to the boundary condition $t = 0$, $n = 0$, $\dot{n} = 0$. The solution is obtained by finding an integrating factor ρ such that

[13] $$\rho\dot{n} + \rho k_3 n = \frac{\mathrm{d}(\rho n)}{\mathrm{d}t} = n\dot{\rho} + \rho\dot{n}$$

Comparison of coefficients leads to $\dot{\rho} = \rho k_3$ where

[14] $$\rho = \mathrm{e}^{k_3 t}$$

Then

[15] $$\frac{\mathrm{d}(\rho n)}{\mathrm{d}t} = \rho k_2 M\,(\mathrm{e}^{-Ft} - \mathrm{e}^{-Gt})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

or

$$[16] \quad ne^{k_3 t} = \int_0^t e^{k_3 t}\, k_2 M\, (e^{-Ft} - e^{-Gt})\, dt$$

Integration then leads to

$$[17] \quad n = \left(\frac{k_2 M}{k_3 - F}\right) e^{-Ft} - \left(\frac{k_2 M}{k_3 - G}\right) e^{-Gt} - k_2 M \left(\frac{1}{k_3 - F} - \frac{1}{k_3 - G}\right) e^{-k_3 t}$$

Substitution of this into eq. 4 and integration subject to the boundary condition $t = 0$, $n = 0$, $y = 0$ gives

$$[18] \quad y = \frac{k_2 k_3 M}{F(k_3 - F)} (1 - e^{-Ft}) - \frac{k_2 k_3 M}{G(k_3 - G)} (1 - e^{-Gt}) - k_2 M \left(\frac{1}{k_3 - F} - \frac{1}{k_3 - G}\right)(1 - e^{-k_3 t})$$

This is the general equation for the time course of production of the second product Y.

When $t \to \infty$ it is possible to show, by expressing F, G, and M in terms of eqs. 6–8, that y reaches a limiting value of a_0; *i.e.* all of the substrate is eventually converted into product. There is no steady state, y rising in a complex exponential fashion until it becomes a_0.

An Approximate Solution

Under many conditions the Y production may be satisfactorily approximated by an expression involving only a single exponential term $e^{-k_3 t}$. In general $P^2 \gg Q$ and $G \gg F$, in which case, by a single expansion, it can be shown that

$$[19] \quad F \approx \frac{Q}{P}$$

$$[20] \quad G \approx P$$

If in addition

$$[21] \quad F \gg k_3$$

eq. 18 will be dominated by the final term and reduces, with the above inequalities, to

$$[22] \quad y = a_0 (1 - e^{-k_3 t})$$

The inequality 21 requires that

$$[23] \quad \frac{k_1 k_2 e_0}{k_1 e_0 + k_{-1} + k_2} \gg k_3$$

which requires that k_2 is sufficiently large in comparison with k_3, and is not too large in comparison with $k_1 e_0$. The analysis of experimental results in terms of the simplified eq. 22 obviously must be done in conjunction with other non-steady-state studies in which the relative magnitude of $k_1 e_0$ and k_2 can be established.

Primary Processes in the Vacuum Ultraviolet Photolysis of Ethyl Fluoride at 147 nm[1]

S. C. CHAN,[2] Y. INEL,[3] AND E. TSCHUIKOW-ROUX

Department of Chemistry, University of Calgary, Calgary 44, Alberta

Received January 13, 1972

The photolysis of C_2H_5F at 147 nm was studied at room temperature. The principal products include C_2H_3F, C_2H_2, C_2H_4, CH_4, and C_2H_6. The principal primary photochemical reactions involve the molecular elimination of HF and H_2, and, to a lesser extent, C—F and C—C bond fission. The effect of reactant and added inert gas pressure on the product yields has been investigated and it was found that the stabilization/decomposition ratio, C_2H_4/C_2H_2, displays opposite pressure dependence with ethyl fluoride and argon. This result is interpreted in terms of the higher energy transfer efficiency of the C_2H_5F molecule.

La photolyse à 147 nm de C_2H_5F a été étudiée à la température de la pièce. Les produits principaux incluent C_2H_3F, C_2H_2, C_2H_6, CH_4, et C_2H_6. Les principales réactions photochimiques primaires impliquent l'élimination moléculaire de HF et de H_2, et, à un degré moindre, la rupture des liaisons C—F et C—C. L'effet des corps réagissants et de l'addition de gaz inertes sur les rendements en produits a été étudié et il a été trouvé que le rapport stabilisation/décomposition, C_2H_4/C_2H_2, joue dans le sens inverse d'une dépendance de la pression avec le fluorure d'éthyle et l'argon. Ce résultat est interprété en termes d'une efficacité de transfert d'énergie plus élevée pour la molécule de C_2H_5F.

Canadian Journal of Chemistry, **50**, 1443 (1972)

Introduction

The unimolecular decomposition of C_2H_5F has been the subject of investigation by several workers. In the shock tube pyrolysis of C_2H_5F (1), the primary reaction was found to be molecular elimination of HF. The same mechanism was also observed in the case of excited C_2H_5F formed by chemical activation (2), while in the mercury photosensitized decomposition (3) H atom elimination appeared to be predominant. In the vacuum-ultraviolet photolysis at 147 nm the amount of energy available is very large (194 kcal) leading to a high level of excitation of the initially energized C_2H_5F molecules, and hence several reaction paths could be possible. A preliminary study of this system at 25 °C was carried out in order to identify the primary photochemical reactions.

Experimental

The experimental method was the same as described previously (4). A standard liquid oxygen cooled xenon resonance lamp was used as the light source. The lamp was equipped with a LiF window and was operated from a microwave power generator (Raytheon, Model PGM-10). The emission spectrum of the lamp which was scanned from 110 to 190 nm, showed the prominent resonance line at 147 nm and a minor contribution (~1%) at 129.6 nm. A Watson gas circulation pump was incorporated as part of the reaction vessel to prevent secondary photolysis. Analysis of products was performed by gas chromatography at 50 °C (Varian Aerograph, Model 1700) using a flame ionization detector. A 10 foot Porapak N column (80–100 mesh) was used and the flow rate of the He carrier gas was 30 ml/min. The reactant which was obtained from Peninsular Chemresearch Inc. was purified by pumping it at ethanol slush bath temperature (−117 °C) to remove low boiling impurities. Chromatographic analysis showed a residual impurity of less than 0.1% isobutane. Matheson nitric oxide and

argon of 98.5 and 99.995% stated purity, respectively, were used without further purification.

Results and Discussion

The principal reaction products are C_2H_3F, C_2H_2, C_2H_4, CH_4, and C_2H_6. No attempt was made to identify other minor products with retention times longer than that of the reactant. Preliminary experiments have demonstrated that at short photolysis time and low conversion (< 1%) the yield of products is linear with respect to the irradiation time (Fig. 1). No deviation from linearity was observed up to at least 12 min, which indicates that within this time scale, secondary photolysis of the reaction products is not important. All subsequent diagnostic experiments had irradiation times of either 10 or 15 min.

The presence of C_2H_4 and C_2H_3F as products points to the possibilities of the following primary reactions:

[1] $C_2H_5F \xrightarrow{h\nu} C_2H_5F\dagger$

[2] $C_2H_5F\dagger \longrightarrow C_2H_4^* + HF$

[3] $\longrightarrow C_2H_5\cdot^* + F$

[4] $\longrightarrow C_2H_3F^* + H_2$

[5] $\longrightarrow C_2H_4F\cdot^* + H$

The thermochemical data of these and some subsequent reactions are given in Fig. 2. Although reactions 2 to 5 are all endothermic, they are energetically allowed since the energy in the excited C_2H_5F is 194 kcal. The radicals produced in reactions 3 and 4 could split H atoms to give ethylene and vinyl fluoride

[6] $C_2H_5\cdot^* \rightarrow C_2H_4 + H$

[7] $C_2H_4F\cdot^* \rightarrow C_2H_3F + H$

The ethylene and vinyl fluoride molecules produced in reactions 2 and 4 respectively are

"hot" and could undergo further decomposition to give acetylene. In contrast, those molecules that are produced by radical decomposition, reactions 6 and 7, do not have sufficient energy to split further (see Fig. 2).

[8] $$C_2H_4^* \rightarrow C_2H_2 + H_2$$

[9] $$\rightarrow C_2H_3 + H$$

[10] $$C_2H_3F^* \rightarrow C_2H_2 + HF$$

[11] $$\rightarrow C_2H_3 + F$$

[12] $$C_2H_3 \rightarrow C_2H_2 + H$$

The activation energy of reaction 2 has been shown to be 60 kcal (1) and that of reaction 4 could not be less than 70 kcal (5), hence the excess energy in the excited C_2H_5F molecules with respect to these two reactions is 134 kcal and less than 124 kcal, respectively (Fig. 2). From an energetic point of view, these two reaction channels should be competitive, with the former slightly favored. The product distribution shows that whereas the yield of C_2H_3F and C_2H_2 is comparable the yield of C_2H_4 is much less, and hence a necessary conclusion is that the precursor of C_2H_2 is mainly the excited C_2H_4.

When ~30% of NO was added to the reactant (Runs 4 and 5), the yield of C_2H_4 and C_2H_2 decreased, which suggests that the radical reactions 6 and 12 are partly responsible for their formation. On the other hand, the results also indicate that these reactions play only a minor role: in the case of acetylene, the radical mechanism accounts for less than one-sixth of its yield; while in the case of ethylene, the yield is decreased by one-half, but it should be emphasized that most of the ethylene (~90%) initially formed by molecular elimination decomposes into acetylene (Table 1). The yield of C_2H_3F is unaffected by the presence of NO which implies that the radical reactions 5 and 7 are not important in its production. This then suggests that C_2H_3F is indeed produced by the molecular elimination reaction 4. If so, it is somewhat surprising to find that these excited vinyl fluoride molecules do not further decompose into C_2H_2 and HF since the permissible maximum excess energy is 91 kcal with respect to HF elimination (Fig. 2*c*). Photolysis of C_2H_3F at 147 nm has, however, demonstrated that at low pressure HF elimination may be insignificant (4).

Some experiments were carried out with excess nitric oxide; however, the additional NO would probably only act as an inert additive and favor the stabilization of C_2H_4 with respect to its decomposition into C_2H_2. In addition, it was also observed that the presence of an inert additive, such as Ar, reduces the absolute yield of all products. This could be explained by the stabilization of the initially energized C_2H_5F molecules.

Further, a most interesting observation is the variation of the ratio C_2H_4/C_2H_2 with total pressure. Since C_2H_4 is the precursor of C_2H_2,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

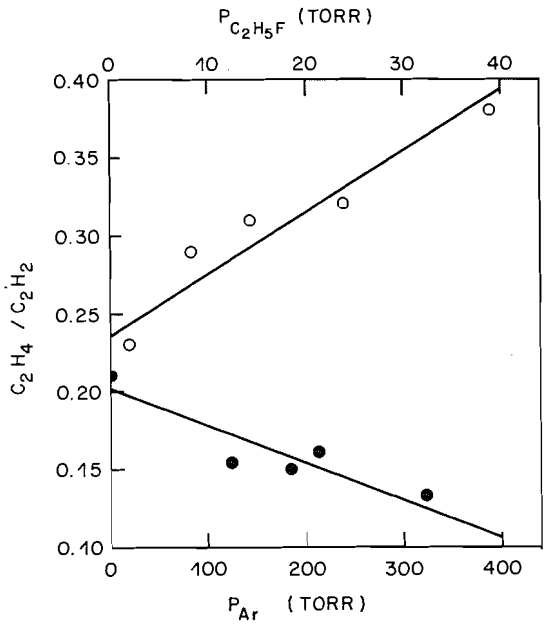

FIG. 3. Variation of the ratio C_2H_4/C_2H_2 with C_2H_5F (open circles) and Ar pressure (filled circles).

this ratio reflects the competition between stabilization and decomposition. In the pure C_2H_5F system, the ratio increases with pressure, whereas in the C_2H_5F–Ar system with a constant amount of C_2H_5F, the ratio decreases with increasing Ar pressure (Fig. 3). It is proposed that the difference in the deactivating efficiency between C_2H_5F and Ar is instrumental in these observed opposite pressure effects. Part of the C_2H_4 molecules are produced by the decomposition of $C_2H_5\cdot$ (reaction 6) and they are stable towards further decomposition. Inert added gas in the system could stabilize the radicals and thus have a diminishing effect on the ratio C_2H_4/C_2H_2. It has been shown that the energy transfer efficiency of a molecule in general increases with its molecular complexity (6); it is thus expected that C_2H_5F is much more efficient than argon. For example, it has been shown (5) in the case of highly excited vinyl fluoride that CF_4 is about ten times more efficient than He in deactivating the "hot" molecule. Ethylene produced by HF elimination from C_2H_5F may have as much as 186 kcal of energy; the activation energy for its decomposition into C_2H_2 is 80 kcal (7), hence its possible excess energy is 106 kcal (Fig. 2*a*). Ethyl radicals produced by F elimination (reaction 3) may have 89 kcal of energy. The endothermicity for decomposition into C_2H_4 and H is 39 kcal, and the activation energy of the reverse reaction is ~2 kcal (8), hence the activation energy of the forward reaction is 41 kcal and thus $C_2H_5\cdot$ has a maximum excess energy of 48 kcal with respect to its decomposition, Fig. 2*b*. Therefore, the excess energy of C_2H_5 radical is much less than that of C_2H_4. While this does not necessarily mean that its rate of decomposition is also slower, our results as discussed below seem to indicate that it is the case. Ethyl fluoride being a polyatomic molecule is expected to be very efficient in removing energy from both the excited C_2H_4 and $C_2H_5\cdot$; however, the formation of the radical (reaction 3) and its subsequent decomposition to ethylene (reaction 6) is only a minor reaction as compared to the initial production of ethylene (reaction 2) by a molecular reaction, hence the stabilization of C_2H_4 is dominant and the ratio C_2H_4/C_2H_2 increases with the pressure of C_2H_5F. On the other hand, argon being a monatomic gas is not an efficient deactivator. Its stabilizing effect would be negligible in the decomposition of C_2H_4, but a small effect may be expected in the case of $C_2H_5\cdot$ decomposition in that fewer deactivating collisions would be required to render the radical "undecomposable". This could explain the observed decrease in the ratio C_2H_4/C_2H_2 with increasing argon pressure. One could speculate that at sufficiently high argon pressure, this trend will be reversed. In order to study the variation of C_2H_4/C_2H_2 with pressure as a simple stabilization–decomposition competition, one has to remove the radical reaction. Indeed, in the C_2H_5F–NO–Ar system, we observed that the ratio C_2H_4/C_2H_2 does increase with Ar pressure (Runs 6 and 8).

In the above discussion and also in Fig. 2, we have assumed that all the excess energy resides in the larger species produced in a reaction. This is in general not true, but the error thus introduced will not invalidate the argument put forward.

Our results also indicate that C—C bond fission may occur in the primary photochemical act as shown indirectly by the presence of CH_4 and C_2H_6 in the product mixture. There is some evidence that CH_4 is produced by a molecular mechanism.

Silver Plated Bimolecular Lipid Membranes

A. PETKAU AND W. S. CHELACK

Medical Biophysics Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received November 3, 1971

The electrochemical reduction of silver ions at the surface of a model phospholipid membrane proceeds without the application of an electric field. The silver deposition is dependent on I^- and I_2. The charge transfer complexes formed by iodine with phospholipids and cholesterol are the most probable donors for the electron transfer reaction. Cholesterol membranes do not show the silver deposition unless an external electrical field is applied. An account for the difference is given on the basis of dissimilar ion distribution profiles within phospholipid and cholesterol membranes.

La réduction électrochimique des ions argents à la surface d'une membrane de phospholipide se fait sans l'application d'un champ électrique. La décomposition de l'argent ne dépend que de I^- et de I_2. Les complexes de transfert de charge, formés par l'iode avec les phospholipides et le cholestérol, sont probablement les donneurs lors de la réaction de transfert électronique. Les membranes de cholestérol ne provoquent pas de décomposition d'argent à moins qu'un champ électrique ne soit appliqué. Ces différences sont rationalisées sur la base d'une distribution ionique différente à l'intérieur des membranes de phospholipide et de cholestérol.

Canadian Journal of Chemistry, **50**, 1448 (1972)

Introduction

The existence of electrochemical reactions at membrane surfaces has been suggested as a basis for understanding the membrane potential and some aspects of ion transport (1). The model proposes that the electron transfer reaction is accelerated by an electric field applied across the double layer of a membrane/water interface. Recently, the electrochemical formation of metallic films of silver, platinum, and mercury at the surface of a membrane prepared from a solution of oxidized cholesterol has been described (2). The development of the metallic film was only seen following the application of a 50 mV potential in a direction which moved negative charge carriers from the iodide side to the metal ion side of the membrane. In terms of relating this phenomenon to the foregoing model it is of interest to determine whether the externally applied field is essential. It is conceivable that the existence of dissimilar electrochemical processes at the two intrafaces of a membrane might generate potential gradients within it that facilitated the deposition of the metal film at one intraface. In this report the results of attempts to silver plate cholesterol and phospholipid membranes in the absence of an applied electric field are described. It was found that cholesterol membranes did not develop any visible metallic film while phospholipid membranes did.

Experimental Procedure

Membrane Material

The composition of the phospholipid material has been described previously (3). In our experience the formation of a durable membrane lasting up to 21 days requires that cerebrosides, phosphatidylethanolamine, phosphatidyl inositol, and phosphatidyl serine are present in the solution from which the membrane is made. It therefore seems likely that these phospholipid components were present in the membrane as well.

Fatty acid analysis of the membrane material by gas chromatography indicated that about half of them contained one or more unsaturated carbon–carbon bonds.

Cholesterol (Reagent grade, Fisher) chromatographed as a single spot and was used without further purification.

Membrane Formation

The phospholipid material was dissolved in a minimal quantity of the apolar solvent, *n*-tetradecane, and then applied by the brush technique (4) to a 3 mm diameter aperture in a Teflon septum separating the two 4 ml aqueous compartments of a lucite cell. The lucite cell was symmetrically shaped about the Teflon septum and attached to the stage of a horizontally mounted microscope by means of a ball bearing. Microscopic observation of either side of the membrane under obliquely incident light was possible by rotating the cell back and forth through an angle of 180°. Once a membrane was formed in distilled water at 37 °C and had thinned to a bilayer, the plating solutions of reagent grade $AgNO_3$ (20 μM), KI (20 μM), and I_2 (2 μM), in that order, were added to the water. The $AgNO_3$ and KI, I_2 solutions were added to opposite sides of the membrane. Both sides of the membrane were then observed for the appearance of silver.

Results

Within 3–5 min after the addition of iodine a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

fine granular deposit became visible on the Ag^+ ion side of the membrane. In 15 min the granules became more coarse and had the reflectance, lustre, and metallic appearance of silver. The plated membrane ruptured within 30 min unless the initial amount of $AgNO_3$, added to one compartment, was reduced to 2 μM. In this case the membrane would last at least 7 h but the density of the sparkling granules was diminished giving the affected side of the membrane a speckled appearance. The opposite side of the membrane, exposed to KI and I_2, remained black as before.

The plating process was carried out in darkness as well, to determine if the microscope illuminating light might have had any noticeable effect. No change in the time of occurrence or in the appearance of the granules was observed. Illumination of the membrane was therefore not essential to the development of the silver deposit, suggesting that it was not due to a photochemical effect.

The metallic nature of the silver deposit was investigated by an indirect method. Color transparencies of the deposit were taken and compared both by transmission and incident light microscopy with similar transparencies obtained by photographing under the same light films (10–1000 Å in thickness) of Ag, AgI, and $AgNO_3$ deposited on pieces of darkened B & W film. It was found that the color transparencies of the Ag, AgI, and $AgNO_3$ films could be readily distinguished from one another and that those obtained of the Ag film corresponded with the color transparencies of the silver deposit seen on the black phospholipid membrane. Additional evidence for the metallic nature of the silver deposit was obtained by confirming earlier work (2) that the deposit did not reduce the conductivity of the membrane. By comparing the similarity in appearance of the two sets of transparencies it could be estimated that the thickness of the silver deposit on the membrane was somewhere between 10–100 Å.

The nature of the silver deposition reaction was investigated by measuring the amount of time (plating time) required to reduce a given quantity of Ag^+, as determined by visual inspection of the deposit, when the concentration of the reactants was varied one at a time. In Fig. 1 the dependence of the plating time on the concentration of iodide (I^-), keeping $[Ag^+] =$ 2 μM and $[I_2] = 0.02$ μM, is shown on a log–log plot. A first-order reaction is suggested by the linear relationship. Since the amount of Ag^+ reduced is an infinitesimal amount of the total number of Ag^+ ions initially present in the one 4 ml compartment the result shown in Fig. 1 does not distinguish between a homogeneous and heterogeneous reaction involving I^-. A similar linear relationship was obtained between the plating time and the I_2 concentration keeping $[Ag^+] = 2$ μM and $[I^-] = 20$ μM.

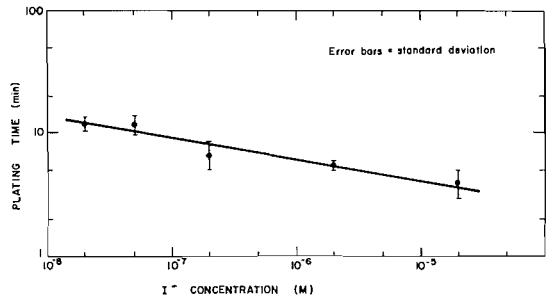

FIG. 1. Plating time vs. I^- concentration in the aqueous phase. $[Ag^+] = 2$ μM; $[I_2] = 0.02$ μM. Temperature = 37 °C.

The addition of I_2 to the aqueous phase containing the iodide ions was necessary since no plating was apparent without it. The effect of I_2 in promoting the silver plating might be attributable to the greatly increased permeability of the membrane to iodide due to the formation of polyiodides (I_3^-, I_5^-, etc.). Because of their larger size and lower surface charge density the polyiodides partition into the low dielectric region of the membrane phase more readily than iodide (5). The polyiodides, particularly I_3^-, may therefore be the source of electrons for the reduction of Ag^+. Alternatively, the formation of donor–acceptor complexes of I_2 with a lipid membrane (17) may increase the electrical conductivity of the membrane sufficiently to allow the silver reduction to occur at a measurable rate. Furthermore, the deposit of metallic silver on the membrane may then be interpreted as support for the electronic nature of the donor–acceptor charge transfer reactions (18).

In Fig. 2 the dependence of the plating time on the concentration of Ag^+, keeping $[I^-] = 20$ μM and $[I_2] = 2$ μM, is shown as a semi-log plot. The linear relationship with negative slope does not suggest a first-order reaction involving Ag^+ but is consistent with the fact that the total

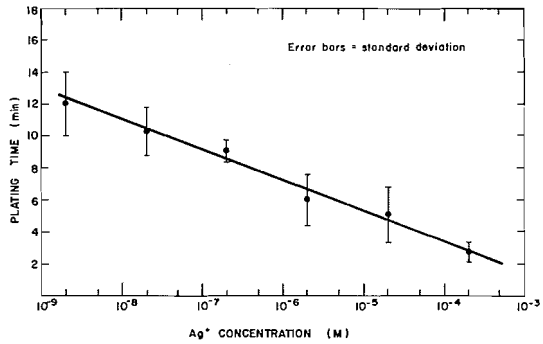

FIG. 2. Plating time vs. Ag^+ concentration in the aqueous phase. $[I^-] = 20\ \mu M$; $[I_2] = 2\ \mu M$. Temperature = 37 °C.

number of Ag^+ ions sorbed to the membrane at equilibrium will depend on the Ag^+ concentration in the aqueous phase as well as on the time required for an equilibrium distribution to be achieved.

With $[AgNO_3] = 2\ \mu M$ in one compartment and $[KI] = 2\ \mu M$, $[I_2] = 0.02\ \mu M$ in the other, the phospholipid membrane developed within a few seconds a self electromotive force of 132 mV as measured with a pair of closely matched platinum electrodes and a high impedance electrometer voltmeter. The aqueous phase containing the Ag^+ was positive. Increasing the resultant electric field by the application in the same direction of transmembrane potentials between 0–300 mV did not alter the plating time appreciably. The limitation may be due to space charge effects within the membrane. On the other hand reversal in polarity of the applied potential (10–100 mV) increased the plating time exponentially. At −100 mV no evidence of a deposit on the Ag^+ side of the membrane was seen.

Cholesterol membranes generated a self electromotive force of 82 mV (Ag^+ solution positive) when separating aqueous solutions of $AgNO_3$ (2 μM) from KI (2 μM) and I_2 (0.02 μM). The magnitude of the transmembrane potential is substantially less than the 132 mV measured for phospholipid membranes. In the absence of any relative change in electrical conductivity of the two kinds of membranes in the presence of I^- and I_2 (5, 6) this difference is likely due to dissimilar ion distributions within the membranes and will be discussed later. Attempts to silver plate membranes formed from a solution of chromatographically pure

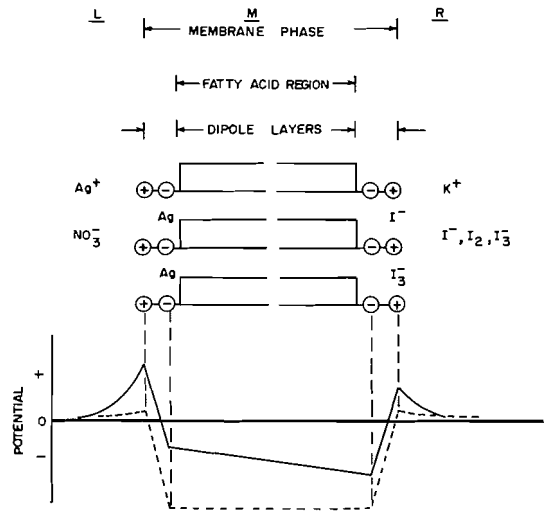

FIG. 3. A schematic illustration of silver plating on the left hand side L of an idealized black, bimolecular, phospholipid membrane M of area 0.06 cm^2. Following the addition of $AgNO_3$ (20 μM) and KI (20 μM), I_2 (2 μM) to aqueous phases L and R, respectively, the initial potential profile, represented for the case of distilled water by the broken line in the bottom of the diagram, is changed in a manner qualitatively illustrated by the solid line. Electron transfer to sorbed Ag^+ in intraface L from charge transfer complexes bound within the membrane is facilitated by the resultant electric fields. The silver deposit is visible within 5 min under low power microscopy (35×) of membrane surface L while surface R remains black.

cholesterol in *n*-tetradecane failed unless an external electric field was applied. A potential of 50 mV (Ag^+ solution positive) resulted in silver plating in 5–6 min.

Discussion

A basis for the difference in applied electric field requirements for silver plating to occur on phospholipid and cholesterol membranes may be sought in their structures. A number of components of the phospholipid material, from which the membranes were made, contain hydrophilic groups with a permanent dipole at near neutral p*H*. While the orientation of the hydrophilic groups with respect to the membrane is not firmly established the available evidence favors a distribution of orientations (7–9) rather than the perpendicular (10, 11) or coplanar (12, 13) alone. Sorption of counterions may realign a major proportion of the polar groups in the fully extended perpendicular direction (14) as shown schematically in Fig. 3.

The derivative force of the intrafacial potential existing in the region of the fixed dipoles then redistributes the counterions. Calculations have shown that the density of cations is maximal in the plane of fixed negative charge while the population of anions is highest in the plane of fixed positive charge. Furthermore, the concentration of counterions may be much higher in the polar layers than in the nearby aqueous phase (14). The redistribution alters the intrafacial potential profile somewhat in a manner shown by the solid line in the bottom diagram of Fig. 3. The magnitude of the change in the maximum and minimum potentials within the dipole layer from their values in distilled water, given by the broken line, depends on the densities of the counterions within the layer which, in turn, may be related to the affinity of the membrane to them (15). The ionic species in R, particularly I_3^-, permeate the membrane phase more readily than those in L; therefore the maximum and minimum potentials in the dipole layer of intraface R will be less than their respective values in intraface L. The solid line joining the two potential minima may then indicate in a general way the potential gradient across the low dielectric, fatty acid region. This potential may bias electron transfer from donors within the membrane to the sorbed Ag^+ ions. The strong positive potential ($4\,kT/e$ or more where the symbols have their usual meaning (14)) in the plane of fixed positive charge of intraface L is perhaps of more importance in facilitating electron entry at the anodic sites, that is, at the sorbed Ag^+ ions.

The development of the potential of 132 mV prior to any evidence of silver plating of the phospholipid membrane may then have an electrochemical component. This suggests an explanation for the failure of cholesterol membranes to silver plate in the absence of an applied potential. Cholesterol membranes lack the dipole layers within the membrane phase, the intrafacial potentials associated with them, and consequently the capacity to generate the increased ion density and intrafacial electric field similar to that of the bimolecular phospholipid membrane. An external potential must therefore be applied to satisfy the silver plating requirement of an increased Ag^+ ion density at the cholesterol membrane–water interface and/or a suitable electric field to promote electron transfer (16).

The electron transfer reaction of the plating process may be represented by the following redox couples:

$$2I^- \rightarrow I_2 + 2e^-$$
$$Ag \leftarrow Ag^+ + e^-$$

The reducing and oxidizing components are initially sorbed to opposite sides of the phospholipid membrane. However, the polyiodide ions (I_{2n+1}^-) are readily formed in the presence of iodine and they have a strong affinity for phospholipid membranes (6). The possibility that the plating process is simply the result of I_{2n+1}^- diffusion through the membrane is unlikely for the following reasons. The photographic results and the conductivity measurements indicate that the silver deposit is metallic and not a precipitate of AgI or $AgNO_3$. The lack of any measurable flux of ^{131}I through a lipid membrane in the presence of KI and under conditions where ^{131}I-labelled I_{2n+1}^- ions or I_2 diffused along favorable electrical and/or chemical gradients (6) suggests further that the polyiodide ions within the membrane are bound. This is consistent with spectrophotometric evidence for iodine complexes both with phospholipids and cholesterol (17). The bound complexes may, however, undergo relaxations (19) and transfer charge in a manner that is formally equivalent to diffusion of I_{2n+1}^- through the membrane. The electronic nature of the charge transfer is consistent with the mechanism of conductivity of a phospholipid membrane in an iodide–iodine system (19) and accounts for the silver deposition as well.

The skillful technical assistance of Mrs. M. C. Shierman is much appreciated. The helpful comments of Drs. J. O'M. Bockris and L. J. Mandel on the manuscript are acknowledged.

Infrared and Raman Spectra of Single Crystals of Anhydrous Strontium Formate

N. R. McQUAKER[1] AND K. B. HARVEY[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 20, 1971

The infrared absorption of single crystals of anhydrous strontium formate has been measured in the region 4000 to 500 cm^{-1}. The internal fundamentals of two sets of crystallographically non-equivalent types of formate ions are identified. Frequencies of external fundamentals are tentatively inferred from absorption bands appearing in the second order spectrum. Measurement of laser excited Raman spectra in the region 700–10 cm^{-1} has yielded assignments for all of the expected translational modes. None of the librational modes were observed.

L'absorption infrarouge de monocristaux de formiate de sodium anhydre a été mesurée dans la région allant de 4000 à 500 cm^{-1}. Les vibrations fondamentales internes de deux séries d'ions formates de types de cristallographie non équivalents sont identifiées. Les fréquences de vibrations fondamentales externes sont déduites expérimentalement des bandes d'absorption apparaissant dans le spectre du second ordre. La mesure dans la région 700–10 cm^{-1} du spectre Raman obtenu par excitation au laser a permis d'attribuer tous les modes de translation attendus; aucun mode librationnel n'a été observé.

Canadian Journal of Chemistry, **50**, 1453 (1972)

Introduction

The mid-infrared absorption spectrum of polycrystalline $Sr(HCO_2)_2$ has been reported by previous workers (1–3). Evidently no single crystal absorption studies have been reported. The X-ray crystal studies of $Sr(HCO_2)_2$ (4, 5) indicate an orthorhombic structure (D_2^4-$P2_12_12_1$) with four molecules per unit cell. Under the D_2^4 space group all atoms must lie on general positions of multiplicity four. Thus, there are two sets of crystallographically independent formate ions. The vibrational spectrum of the internal fundamentals should be sensitive to the presence of the two types of formate ions and indeed the expected frequency doubling has been observed (1–3). However, the assignments are incomplete and it was hoped that by using single crystals and polarized radiation that more complete assignments could be made. This has been possible and in addition frequencies of external fundamentals are inferred from absorption bands appearing in the second order spectrum. In order to check for the presence of these external fundamentals we have measured the laser excited Raman spectra in the region 700–10 cm^{-1}. Assignments are made for all of the expected translations. The librations, however, did not appear with observable intensity.

The mid-infrared spectra of polycrystalline $Sr(HCO_2)_2$ and $Sr(DCO_2)_2$ have also been recorded.

Experimental

The $Sr(HCO_2)_2$ was obtained from Baker and Adamson Ltd. and the $Sr(DCO_2)_2$ was obtained from Merke, Sharp, and Dohme Ltd. Both compounds were of reagent grade. The single crystals of $Sr(HCO_2)_2$ were grown by controlled evaporation of a saturated solution held at 85 °C. After three to four weeks of growth a typical crystal (of sphenoidal habit) had dimensions of 25 × 15 × 10 mm. The principal face of these crystals was the (010) face elongated in the *c* direction.

In the polycrystalline studies the samples were prepared as thin films. These films were mechanically deposited on potassium bromide supports. The technique used has been described elsewhere (6). The thin single crystal slices were prepared using a refinement of the technique described by Charlton and Harvey (7). A polarizing microscope was used to determine the relative orientation of the crystal axes and to confirm the quality of the crystal. In all cases the crystals were clear and exhibited sharp extinction. Observation of the interference figures also allowed us to confirm that the crystals were ground to within 2° of the perpendicular of the axis of observation. The thicknesses of the crystals were measured on a Zeiss Light-section microscope and were found to be approximately 25 μ.

The infrared spectra were recorded in the region 4000–500 cm^{-1} using a Perkin–Elmer 421 spectrometer. All spectra were recorded against a dry air background purged of CO_2. The spectrometer was calibrated against known spectra (8) and the error of measurement is estimated to be less than ± 2 cm^{-1}.

The laser excited Raman spectra of the single crystals were recorded using a Spex (model 1400) spectrophotometer which was equipped with a cooled ITT photolube detector (FW-130) and a Spectra Physics 165 Argon laser. A right angle scattering geometry was used and the exciting wave-

length used was the 5145 Å line at a power of around 500 mW. The instrument was calibrated with a neon discharge lamp and the uncertainty in the measured frequencies is estimated to be less than ± 2 cm^{-1}.

Results and Discussion

Internal Lattice Vibrations

Under the D_2 factor group the irreducible representation for the internal fundamentals may be summarized as

$$\Gamma(\text{internal}) = 12a + 12b_1 + 12b_2 + 12b_3$$

These 48 internal normal vibrations may be considered to arise from the 6 normal vibrations of the HCO_2^- ion through the presence of the two sets of four crystallographically independent formate ions in the unit cell. The correlation table for the factor group (correlation field) splitting of the HCO_2^- ion appears in Table 1.

Reference to Table 1 shows that under D_2 each free ion mode is split into four crystal vibrations of symmetries a, b_1, b_2, and b_3. The b_1, b_2, and b_3 components of the free ion mode appear in the infrared single crystal spectra when the incident radiation is polarized along the $z(c)$, $y(b)$, and $x(a)$ axes, respectively. The resulting $b_1/b_2/b_3$ splittings are a direct measure of the correlation field splitting. However, in practice it is usually found that correlation field effects do not give significant splittings (see for example, ref. 9). Accordingly, we may make the assignments according to the following scheme: ν_1 through ν_6 for the first set of four crystallographically independent HCO_2^- ions and ν_1' through ν_6' for the second set. We will subsequently refer to formate ions of the first and second sets as formate ions of types I and II.

Even though we do not expect significant $b_1/b_2/b_3$ frequency shifts to be associated with a particular free ion mode we can expect significant $b_1/b_2/b_3$ intensity changes. This is because in the single crystal the orientations of the oscillating dipoles which give rise to the internal fundamentals are fixed relative to the incident polarized radiation. The orientation of the various dipoles will depend upon the location of the hydrogen, oxygen and carbon atoms of formate ions I and II. The positions of the hydrogen atoms are not known. However, the positions of the oxygen and carbon atoms fix C—O bond lengths of 1.24 Å in all cases (4, 5) and if we assume effective C_{2v} site symmetries for formate ions I and II we can compute the various dipole orientations relative to the crystal axes. In the limit of the oriented gas model (see for example, ref. 10) the relative infrared absorption intensities along the x, y, and z axes are given by the appropriate values of the squares of the dipole direction cosines. In Table 2 the relative intensities along the x, y, and z axes are given for the C_{2v} vibrations, ν_i and ν_i', associated with formate ions I and II. The magnitude of the ν_i/ν_i' splittings will largely be a reflection of differences in the C_{2v} geometry of ions of types I and II. The parameters that can show variation without destroying the assumed C_{2v} geometries are the C—H bond lengths and the O—C—O bond angles. It is known that formate ions of type I have an O—C—O bond angle of 130° and that those of type II have a corresponding bond angle of 129° (4, 5). Since the positions of the hydrogen

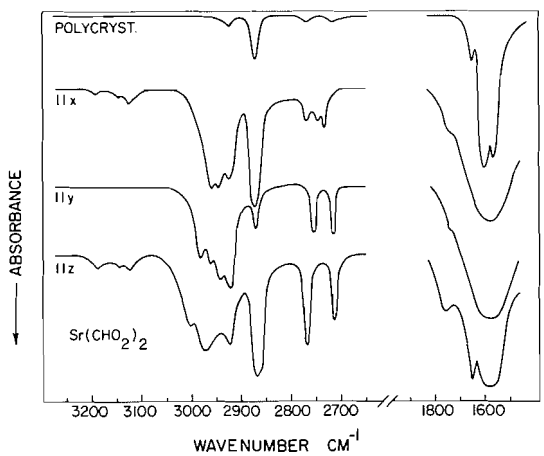

FIG. 1. Infrared spectra in the region 3300–1500 cm^{-1} of polycrystalline $Sr(HCO_2)_2$ and single crystal slices of $Sr(HCO_2)_2$ polarized along the x, y, and z axes. The thickness of the crystal slices is 25 ± 3 μ.

atoms are not known any difference in the C—H bond lengths cannot be compared.

There is only one $Sr(HCO_2)_2$ internal fundamental which does not show a ν_i/ν_i' splitting (or frequency doubling) and this is $\nu_1/\nu_1'(a_1)$. In both the polycrystalline and single crystal spectra (Fig. 1) a single ν_1/ν_1' absorption at 2872 cm^{-1} (Tables 3 and 4) is observed. If equal ν_1 and ν_1' oscillator strengths are assumed the strong ν_1/ν_1' intensities observed along the x and z axes and the weak intensity observed along the y axis can be compared with a predicted $x/y/z$ intensity ratio of 0.8/0.1/1.1. As already suggested the remaining two internal fundamentals possessing a_1 symmetry under C_{2v} show frequency doubling. In the polycrystalline spectrum of $Sr(HCO_2)_2$ there are four absorptions in the vicinity of $\nu_2/\nu_2'(a_1)$ (Fig. 2). These appear at 1349, 1359.5, 1362.5, and 1368 cm^{-1}. In the single crystal spectra very intense absorptions appear at 1360 cm^{-1} along both the x and z axes and a less intense absorption appears at 1363 cm^{-1} along the y axis. Since Table 2 indicates that ν_2' will have essentially zero intensity along the y axis the 1363 cm^{-1} absorption must be assigned as ν_2. The 1360 cm^{-1} absorption can then be assigned as ν_2'. The 1349 and 1368 cm^{-1} absorptions appearing in the polycrystalline spectrum are evidently obscured by the intense ν_2/ν_2' absorptions appearing in the single crystal spectra. These two apparently anomalous absorptions

*The calculated second order frequencies use $\nu_i/\nu_i' = (\nu_i + \nu_i')/2$. $\nu_4/\nu_4' = 1580\ cm^{-1}$ has components at 1570 and 1593 cm^{-1} (see Table 3). The calculated second order frequencies use $\nu_4 = 1570\ cm^{-1}$ and $\nu_4' = 1593\ cm^{-1}$.

†v = very, s = strong, m = medium, w = weak.

may be associated with the lines observed at 1374 and 1383 cm^{-1} in the single crystal spectra. Their assignment is discussed later. The final internal vibration of a_1 symmetry is $\nu_3/\nu_3'(a_1)$. It is found that in the polycrystalline spectrum there are three absorptions in the vicinity of ν_3/ν_3'. These appear at 763, 779.5, and 783.5 cm^{-1}. Of these only the 763 cm^{-1} line appears along the y axis. Since ν_3' will have essentially zero intensity along the y axis the assignment

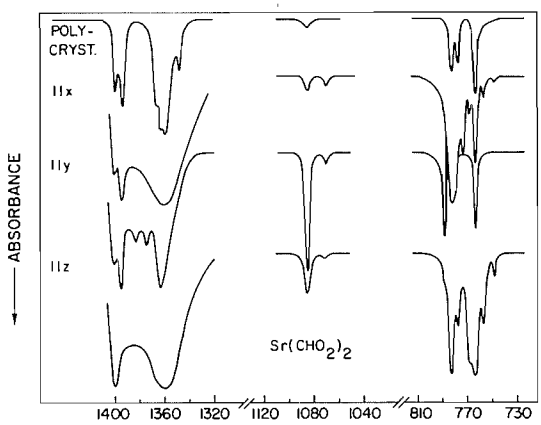

FIG. 2. Infrared spectra in the region 1500–700 cm^{-1} of polycrystalline $Sr(HCO_2)_2$ and single crystal slices of $Sr(HCO_2)_2$ polarized along the x, y, and z axes. The thickness of the crystal slices is 25 ± 3 μ.

suggested for the 763 cm^{-1} line is ν_3. The observed ν_3 intensity ratios of medium/medium/very strong along the $x/y/z$ axes are in agreement with the predicted ratio of 0.07/0.09/0.84. The 783.5 cm^{-1} absorption has an intensity ratio along the x/z axes of very strong/strong. This ratio is consistent with the predicted ν_3' ratio of 0.75/0.25. We may note that ν_3/ν_3' may be considered as an O—C—O bending vibration and that the frequency shift $\nu_3' - \nu_3 = 20.5$ cm^{-1} is compatible with the one degree decrease in the O—C—O bond angle as we go from formate ion I to formate ion II. Evidently the apparently anomalous line observed at 779.5 cm^{-1} in the polycrystalline spectrum must be considered along with the additional lines appearing in the single crystal spectra at 748, 756, 766, 775, and 786 cm^{-1}. The assignment of these lines is discussed in the following section.

Under C_{2v} there are two internal vibrations of b_1 symmetry. These are ν_4/ν_4' and ν_5/ν_5'. In the polycrystalline spectrum ν_4/ν_4' frequencies appear at 1570 and 1593 cm^{-1}. In the single crystal spectra the resolution of this doublet is completely obscured by very intense absorptions which appear along all three crystal axes. The ν_5/ν_5' frequencies at 1393 and 1399 cm^{-1} appear in the polycrystalline spectrum as a well resolved doublet. The predicted intensity of ν_5 along the z axis is essentially zero. Thus the absorption appearing along the z axis at 1399 cm^{-1} is assigned as ν_5'. As expected both ν_5 and ν_5' appear with considerable intensity along both the x and y axes.

The one remaining C_{2v} internal vibration is $\nu_6/\nu_6'(b_2)$. Only one component is observed in the polycrystalline spectrum. It appears at 1084 cm^{-1}. The observed single crystal intensities of the 1084 cm^{-1} absorption along the $x/y/z$ axes are very weak/very strong/weak. These may be compared with the corresponding predicted ν_6' intensities of 0.07/0.72/0.21. In the single crystal spectra ν_6 appears only very weakly at 1070 cm^{-1} along all three crystal axes. Comparison of intensities shows that the ν_6' intensity is much greater than the ν_6 intensity. Evidently the different C_{2v} geometries of formate ions I and II result in markedly different oscillator strengths in the case of ν_6 and ν_6'.

The foregoing results have shown that the assumption of effective C_{2v} site symmetries for formate ions I and II predicts relative intensities for the internal vibrations which are consistent with experimental observation. Thus, we may conclude that the assumption of effective C_{2v} site symmetries is a reasonably good one. Using this assumption we have been able to distinguish between the assignments ν_i and ν_i'. These assignments are summarized in Tables 3 and 4. Table 3 also includes the previously unreported frequencies of the internal fundamentals of $Sr(DCO_2)_2$. It is seen that the ν_i/ν_i' frequency doubling where $i = 2$, 3, and 4 is of comparable magnitude in both $Sr(HCO_2)_2$ and $Sr(DCO_2)_2$. This, however, is not the case for ν_1/ν_1' and ν_5/ν_5'. These frequencies are dependent on the motions of the hydrogen and deuterium atoms and the much greater ν_1/ν_1' and ν_5/ν_5' frequency doubling in $Sr(DCO_2)_2$ suggests a non-equivalence associated with the deuterium atoms of formate ions I and II which is not present in the case of $Sr(HCO_2)_2$.

Combinations and Overtones

We may associate the $Sr(HCO_2)_2$ absorptions appearing at 748, 756, 766, 775, 779.5, and 786 cm^{-1} in the single crystal spectra with the 772 cm^{-1} absorption appearing in the polycrystalline spectrum of $Sr(DCO_2)_2$. The close correspondence between the $Sr(HCO_2)_2$ wavenumbers and the $Sr(DCO_2)_2$ wavenumber suggests that hydrogen atom motion does not play a significant role in determining these second

order frequencies. Tentative assignments are to overtones and combinations involving librational motions about the C—H and C—D axes. The assumption of these assignments places frequencies for the librational motion of the oxygen atoms in the region 374–398 cm^{-1}. We may note that the unusually strong intensity of some of these second order absorptions may be due to Fermi resonance with ν_3 and ν_3'.

The intensities of the $Sr(HCO_2)_2$ bands at 1349, 1368, 1374, and 1383 cm^{-1} are also likely enhanced by Fermi resonance; *i.e.*, ν_2/ν_2' and ν_5/ν_5' lie nearby. It is possible that these apparently anomalous lines are due to overtones and combinations involving librational motions perpendicular to the C—H axes. The frequencies of these librational motions will be strongly dependent on the motion of the hydrogen atoms. This would explain the absence of these second order absorptions in the vicinity of ν_2/ν_2' in the $Sr(DCO_2)_2$ spectrum. The assumption of the assignments mentioned placed frequencies for librational motions involving motion of the hydrogen atom in the region 674–691 cm^{-1}. Although this region of the spectrum was studied the expected first order absorptions did not appear. This is analogous to the case for both the NH_4^+ ions (9, 11) and BH_4^- ions (6, 12) where the expected librational frequencies appear only in the second and third order spectra.

There are three bands appearing on the high wavenumber side of ν_4/ν_4' which may be assigned as ν_4/ν_4' in combination with translations. If we place ν_4/ν_4' at 1580 cm^{-1} the inferred translational frequencies are placed at 70, 155, and 180 cm^{-1}. Absorption bands assigned as ν_4 in combination with translations are also observed in the single crystal spectra of $Na(HCO_2)$(7). In this case the inferred translational frequencies are placed at 57, 107, and 138 cm^{-1}.

All the remaining bands appearing in the second order spectrum may be tentatively assigned to either combinations or overtones of internal fundamentals (see Table 4). The observed ($k = 0$) frequencies of the internal fundamentals may be used to predict the frequencies of combinations and overtones in the zero wavevector limit. Thus, discrepancies between observed and calculated second order frequencies may be due to the combination of phonons of non zero (but equal and opposite) wavevector (13) as well as to anharmonicity and Fermi resonance effects. The enhanced intensities of the combination and overtone bands in the region 2700–3025 cm^{-1} are likely due to Fermi resonance with ν_1/ν_1' which lies at 2872 cm^{-1}.

A summary of the second order wavenumbers appears in Table 4.

External Lattice Vibrations

The external lattice vibrations include those of optical translatory (o.t.), optical libratory (o.l.), and acoustical translatory (a.t.) origin. The respective irreducible representations are

$$\Gamma(\text{o.t.}) = 9a + 8b_1 + 8b_2 + 8b_3$$

$$\Gamma(\text{o.l.}) = 6a + 6b_1 + 6b_2 + 6b_3$$

$$\Gamma(\text{a.t.}) = b_1 + b_2 + b_3$$

Optical crystal modes of all four symmetry species are Raman active. The Raman tensor elements and their corresponding symmetry species are: α_{xx}, α_{yy}, and α_{zz} for a; α_{xy} for b_1; α_{zx} for b_2, and α_{yz} for b_3. As previously indicated, crystal modes of b_1, b_2, and b_3 symmetries are infrared active and are polarized along the $z(c)$, $y(b)$, and $x(a)$ crystal axes, respectively. We may note that the infrared active vibrations may be split due to the accompanying long range electrostatic forces. For example, $b_1 \rightarrow b_1(\text{TO}) + b_1(\text{LO})$ where TO and LO respectively refer to transverse optical and longitudinal optical phonons. The TO/LO phonons are expected to appear in the Raman spectrum when the direction of phonon propagation is perpendicular/parallel to the phonon polarization. Since $Sr(HCO_2)_2$ is anisotropic the magnitude of the frequency difference for a particular TO/LO splitting will depend upon the direction of phonon propagation with respect to the appropriate crystal axis.

In the present work attempts to observe the LO modes were unsuccessful. Apparently the signs of the electro-optic coupling coefficients are such that destructive interference occurs (13). This has also been found to be the case for the ammonium halides (9, 14).

Reference to Fig. 3 shows the spectra for the α_{zz}, α_{xz}, α_{xy}, and α_{zy} polarizations. The notation used to label the spectra is the same as that introduced by Damen, Porto, and Tell (15). For example, the spectrum labelled $y(zz)x$ corre-

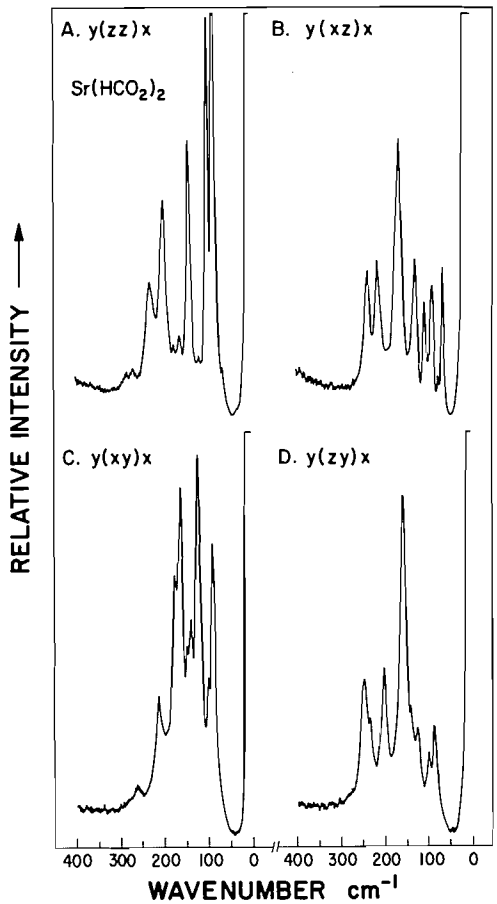

FIG. 3. Raman spectra in the region 0–400 cm^{-1} of a single crystal of $Sr(HCO_2)_2$: (*A*), α_{zz} component showing *a* vibrations; (*B*), α_{xz} component showing b_2 vibrations; (*C*), α_{xy} component showing b_1 vibrations; (*D*), α_{zy} component showing b_3 vibrations.

sponds to a right angle scattering geometry with the incident radiation propagating in the *y* direction (polarized in the *z* direction) and the scattered radiation propagating in the *x* direction (polarized in the *z* direction). The polarizability tensor α_{zz} determines this spectrum.

It was found that crystal modes arising from librations of the HCO_2^- ions did not appear with observable intensity. This also compares with the case of the ammonium halides where the expected librational modes appear very weakly, if at all (9, 16). However, it is seen from Table 5 that all 33 of the crystal modes arising from translations of the HCO_2^- and Sr^+ ions have been accounted for. Since $Sr(HCO_2)_2$ has

TABLE 5. Translational frequencies (cm^{-1}) of anhydrous strontium formate*

a symmetry	b_1 symmetry	b_2 symmetry	b_3 symmetry

64 vvw			

*v = very, w = weak, m = medium, s = strong.

4 Sr^+ ions and 8 HCO_2^- ions per unit cell the accidental degeneracies and near degeneracies observed can be expected. The observation of translational frequencies in the region 60–250 cm^{-1} is consistent with the continuous infrared absorption observed in the region ν_4/ν_4' to $\nu_4/\nu_4' + 250\ cm^{-1}$ where the ν_4/ν_4' frequency is taken as 1580 cm^{-1}. If we assume the combination of $k = 0$ phonons for the three absorption maxima of origin ν_4/ν_4' + translation appearing in the ν_4/ν_4' to $\nu_4/\nu_4' + 250\ cm^{-1}$ region then $k = 0$ translations are predicted at 70, 155, and 180 cm^{-1}. These frequencies compare with the Raman frequencies observed at 72, 156, and 175 cm^{-1}.

Three scatterings in addition to the translations assigned in Table 5 appear. These are observed at 263 cm^{-1} (*xy* polarization) and 269 and 282 cm^{-1} (*zz* polarization). It is likely that these scatterings are due to multiphonon processes involving the combination of two translations. Since the $k = 0$ selection rules are relaxed either optical or acoustical phonons of equal and opposite wavevector may contribute to the intensity of the scatterings at 263, 269, and 282 cm^{-1}.

Thanks are due to Professors A. Anderson and B. H. Torrie of University of Waterloo for the use of their Raman facility. The financial assistance of the National Research Council of Canada and of the University of British Columbia is gratefully acknowledged.

The Effect of Aromatic Tertiary Amines on the Copper(II) Catalyzed Decarboxylation of 3-Oxo-Glutaric Acid

K. N. LEONG AND M. W. LISTER

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received November 24, 1971

The kinetics of the copper(II) catalyzed decarboxylation of 3-oxo-glutaric acid have been investigated in unbuffered solutions at 25 °C and 0.60 *M* ionic strength, both in the presence of aromatic tertiary amines, and with hydrated copper ions alone. The amines used were 2,2′-bipyridyl and 1,10-phenanthroline. Equilibrium constants for the formation of the various copper complexes were determined with a copper ion selective electrode, particularly for the species CuAB, where A is the 3-oxo-glutarate ion, and B is an aromatic amine. The kinetic behavior was then interpreted as arising from the simultaneous decarboxylation of all the species present containing a 3-oxo-glutarate ligand. The resulting rate constants indicated that some kinetic effect was transmitted through the copper from the base to the 3-oxo-glutarate, but the effect was relatively small, and the bulk of the catalytic effect caused by the base arose from changes in equilibrium concentrations.

Les cinétiques de la décarboxylation de l'acide oxo-3 glutarique, catalysé par le cuivre(II), ont été étudiées dans des solutions non tamponées à 25 °C et à une force ionique de 0.60 *M*; ceci à la fois en présence d'amines aromatiques tertiaires et avec des ions hydratés du cuivre uniquement. Les amines utilisées sont la bipyridyle-2,2′ et la phénanthroline-1,10. Les constantes d'équilibre pour la formation des divers complexes du cuivre ont été déterminées au moyen d'une électrode sélectives en cuivre, spécialement dans le cas d'espèces CuAB, où A est l'ion oxo-3 glutarate et B une amine aromatique. Le comportement cinétique a alors été interprété en fonction d'une décarboxylation simultanée de toutes les espèces présentes contenant le ligand oxo-3 glutarate. Les constantes de vitesse qui en résultent, indiquent qu'un certain effet cinétique est transmis de la base vers l'oxo-3 glutarate par l'intermédiaire du cuivre; cet effet demeure cependant petit et l'importance de l'effet catalytique provoqué par la base provient de modifications dans les concentrations à l'équilibre.

Introduction

The decarboxylation of β-keto dicarboxylic acids is catalyzed by transition metal ions (1), and the reaction has been shown to occur through the spontaneous decomposition of the 1:1 complex of formula MA^-, where M^{2+} is a divalent metal ion, and A^{2-} is the dianion of the keto acid. The catalytic effect of the metal ion may be appreciably enhanced when the 1:1 complexes of the metal ion are added instead of simply the hydrated metal ion (2–7). Presumably the decarboxylation now proceeds through a new reactive species, and it is shown in the present work that reasonably consistent rate constants are obtained, if it is assumed that this species is the 1:1:1 tertiary complex MAB, where B is the amine. Since aliphatic amines and phosphines are relatively ineffective in promoting decomposition, it is presumed that the delocalized π-systems of the aromatic amine are involved. The overall catalytic rate constant, k_{cat}, is defined by

$$d[CO_2]/dt = k_{H_2A}[H_2A] + k_{HA^-}[HA^-] + k_{A^{2-}}[A^{2-}] + k_{cat}T_M[A^{2-}]$$

where T_M is the total metal ion concentration, and k_{H_2A}, k_{HA} and $k_{A^{2-}}$ are the first-order rate constants of the unionized acid, the monoanion, and the dianion, respectively. If the mechanism of the metal ion catalysis is made up of two parts.

$$M^{2+} + A^{2-} \overset{K_{MA}}{\rightleftharpoons} MA \xrightarrow{k_{MA}} CO_2 + \text{product}$$

and

$$MB^2 + A^{2-} \overset{K_{MAB}}{\rightleftharpoons} MAB \xrightarrow{k_{MAB}} CO_2 + \text{product}$$

then k_{cat} is evidently a function of both the equilibrium constants K_{MA} and K_{MAB}, and the rate constants k_{MA} and k_{MAB}. Thus the enhanced catalytic effect caused by the amine may result from either changes in equilibrium constants, or in rate constants, or in both. These two effects can be separated by means of kinetic measurements alone (5), provided enough data are available, but in the present work it was felt that more accuracy would be achieved by measuring the equilibrium constants separately, and using them to interpret the kinetic data. The equilibrium measurements were made by means of a copper(II) ion sensitive electrode. This paper reports equilibrium and kinetic measure-

ments on the decomposition of 3-oxo-glutaric acid in the presence of 2,2′-bipyridyl and 1,10-phenanthroline.

Experimental

Chemicals

3-Oxo-glutaric acid, prepared essentially as described by Ingold and Nickolls (8), was recrystallized from ethyl acetate and stored over silica gel in an evacuated desiccator. The melting point was 134–135 °C, and the apparent molecular weight, determined by titration against sodium hydroxide was 146.3 (calculated for $C_5H_6O_5$ is 146.1). The purity of the acid was also determined from the amount of carbon dioxide released on complete decarboxylation, and this agreed to within 0.2% with the calculated amount.

All other chemicals were of reagent grade. 2,2′-bipyridyl and 1,10-phenanthroline were obtained from the Fisher Scientific Company, and were recrystallized from water. The melting points were then 70.3 and 101.5 °C, respectively. Copper(II) nitrate and sodium nitrate (used to control ionic strength) were "Baker Analysed" reagents, and were recrystallized from water. The stock solutions of copper(II) nitrate were analyzed by EDTA titration.

Potentiometric Measurements

Equilibria were investigated by potentiometric measurements on a Beckman research p*H* meter. All measurements were on solutions at 25.00 ± 0.01 °C, and at a constant ionic strength of 0.60 *M*, adjusted by sodium nitrate. Equilibrium constants for copper complex formation were determined by means of a copper(II) ion selective electrode (model 94-29, Orion Research Inc.). The electrode was calibrated by means of copper(II) nitrate solutions varying from 1.00×10^{-4} to 2.00×10^{-2} *M*, containing also 0.60 *M* sodium nitrate. A plot of electrode potential against log $[Cu^{2+}]$ gave a very good straight line, with a slope of 29.60 mV. This calibration allowed the measured voltages to be interpreted as copper(II) concentrations, and from these concentration equilibrium constants were calculated.

The hydrogen ion concentrations were obtained by means of a glass electrode, with a calomel reference electrode, using the Beckman research p*H* meter. The meter was standardized with 0.05 *M* potassium hydrogen phthalate at 25.0 °C. It was then calibrated in terms of hydrogen ion concentration by measurements on dilute nitric acid in 0.6 *M* sodium nitrate. It was found that the p*H* reading and $-\log [H^+]$ differed by a constant factor. Consequently, meter readings could be converted to hydrogen ion concentrations.

Kinetic Measurements

These were carried out manometrically in a constant volume apparatus. The manometer was regularly calibrated by the carbon dioxide liberated from known amounts of sodium bicarbonate plus acid. In each kinetic run a weighed amount of 3-oxo-glutaric acid, usually 17 to 18 mg, was suspended above 10 ml of a solution containing the other reagents. The 3-oxo-glutaric acid was in a container which could be released by a magnetically operated plunger. The solution was frozen, and the apparatus was evacuated and sealed. The solution and manometer were then completely immersed in a thermostat at 25 °C. The 3-oxo-glutaric acid was introduced by withdrawing the plunger, and the reaction was followed by measurements of pressure.

Results

Stability Constants of Copper(II) 3-Oxo-glutarate Complex

Known volumes of stock solutions of 3-oxo-glutaric acid, sodium hydroxide, sodium nitrate, and copper(II) nitrate (this was added last) were pipetted into a double-walled beaker maintained at 25.0 °C. The copper ion selective electrode and the reference electrode were placed in the solution, and the voltage readings were noted at 1 min intervals for 10 min. In general the potential was unchanged over this period, but small drifts (less than 0.05 mV per min) occurred in some cases. The potential used in calculation was then the value extrapolated to the time of mixing. Glass electrode measurements were more difficult as the p*H* drifted at the rate of about 0.01 p*H* units per min, owing to the decarboxylation reaction. The p*H* values used were those extrapolated to the time of mixing. The p*H* was always well below 4, to avoid enolization of the CuA complex which had been shown to occur at higher p*H* (9). It will be seen below that there is no drift in the calculated equilibrium constants with p*H*, so presumably the assumption, made in the calculations, that negligible enolization occurs, is justified. The results are given in Table 1. The equilibrium constant, K_{CuA}, defined as $[CuA]/[Cu^{2+}][A^{2-}]$, was calculated on the assumption that only H_2A, HA^-, A^{2-}, Cu^{2+}, CuA, H^+, and NO_3^- were present (apart from sodium nitrate). The ionization constants of 3-oxo-glutaric acid were taken to be 9.70×10^{-4} and 1.52×10^{-4} (9).

In Table 1, T_s is the total concentration of 3-oxo-glutaric acid, T_M is the total copper, and [NaOH] is the net concentration of added sodium hydroxide, after allowing for its reaction with nitric acid contained in the stock copper nitrate solution; it would, of course, also react with the 3-oxo-glutaric acid. The mean value of K_{CuA} is 150 M^{-1}, with a root-mean-square deviation of 4. This may be compared with the value of 114 M^{-1} (root-mean-square deviation of 40) obtained earlier from concentration cell measurements (9).

Stability Constants of Copper(II) Ternary Complexes

The equilibrium constants, K_{CuAB}, defined by $K_{CuAB} = [CuAB]/[CuB^{2+}][A^{2-}]$, where B is 2,2′-bipyridyl or 1,10-phenanthroline, were also determined by the copper ion selective electrode. The techniques were the same as before, except that the stock copper nitrate solution had had an equimolar amount of one of the amines added to it. The results are given in Tables 2 and 3. As before, the pH was adjusted by sodium hydroxide, and the concentrations given are those in excess of the nitric acid contained in the stock copper solution. In calculations of K_{CuAB}, the solutions were considered to contain the following species: H_2A, HA^-, A^{2-}, Cu^{2+}, CuA, CuB^{2+}, CuB_2^{2+}, CuAB, H^+, Na^+ and NO_3^-. Sodium nitrate was used to adjust the ionic strength to 0.60, as before. Since only one new constant, K_{CuAB}, is being determined, a value can be found from each mixture, by means of the usual mass balance and equilibrium equations; these values are given in Tables 2 and 3. The calculations also require values for the acid ionization constants of the BH^+ species, and stability constants for

the formation of CuB^{2+} and CuB_2^{2+}. The values used were for 2,2′-bipyridyl: $K_{BH^+} = 3.30 \times 10^{-5}$ (10), $K_{CuB} = 1.26 \times 10^8$, and $\beta_{CuB_2} = 2.98 \times 10^{13}$ (11); and for 1,10-phenanthroline, $K_{BH^+} = 1.10 \times 10^{-5}$ (12), $K_{CuB} = 1.12 \times 10^9$, and $\beta_{CuB_2} = 5.62 \times 10^{15}$ (11).

The average values of K_{CuAB}, with their root-mean-square deviations, are: B = 2,2′-bipyridyl, $K_{CuAB} = 364$ (r.m.s. = 33); B = 1,10-phenanthroline, $K_{CuAB} = 268$ (r.m.s. = 44).

Kinetic Measurements

Mixtures containing copper(II) nitrate, 3-oxo-glutaric acid, and aromatic amine were made up, adjusted to a pH between 3 and 4, and their rates of carbon dioxide evolution were measured, as described above. The rate was always found to be first order in total 3-oxo-glutaric acid, and the apparent rate constant, k_{obs}, defined by

$$d[CO_2]/dt = k_{obs}T_s$$

was calculated for each run. It is known that H_2A, HA^-, A^{2-} and CuA all decarboxylate, and hence contribute to k_{obs}; and in the calculations below we have assumed that the CuAB species also contribute. The product of the reaction, 3-oxo-butanoic acid itself decarboxylates, but experiments have shown (9, 13) that its rate of decarboxylation is much slower, and is not catalyzed by copper (14). Consequently this possible second stage was ignored. With these assumptions, k_{obs} is related to the various rate constants by the equation

$$k_{obs}.T_s = k_{H_2A}[H_2A] + k_{HA^-}[HA^-] + k_{A^{2-}}[A^{2-}] + k_{CuA}[CuA]$$

where k_{H_2A}, etc. are the first-order rate constants for the decomposition of the corresponding species. When an aromatic base was present, an additional term k_{CuAB}[CuAB] was included in the equation. The values of k_{H_2A}, k_{HA^-}, $K_{A^{2-}}$ were known from earlier work (9), and at 25 °C and an ionic strength of 0.60 were taken to be: $k_{H_2A} = 2.08 \times 10^{-5}$, $k_{HA^-} = 4.83 \times 10^{-5}$, and $k_{A^{2-}} = 0.17 \times 10^{-5}$ s^{-1}. Table 4 gives the results of some further measurements on the rate of the copper-catalyzed reaction, as before at 25 °C and an ionic strength of 0.60. The mean value of k_{CuA} is 1.95×10^{-3} s^{-1} with a root-mean-square deviation of 0.07×10^{-3}. This is lower than the value reported earlier (9), but much of the difference arises from the revised value of the equilibrium constant K_{CuA}. It can be seen from Table 4 that k_{CuA} did not change with pH over the range investigated.

Results with amines also present are given in Tables 5 and 6. The reactions were followed to 65 to 70% completion, and gave good first-order plots over this range. The equilibrium concentrations of all species were calculated, and hence k_{CuAB}. It might have been expected that, owing to the various competing reactions and equilibria, a first-order plot would not be closely followed, but in fact it was. This can be explained, at least in part, by supposing that the 3-oxo-butanoic acid also formed complexes with the copper ions and with CuB^{2+} ions to much the same extent as 3-oxo-glutaric acid, and that the bulk of the reaction arose from the catalyzed part. As before, experiments were at 25 °C and an ionic strength of 0.60. Although there is some scatter of the values of k_{CuAB}, they seem to be constant enough to support the view that a species of formula CuAB is responsible for changes in the rate on adding the aromatic

amine. It can be seen that there is no drift with pH over the range used. The average values of k_{CuAB} and root-mean-square deviations are: B = 2,2′-bipyridyl, $k_{CuAB} = 2.65 \times 10^{-3}$ s^{-1} (r.m.s. = 0.07); B = 1,10-phenanthroline, $k_{CuAB} = 1.70 \times 10^{-3}$ s^{-1} (r.m.s. = 0.06).

Discussion

The results of the present work, and some other relevant data, are summarized in Table 7, where the logarithms of various equilibrium or rate constants are given. The equilibrium constants are all for reactions of the type $X + Y \rightleftharpoons XY$, and the columns are accordingly headed X or Y, and $K = [XY]/[X][Y]$. Where CuB^{2+} is mentioned, B is the same base as appears in the first column.

Some comments may first be made on the equilibrium constants. As is commonly found, the stronger amine base also binds more strongly to Cu^{2+}, but A^{2-}, though of comparable strength as a base, attaches much less strongly to Cu^{2+}. The constants for the attachment of A^{2-} to CuB^{2+} are not very different from that for A^{2-} to Cu^{2+} (hydrated). The stronger amine base gives the weaker combination of A^{2-} to CuB^{2+}, possibly because the stronger base has transferred somewhat more negative charge to the copper ion, and so has weakened its attraction to the negatively charged A^{2-}. If the reaction $A^{2-} + Cu^{2+} \rightarrow CuA$ is considered as one of this series, with water molecules acting as the base already bound to copper, then the equilibrium constant and the basicity of water do not fit this trend: A^{2-} attaches much less strongly to Cu^{2+}aq than might be expected from the basicity of water. This difference is presumably due to the possibility of back-bonding from the copper to the empty orbitals in the π electron systems of the aromatic amines, which would make the copper atom to be relatively more positively charged. However, the effect, at least as estimated from the equilibrium constants, is apparently not very large.

It was noted above that a second molecule

of base, in CuB_2^{2+}, is attached appreciably less strongly than the first. This must also be true of the 3-oxo-glutarate ion, since the values of K_{CuA}, obtained above on the assumption that no CuA_2^{2-} was present, were fairly constant. The presence of considerable quantities of CuA_2^{2-} would lead to variations in the values of K_{CuA} obtained from different runs. It was in fact found that if the values of K_{CuA} are plotted against $[A^{2-}]$, and a line is drawn through the points by least-mean-squares, this line has a positive slope corresponding to β_{CuA_2} (defined as $[CuA_2^{2-}]/[Cu^{2+}][A^{2-}]^2$) equal to 1300 M^{-2}. The scatter of points is so large that this value is not very reliable, but it is true to say that the constant could not be much larger without the presence of CuA_2^{2-} being obvious from the measurements. If this value of β_{CuA_2} is correct, only about 0.5 to 2.5% of the total copper would be present as CuA_2^{2-} in our runs measuring K_{CuA}, while 25 to 50% is present as CuA, and somewhat lower percentages would hold for the kinetic runs. The matter is raised here because it is evident that CuAB is relatively stable compared with CuA_2^{2-} and CuB_2^{2+}. The equilibrium constant of

$$CuA_2^{2-} + CuB_2^{2+} \rightleftharpoons 2\,CuAB$$

is equal to $K_{CuAB}^2 K_{CuB}^2/\beta_{CuA_2}\beta_{CuB_2}$; and if β_{CuA_2} is taken as 1300 M^{-2}, then this reaction has an equilibrium constant of 40 000 if B = 2,2′-bipyridyl, and 12 000 if B = 1,10-phenanthroline. The CuAB species is more strongly favored for the weaker base. If A and B were attached at random to the copper, the equilibrium constant would be 4, and even allowing for the uncertainty in β_{CuA_2} there can be no doubt that the actual equilibrium constant is considerably larger. Other examples of this selective effect are, of course, known, for instance in the stability of the rather similar catecholiato-2,2′-bipyridyl copper(II) complex (15).

The rate constants collected in Table 7 also show effects from the ligand B, but not to a great extent; and indeed one of the main conclusions to be drawn from this work is that, at least for the present system, large changes in reactivity are not induced in the 3-oxo-glutaric acid by effects transmitted through the copper. It is, of course, true that we are comparing the effect of CuB^{2+} with a hydrated copper, possibly $Cu(H_2O)_2^{2+}$ attached to A^{2-}, but both 2,2-bipyridyl and 1,10-phenanthroline induce considerably larger ligand field splitting than does water; see, for instance, ref. 16. The ligand field splitting is almost the same for these two bases, while their effect on the rate of reaction is in a different direction. The gross catalytic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

effect, that is the actual acceleration of the reaction, is proportional to K_{CuAB}, k_{CuAB}, and this product is 0.96 for 2,2′-bipyridyl, 0.48 for 1,10-phenanthroline, as compared with 0.34 for hydrated copper ions. These numbers show that the accelerating effect of the base largely arises from changes in the equilibrium concentrations in the solution. At present it does not seem possible to suggest detailed reasons for the small changes observed in the rate constants.

Magnetic Susceptibilities of $^2T_2$ Ions. Part 1

ALAN D. WESTLAND

Department of Chemistry, University of Ottawa, Ottawa, Canada, K1N 6N5

Received November 4, 1971

An expression for the magnetic susceptibility of octahedral d^1 complexes is derived exactly in terms of an orbital reduction factor k taking into account the presence of the formal ^2E excited state. Sample calculations show that the improved expression gives results for susceptibility which are lower at times by several percent from those given by previous expressions. The results given by Figgis using Kotani's method are adequately precise when the spin–orbit coupling constant is no larger than $\sim 0.1\ Dq$.

Une expression pour la susceptibilité magnétique des complexes octaédraux d^1 est dérivée exactement en termes de facteur k de réduction d'orbitale qui tient compte de la présence de l'état excité défini ^2E. Des exemples de calculs montrent que l'expression améliorée donnent des résultats pour la susceptibilité qui sont plus bas dans certains cas de plusieurs pourcents par rapport à ceux donnés par les expressions précédentes. Les résultats donnés par Figgis utilisant la méthode de Kotani sont d'une précision convenable lorsque la constante de couplage spin–orbite n'est pas plus grande que $\sim 0.1\ Dq$.

Canadian Journal of Chemistry, **50**, 1468 (1972)

Introduction

The magnetic behavior of T-state ions shows large departures from spin-only character. The effective magnetic moment of octahedral d^1 and d^4 ions shows particularly strong temperature dependence with decreasing temperature, approaching zero at $T = 0$ in some instances, *e.g.* in ReF_6 (1). Kotani (2) and Liehr (3) have provided the theoretical background for an understanding of such behavior. However, the expressions given by these authors for the magnetic susceptibility of d^1 ions contain assumptions which have a considerable effect upon the results of calculations. Gerloch (4) has treated fully the similar case of d^9 ions in a tetrahedral field and included axial distortion in his calculations. His basis set of wavefunctions were not diagonalized with respect to spin–orbit coupling and this fact combined with the complications due to distortion made it impossible to write down an explicit expression for the susceptibility. We report here an exact expression for the susceptibility of $^2T_2$ ions and show thereby the extent to which the Kotani and Liehr expressions are in error. As Gerloch has treated d^9 ions already (4), we shall concentrate here on the d^1 case.

The $^2T_{2g}$ state gives under the influence of spin–orbit coupling a ground state quartet, $\Gamma_8(T_{2g})$ and a doublet, $\Gamma_7(T_{2g})$. There is a further quartet, $\Gamma_8(E_g)$, lying at still higher energy. The eigenfunctions corresponding to these states can be called $\Psi_8(t_{2g})^{a,b,c,d}$, $\Psi_7(t_{2g})^{a,b}$, and $\Psi_8(e_g)^{a,b,c,d}$, where the superscripts designate individual spinors. Using zero-order functions the matrix elements for the magnetic operator

$$\langle \Psi_8(t_{2g}) | l_z + 2s_z | \Psi_8(t_{2g}) \rangle$$

are zero so there is no paramagnetic contribution from the ground state through the first-order Zeeman terms. There is a second-order Zeeman contribution because the non-diagonal matrix elements

$$\langle \Psi_8(t_{2g}) | l_z + 2s_z | \Psi_7(t_{2g}) \rangle$$

are non-zero. To this temperature independent contribution to the susceptibility, Kotani added the first-order terms arising from thermal excitation to the $\Gamma_7(T_{2g})$ state. This is relevant when the energy difference between the $\Gamma_7(T_{2g})$ and $\Gamma_8(T_{2g})$ states is not large with respect to kT. This energy difference is $3\zeta/2$ where ζ is the spin–orbit coupling constant (3).

Liehr argued that when $\zeta \gg kT$, *i.e.* for heavy elements, the excitation to the $\Gamma_7(T_{2g})$ state is unimportant, but mixing of the $\Psi_8(e_g)$ wavefunctions into the $\Gamma_8(T_{2g})$ functions becomes quite important. Such intermixing makes the ground state diagonal matrix elements non-zero and a temperature dependent contribution to the susceptibility is produced. The susceptibility of heavy d^1 ions always shows some temperature dependence.

While Kotani neglected the intermixing of

For personal use only.

wavefunctions, Liehr allowed the wavefunctions to mix and applied the resulting corrections to the diagonal matrix elements. The resulting expressions of Kotani and Liehr are useful in calculations dealing with first row and third row elements, respectively. It seemed doubtful that either expression would give accurately the magnetic susceptibility of certain second row ions such as $NbCl_6^{2-}$. We have now corrected the off-diagonal matrix elements to take account of orbital mixing and this has resulted in a decrease in calculated susceptibilities which amounted to several percent in some cases.

Theory

Wavefunctions

First order corrected strong field wavefunctions took the form

$$\Psi_8^s(t_{2g}) = \sin\eta\Gamma_8^s(t_{2g}) - \cos\eta\Gamma_8^s(e_g)$$

where

$$s = a, b, c, d$$

and

$$\tan 2\eta = -\frac{\sqrt{6}\zeta}{\zeta/2 + 10Dg}$$

and $\Gamma_8^s(t_{2g})$ as well as $\Gamma_7^s(t_{2g})$ and $\Gamma_8^s(e_g)$ are zero-order d orbitals transforming correctly under the double group O' (5). Hereinafter we use

$$\Psi_7^s(t_{2g}) = \Gamma_7^s(t_{2g})$$

Matrix Elements

The wavefunctions are diagonal under spin–orbit coupling. The energy matrix is thus

$$\begin{array}{cc} \Gamma_8(T_{2g}) & \Gamma_7(T_{2g}) \\ \left|\begin{array}{cc} -\frac{\zeta}{2} - \sqrt{\frac{3}{2}}\,\zeta\cot\eta & 0 \\ 0 & \zeta \end{array}\right| & \end{array}$$

The general matrix element under the magnetic operator is

$$\langle\Psi_n^s(t_{2g})|kl_z + 2s_z|\Psi_m^s(t_{2g})\rangle\beta H$$

Here k is the orbital reduction factor (6). It may be noted that Figgis revised Kotani's work by incorporating k into the magnetic operator (7). The use of a single k parameter to account for the reduction of all matrix elements is not entirely satisfactory (8), but little else can be done at this time. Liehr implicitly set k equal to unity. The energy matrix becomes

$$\begin{array}{cccccc} \Psi_8^a(t_{2g}) & \Psi_7^a(t_{2g}) & \Psi_8^b(t_{2g}) & \Psi_7^b(t_{2g}) & \Psi_8^c(t_{2g}) & \Psi_8^d(t_{2g}) \\ \left|\begin{array}{cccccc} a_{11} & a_{12} & & & & \\ & a_{22} & & & & \\ & & a_{33} & a_{34} & & \\ & & & a_{44} & & \\ & & & & a_{55} & \\ & & & & & a_{66} \end{array}\right| & & & & & \end{array}$$

where

$$a_{11} = \left[\frac{k-1}{3}\sin^2\eta + \frac{8k}{6}\sin\eta\cos\eta - \cos^2\eta\right]\beta H$$

$$a_{12} = \left\{\frac{\sqrt{2}}{3}\sin\eta\left[k + 1 + \sin\eta - \frac{2k}{3}\cos\eta\right]\right\}\beta H$$

$$a_{22} = \frac{2k+1}{3}\beta H$$

$$a_{33} = -a_{11}$$

$$a_{34} = a_{12}$$

$$a_{44} = -a_{22}$$

$$a_{55} = [(1-k)\sin^2\eta - \cos^2\eta]\beta H$$

$$a_{66} = -a_{55}$$

The magnetic susceptibility may be obtained from the standard formula (9) using the above listed independent matrix elements. We therefore have

$$[1]\quad \chi_M = N(2e^{\zeta/kT} + e^{-\zeta/kT})^{-1}\left\{\left[\frac{(a_{11}/H)^2 + (a_{55}/H)^2}{kT} + \frac{4}{3\zeta}(a_{12}/H)^2\right]e^{\zeta/2kT} + \left[\frac{(a_{22}/H)^2}{kT} - \frac{4}{3\zeta}(a_{12}/H)^2\right]e^{-\zeta/kT}\right\}$$

If ζ is large relative to kT, the quantity $e^{-\zeta/kT}$ becomes negligible and the susceptibility is given by

$$[2]\quad \chi_M = N\left[\frac{(a_{11}/H)^2 + (a_{55}/H)^2}{kT} + \frac{2}{3\zeta}(a_{12}/H)^2\right]$$

When $k = 1.0$ this differs from Liehr's expression only in the term a_{12} being more accurate but, as is shown below, this is an important difference. Following Liehr, we may make the

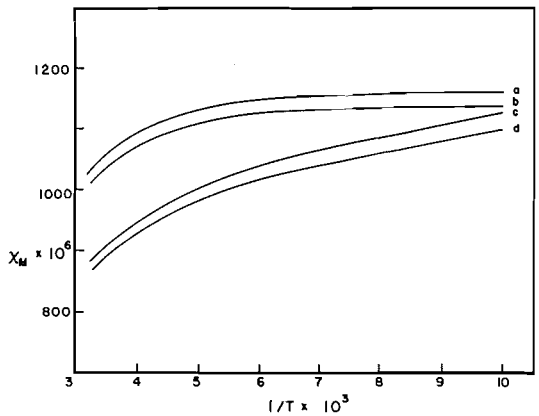

FIG. 1. Calculated mole susceptibility in e.s.u. for $\zeta = 300\ cm^{-1}$, $Dq = 2500\ cm^{-1}$. (*a*) Kotani equation, $k = 1.0$. (*b*) Equation 1, $k = 1.0$. (*c*) Kotani equation, $k = 0.7$. (*d*) equation 1, $k = 0.7$.

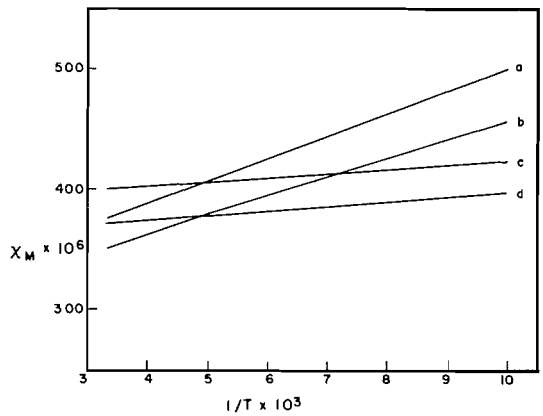

FIG. 2. Calculated mole susceptibility in e.s.u. for $\zeta = 900\ cm^{-1}$, $Dq = 2500\ cm^{-1}$. (*a*) Kotani equation, $k = 0.7$. (*b*) Equation 1, $k = 0.7$. (*c*) Liehr equation, $k = 1.0$. (*d*) Equation 1, $k = 1.0$.

expression easier to handle by writing it as

$$[3]\quad \chi_M = \frac{N\beta^2}{3kT}[1/4(1+\cos 2\eta)(19 - 13\cos 2\eta - 4\sqrt{6}\sin 2\eta)] + \frac{2N}{3\zeta}(a_{12}/H)^2$$

It is most probable that k will differ from unity in any specific instance so that expression 3 probably has little general applicability. Programs for these various expressions were written in Fortran and the results compared with those from previous methods of calculation.

Results and Discussion of Sample Calculations

Good agreement is expected between eq. 1 and the Kotani–Figgis calculations when the spin–orbit coupling is small relative to Dq. Figure 1 shows a comparison of results for a rather extreme case of $\zeta = 300\ cm^{-1}$ and $Dq = 2500\ cm^{-1}$. The agreement is good enough for dealing with typical experimental data in which errors of $\pm 1\%$ are to be expected. The difference between the calculations should get larger with increasing ζ. Figure 2 shows an example of this for $\zeta = 900\ cm^{-1}$ and $k = 0.7$. Here the difference is $\sim 9\%$ at 100 °K. For this choice of parameters (but with $k = 1.0$ of course) the Liehr expression also gives differing results. The magnetic susceptibility of MoX_6^- would therefore be given accurately only by the more detailed calculation.

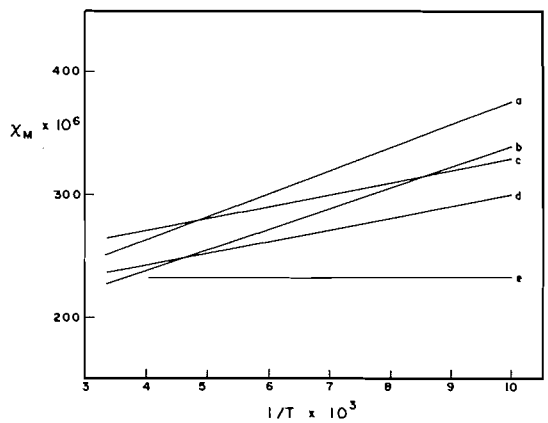

FIG. 3. Calculated mole susceptibility in e.s.u. for $\zeta = 1500\ cm^{-1}$, $Dq = 2500\ cm^{-1}$. (*a*) Kotani equation, $k = 0.7$. (*b*) Equation 1, $k = 0.7$. (*c*) Liehr equation, $k = 1.0$. (*d*) Equation 1, $k = 1.0$. (*e*) Kotani equation, $k = 1.0$.

We originally expected good results from the Liehr expression when ζ was several times kT in magnitude. For $\zeta = 1500\ cm^{-1}$ and $Dq = 2500\ cm^{-1}$, we see from Fig. 3 that considerable discrepancy persists. This originates in the temperature independent term owing to the fact that Liehr did not include mixing of the $\Gamma_8(T_{2g})$ and $\Gamma_8(E_g)$ states in the second-order Zeeman effect. The second-order term is more important in general than the temperature dependent part.

The Kotani–Figgis calculation is correct near the room temperature but there is virtually no temperature dependent contribution when $k = 1.0$. The error is consequently very large at low

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

temperatures. When k is small, the Kotani–Figgis procedure gives a fairly good estimate of the temperature dependent term but the temperature independent part is not correct.

It may be concluded that the detailed calculation is called for over almost the whole range of possible values of the spin–orbit coupling parameter. However, it is found that there is virtually exact agreement between the results of eq. 2 and those of eq. 1 for most choices of ζ and Dq. Equation 2, which can be used without the aid of a computer, is thus to be preferred in most cases. Calculations with eq. 2 are accurate to about 0.1% when $\zeta = 4kT$, to 0.5% when $\zeta = 3kT$, and are high by 3.6% when $\zeta = 2kT$.

Susceptibilities which are linear in $1/T$ are accurately given by eq. 2 but as promotion of electrons to the $\Gamma_7(T_{2g})$ state becomes appreciable with increasing temperature, the true susceptibility begins to fall short of that given by the linear relationship.

Some general statements can be made about axial distortions. If the octahedron is subjected to an elongation along a three-fold or four-fold axis, there is very little effect on the susceptibility at low temperatures. At high temperatures there will be a slight drop in susceptibility as indicated by Figgis' data (7). Compression along an axis has a large effect, especially at low temperatures where the susceptibility tends to be increased. The error involved in neglect of orbital mixing decreases with increasing distortion, so that for highly distorted complexes, Figgis' results are probably quite accurate. Large distortions are to be expected only with substituted octahedra, MX_3Y_3, etc.

Etude spectroscopique des dérivés du peroxyde d'hydrogène. V. Les percarbonates $KHCO_4$ et $K_2C_2O_6$ [1]

PAUL A. GIGUÈRE ET DENIS LEMAIRE

Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec 10, Québec

Reçu le 15 décembre 1971

Les deux percarbonates $KHCO_4$ et $K_2C_2O_6$ ont été préparés à l'état pur en vue d'étudier leurs spectres infrarouges et Raman. Le permonocarbonate est assez instable et fortement hygroscopique. L'anion HCO_4^- forme des ponts d'hydrogène très forts, quoique un peu moins que ceux du bicarbonate HCO_3^-. Quant à l'anion $C_2O_6^{2-}$, il semble plan et centrosymétrique d'après le petit nombre de bandes en infrarouge et en Raman. Dans ces deux ions la vibration de valence O—O a une fréquence assez voisine de celle de H_2O_2, dû sans doute au couplage avec des vibrations voisines. Pour fin de comparaison on a étudié de la même façon le peroxyhydrate $K_2CO_3.3H_2O_2$.

The two percarbonates $KHCO_4$ and $K_2C_2O_6$ were prepared by chemical or electrolytic methods in order to measure their infrared and Raman spectra. The permonocarbonate is unstable and very hygroscopic. The HCO_4^- anion forms quite strong intermolecular hydrogen bonds, although somewhat less so than the bicarbonate anion. As for the $C_2O_6^{2-}$ anion, the rather small number of its infrared and Raman bands suggests a planar and centrosymmetric configuration. In both percarbonates the O—O vibration shows nearly the same frequency as in H_2O_2, presumably due to coupling with neighboring vibrations. For comparison purposes the peroxyhydrate $K_2CO_3.3H_2O_2$ was studied likewise.

Canadian Journal of Chemistry, **50**, 1472 (1972)

Introduction

Les percarbonates alcalins, qui entrent dans la composition de plusieurs détersifs domestiques, sont connus depuis très longtemps. En fait les premières descriptions de préparations par électrolyse remontent à la fin du siècle dernier (1, 2). Cependant, ils ont été l'objet de sérieuses controverses quant à leur nature et à leur composition. La difficulté venait d'abord de leur caractère instable et hygroscopique qui les rend difficiles à isoler à l'état pur. De plus, on les a longtemps confondus avec les peroxyhydrates des carbonates ou bicarbonates alcalins qui, eux aussi, dégagent de l'oxygène actif par hydrolyse. Le test dit de Riesenfeld-Liebhafsky (3), qui a servi pendant longtemps à distinguer entre les persels et les peroxyhydrates, n'a en fait de valeur absolue que lorsqu'il est positif (4, 5). Aujourd'hui, grâce aux méthodes physiques comme la spectroscopie, on peut distinguer entre les vrais percarbonates et les carbonates peroxyhydratés.

Les premiers, qui sont le résultat d'une réaction chimique, sont de deux sortes; soit les permonocarbonates, de formule $MHCO_4$, et les perdicarbonates, $M_2C_2O_6$. (Les composés de formule M_2CO_4 rapportés dans la littérature (4) ne semblent pas réels.) Par contre, les peroxyhydrates s'obtiennent pas simple cristallisation d'un carbonate à partir d'une solution aqueuse de peroxyde d'hydrogène. Ils sont difficiles à caractériser comme entités définies.

On ne possède aucune donnée sur la structure de ces composés. La seule étude par diffraction des rayons X de $K_2C_2O_6$ a été faite par la méthode des poudres pour fins analytiques (6). Elle n'a pas permis d'établir la symétrie ni les dimensions de la maille fondamentale. Le spectre infrarouge, étudié par les mêmes auteurs, a été interprété selon une formule entièrement covalente, ce qui ne saurait convenir. Les carbonates de sodium et de potassium peroxyhydratés ont déjà été étudiés par spectroscopie infrarouge et par analyse thermique différentielle (7).

Méthodes expérimentales

Nous avons suivi la méthode décrite par Firsova et ses collaborateurs (8) qui consiste à ajouter lentement du peroxyde d'hydrogène assez concentré à une solution refroidie à -20 °C, de KOH à 50% dans l'eau, de façon à atteindre un rapport KOH/H_2O_2 de 1. On y fait ensuite passer un courant de gaz carbonique pendant une heure environ. Le précité blanc ainsi obtenu est filtré à froid sur un entonnoir à disque de verre fritté, puis lavé avec de l'alcool absolu et de l'éther anhydre, préalablement re-

[1]Présenté au 18ième Symposium de Spectroscopie du Canada à Toronto, octobre 1971.

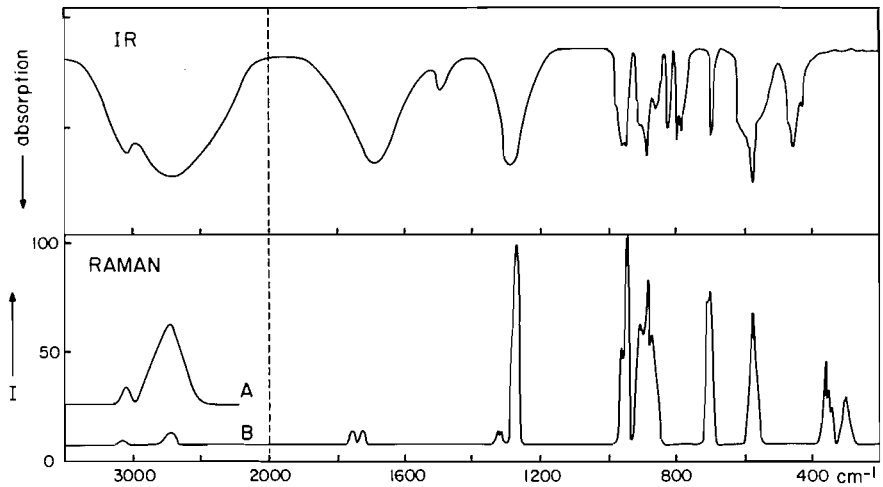

FIG. 1. Spectres de vibration de $KHCO_4$ à la température de l'azote liquide.

froidis, et finalement séché dans un courant d'air très sec. Parce que $KHCO_4$ perd lentement de son oxygène actif, même à température ambiante, nos spectres ont toujours été pris avec des échantillons frais. Pour plus de certitude nous avons analysé le produit utilisé, d'abord par acidimétrie, après décomposition du peroxyde avec MnO_2, puis par émission atomique pour doser le potassium. Les résultats concordaient avec la formule à 0.5% près.

Les échantillons de $K_2C_2O_6$ ont été préparés par électrolyse selon la technique décrite par Firsova (9). Le produit final était un solide pulvérulent, blanc, légèrement teinté de bleu tel que noté par les auteurs russes. Quoique beaucoup plus stable que $KHCO_4$, le perdicarbonate $K_2C_2O_6$ est hygroscopique et s'hydrolyse facilement en bicarbonate avec perte d'oxygène. Enfin le peroxyhydrate de formule hypothétique $K_2CO_3.3H_2O_2$ a été obtenu tel que décrit précédemment (4, 10).

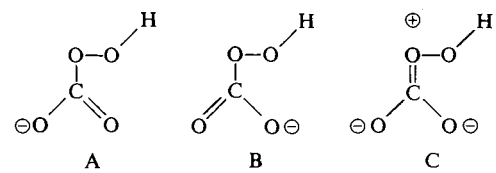
Pour les spectres infrarouges les échantillons furent préparés par dispersion, sous l'atmosphère rigoureusement sèche, des poudres finement broyées dans du Nujol, du Fluorolube ou de l'hexachloro-1,3 butadiène, selon les régions à étudier. On étalait la suspension entre deux disques de NaCl ou de CsI, sauf dans le cas de $KHCO_4$ qui attaquait ces matériaux. Il a fallu alors employer des disques neufs de AgCl. Notons que la technique de la pastille de KBr, utilisée par les auteurs russes (6) avec $K_2C_2O_6$, donne des spectres de qualité inférieure. A en juger par la diminution d'intensité des bandes du percarbonate, ce dernier doit réagir lentement avec le bromure. Avec $KHCO_4$ la réaction était beaucoup plus rapide. Kyrki (11) a rapporté un phénomène semblable, quoique moins prononcé, avec le persulfate $KHSO_5$.

Pour l'infrarouge lointain la dispersion de $K_2C_2O_6$ dans le Nujol était pressée entre des disques de silicum. Enfin pour l'étude de l'effet Raman, la poudre tassée dans un capillaire de Pyrex était éclairée à incidence normale par le faisceau laser. Le percarbonate $K_2C_2O_6$ a pu être ainsi étudié à température ambiante, mais avec $KHCO_4$ et le peroxyhydrate il a fallu refroidir les échantillons avec de l'azote liquide pour empêcher la décomposition par le faisceau laser à argon ionisé (Coherent Radiation, modèle 52). Les spectromètres étaient les mêmes que précédemment (12).

Discussion des résultats

Le percarbonate $KHCO_4$

Les bandes infrarouges et Raman (Fig. 1) ont été attribuées (Tableau 1) dans l'hypothèse d'une configuration plane de l'anion HCO_4^-. Celle-ci en effet nous semble plus probable (du moins pour le squelette) étant donné que la résonance entre les trois structures canoniques doit conférer un certain caractère π à la liaison C—O_2H. De toute façon les spectres ne sauraient nous renseigner là-dessus puisque même selon la symétrie C_s toutes les vibrations doivent être actives tant en infrarouge qu'en Raman.



Ainsi les douze vibrations fondamentales se répartissent en neuf de classe a′ (dans le plan) et trois a″ (hors du plan). Pour fin de comparaison nous donnons également les fréquences en infrarouge de l'anion HCO_3^- (13). A noter que les bandes les plus fortes de ce dernier à 1960/1943 et 1017 cm^{-1} sont absentes de nos spectres des deux percarbonates. C'est là la meilleure preuve de la pureté chimique de

nos échantillons, puisque les percarbonates se décomposent ou s'hydrolysent en bicarbonates (4, 8).

La fréquence de ν_{O-H} est ici relativement basse, quoique moins basse que dans les bicarbonates (13–16). Ces derniers forment des liaisons hydrogène particulièrement fortes, avec des distances O—H...O de 2.61 Å. D'après les relations empiriques usuelles on peut évaluer ces distances à 2.64 Å dans HCO_4^-, et les distances O—H, à environ 1.04 Å; ce qui correspond à une énergie de l'ordre de 7 kcal mol^{-1}. On peut donc en conclure que ces liaisons hydrogène sont du type inter-, et non pas intramoléculaire. En effet, dans ce dernier cas elles seraient beaucoup plus faibles (distance H...O d'à peu près 1.9 Å) et non linéaires.

Les vibrations du squelette ont été attribuées sans tenir compte des effets de couplage possible. Les vibrations de valence C=O ont des fréquences légèrement inférieures, et celle de la liaison C—O, de beaucoup inférieure aux vibrations correspondantes dans l'anion HCO_3^-. On a une situation analogue dans H_2SO_5 par rapport à H_2SO_4 (11, 12). Quant à la vibration de valence O—O, on retrouve ici pratiquement la même fréquence que dans la molécule H_2O_2 (3), tout comme dans l'acide de Caro et ses sels. Notons en passant que cette vibration O—O se traduit par un triplet en Raman. (Le pic à 906 cm^{-1} semble trop aigu pour le mode de torsion OH.) C'est une indication que la maille cristalline contient plus de deux anions, avec vibrations en phase et hors de phase. La même explication vaut pour la multiplicité des composantes de la bande de déformation ν_7 en infrarouge.

Le percarbonate $K_2C_2O_6$

A priori deux configurations sont possibles pour l'anion $C_2O_6^{2-}$ selon que les deux groupes CO_3 reliés par le pont peroxyde sont dans le même plan ou non. La première semble plus probable; d'abord par analogie avec l'anion persulfate $S_2O_8^{2-}$ (17), et ensuite d'après les indications de nos spectres (Fig. 2). En effet, le nombre de bandes y est assez restreint. Il est vrai qu'elles coïncident parfois en infrarouge et en Raman, mais ceci est inévitable vu la multiplicité de certains modes. Selon une structure plane et centrosymétrique (C_{2h}) les dix-huit fondamentales de l'anion $C_2O_6^{2-}$ se subdivisent en quatre classes (Tableau 2).

Nos attributions ne tiennent pas compte des effets de couplage particulièrement importants dans la région de 700 à 900 cm^{-1}. C'est sans doute à ce phénomène qu'il faut attribuer la fréquence remarquablement élevée de la vibration de valence O—O. Intuitivement on s'attendrait à une fréquence sensiblement inférieure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

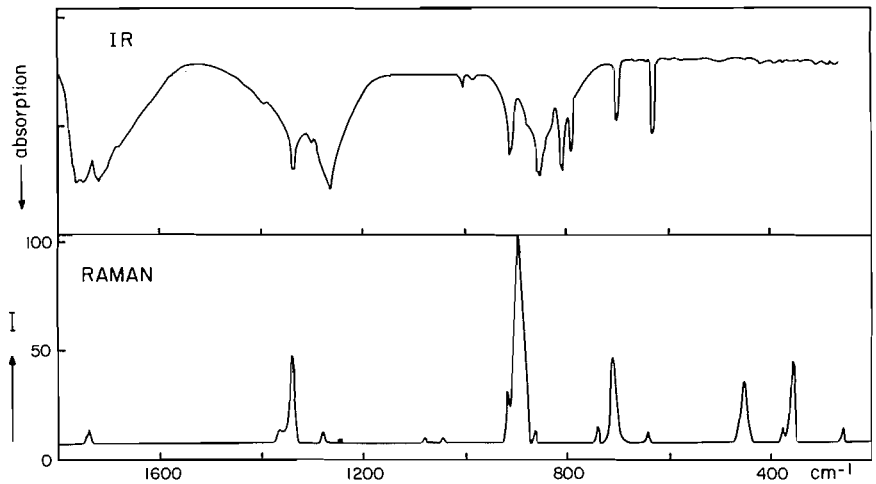

FIG. 2. Spectres de vibration à température ambiante d'un échantillon de $K_2C_2O_6$ préparé par électrolyse de K_2CO_3.

d'après l'effet de masse. Ainsi dans le cas quelque peu analogue de l'anion $S_2O_8^{2-}$ la vibration O—O se situe vers 830 cm^{-1} (18). Mais alors que dans ce dernier la vibration la plus proche est à 1090 cm^{-1}, dans $C_2O_6^{2-}$ au contraire les vibrations C—O sont beaucoup plus rapprochées. Les modes de torsion autour des liaisons C—O et O—O peuvent être identifiés d'après leur symétrie. Ainsi la plus basse fréquence Raman à 353 cm^{-1} doit appartenir au mode symétrique ν_9. La fréquence infrarouge la plus rapprochée est à 282 cm^{-1}. L'écart considérable s'explique par le couplage interne assez faible. Les forces de rappel sont surtout d'origine externe dans ce cas-ci.

De façon générale nos spectres infrarouges concordent assez bien avec ceux des auteurs soviétiques (6), sauf que leurs fréquences sont

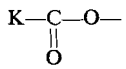
toutes décalées de quelque 10 cm^{-1} par rapport aux nôtres. En outre ils n'ont pu résoudre toutes les composantes des bandes entre 800 et 1000 cm^{-1}. Aussi, en l'absence de données Raman, ont-ils attribué à la vibration O—O leur forte bande à 878 cm^{-1}. Par ailleurs leur interprétation selon une structure entièrement covalente les conduit à représenter l'atome de carbone avec une seule liaison double et deux liaisons simples, soit



Une telle structure est évidemment inacceptable d'après la théorie de la liaison chimique. Il ne fait aucun doute que les percarbonates alcalins sont de nature ionique.

Les peroxyhydrates

Les carbonates alcalins peroxydratés sont trop instables pour être isolés à l'état pur. On a prouvé par l'analyse thermique différentielle (7) qu'ils contiennent toujours plus ou moins d'eau, d'où les diverses formules qu'on trouve dans la littérature. La situation se complique encore du fait que les carbonates mêmes, qui sont assez hygroscopiques, montrent des différences considérables dans leurs spectres lors de l'hydratation (19). Il n'est donc pas surprenant que les spectres des peroxyhydrates varient beaucoup d'un échantillon à l'autre, et même avec le temps pour un échantillon donné.

La Fig. 3 a été reconstituée d'après les spectres d'échantillons censés de composition $K_2CO_3.3H_2O_2$. Cependant la bande à 1650 cm^{-1} atteste bien la présence d'eau (de cristallisation ou de décomposition). Les fréquences principales correspondent bien à celles déjà trouvées (7) mais notre interprétation diffère dans certains cas. Ainsi des deux bandes de valence O—H à 3300 et 2700 cm^{-1}, nous attribuons la seconde aux liaisons hydrogène avec les anions carbonate, vraisemblablement plus fortes que les autres, entre H_2O_2 et H_2O. Les fondamentales de l'anion CO_3^{2-} sont diversement affectées dans les peroxyhydrates. Ainsi le mode de valence antisymétrique, qui donne un doublet dans le carbonate anhydre et son hydrate, ne produit ici qu'une seule bande large vers 1420 cm^{-1} en infrarouge. Par contre le mode symétrique, absent en infrarouge dans le carbonate anhydre, donne une bande fine à 1060 cm^{-1} dans l'hydrate et à 1013 cm^{-1} dans le peroxyhydrate. En Raman on trouve un doublet à 1071/1026 cm^{-1}. La bande assez large à 980 cm^{-1} en infrarouge seulement a été attribuée (7) à la rotation gênée ou libration des molécules d'eau. Nous croyons qu'elle appartient plutôt aux molécules de peroxyde vu l'analogie avec la bande à 940 cm^{-1} dans $KF.H_2O_2$ (20). La vibration de valence O—O du peroxyde d'hydrogène est difficile à identifier car elle coïncide exactement avec la déformation dans le plan de CO_3^{2-}. Cette dernière est probablement seule à l'origine du doublet à 865–830

For personal use only.

cm^{-1} en infrarouge car la bande O—O des peroxydes symétriques n'y est jamais très intense. En Raman, au contraire, la vibration ν_2 du carbonate est souvent absente ou très faible, même dans le cas des hydrates. Le pic intense à 865 cm^{-1} avec pics secondaires à 870 et 876 cm^{-1} serait donc dû surtout à ν_{O-O}. Enfin une étude spectroscopique plus poussée de ces composés mal définis ne semble pas justifiable pour le moment vu l'intérêt plutôt académique de la question.

Ce travail a été exécuté avec l'aide financière du Conseil National de Recherches du Canada. Les auteurs remercient le professeur O. Gübeli pour les analyses par émission atomique et le docteur J. L. Arnau pour l'enregistrement des spectres Raman.

The Constituents of *Nauclea diderrichii*. Part II. Isolation and Classification of Constituents; Simple β-Carboline and Pyridine Alkaloids[1]

STEWART MCLEAN AND D. G. MURRAY

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 25, 1971

The bark of *Nauclea diderrichii* (Rubiaceae) has afforded a considerable number of constituents, mainly alkaloids. For convenience these have been placed in four categories: (*1*) simple β-carbolines, (*2*) simple pyridines, (*3*) indole-pyridines, and (*4*) miscellaneous substances. Isolation procedures and the elucidation of the structures of constituents in categories (*1*) and (*2*) are described in this paper. Spectroscopic evidence supported by synthesis has been used to assign structures **1**, **2**, **3**, and **4** to the four simple β-carbolines and structures **5**, **6**, **7**, and **8** to the four simple pyridines isolated.

L'écorce du *Nauclea diderrichii* (Rubiaceae) a donné un nombre considérable de produits constitués surtout d'alcaloides. Dans un but pratique, ceux-ci ont été classés en quatre catégories: (*1*) les β-carbolines simples, (*2*) les pyridines simples, (*3*) les indoles-pyridines, et (*4*) les substances diverses. Les moyens de purification ainsi que la détermination des structures des substances appartenant à la catégorie (*1*) et (*2*) sont décrits dans cet article. Des preuves spectroscopiques et des synthèses ont permis d'attribuer les structures **1**, **2**, **3**, et **4** aux quatre β-carbolines simples et les structures **5**, **6**, **7**, et **8** aux quatre pyridines simples isolées.

Canadian Journal of Chemistry, **50**, 1478 (1972)

We recently described in a preliminary communication (1*a*) the isolation of a number of alkaloids from the bark of a West African tree, *Nauclea diderrichii* (*Sarcocephalus diderrichii*). We were able to demonstrate the co-occurrence of indole alkaloids, presumed to be derived from tryptamine or tryptophan, and pyridine alkaloids that are probably of monoterpenoid origin, and evidence was presented that some of the alkaloids isolated, referred to as indole-pyridines, contained structural units derived from both of these classes and were of considerable structural novelty. In the present discussion attention will be focussed on the simpler alkaloids to which structures have been confidently assigned; experience with these alkaloids has helped us to discern in the more complex alkaloids (1*b*) structural features which appear to reveal a pattern, probably related to the biogenetic origins of these secondary plant metabolites (1*c*), which can then be applied to generate or test suggestions regarding the structures of some of the more complex alkaloids.

Isolation and Classification of Constituents

Although the genus *Nauclea* L. (*Sarcocephalus* Afzel. ex R. Br.) of the family Rubiaceae is widely distributed in tropical areas (2), contains species with reputations in native medicine (3), and is botanically closely related (4) to species from which constituents of considerable chemical interest have been isolated, it appears to have attracted remarkably little phytochemical interest (3).

We have investigated the bark of *N. diderrichii*, obtained from Nigeria, and isolated a considerable number of constituents, principally alkaloids, of chemical interest. Isolation procedures used were based on those commonly used for the extraction of alkaloids: typically, the dried, ground bark was extracted repeatedly with cold methanol, the extract was concentrated under reduced pressure, the components were partitioned between dilute hydrochloric acid and chloroform, and the basic fraction was recovered from the acidic solution after it had been treated with ammonia. The crude "total bases" isolated corresponded to between 0.01 and 0.075% of the dried bark. It should be noted that included in the "total bases" were components which were later found to be non-basic and that the use of ammonia as a standard practice in the extraction and the subsequent chromatography led to questions which will be discussed subsequently (1*b*). The t.l.c. showed that the "total bases" comprised an extremely complex mixture of components, and repeated preparative t.l.c. was required to effect their separation. In some cases it was possible to purify the compounds isolated

[1]Our preliminary communication (1*a*) is considered to be Part I of this series. This account is taken from the Ph.D. thesis of D. G. Murray, University of Toronto, 1971.

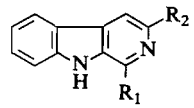
to a satisfactory level of homogeneity, but in others the very small amount of material available precluded further purification, and material that would, under better circumstances, have been considered of unsatisfactory homogeneity was studied.

In no case, however, was sufficient material available for investigation of its structure by standard methods requiring combustion analysis and rational degradation. Instead, it was necessary in every case to carry out first a careful mass spectrometric examination of the component to determine its molecular formula and to obtain any available structural information from its fragmentation pattern; other spectroscopic methods were then used, to the extent that the amount of material and its solubility allowed, in order to derive as much additional structural information as possible. On the basis of the information thus obtained, a structure was proposed as a working hypothesis with a degree of confidence that varied from case to case. It was then necessary to turn either to direct comparison with authentic material in the few cases where the compound appeared to have been described previously, or to an unambiguous synthesis of the compound when no previous account of a substance of the proposed structure could be found.

At the present time it has not been possible to carry the elucidation of structure to a satisfactory conclusion in every case, but sufficient progress has been made to allow us to see the development of a pattern in the structures that is of considerable interest and significance in the chemistry of secondary plant metabolites, and this has induced us to report our present results even in those cases where the evidence allows only a part structure to be proposed or a structural hypothesis to be advanced tentatively. It is convenient at this stage to divide the materials isolated into four categories: (*1*) simple β-carbolines, (*2*) simple pyridines, (*3*) indole-pyridines (N_3 alkaloids which appear to contain a tryptamine-derived unit and an independent pyridine unit), and (*4*) miscellaneous substances.

(1) Simple β-Carbolines

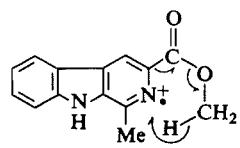
The four products (**1**, **2**, **3**, **4**) isolated that are in this category are conveniently described first since they were easily related to compounds of known structure. The identity of harman (**1**), a widely distributed and well-known alkaloid, was confirmed by comparison with authentic material. 3-Carbomethoxyharman (**2**) does not appear to have been obtained previously as a natural product, but a glycoside of the free acid has been found (5) and the ester has been synthesized from tryptophan (6); synthetic material we obtained by the same procedure (6) served to confirm the identity of natural **2**. 1-Carbomethoxynorharman (**3**) has previously been described as a natural product (7); it has also been synthesized from harman (8) and this synthesis was used to establish the identity of our natural material. 1-Carboxamidonorharman (**4**) seems not to have been described previously; its identity was established by comparison with an authentic sample derived from synthetic **3**.

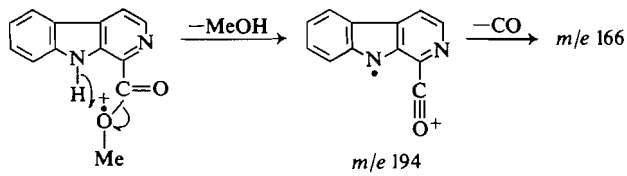


1 $R_1 = Me$; $R_2 = H$
2 $R_1 = Me$; $R_2 = CO_2Me$
3 $R_1 = CO_2Me$; $R_2 = H$
4 $R_1 = CONH_2$; $R_2 = H$

It is recognized that **4** may be an artifact derived from **3** or a related compound during the isolation process, which involved the use of ammonia at two stages. Attempts to prepare **3** and **4** via the corresponding acid chloride were abandoned in favor of Fischer esterification of the carboxylic acid and ammonolysis of the ester when it was found that the treatment of the hydrochloride of the carboxylic acid with refluxing thionyl chloride led to a considerable amount of chlorination of the β-carboline; the corresponding chlorination of a pyridine ring is known to occur (9), but under somewhat more vigorous conditions than we used.

A few features of the mass spectra of these β-carbolines (10) deserve comment since they have some diagnostic value. The base peak at M − 58 (5) in the spectrum of **2** does not correspond to an ion in the normal fragmentation pattern of an ester of an aromatic acid (11) (for which peaks are also present), and is best accounted for on the basis of a process such as:



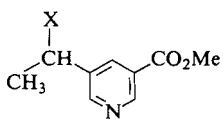


SCHEME 1

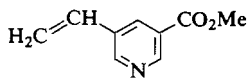
Accurate mass measurements and metastable ion evidence support this proposal. A corresponding fragmentation would be expected for **3** and the M − 58 peak is, indeed, prominent; however, the base peak is at M − 60 and apparently arises from a process involving the indole nitrogen (see Scheme 1). A significant peak is visible at *m/e* 194, and accurate mass measurements and metastable ion evidence are in accord with the sequence shown. Fragmentation of **4** apparently follows closely related pathways leading to peaks corresponding to M − CONH, M − NH_3 and M − $CONH_3$; accurate mass measurements and metastable ion evidence again provided support for the proposal, and replacement with deuterium of the hydrogen atoms bonded to nitrogen produced the anticipated spectral shifts.

(2) Simple Pyridines

Four alkaloids (**5**, **6**, **7**, **8**) in this class were isolated, and their structures were assigned on the basis of their spectroscopic properties and confirmed by synthesis. Despite the structural simplicity of the compounds, only two of them (**6** and **8**) could be found in the literature, and these appear in a patent (12) without description of their physical characteristics or origin.



5 X = OMe
6 X = OH
7 X = NH_2

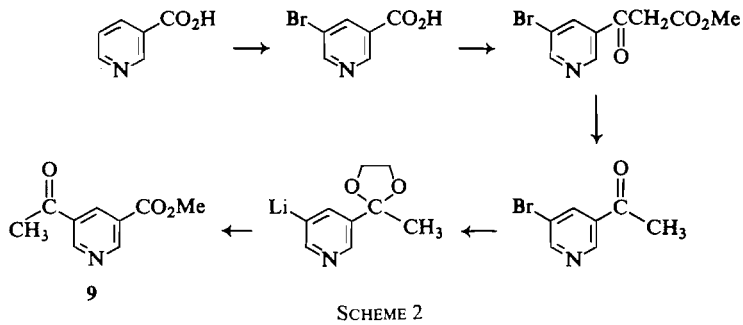


8

In each case the molecular formula was determined from the mass spectrum; the parent ion of **7** was not observed but its formula was determined by accurate mass measurement of fragment ions (M − 1 and M − 15). The spectrum of each of the alkaloids (**5**, **6**, **7**) with a saturated side-chain showed significant M − 1 and M − 15 peaks, the latter providing the base peak, which are attributed to fragmentation with loss of the methine hydrogen or methyl group of the side-chain. The normal aromatic ester fragmentation (11) is less clearly visible in these spectra, but in the spectrum of **8** it represents the dominant pathway and intense M − 31 and M − 59 peaks are observed.

The i.r. spectrum of each alkaloid showed a peak at 5.80 μ (with a shoulder at 5.82 μ), and the n.m.r. spectrum showed a methyl singlet near τ 6, indicative of the carbomethoxy function assigned to the alkaloid. The i.r. and n.m.r. spectra also provided the evidence that led to the recognition of the structure of the side-chain characteristic of each alkaloid, and the appearance, in the region of the n.m.r. spectrum associated with the protons of a pyridine ring, of an AMX pattern with $J_{AM} \simeq 0$ and $J_{AX} \simeq J_{MX} \simeq 2$ Hz allowed the substitution pattern of the ring to be assigned with confidence. It was observed that the appearance of the AMX pattern in the n.m.r. was markedly affected by the condition of the sample, and the presence of a trace of acid caused loss of the fine structure, with the signals at lower field being most strongly affected; the amount of peak broadening exhibited varied considerably and unpredictably, so that in some cases it was almost negligible, while in others it was sufficient to cause the signals to be submerged in the background noise. This was of considerable practical importance both here and in later cases, since spectroscopic samples that appeared pure in other respects were frequently clearly contaminated with slight traces of acid and it became our standard practice to remove the broadening by shaking the solution of the sample in chloroform-*d* with an aqueous base. The situation is also of considerable intrinsic interest since a detailed explanation of it encounters difficulties. It appears to have been observed previously (13) but was attributed to other causes, and several studies of the spectra of pyridinium salts and the influence of acidic solvents on the spectra of pyridines have been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME 2

reported (14) but without reference to the effect of traces of acid in a solvent such as chloroform-*d*.

The structures **5**, **6**, **7**, and **8** were finally established by comparisons of natural and synthetic materials. The synthetic route (Scheme 2), which proved unexpectedly troublesome, required the preparation of the key intermediate 3-acetyl-5-carbomethoxypyridine (**9**). An obvious route to the intermediate can be drawn from 3,5-pyridinedicarboxylic acid and requires a Claisen condensation of methyl acetate at one carbomethoxy group of the diester, but this gave unsatisfactory results, even though it appears to have worked well for the ethyl ester (15); the utilization of sodium methylsulfinylmethide (16) did not prove a successful variant. The reaction of dimethylcadmium with the acid chloride of 5-carbomethoxy-3-pyridinecarboxylic acid, for which we developed a satisfactory synthesis similar to one described recently by Wenkert *et al.* (17), led to some of the required product, but the yield was unsatisfactory, and the product ketone was contaminated with substantial amounts of the carbinol resulting from further reaction of the ketone with dimethylcadmium. The most successful route to **9** started with nicotinic acid which was converted through the hydrochloride of its acid chloride to 5-bromonicotinic acid; this, after esterification, was converted to the corresponding methyl ketone by Claisen condensation (18); the ketone was then protected as the ethylene ketal, the pyridyllithium compound was formed, and this was converted to **9** by carbonation and esterification.

Sodium borohydride reduced **9** to **6**, structurally identical with the natural material. The synthetic alcohol **6** was converted by methanolysis of its mesylate to the methyl ether **5**, structurally identical with the natural alkaloid. The dehydration of **6** to **8** was successfully accomplished by treatment with phosphorus pentoxide (19) or *p*-toluenesulfonic acid and this provided material suitable for establishing the structure of the alkaloid; it can be noted, however, that yields in this reaction were variable and that polymerization of **6** was a serious side reaction in the toluenesulfonic acid procedure. Reduction by zinc and acetic acid of the oxime of **9** formed **7**, structurally identical with the natural alkaloid.

The natural materials (**5**–**8**) were obtained in small quantities as oils and, with the exception of one sample of **5**, resisted attempts to crystallize them. These materials, **8** excepted, showed optical activity but because of the small amount of material available, specific rotations could not be determined with precision and confidence and it could not be established whether partial racemization of some of the samples had occurred in the case of **6** or whether variations arose from differences in the purity of the samples and instrumental difficulties. The synthetic samples were, of course, racemic and with the exception of **7**, were obtained crystalline.

Experimental

Melting points were determined on a calibrated Thomas–Kofler micro hot stage unless otherwise specified. Unless otherwise indicated, chloroform solutions were used to obtain i.r. spectra and the wavelengths of significant absorptions are reported in μ. Methanol solutions were used to obtain u.v. spectra and the wavelengths of maximum absorption (λ_{max}) are reported in mμ followed by the extinction coefficient (ε) in parentheses. Chloroform-*d* solutions with tetramethylsilane as an internal standard were used to obtain n.m.r. spectra and chemical shifts are reported on the τ scale followed in parentheses with an indication of the multiplicity of the signal and the number of protons associated with it; an indication is given for those n.m.r. spectra which were obtained after the chloroform-*d* solution had been shaken with base, usually 10% potassium carbonate in deuterium oxide. Spectrometers used were a

For personal use only.

Perkin–Elmer 237B for i.r. spectra, a Bausch and Lomb Spectronic 505, a Perkin–Elmer 350, or a Unicam SP.800A for u.v. spectra, and a Varian A-60, A-56/60D, T-60, or HA-100 for n.m.r. spectra (values at 100 MHz are reported unless otherwise indicated). Routine mass spectra were determined at 70 eV on a CEC 21-490 or an AEI MS-902 spectrometer and the *m/e* values of significant ions are reported followed in parentheses with a figure showing the height of the peak relative to that of the base peak (100%); accurate mass measurements were made on the AEI MS-902 spectrometer. Optical rotations were determined with a Bendix–Ericsson ETL-NPL Automatic Polarimeter Type 143A. Analytical t.l.c. procedures used pre-coated Merck silica gel F254 plates, aluminum oxide F254 type T plates, cellulose F plates, or Baker-flex aluminum oxide 1B-F sheets. Preparative t.l.c. was carried out with hand-coated plates (0.5 or 1.0 mm) prepared from Merck silica gel G or aluminum oxide G type E with 3% of an electronic phosphor (excited at 254 mμ) present, or with pre-coated Merck silica gel F254 or aluminum oxide F254 type T plates which contained an electronic phosphor. Chromatograms were examined by irradiation at 254 mμ, and also by exposure of the plates to iodine in some cases.

The *N. diderrichii* bark was obtained through the good offices of Professor D. M. James, Department of Pharmacology, University of Ibadan, Nigeria. The present work was carried out on six shipments of bark, received over a period of several years and apparently collected from trees of various ages.

Standard Isolation and Extraction Procedures

Coarsely ground dry bark was covered with methanol and allowed to soak for 24 h, the methanol was drained off, and the procedure was repeated with fresh methanol.[2] The extract obtained was filtered and concentrated under reduced pressure to about 5% of its original volume, and the material obtained from four successive extractions was pooled. The concentrate was acidified with 5% hydrochloric acid and extracted twice with chloroform. The aqueous phase was basified with 10% ammonia and extracted three times with chloroform (about one third of the volume of the aqueous solution each time). This chloroform extract was washed with water, concentrated under reduced pressure to about 5% of its original volume, and thoroughly extracted with 5% hydrochloric acid. The acidic extract was then basified with 5% ammonia and thoroughly extracted with chloroform. The final chloroform extract, after it had been washed with water and concentrated under reduced pressure provided the "total bases" as a brown syrup (about 0.05% of the starting bark).

The "total bases" were subjected to a primary separation by preparative t.l.c. using silica gel plates and elution with 84:14:1 methylene chloride – methanol–ammonia (concentrated). This separation afforded about 12 fractions, each of which was examined by analytical t.l.c. to determine the best conditions for further separation. The secondary separation was carried out by preparative t.l.c. on silica gel or alumina plates and elution by various combinations of the following solvents: hexane, benzene, ether, ethyl acetate, acetone, methanol, methylene chloride, and chloroform. Systems of particular value were 5:2:3 benzene–acetone–methanol for the more polar fractions, 7:2:1 methylene chloride–acetone–methanol for intermediate cases, and 6:4 hexane–acetone for less polar fractions. Each fraction obtained was subjected to further separations by preparative t.l.c. in the manner just described until each component was obtained in as homogeneous a condition as seemed possible.

In runs which avoided ammonia, it was replaced by 10% aqueous sodium carbonate during the extraction and by triethylamine during the separation by t.l.c.

Simple β-Carbolines

Harman (1)

Harman was obtained as a white solid, m.p. 205–229°,[3] which was identical with authentic harman, m.p. 238°; the t.l.c. behavior (four systems) and the i.r., n.m.r., and mass spectra of the two samples were compared to establish their identity.

3-Carbomethoxyharman (2)

Compound **2** was obtained, after recrystallization from methanol, as a white solid, m.p. 249–253° (dec.). Spectroscopic characteristics: i.r. 2.90 (sharp), 3.07 (broad), 5.82; n.m.r. (60 MHz) 0.95 (broad; 1), 1.16 (s; 1), 1.77 (d, $J = 8$ Hz; 1), 2.2–2.9 (complex; 3), 5.98 (s; 3), 7.18 (s; 3); mass spectrum 241 (7), 240 (29), 209 (4), 183 (16), 182 (100), 181 (35), 180 (4), 179 (8), 155 (4), 154 (13), 153 (5), 128 (5), 127 (8), 105 (17), 91 (6), 90.5 (4), 77 (14), 76 (5), 63 (4), 51 (4); metastable 138.1 (calcd. for 240 → 182: 138.0); mass measurements calcd. (found): $C_{14}H_{12}N_2O_2$, 240.08988 (240.0898); $C_{13}H_9N_2O$, 209.07149 (209.0711); $C_{12}H_{10}N_2$, 182.08440 (182.0845); $C_{12}H_9N_2$, 181.07657 (181.0764). An authentic sample of 3-carbomethoxyharman was synthesized (6) and obtained as fine needles, m.p. 250–253° (lit. (6, 5) 245°, 252–253°) and shown to be spectroscopically identical with the natural material isolated and to have the same t.l.c. behavior.

1-Carbomethoxynorharman (3)

Compound **3** was obtained as white crystals, m.p. 162–167°, by sublimation of the crude base and recrystallization of the sublimate from acetone–hexane. Spectroscopic characteristics: i.r. 2.91 (sharp), 5.77 (weak), 5.89 (strong); mass spectrum 227 (10), 226 (63), 194 (15), 169 (11), 168 (84), 167 (25), 166 (100), 165 (8), 140 (19), 139 (18), 114 (12), 113 (8), 88 (5), 84 (5), 83.5 (5), 83 (6), 63 (5); metastables 142.1 (calcd. for 194 → 166: 142.0), 124.8 (calcd. for 226 → 168: 124.8); mass measurements calcd. (found): $C_{12}H_6N_2O$, 194.04801 (194.0476); $C_{11}H_8N_2$, 168.06875 (168.0684); $C_{11}H_6N_2$, 166.05310 (166.0531). An authentic sample of 1-carbomethoxynorharman was synthesized by condensation of harman with benzaldehyde followed by oxidation with potassium permanganate in aqueous pyridine and Fischer esterification of the free acid produced; procedures used followed those in the literature (8) with minor modifications. The crystalline product, m.p. 160–166° (lit. (8) 165–166°, 168°) was spectroscopically identical with the natural material isolated and had the same t.l.c. behavior; n.m.r. 0.13 (broad; 1), 1.49 (d, $J = 5$ Hz; 1), 1.95 (d, $J = 7$ Hz, with further splitting; 1), 2.02 (d, $J = 5$ Hz; 1), 2.2–2.8 (complex; 3), 5.93 (s; 3).

[2]A referee has commented that this procedure may lead to the production of methylesters as artifacts.

[3]As with many of the components obtained in this way, insufficient material was available to allow its purification to a sharp melting point by repeated recrystallization.

For personal use only.

1-Carboxamidonorharman (4)

Compound **4** was isolated as a crystalline solid which was sublimed and then recrystallized from methylene chloride; it was obtained as white needles, m.p. 224–226° (sealed tube). Spectroscopic characteristics: i.r. 2.84, 2.91 (sharp), 2.95 (sharp), 5.97; u.v. 214 (36 000), 240 (shoulder, 17 400), 244 (18 200), 250 (shoulder, 17 000), 270 (17 800), 298 (10 000), 366 (5900); mass spectrum 212 (16), 211 (100), 194 (27), 168 (21), 167 (21), 166 (96), 165 (9), 141 (5), 140 (19), 139 (19), 114 (14), 113 (8), 105.5 (7), 88 (6), 63 (6), 57 (6), 55 (6), 44 (8), 41 (6); metastables 178.2 (calcd. for 211 → 194: 178.4), 142.1 (calcd. for 194 → 166: 142.0); mass measurements calcd. (found): $C_{12}H_9N_3O$, 211.07456 (211.0747); $C_{12}H_6N_2O$, 194.04801 (194.0475); $C_{11}H_8N_2$, 168.06875 (168.0684); $C_{11}H_6N_2$, 166.05310 (166.0532). An authentic sample of 1-carboxamidonorharman was synthesized by dissolving the corresponding methyl ester, **3**, in methylene chloride and stirring the solution for a prolonged period (2–3 weeks) at room temperature with concentrated aqueous ammonia. This afforded material, m.p. 227–229° (sealed tube) identical in spectra and t.l.c. behavior with the natural material; n.m.r. 1.58 (d, $J = 5.5$ Hz; 1), 1.84 (d, $J = 7.5$ Hz, with further splitting; 1), 1.89 (d, $J = 5.5$ Hz; 1), 2.2–2.9 (complex; 3).

Simple Pyridines

Members of this group were obtained as oils (**5** subsequently crystallized) and their structures were deduced from their spectroscopic characteristics. Authentic (racemic) samples of these compounds were synthesized and identities were established by comparison of the t.l.c. behavior (at least four systems) and the i.r., n.m.r., and mass spectra of the natural and synthetic materials.

3-Acetyl-5-carbomethoxypyridine (9)

3-Acetyl-5-bromopyridine was prepared from nicotinic acid essentially by the method of Bachman and Micucci (18) and converted to its ethylene ketal (95% yield) by treatment of a refluxing solution of the ketone in benzene with excess ethylene glycol and a catalytic amount of *p*-toluenesulfonic acid in a Dean–Stark apparatus for 1 day. The product, after sublimation and recrystallization from methylene chloride, formed thick, colorless plates, m.p. 77–78°.

Anal. Calcd. for $C_9H_{10}NO_2Br$: C, 44.29; H, 4.13; N, 5.74; Br, 32.74. Found: C, 44.10; H, 4.27; N, 5.59; Br, 33.22.

A solution of the ketal (11.5 g; 47 mmol) in 60 ml of dry tetrahydrofuran was slowly added to a solution of *n*-butyllithium (about 220 mmol) in 90 ml of hexane diluted with 100 ml of tetrahydrofuran and maintained in a bath at −40° under dry nitrogen. The temperature was allowed to rise to −15° over 15 min, and the reaction mixture was poured on to 500 g of freshly crushed Dry Ice which was kept agitated during this period and for a further 5 min. The brown residue which remained after the solvent and excess Dry Ice had evaporated was partitioned between chloroform and 10% aqueous ammonia. The aqueous phase was acidified with concentrated hydrochloric acid, washed with chloroform, neutralized with concentrated ammonia, and evaporated to dryness, the last traces of moisture being removed under vacuum (≃1 mm). The residue was ground to a powder and treated for 24 h with 700 ml of refluxing methanol containing 3% of hydrogen chloride. The reaction mixture was cooled to about 35°, and about 600 ml of the solvent was removed under reduced pressure with no increase in temperature; 800 ml of 5% hydrochloric acid was then added to the solution at room temperature and the acidic solution was allowed to remain for 30 min (to hydrolyze the dimethyl ketal formed during the esterification). The solution was then cooled, made basic with concentrated ammonia, and thoroughly extracted with chloroform. The extract afforded a brown solid (3.3 g; about 39% yield) which was taken up in 400 ml of boiling hexane, a small amount of insoluble residue was removed, and the solution was evaporated to dryness. The product, **9**, was recrystallized from water and obtained as white needles, m.p. 90–92°.

Anal. Calcd. for $C_9H_9NO_3$: C, 60.33; H, 5.06; N, 7.82. Found: C, 60.08; H, 5.35; N, 7.99.

The i.r. 5.79, 5.91; n.m.r. (60 MHz) 0.55 (d, $J = 2$ Hz; 1), 0.62 (d, $J = 2$ Hz; 1), 1.15 (3 peaks, 2 Hz spacings; 1), 5.97 (s; 3), 7.30 (s; 3); mass spectrum 180 (5), 179 (42), 165 (10), 164 (100), 148 (18), 137 (10), 136 (33), 120 (10), 104 (18), 78 (13), 50 (12), 43 (34).

3-Carbomethoxy-5-chlorocarbonylpyridine

This pyridine was prepared by the partial hydrolysis of methyl dinicotinate and treatment of the acid formed with thionyl chloride. A solution of potassium hydroxide (1.2 g; 22 mmol) in 20 ml of methanol containing 2 ml of water was added dropwise over 10 min to a stirred solution of dimethyl 3,5-pyridinedicarboxylate (4.00 g; 20.5 mmol) in 60 ml of methanol, and the solution was stirred at room temperature for 3 days. Solvent was removed under reduced pressure and the white residue was partitioned between water and methylene chloride (600 mg of starting material was recovered from the organic phase). The aqueous solution was evaporated to dryness under reduced pressure, and the white residue was ground to a coarse powder and refluxed in a dry atmosphere for 6 h in 150 ml of benzene containing 30 ml of thionyl chloride. Removal of the solvent and unchanged thionyl chloride under reduced pressure left a white residue and trituration of this with a solvent (dry benzene or ethanol-free chloroform) afforded a solution of the required acid chloride that was used in subsequent reactions. Evaporation of the solvent (benzene) left a solid residue (3.0 g) from which a crystalline sample of the acid chloride was obtained, m.p. 74–79° (lit. (17) 78°) after recrystallization from hexane; i.r. (methylene chloride) 5.66, 5.78; n.m.r. (60 MHz) 0.48 (d, $J = 2$ Hz; 1), 0.51 (d, $J = 2$ Hz; 1), 1.00 (3 peaks, 2 Hz spacings; 1), 5.97 (s, 3).

Treatment of a solution of the acid chloride in benzene with excess dimethylcadmium converted it to the ketone **9**, but yields were unsatisfactory and substantial amounts of the corresponding carbinol were also obtained.

3-Carbomethoxy-5-(1'-hydroxyethyl)pyridine (6)

A solution of sodium borohydride (102 mg; 2.7 mmol) in 10 ml of methanol was added with stirring over a period of 3 min to a solution of the ketone **9** (800 mg; 4.5 mmol) in 35 ml of methanol cooled to 5°. The reaction mixture was stirred at 5° for 5 min and at room temperature for 30 min, and 200 ml of 5% hydrochloric acid was added. After 30 min the solution was basified with ammonia and extracted with methylene chloride. The extract afforded a residue (692 mg; about 86% yield) which, when recrystallized from acetone, yielded the alcohol **6** as stout, colorless crystals, m.p. 53–56° (*p*-nitrobenzoate, m.p. 139–142°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Anal. Calcd. for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.81; H, 6.11; N, 7.77.

The i.r. 2.78 (sharp), 2.97 (broad), 5.80, 5.82 (shoulder); u.v. 216 (7600), 267 (2450), 274 (shoulder); n.m.r. 0.91 (d, $J = 2$ Hz; 1), 1.21 (d, $J = 2$ Hz; 1), 1.61 (3 peaks, 2 Hz spacings; 1), 4.93 (q, $J = 7$ Hz; 1), 6.03 (s; 3), 6.17 (broad; 1), 8.46 (d, $J = 7$ Hz; 3); mass spectrum 181 (22), 180 (6), 167 (10), 166 (100), 164 (10), 150 (16), 138 (47), 134 (22), 106 (20), 104 (18), 78 (18), 77 (13), 59 (10), 51 (15), 50 (10), 43 (18).

This material was identical by the criteria listed above with the natural material; samples of natural **6** from two different lots of plant material showed $[\alpha]_D^{26}$ +23° (*c* 2.5, MeOH) and $[\alpha]_D^{25}$ +14° (*c* 2.2, MeOH).

3-Carbomethoxy-5-(1'-methoxyethyl)pyridine (5)

The synthetic alcohol **6** (1.67 g; 9.2 mmol) was converted to its mesylate by treatment for 3 days at −12 to −15° with 2.4 ml of methanesulfonyl chloride (31.6 mmol) in 40 ml of dry pyridine. The mesylate, which was obtained as a gummy solid (2.36 g), was refluxed in 25 ml of anhydrous methanol for 2 h. The reaction mixture was concentrated to an oil, treated with 150 ml of 5% aqueous potassium carbonate, and extracted with methylene chloride. The extract afforded a product (1.53 g) which was the desired ether **5** contaminated with about 15% of the starting alcohol **6**. By preparative t.l.c. (silica gel, 92:8 methylene chloride–methanol) the ether **5** (981 mg, 55% conversion) was obtained substantially pure; after sublimation and recrystallization from hexane it formed white needles, m.p. 43–46°. An analytical sample was obtained by resublimation of this product.

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.47; H, 6.78; N, 7.19.

The i.r. 5.80, 5.82 (shoulder); u.v. 216 (8300), 266 (2600), 273 (shoulder); n.m.r. (60 MHz) 0.77 (d, $J = 2$ Hz; 1), 1.19 (d, $J = 2$ Hz; 1), 1.65 (3 peaks, 2 Hz spacings; 1), 5.53 (q, $J = 7$ Hz; 1), 6.00 (s; 3), 6.70 (s; 3), 8.51 (d, $J = 7$ Hz; 3); mass spectrum 195 (4), 194 (5), 181 (12), 180 (100), 174 (3), 164 (17), 138 (6), 134 (5), 104 (10), 87 (8), 78 (6), 77 (8), 59 (12), 43 (19).

This product was identical by the criteria listed above with the natural material; natural **5** was obtained as an oil, $[\alpha]_D^{26}$ +50° (c 5.0, MeOH). A sample of natural **5** crystallized on prolonged standing at −15°, and sublimation and recrystallization of this from hexane afforded white needles, m.p. 47–48°.

3-Carbomethoxy-5-vinylpyridine (8)

A mixture of the synthetic alcohol **6** (817 mg; 4.5 mmol), phosphorus pentoxide (6.4 g; 45 mmol), and *m*-dinitrobenzene (590 mg) in 200 ml of xylene was stirred and refluxed for 1.75 h with exclusion of moisture. The reaction mixture was cooled in an ice bath and the supernatant liquor was separated by decantation from the gummy residue that remained. Both the liquid phase and the residue were thoroughly extracted with 10% hydrochloric acid to which ice had been added. The combined acid extracts were washed with benzene, cooled, basified with concentrated ammonia, and extracted with methylene chloride. The extract was concentrated to a syrup which was subjected to separation by t.l.c. (silica gel, 95:5 methylene chloride–methanol). The dehydrated product (110 mg; 15% yield; variable) was obtained as a syrup which was recrystallized from chilled hexane. (A procedure using *p*-toluenesulfonic acid in place of phosphorus pentoxide also provided **8** but it was contaminated with a polymer that appeared to result from transesterification of **6**.) The product (**8**) was obtained as sticky needles which melted over the range 50–75°. Spectroscopic characteristics: i.r. 5.80, 5.82 (shoulder), 6.13; u.v. 215 (15 500, end absorption), 241 (7400), 283 (1800); n.m.r. (60 MHz) 0.89 (d, $J = 2$ Hz; 1), 1.21 (d, $J = 2$ Hz; 1), 1.66 (3 peaks, 2 Hz spacings; 1), 3.23 (dd, J values 18, 11 Hz; 1), 4.07 (d, $J = 18$ Hz; 1), 4.53 (d, $J = 11$ Hz; 1), 6.03 (s; 3); mass spectrum 164 (14), 163 (100), 162 (3), 133 (11), 132 (98), 131 (11), 104 (63), 77 (27), 51 (29); mass measurement calcd. (found): $C_9H_9NO_2$, 163.06333 (163.0634).

This product was identical by the criteria listed above with the natural material **8**, which was obtained as an oil.

3-Carbomethoxy-5-(1'-aminoethyl)pyridine (7)

The ketone **9** (1.00 g; 5.6 mmol) was converted to its oxime by adding a solution of hydroxylamine hydrochloride (1.56 g; 22.4 mmol) and sodium carbonate (1.21 g; 11.4 mmol) in 6 ml of water to a solution of the ketone in 10 ml of methanol and heating the mixture on a steam bath for 1 h. Dilution with water and extraction with methylene chloride afforded the oxime (53% yield) which was recrystallized from methanol and obtained as white needles, m.p. 169–171°.

Anal. Calcd. for $C_9H_{10}N_2O_3$: C, 55.66; H, 5.19; N, 14.43. Found: C, 55.79; H, 5.29; N, 14.49.

The i.r. 2.80 (sharp), 3.04 (broad), 5.79, 6.14 (weak); n.m.r. (60 MHz) 0.76 (d, $J = 2$ Hz; 1), 0.83 (d, $J = 2$ Hz; 1), 1.42 (3 peaks, 2 Hz spacings; 1), 6.00 (s; 3), 7.68 (s; 3); mass spectrum 195 (11), 194 (100), 178 (60), 163 (84), 162 (13), 147 (10), 136 (11), 135 (20), 122 (24), 120 (11), 119 (10), 104 (14), 78 (11), 50 (12), 42 (18).

Zinc powder (13 g; 200 mmol) was added over a period of 2.25 h to a stirred solution of the oxime (576 mg; 3.0 mmol) in 50 ml of glacial acetic acid containing 6 ml of water. After the mixture had been filtered and the residue washed with 100 ml of dilute acetic acid, the filtrate and washings were diluted with 400 ml of water, made basic with concentrated ammonia, and thoroughly extracted with methylene chloride. The amine **7** (491 mg; 75% yield) was obtained from the extract as a syrup with the following spectroscopic characteristics: i.r. 3.01 (broad), 5.82, 5.80 (shoulder); u.v. 217 (10 700), 268 (2950); n.m.r. (60 MHz) 0.99 (d, $J = 2$ Hz; 1), 1.21 (d, $J = 2$ Hz; 1), 1.66 (3 peaks, 2 Hz spacings; 1), 5.72 (q, $J = 7$ Hz; 1), 6.03 (s; 3), 7.83 (broad; 2), 8.56 (d, $J = 7$ Hz; 3); mass spectrum 180 (2), 179 (6), 166 (22), 165 (100), 149 (7), 138 (10), 107 (7), 106 (7), 105 (8), 104 (6), 78 (8), 77 (5), 44 (25); mass measurements calcd. (found): $C_9H_{11}N_2O_2$, 179.08205 (179.0828); $C_8H_9N_2O_2$, 165.06640 (165.0663); $C_8H_9N_2O$, 149.07149 (149.0718); $C_7H_8NO_2$, 138.05550 (138.0556).

The *p*-nitrobenzoyl derivative was obtained as white needles, m.p. 154–157° (phase change 100–110°).

Anal. Calcd. for $C_{16}H_{15}N_3O_5$: C, 58.35; H, 4.59; N, 12.76. Found: C, 58.64; H, 4.80; N, 12.75.

Synthetic and natural **7** were identical by the criteria listed above; the natural material was an oil which was optically active, $[\alpha]_D^{25}$ +27° (c 0.34, MeOH), but this value may contain a substantial error because of the small amount of sample available.

This work was supported by a grant from the National Research Council of Canada; scholarships (to D.G.M.)

from the same source and from the Province of Ontario are also gratefully acknowledged. We thank Professor D. M. James and Dr. S. O. A. Bamgbose for plant collections and for their interest in this work.

The Constituents of *Nauclea diderrichii*. Part III. Indole-Pyridine Alkaloids

D. G. MURRAY, A. SZAKOLCAI, AND STEWART MCLEAN
Department of Chemistry, University of Toronto, Toronto 181, Ontario

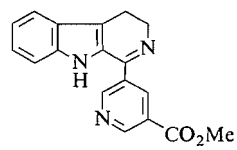
Received October 25, 1971

Six alkaloids isolated from the bark of *Nauclea diderrichii* have been shown to have structures that contain both indole and pyridine units. Because of the small amounts available of each constituent, investigation of structure has been confined mainly to the application of spectroscopic techniques; these have shown that all of these alkaloids belong to the novel indole-pyridine class, and have led us to propose structures or part structures with varying degrees of confidence for each of the alkaloids. Structure **1** was deduced for naucledine, $C_{18}H_{15}N_3O_2$, and confirmed by synthesis. Its spectroscopic characteristics indicate that naucleder ine, $C_{19}H_{19}N_3O_2$, has structure **3**, but this has not yet been confirmed by synthesis. Evidence is presented that nauclechine, $C_{21}H_{21}N_3O_3$, has part structures **6** and **7**, and it is suggested that these can be incorporated in structure **8**. A working hypothesis for the structure of nauclexine, $C_{18}H_{17}N_3O_2$, is represented by **9**. Two alkaloids, ND-363C, $C_{21}H_{21}N_3O_3$, and ND-305B, $C_{19}H_{19}N_3O$, are closely related, the latter being formally derived from the former by removal of a carbomethoxy group; each appears to exist as an equilibratible pair of isomers containing an indolic (substituted β-carboline) and a pyridine part linked together in a manner which may incorporate a spiro carbinolamine ether (as in **12**) that can form ring-opened or solvated derivatives in some solvents.

Il a été montré que six alcaloides isolés à partir de l'écorce de *Nauclea diderrichii* ont des structures comprenant à la fois des unités indole et pyridine. Par suite des petites quantités disponibles, la détermination de structure s'est faite essentiellement par des techniques spectroscopiques; celles-ci ont montré que tous ces alcaloides appartiennent à la nouvelle classe indole-pyridine. Cela nous a conduit à proposer des structures ou des parties de structure, dépendant du degré de confiance pour chacun des alcaloides. La structure **1**, proposée pour la naucl édine, $C_{18}H_{15}N_3O_2$, a été confirmée par synthèse. Les propriétés spectroscopiques de la naucl édérine, $C_{19}H_{19}N_3O_2$, nous font proposer la structure **3**, mais cela n'a pas encore été confirmé par synthèse. Des preuves sont présentées d'après lesquelles la naucléchine, $C_{21}H_{21}N_3O_3$, aurait en partie les structures **6** et **7**, et il est suggéré que celles-ci peuvent être incorporées dans la structure **8**. Une hypothèse de travail pour la structure de la naucléxine, $C_{18}H_{17}N_3O_2$, est représentée par **9**. Deux alcaloides, ND-363C, $C_{21}H_{21}N_3O_3$, et ND-305B, $C_{19}H_{19}N_3O$, sont étroitement apparentés; le dernier dérivant du premier par abstraction du groupe carbométhoxy; chacun semble exister sous forme d'une paire d'isomères équilibrable, contenant une partie indolique (β-carboline substituée) et une partie pyridinique, liées entre eux d'une façon qui pourrait faire intervenir un spiro carbinolamine éther (comme dans **12**) qui peut donner des produits d'ouverture de cycle ou des produits solvatés dans certains solvants.

Canadian Journal of Chemistry, **50**, 1486 (1972)

We have recently described the isolation from the bark of *Nauclea diderrichii* of a considerable number of constituents which we have placed for convenience in four categories (1, 2). The alkaloids of the first two categories, β-carbolines and pyridines, have already been described in detail (2) and we turn now to the third category, a novel group of alkaloids which we have called the indole-pyridines. Six alkaloids have been placed in this category, and although the complete structure of only one of them has been established with complete confidence at this time, their structural novelty leads us to report the evidence which allows us to place them in this category and to assign to each a provisional structure or part structure. Since the appearance of our preliminary communication (1), the isolation from another member of the Rubiaceae of two other alkaloids of this class has been reported (3).



1

The first alkaloid, which we shall call naucledine, has been assigned structure **1**. It was isolated as crystals which melted over the range 84–90°; the wide range may result from the thermal instability of the compound, a dihydro-β-carboline. The formula, $C_{18}H_{15}N_3O_2$, was derived from its mass spectrum, which showed

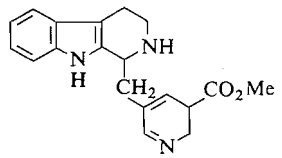
a strong parent ion and, apart from a strong M − 1 peak, fragment ions of low relative intensity. The complex u.v. spectrum included a prominent peak at 328 mμ which showed a marked bathochromic and hyperchromic change in the presence of acid; this appearance and behavior is very similar to that described for the spectra of 1-aryl-3,4-dihydro-β-carbolines (4). The i.r. spectrum showed the sharp peak at 2.90 μ characteristic of an unassociated indolic NH group and carbonyl absorption near 5.80 μ which resembled that ascribed to the methyl ester functions of the pyridine alkaloids described previously (2). The characteristic signals of the aromatic protons of an indole appeared in the n.m.r. spectrum between τ 2.2 and 3.0 and the signals associated with a 3,5-disubstituted pyridine (2) appear at τ 0.81, 0.85, and 1.33; treatment of the sample with NaOD in D_2O was required to remove broadening of the pyridyl protons, and this also removed the indolic NH signal. The *O*-methyl signal was at τ 6.04, and the remaining four protons produced a symmetrical pattern of two-proton multiplets ("triplets") at τ 5.90 and 7.00 which resembled the pattern produced by the corresponding methylene groups of oxogambirtannine (5).

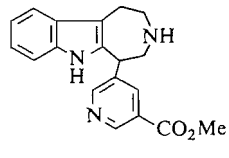
The structure of naucledine, **1**, was deduced from the results outlined here, and confirmed by synthesis of **1** from the acid chloride of 5-carbomethoxy-3-pyridinecarboxylic acid, available from the synthetic work we have already described in connection with the pyridine alkaloids (2). The synthesis was effected by the reaction of the acid chloride with tryptamine and the cyclization of the amide so formed to **1**, identical with natural naucledine, under Bischler–Napieralski conditions. As a preliminary to this synthesis we carried out the corresponding reactions starting with the model compounds 3- and 4-pyridinecarboxylic acid in order to discover conditions suitable for each step; this exploration was all the more necessary in the light of a report (6) that the Bischler–Napieralski cyclization failed with the amide derived from tryptamine and 3-pyridinecarboxylic acid. Our initial efforts confirmed that the cyclization failed under the conditions described (6), but we found that cyclization of the amides was successful in refluxing phosphorus oxychloride, albeit with extremely low conversion in the case of the isomer derived from 4-pyridinecarboxylic acid, and these conditions were then used in the synthesis of naucledine. In each case these Bischler–Napieralski conditions led to the formation of a by-product which appeared to be the aromatized β-carboline.

The second alkaloid in this category, which we shall refer to as naucledérine, has the formula $C_{19}H_{19}N_3O_2$ and is crystalline, but, once again, our samples melted over a considerable range, 102–124°, and showed signs of resolidifying and remelting at a higher temperature. The u.v. spectrum with a maximum at 276 mμ (ε, 9550) and a shoulder at 290 mμ could be accounted for as the summation of separate indole and pyridine chromophores (in contrast to the case of naucledine), and the i.r. spectrum showed N—H absorption, including a sharp 2.90 μ peak, and the 5.80 μ absorption characteristic of the ester group of the pyridine alkaloids described previously (2). The n.m.r. spectrum showed the patterns characteristic of aromatic protons of an indole and of a 3,5-disubstituted pyridine, and a three-proton singlet at τ 6.14 indicated that a methyl ester was present; one of the aliphatic protons formed an apparent triplet with 4 Hz spacings at τ 5.73 and the remainder were responsible for a complex pattern near τ 6.8. Peaks, which were removed when the sample was treated with D_2O, appeared at τ 1.61 and 7.55 and were attributed to the NH protons of an indole and an aliphatic secondary amine, respectively; support for the latter assignment was obtained when naucledérine formed an amide on acylation.

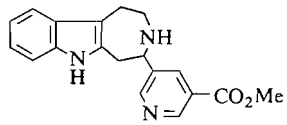
If it is assumed that naucledérine is derived from tryptamine without modification of the $—CH_2CH_2N<$ unit, three structures (**2**, **3**, **4**) must be considered for the alkaloid on the basis of the evidence presented so far. The mass spectrum provided evidence that structure **2** is a very unlikely possibility since it contained no significant peak at *m/e* 171, which corresponds to the most abundant fragment ion in the spectrum of 1-alkyltetrahydro-β-carbolines (7). Instead, the base peak was at *m/e* 279 ($M - C_2H_4N$ by accurate mass measurement), and the molecular ion peak was next in intensity, followed by a strong peak corresponding to $M - CH_3N$. Fragmentations of **3**



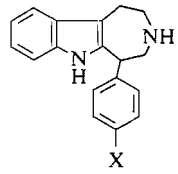
2



3



4



5

leading to the observed ions can be postulated, but it is more difficult to provide a rational explanation for the loss of C_2H_4N as the principal fragmentation of a molecule of formula **4**. Compounds of formula **5** have been described recently (8) and we are extremely grateful to Dr. K. Freter for generous samples of **5** (X = H and X = Cl). These show a marked similarity to naucleferine in their spectroscopic characteristics, particularly significant being the mass spectral fragmentation pattern which corresponded closely to that of naucleferine, especially with respect to the most intense peaks. The n.m.r. spectrum of **5** (X = Cl) also resembled that of naucleferine in showing the signal for one proton as an apparent triplet with 4.5 Hz spacings at τ 5.79, a multiplet near τ 6.8 attributed to the aliphatic protons, and the signal for the NH proton of the seven-membered ring at τ 7.63. The evidence presented here leads us to propose with a considerable degree of confidence that naucleferine has structure **3**, and we are currently attempting to establish this with complete certainty by a total synthesis.

The third alkaloid of this class, given the name nauclechine, m.p. 108–114°, has the formula $C_{21}H_{21}N_3O_3$. As with naucleferine, its u.v. spectrum is compatible with the presence in the molecule of separate indole and pyridine chromophores, and its i.r. spectrum shows strong absorption in the 2.8–3.1 μ region with a sharp peak, appropriate for an indolic NH, at 2.91 μ, and a carbonyl peak at a wavelength, 5.83 μ, very slightly longer than that observed previously in the spectra of the esters of 3-pyridinecarboxylic acids (2). A three-proton singlet at τ 5.94 in the n.m.r. spectrum supported the proposal that we again had the methyl ester of a pyridinecarboxylic acid, and the signals for the aromatic protons and the exchangeable NH proton of an indole were also present; when the sample was treated with D_2O, in addition to the loss of the indole NH signal at τ 1.28, a peak was lost from the envelope near τ 6.2, and this peak is attributed to the OH proton of an alcohol. The n.m.r. spectrum also provided evidence that the molecule contained a pyridine unit, but, in this case the signals observed were one-proton singlets at τ 0.98 and 1.42, and are assigned to the protons at positions 2 and 6 of a 3,4,5-trisubstituted pyridine. The part of the spectrum associated with aliphatic protons is complex, but a one-proton doublet, $J = 6.5$ Hz (slightly broadened by further weak coupling) at τ 5.08 is well separated on the low field side, and is attributed to a proton on a carbon atom carrying an OH group and attached to a pyridine ring; double irradiation showed that this proton was coupled to a proton at τ 6.49, which appeared to have an additional coupling, $J = 12.5$ Hz, to a third proton at τ 7.19; two slightly broadened peaks at the edge of the aliphatic envelope can be accounted for as the low field component (a doublet at τ 5.80, $J = 15.0$ Hz) of a second, independent three-spin system in which the proton at lowest field is coupled strongly ($J = 15.0$ Hz) to a proton at τ 6.54 and weakly ($J < 1$ Hz) to a proton at τ 6.22, and the latter two protons are themselves coupled with $J = 9.0$ Hz. In the mass spectrum the molecular ion at *m/e* 363 provides the base peak, an intense M − 1 peak is present, and strong peaks are observed at *m/e* 184, 183, 170, 169, and 156, a pattern that is characteristic of the tetrahydro-β-carbolines, such as yohimbine, in which positions 1 and 2 are further annelated; the spectrum in these regions bears, in fact, a strong resemblance to that of ajmalicine, and accurate mass measurement of the ions listed shows, furthermore, that they have the same formulae as those appearing in the fragmentation of ajmalicine (9). In addition, the spectrum has peaks at *m/e* 332 (M − OCH_3) and 346 (M − OH), and these fragmentations, verified by accurate mass measurements, are characteristic of the methyl ester of an aromatic carboxylic acid and a benzylic-type alcohol, respectively (10).

The evidence presented here is entirely in accord with the presence of both of the part

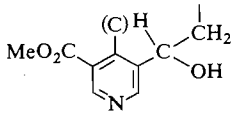
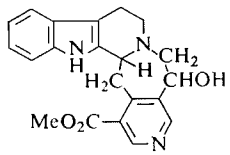
6

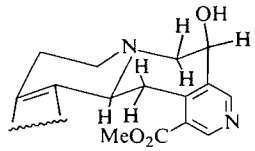


7

structures **6** and **7** in nauclechine. In particular, the mass spectral evidence for **6**, with no further substitution of the tetrahydro-β-carboline, is compelling; the n.m.r. evidence requires a 3,4,5-trisubstituted pyridine as in **7** and the n.m.r., i.r., and mass spectra all indicate the types of substituents illustrated, but they do not show unequivocally that the groups are in the order shown. The order appears probable when comparison is made with the simple pyridine alkaloids described previously, and when **6** and **7** are combined in **8**, a credible explanation can be given of all of the available data. In addition to the features already dis-



8



8*a*

cussed with respect to the individual part structures, the protons on the seven-membered ring incorporated in **8** would be expected to give rise in the n.m.r. spectrum to two separate three-spin systems, and the analysis outlined above shows that the spectrum does satisfy this requirement. A reasonable stereochemical arrangement (**8***a*) of the molecule can be suggested in explanation of the coupling constants observed: in each three-spin system the methylene protons have a strong mutual coupling, but only one proton in each pair has the appropriate angular relationship with the vicinal proton to couple appreciably with it; the chemical shift assignments are reasonable, with the proton on the carbon bearing the OH group being at lowest field (τ 5.08) in one set, but in the other three-spin set, the low field resonance (τ 5.80) must be assigned to the quasi-equatorial methylene proton, and its unusually low value must be associated with the location of the proton in the plane of the pyridine ring and adjacent to the carbomethoxy group. The presence of a Bohlmann band (11) in the i.r. spectrum is in accord with the suggested stereochemistry.

In summary, we propose that the structure of nauclechine is constituted of the components **6** and **7**; **8** represents a combination of these part structures that is entirely in accord with the available data, but the evidence falls short of establishing unequivocally that nauclechine has this structure.

The fourth alkaloid, which we shall refer to as nauclexine, was isolated as a small amount of crystalline substance, $C_{18}H_{17}N_3O_2$, m.p. 229–232°, from only one lot of bark. Its u.v. spectrum, which clearly distinguishes it from the other alkaloids we have obtained, indicates that it is a 2-acylindole, but its intense absorption at 300 mμ, which is unaffected by the addition of either acid or base, is at a wavelength 10–15 mμ shorter than that of typical 2-acylindole alkaloids (12). Its i.r. spectrum shows a very strong peak at 6.13 μ at the upper end of the range associated with the carbonyl group of 2-acylindole alkaloids and about 0.05 μ above a typical value (12); the i.r. spectrum also shows a sharp peak at 2.91 μ, indicative of an indolic NH, superimposed on a broader peak centered at about 3.05 μ. Because of the poor solubility of nauclexine in chloroform-*d*, its n.m.r. spectrum was obtained under special conditions (see Experimental). In the aromatic region of the spectrum, evidence of an indole was present, but the broadening of the lower field peaks associated with protons on a pyridine ring did not allow a confident assignment of the substitution pattern on the pyridine ring to be made. The only other useful deduction that can be drawn from the spectrum is that a multiplet at τ 4.89 has the characteristics expected for the signal of a proton on a carbon attached to a pyridine ring and carrying an OH group. There is, therefore, presumptive evidence that nauclexine contains a disubstituted pyridine ring and a 2-acylindole unit. If the molecule retains the $—CH_2CH_2N<$ unit of a tryptamine precursor, only one carbon atom remains unassigned and this must be placed between the nitrogen and the CHOH unit since the alkaloid does not appear to be a carbinolamine.

If all of these deductions were firmly grounded, and the usual 3,5-disubstitution pattern of the pyridine ring could be established, structure

9

9 would represent nauclexine; unfortunately the quality of the data does not permit us to go further than suggesting this interesting structure as a working hypothesis. The unusual 11-membered ring, produced by a meta-bridging of the pyridine ring, has the virtue of providing an explanation for the failure of the amine and ketone to form a transannular carbinolamine bridge since such a bridge would produce a very highly strained system; however, a severe constraint of this sort is not obligatory since the position of the equilibrium between the amino ketone and carbinolamine forms can depend on more subtle stereochemical features than this (13). The mass spectrum of nauclexine is compatible with structure **9**. It is characterized by the presence of an extremely intense peak at *m/e* 199 ($C_{12}H_{11}N_2O$ by accurate mass measurement), much stronger than any other peak in the spectrum, which can be assigned to an ion resulting from loss of the pyridine by fragmentation at the picolyl position and, accompanied by a hydrogen transfer, cleavage between the carbonyl group and the pyridine ring. Peaks corresponding to those in picraphylline and burnamicine (14) were observed at *m/e* 129, 130, 143, and 144; significant peaks were also observed at *m/e* 157, 169, 170, 171, and 184. The absence of a peak corresponding to M − OH was unexpected, but it may be noted that all of the peaks corresponding to ions, including the parent ion, of higher mass than the base peak were of low intensity.

The next alkaloid, which we shall refer to by its laboratory designation ND-363C (the number indicating the assigned molecular weight), was isolated as a viscous syrup which, on the basis of its t.l.c. behavior, appeared to be homogeneous. The formula $C_{21}H_{21}N_3O_3$ was assigned to it by accurate mass measurement of the parent ion in the mass spectrum, and evidence was seen in the i.r. spectrum that we once again had a molecule which was both an indole (2.90 μ) and a carbomethoxypyridine (5.80 μ). The u.v. spectrum was extremely distinctive: ND-363C, in methanol containing added alkali, produced a spectrum with absorption of moderate intensity between 250 and 300 mμ that was very similar to that of the alkaloids containing separate indole and pyridine chromophores, while a solution in methanol containing added acid produced a dramatically different spectrum, characterized by intense absorption at 364 mμ, and the spectrum of a solution in methanol alone showed both sets of peaks with intensities between the limits in acid and alkali. The n.m.r. spectrum of ND-363C is extremely complex, but a considerable simplification in its interpretation can be achieved if it is postulated that it arises from two closely related species present in equal concentrations so that each set of peaks is doubled (but sometimes coincident). In the low field region of the spectrum, four doublets, at τ 0.85, 0.99, 1.17, and 1.50, and two triplets, at τ 1.68 and 2.20, can be assigned to overlapping patterns resulting from two 3,5-disubstituted pyridines; complex absorption between τ 2.5 and 3.0 has an integrated area on this basis corresponding to the aromatic protons of two indole moieties; multiplets at τ 4.70 and 5.08 each of which has the appearance of an X part of an AMX system, can each be assigned to one proton and singlets at τ 6.09 and 6.34 are associated with two different methyl esters; signals that correspond to protons exchangeable with D_2O are present at τ 0.99 and 8.22 but it is difficult to be confident about the number of protons related to them, the low field peak being reasonably assigned on the present basis to the superimposition of the NH signals of two indole units but the high field peak being considerably more intense (it could correspond to as many as three protons on each of the two molecular species); the remaining signals fall between τ 6 and 7.5 and are complex and poorly resolved.

The doubling of the n.m.r. spectrum could arise if ND-363C were a dimeric or pseudodimeric molecule (15), but we have no evidence that the molecular weight is higher than the assigned value, and at present we prefer to explain our results by proposing that ND-363C exists as two isomers that can be readily equilibrated and are, therefore, inseparable by t.l.c. The u.v. spectra of ND-363C are compatible with the presence in the molecule of the car-

10 **10*a*** **10*b*** **10*c***

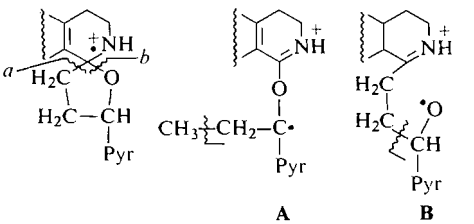
11 **12** **12*a***

binolamine ether of part structure **10** which can equilibrate with the open form **10*a***; in addition, the i.r. and n.m.r. evidence points to the presence of two units of part structure **11**, the multiplets at τ 4.70 and 5.08 being taken as evidence for the presence of a hydrogen on a carbon bearing an oxygen, a methylene group and a pyridine ring. If **10** and **11** are now combined in **12**, it can be seen that ND-363C could well exist in chloroform solution as the two diastereoisomers of **12**, epimeric at the spiro junction, equilibratible through **10*a***, of comparable free energy, and therefore present in approximately equal concentrations. Evidence contrary to this hypothesis is seen in the u.v. spectrum of ND-363C in neutral methanol where it is assumed that a considerable amount of the form **10*a*** is present and it is necessary to argue that the discrepancy arises because of the different solvents used to obtain the u.v. and n.m.r. spectra. It is more difficult to find a satisfactory explanation for the presence at τ 8.22 in the n.m.r. spectrum of strong peak that is removed by treatment of the sample with deuterium oxide. It is tempting to suggest that the equilibrium mixture contains a further component that is a hydrated species such as **10*b*** or *c*, and it can be seen that all of these structures can be derived, at least formally, by cyclizations of the open keto form, **12*a***, of the molecule through condensations of the carbonyl group with the hydroxy or amino functions or both; it should be noted, however, that only those derivatives which are chiral at both carbon centers bearing an oxygen function can exist as diastereoisomeric pairs and that the n.m.r. evidence can be satisfied only if all of the protons on oxygen or nitrogen have effectively the same chemical shift, but interconversion of diastereoisomers is not rapid enough to produce time-averaged signals in the rest of the molecule. The mass spectrum provides no evidence that the isolated sample is hydrated, and, although it is possible that a complex equilibrium between different forms, each of which predominates under different conditions, may supply the complete explanation, further work, when we have isolated sufficient alkaloid, will be required to establish this.

The mass spectrum of ND-363C provided evidence that the molecular formula is $C_{21}H_{21}N_3O_3$ and that no ions of higher mass, corresponding to a dimeric alkaloid and its fragment ions or a hydrated species, could be found; the appearance of peaks at *m/e* 130, 156, and 169 and the absence of an appreciable M − 1 peak supported the postulate that the structure was based on a tetrahydro-β-carboline which lacked a hydrogen at C-1 (9), and the presence of a peak corresponding to M − OCH_3 was in accord with the presence of the methyl ester of a pyridinecarboxylic acid (10). However, two peaks in the spectrum present problems on first examination; the base peak at *m/e* 348, which corresponds to M − CH_3 and the prominent peak at *m/e* 198. The loss of a methyl radical is a rare but not unprecedented fragmentation process (16) if the molecule does not have a preformed methyl group but we know of no case in which such a fragmentation produces the base peak. The n.m.r. spectrum of ND-363C provided no evidence for the presence of a methyl group, other than that of the ester function which would not be expected to frag-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ment by loss of a methyl radical (10). We have sought to reconcile these conflicting pieces of evidence by utilizing a distinctive feature of **12**. An important site of cleavage of the molecular ion of **12** can be expected to be the spiro center, and two ions formed by rupture at *a* or *b* are of particular significance, the former leading, after transfer of a hydrogen, to ion **A** which can be expected to form a stable fragment



A **B**

ion by loss of a methyl radical; rupture at *b* would lead to ion **B** which would then lose the pyridyl portion of the molecule along with the CHO unit as an uncharged fragment and leave an ion of *m/e* 198.

A further alkaloid, designated ND-305B, appears to be very closely related to ND-363C, and, indeed, all of the observable properties of ND-305B can be accounted for on the basis that its structure is the same as that of ND-363C with the carbomethoxy group removed. It has the formula $C_{19}H_{19}N_3O$, its i.r. spectrum lacks the carbonyl absorption but retains the NH absorption, and its u.v. spectrum resembles that of ND-363C both in appearance and in behavior in acid or base. The n.m.r. spectrum of ND-305B shows a very close correspondence to that of ND-363C except that the methoxyl signals are now absent and the protons of the pyridine ring lead to a complex multiplet in the low field region of the spectrum. As with ND-363C, the problem regarding the presence of a high field signal, now at τ 8.21 due to protons exchangeable with D_2O also remains, as does the question of the origin of peaks at $M - CH_3$ and *m/e* 198 in the mass spectrum of ND-305B; the latter data do, however, demonstrate that the methyl radical is not lost from a carbomethoxy group (in ND-363C such a process was conceivable but highly improbable), and that the *m/e* 198 peak arises from the portion of the molecule that does not contain the pyridine ring. In short, the above discussion of the nature of ND-363C applies equally well to ND-305B, except that the carbomethoxy group is absent in the latter, and the results obtained for ND-305B buttress to some extent the conclusions based on ND-363C alone. The alkaloids, apparently equilibratible pairs of isomers, contain an indole (substituted β-carboline) part and a pyridine part which are linked together in a manner that has not yet been fully explained, but probably involves a function such as a carbinolamine ether that allows equilibration through a reversible cyclization.

In summary, the evidence presented allows us to place the six alkaloids in the novel class we have called the indole-pyridines; the complete structure of naucledine has been deduced and confirmed by synthesis, while for the other alkaloids additional features of their structures have been described and structural proposals have been advanced with varying degrees of confidence. However, there still remains the question of whether or not these are truly natural products, or whether they are artifacts produced in isolation procedures which used ammonia (2). It is known that some so-called pyridine alkaloids arise in this way (17). In our studies we have attempted to rule out this possibility by carrying out an isolation and separation of the alkaloids by a procedure that rigorously avoided the use of ammonia (2). Unfortunately, the only base isolated and identified on that occasion was a simple pyridine (compound **6** in ref. 2); while this result shows that the pyridine nucleus did not necessarily arise by the incorporation of ammonia used in the isolation procedure, the absence of the more interesting and more complex indole-pyridines described above is cause for concern. However, if these substances were artifacts, they would nevertheless have been the transformation products of natural precursors which were, themselves, structurally related indole alkaloids, and these were not isolated either under these conditions. We have noted previously (2) that the yields of individual alkaloids from different batches of bark were extremely variable and we consequently consider that the status of the indole-pyridines as natural products is still not proven; their interest as chemical entities remains, regardless of their origin.

Experimental

A description of routine instrumentation, spectroscopic conditions, extraction procedures, etc. has already been given (2).

Naucledérine

Naucledine was separated in t.l.c. systems of relatively low polarity. It was recrystallized from methanol and obtained as pale yellow needles, melting over the range 84–90°. Spectroscopic characteristics: i.r. 2.90 (sharp), 3.07 (broad), 5.79, 5.82 (shoulder); u.v. 220 (26 000, end absorption), 232 (shoulder), 248 (shoulder), 267 (shoulder), 328 (8900); 352 (shoulder); in MeOH–HCl 220 (18 000; end absorption), 252 (9800), 269 (shoulder), 306 (13 000); n.m.r. (solution treated with 6% NaOD in D_2O) 0.81 (d, $J = 2$ Hz; 1), 0.85 (d, $J = 2$ Hz; 1), 1.33 (3 peaks, 2 Hz spacings; 1) (prior to treatment of the sample with NaOD, these three signals gave unresolved single peaks and an additional one-proton peak appeared at 1.05), 2.2–3.0 (complex; 4), 5.90 and 7.00 (each 3 peaks, 8 Hz spacings; each 2), 6.04 (s; 3); mass spectrum 306 (20), 305 (100), 304 (85), 303 (15), 290 (3), 277 (5), 276 (4), 247 (7), 246 (8), 245 (12), 244 (11), 219 (9), 218 (18), 217 (14), 216 (6), 191 (5), 190 (7), 143 (12), 140 (6), 123 (6), 122.5 (8), 115 (8), 109 (6), 95.5 (7); metastable 303.7 (calcd. for 305 → 304: 303.1); mass measurements calcd. (found): $C_{18}H_{15}N_3O_2$, 305.11643 (305.1181); $C_{17}H_{13}N_2O_2$, 277.09770 (277.0966); $C_{16}H_{11}N_3$, 245.09530 (245.0950); $C_{15}H_{10}N_2$, 218.08440 (218.0835); $C_{10}H_9N$, 143.07350 (143.0743).

Naucledérine

Naucledérine was obtained from fairly polar t.l.c. systems. It was obtained as a syrup which was soluble in methanol and this solution deposited crystals which were then almost insoluble in methanol. The crystals melted over a wide range, typically 102–124°, partially resolidified on further heating and remelted at higher temperatures, typically in the range 172–183°. Two different samples of the crystals had $[\alpha]_D^{26}$ −13° (c 0.8, $CHCl_3$) and $[\alpha]_D^{25}$ 0° (c 3.3, $CHCl_3$). Spectroscopic characteristics: i.r. 2.90 (sharp), 3.03 (broad), 5.80, 5.82 (shoulder); u.v. 224 (40 700), 276 (9550), 290 (shoulder); n.m.r. (solution treated with K_2CO_3/D_2O) 1.03 (d, $J = 2$ Hz; 1), 1.48 (d, $J = 2$ Hz; 1), 1.88 (3 peaks, 2 Hz spacings; 1) (prior to treatment of the sample with K_2CO_3/D_2O, these three signals gave unresolved single peaks and an additional one-proton peak appeared at 1.61), 2.4–3.0 (complex; 4), 5.73 (3 peaks, 4 Hz separations; 1), 6.14 (s; 3), 6.5–7.0 (complex; 6), (2.45 (broad; 1; present only prior to treatment of sample with D_2O)); mass spectrum (a peak at 335 of variable intensity was probably produced by a contaminant), 322 (13), 321 (59), 293 (9), 292 (44), 291 (17), 280 (20), 279 (100), 277 (14), 266 (3), 247 (6), 233 (7), 219 (12), 218 (8), 204 (7), 191 (4), 167 (6), 165 (5), 156 (4), 130 (7), 57 (7), 43 (10), 42 (12); metastables 290.2 (calcd. for 292 → 291: 290.0), 265.8 (calcd. for 321 → 292: 265.7), 262.9 (calcd. for 292 → 277: 262.4), 242.5 (calcd. for 321 → 279: 242.5); mass measurements calcd. (found): $C_{19}H_{19}N_3O_2$, 321.14773 (321.1468); $C_{18}H_{16}N_2O_2$, 292.12118 (292.1210); $C_{17}H_{15}N_2O_2$, 279.11335 (279.1124); $C_{17}H_{13}N_2O_2$, 277.09770 (277.0977); $C_{16}H_{14}N_2O_2$, 266.10553 (266.1051); $C_{15}H_{11}N_2$, 219.09222 (219.0914); $C_{10}H_{13}N_3O$, 191.10586 (191.1057); $C_8H_{13}N_3O$, 167.10586 (167.1056). *p*-Bromobenzoyl chloride in pyridine reacted with the alkaloid to form a crystalline derivative, m.p. 207–210°; i.r. 2.90 (sharp), 3.06 (broad), 5.80, 5.83 (shoulder), 6.15; mass measurements calcd. (found): $C_{26}H_{22}N_3O_3{}^{81}Br$, 505.08254 (505.0828); $C_{26}H_{22}N_3O_3{}^{79}Br$, 503.08451 (503.0835); $C_{19}H_{16}N_2O_2$ (fragment ion) 304.12118 (304.1212).

The model 5-phenylhexahydroazepinoindole **5** (X = H) kindly provided by Dr. K. Freter (Pharma-Research Canada, Ltd.) provided the following mass spectrum: 263 (10), 262 (47), 234 (5), 233 (27), 232 (16), 230 (4), 221 (18), 220 (100), 219 (7), 218 (15), 217 (16), 204 (5), 115 (5), 108.5 (4), 43 (4), 42 (5); metastables 216.5 (calcd. for 220 → 218: 216.1), 208.1 (calcd. for 233 → 220: 207.7), 207.1 (calcd. for 262 → 233: 207.2), 203.8 (calcd. for 233 → 218: 204.0), 184.8 (calcd. for 262 → 220: 184.7); mass measurements calcd. (found): $C_{18}H_{18}N_2$, 262.14700 (262.1471); $C_{17}H_{15}N$, 233.12045 (233.1194); $C_{16}H_{14}N$, 220.11262 (220.1132). The corresponding chloro derivative **5** (X = Cl) showed: 289 (19), 297 (12), 296 (58), 294 (5), 269 (11), 268 (12), 267 (32), 266 (18), 257 (6), 256 (33), 255 (20), 254 (100), 252 (7), 232 (25), 231 (10), 230 (10), 219 (13), 218 (32), 217 (35), 216 (6), 204 (6), 148 (7), 130 (11), 115 (7), 108.5 (5), 102 (5), 43 (11), 42 (14).

Nauclechine

Nauclechine was obtained from t.l.c. systems of intermediate polarity. It was recrystallized from chilled methanol and isolated as white crystals, m.p. 108–114°. Spectroscopic characteristics: i.r. 2.91 (sharp), 3.00 (broad), 3.60 (Bohlmann band (11)), 5.83; u.v. 224 (40 700), 272 (10 050), 288 (shoulder); n.m.r. (solution treated with K_2CO_3/D_2O) 0.98 (s; 1), 1.42 (s; 1) (prior to treatment of the sample with K_2CO_3/D_2O these two peaks were broadened and an additional one-proton peak appeared at 1.28), 2.4–3.0 (complex; 4), 5.08 (2 peaks, 6.5 Hz spacing; collapsed to singlet by irradiation at 6.49; 1), 5.80 (2 peaks, 15.0 Hz spacing; 1), 5.94 (s; 3), 6–7.5 (complex; 8; included in this was a set of peaks centered at 6.49 indicating one proton with J values 12.5 and 6.5 Hz, the latter coupling being removed by irradiation at 5.08; the signals overlapped a set of peaks indicating one proton with J values 15.0 and 9.0 Hz; pairs of peaks with spacings of 9.0 and 12.5 Hz respectively appeared at 6.22 and 7.19; an additional broad signal at ≃6.2 was present only prior to treatment of the sample with D_2O); mass spectrum 364 (23), 363 (100), 362 (87), 361 (5), 348 (5), 347 (6), 346 (22), 332 (10), 303 (5), 185 (10), 184 (48), 183 (43), 182 (7), 171 (13), 170 (39), 169 (55), 168 (10), 167 (6), 157 (9), 156 (32), 155 (10), 154 (11), 144 (16), 143 (16), 142 (6), 130 (11), 129 (9), 128 (8), 127 (5), 117 (5), 116 (5), 115 (10), 86 (6), 84 (9), 77 (7), 65 (5), 57 (5), 51 (5), 49 (12), 43 (8), 42 (9), 41 (5); metastable 361.6 (calcd. for 363 → 362: 361.0); 15 eV spectrum 363 (100), 362 (29), 184 (6), 183 (6), 170 (6); mass measurements calcd. (found): $C_{21}H_{21}N_3O_3$, 363.15829 (363.1575); $C_{21}H_{20}N_3O_2$, 346.15555 (346.1551); $C_{20}H_{18}N_3O_2$, 332.13990 (332.1398), $C_{12}H_{12}N_2$, 184.10005 (184.1006); $C_{12}H_{11}N_2$, 183.09222 (183.0923), $C_{11}H_9N_2$, 169.0760 (169.07657), $C_{11}H_{10}N$, 156.0815 (156.08132).

Nauclexine

Nauclexine was obtained from t.l.c. systems of intermediate polarity. It was recrystallized from a mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of methylene chloride and methanol and isolated as off-white needles, m.p. 229–232°, which appeared to be weakly laevorotatory in methanol but an accurate value for the specific rotation could not be measured because of the very small amount of material available. Spectroscopic characteristics: i.r. 2.91 (sharp), 3.05 (broad), 6.13 (v. strong); u.v. 226 (17 800), 235 (14 800), 300 (15 850); n.m.r. (dilute solution in 98:2 $CDCl_3$–CD_3OD; 150 scans CAT; peak areas obtained only very approximately) 0.21 (broad; 1), 2.0–3.0 (complex; ?), 4.89 (m; 1), 6.0–7.1 (complex; 6); (dilute solution in 1:1 $CDCl_3$–CD_3OD; 150 scans CAT) additional (one-proton ?) peaks appear at 0.97, 1.36, and 1.53; the 4.89 multiplet appears to have 4 peaks with 5.0, 2.5, and 5.0 Hz spacings, and at 7.03 there is an apparent two-proton triplet, $J = 7.0$ Hz; mass spectrum 307 (9), 200 (20), 199 (100), 184 (2), 171 (5), 170 (5), 169 (8), 157 (4), 144 (10), 143 (8), 130 (6), 129 (9), 128 (5), 115 (6), 102 (4), metastables 168.7 (calcd. for 171 → 170: 169.0), 147.0 (calcd. for 199 → 171: 146.9), 145.2 (calcd. for 199 → 170: 145.2), 129.0 (calcd. for 307 → 199: 129.0), 121.3 (calcd. for 171 → 144: 121.3); 15 eV spectrum 307 (100), 199 (40); mass measurements calcd. (found): $C_{18}H_{17}N_3O_2$, 307.13208 (307.1336); $C_{12}H_{11}N_2O$, 199.08714 (199.0869); $C_{11}H_9N_2$, 169.07657 (169.0764); $C_{10}H_{10}N$, 144.08132 (144.0816); C_9H_7, 115.05478 (115.0546).

Alkaloid ND-363C

This alkaloid was separated by moderately polar t.l.c. systems and was obtained as a syrup which appeared homogeneous in five t.l.c. systems. Spectroscopic characteristics: i.r. 2.90 (sharp), 3.04 (broad), 5.80, 5.82 (shoulder); u.v. 223 (31 500), 252 (6900), 271 (7100), 291 (4800), 360 (6500); in MeOH–HCl 223 (16 200, end absorption), 250 (11 200), 266 (shoulder), 364 (18 600); in MeOH–KOH 223 (38 900), 274 (8700), 281 (shoulder), 290 (shoulder); n.m.r. (solution treated with K_2CO_3/D_2O; the number of protons assigned to each signal is based on the assumption that two $C_{21}H_{21}N_3O_3$ units are present) 0.85 (d, $J = 2$ Hz; 1), 0.99 (d, $J = 2$ Hz; 1), 1.17 (d, $J = 2$ Hz; 1), 1.50 (d, $J = 2$ Hz; 1); 1.68 (3 peaks, 2 Hz spacings; 1), 2.20 (3 peaks; 2 Hz spacings; 1), (prior to treatment of the sample with K_2CO_3/D_2O, these six signals appeared as unresolved peaks and the 0.99 signal corresponded to a total of 3 protons), 2.4–3.0 (complex; 8), 4.70 (4 peaks, spacings 6, 3, and 6 Hz; 1), 5.08 (4 peaks, spacings 6, 1, and 6 Hz; 1), 6.09 (s; 3), 6.34 (s; 3), 6.4–7.5 (complex; ≃16), 8.22 (s; ≃6; present only prior to treatment of the sample with D_2O); mass spectrum 364 (6), 363 (18), 349 (24), 348 (100), 332 (2), 316 (4), 199 (7), 198 (25), 197 (6), 172 (9), 170 (7), 169 (12), 165 (5), 164 (13), 157 (6), 156 (6), 155 (9), 154 (7), 144 (10), 143 (6), 134 (5), 130 (11), 129 (9), 128 (5), 115 (6), 104 (5), 77 (7); metastables 334.0 (calcd. for 363 → 348: 333.6), 287.0 (calcd. for 348 → 316: 286.9); 13 eV spectrum 363 (100), 348 (39), 198 (91); mass measurements calcd. (found): $C_{21}H_{21}N_3O_3$, 363.15829 (363.1578); $C_{20}H_{18}N_3O_3$, 348.13482 (348.1345); $C_{20}H_{18}N_3O_2$, 332.13990 (332.1401); $C_{19}H_{14}N_3O_2$, 316.10860 (316.1089).

Alkaloid ND-305B

This alkaloid was separated by more polar t.l.c. systems and was obtained as a syrup that appeared by t.l.c. to be homogeneous. Spectroscopic characteristics: i.r. 2.90 (sharp), 3.10 (broad); u.v. 224 (30 900), 250 (shoulder), 262 (shoulder), 284 (7800), 292 (7250), 310 (shoulder), 360 (5400); in MeOH–HCl 224 (16 200, end absorption), 251 (13 800), 365 (17 400); in MeOH–KOH 215 (47 900, end absorption), 223 (shoulder), 269 (10 250), 283 (9800), 291 (shoulder); n.m.r. (solution treated with K_2CO_3/D_2O; the number of protons assigned to each signal is based on the assumption that two $C_{19}H_{19}N_3O$ units are present) 1.3–1.5 (complex; ≃6; prior to treatment of the sample with D_2O the peak at 1.32 was higher), 2.2 (two peaks, 7 Hz spacing and fine splitting; 1), 2.47 (m; ≃1), 2.5–3.0 (complex; ≃8), 4.71 (4 peaks, spacings 6, 3, and 6 Hz; 1), 5.08 (4 peaks, spacings 6, 1, and 6 Hz; 1), 6.1–7.6 (complex; ≃18), 8.21 (s; ≃6; present only prior to treatment of the sample with D_2O); mass spectrum 305 (16), 291 (23), 290 (100), 199 (13), 198 (20), 183 (9), 182 (10), 156 (7), 155 (9), 154 (8), 144 (10), 143 (7), 130 (12), 129 (10), 128 (7), 115 (7), 106 (19), 78 (12), 77 (10); metastable 275.9 (calcd. for 305 → 290: 275.7); mass measurements calcd. (found): $C_{19}H_{19}N_3O$, 305.15281 (305.1531); $C_{18}H_{16}N_3O$, 290.12934 (290.1299).

Synthesis of 1-(3'-Pyridyl)-3,4-dihydro-β-carboline (Model Compound)

N-Nicotinoyl-β-(3-indolyl)ethylamine (125 mg; 0.47 mmol) prepared from tryptamine and the hydrochloride of nicotinoyl chloride (6), was suspended in phosphorus oxychloride (13.4 g; 87 mmol) and the mixture was refluxed for 2 h. Phosphorus oxychloride was removed on a rotary evaporator, the brown oily residue was dissolved in dilute acetic acid and, after filtration, the solution was made basic with ammonia and extracted with chloroform. The extract afforded a brown oil which was purified by preparative t.l.c. on silica gel with elution by 99:1 acetone–methanol. The product was obtained as an oil (34 mg; 28% yield) which could not be crystallized. Spectroscopic characteristics: i.r. 2.89, 6.18, 6.29, 6.37, 6.54; u.v. 213 (end absorption), 230 (shoulder), 244 (shoulder), 328 (9500); n.m.r. (solution treated with $NaOD/D_2O$) −0.85 (s; 1; observed only prior to treatment with D_2O), 1.03 (d, $J = 2$ Hz; 1); 1.68 (dd, J values 6, 2 Hz; 1), 1.96 (dt, J values 8, 2 Hz; 1), 2.42 (m; 1), 2.80 (complex; 4), 6.99 (3 peaks, 8 Hz spacings; 2), 7.06 (3 peaks, 8 Hz spacings; 2).

Synthesis of Naucledine (1)

3-Carbomethoxy-5-chlorocarbonylpyridine (2.4 g; 12 mmol) in 120 ml of carefully dried ethanol-free chloroform (2) was added to tryptamine (2.4 g; 15 mmol) dissolved in 60 ml of dry ethanol-free chloroform and 90 ml of dry pyridine, and refluxed for 2.5 h. Precipitated salts were removed by filtration and the filtrate was evaporated to dryness in a rotary evaporator. The residue was treated with 200 ml of 5% ammonia and extracted with four 100 ml portions of chloroform. The extract afforded a white residue (2.5 g) from which the tryptamide (1.0 g; 50% yield) was obtained as crystals, m.p. 168.5–169.5°, by recrystallization from methanol.

Anal. Calcd. for $C_{18}H_{17}N_3O_3$: C, 66.86; H, 5.30; N, 13.00. Found: C, 67.12; H, 5.33; N, 12.96.

Spectroscopic characteristics; i.r. (Nujol) 2.98 (sharp), 3.01 (broad), 5.85, 6.02, 6.24, 6.45; u.v. 222 (end absorption), 273 (10 100), 290 (8300); n.m.r. (DMSO-d_6) −0.90 (s; 1), 0.65 (d, $J = 2$ Hz; 1), 0.73 (d, $J = 2$ Hz; 1), 0.88 (t, $J = 5$ Hz; 1), 1.22 (3 peaks, 2 Hz spacings; 1), 2.2–3.1 (complex;

5), 6.08 (s; 3), 6.36 (m; 2), 6.96 (3 peaks, 7 Hz spacings; 2); mass spectrum 323 (10), 164 (6), 144 (18), 143 (100), 131 (13), 130 (82), 103 (10), 44 (22), 43 (51).

Treatment of the tryptamide (1.0 g; 3.1 mmol) with phosphorus oxychloride (100 g) in the manner described above for the model compound yielded a crude product (0.61 g) from which naucledine (52% yield) could be obtained by preparative t.l.c. on silica gel with elution by 99:1 acetone–methanol. The synthetic material, m.p. 84–90° (dec.) did not depress the melting point of natural naucledine and the two materials were identical in t.l.c. and spectroscopic characteristics.

Anal. Calcd. for $C_{18}H_{15}N_3O_2$: C, 70.80; H, 4.95; N, 13.76. Found: C, 70.66; H, 5.00; N, 13.50.

The Constituents of *Nauclea diderrichii*. Part IV. Miscellaneous Substances; Biogenetic Considerations

STEWART MCLEAN AND D. G. MURRAY
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 25, 1971

Basic substances isolated from the bark of *Nauclea diderrichii* and not placed in one of the three earlier alkaloidal categories include an alkaloid, $C_{21}H_{26}N_2O_4$, designated ND-370, and an amorphous material that appears to be an alkaloidal glycoside. Also isolated were the non-basic substances benzamide and antiarol (3,4,5-trimethoxyphenol), and two monoterpenoids given the names naucleol and naucledal; the spectroscopic characteristics of naucleol, $C_9H_{14}O_3$, can be accounted for by structure **1***a*, and those of naucledal, $C_{10}H_{12}O_4$, by structure **2***a*, but the data do not establish the structures unequivocally. The structural relationships between the various constituents isolated from this plant and their possible biogenetic implications are discussed.

Les substances basiques isolées à partir de l'écorce de *Nauclea diderrichii*, et qui n'appartiennent pas à l'une des trois premières catégories d'alcaloides, incluent un alcaloide, $C_{21}H_{26}N_2O_4$, désigné par ND-370, et un produit amorphe qui semble être un glycoside du type alcaloide. Il a également été isolé les substances non basiques, benzamide et antiarol (triméthoxy-3,4,5 phénol), et deux monoterpénoides auxquels il a été donné les noms de naucléol et nauclédal. Les caractéristiques spectroscopiques du naucléol, $C_9H_{14}O_3$, peuvent être rationalisées par la structure **1***a*, et celles du nauclédal, $C_{10}H_{12}O_4$, par la structure **2***a*; les données ne permettent cependant pas d'établir les structures d'une façon certaine. Les relations de structure entre les différents produits isolés à partir de cette plante et leurs incidences biogénétiques possibles sont discutées.

Canadian Journal of Chemistry, **50**, 1496 (1972)

In our study of the bark of *Nauclea diderrichii* we divided the constituents extracted into four categories (1, 2); we have discussed already the alkaloids of the first three categories (2, 3) and we turn now to the fourth category, miscellaneous substances, which includes alkaloids that do not fit in an earlier category and non-basic compounds. With the completion of an account of the four categories of constituents, a review of their structural characteristics reveals relationships of probable biogenetic significance, and the pattern that becomes apparent then provides some reinforcement for the structural assignments that have been made, in some cases very tentatively, on spectroscopic grounds (3).

(a) Alkaloids

Two alkaloids of undetermined structure are presently placed in this category. The first, m.p. 209–211°, designated ND-370, has the formula $C_{21}H_{26}N_2O_4$, isomeric with a number of tryptamine–monoterpene alkaloids, but does not appear to be identical with any alkaloid described previously. The second alkaloid is an amorphous substance of high molecular weight, which we believe is an alkaloidal glycoside, but we have not yet succeeded in obtaining the aglycone.

(b) Non-basic Compounds

Although the original plant extract was subjected to a sequence of acid–base partitions (2), several fractions ultimately separated by t.l.c. proved to be non-basic, a situation that is not without precedent (4). Two compounds of established structure are benzamide and antiarol; the isolation of benzamide from a plant has only rarely been described (4*a*, 5) and it may well be an artifact of our isolation procedure, which used ammonia at two stages; antiarol, 3,4,5-trimethoxyphenol, is also of fairly rare occurrence (6).

Two compounds appear to be monoterpenoids that have not been described previously. The first, which we shall call naucleol, is a colorless oil of formula $C_9H_{14}O_3$, based on accurate mass measurement of the parent ion in its mass spectrum. The i.r. spectrum provided evidence that the molecule contained an alcohol function, a δ-lactone and a trisubstituted ethylene grouping. The n.m.r. spectrum showed a one-proton quartet at τ 4.38, $J = 7$ Hz, that was slightly broadened and a three-proton doublet at τ 8.30, $J = 7$ Hz, and double irradiation confirmed that the protons responsible for these multiplets were mutually coupled; this provides evidence that the trisubstituted ethylene contained $CH_3CH{=}C<$.

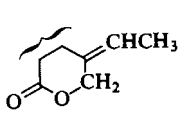
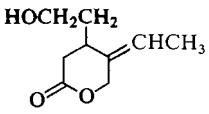
A set of four peaks (broadened only very slightly by further coupling) at τ 5.33 was shown by comparison of the 100 MHz and 60 MHz spectra to be an AB quartet with $J = 13$ Hz; the chemical shift of the multiplet and the absence of vicinal coupling, taken with the evidence that a δ-lactone is present, lead us to conclude that the quartet arises from the methylene group shown explicitly in part structure **1**.



1



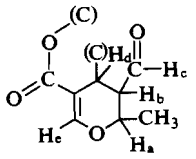
1*a*

A signal at τ 7.0, removed on treatment of the sample with D_2O, and a two-proton triplet at τ 6.32, $J = 6$ Hz, which was shown by double irradiation to be coupled to a two-proton multiplet at about τ 8.3 (overlapping the methyl doublet) provide evidence that the remainder of the molecule consists of a hydroxyethyl side chain, which clearly must be placed α or β to the carbonyl group. The three protons so far unaccounted for give rise to two sets of signals in the n.m.r. spectrum that can be interpreted as forming an ABX pattern (with some further couplings present), as would be expected for either placement of the hydroxyethyl side chain; a set of eight sharp peaks centered at τ 7.35 can be recognized as the AB part of the pattern ($J_{AB} = 16$ Hz) and this has no appreciable coupling involving protons outside of the ABX set, while the X proton appears to give a broad unresolved multiplet at about τ 6.9. It is difficult to use the chemical shift evidence to place the hydroxyethyl side chain, but the couplings just described, which indicate that the AB protons have a geminal relationship and that neither is involved in allylic coupling, lead us to favor placement at the β-carbon, as shown in **1***a*. At the present moment no strong evidence can be brought to bear on the question of the stereochemistry of the ethylidene side chain.

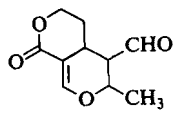
The mass spectrum of naucleol can be rationalized on the basis of structure **1***a*, but does not provide *a priori* evidence for this structure. The spectrum is complex and included in it are peaks corresponding to $M - CH_3$, $M - H_2O$, $M - (H_2O + C_2H_4)$ and the base peak at *m/e* 81 ($C_6H_9^+$).

A small amount of the second monoterpenoid, designated naucledal, was obtained as a colorless syrup from one lot of plant material. Since the substance seemed to be rather unstable, particularly in the presence of base, it proved to be impossible to obtain it homogeneous, and the presence of persistent impurities made an interpretation of the spectroscopic data more than usually difficult since a judgment had to be made about which peaks were associated with the principal component and which were produced by impurities. Nevertheless, some features of the molecule appear to be well established and of sufficient interest to warrant their description.

The formula was shown by accurate mass measurement of the parent ion in the mass spectrum to be $C_{10}H_{12}O_4$. The u.v. spectrum showed an absorption maximum at 246 mμ ($\varepsilon \simeq 6600$) with a shoulder at 285 mμ, but considerable doubt about the value of the extinction coefficients remains because of the inhomogeneity of the sample. The i.r. spectrum showed a weak band at 3.66 μ, strong and broad absorption at 5.80–5.89 μ, and a sharp intense peak at 6.21 μ; it was concluded that absorption in the OH-stretching region was due to the presence of an impurity. These spectroscopic characteristics are consistent with the presence in the molecule of an aldehyde group and an iridoid system, $RO_2C—C{=}C—O$ (7). The n.m.r. spectrum provides confirmation for the presence in the molecule of an aldehyde group since there is a one-proton doublet at τ 0.04, $J = 2.5$ Hz; double irradiation showed that the proton responsible for this is coupled to a proton which gives rise to a doublet of doublets at τ 7.58 with J values of 10 and 2.5 Hz. The 10 Hz coupling of the latter appears to be with a proton which gives rise to a multiplet which is part of a complex pattern near τ 5.63; irradiation at τ 5.63 also caused the collapse of a three-proton doublet, $J = 6$ Hz, at τ 8.53. A further significant signal is an apparent doublet at τ 2.22, $J = 2$ Hz, associated with one proton. If the evidence for the presence of both an aldehyde and an iridoid system can be accepted, the part structure **2** is compatible with the n.m.r. chemical shifts of all of the protons shown explicitly and, with the reservation that the coupling constant between H_b and H_d appears to be about zero, the J values ($J_{ab} = 10$; $J_{bc} = 2.5$; $J_{de} = 2$ Hz) are reasonable for this structure (8). Completion of the



2



2*a*

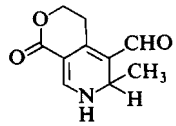
structure to afford **2***a* provides a reasonable working hypothesis for naucledal. The mass spectrum is again complex and relatively uninformative with regard to structure: there is an appreciable molecular ion and, among others, significant peaks for $M - CH_3$, $M - H_2O$, and $M - CHO$.

Biogenetic Considerations

The co-occurrence of simple β-carbolines, simple pyridines, and the alkaloids we have called indole–pyridines raises questions of considerable interest regarding their biosynthesis, and the isolation of monoterpenoids and a constituent that appears to be a tryptamine–monoterpene indole alkaloid makes the metabolic situation even more intriguing. Although detailed biogenetic speculation can not be justified, a few comments on the structural relationships observed and their possible significance appear appropriate.

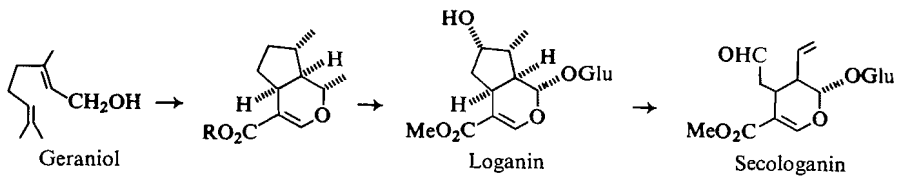
It is generally accepted that alkaloidal β-carbolines are derived from tryptophan, and the recent intense interest in the biosynthesis of the *Corynanthe–Strychnos, Aspidosperma,* and *Iboga* groups of alkaloids has led to the recognition that these alkaloids are formed from a tryptamine unit and a monoterpenoid unit, and the description of many of the details of the intricate network of metabolic pathways involved has now been placed on a firm experimental foundation (9). The so-called pyridine alkaloids (10) fall into two classes: those that are of monoterpenoid origin and those that are not.

Naucleol and naucledal are clearly monoterpenoid and the relationship between the structures advanced for them (**1***a* and **2***a*, respectively) and intermediates on the pathway leading from mevalonate through geraniol, loganin, and secologanin (9) can readily be seen (Scheme 1). Routes to **1***a* from loganin or one of its congeners require the removal of a one-carbon unit, the opening of the cyclopentane ring and adjustment of the oxidation level; a route from secologanin to 2*a* can readily be suggested, and, in this connection, the structural relationship between **2***a* and the alkaloid gentioflavine, which has been shown to be of mevalonate origin (11), is noteworthy.



Gentioflavine

The simple pyridine alkaloids we have isolated (2) are 3,5-disubstituted, a pattern that appears to be without precedent in known pyridine alkaloids; routes to 3,4,5-tri-substituted pyridine alkaloids from monoterpenoid precursors through, for example, secologanin can readily be seen, and in the present cases it is probable that the substituent has been lost from position 4 at some stage. The simple β-carbolines (2) appear to be derived from tryptamine or tryptophan and a second component of uncertain origin, while the alkaloids we have isolated and called indole-pyridines (3) appear to be derived from tryptamine and a pyridine unit related to the simple pyridine alkaloids present in the plant. The pyridine unit is generally 3,5-disubstituted, the same pattern as that found in the simple pyridines; an exception to this generalization, nauclechine (3), with a 3,4,5-trisubstituted pyridine unit, provides support for the supposition that the pyridine units in the other alkaloids have lost the substituent originally present at position 4. With building blocks of 3,5-disubstituted (as in **3**) and 3,4,5-trisubstituted (as in **4**) pyridines available,



Geraniol Loganin Secologanin

routes to all of the structures proposed for the indole–pyridine alkaloids (3) can be suggested.

In the case of naucledine, the structure of which has been established, one carbon of the two-carbon side chain of the precursor **3** has been lost, while in naucledine the complete two-carbon unit is retained and, in the structure (**5**) preferred for the alkaloid, it is incorporated in a tetrahydroazepine ring. It is attractive to speculate that both alkaloids were derived from a precursor (**3**) in which an oxidized two-carbon side chain condensed with tryptamine and then lost a one-carbon unit by, for example, decarboxylation to form naucledine or underwent ring expansion to lead on to naucledine. Nauclechine provides the example of an alkaloid derived from a precursor of form **4**, and the structure (**6**) suggested for it fits nicely into the pattern; furthermore, it is instructive to examine this structure in conjunction with the structures of alkaloids which incorporate a secologanin unit with little modification, such as vincoside and strictosidine (12) and some of the alkaloids of *Adina cordifolia* (13). Nauclexine is constructed from a tryptamine unit and a disubstituted pyridine unit but considerable uncertainty remains regarding the details of its structure; however, structure **7**, which has been very tentatively suggested for it, fits the present pattern. The related alkaloids ND-363C and ND-305B can also be considered to be derived from a unit such as **3**, decarbomethoxylated in the case of ND-305B, and a tryptamine unit; it is clear, however, that a further two-carbon unit must be incorporated and, even if structures based on **8** can be established for these alkaloids,

the order in which the necessary linkages are made is uncertain.

However, it is also possible to suggest that the indole–pyridine alkaloids could arise by a process that first unites the tryptamine and monoterpenoid components (and the isolation of ND-370 indicates that this path is open in any case) and the latter is subsequently transformed into a pyridine. This question can be usefully pursued only when it has been established that these materials are genuine natural products (3); however, the substances we have isolated, regardless of their origin, provide a valid problem in structural chemistry, and the fact that structural relationships between the more complex alkaloids and possible simpler precursors can be recognized and chemically reasonable routes for the elaboration of larger molecules can be proposed, provides some support for the tentative assignments made to some of the indole–pyridine alkaloids.

Experimental

Details of standard instrumentation, spectroscopic and chromatographic conditions, and isolation procedures have already been given (2).

ND-370

This alkaloid was isolated as a solid which, on recrystallization from methanol, formed white needles, m.p. 203–209° (phase change 77–84°); sublimed material, m.p. 209–211°. Spectroscopic characteristics: i.r. 2.90 (sharp), 3.03 (broad); u.v. 221 (18 200), 248 (4600), 268 (3500), 290 (shoulder), 363 (7250); in MeOH–HCl 221 (8500; end absorption), 246 (7600), 364 (15 500); in MeOH–KOH 223 (25 700), 274 (5900), 281 (6000), 290 (4700); n.m.r. 1.62 (s; 1; removed by D_2O), 2.4–3.0 (complex; 4), 5.08 (d, $J = 3.5$ Hz; 1), 5.18 (dd, J values 10 and 2.5 Hz; 1), 5.46 (d, $J = 6.5$ Hz, with further splitting; 1), 6.07 (d, $J = 10.5$ Hz; 1), 6.46 (s; 3), 6.55 (s; 3), 6.7–8.7 (complex; $\simeq 11$); mass spectrum 370 (5), 369 (2.5), 339 (4.5), 310 (5), 278 (2), 269 (2), 268 (3), 254 (2.5), 253 (20), 252 (100), 251 (3.5), 225 (3), 223 (4), 212 (2), 211 (3), 209 (2), 199 (3), 198 (5), 186 (3), 184 (2), 170 (3), 169 (2.5), 168 (2), 167 (2), 158 (2), 157 (4), 156 (2.5), 155 (2.5), 154 (2), 143 (3), 134.5 (3), 130 (3), 129 (6), 128 (2), 115 (2), 94 (4), 85 (3), 84 (2), 67 (2); metastables 260.2 (calcd. for 370 → 310: 259.8), 249.3 (calcd. for 310 → 278: 249.2), 204.9 (calcd. for 310 → 252: 204.9), 197.4 (calcd. for 252 → 223: 197.3); mass measurements calcd. (found): $C_{21}H_{26}N_2O_4$, 370.18926 (370.1884); $C_{20}H_{23}N_2O_3$, 339.17087 (339.1709); $C_{19}H_{22}N_2O_2$, 310.16813 (310.1681); $C_{18}H_{18}N_2O$, 278.14191 (278.1413); $C_{16}H_{17}N_2O_2$, 269.12900 (269.1283); $C_{16}H_{16}N_2O$, 252.12626 (252.1265).

Naucleol

Naucleol was obtained as syrup which could not be freed of small amounts of contaminants. Spectroscopic characteristics: i.r. 2.77 (sharp), 2.90 (broad), 5.74, 5.97 (v. weak); (liquid film) 2.93 (broad), 5.78, 5.97 (shoulder), 12.09; n.m.r. 4.38 (q, $J = 7$ Hz, with further splitting $\simeq 1$ Hz; 1; collapsed to broadened singlet by irradiation at 8.30), 5.33 (4 slightly broadened peaks, spacings 13, 12, and 13 Hz; at 60 MHz spacings are 13, 5, and 13 Hz; 2), 6.32 (t, $J = 6$ Hz, collapsed by irradiation at 8.30; 2), 6.7–7.1 (complex; 2; treatment with D_2O reduces area at $\simeq 7.0$), 7.35 (AB part of ABX system, $J_{AB} = 16$ Hz, $J_{AX} \simeq 6$ Hz, $J_{BX} \simeq 6.5$ Hz), 8.30 (d, $J = 7$ Hz, superimposed on broader multiplet; total 5; irradiation at 4.38 collapsed the doublet, and irradiation at 6.32 caused partial collapse of the multiplet); mass spectrum 171 (7), 170 (30), 169 (2), 155 (19), 153 (7), 152 (18), 142 (10), 141 (62), 140 (6), 139 (6), 137 (9), 127 (20), 126 (33), 125 (44), 124 (29), 123 (13), 111 (73), 110 (23), 109 (34), 108 (12), 107 (20), 99 (31), 98 (32), 97 (43), 96 (22), 95 (60), 93 (32), 91 (19), 83 (32), 82 (31), 81 (100), 80 (23), 79 (60), 77 (26), 71 (30), 69 (51), 67 (75), 55 (71), 54 (22), 53 (48), 43 (57), 42 (25), 41 (98), 39 (62), 31 (36); metastables 135.9 (calcd. for 170 → 152: 135.9), 121.1 (calcd. for 155 → 137: 121.1), 117.0 (calcd. for 170 → 141: 117.0), 101.2 (calcd. for 152 → 124: 101.2), 93.5 (calcd. for 170 → 126: 93.4), 78.1 (calcd. for 152 → 109: 78.2), 77.1 (calcd. for 81 → 79: 77.0), 72.5 (calcd. for 170 → 111: 72.5); mass measurements calcd. (found): $C_9H_{14}O_3$, 170.09430 (170.0935); $C_8H_{11}O_3$, 155.07082 (155.0710); $C_9H_{12}O_2$, 152.08373 (152.0837); $C_8H_{13}O_2$, 141.09156 (141.0914); $C_7H_9O_3$, 141.05517 (141.0552); $C_7H_{10}O_2$, 126.06808 (126.0678); $C_7H_9O_2$, 125.06026 (125.0600); $C_8H_{12}O$, 124.08882 (124.0888); $C_7H_8O_2$, 124.05243 (124.0524); $C_7H_{11}O$, 111.08099 (111.0810); C_7H_{11}, 95.08608 (95.0862); C_6H_7O, 95.04969 (95.0494).

Naucledal

Naucledal was isolated as a small amount of colorless syrup that could not be obtained free of impurities. Spectroscopic characteristics: i.r. 2.8 (impurity ?), 3.66 (weak), 5.80–5.89 (broad and strong), 6.21 (sharp and strong); u.v. 246 ($\simeq 6600$), 285 ($\simeq 1300$; shoulder); n.m.r. (60 MHz), 0.04 (d, $J = 2.5$ Hz; 1; collapsed by irradiation at 7.58), 2.22 (d, $J = 2$ Hz slightly broadened; 1), 3.2 (broad; impurity ?), 5.0–8.8 complex spectrum in which can be seen at 7.58 (dd, J values 10, 2.5 Hz; 2.5 Hz coupling removed by irradiation near 0.04 and multiplet partially collapsed by irradiation at 5.63; 1) and at 8.53 (d, $J = 6$ Hz; collapsed by irradiation at 5.63; 3); mass spectrum 197 (6), 196 (35), 181 (32), 178 (29), 170 (10), 169 (8), 168 (8), 167 (38), 165 (12), 153 (10), 152 (20), 151 (10), 150 (12), 149 (12), 141 (18), 140 (10), 139 (30), 137 (10), 135 (10), 127 (17), 126 (11), 125 (20), 124 (12), 123 (14), 122 (12), 121 (22), 111 (21), 109 (23), 108 (15), 105 (11), 98 (24), 97 (31), 95 (37), 93 (22), 91 (26), 81 (50), 79 (41), 77 (28), 69 (55), 67 (44), 55 (45), 53 (49), 43 (56), 41 (100), 39 (89); metastables 167.0 (calcd. for 196 → 181: 167.2), 161.7 (calcd. for 196 → 178: 161.7), 142.1 (calcd. for 196 → 167: 142.3), 105.2 (calcd. for 139 → 121: 105.3), 89.1 (calcd. for 167 → 122: 89.1), 78.1 (calcd. for 111 → 93: 77.9), 77.1 (calcd. for 81 → 79: 77.1); mass measurements calcd. (found): $C_{10}H_{12}O_4$, 196.07356 (196.0732); $C_9H_9O_4$, 181.05009 (181.0501); $C_{10}H_{10}O_3$, 178.06300 (178.0628); $C_9H_{11}O_3$, 167.07082 (167.0708); $C_8H_{11}O_2$, 139.07591 (139.0755).

Benzamide and antiarol (3,4,5-trimethoxyphenol) were isolated and identified by comparison with authentic samples; the reference sample of antiarol (6, 14) was kindly furnished by Professor Carl Djerassi.

This work was supported by a grant from the National Research Council of Canada; scholarships (to D.G.M.) from the same source and from the Province of Ontario are also gratefully acknowledged. This account is taken from the Ph.D. Thesis of D.G.M., University of Toronto, 1971.

The Influence of the 2-Alkoxy Group and of C-5 Substituents on the Direction of Reductive Cleavage of 2-Alkoxytetrahydrofurans by AlH_2Cl in Ether Solution[1]

P. C. Loewen, Miss L. P. Makhubu, and R. K. Brown

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 29, 1971

The AlH_2Cl hydrogenolysis of ether solutions of 2-alkoxytetrahydrofurans in which the alkoxy group is either CH_3O, C_2H_5O, *i*-C_3H_7O, or *t*-C_4H_9O, gives only those products resulting from ring C—O bond cleavage. However, substituents at C-5 of 2-methoxytetrahydrofuran exert a strong effect on the ratio of ring to *exo* C—O bond cleavage. Thus, alkyl (electron donor) groups at C-5 promote an increase in the amount of *exo* cleavage, the proportion increasing from 62.5 to 100% as the C-5 alkyl group is changed from CH_3 to *t*-C_4H_9. In contrast, electron withdrawing substituents, CH_3OCH_2— and C_6H_5, at C-5 favor ring cleavage to the extent of 93 and 84% respectively.

The results are interpreted in terms of the influence that these substituents exert through their electronic properties on the relative ease of attainment of the transition state leading to either ring C—O or *exo* C—O bond cleavage. However, evidence is provided to show that the bulk steric effect of these substituents also controls, though to a minor extent, the proportion of ring to *exo* cleavage.

Les hydrogénolyses par AlH_2Cl de solutions éthérées de tétrahydrofurannes alcoolates-2, où le group alcoolate est soit CH_3O, C_2H_5O, *i*-C_3H_7O, ou *t*-C_4H_9O, conduisent uniquement aux produits résultant de la rupture de la liaison C—O du cycle. Cependant, les substituants sur C-5 dans le méthoxy-2 tétrahydrofuranne, exercent un effet important sur le rapport: rupture de la liaison C—O du cycle sur rupture de la liaison C—O exocyclique. C'est ainsi que des groupes alkyles (donneurs d'électrons) sur C-5 favorisent le pourcentage de clivage exocyclique; les pourcentages augmentant de 62.5 à 100% si le groupe alkyle passe de CH_3 à *t*-C_4H_9. Au contraire, des substituants en C-5 attracteurs d'électrons, CH_3OCH_2— et C_6H_5, favorisent la rupture du cycle jusqu'à des proportions de 93 et 84% respectivement.

Les résultats sont interprétés en fonction de l'influence qu'exercent ces substituants, par leurs propriétés électroniques, sur la facilité relative de formation de l'état de transition conduisant ultérieurement à la rupture de la liaison C—O soit du cycle soit exocyclique. Cependant, des preuves ont été apportées afin de montrer que l'encombrement stérique de ces substituants contrôle également, bien qu'à un degré moindre, les proportions de clivage cyclique et exocyclique.

Canadian Journal of Chemistry, **50**, 1502 (1972)

Introduction

It has been shown (1) that the proportion of ring C—O bond cleavage to side chain C—O bond cleavage of 2-alkoxytetrahydropyrans (Scheme 1, **1**, $n = 2$) resulting from the hydrogenolysis by a 1:1 mixture of $AlCl_3$ and $LiAlH_4$ in ether depends upon the nature of the alkyl group of the 2-alkoxy substituent and also upon the nature of the C-6 substituent. The percent ring cleavage increased in the order 30, 60, 60, 82, 87 when the alkyl group of the 2-alkoxytetrahydropyran was CH_3, C_2H_5, *n*-C_4H_9, *i*-C_3H_9, and *t*-C_4H_9 respectively (**1**, $R' = H$ in each case). This was attributed to the relative electron donor ability of the alkyl group of the 2-alkoxy moiety to facilitate attainment of the transition state leading to the intermediate oxocarbonium ion involved in ring cleavage compared to the ease of obtaining the alternate intermediate oxocarbonium ion involved in the departure of the 2-alkoxy group with simultaneous ring retention (Scheme 1, routes *a* and *b* respectively, $n = 2$, $R' = H$, R = alkyl). Attainment of the transition state leading to the oxocarbonium ion was considered to be the slow and rate determining step, while hydride addition to this ion was fast and nonreversible. A similar explanation, involving the C-6 substituent was advanced to explain the 6, 60, and 80% proportion of ring cleavage found in the $LiAlH_4$–$AlCl_3$ hydrogenolysis respectively of the *cis–trans* mixture of 6-methyl-2-methoxy-

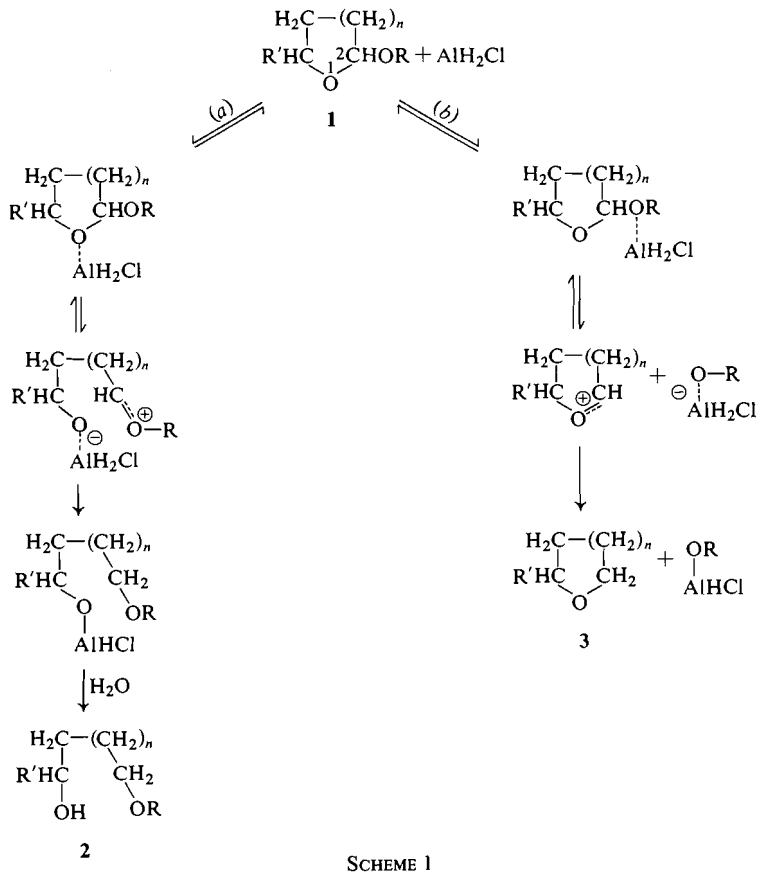

SCHEME 1

tetrahydropyran, and the separate *cis* and *trans* isomers of 2-methoxy-6-methoxymethyltetrahydropyran (1).

The present paper describes the results of the extension of this study to the hydrogenolysis by 1:1 $LiAlH_4$–$AlCl_3$ (*i.e.* AlH_2Cl (2, 3)) of 2-alkoxytetrahydrofurans and of some 5-substituted 2-methoxytetrahydrofurans (Scheme 1, **1**, $n = 1$).

Results and Discussion

Preparation of 2-Alkoxytetrahydrofurans and 5-Substituted 2-Alkoxytetrahydrofurans

The unsubstituted 2-alkoxytetrahydrofurans were prepared by the reaction of the appropriate alcohol with α-formyl-γ-butyrolactone (previously obtained from the base-catalyzed reaction of γ-butyrolactone (**4**, R′ = H) with ethyl formate), followed by alkaline hydrolysis and subsequent decarboxylation of the product (Scheme 2), a procedure based on that of Korte *et al.* (4, 5). For R′ = H, the yield of the ester **6** decreased in the order 90, 41, 29, ~0% when R was CH_3, C_2H_5, *i*-C_3H_7, and *t*-C_4H_9 respectively, a result thought to be due to the relatively greater steric interference of R as its bulk increased. Decarboxylation of the 2-alkoxy-3-carboxytetrahydrofuran in the conversion of **6** to **7** was accompanied by the dihydrofuran **8**. However, by the acid-catalyzed reaction of the mixture of **7** and **8** with the alcohol ROH, **7** could be obtained quite readily, free of **8**.

The same procedure shown in Scheme 2 was used to convert the γ-substituted γ-butyrolactones **4** (R′ = CH_3, *i*-C_3H_7, *t*-C_4H_9) to the corresponding 2-methoxy-5-substituted tetrahydrofurans. Apart from the commercially available γ-valerolactone (**4**, R′ = CH_3), the required γ-alkyl-γ-butyrolactones were made satisfactorily by the reaction of the appropriate

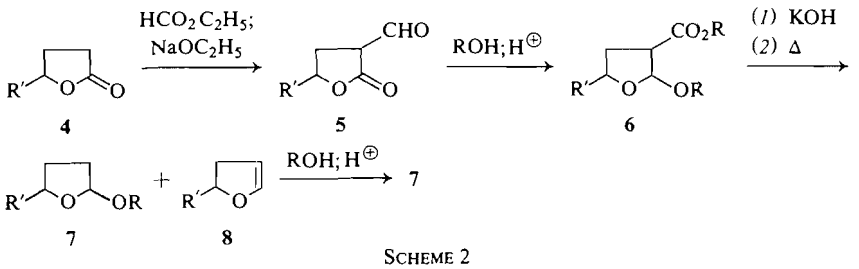
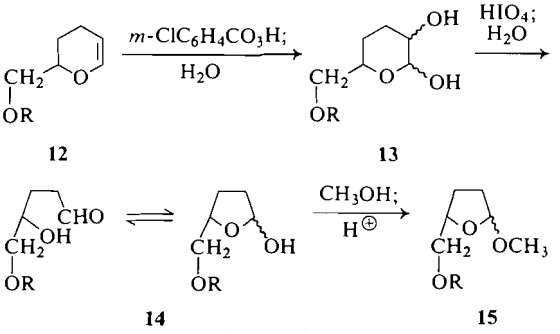


SCHEME 2

methyl ketones **9** ($R' = i\text{-}C_3H_7$ or $t\text{-}C_4H_9$) with dimethylamine and titanium tetrachloride (Scheme 3), a method which produces the terminal enamine **10** (6), which was then condensed with ethyl bromoacetate to provide the γ-ketoester **11** (7). The ester **11** could then be reduced and the product subsequently cyclized to the γ-substituted γ-butyrolactone **4** (Scheme 3). This method was unsuccessful for the preparation of γ-phenyl-γ-butyrolactone from acetophenone, since the conversion of **11** ($R' = C_6H_5$) to **4** ($R' = C_6H_5$) with sodium borohydride (Scheme 3) was quite unsatisfactory. However, **4** ($R' = C_6H_5$) could be obtained in satisfactory yield from the base-catalyzed reaction of styrene oxide with diethyl malonate, and the product hydrolyzed and decarboxylated.

We were unable to prepare γ-methoxymethyl-γ-butyrolactone (**4**, $R' = CH_3OCH_2$) to take advantage of its conversion to **7** ($R' = CH_3OCH_2$, $R = CH_3$) by the route shown in Scheme 2. However, 2-methoxy-5-methoxymethyltetrahydrofuran was made satisfactorily by the reaction of a peroxy acid with the methyl ether of 2-hydroxymethyl-2,3-dihydro-3*H*-pyran (**12**, $R = CH_3$) to produce the diol **13** (8) which in turn was oxidized with metaperiodic acid (Scheme 4). To avoid extensive decomposition, the product **14** was not isolated or purified, but instead subjected directly to acid-catalyzed reaction with methanol to produce the acetal **15** ($R = CH_3$).



SCHEME 4

Hydrogenolyses

(a) Of 2-Alkoxytetrahydrofurans

Only two products were obtained from the hydrogenolysis of each of the 2-alkoxytetrahydrofurans (*cf.* routes *a* and *b* in Scheme 1, $n = 1$). These usually were easily identified by comparison of the g.l.c. retention times with those of authentic samples. In all cases of doubt, the products were isolated by preparative g.l.c. and then identified by comparison of their p.m.r. and i.r. spectra and physical constants with those of authentic compounds. In those

*This time generally was more than enough for complete reaction. Most were complete in a fraction of the time indicated and in these cases no starting material remained. All products were stable to the reaction conditions.

†Recovery was based on the actual % yield of product C obtained by distillation and does not include B or CH_3OH since the latter could not be estimated by g.l.c.

‡*cis–trans* mixtures of A were reduced in each case. The p.m.r. spectra indicated that the two isomers were present in the ratio from 1:1 to 2:3.

cases wherein authentic compounds were not available or reported, the isolated products were characterized in the usual way. All hydrogenolysis products were stable under the reaction conditions. Product ratios were determined by g.l.c. peak areas, uncorrected for detector response since usually the observed areas corresponded well within 5% of the expected area, and only a few deviated at the most by 10%. In all cases there was no doubt as to the preferred direction of reductive cleavage. The results of the hydrogenolysis reactions are shown in Table 1 in which structure A represents the substituted or unsubstituted 2-alkoxytetrahydrofuran while structures B and C represent the products from *exo* cleavage and ring (*endo*) cleavage respectively.

Experiments 1–4 in Table 1 show that when R′ = H in A, only ring cleavage occurs, regardless of whether R is CH_3, C_2H_5, i-C_3H_7, or t-C_4H_9. This is in sharp contrast to the findings for the hydrogenolysis of the analogous 2-alkoxytetrahydropyrans where both ring and *exo* cleavage products were formed, with the latter decreasing in relative amount as the alkyl group changed from CH_3 to t-C_4H_9. It is clear that exclusive ring cleavage occurs regardless of the inductive or steric effect of the alkyl substituent R. Since it has been shown that there is a stronger association of Lewis acids with tetrahydrofuran than with the analogous acyclic ether (9–11), it is possible that this factor submerges any inductive or steric influence of the alkyl group R and hence the Lewis acid AlH_2Cl associates exclusively or nearly so with the ring oxygen, the first step in the reductive cleavage of the C—O bond of acetals. It is to be expected that the stronger association of the Lewis acid with the ring oxygen would produce a greater extent of C—O bond breaking in the transition state, resulting in the strong preference for ring cleavage (route *a*, Scheme 1, $n = 1$, R′ = H). That a polar effect of the alkyl group is still operative, although it is unable to manifest itself in terms of the direction of reductive cleavage, is clearly shown by the competitive reaction of a 1:1 mixture of 2-ethoxy- and 2-t-butoxytetrahydrofuran with a limited amount of AlH_2Cl, sufficient to hydrogenolyze only one-half of the total acetal. It was found again that only ring cleavage products were obtained, but the ratio of the 2-t-butoxy- to 2-ethoxytetrahydrofuran reduced was 78:22, thus showing that the t-butyl group is more

effective in facilitating attainment of the transition state leading to oxocarbonium ion formation.

Eliel *et al.* (12) have reported the hydrogenolysis of four 2-alkoxytetrahydrofurans by a mixture of $AlCl_3$ and $LiAlH_4$ and found that generally both *exo* and *endo* cleavage occurred. The percentage of *exo* and *endo* cleavage products actually obtained by them in each case where the alkyl group was *t*-butyl, cyclohexyl, *n*-hexyl, and benzyl were, respectively, a trace and 58, 15 and 63, 40 and 27, 83 and 4. They concluded from this that the steric effect of the C-2 alkoxy group was more important than was the basicity of the ring oxygen in directing the course of reductive cleavage. The discrepancy between our results and those reported (12) might be due to the fact that we employed as reducing system a 1:1 mixture of $AlCl_3$ and $LiAlH_4$ which provides AlH_2Cl (2, 3) whereas Eliel *et al.* (12) used a 4:1 mixture of $AlCl_3$ and $LiAlH_4$, which provides a 1:4 mixture of $AlCl_3$ and $AlHCl_2$ (2, 3). This view is supported by the data in Table 2 which show the results of the hydrogenolysis of 2-benzyloxytetrahydrofuran by the series of reagents AlH_3, AlH_2Cl, $AlHCl_2$, and the 4:1 mixture of $AlHCl_2$ with $AlCl_3$ (Eliel's reagent). The latter two hydrogenolyzing reagents provide the *exo* and *endo* cleavage products, B and C, in the proportion 90.5:9.5 and 91.3:8.7 respectively, nearly the same as the proportion of 83:4 reported (12). However, reduction by AlH_2Cl provides the same products in the proportion *exo*:*endo* = 48.5:51.5. The failure to obtain exclusive ring cleavage with AlH_2Cl as was found for the alkoxytetrahydrofurans may be due to the electron withdrawing character of the phenyl group which would then cause the benzyloxy moiety to destabilize the transition state leading to ring cleavage, thus overcoming to some extent the overwhelming tendency of the Lewis acid to coordinate with the ring oxygen which is followed by ring cleavage. AlH_3 also provides the *exo* and *endo* cleavage products, but in the proportion 20.5:79.5. It is clear from the data in Table 2 that those hydrogenolyzing agents which are the strongest Lewis acids provide the greatest proportion of *exo* cleavage.

(b) Of 5-Substituted 2-Alkoxytetrahydrofurans

Hydrogenolysis of the 5-alkyl-2-methoxytetrahydrofurans, as *cis–trans* mixtures, provides both *exo* and *endo* cleavage products B and C. As the C-5 alkyl group R′ is changed from CH_3 to i-C_3H_7 to t-C_4H_9, the percent *exo* cleavage is respectively 62.5, 86, and ~100% (experiments 6–8, Table 1). It is clear that in these three cases, the greater "basicity" of the ring oxygen is counteracted by other forces. Two factors, either separately or in concert, could account for these results. The first is due to the electron donor property of the C-5 alkyl group (R′) competing progressively more effectively in lowering the energy required to attain the transition state leading to the formation of the oxocarbonium ion involved in ring retention, than does the *exo* oxygen's alkyl group in attaining the alternate oxocarbonium ion (*i.e.* route *b* is preferred over route *a* in Scheme 1). The second factor is due to the steric effect of the C-5 alkyl substituent, added to that of the C-2 methoxy group, decreasing the ease of associa-

For personal use only.

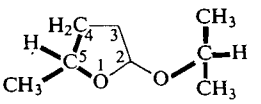
tion of the Lewis acid with the ring oxygen, thus causing preference for route *b* (Scheme 1). It is to be noted that such a steric effect has been advanced to account for the lower "basicity" of 2-methyltetrahydrofuran and of 2,5-dimethyltetrahydrofuran compared to that of tetrahydrofuran itself (10, 11).

In an attempt to determine the relative effectiveness of the polar and steric influences, substituents were incorporated in structure **1** at C-5, which provided the bulk required, but were electron withdrawing in character. If the steric effect is predominant, hydrogenolysis of these C-5 substituted 2-methoxytetrahydrofurans should provide primarily B, the product from *exo* cleavage (route *b*, Scheme 1). On the other hand, if the polar effect is of predominant importance, then the ring cleavage product C should be preferred (route *a*, Scheme 1). In this connection it is known that the phenyl group has an effective bulk slightly greater than that of the isopropyl group, as shown by their respective A values of 2.1–3.0[2] and 1.8–2.5 kcal/mol determined in the cyclohexane system (13). Experiments 5 and 9 (Table 1) show that hydrogenolysis of 2-methoxy-5-methoxymethyltetrahydrofuran and of 2-methoxy-5-phenyltetrahydrofuran (both as *cis–trans* mixtures) provide the ring cleavage products in the proportion of 93.5 and 84.5% respectively. This appears to show that it is the electronic rather than the steric effect which is of major importance in determining the direction of reductive cleavage. However, the ability of oxygen ethers and of the phenyl group to associate with Lewis acids such as $AlCl_3$, and thus quite likely with AlH_2Cl, might cause the C-5 substituents, $R' = CH_3OCH_2$ and C_6H_5, to assist in keeping the AlH_2Cl in the vicinity of the ring oxygen, rather than with the C-2 oxygen atom, and in this way favor ring cleavage.

A further attempt to determine the relative effectiveness of polar and steric influences was made by hydrogenolyzing 5-methyl-2-isopropoxytetrahydrofuran. In this compound the polar effects on the acetal unit of the isopropyl group and of the portion of the structure at C-5



D

should be similar since the latter moiety approximates the isopropyl group in its electron donor ability. This feature is shown in structure D in which the comparable sections are emphasized. In this case only the bulk of the substituents and the relative "basicity" of the two oxygen atoms should control the direction of reductive cleavage. Experiment 10, Table 1, shows that ring cleavage occurs to the extent of 93.2%. This clearly demonstrates the importance of the greater "basicity" of the ring oxygen. If steric effects were predominant in controlling the direction of cleavage, one would expect that 5-methyl-2-isopropoxytetrahydrofuran (experiment 10) would suffer *exo* cleavage *at least* to the same extent as did 5-methyl-2-methoxytetrahydrofuran (experiment 6). This is clearly not the case, and fortifies our view that electronic factors as well as the "basicity" of the ring oxygen play dominant roles in the direction of reductive cleavage of 2-alkoxytetrahydrofurans. However, the fact that 2-isopropoxytetrahydrofuran undergoes *only* ring cleavage (experiment 3) while 5-methyl-2-isopropoxytetrahydrofuran provides, upon hydrogenolyses, as much as 6.8% of the *exo* cleavage product, B, might be interpreted as evidence that some steric effect is exerted by the C-5 substituent. Hence the steric effect of the C-5 substituent could provide at least some of the reason why hydrogenolysis of 5-alkyl-2-methoxytetrahydrofuran produces an increasing proportion of *exo* cleavage product B (62.5 → 86 → 100%) as the C-5 group is changed from CH_3 to i-C_3H_7 to t-C_4H_9.

All of the 5-substituted 2-alkoxytetrahydrofurans were mixtures of the *cis* and *trans* isomers, a fact readily determined by the two sets of quartets in the p.m.r. spectrum of each compound due to the anomeric proton. The signal areas showed that the proportion of isomers ranged from 1:1 to 3:2, but we were unable to determine which of the 3:2 mixture was *cis* or *trans*. Although it has been shown that the signals for the α protons of *trans*-2,5-dimethyltetrahydropyran appear at lower field than do those of the *cis* isomer (14, 15), the signals for the α protons of several other *cis*-

[2]Recent calculations involving phenylcyclohexane (35) show that the energy difference could be as high as 3.6 kcal/mol between the axial phenyl group in the preferred "perpendicular" orientation and the equatorial phenyl group in the preferred "parallel" orientation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

trans-2,5-disubstituted tetrahydrofurans appeared either at nearly the same position in the spectrum or in some cases the *trans* α proton signals occurred at slightly higher field than did those of the *cis* isomer. Accordingly, the p.m.r. spectrum was of no assistance in identifying the *cis* or *trans* isomer. All our attempts to separate the isomers by g.l.c. failed, in spite of the variety of columns employed. Our interest in identifying the *cis* or *trans* isomer lay in the possibility that one isomer might prefer to undergo *exo* cleavage, while the other would prefer *endo* cleavage. This might well have been the situation for 5-methyl-2-methoxytetrahydrofuran since the ratio of *exo*:*endo* cleavage is 62.5:37.5 while the isomer ratio is 3:2. However, since all the other 5-substituted 2-alkoxytetrahydrofurans employed in this work hydrogenolyzed either *exo* or *endo* to the extent of at least 80% while their proportion of *cis–trans* isomers ranged from 1:1 to 3:2, it is unlikely that the relative amount of *cis* and *trans* isomers is an important factor in determining the direction of hydrogenolysis. This view is supported by the results obtained from the treatment of the *cis–trans* mixtures of each of the three compounds 5-methyl-, 5-isopropyl-, and 5-*t*-butyl-2-methoxytetrahydrofuran with an amount of AlH_2Cl insufficient to hydrogenolyze all of the acetal. In all three cases the proportion of *cis–trans* isomers in the remaining unreacted material was the same as that in the starting material, and also the proportion of *exo* to *endo* cleavage was the same as that found when complete hydrogenolysis occurred.

Experimental

All boiling points and melting points are uncorrected.

Gas liquid chromatographic analyses were made with an F and M model 700 instrument equipped with 12 ft × 1/8 in. columns packed with either (*a*) Carbowax 20 M, 20% on Gas-Chrom P (60–80 mesh), (*b*) Apiezon T or Apiezon L, 10% on Chromosorb W (60–80 mesh), or (*c*) butanediol succinate, 20% on Chromosorb W (60–80 mesh). Helium was the carrier gas at a flow rate of ~40 ml/min. For preparative g.l.c., an Aerograph Autoprep, Model A-700 (Wilkens Instrument and Research Co.) was used. The columns employed were (*a*) 12 ft × 1/4 in. packed with Carbowax 20 M, 20% on Gas Chrom P (60–80 mesh), (*b*) 12 ft × 1/4 in., packed with butanediol succinate, 20% on Chromosorb W (60–80 mesh), (*c*) 6 ft × 1/4 in., packed with Apiezon T, 10% on Chromosorb W (30–60 mesh), and (*d*) 12 ft × 1/4 in., packed with 10% Carbowax 20 M and 10% silicone rubber on Chromosorb W (30–60 mesh). Helium was the carrier gas. The type of column and its temperature was dependent on the boiling point of the compounds. For most analyses on the F and M, Model 700, the temperature was linearly programmed to achieve better resolution, with a temperature increase of 15 °C/min starting from 50 °C. The terminal temperature depended upon column stability.

Quantitative analyses by g.l.c. were made by measuring the signal areas directly, uncorrected for detector response since observed and correct areas differed by less than 5% in most cases, though in a few this difference was as much as 10%.

The i.r. spectra were recorded with a Perkin–Elmer Model 337 instrument.

The p.m.r. spectra, all referred to tetramethylsilane, were recorded with a Varian Associates A-60 instrument operated by Mr. R. Swindlehurst and assistants, and an HR-100 spectrometer operated by Mr. G. Bigham. The p.m.r. spectra of all new compounds described below agreed completely with the structures proposed.

Elemental analyses were carried out by Mrs. D. Mahlow of this Department. These agreed well with the expected values.

Solvents were removed by rotary evaporator under reduced pressure unless otherwise stated.

Preparation of 2-Alkoxytetrahydrofurans (see Table 3)

The 2-alkoxy-3-carboalkoxytetrahydrofurans (compounds **1–4** in Table 3) were prepared by the published procedure (4). These were saponified (4) and decarboxylated at 100–120° to provide compounds **5–7**. Compounds **8** and **9** were prepared by literature directions (12).

Preparation of 5-Substituted 2-Alkoxytetrahydrofurans

cis-trans-5-Methyl-2-methoxytetrahydrofuran

3-Carbomethoxy-5-methyl-2-methoxytetrahydrofuran (5), b.p. 97° at 20 mm, η_D^{26} 1.4310; lit. b.p. 84° at 9 mm (5), was saponified (4) to the acid, yield 92%. The oil was decarboxylated at 100–110° to *cis-trans*-5-methyl-2-methoxytetrahydrofuran; yield 42%, b.p. 108–109° at 695 mm; η_D^{30} 1.4127, η_D^{22} 1.4080.

cis-trans-5-Isopropyl-2-methoxytetrahydrofuran

The reaction of 5.7 g (0.05 mol) of 2-dimethylamino-3-methyl-1-butene (6) with 8.35 g (0.05 mol) of ethyl bromoacetate following general directions (7) provided 2.3 g (32%) of *methyl β-isobutyrylpropionate*, b.p. 86–87° at 8 mm; η_D^{22} 1.4270.

A cold (0°) solution of methyl β-isobutyrylpropionate (2.0 g, 0.013 mol) in 20 ml of dry methanol was vigorously stirred while sodium borohydride (0.25 g, 0.0064 mol) was added in small portions. The mixture was then stirred overnight at room temperature. Excess methanol was then removed and 4 ml of aqueous sulfuric acid (1:1) was added to the stirred residue. The ether extracts (3 × 30 ml) were dried ($MgSO_4$), and freed from solvent. Distillation gave 1.5 g (93%) of γ-isopropyl-γ-butyrolactone, b.p. 56° at 0.5 mm; η_D^{20} 1.4416; lit. b.p. 98° at 15 mm; η_D^{25} 1.4410 (18).

The lactone (3.6 g, 0.15 mol) was condensed with ethyl formate according to general directions (4) to provide 16 g (81%) of *3-carbomethoxy-5-isopropyl-2-methoxytetrahydrofuran*, b.p. 70° at 1 mm; η_D^{24} 1.4392. This ester (6 g, 0.03 mol) was saponified (4) to give 4.1 g (74%) of the crude viscous

*Isolation gave only 3-carbo-t-butoxy-4,5-dihydrofuran, m.p. 45–46°.

liquid *3-carboxy-5-isopropyl-2-methoxytetrahydrofuran.* This crude acid, in 20 ml of quinoline containing a trace of cupric sulfate, was heated at 200–210° under nitrogen. The product, collected in a Dry Ice–acetone cooled flask, contained *5-isopropyl-2-methoxytetrahydrofuran* contaminated with *2-isopropyl-2,3-dihydrofuran.* Treatment of this mixture for 6 h at room temperature with 5 ml of methanol containing a trace of *p*-toluenesulfonic acid, followed by addition of sodium carbonate (2 g), filtration, and distillation, gave *cis-trans-5-isopropyl-2-methoxytetrahydrofuran* (28% from the γ-isopropyl-γ-butyrolactone), b.p. 80° at 95 mm; η_D^{25} 1.4172. The g.l.c. analysis on butanediol succinate column showed two overlapping peaks in the area ratio of ~3:2.

cis-trans-5-t-Butyl-2-methoxytetrahydrofuran

Pinacolone (19) obtained from pinacol hydrate (20), was converted to the enamine 2-dimethylamino-3,3-dimethyl-1-butene (6), yield, 63%, b.p. 105° at 690 mm; η_D^{22} 1.4308; lit. b.p. 57° at 71 mm; η_D^{25} 1.4293 (6).

From the enamine (45 g) and ethyl bromoacetate there was obtained 16 g (38%) of *methyl β-pivalylpropionate* following the directions used for the reaction of methyl α-bromopropionate with enamines (7); b.p. 80° at 4 mm; η_D^{22} 1.4303.

Sodium borohydride reduction of methyl β-pivalylpropionate, followed by acid-catalyzed cyclization of the product as described above for the conversion of methyl β-isobutyrylpropionate to γ-isopropyl-γ-butyrolactone, gave γ-*t*-butyl-γ-butyrolactone; yield, 98% from the ketoester, b.p. 74° at 2 mm; η_D^{22} 1.4453.

Reaction of this lactone with ethyl formate (4) gave a 63% yield of crude *5-t-butyl-3-carbomethoxy-2-methoxytetrahydrofuran* containing 3–4% of unreacted lactone which could not be removed by usual fractional distillation; b.p. of crude, 95% at 3 mm; η_D^{25} 1.4380. The crude ester was saponified (4) and the impure free acid decarboxylated in quinoline as above to provide *cis-trans-5-t-butyl-2-methoxytetrahydrofuran*; yield from the lactone, 10%; b.p. 97° at 110 mm; η_D^{23} 1.4257. The g.l.c. on butanediol succinate showed two separate peaks in the area ratio 55:45.

cis-trans-2-Methoxy-5-phenyltetrahydrofuran

γ-Phenyl-γ-butyrolactone was prepared by the reaction of styrene oxide (21) with diethyl malonate as described (22) but with sodium hydride in 1,2-dimethoxyethane under nitrogen as the condensing system; yield, 54%; b.p. 123° at 0.8 mm; η_D^{23} 1.5392; lit. b.p. 130° at 1.5 mm (22); $\eta_D^{15.4}$ 1.5418 (23).

Reaction of this lactone with ethyl formate (4) gave *3-carbomethoxy-2-methoxy-5-phenyltetrahydrofuran*; yield, 78%; b.p. 125° at 0.5 mm; η_D^{22} 1.5124.

Saponification (4) gave the free acid which was decarboxylated (4) to *cis-trans-2-methoxy-5-phenyltetrahydrofuran* (54% from the lactone); b.p. 85° at 0.8 mm; η_D^{24} 1.5130. The g.l.c. on an Apiezon T column showed a single broad peak for the *cis–trans* mixture.

cis-trans-2-Methoxy-5-methoxymethyltetrahydrofuran

Methylation (25) of 2-hydroxymethyl-3,4-dihydro-2*H*-pyran (24) gave a 70% yield of *2-methoxymethyl-3,4-dihydro-2H-pyran*; b.p. 58–60° at 30 mm; η_D^{24} 1.4458; lit. b.p. 60° at 20 mm; $\eta_D^{17.5}$ 1.4508 (26).

To a solution of 80% *m*-chloroperoxybenzoic acid (55 g, 0.2 mol) in 400 ml of wet ether at 0°, was added dropwise 2-methoxymethyl-3,4-dihydro-2*H*-pyran (26 g, 0.2 mol). The mixture was warmed to room temperature, stirred for 24 h, then freed from ether. A chloroform solution of the residue, separated from the sparingly soluble *m*-chlorobenzoic acid, was washed with aqueous sodium bicarbonate till neutral. The bicarbonate washings in turn were washed with chloroform. The combined chloroform extracts were dried ($MgSO_4$), separated from the solid and freed from solvent to give 30 g (99%) of crude *2,3-dihydroxy-6-methoxymethyltetrahydropyran.* The crude diol (16 g, 0.1 mol) was added dropwise to a solution of periodic acid (22.5 g, 0.1 mol) in 200 ml of a 1:1 mixture of dioxane and water. The resulting mixture was stirred for 12 h, then neutralized with solid sodium bicarbonate. The slightly alkaline solution was extracted continuously for 24 h with chloroform and the extracts dried with $MgSO_4$ containing some sodium thiosulfate to remove iodine. The filtered solution was freed from solvent to give 11.5 g (88.5%) of the crude hemiacetal *cis-trans-2-hydroxy-5-methoxymethyltetrahydrofuran.* This was dissolved in 100 ml of dry methanol containing a few drops of concentrated hydrochloric acid and left at room temperature for 6 h. This was then stirred for 15 min with excess solid sodium bicarbonate. Removal of the solid, and separation of solvent by fractional distillation gave a residue

For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which was distilled to provide *cis-trans-2-methoxy-5-methoxymethyltetrahydrofuran*; yield, 7.1 g (55%); b.p. 65° at 50 mm; η_D^{25} 1.4242.

cis-trans-2-Isopropoxy-5-methyltetrahydrofuran

A solution of 6.8 g (0.05 mol) of 2-methoxy-5-methyltetrahydrofuran in 20 ml of isopropyl alcohol containing a trace of *p*-toluenesulfonic acid was heated in an apparatus arranged for downward distillation while nitrogen was bubbled through the solution. A mixture of methanol and isopropyl alcohol distilled between 60–80°. Distillation was continued till only isopropyl alcohol came over (80°). The cooled residue was stirred with solid sodium bicarbonate, filtered, and fractionally distilled to give 4.3 g (60%) of the furan; b.p. 136–139° at 700 mm; η_D^{25} 1.4112.

The g.l.c. on butanediol succinate showed one broad symmetrical peak.

Preparation of Authentic Hydrogenolysis Products

The 4-Alkoxy-1-butanols from Ring Cleavage of 2-Alkoxytetrahydrofurans

The following compounds were prepared by the general procedure (12) starting with 4-chloro-1-butanol and 3,4-dihydropyran and then using the appropriate alcohol.

4-Methoxy-1-butanol, b.p. 60° at 19 mm; η_D^{26} 1.4194; lit. b.p. 59–63° at 7 mm; η_D^{25} 1.4189 (27).

4-Ethoxy-1-butanol, b.p. 78° at 18 mm; η_D^{26} 1.4201; lit. b.p. 83–84° at 16 mm; η_D^{20} 1.4229 (28).

4-Isopropoxy-1-butanol, b.p. 87° at 15 mm; η_D^{24} 1.4237.

4-t-Butoxy-1-butanol was obtained in 86% yield from AlH_2Cl hydrogenolysis of 2-*t*-butoxytetrahydrofuran (see below for general method); b.p. 95–96° at 17 mm; η_D^{25} 1.4253; lit. b.p. 72–74° at 10 mm; η_D^{18} 1.4301 (12).

Compounds Expected from Ring Cleavage of 5-Substituted-2-alkoxytetrahydrofurans

5-Methoxy-2-pentanol

This compound was obtained as the chief product from the AlH_2Cl hydrogenolysis of 2-methoxy-5-methyltetrahydrofuran by the general procedure described later in this paper; yield, 50%; b.p. 65° at 20 mm; η_D^{25} 1.4220.

6-Methoxy-2-methyl-3-hexanol

A solution of 11 g (0.085 mol) of γ-isopropyl-γ-butyrolactone (see above for preparation of *cis-trans*-5-isopropyl-2-methoxytetrahydrofuran) in 10 ml of dry ether was added dropwise to a solution of lithium aluminum hydride (2.0 g, 0.053 mol) in 100 ml of ether kept at 5° in an ice bath. After the addition, the mixture was stirred for 2 h at room temperature and then an aqueous 15% solution of potassium hydroxide was added till no further lithium aluminate precipitated. The solid was separated and the filtrate freed from ether. The residue was distilled to give *5-methyl-1,4-hexanediol* as a colorless liquid (7.6 g, 69%); b.p. 80° at 0.1 mm; η_D^{19} 1.4553.

To a vigorously stirred solution of this diol (2.5 g, 0.019 mol) and methyl iodide (5.4 g, 0.038 mol) in 50 ml of dry 1,2-dimethoxyethane (DME) was added 0.76 g (0.019 mol) of sodium hydride (obtained from 60% sodium hydride in paraffin washed with pentane and dried under nitrogen) in small portions. The resulting mixture was stirred at room temperature for 2 h, then freed from DME. An ether solution of the residue was filtered and the filtrate dried ($MgSO_4$) and subsequently freed from solid and from ether. The residue when distilled gave *6-methoxy-2-methyl-3-hexanol* as a colorless liquid, b.p. 58° at 1 mm; η_D^{20} 1.4343.

The g.l.c. analysis showed only one symmetrical peak with retention time identical to that of the high boiling product obtained from the hydrogenolysis of 5-isopropyl-2-methoxytetrahydrofuran.

6-Methoxy-2,2-dimethyl-3-hexanol

A solution of lithium aluminum hydride (2.4 g, 0.063 mol) in 100 ml of dry ether was cooled in ice to 5° and added dropwise to a solution of 10 g (0.058 mol) of methyl β-pivalylpropionate (see above for preparation of *cis-trans*-5-*t*-butyl-2-methoxytetrahydrofuran) in 20 ml of ether. The reaction mixture was then treated as described for the analogous reduction of γ-isopropyl-γ-butyrolactone with the hydride; yield of *5,5-dimethyl-1,4-hexanediol*, 8.1 g (81%); b.p. 82–84° at 0.1 mm; η_D^{24} 1.4565.

Monomethylation of this diol followed the same procedure described above for the monomethylation of 5-methyl-1,4-hexanediol, to provide *6-methoxy-2,2-dimethyl-3-hexanol* in 61% yield; b.p. 82–83° at 6 mm; η_D^{24} 1.4350.

The g.l.c. showed a single symmetrical peak with retention time identical to that of the trace amount of high boiling product obtained from the hydrogenolysis of 5-*t*-butyl-2-methoxytetrahydrofuran.

4-Methoxy-1-phenyl-1-butanol

The reaction (29) of diethyl malonate with 1-bromo-2-methoxyethane, but using sodium hydride in dry DME under nitrogen, gave 36 g (45%) of *diethyl (2-methoxyethyl)-malonate*; b.p. 111° at 6 mm; η_D^{22} 1.4238; lit. b.p. 110° at 6 mm (29). Hydrolysis (29) gave 4-methoxybutyric acid (82%); b.p. 93° at 4 mm; η_D^{25} 1.4226; lit. b.p. 105° at 7 mm; η_D^{20} 1.4251 (29). Acid-catalyzed reaction of the acid with methanol gave *methyl 4-methoxybutyrate* (45%), b.p. 100° at 100 mm; η_D^{24} 1.4058.

Lithium metal (0.32 g, 0.04 mol) was added to vigorously stirred dry ether (100 ml) which had been flushed with dry nitrogen. To this stirred suspension was added dropwise, 3.14 g (0.02 mol) of bromobenzene. After all the metal had been consumed, the solution under nitrogen was stirred at room temperature for 2 h, and then 1.2 g (0.01 mol) of 4-methoxybutyric acid in 50 ml of ether was added slowly. The solution was stirred overnight at room temperature. Water (10 ml) was then slowly added to the stirred mixture. The ether layer was separated and dried ($MgSO_4$). Removal of the solid and then the solvent gave crude *4-methoxy-1-phenyl-1-butanone*. To this ketone (0.9 g, 0.051 mol), dissolved in 30 ml of dry tetrahydrofuran cooled to −10° in a Dry Ice–acetone bath, was added 1.0 g (0.026 mol) of sodium borohydride. After the addition, the solution was stirred overnight at room temperature and then carefully neutralized with 50% aqueous sulfuric acid using a drop of phenolphthalein as indicator. The excess tetrahydrofuran was removed and the residue dissolved in ether. The solid was separated by filtration and the filtrate freed from ether. Distillation of the residue gave 0.8 g (89%) of *4-methoxy-1-phenyl-1-butanol*; b.p. 94–95° at 0.1 mm; η_D^{23} 1.5150.

The g.l.c. on a column containing Apiezon T showed a single symmetrical peak with retention time identical to that of the high boiling product from the hydrogenolysis of 2-methoxy-5-phenyltetrahydrofuran.

5-Isopropoxy-2-pentanol

This was obtained as the chief product from AlH_2Cl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hydrogenolysis of 2-isopropoxy-5-methyltetrahydrofuran according to the procedure described later in this paper. The alcohol was isolated from the mixture of products by preparative g.l.c. on a butanediol succinate column. The microboiling point was 65–66° at 8 mm; η_D^{24} 1.4225.

Compounds Expected from exo Cleavage; the 2-Alkyltetrahydrofurans and 2-Phenyltetrahydrofuran

Tetrahydrofuran and *2-methyltetrahydrofuran*, from Eastman Kodak Co.

2-Isopropyltetrahydrofuran

The following extensive modification of the general procedure (30) for conversion of a 1,4-diol to the tetrahydrofuran was employed. *p*-Toluenesulfonylchloride (9.8 g, 0.052 mol) in a minimum amount of 2,6-lutidine was added dropwise to a hot (100°) stirred solution of 6.8 g (0.052 mol) of 5-methyl-1,4-hexanediol (prepared above) in 25 ml of 2,6-lutidine. The solution was then stirred for 1 h at 100°, and subsequently distilled. The material boiling at 120–130° was redistilled through a 3-in. Vigreux column; b.p. 114° at 700 mm; g.l.c. showed it to contain 2,6-lutidine (10%). Preparative g.l.c. on a butanediol succinate column at 150° gave pure *2-isopropyltetrahydrofuran*, η_D^{19} 1.4217. The g.l.c. showed one symmetrical peak with retention time identical to that for the low boiling product obtained from the hydrogenolysis of 5-isopropyl-2-methoxytetrahydrofuran.

2-t-Butyltetrahydrofuran

The compound, 5,5-dimethyl-1,4-hexanediol (prepared above) was cyclized to *t-butyltetrahydrofuran* by the modified method used to make 2-isopropyltetrahydrofuran. 2,4,6-Collidine was used in place of 2,6-lutidine and the solution obtained after the period of heating at 100° was stirred into ether. The residue, after removal of solid and solvent, distilled at 125° at 695 mm. The collidine impurity was removed by preparative g.l.c. on a Carbowax column at 150°; η_D^{22} 1.4248.

2-Phenyltetrahydrofuran

$LiAlH_4$ reduction of methyl β-benzoylpropionate (prepared above) by the method used above to reduce methyl β-pivalylpropionate gave *1-phenyl-1,4-butanediol* (84%); b.p. 129–130° at 0.3 mm; η_D^{23} 1.5409. The liquid solidified on standing, m.p. 65–66°.

The diol was cyclized to *2-phenyltetrahydrofuran* by the method used to prepare 2-*t*-butyltetrahydrofuran above but 2,6-lutidine was the base employed. The product boiled at 80° at 3 mm but contained some lutidine. Preparative g.l.c. on an Apiezon T column gave pure material; η_D^{23} 1.5283; lit. b.p. 107 at 15 mm; η_D^{20} 1.5299 (31).

2-Methoxymethyltetrahydrofuran

Reaction of furfuryl alcohol with methyl iodide and sodium hydride (25) gave *2-methoxymethylfuran* (40%); b.p. 80° at 120 mm; η_D^{23} 1.4521; lit. b.p. 134–135° at 762 mm; η_D^{20} 1.4573 (32).

The 2-methoxymethylfuran (5.6 g, 0.05 mol), hydrogenated at 60 p.s.i. and room temperature with rhodium on alumina (33), gave 3.85 g (69%) of 2-methoxytetrahydrofuran; b.p. 90° at 135 mm; η_D^{23} 1.4248; lit. b.p. 140–144° at 715 mm (34).

The g.l.c. showed one symmetrical peak of retention time identical to that of the minor product obtained from hydrogenolysis of 2-methoxy-5-methoxymethyltetrahydrofuran.

General Procedure for the Hydrogenolysis of 2-Alkoxytetrahydrofurans

To a solution of lithium aluminum hydride (0.30 g, 0.0079 mol) in 30 ml of dry ether, cooled to 5° in an ice bath, was added dropwise an ether solution of aluminum chloride, previously prepared by the addition of 1.05 g (0.0079 mol) of the aluminum chloride in small portions to 30 ml of dry ether kept at 5°. The resulting "mixed hydride" (AlH_2Cl (2, 3)) solution was stirred at room temperature for 15 min and then a solution of the 2-alkoxytetrahydrofuran (0.0156 mol) in ether (30 ml) was added dropwise. The resulting mixture was stirred at room temperature for the appropriate time (usually 2 h), whereupon an aqueous 15% solution of potassium hydroxide was slowly dropped in until no further reaction occurred. The colorless precipitate of lithium aluminate was separated by filtration and washed with ether. The combined washings and filtrate were freed from solvent by fractional distillation. The residue (recovery 80–95%) was analyzed by g.l.c. and the products identified by comparison of their retention times with those of authentic substances. In cases of doubt regarding identity the products were isolated by preparative g.l.c. and their i.r. and p.m.r. spectra were compared with those of authentic substances.

The authors thank the National Research Council of Canada for financial support for a part of this work.

One of us (P. C. Loewen) thanks the National Research Council of Canada for the award of a Bursary, and the Isaac Killam Memorial Fund of the University of Alberta for the award of a Fellowship.

Acidity Function Behavior in Aqueous-organic Solvents. I. The H_0, H_0''', and H_A Functions in 70% DMSO–H_2O

KEITH YATES AND GRAEME WELCH[1]

Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 9, 1971

The H_0, H_0''', and (in part) the H_A acidity functions have been determined in 70% DMSO–water for the sulfuric acid concentration range 0–85%. In sharp contrast to purely aqueous acid systems the H_0 (primary aniline) and H_0''' (tertiary aniline) scales in DMSO–water are closely parallel over a wide range of acidity. This provides clear experimental demonstration that linearity of log (ionization ratio) *vs.* acidity function with unit slope is not a sufficient condition that a base is obeying a given acidity function. When the three acidity functions in DMSO–water are shifted to a purely aqueous standard state, their order is completely reversed from that observed in aqueous acids. These differences in behavior are discussed in terms of cation solvation by DMSO molecules only.

Les fonctions d'acidité H_0, H_0''', et (en partie) H_A, ont été déterminées dans un mélange à 70% DMSO–eau pour des concentrations en acide sulfurique allant de 0 à 85%. A l'encontre des systèmes acides purement aqueux, les échelles H_0 (aniline primaire) et H_0''' (aniline tertiaire) sont, dans le DMSO–eau, étroitement parallèles sur une vaste échelle d'acidité. Ceci constitue une bonne preuve expérimentale d'après laquelle la linéarité du log (rapport d'ionisation) par rapport à la fonction d'acidité avec une pente unitaire ne constitue pas une condition suffisante pour affirmer qu'une base obéit à une fonction d'acidité donnée. Lorsque les trois fonctions d'acidité dans le DMSO–eau sont déplacées vers un état standard purement aqueux, leur ordre est complètement inversé par rapport à celui observé en milieu acide aqueux. Ces différences de comportements sont rationalisées en termes d'une solvatation cationique par les seules molécules de DMSO.

Canadian Journal of Chemistry, **50**, 1513 (1972)

Introduction

In the 14 years following the Paul and Long (1) review of the Hammett acidity function H_0 (2), confidence in the generality and utility of this concept has been seriously undermined. Recent work in this field has concentrated on the construction of a variety of acidity scales[2] based on structurally different classes of organic base, or has been essentially empirical in its approach. Examples of the latter are the determination of pK_a values based on H_0 at half-protonation (3), the ϕ-parameter treatment of Bunnett and Olsen (4), the *m*-value approach of Yates and McClelland (5) and more recently the $\Delta H - \Delta G$ correlations studied by Arnett and co-workers (6). Although these methods may give reasonable estimates of the relative basicities of a series of organic compounds (4), or may prove useful in rate-acidity correlations (4, 5), there is considerable uncertainty associated with the relationship between the pK_a values obtained and the defined standard state (usually dilute aqueous solution). Apart from the intrinsic desirability of trying to place all weak bases on a common quantitative scale, the very large number of organic reactions which involve proton transfers between weakly basic sites require a much more complete knowledge of acidity function behavior.

Although attempts have been made to explain the differences between various acidity functions in terms of the hydration requirements of the indicator species involved (9–11), these have not been quantitatively successful, and it appears that neither the increasing number of aqueous acidity functions nor empirical correlation methods are likely to provide a better fundamental understanding of the problem.

The greater proportion of acidity function work has concentrated on strong mineral acid – water solvent systems, and there is much less information available concerning the comparable behavior of acidity functions in non-aqueous or partly aqueous solutions. A more extensive knowledge of their behavior in these systems might be expected to lead to interesting comparisons and possibly a better insight into the acidity function problem. Although a few attempts have been made in this direction (12, 13), most acidity scales in other than purely

[1]Present address: Department of Chemistry, McGill University, Montreal, Quebec.

[2]Two recent reviews (7, 8) give comprehensive accounts of these acidity functions and their measurement.

aqueous-mineral acid solutions have been constructed with more practical aims such as application to specific kinetic problems. In this and succeeding papers in the series, work will be described concerning an investigation into the comparative behavior of structurally different bases in a predominantly non-aqueous solvent system, sulfuric acid in DMSO–water. It was hoped that by studying not only the acidity functions themselves, but also solvent effects on pK_a values and activity coefficients, a better insight would be obtained into the reasons for the divergent behavior observed in purely aqueous-acid systems, which has been termed by Arnett and Mach (14) "acidity function failure". In this paper the comparative behavior of the H_0, H_0''', and in part, the H_A functions in 70% DMSO–water are considered, and contrasted with available data in purely aqueous acid systems.

Experimental

Solvents

Dimethyl sulfoxide (Fisher Reagent grade) was purified by a modification[3] of the fractional distillation method of Schläfer and Schaffernicht (15). The purity was checked by freezing point determination, only samples with f.p. above 18.54 °C being accepted. The physical properties of the DMSO were in good agreement with those tabulated by Butler (16), Martin *et al.* (17), and Agamie (18). Sulfuric acid solutions were prepared by diluting ice cold solutions of aqueous sulfuric acid with a cooled solution of DMSO–H_2O of the appropriate concentration to yield a final composition containing H_2SO_4 in 70% (w/w) DMSO–H_2O. The H_2SO_4 concentration was checked by potentiometric titration with standardized aqueous alkali. The acids were stored in glass bottles fitted with ground glass stoppers. Specimen acids were checked periodically but showed no change of titre with time. Acids more than 3 months old, however, developed a strong odor and showed evidence of weak absorption in the 300–260 nm regions of the u.v. spectrum. These acids were discarded.

Indicators

The indicators used to construct the H_0 and H_0''' acidity scales are listed in Tables 1 and 2.

Indicators 4, 6–15 (Table 1) and 3–14 (Table 2) form series used previously to construct H_0 (19) and H_0''' (20) scales in this laboratory. Indicators 1, 2, and 5 (Table 1) and 1 (Table 2) were commercially available compounds, which were recrystallized or sublimed to constant m.p., Table 1: 1, 112° (lit. (21) 112°); 2, 62° (lit. (21) 63°) 5, 162° (lit. (22) 163°); Table 2: 1, 63° (lit. (22) 63°).

N,N-Dimethyl-3-methyl-4-nitroaniline and 3-methyl-4-nitroaniline were prepared by nitration of *N,N*-dimethyl-*m*-toluidine, and *m*-toluidine respectively, using standard methods. Nitration of *N,N*-dimethyl-*m*-toluidine gave only the desired product which was purified by recrystallization from aqueous ethanol, m.p. 84° (lit. (22) 84°). Nitration of *m*-toluidine gave a mixture of 3-methyl-6-nitroaniline and 3-methyl-4-nitroaniline which were separated on an alumina column using benzene as eluant. 3-Methyl-4-nitroaniline had m.p. 133° (lit. (22) 134°).

2-Pyrrolecarboxamide and 4-methoxybenzamide were samples prepared previously to construct the H_A acidity scale (11).

The preparation of indicator solutions and the spectro-

[3]Details of this method are given in the Ph.D. Thesis of G. Welch, University of Toronto, Toronto, Ontario, 1969.

photometric measurements were carried out (at least in duplicate) by standard methods.

Treatment of Data

(*i*) Absorbance values at each acid concentration were interpolated from the recorder trace at a number of wavelengths (usually 5 to 7) symmetrically disposed about λ_{max}. (*ii*) The absorbance values at λ_{max} were plotted against concentration to give the usual sigmoid curves from which the best values of A_B and A_{BH^+} (18) were interpolated. The acid concentrations from which these values were chosen were then used to define A_B and A_{BH^+} at other wavelengths. (*iii*) The log *I* (*I* = ionization ratio = $[BH^+]/[B]$) values were calculated for each wavelength at a given acid concentration and the mean and standard deviation of log *I* calculated. It was hoped that *i* and *ii* would minimize any medium effect on *A*, A_B, and A_{BH^+} (which were in any case usually small in this solvent system) and that *iii* would reduce random experimental error to a minimum and give an indication of its magnitude. The values of λ_{max}, log *I*, σ (log *I*), and absorbance (at λ_{max}) are shown in Table 3.

Experimental Error in log I Values

Kresge and Chen (23) have shown that the error function for log *I* of aniline indicators is approximately symmetrical about log $I = 0$ and has a shallow minimum over the range log $I = \pm 1.5$. This treatment assumes that the spectrophotometer error is independent of the absorbance, but for the Bausch and Lomb 505 used in this work the error was found to be an approximately linear function of this quantity. Introduction of this variable into the error function results in a considerable asymmetry (minimum error at log $I = \pm 0.4$) and this was confirmed by comparison of the calculated error function with the experimental σ (log *I*) values. On this basis the overlap procedure for the log *I* – concentration curves was carried out where possible over the range −1.0 to +1.5.

Results and Discussion

Choice of Solvent System

The particular choice of 70% DMSO–H_2O as solvent system for the acid was based on two main considerations. Firstly, it is of sufficiently high dielectric constant that normal dissociation equilibria will be uncomplicated by ionic association phenomena. Secondly, it is sufficiently different from purely aqueous acid systems that other than trivial changes might be observed. The system pure DMSO–H_2SO_4[4] also seems satisfactory to meet the above requirements but was rejected for practical reasons, particularly because the high solubility of organic indicators in DMSO would preclude facile determination of activity coefficients by solubility measurements.

[4]Since the start of this work an H_0 acidity function has been reported for pure DMSO–H_2SO_4 (24).

Despite the fact that a three-component system (H_2SO_4–DMSO–H_2O) is intrinsically less desirable, the particular solvent composition 70% (w/w) DMSO–H_2O has a number of attractive features. The dielectric constant (61.7) (25) is sufficiently high to prevent significant ion-pairing phenomena, and more important, it has been shown that in this mole fraction region (*ca.* 2:1; H_2O:DMSO) the solvent properties are least like those of either of the pure solvents (26–28). Although DMSO, like water, is a highly associated solvent (29), the degree of disorganization with respect to the pure liquids in the solvent structure of the binary system is at a maximum (28, 30, 31) near the composition chosen. It was hoped that replacement of the solvent by added H_2SO_4 would thus result in a much less drastic alteration of the solvent characteristics than would be the case either with pure DMSO or pure water as solvent. This expectation is supported by the small variations in activity coefficient for neutral aniline bases in this particular solvent mixture (32).

Results

The H_0 and H_0''' acidity scales were constructed in 70% (w/w) DMSO–H_2O by standard methods using the established sequence of primary aniline indicators (Table 1) listed by Jorgenson and Hartter (33) and tertiary aniline indicators (Table 2) listed by Arnett and Mach (10). In addition, the lower acidity of this solvent system required the use of five more strongly basic indicators which are indicated in Tables 1 and 2.

The log I values for each set of indicators showed very satisfactory parallelism when plotted against % H_2SO_4 (w/w) in the conventional manner, except indicator 8 (2,5-dichloro-4-nitroaniline). This indicator was therefore omitted from the overlap calculation of H_0.[5] The parallelism of the remaining indicator slopes, within the measurable protonation range, demonstrates that each set conforms to the necessary condition of the Hammett activity coefficient postulate, despite the radical change in solvent composition. Thus construction of acidity scales is a no less valid procedure in this system than in purely aqueous mineral acid solutions.

[5]Details of the calculations and indicator curves are available elsewhere (34).

The pK_a values for the "anchor" indicators, 3-nitroaniline and *N*,*N* dimethyl-3-nitroaniline, were obtained from the least squares intercepts of plots of log $C_B C_{H^+}/C_{BH^+}$ *vs.* C_{H^+}. The values obtained were 0.78 and 0.16 respectively. The probable error in these values is ± 0.02 log units and the value for 3-nitroaniline is in excellent agreement with that interpolated from the results of Wolford (35) (0.80). No previous values for the tertiary aniline could be found, but the low value is in qualitative agreement with the pK_a values obtained for other tertiary anilines in DMSO–H_2O (36).

The pK_a values for the less basic indicators were obtained from the usual overlap technique (19, 33). The log I values were overlapped in the protonation region from log $I = -1.0$ to $+1.5$, the asymmetry arising from the analysis of the standard deviations of the individual log I values (see Experimental). The only significant exceptions to this were indicators 9 (-1.33 at 40%) and 15 (-1.27 at 72%) and indicator 7 (-1.22 at 34%) where the extended log I range was necessary to achieve a reasonable degree of overlap. These values are still within the normal accepted range, and the average degree of uncertainty in the Δ log I values (~ 0.05 log unit) is within the usual range of uncertainty for measurements of this type. The H_0 and H_0''' were calculated from the pK_a values and log I values interpolated from the regression lines, using the equation

$$H_0 = pK_a - \log I$$

The H_0 and H_0''' values derived from each indicator were averaged and are shown in Tables 3 and 4 along with the mean deviation of each point. The two functions are plotted in Fig. 1 and it can be seen that smooth curves may be drawn through the experimental points. At low concentrations (less than 5% H_2SO_4) the two functions converge satisfactorily to define the beginning of a pH scale for this solvent system.

It was originally hoped that the H_A (amide) acidity function (11) could also be constructed in this solvent system. However, the end absorption of the DMSO in the solvent limited spectrophotometric measurements to only two indicators, 2-pyrrolecarboxamide and 4-methoxybenzamide.

Discussion

Although the relationship between the H_0 and H_0'' functions in 70% DMSO–H_2O is qualitatively similar to that observed in aqueous acid systems (10), there are two very significant differences. Firstly, at low acid concentrations, H_0 is the more negative function, as shown in Fig. 2. This result is opposite to that observed

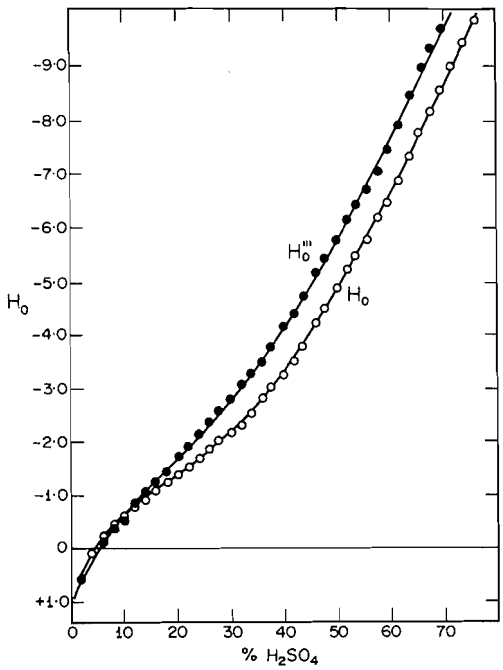

FIG. 1. Curves of the H_0 and H_0''' acidity functions in 70% DMSO–H_2O as a function of acid concentration.

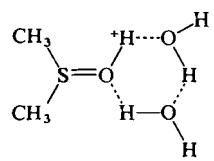
for strong mineral acid – water systems, but is similar to the behavior observed by Arnett in *p*-toluenesulfonic acid.[6] Secondly, for most of the acid concentration range, the two acidity functions are essentially parallel as shown in Fig. 1, unlike in aqueous systems where the two functions continually diverge. Again, Arnett and Mach have reported similar (14) behavior for H_0 and H_0''' in aqueous *p*-toluenesulfonic acid, but in this system only a limited range of acidity could be studied.

The rapid divergence of H_0 and H_0''' in purely aqueous acids (which exceeds experimental error even in 4% H_2SO_4) indicates that the solvation requirements of anilinium ions are extremely sensitive to structure, in aqueous solutions. In the DMSO–H_2O system, although the very strong hydrogen-bonding capabilities of DMSO might have been expected to maintain, or increase the difference between anilinium and *N*,*N*-dimethylanilinium ion solvation, it apparently does not. This suggests that perhaps only one DMSO molecule can be really effective in stabilizing both types of ion, through formation of one strong hydrogen-bond. Arnett and Mach (14) have suggested that the analogous behavior observed in *p*-toluenesulfonic acid might be due to a strong salting in effect on the neutral base. This does not readily explain the crossing of the two functions, and in DMSO–H_2O both ions and neutral bases are strongly salted in. Activity coefficient measurements (32) show that both primary and tertiary anilines are salted in to almost the same extent, and that the difference in protonation behavior arises mainly from the activity coefficient behavior of the ionic species.

Acidity Function "Failure"

The most important difference between the aqueous and 70% DMSO–H_2O acidity scales is the near parallelism of H_0 and H_0''' in the latter solvent, as shown in Fig. 1. The difference in acidity function behavior between the two solvent systems is plotted in Fig. 3 in the manner suggested by Arnett and Mach (14), as a measure of acidity function "failure". It is evident that such "failure" occurs in both systems, but that it is less serious in DMSO–H_2O, particularly at high acid concentrations. It is interesting that in both systems, the point where acidity function differences start to level off corresponds to the region where the basic solvent molecules are fully protonated. In DMSO–H_2O this occurs at lower acid concentrations because of the higher molecular weight of DMSO; since this is approximately 100 times more basic than water (37), the proportion of hydronium ions in any solution should be low. It is interesting that in the regions where acidity function levelling occurs in DMSO–H_2O there are still free (unprotonated) water molecules available. That levelling still occurs suggests that these molecules are primarily involved in solvating protonated DMSO,[7] perhaps in a 2:1 structure as shown



[6]Although the difference shown in Fig. 2 is small, it is outside the limits of experimental error and the ultimate convergence of H_0 and H_0''' at the lowest concentrations shows that it does not arise from an error in one of the "anchor" pK_a values.

[7]It has been generally assumed that protonation of DMSO occurs on oxygen. However, Olah *et al.* have recently reported evidence in favor of protonation on sulfur in superacid solutions (38).

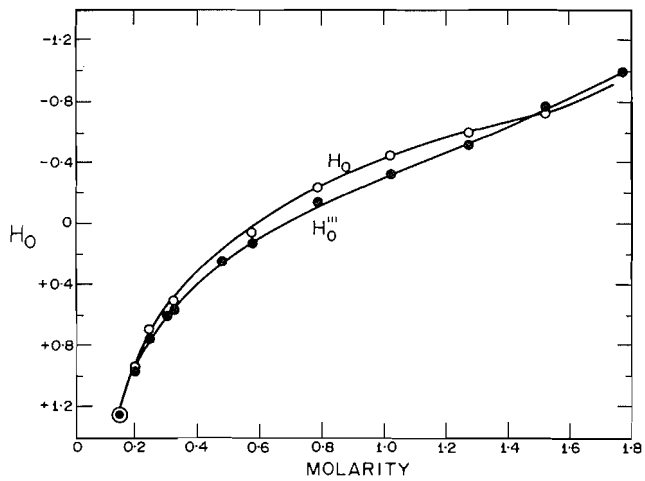


FIG. 2. Curves of the H_0 and H_0''' acidity functions in 70% DMSO–H_2O at low acid concentration.

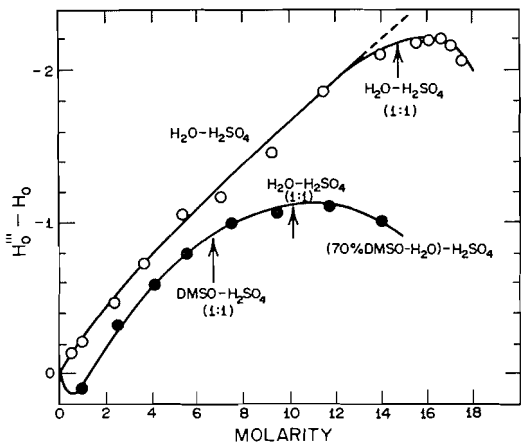

FIG. 3. Plots of $H_0''' - H_0$ as a measure of "acidity function failure" in aqueous H_2SO_4 and in (70% DMSO–H_2O)–H_2SO_4.

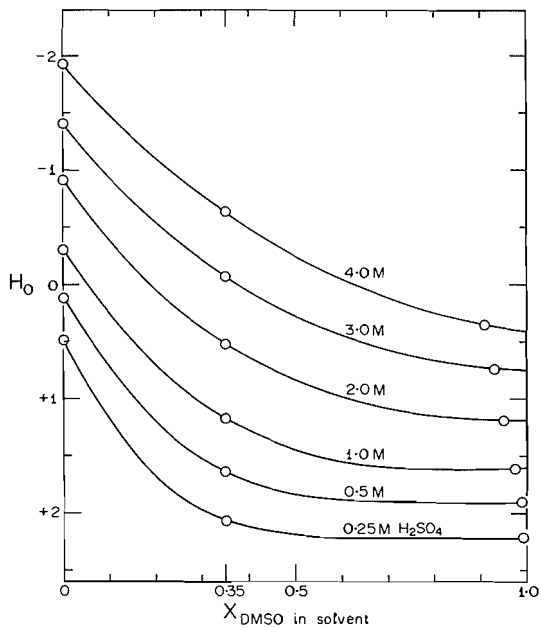

FIG. 4. Dependence of H_0 on solvent composition in the DMSO–H_2O system as a function of acid concentration.

The possibility that H_2O is significantly protonated in these systems can be discounted from a consideration of the effect of solvent composition on acidity in DMSO–H_2O systems. Using the limited data available (24) values of the H_0 function at different acid concentrations are plotted against mole fraction of water in Fig. 4. It is evident that although 70% DMSO–H_2O contains twice as many water molecules as DMSO molecules, the overall behavior of this system resembles that of pure DMSO–acid solutions much more closely than that of purely aqueous acids.

Two important points arise from the above discussion. Firstly, over an extensive range of acidity the DMSO–H_2O system has the potential of exhibiting ideal acidity function behavior with respect to primary and tertiary anilines, and possibly other types of base. For example, if the standard state were to be shifted from the pure solvent to the concentrated acid region, the two scales H_0 and H_0''' could be made to be almost superimposable over a range of about 7 H_0 units. It may be that other DMSO–H_2O compositions could be used to define a general

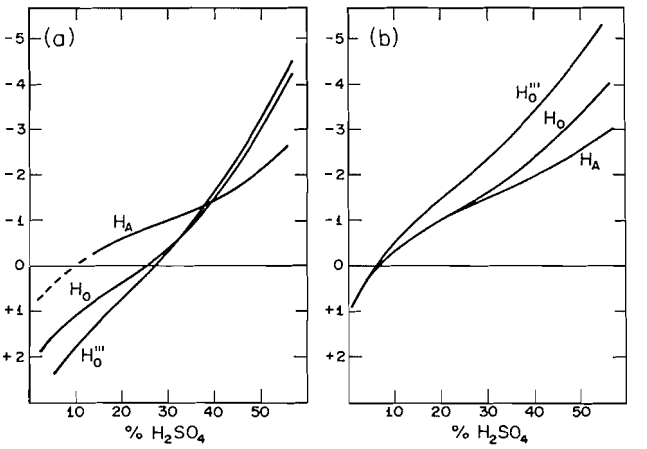

FIG. 5. Comparison of the H_0, H_0''', and H_A acidity scales in (*a*) 70% DMSO–H_2O and (*b*) H_2O, both referred to dilute aqueous solution as standard state.

acidity scale, applicable for the direct quantitative comparison of weak organic bases of a variety of different structural types. If this were possible it would be very valuable in restoring the utility of the acidity function approach to both equilibria and kinetics.

Secondly, the extensive parallelism of the two scales provides an excellent illustration that a log (indicator-ratio) – H_0 slope of unity is not a *sufficient* condition that the Hammett activity coefficient postulate be satisfied (*i.e.* $\log f_B f_{AH^+}/f_{BH^+} f_A = 0$). Either of the scales in DMSO–H_2O would give unit slope for both primary and tertiary anilines of a wide range of basicity, but if the incorrect scale were chosen, the pK_a values obtained would be in error by at least one log unit with respect to the defined standard state.

Amide Bases in DMSO–H_2O

It is unfortunate that practical difficulties have prevented the construction of an H_A scale in the solvent system. Even if the problems concerning the spectrophotometric measurements were overcome the weakly acidic nature of the solvent combined with the generally weak basicity of amides would make the determination of the pK_a for a suitable "anchor" indicator very difficult. The method of establishing the H_A function in aqueous acids (11) could not be used in DMSO–H_2O either, since the log I curves for 2-pyrrolecarboxamide and 2-nitroaniline are not only not parallel, but actually intersect in the measureable log I region.

However, the amides investigated appear to be stronger bases in DMSO–H_2O than might have been expected. The log I curves are shifted to lower concentrations with respect to 2-nitroaniline than is the case in aqueous acids. The reason for this is not clear, but it may reflect a greater sensitivity of the amide conjugate acid molecules to solvation by DMSO, compared with anilinium ions.

Acidity Functions in DMSO–H_2O Referred to the Aqueous Standard State

In order to avoid ambiguities in interpretation, the discussion so far has dealt with acidity functions based on a standard state of 70% DMSO–H_2O. The more usual procedure is to refer non-aqueous acidity scales to a standard state of ideal dilute aqueous solution. The validity of this procedure is sometimes questionable and the acidity scale thus defined may not be independent of the nature of the initial "anchor" indicator (12). In the present case the procedure appears to be justified by the parallel indicator plots obtained (also see later) and has been carried out by anchoring the scales to the aqueous pK_a of the initial indicator (H_0, 3-nitroaniline, pK_a = 2.5 (39); H_0''' *N,N*-dimethyl 3-nitroaniline, pK_a = 2.63 (40); H_A, 2-pyrrolecarboxamide, pK_a = 1.23) (11). The graphs of the three functions (referred to the aqueous standard state) in the two solvent systems (H_2O and DMSO–H_2O) are shown in Fig. 5.

The replacement of some of the water molecules in the solvent by DMSO clearly produces a dramatic change in the relationship between

For personal use only.

the different acidity functions; in fact at moderate H_2SO_4 concentrations the relative order of the three scales has been completely reversed from the situation in aqueous systems. Also despite the DMSO–H_2O medium being considerably less acidic than a purely aqueous medium the weakly basic amides are protonated nearly 1000 times more readily than the strongly basic tertiary anilines, relative to their behavior in aqueous solutions.

The considerable differentiation between the acidity scales in this solvent raises a number of questions about the interpretation of divergent behavior in aqueous mineral acids. Following the work of Taft (9) these differences have been frequently interpreted in terms of the numbers of possible hydrogen bonding sites available. In order to explain the apparent hydration changes occurring during protonation of amides in aqueous solutions, multiple hydrogen bonded structures have been postulated (11).

Apart from the neglect of activity coefficient terms, this type of interpretation must now be considered of dubious value since it assumes that the interaction energy is of comparable magnitude for each of the different hydrogen bonds possible. In the DMSO–H_2O system similar multiple hydrogen bonded structures are not possible, because DMSO cannot act as a proton donor. As a result only three DMSO molecules at most may be used to stabilize the amidonium ion, the same number as may be formally ascribed to the anilinium ion.

In this case solvation must be of a completely different nature, involving either weak S...H—O hydrogen bonds, or dipolar interactions of the type suggested to explain the properties of pure DMSO (29). Despite the similarity in the number of specific hydrogen bond sites for DMSO in amides and primary amines, the relative behavior of H_A and H_0 is very different; also despite the difference in these sites between primary and tertiary amines the H_0 and H_0''' functions are much more similar. This suggests that solvent stabilization of cations of weak organic bases must involve highly specific interactions which cannot be suitably represented by simple parametric functions of the bulk solvent activity.

In Fig. 5*a* the three acidity functions do not converge to a single line in dilute solution. This is the expected result since the acidity value measures the relative protonating ability of the solvent with respect to an infinitely dilute solution of acid in water. There is no reason for this difference to be the same for different structural bases. However, when the scales are plotted on a suitable concentration scale, such as mole fraction H_2SO_4, then $H_0(H_2O)$, and H_0(DMSO–H_2O) converge at high concentrations. This is a necessary and valid confirmation that both acidity scales are thermodynamically consistent, since the protonating ability of 100% H_2SO_4 toward a given type of base, with respect to the aqueous standard state, should be identical irrespective of the solvent through which it is approached.

The choice of water as a standard state is purely arbitrary, and the acidity functions shown in Fig. 5 owe their relative positions to the *difference* in the specific interactions in pure water and pure DMSO–H_2O. The question of the choice of standard states, the pK_a values obtained in DMSO–H_2O and the relationship of these factors to acidity function behavior will be considered in a later paper in this series.

The continued financial assistance of the National Research Council of Canada is gratefully acknowledged. We are also grateful to the Government of the Province of Ontario for awards of Ontario Graduate Fellowships to one of us (G.J.W.) and to Prof. E. M. Arnett for the gift of eleven tertiary aniline indicators.

The Electron Paramagnetic Resonance Spectrum of the Phenalane Anion[1]

D. H. PASKOVICH[2] AND A. H. REDDOCH

Division of Chemistry, National Research Council of Canada, Ottawa K1A 0R6, Canada

Received November 18, 1971

The phenalane anion has been prepared by the reaction of alkali metals in ether solutions of both phenalane and phenalene. The electron paramagnetic resonance spectra of both the radical and of its ion pairs with sodium and with lithium in THF are reported. At room temperature there is an alternating linewidth involving the β protons caused by conformational interconversion of the axial and equatorial positions. At -80 °C the γ protons are not equivalent and the corresponding coupling constants are resolved.

L'anion phénalane a été préparé par l'actione des métaux alcalins sur des solutions éthérées de phénalane et de phénalène. Les spectres r.p.e. du radical ainsi que ceux des paires d'ions formées entre celui-ci et le sodium ou le lithium dans le THF, sont rapportés. A la température de la pièce, il se produit une alternation de largeur de raie impliquant les protons en β et provoquée par une interconversion conformationnelle des positions axiales et équatoriales. A -80 °C les protons en γ ne sont pas équivalents et les constantes correspondantes de couplage peuvent être résolues.

Canadian Journal of Chemistry, **50**, 1523 (1972)

Introduction

In the course of a study of the chemistry and e.p.r. spectra of aromatic hydrocarbon radicals (1, 2) a new species, the phenalane anion, has been prepared. This is an alkyl substituted naphthalene and the coupling constants of its e.p.r. spectrum are consistent with those of a number of other such species including 1,8-dimethylnaphthalene (3, 4), trihydropyrenyl (1), and acenaphthene (5). The dynamic aspects of this radical as reflected in the alternating linewidth of the β protons are consistent with those of the related species trihydropyrenyl (1) and the hexahydropyrene anion (6, 7). In these three cases the conformational changes become slow enough at low temperatures to show the inequivalence of the axial and equatorial β protons. A similar splitting could occur for the γ protons since they are geometrically inequivalent in these conformations, although a lower temperature may be required since the smaller difference is more readily averaged. This splitting has not in fact been reported for trihydropyrenyl but it is reported here for the phenalane anion. A recent reinterpretation (8) of the hexahydropyrene anion spectrum shows that such a splitting occurs there also, although it is unresolved.

Experimental

The phenalane anion was prepared from phenalane by treating the hydrocarbon with sodium or lithium in either 1,2-dimethoxyethane (DME) or tetrahydrofuran (THF). The solvents were purified by distillation from $LiAlH_4$ and were stored *in vacuo* over benzophenone ketyl. The radical was prepared by reacting an ether solution of the hydrocarbon with a sodium mirror in a pyrex U-tube using high-vacuum technique. When lithium was used, freshly cut pieces of metal were added to the tube just before evacuation.

Sodium phenalanide in THF formed an ion pair. In DME it gave a poorly resolved e.p.r. spectrum at room temperature which was probably that of the ion pair. At -80 °C in DME the spectrum was that of the free ion. Lithium phenalanide formed an ion pair in THF at 26 °C which dissociated on dilution or cooling. In DME it appeared to be dissociated at 26 °C and below.

The same radical anion was also produced from phenalene by a multistep reduction in either THF or DME. In view of the drying technique described above for the ethers, water is not likely to be the source of the protons for the reduction of the phenalene. However, instances are known where the ether is a proton source when intensive alkali reduction is attempted (9–11).

Phenalene in solution gives a well-resolved spectrum of the neutral phenalenyl radical which presumably is formed by the decomposition of a peroxy intermediate arising from the reaction of the hydrocarbon with traces of atmospheric oxygen (12). When an ethereal solution of phenalene is reacted with an alkali metal the phenalenyl e.p.r. spectrum rapidly disappears as this species is reduced to a diamagnetic monoanion. Further reduction produces a dianion which abstracts a proton from the ether solvent. This partially reduced species then undergoes further stepwise reduction until the phenalanide ion is produced.

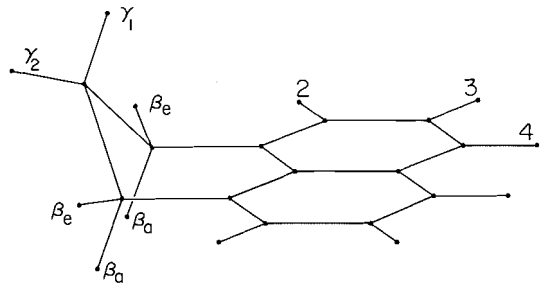

FIG. 1. Structure of phenalane anion and nomenclature used.

The spectra were studied with a Varian E3 spectrometer together with a Varian variable temperature accessory.

Discussion

The proton coupling constants for the phenalane anion (Fig. 1) at room temperature (Fig. 2) are reported in Table 1 together with corresponding values for some other substituted naphthalene anions. For these latter species only the values of the coupling constants relevant to the discussion are included and the various proton sites have been arbitrarily numbered and lettered to correspond with the designations used here for the analogous sites in the phenalane anion. Within the limited precision of the present measurements, about 0.02 G, the coupling constants did not change significantly with temperature, solvent or ion pair formation, except for the splitting of the β and γ protons at low temperature. At $-80\,^{\circ}C$ (Fig. 3) the γ protons of the phenalanide radical, which have a coupling constant of 0.43 G at room temperature, show values of 0.53 and 0.36 G, while the individual coupling constants of the axial and equatorial β protons are 8.62 and 2.24 G respectively. Since $a\ (25\,^{\circ}C) = 0.43$ is almost exactly the average of 0.53 and 0.36 it is clear that the latter two coupling constants have the same sign. Similarly since $a_{\beta} + a_{\beta'} = 10.75$ is almost exactly the sum of 8.62 and 2.24 these two constants must also have a common sign although not necessarily that of the γ protons. The aromatic protons at $-80\,^{\circ}C$ have coupling constants of 4.49, 1.90, and 1.55 G. In the ion pair with Na in the THF at 26 °C the Na coupling constant is 0.92 G. The corresponding Li coupling in THF at 26 °C is 0.18 G.

The assignments of the proton coupling constants of the phenalane anion are made by analogy with the other species cited in the table. The assignments for most of these other species, except acenaphthene (5), are essentially theoretical and have not been proven by deuteration. The resulting picture for phenalane seems quite reasonable but the 2 and 3 positions must be regarded as tentative in the absence of deuteration experiments.

The reduction of symmetry caused by the aliphatic substituents on the naphthalene, as measured by the difference $a_2 - a_3$ is greater in phenalanide than in dimethylnaphthalenide but less so than in acenaphthenide. The coupling constants a_4 also suggest this reduction in that they decrease monotonically but not linearly as $a_3 - a_2$ increases. The sum $a_2 + a_3$, although fairly constant for each of the substituted molecules, is less than in naphthalenide (13), while the lowest values occur in hexahydropyrenide, pyracenide (14), and diplieadanide (15) where there are two bridges which may be regarded as four alkyl substituents. This result probably reflects a spin density reduction in the aromatic part of the radical by the alkyl groups in a manner similar to that discussed by Fischer (16) for methyl substituents in alkyl radicals, although in the latter case the effect is larger. As Fischer points out, such effects may become more complex in charged species such as those considered here. Moreover, in these polyatomic aromatics it is really the total spin density in the π system rather than that on individual carbons which should be considered to avoid the effects of spin redistribution within that system caused by the substituents. Other details of the coupling constants of the aromatic protons seem reasonable. A very detailed treatment of the spin densities of alkyl substituted naphthalenes has been given by Moss *et al.* (17). In view of the difficulties they encountered, this topic will not be pursued further here.

The e.p.r. spectra of several radicals with —$(CH_2)_3$— bridges have now been reported including trihydropyrenyl (1), both the cation and the anion of hexahydropyrene (6, 7) and the present example of the phenalane anion. As can be seen in Table 2 the ratio of the coupling constants of the axial and equatorial β protons is near 4 in each case. This value reflects the

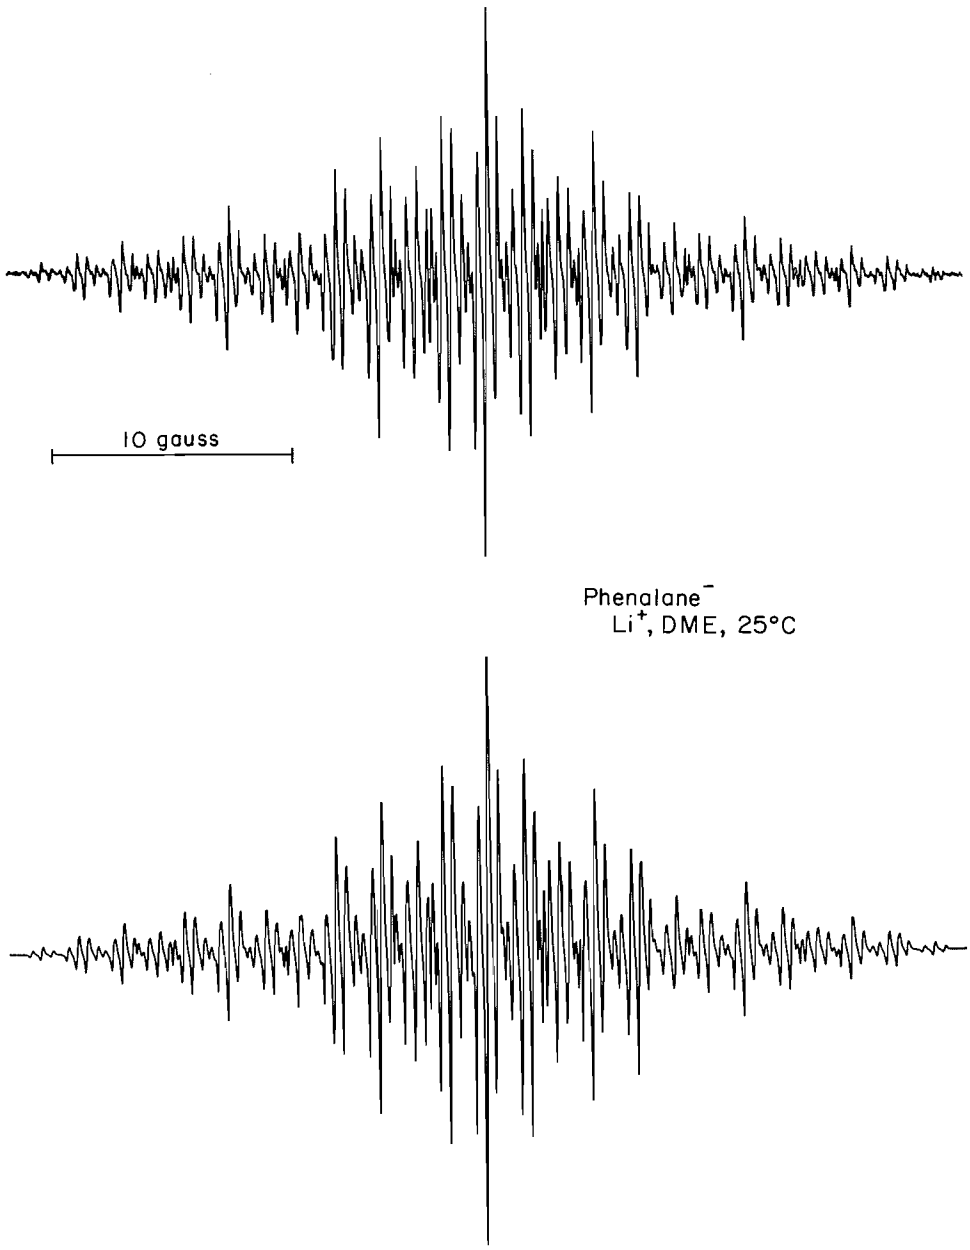

FIG. 2. The e.p.r. spectrum of phenalane anion at room temperature. The upper is experimental, the lower simulated using coupling constants (gauss): $a_2 = 1.52$, $a_3 = 1.89$, $a_4 = 4.44$, $a_a + a_e = 10.75$, $a_\gamma = 0.43$, and width = 0.07. The alternating linewidth limit in which the β protons give a 1:4:1 triplet is assumed.

common geometry of these species as the following discussion will show.

The coupling constants of β protons in aliphatic radicals may be described by the equation suggested by Heller and McConnell (18),

$$a = (B_0 + B_2 \cos^2 \theta)\rho \quad [1]$$

where θ is the angle between the projections of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

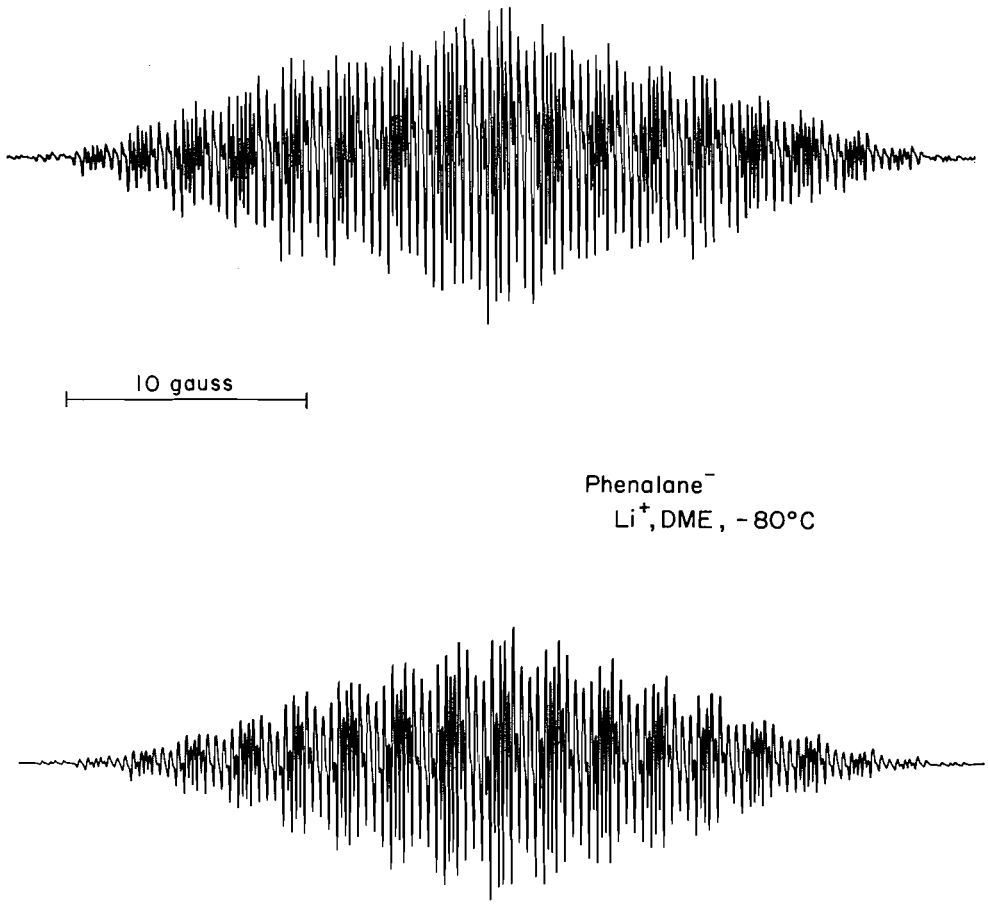

FIG. 3. The e.p.r. spectrum of phenalane anion at −80 °C. The upper is experimental, the lower simulated using coupling constants (gauss): $a_2 = 1.55$, $a_3 = 1.90$, $a_4 = 4.49$, $a_a = 8.62$, $a_e = 2.24$, $a_{\gamma 1} = 0.53$, $a_{\gamma 2} = 0.36$, and width = 0.07.

the CH bond and the axis of the p orbital on a plane perpendicular to the C—C bond. Whiffen (19) has proposed that $B_0 = 3.6$ and $B_2 = 51$ G. If it is assumed that the axial and equatorial angles differ by 120°, *i.e.*

$$\theta_e = \theta_a + 120° \quad [2]$$

then eq. 1, applied to the two coupling constants, yields the following equations:

$$a_a = (B_0 + B_2 \cos^2 \theta_a)\rho \quad [3a]$$

$$a_e = [B_0 + B_2 \cos^2 (\theta_a + 120°)]\rho \quad [3b]$$

By dividing eq. 3*a* by eq. 3*b*, ρ is eliminated.

$$a_a/a_e = (\cos^2 \theta_a + B_0/B_2)/[\cos^2 (\theta_a + 120°) + B_0/B_2] \quad [4]$$

This can be solved for θ_a and, from eq. 3*a*, ρ can be obtained.

The results for each of the species are shown in Table 2. For comparison, the axial angle calculated geometrically assuming tetrahedral and trigonal bond angles with aliphatic and aromatic bond lengths of 1.541 and 1.395 Å is −3.4°, *i.e.* the axial C—H bonds point slightly toward each other. This implies a slight strain of about 3° at the γ carbon, which however, may be distributed around the ring.

The agreement between the angles calculated from the coupling constants and those calculated geometrically is remarkable. In the case of the trihydropyrenyl the calculated spin density 0.219 is also very good, the value from McConnell's relation being 6.3/28 = 0.225 and

the McLachlan value being 0.218 (20). The spin densities derived for the other species are not very good as can be seen by comparing the values for the hexahydropyrene anion and cation. The reason for this is that Whiffen's coefficients were selected for systems with the spin in a nonbonding orbital and hence will not apply to ion radicals with hyperconjugation. However since $B_0 \ll B_2$ the calculated angles are not very dependent on B_2. Thus if B_0 is taken as 0, eq. 4 is independent of B_2 and the resulting angles are in the range $-0.1°$ to $1.0°$, which are still reasonable. Moreover if the ratio B_0/B_2 were not strongly dependent on the charge of the radicals, as may be approximately true, then the above values would again yield good angles but poor spin densities for the ions.

In addition to the solution $\theta_a = -3.7°$ for eq. 4 when $a_a/a_c = 4$, there is another solution $\theta_a \simeq -45°$. This, curiously, applies to the diplieadane anion (15) where the coupling constant ratio is also approximately 4. The solutions for the two conformers are given in Table 2. These are also in very good agreement with the angle expected geometrically of 42.5°. The geometric value could be in error by about 1° because of a small amount of strain which can be seen in the geometric model and which will probably be distributed over the various bond angles. Claridge *et al.* (15) did not get quite such good agreement because they neglected B_0 in eq. 4. This is not as good an approximation for diplieadane where the $\cos^2$ terms are small, as it is in the other ions.

The γ protons are not geometrically equivalent in the static conformations and their coupling constants should be different. This has been seen by ENDOR experiments in a somewhat different radical, di-*t*-butylcyclohexylphenoxy, by Adams and Atherton (21). In a reinterpretation of the hexahydropyrene anion spectrum Claridge and Peake (8) have deduced from the line shape that at low temperatures the proton coupling constants are 0.50 and 0.36 G. These values are very similar to those reported here for the phenalane anion, where the splitting has been resolved.

An attempt was made to apply the spin polarization theory of Barfield (22) to the radicals in Table 2. Since this model was applied to a localized spin on a single aliphatic chain it was adapted for the present purposes by taking $a_\gamma = B'(c_1^2 + c_8^2)$ where B' is Barfield's a_γ as given by his eq. 32 and c_1 and c_8 are Hüchel coefficients for the lowest antibonding orbital of naphthalene. (An alternative form $B'(c_1 + c_8)^2$ does

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

not apply here, giving $a_\gamma = 0$ since $c_1 = -c_8$ by symmetry.) The result is $a_{\gamma 1} = 0.17$ and $a_{\gamma 2} = -0.06$ G. These magnitudes and opposite signs, which are obtained for any reasonable geometry, do not agree with the experimental results. This failure may result, as Barfield suspected (22), from long range couplings. It should be noted however that these γ protons cannot have direct overlap or hyperconjugative interaction with the unpaired electron for reasons of symmetry. Such interactions are possible with some of the other spin polarized π electrons, however.

The Na coupling constant with phenalane is only slightly smaller than that with naphthalene in THF (13), 1.04 G, or with acenaphthene in THF (23), 1.08 G. Similarly the Li coupling with phenalane is the same as that with naphthalene in THF (13), 0.18 G. Since the alkali ion splittings should be rather sensitive to the structure of the ion pair (24) these results suggest that the position of the cation in THF is not much affected by the addition of the aliphatic substituents to the naphthalene skeleton.

We are grateful to Drs. R. F. Adams and N. M. Atherton for showing us a preprint of their work on conformational effects prior to publication. We are also indebted to Drs. R. F. C. Claridge and B. M. Peake for sending us a manuscript, part of which was devoted to the phenalanide radical. Where our papers overlap, the agreement is quite satisfying.

Complex Fluorides with Perovskite Structure: Thermal Analyses, Calorimetry, and Infrared Spectra

K. C. PATIL AND E. A. SECCO

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received August 13, 1971

Thermal decomposition and infrared spectral results are reported for complex fluorides of the type NH_4MF_3 where M = Cd, Zn, Cu, Ni, Co, Mn.

On rapporte les résultats relatifs aux décompositions thermiques et aux spectres infrarouges de complexes fluorés du type NH_4MF_3 avec M = Cd, Zn, Cu, Ni, Co, Mn.

Canadian Journal of Chemistry, **50**, 1529 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Introduction

Complex fluorides of the type AMF_3, where A = alkali metal and M = bivalent transition metal, with a perovskite structure have attracted some interest (1). X-Ray diffraction, magnetic and i.r. studies have been reported (2–6). Nagakawa *et al.* (7) and more recently, Lane *et al.* (8) have carried out normal coordinate analysis of the vibrational spectrum of this compound type in the region 700–200 cm^{-1} and have assigned all the observed i.r. absorption frequencies.

The purpose of this paper is to complement the work by Roscoe and Haendler (9) and report the mode of decomposition, heat of decomposition, and infrared spectral data for NH_4MF_3, where M = Cd, Zn, Cu, Ni, Co, Mn.

Experimental

All the compounds studied here were prepared by following accepted procedures (2, 4). These compounds were identified by their X-ray diffraction patterns (10) recorded on a Norelco diffractometer unit using CuK_α radiation or MoK_α radiation as previously described (11).

Thermal analyses and calorimetry were done with the instrumentation and platinum ware described earlier (12–14).

The i.r. spectra of the compounds were recorded on a Perkin–Elmer Model 180 spectrophotometer using the standard pellet technique with KBr as the matrix material or as Nujol mulls with CsI windows.

Results and Discussion

The results of thermogravimetry and differential thermal analyses, along with heat of decomposition data, are tabulated in Table 1. The observed weight losses from TG and the single endotherm observed in DTA heating curves show all the compounds to decompose in one step to yield the simple metal fluoride as the residue, *viz.*,

$$[1] \qquad NH_4MF_{3(s)} \rightarrow MF_{2(s)} + NH_4F_{(g)}$$

The metal fluoride was confirmed by its characteristic X-ray diffraction pattern.

The last column listing the ΔH of decomposition shows a quasi-constant value of 34 ± 1 kcal/mol for most compounds, suggesting the

*s = strong; m = medium; w = weak; sh = shoulder.

nature of bonding between the MF_2 and NH_4F units to be strikingly similar in these compounds.

The i.r. absorption frequencies with their assignments in the 4000–180 cm^{-1} region are presented in Table 2; the assignments are made on the model reported for AMF_3 compounds (4, 7, 8). Our spectral data display a high degree of internal consistency for the various assignments; these data are also in agreement with the existing literature values.

The slight variation in the observed lattice frequencies, 390–425 cm^{-1}, is attributed to the nature of the metal. On the other hand, the higher lattice frequency in the case of NH_4CuF_3 is assumed to originate from a distorted perovskite structure (2). The observation of the 1800 cm^{-1} in NH_4CdF_3 is believed to arise from the combination $(\nu_4 + \nu_6)$ and its presence is rationalized in terms of increased H-bonding.

Grateful acknowledgment is made to the National Research Council of Canada and the University Council for Research for financial support of this research program.

Photolysis of Di-*tert*-butyl Peroxide at High Pressure

C. K. YIP AND H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received November 15, 1971

Di-*tert*-butyl peroxide has been photolyzed at 2537 Å in the gaseous phase in the presence of up to 47 amagats (2.10 mol/l) of propane and of cyclopropane. It was confirmed that no acetone is formed in the limit of infinite hydrocarbon concentration and therefore that the primary *chemical* act leading to the eventual formation of acetone is the formation of two *tert*-butoxy radicals from the excited peroxide molecule; in addition, some crude information was obtained concerning relative rates of photochemical *vs.* deactivation processes. It was also found that at these densities the *tert*-butoxy radical formed in the photolysis of di-*tert*-butyl peroxide did not appear to differ in chemical reactivity from the *tert*-butoxy radical formed in the thermal decomposition of di-*tert*-butyl peroxide.

Le peroxyde de di-*tert*-butyle a été photolysé en phase gazeuse à 2537 Å en présence d'une quantité allant jusqu'à 47 "amagats" (2.10 mol/l) de propane et de cyclopropane. On a confirmé l'absence de toute formation d'acétone dans la limite d'une concentration infinie en hydrocarbure et de là, que la première attaque chimique conduisant à la formation éventuelle d'acétone est la formation de deux radicaux tertio-butoxyles à partir de la molécule de peroxyde excitée; de plus, on a obtenu quelques informations brutes concernant le rapport des vitesses relatives du processus photochimique et du processus de désactivation. On a également trouvé que pour ces concentrations, le radical tertio-butoxyle issu de la photolyse du peroxyde de ditertio-butyle ne semble pas avoir une réactivité chimique différente du même radical issu du même peroxyde formé lors de la décomposition thermique.

We have shown recently, from a study of the thermal decomposition of di-*tert*-butyl peroxide in the presence of high pressures of propane, that the primary process in the thermal decomposition of the peroxide is the formation of two *tert*-butoxy radicals (1). The reader should not be misled by the use of the word pressure into thinking that these experiments are concerned with the theory of unimolecular reactions, nor with the transition state theory: pressure, in the sense used here, is synonymous with density or concentration, but the use of the word pressure more clearly conveys the nature of the experimental techniques; the purpose is simply to establish a relationship between the rates of formation of reaction products and the *concentration* of the reactant substrate, and hence by extrapolation to infinite concentration of the substrate, to make inferences concerning the primary act in the initiating reaction. In this paper, we describe an attempt to extend our earlier work on the thermal decomposition of di-*tert*-butyl peroxide to the parallel photochemical decomposition.

Experimental Details

The preparation and purification of all the materials, the ferrioxalate actinometry, and the methods of analysis used in this work have all been documented adequately in earlier papers (1–4).

The photolysis cell was constructed (5) from stainless steel: it consisted of two parts, the body which had a bore of 0.375 in., and a lid to which the window was attached; the two parts were bolted together and the assembled vessel had an internal volume of 12 cc. Since the cell was filled by conventional vacuum techniques, it was necessary for the window seal to operate under both high pressures and a vacuum. The window itself was a 1 in. diameter, 0.375 in. thick, polished quartz plate. The basis of the high-pressure seal was simply the abutment of the polished quartz plate onto the polished stainless-steel surface of the lid of the vessel, together with a very thin smear of lubricant. Using silicone grease, for example, the vessel was tested up to 50 amagats of CO_2 at room temperature, but for higher temperature work with hydrocarbons, we used a thin film of Dow Corning silicone adhesive; this proved to be highly satisfactory, and although it can be removed with acetic acid, we have not so far found it necessary to dismantle the seal. For vacuum work, it was necessary to support the window from the inside against atmospheric pressure: this was done with a stainless-steel spring of suitable strength. There were two O-ring seals in the system, one between the body of the vessel and the lid, and the other at a union to the filling tube: in our early experiments, we sealed these with conventional neoprene O-rings, but their absorptive capacity for hydrocarbons, and particularly for acetone, was far too great and gave rise to irreproducible results: lead O-rings on the other hand were perfectly satisfactory.

The cell was filled on a vacuum line using liquid nitrogen to trap the materials into the bottom of the vessel: it was then isolated (with a needle valve close to the filling-tube union) and transferred to a temperature-controlled oil bath, where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

it was illuminated for the required time from a low-pressure mercury lamp placed directly above the vessel; it was then reattached to the vacuum system for the analysis of the reaction products, as described previously (1–3). Care was taken to ensure the lamp operated under similar conditions in each experiment, and that its position was the same in relation to the cell, but no attempt was made to monitor the light intensity. However, the internal consistency of the results of experiments carried out in random order confirms an acceptable consistency of light intensity throughout this series of experiments; in fact, however, constancy of the light intensity is unimportant in respect of the principal aims of this work, as described in (*b*) and (*c*) below.

The extinction coefficient of gaseous di-*tert*-butyl peroxide is quite low (6.14 l mol^{-1} cm^{-1} at 2537 Å and 1.31 mol^{-1} cm^{-1} at 3130 Å) (6) and it was necessary with our particular lamp to irradiate the cell for from 1–3 h (depending on pressure) in order to achieve 1% decomposition: initial amounts of peroxide of about 9.8×10^{-5} mol were found to be sufficient to achieve a reliable analysis. The principal output of the lamp was at 2537 Å, with weaker lines near 2968 and 3022 Å and so on into the visible. Interposing a 1 mm Pyrex plate between the lamp and the reaction vessel reduced the photolysis yields below our level of detection, and since only the radiation at 2537 Å was removed by the glass, it can be safely assumed that we are concerned with a photochemical process initiated almost exclusively by radiation with a wavelength of 2537 Å. We hope that in future experiments of this kind, it will be possible to study an interesting molecule with a higher extinction coefficient, in which case proper wavelength selection by monochromator would be possible.

The rate of the homogeneous thermal decomposition ceases to be significant below 90 °C (2), but there appears to be a small heterogeneous reaction at lower temperatures, and we were forced to operate at 70 °C in order to reduce the dark-reaction corrections to less than 10% of the smallest product in all cases.

Results and Discussion

(a) Variation of Overall Quantum Yield with Hydrocarbon Concentration

The simplest possible photochemical reaction scheme that one can write is

[1] $$P + h\nu \rightarrow P^*$$

[2] $$P^* + M \rightarrow P + M$$

[2′] $$P^* + P \rightarrow P + P$$

[3] $$P^* \rightarrow P + h\nu,\ h\nu'$$

[4] $$P^* \rightarrow 2t\text{-BuO}$$

where P represents the peroxide molecule, and M represents a substrate molecule. In this crude treatment, step 3 will be ignored since the small amounts, if any, of fluorescence and phosphorescence which could occur would be impossible to distinguish kinetically with the other uncertainties which are present. Thus a steady-state

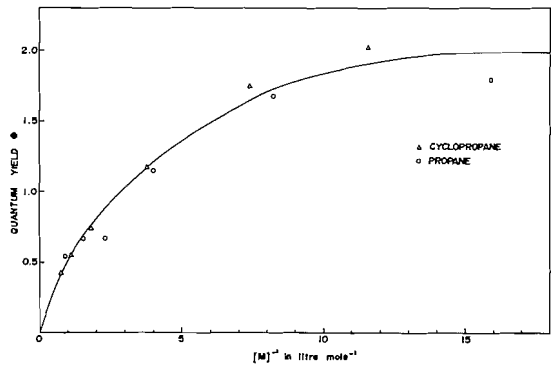

FIG. 1. Overall quantum yield for the photolysis of di-*tert*-butyl peroxide in the presence of propane and cyclopropane (M) at 70 °C.

treatment suggests that the quantum yield of *tert*-butoxy radicals, measured from the sum of the rates of formation of acetone and *tert*-butanol will have two limiting forms, *viz*:

$$\text{As } [M] \rightarrow \infty \qquad \Phi \rightarrow \frac{2k_4}{k_2[M]}$$

$$\text{As } [M] \rightarrow 0 \qquad \Phi \rightarrow \frac{2k_4}{k_2'[P] + k_4} \rightarrow 2 \quad (\text{as } [P] \rightarrow 0)$$

Thus, one would expect the quantum yield to fall from $\Phi = 2$ as the concentration of M is increased, and eventually tend to zero at high [M], hyperbolically. It is well known (6–8) that the low pressure quantum yield is about 2, and our own rough measurements support this observation. The variation of overall quantum yield with substrate concentration is shown in Fig. 1 in the form of a plot of Φ against $[M]^{-1}$; propane and cyclopropane are more or less indistinguishable from each other in their behavior. One would have perhaps expected the plot to become linear before concentrations of 1 mol/l (22.4 amagats) were reached, and this may indicate that the denominator in the high pressure expression for the quantum yield is wrong by an additive constant, possibly owing to the omission of processes like reaction 3. Nevertheless, it would appear that for both hydrocarbons $2k_4/k_2$ is of the order of 0.5 mol l^{-1}: the upper limit of k_2 will be of the order of the collision number *i.e.* 4.4×10^{11} mol^{-1} l s^{-1}; thus k_4 has an upper limit of about 1×10^{11} s^{-1}, but more precise information on k_2 will be

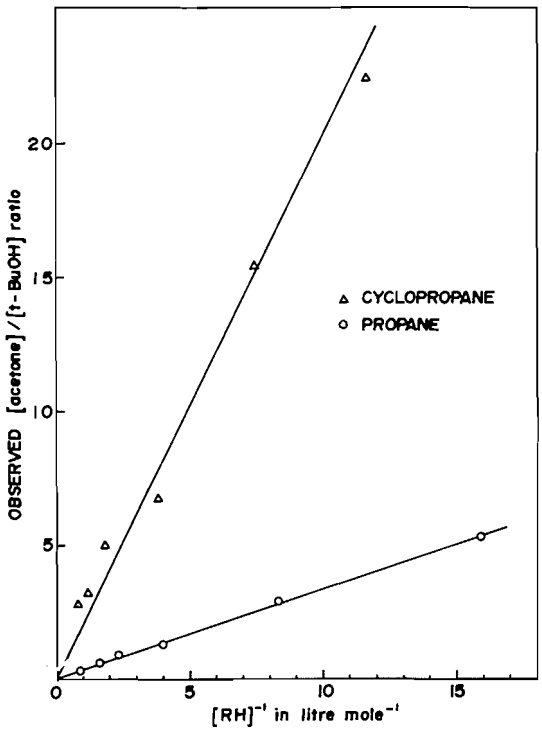

FIG. 2. Variation of [acetone]/[*t*-BuOH] ratio as a function of hydrocarbon concentration at 70 °C; propane: $k_5/k_6 = 0.34$ mol l^{-1}; cyclopropane: $k_5/k_6 = 2.0$ mol l^{-1}.

required before a more realistic value for the lifetime of P* can be given.

(b) Variation of the Ratio of Acetone to tert-Butanol Formation with Hydrocarbon Concentration

The question then arises as to whether step 4 represents the only "chemical" step by which the excited peroxide molecule P* decomposes with the eventual formation of either *tert*-butanol or (acetone plus ethane), or whether there are any concerted processes which form acetone directly. Evidence from liquid phase photolyses would suggest that there is no direct formation of acetone (9) since at quite a low temperature with reactive substrates, no acetone was found. However, these observations are qualitative in nature, and do not reveal the quantitative complementary yield feature described below.

Following our earlier analysis of the problem in the case of the thermal decomposition of di-*tert*-butyl peroxide (1), we plot in Fig. 2 the ratio of the rate of formation of acetone to that of *tert*-butanol against the reciprocal of the hydrocarbon concentration $[RH]^{-1}$, where RH is either propane or cyclopropane. At high RH concentrations, the reaction scheme suggested by McMillan and Wijnen (10) should reduce to

[4] $\quad P^* \rightarrow 2t\text{-BuO}$

[5] $\quad t\text{-BuO} \rightarrow CH_3COCH_3 + CH_3$

[6] $\quad t\text{-BuO} + RH \rightarrow t\text{-BuOH} + \text{etc.}$

whence such plots should be straight lines passing through the origin with slopes of k_5/k_6. For both hydrocarbons, the observed acetone/*tert*-butanol ratios do fall on acceptable straight lines passing through the origin. This shows unambiguously that, as in the thermal reaction (1), the *tert*-butoxy radical is the sole precursor of acetone, and that therefore the dominant primary chemical act is the formation of two *tert*-butoxy radicals; of course, there may also be other minor primary photochemical processes, such as the one which is said to give oxygen and butyl radicals (11).

(c) Relative Reactivities of tert-Butoxy Radicals Formed Thermally and Photochemically

The results of the preceding sections, together with our earlier results on the thermal decomposition (1) demonstrate that in both cases, the sequence of reactions 4–6 represents satisfactorily, at high hydrocarbon concentration, the evolution of the reaction once the critical state has been passed. Whilst the critical state is not necessarily the P* in reaction 4, but could be some precursor of P*, it is clear that the critical states are different in the two cases. In the thermal case, at the high-pressure limit, it is simply a molecule containing more than the critical energy $\varepsilon^*(\varepsilon^* \approx 38$ kcal/mol) within its internal degrees of freedom. In the photochemical case, the molecule P* could have up to 112 kcal/mol of internal energy, distributed between electronic, vibrational, and rotational excitation, and the actual amount, and its distribution will depend very much upon the history of the molecule since the spectroscopic absorption took place. McMillan (8) has suggested that in the 100 Torr total-pressure range, the photolysis of di-*tert*-butyl peroxide yields excited *tert*-butoxy radicals whose rate constant for abstraction from isobutane (k_6) is normal, but whose rate constant for dissociation (k_5) is enhanced, and

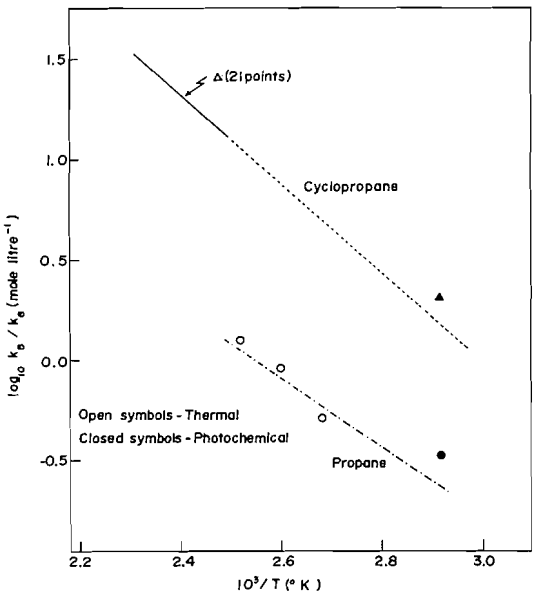

FIG. 3. Comparison of k_5/k_6 for thermally and photochemically produced *tert*-butoxy radicals.

that this excitation can be collisionally quenched. The fact that the data in Fig. 2 fall on acceptable straight lines implies that in all our experiments the collision rate is sufficiently high that all our *tert*-butoxy radicals are thermalized. Figure 3 shows an attempt to corroborate this conclusion in that it compares our earlier thermal data for propane and cyclopropane (the latter all taken at densities above 1 mol l^{-1} of hydrocarbon) with the present photochemical data (taken at densities in the range 0.05 to 1 mol l^{-1}). It can be seen that the value of k_5/k_6 for cyclopropane obtained in the photochemical experiments at 70 °C lies very close to the extrapolation of our higher-temperature thermal data (3); likewise for propane, somewhat less convincingly, since the original thermal data (1) are somewhat scattered. Thus our conclusion would be that in this pressure range we cannot distinguish between the reactivities of *tert*-butoxy radicals formed from di-*tert*-butyl peroxide either thermally, or photochemically by 2537 Å radiation.

Finally, we note that there is a high-pressure thermal value for k_5/k_6 with isobutane at one temperature (3) which lies very close indeed to the Arrhenius extrapolation of the low-pressure photolysis data of McMillan (12): however, interpretation of the latter results appears to be complicated by the hot-radical effects noted above (8) allowance for which spoils the agreement; it is also possible to deduce crude data for k_5/k_6 from experiments using *tert*-butyl hypochlorite as a photolytic source at about 200 Torr (13), but these results do not extrapolate well either towards the high-pressure high-temperature thermal result. However, unimolecular fall-off effects can be discounted as a source of these discrepancies since it is known (14, 15) that $P_{1/2}$ for reaction 5 is about 80 Torr near 500 °K: all the low pressure photolysis experiments were performed near 300 °K (12, 13), and since it is generally expected (16) that the fall-off moves to lower pressures at lower temperature, one would not expect the rate in the 100–200 Torr region to be more than about 20% below its high-pressure limit; this leaves the data on k_5/k_6 for RH = isobutane in a relatively unsatisfactory state.

Spectroscopie de masse des *gem*-diesters cycliques. Fragment anhydride

KRZYSZTOF JANKOWSKI, JEAN COUTURIER, ET JEAN-YVES DAIGLE
Département de Chimie, Université de Moncton, Moncton, Nouveau-Brunswick

Reçu le 16 mars 1971[1]

La spectroscopie de masse des quatre *gem*-diesters sur les cycles à trois, quatre, cinq, et six est apportée. L'analyse des spectres est présentée par les schémas 1–5 et tableaux. Les ions métastables permettent d'identifier le fragment anhydride.

Mass spectra of four *gem*-diesters on three-, four-, five-, and six-member rings are analyzed. The fragmentation patterns of the investigated compounds supported by metastable ions are illustrated by Schemes 1–5 and Tables. A new fragment anhydride is proposed.

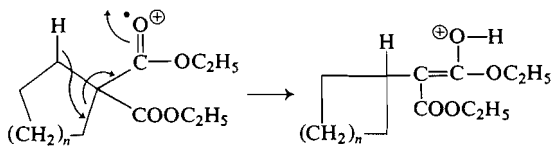
Canadian Journal of Chemistry, **50**, 1535 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Les spectres de masse de quelques *gem*-diesters ont été l'objet de quelques publications (1, 2). Dans cet article nous analysons les spectres de masse des quatre *gem*-diesters: le cyclopropanedicarboxylate-1,1 d'éthyle (**1**), cyclobutanedicarboxylate-1,1 d'éthyle (**2**), cyclopentanedicarboxylate-1,1 d'éthyle (**3**), et cyclohexanedicarboxylate-1,1 d'éthyle (**4**).

Malgré la ressemblance des structures des quatre produits, le comportement de l'ester sur le cycle à trois est bien différent de celui sur le cycle à quatre, et seulement pour les esters sur les cycles à cinq et à six peut-on observer certaines analogies. Les quatre diesters représentent des systèmes à deux centres ionisables: groupement carbonyle ou oxygène du groupement éthoxy.

Les pics moléculaires sont de très faible intensité, ne dépassant pas 4%, et on n'observe pas de pic $M^{\oplus} - 1$. Les pics parents pour les produits **3** et **4** sont des fragments hydrocarboniques C_nH_{2n-1} provenant de la rupture des cycles correspondants:



$n = 1$ ou 2 — *m/e* 55 ou 69 (100%)

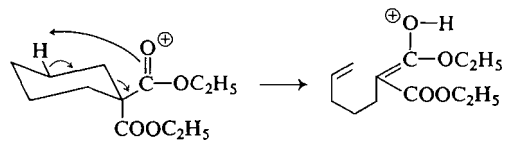
Le même fragment est peu intense pour la rupture des cycles à trois et à quatre (les produits **1** et **2**). La fragmentation du dérivé deutérié d_4 du composé **4**, le produit **5**, ayant les deutériums introduits dans les positions 2′ et 6′, donne le pic parent à 72, et confirme cette voie de la fragmentation.

Le pic parent pour le produit **1** (*m/e* 141) correspond à la rupture classique (3) d'une des liaisons CO—OEt, avec la formation d'un ion $R—CO^{\oplus}$ (une perte de $29—OC_2H_5$). Cette fragmentation devient peu importante pour les produits **2**–**4** suivant l'ordre croissant du cycle.

Le diester **2** donne le pic parent à *m/e* 29 correspondant à la rupture du type:

$$R—CO—\dot{O}^{\oplus}—C_2H_5 \rightarrow C_2H_5^{\oplus} + R—CO—O^{\bullet}$$

Ce mode de fragmentation classique des esters (3) est assez important pour les autres esters (35–75%).



Les ruptures classiques des esters prévoient également la formation des pics correspondant à la fragmentation "H" selon Biemann (3, 4). Nous mentionnons également cette possibilité, certains pics importants résultent de cette fragmentation, surtout pour les cycles à cinq et à six. Surtout pour le produit **5** observe-t-on le fragment hydrocarbonique correspondant au transfert d'hydrogène en β de la substitution (intensité = 60%).

Quant aux clivages α (tableau 1) plusieurs pics sont identifiés, correspondant aux fragmentations du type $R—COOR_1 \rightarrow R_1^{\oplus}$, $R—C{\equiv}O^{\oplus}$, $OR_1^{\oplus}$, $R—COO^{\oplus}$. On n'observe pas de fragment du type $R—COOR_1^{\oplus} - 18$, correspondant à une perte d'eau, normalement présent dans les

spectres des esters (3). Nous avons également observé le fragment $M^{\oplus} - 27$, qui a déjà été mentionné par d'autres auteurs (2), et qui a été identifié comme résultant d'une perte de C_2H_3 (ions métastables, voir également le schéma 2 et tableau 3).

Nous avons également identifié quelques fragmentations non classiques. D'abord, des fragments anhydrides *b* et *c* sont supportés par toute une série d'ions métastables (schéma 1 et tableau 2) pour les produits **2**–**4**. Les ions métastables pour le produit **1** ne sont pas observés. Toutefois, d'autres fragments possédant la même masse que *b* peuvent être suggérés.

Les fragments *c* peuvent aussi être obtenus comme le résultat des clivages représentés par schéma 2 (tableau 3). Cette fragmentation n'a pas été retracée pour le produit **1** et **2**. Biemann et collaborateurs en discutant le cas d'octoile mentionnent une structure semblable (4, 5).

SCHÉMA 4

Une autre fragmentation, mentionnée par la littérature (1) a été trouvée par des ions métastables et l'étude du spectre du produit deutérié. En effet, les produits **3**, **4**, et **5** donnent le clivage malonique selon le schéma 3 (tableau 4).

Finalement, le produit deutérié **5** a été utilisé pour retracer la fragmentation cétènique selon le schéma 4 (tableau 5). Cette fragmentation a été observée pour tous les produits et confirmée par les ions métastables. Le fragment *g* pour le cycle à six peut également donner le clivage rétro-Diels–Alder (schéma 5). Cette fragmentation est supportée par l'ion métastable comme dans le schéma 5. Des fragmentations pareilles ont déjà été observées (1, 2).

Partie expérimentale

Les spectres de masse ont été enregistrés sur un appareil Hitachi RMU-6D et Picker-AEI-MS 30 (250°, 70eV). Les spectres ne sont pas corrigés sur l'abondance isotopique naturelle. Les composés **1**–**3** sont des produits commerciaux (Fluka, pureté minimum de 99%), le produit **4** a été obtenu

Spectroscopie de masse des *gem*-diesters épimères

KRZYSZTOF JANKOWSKI, JEAN COUTURIER, ET ROBERT TOWER
Département de Chimie, Université de Moncton, Moncton, Nouveau-Brunswick

Reçu le 12 août 1971

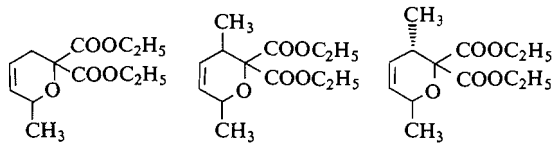
Nous présentons l'analyse des spectres de masse de trois *gem*-diesters dihydropyranniques substitués en position 2. Nous avons identifié, entre autre, la fragmentation rétro-Diels–Alder, absente pour les autres produits dans cette famille. La fragmentation majoritaire a été l'aromatisation du cycle dihydropyrannique.

The analysis of mass spectra of three 2-substituted dihydropyran *gem*-diesters is presented. The retro-Diels–Alder fragmentation, absent in the other members of the group, was identified. The major fragmentation was the aromatization of the dihydropyran ring.

Canadian Journal of Chemistry, **50**, 1539 (1972)

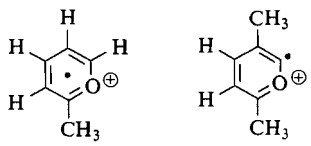
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Nous avons récemment apporté quelques précisions sur la fragmentation des *gem*-diesters sur les dihydropyrannes ou les composés carbocycliques (1–3). Présentement, nous analysons les spectres de masse de trois produits: méthyl-2 dihydro-5,6-α-pyranne-dicarboxylate-6,6 d'éthyle (**1**), le diméthyl-2β,5β-dihydro-5,6-α-pyranne-dicarboxylate-6,6 d'éthyle (**2**), et le diméthyl-2β,5α-dihydro-5,6-α-pyranne-dicarboxylate-6,6 d'éthyle (**3**). Les épimères **2** et **3** doivent normalement donner le même spectre (4). En effet, nous avons observé les mêmes fragments, mais l'intensité des fragments enregistrés plusieurs fois dans les mêmes conditions est différente pour les épimères **2** et **3**. Il est à souligner que les différences dans l'intensité des ions des deux épimères sont normalement beaucoup plus petites.



1 **2** **3**

Les ions moléculaires des trois produits sont très peu intenses et correspondent à une ionisation de l'oxygène du cycle. L'ionisation de l'oxygène du carbonyle n'a pas été retracée.

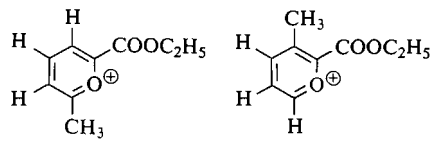


$P^{\oplus}$ (**1**) $P^{\oplus}$ (**2**)

Le processus majoritaire de la fragmentation est celui de l'aromatisation du cycle.

Un ion de base pour le produit **1** ($m/e = 95$) possède une structure aromatique. Le produit **2** donne un ion de base du même genre que le précédant ($m/e = 108$).

Le produit épimère **3** a donné un ion 100% à $m/e = 167$, ce qui correspond en plus à une perte d'un des deux groupements méthyles (en position 2 ou 5). Les ions possibles peuvent donc être $P_1^{\oplus}$ (**3**) ou $P_2^{\oplus}$ (**3**).



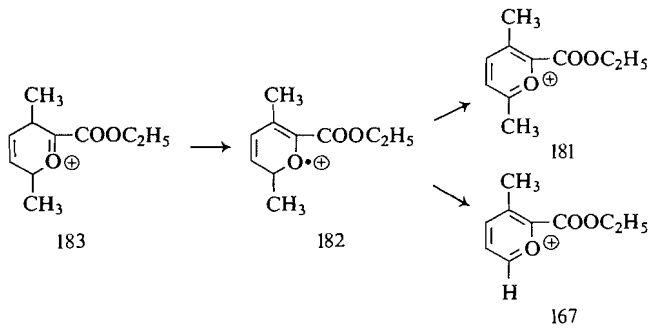
$P_1^{\oplus}$ (**3**) $P_2^{\oplus}$ (**3**)

Nous avons choisi une structure $P_2^{\oplus}$ (**3**) comme étant plus probable à l'issu de l'argumentation suivante:

(*a*) La fragmentation doit se faire d'abord dans une position 5, *p.ex.* la conjugaison avec le carbonyle (voir schéma 1).

(*b*) Une perte d'un hydrogène en position 5 dans l'étape de la formation d'un ion 100% va donner un radical plus stable qu'une perte de CH_3 dans la même position. Un ion $m/e = 182$ est donc très intense.

(*c*) A partir d'un $m/e = 182$ il n'y a pratiquement pas de perte d'hydrogène en position 5 (intensité $m/e = 181$ inférieure à 3%), mais le fragment correspondant à une perte de 15 unités donne un ion 100%.



183 182 181 167

SCHÉMA 1

(*d*) Finalement, le produit **1** démontre également un ion intense à $m/e = 154$ (voir schéma 2) obtenu à partir d'un ion $m/e = 169$ en l'absence

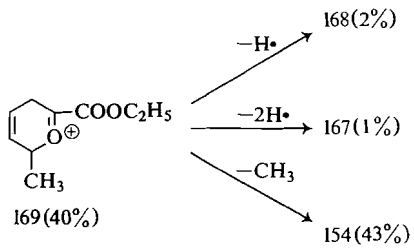


SCHÉMA 2

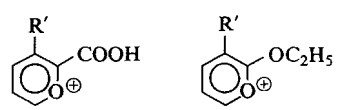
du fragment $m/e = 167$, ce qui prouve indirectement notre proposition. Le fragment analogue ($m/e = 167$) pour le produit **2** est également fort ($\sim 60\%$). Ceci semble prouver une dépendance de la facilité de départ du méthyl-5 et sa position dans l'espace. Les principaux fragments observés s'expliquent par schéma 3.

La majorité des fragmentations présentées dans le schéma 3 sont identiques avec celles déjà mentionnées par nous-mêmes (1–3). La structure *a*, possèdant le même poids moléculaire que la structure *b*, a été choisie en se servant de la méthode de détermination de masse exacte (exact mass measurement).

En effet, nous avons trouvé pour le produit **2** la composition $C_7H_7O_3$ (masse calculée: 139.0392, observée: 139.0407), au lieu de $C_8H_{11}O_2$ (masse calculée: 139.0759).

Dans une région inférieure à $m/e = 90$, on retrouve les fragments bien connus pour les



a $C_7H_7O_3$ (139) *b* $C_8H_{11}O_2$ (139)

clivages aromatiques des groupements ester et des fragments du type des ions cyclopropylydiums. Les plus intenses sont $m/e = 66$, 54, et 42 pour les produits **2** et **3**, ainsi que 67 et 43 pour le produit **1** (voir schéma 4). Pour le produit **2**, la fragmentation $a \rightarrow b$ est supportée par un ion métastable à 44.5 (calculée, 44.2). Cependant, les fragments du type *b* peuvent être obtenus par la voie compétitive plutôt que par la voie consécutive.

Contrairement aux cas déjà examinés, le clivage malonique (1, 3) n'a pas été retracé. On n'observe également pas de fragments $M^{\oplus} - 43$, ce qu'élimine une possibilité de l'ionisation du carbonyle. Vraisemblablement, la substitution d'une position 2 du cycle empêche cette rupture. On ne remarque pas l'ion anhydride (3).

Outre les processus de la fragmentation déjà décrits, nous avons confirmé par les ions métastables quelques fragmentations importantes (tableau 1).

L'identification de la fragmentation rétro-Diels–Alder, suggérée pour les autres produits dans cette série (1), constitue une particularité de ces spectres. Nous avons constaté que la substitution d'une position 2 du cycle dihydropyrannique est absolument importante pour observer cette dernière fragmentation. La substitution des positions 3 et 4 par un alkyle ou d'une position 2 par un radical alkoxy ne fait pas apparaître cette fragmentation (5–6).

Les dérivés pyranniques se caractérisent par des clivages menant à la formation de fragments diéniques (7, 8).

On dénote l'absence du fragment correspondant à une partie diénophile déjà observé (1). Ceci démontre l'importance de la substitution dans la position 2 pour ce genre de clivages.

SCHÉMA 4

L'augmentation de la température d'enregistrement du spectre augmente l'intensité des fragments correspondant à la fragmentation rétro-Diels–Alder. Cependant, même si le fragment diénophile ($m/e = 174$) apparaît, ceci peut s'expliquer par un clivage thermique (9).

Partie expérimentale

Les spectres de masse ont été réalisés sur des appareils Varian MAT 111, et AEI MS-30 (250°, 70 eV). Seuls les pics d'intensité relative $\geqslant 4\%$ sont mentionnés, exception faite des ions moléculaires (Fig. 1). Les spectres ont été

An Unusual Oppenauer Oxidation of (±) Ophiocarpine

V. ŠMULA AND R. H. F. MANSKE
Department of Chemistry, University of Waterloo, Waterloo, Ontario

AND

R. RODRIGO
Waterloo Lutheran University, Waterloo, Ontario

Received November 23, 1971

The Oppenauer oxidation of (±) ophiocarpine has been carried out to yield 3-(2′-vinyl-3′,4′-methylenedioxy) phenyl-4-hydroxyisoquinoline (**2**). Photolysis of this compound gave 3,4-dimethoxy-11,12-methylenedioxy-8,9-dihydro[1]benzoxepino(2,3-*c*) isoquinoline (**7**), whereas photolysis of the methyl ether of **2** produced *N*-norchelerythrine.

La réaction d'oxydation d'Oppenauer sur la (±) ophiocarpine conduit au 3-(2′-vinyl-3′,4′-méthylènedioxy) phényl-4-hydroxyisoquinoléine (**2**). La photolyse de ce composé conduit au 3,4-diméthoxy-11,12-méthylènedioxy-8,9-dihydro[1]benzoxepino(2,3-*c*) isoquinoléine (**7**), alors que la photolyse de l'éther méthylé de **2** conduit au *N*-norchelerythrine.

Canadian Journal of Chemistry, **50**, 1544 (1972)

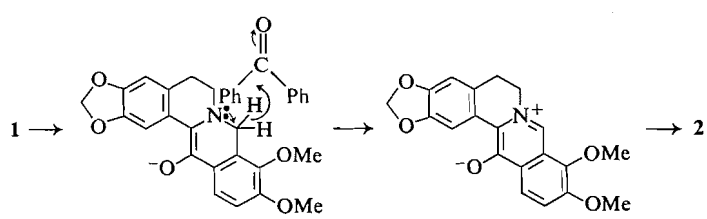
The modified (1) Oppenauer oxidation of a secondary alcohol function has been previously used with some success in the alkaloid field (2). We have applied this reaction to the oxidation of (±) ophiocarpine (**1**).

The benzylic secondary alcohol group in ophiocarpine might be expected to suffer oxidation under the conditions of the reaction and the resulting 13-ketotetrahydroberberine would almost certainly undergo further transformations in the presence of the strong base used. Such compounds have not been isolated, presumably because of their facile dehydrogenation to 13-hydroxyprotoberberinium salts. Hence our interest in this reaction.

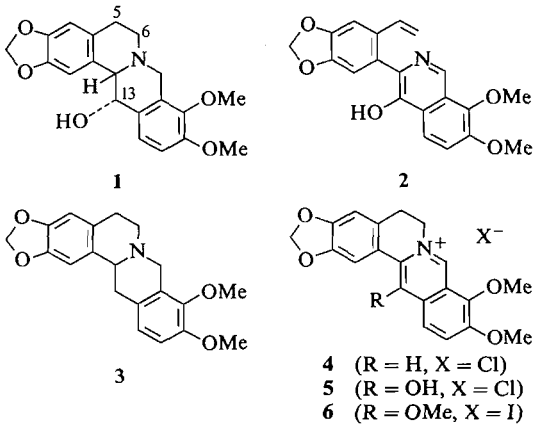
The oxidation carried out under Woodward's (1) conditions using dioxan as the solvent gave in *ca.* 60% yield 3-(2′-vinyl-3′,4′-methylenedioxy) phenyl-4-hydroxy-7,8-dimethoxyisoquinoline (**2**). The structure of **2** was evident from its p.m.r. spectrum which showed the characteristic pattern for the ABX system of the styrene unit with the coupling constants and chemical shifts of expected magnitude. The spectrum also contained a singlet integrating for one proton at δ 9.08 which could be assigned to the H-1 of the isoquinoline system (3). The resonances of the remaining protons were unexceptional. This structure was supported by the i.r. spectrum, (ν_{-OH} 3540 cm^{-1}) and by elemental analysis.

Several mechanisms may be written to rationalize the formation of this interesting product. By analogy with Woodward's original proposal (1) for the oxidation of the secondary alcohol group, it is possible to visualize a similar oxidation at the tertiary nitrogen atom which could be followed by a Hofmann elimination to yield **2** (Scheme 1).

In order to test this hypothesis the reaction was repeated with (±) canadine (**3**) and with berberinium chloride (**4**). In both cases the

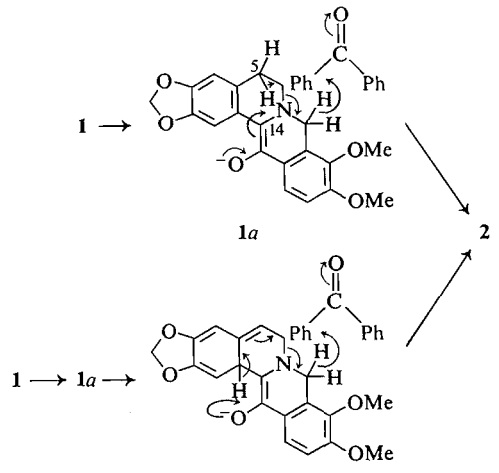


SCHEME 1



starting material was recovered and no elimination products were obtained. The reaction was successful however, with 13-hydroxyberberinium chloride (**5**) and 13-methoxyberberinium iodide (**6**) (4). The product **2** was obtained in *ca.* 60% yield in the former case and *ca.* 20% yield in the latter.

It is therefore evident that the reaction does not take place via a simple Hofmann degradation and that the presence of an oxygen function at C-13 is indispensable for proton abstraction at C-5 and cleavage of the C_6—N bond. Two different mechanisms which recognize this fact are illustrated in Scheme 2. In the first instance proton transfer directly across ring B (in the boat conformation) from C-5 to -14 is postulated. Alternatively, the results may be rationalized by proposing a 1,3 proton transfer which is followed by a concerted rearrangement–elimination step. Minor variations of either mechanism could account for all the results stated above. There is however no easy way of deciding between them.



SCHEME 2

It has been recently shown (5) that *N*-methyl-1,2-dihydroisoquinolines similar to **2** are smoothly converted through an electrocyclic process to benzophenanthridine derivatives upon photolysis under suitable conditions. The photolysis of **2** was therefore attempted using a 3500 Å lamp and Pyrex filter under nitrogen in benzene solution.

This gave, *inter alia* the oxepine **7** readily recognized by the absence of the vinyl signals and presence of an A_2X_2 system consisting of two triplets centered at 4.8 and 2.83 δ (J_{AX} = 6.0 Hz). This structure was confirmed by the i.r. spectrum of **7** which was lacking in hydroxyl absorption. The oxepine **7** appears to be the first example of a new tetracyclic system.

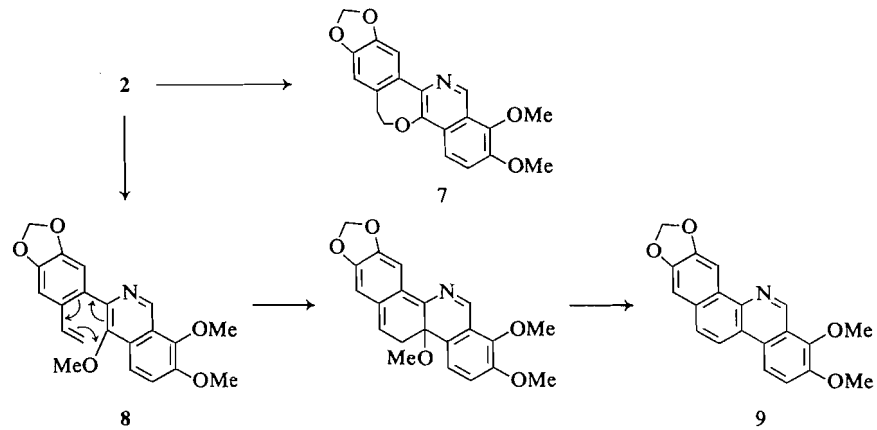
In order to block such a photo-addition reaction compound **2** was methylated with diazomethane to the *O*-methyl ether **8** which showed the presence of the extra methoxyl group at 3.62 δ in its p.m.r. spectrum, an upfield shift of > 0.4 p.p.m. from the other two methoxyl groups at 4.06 and 4.14 δ. This shift is easily accounted for by the anisotropic effect of the benzene ring at position 3 of the isoquinoline system, in a non-coplanar conformation.

Photolysis of **8** under the same conditions as before led directly to *N*-norchelerythrine **9**. By analogy with the earlier work (5) the conversion may be regarded as an electrocyclic process followed by spontaneous elimination of methanol and concomitant aromatization (Scheme 3). The n.m.r. spectrum of **9** was fully compatible with its structure while the m.p. and the u.v. spectrum were identical with that of *N*-norchelerythrine already published (6).

This reaction therefore completes a three step conversion of a protoberberine to a fully aromatic benzophenanthridine. It may have some practical advantages over the earlier method (5) in that no dehydrogenation steps are required subsequent to the photolysis.

Experimental

Melting points were determined using a Fisher Meltemp unit and are uncorrected. The p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spec-



SCHEME 3

trometer. Samples were dissolved in $CDCl_3$, unless otherwise specified, using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS. A Beckman I.R. 10 spectrometer was used to record the i.r. spectra and a Coleman–Hitachi EPS-3T spectrophotometer was used for the u.v. spectra.

3-(2'-Vinyl-3',4'-methylenedioxy)phenyl-4-hydroxy-7,8-dimethoxy Isoquinoline (2)

(*a*) Ophiocarpine (57 mg) in dry dioxan (3.5 ml) was refluxed under nitrogen with potassium *t*-butoxide (80 mg) and benzophenone (150 mg) for 20 h. The solvent was removed under reduced pressure and the residue extracted with 2% hydrochloric acid. The acid extract was washed with ether, basified with ammonia, extracted with chloroform, dried ($MgSO_4$) and evaporated to dryness. The residue was crystallized from methanol (33 mg) m.p. 191–192°.

The u.v. spectrum: λ_{max}^{EtOH} 235, 270(sh), 302, and 355 nm; log ε_{max} 4.56, 4.29, 4.12, and 3.61 respectively. The i.r. spectrum: $\nu_{max}^{CHCl_3}$ 3540 cm^{-1}. The n.m.r. spectrum (δ): 4.02 (3H, s) and 4.05 (3H, s), 6.00 (2H, s), 6.88 (1H, s), 7.17 (1H, s), 9.15 (1H, s), 5.11 (1H, d, d) 5.61 (1H, d, d) 6.44 (1H, q) ($J_{AB} = 18$ and $J_{AX} = 11$ Hz); 7.47 (1H, d) 7.95 (1H, d) ($J_{AB} = 9$ Hz).

Anal. Calcd. for $C_{20}H_{17}NO_5$: C, 68.37; H, 4.88; N, 3.99. Found: C, 68.31; H, 5.14; N, 4.26.

(*b*) 13-Hydroxyberberinium chloride (**5**, 52 mg) in dry dioxan (10 ml) was refluxed under nitrogen with potassium *t*-butoxide (79 mg) and benzophenone (140 mg) for 42 h. The solvent was evaporated under reduced pressure and the residue extracted with 2% hydrochloric acid. The acid extract was washed with ether, basified with ammonia, extracted with chloroform, dried ($MgSO_4$), and evaporated. The residue was purified by t.l.c. (silica gel chloroform – 5% acetone) and crystallized from methanol (26 mg). It was identical in all its properties with **2**.

(*c*) 13-Methoxyberberinium iodide (**6**, 116 mg) in dry dioxan (12 ml) was refluxed under nitrogen with benzophenone (500 mg) and potassium *t*-butoxide (230 mg) for 36 h. The subsequent isolation and purification was carried out as before (17 mg.).

Reactions *b* and *c* were also successful without benzophenone. (±) Canadine (**3**) and berberinium chloride (**4**) were recovered unchanged after reactions by the above procedure.

Methylation of 2

Compound **2** (372 mg) was dissolved in methylene chloride (30 ml) and treated with excess ethereal diazomethane at room temperature for 24 h. The solvents and excess diazomethane were allowed to evaporate and the residue purified by chromatography on a silica gel column in benzene–acetone (9:1). The product **8**, was a thick oily semi-solid (310 mg) homogeneous on t.l.c. The n.m.r. spectrum; virtually identical with **2** but for an extra singlet (3H) at 3.62 δ.

3,4-Dimethoxy-11,12-methylenedioxy-8,9-dihydro[1]-benzoxepino[2,3-c] Isoquinoline (7)

Compound **2** (75 mg) was dissolved in dry benzene (100 ml) and irradiated in a Rayonet reactor at 3500 Å under nitrogen for 2 h. The solvent was evaporated and the residue purified by preparative t.l.c. (silica gel, benzene–acetone, 9:1) and crystallized from ethanol (25 mg) m.p. 145–147°. The u.v. spectrum: λ_{max}^{EtOH} 233, 264, 320, and 363 nm; log ε_{max} 4.59, 4.33, 4.34, and 3.82 respectively. The n.m.r. spectrum (δ): 2.83 (2H, t) and 4.80 (2H, t) ($J_{AX} = 6$ Hz), 4.01 (3H, s) 4.06 (3H, s), 5.98 (2H, s), 6.75 (1H, s), 7.47 (1H, s), 9.13 (1H, s), 7.45 (1H, d), and 7.95 (1H, d) ($J_{AB} = 9.0$ Hz).

Anal. Calcd. for $C_{20}H_{17}NO_5$: C, 68.37; H, 4.88; N, 3.99. Found: C, 68.50; H, 5.06; N, 3.99.

N-Norchelerythrine (9)

Compound **8** (100 mg) in dry benzene (50 ml) was irradiated in a Rayonet reactor at 3500 Å under nitrogen for 4 h. The mixture was worked-up as before to yield the product which was crystallized from ethanol (52 mg), m.p. 215° (lit. 212–214°). The u.v. spectrum was identical with that already published (6). The n.m.r. spectrum (δ): 4.10 (3H, s), 4.17 (3H, s), 6.16 (2H, s), 7.24 (1H, s), 8.75 (1H, s), 9.78 (1H, s) 7.58 (1H, d), and 8.36 (2H, d) ($J_{AB} = 9.2$ Hz) and 7.86 (1H, d) ($J_{A'B'} = 9.0$ Hz).

We wish to thank Dr. D. B. MacLean, McMaster University, Hamilton, Ontario for the 100 MHz n.m.r. spectrum of

cis-5-Cyclooctene-1,2-dione and its Ethylene Ketals[1]

PETER YATES, E. G. LEWARS, AND P. H. MCCABE
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received December 21, 1971

Oxidation of *cis-cis*-1,5-cyclooctadiene with hydrogen peroxide gives *cis*-5-cyclooctene-*trans*-1,2-diol (**3**) which is converted to *cis*-5-cyclooctene-1,2-dione (**6**) on treatment with dimethyl sulfoxide and acetic anhydride. Bromination of **6** is accompanied by transannular bonding to give a dibromo keto ether **9***a* or *b*. Ketalization of **6** with ethylene glycol gives a monoketal **11** and two diketals **12** and **13** with 1,3-dioxolane and 1,4-dioxane rings, respectively. Bromination of **12** with bromine or pyridinium perbromide is accompanied by transannular bonding and fission of one of the 1,3-dioxolane rings to give a dibromo monoketal ether **15***a* (or *b*). Bromination of **12** with *N*-bromosuccinimide followed by dehydrobromination gives a cyclooctadiene-1,2-dione diketal **20***a* (or *b*).

L'oxydation par l'eau oxygénée du cyclooctadiène-1,5 *cis-cis* donne le *cis*-cyclooctène-5 diol-1,2 *trans* (**3**) qui est converti en *cis*-cyclooctène-5 dione-1,2 (**6**) par traitement avec le diméthylsulfoxyde et l'anhydride acétique. La bromation de **6** est suivie de la formation d'une liaison transannulaire pour conduire au dibromocétoéther **9***a* ou *b*. La cétalisation de **6** avec l'éthylèneglycol donne un monocétal **11** et deux dicétals **12** et **13** avec respectivement des cycles dioxolane-1,3 et dioxane-1,4. La bromation de **12** par le brome ou par le perbromure de pyridinium est suivie de la formation d'une liaison transannulaire et de la scission d'un des cycles dioxolane-1,3 pour donner un dibromo monocétaléther **15***a* (ou *b*). La bromation de **12** par le *N*-bromosuccinimide suivie d'une déhydrobromation, conduit au cyclooctadiène dione-1,2 dicétal **20***a* (ou *b*).

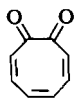
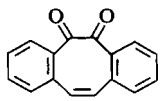
In an earlier paper in this series (2) we discussed the interest underlying the chemistry of 1,2-cyclooctatetraenoquinone (**1**) and its 1,4 isomer as a result of their potential aromaticity. We described a synthesis of dibenzo[*a*,*e*]cyclooctene-5,6-diene (**2**), the dibenzo analogue of **1**, and demonstrated that its eight-membered ring is not aromatic. It was pointed out that the latter observation could not be taken as implying the absence of aromaticity in the parent monocyclic compound **1**, since the benzenoid rings of **2** might damp the aromaticity of the eight-membered ring (3). We report now on some synthetic approaches to **1**, which, although not crowned with success, have provided results of interest in the area of eight-membered ring chemistry.



1



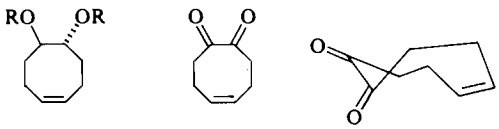
2

Oxidation of *cis-cis*-1,5-cyclooctadiene with hydrogen peroxide and formic acid followed by basic hydrolysis gave *cis*-5-cyclooctene-*trans*-1,2-diol (**3**) as a colorless oil in 55% yield. The stereochemistry is assigned as *trans* on the basis of analogy with analogous hydroxylation reactions (4). The preparation of this diol by hydrolysis of the corresponding epoxide has been reported previously in the patent literature (5) and in a review (6). The diol afforded an oily diacetate (**4**) and a crystalline dibrosylate (**5**); the spectra of **3**–**5** were in full accord with these structural assignments (see Experimental).

Oxidation of **3** with dimethyl sulfoxide and acetic anhydride (7) gave *cis*-5-cyclooctene-1,2-dione (**6**) as a very pale yellow crystalline solid in 30–50% yield.[2] Its i.r. spectrum showed bands at 5.80 and 5.85 μ, which can be attributed to the antisymmetrical and symmetrical coupled stretching vibrations of the two carbonyl groups (9). The relatively small separation of these bands indicates that the coupling is weak. This is in accord with the existence of **6** in the conformation **7** in which the non-bonding interactions of the hydrogen atoms and the dipole–dipole interaction of the carbonyl groups are minimized. The intercarbonyl angle in this conformation is *ca.* 120°, which would account

[1]Cyclooctatetraenoquinones. III. For paper II in this series, see ref. 1*a*. A preliminary account of part of this work has appeared (1*b*).

[2]The dione **6** was also obtained, in low yield, when 1,2-dibromo-*cis*-5-cyclooctene (8) was heated with collidine and dimethyl sulfoxide.

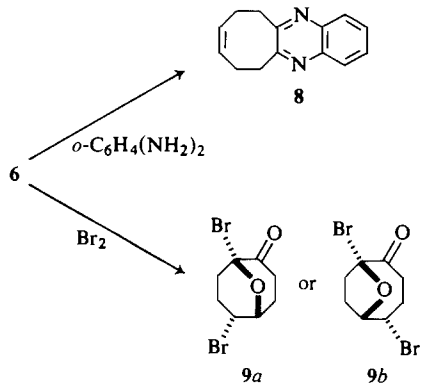


3 R = H
4 R = $COCH_3$
5 R = $SO_2C_6H_4Br$-*p*

6 7

for the fact that the carbonyl-stretching vibrations are only weakly coupled (10). The u.v. spectrum of **6** has maxima at 281 (ε 35), 289 (sh, ε 31), and 347 mμ (ε 17). This contrasts with many α-diketones which are bright yellow due to maxima in their electronic spectra at >360 mμ. However, it is well established (11) that this long wavelength maximum is shifted to shorter wavelength when the intercarbonyl angle is in the range 90–140°. In particular the spectrum may be compared with that of 3,3,8,8-tetramethylcyclooctane-1,2-dione: *ca.* 287 (ε 35), 296 (ε 43), and 343 mμ (ε 21) (12). This diketone is considered to exist in a crown conformation in which the intercarbonyl angle is 110–140°. The close similarity of its spectrum to that of **6** shows that no special effect due to non-bonded interaction of the ethylenic and carbonyl systems of the latter can be adduced from its electronic spectrum.

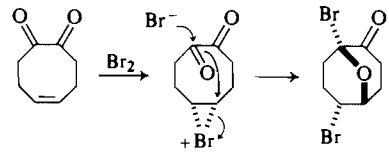
Treatment of **6** with *o*-phenylenediamine in boiling acetic acid gave the quinoxaline **8**. Treatment with bromine in carbon tetrachloride gave a dibromo compound. The i.r. spectrum of this product showed that bromination had been accompanied by transannular bonding to give a keto ether with structure **9***a* or *b*. A band at 5.76 μ is attributable to the carbonyl-stretching vibration shifted to lower wavelength than normal because of dipole–dipole interaction



8

6 → (o-$C_6H_4(NH_2)_2$) → **8**
6 → (Br_2) → **9***a* or **9***b*

with the adjacent carbon–bromine bond, and strong bands between 9 and 10.5 μ, absent in the spectrum of **6**, are attributable to the ether linkage. The p.m.r. spectrum of the bromination product is also in accord with this formulation, showing two one-proton multiplets at δ 4.1–4.6 and 4.6–5.0. The formation of **9***a* (or *b*) is considered to occur via the bromonium ion **10** (Scheme 1). The stereochemistry depicted in **9***a* (and *b*) is assigned on the basis of Scheme 1. Attempted bromination of **6** with *N*-bromosuccinimide gave intractable tarry mixtures.



6 **10** **9***a*

SCHEME 1

Treatment of **6** with ethylene glycol and *p*-toluenesulfonic acid in boiling dichloromethane in a Soxhlet apparatus with calcium hydride or molecular sieves in the thimble gave a mixture of three products, **11**–**13**. The product distribution (determined by v.p.c.) as a function of time is shown in Table 1. Thus, the diketal **12** could be obtained in good yield by crystallization of the product mixture after the reaction had been allowed to proceed for 2 weeks, while the diketal **13** could be isolated, albeit in low yield, by crystallization of the product mixture after 2–3 days at reflux. The monoketal **11** was best obtained by treatment of **6** with acetone ethylene ketal and boron trifluoride etherate for 5 h at 25°; the major product was **11**, which was

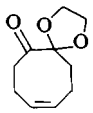
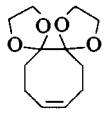
accompanied by **12** and unconsumed **6**. The spectra of the ketals are given in Table 2.

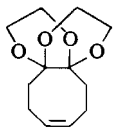
The structures of the diketals **12** and **13** were assigned on the basis of deketalization studies. Treatment of **13** in acetone with boron trifluoride etherate or concentrated hydrochloric acid at room temperature gave the diketone **6**,



11



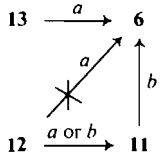
12



13

while treatment of **12** gave the monoketal **11**, which was stable under these conditions. Reaction of **12** in ether with 6 *N* hydrochloric acid rapidly gave **11**, which was slowly converted to **6**. These observations, which are summarized in Scheme 2, show that **13** is converted to **6** without forming **11**, while **12** is converted to **6** via **11**, in accord with the structural assignments.

Corroboratory evidence for these assignments is provided by the mass spectra of the diketals and their relationship to the mass



a $BF_3 \cdot Et_2O$ or 12 *N* HCl aqueous in acetone
b 6 *N* HCl aqueous in ether

SCHEME 2

spectrum of the monoketal. It is clear that there is a close relationship of the spectrum of **11** with that of **12**, but not of **13**. The salient features of the spectra of **11** and **12** can be interpreted in terms of Scheme 3, which involves processes that have been postulated previously to account for the mass spectra of related compounds (13, 14). The spectrum of **13** is considerably more complex than that of **12**; it can be interpreted in terms of earlier postulates (14), but detailed discussion is deferred in the absence of accurate

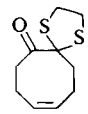
mass measurements. Attention may be drawn, however, to the strong peak at *m/e* 86, which most probably has the same origin as the peaks at *m/e* 86 in the spectra of **11** and **12**. This may at first sight be considered to be anomalous; however, Fuchs (14*a*) has observed related fragmentations of 1,4,5,8-tetraoxadecalins upon electron impact to ions considered to be dioxolane derivatives.

The relationship among the p.m.r. spectra of **11**–**13** also corroborates these structural assignments. The multiplets due to the protons of the $-OCH_2CH_2O-$ groups in the spectra of **11** and **12** are considerably narrower than the corresponding multiplet in the spectrum of **13**, which appears as a well-defined AA′BB′ system. This difference is attributable to the greater rigidity of the dioxane rings in **13** relative to the dioxolane rings in **12** (14*a*). It is also noteworthy that the $-OCH_2CH_2O-$ multiplet in **12** is centered at slightly lower field than that in **13** in correspondence with observations on related pairs of isomers (14*a*).

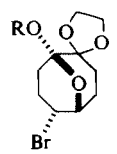
It can be seen from Table 1 that while **13** is formed more rapidly than **12**, the latter is highly favored thermodynamically. The greater stability of **12** is attributable both to entropy (*vide supra*) and enthalpy factors. The latter stem from the more severe non-bonded interactions in **13**, which must perforce have the dioxane rings *cis* fused. The same stability relationship appears to hold for the two diketals of 1,2-cyclohexanedione, although in this case insufficient data are available for rigorous structural assignment (15). The stability relationship is reversed in the case of the diketals of acenaphthenequinone; this relationship has been interpreted in terms of the relative stabilities of diprotonated intermediates (14*b*). However, we consider that it reflects the greater thermodynamic stability of the dioxane type diketal relative to the dioxolane type diketal in this case, due to the absence of non-bonded interactions of the dioxane ring hydrogen atoms with the hydrogen atoms of the diketone residue, thus making the interactions in the dioxolane rings systems paramount in determining the stability relationship.

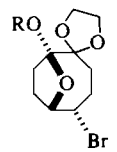
A brief study was also made of the *thio*-ketalization of **6**. Treatment with 1,2-ethanedithiol and boron trifluoride in ether at room temperature gave the monothioketal **14**; however, prolonged reaction with these reagents at room temperature or at reflux failed to produce a dithioketal. The monothioketal **14** was resistant to hydrolysis with mercuric chloride and cadmium carbonate in aqueous acetone (*cf.* (16)), and was not further investigated.



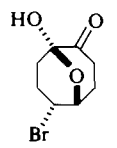
14

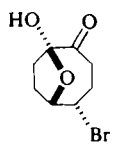
Bromination of diketal **12** with bromine or pyridinium perbromide gave a dibromo compound whose p.m.r. spectrum indicated that it was not the product derived by simple addition of bromine to the double bond of **12**. The nature of the product was revealed when it was found that treatment with potassium *t*-butoxide in ether gave a monodehydrobromination product whose spectra indicated the presence of a vinyl ether group,$-OCH=CH_2$. The presence of this group was confirmed by the fact that hydrolysis of the dehydrobromination product with boiling acidic methanol gave acetaldehyde, identified as its 2,4-dinitrophenylhydrazone. On the basis of these observations the dibromo compound is formulated as **15***a* or *b* and its dehydrobromination product as **16***a* or *b*. The other product formed in the hydrolysis of **16**, which could also be obtained by hydrolysis of **15**, was not fully characterized, but its spectra were consistent with its formulation as **17***a* or *b*.





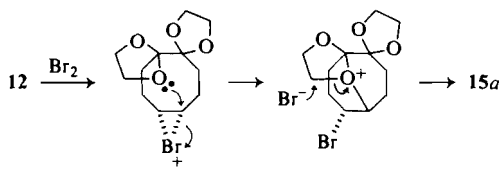
15*a* R = CH_2CH_2Br **15***b* R = CH_2CH_2Br
16*a* R = $CH=CH_2$ **16***b* R = $CH=CH_2$





17*a* **17***b*

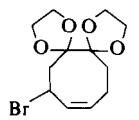
The formation of **15***a* from **12** is envisaged to occur via the bromonium ion **18** as in Scheme 4 (a closely related scheme would lead to **15***b*). The stereochemistry shown in **15**–**17** is assigned on the basis of Scheme 4.



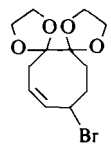
18

SCHEME 4

Bromination of the diketal **12** on a small scale with *N*-bromosuccinimide or 1,3-dibromo-5,5-dimethylhydantoin gave a monobromo compound that is formulated as **19***a* or *b* on the basis of its p.m.r. spectrum and its conversion to a conjugated diene on dehydrobromination (*vide infra*). Unfortunately, the reaction was capricious and the yield of **19** was very variable. Large scale reactions gave low yields of **19**, which was accompanied by two dibromination products.



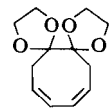
19*a*



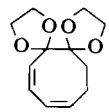
19*b*

One of these was found to be identical with the dibromo compound **15** obtained from the reaction of **12** with bromine or pyridinium perbromide. The other had similar spectra and is considered to be the other member of the **15***a*, **15***b* pair.

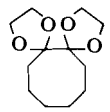
Dehydrobromination of **19** with potassium *t*-butoxide in dimethyl sulfoxide gave a product $C_{12}H_{16}O_4$ that is assigned structure **20***a* or *b*[3] on the basis of the following data. Its i.r. spectrum showed a weak-to-medium intensity band at 6.14 μ, similar to that in 1,3-cyclooctadiene. Its u.v. spectrum showed the presence of a *cisoid* conjugated diene system: $\lambda_{max}^{C_6H_{14}}$ 230 mμ (ε 4300) (*cf.* 1,3-cyclooctadiene: $\lambda_{max}^{C_6H_{14}}$ 227 mμ (ε 5500)). Its p.m.r. spectrum had signals at δ 2.1–2.7 (m, 4 H), 3.8–4.05 (m, 8 H), 5.65–6.0 (m, 4 H). On hydrogenation over palladium/charcoal it gave the diketal **21** of 1,2-cyclooctanedione, which was also obtained by hydrogenation of **12**, and whose structure was established by its preparation from 1,2-cyclooctanedione and ethylene glycol in the presence of *p*-toluenesulfonic acid.[4]



20*a*



20*b*



21

Experimental

Melting points were determined in capillary tubes with a Thomas-Hoover "Uni-Melt" apparatus. Melting and boiling points are uncorrected. The i.r. spectra were recorded in carbon tetrachloride, unless otherwise specified, n.m.r. spectra were recorded in deuteriochloroform, unless otherwise specified. The t.l.c. was carried out on silica gel with development with dichloromethane. Solutions in organic solvents were dried with anhydrous magnesium sulfate. "Aqueous work-up" signifies that the reaction solution was poured into about three times its volume of water, the mixture was extracted three times with dichloromethane, and the dichloromethane solution was washed three times with water, dried, and evaporated.

cis-5-Cyclooctene-trans-1,2-diol (3)

In a 1-l round-bottomed flask equipped with a magnetic stirring bar, a dropping funnel, and a thermometer, was placed *cis-cis*-1,5-cyclooctadiene (57 ml, 50 g, 0.46 mol). The flask was immersed in an ice bath, and stirring was commenced. A mixture of hydrogen peroxide (33%; 50 ml, 55 g, 0.50 mol) and 99% formic acid (310 ml) was added at a rate such as to keep the temperature of the reaction mixture at 40–45°; this required 30 min. When almost all of the hydrogen peroxide and formic acid had been added, the remaining portion was added at a rate such as to allow the temperature of the reaction mixture to reach 55°, when the mixture became homogeneous. The mixture was stirred for 5 min without cooling, during which the temperature showed no tendency to rise, and then heated at 65° for 2 h, at the end of which period peracid was shown to be absent (negative starch–iodide reaction). Formic acid and water (270 ml) were removed at the rotary evaporator. The residue was stirred and cooled in an ice-bath while a solution of sodium hydroxide (28 g, 0.7 mol) in water (120 ml) was cautiously added. The mixture was heated on the steam bath for 2 h. Concentrated hydrochloric acid was added to make the reaction mixture neutral. The mixture was heated on the steam bath, and the water was removed by flash distillation at the water aspirator. The residue was distilled to give **3** as a clear, colorless, virtually odorless, mobile oil (26 g, 39%), b.p. 99–100° (0.45 mm) (lit. (5) 153–155° (16 mm)); λ_{max} (liquid film) 3.01 μ; $\delta(CCl_4)$ 1.2–2.8 (m, 8 H), 3.4–3.7 (m, 2 H), 4.30 (broad s, 2 H), 5.58 (t, $J = 4$ Hz, 2 H).

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 67.65; H, 9.87.

When **3** was prepared on a 1 *M* scale, it was found con-

[3]It is not excluded that the diene is a mixture of **20***a* and *b*. Preliminary experiments indicated that this product could be brominated with *N*-bromosuccinimide to give a monobromo derivative; however, this route to the corresponding triene was not pursued because of the difficulties encountered in the preparation of **19**.

[4]Compound **21** was the major product formed on diketalization of 1,2-cyclooctanedione; its p.m.r. spectrum is in accord with the assignment to it of a structure analogous to **12** rather than **13** (*vide supra*). It is not excluded that a diketal analogous to **13** is also formed.

venient to extract the alkaline reaction mixture with chloroform; the chloroform extracts were dried and evaporated, and the residue was distilled to give **3** in 55% yield.

cis-5-Cyclooctene-trans-1,2-diol Diacetate (4)

In a 10-ml Erlenmeyer flask were placed the diol **3** (1.05 g, 7.4 mmol), acetic anhydride (6 ml), and concentrated sulfuric acid (1 drop). The flask was stoppered and the mixture was left at 23° for 13 h. The reaction mixture was poured into water (30 ml) and allowed to stand at 23° for 5 h with occasional swirling. The reaction mixture now consisted of a pale yellow oil beneath an aqueous layer; it was left at 2° for 6 days, but crystallization of the oil did not occur. The aqueous layer was extracted with dichloromethane, and the extract was washed with water, dried, and evaporated to give a pale yellow liquid, which was combined with the oil from the original reaction mixture to give the crude diacetate **4** (1.3 g, 77%). Vapor phase chromatography (10% NPGS on Chromosorb P, 10 ft × 0.25 in. copper column, 200°) indicated the presence of *ca.* 90% of one component; this was collected to give the diacetate **4** as a colorless liquid; λ_{max} 5.74, 7.30, 8.15 μ; $\delta(CCl_4)$ 1.4–2.8 (m, 14 H, including s, δ 1.93), 5.02 (t, $J = 4$ Hz, 2 H), 5.67 (t, $J = 5$ Hz, 2 H).

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02. Found: C, 63.64; H, 7.94.

cis-5-Cyclooctene-trans-1,2-diol Bis-p-bromobenzenesulfonate (5)

The diol **3** (0.50 g, 3.5 mmol) in pyridine (5 ml) was stirred at 0°, and powdered *p*-bromobenzenesulfonyl chloide (1.80 g, 7.0 mmol) was added during 1 min. The colorless solution was maintained at 10° for 12 h. The reaction mixture was poured into 5% hydrochloric acid (70 ml), and the resulting suspension was extracted with ether (4 × 30 ml). The combined ethereal extracts were washed once with water, once with saturated aqueous sodium bicarbonate, and once with brine. The organic layer was dried, and most of the ether was removed on the rotary evaporator to give the dibrosylate **5** as colorless needles (636 mg, 30%), m.p. 126–127° (dec.); δ 1.7–2.6 (m, 8 H), 4.75–5.0 (m, 2 H), 5.5–5.7 (m, 2 H), 7.4–7.8 (m, 8 H).

Anal. Calcd. for $C_{20}H_{20}Br_2O_6S_2$: C, 41.39; H, 3.47; Br, 27.54; S, 11.05. Found: C, 41.65; H, 3.35; Br, 27.66; S, 11.05.

cis-5-Cyclooctene-1,2-dione (6)

The diol **3** (41 g), dimethyl sulfoxide (Fisher Certified, dried with Linde type 4A molecular sieves; 400 ml), and acetic anhydride (200 ml) were allowed to stand at 23° for 24 h in a stoppered flask. The light yellow–green reaction mixture was poured into 1 *N* hydrochloric acid (1200 ml) with cooling with a water bath at room temperature, and the mixture was stirred for 40 min while being maintained at room temperature. The mixture was extracted with dichloromethane (3 × 200 ml), and the dichloromethane extracts were washed twice with water and once with dilute aqueous sodium bicarbonate. The organic layer was dried and evaporated to give a yellow–green liquid, which was distilled to give the enedione **6** as a light yellow–green liquid (17 g; 43%), b.p. 60–72° (*ca.* 0.3 mm). This was redistilled to give 14 g (35%) of **6**, b.p. 45–56° (0.25 mm). Crystallization was effected by dissolving the liquid in pentane and leaving the solution at −20° for a few hours. This gave **6** as a pale yellow–green solid (12.5 g, 31%), m.p. 31–35°; recrystallization gave virtually colorless prisms, m.p. 35–36°; λ_{max} 5.80, 5.85 μ; λ_{max} (C_6H_{14}) 281 (ε 35), 290 (sh, ε 31), 346 (ε 17) mμ (end absorption; ε 370 at 220 mμ); $\delta(CCl_4)$ 2.1–2.8 (m, 8 H), 5.6–6.0 (m, 2 H); *m/e* 138.

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.54; H, 7.30. Found: C, 69.25; H, 7.31.

Reaction of 1,2-Dibromo-cis-5-cyclooctene with Dimethyl Sulfoxide and Collidine. Formation of 6

1,2-Dibromo-*cis*-5-cyclooctene was prepared by treating *cis-cis*-1,5-cyclooctadiene with bromine as described by Willstätter and Veraguth (8). The product was a colorless, very air-sensitive liquid, b.p. 104–105° (2 mm) (lit. (8) b.p. 142–143° (14 mm)); $\delta(CCl_4)$ 1.5–3.1 (m, 8 H), 4.4–4.9 (m, 2 H), 5.5–5.9 (m, 2 H).

1,2-Dibromo-*cis*-5-cyclooctene (415 mg, 1.55 mmol), collidine (2 ml), and dimethyl sulfoxide (5 ml) (17) were heated at 125° under nitrogen for 24 h. The very dark mixture was poured into an equal volume of water and the mixture was extracted with dichloromethane. The dichloromethane extracts were washed successively with dilute hydrochloric acid, aqueous sodium bicarbonate, and water. The organic layer was dried and evaporated to give a mobile orange liquid (88 mg); λ_{max} 5.75, 5.81, 5.86, 6.01 μ. Vapor phase chromatography (10% NPGS on Chromosorb P, 10 ft × 0.25 in. copper column, temperature programmed from 150–220° at 5.9°/min) showed more than nine major peaks. The component with retention time identical with that of **6** was collected and shown to be **6** by i.r. spectral comparison.

Reaction of 6 with o-Phenylenediamine. Formation of 8

The enedione **6** (1.00 g, 7.25 mmol), *o*-phenylenediamine (0.784 g, 7.24 mmol), and acetic acid (18 ml) were heated on the steam bath for 1 h. Water (*ca.* 60 ml) was added to the hot solution until it was slightly cloudy, and the solution was allowed to cool. The solution deposited **8** as almost colorless needles (1.33 g, 87.5%), m.p. 118–119°; δ 2.45–2.9 (m, 4 H), 3.1–3.5 (m, 4 H), 5.45 (m, 2 H), 7.4–8.1 (m, 4 H).

Anal. Calcd. for $C_{14}H_{14}N_2$: C, 79.96; H, 6.71; N, 13.32. Found: C, 80.12; H, 6.69; N, 13.31.

Reaction of 6 with Bromine. Formation of 9a or b

Bromine (236 mg, 1.47 mmol) in carbon tetrachloride (1 ml) was added to the enedione (200 mg, 1.45 mmol) in carbon tetrachloride (1 ml) at −30°. The solution was allowed to warm to room temperature, during the course of which the orange color of the bromine faded. The solution was evaporated at 30° to give a viscous, light amber oil (430 mg). This was subjected to preparative t.l.c.; from the main band there was obtained the dibromide **9***a* or *b* (173 mg, 40%), m.p. 70–72°. Recrystallization from ether gave colorless prisms, m.p. 77–77.5°; λ_{max} 5.76, 9.25, 9.75, 10.36 μ; $\delta(CCl_4)$ 1.7–3.1 (m, 8 H), 4.1–4.6 (m, 1 H), 4.6–5.0 (m, 1 H); *m/e* 296, 298, 300.

Anal. Calcd. for $C_8H_{10}Br_2O_2$: C, 32.24; H, 3.38; Br, 53.63. Found: C, 32.43; H, 3.45; Br, 54.01.

Ketalization of 6.[5] *Formation of 11, 12, and 13*[6] *and their Reconversion to 6*

(a) Monoketal 11

The enedione **6** (2.00 g, 14.5 mmol) was dissolved in

[5]See, also, Table 1.

[6]See Table 2 for spectra of compounds **11**, **12**, and **13**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acetone ethylene ketal (18) (7.5 g, 72.5 mmol) in benzene (10 ml), and boron trifluoride etherate (0.5 ml) was added. The mixture was allowed to stand at 25° for 5 h, when v.p.c. (3% SE-30 on Chromosorb P, 10 ft × 0.25 in. copper column, 200°) indicated it to consist of the enedione **6**, the monoketal **11**, and the diketal **12**, in the ratio 14:65:21. The reaction mixture was poured into aqueous 5% sodium bicarbonate, and the mixture was extracted twice with dichloromethane. The extracts were shaken once with brine, dried, and evaporated to give a yellow oil (2.35 g). Recrystallization from dichloromethane–hexane gave sticky, off-white platelets which were sublimed at 60° (0.01 mm) to give the monoketal **11** as a snow white solid (689 mg, 26%), m.p. 58–62°. Resublimation gave short needles, m.p. 63.5–64.5°.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74. Found: C, 65.79; H, 7.61.

The monoketal **11** was unaffected by treatment with acetone containing catalytic amounts of boron trifluoride etherate or hydrochloric acid, but could be converted to the enedione **6** by treatment with aqueous acid (*vide infra*).

(b) Diketal ***12***

In a 500-ml, two-necked, round-bottomed flask fitted with a glass stopper and a Soxhlet extractor holding calcium hydride were placed the enedione **6** (19.48 g, 0.141 mol), ethylene glycol (53.59 g, 0.86 mol), *p*-toluenesulfonic acid (1.0 g), and dichloromethane (300 ml). The mixture was heated at reflux, and the reaction was monitored by withdrawing aliquots and quickly replacing the stopper; the aliquots were subjected without work-up to v.p.c. analysis (3% SE-30 on Chromosorb P, 10 ft × 0.25 in. copper column, 200°). After 12 days, more *p*-toluenesulfonic acid (1.0 g) was added, and after 14 days, a further 1-g portion was added. After 16 days the product mixture consisted of the monoketal **11**, diketal **12**, and diketal **13** in the ratio 7:91:2. The mixture was concentrated to 80 ml by distillation. The concentrate was shaken once with saturated aqueous sodium bicarbonate (80 ml) and once with water (80 ml) and the organic layer was dried. The resulting amber solution was passed through a column of basic alumina (Woelm, activity 1; 35 g, 6.5 × 3 cm) to give an almost colorless solution that was evaporated to give 27.8 g (87%) of diketal **12** (92% purity (v.p.c.)) as a pale yellow oil which soon crystallized. Recrystallization from hexane gave 24.4 g (76%) of **12**, m.p. 67.5–68°.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02; O, 28.29. Found: C, 64.03; H, 7.94; O, 28.59.

The diketal **12** could be readily converted to the monoketal **11** as follows. The diketal (50 mg), 4 *N* hydrochloric acid (6 ml) and ether (7 ml) were stirred at 23°. The reaction was monitored by withdrawing aliquots of the upper, ethereal layer, running these through a little magnesium sulfate, washing the drying agent with a dry ether, evaporating the combined, dried, ethereal solutions and recording the i.r. spectrum. After 2.5 h, the upper, ethereal layer was removed, and the aqueous layer was extracted once with ether. The combined ethereal solutions were shaken once with water and once with brine, and the organic layer was dried and evaporated to give a colorless oil (37 mg, 92%), the i.r. spectrum of which was identical with that of monoketal **11**. The oil was recrystallized from hexane to give rosettes of colorless elongated prisms (32 mg, 79%), m.p. 63–64°; mixed m.p. with monoketal **11** (m.p. 64–65°), 64–64.5°. The diketal **12** was also readily converted to **11** with acetone containing a little hydrochloric acid or boron trifluoride etherate, as shown by v.p.c. analyses; under these conditions **11** was not converted to the enedione **6** after several days.

The diketal **12** (40 mg), 6 *N* hydrochloric acid (5 ml), and ether (2.5 ml) were stirred at 23°. The reaction was monitored by withdrawing aliquots of the ethereal layer and subjecting them without work-up to v.p.c. analysis (3% SE-30 on Chromosorb P, 10 ft × 0.25 in. copper column, 200°). After 40 min the reaction mixture consisted of the enedione **6** and the monoketal **11** in the ratio 1:99; none of the diketal **12** was detected. After 63 h the ratio of **6** to **11** was 60:40. After 9 days the mixture contained only about 1% of **11**. The ethereal layer was extracted twice with dichloromethane, and the combined dichloromethane and ethereal solutions were washed once with water, dried, and evaporated to give **6** (20 mg, 83%) as a colorless oil which soon crystallized. The i.r. spectrum of this oil was very similar to that of pure **6**. Molecular distillation at 60°/10 mm gave a colorless oil shown to be **6** by i.r. and n.m.r. spectral comparison and by t.l.c. and v.p.c. analysis.

(c) Diketal ***13***

In a 100-ml, two-necked, round-bottomed flask fitted with a glass stopper and a Soxhlet extractor holding Linde type 4A molecular sieves, were placed the enedione **6** (1.00 g, 7.25 mmol), ethylene glycol (1.02 g, 16.4 mmol), *p*-toluenesulfonic acid (50 mg), and dichloromethane (70 ml). The mixture was heated at reflux, and the reaction was monitored by withdrawing a few drops of the solution and quickly replacing the stopper; the aliquot was evaporated and its i.r. spectrum was compared with that of a zero-time aliquot. After 71 h, the decrease in intensity of the carbonyl-stretching band appeared to have ceased. More ethylene glycol (0.5 g) and *p*-toluenesulfonic acid (50 mg) were added, and heating was continued. After 117 h, the carbonyl band was very weak. The nearly colorless solution was shaken with 70 ml of saturated aqueous sodium bicarbonate, and the organic layer was washed twice with water, dried, and evaporated to give a mushy, light yellow solid (1.27 g); λ_{max} 5.80 (vw), 8.5, 9.1, 9.2, 9.3 μ. Recrystallization from hexane gave diketal **13** as colorless platelets (211 mg, 13%), m.p. 118–121°. Further recrystallization gave **13**, m.p. 121–122°.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.70, H, 8.02. Found: C, 63.55; H, 7.92.

When the diketal **13** (3 mg) was dissolved in acetone (0.5 ml) and concentrated hydrochloric acid (1 drop) was added, t.l.c. indicated that comparable amounts of **13** and the enedione **6** were present after 5 h. Another drop of hydrochloric acid was added after 24 h. After 43 h at 23°, t.l.c. showed essentially only one spot, corresponding to **6**. The solution was evaporated to give an oil the i.r. spectrum of which was virtually identical with that of **6**. Treatment of **13** with acetone containing a catalytic quantity of boron trifluoride etherate also effected conversion to **6**.

Thioketalization of ***6****. Formation of* ***14***

A solution of **6** (103 mg, 0.75 mmol) in anhydrous ether (20 ml) was treated with 1,2-ethanedithiol (0.70 ml, 8.2 mmol) and boron trifluoride etherate (4 ml). After the mixture had stood at room temperature for 44 h it was diluted with ether and washed with dilute aqueous sodium hydroxide and water. The ethereal solution was dried and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

evaporated to give **14** as a pale yellow viscous oil (140 mg, 88%). Trituration with hexane–dichloromethane in a Dry Ice bath gave a solid, which was crystallized from hexane–ether to give colorless needles, m.p. 48–49°; λ_{max} 5.88 μ; δ 2.0–3.0 (m, 8 H), 3.23 (s, 4 H), 5.65 (m, 2 H); *m/e* 214.

Anal. Calcd. for $C_{10}H_{14}OS_2$: C, 56.03; H, 6.58; S, 29.92. Found: C, 56.00; H, 6.34; S, 29.96.

Extension of the reaction time to 116 h at room temperature or 70 h at reflux did not lead to further reaction of the monothioketal.

Bromination of ***12*** *with Pyridinium Perbromide or Bromine. Formation of* ***15***

In a 10-ml Erlenmeyer flask were placed the diketal **12** (200 mg, 0.885 mmol), pyridinium perbromide ("pyridinium hydrobromide perbromide") (283.5 mol), and hexane (6 ml). The flask was stoppered and the mixture was stirred at 23° for 70 min, during the course of which the red color of the perbromide faded. When the contents of the flask had become almost colorless, starch–iodide paper showed the absence of perbromide. The mixture was filtered and the pyridinium bromide (146 mg, 104%) was washed well with hexane. The combined hexane solutions were concentrated and warmed to dissolve the solid that separated. On standing the solution deposited **15** as colorless needles (266 mg, 94%), m.p. 76–77.5°; λ_{max} 9.48 μ; δ 1.7–2.6 (m, 8 H), 3.3–3.6 (m, 2 H), 3.6–4.4 (m, 7 H), 4.4–4.8 (m, 1 H); *m/e* 384, 386, 388.

Anal. Calcd. for $C_{12}H_{18}Br_2O_4$: C, 37.33; H, 4.70; Br, 41.40. Found: C, 37.14; H, 4.84; Br, 41.60.

When **12** was treated with bromine in carbon tetrachloride, evaporation of the solution gave an oil, whose i.r. spectrum was virtually identical with that of **15**.

Dehydrobromination of ***15****. Formation of* ***16***

In a 50-ml Erlenmeyer flask were placed **15** (386 mg, 1.00 mmol), potassium *t*-butoxide (229 mg, 2.04 mmol), and ether (20 ml). The flask was stoppered and the mixture was stirred at 23° for 30 min, when t.l.c. indicated that no starting material was present. The mixture was washed with water (20 ml) and with brine (50 ml), dried, and evaporated to give **16** (297 mg, 98%) as a colorless oil which soon crystallized. Recrystallization from hexane gave colorless needles (182 mg, 61%), m.p. 81–82°; λ_{max} 6.13 (m), 9.36 (sh), 9.44 μ; δ 1.6–2.8 (m, 8 H), 3.7–4.2 (m, 6 H), 4.41 (d, $J = 14$ Hz, 1 H), 4.6–4.9 (m, 1 H), 6.64 (dd, $J = 6.5$, 14 Hz, 1 H); *m/e* 304, 306.

Anal. Calcd. for $C_{12}H_{17}BrO_4$: C, 47.23; H, 5.62; Br, 26.19. Found: C, 47.13; H, 5.56; Br, 26.37.

Hydrolysis of ***15****. Formation of* ***17***

Compound **15** (300 mg), methanol (10 ml), and 5 *N* hydrochloric acid (5 ml) were heated at reflux. The reaction was monitored by withdrawing aliquots, evaporating them, evacuating at < 1 mm to remove water, and recording the i.r. spectra and thin layer chromatograms of the residues. After 48 h, 3 ml of concentrated hydrochloric acid was added. After 5 days, t.l.c. showed mainly one spot, of lower mobility than **15**. Aqueous work-up gave **17** as a colorless oil (137 mg, 75%). Crystallization from dichloromethane–hexane gave colorless prisms, m.p. 91–100°; on recrystallization the melting point varied erratically, although it was always in the range 80–100°. The compound showed one spot on t.l.c. Sublimation at 90° (0.01 mm) gave a colorless solid, m.p. 75–81°; λ_{max} 2.95 (m), 5.83 μ; δ 1.7–3.0 (m, 8 H), 4.0–5.0 (m, *ca.* 3 H); *m/e* 234, 236.

Hydrolysis of ***16****. Formation of Acetaldehyde and* ***17***

In a 50-ml two-necked flask fitted with a nitrogen inlet tube and a condenser were placed **16** (315 mg, 1.03 mmol), methanol (10 ml), and 5 *N* hydrochloric acid (5 ml). The mixture was heated at reflux for 2.5 h while a slow stream of nitrogen was passed through the flask and the condenser into two testtubes, each holding a solution of 2,4-dinitrophenylhydrazine (200 mg, 1.0 mmol) in methanol (8 ml) containing concentrated sulfuric acid (20 drops). Yellow needles were deposited in the first, but not the second, of these tubes. After 1.5 h the tubes were interchanged, but no solid was deposited in the tube that held the clear dinitrophenylhydrazine solution after a further 1 h; however, t.l.c. showed that acetaldehyde 2,4-dinitrophenylhydrazone was present in solution. The yellow needles (93 mg), m.p. 147–149°, were collected by filtration. Recrystallization from methanol gave yellow needles, m.p. 166.5–168°, identified as acetaldehyde 2,4-dinitrophenylhydrazone by mixed m.p. 167–168° with an authentic sample (m.p. 167–168°), and by i.r. spectral and t.l.c. comparison. Further acetaldehyde 2,4-dinitrophenylhydrazone (132 mg; total yield of crude product, 97%) could be isolated by aqueous work-up of the filtrate from the tube containing the crystalline product and the clear solution from the other tube.

Aqueous work-up of the reaction mixture from the hydrolysis of **16** gave **17** as a turbid oil (236 mg, 98%). Crystallization from dichloromethane–hexane gave colorless prisms, m.p. 83–95°; the m.p. varied erratically on further crystallization, but remained in the range 80–95°. This compound was identical with that obtained above by hydrolysis of the dibromide **15**.

Bromination of ***12*** *with N-Bromosuccinimide or 1,3-Dibromo-5,5-dimethylhydantoin. Formation of* ***19***

The diketal **12** (505 mg, 2.23 mmol), *N*-bromosuccinimide (829 mg, 4.65 mmol), azobisisobutyronitrile (26 mg), and carbon tetrachloride (25 ml) were heated at reflux under a drying tube for 1 h. The mixture was allowed to cool and the opalescent solution was filtered through a plug of glass wool. The filtrate was evaporated, and the residue was freed of β-bromopropionyl isocyanate (19) at 23° (0.1 mm). The resulting colorless oil was swirled with carbon tetrachloride, and the cloudy solution was passed through a short column of basic alumina (Woelm activity, grade 1; 5 g, 10 × 0.7 cm). The eluate was evaporated to give the bromo compound **19** as a colorless oil (501 mg, 74%) that partially crystallized on standing. Recrystallization from hexane gave colorless prisms, m.p. 102–103°; δ 1.45–3.0 (m, 6 H), 3.8–4.3 (m, 8 H), 4.8–5.55 (m, 1 H), 5.6–6.0 (m, 2 H); *m/e* 304, 306.

Anal. Calcd. for $C_{12}H_{17}BrO_4$: C, 47.23; H, 5.62; Br, 26.19. Found: C, 47.14; H, 5.52; Br, 26.24.

Similar treatment of **12** with 1,3-dibromo-5,5-dimethylhydantoin and azobisisobutyronitrile in hexane also gave **19**. With this reagent, as with *N*-bromosuccinimide, the yields of **19** were very variable, and were considerably reduced when the scale of the reaction was increased. Chromatography of a crude reaction product mixture that was shown by p.m.r. spectroscopy to contain a low proportion of **19** was carried out on basic alumina (Woelm activity, grade 1) in carbon tetrachloride. Elution with this solvent followed

by 10–50% dichloromethane in carbon tetrachloride gave in addition to **19**, the dibromo compound, **15***a* (or *b*), obtained from the reaction of **12** with pyridinium perbromide, and another dibromo compound, **15***b* (or *a*), which was obtained as colorless broad needles, m.p. 80–81°, after crystallization from hexane; δ 1.7–2.6 (m, 8 H), 3.3–3.6 (m, 2 H), 3.8–4.5 (m, 8 H).

Anal. Calcd. for $C_{12}H_{18}Br_2O_4$: C, 37.33; H, 4.70; Br, 41.40. Found: C, 37.48; H, 4.62; Br, 41.30.

Dehydrobromination of ***19****. Formation of* ***20***

A 50-ml, two-necked flask fitted with a septum cap and a nitrogen inlet tube connected to a mercury bubbler was flame-dried at 20 mm, and the hot flask was filled with nitrogen by admitting nitrogen and evacuating three times. In the flask were quickly placed a magnetic stirring bar and potassium *t*-butoxide (355 mg, 3.18 mmol). The flask was again evacuated and filled with nitrogen twice. Dimethyl sulfoxide (Fisher Certified, dried with molecular sieves; 10 ml) was injected through the septum cap and the mixture was stirred to dissolve the potassium *t*-butoxide, and then the bromo compound **19** (674 mg, 2.21 mmol) in dimethyl sulfoxide (10 ml) was injected. The reaction mixture was stirred under nitrogen at 23° for 12 h. Aqueous work-up gave the crude diene **20** as a yellow oil (390 mg, 79%). This was chromatographed on a column of basic alumina (Woelm activity, grade 1; 9.5 × 1.0 cm). Elution with benzene gave **20** as a colorless, mobile liquid (238 mg, 48%). The crude diene could also be purified by molecular distillation at 80° (0.01 mm). This gave a colorless mobile liquid; λ_{max} 6.14 μ (w); λ_{max} (C_6H_{14}) 230 mμ (ε 4300); δ (CCl_4) 2.1–2.7 (4 H), 3.8–4.05 (m, 8 H), 5.65–6.0 (m, 4 H); *m/e* 224.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.23; H, 7.48.

When **19** was subjected to v.p.c. (10% SE-30 on Chromosorb P, 10 ft × 0.25 in. copper column, 200°) it decomposed, giving rise to four peaks. The material corresponding to the peak of shortest retention time (28%) was collected. It was shown to be **20** by i.r. spectral, v.p.c., and t.l.c. comparison.

1,2-Cyclooctanedione Diketal ***21***

The diketal **12** (207 mg) in ethyl acetate (3 ml) was hydrogenated over 10% palladium/charcoal at room temperature and atmospheric pressure. After 2.5 h 1 *M* equiv of hydrogen had been taken up and there was no further uptake. Filtration and evaporation of the solution followed by evacuation at 0.01 mm for 5 min gave **21** (169 mg, 81%) as a colorless oil; λ_{max} 8.46, 9.22, 9.54, 10.52 μ; δ 1.4–2.0 (m, 12 H), 3.7–4.0 (m, 8 H).

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83. Found: C, 63.28; H, 8.90.

Hydrogenation of the diketal **20** under the same conditions gave a colorless oil (87%) with an i.r. spectrum very similar to that of the product from **12**, but with an additional weak band at 5.74 μ. Preparative v.p.c. (10% SE-30 on Chromosorb P, 200°) gave a product that was shown to be **21** by i.r. and p.m.r. spectral comparison and by mixed v.p.c. and t.l.c. analysis.

Treatment of 1,2-cyclooctanedione with ethylene glycol and *p*-toluenesulfonic acid in dichloromethane as for the ketalization of **6** to **12** gave a product mixture that was shown by v.p.c. analysis to consist largely of one component. Isolation of this by preparative v.p.c. (10% SE-30 on Chromosorb P, 200°) gave a colorless oil that was shown to be **21** as before.

Primary Yields and Mechanisms in the Radiolysis of N_2O from High Intensity Electron Pulse Irradiations of N_2O–O_2 Mixtures[1]

C. WILLIS,[2] A. W. BOYD, AND P. E. BINDNER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received November 15, 1971

The yields of N_2, O_2, NO, and O_3 have been measured from the Febetron radiolysis of N_2O–O_2 mixtures with and without SF_6. A mechanism consistent with the yields from 0–100% O_2 and with known ionic abundances and reaction rate data has been derived. The major features of this mechanism are both dissociative neutralization of N_2O^+ and excitation of N_2O to give $N_2(X^1\Sigma)$ and $O(^1D)$ and smaller amounts of $N_2(B^3\Pi)$ and $O(^3P)$. The large yields of NO and N_2 observed are mainly due to reaction of $O(^1D)$ with N_2O to give both N_2 and O_2 and NO.

Les rendements en N_2, O_2 et NO et O_3 ont été mesurés à partir de la radiolyse Febetron des mélanges de N_2O–O_2 avec et sans SF_6. Un mécanisme tenant compte des rendements de 0 à 100% en O_2, des abondances ioniques connues et des données cinétiques de la réaction, a été déduit. Les caractéristiques majeures de ce schéma sont à la fois une neutralisation dissociative de N_2O^+ et une excitation de N_2O pour donner $N_2(X^1\Sigma)$ et $O(^1D)$ ainsi que des quantités plus faibles en $N_2(B^3\Pi)$ et $O(^3P)$. Les rendements élevés en NO et N_2 obtenus sont dus essentiellement à la réaction de $O(^1D)$ avec N_2O qui conduit à N_2, O_2 et NO.

Canadian Journal of Chemistry, **50**, 1557 (1972)

Introduction

The radiolytic behavior of nitrous oxide has been extensively investigated (1–11) but the identities and yields of the primary species and the mechanisms leading to the stable products are still uncertain. Nitrous oxide dissociates to give nitrogen atoms, oxygen atoms, nitrogen molecules, and nitric oxide molecules in various energy states but because of their high reactivity with N_2O most of these species are not easily scavenged.

A second more general problem is that of determining which ionic reactions occur. In gas phase radiolysis at conventional low dose rates (10^{16}–10^{20} eV g^{-1} s^{-1}) a variety of ion–molecule reactions often occur before charge neutralization so that the primary ionic species cannot easily be related to product yields. The ionic behavior of nitrous oxide is further complicated by dissociative electron attachment.

We have previously shown (11, 12) that at the very high dose rates (10^{26}–10^{28} eV g^{-1} s^{-1}) from Febetron pulses the reduction in ion-lifetime with respect to neutralization eliminates many ion–molecule reactions and allows identification of the neutralization products of the primary ions. In this work the reduction at high dose rates in the stable product yields on the addition of SF_6 is assumed to be due to the suppression of dissociative neutralization of the primary positive ions. This has been shown to be the most probable behavior of SF_6 in a number of gaseous systems. We have determined the reduction in the product yields of N_2O on the addition of SF_6 at high dose rates (11, 13). These results combined with the mass spectrum of N_2O (from conventional mass spectrometry) and ion–molecule reaction rate data do give some information as to the products of the neutralization reactions but not enough to obtain the yields of the primary species.

The approach taken in the present work was to measure the ozone yield in N_2O–O_2 mixtures with and without SF_6. Although this is very complicated in continuous irradiation it can be done easily for single Febetron pulses. This allows us to distinguish $O(^1S)$, $O(^1D)$ and $O(^3P)$ oxygen atoms. It is known that both singlet states react rapidly with N_2O whereas the triplet ground state does not.

These data, taken in conjunction with the extensive work of Young, Black, and Slanger (14–19) on the photochemistry of N_2O and on the behavior of the various species formed, have allowed us to present a fairly complete mechanism for the radiolytic behavior of N_2O and N_2O–O_2 mixtures and also to add to our understanding of the radiolytic behavior of O_2.

Experimental

Irradiations

The irradiation source used, a Febetron 705,[3] has been described previously (20, 21). For the determination of nitrogen, oxygen, and nitrite yields the samples were irradiated in quartz cells (22). The ozone yields were determined using a stainless steel optical cell with internal mirrors and a conventional optical detection system (23). The quartz cells had volumes of 80 ml and the average dose in these was 10^{20} eV g^{-1}. The volume of the optical cell was 1 l and the average dose 10^{19} eV g^{-1}.

Dosimetry

The dose in the quartz cells was determined by irradiations of pure N_2O at 1 atm pressure taking $G(N_2) = 12.4 \pm 0.3$. This value has previously been determined absolutely for the conditions of the experiments by adiabatic calorimetry (24, 25). The dose in the optical system was determined by irradiations of pure oxygen between 200 and 600 Torr taking $G(O_3) = 12.8 \pm 0.6$ (26–29).

Analyses

N_2, O_2

These were determined for pure N_2O using a McLeod gauge and a calibrated CEC 610 mass spectrometer. In the N_2O–O_2 mixtures, nitrogen was determined by gas chromatography using a 15C Loenco gas chromatograph with a Linde 5X molecular sieve column and thermal conductivity detection.

NO, NO_2

The NO formed in both N_2O and N_2O–O_2 was converted to NO_2 before analysis by freezing in liquid N_2. The NO_2 was measured using the method of Shinn (30). Our use of this method has been previously described (31).

O_3

The ozone from N_2O–O_2 mixtures was determined optically at 254 nm (32). The concentration of ozone in the optical cell was measured at three different times after the pulse: at ~10 ms, this gave the ozone yields, $G(O_3)_0$, prior to any appreciable reaction with NO; at ~10 s, this gave the ozone yield, $G(O_3)_i$, after all the NO in the system had reacted; and at ~30 min, this gave the ozone yield, $G(O_3)_f$, after the reaction with NO_2 was complete but before any appreciable thermal decomposition of O_3.

[1] $$NO + O_3 \rightarrow NO_2 + O_2$$
$$k_1 = 1.25 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \quad (33)$$

[2] $$NO_2 + O_3 \rightarrow NO_3 + O_2$$
$$k_2 = 7 \times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \quad (33)$$

Materials

The N_2O, O_2, and SF_6 were all Matheson C.P. grade. For the N_2, O_2, and nitrite determinations the N_2O and SF_6 were freed of permanent gases by several freeze–pump–thaw cycles. No difference in O_3 yields was observed using both purified N_2O and SF_6 and these gases taken directly from the tank. The reagents used in the nitrite determination were aqueous solutions of Fisher (Reagent grade) *N*-naphthylethylenediamine dihydrochloride 0.1%, Eastman Organic Chemicals (C.P.) sulfanilamide 0.2%, and Anachemia (Reagent Grade) HCl 5 *N* solution.

[3]Manufactured by Field Emission Corporation, McMinnville, Oregon, U.S.A.

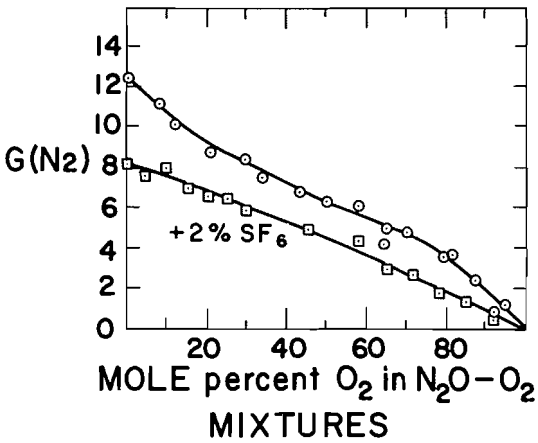

FIG. 1. Nitrogen yields from the Febetron radiolysis of N_2O–O_2 mixtures at 2×10^{27} eV g^{-1} s^{-1}, 700 Torr, and 25 °C.

Results

N_2 Yields

The nitrogen yield from pure N_2O is $G(N_2) = 12.4$ and this is reduced to $G(N_2) = 8.1$ on the addition of SF_6. The nitrogen yields in N_2O–O_2 mixtures are shown in Fig. 1.

O_2 Yield

The residual yield of O_2 in pure N_2O is $G(O_2)_r = 2.1 \pm 0.2$ as determined by mass spectrometry and gas chromatography. This oxygen yield is measured after all nitric oxide has reacted to give nitrogen dioxide.

[3] $$2NO + O_2 \rightarrow 2NO_2$$

[3*a*] $$NO + O \rightarrow NO_2$$

This oxygen yield, taken in conjunction with the nitrogen yield, by mass balance for the three product system N_2, O_2, NO_2 gives $G(NO_2)_r = 5.5$.

$$G(NO_2)_r = \tfrac{2}{3}(G(N_2) - 2G(O_2)_r)$$

Assuming all the nitrogen dioxide originates via reaction 3 or 3*a*, the initial oxygen yield formed in the radiolysis can be calculated by mass balance to be $G(O_2)_i = 4.8$.

$$G(O_2)_i = \tfrac{1}{2}(G(N_2) - \tfrac{1}{2}G(NO))$$

where
$$G(NO) = G(NO_2)_r = 5.5$$

In the presence of SF_6 the measured yield of O_2 is $G(O_2)_r \approx 1.0$ and hence for the three product system N_2, O_2, NO the initial yields are $G(O_2)_i \approx 3$, $G(NO) \approx 4$.

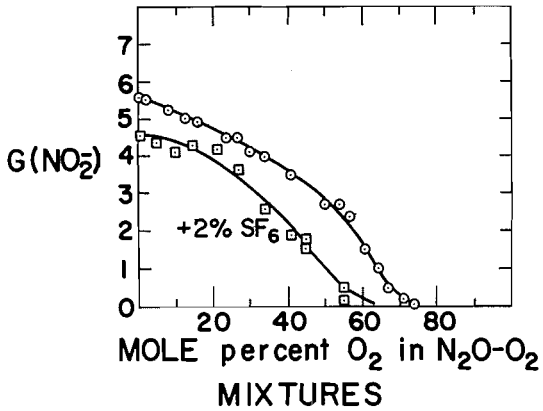

FIG. 2. Nitrite yields from the Febetron radiolysis of N_2O–O_2 mixtures at 2×10^{27} eV g^{-1} s^{-1}, 700 Torr, and 25 °C.

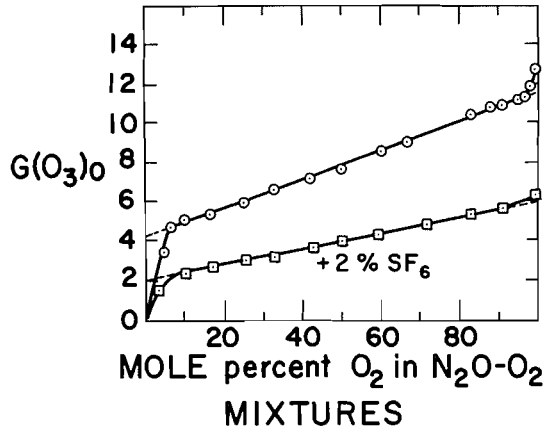

FIG. 4. Initial ozone yields in the Febetron radiolysis of N_2O–O_2 mixtures at 2×10^{26} eV g^{-1} s^{-1}, 700 Torr, and 25 °C.

NO Yields

Assuming no NO_2 is formed initially, the yield of NO from pure N_2O from the analysis of nitrite ion is $G(NO) = 5.6$ in good agreement with that derived from the residual O_2 yield. In N_2O–SF_6 this yield is reduced to $G(NO) = 4.6$ in fair agreement with the O_2 measurements.

In the N_2O–O_2 mixtures we tried to determine the NO yield from both nitrite measurements and the difference in O_3 yields ($G(NO) = G(O_3)_0 - G(O_3)_i$). The results are shown in Figs. 2 and 3. As can be seen the two sets of values do not agree. In the presence of O_3 the NO_2 formed in reaction 1 will react as in reaction 2.

[2] $$NO_2 + O_3 \rightarrow NO_3 + O_2$$

The lower yields obtained by the nitrite method can then be explained by the disappearance of NO_3 in reaction 4

[4] $$NO_3 + NO_2 \rightarrow N_2O_5$$

In the presence of SF_6 neither method appears to be reliable. Again, assuming no NO_2 is formed initially the yields of NO from the O_3 difference measurements $G(NO) \approx 1$ are much lower than those obtained from nitrite measurements and this implies that SF_6 interferes with the analytical method using O_3 yield differences.

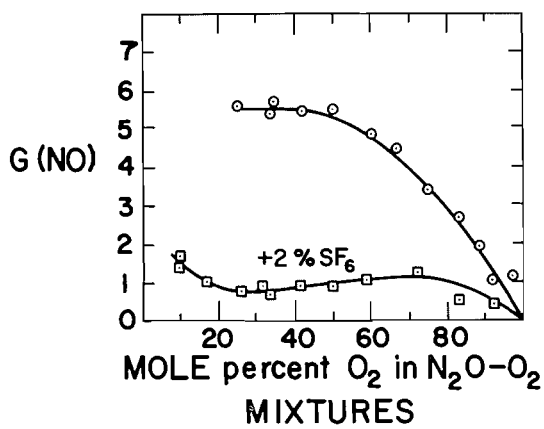

FIG. 3. Nitric oxide yields from the difference in O_3 yields from the Febetron radiolysis of N_2O–O_2 mixtures at 2×10^{26} eV g^{-1} s^{-1}, 700 Torr, and 25 °C.

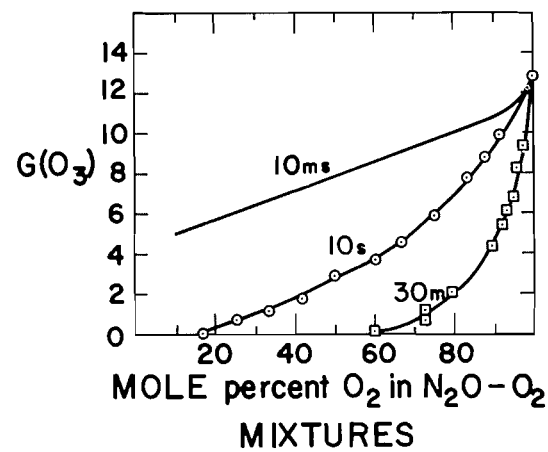

FIG. 5. Ozone yields in the Febetron radiolysis of N_2O–O_2 mixtures at 2×10^{26} eV g^{-1} s^{-1}, 700 Torr, and 25 °C at different times after the pulse.

TABLE 1. Stable product yields in the radiolysis of N_2O and N_2O–SF_6

Parameter	Value		
	Pure N_2O	$N_2O + SF_6$	ΔG
Dose rate = 10^{26}–10^{27} eV g^{-1} s^{-1}			
$G(N_2)$	12.4±0.3	8.1	4.3
$G(O_2)$	4.8	2.9	1.9
$G(NO)$	5.6	4.6	1.0
$G(-N_2O)$	15.2	10.4	4.8
$G(O_3)_0$ (extrapolated)	4.3	1.9	2.4
Dose rate = 10^{16} eV g^{-1} s^{-1}			
$G(N_2)$	10.0	8.1	1.9
$G(O_2)$	3.8	3.2	0.6
$G(NO)$	5.1	3.3	1.8
$G(-N_2O)$	12.5	9.7	2.8

The ozone yields determined from measurement of the ozone concentration at 10 ms after the electron pulse, $G(O_3)_0$, are shown in Fig. 4. As can be seen, the intercepts with the yield axis for pure N_2O extrapolated from intermediate concentrations of O_2 are 4.3 G units in the absence and 1.9 G units in the presence of SF_6.

Figure 5 gives the ozone yields at the three times described above. Using kinetic photometry the decrease in the ozone concentration as a function of time due to reaction with NO_2 was measured in the range 10–1000 s. The order of the disappearance reaction was greater than 1 and the half-life was ~200 s. The rate appeared to be inversely proportional to pressure over the range 300–1000 Torr.

Discussion

The discussion of the results will be in two parts, pure N_2O and N_2O–O_2 mixtures.

Pure N_2O

Our high dose rate yields of stable products from pure N_2O are given in Table 1 along with the yields obtained at low dose rates by Takao and Shida (8). Their values for pure N_2O are in good agreement with those of Jones and Sworski (5). Also included in this table are the values of $G(O_3)_0$ extrapolated from intermediate concentrations of oxygen to pure N_2O. As will become evident from the following discussion, this extrapolated ozone yield is considered to be a direct measure of the yield of oxygen atoms in a ^3P state.

To use the values from Table 1 to determine the yields of primary species and the mechanisms in N_2O radiolysis it is necessary to consider the possible ionic and neutral species. Reactions of ionic species and neutral species relevant to both pure N_2O and N_2O–O_2 mixtures are listed in Tables 2 and 3. These will be discussed in detail in the following sections.

Ionic Processes

The energy required to form an ion pair in nitrous oxide is 32.9 eV (34) and hence $G(e^-) = 3.05$. Taking this value in conjunction with mass spectrometrically measured abundances (35), the yields of the primary positive ions are as follows:

[5] $N_2O \rightarrow N_2O^+ + e$ $\quad G = 1.90$

[6] $N_2O \rightarrow NO^+ + N + e$ $\quad G = 0.59$

[7] $N_2O \rightarrow N^+ + NO + e$ $\quad G = 0.25$

[8] $N_2O \rightarrow N_2^+ + O + e$ $\quad G = 0.21$

[9] $N_2O \rightarrow O^+ + N_2 + e$ $\quad G = 0.10$

The low ionization potential of nitric oxide ($I.P.$ $(NO^+) = 9.25$ eV (36)) precludes any charge transfer from this ion to N_2O ($I.P.$ $(N_2O^+) = 12.88$ eV (36)) and we must assume NO^+ ions survive to be neutralized by a negative ion. N^+ ions, formed in reaction 7, will react with N_2O to give NO^+ and N_2, as in reaction 10

[10] $N^+ + N_2O \rightarrow NO^+ + N_2$

N_2^+ ions can react with N_2O in two ways, reactions 11 and 12

[11] $N_2^+ + N_2O \rightarrow NO^+ + N_2 + N$

[12] $N_2^+ + N_2O \rightarrow N_2O^+ + N_2$

O^+ ions can also react in two ways, reactions 13 and 14

[13] $O^+ + N_2O \rightarrow N_2O^+ + O$

[14] $O^+ + N_2O \rightarrow N_2 + O_2^+$

but because of the low yield of O^+ and the low value of k_{14} reaction 14 will be neglected.

These are the only ion–molecule reactions expected to occur in the single pulse, high dose rate radiolysis of pure N_2O. As we have discussed previously (11) the rate constant for the attachment of the electron to N_2O is far too low for this reaction to compete with neutralization even at atmospheric pressure for Febetron dose rates. Similarly any ionic reactions with

TABLE 2. Ionic reactions relevant to N_2O and N_2O–O_2 mixtures

Reaction	Rate constant (cm^3 molecule^{-1} s^{-1})	Reference

products including those suggested by Gorden and Ausloos (4) can be neglected at these dose rates. Thus before neutralization the yields of species from reactions 5–14 should be those given in Table 4.

Consider, now, how the yields of the ionic and neutral species in Table 4 can be related to the product yields in Table 1. The addition of SF_6 will be assumed to suppress dissociative neutralization.

The two positive ions, resulting from primary ionic processes, are NO^+ and N_2O^+. The neutralization of NO^+ by a free electron is certainly dissociative and may give both $N(^2D)$ and $N(^4S)$ nitrogen atoms (37). Considering the energy level diagram of Gilmore (38), the most probable neutralization reactions are

[15] $NO^+ + e \rightarrow N(^2D) + O(^3P)$

[16] $NO^+ + e \rightarrow N(^4S) + O(^1D)$

The $N(^2D)$ atoms will then react with N_2O via reaction 17 and the $O(^1D)$ atoms via reactions 18 and 19.

[17] $N(^2D) + N_2O \rightarrow N_2 + NO$

[18] $O(^1D) + N_2O \rightarrow N_2 + O_2$

[19] $O(^1D) + N_2O \rightarrow 2NO$

The products of the neutralization of N_2O^+ by a free electron are not known nor is a detailed energy level diagram of N_2O available. Possible neutralization reactions are

[20] $N_2O^+ + e \rightarrow N_2(X^1\Sigma) + O(^1D)$ (or $O(^1S)$)

[21] $N_2O^+ + e \rightarrow N_2(B^3\Pi) + O(^3P)$

[22] $N_2O^+ + e \rightarrow N(^2D) + NO(X^2\Pi)$

[23] $N_2O^+ + e \rightarrow N_2(A^3\Sigma) + O(^3P)$

[24] $N_2O^+ + e \rightarrow N(^4S) + NO$

Since $N(^4S)$ will react very rapidly with NO to form $N_2(X^1\Sigma)$ and $O(^3P)$, via reaction 25

[25] $N(^4S) + NO \rightarrow N_2(X^1\Sigma) + O(^3P)$

TABLE 5. Neutralization reactions in pure N_2O

	Reaction	Yield
[15]	$NO^+ + e \rightarrow N(^2D) + O(^3P)$	a
[16]	$NO^+ + e \rightarrow N(^4S) + O(^1D)$	b
[20]	$N_2O^+ + e \rightarrow N_2(X^1\Sigma) + O(^1D)$	c
[21]	$N_2O^+ + e \rightarrow N_2(B^3\Pi) + O(^3P)$	d
[22]	$N_2O^+ + e \rightarrow N(^2D) + NO$	e
[23]	$N_2O^+ + e \rightarrow N_2(A^3\Sigma) + O(^3P)$	f
[17]	$N(^2D) + N_2O \rightarrow N_2 + NO$	$a + e$
[18]	$O(^1D) + N_2O \rightarrow N_2 + O_2$	$\frac{1}{2}(b + c)$
[19]	$O(^1D) + N_2O \rightarrow 2NO$	$\frac{1}{2}(b + c)$
[27]	$N_2(B^3\Pi) + N_2O \rightarrow 2N_2(X^1\Sigma) + O(^3P)$	d
[26]	$N_2(A^3\Sigma) + N_2O \rightarrow N_2(X^1\Sigma) + N_2O$	f
[29]	$NO^+ + SF_6^- \rightarrow NO\ (+ SF_6)$	
[30]	$N_2O^+ + SF_6^- \rightarrow N_2O\ (+ SF_6)$	

the extent of the various reactions. Table 5 shows a listing of the processes associated with neutralization. From this we can derive the following relationships[4]

$$\Delta G(N_2) = 4.3 = a + \frac{3b}{2} + \frac{3c}{2} + 2d + e + f$$

$$\Delta G(NO) = 1.0 + 0.93 = a + c + 2e$$

$$\Delta G(O(^3P)) = 2.4 = a + b + 2d + f$$

$$\Delta G(N_2O^+) = 2.12 = c + d + e + f$$

$$\Delta G(NO^+) = 0.93 = a + b$$

The equivalent equation for $\Delta G(O_2)$ is not a further equation as it can be considered to have been derived by mass balance. Thus we have 6 unknown parameters and only 5 equations and a unique solution is not possible. The relationships which can be uniquely derived are as follows: from neutralization

$$G(N_2(A^3\Sigma)) = f = 0.37$$

$$G(N_2(B^3\Pi)) = d = 0.55$$

$$G(O(^1D)) = (b + c) = 1.40$$

$$G(N(^2D)) = (a + e) = 0.73$$

and

$$c + e = 1.20$$

As will be shown below, very little $N(^2D)$ is formed from N_2O by direct excitation (less than 1%). If we assume that very little is formed by neutralization reactions, *i.e.* $e \approx 0$, then we can obtain a complete solution giving

$$a = 0.73$$

$$b = 0.20$$

$$c = 1.20$$

Neutral Processes

The measured product yields from N_2O–SF_6 mixtures are

$$G(N_2) = 8.1$$

$$G(O_2) = 2.9$$

$$G(NO) = 4.6$$

and

$$G(O^3P) = 1.8$$

The contributions from ionic processes other than neutralization are (see Table 4)

$$G(N_2) = 0.56$$

$$G(NO) = 0.25$$

$$G(O\ \text{atoms}) = 0.31$$

$$G(N\ \text{atoms}) = 0.68$$

[4]Reaction 25 adds $\frac{1}{2}b$ to $\Delta G(N_2)$, eliminates b from $\Delta G(NO)$ and adds b to $\Delta GO(^3P)$.

If we assume both N atoms and O atoms are in their ground states, ^4S and ^3P, respectively, then all $N(^4S)$ will react with NO, as in reaction 25. The net contributions from neutral dissociation will be

$$G(N_2)_n = 8.1 - 1.24 = 6.86$$

$$G(NO)_n = 4.6 + 0.68 - 0.25 - 0.93 = 4.10$$

$$G(O_2)_n = 2.9 - 0.5 = 2.40 - \tfrac{1}{2}G(O^3P) = 2.00$$

$$G(O(^3P))_n = 1.8 - 0.99 = 0.81$$

where the -0.93 contribution to $G(NO)_n$ comes from reaction 29.

Using a similar argument to that used when discussing neutralization reactions for N_2O^+, possible distinguishable dissociations are

[31] $N_2O \rightsquigarrow N_2(X^1\Sigma) + O(^1D)$ (or ^1S)

[32] $N_2O \rightsquigarrow N_2(A^3\Sigma) + O^3(P)$

[33] $N_2O \rightsquigarrow N_2(B^3\Pi) + O^3(P)$

[34] $N_2O \rightsquigarrow N(^2D) + NO$

Taking the yields of these reactions to be g, h, i, and j, respectively and using the reaction data of the species involved the following relationships can be derived

$$G(N_2)_n = 6.86 = \tfrac{3}{2}g + h + 2i + j$$

$$G(NO)_n = 4.10 = 2j + g$$

$$G(O_2)_n = 2.00 = \tfrac{1}{2}g$$

$$G(O(^3P))_n = 0.81 = h + 2i$$

Again, solving these equations simultaneously, we do not get a complete solution. We get

$$g = 4.00, \quad (h + i) = 0.81, \quad \text{and} \quad j = 0.05$$

This implies that, only 1% of the neutral dissociative excitation process yields $N(^2D)$ + NO ($j = 0.05$). Thus, as stated the parallel dissociation occurring in neutralization would not be expected to be very large and will be neglected giving a unique solution to simultaneous equations for neutralization.

The same argument cannot be used to resolve h and i for the neutral dissociative processes. Formation of $N_2(B^3\Pi)$ followed by subsequent reaction with N_2O cannot be distinguished from direct formation of $N_2(A^3\Sigma)$ followed by simple quenching. To that extent, differentiation becomes somewhat academic and we shall arbitrarily assume that no $N_2(B^3\Pi)$ is formed *i.e.* $i = 0$.

TABLE 6. Overall mechanism for N_2O radiolysis

Reaction		G
$N_2O \rightsquigarrow N_2O^+ + e$		1.90
$NO^+ + N + e$		0.59
$N^+ + NO + e$		0.25
$N_2^+ + O + e$		0.21
$O^+ + N_2 + e$		0.10
	Total	3.05
$N_2O \rightsquigarrow N_2(X^1\Sigma) + O(^1D)$		4.00
$N_2(A^3\Sigma) + O(^3P)$		0.81
$N(^2D) + NO(X^2\Pi)$		0.05
	Total	4.86

The primary yields for pure N_2O are given in Table 6. These species react as in Table 5 to give the observed stable product yields.

N_2O–O_2 Mixtures

The value of W for O_2 is 30.6 eV/ion pair (39) and from mass spectrometric results (see refs. 37–43 in ref. 27) the yields of reactions 35 and 36 are

[35] $O_2 \rightsquigarrow O_2^+ + e$ $\quad G = 3.17$

[36] $O_2 \rightsquigarrow O^+ + O + e$ $\quad G = 0.1$

The total yield of O atoms from direct excitation in O_2 is 6.2 (27). Small amounts of N_2O added to oxygen decrease the measured ozone yield by about 1.0 G unit. Since the ionization potential of N_2O is greater than that of O_2 this decrease cannot be due to charge exchange. But, as the data listed in Table 3 show $O(^1S)$ reacts about 100 times faster with N_2O than with O_2. This decrease can therefore be taken as a measure of the $O(^1S)$ yield in pure oxygen radiolysis. The equivalent results in O_2–SF_6 mixtures give a decrease in yield with N_2O of ~ 0.3 G units. Thus, it would seem that there is a neutralization yield of $O(^1S)$ from oxygen of $G(O(^1S))_{ionic} = 0.7$.

If we assume that both direct excitation and neutralization yield one singlet state oxygen atom and one triplet state oxygen atom, then the yields from oxygen would be

Neutralization

[37] $O_2^+ + (O_2^-) \rightarrow O_2 + O^1D + O^3P$
$G = 2.57 \quad 2.57$

[38] $O_2^+ + (O_2^-) \rightarrow O_2 + O^1S + O^3P$
$G = 0.7 \quad 0.7$

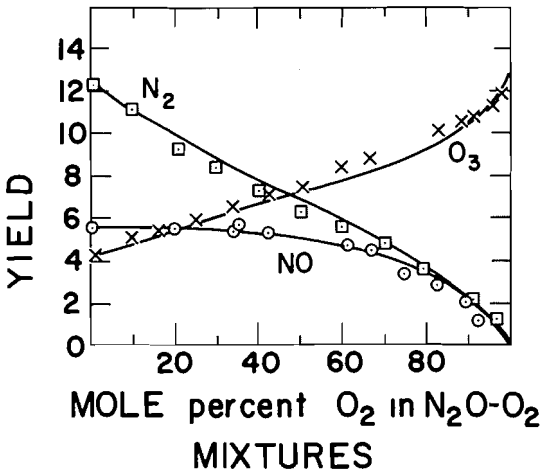

FIG. 6. Comparison of experimental and calculated yields in the Febetron radiolysis of N_2O–O_2 mixtures. —, Calculated values; □, $G(N_2)$ experimental value; ○, G(NO) experimental value; ×, $G(O_3)$ experimental value.

Excitation

[39] $O_2 \rightsquigarrow O^1D + O^3P$
$G = 2.75 \quad 2.75$

[40] $O_2 \rightsquigarrow O^1S + O^3P$
$G = 0.3 \quad 0.3$

A ratio of 9:1 for reactions 37 and 38 has been obtained by Zipf (40) by direct observation of $O(^1D)$ and $O(^1S)$ in an afterglow in O_2–rare gas mixtures. In pure oxygen the fate of both $O(^1D)$ and $O(^1S)$ will be deactivation to $O(^3P)$ ultimately leading to ozone (at high dose rates). However, in O_2–N_2O mixtures the $O(^1D)$ and $O(^1S)$ will react in accordance with the data given in Table 3.

We now have the yields of the primary species in both pure N_2O and pure O_2. Combining these yields with the rate constants for the reactions of these species given in Tables 2 and 3 and the mole fractions of N_2O and O_2 will give values for the final products in the N_2O–O_2 mixtures. Since practically all of the primary species react only with N_2O or O_2 the product yields can be estimated by simple arithmetic. However, calculation by computer is much less tedious, easier, and more accurate. The programs developed by Schmidt (41, 42) have proved to be very useful for this type of calculation. The input to this program consisted of the primary species yields in the mixtures obtained from the values in Table 6 and reactions 37–40 and the weight fractions of N_2O and O_2, the reactions and rate constants in Table 3 and the molar concentrations of N_2O and O_2.

As noted in Table 2 the rate of charge transfer from N_2O^+ to O_2 is not known. If we assume that there is no charge exchange or if we assume that charge exchange is very rapid (*i.e.* with a rate constant of 5×10^{-10} cm^3 molecule^{-1} s^{-1}) then a reasonably good fit of the calculated yields to the experimental yields is obtained. This fit can be improved by assuming a rate constant for charge exchange from N_2O^+ to O_2 of 1.2×10^{-11} cm^3 molecule^{-1} s^{-1}. The calculated yields using this value for k are compared with the experimental results in Fig. 6.

Conclusions

The mechanism for the Febetron radiolysis of N_2O presented in this paper gives good agreement with the experimental yields when used as the basis for calculating yields in N_2O–O_2 mixtures.

This agreement and the simple relationship between excitation processes and the resultant product yields shows that the major excitation reaction in N_2O is formation of $N_2(X^1\Sigma)$ and $O(^1D)$. As discussed, the other excitation reactions may give, in addition to $O(^3P)$, $N_2(A^3\Sigma)$, or $N_2(B^3\Pi)$ and we cannot distinguish between formation of these two excited states of N_2.

Because of the formation of NO^+ as well as N_2O^+ the contributions of the possible neutralizations are more difficult to determine. We have had to neglect the formation of $N(^2D)$ and NO in N_2O^+ neutralization to obtain values for the other neutralization reactions of N_2O^+ and those of NO^+.

Further work is needed to justify this neglect and to determine the yields of $N_2(A^3\Sigma)$ and $N_2(B^3\Pi)$ in excitation.

The product yields in the N_2O–O_2 mixtures in addition to testing the mechanism for N_2O provide values for the yields of $O(^1S)$, $O(^1D)$, and $O(^3P)$ in the neutralization of O_2^+ and the excitation of O_2.

Since the ionic reactions occurring in N_2O at low dose rates are not known it is difficult to determine the consistency of our mechanism with low dose rate product yields. As shown in

Table 1 the yields at the two dose rates in the presence of SF_6 are similar but this similarity may be in part fortuitous. It is reasonable, however, to assume that the yields from dissociative excitation are dose-rate independent.

The same considerations apply to the yields in the nitrous oxide–hydrocarbon mixtures of Takao *et al.* (9). Their qualitative conclusions concerning formation of both excited and ground state O atoms are in agreement with our mechanism. But because the ionic contributions are not known no quantitative comparison can be made.

The Acid-catalyzed Isomerization of the Adducts of Azodiacyls with Cyclopentadiene and 1,3-Cyclohexadiene

MISS C. Y-J. CHUNG, DONALD MACKAY, AND T. D. SAUER

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received December 2, 1971

The isomerization of the Diels–Alder adducts of azodiacyls with cyclopentadiene and 1,3-cyclohexadiene is powerfully catalyzed by strong protic acids and by Lewis acids. In adducts from *p*-substituted azodibenzoyls with cyclopentadiene the catalytic effect increases with electron release by the substituent.

L'isomérisation des produits d'addition de la réaction de Diels–Alder entre les azodiacyles et le cyclopentadiène et le cyclohexadiène-1,3 est très fortement catalysée par des acides protiques forts et par les acides de Lewis. Dans les produits d'addition entre les azodibenzoyles *p*-substitués et le cyclopentadiène, l'effet catalytique augmente avec l'effet donneur d'électrons du substituant.

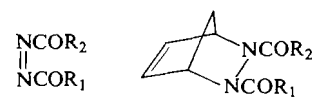
A number of reactions which proceed by [3,3] sigmatropic pathways are known to be catalyzed by Lewis acids (1–3) or by protic acids (2, 4–8). Many of these isomerizations involve allyl substituents in the Claisen (1), the dienol-benzene (6), or the dienone-phenol (7, 8) rearrangements. The catalyzed reactions are not all necessarily concerted (5).

Recently we have shown that the adducts **2** of azodiacyls **1** and cyclopentadiene undergo a [3,3] sigmatropic rearrangement to the racemic ($R_1 = R_2$) or isomeric ($R_1 \neq R_2$) *cis* bicyclic 1,3,4-oxadiazines **3** and **4** (9, 10). We now wish to report that this isomerization also is exceedingly sensitive to acid catalysis and to show how this catalysis can be utilized in studies of these and related isomerizations.

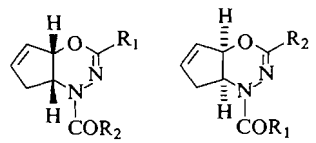
Qualitatively the effect could be simply demonstrated by adding traces of strong acids, *e.g.* hydrogen chloride or trifluoroacetic acid (TFA) to solutions of **2***a* in a wide range of solvents and evaporating the solutions to give the pure oxadiazine. In an inadvertent proof of the catalysis an attempt to purify a slightly colored sample of the very labile adduct **2***b* (10) in a pentane solution containing commercial activated charcoal led to the recovery of pure **3***b*;[1] the charcoal was found to give a p*H* of 2 to an aqueous suspension.

On a more quantitative basis (Table 1) the half-life of **2***a* which was 11 h in heptane at 62° was reduced to 1.3 s by the inclusion of 1.3×10^{-1} *M* TFA (1% v/v) or to 1.3 min by 1.3×10^{-2} *M* hydrogen chloride. Similarly 1.3×10^{-1} *M* TFA reduced the half-life of **2***b* in heptane at 52° from 22 min to 2.0 s. The isomerizations, which were all cleanly first order in adduct, were followed by u.v. spectrophotometry of dilute solutions (*ca.* 10^{-4} *M*), the slow thermal ones by the repeated scan technique (9), and the fast acid-catalyzed ones by following the development of the C=N chromophore of **3***a* at 290 nm and of **3***b* at 250 nm.

On a preparative scale the isomerization of **2***a* could be achieved under a wide range of conditions, at room temperature or by heating, in solutions containing TFA in excess or in amounts as little as 0.1 equiv. Typically a 2% solution of **2***a* in benzene could be isomerized



1 **2**



3 **4**

a $R_1 = R_2 = Ph$
b $R_1 = R_2 = CMe_3$
c $R_1 = R_2 = p\text{-}MeOC_6H_4$
d $R_1 = R_2 = p\text{-}O_2NC_6H_4$
e $R_1 = p\text{-}O_2NC_6H_4$; $R_2 = p\text{-}MeOC_6H_4$

[1]For racemic oxadiazines the simple notation for one enantiomer will be used.

TABLE I. Uncatalyzed and acid-catalyzed isomerization of adducts of azodiacyls in heptane

Adduct	Temperature (°C)	Acid concentration (M)	Half-life (s)
2*a*	62	—	3.9×10^4
		1.3×10^{-1}*	1.3
		1.3×10^{-2}†	78
		2.8‡	5.4×10^3
2*b*	52	—	1.3×10^3
		1.3×10^{-1}*	2.0
7	62	—	1.6×10^9§
		1.3×10^{-1}*	5.1×10^4

*TFA.
†Hydrogen chloride.
‡Acetic acid.
§Estimated by comparison of catalyzed isomerization rates of 7 and **2***a*, see text.

by refluxing for 3 min with 0.1 equiv of TFA. In all cases evaporation of the solutions gave crystalline product containing a small amount of TFA derived material (weak i.r. absorption at 1780 cm^{-1}) but washing with dilute ammonia removed this to give the oxadiazine in high yield (>90%) and purity.

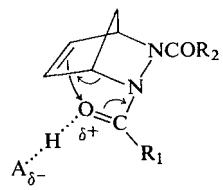
The conversion of **2***a* into **3***a* is in fact quantitative, all solution spectra of **2***a* in the presence of TFA eventually becoming superimposable on those of pure **3***a* with the same amount of TFA added. The changes in the spectra of **3***a* induced by TFA are very minor suggesting that protonation of **3***a* is negligible. Thus the u.v. absorption band of the PhC=N chromophore in heptane was unreduced in intensity by the addition of 1.3×10^{-1} M TFA and showed a hypsochromic shift of only 6 nm. Though complete protonation transfer to pyridine, quinoline, and other heterocyclic bases by TFA in hexane has been detected by u.v. spectroscopy (11), it is likely that with the much less basic heterocycle **3***a* only proton association can occur in saturated hydrocarbon solvents. The observed band shift in heptane may be due to this.

The generality of the catalysis was explored for other protic acids and for Lewis acids. The isomerization of **2***a* was followed by n.m.r. spectroscopy in the presence of *p*-toluenesulfonic acid (0.2 equiv), boron trifluoride etherate (0.2 equiv), and tin (IV) chloride (1.0 equiv). In each case the reaction was markedly accelerated and was essentially quantitative on work-up of the solutions. Acetic acid was, however, rather ineffective; a 17% (v/v, 2.8 M) solution of it in heptane at 62° isomerized **2***a* only seven times faster than the isomerization in pure heptane.

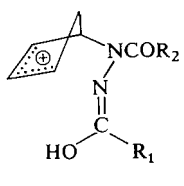
Aqueous hydrochloric acid also catalyzed the isomerization but first order kinetics were not observed on u.v. analysis, the oxadiazine being slowly hydrolyzed. Thus solutions of **2***a* and **3***a* in excess of 0.1 M aqueous ethanolic hydrochloric acid for 1 day at room temperature gave identical end products containing at least four components (t.l.c.) and showing strong absorption in the OH/NH region of the i.r. spectrum. The instability of the dihydro derivative of **3***a* to aqueous acid has already been discussed (9).

The nature of the complex between the acid and the substrate in the transition state in hydrocarbon solvents must be speculative. The site of complexation is probably the same as that of protonation in solvents where proton transfer is possible. In simple amides the evidence is now conclusive that protonation occurs on oxygen (12), but no comparable studies have been carried out on hydrazides.

If, by analogy with amides, complexation in hydrocarbon solvents occurs at oxygen, then for a concerted reaction the representation **5** might reasonably describe the geometry leading to the transition state for the product **3**; in **5** the electrophilic oxygen initiates attack by the olefinic π electrons. A similar picture pertains to complexation at nitrogen, the likelihood of this alternative depending on the pyramidal (sp^3) as opposed to the planar (sp^2) character of the N—C=O system, since if the former is dominant complexation, like protonation, would relieve repulsion between lone electron pairs.[2] The involvement of an open protonated structure, *e.g.* **6**, in a non-concerted pathway cannot be discounted. In the absence of species



5



6

[2]As a referee has suggested, even if the *N*-complexed (or protonated) species is less stable than its *O*-counterpart it might nevertheless provide the preferred isomerization path; the two species would of course be in rapid equilibrium.

TABLE 2. Effect of *p*-substituent on the ratio of TFA (1.3×10^{-3} *M*)-catalyzed to uncatalyzed isomerization in benzene at 70.0°

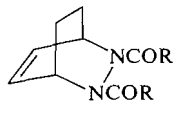
Adduct **2**	*p*-Substituent	Uncatalyzed half-life (min)	Catalyzed half-life (min)	Rate enhancement
d	NO_2	32.4	20.0	1.6
a	H	145	1.38	105
c	MeO	95	0.17	560

capable of diverting it, the ring closure of **6** might be highly stereospecific and lead to the observed high yields of *cis* oxadiazines.

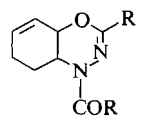
There are two predictable consequences of the invocation of **5**, or its *N*-complexed counterpart. The first is that in the case of two different symmetrical adducts under the same conditions that with the more basic amide group should be more susceptible to catalytic rate enhancement relative to the uncatalyzed (thermal) reaction. This is vividly borne out by the isomerization rates of **2***a*, *c*, and *d* in benzene at 70° (Table 2) in which the ratio of catalyzed (1.3×10^{-3} *M* TFA) to uncatalyzed rates increases with electron release from the aryl group.

The second consequence is that in the transformation of an unsymmetrical adduct ($R_1 \neq R_2$) to the mixture of isomeric oxadiazines, the isomer distribution for the thermal reaction must alter for the catalyzed reaction in the direction of the isomer derived through the transition state complexed at the more basic amide group. This is well illustrated utilizing again the substituent effects of the nitro and methoxy groups. In the absence of acid the yield from **2***e* of oxadiazine **4***e* was $40 \pm 5\%$ (10) but with 1.3×10^{-1} *M* TFA it was $85 \pm 5\%$, showing the predicted increase in participation of the anisamide group. A practical method is thus suggested of improving the yields of those oxadiazines which are minor products in the thermal isomerization of unsymmetrical adducts.

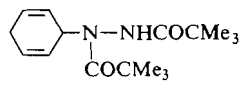
As part of a general study of the effect of the nature of the bridge on the stability of adducts of azodiacyls and cyclic 1,3-dienes we synthesized the [2.2.2]diazabicyclo derivatives **7**, m.p. 157–158°, and **8**, m.p. 126.5–127.5°, from cyclohexadiene in yields of 60 and 28% respectively. These adducts, unlike their cyclopentadiene counterparts, were completely stable at temperatures up to 150°. At 200° isomerization was complete in 1.5 h for **7** and 45 min for **8** (cf. likewise the greater stability of **2***a* than *b* (10)). The products **9**, m.p. 164.5–165.5°, and **10**, m.p. 66–67°, were identified as oxadiazines by their spectroscopic properties, in particular by the C=N chromophore in the u.v. spectrum at 294 nm for **9** and at 240 nm for **10**, and by the diagnostic (9, 10) splitting pattern of the *cis* tertiary hydrogens in the n.m.r. spectrum.[3]



7 R = Ph
8 R = CMe_3



9 R = Ph
10 R = CMe_3



11

Rate values in solution could not therefore be obtained for **7** and **8** using the u.v. analytical technique described for the cyclopentadiene adducts, which isomerized readily in solution <90°. In view of the powerful catalytic effect of acids discussed above it seemed reasonable that isomerization rates for **7** and **8** might be brought within a range suitable for determination by u.v. spectrophotometry.

Refluxing of **7** in benzene containing 1.3×10^{-1} *M* TFA for 20 h indeed gave an 88% yield of **9**, along with small amounts of NH/OH containing material (i.r. spectrum), presumably arising by a solvolytic process. When the acid-catalyzed (1.3×10^{-1} *M*) reaction was followed

[3]The properties of the dihydro derivative of **9**, and of its precursor **7** and its dihydro derivative, were the same as those described (13, 14) for samples obtained by independent synthesis.

by repeated scan u.v. spectrophotometry at 62° in heptane the first order rate plot gave, as expected, a straight line fit only for the early stages. From the initial slope a rate constant of isomerization of 1.35×10^{-5} s^{-1} was obtained, corresponding to a half-life of 14.3 h. This value is greater than that for the adduct **2***a* by a factor of 3.9×10^4, representing a $\Delta\Delta G^{\ddagger}$ of 7.0 kcal mol^{-1} between the two adducts.

If the isomerizations for the [2.2.1] and the [2.2.2] ring systems are mechanistically analogous in both the catalyzed and the uncatalyzed case, so that the only energy differences in the $\Delta G^{\ddagger}$ terms arise from the differences in the bridge size, then the $\Delta\Delta G^{\ddagger}$ value is also applicable to the uncatalyzed reaction. On this basis the uncatalyzed rate constant for **7** in heptane at 62° has an estimated value of 4.4×10^{-10} s^{-1}, corresponding to a half-life of about 50 years.

Solvolytic pathways appeared to predominate when the isomerization of **8** was attempted in the presence of TFA in refluxing heptane. No **10** could be detected among the several products though it was in fact shown to be stable to the reaction conditions. Boron trifluoride etherate was more successful. A 1.6×10^{-3} *M* solution of it in heptane caused a 50% conversion of **8** to **10** after reflux for 15 min. Longer reflux times or higher catalyst concentrations led to the accumulation of by-products.

The synthesis of both cyclohexadiene adducts **7** and **8** was accompanied by the formation of much NH containing material which in the case of the azodibenzoyl reaction was not examined further. The azodipivaloyl reaction gave, as well as **8**, its dihydro derivative dipivaloylhydrazine, isolated in 40% yield from the total reaction product by water extraction (and probably arising by oxidation of cyclohexadiene to benzene), as well as a second 1:1 product of the azo compound and the diene. The latter was separated from **8** in 14% yield by silica gel chromatography, and was shown to be the product **11** of the "ene reaction" of the azo compound with the diene; this pathway is known to be the main one in the reaction of the diene with diethyl azodicarboxylate (15). The identity of **11** follows from the symmetrical pattern of the four vinyl protons and the presence of one N—H exchangeable with D_2O in its n.m.r. spectrum, and from the appearance only of end absorption in its u.v. spectrum.

Experimental

The following spectrometers were used: for i.r., a Beckman IR 10; for u.v., a Coleman EPS-3T Hitachi with a cell compartment heated by a constant temperature circulating pump; for n.m.r., a Varian T60 or HA100.

Microanalyses were done by The Baron Consulting Co., P.O. Box 663, Orange, Conn., U.S.A.

Solvents were purified and dried by conventional means. Anhydrous magnesium sulfate was used as drying agents for solutions in organic solvents. Melting points are uncorrected.

Compounds 1–4

All the azo compounds **1**, the adducts **2**, and their isomers **3** and **4** have been described or referred to earlier (10).

2,3-Dibenzoyl-2,3-diazabicyclo[2.2.2]oct-5-ene (7)

A solution of azodibenzoyl (1.19 g, 5 mmol) and 1,3-cyclohexadiene (Aldrich Chemical Co., 1.2 g, 15 mmol) in carbon tetrachloride (20 ml) was kept in the dark at room temperature for 20 h. Removal of some crystalline material (NH absorption in its i.r. spectrum) and concentration of the faintly orange filtrate gave slightly impure **7** (60%). Three crystallizations from ethanol and drying at 80° for 20 h gave prisms, m.p. 157–158° (lit. (14) m.p. 151–152°); $\nu(CCl_4)$ 1697, 1659 cm^{-1} (C=O); λ_{max} (EtOH) 220 (ε 14 500), 255 nm (ε 7850); $\tau(CDCl_3)$ 2.2–2.8 (10 phenyl H), 3.5 (2 vinyl H, broad), 4.6 and 5.2 (2 *tert* H, both broad[4]), 7.7 (2 methylene H, broad), 8.5, 8.7 p.p.m. (2 methylene H, doublet).

Hydrogenation of **7** was carried out in ethanol using di-imide generated by reaction of hydrazine with hydrogen peroxide. A solution of **7** (0.318 g, 1 mmol) in ethanol (15 ml) containing 95% hydrazine (1.2 ml) was brought to about 50° and 50% hydrogen peroxide (1.2 ml) in ethanol (6 ml) was added dropwise with vigorous stirring at a rate so as to maintain the temperature below the boiling point. The solution was finally stirred for 1/2 h and evaporated and the residue twice crystallized from aqueous ethanol giving 2,3-dibenzoyl-2,3-diazabicyclo[2.2.2]octane (80%) as needles, m.p. 174–176° (lit. (14) m.p. 171.5–172.5°); ν(Nujol) 1668 and 1632 cm^{-1} (C=O); λ_{max} (EtOH) (ε 15 700), 250 nm (ε 7580); $\tau(CDCl_3)$ 2.2–2.9 (10 phenyl H), 5.1 and 5.9 (2 *tert* H, both broad), 7.4–8.7 p.p.m. (8 methylene H).

cis-1-Benzoyl-4a,7,8,8a-tetrahydro-3-phenyl-1H-4,1,2-benzoxadiazine (9)

The adduct **7** was kept at 200° in a sealed evacuated tube for 1.5 h. The slightly colored melt crystallized on cooling and had an i.r. spectrum identical with that of analytical oxadiazine obtained as needles, m.p. 164.5–165.5°, from ethanol; $\nu(CCl_4)$ 1660 and 1650 (C=O, C=N, not necessarily respectively) 1091 cm^{-1} (C—O—C); λ_{max} (EtOH) 294 nm (ε 16 900); $\tau(CDCl_3$, 100 MHz) 2.1–2.9 (10 phenyl H), 3.7–4.1 (2 vinyl H, overlapping with complex splitting), 5.13 (C_{8a}—H, two triplets, $J_{8a,4a} = J_{8a,8A} = 3.6$ Hz, $J_{8a,8B} = 12$ Hz), 5.42 (H_{4a}, triplet containing $J = 3.6$ and another comparable splitting), 7.6 (C-7 methylene H_2, complex), 7.9, 8.3 p.p.m. (C-8 methylene AB system, $J_{AB} = 12$ Hz).

[4]They coalesce at higher temperatures. A fuller account of the properties and stability of 2,3-diazabicyclo[2.2.*n*] adducts from azodibenzoyl will be discussed in a forthcoming publication.

Anal. Calcd. for $C_{20}H_{18}N_2O_2$: C, 75.45; H, 5.70; N, 8.80. Found: C, 75.16; H, 5.66; N, 8.34.

Hydrogenation with di-imide, as described for 7, gave *cis*-1-benzoyl-4*a*,5,6,7,8,8*a*-hexahydro-3-phenyl-1*H*-4,1,2-benzoxadiazine (82%), m.p. 162.5–163.5° (lit. (13) m.p. 163–164°) on crystallization from ethanol; $\nu(CCl_4)$ 1636, 1625 (C=O, C=N), 1094 cm^{-1} (C—O—C); λ_{max} (EtOH) 220 (ε 16 500), 291 nm (ε 15 800); $\tau(CDCl_3)$ 2.0–2.8 (10 phenyl H), 5.15 and 5.50 (2 *tert* H, both complex), 7.5–8.6 p.p.m. (8 methylene H).

*2,3-Dipivaloyl-2,3-diazabicyclo[2.2.2]oct-5-ene (**8**)*

A solution of azodipivaloyl (7.6 g, 38 mmol) and 1,3-cyclohexadiene (6.0 g, 75 mmol) in carbon tetrachloride (75 ml) was refluxed in the dark under nitrogen for 3 days. The red–brown solution was evaporated and the residual gum was triturated with hexane to give an off-white solid (9.0 g) containing three major and one minor product (t.l.c. on silica gel). Extraction of the solid with water gave from the extracts 1,2-dipivaloylhydrazine (3.0 g, 40%), which was purified by sublimation and identified by m.p. and mixed m.p., and by its i.r. and n.m.r. spectrum.

The water insoluble fraction was chromatographed in portions on silica gel using as eluant a mixture of ether: benzene: petroleum ether: ethyl acetate in the proportions 1:2:10:10. The first and main fraction was the *adduct* **8** (3.0 g total, 28%) which was crystallized from aqueous acetone as long needles, m.p. 126.5–127.5°; $\nu(CCl_4)$ 1712, 1642 cm^{-1} (C=O); u.v. end absorption only (EtOH or *iso*-octane); $\tau(CDCl_3)$ 3.57 (2 vinyl H, triplet, $J = 4.0$ Hz), 4.97 (2 *tert* H, broad singlet), 7.67–8.17 (4 methylene H, complex), 8.73 p.p.m. (18 *tert*-butyl H, singlet).

Anal. Calcd. for $C_{16}H_{26}N_2O_2$: C, 69.03; H, 9.41; N, 10.06. Found: C, 69.27; H, 9.64; N, 10.06.

Further elution gave the "ene" product *1,2-dipivaloyl-1-(2,5-cyclohexadienyl)hydrazine* (**11**) (1.50 g total, 14%), an analytical sample of which was prepared by recrystallization from aqueous acetone and then vacuum sublimation as fine prisms, m.p. 159–160°; $\nu(CCl_4)$ 3405 (NH, broad), 1715, 1657 cm^{-1} (C=O); u.v. end absorption only (EtOH); $\tau(CDCl_3$, 100 MHz) 2.99 (1 NH, broad singlet, exchangeable with NaOD), 3.97 (C_2—H and C_6—H, broad unsymmetrical doublet, $J = 10$ Hz, A_2 portion of A_2B_2), 4.19 (C_1—H, center portion only visible, but chemically shifted downfield from $C_{2,6}$—H as a broad multiplet in benzene-d_6), 4.37 (C_3—H and C_5—H, B_2 portion), 7.33 (C-4 methylene H_2, complex, at least 10 lines), 8.76, 8.80 p.p.m. (9 *tert* butyl H each, sharp singlets).

Anal. Found: C, 68.98; H, 9.33; N, 10.51.

*cis-1-Pivaloyl-4a,7,8,8a-tetrahydro-3-tert-butyl-1H-4,1,2-benzoxadiazine (**10**)*

The adduct **8** was heated in a sealed evacuated tube at 200° for 45 min. The *oxadiazine* **10** crystallized on cooling and had m.p. 64.5–66° directly. Recrystallization from aqueous acetone raised this to 66–67°; $\nu(CCl_4)$ 1650 cm^{-1} (C=O, C=N); λ_{max} (EtOH) 240 nm (ε 12 000); $\tau(CDCl_3$, 100 MHz) 3.97 (C_5—H, two triplets, $J_{5,6} = 9.5$, $J_{5,4a} = 3.3$ Hz), 4.12 (C_6—H, complex), 5.44 (C_{8a}—H, two triplets, $J_{8a,4a} = J_{8a,8A} = 3.6$, $J_{8a,8B} = 12$ Hz), 5.73 (C_{4a}—H, broadened triplet containing $J = 3.3$ and 3.6 Hz), 7.7 (C-7 methylene H_2, complex), 8.3 (C-8 methylene H_2, complex), 8.64 and 8.80 p.p.m. (9 *tert* butyl H each, sharp singlets).

Anal. Calcd. for $C_{16}H_{26}N_2O_2$: C, 69.03; H, 9.41; N, 10.06. Found: C, 69.11; H, 9.25; N, 9.98.

*TFA-Catalyzed Isomerization of **2a** to **3a** on a Preparative Scale*

TFA (4.9 μl, 0.1 equiv) was added to a refluxing solution of **2***a* (200 mg, 0.66 mmol) in benzene and the refluxing was maintained for 3 min. The solution was evaporated, the residue was triturated with two drops of methanol to induce crystallization, dilute aqueous ammonia was added, and the precipitate (180 mg, 90%) was collected. Its i.r. spectrum was superimposable on that of analytically pure **3***a*.

*Effect of Aqueous Acid on **2a** and **3a***

Solutions of the adduct **2***a* or its isomer **3***a* (152 mg, 0.5 mmol) in 77% aqueous ethanol containing 0.10 *M* hydrochloric acid reacted completely in about 1 day at room temperature. Evaporation gave gummy solid residues which were identical in all respects, having superimposable i.r. and u.v. spectra and containing four components (t.l.c.).

The effect of the same solvent medium on a very dilute solution (*ca.* 10^{-4} *M*) of adduct was monitored at 35° by following the increase in absorbance at 290 nm (see below for details of kinetic experiments), which reached a maximum after 55 min and then began to fall. An estimate of the initial slope of a first order rate plot gave a half-life of 20 min.

*Isomerization of **2a** by Other Catalysts*

In the following the isomerization of the adduct **2***a* was followed by n.m.r. spectroscopy (probe temperature 35°).

(a) p-Toluenesulfonic acid: 19 mg (0.2 equiv) was added to a solution of the adduct (152 mg, 0.5 mmol) in dimethylsulfoxide-d_6 (1 ml). Reaction was complete in about 8 h.

(b) Boron trifluoride etherate: 14.2 mg (0.2 equiv) in chloroform-*d* (0.25 ml) was added to a solution of the adduct (152 mg, 0.5 mmol) in chloroform-*d* (0.25 ml). Reaction was complete before the spectrum could be run.

(c) Tin(IV) chloride: 26 mg (1 equiv) in methylene chloride (0.5 ml) was added to a solution of the adduct (76 mg, 0.25 mmol) in methylene chloride (0.5 ml). The reaction was monitored in the region of absorption of the CH_2 group and was complete in about 4 min. Lesser amounts of catalyst caused incomplete isomerization.

In the work-up for reactions *a* and *b* the solutions from the n.m.r. tube were evaporated to dryness in a stream of nitrogen and dilute aqueous ammonia was added. The oxadiazine crystallized and was filtered off. The i.r. spectrum was identical with that of analytically pure material.

In reaction *c*, dilute aqueous ammonia was added and the methylene chloride extracts were dried and evaporated. The residue was slightly gummy and had a weak absorption in the NH region of its i.r. spectrum, but one crystallization from aqueous methanol gave pure oxadiazine.

*TFA-Catalyzed Isomerization of **2e** to **3e** and **4e***

A solution of **2***e* (0.2 g, 0.69 mmol) in benzene (50 ml) containing TFA (1.3×10^{-1} *M*) was refluxed for 2 min and then evaporated. Integration of the methoxy signals in the n.m.r. spectrum at 100 MHz (10) showed the presence of 85 ± 5% of **4***e*, before and after work-up with dilute aqueous ammonia.

*TFA-Catalyzed Isomerization of **7** to **9***

A solution of 7 (80 mg, 0.25 mmol) in benzene (30 ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

containing TFA (1%, 1.3×10^{-1} *M*) was refluxed for 20 h and then evaporated to dryness in a stream of nitrogen. An excess of dilute aqueous ammonia was added and the crystalline residue (70 mg, 88%) filtered off. Its spectrum was the same as that of pure **9**, and it had m.p. and mixed m.p. 163.5–164.5° after crystallization from aqueous ethanol. The balance of the reaction product was found in the ammoniacal filtrate by evaporation to dryness and extraction of the residue with methylene chloride which gave a gummy solid with i.r. absorption in the OH/NH and C=O regions.

Attempted Isomerization of **8** *to* **10** *with Acid Catalysts*

(a) Trifluoroacetic Acid

A sample of **8** was refluxed in heptane containing 1.3×10^{-1} *M* TFA for 15 min and evaporated. The residue was taken up in carbon tetrachloride and extracted with aqueous ammonia. The organic layer was dried and shown by t.l.c. on silica gel to contain at least four products, none of which was **8** or **10**.

Control experiment: A sample of **10** was recovered essentially pure when refluxed as above for 20 min.

(b) Boron Trifluoride Etherate

The adduct (0.318 g, 1.14 mmol) was refluxed for 15 min in heptane (45 ml) containing 1.6×10^{-3} *M* boron trifluoride etherate and the clear solution was evaporated under reduced pressure. The n.m.r. analysis of the residue in carbon tetrachloride showed it to be an equimolar mixture of **8** and **10**; silica gel t.l.c. showed a trace of a third substance. Column chromatography on silica gel using ether:benzene:petroleum ether:ethyl acetate in the proportions 1:2:20:20 as eluant gave the oxadiazine (163 mg, 51%) as the first material eluted, identified by n.m.r. and i.r. spectroscopy.

Refluxing with a more concentrated (1.8×10^{-2} *M*) solution of TFA for 30 min caused complete reaction of **8**, but the oxadiazine was then contaminated with two N—H containing products.

Kinetic Determinations by Ultraviolet Spectrophotometry

Dilute solutions in the range 10^{-4}–10^{-5} *M* were used in 10 mm quartz cells (Hellma Canada Ltd.) with Teflon stoppers. These gave an excellent fit, allowing no evaporation losses over periods of several days, even within 10° of the solvent boiling point.

The purely thermal reactions in heptane and the reaction in heptane containing acetic acid were carried out by the repeated scan technique used in earlier work (9). The thermal reactions in benzene were followed by measuring the increase in absorbance with time at a suitable fixed wavelength, 325 nm for **2***a*, 335 nm for **2***c*, and 340 nm for **2***d*.

All the TFA-catalyzed reactions on the compounds **2***a–d* were also followed at a fixed wavelength using an external recorder (Beckman Ten-Inch Linear) running at a suitable high speed. An average of at least three runs was used in each case. The solutions in the cell were all brought to the required temperature and the TFA introduced using a 10 or 50 μl syringe as appropriate. For reactions whose half-lives were greater than a few seconds the cell was stoppered, shaken manually, and immediately returned to the compartment. For the very fast reactions the cell compartment lid was replaced by a styrofoam cover fitted with an electrical contact and a hole directly above the sample cell. Through this and through one of two holes in the Teflon stopper of the cell passed a stainless steel stirrer; the other hole permitted passage of the syringe needle. Immediately after injection of the TFA the solution was stirred with two strokes of the stirrer which was then held above the light path while the absorbance change was being recorded.

In the hydrogen chloride-catalyzed reaction the heptane was saturated with the gas and the solution standardized by titration. The required amount was then introduced with the microsyringe.

All the reactions, catalyzed or uncatalyzed, gave excellent first order kinetics throughout.

The isomerization of **7** in heptane at 62° in the presence of 1.3×10^{-1} *M* TFA was also followed by the repeated scan technique. The curves passed through an isobestic point at 263 nm for the first 5 h but then drifted away from this point. A pure sample of the oxadiazine **9** was used to obtain a value for A_∞, the final absorbance which would have been observed in a quantitative isomerization. The initial slope of the plot of $\ln (A_\infty - A_t)$ against t gave the rate constant for the isomerization.

We wish to thank the National Research Council of Canada for financial assistance.
