2-Aryloxytetrahydrofurans. Their Reductive Cleavage by Ether Solutions of AlH_2Cl and their Cleavage and Rearrangement by Ether Solutions of $AlCl_3$ [1]

P. C. Loewen and R. K. Brown

The Department of Chemistry, University of Alberta, Edmonton, Alberta

Received February 14, 1972

The hydrogenolysis of 2-aryloxytetrahydrofurans by excess AlH_2Cl gave, in excellent yield, only those products expected from *exo* C—O bond cleavage regardless of the nature of the substituent in the aryl ring. None of the 4-aryloxy-1-butanol, the product expected from ring cleavage, was detected. The reaction was very much faster than the corresponding AlH_2Cl hydrogenolysis of 2-alkoxytetrahydrofurans which is known to give only ring cleavage products under similar conditions.

Treatment of 2-aryloxytetrahydrofurans or pyrans with $AlCl_3$ in ether, resulted in acid-catalyzed cleavage to the corresponding phenol and dihydrofuran or dihydropyran, the latter immediately forming polymeric products. For those 2-aryloxytetrahydrofurans or pyrans, unsubstituted, or substituted with electron donor groups in the aryl ring, another product was obtained which resulted from electrophilic attack of one protonated dihydrofuran or pyran on the ortho or para position of the phenol. These rearrangement products were also obtained in small amounts as byproducts when 2-aryloxytetrahydrofurans were hydrogenolyzed with insufficient AlH_2Cl.

L'hydrogène des aryloxy-2 tétrahydrofurannes par un excès de AlH_2Cl donne, avec un rendement excellent, les produits attendus à partir seulement du clivage de la liaison C—O *exo*, quelle que soit la nature du substituant du cycle aryle. Aucun aryloxy-4 butanol-1, produit attendu de l'ouverture de cycle, n'a pu être détecté. La réaction est beaucoup plus rapide que pour l'hydrogénolyse des alkoxy-2 tétrahydrofurannes par AlH_2Cl, connue pour donner seulement des produits d'ouverture de cycle, dans des conditions identiques.

Le traitement des aryloxy-2 tétrahydrofurannes ou pyrannes par $AlCl_3$ dans l'éther entraîne une ouverture acido-catalysée conduisant au phénol correspondant, au dihydrofuranne ou dihydropyranne, ce dernier formant immédiatement des polymères. Pour ces aryloxy-2 tétrahydrofurannes ou pyrannes, substitués ou non par des groupes électrodonneurs sur le cycle aryle, un autre produit est obtenu résultant d'une attaque électrophile du dihydrofuranne ou pyranne protoné sur la position ortho ou para du phénol. Ces produits réarrangés sont également obtenus en petites quantités, en tant que sous-produits, lors de l'hydrogénolyse des aryloxy-2 tétra-hydrofurannes par AlH_2Cl en défaut.

Introduction

It has been reported (1) that the reductive cleavage by a 1:1 mixture of lithium aluminum hydride and aluminum chloride in ether of 2-phenoxytetrahydropyran and of 2-*p*-tolyloxytetrahydropyran provides exclusively tetrahydropyran and the corresponding phenol, products of *exo* C—O bond cleavage. This has been attributed to the electron-withdrawing effect of these aryl substituents strongly destabilizing the transition state leading to the formation of that oxocarbonium ion involved in ring cleavage (route *a*, Scheme 1, $n = 2$, $R' = H$, $R = aryl$), thus permitting exclusive formation and reaction of the oxocarbonium ion involved in ring retention (route *b*, Scheme 1).

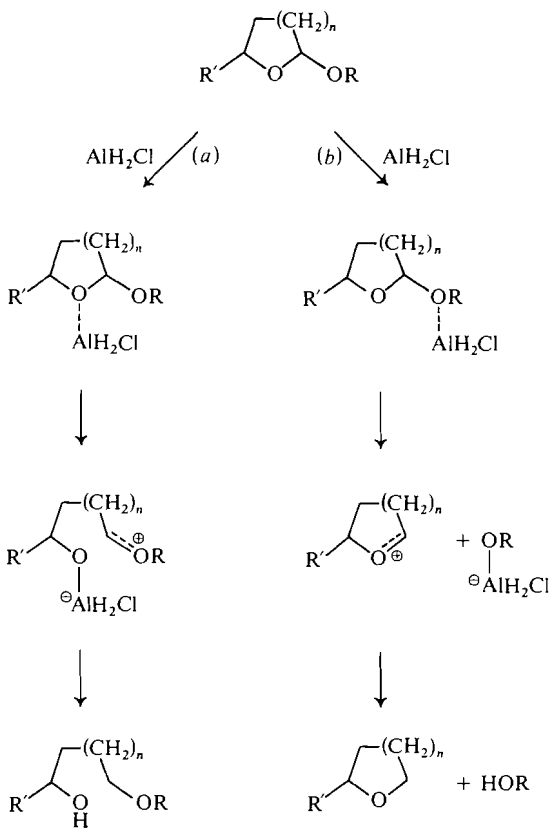
This paper describes the results of a study of the hydrogenolysis by a 1:1 mixture of lithium aluminum hydride and aluminum chloride (*i.e.*, AlH_2Cl (2, 3)) of ether solutions of a number of 2-aryloxytetrahydrofurans, and also of the tendency for certain of the 2-aryloxytetrahydrofurans and the homologous pyrans to undergo rearrangement in competition with the normal cleavage reaction in the presence of the Lewis acid $AlCl_3$.

Results and Discussion

Hydrogenolysis of 2-Aryloxytetrahydrofurans with AlH_2Cl

The general hydrogenolysis procedure was the same as that used for the reductive cleavage of 2-alkoxytetrahydrofurans (4), an advantageous modification of the method reported previously (1). Products were found to be stable

[1]Taken in part from the thesis of P. C. Loewen submitted to the Faculty of Graduate Studies and Research, University of Alberta, in partial fulfillment of the requirements for the Ph.D. degree.



SCHEME 1

under the reaction conditions, and were identified by comparison of their g.l.c. retention times with those of authentic samples, or in cases of doubt, by actual isolation and subsequent identification or characterization, of the products. The results of these reactions are shown in Table 1.

Experiments 1–5 show that regardless of the nature of the substituent or its position in the aromatic ring R, the 2-aryloxytetrahydrofurans are cleaved only at the *exo* C—O bond to produce tetrahydrofuran and the phenol. This agrees with the findings for the hydrogenolysis of the 2-aryloxytetrahydropyrans (1) but is in sharp contrast to the exclusive ring cleavage observed in the hydrogenolysis with AlH_2Cl of 2-alkoxytetrahydrofurans (4), and to the production of both ring and *exo* cleavage products in the hydrogenolysis of 2-alkoxytetrahydropyrans (1).

A second and significant observation from Table 1, and one which is amplified by the results shown in Table 2, is that the reductive cleavage of the 2-aryloxytetrahydrofurans is very fast, completed well within 10 min, and is very much faster than the analogous cleavage of 2-alkoxytetrahydrofurans. The latter fact is clearly demonstrated when mixtures of equimolar quantities of 2-aryloxy- and 2-ethoxytetrahydrofuran are hydrogenolyzed with an amount of AlH_2Cl sufficient to reduce only half of the total amount of this mixture of acetals. In each case, hydrogenolysis of the 2-aryloxytetrahydrofuran occurred exclusively and completely (Table 2), with no evidence (by g.l.c.) of any cleavage of the 2-ethoxytetrahydrofuran.

Although the phenoxy group has electron donor properties ($\sigma = -0.320$, (5); $\sigma^+ = -0.5$, (6)) which would stabilize the transition state leading to the oxocarbonium ion involved in ring cleavage (route *a*, Scheme 1), the absence of any observable ring cleavage products from the hydrogenolysis of *any* of the 2-aryloxytetrahydrofurans (Table 1) regardless of the type of substituent in the aryl ring, indicates quite clearly that such electronic stabilization or destabilization by the 2-aryloxy substituent is insignificant in determining the direction of cleavage (route *a* or *b*, Scheme 1). It is suggested here that the feature which causes only *exo* C—O bond cleavage in the hydrogenolysis of 2-aryloxytetrahydrofurans is the π electron system of the aryl ring which, with its attached oxygen atom provides a region of high electron concentration which attracts the Lewis acid. The aryloxy group with the associated Lewis acid becomes a good "leaving group" whose departure is facilitated by the ability of the ring oxygen to stabilize the positive charge which develops on C-2 (route *b*, Scheme 1). Alternative association of the Lewis acid with the ring oxygen followed by ring C—O bond cleavage, or transfer of the Lewis acid from the aryloxy group to the ring before *exo* C—O bond cleavage takes place, apparently is insignificant. Since C—O bond cleavage of acetals is considered to be the rate determining step in their hydrolysis (7) or hydrogenolysis (8), the stabilization of the aryloxy anion by the associated Lewis acid to provide a good leaving group would account for the much greater rate of hydrogenolysis of the 2-aryloxytetrahydrofurans compared to that of the 2-alkoxytetrahydrofurans.

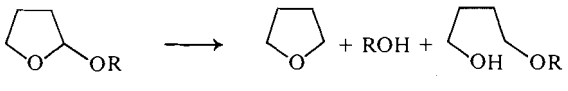
TABLE 1. Room temperature hydrogenolysis of ether solutions of 2-aryloxytetrahydrofurans with AlH_2Cl*



A B C

Experiment no.	Compound A with R as	Total material recovery (%)	B (as % of reduced product)	C
1	C_6H_5—	85	100	0
2	2,6-$Cl_2C_6H_3$—	95	100	0
3	2,6-$(CH_3)_2C_6H_3$—	90	100	0
4	3,5-$(CH_3)_2C_6H_3$—	90	100	0
5	4-*t*-$C_4H_9C_6H_4$—	94	100	0

*Although reduction was fast and generally complete within 10 min, the reduction time was extended to 2 h in each case to ensure complete reaction. Equimolar mixtures of $LiAlH_4$, $AlCl_3$, and the acetal were used, thus ensuring a large excess of reducing agent.

TABLE 2. Competitive hydrogenolysis at room temperature of ether solutions of equimolar mixtures of a 2-aryloxytetrahydrofuran and 2-ethoxytetrahydrofuran with a limited amount of AlH_2Cl*

A B A C

Experiment no.	R in Compound B	Total material recovery (%)	Amount of A reduced (%)	Amount of B reduced (%)†
1	2,6-$(CH_3)_2C_6H_3$—	95	0	100
2	C_6H_5—	95	0	100
3	2,6-$Cl_2C_6H_3$—	82	0	100

*The molar ratio of A:B:AlH_2Cl at the beginning of the reaction was 1:1:0.5. Reaction time was extended to 2 h, to ensure completion of reaction.

†A very small amount of high boiling material was obtained. This was later identified as a rearrangement product from the 2-aryloxytetrahydrofuran (see below).

There are two observations in a previous paper (4) which are in agreement with this view. It was shown that although 2-methoxytetrahydrofuran gave only the ring cleavage product when hydrogenolyzed with AlH_2Cl, 2-methoxy-5-methoxymethyltetrahydrofuran and 2-methoxy-5-phenyltetrahydrofuran each gave both ring cleavage and *exo* C—O bond cleavage products, respectively, in the ratio 93.5:6.5 in the former acetal and 84.3:15.7 in the latter. This could be due to association of the Lewis acid to some extent with the C-5 methoxymethyl group, and especially with the C-5 phenyl group, rather than only with the adjacent ring oxygen atom,[2] sufficiently to allow a second molecule of AlH_2Cl to attack the *exo* oxygen and bring about some reductive cleavage of the *exo* C—O bond. Also, it was shown that AlH_2Cl hydrogenolysis of 2-benzyloxytetrahydrofuran gave in excellent yield *both exo* and *endo* (ring) C—O cleavage products in the ratio 48.5:51.5, respectively (Table 2, experiment 2 in ref. 4). Here also, the 48.5% *exo* cleavage experienced by 2-benzyloxytetrahydrofuran could be attributed to the strong tendency for the Lewis acid to associate with the aryl ring rather than practically completely with the more "basic" ring oxygen atom (a feature considered to be responsible for the exclusive ring cleavage experienced by 2-methoxytetrahydrofuran as well as all the other 2-alkoxytetrahydrofurans (4)), thus markedly improving the "leaving" ability of the

[2]The Lewis acid must associate with the ring oxygen atom if ring cleavage is to occur.

*The proportion of the 2-aryloxy compound and $AlCl_3$ was 1:0.25 equivalents respectively.
†Estimated by g.l.c. measurement of the phenol produced. The dihydrofuran (or pyran) could not be measured since it polymerized immediately.
‡The remainder of the isolated product (73%) was the coupling product 4,4′-dihydroxy-3,3′,5,5′-tetramethylbiphenyl, a type of product not detected in the reactions of the other 2-aryloxy compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

benzyloxy group. As well, the Lewis acid associated with the aryl ring would be in a position to transfer easily to the *exo* oxygen, a position leading to *exo* C—O bond cleavage. The degree of such preferred association of the Lewis acid with the aryl ring system appears to depend on the strength of the Lewis acid, since experiments 1–4, Table 2 of ref. 4 show that the proportion of *exo* cleavage of 2-benzyloxytetrahydrofuran increases from 20.5 to 91.3% as the Lewis acid strength of the hydrogenolyzing reagent is increased.

Reaction of 2-Aryloxytetrahydrofurans and 2-Aryloxytetrahydropyrans with $AlCl_3$ in Ether

In the competitive reaction of equimolar quantities of a 2-aryloxytetrahydrofuran and 2-ethoxytetrahydrofuran with an amount of AlH_2Cl sufficient to reduce only one half of the total amount of the acetal mixture, a very small amount of high boiling material was formed in some of the reactions (Table 2). The retention times of these substances were similar to those of authentic 4-aryloxy-1-butanols, products expected from reductive ring cleavage of the 2-aryloxytetrahydrofurans. However, the amount formed was insufficient for their isolation by g.l.c. and subsequent positive identification. Related to this was the observation that attempts at competitive hydrogenolysis of equimolar mixtures of two 2-aryloxytetrahydrofurans with an amount of AlH_2Cl sufficient only to reductively cleave half of the total acetal mixture, always resulted in reaction of the acetal to the extent of 75 to 100%. Accordingly it was suspected that the 2-aryloxytetrahydrofurans were not only being hydrogenolyzed by the AlH_2Cl but also subjected to a reaction caused by the Lewis acidity of the aluminum species. That this was so is shown by the results of the reaction of ether solutions of 2-aryloxytetrahydrofurans and also of 2-aryloxytetrahydropyrans with $AlCl_3$ (Table 3). The products in each case were analyzed by g.l.c. For those experiments where the g.l.c. yield of the rearranged product was 16% or more, (experiments 2, 4, and 5) it was possible to isolate by chromatography a sufficient quantity of it for purification and positive identification. For the other cases (experiments 1, 6, and 7) of lower yield of the rearrangement products, isolation was very difficult, hence these were assigned structures on the basis of the similarity of their retention times to those of the compounds actually isolated and whose structures were established.

The data shows that in all cases the expected acid-catalyzed cleavage of the acetal occurred at least as part of the reaction, to produce the dihydrofuran (or pyran) and the corresponding phenol. The dihydrofuran or pyran could not be estimated readily since it polymerized under the reaction conditions. However, it was measured indirectly by the g.l.c. analysis of the phenolic product B, formed in an amount equal to the dihydro compound. The other product obtained (C in Table 3) was that resulting from a rearrangement due to an electrophilic attack by the protonated dihydrofuran or pyran on the phenolic material which arose from acid-catalyzed *exo* C—O bond cleavage. The relative amount of C obtained depended upon the type of substituent in the aromatic ring, being greatest when two activating alkyl groups were in the ring (75 and 70%, experiments 2 and 5) and least when deactivating groups (chlorine) were in the ring (0%, experiment 3). Attack by the protonated dihydrofuran (or pyran) occurred on the aromatic nucleus in the position ortho to the hydroxyl substituent, if this position was free (experiments 1, 2, 5–7), but if the ortho position was blocked, then the para position was the point of attack (experiment 4). The retention times of the small amount of high boiling material obtained in the competitive reaction shown in experiments 1 and 2 of Table 2 were identical to those of compound C of experiments 1 and 4 in Table 3, and distinctly different from those of the expected 4-aryloxy-1-butanols. Hence these must have arisen from the Lewis acid property of the reagent AlH_2Cl.

Experimental

Boiling points are uncorrected.

Preparative g.l.c. and g.l.c. analyses were carried out with the columns and instruments described previously (4). Quantitative g.l.c. analyses were made by measuring the signal area directly, uncorrected for detector response, since observed and correct areas usually differed by less than 5%, though in a few cases this difference was as much as, but no more than 10%.

I.r. spectra were recorded with a Perkin–Elmer Model 337 instrument.

P.m.r. spectra were recorded with a Varian Associates A60 instrument operated by Mr. R. Swindlehurst, and an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

HR-100 spectrometer operated by Mr. G. Bigham. The i.r. and p.m.r. spectra, taken for all compounds described, agreed well with the structures proposed.

Elemental analyses were performed by Mrs. D. Mahlow of this Department.

Solvents were removed by rotary evaporator unless otherwise noted.

Preparation of 2-Aryloxytetrahydrofurans and Pyrans

These were prepared by the acid-catalyzed reaction of 2,3-dihydrofuran or 3,4-dihydro-2*H*-pyran with the appropriate phenol, following published directions (9), but with the following modification. Following completion of the reaction, the cooled mixture was diluted with ether and treated with Claisen's alkali (10) which effectively removed the excess phenolic reagent. The ether layers were dried ($MgSO_4$) and separated from solid and solvent and the residue distilled. The products and their physical constants are shown in Table 4.

Preparation of 4-Aryloxy-1-butanols. Possible Ring Cleavage Products from the Hydrogenolysis of 2-Aryloxytetrahydrofurans

The precursors, the *1-aryloxy-3-bromopropanes*, were prepared by the reaction of 1,3-dibromopropane with the appropriate phenol following published directions (11) but using sodium hydride as the base and 1,2-dimethoxyethane as solvent. The products and their physical constants are listed in Table 5. Following published general directions (11), the 1-aryloxy-3-bromopropanes were converted to the corresponding 4-aryloxybutyronitriles, and these in turn were changed to the ethyl 4-aryloxybutyrates. The latter were then reduced with lithium aluminum hydride in ether, as usual, to the 4-aryloxy-1-butanols. The boiling points and refractive indices of these nitriles, esters and alcohols are shown in Table 5.

Hydrogenolysis of 2-Aryloxytetrahydrofurans

The general procedure was the same as that employed for the hydrogenolysis of 2-alkoxytetrahydrofurans (4). The results are shown in Table 1.

$AlCl_3$-Catalyzed Rearrangement of 2-Aryloxytetrahydrofurans and Pyrans. General Procedure

To a vigorously stirred solution of anhydrous aluminum chloride (0.17 g, 0.00125 mol) in 30 ml of dry ether at room temperature was added 0.96 g (0.005 mol) of 2-(3,5-dimethylphenoxy)tetrahydrofuran. The mixture became pale orange while it was stirred for an additional 10 min. An aqueous 15% solution of potassium hydroxide was added to discharge the color (0.25 ml). The ether solution was separated by decantation and freed from solvent by fractional distillation. G.l.c. analysis of the residue (0.90 g, 94%) gave the results shown in Table 3 for experiment 2. Results of the reactions of the other 2-aryloxytetrahydrofurans and pyrans are shown also in Table 3. No 2,3-dihydrofuran was detected in the products of reactions involving the tetrahydrofurans, but a very small amount of 3,4-dihydro-2*H*-pyran was found by g.l.c., in the product mixture arising from the $AlCl_3$ reaction with 2-aryloxytetrahydropyrans.

Isolation of Products of the $AlCl_3$-Catalyzed Rearrangements

(a) From 2-(3,5-Dimethylphenoxy)tetrahydrofuran

The residue (0.9 g) from the reaction of this furan with $AlCl_3$ (see above) was chromatographed on 20 g of acid-washed alumina. A 4:1 mixture of Skellysolve B and chloroform was the eluant, and 75-ml fractions were collected. The first fraction contained no product, whereas a colorless oil was obtained from fractions 2 and 3. The oil solidified on standing. Recrystallization from Skellysolve B gave colorless crystals (0.5 g, 55%) of *2-(4,6-dimethyl-2-hydroxyphenyl)-tetrahydrofuran*, m.p. 65–67°.

Methylation according to general directions (12) gave 2-(4,6-dimethyl-2-methoxyphenyl)tetrahydrofuran, b.p. 98–100° at 0.3 mm; η_D^{20} 1.5388. This was identical with authentic *2-(4,6-dimethyl-2-methoxyphenyl)tetrahydrofuran* prepared below.

(b) From 2-(3,5-Dimethylphenoxy)tetrahydropyran

Rearrangement with $AlCl_3$ as above gave the product *2-(4,6-dimethyl-2-hydroxyphenyl)tetrahydropyran*, m.p. 87–89°.

(c) From 2-(2,6-Dimethylphenoxy)tetrahydrofuran

Rearrangement of this furan with $AlCl_3$ as above gave a residue (88.5%) which deposited an ether-insoluble solid. Trituration of the mixture with ether, followed by filtration, gave a colorless solid in 73% yield, m.p. 213–215°, identical in all respects with authentic *4,4'-dihydroxy-3,3',5,5'-tetramethylbiphenyl* (13). The ether filtrate, freed from solvent, gave a residue which was methylated (12). The product when distilled gave 2,6-dimethylanisole (10%) and a 10% yield of *2-(3,5-dimethyl-4-methoxyphenyl)tetrahydrofuran*, b.p. 105° at 0.5 mm; η_D^{25} 1.5175. This was identical with authentic material prepared below.

Authentic 2-(4,6-Dimethyl-2-methoxyphenyl)tetrahydrofuran

Succinic anhydride (7.8 g, 0.077 mol) was condensed with 3,5-dimethylanisole (10.5 g, 0.077 mol) by the published general procedure (14) to produce *β-(4,6-dimethyl-2-methoxybenzoyl)propionic acid*. The crude acid was crystallized best by solution in chloroform (200 ml) and reducing the volume of the dried ($MgSO_4$) solution to 75 ml. Careful addition of Skellysolve B to cloudiness, and preservation of the mixture in a refrigerator for 18 h, gave pure material (14 g, 78%), m.p. 97–99°.

The acid was converted to 1-(4,6-dimethyl-2-methoxyphenyl)-1,4-butanediol by reduction with lithium aluminum hydride as usual. The crude diol (91% yield) was cyclized by the same method used to convert 1-phenyl-1,4-butanediol to 2-phenyltetrahydrofuran (4). The small amount of contaminating *p*-toluenesulfonyl chloride could be removed only by heating the impure 2-substituted tetrahydrofuran with 15% aqueous potassium hydroxide under reflux. Ether extracts of the cooled mixture were dried ($MgSO_4$) and freed from solvent. The residue on distillation provided a 38% yield of pure *2-(4,6-dimethyl-2-methoxyphenyl)tetrahydrofuran*, b.p. 100–102° at 0.5 mm; η_D^{22} 1.5375.

Authentic 2-(3,5-Dimethyl-4-methoxyphenyl)tetrahydrofuran

The reaction (14) of succinic anhydride with 2,6-dimethylanisole as above gave *β*-(3,5-dimethyl-4-methoxybenzoyl)-propionic acid, yield, 72%, m.p. 108–110°; lit. m.p. 114–115° (15).

Reduction of the acid with lithium aluminum hydride gave the crude oil *1-(3,5-dimethyl-4-methoxyphenyl)-1,4-butanediol* (90%) which was cyclized as above to *2-(3,5-*

Pyrochlores. VIII. Studies of some 2–5 Pyrochlores and Related Compounds and Minerals[1]

FRANÇOIS BRISSE,[2] DAVID J. STEWART,[3] V. SEIDL,[4] AND OSVALD KNOP

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received June 8, 1972

The cubic pyrochlores $Cd_2Nb_2O_7$, $Cd_2Ta_2O_7$, $Sn_2Nb_2O_7$, $Sn_2Ta_2O_7$, $Cd_2Sb_2O_7$, $Ca_2Sb_2O_7$, $Mn_2Sb_2O_7$, $Pb_2Sb_2O_7$, and related compounds were prepared and investigated by a number of methods. On heating above 700°, $Ca_2Sb_2O_7$(pyrochlore) transformed to $Ca_2Sb_2O_7$(weberite), while $Pb_2Sb_2O_7$(pyrochlore) changed to a rhombohedrally distorted $Pb_2Sb_2O_7$ pyrochlore. Refinement of the crystal structures of $Cd_2Nb_2O_7$ and $Cd_2Ta_2O_7$ from powder diffractometer intensities yielded 0.434(2) and 0.434(3) respectively as the best estimates of $x(O_2)$. Specimens of natural bindheimite and stibiconite were also examined. Stibiconite from San Luís Potosí (Mexico) was shown, on the evidence of its Mössbauer ^{121}Sb spectrum, to contain Sb(V) and Sb(III) in the approximate ratio of 0.2.

$BaCd_2Cl_6 \cdot 5H_2O$ and $BaCd_2Cl_6 \cdot 2H_2O$ both give powder diffraction patterns of the pyrochlore type. The chlorine could be partially replaced by Br to give mixed crystals $BaCd_2Cl_{6-z}Br_z \cdot 5H_2O$ almost up to $z = 2$.

The crystal chemistry of 2–5 oxide pyrochlores and the relationship of the weberite to the pyrochlore phases are discussed.

Les composés cubiques de type pyrochlore $Cd_2Nb_2O_7$, $Cd_2Ta_2O_7$, $Sn_2Nb_2O_7$, $Sn_2Ta_2O_7$, $Cd_2Sb_2O_7$, $Ca_2Sb_2O_7$, $Mn_2Sb_2O_7$, $Pb_2Sb_2O_7$ ainsi que quelques autres qui s'y rattachent ont été préparés et examinés par différentes méthodes. $Ca_2Sb_2O_7$(pyrochlore) se transforme au dessus de 700° en $Ca_2Sb_2O_7$(wébérite) alors que $Pb_2Sb_2O_7$(pyrochlore) se transforme en $Pb_2Sb_2O_7$(pyrochlore à déformation rhomboèdrique). L'affinement des structures cristallines de $Cd_2Nb_2O_7$ et de $Cd_2Ta_2O_7$, à partir d'intensités obtenues avec un diffractomètre de poudre, donne comme valeurs les plus probables de $x(O_2)$:0.434(2) et 0.434(3) respectivement. On a aussi examiné les minéraux bindheimite et stibiconite. Le spectre Mössbauer de ^{121}Sb montre que la stibiconite de San Luís Potosí (Mexique) contient Sb(V) et Sb(III) approximativement dans le rapport de 0.2.

Les diagrammes de poudre de $BaCd_2Cl_6 \cdot 5H_2O$ et de $BaCd_2Cl_6 \cdot 2H_2O$ sont du type pyrochlore. Le brome peut partiellement remplacer le chlore pour former des cristaux mixtes $BaCd_2Cl_{6-z}Br_z \cdot 5H_2O$ jusqu'à z presque égal à 2.

On discute de la cristallochimie des pyrochlores oxygénés de type 2–5 ainsi que de la relation entre les phases pyrochlore et wébérite.

Canadian Journal of Chemistry, **50**, 3648 (1972)

As a sequel to our previous investigations of oxide pyrochlores of compositions $A_2^{3+}B_2^{4+}O_7$ (3–4 pyrochlores) and $A_2^{1+}B_2^{5+}O_6$ (1–5 pyrochlores) (1–8), some corresponding 2–5 pyrochlores have been studied.

Minerals of this type (pyrochlore, microlite etc.) have been known for a long time, and the discovery of ferroelectricity in $Cd_2Nb_2O_7$ (9) initiated a search for similar compounds with unusual dielectric properties. This search has proved disappointing in that it has uncovered but a minuscule number of new ferroelectrics of this structure type. It showed, however, that for some combinations of divalent and pentavalent cations the composition of the pyrochlore (*P*) phase is not limited to the ideal $A_2B_2O_7$ stoichiometry, while for other combinations *only* hypostoichiometric *P* phases can be prepared by conventional methods. The 2–5 pyrochlores are then best described by the general formula $A_{1+z}B_2O_{6+z}$. The range of z is determined by the particular combination of A and B, and may include unity.

The stability of the *P* structure can be correlated, for 3–4 pyrochlores, with the ionic size and radius ratio of the cations (10). A similar correlation is less satisfactory for the 2–5 pyrochlores (11). Pentavalent cations of suitable size and chemistry are relatively few, and the absence, among divalent elements, of an extensive sequence of closely related ions, such as that formed by the trivalent lanthanons, makes each of the 2–5 *P* phases more unique. The

polarizing action of the B ions, and the polarizability of the A ions, are increased in the 2–5 series and therefore more important as structure-determining factors than in the 3–4 series.

Substituted 2–5 pyrochlores analogous to natural pyrochlore, which has the generic formula $NaCaNb_2O_6OH$, can also be prepared with F^- (*cf.* for example refs. 12–14), and very likely also with OH^- (15), substituting for O^{2-} in the ideal pyrochlore formula. For example, replacing even a very small amount of oxygen in $Ca_2Sb_2O_7$, which normally has the weberite (*W*) structure, by F^- causes the antimonate to adopt the *P* structure (12). Thus evidently substitution in the anion sublattice has a strong effect in determining the structure of $A_2^{2+}B_2^{5+}O_7$ oxides. When such substitution is present but not recognized, it may contribute to the poor correlation of stability of the P structure with cation size and $r(A^{2+}):r(B^{5+})$ ratio alone.

The main purpose of this investigation is to establish a more reliable basis for a crystal chemistry of stoichiometric 2–5 oxide pyrochlores, both by attempting to verify and reconcile earlier literature reports, often contradictory, and by obtaining and examining completely new evidence.

Experimental

The purity and source of supply of most of the starting materials have been described elsewhere (1–6). In addition the following compounds were used: black SnO (typical analysis, in p.p.m., 200 Cl, 50 SO_4, 100 Fe), MnO_2, $CaCO_3$, $CdCO_3$, $CdCl_2 \cdot 2\frac{1}{2}H_2O$, $CdBr_2 \cdot 4H_2O$, $SrCl_2 \cdot 6H_2O$ (Fisher Certified Reagents); $BaBr_2 \cdot 2H_2O$ (Fisher Laboratory Chemical); $PbCO_3$ (reagent grade, Anachema Chemicals Ltd.); $MnCO_3$, PbO, $SbCl_5$ (Baker Analyzed Reagents); and Nb_2O_5 and Ta_2O_5 (3N, CIBA "optical grade").

Preparations were carried out essentially as described in previous accounts (1–6) except as noted (Table 1). The dry-mixed reactants were fired either in air or sealed in evacuated quartz-glass ampoules. In the latter case pellets of the dry-mixed powders were sometimes contained in small crucibles of recrystallized alumina (*e.g.* to prepare the Sn(II) pyrochlores). When there was a possibility that oxidation, reduction, or decomposition would occur during firing, preliminary thermogravimetric analysis (t.g.a.) was made to assist in determining optimum conditions for the preparation. T.g.a. of the reactant mixture during reactive firing was also carried out in cases such as the preparation of $Pb_2Sb_2O_7$ from PbO_2 and Sb_2O_3, to verify that no overall weight loss occurs.

A hydrothermal synthesis of lead antimonate from $PbO_2 + Sb_2O_3$ was attempted by placing the reactant mixture together with an excess of water contained in a recrystallized-alumina crucible, in a small steel bomb and keeping the charge at 350° for 24 h.

Ca, Cd, Mn, and Pb antimonates were prepared by a method previously described by Baccaredda (16). The original suggestion called for firing an excess of the appropriate metal salt with antimonic acid and leaching out the unreacted metal salt with boiling water or some other suitable agent. However, to ensure 1:1 ratios of M to Sb in the products, we used stoichiometric proportions of reactants. The antimonic acid was prepared as described in ref. 6 and reacted with $PbAc_2 \cdot 3H_2O$, $CdAc_2 \cdot 3H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, or $MnAc_2 \cdot 4H_2O$.

"$BaCd_2Cl_6$" and other mixed anhydrous chlorides were prepared by fusing mixtures of the simple chlorides at 550–600° in a platinum crucible. The charge was maintained in the molten state for 10–15 min and cooled in the furnace.

The hydrated mixed chlorides were obtained by dissolving calculated amounts of the simple chlorides in distilled water and allowing the mixed solution to crystallize slowly at room temperature. Alternatively, the mixed solution was heated to saturation, in which case crystals appeared quickly on cooling.

For details of the t.g.a., X-ray, infrared, and dielectric techniques as well as of the structure refinement by least squares refs. 1–3 and 5 may be consulted. Ni-filtered Cu K radiation was used for photographic work and also for powder diffractometry. However, in the concluding stages of this investigation a curved LiF-crystal focussing monochromator became available which gave very low backgrounds with unfiltered Cu K radiation.

Results

Cadmium Niobate and Tantalate

The lattice parameters of $Cd_2Nb_2O_7$ and $Cd_2Ta_2O_7$ agreed well with the values reported earlier by other authors (Table 1).

The permittivity *vs.* temperature curve of the niobate between room temperature and 4.2 °K was in good agreement with a similar curve reported by Jona *et al.* (17). The room-temperature permittivity was 360 and the maximum permittivity, 2420 (at 178 °K).

No ferroelectric transition was observed by permittivity measurements in $Cd_2Ta_2O_7$ between ambient temperature and 4.2 °K.

Calcium Niobate and Tantalate

With one exception (18), attempts by a number of authors to prepare a $Ca_2Nb_2O_7$ pyrochlore have always resulted in a product whose symmetry was eventually determined as monoclinic (19; *cf.* also refs. 20 and 21) and whose lattice parameters resemble remarkably those of $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ (22). According to a preliminary description (21) the structure of $Ca_2Nb_2O_7$ consists of slabs of nearly regular perovskite structure arranged in a manner dif-

ferent from other known structures. The cubic $Ca_2Nb_2O_7$ ($a = 10.37$ Å) reported by Lamure and Colas (18) was prepared under rather special conditions and may have been non-stoichiometric or fluorine-stabilized.

However, the corresponding tantalate has been variously described as "pyrochlore" (11, 23, 24), "pyrochlore-type" (25), "distorted pyrochlore" (26), and "not pyrochlore" (27). Despite numerous attempts involving different heat treatments, stoichiometry and reactants we were unable to obtain a single-phase *P* product. Using tantalic acid and $CaCO_3$, which Byström (23) claimed gave a *P* product at 1200°, yielded the same material as we obtained in all other cases. This was apparently the same product as obtained by Aleshin and Roy (11), who described their material as "*P* + trace". However, they claimed to have obtained a single-phase $Ca_2Ta_2O_7(P)$ upon further firing. The only other reference to $Ca_2Ta_2O_7$ being *P* is in a study of the constitution diagram for the $CaO-Ta_2O_5$ system made by Reeve (24).

The strongest lines of the X-ray powder pattern we obtained for $Ca_2Ta_2O_7$ in all preparations can be indexed on a *P* unit cell of 10.399(8) Å. The additional lines could not be accounted for by considering distortion of the cubic *P* cell, since the majority of the lines did not appear to be displaced from their expected positions for the cubic *P* structure. Doubling or tripling of the cubic unit cell also was ineffective in explaining the extra lines. The additional lines should therefore belong to a second phase, possibly originating in incomplete reaction, but we were unable to identify it as any Ca or Ta oxide or any of the other Ca tantalates so far reported.

Tin(II) Niobate and Tantalate

The question whether $Sn_2^{2+}Nb_2^{5+}O_7$ and $Sn_2^{2+}Ta_2^{5+}O_7$ can be prepared as cubic pyrochlores appeared of considerable interest. Successful preparation of these two compounds would enable the effective radius of Sn^{2+} to be estimated for a 6 + 2 oxygen coordination at a centrosymmetric site of relatively high symmetry, $\bar{3}m$, which by itself would be valuable. That $Sn_2Ta_2O_7$ exists was first suggested by Gasperin (28, 29), who found yellow microscopic crystals giving a diffraction pattern of the *P* type among the products of high-temperature reactions involving Sn, SnO_2, and Ta_2O_5, but their quantities were too small for chemical analysis and their composition was surmized from circumstantial evidence. A cubic $Sn_2Ta_2O_7$ pyrochlore was later reported by Trunov *et al.* (30).[5]

Our initial attempt to prepare $Sn_2Nb_2O_7$ resulted in a bright orange-yellow product whose *P* powder pattern contained very weak extra lines ascribable to β-Sn (sample *i*, Table 1). Reducing the Sn:Nb ratio in the reactant mixture still did not yield a single-phase product; on the contrary, foreign lines not belonging to Sn or SnO_2 appeared (intended composition, $Sn_{1.5}Nb_2O_{6.5}$, Table 1). However, a subsequent paper by Bodiot (32) reported the preparation of the niobate by much the same procedure and claimed a single-phase product; the firing schedule was almost identical with ours. A further attempt at preparing the compound using a very gradual increase in temperature *did* produce a single-phase pyrochlore (sample *ii*, Table 1). Considering that sample *i* was not single-phase, the difference between the lattice parameter of its *P* phase and that of Bodiot's product was very small.

Our initial preparation of Sn(II) tantalate produced a greenish-white compound with a powder pattern of the *P* type, with *very* weak extra lines present. The lattice parameter again agreed very well with the value reported subsequently by Bodiot. A second preparation (sample *ii*) yielded a completely homogeneous product.

Bodiot has reported the homogeneity range of the $Sn_{1+z}B_2O_{6+z}$ niobate and tantalate pyrochlores to extend from $z = 1$ to $z = 1.74$, while from the account of Trunov *et al.* $z = 2$ seems to be the upper limit of the range for the tantalate. There is nothing in either paper to suggest that at $z = 1$ the *P* phase is not a normal pyrochlore $Sn_2^{2+}B_2^{5+}O_7$ with a "classical" distribution of the atoms, *i.e.*, analogous to that in $Er_2Ti_2O_7$ (1). However, attempts to refine the structures of our first niobate and tantalate

[5]A mineral, *sukulaite*, stated to be isotypic with microlite and thus of the *P* type ($a = 10.57$ Å), was found as narrow rims or aggregates (grain size approx. 5 μ) in wodginite inclusions in tantalian cassiterite (31). The Sn:Nb:Ta ratio, as determined by microprobe analysis, would correspond to the formula $Sn_2(Nb_{0.22}Ta_{0.78})_2O_7$ if minor Fe and Mn are disregarded and the tin is assumed to be Sn(II).

preparations from integrated powder diffractometer intensities were unsatisfactory even when allowance was made, in the compositions assumed, for departures from ideal stoichiometry that were thought consistent with the estimated intensities of the foreign-phase powder lines (*vide infra*). This and certain other considerations prompted us to initiate a more detailed investigation of the two pyrochlores by Mössbauer ^{119}Sn spectroscopy and other methods (33).

Antimonates: Method of Preparation

Attempts at synthesizing *P*-type antimonates have been made ever since the discovery of the minerals bindheimite and stibiconite.[6] The products were, however, mostly other than pyrochlores. The only generally successful method by which $M_2Sb_2O_7$ (M = Ca, Cd, Pb) pyrochlores have been obtained is that described by Baccaredda (16): a hydrated salt of M is fused with antimonic acid at low heat followed by calcining at 300–400°. Using dry reactants, such as an MO oxide and an antimony oxide, has usually been found to produce antimonates having structures not of the (cubic) *P* type.

In view of the known ability of OH^- to stabilize the *P* structure and the fact that bindheimite and stibiconite invariably contain OH^- or H_2O (34), it might be thought that the success of Baccaredda's method lies in its use of hydrated reactants. The products obtained by it might therefore contain OH^- or H_2O and would not be stoichiometric $M_2Sb_2O_7$ pyrochlores. However, we were unable to detect any absorption due to hydrogenic species in the infrared spectra of our preparations of antimonates made by the Baccaredda method. Furthermore, using antimonic acid and a nonhydrated metal salt did not always give a *P*-type product. The explanation for the success of the method seems rather to lie in the low temperature required for the reaction (100–200°), and perhaps also in the use of an antimony oxide which already has the *P* structure (*cf.* ref. 7 for details of the structure of antimonic acid). We have found both $Ca_2Sb_2O_7$ and $Pb_2Sb_2O_7$ pyrochlores to be metastable with respect to temperature, so that mild reaction conditions are a necessity if these *P* phases are to be obtained at all.

[6]Bindheimite is an oxide mineral containing mainly Sb and Pb, while stibiconite contains Sb and some Ca. Both give X-ray powder patterns of the *P* type.

Calcium Antimonate

The X-ray powder lines of $Ca_2Sb_2O_7(P)$ were always somewhat diffuse at high angles. Above 700° lines of a *W* pattern developed until finally the yellow-ochre material transformed to give a white powder with a sharp pattern of the *W* type. Our attempts to prepare $Ca_2Sb_2O_7(P)$ from $CaCO_3$ and Sb_2O_3 always resulted directly in the formation of an antimonate with the *W* structure. Other authors have reported the same results (13, 23).

The *P* structure can be stabilized by the substitution of very small amounts of F^- for O^{2-} in the anion sublattice. Thus Butler *et al.* (13) have prepared $Ca_2Sb_2O_{6.5}F$, as well as similar formulations containing less fluorine, all of the *P* type and stable to temperatures of 1000°. Aia *et al.* (12) have reported a similar preparation of $Ca_{1.56}Sb_2O_{6.37}F_{0.44}$ and have carried out an X-ray refinement of its structure (Table 4). The lattice parameter of their material was 10.300(2) Å, which differs only slightly from our value for $Ca_2Sb_2O_7(P)$ (Table 1).

Lead Antimonate

Unlike the Ca compound, $Pb_2Sb_2O_7(P)$ can be prepared with a well-defined X-ray powder pattern. The yellow powder we obtained using Baccaredda's method and after firing to 730° gave sharp, well-resolved lines even at high angles. This is in contrast with Baccaredda's findings for his preparation of $Pb_2Sb_2O_7$: the positions of only eight, low-angle lines of the pattern were measured and these only to poor accuracy. It seems likely that his material was fired to only about 400°, at which temperature the powder pattern is still diffuse. The lattice parameter of our $Pb_2Sb_2O_7(P)$ decreased slightly on heating the compound from 400 to 700°.

When $Pb_2Sb_2O_7(P)$ was heated above 730°, it transformed into a rhombohedrally distorted pyrochlore phase P_{rh} without loss of weight. P_{rh} is also the phase which results by firing dry-mixed oxides: the lattice parameters of a product obtained at 900° (Table 1) were a_{rh} = 10.677(1) Å, $\alpha = 87.70(5)°$. These values are in

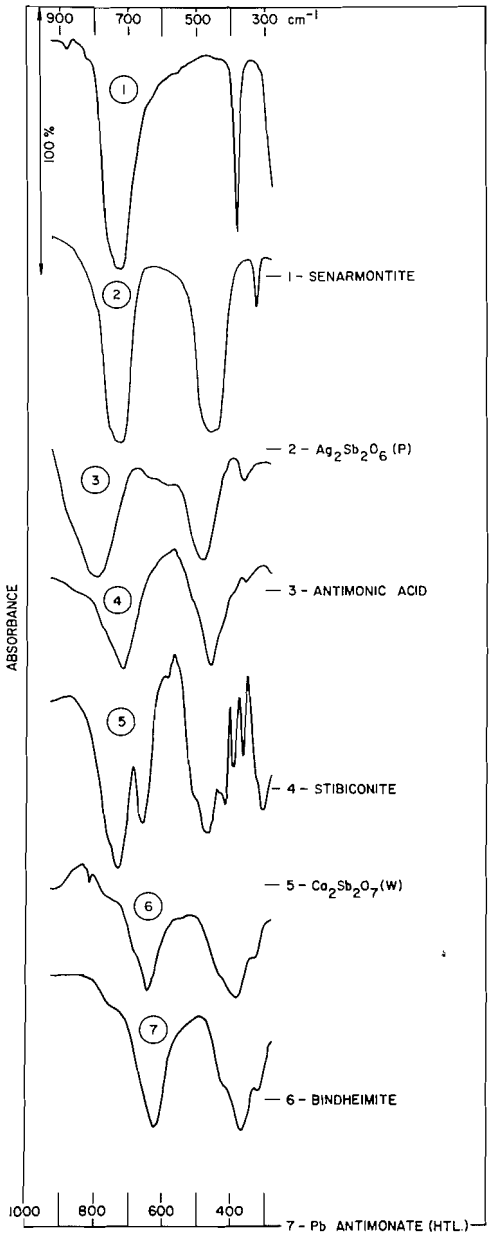

FIG. 1. Infrared spectra of Sb_2O_3 (senarmontite, 1) and antimonates of pyrochlore (2, 3, 4, 6, 7?) and weberite (5) types obtained with compensated KBr pellets. The 100% absorbance values for the individual compounds are indicated by short horizontal lines; HTL, hydrothermal.

reasonable agreement with those reported recently by Moisan *et al.* (35) for a sample fired in a sealed container, 10.64(1) Å and 87.85(5)°, if one takes into account the effect of the small difference in composition which probably existed between their preparation and ours.[7] These authors dispose of the question of existence of $Pb_2Sb_2O_7(P)$ by suggesting that it actually has a formula of $Pb_{2-u}Sb_2O_{7-u}$, in analogy with the defect pyrochlore $Pb_{2-u}Nb_2O_{7-u}$ of ref. 9. Since the transformation $P \rightarrow P_{rh}$ took place without change in weight, this view is not consistent with the observed facts.[8]

We were also able to prepare an ochre-colored fine powder that gave an X-ray pattern of the F (P?) type, by hydrothermal synthesis from $2PbO_2 + Sb_2O_3$ (see Experimental). However, the reflections were only poorly developed.

Bindheimite and Stibiconite

A *bindheimite* specimen from Otjimboyo East, S.W. Africa (BM 1929, 1843) gave a sharp powder pattern of the P type. The lattice parameter, 10.447(2) Å, was in excellent agreement with the value of 10.4480(4) Å reported by Bothwell *et al.* (38).[9] Another specimen (Endellion, Cornwall; BM 26757) gave a fluorite-type pattern resembling that of the product of the hydrothermal synthesis, but the material was not sufficiently crystalline to observe the weak P lines that may have been present. There was no visible change in the pattern on heating the material to 500° for 24 h.

The i.r. spectra of both mineral specimens before heat treatment and of the hydrothermal product were similar. They all contained the two strong bands between 800 and 300 cm^{-1} characteristic of P antimonates (Fig. 1) and a strong OH stretching band centered at 3400 cm^{-1}.

[7]Pb and Sb both begin to volatilize from the antimonate at temperatures of about 800°.

[8]Analogy with $Pb_{2-u}Nb_2O_{7-u}$ would require a substantial loss of weight on transformation or the appearance of a second phase: for the niobate, $u = 0.5$ corresponds to a P phase and $u = 0$ to a P_{rh} phase, but for $0 < u < 0.5$ two-phase mixtures have been reported (37), and a similar situation appears to exist for $Pb_{2-u}Ta_2O_{7-u}$ (15, 36, 37). A preparation intended to yield $Pb_{1.5}Sb_2O_{6.5}$ resulted in a mixture of $PbSb_2O_6$ + another phase (Table 1).

[9]Values quoted for the lattice parameter of bindheimite range from 10.39 Å (converted from kX) (39) to 10.47 Å (34). They are lower than the value for synthetic $Pb_2Sb_2O_7$ (P), reflecting deficiency in the Pb content.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A specimen of *stibiconite* from San Luís Potosí, Mexico,[10] was well crystallized and gave sharp powder patterns. The value of a_0 was 10.292(2) Å, as compared with 10.321(8) Å for synthetic $Ca_2Sb_2O_7(P)$ (Table 1) and 10.34–10.38 Å for antimonic acid (7). Although there was a weight loss of 6.7% on heating to 950° (t.g.a.), the *P* structure was retained and the crystallinity improved. The i.r. spectrum of the untreated material in the 900–300 cm^{-1} region was of the same type as the spectra of bindheimite, antimonic acid, $AgSbO_3(P)$, and Sb_2O_3 (senarmontite). It did not exhibit the fine structure and splitting evident in the spectrum of $Ca_2Sb_2O_7(W)$ (Fig. 1).

A Mössbauer ^{121}Sb spectrum of this stibiconite contained resonant absorptions of both Sb(III) and Sb(V). Computer-fitting of eight Lorentzian lines gave isomer shifts, relative to InSb at 77 °K, of −6.0(2) mm/s for Sb(III) and +9.57(4) mm/s for Sb(V). The respective quadrupole splittings were +15(3) and ±4(1) mm/s, and the corresponding line widths were 3.4(8) and 3.36(15) mm/s. These values are comparable to those in antimonic acid and Sb_6O_{13} (7). The ratio of the Sb(III):Sb(V) peak areas, 0.18(3), may be taken, approximately, to be the Sb(III):Sb(V) population ratio in the sample.[11] Stibiconite is thus a "reduced" nonstoichiometric pyrochlore rather than a 2–5 pyrochlore. The Mössbauer spectrum provides a direct confirmation of the correctness of the general formula $(Sb^{3+}, Ca)_y Sb^{5+}_{2-z}(O, OH, H_2O)_{6-7}$ which was proposed for stibiconite by Vitaliano and Mason (40) on the basis of their chemical analyses for oxygen. Stibiconite was the only one among the antimonate minerals they examined which these authors considered as containing both valences of antimony (34).

[10]Semiquantitative spectrographic analysis of this material gave the following result: Sb, medium; Ca, medium high; silica, low medium; Na, 0.3%; Al, Mg, 0.05%; Sr, 0.03%; Pb, 0.02%; Ba, Ti, V, Fe, 0.01%; Ni, 0.002%; Mn, Cu, Ag, <0.001%. Examination of thin and polished sections revealed amorphous silica and numerous calcite inclusions. It is probable that most of the calcium is contained in the carbonate.

[11]For comments on the validity of this assumption and for details of apparatus and computer-fitting see refs. 7 and 8. For the Sb(V) absorption equally good fit was obtained with either sign of the quadrupole splitting, *i.e.* within the experimental uncertainty the Sb(V) line is symmetric.

Manganese Antimonate

$Mn_2Sb_2O_7(P)$ is also metastable, though largely owing to the strong tendency of the Mn^{2+} to oxidize. We were able to prepare the grey-green $Mn_2Sb_2O_7(P)$ both from antimonic acid and Mn^{2+} acetate (Baccaredda's method) and from $2MnO_2 + Sb_2O_3$. In air the compound was stable only to about 600°, and its powder pattern was not well defined.

As with $Ca_2Sb_2O_7$, the introduction of F^- into the anion sublattice stabilizes the *P* structure. Aia *et al.* (12) report preparation of a *P*-type manganese fluoantimonate with a_0 of 10.141(3) Å but were unable to determine its precise stoichiometry.

Cadmium Antimonate

The single crystal which Byström (23) found in his $Cd_2Sb_2O_7$ preparation and examined by Weissenberg photography had a structure of the *W* type. However, we did not succeed in preparing such a compound. All our preparations, whether by Baccaredda's method or from $CdO + Sb_2O_3$, gave a green powder having an X-ray powder pattern of the *P* type. The product obtained by Baccaredda's method gave a well-defined powder pattern of a somewhat better quality than the product synthesized from the oxides. There was no indication of any structural transformation, and the material was stable at 900° when slow loss of CdO occurred. Recently Moisan *et al.* (35) have also found $Cd_2Sb_2O_7$ to have the *P* structure (Table 1).

Strontium and Sn(II) Antimonates

Attempts to prepare $Sr_2Sb_2O_7$ and $Sn_2Sb_2O_7$ with the *P* structure were unsuccessful, even when using Baccaredda's method. The $Sr_2Sb_2O_7$ preparation always gave powder patterns of the *W* type, and no single phase could be obtained from reactions intended to yield $Sn_2Sb_2O_7$.

Mixed Antimonates $(Cd,Ca)_2Sb_2O_7$ and $(Cd,Sr)_2Sb_2O_7$

Samples of the overall compositions $Cd_{2-u}M_uSb_2O_7$ ($u = 0.5, 1, 1.5, 2$) were prepared by adding acetic acid to the requisite amounts of dry-mixed carbonates + Sb_2O_3 in a platinum crucible, evaporating to dryness and firing the residues, with intermediate grinding, at successively higher temperatures, ultimately

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

at 850–900° for 3 days. Repeated firing at 700° for several days gave powder patterns of poor quality.

In the Ca series *P* reflections plus those of another phase(s) were clearly visible at $u = 0.5$ and 1, with a progressive increase in $a(P)$. The pattern for $u = 1.5$ could not be interpreted with confidence. It appeared to contain neither *P* nor *W* reflections, and the solid-state reaction may have been incomplete. The *W* pattern observed at $u = 2$ was well defined.

In the Sr series the *P* lines were present even at $u = 1.5$. No foreign lines were observed at $u = 0.5$, but the *P* lines were appreciably broadened, indicating possible presence of two or more *P* phases of different compositions as a result of incomplete reaction. Weak lines of an unidentified phase were seen in the $u = 1$ product. At $u = 1.5$ the pattern was essentially that of *W* with very weak *P* lines possibly present, while at $u = 2$ the *W* pattern was sharp and well defined. The $a(P)$ increased with u.

The degree of completeness of reaction and equilibrium in these exploratory experiments is uncertain, but as the variation of $a(P)$ with the overall composition indicates, limited substitution of Cd in $Cd_2Sb_2O_7(P)$ by Ca or Sr is possible, assuming of course that the stoichiometry of the mixed *P* phases remains essentially unchanged.

Chlorides

Ferrari and Cavalca (41; *cf.* also ref. 42) prepared $BaCd_2Cl_6 \cdot 5H_2O$ with a *P*-type powder pattern ($a \sim 13.85$ Å) by crystallization from a mixed solution of the simple chlorides. They reported that the product of dehydration at 200° gave a *P*-type pattern identical with that of the fresh crystal, from which they concluded that the five molecules of water were of zeolitic nature.

Our t.g.a. dehydration curve of the pentahydrate (Fig. 2) indicated the existence, at 110–115°, of a stable dihydrate. The dihydrate also gave a *P*-type pattern, and there was little or no difference between the lattice parameters of the dihydrate, 13.813(2) Å, and the pentahydrate, 13.814(2) Å. The three molecules of water removable at the relatively low temperature are thus probably zeolitic.

When the dihydrate (or the pentahydrate) was kept at 160°, the chloride was completely

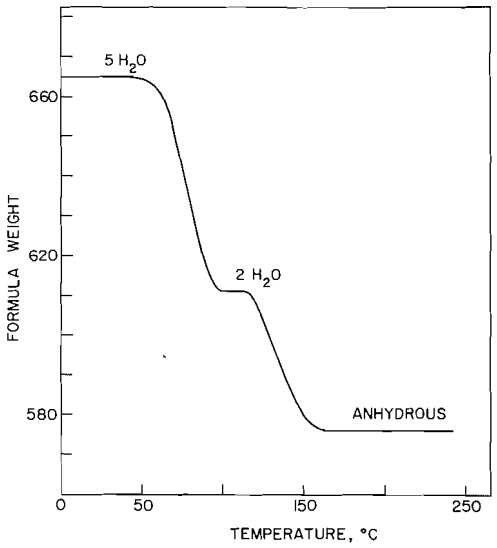

FIG. 2. T.g.a. curve of $BaCd_2Cl_6 \cdot 5H_2O$ in stagnant air. Heating rate, 1°/min.

dehydrated, but contrary to Ferrari and Cavalca's statement the powder pattern of the anhydrous material was not of the *P*-type. It clearly corresponded to a mixture, one of the constituents being $CdCl_2$. The numerous lines of the other phase(s) could not be identified with certainty. A product with the same powder pattern was obtained by fusing $BaCl_2$ and $CdCl_2$ in the requisite proportion. These observations are consistent with Sandonnini's (43) claim that there are no compounds in the system $BaCl_2 - CdCl_2$ and that the system is of the simple eutectic type.

Attempts to replace, by crystallization or by fusion, Ba with Sr or Pb, and Cd with Hg, failed. However, the chlorine could be partially replaced by bromine. This was evident from the change in a_0 of crystals obtained from solutions with different concentrations in Cl^- and Br^-:

†Focussing monochromator in diffracted beam.

The presence of the slightly larger Br^- ion resulted in an increase of the lattice parameter. For $z = 2$ two kinds of crystals were obtained, which indicated that the acceptable amount of Br^- in the structure had reached a limit. In a plot of $a_0(P)$ against the intended z all five points fall on a smooth curve. This suggests that the limiting value of z is close to 2, but a proper correlation will have to await a more detailed study including determinations of Cl and Br in the solid-solution phase after proper equilibration.

Structure Refinements

The crystal structures of Cd niobate and tantalate were refined from powder diffractometer data using *ad hoc* full-matrix programs and (*i*) individual isotropic temperature factors or (*ii*) an overall temperature factor. Weighting schemes W3 (44) and W4 were used; the latter is defined by $w(hkl) = \varepsilon^{-1}(hkl)$, where $\varepsilon(hkl)$ is the standard deviation of $I_o(hkl)$ obtained from several measurements. The initial values of the parameters were K, 1.000; $x(O_2)$, 0.4200; B(Cd), 0.15 Å^2; $B(B^{5+})$, 0.60 Å^2; $B(O_1) = B(O_2)$, 1.50 Å^2; B(overall), 1.00 Å^2. The ionic scattering factors for Cd^{2+}, Nb^{5+}, Ta^{5+} (45) and O^{2-} (46) were corrected for dispersion (both parts, ref. 47).

Integrated diffractometer intensities were collected at least in quadruplicate. The structures were refined both from $|F_o|$'s of single reflections and from intensities. In the F-refinements all single reflections permitted in *Fd3m* up to and including 10.6.6 were used. The $|F_o|$'s of reflections whose intensities were too weak to be counted were entered at 4/9 of the standard deviation of the local background count over 1°(2θ). A similar procedure was adopted for the I-refinements. The exception was the refinement 11*a* (Table 2) of the niobate, in which *measured* monochromatized intensities of all reflections up to and including 10.6.6 were utilized.

The discrepancy indices of the individual refinements were quite low (Table 2) and the agreement of I_o and I_c was very satisfactory (Table 3). However, the values of $x(O_2)$ varied, for the best refinements, by as much as 0.002, which was also the order of magnitude of $\sigma(x)$. About 60% of the observed intensities were below 1% of $I_c(222) = 100$, and at least one half of these 60% were below 0.1%. The latter category contains almost all those reflections to whose intensity the metal atoms make no contribution. Thus the very reflections on which an accurate determination of $x(O_2)$ depends are of doubtful quality. This situation is rendered even more unfavorable by the large scattering powers of the metal atoms relative to oxygen.

The best estimate of $x(O_2)$ appears to be 0.434(2) for the niobate and 0.434(3) for the tantalate. Any difference that might be expected between the two compounds is completely

*The contents of the *P* unit cell (space group *Fd3m*) are 16 A^{2+} in 16(*c*) [000 etc.], 16 B^{5+} in 16(*d*) [$\frac{1}{2}\frac{1}{2}\frac{1}{2}$ etc.], 8 O_1 in 8(*a*) [$\pm$(1/8, 1/8, 1/8) etc.], 48 O_2 in 48(*f*) [*x*, 1/8, 1/8 etc.] (*cf.* ref. 1). The above values of $x(O_2)$ refer to origin in 16(*c*), *i.e.* Sleight's choice A_0 (51). Close examination of the original papers shows that for $Cd_2Ta_2O_7$ (23) and $Cd_2Nb_2O_7$ (17, 69) the origin was placed in 8(*a*) (Sleight's choice O_0), in accordance with the description of *Fd3m* in ref. 66. The dispute on this point (70, 71) may thus be regarded as settled.

TABLE 5. Apparent interatomic distances and bond angles in $Cd_2Nb_2O_7$ and $Cd_2Ta_2O_7$*

*For atomic positions see Table 4 of ref. 1 and for relations between bond angles, Table VII of ref. 5. The uncertainty limits are based on $3\sigma(x)$, and on $4\sigma(a_0)$ for distances independent of $x(O_2)$.

pared with corresponding M—O distances in other compounds (Table 6). The B—O_2 distances are not very different from average values of Nb—O and Ta—O distances in NbO_6 and TaO_6 groupings, but the Cd—O_2 distance equals or exceeds the largest Cd—O distance so far reported, that in $Cd(NO_3)_2 \cdot 4D_2O$.

Compared with the results for the two Cd pyrochlores, the Sn(II) phases (samples *i*) refined poorly. The *R* value for $Sn_2Ta_2O_7$ could not be reduced below 7.6% and the $x(O_2) = 0.448$ and *B*(Sn) values were unreasonably high. The niobate refined to 6.9%; $x(O_2) = 0.436$ fell in the expected range, but both *B*(Sn) and *B*(Nb) were too high, and there were considerable discrepancies in the intensity agreement for some of the reflections. Keeping in mind that samples *i* were not completely homogeneous, allowance was made in the overall formula for a decrease in the intended Sn content, but neither this nor attempts to adjust the populations of the 16(*c*) and 16(*d*) sites by assuming reduced or mixed occupancies produced satisfactory results. Since density measurements on the final, homogeneous preparations (samples *ii*) indicated incompletely occupied unit cells, the necessity of determining whether mixed valency states were present became apparent. Results of a Mössbauer ^{121}Sb investigation will be communicated in another paper of this series (33).

Discussion

Lattice Parameters

The lattice parameter of the *P* antimonates varies linearly with the ionic radius $r(A^{2+})$ for 8-coordination (Fig. 3*A*).

The straight line for the *P* niobates and tantalates, drawn parallel to the antimonates lines, is only tentative, for only Cd, Hg, and Sn

have been reported to form cubic pyrochlores. It accommodates the experimental points reasonably well. The point for $(2V)^{1/3}$ of $Ca_2Nb_2O_7$ (19, 20) and the "$a_0(P)$" of $Ca_2Ta_2O_7$ fall only slightly below it. The a_0 values for Cd niobate and tantalate are very similar, as are those for the Hg compounds, but they differ significantly for Bodiot's $Sn_2Nb_2O_7$ and $Sn_2Ta_2O_7$ (both stated to be stoichiometric) and so do the $V^{1/3}$ values for the rhombohedrally distorted pyrochlores $Pb_2Nb_2O_7$ and $Pb_2Ta_2O_7$. Furthermore, the sequence followed by the a_0 values in corresponding Nb–Ta pairs is not the same for the different A^{2+}.

The slope of the line through the points for Cd_2TiWO_7 and Sn_2TiWO_7 (48) is similar to that for the antimonates, but $a_0(Pb_2TiWO_7)$ is too low.

Tentative straight lines have been drawn in Fig. 3*A* through the $V^{1/3}$ (or $(2V)^{1/3}$) points for $Ca_2Nb_2O_7$, $Sr_2Nb_2O_7$, $Sr_2Ta_2O_7$,[12] $Ba_2Nb_2O_7$, and $Ba_2Ta_2O_7$, and for the three uranates. The trends that seem to emerge despite the discrepancies in the descriptions of the unit cells of these compounds must be regarded as provisional.

[12]Whiston and Smith (49) found no evidence for $Sr_2Ta_2O_7$ in their investigation of the system $SrO-Ta_2O_5$, nor do they mention $Ba_2Nb_2O_7$ among the compounds they identified in the system $BaO-Nb_2O_5$.

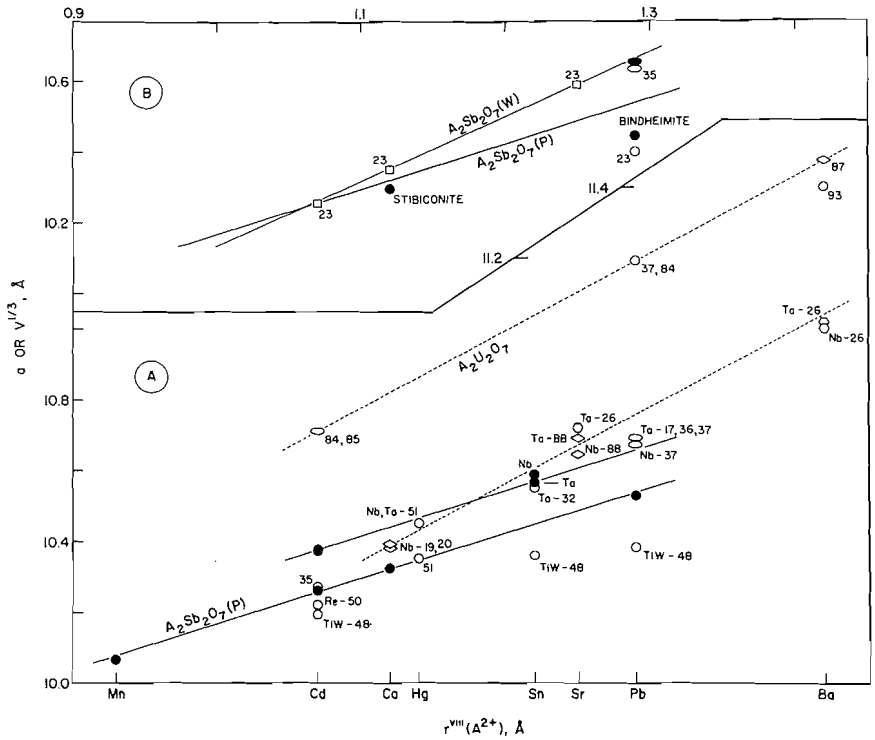

FIG. 3. (*A*) Lattice parameter (or $V^{1/3}$) of stoichiometric $A_2^{2+}B_2^{5+}O_7$ pyrochlores and related compounds plotted against Shannon and Prewitt's (52) ionic radius $r^{VIII}(A^{2+})$. For explanation of symbols see Fig. 4. Full symbols refer to compounds investigated in the present work. Open symbols are for compounds reported in the literature (reference numbers shown): (*B*) Comparison of pyrochlore- and weberite-type $A_2Sb_2O_7$ antimonates.

The Positional Parameter $x(O_2)$

Examination of the $x(O_2)$ values for 2–5 pyrochlores (Table 4) reveals no real evidence that the ideal value of $7/16 = 0.4375$ is exceeded or even reached. The only value greater than 7/16, 0.441(7) for $Cd_2Re_2O_7$, was not regarded as definite evidence for distortion of the ReO_6 octahedra by the authors who reported it (50): by the same token it cannot be viewed as evidence for the *absence* of distortion. The ideal value is, however, approached by our $x(O_2) + \sigma(x)$ values for Cd niobate and tantalate.

While the results available to-date strongly indicate that the BO_6 octahedra in cubic 2–5 pyrochlores (and *a fortiori* in cubic 3–4 oxide pyrochlores; *cf.* refs. 3–5, 10) are never regular, this conclusion is not necessarily definitive. The large disparity of the X-ray scattering factors of the metal and oxygen atoms implies that the appreciable uncertainty in $x(O_2)$ values is inherent in determinations by X-ray diffraction. It is unfortunate that the 2–5 pyrochlores whose reported $x(O_2)$ values are closest to 7/16, and thus most important for resolving the doubt, contain Cd and are therefore unsuitable for neutron diffraction. Methods that are sensitive to site symmetry (Mössbauer and other spectroscopic methods) cannot be expected to decide unambiguously between distorted and regular BO_6 octahedra either: the site symmetry of the B atoms at 16(*d*) is $\bar{3}m$, so for $x(O_2) = 7/16$ the octahedra are only metrically, not crystallographically regular.

The $x(O_2)$ values in 2–5 oxide pyrochlores are higher than in 3–4 pyrochlores. The observed range in the 3–4 series is approximately 0.408–0.428 (and may be expected to extend as high as 0.432 in the high-pressure pyrochlore $Gd_2Ge_2O_7$), whereas the lowest value so far reported for the 2–5 series is 0.427(2) ($Hg_2Nb_2O_7$, Table 4). In $A_2^{3+}B_2^{4+}O_7$ pyrochlores the empirical lower limit coincides

approximately with the $x(O_2)$ value at which the electrostatic (Madelung) lattice energy *vs.* $x(O_2)$ curve calculated for the completely ordered *P* structure intersects the corresponding curve for a structure random with respect to A and B (10).[13] However, for 2–5 pyrochlores the two curves do not intersect above $x(O_2) = 0.375$, the value which is appropriate to the defect fluorite structure. It is thus doubtful that the observed $x(O_2)$ range for 2–5 pyrochlores can be derived from a simple electrostatic model which does not take detailed account of cation–anion and anion–anion repulsive forces. In any case the upper limit of the range can be determined from such a model neither for the 2–5 nor for the 3–4 phases.

Attempts to define the existence field of $A_2^{2+}B_2^{5+}O_7$ pyrochlores in terms of the radius ratio $r(A^{2+}):r(B^{5+})$, and to correlate $x(O_2)$ with this ratio, lead to confused results. The structures of only four of the known stoichiometric 2–5 pyrochlores have been refined (Table 4); the $Cd_2Re_2O_7$ phase might contain $Re^{4+} + Re^{6+}$. This leaves Cd niobate and tantalate, and Hg niobate; estimates have been made for Hg tantalate and antimonate (51). A plot of $x(O_2)$ *vs.* radius ratio thus consists of essentially three points (Cd niobate and tantalate have closely similar values) and shows a trend opposite to that observed for 3–4 pyrochlores, *viz.* a decrease of $x(O_2)$ with increasing value of the radius ratio. When Shannon and Prewitt's (52) tentative value of $r(Re^{5+})$ for 6-coordination, 0.52 Å, is used to include $Cd_2Re_2O_7$ in the plot, the trend disappears altogether. On the other hand, a recognizable trend emerges when $x(O_2)$ is plotted against lattice parameter: $x(O_2)$ decreases with increasing a_0. This is again the opposite of what is observed for the A^{3+} titanates and stannates (3, 5), although allowance must be made for the fact that an attempt is being made here to compare on equal basis compounds which belong to different 2–5 composition series.

Similar uncertainties are evident when one tries to delineate the existence field of 2–5 oxide pyrochlores. The only A atoms known to date to form 2–5 pyrochlores are Mn, Cd, Ca, Hg, Sn, and Pb. The number and size range of eligible B atoms are very small: Nb, Ta, Sb, U, and Re (so far only $Cd_2Re_2O_7$ known). Combinations of W^{6+} with B^{4+} (Ti, Sn, Zr) have also been reported (48, 53) to form pyrochlores with A^{2+}, though in ref. 53 the B:W ratios are greater than unity.

An attempt to assess the role of the size factor (at ordinary pressures) is made in Fig. 4. The "ionic" radii of A and B atoms, in 8- and 6-coordination respectively, are those of ref. 52. The exception is the effective radius of Re^{5+}, which is unlikely to be 0.52 Å, as estimated by Shannon and Prewitt from the lattice parameter of $Cd_2Re_2O_7$. Comparison of the *a* (or $V^{1/3}$) values for Cd uranate, tantalate, niobate, antimonate, and Cd_2TiWO_7 points to 0.59(2) Å as a more reasonable value. The average of $r(Re^{4+})$ and $r(Re^{6+})$ is 0.58 Å (52).

The compositions of the stoichiometric cubic *P* phases known to-date fall between the $r^{VIII}(A^{2+}):r^{VI}(B^{5+})$ values of 1.5 and 2.2, and between $r^{VIII}(A^{2+})$ values of *ca.* 0.92 and 1.32 Å (0.83 and 1.18 Å if $r^{VI}(A^{2+})$ is used). Converted to $r^{VI}(A^{2+}):r^{VI}(B^{5+})$ the radius-ratio limits are 1.35 and 2.0, which compares to approximately 1.2 and 1.6 for the stoichiometric 3–4 pyrochlores.[14] These radius-ratio limits in fact accommodate also all the known distorted oxide pyrochlores and weberites with the exception of $Cd_2U_2O_7$ (reported to be P_{rh}), for which the lower limit should be 1.4 rather than 1.5.

Pentavalent vanadium is evidently too small to form *P* phases. Like P(V) and As(V) in pyrophosphates and pyroarsenates (for examples in $Mg_2As_2O_7$, ref. 54), it is present in pyrovanadate structures as the $V_2O_7^{4-}$ ion, as in the thortveitite-type $Mn_2V_2O_7$ (55) and $Cd_2V_2O_7$ (56). No work seems to have been done on Mo^{5+} and W^{5+} compositions.

Niobium and tantalum are 2–5 pyrochlore formers *par excellence*, though the true symmetry of $Ca_2Ta_2O_7$ is yet to be settled and $Ca_2Nb_2O_7$ and the Sr and Ba compounds are not pyrochlores. That $Ca_2B_2^{5+}O_7$ phases should have different crystal structures depending on whether B is Sb, Nb, or Ta, and in spite of the similarity of the effective radii of the three ions, is not peculiar to this stoichiometry. Similar diversity is known to exist for $Li_3B^{5+}O_5$ and, to

[13]The electrostatic lattice energies in ref. 10 are normalized to $a_0 = 10$ Å.

[14]The upper limit would be about 1.72 if the high-pressure pyrochlore $Gd_2Ge_2O_7$ is included.

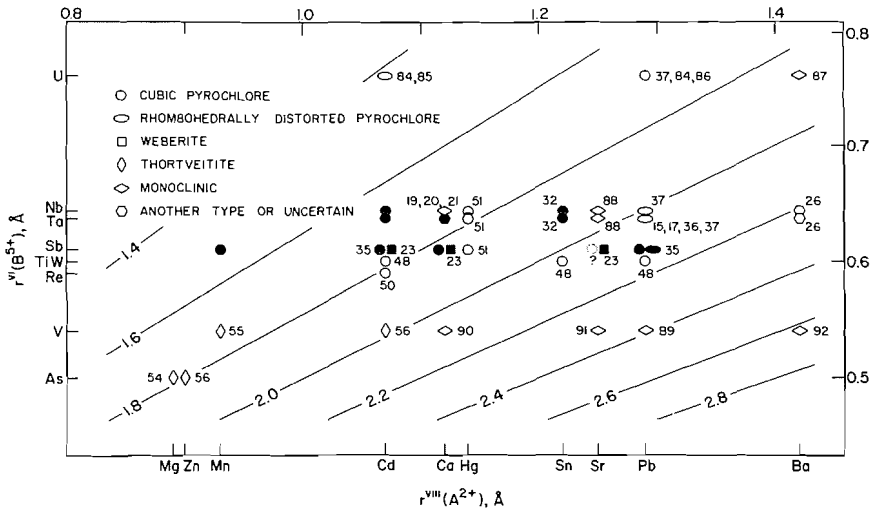

FIG. 4. Existence field of stoichiometric 2–5 oxide pyrochlores in terms of Shannon and Prewitt's ionic radii. The radii of Nb^{5+} and Ta^{5+} are slightly offset relative to one another to separate the points for the niobates and tantalates. The symbol for "thortveitite" implies that the monoclinic crystal structure has been definitely identified as isotypic with thortveitite. The straight lines represent loci of equal $r^{VIII}(A^{2+}):r^{VI}(B^{5+})$ ratios.

a lesser degree, for $A^{2+}B_2^{5+}O_6$ and some other complex oxides; possible reasons for such behavior have been discussed qualitatively by Blasse (57).

Clearly it is significant that in $A_2^{2+}B_2^{5+}O_7$ pyrochlores that form readily and in preference to other structure types the A^{2+} ion has, formally, a d^{10} (or a d^5) configuration, perhaps in relation to polarizability. While $Pb_2Nb_2O_7$ forms a very extensive solid solution with $Cd_2Nb_2O_7$, up to about 90 mol%, the homogeneous $Cd_{2-u}Ca_uNb_2O_7$ *P* phase persists to *u* less than 0.4, in spite of the close similarity of the ionic radii of Cd^{2+} and Ca^{2+} (17). No conclusions can be drawn at present as to possible restrictions on the nature of the B atom. While Sb is the only non-transition B element known to occur in $A_2^{2+}B_2^{5+}O_7$ pyrochlores, there are no other pentavalent non-transition ions of suitable size and existing under ordinary conditions.

Pyrochlore and Weberite Structures as Polymorph Alternatives

A number of observations point to the possibility that the *W* structure is, at least for the stoichiometric antimonates, a dimorph alternative to the *P* structure.

$Cd_2Sb_2O_7$ and $Ca_2Sb_2O_7$ have been reported by some authors to occur with the *P* structure but with the *W* structure by others. In particular, Byström's (23) claim that his $Cd_2Sb_2O_7$ preparation had the *W* structure cannot be discounted, as his conclusion was based on single-crystal diffraction photographs and density of the antimonate. $Ca_2Sb_2O_7(P)$ forms only when antimonic acid and low firing temperatures are employed in the preparation. It transforms into *W* on heating above 700°. However, the existence of $Sr_2Sb_2O_7$ as *W* rather than *P* is undisputed.

When Byström's unit-cell dimensions (converted to Å) of the weberite Cd, Ca, and Sr antimonates are used to calculate "*a*" $= (2V)^{1/3}$ and the resulting values are plotted against $r(A^{2+})$ (Fig. 3*B*), it is seen that the point for $Cd_2Sb_2O_7(W)$ practically coincides with that for $Cd_2Sb_2O_7(P)$, while the points for $Ca_2Sb_2O_7(W)$ and $Sr_2Sb_2O_7(W)$ are significantly above the *P* line. This is true even when an uncertainty as large as ± 0.02 Å is assigned to the $(2V)^{1/3}$ values. Moreover, the three *W* points are on a straight line. The weberites thus have consistently larger (normalized) unit-cell volumes, but the *W* and *P* lines cross at approximately $r(Cd^{2+})$.

The observed facts can be explained if *W* is assumed to be the high-temperature phase of

these compounds. The $P \rightarrow W$ transformation temperature of the Ca compound must be above 700° but below 1100° (*cf.* Table 1); under ordinary conditions the transformation may well be irreversible, similar to the perovskite → ilmenite transformation in $CdTiO_3$ (58) and $CdSnO_3$ (59). Unlike for $CdTiO_3$, however, the high-temperature phase, *W*, is less dense than the low-temperature phase, and so increased pressure would tend to convert *W* into *P*, thereby extending the *P* stability field in the *p*–*T* diagram of $Ca_2Sb_2O_7$. For $Cd_2Sb_2O_7$ the $P \rightarrow W$ transformation temperature must be above 1000°: $Cd_2Sb_2O_7$ sealed in a gold tube which was kept for 24 h at 950–1000° and rapidly cooled in air had the *P* structure (35). Unfortunately Byström did not report the firing temperature which produced the *W* phase in his investigation, and the exact stoichiometry of the single crystal he used was not known.

For $Sr_2Sb_2O_7$ the transformation temperature must be well below 700°. Application of high pressure during reactive firing of SrO + $SrSb_2O_6$ or to $Sr_2Sb_2O_7(W)$ at elevated temperatures ought to produce $Sr_2Sb_2O_7(P)$. The latter experiment would verify the assumption of *P* and *W* being polymorphs.

It is not surprising that with ions in the size range of Cd^{2+} and Ca^{2+} both phases occur at ordinary pressures. Cd^{2+} is at the ilmenite–perovskite boundary for $A^{2+}B^{4+}O_3$ compounds, and Ca^{2+} at the calcite–aragonite boundary for $A^{2+}CO_3$ carbonates. However, the fact that we were able to prepare $Pb_2Sb_2O_7(P)$ by Baccaredda's method but not $Sr_2Sb_2O_7(P)$ seems to indicate that factors other than relative ionic size are involved. The readiness with which Pb^{2+} enters pyrochlore structures, in spite of its large size, has occasioned comment already by Aleshin and Roy (11), who suggested the large polarizability of the ion as the reason for this behavior.

The "a" = $V^{1/3}$ of the rhombohedrally distorted P_{rh} dimorph, into which $Pb_2Sb_2O_7(P)$ transforms on heating above 730°, almost falls on the extension of the *W* line in Fig. 3*B*. This would suggest that the P_{rh} structure is an alternative preferred by $Pb_2Sb_2O_7$ to the *W* structure under conditions where the latter might be expected to be stable.

It is odd that the only oxide weberites so far known are the Cd, Ca, and Sr antimonates. Contrary to an earlier claim by Rooksby and White (60), the orthorhombic compounds Ln_3NbO_7 and Ln_3TaO_7 (Ln = La, Nd) are not of the *W* type. Their space group is not *Imm*2, as reported for weberite, but *Pnam* (61; *cf.* also ref. 62). Further representatives of this structure type, $Sm_2B^{3+}NbO_7$ (B = Sm,[15] ... Lu, Y), have recently been reported (63). In addition, the low-temperature forms of La_3SbO_7 and Pr_3SbO_7 have been stated to transform to "highly distorted *P*" structures on heating at 1400°/60 h and 1450°/78 h respectively; neither the low nor the high-temperature structures are of the *W* or thortveitite types (64). However, the spacings and intensities reported for the powder diffraction patterns of these high-temperature forms (64) show strong similarities to those given by Savchenko *et al.* (65) for Ln_3NbO_7 (Ln = La, Ce, Pr).[16] This would suggest that the structures of the two high-temperature antimonates are of the same, or a closely similar, type as those of the orthorhombic niobate phases.

Chlorides

Ferrari and Cavalca's (41) claim that the structure of $BaCd_2Cl_6 \cdot 5H_2O$ is of the *P* type is based on a comparison of photometric powder intensities with those calculated from the model

16(*c*)	16(*d*)	48(*f*)
8 Ba	16 Cd	48 Cl ($x = 0.44$)

(*Fd*3*m*; converted to origin at center in 16(*c*); *B*(overall) = 1.5 Å^2, atomic scattering factors from ref. 66, Vol. 2). The appreciable water content was disregarded. By present-day stan-

[15] Sm_3NbO_7 is stated to be cubic (*F* or *P*) in ref. 60 but orthorhombic (*Pnam*), and transforming to *F* at around 1800°, in ref. 61. While Rooksby and White's (60) standard firing schedule was 1000°/2 h followed by 1400°/2 h, they also mention that in some instances pressed pellets of the ball-milled simple oxides were heated to 1800° and above with an oxyhydrogen flame, without however listing the compositions so treated. It seems likely that their Sm_3NbO_7 was prepared in this way and did not transform to the orthorhombic form, in spite of being possibly annealed at 1300°.

[16] The reported niobate patterns do not contain the weak lines that would correspond to those listed in the antimonate patterns. However, the erratic backgrounds of the diffractograms in Fig. 2 of ref. 65 do not exclude the possibility that additional, weak lines may have been present but escaped notice.

dards the intensity agreement is poor, but in view of the appreciable scattering powers of Ba and Cd and of the fact that all the Cl atoms are placed in equivalent sites, the approximate correctness of the assumed structure is likely. The water molecules are supposed to be accommodated in the voids of the structure resulting from unoccupied sites (presumably 8(*a*)). No clear suggestion is made as to how as many as 40 H_2O molecules are to be distributed over possible equipoints; this is much the same problem as where to accommodate the water molecules in antimonic acid, which is also of the *P* type (*cf.* ref. 7).

The existence of a dihydrate seems to suggest that the 16 H_2O molecules per unit cell are distributed over the 8(*a*) sites and the available 16(*c*) sites left vacant owing to the incomplete occupancy of 16(*c*) by Ba atoms. Occupancy of 8(*a*) in crystal structures of the *P* type is very common, while mixed Ba + H_2O occupancy of an equipoint has been postulated in the crystal structure of psilomelane, (Ba, $H_2O)_2Mn_5O_{10}$, in which, ideally, Ba:H_2O = 1:2 (67).

It is not obvious where to place the remaining 24 H_2O molecules per unit cell in the structure of the pentahydrate. Eight molecules could be placed in 8(*b*), thus cancelling the contribution to the diffraction intensity from 8(*a*), while 32(*e*) sites might be considered for the last 16 H_2O molecules.

Although single crystals of the pentahydrate were available, a detailed X-ray study was not attempted at this time. The diffuseness of some of the powder reflections led us to believe that crystals for this purpose would have to be grown more slowly and carefully than was the case in the present investigation.

We should like to express our gratitude to the following individuals: Mr. R. Dayal, for examination of polished sections of stibiconite; Dr. P. G. Embrey (British Museum of Natural History), for mineral specimens (marked BM); Dr. M. Falk, for the use of his infrared spectrometer; Dr. C.-H. Huang, for preparing the mixed antimonates; Dr. M. H. Jericho, for making possible the dielectric investigation; Mr. Y. S. Lim, for carrying out the dielectric measurements; and Dr. F. W. D. Woodhams (University of Aberdeen), for obtaining the Mössbauer spectrum of stibiconite.

Financial support by the National Research Council of Canada and by the Geological Survey of Canada through grants to one of us (O.K.) is hereby acknowledged.

Orientational Dependance of Vicinal and Geminal ^{13}C–^{1}H Coupling[1]

J. A. SCHWARCZ[2] AND A. S. PERLIN

Department of Chemistry, McGill University, Montreal, Quebec

Received April 20, 1972

The effect of changes in the relative orientation of vicinal and geminal ^{13}C and ^{1}H nuclei, and in the disposition of adjacent substituents, on coupling between these nuclei has been examined with a variety of ^{13}C-labelled carbohydrates. Compounds synthesized for this purpose include derivatives of D-glucose-1- and -6-^{13}C and L-idose-6-^{13}C, and related lactones, and the measurements have been made with p.m.r. spectra of these compounds. Vicinal ^{13}C–^{1}H coupling, both through C—C and C—O bonds shows an orientational dependance analogous to that for protons: *i.e.*, dihedral angles of 60–100° are associated with smaller coupling (0–3 Hz) than angles of 140–180° (4.5–5.5 Hz); sp^2 carbon produces splittings of almost twice these values. The observed spacing is smaller when an oxygen atom is in the plane of the coupling pathway than when out of plane, both for vicinal and geminal ^{13}C–^{1}H interactions, and the presence of an extra oxygen also may have a notable impact on the geminal interaction. A study of rotational isomerism in these compounds indicates that the characteristics of coupling between ^{13}C and ^{1}H nuclei may fruitfully be compared with those of H–H coupling in the analysis of such dynamic systems.

L'effet du changement d'orientation des noyaux ^{13}C et ^{1}H vicinaux et géminaux et de la disposition des substituants adjacents, sur le couplage entre ces noyaux, a été examiné sur une série de carbohydrates marqués au ^{13}C. Les composés synthétisés dans ce but sont dérivés du ^{13}C-1 et -6 D-glucose, ^{13}C-6 L-idose, les lactones apparantées et les mesures ont été effectuées sur les spectres r.m.n. de ces composés. Le couplage vicinal ^{13}C–^{1}H, à travers les liaisons C—C et C—O, dépend de l'orientation comme dans le cas des protons à savoir, des couplages plus petits pour les angles dièdres de 60–100° (0–3 Hz) que pour les angles de 140–180° (4.5–5.5 Hz), le carbone sp^2 provoquant un dédoublement de presque deux fois ces valeurs. L'écart observé est plus faible lorsqu'un atome d'oxygène se trouve dans le plan du chemin de couplage, à la fois pour les interactions vicinales et géminales ^{13}C–^{1}H et la présence d'un atome supplémentaire d'oxygène peut se répercuter de façon notable sur l'interaction géminale. L'étude de l'isomérie de rotation dans ces composés fournit des caractéristiques de couplage entre ^{13}C et ^{1}H qui peuvent être comparées fructueusement avec les données du couplage H–H dans l'analyse de tels systèmes dynamiques. Canadian Journal of Chemistry, **50**, 3667 (1972)

The n.m.r. spectra of ^{13}C-enriched α- and β-D-glucopyranose show that axial H-1 of the β-anomer is much less affected by ^{13}C coupling than is equatorial H-1 of the α-anomer (1). Observed spacings of 5–6 and 1 Hz, attributed respectively to coupling between *anti*-oriented $H_{1\alpha}$–$C_{3\alpha}$ and *gauche* $H_{1\beta}$–$C_{3\beta}$, which are close to values anticipated by Karabatsos *et al.* (2), indicate a steric dependance analogous to that of H–H vicinal coupling in these compounds (3). The current study, which utilizes a variety of sugars and derivatives specifically labelled with carbon-13, furnishes a much more extensive description of orientational influences upon vicinal ^{13}C–H coupling.[3] Also, the suggestion (1) that ^{13}C–H geminal coupling is sterically-dependant now receives verification, and some amplification.

When this study was being undertaken, it appeared that ^{13}C enrichment is essential for satisfactory measurement of vicinal and geminal ^{13}C–H coupling. However, with rapid improvements in Fourier transform n.m.r. spectroscopy such parameters are becoming available from natural abundance ^{13}C n.m.r. (c.m.r.) spectra, and hence potentially should be more widely useful as stereochemical probes.

Synthesis of the ^{13}C enriched carbohydrate derivatives reported herein has been expedited by the methodology of ^{14}C-labelling (4). Accordingly, cyanide-^{13}C has been used in the Kiliani–Fischer reaction to build up the carbon-chain of the sugars from lower homologs. However, a major difference in technique stems from the fact that whereas carrier is usually added to facilitate isolation of the radioactive compound, dilution of the ^{13}C-labelled product has of neces-

sity been avoided and more laborious purification frequently required. Also, in the reduction of intermediate aldonolactones to aldoses, it has been found more satisfactory to use an aluminum chloride-modified hydride reduction (5) than the standard sodium amalgam or other hydride reductions (4). Compounds described below include glucose-1- and -6-^{13}C, and L-idose-6-^{13}C, and a variety of their derivatives. The aldohexosyluronolactones and aldohexonolactones synthesized as intermediates have served to provide comparative information about ^{13}C coupling with hydrogen in systems containing sp^2 hybridized carbon. All spacings were measured from p.m.r. spectra at 100 or 220 MHz, in several instances the higher frequency being

necessary for adequate separation of the pertinent proton signals from others, including the strong satellite signals (see Experimental).

Vicinal ^{13}C–H Coupling

The compounds used to furnish different examples of vicinal dihedral angle and the ^{13}C–H coupling that they exhibit are listed in Table 1, and angular dependance based on these data is depicted in Fig. 1. It should be emphasized that although the compounds themselves are well-known, angles subtended by the particular bonds under consideration are not known accurately, especially for solutions of these compounds. Proton–proton coupling has, of course, been taken into account wherever possible as a primary point of reference, but since the interpretation of H–H coupling itself sometimes contains substantial uncertainty (6, 7), the approximate nature of the dihedral angles must be recognized. The curve contained in Fig. 1 is incorporated to illustrate that the arrangement of these points bears a resemblance to the type of plot that has been obtained from calculations (8) of vicinal ^{13}C–H coupling in some simpler molecules.

Since the exact solution geometry of the molecules studied is not known, only approximate dihedral angles have been considered. Thus, for compounds **1**–**7** (Table 1) the listed values of 60° are nominal. Within this group of compounds substantial conformational differences may exist, but the range of such variation surely cannot be as large as that observed among the coupling constants *i.e.*, 3.3 to 1 Hz (Table 1). One possible source of such variation is that vicinal ^{13}C–H coupling is exceedingly sensitive in the 60° region of dihedral angle, *i.e.*, analogous to a steeply sloped portion of the Karplus curve for H–H coupling (6, 7, 9). Changes in s-character and/or electronegativity are not likely to account for these differences, because compound **3**, one of those not exhibiting vicinal coupling differs from the others in that the enriched carbon bears an extra oxygen atom; this should give rise to an *increase* rather than a decrease in $J_{^{13}CCCH}$ (10). A more plausible factor appears to be the orientation of oxygen substituents appended to the interaction pathway, as in H–H vicinal coupling (11, 12). Thus the coupling between *gauche* protons is characteristically 2–3 Hz smaller

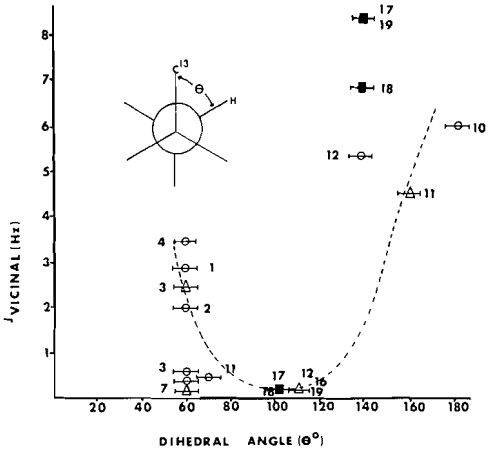

FIG. 1. A plot of ^{13}C–^{1}H vicinal coupling (J, Hz) *vs.* dihedral angle (θ, ±5°) obtained with ^{13}C-labelled carbohydrates (the numbers correspond to compounds listed in Table 1). The broken-line resembles the general shape of the curve plotted from calculated values (8) of J *vs.* θ.

when the O is in the C—C—H plane (as in **9**) than when it is out-of-plane (**8**); *i.e.*, in **9** the O and H are *trans* whereas in **8** they are *gauche*. By analogy, O-3 of **3** is *trans* to ^{13}C-1 and the extent of coupling between ^{13}C-1 and H-5 is correspondingly reduced; the coupling between ^{13}C-3 and H-1 of **7** is similarly affected by virtue of the *trans* relationship between O-1 and ^{13}C-3. Alternatively, O-4 of **1**, **2**, or **4** is *gauche* with respect to ^{13}C-6 and coupling between ^{13}C-6 and H-4 is observed. Additional instances of this kind are given below.

As noted earlier (1) a dihedral angle of nominally 180° is furnished by the spatial relationship between ^{13}C-3 or -5 and H-1 of **10**. The multiplicity of the H-1 signal in this instance shows that more than one interaction of 5–6 Hz is involved. However, the possibility that geminal coupling with ^{13}C-2 also contributes to these broader splittings appears to be small in the light of the discussion presented below.

Other entries in Table 1 deal with five-membered ring, furanose, derivatives. Although these are more flexible than the pyranoses, the fused 1,2-*O*-isopropylidene group that each contains imposes partial rigidity on these rings, and the 3,5,6-tri-*O*-orthoformate (**11**) must have even fewer contributing forms in its conformational itinerary. Especially pertinent in this context is the fact that H_2–H_3 coupling is not ob-

16

served in the spectra of any of these compounds.[4] This is strong evidence that the 2,3-dihedral angle is invariably close to 90°, and that these furanose derivatives may be depicted most satisfactorily by an envelop or twist conformation in which C-3 is above the plane of the ring (14). Such circumstances provide justification for assigning a dihedral angle relationship of about 140° for ^{13}C-1 and H-3 of **12**, and of about 70° for ^{13}C-6 and H-4 of **11**. Little or no coupling is observed in the latter instance, which is consistent with the 60° examples cited above because the ring oxygen of **11** is *anti* with respect to ^{13}C-6.

The introduction of oxygen in place of a carbon along the interaction pathway appears not to alter the general features of these angular dependancies (Table 1). For example, ^{13}C-6 and the ortho-formyl H of **11**, which must be associated through a dihedral angle of close to 160° give rise to a splitting of 4.5 Hz. According to the discussion above on five-membered ring conformations, ^{13}C-1 and H-5 of **12** and **16** are related by a dihedral angle of about 110°, and the observed coupling is ~1 Hz. In **10**, a 180° angle and 5–6 Hz splitting is associated with coupling across the ring oxygen between ^{13}C-5 and H-1 and in **3**, a 60° angle between ^{13}C-1 and H-5 with a splitting of 2.5 Hz. Although the latter value is characteristic of other 60° angles (Table 1), it stands in contrast to the apparent absence of coupling between ^{13}C-1 and H-3 in the same compound. However, it may be noted that the ^{13}C-1–H-5 *gauche* interaction pathway does not contain an in-plane O atom analogous to O-3 and, according to the discussion above, should be expected to generate the size of coupling observed. Another contributing factor could reasonably be differences in the angles C—O—C and C—C—C of the two interaction pathways (10).

An examination (10) of a wide range of com-

[4]The related 3,5,6-tridentate periodate complex of 1,2-*O*-isopropylidene-α-D-glucofuranose also does not show H_2–H_3 coupling (13).

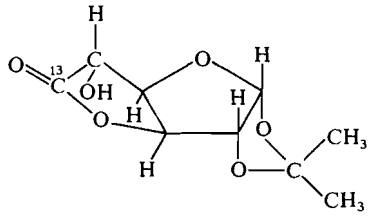
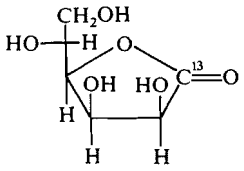
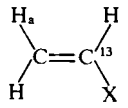
17



18



19



20

pounds has detected no clear correlation between the s-character of a ^{13}C atomic orbital and the magnitude of coupling through three bonds. Hence it is noteworthy that in the current study sp^2 hybridized carbon is found to give rise to much larger values of $J_{^{13}CCCH}$ than encountered previously. Thus, lactones **17**, **18**, and **19** (Table 1), in which the carbonyl carbon is enriched, exhibit vicinal ^{13}C–H coupling that is at least 3–4 Hz larger than observed for sp^3 carbon in this range of dihedral angle. These data provide another indication of the extent to which factors aside from dihedral angle influence the experimentally observed value of J.

Geminal ^{13}C–H Coupling

Geminal coupling also may furnish useful information about the orientation of substituents in cyclic systems. This is suggested by the striking difference between α- and β-D-glucose-1-^{13}C (**5** and **6**), *i.e.* H-2 of the latter anomer exhibits coupling with ^{13}C-1 of 5.7 Hz, whereas H-2 of the α-anomer shows no such coupling (Table 1). Although these findings contrast with the fact that geminal ^{13}C–H splitting of about 4 Hz is seen in the spectra of various acyclic alkyl derivatives (15), it is possible that there is a substantial difference between **5** and **6** in the angle subtended by $^{13}C_1$—C_2—H_2. Furthermore, there appears to be an analogy here to observations (16, 17) made with chloro- or bromoethylene-1-^{13}C (**20**). In **20**, (X = Cl or Br) coupling of −8.3 to −8.5 Hz is found between ^{13}C-1 and the proton *cis* with respect to halogen, but H_a gives rise to a value of +7.1 to +7.5. Similarly, in a series of cyclopropane-1-^{13}C halogen and other derivatives (18) coupling between methylene protons and the geminal ^{13}C is always more negative when the proton and electronegative substituent bear a *cis* relationship, than when *trans*. These geometric differences appear therefore to give rise to opposing contributions to coupling.

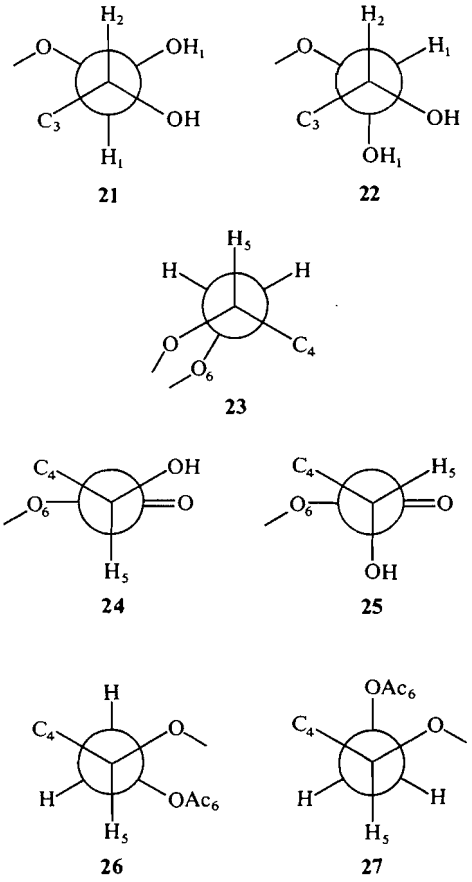
^{13}C-1 of β-D-glucose-1-^{13}C (**6**) is strongly coupled with H-2, whereas coupling of this kind is not detected with the α-anomer (**5**). The enriched carbon of these compounds bears two electronegative substituents, the orientation of the ring oxygen relative to the C_2—H_2 bond is the same in both anomers, but OH-1 is either *gauche* or *anti* to H-2 (**21** or 22).[5] Even if the sign of coupling is not known,[6] in view of the data cited above it is reasonable to expect that these orientational differences could account for the widely divergent coupling characteristics observed. As another example, Newman projection **23** shows that the oxygen on ^{13}C-6 of tri-*O*-orthoformate **10** is constrained in a *trans* orientation relative to H-5. Since this arrangement is analogous to that in α-D-glucose-1-^{13}C (**5**) it is pertinent that, again, coupling between the geminal nuclei is not detected.

Compounds **17** and **18** are another pair of epimers that show a striking difference in geminal coupling. In the light of the comments above, the fact that signal H-5 of the D-glucofuranurono-1,4-lactone (**17**) exhibits coupling of 4.1 Hz with

[5]The disposition of the two O atoms relative to each other and their resultant effects on ^{13}C-1 and H-2 would be a more complete description of these geometric relationships.

[6]Although it is more likely to be negative (see refs. 17, 19).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



^{13}C-6 whereas H-5 of the L-*ido* isomer (**18**) does not suggests that H-5 cannot be *trans* to O-6 in the favored conformation of **17** (*i.e.*, as in **24**) but approaches that situation in **18** (as in **25**). A geminal coupling of 4.8 Hz is found with the related lactone (**19**). If two projections analogous to **24** and **25** are again envisaged here, this coupling may also be taken as an indication that the arrangement corresponding to **24** predominates.

Geminal coupling is strongly influenced as well by the degree of electronegative substitution on the intervening carbon between the geminal ^{13}C and H nuclei (17). The magnitude of this effect in chloroalkanes is large enough (17) to suggest an explanation for the contrasting impact of labelling at C-1 as compared with C-2 of β-D-glucose. That is, H-1 of β-D-glucose-U-^{13}C (7) is not coupled to ^{13}C-2 whereas, as shown above with **6**, there is coupling between H-2 and ^{13}C-1.[7] However, the presence of the extra O on the carbon (C-1) intervening between ^{13}C-2 and H-1 is expected to strongly reduce coupling relative to the reverse pathway (*e.g.*, an extra chlorine on the intervening carbon in chloroalkanes makes the geminal coupling less negative by about 4 Hz (**17**)). For the same reason, it would be anticipated that ^{13}C-2 is not strongly coupled to H-1 of α-D-glucose-U-^{13}C (**10**) and, as discussed above, that the broad splitting of the H-1 signal produced by this compound is due to vicinal coupling with ^{13}C-3 and -5.

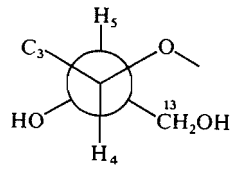
Vicinal and Geminal ^{13}C–H Coupling in Rotamers

Rotational isomerism of carbinol groups exocyclic to five- or six-membered sugar rings has been studied extensively by p.m.r. spectroscopy. However, the interpretation of vicinal H–H coupling within such systems is not straightforward because of time averaging possibilities arising from the rapid interconversion of rotamers. It has been of interest, therefore, to examine vicinal and geminal ^{13}C–H coupling of rotamers of this class as an independant source of information for comparison with the H–H coupling data.

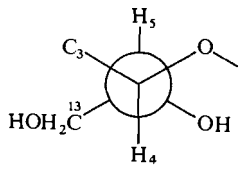
Two preferred rotamers about the 5,6-bond have been advanced for penta-*O*-acetyl-α- or β-D-glucose-6-^{13}C (**1** or **2**): *i.e.*, **26** (20) and **27** (21). Considering possibilities for geminal coupling in the rotamers, a *trans* relationship is found between H-5 and the $^{13}C_6$—O_6 bond in **27**, and a *gauche* one in **26**. Since this corresponds to the inter-relationship described above for β- and α-D-glucose-1-^{13}C (**6** and **5**, respectively), the fact that no geminal coupling is detected between H-5 and ^{13}C-6 appears to be in accord with a preference for **27** rather than **26**.

The p.m.r. spectrum of 1,2-*O*-isopropylidene-α-D-glucofuranose-6-^{13}C (**13**), its L-*ido*-epimer (**14**), or 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose-6-^{13}C (**15**), shows that H-4 and -5 are strongly coupled (14) (see Table 1). For each of these compounds, the large value of $J_{H,H}$ observed (7.5–8 Hz) is consistent with a preponderance of either of two rotamers: in one, H-4 and -5 are eclipsed and in the other, antiperi-

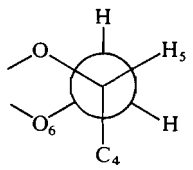
[7]The relative orientation of hydrogens and hydroxyl groups is the same in both pathways but, as noted above, the ^{13}C—C—H angles may not be the same.



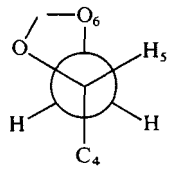
28



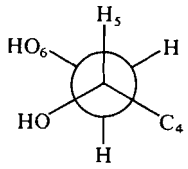
29



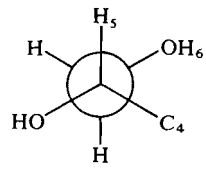
30



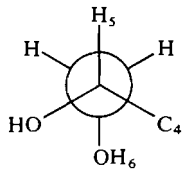
31



32



33



34

planar. On conformational grounds, obviously the latter arrangement (**28**-D-*gluco*, **29**-L-*ido*) is the more likely (14). Hence the small vicinal ^{13}C–H coupling detected (Table 1) agrees with the dihedral angle of nominally 60° relating these two nuclei in **28** or **29**. It is worth noting also that the ring O is *trans* to ^{13}C-6 in **29** but *gauche* in **28** which, according to the data presented above, is consistent in this context with the larger coupling exhibited by the D-*gluco* isomer (**18**).

As to the relative orientation of the 5- and 6-hydroxyl groups in these compounds it is useful to consider the di-*O*-isopropylidene derivative (**15**) because it permits the fewest alternatives: C-5 and C-6 must be constrained in a *gauche* relationship (as in **30** or **31**). Since spin–spin couplings between the 5- and 6-protons are almost equal (Table 1, the smaller value presumably is due to H-6 being *anti* to O-5 (11, 12, 20, 22)), **30** appears to be more favored than **31**. Similarly, from the spectrum of the labelled compound, the fact that geminal coupling between ^{13}C-6 and H-5 is not detectable (Table 1) is more consistent with **30** (in which H-5 is *trans* to O-6), than with **31** (in which they are *gauche*).

$J_{5,6}$ and $J_{5,6'}$ of each of the mono-*O*-isopropylidene derivatives, **13** and **14**, differ substantially (Table 1). However, this does not necessarily mean a preference for rotamers **32** and/or **33**, each of which incorporates an *anti* (6 Hz) and *gauche* (2.7–3.5 Hz) relationship, because the magnitude of the larger spacing (6 Hz) is the same as produced by *gauche* 5,6 orientations in **15** and in "free" rotamers of some other compounds (23, 24). Rotamer **34**, in which O-5 is *trans* to one H-6, is therefore a plausible major contributor. In view of the geminal coupling differences between the anomers of D-glucose-1-^{13}C and of the fact that values for geminal coupling in alkyl derivatives are commonly 4–5 Hz (15–19), the orientations represented by **32** and **33** would both be expected to give rise to perhaps a 4–5 Hz splitting of the H-5 signal due to interaction with ^{13}C-6. Only a small coupling (2 Hz) attributable to the latter source is found in the spectrum of **13**, and none is detected in the spectrum of **14**. Therefore, it appears more likely that an orientation of the primary carbinol group such as shown in **34**, in which H-5 is *trans* to O-6, represents the most highly preferred rotational isomer of these systems.

Directly Bonded ^{13}C–H Coupling

Table 1 lists values measured for coupling between directly bonded ^{13}C and H nuclei. As found earlier with compounds **7** and **10** (1), splitting of the signals produced by anomeric protons (two adjacent O atoms) is substantially larger than that of signals from carbinol protons. Also, there is a difference between anomers (**5** and **10** as compared with **6** and **7**). It is noteworthy that furanose derivatives (**12** and **16**) show much larger anomeric coupling than do the pyranoses. However, a part of this difference may arise from the fact that O-1 of **12** and **16** bears a substituent group, because coupling in other free carbinols is smaller than in substituted carbinols (compare **4**, **13**, **14** with **1**, **2**, **11**, **16**).

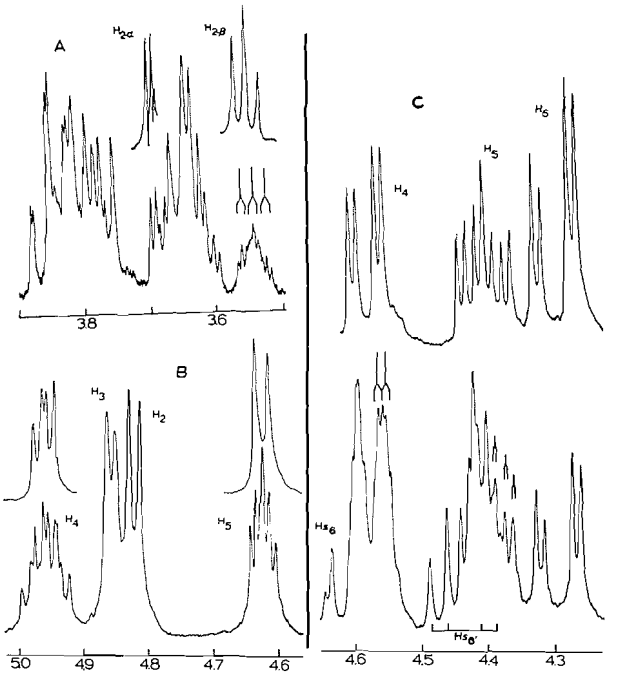

FIG. 2. Partial p.m.r. spectra at 220 MHz of (A) α- and β-D-glucose-1-^{13}C (**5** and **6**) in deuterium oxide; (B) 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone-6-^{13}C (**17**) in chloroform-*d*; (C) 1,2-*O*-isopropylidene-α-D-glucofuranose-6-^{13}C (**12**) in deuterium oxide (Hs-satellite signal). In each instance, the upper signals are those produced by the unlabelled compound.

On the other hand, direct coupling is smaller in cyclohexane than in cyclobutane or cyclopropane (25).

Experimental

Measurement of ^{13}C–H Coupling

^{13}C–H coupling was determined by p.m.r. spectroscopy at 100 and/or 220 MHz.[8] In each instance, the spectrum of the unlabelled compound was analyzed with the aid of spin decoupling (aside from those spectra that have been adequately described elsewhere), and extra splitting due to the ^{13}C nucleus then measured from the spectrum of the isotopically-enriched analog. Figure 2 presents some examples of these data:

(*A*) Geminal coupling in α- and β-D-glucose-1-^{13}C (**5** and **6**) in deuterium oxide. The H-2β triplet at 3.3 p.p.m. (inset) (26) becomes a triplet of doublets attributable to coupling of 5.7 Hz with ^{13}C-1; about half of the original triplet remains unaffected because the degree of enrichment is 55% (see below). A comparison of the H-2α quartet (half of which is reproduced in the inset at 3.6 p.p.m.) with the corresponding signal below, shows that the incorporation of isotope at C-1 has no effect.

[8]Recorded at the Canadian 220 MHz NMR Center, Sheridan Park, Ontario, with the helpful assistance of Dr. A. Grey.

(*B*) Vicinal and geminal coupling in 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone-6-^{13}C (**17**). Signal H-4 exhibits a splitting of 9.0 Hz ascribable to coupling with $^{13}C_6$ via C-5 and -4, whereas the pathway via O-4 and C-3 does not give rise to a discernible interaction between H-3 and ^{13}C-6. Geminal coupling between H-5 and ^{13}C-6 amounts to 4.1 Hz.

(*C*) Vicinal and geminal coupling in 1,2-*O*-isopropylidene-α-D-glucofuranose-6-^{13}C (**12**). Overlap by satellite signals (centered at 4.45 and 4.62 p.p.m.) produced by the two 6-protons partially obscures this spectrum. Nevertheless, the upfield portion of signal H-4 clearly shows a splitting of 2.4 Hz ascribable to coupling with ^{13}C-6. Similarly, the upfield portion of signal H-5 exhibits a line broadening of 2–2.5 Hz; but it is noteworthy that the component of this signal found at 4.44 p.p.m. is much less influenced by the presence of the isotope, an effect that has not been observed in other spectra of this series.

Synthesis of ^{13}C-Labelled Compounds

In general, syntheses were carried out by procedures closely similar to those that have been described for the corresponding ^{14}C-labelled compound, or by other well-known procedures. Isotope was introduced in all instances by the addition of potassium cyanide-^{13}C, 55% enriched (Merck, Sharpe and Dohme Ltd., Montreal, Quebec), to the appropriate aldose.

The methods of synthesis are summarized below; unless

otherwise noted, the products were obtained in crystalline form and had correct melting points.

*1,2-O-Isopropylidene-α-*D*-glucofuranurono-6,3-lactone-6-*^{13}*C (17)*: via treatment of 1,2-*O*-isopropylidene-5-aldehydo-α-D-xylodialdo-1,4-furanose with potassium cyanide ^{13}C according to the conditions of Schaffer and Isbell (4, 27).

*1,2-O-Isopropylidene-α-*D*-glucofuranose-6-*^{13}*C (13)*: by reduction of **17** with sodium borohydride in methanol (28).

*1,2:5,6-Di-O-isopropylidene-α-*D*-glucofuranose-6-*^{13}*C (15)*: by acetonation of **13**.

*1,2-O-Isopropylidene-3,5,6-tri-O-orthoformyl-α-*D*-glucofuranose-6-*^{13}*C (11)*: by treatment of **13** with triethyl orthoformate and hydrogen chloride (29).

*Methyl α-*D*-glucopyranoside-6-*^{13}*C (4)*: acid hydrolysis of **13**, followed by treatment of the liberated α,β-D-glucose-6-^{13}C with hot methanolic hydrogen chloride.

*1,2,3,4,6-Penta-O-acetyl-β-*D*-glucopyranose-6-*^{13}*C (1)*: from α,β-D-glucose-6-^{13}C by acetylation with hot acetic anhydride–anhydrous sodium acetate (30).

*1,2,3,4,6-Penta-*D*-acetyl-α-*D*-glucopyranose-6-*^{13}*C (2)*: by treatment of **1** with acetic anhydride–perchloric acid at 40° (31).

*1,2-O-Isopropylidene-β-*L*-idofuranurono-6,3-lactone-6-*^{13}*C (18)*: obtained as the epimeric product in the preparation of **17** (4, 28).

*1,2,-O-Isopropylidene-β-*L*-idofuranose-6-*^{13}*C (14)*: by reduction of **18** with sodium borohydride in methanol (28).

*α- and β-*D*-Glucose-1-*^{13}*C (5 and 6)*: addition of potassium cyanide-^{13}C to D-arabinose, according to the procedure of Schaffer and Isbell (27) yielded crystalline D-glucono-1,5-lactone-1-^{13}C. The latter, on reduction with lithium aluminum hydride–aluminum chloride (5) afforded **5** and **6**. The individual anomers were not isolated in crystalline form, and their p.m.r. spectra were recorded in admixture (see Fig. 2).

*1,2-O-Isopropylidene- and 1,2:5,6-Di-O-isopropylidene-α-*D*-glucofuranose-6-*^{13}*C (12 and 16)*: isolated by fractional crystallization as products of the acetonation of **5** and **6**.

*1,2,3,4,6-Penta-O-acetyl-β-*D*-glucopyranose-1-*^{13}*C (3)*: by treatment of **5** and **6** with hot acetic anhydride–anhydrous sodium acetate (30).

D-*Mannono-1,4-lactone-1-*^{13}*C (19)*: the epimeric product from the cyanohydration of D-arabinose, isolated during the synthesis of **5** and **6** (28).

The ^{125}Te Mössbauer Absorption Spectra of the Thiourea, Ethylenethiourea, and Tetramethylthiourea Derivatives of Tellurium(II) and Tellurium(IV)

B. M. CHEYNE, C. H. W. JONES, AND P. VASUDEV

Simon Fraser University, Burnaby 2, British Columbia

Received February 17, 1972

The ^{125}Te Mössbauer spectra of a number of Te(II) and Te(IV) complexes of thiourea and related derivatives have been measured. The isomer shifts and quadrupole splittings for several of the compounds are interpreted in terms of a bonding scheme utilizing three-center, two-electron bonds in which the tellurium 5p orbitals participate. The ^{129}I Mössbauer spectrum of *trans*-$TeEtu_2{}^{129}I_2$ is reported and the isomer shift and quadrupole splitting are shown to be consistent with the proposal that the iodine uses only a 5p orbital in bonding to the tellurium.

Nous avons mesuré les spectres Mössbauer, utilisant ^{125}Te de certains complexes de Te(II) et Te(IV) avec la thiourée et de dérivés semblables. Nous interprétons les déplacements d'isomères et les éclatements quadrupolaires de plusieurs de ces composés en termes d'un mécanisme de liaisons à trois centres, deux liaisons électroniques auxquelles participent les orbitales 5p du tellure. Nous rapportons également le spectre Mössbauer utilisant ^{129}I du *trans*-$TeEtu_2{}^{129}I_2$ et montrons qu'il vérifie l'hypothèse que l'iode utilise seulement une orbitale 5p pour sa liaison avec le tellure. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3677 (1972)

Introduction

Although the Mössbauer effect for ^{125}Te has been known for some time, relatively few Mössbauer studies of chemical bonding and structure in tellurium compounds have been reported. The bulk of the work which has been carried out to date has been concerned with the metal tellurides (1, 2), tellurium metal (1, 3), the tellurium–oxygen compounds (4–10), and the tellurium hexahalo- and tetrahalo-compounds (4, 6–9, 11, 12). In the present paper we report on the ^{125}Te Mössbauer absorption spectra of a number of thiourea (Tu), ethylene thiourea (Etu), and tetramethylthiourea (Tmtu) derivatives of tellurium.

The compounds investigated contain tellurium in the formal oxidation states of II and IV, and it was of interest to study the dependence of the Mössbauer isomer shift on the oxidation state of the tellurium and also on the nature of the co-ordinated ligands. The geometry around the tellurium atom in these compounds varies from octahedral to square planar and distorted square planar, and the measurement of the quadrupole splitting for these various coordinations was of considerable interest. The presence of *cis–trans* isomerism in some of these complexes was a further point of interest.

Experimental

The Mössbauer spectra (2 × 256 channel mirror image spectra) were recorded using a Nuclear Science and Engineering Corporation AM-1 spectrometer, equipped with a Texas Instruments Inc. CLF-3 cryoflask, and coupled to a Nuclear Data 2200, 512 channel analyzer. The ^{125}Te and ^{129}I spectra were recorded with the source and absorber at 80 °K. For the ^{125}Te studies a 50 mCi ^{125}I/Cu source supplied by New England Nuclear Corporation was used. The 35.5 keV resonant γ-ray was detected, using a Reuter–Stokes Xe/CO_2 proportional detector (2 atm), by monitoring the 6 keV escape peak. The ^{129}I spectrum was recorded using a $Zn^{129m}Te$ source prepared in this laboratory using ^{129m}Te labelled tellurium metal obtained by neutron irradiating ^{128}Te (>99%) at Chalk River Nuclear Laboratories. The $Zn^{129}Te$ source gave an isomer shift of -0.50 ± 0.04 mm s^{-1} against a $Na^{129}I$ absorber.

The velocity scale of the spectrometer was routinely calibrated using an α-Fe_2O_3 absorber and a 5 mCi ^{57}Co/Pd source. The line spacings in the α-Fe_2O_3 spectrum were taken as those given in ref. 13. A National Bureau of Standards $Na_2(Fe(CN)_5NO).2H_2O$ absorber ($\delta = -0.442$ mm s^{-1}, $\Delta = 1.712$ mm s^{-1}) was also measured against the ^{57}Co/Pd source at a number of velocities to determine the zero velocity of the spectrometer. The two absorbers gave consistent values for the velocity calibration. The δ of α-Fe_2O_3 was found to be $+0.20 \pm 0.01$ mm s^{-1}. A number of standard ^{125}Te spectra were also recorded to allow a ready comparison of the data with that of previous work, since Erickson and Maddock (10) have noted that different sources used in ^{125}Te work in the past have resulted in quite different isomer shifts. All ^{125}Te isomer shifts given in the present work are quoted with respect to the ^{125}I/Cu source, while the ^{129}I result is quoted with respect to the ZnTe source.

14	*trans*-$TeTmtu_2Br_4$	Impure					

*Tu = Thiourea, Etu = Ethylenethiourea, Tmtu = Tetramethylthiourea.
†C and N analyses were carried out in this laboratory using a Perkin-Elmer 240, C, H, and N Analyzer.
‡Te analyses were carried out by Bernhardt Microanalytisches Laboratorium.
§The compound $[TeTu_3(HF_2)_2]_2$ was relatively unstable and turned black on standing. Only C and N analyses were performed on this sample.

The mirror-image spectra were independently fitted to Lorentzians using a computer program kindly provided by Stone (Appendix to ref. 14). The ^{125}Te spectra were fitted without any applied constraints, while the ^{129}I spectrum was fitted constraining all the line-widths as being equal. The program generates χ^2 values which provide an estimate of the goodness of fit to the data, and the χ^2 values for the two halves of each spectrum were always in good agreement. The isomer shift and quadrupole splitting values quoted are the mean values obtained from the two halves of the spectrum. The errors in these parameters were calculated from the standard deviations in the line positions. The half-widths quoted are the mean values obtained for the peaks in the first half of each spectrum.

The ^{125}Te compounds were synthesized in high yields using 75% enriched ^{125}Te obtained from Oak Ridge National Laboratories and using the methods described by Foss *et al.* (15–22). Analysis results for sample preparations using unenriched tellurium are shown in Table 1. The samples of $TeTmtu_2Br_4$ and $TeTmtuCl_2$ were found to contain impurities. Foss *et al.* have reported that the former compound contains $TeTmtuBr_2$ as impurity. Because chemical analyses were not carried out on the ^{125}Te-enriched samples, Raman and i.r. spectra were recorded for the isotopically enriched and unenriched samples and were shown to be identical, although Raman spectra were not obtained for $TeTmtu_2Br_4$ and $TeTmtuCl_2$. Where comparisons could be made, the Raman spectra were in reasonable agreement with those of Hendra and Jovic (23, 24). The ^{125}Te absorbers contained 10–15 mg cm^{-2} of ^{125}Te.

The *trans*-$TeEtu_2{}^{129}I_2$ was synthesized using ^{129}I obtained as $Na^{129}I$ in aqueous solution from Oak Ridge National Laboratories. This absorber contained *ca.* 10 mg cm^{-2} ^{129}I.

Results

The ^{125}Te Mössbauer parameters for the thiourea, ethylenethiourea, and tetramethylthiourea compounds investigated are given in Table 2. The computed fits to the spectra were judged statistically acceptable (the 5% limit on χ^2 is 284 for 247 degrees of freedom) for all of the compounds except $TeTmtu_2Br_4$ and $TeTmtuCl_2$, where the samples were known to contain small amounts of impurities. Sample spectra are shown in Fig. 1. The values given in Table 2 for tellurium metal, tellurium dioxide, and zinc telluride are those measured in the present work.

The ^{129}I Mössbauer data for *trans*-$TeEtu_2{}^{129}I_2$ is presented later in the paper.

Discussion

Structures of the Compounds Studied

Before discussing the significance of the measured Mössbauer parameters, it is relevant to briefly review the structures of these compounds. Foss and co-workers (25–29) have made a detailed and systematic study of the structures of many of the thiourea and related derivatives of Te(II) and Te(IV) and the results of their investigations together with those of

*Tu = Thiourea, Etu = ethylenethiourea, Tmtu = tetramethylthiourea.
†δ with respect to an ^{125}I/Cu source.
‡δ and Δ are the mean values computed from the two halves of the mirror image spectrum. The errors are calculated from the standard deviations of the line-positions.
§2Γ is the average full width at half-maximum for the first half of the mirror image spectrum.
‖χ^2 are again those for the first half of the mirror-image spectrum.

Husebye and George (30) are presented in condensed form in Table 3. The table shows the geometrical configuration for four different types of compounds, and the bond lengths and bond orders for several specific cases. The bond orders were determined using the formula (31)

$$D(n) - D(1) = -0.60 \log n$$

where $D(n)$ is the bond length, $D(1)$ is the sum of the covalent radii, and n is the bond order.

Compound **6**, $[TeTu_3(HF_2)_2]_2$, does not appear in Table 3 and is reported to contain a dimeric cation, $(TeTu_3)_2^{4+}$, in which each tellurium is bonded to two terminal and two bridging thiourea ligands in an approximately square-planar arrangement (29). The compound $TeTmtuCl_2$, which again is not included in Table 3, is reported (22) to have *trans*-chlorines, with a fourth, long chlorine contact *trans* to the sulfur completing a planar arrangement about the tellurium.

Foss (25) has proposed that the bonding in many of these compounds may be described in terms of three-center, two-electron bonds, in which the tellurium employs one 5p orbital to bond to two ligands at 180° to each other. The common occurrence of bond angles close to 90° and 180° at the tellurium, together with the relatively long, weak Te—S bonds observed in those compounds containing the *trans*-S—Te—S configuration, are cited (25) as evidence for such a bonding scheme. For *cis*-$TeTu_2Br_2$, where the Te—S bond is much shorter than that in $TeTu_4^{2+}$ while the Te—Br bond is much longer than that in *trans*-$TeEtu_2Br_2$, it is apparent that as one bond increases in strength the bond *trans* to it weakens, further supporting the three-center, two-electron model. Finally, Foss (25) points out that Hendra and Jovic (23) have interpreted the Raman and i.r. spectra of the $TeTu_4^{2+}$ complexes as showing that the Te—S bond is weaker than the I—Cl bond in the isoelectronic ICl_4^- ion, where three-center bonds involving the iodine 5p orbitals have previously been proposed.

The Isomer Shifts

We may now turn to a discussion of the ^{125}Te isomer shifts. The results of Table 1 show that in all the $Te^{II}Tu_4X_2$, *cis*-$Te^{II}Tu_2X_2$, and *trans*-$Te^{II}Etu_2X_2$ compounds, the Mössbauer isomer shifts span a small range from 0.74 to 1.00 mm s^{-1}, while in the *trans*-$Te^{IV}Tmtu_2X_4$ com-

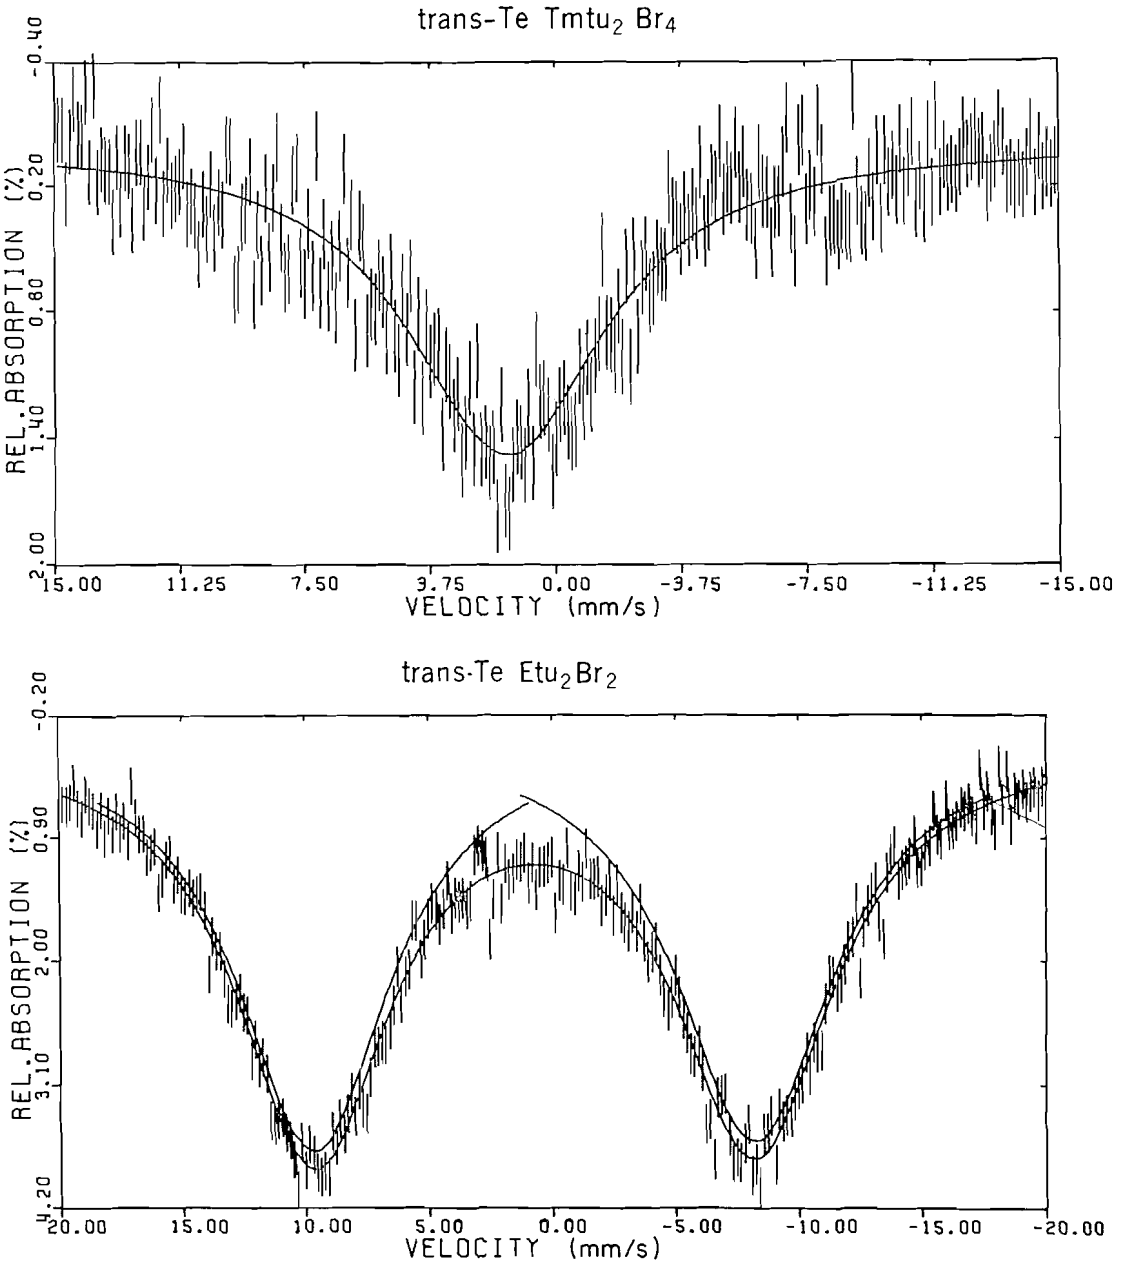

FIG. 1. The ^{125}Te Mössbauer spectra of some of the thiourea complexes as measured at 80 °K.

pounds the isomer shifts are about 1.6 mm s^{-1}. Thus there is a clear differentiation between the isomer shifts for the Te(II) and Te(IV) compounds, the values being more positive for the higher oxidation state. Assuming (32) that $\Delta R/R$, the change in nuclear radius divided by the radius of the ground state, is positive for ^{125}Te, the observed trend in isomer shifts may be readily understood in terms of the bonding scheme proposed by Foss. Thus if the bonding in these compounds occurs principally through the tellurium 5p orbitals, the 5s^2 electrons forming

§Reference 30.

a stereochemically inactive lone-pair, then the removal of 5p electrons would result in deshielding of the $5s^2$ electrons from the nucleus. This would correspond to an increase in $|\psi_s(0)|^2$ and a more positive Mössbauer isomer shift for the higher oxidation states on the tellurium. This is certainly consistent with the trend in isomer shifts observed for the Te(II) and Te(IV) compounds.

The compounds $TeTu_4X_2$ are observed to have the same isomer shift within the error of the measurement, consistent with the presence of the $TeTu_4^{2+}$ cation in each case. As would be expected, the anions X have little influence on the isomer shift. The *trans*-$TeEtu_2X_2$ compounds have the same isomer shift as that for $TeTu_4^{2+}$ and thus there is no measurable effect on δ of substituting the *trans*-X—Te—X three-center bond for the *trans*-S—Te—S configuration. (This point is further borne out by the fact that the *trans*-$TeTmtu_2X_4$ compounds do not have a measurable quadrupole splitting, as will be discussed below.) The Etu ligand and the Tu ligand play an identical role in bonding to the tellurium, as demonstrated by the close agreement of the parameters for $TeTu_4Cl_2$ and $TeEtu_4Cl_2$.

In *cis*-$TeTu_2Cl_2$ and -Br_2 the isomer shifts appear to be less positive than those for $TeTu_4X_2$ and *trans*-$TeEtu_2X_2$, although this difference may not be statistically significant. In the case of *cis*-$TeTu_2X_2$, the Te—S bond order approaches one, and the p-electron density on the tellurium is evidently about the same as that in the $TeTu_4^{2+}$ cation, thus resulting in approximately the same isomer shift. This is certainly consistent with the three-center, two electron bonding scheme, two short, strong Te—S bonds contributing about the same 5p electron density as four long, weak Te—S bonds.

The question arises as to whether the small variations in the isomer shifts for the Te(II) compounds are significant. It may be noted that in *cis*-$TeTu_2Cl_2$ and -Br_2 the geometry around the tellurium shows significant deviations from a regular square-plane (27). Thus the Te—S and Te—X planes intersect at an angle of 11 to 12°, while the S—Te—S bond angles are 93 to 95°. This may indicate the presence of some tellurium 5s character in the bonding, which would tend to make the isomer shift more negative. It is unfortunate that the errors in the isomer shifts do not allow any firm conclusion to be drawn on this point. In the case of $TeTmtuCl_2$ the isomer shift is certainly much less positive than in $TeTu_4^{2+}$ and this would be consistent with the presence of a small amount of s-character. This point will be referred to again following a discussion of the quadrupole splittings.

Before concluding this section, it is of interest to extend the above discussion of the pure p-bonding model a little further. The bonding

scheme proposed above is analogous to that which has previously been used to describe the bonding in the interhalogen compounds. In the ^{129}I and ^{127}I Mössbauer studies of the alkali iodides and the iodine interhalogen compounds (33–35), the isomer shifts have been shown to be directly related to the electron populations of the 5p orbitals on the iodine, the $5s^2$ electrons again forming a non-bonding lone-pair. The iodine 5p electron populations have been independently obtained from n.m.r. and dynamic quadrupole resonance data and this has led to the establishment of a relationship between $\delta(^{129}I)$ and *hp*, where *hp* is the number of p-holes in the closed $5p^6$ configuration of the iodine (34):

$$\delta(^{129}I)_{ZnTe} = 1.50\,hp - 0.54$$

A similar analysis (36, 37) for tellurium has been attempted, using the halogen n.q.r. data of Nakamura *et al.* (38) for the TeX_6^{2-} (X = Cl, Br, I) ions to determine the charge on tellurium. However, this approach is dependent on certain assumptions regarding the bonding s-character of the tellurium and the halogen in these ions (36). A more direct approach is to relate the isomer shift/*hp* plot for ^{129}I to that for ^{125}Te through the ratio of the isomer shifts for these two isotopes (36, 39), $\delta(^{125}Te)/\delta(^{129}I) = +0.29$. This leads to the proposed expression (36, 37) for tellurium

$$\delta(^{125}Te)_{I/Cu} = 0.44\,hp - 0.23$$

where $\delta(^{125}Te)$ is in mm s^{-1}. This expression may be used to examine the *hp* values for the Te(II) and Te(IV) compounds.

The average isomer shift for the $TeTu_4^{2+}$ cation obtained from compounds **1–5** is $+0.92 \pm 0.05$ mm s^{-1}. This corresponds to an *hp* value of 2.5 ± 0.2, where the error includes an estimate of the error in the above isomer shift expression. For the *trans*-$TeTmtu_2X_4$ compounds, since there is no measurable quadrupole splitting the three 5p orbitals on the tellurium must have very similar populations. It may then be proposed that *hp* for these compounds should be just 3/2 times that of the *hp* value for $TeTu_4^{2+}$, *i.e.* 3.9 ± 0.3. The isomer shift of *ca.* 1.6 mm s^{-1} for $TeTmtu_2X_4$ corresponds to an *hp* value of 4.0 ± 0.2, in good agreement with the predicted value. In this admittedly naïve approach, it is assumed that the change in formal oxidation state of the tellurium does not lead to a change in the effective population of the bonding 5p orbitals. In support of such a proposal we may note the following: (*1*) The Te—S bond lengths in $Te^{II}Tu_4^{2+}$ and in *trans*-$Te^{IV}Tmtu_2X_4$ are essentially the same (30). (However, it must be noted that the Te—Br bond in *trans*-$TeTmtu_2Br_4$ is somewhat shorter than that in *trans*-$TeEtu_2Br_2$.) (*2*) For $I^{I}Cl_2^-$, $I^{III}Cl_4^-$, and $I^{V}Cl_6^-$, the bonding 5p orbital populations on the iodine in the three-center Cl—I—Cl configurations were found to be very similar in all three cases, despite the increase in charge on the central atoms (40).

On the basis of the above we may conclude that the values of the isomer shifts for the Te(II) and Te(IV) compounds are consistent with a three-center two-electron bonding scheme utilizing the tellurium 5p orbitals.

The Quadrupole Splittings

Turning to a discussion of the quadrupole splittings, Δ, the immediate point to note is the very large value of Δ for compounds **1–12**. The very large electrostatic field gradient present in all these instances is consistent with the square planar structure for these compounds, and has its origin in the unequal population of the $5p_x$, $5p_y$, and $5p_z$ orbitals.

The similarity in the quadrupole splittings for compounds **1–12** indicates that a similar imbalance in the 5p orbital populations exists in all cases. Within the context of the bonding scheme discussed above, this would imply a similar occupancy of the in-plane $5p_x$ and $5p_y$ orbitals in each case, the $5p_z$ orbital defining the axis of the electrostatic field gradient and containing two, non-bonding electrons.

Thus the similarity in quadrupole splittings for $TeTu_4^{2+}$, *cis*-$TeTu_2X_2$, and *trans*-$TeEtu_2X_2$ is quite consistent with the similarity in isomer shifts for these compounds.

For the case of the $TeTu_4^{2+}$ ion it is possible to examine the significance of the quadrupole splitting in more detail. The quadrupole splitting for a molecule, e^2qQ mol, is related to the imbalance in the p orbital populations through the following expressions (34)

$$e^2qQ \text{ mol} = -Upe^2qQ \text{ atom}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where e^2qQ atom is the quadrupole splitting which would arise in the electrostatic field gradient generated by one $5p_z$ electron, Q is the nuclear quadrupole moment of the 3/2 excited state, and Up is defined by:

$$Up = -Uz + \frac{Ux + Uy}{2}$$

where Ux, Uy, and Uz are the populations of the $5p_x$, $5p_y$, and $5p_z$ orbitals, respectively.

Thus an interpretation of e^2qQ mol in terms of Ux, Uy, and Uz requires a knowledge of e^2qQ atom. A value for e^2qQ atom is available through the calculation of Barnes and Smith (41) of q for one $5p_z$ electron, and through the calculated value of Q, reported by Shikazono (1), Violet *et al.* (3), and Pasternak and Bukshpan (5). These calculations yield

$$e^2qQ \text{ atom} = 570 \pm 60 \text{ Mc s}^{-1}$$

For the centrosymmetric $TeTu_4^{2+}$ ion the asymmetry parameter, η, is zero and

$$e^2qQ_{mol} = 2\Delta = 31.4 \pm 0.3 \text{ mm s}^{-1}$$
$$= 880 \pm 10 \text{ Mc s}^{-1}$$

Then

$$Up = -1.5 \pm 0.2$$

If it is assumed that $Uz = 2$, and $Ux = Uy$, then

$$Ux = Uy = 0.5 \pm 0.2$$

The large uncertainty in Ux and Uy arises from the large uncertainty in e^2qQ atom.

It is of interest to determine whether the isomer shift data are consistent with the above value of Up. Since

$$hp = 6 - (Ux + Uy + Uz)$$

then, if $Uz = 2$ and $Ux = Uy$

$$hp = 4 - 2Ux$$
$$= -2Up$$

The analysis of the isomer shift data presented above yielded a value of $hp = 2.6 \pm 0.2$, and this would lead to $Up = -1.3 \pm 0.1$. Within the very large error, the values of Up obtained from the quadrupole splittings (-1.5 ± 0.2) and isomer shifts (-1.3 ± 0.1) for the $TeTu_4X_2$ compounds are reasonably consistent, providing further support for a pure p-bonding model in these compounds. It may be noted that the above analysis also indicates that the quadrupole splittings observed here are reasonably consistent with the previously reported (1, 3, 5) value of Q of *ca.* 0.2 barn.

Returning to the discussion concerning the compound $TeTmtuCl_2$, in this instance it cannot be assumed that $Ux = Uy$ and thus it is not possible to calculate Up from δ. However, simple inspection of the data shows that while the value of Δ is large, and consistent with a square planar configuration about the tellurium with a large imbalance in 5p electron density between the z axis and x–y plane, the value of δ is significantly smaller than in the other square planar compounds. A rationale for the low value of δ in this compound may lie in the participation of a small amount of tellurium 5s character in the bonding. This would make δ significantly smaller, since as in iodine compounds the participation of even a small fraction of the 5s electrons in bonding would have a direct, large effect in decreasing $|\psi_s(0)|^2$. Thus, the bonding may be principally 5p in character, leading to the large value of Δ, with a small amount of 5s character leading to a small δ. That the bonding in this compound differs from that in the other thiourea derivatives may also explain the formation of an essentially 3-coordinate tellurium with *trans*-chlorines in this instance, the *trans*-$TeEtu_2X_2$ compounds being fully 4-coordinate.

For the compounds *trans*-$TeTmtu_2X_4$ where the Te^{IV} is fully octahedrally co-ordinated, a quadrupole splitting would be expected if the Te—S and Te—X bonds had different bonding characteristics. The absence of a measurable quadrupole splitting in these compounds clearly points to the very similar populations of the $5p_x$, $5p_y$, and $5p_z$ orbitals on the tellurium.

The ^{129}I Mössbauer Absorption Spectrum of trans-$TeEtu_2{}^{129}I_2$

As a further extension of this work, the ^{129}I Mössbauer absorption spectrum of $TeEtu_2{}^{129}I_2$ was measured against a $Zn^{129m}Te$ source. The spectrum was fitted (constraining the linewidths as being equal) to the independent Lorentzians shown in Fig. 2 and the isomer shift and quadrupole coupling calculated using the standard expressions (34). The values ob-

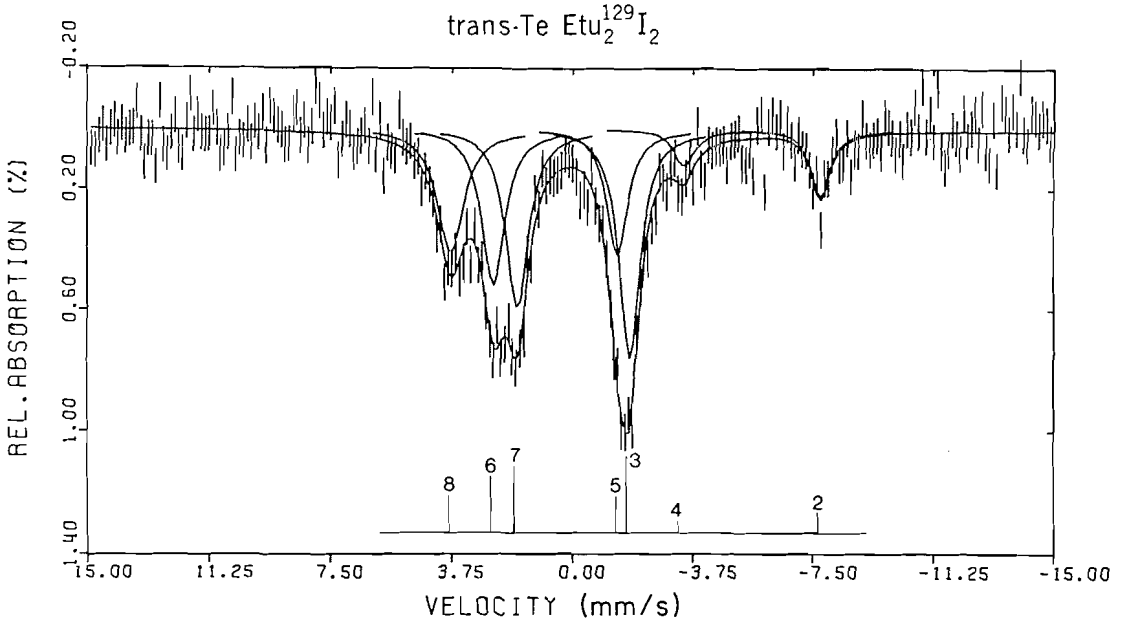

FIG. 2. The ^{129}I Mössbauer spectrum of *trans*-TeEtu$_2{}^{129}$I$_2$ at 80 °K. The computed lines shown had intensities in good agreement with the theoretically predicted values (5).

tained were $\delta = +0.010 \pm 0.001$ mm s^{-1} with respect to ZnTe and $e^2qQ^{129} = -597.7 \pm 6.2$ Mc s^{-1}, $\eta = 0$. The computed line-width was 1.1 mm s^{-1}. The small percent absorption in this experiment derives from the fact that a ^{129m}Te source was used rather than a ^{129}Te source.

If the iodine employs pure p electrons in bonding to the tellurium then the expression (34)

$$\delta = 1.50\,hp - 0.54$$

may be used to calculate hp on the iodine. This yields a value of $hp = 0.37 \pm 0.01$. Furthermore, a value of Up for the iodine may be calculated from e^2qQ^{129}

$$Up = \frac{-e^2qQ^{129}\ \text{mol}}{e^2qQ^{129}\ \text{atom}} = +\frac{597.7}{1605} = +0.37 \pm 0.01$$

where e^2qQ^{129} atom $= e^2qQ^{127}$ atom $\times$ 0.7.

For the case of pure σ-bonding through an iodine p orbital to the tellurium, Up should be equal to hp since

$$hp = 6 - (Ux + Uy + Uz)$$
$$= 2 - Uz \qquad \text{if } Ux = Uy = 2$$

while

$$Up = -Uz + \frac{Ux + Uy}{2}$$
$$= 2 - Uz \qquad \text{if } Ux = Uy = 2$$

Thus, since $hp = Up$, δ and e^2qQ are consistent with the proposal that iodine bonds to the tellurium through an iodine 5p orbital. If there was significant iodine 5s character in the bond then δ would yield a value of hp significantly smaller than Up, while if π-bonding was present Up would be smaller than hp.

The authors wish to thank the National Research Council of Canada for a grant supporting this research, and Dr. F. Brown, Head, Solid State Research Branch, A.E.C.L. Chalk River, for assisting in the production of the Zn^{129m}Te source.

The Influence of the Substrate on Hydrogen – Water Deuterium Exchange over Carbon Supported Platinum[1]

NORMAN HENRY SAGERT AND RITA MARY LOUISE POUTEAU

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba, R0E 1L0

Received May 19, 1972

Rate data for hydrogen – water deuterium isotope exchange are reported for a number of platinum on carbon catalysts whose carbon supports were graphitized to varying degrees before the metal was deposited on the support. The exchange over platinum black was studied for comparison. Over carbon supported catalysts, the rate was almost independent of hydrogen pressure and increased approximately linearly with water pressure. The rate controlling step seems to be the transfer of deuterium between chemisorbed hydrogen atoms and physisorbed HDO.

Activation energies for the rate determining step decreased from 14 kcal/mol over unsupported platinum to as low as 2 kcal/mol over highly graphitized supports. Rates increased with heat treatment temperatures up to 2100 °C. These effects are ascribed to electron transfer from the carbon support to the metal, resulting in a weaker Pt—H bond, and faster exchange. However they may be partially the result of non-linear adsorption of water.

Nous rapportons les données de vitesse d'échange isotopique hydrogène–deutérium dans l'eau pour certains catalyseurs de platine sur carbone dont les supports de carbone furent préalablement traités au graphite à différents degrés, avant que le métal soit déposé sur le support. Pour comparer, nous avons étudié l'échange sur noir de platine. Avec des catalyseurs sur carbone, la vitesse est à peu près indépendante de la pression d'hydrogène et croît approximativement linéairement avec la pression de l'eau. L'étape limitante semble être le transfert de deutérium entre les atomes d'hydrogène chemisorbés et le HDO physisorbé.

Les énergies d'activation pour l'étape limitante diminuent de 14 kcal/mol pour le platine sans support jusqu'à des valeurs aussi faibles que 2 kcal/mol pour les supports à haute teneur en graphite. On remarque une augmentation de vitesse lors de traitements par la chaleur, à des températures allant jusqu'à 2100 °C. Ces effets sont imputés à un transfert d'électron du support de carbone vers le métal, résultant en un lien Pt–H plus faible et un échange plus rapide. Ils peuvent toutefois résulter partiellement de l'adsorption non-linéaire de l'eau. [Traduit par le journal]

Introduction

The role of the support in reactions catalyzed by supported metal catalysts has become an active field of research in recent years (1, 2). While it was previously thought that the support only provided a physical base for the small metal crystallites and also provided some stability against sintering, more recent studies have shown that the support can change the chemical nature of the metal, and thus affect the reaction being studied (1–3). This is an effect on the reaction catalyzed by the metal and is not to be confused with the role of the support in dual function catalysis (4). Since the metal function is being studied, data must be interpreted on a unit metal surface area basis, so these studies have only become possible with the development of methods for measuring metal surface areas in the presence of supports (5).

We previously reported a study of the particle size effect for the catalysis of hydrogen–water deuterium exchange over silica supported platinum (6). The present work is an examination of the role of the support on the same reaction. The reaction was chosen because it is a simple deuterium exchange and no chemical changes occur in the catalyst bed with time. Heat effects can be entirely neglected. If the amount of D_2O is kept low, the only product is HD. This simplifies the kinetics and makes the reaction easy to follow by measuring HD (6, 7). The reaction is also of interest as a method of producing heavy water commercially. Carbons were used as supports because the electronic properties of carbons can easily be varied over a wide range by heat treating to different temperatures (8, 9).

Early in the work, some very unusual temperature dependences were noted. Thus it was necessary to study the kinetics in somewhat more detail than in our previous work on silica supported platinum (6).

Experimental Procedures

Kinetic Studies

Rate measurements were carried out in a flow system at atmospheric pressure as previously described (6). To investigate the rates as a function of hydrogen pressure, provision was made for mixing argon with the hydrogen before the combined stream was saturated with water containing 4% D_2O. Hydrogen and argon flow rates were measured using rotameters calibrated at the pressure of operation with a positive displacement flow meter. Purified argon did not interfere with the gas chromatographic determination of HD. The catalyst reduction procedures were identical to those used earlier (6) except that the final reduction was done at 300 °C.

Materials

The sources and purification of water, D_2O, and hydrogen have been described (6). High purity argon (99.999% min) was passed over copper turnings at 450 °C to remove oxygen and through a Dry Ice trap to remove water.

Platinum black was prepared by reducing an alkaline solution of sodium hexachloroplatinate with formaldehyde at 12 °C. The precipitate was washed carefully to remove sodium, dried at 100 °C, and pre-reduced in a hydrogen stream at 250 °C.

Graphon, which is highly graphitized Spheron 6 (2800 °C) and Thermax, a medium thermal black, were obtained commercially and sieved to 60–80 mesh unless otherwise stated. The Thermax was graphitized to various degrees by heating at different temperatures for 60 min in pure graphite containers in a furnace fitted with graphite heating elements. The heat treatments were done in the presence of 100 Torr of helium. Temperatures were measured with thermocouples or with an optical pyrometer. Catalysts were prepared from the graphitized carbons by wetting with a solution containing the required amount of chloroplatinic acid, followed by evaporating to dryness with stirring. The catalysts were then dried overnight at 100 °C and pre-reduced in 15 g batches at 250 °C. Most catalysts contained 0.5% platinum by weight. The exact amount was determined by atomic absorption spectroscopy (10).

Surface Areas

Total surface areas were measured by adsorption of nitrogen at 77 °K as previously described (6). Metal surface areas were measured by Boudart's hydrogen titration technique (11). To do these titrations, catalysts were subjected to the reduction used for kinetic studies and were then evacuated to 2×10^{-6} Torr while cooling to room temperature. Dry air was slowly admitted to the system and left in contact with the metal for 30 min. The sample was pumped at room temperature until pressures well below 10^{-5} Torr were attained. A hydrogen chemisorption isotherm was then measured volumetrically (6). Techniques used for electron microscopy have been described earlier (6).

Results

With water containing 4% deuterium, the deuterium is virtually all present as HDO and only reaction 1 need be considered.

[1] $$HDO + H_2 \rightleftarrows H_2O + HD$$

Under these conditions the reaction rate k, in moles of D_2 per gram of catalyst per second is given (6, 7) by eq. 2,

[2] $$k = \frac{F}{(\alpha + \gamma)W} \ln \frac{n_e - n_0}{n_e - n}$$

where F is the hydrogen flow rate in mol/s, W is the catalyst weight in g, α is the reciprocal of the equilibrium constant for reaction 1, and γ is the ratio of the hydrogen pressure to the water pressure. The n's refer to deuterium concentrations, before reaction (n_0), after reaction (n), and at equilibrium (n_e). The methods for calculating n_e and α have been given previously (6). Thus k may be calculated from the initial slope of a plot of $\ln (n_e - n_0)/(n_e - n)$ against W/F and unless otherwise noted, all the k's quoted are calculated from such plots, which were generally linear to fairly high conversions (6). This linearity is usually considered to show that the data is not affected by external diffusion, although Chambers and Boudart (12) have shown that this is not a conclusive proof.

At reaction temperatures of 100 °C the catalysts lost about 15% of their activity during a day. The activity was restored by reactivating at 300° for 12 h in a hydrogen stream. At lower temperatures the losses in activity were higher, but were also restored by reactivating at 300 °C. Over half the loss in activity occurred in the first hour, so catalysts were generally conditioned in the water–hydrogen stream for about 40 min. At temperatures over 100 °C the loss in activity was small.

Calculations based on equations given by Satterfield (13) showed that the efficiency factor for pore diffusion was probably close to unity. To confirm this, the particle diameter was varied over a threefold range. Figure 1 shows results obtained for 0.5% Pt on Graphon catalysts. Within experimental error no significant change in rate with particle size was observed even for the fastest rates. Thus the efficiency factor is probably greater than 0.9 (ref. 13, p. 143).

The variations of the rates with hydrogen and water pressure are shown in Figs. 2 and 3 for 0.5% Pt on ungraphitized Thermax and Thermax graphitized at 2100 °C. Figure 2 shows the dependence on the partial pressure of hydrogen, measured at 80 °C with 175 Torr of water vapor. The range and precision of this data were limited by experimental restrictions. Only a

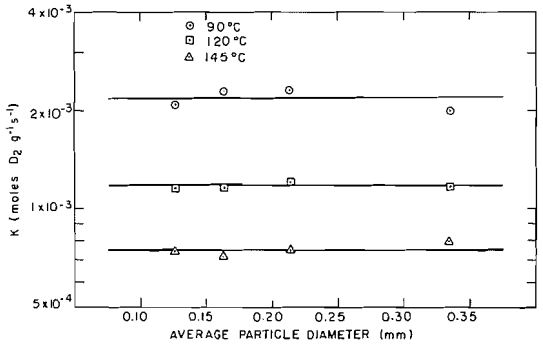

FIG. 1. Influence of catalyst particle size on the reaction rate over $\frac{1}{2}\%$ Pt on Graphon: $P_{H_2O} = 175$ Torr.

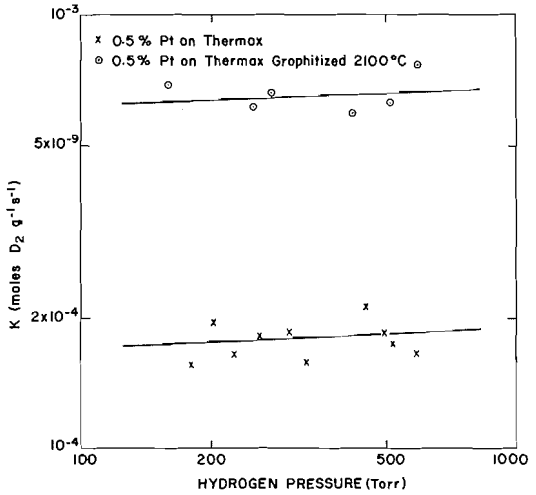

FIG. 2. Variation of rate with changing hydrogen pressure for the two catalysts indicated: reaction temperature = 80 °C; $P_{H_2O} = 175$ Torr.

fourfold variation in hydrogen pressure was possible. Furthermore data could only be obtained at a single hydrogen flow, so the precision is not as good as for other data presented. The reaction order with respect to hydrogen, given by the slope of the lines, is 0.0 ± 0.2. Figure 3 shows the dependence of the rate on water pressure at 100 °C for the same two catalysts. An eightfold range of water pressures was covered and total flow rates could be varied. The order for the 0.5% Pt on ungraphitized Thermax is 0.92. With the graphitized support, the order at lower pressures, as given by the line through the points, is 1.15. In the range of conditions studied, the rate equation is well represented by eq. 3.

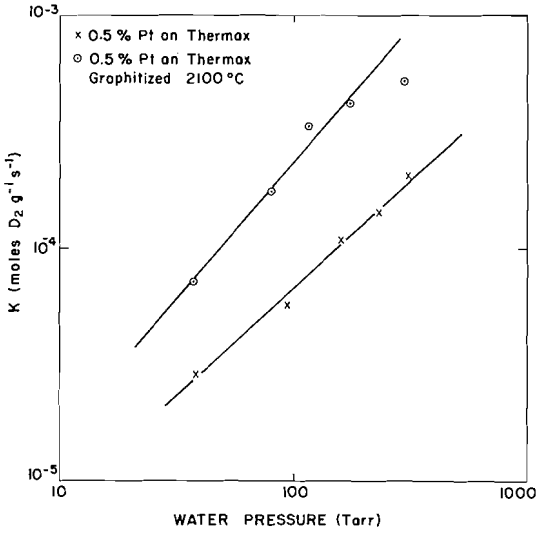

FIG. 3. Variation of rate with changing water pressure for the two catalysts indicated: reaction temperature = 100 °C.

$$[3] \qquad k = k' P_{H_2O}^{1.0 \pm 0.2} \, P_{H_2}^{0.0 \pm 0.2}$$

The lack of hydrogen pressure dependence probably means that a full coverage of hydrogen is maintained. This would be expected from hydrogen chemisorption experiments on supported platinum (5, 11, 14). The dependence on water pressure can be accounted for in terms of variations of adsorbed water coverage. Let us assume that the rate is proportional to water coverage and that this water coverage can be represented by a Langmuir isotherm.

$$[4] \qquad k = k_0 \theta_{H_2O} = k_0 \left(\frac{b P_{H_2O}}{1 + b P_{H_2O}} \right)$$

By plotting k^{-1} *vs.* $P_{H_2O}^{-1}$ an estimate of θ_{H_2O} is obtained which, at 100 Torr H_2O, is 0.1 for platinum on the ungraphitized support and 0.06 for platinum on the graphitized support. Thus water coverages are low and hence proportional to water pressure as observed.

Surface areas were determined using the titration technique of Benson and Boudart (11).

$$[5] \qquad PtO + \tfrac{3}{2}H_2 \rightarrow PtH + H_2O$$

It has been shown recently that eq. 5 is an excellent approximation to the stoichiometry (15). Results of these titrations are shown in Fig. 4. The flat portion of the isotherm was extrapolated

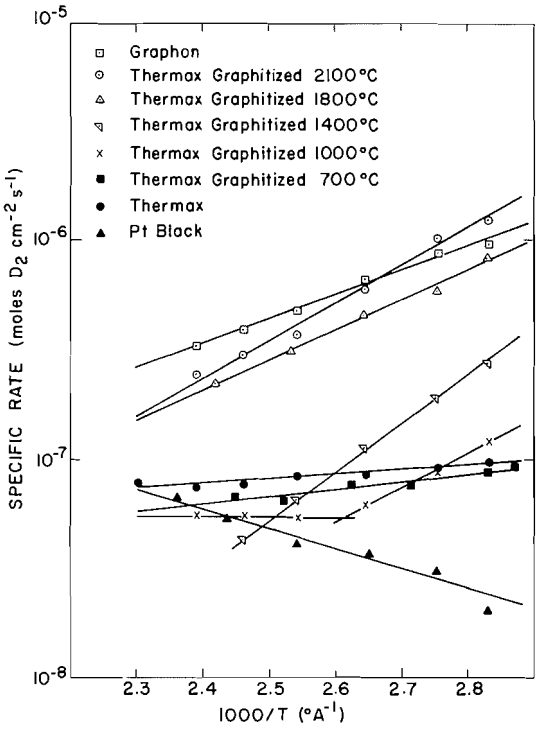

FIG. 5. Arrhenius plots for the catalysts studied: P_{H_2O} = 175 Torr.

to zero pressure and the value for the volume of hydrogen adsorbed was used to calculate the surface area, assuming each platinum atom has an area of 8.9 $Å^2$ (16). The areas correspond to spherical platinum particles with diameters in the range 65 ± 15 Å (Table 1), with the exception of the catalyst prepared over Thermax graphitized at 2100 °C, which has platinum particles of 130 Å diameter. These diameters were verified from electron micrographs which also showed the particles to be approximately spherical on ungraphitized substrates, but to be elongated on graphitized ones. Total surface areas of the Thermax supports are decreased slightly by graphitizing.

Arrhenius plots of the temperature dependence of the rates are shown in Fig. 5. The rates are expressed as specific rates by dividing the rate per gram of catalyst by the platinum area per gram as determined from the hydrogen titrations. For comparison, specific rates are shown over unsupported platinum black, which had been heated in hydrogen to reduce and stabilize its surface area. The unsupported platinum black shows an apparent activation energy of 4.0 kcal/mol, whereas the activation energies over platinum supported on ungra-

TABLE 2. Activation energies for hydrogen–water deuterium exchange on supported platinum

Support	E_{app}	Reference	E_0
Al_2O_3	6.5	20	~16.5
SiO_2	7.5	6	17.5
None	4.0	This work	14.0
Thermax	−1.0	This work	9.0
Graphon	−5.1	This work	4.9
Thermax (2100)	−7.9	This work	2.1

phitized carbon were in the range zero to about 1 kcal/mol negative. With graphitized supports the activation energies become progressively more negative. The results are summarized in Table 2. With supported catalysts no large differences in rate (±30%) and no significant changes in activation energies (±2 kcal/mol) were noted when the inert glass beads were replaced with Teflon or with unplatinized Graphon. Therefore the diluent does not seem to be playing any large part in the reaction, and Graphon is catalytically inert. Similarly, with unsupported platinum no changes in rates were noted within ±20%, and no changes in apparent activation energies within ±1 kcal/mol were noted when the beads were replaced with Teflon or Graphon. Thus whatever the mechanism which produces the changes in rates and activation energies, it does not operate over the distances involved in a mechanical mixture of platinum and Graphon.

Discussion

We have shown above that the rate expression over the region of pressures and temperatures investigated can be satisfactorily expressed by eq. 4. This dependence can be explained in terms of a mechanism involving surface exchange between hydrogen chemisorbed on the platinum and weakly adsorbed water. Hydrogen is adsorbed to the extent of a full monolayer at the temperatures and pressures used (5, 11, 14), and water vapor is not expected to prevent hydrogen chemisorption on platinum (17, 18). The heat of adsorption of water vapor has been shown to be 11 kcal/mol on reduced unsupported platinum (17, 19), whereas the heat of vaporization of water is 10.6 kcal/mol. Thus the net heat of adsorption of water is small on unsupported platinum, and probably fairly small in our system as well. Following Rolston and Goodale (20), we will assume that adsorption of hydrogen and water take place on different sites, I and II, and write the following mechanism

[6] $$H_2(g) + 2(I) \rightleftarrows 2H_{ads}$$

[7] $$HDO(v) + (II) \rightleftarrows HDO_{ads}$$

[8] $$HDO_{ads} + H_{ads} \rightleftarrows H_2O_{ads} + D_{ads}$$

[9] $$H_{ads} + D_{ads} \rightleftarrows HD(g) + 2(I)$$

[10] $$H_2O_{ads} \rightleftarrows H_2O(v) + (II)$$

Rolston and Goodale (20) have derived the rate expression for this scheme, assuming reaction 8 to be rate limiting. They noted that if the transfer rate per gram can be expressed in terms of coverage, then the differential rate (7, 20) is

[11] $$\text{Rate/g} = k(N - \alpha n) = \tfrac{1}{2}(k_8\theta_{HDO}\theta_H - k_{-8}\theta_{H_2O}\theta_D)$$

where N is the mole fraction of deuterium in the water leaving the reactor. If equilibria between the gas and surface phases are established then

[12] $$\theta_{HDO} = \theta_{H_2O}K_7K_{10}\frac{P_{HDO}}{P_{H_2O}}$$

$$\theta_D = \frac{\theta_H}{K_6K_9}\frac{P_{HD}}{P_{H_2}}$$

Since $P_{HDO} = 2NP_{H_2O}$ and $P_{HD} = 2nP_{H_2}$, then noting that $\alpha^{-1} = K_6K_7K_8K_9K_{10}$

[13] $$k = k_8K_7K_{10}\theta_{H_2O}\theta_H$$

An alternative mechanism using reaction 9 as the rate limiting step does not lead to a dependence of k on θ_{H_2O}, as is required.

If equilibrium is maintained between the gas and the surface K_7K_{10} will be constant, and will probably be unity to within a few percent. At high hydrogen pressures θ_H will be constant and almost unity. Thus

[14] $$k \simeq k_8\theta_{H_2O}$$

Rolston and Goodale (20) showed that a Langmuir isotherm was applicable for water coverages in the platinum–alumina system. Our data are not sufficiently precise or extensive to determine if a Langmuir isotherm is applicable. However, we will assume that such is the case. At low coverages the approximation should be sufficiently accurate. If a Langmuir

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

isotherm for water adsorption is used in eq. 14 and the logarithm of the resulting expression is differentiated with respect to $1/T$, then the activation energy is given by eq. 15.

$$[15] \qquad E_{app} = E_0 - (1 - \theta_{H_2O})\lambda_{H_2O}$$

where E_{app} is the measured apparent activation energy, E_0 is the chemical activation energy and λ_{H_2O} is the heat of desorption of water. The true chemical activation energy E_0 will be largely a reflection of the activation energy for reaction 8, the hydrogen isotope switch reaction. We have shown that a reciprocal plot of the data from Figs. 2 and 3 leads to estimates of θ_{H_2O} at 100° of 0.1 for an ungraphitized Thermax support and 0.06 for a Thermax support graphitized at 2100 °C. Taking λ_{H_2O} as 11 kcal/mol, then $(1 - \theta_{H_2O})\lambda_{H_2O}$ has a value close to 10 kcal/mol.

To obtain a comparison with values for other supports we note that Rolston and Goodale (20) have shown that the reaction over a platinum–alumina catalyst is also dependent on water pressure, although in the region in which they worked the power of θ_{H_2O} was between zero and one. Unpublished work from this laboratory has shown that over platinum silica catalysts, the rate is proportional to water pressure from 30 to 200 Torr H_2O. Although it has not been conclusively proven in these cases that eq. 12 holds or that $(1 - \theta_{H_2O})\lambda_{H_2O} \simeq 10$ kcal/mol, we will assume that these conditions hold and obtain E_0 by adding 10 kcal/mol to the reported activation energies over these catalysts.

The resulting E_0 values for carbon and these other supports are shown in Table 2. It is seen that changing the support results in a lowering of E_0 from about 15 kcal/mol for inert supports, or unsupported platinum to about 9 for low temperature carbons and to 3.5 ± 1.5 for high temperature carbons.

The remarkable lowering of E_0, which may be taken as equivalent to a lowering of E_8, is evidence of some type of metal–support interaction. The cause of this metal–support effect has not been completely established. It will be discussed first of all in terms of electron transfer to the platinum. The work function of platinum has been variously measured as 4.1 to 6.3 eV (21). Reference 21 gives 5.36 eV as the preferred value. A recent determination by Bouwman and Sachtler gives 5.7 eV (22). For this discussion it is adequate to take 5.5 eV. The work function of graphite is about 4.6 eV (21). For carbons heated to 400 °C there is a band gap, the energy gap between the bottom of the conduction band and the top of the valence band, of about 1.7 eV. As the carbon is heated to higher and higher temperatures, the valence band rises and the energy gap disappears at a heat treatment temperature (HTT) of about 1100 °C. Generally, impurity levels are thought to exist at an energy of 0.2 to 0.5 eV below the conduction band (9). The present state of knowledge of the band structure of heat-treated carbons has been summarized recently by Mrozowski (8). A totally satisfactory description is not available but it has been well established that for carbon heat-treated above 1000 °C, a large concentration of free carriers is available.

If platinum is put on a graphite surface the platinum should acquire a negative charge because of the difference in work functions of graphite and platinum. The extent to which this charge transfer can occur will not be limited by a corresponding positive charge in the vicinity of the particle since the carriers are free. On the less highly graphitized carbons, the donor impurity levels near the bottom of the conduction band may allow a small charging of the platinum. Some electrons from these donor levels will migrate into the metal until an equilibrium is set up. This results in a positive space charge in the carbon, and a negative charge on the metal, limiting the number of transferable electrons (2).

If the proposed mechanism (reactions 6 to 10) holds, the observed lowering of E_0 is associated in some way with a lowering of the activation energy for reaction 8, the hydrogen switching step. Water is assumed to be weakly bound to the metal with a low net heat of adsorption. Hence it is most reasonable to assume that the major way in which the activation energy E_8 can be lowered is by a change in the Pt—H bonding.

For uncharged platinum, the details of the bonding to hydrogen are somewhat confusing particularly at low temperatures, where both positive and negative changes in film resistance and work function are noted depending on coverage (23). However, at room temperature and above, Mignolet (24) found only an increase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in the work function of platinum when hydrogen was adsorbed and Geus (25) states that Offret observed only an increase in film resistance. This is consistent with the polarization of the platinum–hydrogen bond being $Pt^{\delta+}—H^{\delta-}$ (26).

If the hydrogen is negatively charged, then charging the platinum metal negatively should weaken the platinum–hydrogen bond. In hydrido–platinum complexes, it has been noted that adding electronegative ligands, which withdraw electrons from the platinum atom, significantly strengthens the platinum–hydrogen bond (27). A weakening of the platinum–hydrogen bond will lower the activation energy for reaction 8, particularly if the hydrogen has sufficient hydride character for an encounter complex to be formed similar to that examined by Ritchie and King (28).

It is of interest that this same hydrogen switch mechanism has been proposed by Holleck and Flanagan (29) for the exchange between aqueous solutions and deuterium gas on palladium surfaces at pH greater than 5. In neutral solutions (0.1 N NaCl) they found that keeping the palladium anodic decreased the exchange rate considerably. Thus positively charging the platinum appears to decrease the rate of reaction 8, in agreement with our postulate. Furthermore part of the promoting effect of chromia on the nickel catalyzed hydrogen–water deuterium exchange (7) has been interpreted in terms of the negative charging of nickel by electrons donated from chromia (30).

An entirely different reason for the changes in activation energies must be considered. On the more hydrophilic supports, water adsorption is primarily on the support and this adsorbed water is in equilibrium with water adsorbed on the platinum. As the carbon is graphitized it becomes less hydrophilic and a large decrease in water affinity is noted at a HTT of 1000 °C (31). If decreases in the E_0 and increases in the rate can be attributed to a lowering of the affinity for water, it would be expected that a completely hydrophobic support should give the smallest E_0 and the highest rate. Under these conditions the support would be relatively inert and the reaction should resemble that on unsupported platinum. In fact, with unsupported platinum a high E_0 was observed regardless of the nature of the diluent. Thus the loss of hydrophilic sites on the support is probably not responsible for the observed phenomena. It should be recalled, however, that the transfer of other species from support to metal is possible. Furthermore non-linear adsorption of water on the metal may greatly affect our results. Unfortunately it is difficult to study the adsorption of water on the metal alone in the presence of the support.

We would like to thank D. Faulkner and E. E. Sexton of the Materials Science Section, WNRE, for taking the electron micrographs, N. S. McIntyre of the Analytical Science Branch, WNRE, for the platinum analyses, and A. G. Wikjord and C. F. Musick of the same branch for determining the BET surface areas. Helpful discussions with G. G. Strathdee are gratefully acknowledged.

Hydroxy Complexes of Platinum(II) and Palladium(II)

GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON, ROBERT GEORGE HUNTER, AND JOHN JAMES MCFARLAND

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received June 15, 1972

The preparation of hydroxy bridged complexes, $[M_2(OH)_2L_4][BF_4]_2$, where M = Pt and L = triethylphosphine, triphenylphosphine or pyridine, or where M = Pd and L = triphenylphosphine, is described. The structures are unambiguously established by infrared, nuclear magnetic resonance, and X-ray crystallographic studies. The complexes are surprisingly stable, and in particular, resist bridge cleavage by tertiary phosphines under conditions which easily cleave analogous chloro bridged complexes.

La préparation de complexes pontés hydroxylés $[M_2(OH)_2L_4][BF_4]_2$, où M = Pt et L = triéthylphosphine, triphénylphosphine ou pyridine, ou encore M = Pd et L = triphénylphosphine, est décrite. Les structures ont été établies sans ambiguité par infrarouge, résonance magnétique nucléaire et cristallographie aux rayons-X. Les complexes sont étonamment stables et en particulier, résistent au clivage du pont par les phosphines tertiaires dans des conditions où les analogues chlorés sont facilement clivés.

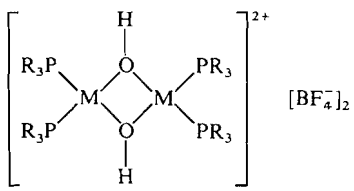
Platinum(II) and palladium(II) may be regarded as soft (class B) acids whereas hydroxide is a hard (class A) base (1). Consequently hydroxy complexes of platinum(II) and palladium(II) are expected to be relatively uncommon and unstable and the paucity of reports of such complexes is consistent with this view. The older literature (see, for example, ref. 2 and references therein) contains references to a number of platinum(II) and palladium(II) hydroxy complexes, especially species containing amine ligands, *e.g.* $M(OH)_2(NH_3)_2$, but prior to the commencement of our work the only detailed modern study was the characterization of $[Pt_2(OH)_2(PPh_2O)_2(PEt_3)_2]$, Ph = phenyl, Et = ethyl, by Chatt and Heaton (3). The reports by Cross and Glockling (4) of $[Pt(OH)(GePh_3)(PEt_3)_2]$ and by Bailar and Itatani (5) of $[PtCl(OH)(PPh_3)_2]$ have subsequently been shown to be incorrect (3, 6). No other tertiary phosphine stabilized hydroxy complexes of platinum(II) or palladium(II) and no hydroxy bridged complexes of these metal ions had been reported. We now report the synthesis and characterization of hydroxy bridged, tertiary phosphine complexes of platinum(II) and palladium(II).

During the progress of our work the complexes $[Pt(OH)(NHSO_2R)(PPh_3)_2]$ (7) and $[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$ (8) have been mentioned in the literature but no detailed characterization has been given. The latter was obtained as a product of oxidation of a platinum azo complex, a quite different preparation to that described below.

Results and Discussion

Reactions of the complexes, $[PtCl_2(PEt_3)_2]$, $[PtCl_2(PPh_3)_2]$, and $[PdCl_2(PPh_3)_2]$, with $AgBF_4$ (1 mol) are known (9) to give chloro bridged complexes, $[M_2Cl_2(PR_3)_4][BF_4]_2$. We now find that reaction of the $[MCl_2(PR_3)_2]$ complexes with 2 mol of $AgBF_4$ (or reaction of the bridged complexes with 1 mol) in moist acetone ($\sim 0.5\%$ H_2O) results in precipitation of AgCl and formation of hydroxy complexes of the type



Structures

Analytical data confirming the stoichiometry of the products are given in Table 1 together with the molar conductance, infrared, and nuclear magnetic resonance data referred to in the following discussion.

The presence of co-ordinated hydroxy groups

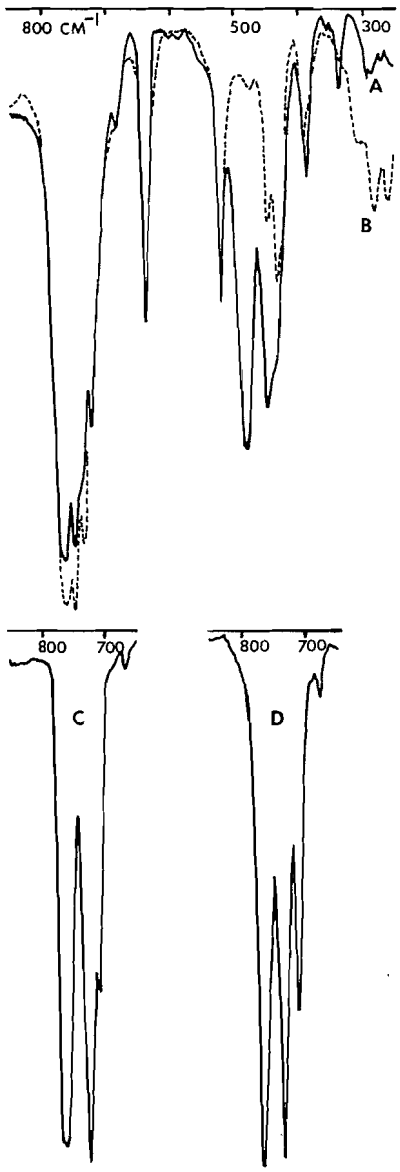

FIG. 1. Infrared spectra, $A = [Pt_2(OH)_2(PEt_3)_4][BF_4]_2$, $B = [Pt_2Cl_2(PEt_3)_4][BF_4]_2$, $C = cis\text{-}[PtCl_2(PEt_3)_2]$, $D = trans\text{-}[PtCl_2(PEt_3)_2]$.

is confirmed by relatively sharp (width at 1/2 height, 30–100 cm^{-1}) infrared absorptions at about 3500 cm^{-1}, shifting to about 2600 cm^{-1} on deuteration. These frequencies are similar to those reported previously for $\alpha\text{-}[Pt_2(OH)_2(PPh_2O)_2(PEt_3)_2]$, 3520 cm^{-1} shifting to 2600 cm^{-1} (3), and for $[(CH_3)_3PtOH]_4$, 3595 cm^{-1} shifting to 2655 cm^{-1} (10), and the value of 3550 cm^{-1} for $[Pt_2(OH)_2(PPh_3)_4][BF_4]$ agrees within experimental error with the previous report (8) of 3545 cm^{-1}. That these bands are due to hydroxyl and not to water is confirmed by the absence of absorption at 1630 cm^{-1} corresponding to the HOH bending mode of water (11). A bridging hydroxyl group is also expected (11, 12) to absorb in the ranges 950–1200 cm^{-1} (MOH bending) and 400–600 cm^{-1} (M—O stretching). In the triphenylphosphine complexes both regions are obscured by BF_4^- and ligand absorptions, respectively, but $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ (Fig. 1) shows a strong band at 480 cm^{-1} which does not occur in the spectrum of the well-known (13) chloride bridged complex, $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$, and is therefore assigned to ν(Pt—O). $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ and $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ have essentially identical spectra except for the PtOH bands described above and the Pt—Cl bands at 260 and 280 cm^{-1}. This comparison is evidence for the dimeric structure of the hydroxy complexes especially since we find the contour of the ligand absorption bands at 700–800 cm^{-1} to be characteristic of the complex type. Spectra of *cis*- and *trans*-$[PtCl_2(PEt_3)_2]$ in this region are included in Fig. 1 to illustrate the type of changes observed.

Further structural evidence comes from the nuclear magnetic resonance spectra. Resonances at 7–8 τ are assigned to the hydroxylic protons and, although these are generally too weak to permit accurate integration or observation of coupling to ^{195}Pt, the relative integrated intensities are approximately correct in all cases. The chemical shifts show considerable solvent dependence but are in general agreement with the previous report (8) of 8.4 τ for the hydroxyl protons of $[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$ in $CDCl_3$ solution. The presence of *cis*-PEt_3 ligands in $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ is confirmed by the appearance of the methyl resonance as an approximately 1:2:2:2:1 quintet centered at 8.85 τ (13).

Attempts to confirm the dimeric structures by conductance measurements proved inconclusive. The molar conductances (Table 1) of 10^{-3} *M* solutions in nitromethane are in the range expected for 2:1 electrolytes (14) but plots of equivalent conductance against square root of

equivalent concentration had slopes of about 1000, suggestive (15) of 3:1 electrolytes. In order to check the possibility of a trimeric structure we undertook molecular weight determinations by crystal density and unit cell measurements. The results are shown in Table 2. Both $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ and $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ have 8 platinum atoms per unit cell and this clearly excludes the possibility of a trimeric cation. Tetrameric and octameric structures can also be excluded by consideration of the translational elements of the space group symmetry and this leaves only a dimeric structure or the chemically unlikely possibility of monomers. For the chloro complex the Weissenberg photographs of the layers perpendicular to *c* can be divided into two sets (*l* even and *l* odd). All the films in each set have approximately the same intensity distribution and the strong areas in one set correspond to the weak areas in the other. The *Z* co-ordinates of the heavy atoms are therefore 0 and 1/2, giving the crystallographic problem a two dimensional aspect, and suggesting a very plausible trial structure based on four dimeric molecules per unit cell. We therefore consider that the above crystallographic and infrared evidence clearly establishes our formulation of both hydroxy and chloro complexes as containing bridged dimeric cations.

Reactivity

These hydroxy complexes are surprisingly stable. They are non-hygroscopic, air-stable solids which can be recovered unchanged from a variety of organic solutions including those in halogenated solvents such as chloroform and dichloromethane. The hydroxy protons are rather non-labile and deuteration requires prolonged stirring (15 h) in D_2O/acetone solution and for the platinum complexes a piperidine catalyst is also necessary. Attempts to determine K_a values for the hydroxy protons by potentiometric titration with hydroxide in nitromethane or methanol resulted in formation of red or brown precipitates, presumably because of reduction to cluster complexes (16), and amine bases such as piperidine did not give satisfactory titration curves.

Reactions of $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$, $[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$, or $[Pd_2(OH)_2(PPh_3)_4][BF_4]_2$ with excess triphenylphosphine (5 mol) give no evidence of bridge cleavage to form complexes having terminal hydroxy ligands whereas the corresponding chloro bridged complexes cleave easily under similar conditions (9). Generally the hydroxy complexes are recovered unchanged although the product of reaction of $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ with triphenylphosphine shows nuclear magnetic resonance evidence for some replacement ($\sim 10\%$) of triethylphosphine by triphenylphosphine. The ν(OH) absorption in the infrared spectrum of this product is unchanged in frequency but slightly decreased in intensity whereas ν(Pt—O) is unchanged, suggesting that some deprotonation may have occurred. The product of reaction of $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ with triethylphosphine shows similar infrared evidence of deprotonation but in neither case could new complexes be isolated and there was no evidence for bridge cleavage.

The failure of these attempted cleavage reactions suggests an unusual stability for the hydroxy bridge relative to terminal hydroxy complexes, especially since kinetic studies (17) show tertiary phosphines to be among the best nucleophiles for platinum(II). This stability of the bridge is further demonstrated by the reaction of $[PtCl(PEt_3)_2(PPh_3)][BF_4]$ with $AgBF_4$ in moist acetone to yield $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ and triphenylphosphine. In this case formation of the bridge involves actual displacement of triphenylphosphine which is very surprising in view of the expected "hard" character of the hydroxy group and "soft" character of the phosphine and platinum(II).

Reaction of $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ with Cl^- (2 mol) also fails to yield a complex having a terminal hydroxy group, the products being $[PtCl_2(PEt_3)_2]$ (1 mol) and the starting complex (1/2 mol). $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ does not react with piperidine whereas $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ cleaves easily under similar conditions.

Other Complexes

Syntheses of several other hydroxy complexes were attempted to investigate the generality of the synthetic procedure. A small yield of $[Pt_2(OH)_2(Py)_4][BF_4]_2$, Py = pyridine, was obtained but reactions of $AgBF_4$ with *trans*-$[PdCl_2(PEt_3)_2]$ or $[Pt_2Cl_4(PEt_3)_2]$ did not yield isolable hydroxy complexes.

Experimental

Silver tetrafluoroborate was from City Chemical Corporation, New York, and was used as received. Complexes, *trans*-$[PdCl_2(PR_3)_2]$ (18), *cis*-$[PtCl_2(PEt_3)_2]$ (19), *cis*-$[PtCl_2(PPh_3)_2]$ (5), *cis*-$[PtCl_2(Py)_2]$ (20), $[Pt_2Cl_4(PEt_3)_2]$ (21), and $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ (9) were prepared as previously described. Solvents were reagent grade and were dried over molecular sieves (type 4A) before use. All reactions were conducted in an atmosphere of dry nitrogen and those involving $AgBF_4$ were conducted in the dark but the products were stable and were isolated and purified in the atmosphere. All products were dried *in vacuo* at 70–80° before recrystallization and spectroscopic study.

Microanalyses were by Schwartzkopf Microanalytical Laboratory, New York. Conductance measurements were made on $\sim 10^{-3}$ *M* solutions in nitromethane using a dip-type cell connected to a Radiometer Model CDM3 Conductivity bridge. Nuclear magnetic resonance spectra were recorded on Perkin–Elmer R12A or Varian HA60 spectrometers with tetramethylsilane as external reference. Infrared spectra were recorded, with accuracy $\pm 5\ cm^{-1}$ from 4000 to $250\ cm^{-1}$, for all products described below, using a Beckman IR 20 spectrophotometer calibrated against polystyrene films or water vapour. Solid samples were examined as Nujol mulls between caesium iodide plates. Where additional characterization is not given these infrared spectra served to identify the products.

Crystal densities were determined by floatation in a mixture of *n*-propyl iodide and 1,2-dibromoethane. Unit cell parameters were determined by Weissenberg and precession photography.

1. Preparations

$[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$

A solution of $AgBF_4$ (0.58 g, 3.0 mmol) in acetone (15 ml) was added dropwise to a stirred solution of *cis*-$[PtCl_2(PEt_3)_2]$ (0.72 g, 1.43 mmol) in moist acetone (~0.5% H_2O) (50 ml) at 25°. After 15 min had elapsed, filtration gave AgCl (0.36 g, 2.5 mmol). Addition of the filtrate to diethyl ether (300 ml) gave an oily precipitate. On standing overnight this precipitate darkened and extraction with acetone left a further quantity of Ag/AgCl mixture.[1] Addition of the acetone extract to stirred diethyl ether gave $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ (0.65 g, 0.61 mmol) as a white precipitate which was recrystallized from acetone by dropwise addition of diethyl ether to give colorless needles.

$[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$

A similar procedure using $AgBF_4$ (0.047 g, 0.24 mmol) and $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ (0.20 g, 0.12 mmol) in a dichloromethane–acetone solvent mixture gave AgCl (0.032 g, 0.22 mmol) and $[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$ (0.17 g, 0.10 mmol). The product was a white precipitate recrystallized from dichloromethane–diethyl ether.[2]

$[Pd_2(OH)_2(PPh_3)_4][BF_4]_2$

A similar procedure using $AgBF_4$ (0.57 g, 2.93 mmol) and *trans*-$[PdCl_2(PPh_3)_2]$ (1.02 g, 1.45 mmol) in a dichloromethane–acetone solvent mixture gave AgCl (0.39 g, 2.72 mmol) and $[Pd_2(OH)_2(PPh_3)_4][BF_4]_2$ (1.0 g, 0.68 mmol). The product was a white precipitate recrystallized from dichloromethane–diethyl ether.[3]

$[Pt_2(OH)_2(Py)_4][BF_4]_2$

A similar procedure using $AgBF_4$ (0.27 g, 1.39 mmol) and *cis*-$[PtCl_2(Py)_2]$ (0.29 g, 0.68 mmol) in a dichloromethane–acetone solvent mixture gave AgCl (0.19 g, 1.33 mmol) and $[Pt_2(OH)_2(Py)_4][BF_4]_2$ (0.10 g, 0.11 mmol). The product was a white precipitate recrystallized from nitromethane–diethyl ether. The low yield may have been due to formation of $Pt(OH)_2(Py)_2$ as the product was very difficult to crystallize and the slightly high C, H, and N analyses and low conductance figure (Table 1) are consistent with contamination of the product by this complex.

$[Pt_2(OH)_2(PPh_3)_4][BPh_4]_2$

$NaBPh_4$ (0.31 g, 0.91 mmol) and $[Pt_2(OH)_2(PPh_3)_4][BF_4]_2$ (0.067 g, 0.041 mmol) were stirred in 1:1 acetone–dichloromethane solution from 3 h at 25°. The resulting cream precipitate of $[Pt_2(OH)_2(PPh_3)_4][BPh_4]_2$ (0.053 g, 0.025 mmol) was recrystallized from dichloromethane–diethyl ether.

[1]This procedure was found to give cleaner products than prolonged stirring of the original reaction mixture.

[2]This recrystallization gave purer products when carried out in the presence of 1–2 mol of triphenylphosphine.

[3]This recrystallization gave purer products when carried out in the presence of 1–2 mol of triphenylphosphine.

Reactions of $[Pt_2Cl_4(PEt_3)_2]$ or trans-$[PdCl_2(PEt_3)_2]$ with $AgBF_4$

These were carried out by similar techniques to those described above but failed to yield isolable hydroxy complexes. Precipitation of AgCl did occur but the Pt- and Pd-containing products were intractable oils.

2. Reactions with Lewis Bases

Reactions of the bridged complexes with potassium chloride, piperidine, triethylphosphine, or triphenylphosphine were conducted in polar organic solvents (CH_3OH, CH_2Cl_2, CH_3NO_2 or $(CH_3)_2CO$) at 25° for reaction times of 5–15 h. Solid products were recovered by addition of diethyl ether to the resulting solutions.

3. Reaction of $[PtCl(PEt_3)_2(PPh_3)][BF_4]$ with $AgBF_4$

$[PtCl(PEt_3)_2(PPh_3)][BF_4]$ was prepared in almost quantitative yield by reaction of PPh_3 with $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ in a procedure similar to that described previously for $[PtCl(PPh_3)_3][BF_4]$ (9). It was characterized by comparison of its infrared and nuclear magnetic resonance spectra with those of the known complexes, $[PtCl(PPh_3)_3][BF_4]$ and $[PdCl(PEt_3)_2(PPh_3)][BPh_4]$ (18).

$AgBF_4$ (0.052 g, 0.27 mmol) and $[PtCl(PEt_3)_2(PPh_3)][BF_4]$ (0.20 g, 0.25 mmol) were stirred in acetone solution at 25° for 2 h. Filtration gave AgCl (0.026 g, 0.18 mmol) and addition of diethyl ether to the filtrate gave $[Pt_2(OH)_2(PEt_3)_4][BF_4]_2$ (0.10 g, 0.09 mmol).

We thank the National Research Council of Canada and the University of Victoria for research grants and the University of Victoria for a postgraduate fellowship (to J.J.M.).

The Crystal Structure of Caesium Oxotetrafluorovanadate(V)

G. W. BUSHNELL AND K. C. MOSS

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received June 22, 1972

The crystal structure of caesium oxotetrafluorovanadate(V) has been solved and refined to an *R*-value of 0.070 using diffractometer measurements. The cell dimensions are: $a = 548.4(2)$ pm, $b = 634.2(2)$ pm, $c = 1403.4(3)$ pm. The space group is *Pnma* (No. 62) with four formula units per cell. Each vanadium atom lies 32.6 pm above the base of a tetragonal pyramid with oxygen at the apex (V=O length = 152.9 pm) and fluorine at the four base corners (mean V—F length = 178.8 pm). The tetragonal pyramids are linked by *cis*-fluorine bridges involving a long V—F bond (V—F(2^1) = 231.2 pm) to give an anionic chain structure. Structural relationships with other fluorides and oxide-fluorides are noted, and the bond lengths are discussed.

Nous avons résolu la structure cristalline de l'oxotétrafluorovanadate(V) de césium et l'avons raffinée jusqu'à obtenir une valeur de *R* de 0.070, au moyen de mesures au diffractomètre. Les dimensions de la maille sont: $a = 548.4(2)$ pm, $b = 634.2(2)$ pm, $c = 1403.4(3)$ pm. Le groupe spatial est *Pnma* (No. 62) avec quatre unités de formule par maille. Chaque atome de vanadium se trouve à 32.6 pm au-dessus de la base d'une pyramide tétragonale, l'oxygène étant au sommet (V=O, longueur = 152.9 pm) et le fluor aux quatre coins de la base (longueur moyenne V—F = 178.8 pm). Les pyramides tétragonales sont reliées au moyen de ponts de fluor *cis*, impliquant un long lien V—F (V—F (2^1) = 231.2 pm), résultant en une structure de chaîne anionique. Nous remarquons les relations de structure existant avec les autres fluorures et oxyde-fluorures et discutons de la longueur des liaisons. [Traduit par le journal]

Introduction

Recently the preparation and spectroscopic properties of $CsVOF_4$ were described by Howell and Moss (1). From ^{51}V and ^{19}F n.m.r. studies in aqueous and non-aqueous HF they concluded that the anion VOF_4^- undergoes rapid rearrangement in solution between C_{4v} and C_{2v} symmetries. Raman and infrared spectra on solid $CsVOF_4$ (200–4000 cm^{-1}) did not give an unequivocal assignment of the stereochemistry of VOF_4^- in the solid state. The spectra were interpreted on the basis that the ion was essentially monomeric, with C_{4v} symmetry, but the possibility of F bridging between the anions was also suggested. This paper reports the crystal structure of $CsVOF_4$ and confirms the tentative suggestions of Howell and Moss.

Experimental

The preparation and analysis of the crystals have already been described (1). Preliminary photographic work was done on a Weissenberg camera with CuK_α radiation. The crystal data are given in Table 1. The crystal dimensions are given in the directions of *a*, *b*, and *c*, respectively. From the systematic absences the space group might have been the noncentrosymmetric $Pn2_1a$ (No. 33 with non-standard setting). No piezoelectric effect was found using a Wooster Mark III piezoelectric test apparatus. Use of the $Pn2_1a$ space group in the middle stages of the refinement did not produce significant departure from the atomic arrangement conforming to *Pnma*, and the refinement was completed satisfactorily in terms of the latter. The cell dimensions were calculated by least squares analysis of 23 2θ measurements made on a Picker 4-circle diffractometer with MoK_α radiation. The density was observed to be too high for flotation type measurements in all the non-aqueous media available. Other methods requiring large quantities of material were not attempted. Ionic volume calculations strongly suggested four formula units per cell. In *Pnma* under these circumstances, the VOF_4^- anion must have the point group symmetry *m*.

Intensity measurements were completed up to $2\theta = 60°$ using MoK_α radiation ($\lambda = 71.069$ pm) and a manually operated 4-circle diffractometer. The instrument was operated in the bisecting position with $\omega = 0$. Reflections were scanned in the $\theta/2\theta$ mode for 1 min at a rate of 2°/min in 2θ. The background counts were measured daily for orientation

checking, and a standard reflection 2,2,4 was examined after every batch of 50 reflections. Of the 770 reflections measured, 660 were classified as observed using the criterion that the net count must exceed the standard deviation of the background count (σ). The measurements between $-\sigma$ and $+\sigma$ were squeezed by a factor of 0.5 into the 0 to $+\sigma$ range. Measurements below $-\sigma$ were given a value very close to zero. The unobserved reflections were included in the structure factor calculations but not in the least squares refinement. Lorentz and polarization factors were applied to all measurements. Absorption corrections were done with a program utilizing a Gaussian grid numerical integration procedure. The number of points used in the a, b, and c directions were 12, 8, and 4, respectively.

Structure Determination

A set of programs supplied by Penfold was used for this investigation (2). The structure was solved from the three dimensional Patterson function. In choosing the scattering factor curves all atoms were assumed to be uncharged. The curves were obtained from the work of Cromer and Waber (3), and the anomalous dispersion corrections of Cromer (4) were used for caesium and vanadium. At first all the light atoms were treated as fluorine. The first structure factor calculation gave an R-value of 0.45. The first Fourier map showed the structure quite clearly. The positions of the light atoms were improved by difference synthesis. The light atom closest to the vanadium atom was assumed to be oxygen. The refinement was by minimization of $w(|F_o| - |F_c|)^2$ using full matrix least squares.[1] The weights were derived from counting statistics and an experimentally determined instrument instability factor using the formulae given by Stout and Jensen (5). A supplementary refinement was done using a suitable algebraically derived weighting scheme. All atoms except F(1) lay on the mirror planes and had their y-coordinates fixed and their B_{12} and B_{23} temperature factors equal to zero in the least squares calculations. The final lowering of the conventional R-value was in the sequence 0.108, 0.071, 0.070, 0.070 (all reflections included).

Results

The fractional atomic coordinates of caesium oxotetrafluorovanadate(V) are listed in Table 2. Figure 1 is an illustration of the unit cell. All atoms except those labelled F(1) lie on the mirror planes at $Y = 0.25$ and $Y = 0.75$. The F(1) atoms occur in mirror pairs. The oxygen atom is at the apex of the approximately tetragonal pyramids drawn. Extra atoms have been added in the a direction to show the connectivity along this axis through assymmetric *cis*-bridging by the fluorine atom F(2). Only the shorter of the two bridge bonds has

III	$X-1, 1+Y, Z$	$X-1, \frac{1}{2}-Y, Z$
IV	$X-\frac{1}{2}, \frac{1}{2}-Y, \frac{1}{2}-Z$	$X-\frac{1}{2}, 1+Y, \frac{1}{2}-Z$
V	$1-X, \frac{1}{2}+Y, -Z$	—
VI	$-X, \frac{1}{2}+Y, -Z$	—

been drawn. This arbitrarily produces five coordinate vanadium atoms. Alternatively the structure might be regarded as containing polymeric ribbons of distorted octahedra. The atoms F(3) are not involved in the bridging.

The bond lengths associated with the vanadium coordination are given in Table 3*a*. From the compilation of effective ionic radii by Shannon and Prewitt (6) we obtain, for the coordination number of six, the values $R(V) = 54$ pm, $R(F) = 133$ pm, $R(O) = 140$ pm, $R(Cs) = 170$ pm. The F(1) pair, F(2), and F(3) make up the square base of the pyramid. Their bond lengths to vanadium are all equal, with the mean value of 178.8 pm only slightly less than the sum of the radii (187 pm). The V—O bond to the apex is short (152.9 pm), whereas the V—F bond *trans* to the oxygen atom is very long (231.2 pm).

The caesium coordination is quite complicated, there being 16 adjacent atoms in the range 302–386 pm. The short end of this range is approximately equal to the sum of the caesium and fluorine radii (303 pm). In Table 3*b* we give the 8 nearest neighbors and their distances from the caesium ion which has the coordinates given in Table 2. Each F(1) entry describes a pair of bonds since there is a mirror plane containing the caesium ion at $Y = 3/4$. Thus, six of the eight nearest neighbors to the caesium ion are space group relatives of F(1).

Table 4 gives the angles subtended at the vanadium atom. Row 1 shows a linear O—V—F(2^{I}) group, but considerable bending from linearity for F(1)—V—F(1) and F(2)—V—F(3). The bending is away from the V—O bond by approximately 10° as shown by the angles of approximately 100° in row 2. The bending is toward F(2^{I}), so that row 3 shows angles of approximately 80°. The mean of the remaining two entries is slightly less than 90°.

A least squares plane calculation was done for the group of four equatorial fluorine atoms (around the polar O—V—F(2^{I}) axis). The quantity minimized was $R = \sum_i W_i P_i^2$ where the weight W_i for atom i is given by $3/[\sigma^2(x_i) + \sigma^2(y_i) + \sigma^2(z_i)]$ and P_i is the perpendicular distance of atom i from the plane. The quantity $\chi^2 = \sum_i P_i^2/\sigma^2(P_i)$ was calculated as an index of the planarity of the group. Using the crystal axis system the equation of the plane was found to be $0.673\,x + 0.740\,z = 3.702$ with $\chi^2 = 7.14$. The group is close to planarity, with F(1), F(2), and F(3) lying −1.1, +1.6, and +1.4 pm from the plane. The vanadium atom lies 32.6 pm from this mean plane.

The bond lengths and angles of the vanadium complex can be described approximately in terms of an octahedron formed by the oxygen and five fluorine atoms. The eight independent values for the length of the octahedral edge have a mean of 258 pm and are contained in the range ±18 pm. The octahedron is elongated by 26 pm along the O—V—F(2^{I}) axis and the vanadium atom is displaced 32.6 pm from the center toward the oxygen atom.

Table 5 gives the anisotropic temperature parameters. The corresponding thermal ellip-

Discussion

The work of Edwards and collaborators (7, 8) has established a set of pentafluoride and oxidetetrafluoride chain structures with *cis*-bridging fluorine atoms. The compounds are VF_5, CrF_5, TcF_5, ReF_5, $MoOF_4$, $ReOF_4$, and $TcOF_4$ (the latter has an alternative trimeric form). Ryan, Mastin, and Reisfeld (9) point out the structural relationship between the doubly charged anionic chain structure of $K_2VO_2F_3$ and the structure of the neutral chains in the compounds mentioned. Caesium oxotetrafluorovanadate(V) has singly charged anionic chains of the same type.

Various V=O bond length measurements are given in Table 6. Vanadium(IV) compounds are included as well as those of vanadium(V). Although the V(V) compounds might be expected to give slightly shorter V=O bonds, no difference is evident. The V=O length in $CsVOF_4$ is a little shorter than usual but not unreasonable. The length was unaltered by the change in the weighting scheme which we tried.

In Table 7 we present an analysis of the V—F bond lengths in $CsVOF_4$ and closely related compounds. We find it necessary to allow for charge, bridging, and a *trans* effect, and have separated these factors as far as possible. Some normal terminal V—F lengths are given in Table 7*a*. They illustrate the charge effect and stand for comparison with the lengths lower in the Table. V—F lengths in two kinds of F-bridge are given in Table 7*b*. The increase is 20–30 pm. Next we examine in Table 7*c* the V—F bonds which are *trans* to a V=O bond. The value of

231 pm in $CsVOF_4$ agrees well with the 234 pm found in VOF_3. Both these bonds are similarly involved in assymmetric *cis*-bridging, the shorter arms of the bridges being 181 and 179 pm, respectively. The *trans* effect presumably causes the assymmetry if not all of the lengthening. Since the *trans* and bridging effects are not clearly separated in these two cases, we have given also the example of the vanadium(IV) compound, Cs_2VF_6, which has recently been reported (16) in an orthorhombic form. Previously the compound was known in cubic, hexagonal, and trigonal forms (17). The crystal structure of orthorhombic Cs_2VF_6 contains isolated VF_6^{2-} ions in which a pure *trans* effect can be seen. Separation of the *trans* and bridging effects is quite impossible for $K_2VO_2F_3$. Each bridging F atom is *trans* to two V=O bonds. The V—F length is given in Table 7*d*, and applies to both arms of the bridge.

The published crystal structure of Cs_2VF_6 (16) is of concern to us, in that the short V—F length of 161 pm challenges the validity of our method of recognizing the oxygen atom in $CsVOF_4$. The evidence published (16) for the identity of the compound Cs_2VF_6 consists of a density determination, a fluorine analysis with a specific ion electrode, and a well refined crystal structure. The latter would not distinguish F from O, nor would it necessarily detect hydrogen atoms which might be present. The orthorhombic structure is very unusual for the A_2MF_6 type of compound for which there is a well developed crystal chemistry (18). The method of preparation using aqueous hydrofluoric acid, in contrast to the fluorine preparations of Liebe, Weise, and Klemm (17), also leaves open the possibility that oxygen may be present in the compound. We therefore assert the correctness of the method by which we have assigned V=O as the short bond in $CsVOF_4$.

E.S.R. Studies of γ-Ray Irradiated Single Crystals of D-Tartaric Acid

J. K. MULCHINOCK[1] AND F. R. HALLETT
Department of Physics, University of Guelph, Guelph, Ontario

AND

F. C. ADAM
Department of Chemistry, University of Calgary, Calgary, Alberta

Received May 8, 1972

Electron spin resonance (e.s.r.) studies on single crystals of normal and deuterated D-tartaric acid have been carried out as part of a larger investigation of radical production and migration in biologically related single crystals. The D-tartaric acid system is especially interesting since the second and third carbon atoms of the molecule, which are chemically identical in solution, become conformationally non-equivalent in the unit cell. The effects of this conformational difference on the e.s.r. spectra are discussed. The radicals identified in this study are consistent with the work of others on similar systems.

Nous avons entrepris des études de résonance paramagnétique électronique (r.p.e.) sur des cristaux uniques d'acide D-tartrique normal et deutéré; ces études font partie d'un programme élaboré d'études sur la production et la migration radicalaires dans les cristaux uniques reliés à la biologie. Nous nous intéressons plus particulièrement à l'acide D-tartrique puisque les second et troisième atomes de carbone de la molécule, chimiquement identiques en solution, deviennent de conformation non équivalente dans la maille. Nous discutons des effets de cette différence conformationnelle sur les spectres r.p.e. Les radicaux identifiés dans cette étude sont consistants avec les travaux d'autres auteurs sur des systèmes semblables.

Introduction

Previous electron spin resonance (e.s.r.) studies by Rao and Gordy (1) and by Moulton and Cernansky (2, 3) have identified some of the radiation-produced free radicals in single crystals of deuterated DL-tartaric acid. The latter workers pointed out that the radicals which they identified were consistent with those proposed by Schwartz, Hanna, and Bales (4) in a mechanism formulated to explain the production and reactions of radicals in single crystals of carboxylic acids after X- or γ-irradiation. However, several of the radicals predicted by this mechanism were not identified in the DL-tartaric acid spectra and some uncertainty as to the validity of the mechanism remained. Much of this uncertainty is removed in our work which is a detailed study of the D-tartaric acid system.

D-Tartaric acid is chemically similar to DL-tartaric acid, but has a substantially different crystal structure. In addition, the interpretation of e.s.r. spectra is greatly aided by the X-ray crystallographic work that has been done on this system by Beevers and Stern (5) and by Okaya, Stemple, and Kay (6). The dimensions of the unit cell axes are $a = 7.71$ Å, $b = 6.00$ Å, and $c = 6.23$ Å. b corresponds to a two-fold screw axis and the a–c angle is 100°. As may be seen from Fig. 1, the five oxygen and carbon atoms at each end of the molecule are located in two planes set at an angle of 54.6° to each other.

Using the numbering system shown in the figure, it may be observed that carbon atoms 1 and 1′, 2 and 2′, 3 and 3′, 4 and 4′ are symmetrically related pairs. Carbon atoms 2 and 3 are indistinguishable when the molecule is in solution; but are conformationally non-equivalent in the crystal and there is no way that they can be related by symmetry operations. This also applies to carbon atoms 1 and 4. Because of this non-equivalence unpaired electron density created at sites 2 and 3 can lead to radicals which have different e.s.r. spectra. Likewise, distinct e.s.r. spectra may also be expected from radicals whose unpaired spin is centered on positions 1 and 4. These observations are of particular importance in the arguments which follow. In the following pages the nature of the radicals observed at −196 °C, −20 °C, and room temperature are discussed and a subjective

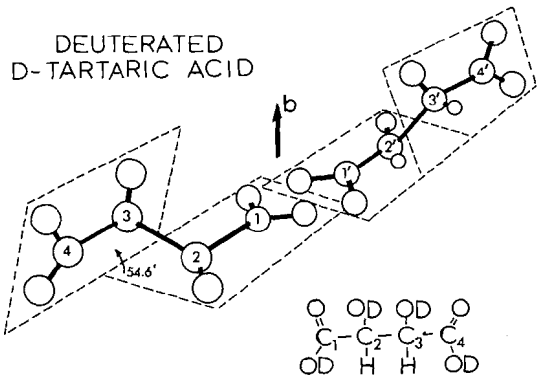

FIG. 1. Positions of atoms in the unit cell in a monoclinic crystal of D-tartaric acid. Deuterated positions are also shown.

interpretation of radical distributions at similar sites is made on the basis of some of the known physical properties of the unit cell. Finally, a mechanism is proposed which explains some of the steps in the radical migration process.

Experimental Procedure

Monoclinic ($P2_1$) single crystals of both normal (Nutritional Biochemical Corporation) and deuterated D-tartaric acid were grown by slow cooling of saturated solutions. Deuteration was accomplished by successive recrystallizations from D_2O to ensure that all exchangeable protons were 99.9% deuterated.

The crystals, which were checked by a polarizing microscope to be single crystals, were irradiated at -196 °C with a ^{60}Co γ-ray source (Gammacell 220, Atomic Energy of Canada Ltd) to a dosage of approximately one Mrad at a dose rate of about 1 Mrad per hour.

All e.s.r. measurements were made on a Varian E-12 X-band spectrometer equipped with Fieldial and a variable temperature apparatus. With the exception of a few room temperature spectra, only first order lines were observed and the corresponding first order spin Hamiltonian

$$\mathcal{H} = \beta\, \mathbf{S.g.H} + \mathbf{S.A.I}$$

was used in calculations. Hyperfine tensors (**A**) and **g** tensors were obtained from data taken at 10° intervals about three mutually perpendicular axes which were chosen to be the *a'bc* axes of the crystal (Fig. 2). Tensors were diagonalized by computer using a method based on the theoretical work of Schonland (7).

Results

Three different radicals were apparent in spectra of normal and deuterated crystals when observation and irradiation were carried out at liquid nitrogen temperatures. Figure 3 shows two typical spectra taken with *b* parallel to the external magnetic field; the lines are numbered to correspond to the three radical types. Experimental hyperfine (A) values and g-values in the $a'b$ plane are given in Fig. 4 for each set of lines. The principal values and direction cosines of the **A** and **g** tensors of these and all radicals appearing at higher temperatures are given in Tables 1 and 2, respectively.

As the crystals were slowly warmed there was a dramatic change in the spectra beginning at approximately -90 °C and tapering off at -20 °C. The strong doublet of Fig. 3*a* began to

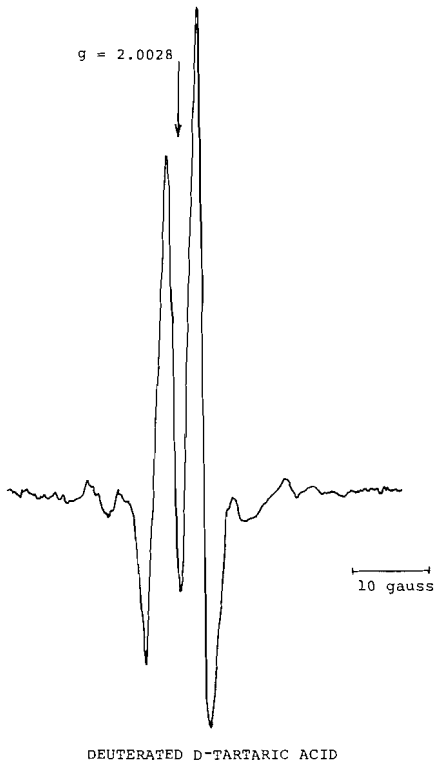

FIG. 6. Typical spectrum obtained after warming to room temperature. Observed at −196 °C.

decrease and eight new lines appeared as shown in Fig. 5. The changes were irreversible and all data was taken after recooling to −196 °C.

The spectra obtained from samples irradiated at liquid nitrogen temperature and warmed to room temperature for several hours and then recooled to liquid nitrogen temperature for observation were identical to spectra resulting from irradiation at room temperature and observation at liquid nitrogen temperature. A typical spectrum resulting from these procedures is shown in Fig. 6 and appears to result from two different radicals. Lines having the characteristics of second order effects were observed in these particular spectra.

Discussion

The primary feature of the spectra observed in deuterated D-tartaric acid single crystals after irradiation at liquid nitrogen is a strong doublet (labelled doublet 3 in Fig. 3) with a splitting of approximately 12 G. This spectrum could arise from any one of a total of the ten possible radicals shown in Fig. 7. Because the strong doublet is weakly anisotropic, it most likely arises from a single β-hydrogen coupling or in other words from a hydrogen situated on the carbon atom adjacent to the site of the unpaired spin. The only radicals that have single β-hydrogens are "A", "B", "D", "G", "H", and "I". In spectra of the non-deuterated crystals these two lines are split by a second isotropic β-hydrogen so that possibilities "B", "G", "H", and "I" are eliminated. Radicals "G" and "H" can also be discounted as these species have never before been reported in single crystal studies and are believed to be extremely unstable. Consequently only radicals "D" and "A" have arrangements of β-protons which are consistent with the observed spectra. Other evidence that will be considered later suggests that radical "D" is observed at room temperature, but not at liquid nitrogen temperature. Thus we ascribe the strong doublet observed at liquid nitrogen to radical "A". Moulton and Cernansky (2) have observed the same radical in DL-tartaric acid.

There are two possible sites for radical "A" in each molecule, *i.e.* positions 1 and 4. The direction cosines of the minimum g-value corresponding to the intense doublet are 0.05, 0.99, 0.08 which suggest that the principal axis of the p-orbital is essentially along b. Consideration of the atomic coordinates of the molecule indicates that p-orbitals on 4 and 4′ are along a whereas p-orbitals on 1 and 1′ should be along b. It may be concluded from this that the intense doublet arises from the carboxyl radical "A" with the unpaired electron primarily on carbon 1 of the D-tartaric acid molecule.

The spectrum shown in Fig. 3 contains another doublet (labelled doublet 1) which demonstrates site splitting at certain orientations. This site splitting arises from symmetrically related sites which become non-equivalent at certain

*Errors based on quality of fit.

angles of rotation with respect to the external magnetic field. Normals to the planes containing sites 4 and 4′ are not parallel and hence site splitting should be observed with this set. Such site splitting is not expected with sites 1 and 1′ as their corresponding normals are parallel. Spectra from non-deuterated samples showed that the lines from the deuterated crystals were further split by a second β-hydrogen. This evidence plus the fact that the direction cosines of the minimum g-values are approximately along a' suggests that these lines probably arise from type "A" radicals situated on sites 4 and 4′. The large difference observed in the doublet splitting and anisotropy between type "A" radicals on sites 1 and 4 (see Table 1) is thought to be a result of differences in both electron densities and bond angles at these two sites. While we prefer this argument we cannot exclude the possibility that doublet 1 arises from the single α-proton of radical "F". In view of all the research done in organic acids this radical seems to be an unlikely candidate. Isotopic labelling studies will probably be necessary to remove the ambiguity.

There is finally another poorly resolved and weakly anisotropic doublet (labelled doublet 2 in Fig. 3) which appears in the liquid nitrogen spectra. This doublet is not additionally split in the non-deuterated crystals. The only radicals which have a β-hydrogen but no adjacent hydroxyl protons are radicals "B" and "G". Since "G" is highly unlikely, we ascribe doublet 2 in Fig. 3 to radical "B". Analysis of the **g**-tensor of the species is somewhat uncertain but it appears that the direction of the orbital containing the unpaired spin is along b.

Conclusive statements regarding the stabilities of radicals "A" and "B" are also difficult because lines due to product radicals formed

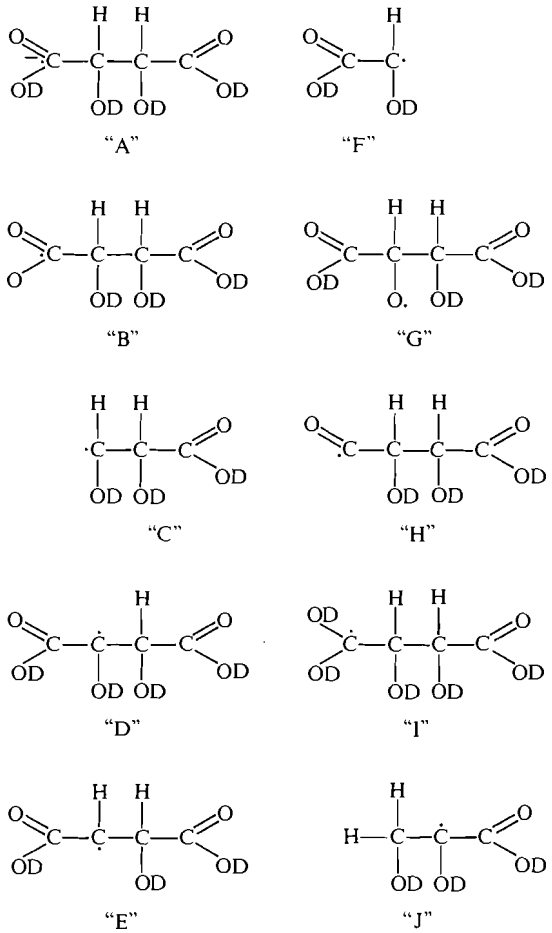

FIG. 7. Possible radicals from D-tartaric acid. Positions that can be deuterated are indicated by the letter D.

by heating mask their decay. Nevertheless, it appears that radical "A" is more stable than radical "B" and lines due to "A" are visible at -20 °C. No trace of the doublet ascribed to radical "B" was found at temperatures greater than -90 °C.

The eight new lines arising after warming to -20 °C are shown in Fig. 5 and are of two types. One set of four lines is typical of α- and β-hydrogen splitting. Radicals types "C" and "E" are the only ones that can give this type of splitting. It is generally believed that decarboxylation by electron transfer is energetically more favorable than hydroxyl radical abstraction. Radical "E" is eliminated because of this argument. Moulton and Cernansky (3) also have concluded that radical "C" is present at -20 °C in DL-tartaric acid.

The minimum g value of this radical is almost along the b axis indicating that the radical probably is situated at sites 2 and 2′. The outside four lines demonstrate site splitting, and are anomalous in that the isotropic hyperfine splitting between them is 50 G. This number is too large for the type of radicals that can occur in this system. Thus two additional lines must exist under the more intense lines found at the center of the spectra. This set of lines is believed to arise from type "C" radicals situated on sites 3 and 3′. The site splitting is consistent with radicals situated on 3 and 3′. Also observed is a single line that is hidden under the right hand line of the intense doublet. This line is thought to be due to a CO_2^- radical that is produced on decarboxylation of the carboxyl groups. We estimate the average g-value of this line to be 2.000 with an uncertainty of 0.002. This agrees with values of $\langle g \rangle$ for the CO_2^- radical obtained by Janecka, Vyas, and Fujimoto (8) and Schwartz, Hanna, and Bales (4). The species is very stable and exists in single crystals at room temperature where it absorbs in the same position in the spectrum.

As deuterated D-tartaric acid was further warmed to room temperature the spectra changed once more with the lines at -20 °C disappearing and eight new lines appearing. Again an intense doublet is seen in the spectra in Fig. 6. These two lines are split by 8 G and are characteristic of a β-hydrogen interaction with the unpaired electron. If one considers all the remaining possibilities in Fig. 7 only radical "D" could give the β-hydrogen splitting observed. The direction cosines associated with the minimum g-value indicate that the p-orbital is along b and resides on sites 2 and 2′. Further evidence that this is radical "D" is observed in the non-deuterated sample where the strong doublet does not split. This would be expected if the β-hydrogen on the oxygen is in the nodal plane of the p-orbital containing the unpaired electron. A model of the unit cell based on atomic positions given by Okaya, Kay and Stemple (6) agrees with this.

The pair of lines next to this intense doublet are believed to be second order lines. Evidence for this is that the intensities are angularly de-

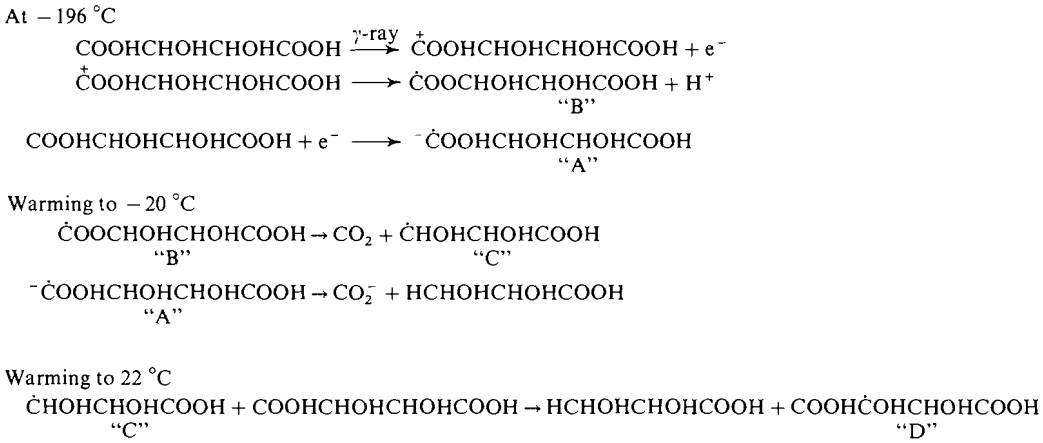

FIG. 8. Mechanism for radical production and migration in D-tartaric acid.

pendent, with virtually no deviation from the constant splitting of 8 G from the major doublet. Rao and Gordy (1) have observed the intense doublet of radical "D" in DL-tartaric acid at room temperature. They also observed a pair of lines separated by 8 G from the intense doublet which were proved to be second order lines by measuring the crystal spectra at two different microwave frequencies.

Also observed in the wings of the room temperature spectra are a set of poorly resolved lines with an isotropic hyperfine splitting of approximately 30 G. These are attributed to radical "D" where the unpaired electron is situated on sites 3 and 3′. These outer lines are broad, which may be due to the site splitting expected for such radicals. The inability to resolve this site splitting leads to an averaging of the *a* and *c* components of the **g** tensor and hence the minimum *g*-value falsely appears to be aligned along *b* instead of the calculated direction *c*. The two outermost lines are believed to be the second order lines arising from radical "D" situated on sites 3 and 3′ since they demonstrate all the required characteristics of second order effects.

Because of the peculiar symmetry properties of D-tartaric acid crystals, it is possible to observe the distribution of radicals at chemically similar, but conformationally different sites. The effect was observed at room temperature where type "D" radicals predominated at site 2 relative to site 3. Similarly, there was a higher concentration of type "C" radicals on position 2 than on position 3 in crystals which had been warmed from −196 to −20 °C. Finally in the spectra observed at −196 °C with no warming of the sample, type "A" anion radicals were identified at site 1 and possibly at site 4. From a crude observation of line widths and intensities it was apparent that there were significantly more radicals on position 1 than on position 4.

There are few apparent reasons for these observations. All that can be suggested at the present time is that the preferred sites, namely 1 and 2 are better able to stabilize radicals. If one considers the positions of atoms in the unit cell as determined by Okaya, Stemple, and Kay (see Fig. 1), the plane containing sites 1 and 2 is somewhat more planar than the plane containing sites 3 and 4 and better able to delocalize the unpaired spin. This plus small differences in bond angles and lengths may account for the radical distributions which we observe.

The radicals previously discussed must all be accounted for not only in terms of spectral identification but also the ease of formation by some sort of chemical mechanism in the solid state.

Because of the high energy of the cobalt 60 γ rays (1.33 MeV) the initial radiation damage should be completely random throughout the crystal. The primary event at this energy is due to Compton scattering which leads to the ejection of energetic electrons from molecular orbitals. These electrons can have sufficient energy to eject other electrons from molecular orbitals. The electron density of tartaric acid is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

greatest at the carboxyl groups and therefore electron ejection should predominate at these sites. Once the electron has been ejected from the carboxyl group it can migrate through the lattice until it is trapped. The large electron affinity of the carboxyl groups also makes them best candidates for trapping sites. If an electron is knocked out of the carboxyl group then the anion species can be formed easily and further decays to the neutral species radical "B". This mechanism is proton migration over a hydrogen bridge and is shown in Fig. 8.

As the sample is warmed a decarboxylation reaction on radical "A" occurs at approximately $-90\,^{\circ}C$ and is complete at $-20\,^{\circ}C$. In this process hydrogen atom migration occurs from the carboxyl species to the adjacent carbon atom. The neutral radical "B" also decarboxylates to give radical "C" and carbon dioxide. At room temperature these secondary radicals are able to abstract hydrogen from positions 2 and 3 of other molecules in the lattice to give the tertiary species "D", which is stable even to temperatures approaching the melting point of the crystal.

These studies support the observation of Moulton and Cernansky on the DL-tartaric acid system, and those of Schwartz, Hanna, and Bales on the succinic acid system. Further work is underway on the *meso*-tartaric acid systems to provide additional confirmation of the mechanism.

This work was supported by Ontario Department of University Affairs grant #640-60. We are indebted to W. A. Bernhard for the use of his computer program and to M. Fujimoto for many valuable discussions.

Rhodium(I) and (III) Complexes of Some Phospholes and Their Behavior as Homogeneous Hydrogenation Catalysts

DAVID G. HOLAH, ALAN N. HUGHES, AND BENJAMIN C. HUI
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received June 20, 1972

Reactions between rhodium(III) chloride hydrate and certain phospholes are described; these result in the formation of both Rh(III) and Rh(I) complexes. The phospholes also react with Rh(I) carbonyl and ethylene complexes. The products of these reactions were investigated as homogeneous catalysts in the hydrogenation of 1-hexene, and some show relative rates of hydrogenation comparable with that of hydridocarbonyltris(triphenylphosphine)rhodium(I) but slower than that of tris(triphenylphosphine)rhodium (I) chloride.

Les réactions entre le chlorure de rhodium(III) hydraté et certains phospholes sont décrites et conduisent aux complexes de Rh(III) et Rh(I). Les phospholes réagissent aussi avec les complexes de Rh(I) carbonyle et éthylène. Les produits de ces réactions ont été étudiés comme catalyseurs en phase homogène dans l'hydrogénation de l'hexène-I et certains d'entre eux donnent des vitesses relatives d'hydrogénation comparables à celles de l'hydrure carbonyltris(triphénylphosphine) rhodium(I) mais inférieures à celles du chlorure de tris(triphénylphosphine)rhodium(I). Introduction

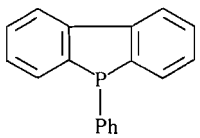
We have previously reported transition metal complexes of 1,2,5-triphenylphosphole (TPP) (a derivative of the aromatic phosphole system) and its oxide (TPPO), sulfide (TPPS), and selenide (1, 2). Coordination of the ligands to the metal ions occurs through the donor atoms in all cases except for the TPPO complexes of Rh(I) where the π-diene system of the ligand is involved (2). In view of the interesting complexes obtained from the rhodium system, a study of reactions between some other unsaturated cyclic phosphines and rhodium halides was undertaken. In this paper, we report some substituted phosphole complexes of Rh(I) and Rh(III), together with preliminary data on the catalytic properties of these compounds.

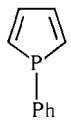
Results and Discussion

(A) Rhodium(III) Complexes

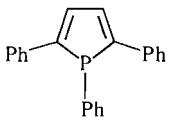
Rhodium(III) chloride trihydrate in ethanol or butanol reacts almost instantly with up to 6-fold excesses of DBP (9-phenyl-9-phosphafluorene) and, under reflux for short periods, PP (1-phenylphosphole) to produce yellow, air-stable solids of composition $RhCl_3L_3$ (L = DBP or PP) which can be recrystallized from methylene chloride. With a similar excess of TPP, the complex $RhCl_3(TPP)$ is formed first (3) in solution, but when the reaction mixture is heated under reflux for at least 24 h, the stable, yellow-brown hydrido complex $RhHCl_2(TPP)_2$ is produced. There appears to be no change in the composition of the $RhCl_3L_3$ complexes when suspensions of these are heated under reflux for long periods.



DBP

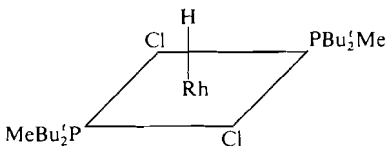


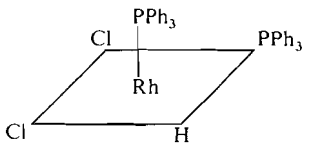
PP



TPP

Little structural information is available from infrared spectra which are very similar to those of the ligands, but it appears that DBP and PP behave in a rather similar manner to some other tertiary alkyl or arylalkyl phosphines (*e.g.* Et_3P, Me_2PhP, Bu^n_3P) which also form (4–6) stable Rh(III) complexes of the type RhX_3L_3. On the other hand the behavior of TPP parallels that of more bulky phosphines which form (6, 7) analogous hydrido species $RhHCl_2L_2$ (L = $Bu^tPr^n_2P$, Bu^i_2MeP, Bu^i_2EtP, or $Bu^i_2Pr^nP$) from $RhCl_3.3H_2O$ and the ligands L. In contrast $RhHCl_2(Ph_3P)_2$ has only been prepared (8) from $RhCl(Ph_3P)_3$ and HCl. The far infrared spectrum of $RhHCl_2(TPP)_2$ shows only one Rh—Cl stretching frequency at 285 cm^{-1}, and vibrations of Rh—Cl containing compounds in





this frequency range have been interpreted (7) as indicating the presence of mutually *trans* chlorine atoms (*cf. cis* chlorine atoms show two Rh—Cl stretching frequencies (7)). The Rh—H stretching frequency in $RhHCl_2(TPP)_2$ occurs at 1990 cm^{-1} compared with 1938 cm^{-1} for $RhHCl_2(Bu^t_2MeP)_2$ (7). These spectral data (as well as n.m.r. data on the latter compound), together with the close similarity in the methods of synthesis of the $RhHCl_2L_2$ complexes (L = TPP, Bu^t_2MeP), suggest that the two complexes have similar structures. In contrast, the $RhHCl_2(Ph_3P)_2$ complex has been assigned (8) a *cis*-chloride structure.

(B) Rhodium(I) Complexes

The products of the reaction between Rh(III) and TPP are very dependent on the solvent and when ethanol is replaced by certain other solvents (in which TPP has a higher solubility), reduction of the Rh(III) occurs. Thus, TPP in chloroform reacts with $RhCl_3.3H_2O$ in methanol (6:1) under reflux conditions to produce an orange solid of composition RhCl(TPPO)(TPP). The infrared spectrum of this complex in the 1100–1200 cm^{-1} region shows that the TPPO is π-bonded to the rhodium (*cf.* ref. 2), and the complex is analogous to $RhCl(TPPO)(Ph_3P)$ which has been previously reported (2). That the rhodium has a stronger affinity towards the π-system of the TPPO in the presence of an excess of TPP again emphasizes the relatively poor donor properties (1) and probably aromatic nature of the substituted phosphole system.

$RhCl_3.3H_2O$ in ethanol reacts with TPPS under reflux to give a brown solid which can be recrystallized from methylene chloride as $RhCl(TPPS).CH_2Cl_2$. The phosphole sulfide, in contrast to TPPO (2), is believed to be bonded to the rhodium through the sulfur atom as shown by a shift in the P—S stretching frequency from 637 cm^{-1} in the free ligand to either 625 or 595 cm^{-1} in the complex. This difference in behavior of the metal towards the O and S donor atoms is not unexpected since rhodium falls into the "class b" acceptor category (9).

Rhodium carbonyl chloride $[RhCl(CO)_2]_2$, in alcoholic solutions, reacts smoothly with an excess of TPP, DBP, or TPPS (1:3) to produce yellow solids characterized as $RhCl(CO)(TPP)_2$, and $RhCl(CO)_2(DBP)$, and black $RhCl(CO)_2$-(TPPS). $RhCl(CO)(TPP)_2$ is also formed from the reaction of $RhCl_3.3H_2O$ with TPP in ethanol under reflux with the subsequent introduction of formaldehyde (10). The carbonyl complexes are likely to have monomeric square planar structures.

The chlorobis(ethylene)rhodium(I) dimer, $[RhCl(C_2H_4)_2]_2$, in methanol solutions reacts with DBP or TPP in a 1:3 ratio under reflux to yield the dimeric complexes $[RhCl(DBP)_2]_2$ and $[RhCl(TPP)_2]_2$. These complexes are air sensitive, apparently taking up oxygen which appears in the form of a broad P=O stretching frequency at 1150 cm^{-1} (*cf.* $[RhCl(Ph_3P)_2]_2$ (11)). Addition of $[RhCl(DBP)_2]_2$ to an excess of DBP (1:6) in methanol under reflux produces an orange-red air-stable solid of composition $RhCl(DBP)_3$. The analogous complex RhCl-$(TPP)_3$ is produced when a 6-fold excess of TPP is heated under reflux with $[RhCl(C_2H_4)_2]_2$ in $CHCl_3$/EtOH (1:1) solution. These complexes are generally similar to other rhodium(I) complexes of tertiary phosphines (5, 6, 11–13).

(C) Catalytic Properties

The activities of the complexes were examined in the homogeneous hydrogenation of 1-hexene. Thus, in a benzene solution and in the presence of Et_3N, $RhHCl_2(TPP)_2$ is an extremely active catalyst for this process at less than 1 atm pressure of hydrogen at 20 °C. There is no activity in the absence of the amine which appears to be essential in stabilizing the proton released as the hydrogen is cleaved heterolytically. This phosphole complex catalyzes the reaction at a rate (Table 1) which is comparable to that at which $RhH(CO)(Ph_3P)_3$ catalyzes this hydrogenation. The similar Rh(III) complexes containing bulky ligands, $RhHCl_2(PBu^tPr^n_2)_2$ and $RhH_2Cl(PBu^t_3)_2$, have recently been reported to be active catalysts for the hydrogena-

§TPP/Rh = 2.

tion of olefins (7), but the other Rh(III) complexes prepared in this work are not active under similar conditions.

The Rh(I) complexes, $RhCl(DBP)_3$, and $[RhCl(DBP)_2]_2$ in benzene solutions also catalyze the 1-hexene hydrogenation at 20 °C; the former being about twice as fast as the latter. The presence of a base is not required and the solutions containing the catalysts generally turned yellow before addition of the olefin, indicative of the formation of a dihydride (11). *In situ* production of a catalytically active species can be achieved by adding $Rh_2Cl_2(C_2H_4)_4$ to a 2-fold excess of DBP (or TPP) in benzene. Instantaneous reaction between the Rh(I) species and the ligand occurs and the rate of hydrogenation by the $Rh_2Cl_2(C_2H_4)_4$/DBP system is the same as when $Rh_2Cl_2(DBP)_4$ itself is used. When Ph_3P is replaced by DBP or TPP, the rate decreases and this is possibly due to the interaction of the phosphorus lone pair electrons with the π-system which results in decreasing the electron density on the Rh atom. Alternatively, steric effects may be responsible for this decrease in activity.

The other Rh(I) complexes, *e.g.* $RhCl(CO)(TPP)_2$, RhCl(TPPO)(TPP), and $[RhCl(TPPO)]_2$ (2), show no activity at 20 °C, and less than 1 atm pressure of hydrogen but the last compound shows a slight activity at 60 °C.

Detailed kinetic studies have been carried out on certain of these systems and will be published separately.

Experimental

1-Phenylphosphole (14), the other phosphole ligands (1), hydridocarbonyltris(triphenylphosphine)rhodium(I) (15), chlorobis(carbonyl)rhodium(I) (16), and chlorobis(ethylene)rhodium(I) (17) were prepared as described in the literature. Rhodium trichloride hydrate was obtained from Engelhard Industries. Reactions generally involved the appropriate rhodium compound in quantities corresponding to ~50 mg Rh in ~100 ml of solvent, and the products were dried by heating under vacuum (10^{-6} Torr) at 30–50 °C.

Microanalyses (Table 2) were carried out on a Perkin–Elmer 240 Elemental Analyzer at this institution. Chloride analyses (2) and physical measurements were made as described previously (18).

For the catalysis experiments, 1-hexene was treated with iron(II) salts, distilled over calcium hydride and stored under nitrogen at all times. Reagent grade benzene was used without further purification. In a typical run (11) the catalyst was weighed into a Teflon basket which was then suspended from a side arm of a 100 ml 3-necked flask. The olefin was contained in a burette fitted to the other side arm and the reaction flask was connected to a standard vacuum system by a condenser.

$RhCl_3(DBP)_3.0.5CH_2Cl_2$

To a solution of DBP in hot ethanol was added a solution of $RhCl_3.3H_2O$ in ethanol (6:1 mole ratio). Precipitation of the product occurred almost immediately and the solution was heated under reflux for $\frac{1}{2}$ h. The hot solution was filtered and the yellow crystals washed with ethanol and ether (95% yield). The product was recrystallized from methylene chloride as $RhCl_3(DBP)_3.0.5CH_2Cl_2$.

The same product was obtained by heating the reaction mixture for 24 h by using 3:1 mole ratio of reactants, or by using butanol as solvent.

$RhCl_3(PP)_3$

PP was added dropwise to $RhCl_3.3H_2O$ (6:1) in hot ethanol and the mixture heated under reflux for $\frac{1}{2}$ h. The yellow solid was filtered off and washed with ethanol and ether (yield 60%).

$RhHCl_2(TPP)_2$

A mixture of $RhCl_3.3H_2O$ and TPP (1:3) in ethanol was heated under reflux for at least 40 h after which the hot solution was filtered. The yellow-brown solid was washed with ethanol and ether (yield 75%).

$RhCl(CO)(TPP)_2$

(*a*) An ethanol solution of $RhCl_3.3H_2O$ was added to a suspension of TPP in hot ethanol (1:4) and the mixture heated under reflux for 10 min during which time the solution turned brown. An excess of formaldehyde was added and a yellow precipitate quickly formed. The mixture was heated under reflux for a further 1 h, filtered, and the yellow crystals washed with chloroform and ether and recrystallized from benzene (yield 75%).

(*b*) TPP suspended in ethanol was added to an ethanol solution of $Rh_2Cl_2(CO)_4$ (3:1) and the mixture heated under reflux for 1 h during which time yellow crystals were formed. These were filtered off and washed with chloroform and ether (yield 85%).

*Calculated values below found.
†Presence of solvent confirmed from n.m.r./mass spectral data.
‡Not including methylene chloride.

$RhCl(CO)_2(DBP).MeOH$

DBP was added to a methanol solution of $Rh_2Cl_2(CO)_4$ (3:1) and the mixture heated under reflux for 2 h. Yellow crystals of the adduct formed and these were collected and washed with methanol and ether (yield 80%).

$RhCl(TPPS).CH_2Cl_2$

A solution of $RhCl_3.3H_2O$ in ethanol was added to TPPS in ethanol (1:2) and the mixture heated under reflux for 15 h. The hot solution was filtered and the resulting brown solid washed with ethanol and ether (yield 90%). The product was recrystallized from methylene chloride/*n*-hexane solution as the methylene chloride adduct.

$RhCl(CO)_2(TPPS).CH_2Cl_2$

TPPS was added to an ethanol solution of $Rh_2Cl_2(CO)_4$ (2:1) and the mixture heated under reflux for 2 h. The black solid was collected, washed with ethanol and ether (yield 50%) and recrystallized from methylene chloride.

$Rh_2Cl_2(DBP)_4$

A mixture of $Rh_2Cl_2(C_2H_4)_4$ and DBP (1:3) in methanol was heated under reflux for 1 h. The solution was filtered at room temperature and the red crystals washed with methanol and ether (yield 85%).

$Rh_2Cl_2(TPP)_4$

A mixture of $Rh_2Cl_2(C_2H_4)_4$ and TPP (1:3) in ethanol was heated under reflux for 2 h. The solution was concentrated, the orange-brown solid filtered off and recrystallized twice from ethanol (yield 65%).

$RhCl(DBP)_3$

The complex $Rh_2Cl_2(DBP)_4$ and DBP (1:6) in methanol were heated under reflux for 1 h and the orange-red crystals which formed were collected and washed with methanol and ether (yield 80%).

$RhCl(TPP)_3$

A mixture of $Rh_2Cl_2(C_2H_4)_4$ and TPP (1:6) in $CHCl_3$/EtOH (1:1) was heated under reflux for 1.5 h. The brown solution was filtered at room temperature, *n*-hexane added and the product was obtained by concentrating the solution. The product was recrystallized from EtOH (yield 60%).

$RhCl(TPPO)(TPP)$

A mixture of $RhCl_3.3H_2O$ (0.13 g) in methanol (10 ml) and TPP (0.84 g) in chloroform (15 ml) (1:6) was heated under reflux for 15 h, the solvent removed and the orange-brown residue extracted into benzene (15 ml). The benzene was removed, the residue extracted into methanol/benzene (1:1) and the solution concentrated to ~10 ml and filtered. The solvent was again removed yielding an orange solid which was recrystallized from ethanol (yield 60%).

We gratefully acknowledge the assistance of the personnel of the Science Instrumentation Laboratory in obtaining micro analytical data.

We also thank the Senate Research Committee of Lakehead University and the National Research Council of Canada for generous financial support.

Photolysis and Thermolysis of Ethyl Diazomalonanilate and of 5-Hydroxy-1,4-diphenyl-1,2,3-triazole in Various Alcohols

NGUYEN THANH BUU AND J. T. EDWARD

Department of Chemistry, McGill University, Montreal, Quebec

Received March 2, 1972

Ethyl diazomalonanilate was photolyzed in three alcohols (methanol, ethanol, and isopropanol) to produce the corresponding ethyl α-alkoxymalonanilates, ethyl alkyl α-*N*-phenylaminomalonates, and ethyl malonanilate. Thermolysis of the diazoanilide in ethanol and isopropanol yielded the same products as photolysis, but in lower yields. The yield of ethyl malonanilate increased with benzophenone sensitization.

Photolysis and thermolysis of 5-hydroxyl-1,4-diphenyl-1,2,3-triazole in isopropanol produced α-isopropoxy-α-phenylacetanilide, isopropyl α-*N*-phenylamino-α-phenylacetate, and 2,5-diketo-1,3,4,6-tetraphenylpiperazine.

Possible mechanisms for the decomposition of both compounds are discussed; an α-lactam may be an intermediate in the formation of the α-*N*-phenylamino esters.

La photolyse du diazomalonanilate d'éthyle dans les trois alcools (méthanol, éthanol, et isopropanol) fournit les trois produits suivants: α-*N*-alkoxymalonanilates d'éthyle, α-*N*-phénylaminomalonates d'éthyle et d'alkyle, et malonanilate d'éthyle. La thermolyse du diazoanilide dans l'éthanol et l'isopropanol produit les mêmes composés que ce de la photolyse, mais avec rendement inférieur. Le rendement du malonanilate d'éthyle s'augmente grandement avec la sensitization par benzophénone.

La photolyse et la thermolyse du 5-hydroxy-1,4-diphényl-1,2,3-triazole dans l'isopropanol fournissent α-isopropoxy-α-phénylacetanilide, α-*N*-phénylamino-α-phénylacetate d'isopropyle, et 2,5-dicéto-1,3,4,6-tetraphénylpiperazine.

Des possibles mécanismes pour la décomposition des deux composés sont discutés; un intermédiaire du genre de α-lactam peut être impliqué dans la formation des esters α-*N*-phénylamino.

Introduction

The photochemical and thermal decomposition of α-diazoesters have recently received considerable attention (1–5). In particular, the photolysis of ethyl diazoacetate in alcohols (2, 3) has led to products resulting from novel reaction paths. The photolysis of α-diazoamides, on the other hand, has been virtually ignored (3), perhaps because of the difficulties encountered in the preparation of these compounds (6).

The most general method for the preparation of α-diazoamides consists of diazotizing an α-amino ester, and then converting the ester into an amide (7). The feasibility of this method is limited by the availability and reactivity of α-amino esters (3).

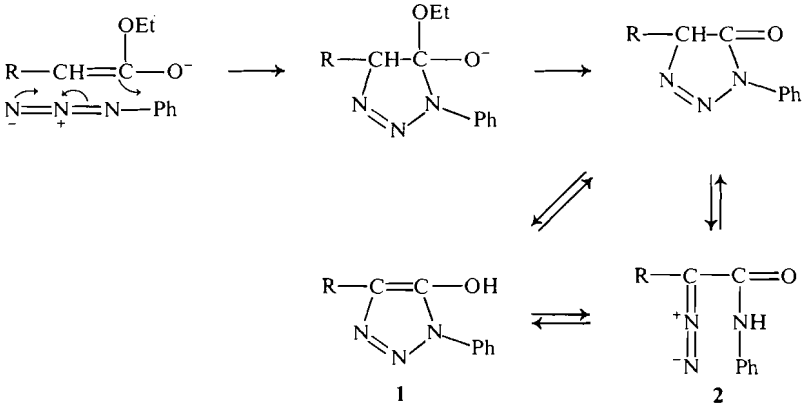
We have used a second method, due to Dimroth (8), in which an azide reacts with the carbanion of an ester to yield a triazole (see Scheme 1). These triazoles are in equilibrium to varying extents with the tautomeric α-diazoamides (9). In the case of the triazole (**1***a*) obtained by reaction of ethyl malonate with phenyl azide, the equilibrium lies to the extent of 99.7% on the side of ethyl diazomalonanilate (**2***a*), because of the electron-withdrawing character of the carbethoxy group. In contrast, diazoacetamide exists to the extent of more than 99% in the form of the triazole tautomer (10), and 5-hydroxy-1,4-diphenyl-1,2,3-triazole (**1***b*), obtained by the reaction of ethyl phenylacetate with phenylazide (11), exists almost completely as the triazole tautomer.

We now report studies of the products from the thermal and photochemical decomposition of the diazoamide **2***a* and of the triazole **1***b*.

Experimental

General Procedures

Photolyses were carried out at temperatures between 10 and 25 °C in a Rayonnet photochemical reactor equipped with eight low-pressure mercury lamps of 2537 Å wavelength, unless otherwise noted. A stream of nitrogen was bubbled through the solution before each irradiation, and photolysis was continued until there was no further change in the i.r. spectrum of the reaction mixture. Solvents were evaporated at reduced pressure, at room temperature, and residues were chromatographed on plates coated with a 1 mm layer of silica containing a fluorescent indicator (Silica Gel H_F254 acc. to Stahl, Canlab, Montreal), using



1

2

a R = EtOCO
b R = Ph

SCHEME 1

chloroform–ether (8:1) as eluant. Products were extracted from the adsorbent by chloroform (Fisher, spectrograde) to which a few drops of methanol had been added to increase polarity. The extracts were dried over sodium sulfate, and concentrated at reduced pressure. I.r. spectra were determined in carbon tetrachloride solution with a Perkin–Elmer 257 (Grating) or a Perkin–Elmer 337 (Prism) spectrophotometer. N.m.r. spectra were obtained using a Varian T-60 or a Varian A-60 instrument, with carbon tetrachloride as solvent and tetramethylsilane as internal standard, unless otherwise stated. Mass spectra were measured on an AEI-MS 902 instrument at an inlet temperature of approximately 150°. Elemental analyses were performed by C. Daesslé, Montreal.

Ethyl Diazomalonanilate (2a)

The procedure of Dimroth (8) was followed with little modification, using phenyl azide prepared by the method of Lindsay and Allen (12). The crude product, after recrystallization twice from petroleum ether (b.p. 30–60°) or pentane, was obtained as yellowish crystals, m.p. 72–73° (lit. 71–72° (8)). The i.r. spectrum (in CCl_4) showed characteristic bands at 3300 (N—H), 2130 ($=\overset{+}{N}=\overline{N}$) 1700 (ester C=O), and 1670 cm^{-1} (amide C=O). The n.m.r. spectrum showed a broad singlet at δ 9.5 (1H, amide), a multiplet at 7.4 (5H, phenyl), a quartet at 4.3 (2H, ethoxy methylene), and a triplet at 1.4 (3H, ethoxy methyl).

When a sample reacted with sodium ethoxide, a white precipitate, m.p. 185–189°, of the sodium salt of **1***a* appeared, as reported by Dimroth (8). On acidification this reverted to **2***a*.

5-Hydroxy-1,4-diphenyl-1,2,3-triazole (1b)

This triazole was prepared in 40% yield by the method of Dimroth and Letsche (11) from ethyl phenylacetate and phenyl azide, and had a melting point of 135–136° (reported m.p. 135° (11)). The i.r. spectrum showed absorption peaks at 3340 (OH), 3030, and 1600 cm^{-1} (phenyl). The mass spectrum showed a molecular-ion peak at *m/e* 237 and a peak of medium intensity at *m/e* 209 corresponding to the loss of nitrogen.

Photolysis of Ethyl Diazomalonanilate in Isopropanol

A solution of ethyl diazomalonanilate (120 mg) in isopropanol (60 ml) was photolyzed for 5 h. The crude residue on thin-layer chromatography showed three major spots having R_f 0.82, 0.67, and 0.48. Separation of the major spots by preparative thick-layer chromatography yielded: (*a*) ethyl α-isopropoxy malonanilate (**3**; R = *i*-Pr), an oil (32 mg, 23% yield) which crystallized slowly in *n*-hexane; (*b*) ethyl isopropyl α-*N*-phenylaminomalonate (**4**; R = *i*-Pr), an oil (34 mg, 25%); and (*c*) ethyl malonanilate (**5**) (42 mg, 36%).

Ethyl α-isopropoxy malonanilate, recrystallized from *n*-hexane, was obtained as white crystals (25 mg), m.p. 42–43°.

Anal. Calcd. for $C_{14}H_{19}NO_4$: C, 63.4; H, 7.2; N, 5.3. Found: C, 63.2; H, 7.3; N, 5.4.

Ethyl isopropyl α-N-phenylaminomalonate was an uncrystallizable oil.

Anal. Calcd. for $C_{14}H_{19}NO_4$: C, 63.4; H, 7.2; N, 5.3. Found: C, 63.4; H, 7.1; N, 5.4.

Ethyl malonanilate was obtained as an oil which in benzene slowly deposited crystals (32 mg), m.p. 36–38°. It had a parent peak at *m/e* 207 in its mass spectrum, and had n.m.r. and i.r. spectra identical to those of an authentic sample prepared from ethyl malonate and aniline by the method of Chattaway and Almstead (13).

When ethyl diazomalonanilate (233 mg) in isopropanol (50 ml) was irradiated at 2537 Å wavelength for 12 h, the proportions of the three major products were almost unchanged (ethyl-α-isopropoxymalonanilate, 22%; ethyl isopropyl α-*N*-phenylaminomalonate, 23%; and ethyl malonanilate, 26%).

Photolysis of Ethyl Diazomalonanilate in Isopropanol in the Presence of Oxygen

A solution of **2***a* (231 mg) in isopropanol (50 ml) was flushed with oxygen for 10 min before being irradiated. A small positive pressure of oxygen was maintained over the solution throughout the irradiation period (8 h). Evapora-

For personal use only.

tion of the solvent left a dark yellow residue, shown on thin-layer chromatography to contain spots corresponding to diethyl α-*N*-phenylaminomalonate and ethyl α-ethoxymalonanilate, but no spot corresponding to ethyl malonanilate. The n.m.r. spectrum of the residue did not reveal any singlet at δ 3.4 characteristic of the methylene protons of the malonanilate.

Benzophenone-sensitized Photolysis of Ethyl Diazomalonanilate in Isopropanol

A solution of **2***a* (233 mg) and benzophenone (92 mg) in isopropanol (50 ml) was photolyzed as described above. Thin-layer chromatography of the reside showed two spots corresponding to benzophenone and ethyl malonanilate. No effort was made to determine the percentage yield of the ester.

Thermolysis of Ethyl Diazomalonanilate in Isopropanol

A solution of ethyl diazomalonanilate (230 mg) in isopropanol (10 ml) in a pressure bottle was heated to 160–170° by an oil bath. After 12 h the solvent was removed at reduced pressure and the crude product separated by preparative thick-layer chromatography into ethyl α-isopropoxymalonanilate (68 mg, 6%), ethyl isopropyl α-*N*-phenylaminomalonate (47 mg, 18%), and ethyl malonanilate (52 mg, 25%).

Photolysis of Ethyl Diazomalonanilate in Ethanol

A solution of ethyl diazomalonanilate (115 mg) in absolute ethanol (50 ml) was photolyzed for 6 h. The crude residue on thin-layer chromatography showed three major products having R_f 0.84, 0.70, and 0.49. Separation of the major products by preparative thick-layer chromatography yielded: (*a*) ethyl α-ethoxymalonanilate, an oil which crystallized from hexane (34 mg, 27%), m.p. 32–35°; (*b*) diethyl α-*N*-phenylaminomalonate, an oil (23 mg, 18%), and (*c*) ethyl malonanilate (34 mg, 32%) identified by comparison with an authentic sample.

Ethyl α-ethoxymalonanilate, recrystallized from pentane (25 mg), had m.p. 31–32°.

Anal. Calcd. for $C_{13}H_{17}NO_4$: C, 62.1; H, 6.8; N, 5.6. Found: C, 61.8; H, 6.7; N, 5.6.

Ethyl α-N-phenylaminomqlonate was an uncrystallizable oil.

Anal. Calcd. for $C_{13}H_{17}NO_4$: C, 62.1; H, 6.8; N, 5.6. Found: C, 62.0; H, 6.9; N, 5.6.

A second irradiation of ethyl diazomalonanilate (230 mg) in absolute ethanol (50 ml) under the same conditions yielded ethyl α-ethoxymalonanilate (60 mg, 24%), diethyl α-*N*-phenylaminomalonate (40 mg, 16%), and ethyl malonanilate (60 mg, 33%).

Photolysis of Ethyl Diazomalonanilate in Ethanol at Low Temperature

A solution of ethyl diazomalonanilate (235 mg) in absolute ethanol (50 ml), cooled by a Dry Ice–acetone mixture, was irradiated by a 450 W Hanovia lamp, contained in a quartz jacket immersed in the reaction mixture. Magnetic stirring of the solution was maintained throughout the photolysis. Aliquots were taken at 20 min intervals to be tested quickly for the presence of α-lactam by i.r. spectroscopy (characteristic C=O absorption at 1835 cm^{-1}). The temperature of the solution was −50 °C at the start of the irradiation, and −5 °C after 20 min of irradiation. No α-lactam was detected. The photolysis was complete after 2 h of irradiation. Evaporation of the solvent left a residue which on thin-layer chromatography showed three major spots R_f 0.84, 0.69, 0.49, corresponding to ethyl α-*N*-phenylaminomalonate, ethyl α-ethoxymalonanilate, and ethyl malonanilate, and three minor spots at lower R_f. Separation by thick-layer chromatography yielded diethyl α-*N*-phenylaminomalonate (36 mg, 14%), ethyl α-ethoxymalonanilate (46 mg, 18%), and ethyl malonanilate (42 mg, 20%), all identified by t.l.c. and i.r. spectra.

Benzophenone-sensitized Photolysis of Ethyl Diazomalonanilate in Ethanol

A solution of **2***a* (232 mg) and benzophenone (92 mg) in absolute ethanol (50 ml), magnetically stirred in a Pyrex vessel, was flushed with a stream of nitrogen and then irradiated by eight high-pressure 3500 Å wavelength Rayonnet lamps for 8 h. Evaporation of the solvent left a yellow oil, shown by thin-layer chromatography to contain benzophenone and ethyl malonanilate. Separation of the residue by preparative thick-layer chromatography yielded ethyl malonanilate (154 mg, 75%) identified by i.r. and n.m.r. spectra.

Thermolysis of Ethyl Diazomalonanilate in Ethanol

A solution of **2***a* (220 mg) in absolute ethanol (10 ml) in a pressure bottle of 100 ml capacity was heated to 160–170° by an oil-bath. After 12 h the solvent was evaporated at reduced pressure. Thin-layer chromatography of the residue showed three major spots and two minor spots. Separation of the major spots by preparative thick-layer chromatography yielded ethyl α-ethoxymalonanilate (51 mg, 20%), ethyl α-*N*-phenylaminomalonate (36 mg, 15%), and ethyl malonanilate (30 mg, 15%).

Photolysis of Ethyl Diazomalonanilate in Methanol

A solution of ethyl diazomalonanilate (120 mg) in methanol (60 ml) was photolyzed for 5 h. The crude residue, on thin-layer chromatography, showed three main spots (R_f at 0.80, 0.73, and 0.47). Separation of the major products by preparative thick-layer chromatography yielded ethyl malonanilate (R_f 0.47, 13 mg, 12%) and an oil (31 mg, 25%) which on a thin-layer plate showed a mixture of two spots (R_f 0.80 and 0.73). A second preparation of this oil after thick-layer chromatography yielded ethyl methyl α-*N*-phenylaminomalonate (R_f 0.73), an uncrystallizable oil (5 mg).

Photolysis of Ethyl Diazomalonanilate in the Presence of Styrene

A solution of ethyl diazomalonanilate (467 mg), styrene (2.1 g), and trinitrobenzene (*ca.* 1.0 mg) in anhydrous ether (60 ml) was photolyzed with radiation of 2537 Å wavelength for 8 h. Evaporation of the solvent left an uncrystallizable yellow oil which on thin-layer chromatography showed five spots. The n.m.r. of the crude residue did not reveal a triplet at δ 4.5 and a doublet at 3.5 and 3.3 characteristic of the corresponding cyclobutanone. No effort was made to isolate and characterize the products.

Photolysis of Ethyl Diazomalonate in Ethanol

A solution of ethyl diazomalonate (377 mg), prepared by the method of Doering and Knox (14), in absolute ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(50 ml) was irradiated with lamps of 2537 Å wavelength. Thin-layer chromatography of the residue showed five products but did not show any spot corresponding to that of ethyl malonate. The n.m.r. of the crude residue did not show any peak at δ 3.4 corresponding to that of the methylene proton of ethyl malonate. No effort was made to isolate the products.

Benzophenone-sensitized Photolysis of Ethyl Diazomalonate in Isopropanol

The photolysis of a solution of ethyl diazomalonate (168 mg) and benzophenone (90 mg) in isopropanol (50 ml) was carried out as above. The reaction mixture was concentrated at room temperature. Thin-layer chromatography of the residue showed two major spots corresponding to benzophenone and ethyl malonate. Separation of the major spots by preparative thick-layer chromatography yielded 98 mg (61%) of ethyl malonate, identified by comparison of the i.r. spectrum with that of an authentic sample.

Attempted Photolysis of Ethyl Malonanilate in Ethanol

A solution of ethyl malonanilate (210 mg) in ethanol (50 ml) was photolyzed for 8 h. Thin-layer chromatography of the solution revealed little change in the composition of the solution. Irradiation for another 8 h period, and evaporation of the solvent left ethyl malonanilate (187 mg) in 90% yield.

Photolysis of 5-Hydroxy-1,4-diphenyl-1,2,3-triazole in Isopropanol

A solution of the triazole **1***b* (238 mg) in isopropanol (100 ml) was irradiated by eight low pressure mercury lamps of 2537 Å wavelength for 12 h. The solvent was evaporated at reduced pressure and the oily residue was extracted with 100 ml of hot *n*-hexane. A brown residue remained which was removed by filtration. Wasteful recrystallization of the residue three times from glacial acetic acid yielded 10 mg (5%) of 2,5-diketo-1,3,4,6-tetraphenylpiperazine (**13**), a white solid, m.p. 275–276° (lit. m.p. 277.5–278° (15)). The i.r. spectrum showed absorption peaks at 3338, 3100, 3030, and 1670 cm^{-1}. The mass spectrum showed a molecular-ion peak at *m/e* 418 with a base peak at *m/e* 209.

The filtrate from the brown residue was concentrated to give a yellow oily residue, which on t.l.c. showed two major spots of R_f 0.76 and 0.59, and three minor spots of lower R_f. Separation of the two major spots by preparative thick-layer chromatography yielded: *(1)* *α-Isopropoxy-α-phenylacetanilide* (**11**) (56 mg), a white solid; m.p. 72–74°; ν_{max} 3300 (N—H), 3100 (phenyl), and 1680 cm^{-1} (amide C=O); mass spectral peaks at *m/e* 150, 120, and 77.

Anal. Calcd. for $C_{17}H_{19}NO_2$: C, 75.8; H, 7.1; N, 5.2. Found: C, 75.8; H, 7.3; N, 5.1.

(2) Isopropyl α-N-phenylamino-α-phenylacetate (**12**), an uncrystallizable oil (20 mg, 7%); ν_{max} 3350 (N—H), 3100 (phenyl), 1720 cm^{-1} (ester C=O), mass spectral peaks at *m/e* 269 and 182.

Thermolysis of 5-Hydroxy-1,4-diphenyl-1,2,3-triazole (1b) in Isopropanol

The thermolysis of this triazole (233 mg) in isopropanol (15 ml) was carried in a pressure bottle immersed in an oil bath heated to 150° for 12 h. Working-up the residue by the procedure described above yielded: the diketopiperazine (16 mg, 8%), α-isopropoxy-α-phenylacetanilide (42 mg, 18%), and isopropyl α-*N*-phenylamino-α-phenylacetate (11 mg, 4%). The products were identified by t.l.c. and i.r. spectra.

Thermolysis of 1,3-Di-tert-butylaziridinone in Methanol

A solution of 1,3-di-tert-butylaziridinone (**18**) (500 mg), was decomposed in boiling methanol (10 ml), following the procedure of Sheehan and Beeson (16), and afforded methyl 2-(*N-t*-butylamino)-3,3-dimethylbutyrate (**19**) (88 mg, 15%) and 2-methoxy-3,3-dimethyl-*N-t*-butylbutyramide (**20**) (176 mg, 30%). The physical constants and the i.r. and n.m.r. spectra of the products were in agreement with those reported by Sheehan and Beeson, but these authors reported different yields (26% of the butyrate and 45% of the butyramide).

Photolysis of 1,3-Di-tert-butylaziridinone in Various Alcohols

The photolyses of this α-lactam (0.553) in methanol, ethanol, and isopropanol (100 ml) were carried out in a Pyrex vessel equipped with an immersion high-pressure Hg lamp (450 W, Hanovia). The reactor was cooled in an ice-water bath to minimize the effects of a possible thermolysis. In all three cases photolysis yielded an oily residue which was shown by n.m.r. to contain no starting material, but also none of the butyrate or butyramide resulting from thermal reaction of the alcohol with the aziridinone. This was confirmed by failure to isolate these products by the procedures which were successful in isolating them from the thermolysis mixture.

Results and Discussion

Structures of Reaction Products

The photolyses and thermolyses of **2***a* in methanol, ethanol, and isopropanol produced in each case three major products: an ethyl α-alkoxymalonanilate (**3**), an α-*N*-phenylaminomalonic ester (**4**), and ethyl malonanilate (**5**) (eq. 1).

The yields of these products isolated by preparative thick-layer chromatography varied only slightly with duration of the photolysis, and are given in Table 1.

The products **3** (R = Et, *i*-Pr) and **4** (R = Me,

Et, and *i*-Pr) are all new compounds; the structures assigned them are based on elemental analyses and spectral properties. Considering first ethyl α-ethoxy- (**3**; R = Et) and α-isopropoxymalonanilates (**3**; R = *i*-Pr), their i.r. spectra showed absorption peaks at 1730 (ester C=O), 1680 (amide I band), 1535 (amide II band), and 3370–3380 cm^{-1} (N—H stretch). Their n.m.r. spectra also showed the peaks expected for the structures **3** (R = Et) and **3** (R = *i*-Pr) (Table 2). Finally, the mass spectra of the two compounds both showed a similar pattern of fragmentation (Table 3), with a molecular-ion peak of small intensity and a parent peak at M − 119 due to the loss of CONPh, perhaps as Ph—N=C=O. The presence of the phenylcarbamoyl group was revealed by a peak of medium intensity at *m/e* 120, due to the characteristic ion $CONHPh^+$ (17), and the elimination of neutral PhNCO which may be visualized to proceed through a six-membered intermediate (Scheme 2). In addition, a peak at *m/e* 93 is also characteristic of anilides (18), and is probably due to the ion $PhNH_2^+$. The other peaks (Table 3) are also readily accommodated by the structures **3** (R = Et and *i*-Pr).

Turning now to the three products assigned the structures **4** (R = Me, Et, and *i*-Pr), these all exhibited *two* i.r. absorption peaks above 1700 cm^{-1} (Table 4) and hence contained two ester groups. The N—H group gave rise to i.r. peaks at approximately δ 4.6, overlapping the methine proton (Table 5). When D_2O was added, exchange took place readily, and the area of the signal at δ 4.6, previously integrating to two

hydrogen atoms, now integrated to one. However, most informative were the mass spectra (Table 6), which showed the familiar fragmentation pattern of α-amino esters (19) with prominent peaks corresponding to the loss of the carbalkoxy groups (fission *a* and *b* in Scheme 3). The base peak in the mass spectra of all three compounds was the ion of *m/e* 104 which resulted from further decomposition of one of these fission fragments by a familiar route (20), as shown in Scheme 3.

The third product obtained in both thermolyses and photolyses of ethyl diazomalonanilate in the three different alcohols was ethyl malonanilate (**5**), identified by comparison with an authentic sample.

Strausz and co-workers (2) found that thermolysis and photolysis of ethyl diazoacetate (**6**; R = H) in isopropanol produced isopropyl α-isopropoxyacetate (**7**; R = H), and proposed that an ion-pair was formed by light-induced heterolysis and exchange with solvent (Scheme 4).

However, we found no trace of the exchanged product **7** (R = PhNHCO) when **2** (= **6**; R = PhNHCO) was heated or photolyzed in isopropanol. Similarly, we found no evidence of exchange of ethyl for methyl when the reaction was carried out in methanol. It seems likely that

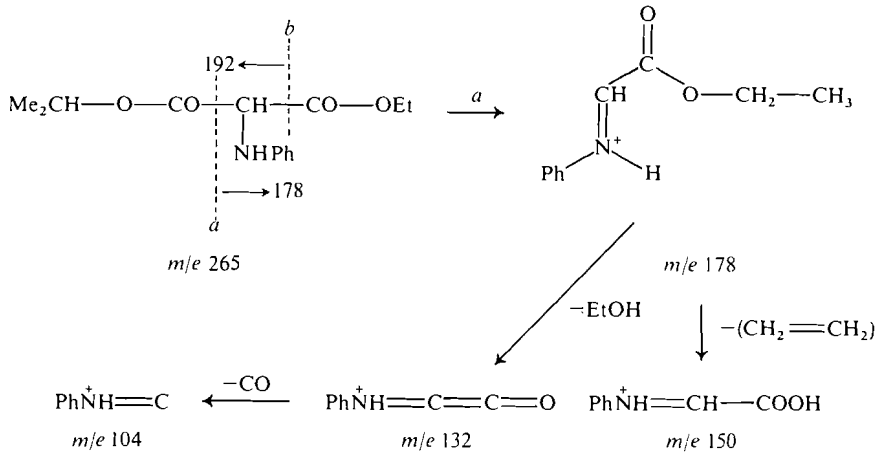
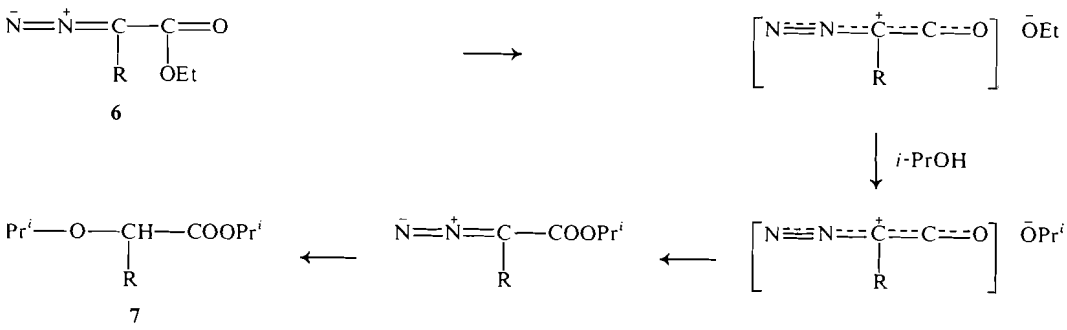


SCHEME 3



SCHEME 4

heterolysis in these cases is prevented by the electron-withdrawing effect of the PhNHCO group, which would destabilize the intermediate carbonium ion.

We also found no evidence of Fries-like rearrangement products (21) from ethyl malonanilate in the product mixture resulting from photolysis of ethyl diazomalonanilate in alcohols, and no reaction took place when a solution of ethyl malonanilate (**8**; R = EtOCO) was photolyzed in ethanol. Photolysis of acetanilide (**8**; R = H) in ethanol is known to give *o*-amino- (**9**; R = H) and *p*-aminoacetophenone (**10**; R = H) (19) (eq. 2), and we confirmed these results in our apparatus, so that the failure of ethyl malonanilate to undergo photolysis cannot be regarded as adventitious.

The photolysis and thermolysis of 5-hydroxy-1,4-diphenyl-1,2,3-triazole (**1***b*) in isopropanol yielded two isomeric products (**11** and **12**) analyzing for $C_{17}H_{19}NO_2$, and a small amount of the crystalline diketopiperazine **13** (eq. 3).

The structure **11** is indicated for one of the isomeric products by its i.r. spectrum, which shows a carbonyl amide absorption at 1675 cm^{-1}, and by its n.m.r. spectrum, which shows a singlet at δ 8.4 (N—H amide). Other n.m.r. peaks at δ 7.4 (multiplet, 10H, phenyl), 4.8 (singlet, 1H, methine), 3.8 (multiplet, 1H, isopropyl), and 1.3 (doublet, 6H, isopropyl methyl)

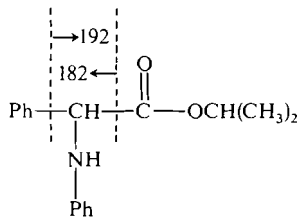
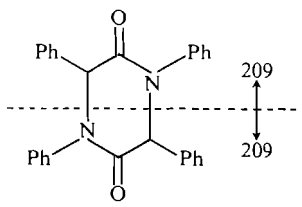
also point to this structure, as does the mass spectrum, with a molecular-ion peak at *m/e* 269, a base peak at 150 (M – PhNCO), and a peak at 120 (Ph—NHCO) (*cf.* Scheme 2).

The structure **12** was assigned to the isomeric product because its i.r. spectrum exhibited an ester carbonyl absorption peak at 1720 cm^{-1}. Its n.m.r. spectrum showed a multiplet at δ 7.2 (10H, phenyl), a broad singlet at 6.4 (1H, N—H) amine, exchangeable with D_2O), a multiplet at 5.1 (1H, isopropyl), a singlet at 4.6 (1H, methine), and a doublet at 1.1 (6H, methyls of isopropyl). Its mass spectrum had a molecular-ion peak at *m/e* 269 and strong peaks at *m/e* 192 and 182 as expected for the structure **12** (*cf.* Scheme 3).



12

The third product was 2,5-diketo-1,3,5,6-tetraphenylpiperazine (**13**) with melting point and i.r. spectrum (CO absorption at 1665 cm^{-1}) corresponding to values in the literature (15). The mass spectrum showed the expected molecular-ion peak at *m/e* 418 and a base peak at *m/e* 209 due to a symmetrical fission, the most likely being the following:



13

which allows for delocalization of charges and odd electrons by the benzene rings.

Spin States of Intermediates Giving the Different Reaction Products from **2***a*

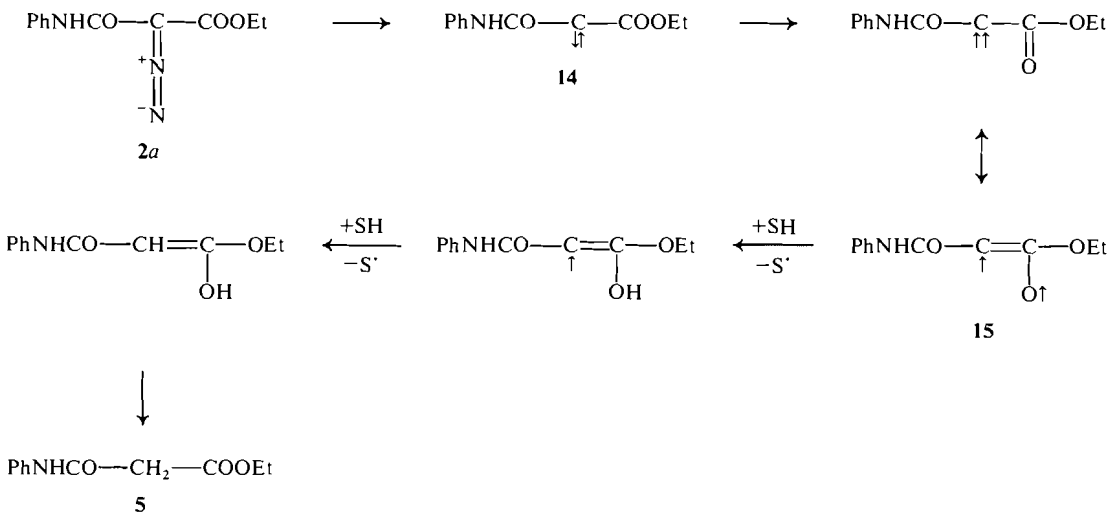
Photolysis or thermal decomposition of ethyl diazomalonanilate (**2***a*) would be expected to cause loss of nitrogen and formation of the singlet carbene **14** which could then drop down to the longer-lived, lower energy triplet **15** (22).

The products **3** (R = Et and *i*-Pr) and **4** (R = Me, Et, and *i*-Pr) probably arise from reaction of the singlet **14** with solvent alcohol, and are formed in the presence of oxygen (a triplet scavenger). The ethers **3** (R = Et and *i*-Pr) could result from insertion of the singlet carbene into the O—H bond of the alcohol, which is an unexceptional reaction (23). The mechanism of formation of the α-*N*-phenylaminomalonic esters (**4**; R = Me, Et, and *i*-Pr) is less obvious and is discussed below.

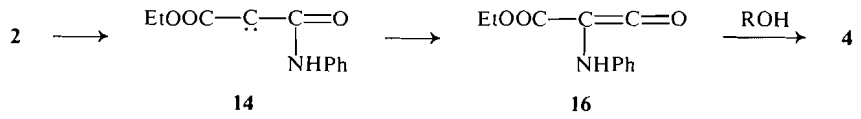
Ethyl malonanilate (**5**) is not formed by photolysis in the presence of oxygen, but is the only product in the absence of oxygen when benzophenone is used as a sensitizer. These facts point to the triplet **15** as an intermediate, which would have to abstract two hydrogen atoms from the solvent alcohols to form **5**. Similarly the triplet state of carbethoxymethylene, from the benzophenone-sensitized photolysis of ethyl diazoacetate, abstracts two protons from cyclohexene to yield ethyl acetate (4), and we have found that the benzophenone-sensitized photolysis of ethyl diazomalonate in isopropanol produced ethyl malonate in good yield. Thus abstraction of two hydrogen atoms from solvent molecules by the triplet carbene seems to go well in the presence of an α-carbonyl group. A tentative mechanism for the formation of ethyl malonanilate (**5**) is shown in Scheme 5.

Mechanism for the Formation of α*-N-Phenylaminomalonates* **4** *from* **2***a*

We may now consider the mechanism for the



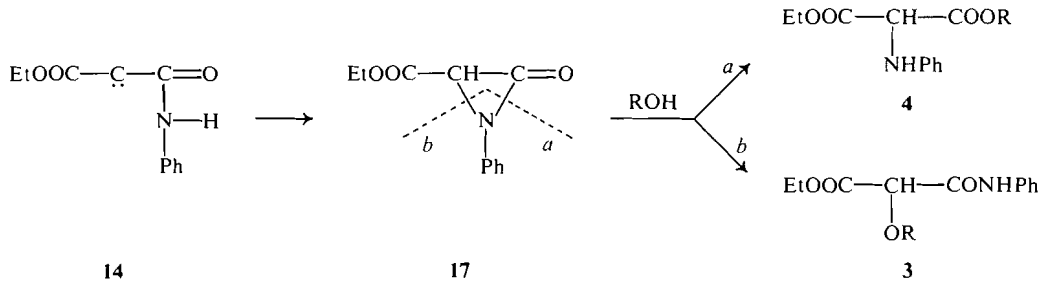
SCHEME 5



SCHEME 6

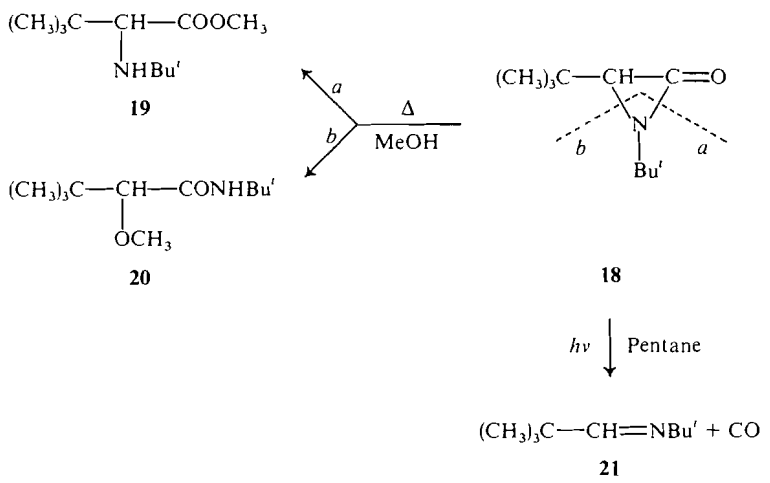
migration of the phenylamino group from its terminal linkage in **2***a* to its attachment to the α-carbon atom in **4** (R = Me, Et, and *i*-Pr). A possible mechanism (which does not specify the precise manner of this migration) would involve the ketene intermediate **16** and is depicted by Scheme 6. Similar ketene intermediates have been postulated to explain the products obtained in the photolysis of phenyl diazoacetate (3) and of ethyl diazoacetate (4). However, efforts to trap the intermediate ketene **16** with styrene did not give any detectable amount of the corresponding cyclobutanone. In any case, this particular rearrangement occurs only with certain diazo-esters: ethyl trifluoroacetyl diazoacetate (24) and diethyl diazomalonate (1) yield the products of methylene attack on solvents rather than rearrangement products. It therefore appears that the presence of electron-withdrawing groups inhibits formation of ketene intermediates.

An alternative and perhaps preferable mechanism to explain the formation of α-*N*-phenylaminomalonic esters (**4**) involves the α-lactam intermediate **17** (Scheme 7). The insertion of the methylene into the N—H bond would yield the α-lactam, which would then react with solvent to give the α-amino ester, corresponding to an acyl-



SCHEME 7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 8

nitrogen bond cleavage (*a*), and an α-alkoxyamide, corresponding to an alkyl-nitrogen bond cleavage (*b*). These two types of ring-opening are known to occur readily. Sheehan and Beeson (16) have reported (and we have confirmed) that 1,3-di-tert-butylaziridinone (**18**) reacts in boiling methanol to give the ester **19** (cleavage *a*) and the amide **20** (cleavage *b*):

Attempts to obtain evidence for such an α-lactam, which would then react with solvent to examination of the reaction mixture obtained when photolysis in ethanol was carried out at a relatively low temperature (−5 °C) were unsuccessful, probably because the α-lactam **17** can be expected to be much less stable than **18** for steric and electronic reasons (16).

Sheehan and Nafissi-V (25) reported that photolysis of **18** in pentane gave carbon monoxide and the imine **21** (see Scheme 8). We found that photolysis of **18** in methanol gave an oily product which contained no **19** or **20**; photolysis in ethanol and isopropanol gave similar results. If the lactam **17** is an intermediate in the formation of **3** and **4**, its subsequent reaction is thermal rather than photolytic.

Mechanism for the Thermolysis and Photolysis of 1b

The thermolysis and photolysis of the triazole **1***b* gave **11** and **12**, completely analogous to the products **3** and **4** obtained by thermolysis or photolysis of the diazoanilide **2***a*. A possible explanation would be that in alcohols the tautomerization **1***b* → **2***b* is very rapid, and that the reactive species is **2***b* rather than **1***b*.[1] Further work is required on the photolysis and thermolysis of **1***b* and **2***a* in solvents in which tautomerization is slow.

It should be noted that the thermal and photochemical products from **2***a* and **1***b* show differences as well as similarities. In the reaction mixture from **1***b* we were unable to detect the presence of α-phenylacetanilide (analogous to **5**, obtained from **2***a*); on the other hand, the diketopiperazine **13** from **1***b* finds no analogue in the products isolated from **2***a*. Sarel and Greenberger (15) obtained this diketopiperazine by a different route, in which they assumed an α-lactam to be an intermediate. We were unable to detect the presence of any appreciable quantity of α-lactam in the reaction mixtures from the photolysis of **1***b* (no i.r. band at 1835 cm^{-1} (26)), but this α-lactam would be expected to be particularly unstable (16).

Grateful acknowledgment is made to the National Research Council of Canada for financial support.

Photolysis of Ethyl Diazomalonanilate in Acetonitrile

NGUYEN THANH BUU AND J. T. EDWARD

Department of Chemistry, McGill University, Montreal, Quebec

Received March 2, 1972

Photolysis of ethyl diazoacetate and of ethyl diazomalonate in acetonitrile gave oxazoles. Photolysis of ethyl diazoacetate in the presence of benzophenone gave an oxazoline incorporating the elements of carbethoxymethylene, benzophenone, and acetonitrile. Photolysis of ethyl diazomalonanilate gave 5-ethoxy-2-methyl-4-phenylcarbamoyloxazole, 5-ethoxy-3-methyl-4-phenylcarbamoylisoxazole, and ethyl α-hydroxymalonanilate. With 2537 Å wavelength radiation the oxazole was formed predominantly; on the other hand, with benzophenone-sensitization, the isoxazole was formed (among other products) but no oxazole. The oxazole was isomerized to the isoxazole when irradiated in the presence of a sensitizer, while the isoxazole was isomerized to the oxazole when irradiated with radiation of 2537 Å wavelength. A tentative mechanism is advanced to explain formation of the different products.

La photolyse du diazoacétate et du diazomalonate d'éthyle dans l'acétonitrile fournit oxazoles, tandis que la photolyse du diazoacétate d'éthyle dans l'acétonitrile en presence du benzophénone fournit une oxazoline incorporant les élements du carbéthoxyméthylène, du benzophénone, et de l'acétonitrile. La photolyse du diazomalonanilate d'éthyle fournit les produits suivants: 5-éthoxy-2-méthyle-4-phénylcarbamoyloxazole, 5-éthoxy-3-méthyle-4-phénylcarbamoylisoxazole, et α-hydroxymalonanilate d'éthyle. Avec des lampes de 2537 Å longeur d'ondes, l'oxazole se forme principalement; par contre, avec la sensitisation par benzophénone l'isoxazole est formé à l'exclusion de l'oxazole. En presence du benzophénone l'irradiation de l'oxazole fournit l'isoxazole, tandis que l'irradiation de l'isoxazole avec des lampes de 2537 Å longeur d'ondes fournit l'oxazole. On propose un possible mécanisme gouvernant la formation des produits différents.

Introduction

The products of the photolysis of ethyl diazomalonanilate in methanol and other alcohols point to the following mechanism: decomposition of the diazo compound into nitrogen and a singlet carbene, which can then (*a*) react with solvent; (*b*) rearrange to an unstable intermediate (α-lactam?) which then reacts with solvent; (*c*) decay to a triplet, which then reacts with solvent. Each of these routes gives a different product (1). An alternative, less probable mechanism involved the prototropic tautomerization of ethyl malonanilate to 4-ethoxycarbonyl-5-hydroxy-1-phenyltriazole, which then lost nitrogen to give a 1,3-diradical. In an attempt to distinguish between these mechanisms, the photolysis of ethyl diazomalonanilate was carried out in a number of aprotic solvents (dioxane, benzene, ether, cyclohexene) in which tautomerization would be expected to be very slow. In all cases a complex mixture of products was obtained, from which no pure compound could be isolated. However, in acetonitrile, a solvent used successfully in other photolyses (2), crystalline products were obtained. These are discussed below; their formation is more readily rationalized by the photolysis of the diazo compound, rather than of its triazole tautomer. Furthermore, photolysis of the simpler esters, ethyl diazoacetate and ethyl diazomalonate, which are incapable of tautomerization to triazoles, was also investigated briefly, and found to give similar products.

Experimental

Photolyses of diazo compounds in acetonitrile were carried out according to the procedure described in ref. 1. Three sets of lamps giving radiation of different wavelengths (2537, 3000, and 3600 Å) were used. When irradiated by lamps giving 2537 Å radiation, the solutions were contained in quartz vessels; when irradiated by lamps giving 3000 or 3600 Å radiation, Pyrex vessels were used.

Photolysis of Ethyl Diazoacetate with 2537 Å Wavelength Radiation

A solution of ethyl diazoacetate (Eastman Chemicals, highest purity, 342 mg) in acetonitrile (Fisher spectrograde, 50 ml) was irradiated for 5 h. Evaporation of the solvent at reduced pressure left an oily residue, shown by i.r. (absence of $=\overset{+}{N}=\overset{-}{N}$ band at 2130 cm^{-1}) and by t.l.c. to contain no starting material ($R_f = 0.70$) but six or seven compounds of R_f between 0.70 and 0.30. These compounds were separated by preparative thick-layer chromotography. The n.m.r. spectrum of only one compound ($R_f = 0.63$) showed the presence of a methyl peak at δ 2.2 (singlet, 3H), as well as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

peaks at 5.8 (singlet, 1H), at 4.0 (quartet, 2H), and at 1.30 (triplet, 3H). Purification by t.l.c. gave approximately 10 mg of 5-ethoxy-2-methyloxazole (**5**; R = H, R′ = Me), a clear viscous oil whose mass spectrum showed a molecular ion peak at *m/e* 127.

Benzophenone-sensitized Photolysis of Ethyl Diazoacetate

A solution of ethyl diazoacetate (335 mg) and benzophenone (91 mg) in acetonitrile (50 ml) was irradiated for 8 h by eight 3500 Å Rayonnet lamps. Evaporation of the solvent left a yellow viscous residue which on t.l.c. showed seven small spots and a major spot at R_f 0.32. Separation of the latter material by thick-layer chromatography, followed by extraction of the silica gel with chloroform containing a trace of methanol, yielded ethyl 2-methyl-5,5-diphenyloxazolin-4-carboxylate (**10**) as an oil (85 mg). Treatment of the oil with 6 *N* HCl solution (5 ml) at room temperature produced, after 1 h of stirring, a precipitate of ethyl 2,2-diphenyl-2-hydroxy-1-acetamidopropionate (**11**) (78 mg), m.p. 158–162°. Recrystallization of **11** from a solution of chloroform–hexane (1:10) yielded 68 mg of yellowish crystals, m.p. 160–161°.

Anal. Calcd. for $C_{19}H_{21}NO_4$: C, 69.7; H, 6.5; N, 4.3. Found: C, 69.4; H, 6.5; N, 4.3.

Diphenyldiazomethane

This red crystalline compound was prepared in 80% yield from benzophenone hydrazone according to the procedure of Miller (3), and had a m.p. of 31–34° (lit. 29–32° (3)).

Photolysis of Diphenyldiazomethane with 2537 Å Wavelength Radiation

The photolysis of diphenyldiazomethane (582 mg) in acetonitrile (50 ml) was carried out for 8 h. After removal of solvent, the residue was extracted with hot ethanol, leaving an insoluble portion (103 mg) of tetraphenylazine (**8**) m.p. 165–167° (lit. 163–163.5° (4)). Its mass spectrum showed a molecular ion peak at *m/e* 360. On cooling, the ethanol solution yielded two further crops (20 mg) of crude **8**, m.p. 172–178°. The mother liquors were concentrated, and a few drops of ether were added. The solution was then allowed to stand overnight at −5 °C, and yielded 32 mg of yellow crystals of tetraphenylethane (**7**), m.p. 208–210° (lit. 209–211° (4)).

Ethyl Diazomalonate

Ethyl malonate was converted into ethyl diazomalonate in three steps, according to procedures in the literature (5, 6). The i.r. spectrum of the crude product revealed a strong absorption at 2140 cm^{-1} due to the diazo group. Efforts to purify the compound by distillation at reduced pressure were unsuccessful.

Photolysis of Ethyl Diazomalonate with 2537 Å Wavelength Radiation

The photolysis of ethyl diazomalonate (531 mg) in acetonitrile (50 ml) was carried out according to the procedure described above for ethyl diazoacetate. The crude product showed five spots on thin-layer chromatography, which were eluted and examined by n.m.r. Only the fraction of R_f 0.62 showed the presence of an isolated methyl group (singlet at δ 2.3). This oily product (53 mg, 10% yield) was isolated by preparative thick-layer chromatography. Its n.m.r. spectrum had two quartets which partly overlapped each other at δ 4–4.6 (4H), a singlet at 2.3 (approximately 3H) and a quartet (overlapping of two triplets) at 1.2–1.6 (6H). Purification of this compound twice by thick-layer chromatography yielded 6 mg of 5-ethoxy-4-ethoxycarbonyl-2-methyloxazole (**5**; R = CO_2Et, R′ = Me), an oil whose mass spectrum revealed a parent peak at *m/e* 199, and a fragmentation pattern as follows: *m/e* (intensity): 199 (33), 171 (40), 154 (45), 126 (33), 125 (100), 101 (55), 43 (100).

Photolysis of Ethyl Diazomalonanilate with 2537 Å Wavelength Radiation

A solution of this diazo compound (230 mg) in acetonitrile (50 ml) was irradiated for 6 h, by which time the i.r. spectrum of the reaction mixture showed that the diazo absorption at 2130 cm^{-1} had disappeared. Evaporation of the solvent at reduced pressure yielded 240 mg of a yellow viscous oil which on t.l.c., with chloroform–ether 10:1 as eluant, showed three major spots, at R_f 0.68, 0.60, and 0.37, and some minor spots. Separation of the major spots by preparative thick-layer chromatography yielded three products: 5-ethoxy-2-methyl-4-phenylcarbamoyloxazole (**12**), R_f 0.68, an oil (85 mg, 35% yield) which crystallized slowly in hexane; 5-ethoxy-3-methyl-4-phenylcarbamoylisoxazole (**13**), R_f 0.60, an oil (25 mg, 10% yield) which crystallized from pentane; and ethyl α-hydroxymalonanilate (**14**), R_f 0.37, an oil (8 mg; 4% yield).

5-Ethoxy-2-methyl-4-phenylcarbamoyloxazole (12) recrystallized twice from pentane, was obtained as white crystals (41 mg), m.p. 64–65°, ν_{max} 3370, 1690, 1670, 1600, and 1550 cm^{-1}.

Anal. Calcd. for $C_{13}H_{14}N_2O_3$: C, 63.4; H, 5.7; N, 11.4. Found: C, 63.6; H, 5.9; N, 11.4.

The mass spectrum had a molecular ion peak of medium intensity at *m/e* 246, and a fragmentation pattern as follows: *m/e* (intensity): 246 (45), 200 (78), 126 (60), 93 (100), 77 (78), 43 (100).

The oxazole **12** (15 mg) dissolved in 59% perchloric acid solution (5 ml). In about 15 min a yellowish perchlorate salt was removed by filtration. On recrystallization from water this gave 17 mg of white crystals, m.p. 178–185° (dec.), whose n.m.r. spectrum in deuterated DMSO showed a singlet at δ 8.3 (1H), a doublet at 7.3 (5H), a singlet at 6.0 (1.5 H, exchangeable with D_2O), a quartet at 4.2 (2H), a singlet at 2.3 (3H), and a triplet at 1.2 (3H).

The perchlorate (12 mg) was dissolved in 2 *N* sodium hydroxide (5 ml) and the solution was extracted with ether. Evaporation of the ether yielded the oxazole **12** as a yellow oil (6 mg), identified by thin-layer chromatography and i.r. spectrum.

5-Ethoxy-3-methyl-4-phenylcarbamoylisoxazole (13) crystallized from pentane in white crystals (16 mg), m.p. 37–39°, ν_{max} 3370, 1690, 1650 (shoulder), 1640, 1545, and 870 cm^{-1}; δ 8.5 (s, 1H), 7.0–7.9 (m, 5H), 2.4 (s, 3H), 4.7 (q, 2H), 1.5 (t, 3H).

Anal. Calcd. for $C_{13}H_{14}N_2O_3$: C, 63.4; H, 5.7; N, 11.4. Found: C, 63.4; H, 5.7; N, 11.4.

The mass spectrum revealed a molecular-ion peak at *m/e* 246, and a fragmentation pattern identical to that of **12**.

The isoxazole dissolved in 59% perchloric acid, but a crystalline perchlorate could not be obtained. When the acidic solution was neutralized with sodium hydroxide and extracted with ether, the isoxazole (identified by i.r. spectrum and thin-layer chromatography) was recovered unchanged.

Ethyl α-Hydroxymalonanilate (14) was an uncrystallizable oil, ν_{max} 3400, 3350, 1710 cm^{-1}; n.m.r. δ 8.7 (s, 1H), 7.2–7.8 (m, 5H), 4.5 (s, 2H), 4.4 (q, 2H), and 1.5 (t, 3H).

Anal. Calcd. for $C_{11}H_{13}NO_4$: C, 59.2; H, 5.9; N, 6.3. Found: C, 59.4; H, 5.9; N, 6.2.

The mass spectrum showed the following peaks (*m/e*; intensity in parentheses): 223 (50), 182 (12), 150 (16), 135 (12), 120 (25), 103 (100), 93 (90), 77 (50), 43 (30).

Photolysis of Ethyl Diazomalonanilate with 3000 Å Wavelength Radiation

A solution of the diazo compound (224 mg) in acetonitrile (50 ml) was irradiated by eight 3000 Å wavelength Rayonnet lamps for 48 h. Evaporation of the solvent left a yellow residue (215 mg) which slowly crystallized. Thin-layer chromatography of the residue showed that the starting material and compounds **12**, **13**, and **14** were present. Separation by preparative thick-layer chromatography yielded **12** (28 mg, 25% yield), **13** (24 mg, 21%), **14** (32 mg, 35%), and starting material (97 mg).

Repetition of the photolysis with a more dilute solution of ethyl diazomalonanilate (120 mg) in acetonitrile (50 ml) yielded **12** (18 mg, 30% yield), **13** (15 mg, 27%), **14** (16 mg, 30%), and starting material (71 mg).

Photolysis of Ethyl Diazomalonanilate with 3000 Å Wavelength Radiation in the Presence of Oxygen

A solution of ethyl diazomalonanilate (231 mg) in acetonitrile (50 ml) was flushed with oxygen for 10 min before being irradiated by 3000 Å lamps. A small positive pressure of oxygen was maintained over the solution throughout the irradiation period (24 h). Evaporation of the solvent left a dark yellow residue, shown by thin-layer chromatography and n.m.r. spectrum to contain starting material and **12**, but no **13**. The residue was dissolved again in acetonitrile, the solution was flushed with oxygen, and was irradiated for another 24 h in the presence of oxygen. Again evaporation of the solvent left a dark yellow oil residue, shown by thin-layer chromatography to contain starting material, **12**, four unidentified products, but no **13**. The absence of **13** was also evident from the n.m.r. spectrum of the crude mixture, which exhibited the methyl absorption of oxazole **12** (singlet at δ 2.5) but no corresponding methyl absorption of isoxazole **13** at higher field.

Benzophenone-sensitized Photolysis of Ethyl Diazomalonanilate

A solution of the diazo compound (237 mg) and benzophenone (91 mg) in acetonitrile (50 ml), magnetically-stirred in a Pyrex vessel, was flushed with a stream of nitrogen and then irradiated by eight 3500 Å wavelength Rayonnet lamps for 8 h. Evaporation of the solvent left a yellow oil, shown by thin-layer chromatography to contain benzophenone, isoxazole **13** and four other compounds of lower R_f. Separation of the mixture by preparative thick-layer chromatography yielded benzophenone (81 mg) and isoxazole **13** (28 mg), identified by n.m.r. and i.r. spectra. The presence of the oxazole **12** could not be detected.

Another solution of the diazomalonanilate (82 mg) in acetonitrile (50 ml) contained in a Pyrex vessel, was irradiated under similar conditions but in the absence of benzophenone. Thin-layer chromatography of the residue showed only starting material and a trace of unidentified compound, R_f 0.21. The residue was recrystallized from petroleum ether (30–60°) to yield 76 mg of starting material.

Irradiation of 5-Ethoxy-3-methyl-4-phenylcarbamoylisoxazole (13) at 2537 Å

A solution of the isoxazole **13** (5 mg) in acetonitrile (4 ml) was irradiated for 8 h. Evaporation of the solvent left a residue which showed on t.l.c. a major spot corresponding to the oxazole **12**, and three other spots of lower R_f, but no starting material. Separation of the major spot by thick-layer chromatography yielded **12** (1 mg), identified by its i.r. spectrum.

Irradiation of 5-Ethoxy-2-methyl-4-phenylcarbamoyloxazole (12) at 2537 Å

A solution of the oxazole **12** (6 mg) in acetonitrile (4 ml) was irradiated for 8 h. The residue on t.l.c. showed starting material and two other spots, but no spot corresponding to the isoxazole (**13**).

Benzophenone-sensitized Isomerization of 5-Ethoxy-2-methyl-4-phenylcarbamoyloxazole (12)

A solution of the oxazole **12** (13 mg) and benzophenone (1 mg) in acetonitrile (4 ml) in a Pyrex tube was irradiated at 3500 Å for 8 h. The residue on t.l.c. showed spots corresponding to isoxazole **13** and benzophenone and two other spots at lower R_f, but no starting material.

Benzophenone-sensitized Irradiation of 5-Ethoxy-2-methyl-4-phenylcarbamoylisoxazole (13)

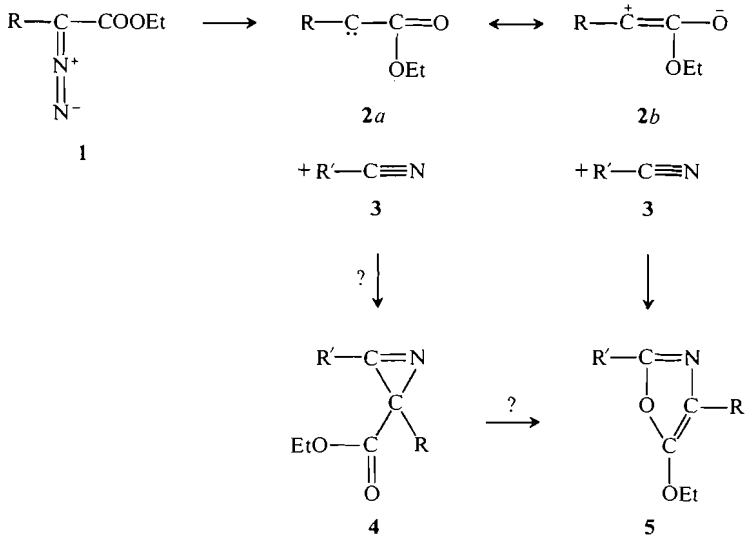
A solution of the isoxazole **13** (2 mg) and benzophenone (1 mg) in acetonitrile (4 ml) was irradiated at 3500 Å for 8 h. The residue showed on t.l.c. starting material **13** but no spot corresponding to that of oxazole **12**.

Results and Discussion

Reactions of Ethyl Diazoacetate

Huisgen *et al.* (7) have shown that a mixture of ethyl diazoacetate (**1**, R = H) and benzonitrile (**3**, R′ = Ph), heated to 140°, gives 5-ethoxy-2-phenyloxazole (**5**, R = H, R′ = Ph). We found that ethyl diazoacetate, photolyzed in acetonitrile (**3**, R = Me), gave (along with several unidentified products) a small yield of a compound of mass 127, which was undoubtedly 5-ethoxy-2-methyloxazole (**5**, R = H, R′ = Me). Thus the n.m.r. spectrum showed a singlet at δ 5.8 (1H), assigned to the olefinic proton, a singlet at 2.2 (3H), assigned to the 2-methyl protons, and the characteristic quartet at 4.0 (2H) and triplet at 2.3 (3H) of the ethoxy group. The mass spectrum showed a molecular ion peak of medium intensity at *m/e* 127, and a base peak at *m/e* 72 due to the loss of OEt.

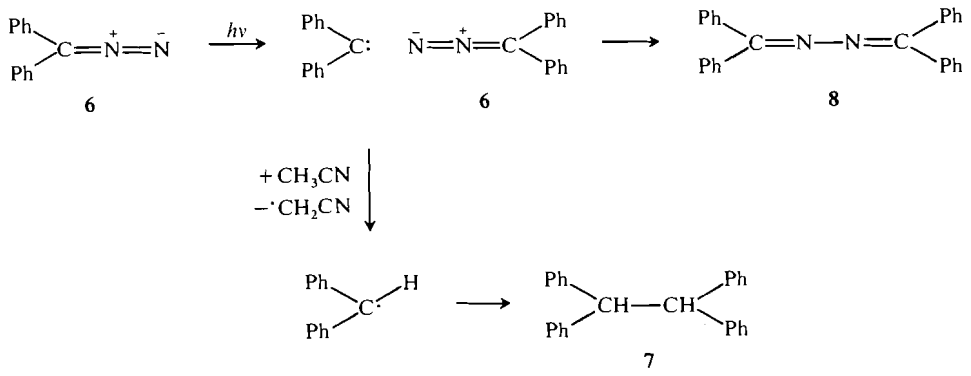
In both the thermal and the photolytic reactions leading to oxazoles it seems likely that the carbethoxymethylene **2** is first formed by



SCHEME 1

decomposition of the diazo ester; Huisgen (8) has suggested that this could then add to the nitrile triple bond to give the acylazirine **4**, which can then rearrange to **5** (see Scheme 1). Such a mechanism seems less likely than the 1,3-dipolar addition (8) of **2** (in its dipolar form **2***b*) to the nitrile to form the oxazole **5** directly, since simple carbenes show little tendency to add to nitrile to form azirines. For example, in the photoreaction of diazomethane with acrylonitrile, methylene adds to the carbon–carbon double bond and not to the nitrile triple bond (9); further, we have found that photolysis of diphenyldiazomethane (**6**) in acetonitrile gave tetraphenylethane (**7**) and tetraphenylazine (**8**), (see Scheme 2), products previously obtained by the decomposition of this diazo compound in aprotic solvents such as benzene (4). No products resulting from the addition of diphenylcarbene to the triple bond could be isolated.

Since the direct photolysis of diazoesters usually produces singlet carbene (10), it is reasonable to assume that the formation of the oxazole **5** is accomplished through reaction of the singlet carbethoxymethylene. In an attempt to confirm this point, the benzophenone-sensitized photolysis of ethyl diazoacetate in acetonitrile was studied. The reaction failed to produce any observable amount of the oxazole **5** (R = H, R = Me). Instead, the oily oxazoline **10** was formed, presumably by the addition of triplet carbethoxymethylene to benzophenone



SCHEME 2

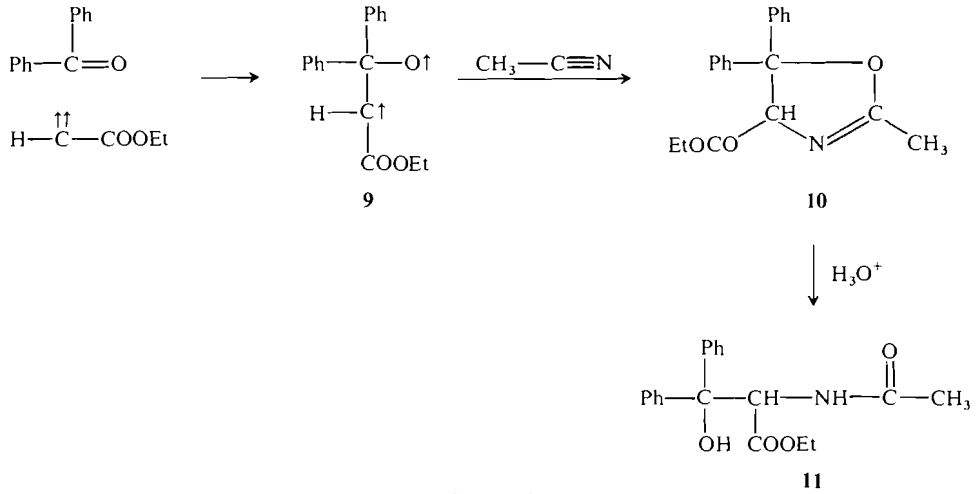
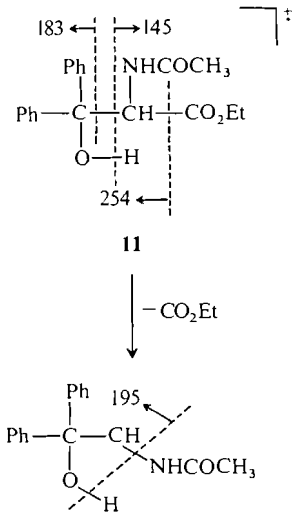


SCHEME 3

and further addition of the diradical intermediate **9** to acetonitrile (Scheme 3).

The oxazoline structure **10** for the oily product was supported by its n.m.r. spectrum, which showed the presence of phenyl groups (multiplet at δ 7.4–8.0), a hydrogen atom at the 4-position (singlet at δ 5.5), a methyl at the 2-position (singlet at δ 2.4), and an ethoxy group (quartet at δ 4.0 and triplet at 1.2). However, more important evidence for the structure **10** came from the hydrolysis of the oil in hydrochloric acid to a crystalline product having the combustion analysis and spectral properties expected for ethyl 2,2-diphenyl-2-hydroxy-1-acetamidopropionate (**11**). Thus its i.r. spectrum showed characteristic absorption peaks at 3680, 3590 (O—H), 3400 (N—H), 1710 (ester C=O) and 1660 cm^{-1} (amide (C=O). Its n.m.r. spectrum showed a multiplet at δ 7.3–8.0 (10H, aromatic protons), a broad singlet at 4.7 (1H, hydroxyl, exchangeable with D_2O), a sharp singlet at 2.0 (3H, acetyl), a quartet at 4.1 (2H, ethoxy methylene), a triplet at 1.0 (3H, ethoxy methyl), a broad doublet at 6.85 (1H, amide, $J = 8.5$ Hz), and a sharp doublet at 5.85 (1H, methine, $J = 8.5$ Hz). The amide hydrogen did not exchange with neutral deuterium oxide, but when deuterium oxide containing a drop of triethylamine was added to a solution of **11** in deuterated DMSO, the signal assigned to the amide proton disappeared, and the methine doublet at δ 5.85 was replaced by a singlet. Finally, the mass spectrum of the compound, besides showing a molecular-ion peak at *m/e* 327 and M + 1 peak at 328, showed a base peak at 183 and strong peaks at 254, 195, and 145, all readily accommodated by the structure **11**:



Reaction of Ethyl Diazomalonate

Ethyl α-diazomalonate (**1**; R = COOEt), photolyzed in acetonitrile, gave a small yield of oily product which was most probably the oxazole **5** (R = COOEt, R′ = CH_3). Thus the n.m.r. spectrum had a singlet at δ 2.3 (3H, 2-methyl), two quartets at 4–4.6 which partly overlap each other (4H, ethoxy methylenes), and a quartet at 1.2–1.6 due to the overlap of two triplets (6H, ethoxy methyls). The mass spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

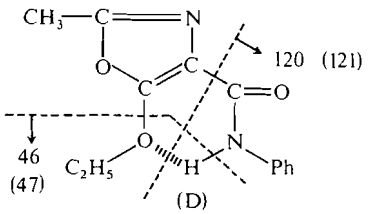
of the compound gave the molecular-ion peak at *m/e* 199 required for **5** (R = COOEt, R′ = Me), with a base peak at *m/e* 154 (M − OEt) and a peak of moderate intensity at *m/e* 125 (M − CO_2Et—H).

Reaction of Ethyl Diazomalonanilate: Structure of Products

The photolysis of ethyl diazomalonanilate (**1**; R = CONHPh) with light of 2537 Å wavelength in acetonitrile yielded two isomeric crystalline products, m.p. 64–65° and m.p. 37–39°, analyzing as $C_{13}H_{14}N_2O_3$, and an oily product analyzing as $C_{11}H_{13}NO_4$.

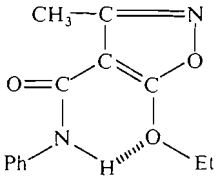
The first compound, m.p. 64–65°, was undoubtedly the expected oxazole **5** (R = CONHPh, R′ = Me). In agreement with this formulation, its i.r. spectrum showed absorption peaks at 3370 and 3300 (N—H), 1690 (amide-I), 1670 (ring C=N), 1620 (C=C), 1600 (phenyl), and 1550 cm^{-1} (amide-II). Its n.m.r. spectrum showed a broad singlet at δ 8.5 (1H; amide N—H, exchangeable with D_2O), an unsymmetrical doublet at 7.6 (5H; phenyl), a singlet at 2.5 (3H, ring methyl), a quartet at 4.3 (2H, ethoxy methylene), and a triplet at 1.45 (3H, ethoxy methyl). The mass spectrum showed, besides a parent peak (*m/e* 246) of medium intensity, a strong M − 46 peak due to the loss of ethanol and a M − 120 peak of medium intensity due to the loss of C_6H_5NHCO. When treated with D_2O containing a trace of triethylamine, the amide proton was readily replaced by deuterium. The mass spectrum then showed a parent peak at *m/e* 247, a M − 121 peak due to loss of C_6H_5NDCO, and a strong M − 47 peak due to the loss of C_2H_5OD. This would seem to indicate that the ethoxyl group is split off with the amide hydrogen or deuterium, possibly from the hydrogen-bonded structure **12**:



12

Oxazoles are fairly strong bases (11), and so the photoproduct formed a crystalline perchlorate, from which it could be recovered on treatment of the salt with sodium hydroxide.

The isomeric product, m.p. 37–39°, was assigned the isoxazole structure **13** because its



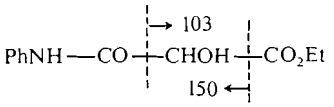
13

i.r. spectrum exhibited a characteristic absorption band at 870 cm^{-1} (absent in the i.r. spectrum of the oxazole **12**) which may be assigned to the stretching of the N—O linkage (12). Its i.r. spectrum also showed absorption peaks at 3370 cm^{-1} (N—H stretching), 1690 (amide-I), 1650 (shoulder, C=N ring), 1640 (C=C), and 1545 cm^{-1} (amide-II). Its n.m.r. spectrum exhibited a broad singlet at δ 8.5 (1H, amide, exchangeable with D_2O), a multiplet at 7–7.9 (5H, aromatic), a singlet at 2.4 (3H, ring methyl), a quartet at 4.7 (2H, ethoxy methylene), and a triplet at 1.5 (3H, ethoxy methyl).

Isoxazoles, like oxazoles, are moderately strong bases (13). The basicity of the photoproduct was indicated by its solubility in acid solution, from which it was precipitated unchanged on basification.

The mass spectrum showed an almost identical fragmentation pattern with that of compound **12**, with a molecular-ion peak of medium intensity at *m/e* 246, a strong M − 46 peak, and a medium M − 120 peak.

The oily product is most plausibly formulated as ethyl α-hydroxymalonanilate (**14**). Its mass



14

spectrum showed, besides the molecular ion peak at *m/e* 223, strong peaks at *m/e* 150 and 103, accounted for by the loss of $COOC_2H_5$ and C_6H_5NHCO. The i.r. spectrum exhibited peaks at 3400 and 3350 (O—H and N—H), 1710 (ester C=O), and 1685 cm^{-1} (shoulder, amide C=O). The n.m.r. spectrum showed a singlet at δ 8.7 (1H, amide), a multiplet at 7.27–7.8 (5H, aro-

TABLE 1. Yields of products from the photolysis of ethyl diazomalonanilate in acetonitrile under different conditions

Conditions (wavelength, additives, etc.)	12 (%)	13 (%)
2537 Å	35	10
3000 Å	28	25
3000 Å + O_2	Present	Absent
3000 Å + benzophenone	Absent	Present

matic), a singlet at 4.5 (2H, overlapping hydroxyl and methine), a quartet at 4.4 (2H, ethoxy methylene), and a triplet at 1.5 (3H, ethoxy methyl). When deuterium oxide was added to a solution of the compound in carbon tetrachloride, the signal at δ 4.5 (hydroxyl and methine) became a sharp singlet (1H, methine).

Effect of Reaction Conditions on Proportions of Products

The formation of **14** probably results from abstraction of hydrogen from the solvent by the carbene **2** (R = CONHPh) to form a radical, which then reacts with dissolved oxygen to form a hydroperoxide and ultimately an alcohol. No attempts were made to study the effect of reaction conditions on its formation.

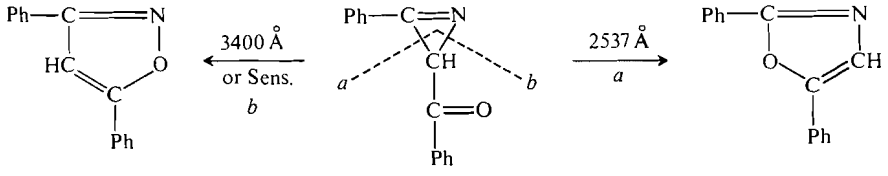
The formation of the isoxazole **13**, relative to that of the oxazole **12**, is dependent on the wavelength of the radiation employed, and on the spin-states of the intermediates, as can be seen from Table 1.

We further found that the two isomers can be interconverted in acetonitrile, and that the conversion depends on the wavelength of the radiation used. Thus with radiation of 2537 Å wavelength, a solution of **13** yielded **12** (among other products), while under these conditions a solution of **12** did not yield **13**. On the other hand, with benzophenone-sensitization **12** was converted into **13**, but not *vice versa*.

Such a wavelength-controlled interconversion has precedent in the work of Ullman and Singh (14), who demonstrated that irradiation of 3,5-diphenylisoxazole (**15**) in ether with radiation of 2537 Å wavelength resulted in the formation of 2,5-diphenyloxazole (**17**), but not when a sensitizer was present. The intermediate in this isomerization was shown to be 3-benzoyl-2-phenylazirine (**16**). This azirine could rearrange to either oxazole or isoxazole, depending on the wavelength of the radiation employed. Thus with radiation having a wavelength of 3100 Å or shorter, the azirine rearranged almost quantitatively to the oxazole **17**, while with radiation having a wavelength of 3340 Å or longer the azirine rearranged to the isoxazole **15**. These results were explained in terms of a selective ring cleavage of the azirine, the triplet state of the excited azirine opening at *b* (see Scheme 4) to yield the isoxazole **15**, and the singlet state opening at *a* to yield the oxazole **17**.

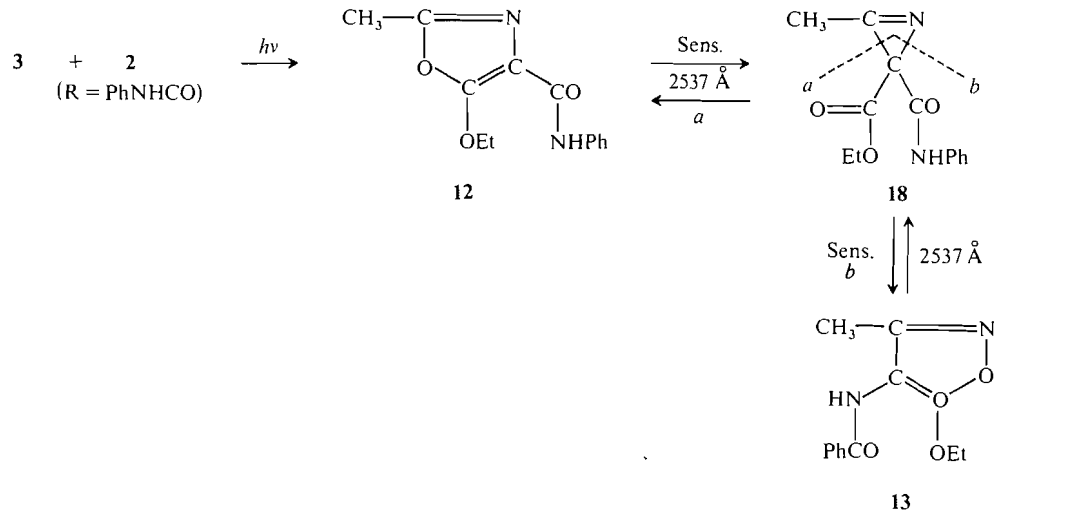
We may postulate a similar intermediate **18** for the interconversion of **12** and **13**, although our attempts to isolate it have been unsuccessful, and a possible scheme for the formation of **12** and **13** is depicted by Scheme 5. The primary product is the oxazole **12**, formed by the 1,3-dipolar addition of singlet **2** (R = PhNHCO) to **3**, and this would account for the fact that photolysis of **1** (R = PhCONH) in acetonitrile in the presence of oxygen, a triplet quencher, gave the oxazole **12** (among the other products), but no **13**.

Reaction with solvent **3** of "hot" **2** (R = PhNHCO), carrying over some of the excess energy resulting from the extrusion of molecular nitrogen from **1** (R = PhNHCO), could give **12** in an excited singlet state, which could decay to a triplet and thence give **13** via **18**. This would account for the small amount of isoxazole **13** formed when ethyl diazomalonanilate (**1**, R =



15 **16** **17**

SCHEME 4



SCHEME 5

PhNHCO) was photolyzed in acetonitrile with 2537 Å wavelength radiation, and its formation (to the exclusion of **12**) when the photolysis was carried out in the presence of benzophenone.

On the Rate Constant for *n*-Pentyl Radical Isomerization

K. W. WATKINS

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

Received May 23, 1972

A new interpretation of the mechanism used by Endrenyi and LeRoy for the calculation of the rate constant for *n*-pentyl isomerization is proposed. The addition of one step to the scheme makes possible a recalculation of the Arrhenius parameters. Significantly different values are found which eliminate the previously reported low *A*-factor.

Une nouvelle interprétation du mécanisme utilisé par Endrenyi et LeRoy pour calculer la constante de vitesse de l'isomérisation du *n*-pentyle, est proposée. L'addition d'une étape au schéma rend possible un nouveau calcul des paramètres d'Arrhénius. Des différences significatives de valeurs ont été trouvées éliminant ainsi le faible facteur *A* rapporté antérieurement. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3738 (1972)

A discrepancy has long been recognized (1) between the reported *A*-factors and those estimated from reasonable entropies of activation for the thermal isomerization of *n*-pentyl (2) and *n*-hexyl (3) radicals.

[1] $$n\text{-}C_5H_{11} \rightarrow sec\text{-}C_5H_{11}$$

[2] $$n\text{-}C_6H_{13} \rightarrow sec\text{-}C_6H_{13}$$

The reported *A*-factors were about $10^7\ s^{-1}$, whereas the theoretical *A*-factors for *n*-pentyl and *n*-hexyl isomerization were estimated to be $10^{10.5-11.0}\ s^{-1}$ (1*b*, 1*c*) and $10^{10}\ s^{-1}$ (4) respectively. The purpose of this communication is to suggest a resolution of this dilemma for *n*-pentyl radical isomerization.

In the case of isomerization of *n*-pentyl radicals by 1,4-hydrogen atom migration, a reinterpretation of the original data of Endrenyi and LeRoy (2) suggests a suitable solution. These workers carried out their kinetic runs at temperatures between 165 and 230°. They assumed that the only reactions of *sec*-pentyl were isomerization back to *n*-pentyl, and combination with methyl. In other reports of *n*-pentyl radical isomerization, both Gordon and McNesby (5) and Wijnen (6) observed that *sec*-pentyl radicals formed from *n*-pentyl isomerization at 300° decomposed. Also, Morganroth and Calvert (7) in a study of the photolysis of *n*-azobutane observed that *n*-butyl radicals began to decompose into ethylene and ethyl radicals at about 157°.

[3] $$CH_3CHCH_2CH_2CH_3 \rightarrow CH_3CH{=}CH_2 + \cdot CH_2CH_3$$

This work proposes that in the calculations of Endrenyi and LeRoy a significant fraction of *sec*-pentyl radicals was not accounted for because they decomposed by reaction 3. A propene balance on their data (8) shows this suggestion to be a reasonable one. The three most important propene forming reactions (excluding 3) are

[4] $$C_3H_7 + CH_3 \rightarrow C_3H_6 + CH_4$$

[5] $$C_3H_7 + C_3H_7 \rightarrow C_3H_6 + C_3H_8$$

[6] $$C_3H_7 + CH_2COCH_3 \rightarrow C_3H_6 + CH_3COCH_3$$

Other reactions yielding C_3H_6 can be imagined but their contribution is relatively unimportant. The rate of formation of propene from these reactions can be estimated by the following expression where known or estimated disproportionation to combination ratios can be used.

$$R'(C_3H_6) = k_4^d R(C_4H_{10}) + k_5^d R_4(C_6H_{14}) + k_6^d R(\text{MBK})$$

$R_4(C_6H_{14})$ is the rate of formation of $n\text{-}C_6H_{14}$ from propyl radical combination. It is estimated from expression (*iv*) (8), $k_5^d = \Delta(n\text{-Pr}, n\text{-Pr}) = 0.15$ (9); k_4^d was estimated to be 0.04, from

TABLE 1. Contributions to $R'(C_3H_6)$

Run (8)	R_4	0.15 R_4	0.04 $R(C_4H_{10})$	0.06 R(MBK)	$R'(C_3H_6)$	$R(C_3H_6)$	Δ
25	2.26	0.34	0.77	0.65	1.76	6.70	4.94
26	1.97	0.30	0.90	0.68	1.88	5.14	3.26
30	1.53	0.23	0.88	0.50	1.61	2.75	1.14
27	1.12	0.17	0.82	0.30	1.29	1.39	0.10
31	0.67	0.10	0.62	0.19	0.91	0.82	−0.09
28	0.41	0.06	0.55	0.10	0.71	0.66	−0.05
29	0.19	0.03	0.37	0.06	0.46	0.37	−0.09

Δ(Me, *n*-Pr) = 0.058 (9), 0.033 (10), and Δ(Me, *n*-Bu) = 0.030 (11). k_6^d was estimated to be 0.06; similar to the value of Δ(Et, *n*-Pr) = 0.065 (9).

Table 1 lists the individual contributions and compares them to $R(C_3H_6)$ from ref. 8. $\Delta = R(C_3H_6) - R'(C_3H_6)$. From Table 1, it can be seen that $R'(C_3H_6)$ accounts well for the observed $R(C_3H_6)$ in runs at temperatures below 186°, but in runs above this temperature, much more propene is produced than $R'(C_3H_6)$ predicts. If this excess propene is attributed to reaction 3, then the rate constant for isomerization can be recalculated. Let R(*sec*-pentyl products) = $R_f(i\text{-}C_6H_{14}) + \Delta$, and substitute it for $R_f(i\text{-}C_6H_{14})$ in the calculation of $k_7k_3^{1/2}/k_8$ (2). This has the effect on an Arrhenius plot of raising the high temperature (502 °K) rate constants by a factor of three, while leaving the low temperature (438 °K) rate constant unchanged. The plot is slightly curved, but a least squares treatment gives $\log (k_7k_3^{1/2}/k_8) = 4.8 - 21/\theta$, where $\theta = 2.3\,RT$ in kcal mol^{-1}. Assuming that $\log A_3 = 13.34$ (12 and references therein), $\log A_8 = 13.64$, and that E_3 and E_8 are zero, one gets $\log k_7 = 11.7 - 21/\theta$.

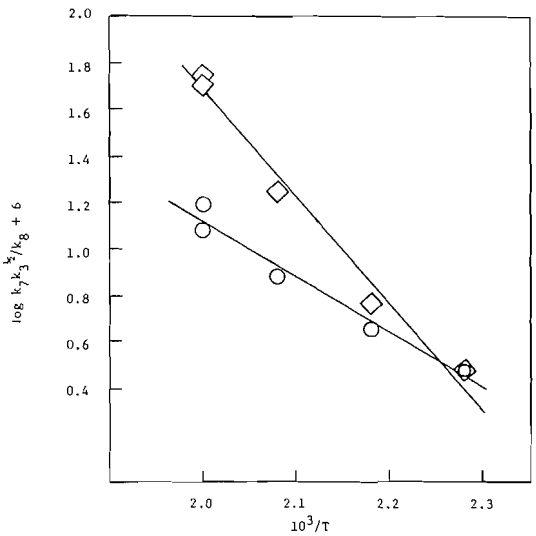

FIG. 1. Arrhenius plot for the isomerization of *n*-pentyl radicals: ○, original data of ref. 2; □, recalculated.

These rate parameters are significantly different from those originally published (2). They are similar to those that agree with the activated complex model, and threshold energy used by Watkins and Lawson (1*a*) to get agreement between their R.R.K.M. theoretical rate constant and the experimental rate constant. The R.R.K.M. theory of unimolecular reactions has been established as a means to correlate chemical activation and thermal data (13). The complex frequencies correspond to $\Delta S^{\ddagger} = 12.2$ cal deg^{-1} mol^{-1}, and $\log A$ (s^{-1}) = 10.6 at 53°. The threshold energy of 19 kcal mol^{-1} corresponds to an activation energy of 18 kcal mol^{-1} (14).

Recently, Watkins (15) reported lower limits to the *A*-factor and activation energy for *n*-pentyl isomerization of $\log A = 8.3$ and $E = 15$ kcal mol^{-1}, respectively. Since complications arose in this work also, the author suggests taking the rate constant at 160° where the complications were least important, and substituting in an activation energy of 20 kcal mol^{-1} to find the *A*-factor. Since k (160°) = 8.1 s^{-1}, $\log A = 11.0$. The agreement between these three independent results is now satisfactory. The Arrhenius parameters for *n*-pentyl isomerization are summarized in Table 2.

TABLE 2. Summary of *n*-pentyl isomerization rate parameters

Rate constant	Reference
$\log k = 11.7 - 21/\theta$	(2) Recalculated
$\log k = 10.6 - 18/\theta$	Complex model in (1*a*)
$\log k = 11.0 - 20/\theta$	(15) Recalculated

Dethioacetalization with Thallium(III) Trifluoroacetate[1]

TSE-LOK HO AND C. M. WONG

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received July 13, 1972

Thioacetals undergo facile hydrolysis on treatment with thallium(III) trifluoroacetate.

Les thioacétals s'hydrolysent facilement lorsqu'on les traite par le trifluoroacétate de thallium(III).
[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3740 (1972)

Of the numerous existing protecting groups for the carbonyl (1), acetals and thioacetals are most commonly used. The acetal group is stable towards basic conditions but it is extremely labile in the presence of mineral acids. Although it is usually believed that it is suitable for masking the carbonyl when a molecule is exposed to organometallic reagents, this is not always true (2, 3). Thioacetals have been utilized only sporadically, mainly because they are obnoxious in smell, and more difficult to hydrolyze. However, besides the facts that thioacetals are easier to prepare, much more stable under a variety of experimental conditions, the development of a versatile synthetic method by Corey and Seebach (4 and references therein), based on nucleophilic attack of 2-lithio-1,3-dithianes, has stimulated a search for better ways of regenerating the carbonyl function.

Burgeoning activities are recorded in the recent literature, outlining different approaches to solving the problem. Thus, dethioacetalization has been effected by chloramine T (5), ceric ammonium nitrate (6), and *via* S-alkylation (7). In this paper, we wish to describe another novel procedure for oxidative hydrolysis of dithioacetals to regenerate the parent carbonyl compounds. This method, utilizing thallium(III) trifluoroacetate, was prompted by our fascination of thallium compounds in mediating organic reactions (Taylor–McKillop reactions) (ref. 8 and previous papers), as well as the consideration that thallium salts may act as soft acids (9), therefore they should combine with sulfur atoms readily.

We observed that the mildly exothermic reaction between thallium(III) trifluoroacetate and a thioacetal in tetrahydrofuran is complete almost instantaneously at room temperature, as indicated by the rapid fading of the initially brown solution to a milky white color. The

TABLE 1. Dethioacetalization with Tl(III) trifluoroacetate

	Aldehyde or ketone	Yield of parent cpd.	Boiling point*
1,3-Dithiolans	Acetophenone	84%	200–205°
	Benzophenone	95%	(45–48°)
	Benzil (mono-)	95%	(93–96°)
	Benzaldehyde	83%	176–180°
1,3-Dithians	Phenylacetone	77%	212–218°
	Cycloheptanone	80%	173–180°

*Boiling points are heating block temperature; melting points in parentheses.

consistently high yields and simple operation involved in this reaction should be of great value to organic synthesis.

Finally, it is of interest to note that unsuccessful attempt of using thallium(I) salts to catalyze dethioacetalization has been reported (10).

Experimental

Infrared spectra were taken in dichloromethane using a Perkin–Elmer 710 Spectrophotometer. N.m.r. spectra were recorded on a Varian A56/60A spectrometer in carbon tetrachloride with tetramethylsilane as internal standard. Melting points are uncorrected.

General Procedure for Dethioacetalization with Thallium(III) Trifluoroacetate

To a solution of the dithioacetal (1.0 mmol) in tetrahydrofuran (2 ml) was added thallium(III) trifluoroacetate (600 mg, *ca.* 1.1 mmol; purchased from Aldrich Chemical Co.). The reaction became mildly exothermic as the thallium salt went into solution, and the brownish mixture soon faded to milky white. After 5 min at room temperature, it was poured into water (10 ml) and extracted with benzene (2 × 15 ml). The combined extracts were washed with dilute sodium bicarbonate, dried over anhydrous magnesium sulfate, and evaporated *in vacuo*. The crude product was purified by passing through a short neutral alumina column and recrystallized or evaporatively distilled. Identification of the carbonyl compounds was performed by comparison of their infrared, n.m.r. spectra with authentic samples.

Yields are listed in Table 1.

The Oxidation of Organic Compounds by Sodium Ruthenate

Donald G. Lee, David T. Hall, and James H. Cleland

Department of Chemistry, The University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received July 20, 1972

The preparation of sodium ruthenate and its use as an oxidant for a variety of organic compounds is decribed.

La préparation du ruthenate de sodium et son utilisation comme oxydant d'une variété de composés organiques sont décrites. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3741 (1972)

The oxidation of organic compounds by ferrate(VI) ion has recently been described (1, 2). The procedure is useful because of its "specificity, mild conditions, and speed of reaction". However, the preparation of ferrate(VI) is difficult and laborious, and the reagent is not particularly stable. The corresponding ruthenate(VI) ion, on the other hand, is extremely stable under basic conditions and very easy to prepare. Consequently we have examined

The combined extracts were washed with dilute sodium bicarbonate, dried over anhydrous magnesium sulfate, and evaporated *in vacuo*. The crude product was purified by passing through a short neutral alumina column and recrystallized or evaporatively distilled. Identification of the carbonyl compounds was performed by comparison of their infrared, n.m.r. spectra with authentic samples.

Yields are listed in Table 1.

The Oxidation of Organic Compounds by Sodium Ruthenate

Donald G. Lee, David T. Hall, and James H. Cleland

Department of Chemistry, The University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received July 20, 1972

The preparation of sodium ruthenate and its use as an oxidant for a variety of organic compounds is decribed.

La préparation du ruthenate de sodium et son utilisation comme oxydant d'une variété de composés organiques sont décrites. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3741 (1972)

The oxidation of organic compounds by ferrate(VI) ion has recently been described (1, 2). The procedure is useful because of its "specificity, mild conditions, and speed of reaction". However, the preparation of ferrate(VI) is difficult and laborious, and the reagent is not particularly stable. The corresponding ruthenate(VI) ion, on the other hand, is extremely stable under basic conditions and very easy to prepare. Consequently we have examined

TABLE 1. Products obtained from sodium ruthenate oxidations

Substrate	Product	Conditions	Yield (%)
Cyclohexanol	Cyclohexanone	1 h, 25°	85
Benzyl alcohol	Benzoic acid	1 h, 25°	97
Cinnamyl alcohol	Cinnamic acid	1 h, 10°	70
Cinnamic acid	No reaction	1 h, 25°	—
	Benzoic acid	4 h, 55°	91
Benzylamine	Benzaldehyde	1 h, 25°	14
Di-*n*-butyl ether	No reaction	11 h, 55°	—

its usefulness as an oxidant and wish here to report a summary of our observations.

Sodium ruthenate was prepared by stirring a solution of ruthenium tetroxide in carbon tetrachloride with aqueous sodium hydroxide. Under these conditions ruthenium tetroxide is reduced (reaction 1) and the highly polar perruthenate ion migrates to the aqueous solution where it slowly converts to ruthenate ion (reaction 2) (3, 4). At sodium hydroxide concentrations greater than 0.4 *M* the ruthenate solution is indefinitely stable at room tempera-

$$[1] \quad 4RuO_4 + 4OH^- \rightarrow 4RuO_4^- + 2H_2O + O_2$$

$$[2] \quad 4RuO_4^- + 4OH^- \rightarrow 4RuO_4^{2-} + 2H_2O + O_2$$

ture and may safely be stored in solution for long periods of time. In less basic solutions it is not completely stable as evidenced by the slow precipitation of ruthenium dioxide. The concentration of ruthenate ion in these solutions can be easily determined spectrophotometrically from its known absorption spectrum (5), and the reaction can then be carried out by dropwise addition of the appropriate quantity of oxidant to a vigorously stirred aqueous suspension of the organic compound. When a 50% excess of organic reductant was used the yields reported in Table 1 were obtained.

A comparison between these results and those reported for the ferrate reaction indicate that ruthenate is a more vigorous oxidant. For example, it gives an 85% yield of cyclohexanone from cyclohexanol, while under comparable conditions ferrate gave a yield of only 20–30% (1). The greater vigor of ruthenate is also illustrated by noting that it oxidizes benzyl alcohol to benzoic acid whereas benzaldehyde is obtained using ferrate ion.

It also appears that ruthenate will attack carbon–carbon double bonds only when high temperatures and longer reaction times are used. This fact makes it an ideal reagent for the oxidation of unsaturated alcohols such as cinnamyl alcohol.

It is also of interest to note that the low reactivity of ruthenate toward carbon–carbon double bonds and ethers is in contrast to the reaction of ruthenium tetroxide which very readily oxidizes compounds containing such functional groups (6).

Experimental

Preparation of Sodium Ruthenate

Five grams of ruthenium dioxide were added to an aqueous solution of sodium periodate (20 g). The solution was stirred vigorously for 10 min and then extracted with 6 × 70 ml of carbon tetrachloride. The aqueous solution remaining was a very pale yellow color indicating that only a small amount of ruthenium tetroxide remained, while the carbon tetrachloride layer was a bright greenish-yellow.

This ruthenium tetroxide solution was added to an equal volume of 1.0 *M* sodium hydroxide and shaken continuously for 2 h. At the end of this time the carbon tetrachloride layer was clear while the upper layer was a very dark orange color. The two layers were separated and the aqueous layer was extracted with 100 ml of carbon tetrachloride to remove any ruthenium tetroxide that might be present. (Ruthenium tetroxide is more soluble in carbon tetrachloride than water with a partition coefficient of 60:1) (7). On standing at room temperature for 2 days the solution became a bright orange color, and exhibited a visible–ultraviolet spectrum characteristic of ruthenate ion. The concentration of the RuO_4^{2-} was estimated by measuring the absorbance at a wavelength of 385 nm; at this wavelength the molar extinction coefficient is known to be 1030 (5).

The Oxidation Reaction

To 100 ml of 1.0 *M* sodium hydroxide 1.5 g of substrate was added. While stirring vigorously sufficient sodium ruthenate to oxidize approximately 1 g of the substrate was added drop by drop. Stirring was continued at room temperature for 1 h after all of the oxidant had been added.

In the cases of cyclohexanol, benzyl alcohol, cinnamyl alcohol, and benzylamine the reaction went to completion in this length of time as shown by the disappearance of the orange color and the appearance of a black precipitate of ruthenium dioxide. However, cinnamic acid and di-*n*-butyl ether were not oxidized under these conditions as evidenced by the persistance of the orange color. When the cinnamic acid solution was heated at 55 °C for 4 h the orange color did, however, disappear indicating that a reaction had taken place. Di-*n*-butyl ether on the other hand did not react even when heated at 50 °C for 11 h.

The solutions obtained from those substrates which reacted were filtered using a fine-fritted funnel to separate ruthenium dioxide (which could then be reused) from the organic products. The products were extracted into diethyl ether with 5 extractions of 75 ml each. The solutions were

dried for 1 h over anhydrous $MgSO_4$, concentrated to approximately 2 ml by rotary evaporation and the products identified by use of g.l.c. and n.m.r.

The aqueous solutions were then acidified with concentrated H_2SO_4 and again extracted with diethyl ether. The ether was evaporated and any non-volatile products were separated and identified using standard techniques.

The authors are grateful to the National Research Council of Canada and to Imperial Oil Enterprises Ltd. for research grants which supported this work.

The Elucidation of the Coupling Constants for the Cyclobutane Ring of the *trans*-Fused 2-Oxabicyclo[4.2.0]octane System

M. PAUL SERVÉ

Department of Chemistry, Wright State University, Dayton, Ohio 45431

Received July 26, 1972

The coupling constant for the fusion hydrogens of a bicyclo[4.2.0]octane ring system has been found using the shift reagent $Eu(fod)_3$.

La constante de couplage pour les hydrogènes au point de jonction du système bicyclo[4.2.0] octane a été trouvée, en utilisant le chélate de terre rare $Eu[fod]_3$.

Canadian Journal of Chemistry, **50**, 3744 (1972)

The size of the coupling constant J is an important tool in the elucidation of the stereochemistry of organic molecules. This is especially true for fused ring systems. The *trans*-fused bicyclo[4.2.0]octane system has been synthesized many times (1). However, the J for the fusion hydrogens on such a system has never been reported either because the splitting pattern was too complex or because one of the fusion hydrogens had been replaced by another substituent.

The molecule 1R*,6S*,7R*,8S*-7,8-diphenyl-2-oxabicyclo[4.2.0]octane (1) has recently been isolated by t.l.c. as a minor product ($< 10\%$ yield) from the photocycloaddition of *cis*-stilbene to 2,3-dihydropyran at 2537 Å. Mass spectral analysis of **1** indicated a 1:1 adduct of the two starting materials. The n.m.r. spectrum of **1** was quite complex. However, addition of the shift reagent $Eu(fod)_3$ (2) sufficiently spread out the spectrum so that spin decoupling experiments could be performed (Fig. 1). The following coupling constants were found: $J_{1,6} = 4.0$; $J_{1,8} = 4.2$; $J_{6,7} = 9.5$; $J_{7,8} = 9.5$ Hz.

The size of $J_{6,7}$ and $J_{7,8}$ indicated a *cis* arrangement for H-7 and -8 (3). Further evidence to support this assignment was obtained by heating **1** in a potassium-*t*-butoxide–*t*-butanol solution for 12 h. Since H-7 and -8 are each benzylic hydrogens, equilibration in strong base should result in their conversion into a *trans*-orientation. There are two *trans*-arrangements possible for H-7 and -8 and each would be expected to give rise to a separate peak in the g.l.p.c. chromatogram. G.l.p.c. analysis showed that as the peak for **1** disappeared two new peaks formed and grew during the 12 h period.

Since the J for the fusion hydrogens of the *cis*-fused bicyclo[4.2.0]octane system has been reported to be greater than 7 Hz (4), a *trans*-ring fusion **1** is indicated. A *trans* arrangement for H-1 and -8 is also indicated by the size of the coupling constant (5).

Thus, thanks to the substitution on the four-membered ring of **1** and the presence of the oxygen atom which enabled the use of the shift reagent, all the coupling constants on the four-membered ring could be elucidated.

Binary Dioxygen Complexes of Nickel; Infrared Spectroscopic Evidence for $Ni(O_2)$ and $(O_2)Ni(O_2)$ in Low Temperature Matrices

H. HUBER AND G. A. OZIN[1]

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario

Received July 26, 1972

The cocondensation reaction of nickel atoms with oxygen or dilute oxygen–argon matrices at 4.2–10 °K gives rise to the first examples of binary transition metal dioxygen complexes. Variable concentration and diffusion controlled warm up studies and $^{16}O_2$, $^{16}O^{18}O$, $^{18}O_2$ isotope substitution studies establish the stoichiometries of the dioxygen complexes of nickel to be $Ni(O_2)$ and $(O_2)Ni(O_2)$. Both complexes have the dioxygen molecule(s) coordinated to the nickel atom in a "sideways" fashion.

La réaction de cocondensation d'atomes de nickel avec des matrices d'oxygène ou d'oxygène dilué-argon à 4.2–10 °K donne lieu aux premiers exemples de complexes de dioxygène métalliques de transition binaire. Les études de réchauffage contrôlées à concentration et à diffusion variables et les études de substitution d'isotopes $^{16}O_2$, $^{16}O^{18}O$, $^{18}O_2$ indiquent que les stoechiométries des complexes de dioxygène du nickel sont $Ni(O_2)$ et $(O_2)Ni(O_2)$. La ou les molécules de ces deux complexes sont coordonnées à l'atome de nickel de façon "latérale". [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3746 (1972)

Several complexes of low valency transition metals such as iridium (1), rhodium (2), ruthenium (3), cobalt (4), and the platinum triad (5) react with oxygen to give adducts, sometimes reversibly.

Dioxygen complexes of this type have recently become of considerable interest to chemists because of their relationship to naturally occurring dioxygen carriers and the reactivity of coordinated dioxygen to various reductants.

However, in most of the complexes reported so far, it appears that the presence of other ligands in the complex in addition to dioxygen is a necessary prerequisite for the isolation of a stable compound. The involvement of these other ligands in the overall bonding scheme is often difficult to assess which can make discussions of the bonding of the O_2 to the metal atom somewhat open to criticism.

In this communication we present data which show for the first time that *binary* dioxygen complexes of nickel are capable of existence under conditions of matrix isolation.

Briefly our experiments consisted of cocondensing nickel atoms (McKay 99.99%) with pure $^{16}O_2$ (Matheson 99.99%); $^{16}O_2$/Ar (1:20; 1:100; 1:200; and 1:500) and $^{16}O_2/^{16}O^{18}O/^{18}O_2$/Ar (1:2:1:800) onto a CsI window cooled to 4.2 or 10 °K by either a liquid helium transfer system or a closed cycle helium refrigerator. The rate of nickel atom deposition was controlled by using a quartz crystal microbalance incorporated into the evaporation furnace (6). The concentration of nickel atoms in the matrix was arranged to be such that the probability of a nickel atom having another nickel atom as a nearest neighbor was 10^{-3}. Matrix gas flows were kept in the range 0.5–2.0 mmol/h, using micrometer needle valves. Matrix infrared spectra were recorded on a Perkin–Elmer 621 spectrophotometer over the frequency range 2000–200 cm^{-1}.

When nickel atoms are cocondensed with dilute $^{16}O_2$/Ar (1:200 or 1:500) matrices a single, strong sharp infrared absorption is observed at 966.2 cm^{-1}, which in a $^{16}O_2/^{16}O^{18}O/^{18}O_2$/Ar (1:2:1:800) matrix splits into a characteristic 1:2:1 *triplet* of bands at 966.2, 940.1, and 913.6 cm^{-1}.

The number and intensity ratio of the bands in this multiplet together with the excellent agreement between their observed and calculated ^{18}O isotopic shifts provide convincing evidence for a molecule containing a *single* dioxygen molecule bonded in a "sideways" fashion to a single nickel atom; that is, the lines at 966.2, 940.1, and 913.6 cm^{-1} are assigned to $Ni(^{16}O_2)$, $Ni(^{16}O^{18}O)$ and $Ni(^{18}O_2)$, respectively. Low frequency bands assignable to Ni–O stretching modes were not observed probably because of

their low extinction coefficients or their occurrence below the low wavenumber limit of our spectrometer (200 cm^{-1}).

In a number of diffusion controlled warm up experiments of the dilute $Ni/^{16}O_2/Ar$ matrices in the temperature range 10–15 °K a sharp infrared absorption at 1062.0 cm^{-1} grows in at the expense of the band previously assigned to $Ni(^{16}O_2)$.

When nickel atoms are cocondensed with pure $^{16}O_2$ matrices at 4.2–10 °K an infrared absorption at 1064 cm^{-1} is found to be the strongest feature in the spectrum and the absorption at 966 cm^{-1} is completely absent. At no stage of the diffusion-controlled warm up experiments in pure $^{16}O_2$ matrices does the absorption at 966 cm^{-1} appear.

We conclude from the warm up data in dilute $^{16}O_2/Ar$ matrices and from the data in pure $^{16}O_2$ matrices that the infrared absorption at 1062.0 cm^{-1} is the O—O stretching mode of a dioxygen complex of nickel containing more than a single molecule of dioxygen.

The stoichiometry of this complex is established from a diffusion-controlled warm up experiment in a $^{16}O_2/^{16}O^{18}O/^{18}O_2/Ar$ (1:2:1:800) matrix, which shows in addition to the infrared absorption at 1062 cm^{-1}, *six* other absorptions at 1052.2, 1045.2, 1035.2, 1018.2, 1016.0, and 1001.4 cm^{-1} which can be assigned to the O—O stretching modes of the various isotopic oxygen molecule permutations of a complex of nickel containing *two* dioxygen molecules, that is $(O_2)Ni(O_2)$.

The multiplets observed in this experiment indicate that two equivalent O_2 molecules are arranged such that the O atoms are equivalent. The simplicity of the multiplet spectrum also indicates that the dioxygen molecules are bonded to the nickel atom in a "sideways" fashion in $(O_2)Ni(O_2)$, thereby filling four coordination sites around the nickel atom. In this context it is worth noting that the four coordination sites around nickel in the complex $Ni(N_2)_4$ are filled by four N_2 molecules bonding to the nickel in an "end-on" fashion (7).

At this stage in our investigations it is not possible to prove whether the dioxygen molecules in $(O_2)Ni(O_2)$ are arranged in a tetrahedral (D_{2d}) or planar (D_{2h}) configuration about the nickel atom, although the observation of a septet rather than a sextet tends to favor the latter.

This work is presently being extended to include Raman, u.v.–visible, and e.s.r. matrix isolation studies, the data from which should yield considerable information concerning the nature of the bonding of the dioxygen molecule to the nickel atom and the electronic structures of $Ni(O_2)$ and $(O_2)Ni(O_2)$.

We thank the National Research Council of Canada and the Research Corporation for financial support.

Synthesis of Lambertianic Acid

R. A. BELL, M. B. GRAVESTOCK, AND V. Y. TAGUCHI

Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 5, 1972

A synthesis of lambertianic acid **2***a* starting from podocarpic acid is described. The central intermediate, diester-ketone **4***b*, is obtained by ozonolysis and hydrogenation, and the exocyclic methylene group in ring B generated via a Reformatsky reaction. The furan ring is attached by nucleophilic attack of 3-lithiofuran, for which an improved preparation is described, on either the acid chloride **7***b* or the aldehyde **16**. The 12-oxygen atom is removed by mesylation of the alcohols **12***a* and *b* and Li–liquid ammonia reduction.

Nous avons dècrit la synthèse de l'acide Lambertianique **2***a* à partir de l'acide podocarpique. La cétone diester, intermédiaire central, est obtenue par ozonolyse et hydrogénation et le groupe méthylene exocyclique du cycle B géneré par une réaction de Réformatsky. Le cycle furannique est lié par l'attaque nucléophile du lithio-3-furanne, pour lequel une meilleure préparation est donnée, au chlorure d'acide **7***b* ou à l'aldehyde **16**. L'atome d'oxygène 12 est éliminé par mésylation des alcools **12***a* et *b* et réduction par le lithium dans l'ammoniac liquide.

Canadian Journal of Chemistry, **50**, 3749 (1972)

The synthesis of diterpenoids based on the labdane, **1**, skeleton[1] has been founded on the initial construction of a bicyclic intermediate with the side chain (carbons 11→16) being added in the final stages. The bicyclic intermediate has either been directly generated (1) or engineered from a preformed tricyclic species (2). We have chosen the latter course for a synthesis of the furano-diterpene, lambertianic acid[2] **2***a*, because it has the advantage of generating an intermediate with carbon atoms 11 and 12 attached to the bicyclic nucleus and also because the oft-synthesized (5) and readily available[3] podocarpic acid, **3***a*, formed a convenient starting material.

The ready transformation in high yield of **3***b* into the bicyclic keto-acid **4***a* by low temperature

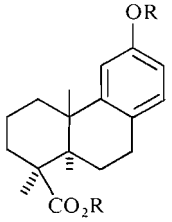
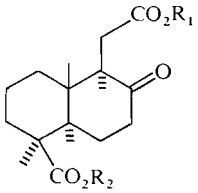
2
a R = H
b R = Me



3
a R = H
b R = Me

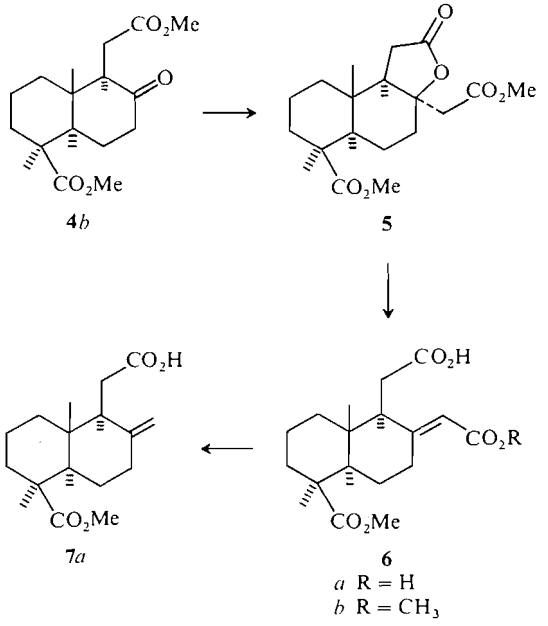


4
a R_1 = H; R_2 = Me
b R_1 = R_2 = Me

[1]The numbering system employed here is that proposed by the informal IUPAC committee on Diterpene Nomenclature, London, July, 1968.

[2]Lambertianic acid (3) is the (+) enantiomer of the naturally occurring daniellic acid (4). Since we use the (+) enantiomer of podocarpic acid **3** (absolute stereochemistry as shown) as a starting material, the final product is optically pure lambertianic acid.

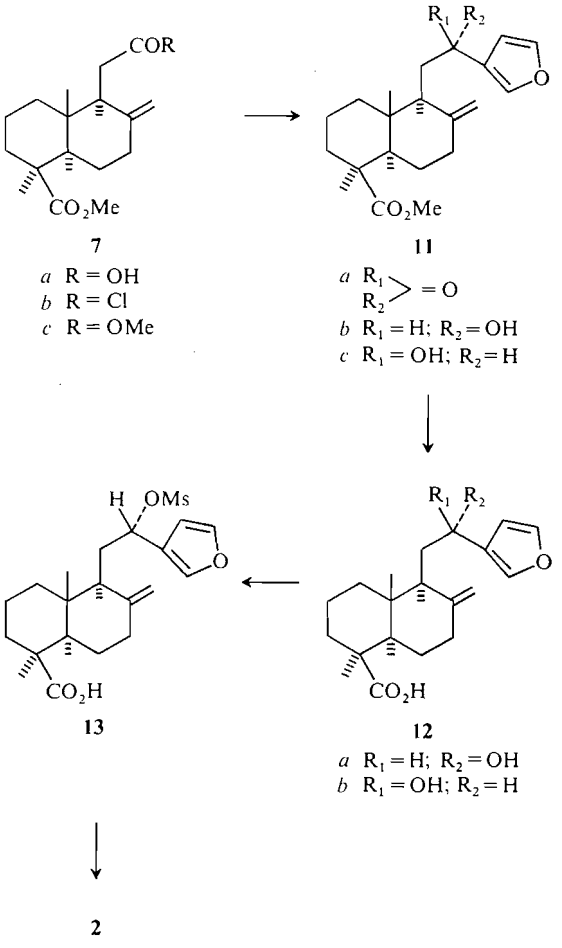
[3]Available from New Zealand Timber Products Ltd., P.O. Box 5784, Auckland, New Zealand.



SCHEME 1

ozonolysis and hydrogenation has already been described (6). The remaining problems to complete a synthesis of lambertianic acid are therefore generation of the exocyclic methylene at C-8 and attachment of the furan ring at C-12. The synthetic intermediates used in the solution of these two problems are shown in Scheme 1, and in Schemes 2 and 4.

The generation of the exocyclic methylene at C-8 was first attempted by means of a direct Wittig reaction. There is a literature precedent (7) for the methylenation of an 8-ketone in the manool series, but in the case of either **4***a* or *b* exhaustive attempts under a wide variety of experimental conditions proved fruitless. The use of methylene magnesium iodide (8) likewise failed and in view of the experience of other workers (9) in similar systems further efforts to introduce the exocyclic methylene directly were abandoned, and consideration was given to the use of the ethoxyacetylene decarboxylation sequence of Stork *et al.* (9), which had already been used by Pelletier *et al.* in the synthesis of polyalthic acid (2*c*). However, before this sequence was attempted, the ester–ketone **4***b* was subjected to the little used, but highly convenient Reformatsky reaction (10) with methyl bromoacetate and active zinc, and it was with some



SCHEME 2

pleasure that we observed the formation in reasonable yield of the lactone-diester **5**. Further experimentation showed that a benzene–dimethoxyethane (DME) solvent mixture (3:1) led to production of **5** in over 90% yield. The presence of DME was mandatory since its absence led to inferior yields of **5** and the simultaneous formation of variable quantities of the known (6) lactone **8**. This latter unsaturated derivative presumably arose through $ZnBr_2$ Lewis acid-catalyzed lactonization of **4***b* to give **9** followed by proton rearrangement from C-11 to C-8 via the lactone enol. When DME is present, the $ZnBr_2$ is strongly solvated and therefore its Lewis acid activity is greatly diminished. The α-configuration at C-8 is assigned on the basis of preferred nucleophilic

a R = H
b R = CH_3

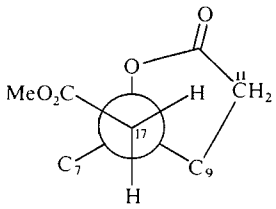

FIG. 1. Newman projection of preferred conformation of lactone **5** that permits facile *trans*-elimination leading to the E-olefin **6**.

attack of the zinc reagent from the less hindered underside of the molecule. Support is found for this in the Grignard reaction of a similar 8-ketone used as an intermediate in the synthesis of manool by Bigley *et al.* (2*a*) and also the behavior of **4***b* with methyl lithium and $NaBH_4$ (11).

The lactone ring of **5** could be opened by treatment with sodium methoxide in methanol, or, more conveniently, with sodium hydroxide in methanol since this reagent led directly to the desired unsaturated diacid **6***a* in 95% yield. There was present in this reaction product a small percentage (*ca.* 3%) of a compound which was assigned the β,γ-unsaturated acid structure **10***a* on evidence which is discussed below. The major diacid was assigned the E-configuration on the basis of the most likely conformation about the C_8—C_{17} bond which would lead to a *trans*-elimination. The conformation (shown in Fig. 1 in Newman projection) with the carbomethoxy group over ring B should be of lowest energy since it minimizes dipolar interactions by placing the carbomethoxy group as far away as possible from the developing carboxylate anion of the lactone ring. No clear evidence for the presence of the 8(17)-Z double bond isomer of **6** could be obtained by either p.m.r. spectroscopy or t.l.c., but the wide-range melting point of even repeatedly crystallized samples of **6** led to the suspicion that there probably was 2–3% of the Z-isomer present. However, the occurrence of this isomer in the elimination product was of secondary importance as both E- and Z-isomers should give the same product on subsequent reaction.

The pyrolytic decarboxylation of the diacid **6** to the monoacid **7***a* was effected in 80% yield following the normal procedure of thermolysis in quinoline (9). However, it was noted that the intermediate β,γ-unsaturated acid, **10***a*, had the double bond in the 8,9- rather than the 7,8-position, since aliquots of the decarboxylation reaction mixture showed an initial rise and then fall in intensity of the C-20 CH_3 (δ 0.80 p.p.m.) absorption of **10***a* in its p.m.r. spectrum. In one large scale run, chromatography of the crude methylated reaction product gave a sample of the triester **10***b* which showed the absence of any vinylic protons. Thus with **10***a* as the pre-decarboxylation intermediate it is possible, *a priori*, for either the C-12 or the C-17 carboxyl group to be lost. Close scrutiny of the p.m.r. spectra and chromatographic fractions of crude decarboxylation reaction mixtures did not show any significant traces of the 9,11-olefin. From the inspection of molecular models, it was concluded that a transition state involving a stereospecific introduction of the 12-carboxyl proton at C-8 in an axial (β) manner to permit continuous overlap of the developing sp^3 orbital at C-8 with the incipient C-11 methylene group (9), would result in severe steric interactions between the C-11 and -1 hydrogens. The corresponding stereoelectronically controlled axial (α) proton transfer from the C-17 carboxyl to C-9 was subject to no steric constraints and the decarboxylation therefore was able to proceed rapidly. The crude acid **7***a* was contaminated with 10–15% of the C-19 carboxylic acid derived from quinoline hydrolysis of the 19-methyl ester and

12 14

SCHEME 3

it was found convenient to methylate the crude products with excess diazomethane and isolate the pure diester **7***c* by chromatography on Florisil. In this way the keto-ester **4***b* could be routinely transformed into the olefin-ester **7***c* in overall yields of 40–50% and this compares more than favorably with the 30% yield obtained from the lithium ethoxyacetylide route (2*c*).

The attachment of the furan ring was initially undertaken by condensation of the acid chloride **7***b* with 3-lithiofuran[4] in ether at −78° (see Scheme 2). The mono-furan derivative **11***a* was obtainable in yields up to 80% and it was anticipated that reductive removal of the C-12 keto group could be readily achieved by one of the many available methods. However, in the sequel all the usual procedures resulted in either recovery of starting material or severe degradation of the furan ring. Thus the Wolf–Kishner reaction, conducted at lower than normal temperatures (14) on the supposedly reactive α-furyl ketone (15) gave an intractable mixture wherein the furan rings had been destroyed in the majority of the product. Indeed, **11***a* was so resistant to derivative formation that even the elegant tosylhydrazone reduction sequence (16) failed. The stubborn and unreactive behavior of the 12-ketone, apparently caused by the steric congestion forced upon it by the exocyclic methylene group at C-8, demanded that an alternative process for the removal of the 12-oxygen function be found. An early paper by Birch (17) had shown that 2-furfuryl alcohol could be reduced to 2-methyl furan by sodium in liquid ammonia and this precedent led to the hope that the 12-oxygen might be removed in a similar manner. Moreover, the methyl ester of methyl desoxypodocarpate had been reported (18) to undergo reductive hydrolysis with Li–liquid ammonia to give the corresponding acid, and it was therefore hoped to obtain lambertianic acid in one step from the isomeric 12-hydroxy-esters, **11***b* and *c*. However, a mixture of the 12-alcohols (obtained from $NaBH_4$ treatment of the 12-ketone[5]) with a moderate excess of Na or Li metal (4–5 equiv) in liquid ammonia showed no reduction of the 12-alcohol, but showed that reduction of the C-19 ester to the alcohol competed with reductive hydrolysis. Indeed, when the analogous reaction of methyl *O*-methylpodocarpate **3***b* with Li–liquid ammonia was repeated under identical reaction conditions, reduction of the ester to alcohol was more than competitive with reductive hydrolysis. It is possible here that some additional factor or contaminant (proton source?) was responsible for the reaction course, but despite exhaustive efforts, the hydrolysis procedure was never satisfactory in our hands. In a further effort to induce removal of the 12-hydroxyl group and minimize reduction at C-19, the free hydroxy-acids **12***a* and *b* (obtained from early trial reductions) were subjected to a massive excess of Li metal (25 equiv). Again the 12-hydroxyl was completely retained, and some reduction of the C-19 acid was noted. This behavior is difficult to rationalize, particularly when it was noted from molecular models that a strong steric interaction exists between C-12 and the exocyclic methylene group. Such steric congestion would be expected to greatly favor formation of the C-12 sp^2 hybridized intermediate **14**, which is a reasonable intermediate (20) following the expulsion of the OH from the furanoid radical-anion (see Scheme 3).

[4]In our hands a modification (see Experimental, and note warning) of the procedure of Gronowitz and Sorlin (12) proved most satisfactory. Other procedures involving the reduction of polyiodo-furans (13) were less convenient.

[5]The 12(R) and 12(S) alcohols were obtained from the $NaBH_4$ reduction in a ratio of 2:3. They were readily separated by column chromatography and their configurations were assigned by analogy with the corresponding 12-hydroxylabdan-19-oic acids (19). Since the present work was aimed at destroying the asymmetry at C-12, the detailed conformational arguments for the configurational assignments are not present here but may be found in ref. 19.

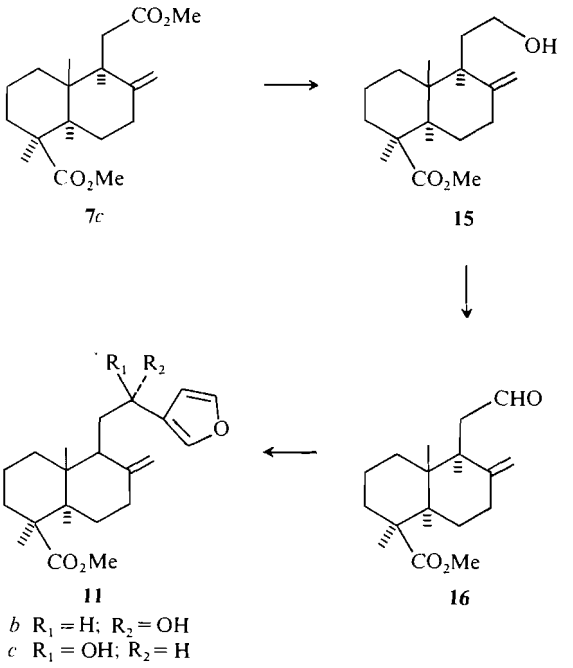
A straightforward solution to this problem would be the transformation of the 12-hydroxyl into a better leaving group in order to facilitate its expulsion during the Li–liquid ammonia reduction stage. However, before this proposal could be reduced to practice, some improvement was necessary in the hydrolysis step of **11** to **12**. Potassium tertiary butoxide in dimethylsulfoxide (DMSO) has been shown (21) to be an especially useful reagent for the hydrolysis of hindered esters; the *t*-butoxide anion effecting an S_N2 displacement on the CH_3 of a methyl ester to give methyl *t*-butyl ether and a carboxylate anion. In our hands the C-19 ester of **11***b* or *c* was cleanly hydrolyzed, but unfortunately the reaction conditions necessary and the strength of the *t*-butoxide base coupled to make elimination of the pseudo-benzylic 12-hydroxyl group a competing process. Moreover the 8(17)-double bond appeared susceptible to migration, and the net result of these competing reactions was to make the overall yields of **12** highly variable. For example, in one medium scale reaction only a 40% yield of combined **12***a* and *b* was obtained after silica gel chromatography. The *t*-butoxide–DMSO reagent was therefore not as satisfactory as had been anticipated, and at this point no highly selective method for achieving the **11** to **12** transformation has been determined. However, from a practical standpoint, adequate supplies of both **12***a* and *b* were available from the *t*-butoxide–DMSO experiments, and the main task of generating a better leaving group at C-12 could be undertaken. The preparation of the mesylate of **12***a* was attempted via the methanesulfonyl chloride–triethylamine procedure (22).[6] Reaction proceeded readily as evidenced by the p.m.r. spectrum of the crude product (upfield shift of the C-17 H_A proton), but the mesylate **13** was exceedingly sensitive to thermal decomposition and could not be isolated in a pure state. It was therefore necessary to prepare the mesylate and immediately subject it to Li–liquid ammonia reduction. When this sequence was carried out using 5 equiv of Li metal a 36% yield of lambertianic acid **2***a* was obtained. This material was identical in its chromatographic and spectral properties with an authentic sample provided by Professor W. G. Dauben. A small sample of the acid was transformed into the ester **2***b* and shown to be identical with the methyl ester derived from natural sources.



b $R_1 = H$; $R_2 = OH$
c $R_1 = OH$; $R_2 = H$

SCHEME 4

In view of the necessity of removing the 12-oxygen atom as the alcohol, it was clear that alternative approaches to **11***b* and *c* could be envisaged. One route which was found to be particularly convenient in practical terms is shown in Scheme 4. The entire sequence, when carried out without purification of the intermediates, gave the alcohols **11***b* and *c* in an overall yield of 52% from the diester **7***c*. The selective reduction of the primary C-12 ester over the highly hindered, axial C-19 ester was readily accomplished with excess $LiAlH_4$ in ether for 45 min at temperatures below 0°. The alcohol **15** was routinely obtained in better than 90% yields. Oxidation of **15** to the aldehyde[7] **16**, was carried out with either the Collins reagent (24) (CrO_3–pyridine in CH_2Cl_2) or the Fetizon reagent (25) (Ag_2CO_3–Celite) in quantitative yield, and the

[6]Attempts to prepare the toluenesulfonate of **12***a* met with no success whatsoever and we interpret this as being a further attestation to the steric crowding at C-12. The ready formation of the mesylate is evidently a consequence of the very high activity of the sulfene precursor (22).

[7]Attempts to prepare the aldehyde **16** in one step from the diester **7***c* with sodium bis(2-methoxyethoxy)aluminum hydride (Vitride) (23) were unsuccessful.

addition of the furan ring effected again with 3-lithiofuran in THF at −78°. In this instance minor stereoselectivity was noted in the generation of the alcohols as the ratio of **11***b* to *c* was 2:1 (from isolation by chromatography).

Summary

A formal total synthesis of lambertianic acid **2***a* has been achieved using podocarpic acid as a relay. The exocyclic methylene at C-8 was introduced via a Reformatsky reaction carried out in benzene–dimethoxyethane as solvent to avoid Lewis acid-catalyzed rearrangements. Decarboxylation of the α,β-unsaturated acid **6** led to excellent yields of the key keto-acid **7***a*. The furan ring of lambertianic acid was introduced by nucleophilic attack of 3-lithio-furan on either the acid chloride **7***b* or the aldehyde **16**. Serious difficulty was encountered in removal of the 12-oxygen function either as the ketone **11***a* or the alcohols **11***b* and *c* and only Li–liquid ammonia reduction of the 12-mesylate **13** afforded reasonable yields of lambertianic acid.

Experimental

Melting points were determined on a Kofler micro hot-stage apparatus and are uncorrected. Spectra were recorded in the following solvents and instruments: i.r. ($CHCl_3$) Perkin–Elmer 337 and Beckman IR5; p.m.r. ($CDCl_3$) Varian Associates A-60, T-60, and HA-100, tetramethylsilane as internal standard; mass spectra, Hitachi Perkin–Elmer RMU-6A (at 80 eV) and C.E.C. 21-110. Carbon and hydrogen microanalyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Michigan. In the experimental descriptions to follow, the organic substrates were isolated via extraction with the appropriate solvent (2×) followed by washing of the combined solvent layer with water, saturated brine, and finally drying with anhydrous Na_2SO_4. The solvents were removed by evaporation at reduced pressure on a Buchi Rotavapor.

17-Carbomethoxy-8β-hydroxy-(13→16)-tetranorlabda-12, 19-dioic Acid

19-Methyl Ester 8β → 12-Lactone (5)

(i) Method using benzene as solvent. Granulated zinc (20 mesh) was activated by the procedure of Johnson and Fieser (26). After the metal had been heated in concentrated sulfuric acid containing a few drops of nitric acid at 100° for about 10 min, the majority of the acid was decanted off, and water added. After vigorous H_2 evolution for a few minutes all traces of acid were removed by repeated washing with water, followed by acetone, ether, and then drying at 110°.

The keto-acid **4***a*, m.p. 171–172°, 5.00 g (16.9 mmol) was dissolved in 250 ml anhydrous benzene in a dry 500 ml three-necked flask fitted with a mechanical stirrer and reflux condenser (a magnetic stirrer bar gave adequate agitation in smaller scale runs). Then 5.20 g (34 mmol) of methylbromoacetate (R) (Eastman), 5 g activated zinc, and 50 mg iodine were added, and the stirred mixture brought rapidly to reflux under nitrogen. Two further additions of 2.60 g methyl bromoacetate, 5 g zinc, and a crystal of iodine, were made after 6 and 12 h reflux. After 24 h total reflux, the reaction mixture was cooled, the zinc complex destroyed in 2 *N* sulfuric acid, and the acidified mixture extracted with benzene (2 × 100 ml) after removal of the initial benzene layer. The combined benzene extracts on usual work-up gave 6.25 g dark yellow oil. P.m.r. analysis indicated some 5% of non-diterpenoid reagent condensation products, 75–80% lactone-ester **5**, 10% starting material, 5% of unsaturated lactone **8**, and a few percent of an unknown compound with a C-20 methyl absorption at 0.63 p.p.m. Extraction of an ethereal solution of the product with saturated $NaHCO_3$ solution served to remove starting material and the unknown component. Two crystallizations of a portion from 2:1 hexane–ethyl acetate gave the analytical sample as colorless needles, m.p. 104.5–105°; i.r. ν_{max} 3025, 3000, 2955, 2855, 1775, 1735, 1720, 1440, 1220(b), 1142, 985, 940, 925 cm^{-1}; p.m.r. δ 0.74 (s, 3H, C-20 CH_3), 1.22 (s, 3H, C-18 CH_3), 3.65 and 3.72 (s and 3H each, C-19 and -21 $COOCH_3$'s) p.p.m.

Anal. Calcd. for $C_{19}H_{28}O_6$: C, 64.75; H, 8.01. Found: C, 64.71; H, 8.01.

(ii) Method using benzene and dimethoxyethane as co-solvent. The keto-acid **4***a*, 3.50 g (12.5 mmol, *ca.* 95% pure) was dissolved in 160 ml dry benzene and 40 ml dry dimethoxyethane (distilled from calcium hydride) and 3.80 g (25 mmol) of methylbromoacetate, 3 g zinc, and a crystal of iodine added. The mixture was mechanically stirred under reflux and a nitrogen atmosphere for 12 h and then a further 3.0 g (20 mmol) methylbromoacetate, 3 g zinc, and crystal of iodine added. After a further 6 h reflux the reaction mixture was cooled and worked-up in similar manner to (*i*), to give 3.97 g yellow oil. The p.m.r. spectrum revealed no discernible unsaturated lactone **8**, 90–95% pure lactone-ester **5** and some 5% starting material.

The oil was chromatographed on 160 g Florosil in 50:50 benzene–petroleum ether (30–60°) and the chromatogram developed with benzene and 5% ethyl acetate–benzene which yielded *ca.* 100 mg of yellow oil which by odor and p.m.r. analysis appeared to be methyl phenylacetate. Further elution with 10% ethyl acetate–benzene gave a total of 2.98 g (75%) of pure (>98%) lactone-ester **5**, m.p. 103–105°.

19-Ethyl Ester 8β → 12-Lactone

Precisely the same procedure was followed as above in (*i*) for the carbomethoxy ester, utilizing 5.70 g (2 mol equiv) ethyl bromoacetate initially and two subsequent additions of 2.85 g (1 mol equiv). However, the extent of conversion was poorer than in (*i*) and p.m.r. analysis indicated some 70% product, 20–25% starting material, and 5% of unsaturated lactone **8**.

Sodium bicarbonate extraction and two crystallizations gave an analytical sample of the ethyl ester of **5**, m.p. 74–75°; i.r. ν_{max} 3025, 3000, 2955, 2855, 1778, 1732, 1722, 1455, 1230(b), 1142, 985, 940, 925 cm^{-1}; p.m.r. δ 0.76 (s, 3H, C-20 CH_3), 1.22 (s, 3H, C-18 CH_3), 1.28 (t, J = 7.0 Hz, 3H, ester $-CH_2 \cdot CH_3$), 3.65 (s, 3H, C-19 $COOCH_3$); 4.20 (q, J = 7.0 Hz, 2H, ester $-CH_2 \cdot CH_3$) p.p.m.

Anal. Calcd. for $C_{20}H_{30}O_6$: C, 65.55; H, 8.25. Found: C, 65.72; H, 8.09.

17-Carbomethoxy-(13→16)-tetranorlabd-8(17)E-ene-12,19-dioic Acid

*19,21-Dimethyl Ester (**6b**)*

The lactone-ester **5**, 3.00 g (8.5 mmol, 95% pure) obtained by direct bicarbonate washing and one crystallization from ethyl acetate–hexane (1:3, at −20°) was dissolved in 50 ml of methanol (dried over $Mg(OCH_3)_2$), and added to a solution of 0.50 g clean sodium metal (22 mmol, 2.5 equiv) in 50 ml of dry methanol under N_2. The solution was heated at reflux under N_2 for 2 h, cooled, and poured into 1 l of 0.5 *N* sulfuric acid, and extracted with benzene (3 × 150 ml). The extracts on usual work-up gave 2.90 g pale yellow "foam" (96.5%). The p.m.r. spectrum indicated a product of 90–95% purity with traces of a component with C-20 methyl absorption at 0.66 p.p.m. Recrystallization from methyl acetate–hexane (1:2) gave 2.63 g of off-white needles, m.p. 150–160°. A second recrystallization gave the analytical sample of the C-17 methyl ester of **6** as colorless needles, m.p. 152–160; i.r. ν_{max} 3600–2400, 2950, 1725, 1715, 1705, 1640, 1425, 1250, 1170 cm^{-1}; u.v. λ_{max} 227 (16 000) (calcd. 224 (+5)) mμ; p.m.r. δ 0.527 (s, 3H, C-20 CH_3), 1.22 (s, 3H, C-18 CH_3), 2.51 (s, broad, $w_{h/2}$ = 3 Hz, 2H, C-11 CH_2), 3.64 and 3.69 (s and 3H each, C-19 and -21 $COOCH_3$'s), 5.55 (s, broad, $w_{h/2}$ = 2.5 Hz, 1H, C-17 vinylic), 9–11 (s, broad, $w_{h/2}$ = 10–60 Hz, C-12 COOH) p.p.m.

Anal. Calcd. for $C_{19}H_{28}O_6$: C, 64.75; H, 8.01. Found: C, 64.58; H, 8.11.

The m.p. range is apparently due to small quantities, *ca.* 3% of the Z-$\Delta^{8,17}$ double bond stereoisomer which is not resolvable by p.m.r. analysis or t.l.c. at this concentration.

*19-Methyl Ester (**6a**)*

*(i) By hydrolysis of αβ-unsaturated ester **6b**.* The αβ-unsaturated ester **6b**, 2.00 g (5.65 mmol) m.p. 150–160° (containing a minimum of 90% of the E-double bond isomer) was dissolved in 150 ml (R) methanol together with 50 ml of 1 *N* sodium hydroxide solution and refluxed under nitrogen for 2 h. The majority of the methanol was removed *in vacuo* and the residue poured into 250 ml of 1 *N* sulfuric acid. The liberated acid was extracted with benzene (3 × 75 ml) and the extracts worked-up in the usual way to give 1.94 g (100%) of an off-white crystalline solid. The p.m.r. spectrum showed at least 90% E-double bond isomer, unsaturated diacid **6a**, with 2–3% **10a** (see below).

*(ii) By hydrolysis of lactone–ester **5**.* The lactone–ester, 2.98 g (m.p. 103–105°, 98% pure, direct from chromatography of the reaction product) was dissolved in 225 ml (R) methanol and 75 ml 1 *N* sodium hydroxide added. The whole was refluxed under N_2 for 2 h. The majority of the methanol was removed *in vacuo* and the residue diluted with water, washed twice with ether, and the aqueous extracts acidified with 2 *N* sulfuric acid. The acidified solution was extracted with benzene (3 × 100 ml) which on usual work-up gave 2.85 g (99%) of a near colorless "foam". The p.m.r. spectrum indicated some 95% of unsaturated diacid **6a**, plus 2–3% of the βγ-unsaturated isomer **10a**. This latter compound was also present as a decarboxylation intermediate and the crude reaction mixture could thus be used directly for decarboxylation (see below). Two crystallizations of a portion from ethyl acetate–hexane (1:2) gave the analytical sample as colorless crystalline clusters m.p. 216–220° (dec. at 205°); i.r. ν_{max} 3500–2500(b), 3010, 1705, 1690, 1640, 1250, 1240(b), 1155, 930 cm^{-1}; u.v. λ_{max} 220 (12 800) mμ; p.m.r. δ 0.54 (s, 3H, C-20 CH_3), 1.22 (s, 3H, C-18 CH_3), 2.52 (s, broad $w_{h/2}$ = 4 Hz 2H, C-11 CH_2), 3.60 (s, 3H, C-19 $COOCH_3$), 4.05 (m, 1H, C-7 H), 5.52 (s, broad $w_{h/2}$ = 3 Hz, 1H, C-17 vinylic), 9–11 (s, broad (15 Hz), 2H, C-12 and -21 COOH's) p.p.m.

Anal. Calcd. for $C_{18}H_{26}O_6$: C, 63.88; H, 7.74. Found: C, 63.60; H, 7.81.

*(13→16)-Tetranorlabd-8(17)-ene-12,19-dioic Acid 19-Methyl Ester (**7a**)*

The αβ-unsaturated diacid **6a** (containing 2–3% βγ-isomer **10a**), 2.00 g (5.90 mmol), was dissolved in 20 ml quinoline (distilled and degassed under nitrogen) together with 50 mg of copper chromite catalyst (see below) in a dry 50 ml flask containing a magnetic stirring bar. The flask was sealed with a reflux (air) condenser and a three-way trap to nitrogen and a water pump. The flask was evacuated with stirring at room temperature, flushing the contents twice with nitrogen, and then finally evacuated while the temperature was raised to 100°. It was then filled with nitrogen and the temperature raised to 230° (silicone oil bath). The mixture was stirred under nitrogen at 230° (±2°) for 1.25 h and then withdrawn from the bath and allowed to cool to room temperature. After diluting the contents of the flask with 200 ml of 1:4 benzene–ether, the whole was extracted with 10% sodium hydroxide solution (4 × 25 ml) and 25 ml water. The extracts were poured onto crushed ice, acidified with 80 ml of 2 *N* sulfuric acid and benzene extracted (3 × 100 ml). Usual work-up of the extracts gave 1.54 g (88%) of a pale yellow oil. The p.m.r. spectrum indicated 80% methylene vinylic absorption at 4.45 and 4.80 p.p.m. due to **7a** (C-20 CH_3 absorption at 0.53 p.p.m.), and also the corresponding C-19 demethylated compound (C-20 CH_3 absorption at 0.63 p.p.m.). In addition there was 10% of unreacted intermediate **10a**, and 10% of other minor components. In the main synthetic sequence the product was purified and fully characterized as the methyl ester **7b**, (see below). However, material from one run was isolated by two crystallizations from (1:3) ethyl acetate–hexane, giving off-white flakes m.p. 153–155° (>98% pure); i.r. ν_{max} 3500–2400(b), 2940, 2855, 1715, 1645, 1460, 1150, 890, 680 cm^{-1}; p.m.r. δ 0.53 (s, 3H, C-20, CH_3), 1.20 (s, 3H, C-18 CH_3), 3.60 (s, 3H, C-19 $COOH_3$), 4.45 and 4.80 (s, and 1H each, both $w_{h/2}$ = 3 Hz, C-17 vinylic CH_2), 9–11 (s, broad $w_{h/2}$ = 10 Hz, 1H, C-12 COOH) p.p.m.

Preparation of Copper Chromite Catalyst

The method of Sherrill and Mellock (27) was essentially used. Concentrated ammonium hydroxide was added to a solution of 63 g (0.25 mol) of ammonium dichromate in 250 ml water until the solution was yellow (chromate). A solution of 120.8 g (0.5 mol) of cupric nitrate dihydrate in 150 ml water was then added in a slow stream to the well-stirred chromate solution. The orange-brown precipitate was filtered off under pressure and dried overnight at 110°.

After pulverizing to a fine powder it was then heated slowly in a porcelain basin over a small flame. After spontaneous decrepitation had ceased it was then roasted strongly so that a fine black powder was finally produced. The powder was suspended in 10% acetic acid in water, filtered, and the process repeated three times in water. The product was finally dried at 110° to give 65 g of "$CuCrO_4$" as a fine black powder.

Dimethyl(13→16)-tetranorlabd-8(17)ene-12,19-dioate (7b)

The crude unsaturated acid **7a** (from the decarboxylation of 2 g of diacid **6a**), 1.54 g, was esterified with ethereal diazomethane, to give 1.60 g (87% from **6a**) of crude methyl ester **7b**, containing some 80% of the desired compound, as a dark yellow oil. The oil was chromatographed on 64 g of Florisil in 50:50 benzene–petroleum ether (30–60°) and the chromatogram developed with the same solvent. Elution with benzene yielded a total of 1.12 g (61% from **6a** of pure (>98%) crystalline unsaturated ester **7b**. The sample for analysis was crystallized from 1:9 ethyl acetate–hexane giving colorless prisms, m.p. 109–110°; i.r. ν_{max} 3020, 2950, 2850, 1735, 1720, 1645, 1440, 1225(b), 1160, 910, 710 cm^{-1}; p.m.r. δ 0.53 (s, 3H, C-20 CH_3), 1.19 (s, 3H, C-18 CH_3), 2.40 (s, 2H, C-11 CH_2), 3.60 and 3.625 (s, and 3H each, C-19 and -12 $COOCH_3$'s), 4.46 and 4.75 (s, and 1H each, both broad $w_{h/2}$ = 3 Hz, C-17 vinylic CH_2) p.p.m.; mass spectrum (high resolution), *m/e* calcd. for $C_{18}H_{28}O_4$, 308.198747; found: 308.200294 (mol. ion).

Anal. Calcd. for $C_{18}H_{28}O_4$: C, 70.10; H, 9.15. Found: C, 70.28; H, 9.24.

Preparation of 3-Iodofuran

The basic procedure of Gronowitz and Sorlin (12) was used, with further modifications due to the work of Wrobel and Dabrowski (28) and as a result of present investigations.

2-Furoic acid, 224 g (2 mol), was dissolved in 3 l of warm (35°) water and added dropwise over 1 h to a well-stirred solution of 320 g (1 mol) mercuric acetate in 5 l water at room temperature. The precipitated solid resulting was filtered under pressure and dried at 0.1 mm room temperature for 2 days to give 316 g (0.81 mol) of 2-(acetoxymercuric)-furoate as a buff powder (81%). This material was pyrolyzed following an adaption of Wrobel's (28) procedure.

WARNING: The mercuric salts should not, under any circumstances, be pyrolyzed in the absence of a solvent as severe and unpredictable explosions can occur.

2-(Acetoxymercuric)-furoate, 200 g (0.512 mol) was suspended in 350 ml xylene in a 1 l three-necked flask, fitted with a Herschberg stirrer, thermometer and a Dean–Stark trap with reflux condenser. The mixture was stirred and heated over 30 min to reflux temperature (*ca.* 140°), and kept at reflux for 1 h, when the trap contained water, xylene/water azeotrope and acetic acid. The temperature was then reduced to 135° and heating and stirring continued for 23 h. After cooling in an ice-bath, 250 ml of 95% acetic acid was added and stirring continued at room temperature for 3 h *only*. By this time nearly all solid matter had dissolved to a dark brown solution which was then poured into 1.7 l water and sodium chloride added until no further precipitation took place. After stirring overnight the mixture was filtered under pressure to give a tan solid which was washed well with water and dried at 0.1 mm room temperature for 36 h, to give 133 g of a tan solid (crude 3-(chloromercuric)-furan, plus a little 2-isomer and mercuric acetate).

The crude material was extracted with ether in a Soxhlet apparatus. The results of the extraction were examined in lots. Thus after 48 h, 34 g of 3-(chloromercuric)-furan was obtained, the p.m.r. spectrum of which showed the presence of 5–6% of the 2-isomer. Another 24 h gave 7.5 g material containing 7–8% 2-isomer. Another 36 h gave 7 g material containing 8–9% of 2-isomer. Further prolonged extraction gave only 3 g containing 30–40% 2-isomer. Batches one to three, combined thus gave 48.5 g of 3-(chloromercuric)-furan containing *ca.* 6% of the 2-isomer, p.m.r. (DMF, p.p.m. relative to center of DMF doublet) δ 3.8 (1H, d, β-H), 4.7 (1H, d, α-H) 5.0 (1H, m, α'-H to O and Hg). This was of a purity comparable to that previously obtained by crystallization of the extracted product (12) and is of adequate purity for final reaction by iodine oxidation. The overall yield from 2-(acetoxymercuric)-furan is thus 51% (assuming initial disproportionation to mercuric acetate and mercuric difuroate) and 31% from starting material. This represents twice the yield previously obtained (12).

3-(Chloromercuric)-furan, 33.5 g (0.11 mol), from the above was suspended in 400 ml water and a solution of 28.0 g (0.11 mol) iodine (I_2), in 36.5 g potassium iodide and 400 ml water was added dropwise to the stirred suspension at room temperature. After the addition was complete, excess iodine was destroyed with sodium thiosulfate and the 3-iodofuran present steam distilled from the reaction mixture by boiling for *ca.* 2 h, (500 ml distillate). The distillate was extracted with ethanol-free ether (3 × 100 ml), and the extracts washed twice with brine, filtered through anhydrous sodium sulfate and evaporated in vacuo at 35° (maximum temperature) to give 16.16 g (75%) of 3-iodofuran as a pale yellow oil. The p.m.r. spectrum indicated 5% of the 2-isomer (12). The substance can be redistilled *in vacuo* but was sufficiently pure for purposes of the present synthesis. It is stable indefinitely at −20° in the dark, p.m.r. (see also ref. 12), δ 6.55 (m, 1H, β-H), 7.3–7.6 (7.45 center) (2H, m, α-H's).

*Methyl 15,16-Epoxy-12-ketolabda-8(17),13(16),14-trien-19-oate (**11a**)*

(a) Preparation of the Acid Chloride 7b

The crystalline unsaturated ester **7c**, 565 mg (1.83 mmol, >98% pure) was refluxed in 90 ml methanol together with 30 ml 1 *N* sodium hydroxide solution for 3 h under nitrogen. The methanol was removed *in vacuo*, the residue diluted with 300 ml water, washed once with 20% benzene in ether, and then acidified with cold 2 *N* sulfuric acid. Benzene extraction and usual work-up gave 530 mg (98%) of 98% pure unsaturated acid **7a**. A portion of the product 235 mg (0.80 mmol) was dissolved in 3 ml methanol in a 10 ml flask and 74 mg (0.88 mmol) (R) sodium bicarbonate added, together with 2 ml of water. After stirring at room temperature for 2 h, when all carbon dioxide evolution had ceased, solvent was removed *in vacuo* on the rotary evaporator and the residue finally dried overnight at 0.1 mm at room temperature.

The product (255 mg sodium salt (0.80 mmol), plus *ca.* 8 mg sodium bicarbonate) was covered with 5 ml benzene containing 1% pyridine in the same 10 ml flask, cooled to partial freezing in an ice-bath, and treated dropwise with 340 mg (2.6 mmol) oxalyl chloride (Eastman) in 3 ml dry benzene. The mixture was stirred at the same temperature for 15 min and then allowed to warm to room temperature with stirring for a further 1.5 h. The solvent and the bulk of the oxalyl chloride were removed *in vacuo* at 30°, the residue flushed with a further 5 ml benzene, and this was also removed in the same way. Finally the residue was dried at 0.1 mm room temperature for 15 min, and taken up in 2 ml anhydrous benzene–3 ml anhydrous ether, for addition to the furyl lithium solution prepared below.

(b) Preparation of 3-Lithiofuran

Methyl lithium (2.40 *M* in ether), 0.50 ml (1.20 mmol), was syringed into a dry 20 ml flask equipped with septum inlet, under an atmosphere of nitrogen. Anhydrous ether,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

2 ml, was also syringed in, and the flask cooled to $-70°$ in a Dry Ice–acetone bath. 3-Iodofuran, 235 mg (1.22 mmol) was then added dropwise by syringe in 5 ml of anhydrous ether and the solution stirred at $-70°$ for 1 h, by which time 3-furyl lithium formation was complete. (*n*-Butyl lithium can also be used (12), when the formation time is faster, but the reagent is more difficult to keep at stable concentration.)

At this time the acid chloride **7***b* solution (from (*a*), above) was taken up in a 10 ml syringe (size 19 needle to prevent possible blockage by precipitated sodium chloride present) and introduced into the 3-furyl lithium solution in a fast stream over 1–3 s. The resultant mixture was then stirred at $-70°$ for a further 30 min and allowed to warm to room temperature over 1–2 h by removal of the cold bath. The product was quenched in 5% sodium dihydrogen phosphate solution, benzene extracted (3 × 75 ml) and worked-up in the usual manner to give 260 mg (95%) of a dark yellow oil. The p.m.r. spectrum showed 80% of the desired keto-furan **11***a*, (furanoid and C-20 methyl absorption), 10% starting material **7***a*, and 10% of minor components (the principal contaminant has a C-20 methyl absorption at 0.50 p.p.m.).

The product was eluted onto 10.5 g Florisil in 50:50 benzene–petroleum ether (30–60°) and developed with the same solvent, finally eluting with pure benzene, giving a total of 182 mg (66%) of 97% pure keto-furan **11***a* as a near-colorless oil. (The oil resisted all attempts at crystallization which is not unexpected since methyl lambertianate **2***b* itself is an oil.) I.r. ν_{max} 2970, 2940, 2875, 1720, 1680, 1645, 1560, 1500, 1210 (broad), 1156, 888, 872 cm^{-1}; u.v. λ_{max} 251 (245) (π–π^*, B); 210 (7200) (end absorption, π–π^*, K); n–π^*, R, band too small to measure; p.m.r. δ 0.59 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.65 (s, 3H, C-19 $COOCH_3$), 4.31 and 4.66 (s, 1H each, broad $w_{h/2} = 3$ Hz, C-17 vinylic CH_2), 6.66 (m, 1H, C-14 β-furanoid H), 7.29 (m, 1H, C-15 α-furanoid H), 7.98 (m, 1H, C-16 α-furanoid H) p.p.m.; high resolution mass spectrum *m/e*: calcd. for $C_{21}H_{28}O_4$: 344.198747; found: 344.199064 (mol. ion), 249 (M-95, β-ketone cleavage).

*Attempts to Form C-12 Ketone Derivatives of (**11***a*)

(a) p-Toluenesulfonyl Hydrazone

The ketone **11***a* was kept with excess *p*-toluenesulfonyl hydrazine in solutions of dry dimethoxyethane–ethanol at room temperature, 50 and 80°. Even when these mixtures were left for up to 10 days at room temperature no reaction occurred, as evidenced by direct *in situ* reaction of the products with sodium borohydride which gave only the alcohols **11***b*/**11***c* resulting from reduction of the starting material. At ethanol reflux temperature, extensive reduction of the 8(17)-double bond took place apparently due to diimide production (29).

Use of *p*-toluenesulfonic acid as a catalyst and isolation of the product revealed two components as judged by p.m.r. inspection, one of which showed a new (31.0 Hz) C-20 methyl absorption. However, sodium borohydride at 60° failed to produce any effect on the mixture. Prolonged refluxing with sodium borohydride in isopropanol overnight gave a complex mixture, probably as a result of Bamford–Stevens (30) reaction via the diazo compound.

(b) Semicarbazone

Heating the ketone at 45° with semicarbazide hydrochloride in methanol–DMF with sufficient sodium bicarbonate to provide the right p*H* (31), produced an ill-defined product resulting from apparent degradation of the furan ring. No reaction occurred overnight at room temperature with this reagent.

(c) Oxime

Boiling hydroxylamine hydrochloride in aqueous pyridine at 110° for 20 h (conditions shown to give reaction with very hindered 11-keto steroids (32)) gave a superficially homogeneous product which appeared to contain oximated material (i.r. evidence), but the p.m.r. spectrum showed a greatly reduced intensity of the furan absorptions indicating destruction of the furan ring.

(d) Thioketal

The ketone **11***a*, 20 mg (0.058 mmol), was placed in 5 ml "pear"-tube and 5 drops (116 mg, 1.12 mmol) ethandithiol added together with 2 drops (20 mg) of boron trifluoride ethereate. The solution was held at room temperature overnight. The product was diluted with benzene washed with 5% sodium hydroxide solution, water, brine, and evaporated to give a dark-pink oil, 22 mg. P.m.r. showed species containing mixed furanoid absorption, and the vinylic protons had shifted downfield, each showing a 4 Hz splitting. When the product was added to 400 mg W-2 Raney nickel (deactivated by refluxing for 1 h in acetone) and stirred at room temperature for 30 min, the final result showed some sulfur removal but considerable double bond reduction.

*Methyl 15,16-Epoxy-12-hydroxylabda-8(17),13(16),14-trien-19-oate (**11***b and c)*

Ketone **11***a* 50 mg, was stirred with excess sodium borohydride in aqueous ethanol overnight at room temperature. The solution was then poured into 5% NaH_2PO_4 solution and benzene extracted. Usual work-up gave 49 mg colorless oil which p.m.r. inspection showed to be a mixture of the two alcohols **11***b* and *c* in the approximate ratio of 3:2 (this same mixture was obtained from borohydride reaction in the abortive tosylations above); i.r. ν_{max} 3620, 3400, 2920, 2850, 1720 (1730 sh), 1640, 1470, 1230, 1160, 1025, 895, and 875 cm^{-1}.

The mixture was chromatographed at 100:1 on Florisil in 50:50 petroleum ether (30–60°)–benzene. Elution with benzene gave 15 mg of the 12(R)-alcohol **11***c* as a colorless oil, p.m.r. δ 0.515 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.58 (s, 3H, C-19 $COOCH_3$), 4.48 (H_A) and 4.86 (H_B) (s and 1H each, broad $w_{h/2} = 3$ Hz, C-17 vinylic H's), 4.71 (m, C-12H), 6.37 (m, 1H, C-14 furanoid H), 7.3 (m, 2H, C-15/16 furanoid) p.p.m. Ethyl acetate (5%)–benzene gave 20 mg of crystalline solid, 12(S)-alcohol **11***b*, p.m.r. δ 0.530 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.55 (s, 3H, C-19 $COOCH_3$) 4.72 (H_A), and 4.88 (H_B) (s and 1H each, $w_{h/2}$ = 3 Hz (H_B) or 4.5 Hz (H_A), C-17 vinylic H's), 4.78 (m, 1H, C-12H, 6.37 (m, 1H, C-14H furanoid), 7.3 (m, 2H, C-15/16H furanoid) p.p.m.

*Methyl 12-Hydroxy-(13→16)-tetranorlabd-8(17)-en-19-oate (**15**)*

A solution of 198 mg (5.21 mmol) of $LiAlH_4$ in 10 ml dry THF was stirred for 30 min at room temperature under a nitrogen atmosphere and then cooled to $-60°$ in a Dry Ice–acetone bath. To this solution was added dropwise a solution of 1.046 g (3.39 mmol) of the diester **7***c* in 15 ml dry THF. Upon completion of the addition, the solution was allowed to warm to $-4°$ and was kept at $-4 \pm 3°$ for 45 min. The reaction was then cooled to $-60°$, quenched with 2.0 ml (20.8 mmol) of EtOAc added dropwise, and allowed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to warm to 0°. At 0°, the mixture was diluted with H_2O (10 ml) and allowed to warm to room temperature. The mixture was acidified to p*H* 6, further diluted with H_2O (150 ml), extracted with 10% benzene–Et_2O (4 × 50 ml) and worked-up in the usual way to give 919 mg (97%) of a colorless oil which showed: p.m.r. δ 0.52 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.60 (s, 3H, C-19 $COOCH_3$), 3.33–3.93 (3H, C-12H's and C-12 OH), 4.53 (s, 1H, $w_{h/2} = 3$ Hz, C-17H_A), 4.85 p.p.m. (s, 1H, $w_{h/2} = 3$ Hz, C-17H_B); i.r. ν_{max} 3630 (non-bonded), 3500 (broad, bonded), 2950, 1710 (C=O), 1640 (C=C), 1440, 1220, 1157, 1094, 1037, 984, 893 cm^{-1}; mass spectrum (80 eV) *m/e* 280 (M^+, calcd. for $C_{17}H_{28}O_3$: 280.2038; found: 280.2048), 249 (M − CH_2OH, calcd. for $C_{16}H_{25}O_2$: 249.1854; found: 249.1848).

*Methyl 12-Oxo-(13→16)-tetranorlabd-8(17)-en-19-oate (**16**)*

(a) Via Dipyridine Chromium(VI) Oxide (24)

Chromium(VI) oxide (8.3 g, 0.083 mol) (dried *in vacuo* over P_2O_5) was added in small portions to 60 ml pyridine (dried over CaH_2) stirred with a mechanical stirrer as nitrogen was passed over it. The mixture became very viscous and after 30 min, petroleum ether was added and the reddish-brown solid was filtered through a Buchner funnel while nitrogen was passed over it via an inverted funnel. The solid was dried *in vacuo* and a quantitative yield of the complex was obtained.

A solution of 56 mg (0.19 mmol) of the ester-alcohol **15** in 5 ml dry methylene chloride was prepared under a nitrogen atmosphere. Similarly, a suspension of 340 mg (1.32 mmol, 7:1 molar ratio) of the dipy–CrO_3 complex in 15 ml dry CH_2Cl_2 was prepared under a nitrogen atmosphere in a flask with a septum inlet. The ester-alcohol solution was syringed into the flask containing the oxidizer and the mixture was stirred for 15 min after which it was poured onto a short column of Florisil. The product was eluted with 50 ml 1:1 benzene–ethyl acetate. Evaporation of the solvent gave 52 mg (100%) of the aldehyde as a colorless oil which showed: p.m.r. δ 0.53 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.58 (s, 3H, C-19 $COOCH_3$), 4.40 (s, 1H, $w_{h/2}$ = 3 Hz, C-17H_A), 4.82 (s, 1H, $w_{h/2} = 3$ Hz, C-17H_B) 9.52 p.p.m. (m, 1H, CHO); i.r. ν_{max} 2950, 2850 (aldehyde C—H) 2725 (aldehyde C—H), 1720 (ester and aldehyde), 1645 (C=C), 1470, 1450, 1435, 1385, 1248, 1225, 1156, 1136, 1094, 1040, 984, 900 cm^{-1}; mass spectrum (80 eV) *m/e* 278 (M^+, calcd. for $C_{17}H_{26}O_3$: 278.1882; found: 278.1894).

(b) Via Ag_2CO_3–Celite (25)

A well-stirred suspension of 56 g (97.9 mmol, 10 equiv) of the reagent in 225 ml benzene was refluxed for 30 min with a Dean–Stark trap. A solution of 2.74 g (9.79 mmol) of the alcohol **15** in 20 ml benzene was added dropwise through an equilibrating separatory funnel. After refluxing for 18 h, the mixture was filtered through a short column of "Celite". Evaporation of the solvent gave 2.62 g (96%) of the aldehyde **16** as a colorless oil which was identical to the aldehyde obtained in (*a*).

*Methyl 15,16-Epoxy-12-hydroxylabd-8(17),13(16),14-trien-19-oate (**11***b and c)*

(a) 3-Lithiofuran

The system composed of a three-necked flask (50 ml), equipped with a nitrogen inlet, equilibrating separatory funnel (25 ml), condenser and drying tube, and magnetic stirrer bar, was flushed with nitrogen and then cooled in a Dry Ice–acetone bath. To this system were added 21 ml (5.24 mmol) of a 2.43 *M* solution of methyllithium in ether and 5 ml dry ether. After sufficient cooling a solution of 0.66 ml (7.00 mmol) of 3-iodofuran in 2 ml dry ether and 2 ml additional ether were added dropwise and the mixture was stirred for 1½ h at −70°.

*(b) Reaction with Aldehyde **16***

To the solution of 3-lithiofuran prepared above was added dropwise a solution of 972 mg (3.50 mmol) of the aldehyde **16** in 7 ml dry ether and 2 ml additional ether and the resulting mixture was stirred for 30 min at −70°. The reaction was quenched with 15 ml of 5% NaH_2PO_4 added dropwise at −70°. After 10 min, the mixture was allowed to warm to room temperature. The reaction mixture was then diluted with water (30 ml) and extracted with ether (3 × 40 ml) and worked-up in the usual way to give 998 mg of a mixture of the two epimeric alcohols which was chromatographed at 50:1 on Florisil in 50:50 petroleum ether (30–60°)–benzene. The alcohols **11***b* and *c* were obtained in a ratio of 2:1 and in 56% total yield from the chromatography. Elution with 15% petroleum ether–benzene gave the (R)-alcohol **11***c* as a colorless oil which showed: p.m.r. δ 0.517 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.58 (s, 3H, C-19 $COOCH_3$), 4.48–4.85 (m, 1H, C-12H), 4.47 (H_A) and 4.87 (H_B) (s and 1H each, broad $w_{h/2}$ = 4 and 3 Hz, C-17 vinylic H's), 6.37 (m, 1H, C-14H furanoid), 7.35 p.p.m. (m, 2H, C-15/16H furanoid): i.r. ν_{max} 3676 (non-bonded), 3448 (broad, bonded), 2941, 2857, 1715 (C=O), 1645 (C=C), 1466, 1449, 1227, 1205, 1160, 1023, 894, 875 cm^{-1}; mass spectrum (80 eV) *m/e* 346 ($M^+ - H_2O$, calcd. for $C_{21}H_{28}O_3$: 328.2038; found: 328.2005). Elution with benzene gave the (S)-alcohol **11***b* as a crystalline solid which showed: p.m.r. δ 0.517 (s, 3H, C-20 CH_3), 1.12 (s, 3H, C-18 CH_3), 3.57 (s, 3H, C-19 $COOCH_3$), 4.48–4.85 (m, 1H, C-12H), 4.72 (H_A) and 4.88 (H_B) (s, and 1H each, broad $w_{h/2}$ = 5 and 4 Hz, C-17 vinylic H's), 6.38 (m, 1H, C-14H furanoid), 7.35 p.p.m. (m, 2H, C-15/16H furanoid); i.r. identical to **11***c*; mass spectrum (80 eV) *m/e* 346 (M^+, calcd. for $C_{21}H_{30}O_4$: 346.2144; found: 346.2141).

15,16-Epoxy-12-hydroxylabda-8(17),13(16),14-trien-19-oic Acid (12a and b)

A solution of 998 mg (2.88 mmol) of the mixed alcohols **11***b* and *c* in 5 ml dry dimethylsulfoxide (DMSO) was prepared under a nitrogen atmosphere in a three-necked flask equipped with a nitrogen inlet, condenser, and an equilibrating separatory funnel. The reaction mixture was warmed to 56° and 43 ml (43.0 mmol) of a 1.0 *N* solution of potassium *t*-butoxide in DMSO was added dropwise. After 2 h at 55–56°, the mixture was poured into 200 ml of rapidly stirred ice-water. This was followed by the addition of 1:1 ether–benzene (80 ml), acidification to p*H* 3, and extraction with additional 1:1 ether–benzene (2 × 80 ml). The combined ethereal layers were worked-up in the usual way to give 823 mg (86%) of the crude acid as a yellow oil. The crude acid was chromatographed on a silica gel column (50:1) in hexane to give the mixed alcohols **12***b* and *c* in 40% yield. The (R)-alcohol **12***b* was eluted with 10% EtOAc–hexane and isolated as a colorless oil which showed: p.m.r. δ 0.60 (s, 3H, C-20 CH_3), 1.25 (s, 3H, C-18 CH_3), 4.48–4.85 (m, 1H, C-12H), 4.48 (H_A) and 4.90 (H_B) (s and 1H each, broad $w_{h/2}$ = 5 Hz, C-17 vinylic H's), 6.00 (broad, 2H,

For personal use only.

—OH's), 6.40 (m, 1H, C-14H furanoid), 7.35 p.p.m. (m, 2H, C-15/16H furanoid); i.r. ν_{max} 3600, 2972, 2938, 2850, 1689 (C=O), 1639 (C=C), 1461, 1444, 1256, 1201, 1021, 891, 871 cm^{-1}; mass spectrum (80 eV) *m/e* 332 ($M^+ - H_2O$, calcd. for $C_{20}H_{26}O_3$: 314.1882; found: 314.1876). The (S)-alcohol was eluted with 25% ethyl acetate–hexane and was isolated as a colorless oil which showed: p.m.r. δ 0.617 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 4.48–4.85 (m, 1H, C-12H), 4.73 (H_A) and 4.90 (H_B) (s and 1H each, $w_{h/2} = 5$ and 4 Hz, C-17 vinylic H's), 6.40 (m, 1H, C-14H furanoid), 7.35 p.p.m. (m, 2H, C-15/16H furanoid); i.r. identical with the (R)-alcohol **12***b* above.

Methyl 15,16-Epoxy-12-hydroxylabda-8(17),13(16),14-trien-19-oate 12(S)-Methanesulfonate

A solution of 45 mg (0.13 mmol) of the alcohol **11***b* in 3 ml dry CH_2Cl_2 was prepared under nitrogen. To this solution was added 91 μl (0.65 mmol) of Et_3N and 0.5 ml CH_2Cl_2 and the resulting mixture was cooled in an ice–salt bath. To this mixture was added 31 μl (0.39 mmol) of mesyl chloride and 0.5 ml CH_2Cl_2 and the whole was stirred for 1.5 h. The reaction mixture was diluted with 60 ml CH_2Cl_2, washed with ice-water, cold 1% HCl, saturated brine, and filtered through Na_2SO_4. Evaporation of the solvent gave 52 mg of a colorless oil whose p.m.r. spectrum showed *ca.* 70% mesylate: p.m.r. δ 0.517 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.58 (s, 6H, C-19 $COOCH_3$ and CH_3SO_2—), 4.37 (H_A) and 4.87 (H_B) (s and 1H each, broad, $w_{h/2} = 3$ and 5 Hz, C-17 vinylic H's), 4.43–4.85 (m, 1H, C-12 H), 6.40 (m, 1H, C-14 H furanoid), 7.33 p.p.m. (m, 2H, C-15/16 H furanoid).

15,16-Epoxy-12-hydroxylabda-8(17),13(16),14-trien-19-oic Acid 12(S)-Methanesulfonate (13)

A solution of 63 mg (0.19 mmol) of the alcohol **12***a* in 3 ml dry CH_2Cl_2 was prepared under nitrogen. To this solution was added 317 μl (2.28 mmol) of Et_3N and the resulting mixture was cooled in an ice–salt bath. To this mixture was added 119 μl (1.52 mmol) of mesyl chloride and 1 ml CH_2Cl_2 and the whole was stirred for 1.5 h. The reaction mixture was diluted with 60 ml CH_2Cl_2, washed with ice-water, cold 1% HCl, saturated brine, and filtered through Na_2SO_4. Evaporation of the solvent gave 57 mg of a yellow oil which decomposed rapidly on standing at room temperature.

Lambertianic Acid (2a)

To a solution of 47 mg (0.14 mmol) of the (S)-alcohol **12***a* in 5 ml dry methylene chloride under nitrogen was added 0.2 ml (1.42 mmol) of triethylamine and the resulting mixture was cooled in an ice–salt bath. After sufficient cooling, 66 μl (0.85 mmol) of mesyl chloride was added and the solution was stirred for $1\frac{1}{2}$ h at $-5°$. The reaction mixture was diluted with 50 ml methylene chloride and washed with cold 2% hydrochloric acid, ice-water, saturated brine, and filtered through anhydrous sodium sulfate. Evaporation of the solvent *in vacuo* gave a brown oil which was immediately redissolved in dry tetrahydrofuran and added to a freshly prepared solution of 10 mg (1.42 mmol) of lithium in 10 ml liquid ammonia. After 1 h, the reaction was quenched with 5 ml saturated NH_4Cl solution and stirred for a further 15 min before the ammonia was allowed to evaporate. Dilution with water gave a solution of p*H* 11. The neutral fraction was extracted with 1:1 ether–benzene (2 × 25 ml) and worked-up in the usual way to give 5 mg of hydrocarbon material. The aqueous layer was acidified to p*H* 1 and extracted with 1:1 ether–benzene (2 × 25 ml) and worked-up in the usual way to give 16 mg (36%) lambertianic acid as a colorless oil which showed: p.m.r. δ 0.60 (s, 3H, C-20 CH_3), 1.22 (s, 3H, C-18 CH_3), 4.57 (H_A) and 4.90 (H_B) (s and 1H each, $w_{h/2} = 4$ Hz, C-17 vinylic H's), 6.27 (m, 1H, C-14 H furanoid), 7.20 (m, 1H, C-16H furanoid), 7.35 p.p.m. (m, 1H, C-15H furanoid); i.r. ν_{max} 2944, 2856, 1694 (C=O), 1644 (C=C), 1467, 1450, 1263, 1233, 1179, 1168, 1063, 1026, 894, 874 cm^{-1}; mass spectrum (80 eV) *m/e* 316 (M^+, calcd. for $C_{20}H_{28}O_3$: 316.2038; found: 316.2004).

Lithium–Liquid Ammonia Reductions

(i) On 11b and c

A three-necked flask fitted with a Dry Ice condenser, septum inlet, and gas inlet was flushed with nitrogen and filled with 20 ml liquid ammonia. To this system was added 27 mg (2.4 mmol, 3.8 equiv) of Li and a solution of 110 mg (0.32 mmol) of a mixture of the alcohols **11***b* and *c* in 5 ml THF. After 30 min, the reaction was quenched with the dropwise addition of 10 ml saturated NH_4Cl. After the bulk of ammonia had evaporated, the mixture was diluted with 50 ml H_2O, acidified to p*H* 4, extracted with 1:1 ether–benzene (2 × 50 ml), and worked-up in the usual way to give 103 mg of an oil. The p.m.r. spectrum showed complete retention of the 12-OH, and partial reduction of the C-19 methyl ester to the alcohol. The i.r. spectrum showed the presence of an acid due to partial hydrolysis of the methyl ester to the acid.

(ii) On Methyl O-Methyl Podocarpate

A solution of 145 mg (0.48 mmol) of methyl O-methyl podocarpate in 5 ml dry THF was added to a freshly-prepared solution of 40 mg (5.76 mmol, 6 equiv) of Li in 15 ml liquid NH_3. The mixture was stirred for 30 min and then quenched with the dropwise addition of 20 ml saturated NH_4Cl solution. The ammonia was allowed to evaporate and the remainder was acidified to p*H* 2 and extracted with 3:1 ether–benzene and worked-up in the usual way to give 118 mg of an oil whose p.m.r. spectrum showed >80% of the reduction product O-methyl podocarpinol.

We wish to thank the National Research Council of Canada for financial support of this work and for a Fellowship to Dr. M. B. Gravestock.

The Reactions of Organometallic Compounds Involving Silicon. Reactions of Triphenyl-, Diphenylmethyl-, and Phenyldimethylsilyl-lithium with 9-Phenylfluorene in Tetrahydrofuran

M. A. HAMID

Department of Chemistry, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, M60 1QD, England

Received March 27, 1972

Triphenyl-, diphenylmethyl-, and phenyldimethylsilyl-lithium react very rapidly with 9-phenylfluorene in tetrahydrofuran (THF) but the reaction can be followed spectroscopically using the stop-flow technique at low temperatures. The order of reaction, found from the dependence of the initial rate of reaction on the initial reactant concentrations, is unity in both 9-phenylfluorene and the relevant organosilyl-lithium reagent. The thermodynamic constants of activation for the reaction between 9-phenylfluorene and triphenylsilyl-lithium (Ph_3SiLi), diphenylmethylsilyl-lithium ($Ph_2MeSiLi$), and phenyldimethylsilyl-lithium ($PhMe_2SiLi$), respectively, are: $\Delta H^* = 4.5$, 4.0, and 4.0 kcal mol^{-1}; $\Delta G^* = 13.0$, 12.5, and 12.5 kcal mol^{-1}; $\Delta S^* = -34.9$, -34.8, and -34.9 cal mol^{-1} deg^{-1}.

Le triphényl-, diphénylméthyl-, et phényldiméthylsilyl-lithium réagissent très rapidement avec le phényl-9 fluorène dans le tétrahydrofurane (THF) et la réaction peut être suivie par spectroscopie en utilisant la technique d'arrêt d'écoulement à basses températures. L'ordre de la réaction, trouvé à partir de la relation entre la vitesse initiale de la réaction et les concentrations initiales du réactant, est de un à la fois pour le phényl-9 fluorène et pour le réactif organosilyllithium correspondant. Les constantes thermodynamiques d'activation pour la réaction entre le phényl-9 fluorène et le triphénylsilyl-lithium (Ph_3SiLi), diphénylméthylsilyl-lithium ($Ph_2MeSiLi$), et phényldiméthylsilyl-lithium ($PhMe_2SiLi$) sont respectivement $\Delta H^* = 4.5$, 4.0 et 4.0 kcal mol^{-1}; $\Delta G^* = 13.0$, 12.5, et 12.5 kcal mol^{-1}; $\Delta S^* = -34.9$, -34.8, et -34.9 cal mol^{-1} deg^{-1}.

The metalation of fluorene by ethyl-lithium (1), *n*-butyl-lithium (2), and *t*-butyl-lithium (3) has been studied in benzene. The reactions were fairly slow and could be studied by any suitable conventional method. The order of reaction in fluorene was found to be unity in each case, and in alkyl-lithium was always fractional due to the alkyl-lithium existing as aggregates. The reactions of Ph_3SiLi, $Ph_2MeSiLi$, and $PhMe_2SiLi$ with fluorene (4) and 9-methylfluorene (5) in THF have already been reported; the results for the reaction of 9-phenylfluorene with Ph_3SiLi, $Ph_2MeSiLi$, and $PhMe_2SiLi$ in THF are now presented.

Experimental

Materials

9-Phenylfluorene was prepared by the reaction of crystallized phosphoric acid with triphenylcarbinol as described by A. Kliegl (6). The 9-phenylfluorene thus obtained was purified by crystallizing three times from pure benzene; the final product, m.p. 145.5–146.5 °C, was collected, and dried under high vacuum (10^{-5} Torr). Hexaphenyldisilane (K & K Laboratories, Inc.) was recrystallized three times from pure xylene and dried under high vacuum conditions; m.p. 369–370 °C.

1,1,2,2-Tetraphenyl-1,2-dimethyldisilane was prepared by the reaction of sodium with diphenylmethylchlorosilane (K & K Laboratories, Inc.) in toluene as described by Gilman *et al.* (7), and was recrystallized three times from ethanol:benzene solution and finally dried and sublimed under high vacuum conditions; m.p. 145.5–146.5 °C.

1,2-Diphenyl-1,1,2,2-tetramethyldisilane was also prepared by the reaction of sodium with phenyldimethylchlorosilane (K & K Laboratories, Inc.) in xylene as described by Gilman *et al.* (7). The 1,2-diphenyl-1,1,2,2-tetramethyldisilane thus prepared was fractionally distilled twice, the middle fraction, b.p. 290–300 °C, was collected and was further purified twice by fractional distillation under high vacuum conditions (10^{-5} Torr).

Tetrahydrofuran (B.D.H. Laboratory Reagent) was purified and dried as described by Evans *et al.* (8).

All the compounds used in this work are known. However, samples obtained were identified and confirmed by their melting points, elemental analyses and n.m.r. spectra. The purity was finally established by g.l.c. using a column of Apiezon L.

Ph_3SiLi, $Ph_2MeSiLi$ and $PhMe_2SiLi$ were prepared by the cleavage of corresponding symmetrical disilanes with lithium in THF as described earlier (9).

Kinetic Measurements

The rates of reaction between organosilyl-lithium and 9-phenylfluorene compounds in tetrahydrofuran were measured by mixing the reagents under high vacuum at low temperatures and using the stop-flow technique (10) to follow the change of optical density at 490 nm, and hence

For personal use only.

TABLE 1. Spectral values for 9-phenylfluoren-9-yl-lithium

Temperature (°C)	λ_{max} (nm)	$10^{-3}\,\varepsilon_{\lambda max}$	λ_{max}	$10^{-3}\,\varepsilon_{\lambda max}$
20	490	3.90	527	3.52
−20	490	4.01	527	3.66
−80	490	4.04	527	3.77

the formation of the product 9-phenylfluoren-9-yl-lithium, with time. The technique used to study the order of reaction in 9-phenylfluorene was to keep the organosilyl-lithium initial concentration and the reaction temperature constant, while varying the 9-phenylfluorene concentration approximately in the ratios 1:2 to 2:1; for the order of reaction in the organosilyl-lithium, the initial concentration was varied while keeping the 9-phenylfluorene and the reaction temperature constant.

Spectra

In the determination of the spectra and the extinction coefficients for the products of the reaction between organosilyl-lithium and 9-phenylfluorene in THF, the organosilyl-lithium was used in slight excess to convert all the 9-phenylfluorene into 9-phenylfluoren-9-yl-lithium. Before mixing the two reactants, the apparatus was evacuated thoroughly and baked while pumping. It was then sealed off from the vacuum line and the reactants were mixed by breaking the internal seals with a glass breaker. A yellow color developed immediately when the two reactants made contact with each other. To ensure that reaction was complete the reaction mixture was shaken and kept at room temperature for a few minutes before sealing the silica optical cells.

To determine the electronic spectra of the compounds at different temperatures, the sealed silica cell containing the sample was placed in a Dewar flask fitted with silica windows and used in conjunction with a Unicam SP 800 spectrophotometer. The temperature of the sample was controlled by passing a jet of cold nitrogen through the Dewar flask. A resistance-type temperature sensor near the sample monitored the gas stream temperature. The gas was cooled by passing it through a coil in liquid nitrogen held in a larger Dewar. The sample was placed approximately 1 in. above the sensor in the gas stream and required about 10–15 min to reach the temperature of the gas. The temperature range studied was from +20 to −80 °C.

Results

The spectra of R_3SiLi reagents in THF showed an absorption maximum at 335 nm. The values obtained for $\varepsilon_{\lambda max}$ were in agreement with those previously (4) reported for R_3SiLi reagents within the experimental error of ±2%. In spite of the intense brown–yellow color of R_3SiLi reagents they do not give any significant absorption in the wavelength region above 450 nm even at a concentration as high as 5×10^{-2} mol l^{-1} (1 mm cell).

The spectrum in THF of 9-phenylfluoren-9-yl-lithium, prepared by mixing the organosilyl-lithium and 9-phenylfluorene reagents at +20 °C, showed two distinct absorption peaks in the visible region, λ_{max} 490 and 527 nm, shoulders at 458 and 550 nm. The estimated extinction coefficients at different temperatures are given in Table 1.

$$*k = \frac{\text{Initial rate}}{[R_3SiLi]_i[9\text{-phenylfluorene}]_i}$$

Kinetics

All the experiments using the stop-flow technique were carried out at −30 °C. The reaction of R_3SiLi with 9-phenylfluorene in THF to give 9-phenylfluoren-9-yl-lithium and silane shows second order kinetics up to at least 90% of the reaction (see Table 2 and Fig. 1). The reaction of R_3SiLi with 9-phenylfluorene in THF is of irreversible nature under the conditions used.

TABLE 2. Data for the second order rate constant k at −30 °C

	Curve No.	10^3 [R_3SiLi]$_i$ (mol l^{-1})	10^3[9-Phenylfluorene]$_i$ (mol l^{-1})	k (l mol^{-1} s^{-1})
Ph_3SiLi	A	3.52	2.45	9.4

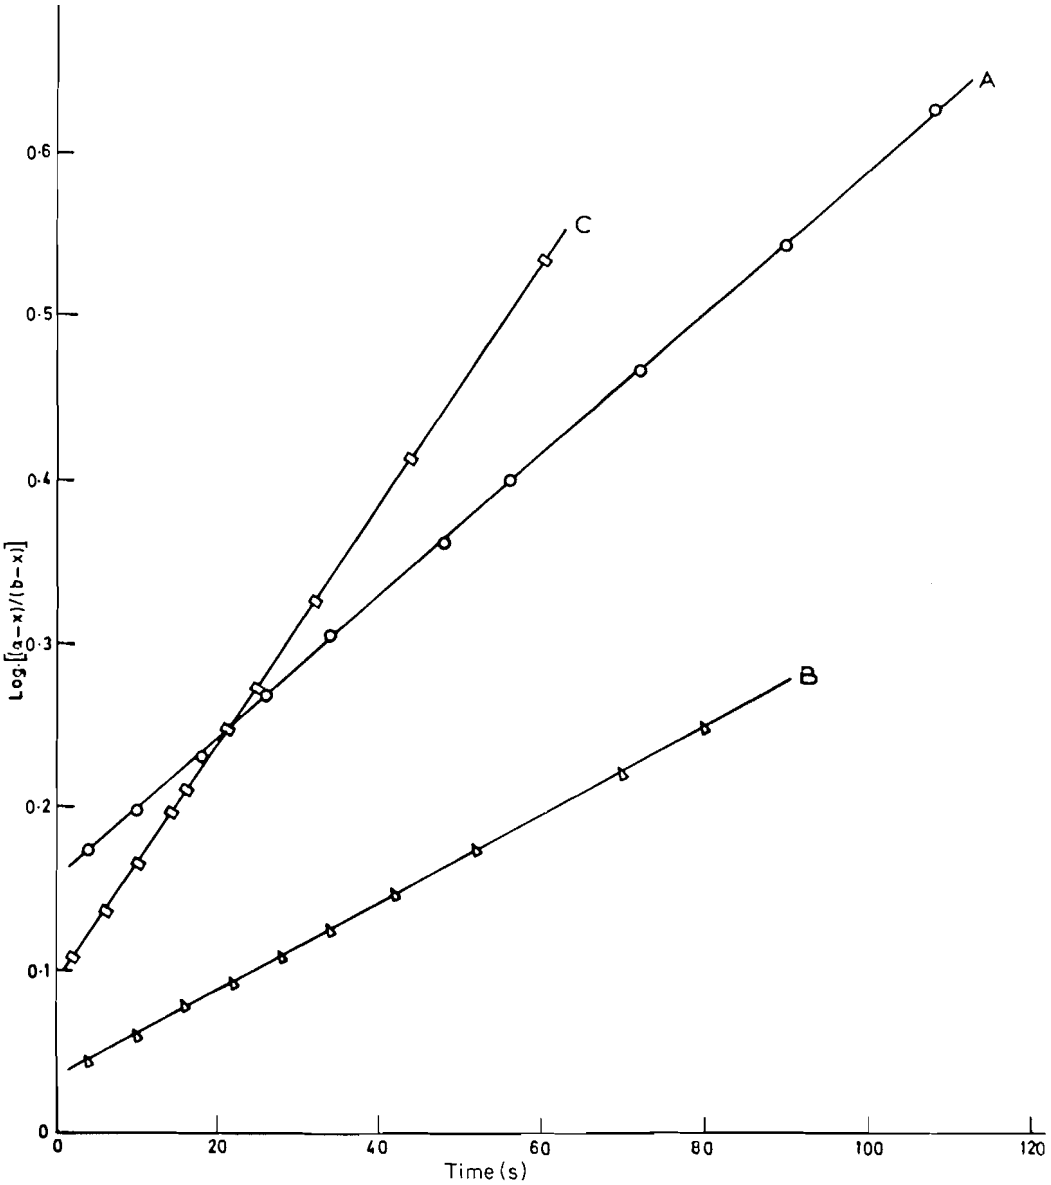

FIG. 1. Second order dependence of reaction rate for the system: R_3SiLi + 9-phenylfluorene in THF at $-30\,^{\circ}C$. (A) $[Ph_3SiLi]_i = 3.52 \times 10^{-3}\ M$; [9-phenylfluorene]$_i = 2.45 \times 10^{-3}\ M$. (B) $[Ph_2MeSiLi]_i = 3.05 \times 10^{-3}\ M$; [9-phenylfluorene]$_i = 2.82 \times 10^{-3}\ M$. (C) $[PhMe_2SiLi]_i = 3.49 \times 10^{-3}\ M$; [9-phenylfluorene]$_i = 2.82 \times 10^{-3}\ M$.

The orders of reaction found from the dependence of the initial rate of reaction on the initial reagent concentration were 1.01 in Ph_3SiLi, 1.02 in $Ph_2MeSiLi$, and 1.01 in $PhMe_2SiLi$. For this sequence of R_3SiLi the order in 9-phenylfluorene was 0.98, 0.98, and 1.1 (see Tables 3 and 4).

The temperature dependence of the initial rate of reaction at constant initial 9-phenylfluorene and R_3SiLi concentrations was measured in the range -6 to $-45\,^{\circ}C$ (see Table 5). The Arrhenius plots gave the following apparent activation energies (kcal mol^{-1}): Ph_3SiLi, 5.0; $Ph_2MeSiLi$, 4.5; $PhMe_2SiLi$, 4.5. The thermodynamic

constants of activation for the reaction between R_3SiLi and 9-phenylfluorene are given in Table 6. The results quoted have the following estimated systematic errors: k, ±7%; $\Delta H^{\ddagger}$ and $\Delta G^{\ddagger}$, ±5%; and $\Delta S^{\ddagger}$, ±9%.

Products of Reactions

For product analysis, three experiments were carried out at −30 °C with varying amounts of Ph_3SiLi and 9-phenylfluorene in THF. On completion of the reaction, the mixtures were quenched with deuterium oxide.

The products formed when a reaction mixture was quenched with D_2O were isolated by distilling off THF; the residue was dissolved in *n*-hexane, washed with water, and dried over $MgSO_4$. The *n*-hexane was then distilled off under reduced pressure and the solid product isolated by fractional crystallization or preparative t.l.c., depending on the ratio of the reactants used. All the compounds obtained were identified by their melting points, n.m.r. spectra, and elemental analyses. The n.m.r. values for 9-phenylfluorene and 9-phenylfluoren-9-yl-deuterium are 1.6–2.8 (m, Ph), 4.55–4.75 (t, CH), and 1.6–2.8 τ (m, Ph), respectively. The results obtained for the remaining components agree with the previously reported values (5).

Discussion

Spectra

The results show that R_3SiLi reacts rapidly with 9-phenylfluorene to give products of 9-phenylfluoren-9-yl-lithium and silane.

Comparison of the values of λ_{max} and $\varepsilon_{\lambda max}$ at 20 °C for 9-phenylfluoren-9-yl-lithium with the corresponding values for 9-fluorenyl-lithium (4) suggests that the substitution of the 9-hydrogen atom by a phenyl group results in bathochromic shift of *ca.* 5–9 nm. However, this shift is in

TABLE 6. Thermodynamic constants of activation for the reaction of R_3SiLi and 9-phenylfluorene in THF at −30 °C*

	Ph_3SiLi	$Ph_2MeSiLi$	$PhMe_2SiLi$

marked contrast to the bathochromic shift of *ca.* 30 nm reported in the case of a 9-fluorenyl-lithium and 9-methylfluoren-9-yl-lithium (5). Streitweiser and Brauman (11) have reported the visible spectrum of 9-phenylfluorene-9-yl-lithium in cyclohexylamine. The slight red shift and the relatively higher $\varepsilon_{\lambda max}$ found in the spectrum of the product obtained by the reaction of R_3SiLi and 9-phenylfluorene in THF could be due to the change of the solvent.

The spectra of 9-phenylfluoren-9-yl-lithium at different temperatures (20 to -80 °C) in THF reveal that $\varepsilon_{\lambda max}$ increases slightly with decrease in temperature (see Table 1). This increase in ε suggests that there is formation of new solvent separated ion-pairs of 9-phenylfluoren-9-yl-lithium, having ε greater than the parent contact ion-pairs, as the temperature decreases. It is surprising that there is no significant change in the spectrum of 9-phenylfluoren-9-yl-lithium with temperature if a new species (solvent separated ion-pairs of 9-phenylfluoren-9-yl-lithium) is forming. It has been suggested however, by Hogen-Esch and Smid (12, 13) that the contact and solvent separated ion-pairs of fluorenyl-lithium are likely to have values of λ_{max} differing by as little as 1 nm which would be difficult to resolve. The spectral changes occurring as the temperature is lowered are reversible.

Dilution of the 9-phenylfluoren-9-yl-lithium reagent and addition of a common ion salt (tetraphenylboron-lithium) have no significant effect on the spectrum.

A relatively small increase with decreasing temperatures in $\varepsilon_{\lambda max}$ for 9-phenylfluoren-9-yl-lithium as compared with 9-fluorenyl-lithium (4) (75% solvent separated ion-pairs at 25 °C (12)) and 9-methylfluoren-9-yl-lithium (5) may be due to the fact that the successive replacement of H or CH_3 by C_6H_5 does lead to a more solvated 9-phenylfluoren-9-yl-lithium at 20 °C. All the experimental results suggest that the new species formed at low temperature is the solvent separated 9-phenylfluoren-9-yl-lithium ion-pairs.

Mechanism of Reaction

Since the orders of reaction observed were unity in both 9-phenylfluorene and the relevant organosilyl-lithium reagents, the rate of formation of 9-phenylfluoren-9-yl-lithium is given by the simple second order expression

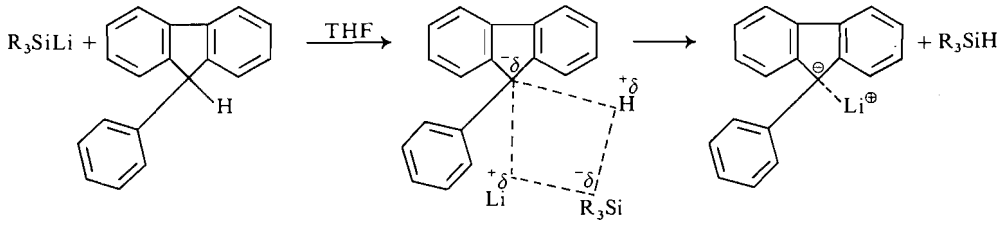
$$\text{Initial rate} = k\,[\text{9-phenylfluorene}]_i[R_3SiLi]_i$$

The first order dependence in organosilyl-lithium reagent suggests that the Ph_3SiLi, $Ph_2MeSiLi$, and $PhMe_2SiLi$ species are in the monomeric form in THF. It is known that *n*-butyl-lithium exists as a hexamer in benzene (2) and as a dimer in THF (14). Furthermore, it has been established that organo-lithium reagents form etherates in diethylether (15) and in THF (16). It seems reasonable to suggest that because the organosilyl-lithium reagents are bulky molecules compared to *n*-butyl-lithium the formation of dimers or trimers is inhibited due to steric hindrance; they prefer to remain as solvated monomers rather than self-associated aggregates in THF.

The values of second order rate constant k obtained by the methods of curve analysis and initial rate agree reasonably well with each other (see Tables 2–4), and the values of thermodynamic constants of activation calculated at -30 °C indicate the following order of decreasing reactivity: $Ph_2MeSiLi \geqslant PhMe_2SiLi > Ph_3SiLi$. The order of reactivity observed for $Ph_2MeSiLi$, and $PhMe_2SiLi$ is not that which would be expected from a consideration of the electronic effects of methyl and phenyl groups. This order of relative reactivities has been reported elsewhere (4, 5, 9, 17–19) and can be interpreted using the arguments suggested by Evans *et al.* (17). However, the exceptionally broad absorption peak exhibited for $PhMe_2SiLi$ (4) reagent may be partly due to interaction between $PhMe_2SiLi$ and THF. It could be suggested in the light of this that $PhMe_2SiLi$ should be more reactive than $Ph_2MeSiLi$ but the former has a stronger interaction with the solvent than the latter, which may be due to the structure of $PhMe_2SiLi$. In other words, steric hindrance may be responsible for the lower reactivity of $PhMe_2SiLi$.

The relative reactivities of organosilyl-lithium with fluorene (4) and 9-phenylfluorene are consistent with the fact that the replacement of a 9-hydrogen atom by a phenyl group enhances the acidity of the hydrocarbon.

The products obtained after the completion of reaction between R_3SiLi and 9-phenylfluorene



Initial state Transition state Final state

SCHEME 1

in THF were treated with D_2O to replace lithium by deuterium for product analysis. The results obtained from product analysis suggest that no disubstituted phenylfluorene or biphenylfluorene was produced during the reaction regardless of relative concentrations of reactants used. Thus the results from product analysis agree with the second order kinetics obtained.

The reaction mechanism which could be postulated on the practical evidence probably involves a four-membered ring transition state as shown in Scheme 1. This transition state may be formed by the interaction of a 9-phenylfluorene molecule with a molecule of R_3SiLi in which case the reaction is second order.

Thiohydantoins. X. Kinetic Studies of the Acid Hydrolysis of 1-Acyl-2-thiohydantoins

WAYNE IRVINE CONGDON[1] AND JOHN THOMAS EDWARD
Department of Chemistry, McGill University, Montreal, Quebec

Received December 13, 1971[2]

The rates of hydrolysis of 22 1-acyl-2-thiohydantoins in aqueous sulfuric acid to give 2-thiohydantoin and a carboxylic acid have been determined. In 0–90% sulfuric acid, hydrolysis takes place by an A-2 mechanism, and the rate reaches a maximum in about 70% acid. In acid more concentrated than about 90%, hydrolysis takes place by an A-1 mechanism, and the rate increases monotonically. Evidence for the two mechanisms comes from Yates r and Bunnett-Olsen ϕ parameters; from entropies of activation; from $\rho\sigma$ and $\rho\sigma^+$ relations; and from steric effects.

On a déterminé les vitesses de l'hydrolyse de 22 acyle-1 thiohydantoïnes-2 dans l'acide sulfurique, fournissant le thiohydantoïne-2 et une acide carboxylique. Dans la zone de concentration de 0–90% d'acide sulfurique, la réaction se passe par un mécanisme A-2, et la vitesse de la reaction atteint un maximum dans une concentration de 70% acide environ. Entre 90–100% concentration d'acide, la réaction suit un mécanisme A-1 et la vitesse de la réaction s'augmente continuellement avec la concentration d'acide. La dualité des mécanismes est supportée par: les paramètres r de Yates et ϕ de Bennett et Olsen; les entropies d'activation; les relations $\rho\sigma$ ou $\rho\sigma^+$; et les effets stériques.

1-Acyl-2-thiohydantoins (B in Scheme 1) are hydrolyzed in aqueous acid exclusively to a carboxylic acid and 2-thiohydantoin (see review in ref. 1); reports to the contrary have been found incorrect (2). The mechanism of this hydrolysis is of interest because of its use in certain modifications (3) of Schlack and Kumpf's procedure (4) for identifying the C-terminal amino acid residue of peptides. In the present paper we show that hydrolysis in aqueous sulfuric acid may take place by an A-2 or an A-1 mechanism, depending on the concentration of acid; the mechanism of the reaction proves to be very similar to that of the acid-catalyzed hydrolysis of *N*-acylthioureas (5).

As a first step it was necessary to study the protonation of 1-acyl-2-thiohydantoins in sulfuric acid. 2-Thiohydantoin itself undergoes mono- and then partial diprotonation as the concentration of sulfuric acid increases from 0 to 100%. Over the range 50 to 80% sulfuric acid changes in the u.v. spectrum indicate protonation to be taking place on the thiocarbonyl sulfur ($pK_{BH^+} = -4.83$), the extent of protonation depending on the H_0 value of the solution (6). We have observed that the spectral changes taking place as the acid concentration is increased above 90% indicate the beginning of a second protonation, this time on the carbonyl oxygen (5). In 100% acid 2-thiohydantoin is about half converted into the diprotonated species.[3]

We have found that 1-acyl-2-thiohydantoins show very similar changes in their u.v. spectra when they are dissolved in varying concentrations of acid. However, a quantitative determination of the extent of their protonation was made difficult by their rapid hydrolysis. Eventually, it was found that 1-*o*-iodobenzoyl-2-thiohydantoin was sufficiently stable in different concentrations of acid at 25.3 °C to give the spectra shown in Fig. 1. The character of the spectral changes indicated protonation to be taking place first on the sulfur atom (5) to give the cation BH^+ (see Scheme 1). Analysis of the spectral changes by conventional methods (7, 8) showed that the ionization ratio ($[BH^+]/[B]$) was proportional to h_0 (Fig. 2), and that the pK_{BH^+} was -6.8.

By lowering the temperature of the solutions to 9.4 °C, and by extrapolating absorbance readings back to the time of mixing, it was possible to measure the u.v. absorbance of 1-ben-

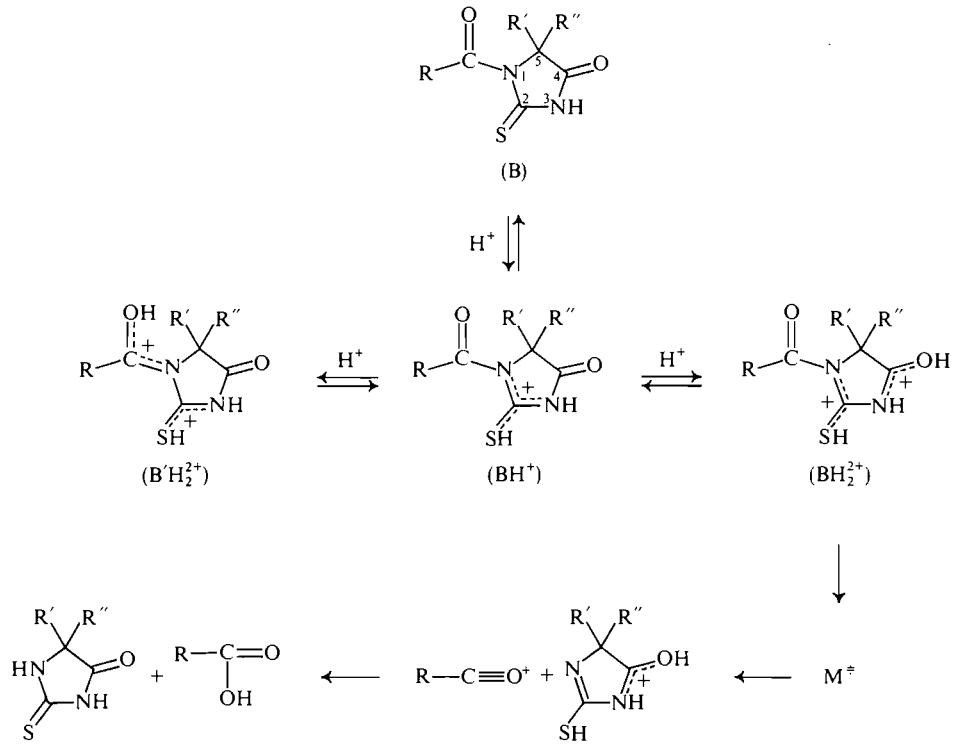

SCHEME 1

zoyl-2-thiohydantoin and of 1-*m*-trifluoromethylbenzoyl-2-thiohydantoin in different concentrations of acid. Again, the ionization ratio was found to follow h_0 (Fig. 2), and the pK_{BH^+} values of -6.6 and -6.7, respectively, were obtained. The similarity of these values indicates that the basicity at the sulfur atom is little affected by substitution in the benzene ring. A more precise analysis (*e.g.* a $\rho\sigma$ analysis) is not warranted, in view of the limited accuracy

of the pK_{BH^+} values, but obviously ρ for the reaction approaches zero.

In acid concentrations above about 94%, spectral changes similar to those accompanying the diprotonation of *N*-acylthioureas (5) were observed, suggesting the formation of the cations BH_2^{2+} and $B'H_2^{2+}$ (Scheme 1); however, no systematic study of these changes was made because hydrolysis of the 1-acyl-2-thiohydantoins was too rapid. The kinetic results described below were best accommodated by postulating the formation of the *O*-protonated AH^+ in addition to the *S*-protonated BH^+ in dilute acid (Scheme 2), but the character of the spectral changes (*cf.* ref. 5) indicated only BH^+ to contribute significantly to the acid-base equilibrium.

The hydrolysis, followed by u.v. absorbance changes, was found to follow first-order kinetics in the large excess of acid used. The pseudo-first-order rate constants (k_ψ) for the hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin in 6–99% sulfuric acid are given in Table 1. The rate constants increased with acid concentration up

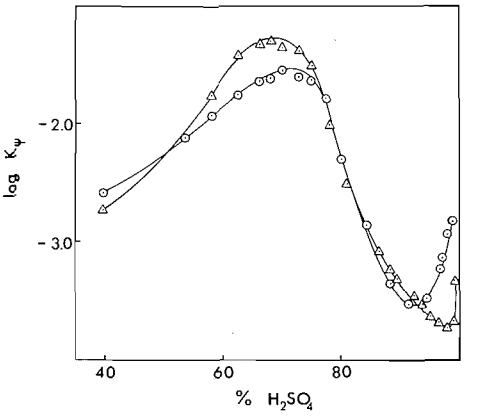

FIG. 3. Plot of log k_ψ at 25.3° *vs.* percent sulfuric acid for 1-acetyl-5,5-dimethyl-2-thiohydantoin (○) and 1-acetyl-2-thiohydantoin (△).

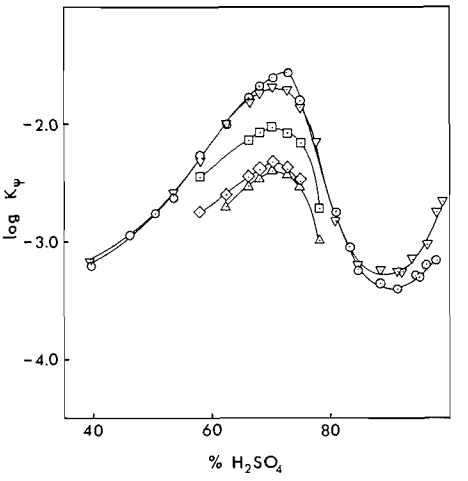

FIG. 4. A plot of log k_ψ at 25.3 °C *vs.* concentration of sulfuric acid for 1-benzoyl-3-phenyl-2-thiohydantoin (○); 1-benzoyl-2-thiohydantoin (▽); 1-benzoyl-5-methyl-2-thiohydantoin (□); 1-benzoyl-5-sec-butyl-2-thiohydantoin (◇); and 1-benzoyl-5-isopropyl-2-thiohydantoin (△).

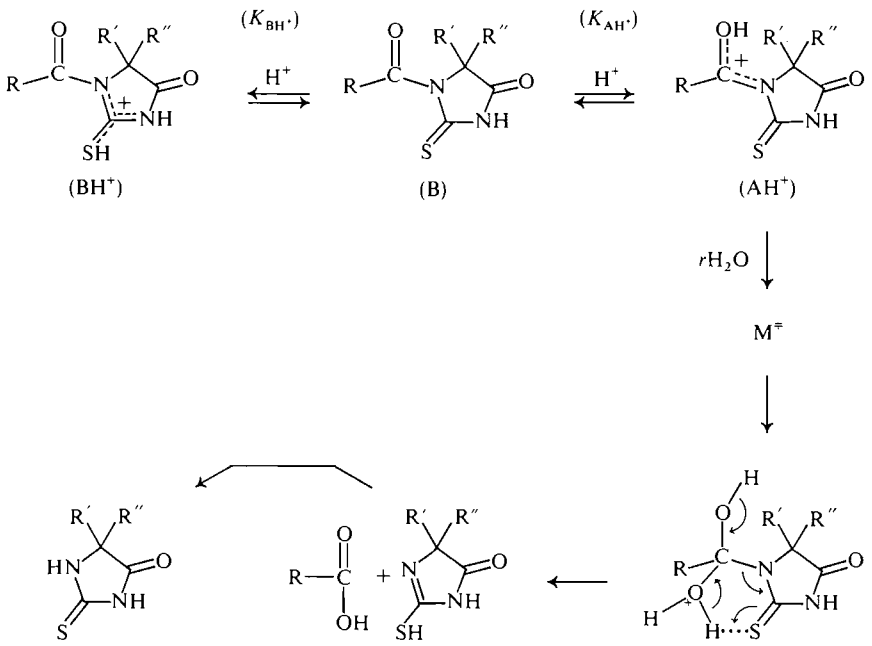
to a maximum in about 70% acid, then decreased to a minimum in about 92% acid, and then increased again, as shown in Fig. 3. Also shown in this figure is the rate profile for 1-acetyl-2-thiohydantoin, which is fairly similar to that of the 5,5-dimethyl derivative over most of the range of acid concentrations, but has a rate minimum in about 98% acid. Other 1-acyl-2-thiohydantoins showed somewhat similar rate-concentration profiles, as shown in Figs. 4 and 5, with maximum rates in about 70% acid.



SCHEME 2

However, the positions of the minima varied considerably, and none could be observed for the hydrolysis of 1-*m*-trifluoromethylbenzoyl-2-thiohydantoin (see Fig. 5).

From analogy with similar rate profiles already reported (9), these results suggest an A-2 mechanism for hydrolysis in approximately 0–90% acid, followed by an A-1 mechanism for hydrolysis of most (but not all) of the 1-acyl-2-thiohydantoins in higher concentrations of acid. This dualism of mechanism would explain most of the qualitative features of the rate profiles, if it is assumed that the A-2 hydrolysis takes place by the mechanism outlined in Scheme 2, and the A-1 hydrolysis by the mechanism outlined in Scheme 1. Geminal dimethyl substitution at the 5-position should not affect

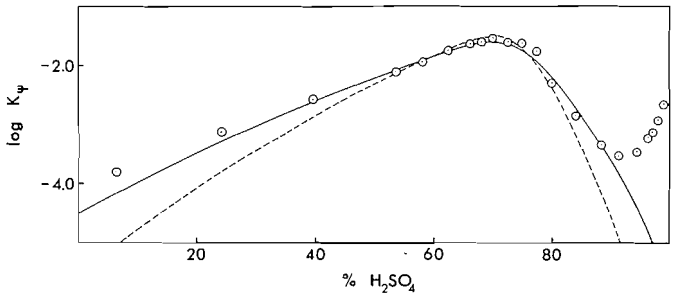

FIG. 7. Rate–acidity dependence for the hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin in aqueous sulfuric acid at 25.3 °C. Points: experimental k_ψ (in s^{-1}).——The theoretical curve derived from eq. 1.---The theoretical curve derived from eq. 2.

appreciably the basicity of the various centers, but should slow down the A-2 reaction (by steric hindrance in the step: $AH^+ + rH_2O \rightarrow$ intermediate), and should accelerate the A-1 reaction (by steric acceleration of the *N*-acyl fisson). This would account for the change in the position of the minimum in the rate profile on going from 1-acetyl-2-thiohydantoin to 1-acetyl-5,5-dimethyl-2-thiohydantoin (Fig. 3). The general effect of 5-substitution in decreasing the rate of the A-2 reaction is illustrated in Fig. 4. Electron-withdrawing substituents on the benzene ring of substituted 1-benzoyl-2-thiohydantoins should, from analogy with the behavior of substituted benzamides (10), shift the maximum of the rate profile to higher acidities, and this effect is shown to a very slight extent (Fig. 5); much more dramatic is the effect in inhibiting the A-1 reaction (see Fig. 5) by destabilizing the acylium ion. The stability of 1-*o*-iodobenzoyl-2-thiohydantoin arises from both the steric effect of the large iodine atom in slowing the A-2 reaction, and its electronic effect in slowing the A-1 reaction.

The duality of mechanism is supported by various quantitative analyses of the kinetic data. This evidence is as follows:

(1) Hydration Parameters

Yates and his coworkers (11) have modified the original Bunnett hydration parameter treatment (12) to take account of the correct acidity function to apply to the protonation of the substrate being hydrolyzed. In the present case it is most reasonable to assume that the extent of protonation of B to give the reactive intermediate AH^+ (Scheme 2) is governed by the acidity function H_A (13), and that $[AH^+] \ll [BH^+]$ (*cf.* ref. 5). In such a case, the mechanism of Scheme 2 necessitates the following rate expression:

$$[1] \quad k_\psi = \{(k_1 h_A a_{H_2O}^r f_{AH^+})/(K_{AH^+} f_+)\} \times \{K_{BH^+}/(K_{BH^+} + h_0)\}$$

where k_1 is the rate constant for the reaction: $AH^+ + rH_2O \rightarrow$ products; a_{H_2O} is the activity of water; the f's are activity coefficients; and the other symbols can be understood by reference to Scheme 2. A plot against log a_{H_2O} of $(\log k_\psi + H_A - \log \{K_{BH^+}/(K_{BH^+} + h_0)\})$ for 1-acetyl-5,5-dimethyl-2-thiohydantoin, assuming $pK_{BH^+} = -6.4$,[4] gives a fairly good straight line between 24.2 and 88.4% sulfuric acid (correlation coefficient 0.9977) (see Fig. 6), as required by eq. 1 if (f_{AH^+}/f_+) is invariant with acid concentration. The r value of 0.61 given by the slope of this line is considerably lower than usual for amide hydrolyses (11); however, r values are found to become lower for hydrolyses in more concentrated acids (5). In any case, the change in slope above 84.2% acid is clearly indicative of a change from an A-2 to an A-1 mechanism (9). The intercept shown in Fig. 6 gives $\log (k_1 f_{AH^+}/K_{AH^+} f_+) = -4.45$ (if we make the usual assumption that the activity coefficient ratio is invariant with acid concentration (14)). Use of this value, and $r = 0.61$, gives the theoretical curve for the rates of hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin shown in Fig. 7.

[4]1-Benzoyl-2-thiohydantoin has a pK_{BH^+} of -6.6; substitution of methyl groups at the 5-position should affect the basicity very little, but substitution of the phenyl by a methyl group would be expected to strengthen the basicity slightly. The results of the calculations are not greatly affected by small variations in the precise pK_{BH^+} assumed.

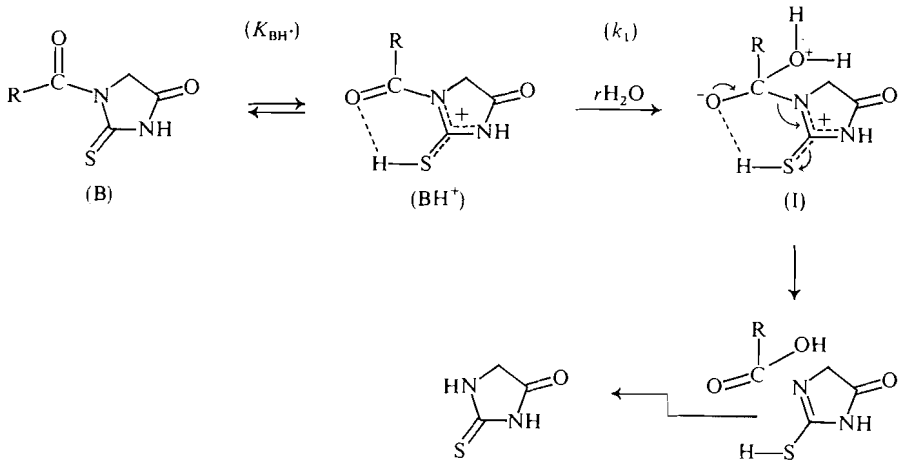

SCHEME 3

The agreement with the experimental points is reasonably good in view of the various assumptions, and offers strong support for the A-2 mechanism outlined in Scheme 2. An alternative mechanism would be that of Scheme 3, which would lead to the following rate equation:

$$[2] \quad k_\psi = \{k_1 a^r_{H_2O} f_{BH^+}/f_\ddagger\}\{h_0/(K_{BH^+} + h_0)\}$$

Analysis of the kinetic data by this equation yields $r = 1.65$ and $\log (k_1 f_{BH^+}/f_\ddagger) = -1.0$, but the fit with the experimental results is much poorer, as shown in Fig. 7.

Bunnett and Olsen (15) have produced an equation, based on a modification of the original hydration hypothesis (12), which has proved highly successful in predicting the variation of the rates of acid-catalyzed reactions with acid concentration. Applied to the kinetic situation of Scheme 2, this equation becomes

$$[3] \quad \log k_\psi + H_0 - \log\{K_{BH^+}/(K_{BH^+} + h_0)\} = \Phi(H_0 + \log[H^+]) + \text{constant}$$

A plot of $(\log k_\psi + H_0 - \log\{K_{BH^+}/(K_{BH^+} + h_0)\}$ against $(H_0 + \log[H^+])$ (assuming $[H^+] = [H_2SO_4]$ (16)) gives a curve of gratifying linearity up to 88% sulfuric acid, having a slope $\Phi = 0.81$, normal for an amide hydrolysis by an A-2 mechanism. Again, the change to a slope of $\Phi = -0.98$ in acid concentrations above 88% is indicative of a change to an A-1 mechanism. (see Fig. 8).

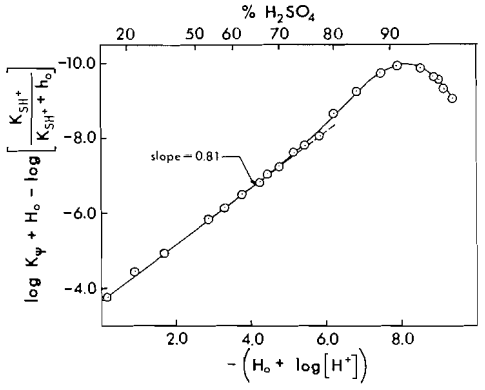

FIG. 8. A plot of $\{\log k_\psi + H_0 - \log [K_{SH^+} + (K_{SH^+} + h_0)]\}$ *vs.* $\{H_0 + \log [H^+]\}$ for 1-acetyl-5,5-dimethyl-2-thiohydantoin.

It is not possible to deduce a kinetic expression for the A-1 hydrolysis based on Scheme 1, because the required h_A values of strong sulfuric acid solutions are not available.

(2) Entropies of Activation

Plots of $\log k_\psi$ against $1/T$ for 1-acetyl-, 1-benzoyl-, and 1-acetyl-5,5-dimethyl-2-thiohydantoin gave straight lines from which entropies of activation ($\Delta S^\ddagger$) were calculated (Table 2). For hydrolyses in 39.6 and 84.9% sulfuric acid, these had about the values (near -20 e.u.) expected for an A-2 reaction (17); the marked increase in $\Delta S^\ddagger$ for hydrolyses in more concentrated acids was indicative of a change to an A-1 mechanism. In 96.4% sulfuric acid hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin would be expected to take place

(96.4)	35.5	24.2 ± 0.60			
	49.6	124.0 ± 4.00			
	58.1	266.0 ± 12.0			
1-Benzoyl-2-thiohydantoin	25.3	6.9 ± 0.10	8.6 ± 0.2	−21 ± 2	16 ± 2
(39.6)	35.5	16.8 ± 0.20			
	45.6	37.1 ± 0.72			

*Value obtained by interpolation from the rate profile.

nearly completely by the A-1 mechanism (see Table 1 and Figs. 3 and 7), and ΔS^* was −2 e.u., while hydrolysis of 1-acetyl-2-thiohydantoin would be expected, from inspection of Fig. 3, to be about 70% A-2 and 30% A-1, and ΔS^* was −5 e.u. Lack of information on the extent and position of diprotonation prevents a further interpretation of these values.

(3) Hammett $\rho\sigma$ and $\rho\sigma^+$ Relations

The rate profile for 1-benzoyl-2-thiohydantoin (Fig. 5) suggests an A-2 mechanism of hydrolysis in 0–90% acid and an A-1 mechanism in 90–100% acid. The rate constants (k_ψ) for the hydrolysis of 13 substituted 1-benzoyl-2-thiohydantoins in 58.0% sulfuric acid, of 10 substituted 1-benzoyl compounds in 84.6% sulfuric acid, and of 10 substituted 1-benzoyl compounds in 93.8% acid are given in Table 3 and Figs. 9 and 10.

An A-2 mechanism would be expected to result in log k_ψ varying as σ rather than σ^+; and this indeed is found for hydrolyses in 58.0% sulfuric acid, as shown in Fig. 9. The ρ given by the slope of the line is −0.41. A small value of ρ would be expected from the mechanism of Scheme 2 because of the compensating effects of substituents on the various pre-equilibria as well as on the rate-determining step; an exact estimate of the separate ρ values is difficult in the present case.[5] The mechanism of Scheme 3 might be expected to lead, however, to a larger ρ value than −0.41: ρ_1 for the step $B \rightleftharpoons BH^+$ should approach zero, but ρ_2 for the step $BH^+ + rH_2O \rightarrow$ products would be expected to be about +1 (19), so that the overall ρ_{ov} ($= \rho_1 + \rho_2$) should be about +1.

An A-1 mechanism would be expected to result in log k_ψ varying as σ^+ rather than σ: this is observed for hydrolysis in 93.8% acid (Fig. 9). The value of ρ (−2.51) thus obtained has about the magnitude observed for other A-1 reactions yielding acylium ions (21).

In 84.6% sulfuric acid, the plot of log k_ψ *vs.* σ changes slope at $\sigma \approx 0$ (Fig. 10). This is con-

[5]Models indicate that for the conformation of B shown in Scheme 1, the benzene ring cannot be coplanar with the carbonyl group (in such cases the carbonyl group is generally coplanar with trigonal nitrogen in preference to phenyl (18)). This would result in ρ values different from those of analogous substituted phenyl compounds in which the benzene ring approached coplanarity with the carbonyl group.

sonant with a mechanism dependent on the nature of the substituents in the benzoyl group: electron-releasing groups promote reaction by an A-1 mechanism (hence the steep slope of the line on the left-hand side of Fig. 10); electron-withdrawing groups ensure that the A-2 mechanism still predominates at this acid concentration (hence the small slope of the line on the right hand side of Fig. 10). This evidence can also be construed in support of the mechanism of Scheme 2 rather than that of Scheme 3.

(4) C-5 Substituent Effects

As shown in Fig. 4, substituents at the 5-position reduce the height but do not greatly alter the position of the rate maximum in plots of log k_ψ *vs.* acid concentration. From Fig. 3 it is apparent, however, that they do alter the position and depth of the minimum. The effect of C-5 substituents on the height of the maximum is interpretable in terms of steric hindrance to attack of water on the protonated substrate, as might be expected for an A-2 mechanism. Comparison of the entropy and enthalpy values for 1-acetyl- and 1-acetyl-5,5-dimethyl-2-thiohydantoin in 39.6% acid (Table 2) (bearing in mind the error discussion in ref. 17) leads to the following relative values: $T\Delta\Delta S^{\ddagger} = 1.5$ kcal; $\Delta\Delta H^{\ddagger} = 1.6$ kcal. The results are similar to those for formation and hydrolysis of semicarbazones (22) of substituted ketones. This decrease in $\Delta S^{\ddagger}$ is in agreement with the modified Hammett–Price rule for a reaction in a

*Analysis reported by Liu (26).

highly polar solvent having a highly polar transition state (23), in that the more highly complex molecule (with substituents adjacent to the reaction center) has a lower activation entropy.

(5) N-3 Substituents

As seen in Fig. 4, replacement of hydrogen by a phenyl group at the N-3 position increases the height of the maximum but does not affect its position in a plot of log k_ψ *vs.* percent acid. Also it may be noted that it decreases the minimum rate but not the position of the minimum. The phenyl group as noted earlier is more electron-withdrawing than hydrogen ($pK_{BH^+} = -4.83$ for 2-thiohydantoin and -5.18 for 3-phenyl-2-thiohydantoin (6)) so that one might expect a higher maximum for the A-2 mechanism, since the 3-phenyl-2-thiohydantoin would be a better leaving group. The result in concentrated acid is more important. For the A-1 hydrolysis of *m*- and *p*-(anilide) substituted mesitoylanilides in 96.2% sulfuric acid at 25 °C (which proceeds by *N*-protonation of the anilide) $\rho = 2.3$ (6). If one were to assume a similar mechanism for the A-1 hydrolysis of 1-acyl-2-thiohydantoins, one would expect the 3-phenyl group to enhance the rate. Instead, it decreases it by 30% (Table 4). This can be interpreted as support for an A-1 mechanism involving protonation of the C-4 carbonyl to give BH_2^{2+} (Scheme 1), since the basicity of this carbonyl should be appreciably affected by substituting a phenyl group at the N-3 position.

Experimental

Materials

1-Acyl-2-thiohydantoins were synthesized according to the method of Johnson and Nicolet (24), and were recrystallized from methanol or ethanol. 1-Benzoyl-3-phenyl-2-thiohydantoin (2) was a gift of J. K. Liu. Melting points (Table 5) were determined on a hot stage microscope and are uncorrected. Analyses were done by A. Bernhardt of West Germany, and are recorded in Table 6.

Basicity Measurements

Ultraviolet absorbance measurements were conducted in thermostatted 1 cm quartz cells in a Unicam recording SP-800 spectrophotometer following the general procedures of ref. 25, and are given in Table 7. Calculation by the usual procedures (25) gave the data shown plotted in Fig. 2.

Rate Measurements

Acid (3.00 ml) of known concentration was allowed to come to thermal equilibrium in a thermostatted (±0.1 °C) spectrophotometer cell with a Teflon stopper. Methanolic stock solution (8–10 μl) of the 1-acyl-2-thiohydantoin was then injected into the solution using a Hamilton syringe with a Chaney adaptor. The cell was shaken, placed back in the thermostatted cell block, and spectra were recorded after 3–10 min (shown in separate experiments to be sufficient to re-establish thermal equilibrium). Absorbance (A) measurements were made, most often at about 300 nm, but calculated rates were unaffected by the wavelength chosen. Rates were followed for at least two half-lives, and absorbance values for complete hydrolysis (A_∞) taken after 6–10 half-lives. Products were stable under reaction conditions, and in all cases the final spectrum was identical to that of an equimolar mixture of 2-thiohydantoin and the carboxylic

acid in the concentration of sulfuric acid used. Rate coefficients were calculated on an IBM-360 computer by a least squares program for log $(A_t - A_\infty)$ *vs.* time. Duplicate kinetic runs agreed to within 4%, and in nearly all cases correlation coefficients better than 0.998 for eight points were obtained. It was found that k_ψ was unaffected by substrate concentration over the range $5 \times 10^{-5} - 2 \times 10^{-3}$ M. Detailed numerical data for each run are recorded in ref. 29.

The financial support of the National Research Council of Canada is gratefully acknowledged. We are also most grateful to Dr. J. K. Liu for much preliminary experimentation, and to Professor R. J. Gillespie for informing us of his cryoscopic and conductometric studies of the ionization of 2-thiohydantoin in 100% sulfuric acid.

Thiohydantoins. XI. Kinetic Studies of the Alkaline Hydrolysis of 1-Acyl-2-thiohydantoins

WAYNE I. CONGDON[1] AND JOHN T. EDWARD
Department of Chemistry, McGill University, Montreal, Quebec

Received April 10, 1972

1-Acyl-2-thiohydantoins ionize in alkaline solution ($pK \sim 7$). In solutions more alkaline than $pH > 11$ they are rapidly hydrolyzed to 2-thiohydantoin and a carboxylic acid, by attack of a hydroxide ion on the conjugate base of the 1-acyl-2-thiohydantoin. Possible mechanisms to accord with the entropy of activation, which is less negative than usual for base-catalyzed amide hydrolyses, are discussed. 1-Benzoyl-2-thiohydantoin hydrolyzes more rapidly than 1-acetyl-2-thiohydantoin, possibly because the ground state of the former molecule is destabilized by steric effects.

Les acyl-1 thiohydantoïnes-2 s'ionisent en milieu alcalin ($pK \sim 7$). En milieu plus alcalin ($pH > 11$) ils s'hydrolisent rapidement aux acides carboxyliques et à thiohydantoïne-2, par l'attaque de l'ion hydroxide à la base conjuguée de l'acyl-1 thiohydantoïne-2. On réfléchit sur les mécanismes qui peuvent être en accord avec l'entropie de l'activation, qui est moins négative que les entropies de l'activation pour les amides plus ordinaires. Le benzoyl-1 thiohydantoïne-2 s'hydrolyse plus vite que l'acétyl-1 thiohydantoïne-2, peut-être parce que le premier est déstabilisé par les effets stériques.

The study of the deacylation of 1-acyl-2-thiohydantoins (**1**) by acid or alkali (1) is of interest in connection with the procedure of Schlack and Kumpf (2) for the stepwise degradation of peptides or proteins. This procedure received only desultory attention for many years (3), but lately has been the focus of renewed interest (4). It consists of reacting the C-terminal amino acid of a polypeptide (RCO—NHCH$_1$R″—COOH) or protein with ammonium thiocyanate to give a 2-thiohydantoin derivative, attached to the remainder of the peptide chain by a 1-acyl linkage, as in **1** (R = polypeptide, R′ = H). This 1-acyl linkage can then be selectively cleaved by acid or alkali under unusually mild conditions (1) to give the polypeptide (**2**) minus its original C-terminal amino acid, the latter being now incorporated in a 2-thiohydantoin (**3**) (see eq. 1). This facility of hydrolysis is shared by other amides (5–7) and esters (8) having electron-attracting groups attached to the nitrogen or oxygen atom which separates from the acyl group in hydrolysis; there is a very rough correlation between the rate of the reaction and the stability of the anion A^- derived by ionization of the amino or alcohol moiety HA formed in the hydrolysis (as measured by the pK_{HA} of HA (9–11)).

The mechanisms for the alkaline hydrolysis of various amides differ with regard to the timing of various proton-transfers (see DeWolfe and Newcomb (12) for an excellent, brief review), and reference to them will be made later. However, we should first note that *p*-nitroacetanilide (pK_{HA} 13.8 (6)) and diacetylimine (**6**) (pK_{HA} 12.9 (7)) ionize as acids in dilute aqueous sodium hydroxide. Kinetic studies (6, 7) indicate that the hydrolysis of both of these compounds takes place by attack of hydroxide ion on the unionized compound (*e.g.*, **6**), and not on the anion (*e.g.*, **5**), presumably because the negative charge of the latter is delocalized over the amide

[1] 
4 **1** **2** **3**

[1]Holder of NRCC Studentship, 1968–1970.

[2] 
carbonyl group and decreases its electrophilic character drastically (see eq. 2).

1-Acyl-2-thiohydantoins also ionize as weak acids ($\mathbf{1} \rightarrow \mathbf{4} + H^+$), and have pK_a values of 6.5–7.0 (Table 1). Consequently, in the solutions more alkaline than pH 9, in which they begin to be hydrolyzed at appreciable rates, they must be more than 99% in the ionized form **4**. However, the negative charge of **4** is not delocalized over the 1-acyl carbonyl group which is attacked in hydrolysis, and so this charge might be expected to reduce its reactivity by a factor of about 10^2 (*cf.* ref. 13) or less. In such a case the greater reactivity of **1** would not be expected to compensate for the greater abundance of **4**. This expectation is realized: the rates for the hydrolysis of various 1-acyl-2-thiohydantoins in a large excess of buffer or alkali (at constant ionic strength) is first-order in hydroxide ion concentration, as shown by the invariance of the second order rate constants k_b ($=k_\psi/[OH^-]$) in Table 2. Consequently, hydrolysis must proceed mainly by attack of

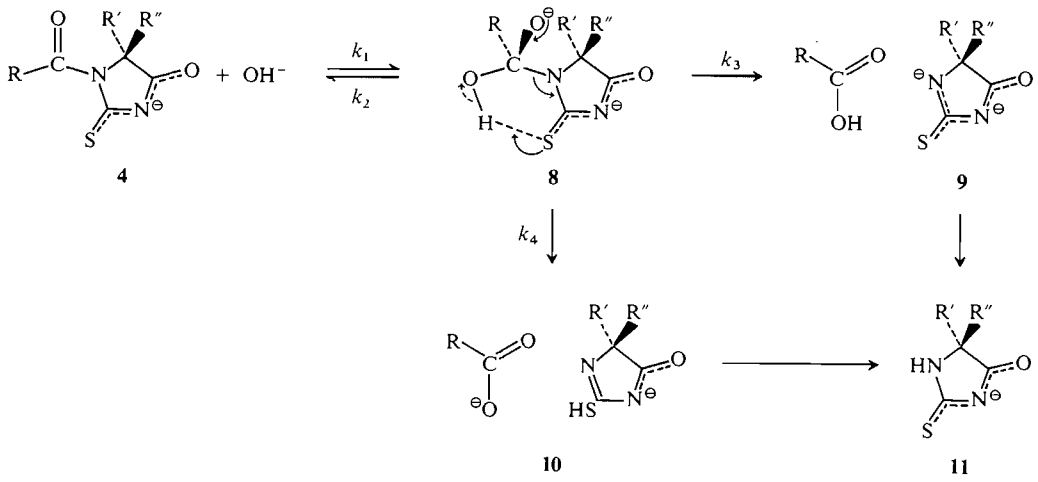

SCHEME 1

hydroxide ion on the anion **4** (*cf.* discussion in ref. 7).

This accords with observations of the effect of ionic strength on the rate of the reaction. For a reaction between two charged ions the observed rate will be given by:

$$[3] \quad \log k_b = \log k_0 + 1.02\, Z_a Z_b \sqrt{\mu}/(1+\sqrt{\mu})$$

where k_0 is the second order rate constant at zero ionic strength, and μ is the ionic strength (14*a*). In the present instance the ionic charges $Z_a = Z_b = -1$, so that k_b increases with ionic strength. The plot of $\log k_b$ for the hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin *vs.* $\sqrt{\mu}/(1+\sqrt{\mu})$ gives a curve similar to that obtained for the base-catalyzed hydrolysis of a series of dicarboxylic acid half esters EtO—CO—$(CH_2)_n$—CO_2^- ($n = 0$–4) (15), with the slope approaching unity as $\mu \to 0$. This is shown in Fig. 1, which indicates that the second-order rate constant more than doubles on going from $\mu = 0$ to $\mu = 1$.

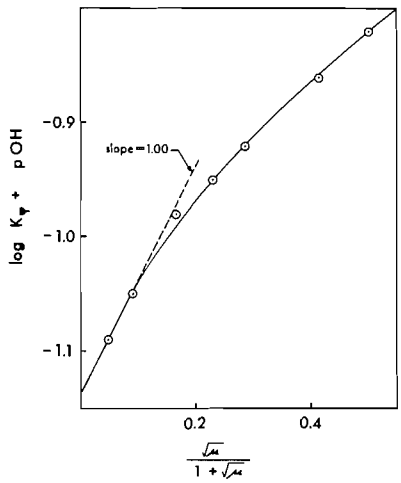

FIG. 1. A plot of $\log k_b$ ($\equiv \log k_\psi + pOH$) (in l mol^{-1} s^{-1}) against $\sqrt{\mu}/(1+\sqrt{\mu})$ for 1-acetyl-5,5-dimethyl-2-thiohydantoin at 25.4 °C.

The mechanisms which best accommodate these and other experimental facts discussed below are outlined in Scheme 1. Formation of the tetrahedral intermediate **8** (*cf.* refs. 5, 6, 12) will be hindered by bulky groups at the 5-position, particularly if hydrogen-bonding between the new hydroxyl group and the strongly basic sulfur atom, as shown in **8**, causes eclipsing of the groups at the 5-position with groups in the newly-tetrahedral atom. Steric hindrance will be especially severe for the solvated anionic oxygen. This may explain the retardation of alkaline hydrolysis by substitution, and more especially by geminal disubstitution, at the 5-position, as shown in Table 4. Substitution at this position is less effective in retarding acid-catalyzed hydrolysis, as can be seen by comparing the last two columns of Table 3, although it has usually been thought that steric effects on both base- and acid-catalyzed hydrolyses are the same (16). The

[a]Based on $k_b = k_\psi/[OH^-]$ in l mol^{-1} s^{-1}.
[b]The standard state for ΔS^+ utilizing k_b is 1 mol per liter and Δn^+ in the Arrhenius equation is assumed small since this is a bimolecular reaction in solution (14*b*).
[c]These values have been corrected for the effect of ionic strength at one temperature (25.3 °C).

difference in the present instance may reflect the difference in the proximity of the 5-substituents to the charged centers in **8** and in **12**, the tetrahedral intermediates for alkaline- and acid-catalyzed hydrolysis (17) respectively, and hence their different effects on the solvation required to stabilize these charged intermediates (see eq. 4).

The mechanism of Scheme 1 also takes account of measurements of the Arrhenius parameters for the base-catalyzed hydrolysis, which show its rapidity to be determined chiefly

[4] 
12

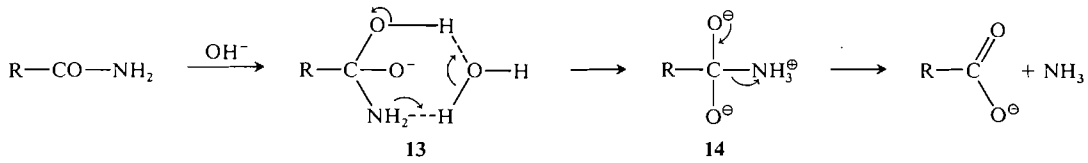

SCHEME 2

by favorable entropy factors. Plots of log $(k_\psi/[OH^-])^2$ against $1/T$ (shown in Fig. 2) give straight lines, the slopes of which give the activation energy ($E_a/2.3R$) in kcal mol^{-1} and the intercept, the logarithm of the frequency factor, log A_t, in 1 mol^{-1} s^{-1} (Table 4). This must be modified for the effect of ionic strength at one temperature to obtain meaningful entropy values.

The results in Table 4 show that the very rapid hydrolyses of 1-acetyl-2-thiohydantoin (**1**; R = Me, R′ = R″ = H) and of 1-benzoyl-2-thiohydantoin (**1**; R = Ph, R′ = R″ = H) are due to favorable entropy factors, as measured by the A_t values for the reactions, and not to low energies of activation. (For comparison,

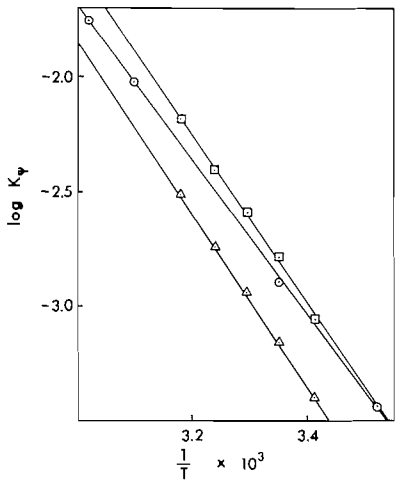

FIG. 2. Arrhenius plots for the hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin (○), 1-benzoyl-2-thiohydantoin (□), and 1-acetyl-2-thiohydantoin (△) in phosphate buffer (see Table 5).

[2]Hydroxide ion concentration was calculated from pH measurements of buffer solutions at 25°. However, the hydroxide ion activity (or concentration) will not be constant for the same buffer composition but different temperatures, so the activation parameters must be regarded as only approximate. We are indebted to a referee for making this point.

log A_t for the alkaline hydrolysis of acetamide and benzamide is 4.4 and 4.2 l mol^{-1} s^{-1}, respectively, and E_a is 14.3 and 12 kcal^{-1} mol^{-1}, respectively (18)). The A_t values are derived from the overall rate constant k_b, which according to the steady-state principle applied to the mechanism of Scheme 1, should be given by

$$[5] \qquad k_b = \frac{k_1(k_3 + k_4)}{k_2 + k_3 + k_4}$$

In such a case the frequency factor A_t should depend on the individual frequency factors for the different reactions k_1, k_2, k_3, and k_4 (19). In general, the frequency factor is reduced by about 10^2 by electrostatic effects between two particles each bearing a charge of -1 (14*c*). If in the present instance the frequency factor for k_1 is so reduced, the high values of A_t must result from compensation by very high values for the frequency factors for k_3 and k_4, as compared with the frequency factor for the corresponding step in the hydrolysis of acetamide or benzamide (19). The latter is expected to be low because of stringent requirements for the ordering of solvent if, as seems probable (*cf.* refs. 5, 12), the mechanism for the hydrolysis is given by Scheme 2 with the formation of the zwitterion **14** (or something closely similar). On the other hand, the breakdown of the tetrahedral intermediate **8** for the hydrolysis of 1-acyl-2-thiohydantoins either does not require a proton-transfer (in the k_3 route), and leads to a dianion (**9**) with low solvation requirements (unlike **14**) because of the dispersal of the double charge, or else requires a proton-transfer (in the k_4 route) which can be effected internally without the necessity for ordering of solvent (as required in **13** → **14**).

While both routes (k_3 and k_4) of Scheme 1 are compatible with the evidence to date, it is difficult to know whether in fact both are kinetically significant, or whether the hydrolysis

proceeds by essentially only one route. Further investigations (*e.g.* of solvent isotope effects) would seem to be required.

A second factor promoting the rapid hydrolysis of 1-acyl-2-thiohydantoins in alkali is steric. This is shown up by an examination of the relative rates of hydrolysis of 1-acetyl- and of 1-benzoyl-2-thiohydantoin. In general, one expects amides and esters of acetic acid to be hydrolyzed more rapidly than the corresponding esters and amides of benzoic acid, and this is usually found true, as shown in Table 5. Thus ethyl acetate is saponified 11 times more rapidly than ethyl benzoate: the latter is stabilized by resonance interaction (admittedly weak (20)) between the benzene ring and the ester carbonyl group, and this resonance stabilization is lost in forming the tetrahedral intermediate. (The difference in rates becomes less for the amides, to the extent that the nitrogen atom releases electrons to the carbonyl group more readily than the oxygen atom, and so lessens the importance of phenyl–carbonyl resonance interaction.) However, surprisingly, the 1-benzoyl-2-thiohydantoins are found to hydrolyze in alkaline solution more *rapidly* than the corresponding 1-acetyl-2-thiohydantoins (Table 5).

Obviously a new factor is at work which is missing from the first three pairs of compounds of Table 5, and an examination of models suggests that this factor is steric. The 1-acyl group can be expected to be as much as possible coplanar with the thiohydantoin ring in order to maximize its amide-type resonance interaction with N-1 (21). For 1-acetyl-2-thiohydantoin, two coplanar conformations are possible: that in which the acyl carbonyl and the thiocarbonyl groups are aligned parallel; and that shown in Fig. 3, in which the acyl oxygen and thiocarbonyl sulfur are separated as much as possible. The former conformation involves very strong dipolar repulsions, and is expected to be strongly disfavored (22). However, for 1-benzoyl-2-thiohydantoin, the conformation which maintains the coplanarity of the acyl group with the thiohydantoin ring, and which avoids the dipolar repulsions, requires the benzene ring to be twisted about 90° out of the plane of the acyl group in order to avoid steric interference between the bulky sulfur atom and the ortho-hydrogens of the benzene ring (see Fig. 4).

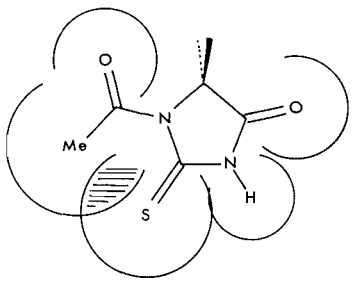

FIG. 3. Scale drawing of 1-acetyl-2-thiohydantoin, using bond-lengths and van der Waals radii from crystallographic studies of related compounds (32). The van der Waals radii for hydrogen and for the methyl group may be somewhat too large (33), and hence the overlap of methyl and sulfur would not seriously affect coplanarity of the acetyl group with the rest of the molecule.

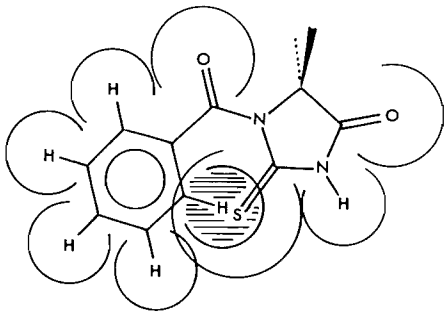

FIG. 4. Scale drawing of 1-benzoyl-2-thiohydantoin.

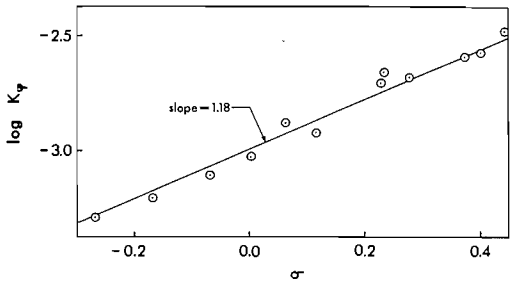

FIG. 5. A plot of log k_ψ against σ for *m*- and *p*- substituted 1-benzoyl-2-thiohydantoins (c.c.: 0.9902; s.d.: 0.05) in aqueous phosphate buffer, p*H* 10.75, $\mu = 0.42$, at 25.3 °C.

In fact, it seems likely that the steric congestion in 1-benzoyl-2-thiohydantoin is relieved by some rotation about *both* the phenyl—CO and the CO—N_1 bonds,[3] because the Hammett reaction constant ρ, given by the slope (1.18) of the plot of log k_ψ against σ for 12 *m*- and *p*-substituted 1-benzoyl-2-thiohydantoins (Table 7 and Fig. 5), has a value very close to that (1.055 (23)) reported for the alkaline hydrolysis of *m*- and *p*- substituted benzamides. This closeness is probably due to the operation of two opposing sets of factors. The lessening of electron-release from N-1 because of the juxtaposed thiocarbonyl, and because of twisting about the CO—N_1 bond, should increase ρ above 1.055; the lessening of resonance interaction between *m*- and *p*- substituents and the carbonyl group, by twisting about the phenyl—CO bond, should decrease ρ below 1.055 (24). The twisting about both Ph—CO and CO—N_1 should make the formation of the tetrahedral intermediate less costly (in terms of the loss of resonance energy), and should explain why the hydrolysis of 1-benzoyl-2-thiohydantoin goes faster than the hydrolysis of 1-acetyl-2-thiohydantoin.

It can be seen from Fig. 3 that any increase in size beyond that of the methyl group of 1-acetyl-2-thiohydantoin will lead to steric congestion between thiocarbonyl sulfur and the acyl group. This will be true for the acyl group derived from any amino acid, and so the 2-thiohydantoin derivative formed from the C-terminal amino acid of any peptide should be expected to be hydrolyzed in alkali at a greater rate than is 1-acetyl-2-thiohydantoin. It would seem, then, that the facility of Schlack and Kumpf's procedure for degrading peptides depends on favorable entropy and steric effects in the hydrolysis of the 2-thiohydantoin intermediates.

It is evident from Table 5 that the greater ease of acid-catalyzed hydrolysis of acetyl as compared with benzoyl derivatives extends to the hydrolysis of 1-acyl-2-thiohydantoins, in spite of the steric effects destabilizing the benzoyl derivatives. These effects would be expected to increase the rate of attack of water on the protonated 1-acyl-2-thiohydantoin to form the tetrahedral intermediate **12**; however, it is

[3]Alternatively, coplanarity of the benzene ring and the carbonyl group can be maintained if the alternative conformation having parallel carbonyl and thiocarbonyl groups is adopted. This conformation would explain the greater reactivity of 1-benzoyl- as compared with 1-acetyl-2-thiohydantoin, but is made less likely by the Hammett ρ value for the reaction.

apparent that this is more than offset by the decrease in the basicity of the 1-acyl group resulting from diminished Ph—CO and CO—N_1 resonance interaction (*cf.* refs. 25, 26).

Experimental

All compounds were made and purified according to the procedure of Johnson and Nicolet (27). Most were known compounds; physical properties are listed in Table 7 for compounds not described in ref. 17. Buffer solutions were made using Fisher reagent grade KCl, K_2HPO_4, K_3PO_4 and distilled water. p*H* values were measured at 25.4 °C using a TTT-1 automatic titrator and a Radiometer 202-C electrode *vs.* a saturated calomel electrode. p*H* values were found to remain constant during the reaction. For buffer solutions above p*H* of 12, standard B.D.H. sodium hydroxide (1 *N*) was used with KCl to prepare solutions; the p*H* values reported were calculated from the relation: $pH = 14 + \log [OH^-]$.

For the kinetic runs, 3.00 ml of buffer was allowed to come to thermal equilibrium in a stoppered u.v. cell contained in a thermostatted cell compartment. A methanolic solution (10 μl) of 1-acyl-2-thiohydantoin was then injected, using a Hamilton syringe with Chaney adaptor, the cell was vigorously shaken, and the absorbance (D) at constant wavelength was recorded by a Unicam SP 800 recording u.v. spectrophotometer fitted with scale expander and slave recorder attachments. Measurements were always made in the region 300–330 nm, because the 2-thiohydantoin has no appreciable absorption in this region, and so its further hydrolysis has no spectral consequences. Results were analyzed by a linear least squares program using log $(D_t - D_\infty)$ *vs.* time. D_∞ was taken after 7–10 half-lives, and for several slow reactions Guggenheim's method was used. Correlation coefficients for individual runs were generally greater than 0.999 for 8 points, and separate runs were found to be reproducible to within 3–4%. The experimental data on which some of the entries of Table 6 are based are given in Table 8.

We acknowledge gratefully much preliminary experimentation by Dr. J. K. Liu, helpful criticism by Professor R. Stewart, and financial support from the National Research Council of Canada.

The Trifluoroacetic Acid Solvent System. Part IV. Triple Ions

M. G. HARRISS AND J. B. MILNE

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received June 5, 1972

Electrolytes studied in 100% trifluoroacetic acid exhibit a minimum in equivalent conductivity with increasing solute concentration. This behavior is accounted for by the formation of triple-ions at higher concentrations. Triple-ion dissociation constants, k, have been evaluated and, in general, they show the opposite trend with changing ion size to that of the ion-pair dissociation constants; that is the triple-ions of smaller ions are more dissociated. The experimentally observed trend is accounted for by using a partial ionic charge instead of unit charge for the ion-pair charges in the theoretical Fuoss expression for k.

The excellent extrapolation of the triple-ion data to give a value of $\Lambda^0 K_d$ for the ion-pair, which agrees well with that determined from a Fuoss plot, permits an estimate of Λ^0 for LiO_2CCF_3 from the triple-ion data.

Les électrolytes étudiés dans l'acide trifluoroacétique à 100% montrent un minimum, à conductivité équivalente, pour une concentration croissante en soluté. Ce phénomène s'explique par la formation d'ions triples en concentrations élevées. Les constantes de dissociation des ions triples k ont été évaluées; elles varient généralement en sens contraire, par rapport aux constantes de dissociation des paires d'ions, avec le changement dans la taille de l'ion. Cette tendance, observée expérimentalement, a été interpretée en utilisant une charge ionique partielle, au lieu de l'unité pour les charges des paires d'ions dans l'expression théorique de Fuoss pour k.

L'excellente extrapolation des données sur l'ion triple pour la valeur $\Lambda^0 K_d$ de la paire d'ion, en bon accord avec la valeur tirée de la courbe de Fuoss, permet une estimation de Λ^0 pour LiO_2CCF_3 à partir des données sur l'ion triple. [Traduit par le journal]

Introduction

A plot of equivalent conductivity *vs.* concentration for electrolytes in solvents of dielectric constant <20 exhibits a minimum if sufficiently high concentrations are studied. This has long been known for many of the classical non-aqueous solvents of interest to inorganic chemists such as ammonia (1), sulfur dioxide (2), acetic acid (3) and, more recently, 100% hydrogen chloride (4). The effect was accounted for by the proposal of Fuoss and Kraus that triple-ions are formed in these solutions (5). The equilibria concerned account for the initial decrease in concentration of current-carrying species per mole of added solute, followed by the subsequent increase with the formation of triple-ions

$$3A^+ + 3B^- \rightleftarrows 3AB \rightleftarrows A_2B^+ + AB_2^-$$

The mathematical treatment of the electrical conductivity data in the concentration region of triple-ion formation has been presented often (5–8) and will not be repeated here. The treatment accounts very well for the experimental observations.

Davies (9) has put forward another theory to account for the minimum in solvents of $\varepsilon \sim 12$ or greater which is based upon activity effects. He suggests that, in the expression for the thermodynamic equilibrium constant for ion-pair dissociation

$$K_D = \frac{f^2 c\gamma^2}{f_{i,pr}(1-\gamma)}$$

if the function $f^2 c/f_{i,pr}$ passes through a maximum with increasing concentration, γ and Λ will exhibit a minimum.

On the basis of the knowledge acquired for the concentration region where simple ion-pair equilibria are involved (10, 11), extension of the interpretation to higher concentrations, more usual in the use of this solvent for preparative purposes and kinetic studies (12–14) is possible and forms the subject of this work.

Experimental

Details of the purification of materials and procedure for the measurement of electrical conductivities are given in Parts I and III (10, 11). Triple-ion dissociation constants, k, were evaluated by a least-mean-squares plot of eqs. 2 and 3 (see below), which was conducted

For personal use only.

and extrapolated by computer. The evaluation of the limiting equivalent conductivity of the single-ions, Λ^0, from specific conductances in the triple-ion region and a single point in the ion-pair region was performed by computer also.

Results and Discussion

Evaluation of Triple-Ion Dissociation Constants

The results of conductivity measurements for solutes in the triple-ion concentration region are given in Table 1. A minimum in Λ is observed in all cases except for $B(O_2CCF_3)_3$. A curve of Λ *vs.* $\sqrt{c}$, synthesized for any of the electrolytes using the data from the ion-pair concentration region and the extended Debye–Hückel expression for the activity coefficient, shows no minimum; this eliminates Davies' "Dissociation Minimum" theory (9) as a possible explanation of the results. However the data are readily interpreted in terms of triple-ion formation.

The triple-ion dissociation equilibria are

$$A_2B^+ \overset{k_+}{\rightleftarrows} AB + A^+$$

$$AB_2^- \overset{k_-}{\rightleftarrows} AB + B^-$$

In no instance has a complete solution for k_+, k_- and the individual λ_T^0 for the triple-ions in any solvent ever been accomplished; the simplifying assumption that $k_+ = k_- = k$ is required to effect a solution. The simple treatment (8), which ignores long range interionic effects, yields the expression

$$[1] \qquad c^{1/2}\Lambda = \sqrt{K_D}\Lambda^0 + \frac{\sqrt{K_D}\Lambda_T^0}{k}\, c$$

where K_D is the ion-pair dissociation constant and Λ_T^0 is the equivalent conductivity of the hypothetical electrolyte $[M_2A^+][MA_2^-]$. According to this expression, a plot of $c^{1/2}\Lambda$ *vs.* c will yield a straight line with an intercept, $\sqrt{K_D}\Lambda^0$ and slope, $\sqrt{K_D}\Lambda_T^0/k$. A more sophisticated equation which introduces a blanket correction for long range interionic effects (5–7) is given by:

$$[2] \qquad \frac{c^{1/2} f\Lambda}{\left\{1 - \dfrac{(B_1\Lambda^0 + B_2)\sqrt{c\Lambda}}{(\Lambda^0)^{3/2}}\right\}\left(1 - \dfrac{\Lambda}{\Lambda^0}\right)^{1/2}} = \sqrt{K_D}\Lambda^0 + \frac{\sqrt{K_D}\Lambda_T^0}{k}\, 1\left(-\frac{\Lambda}{\Lambda^0}\right)c$$

where B_1 and B_2 are defined as in (8) and the other parameters are defined as above. A plot of this expression yields the same slope and intercept as for the simpler expression. Elimina-

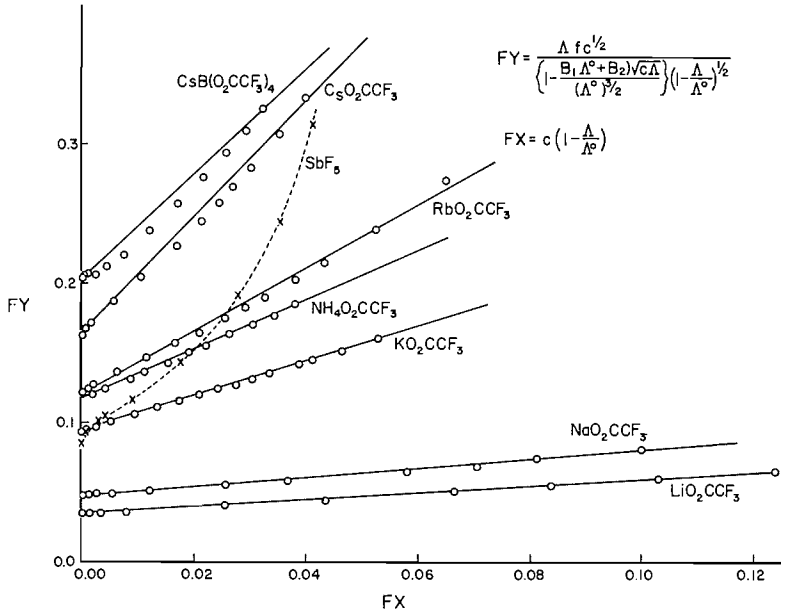

FIG. 1. Triple-ion plots with long-range interionic effects allowed for (eq. 2).

tion of $\sqrt{K_D}$ between the slope and intercept gives

$$\frac{\text{Intercept}}{\text{Slope}} = \frac{\Lambda}{\Lambda_T^0} k$$

and a knowledge of the ratio of $\Lambda^\circ/\Lambda_T^0$ permits evaluation of the triple-ion dissociation constant, k. Various assumptions and estimates of this ratio ranging from 0.33 to 0.82 have been used (5, 7, 15).

The results of the plot by the method of least squares of both eqs. 1 and 2 are given in Table 2 and the plots for eq. 2, are shown in Fig. 1. In the evaluation of eq. 2, the extended Debye–Hückel expression for the activity coefficient was used with "a", the distance of closest approach, set at the value for the ion-pair (10). Since the proportion of single ions to triple-ions will change with concentration, "a" will be a function of concentration but this effect will be small and has been ignored in this treatment. Both K_D from the Fuoss plot (ion-pair region) (10) and that calculated from the triple-ion plot intercept, using Λ° from the Fuoss extrapolation (10), (K_D') are given in Table 2 as well as the % error in K_D' as determined from the mean % deviation of the experimental points from the line. The triple-ion dissociation constants have been determined assuming $\Lambda_D^0/\Lambda^0 = 0.43$. This ratio is arrived at by assuming Stoke's law dependence of mobility on ion diameter and taking the average triple-ion diameter to be 7/3 that of the single ions, that is the average for the three orientations of the triple ion along the Cartesian coordinates. From the data in Table 2 it may be seen that for all but the solutes $B(O_2CCF_3)_3$ and SbF_5, the more refined treatment (eq. 2) gives a better description of the behavior as judged by the % error in K_D' and the excellent agreement between the ion-pair dissociation constant calculated from the triple-ion plot (K_D') and that from the Fuoss extrapolation (K_D). From Fig. 1, however, it may be seen that serious departures from straight line behavior occur for some of the solutes, especially those with low single ion mobilities. Positive deviations of FY (see Fig. 1) are expected for solutes with small Λ^0 since in such cases the denominator of FY will approach zero at relatively low concentrations; that is when

$$\frac{(B_1\Lambda^0 + B_2)\sqrt{c\Lambda}}{(\Lambda^0)^{3/2}} \approx 1$$

For example the denominator of FY becomes zero for SbF_5 when $c = 0.067$ M. The source of

these departures may be traced back to the use of the Limiting Law for electrical conductance in the derivation of eq. 2.

No minimum in equivalent conductivity is observed for the solute $B(O_2CCF_3)_3$ up to 0.1 *M*. This solute is known to weakly ionized (as opposed to dissociated) (11) and the concentration of ions and ion-pairs is probably not sufficiently high to permit triple-ion formation at the concentrations studied.

Evaluation of Λ^0 from Electrical Conductivity Measurements in the Triple-ion Region

For most of the solutes studied the agreement between K_D, calculated from the Fuoss extrapolation and that determined from the intercept of the triple-ion plot using eq. 2, was sufficiently good that an attempt was made to evaluate Λ^0 for LiO_2CCF_3, for which Fuoss extrapolation was not possible (10), in the following way. A series of K_D were generated for various values of "*a*" by use of the theoretical Fuoss equation for ion-pair dissociation (ref. 6, p.213). From these, using the highest concentration specific conductance point in the ion-pair region (10^3 $c = 0.1797$ mol l^{-1}; 10^6 $K_{sp} = 0.4906$ ohm^{-1} cm^{-1}), which should be the least affected by solvent self-dissociation or impurity ions (see (10)), a series of Λ^0 were calculated, using the expressions for Λ and K_D applicable in the ion-pair region (10). The Λ^0 were then used to extrapolate the data for the triple-ion region and to evaluate K_D' from the intercepts. The best Λ^0 was that which gave the closest agreement between the K_D assumed and that calculated from data in the triple-ion region. Table 3 gives a list of Λ^0 for the univalent trifluoroacetates calculated in this way. Λ^0 from Fuoss extrapolations are given for comparison. The data show that the procedure gives a reasonably accurate estimate of Λ^0. The Li^+ ion is more mobile than the Na^+ ion in trifluoroacetic acid, continuing the trend of greater mobility for the smaller cation and emphasizing further the low solvating capacity of this solvent for cations (10).

Comparison with the Theoretical Expressions for k_T

The order of the triple-ion dissociation constants in Table 2 as determined by either eq. 1 or 2, in relation to ion size, is interesting. The triple-ions of the univalent trifluoroacetates from

TABLE 3. Comparison of Λ^0 (ohm^{-1} cm^2 equiv^{-1}), calculated from the ion-pair (Λ^0) and triple-ion ($\Lambda^{0\prime}$) regions

Solute	Λ^0	Λ^0
LiO_2CCF_3	—	112
NaO_2CCF_3	73.79	73
KO_2CCF_3	63.73	66
$NH_4O_2CCF_3$	54.73	54
RbO_2CCF_3	58.60	59
CsO_2CCF_3	51.76	56

NaO_2CCF_3 to CsO_2CCF_3 are more dissociated the smaller the cation; exactly the opposite to the change in degree of dissociation of the ion-pair to single ions and to that predicted on electrostatic grounds alone. The trend in k is reversed, however, for LiO_2CCF_3 and $CsB(O_2CCF_3)_4$ in as much as the triple-ions of LiO_2CCF_3 are less dissociated than those of NaO_2CCF_3 and those of $CsB(O_2CCF_3)_4$ are more dissociated than for CsO_2CCF_3.

Two theoretical expressions for the triple-ion dissociation constant have been derived. The Fuoss–Kraus expression (5) is given by

$$[3] \qquad k^{-1} = \frac{2\pi Na^3}{1000} I(b)$$

where "*a*" is the distance of closest approach of the ion to the ion-pair and $I(b)$ is a tabulated function. This expression is analogous to that for ion-pair dissociation derived by Bjerrum and suffers from the same objections in ignoring the molecularity of the solvent. Fuoss has derived an expression for triple-ion dissociation based upon a molecular approach

$$[4] \qquad k^{-1} = \frac{\pi Na^3}{1000} \exp\,(b/2 - 3 - E_s/kT)$$

$$b = \frac{z_1 z_2 e^2}{\varepsilon kTa}$$

and E_s is the solvation energy change occurring on association of the ion-pair and the ion (other constants are defined above or in (8)). The -3 in the exponential function allows for the entropy change associated with the solute species (6).

Table 4 gives a comparison of calculated k with experimental values. For evaluation of the theoretical expression "*a*" has been set equal

to 1.5 × the value of "a" for the ion-pair. It may be seen that the earlier theoretical expression (eq. 3) predicts the observed general trend in k with increasing cation size although the behavior of LiO_2CCF_3 and $CsB(O_2CCF_3)_4$ is not accounted for.

For the evaluation of the Fuoss expression (eq. 4) a value for E_s is required and this has been determined in only one instance (ref. 6, p. 262). Table 4 shows, however, that, calculation using eq. 4 with exp ($b/2$) or exp ($b/2 - 3$) gives changes in k with the opposite general trend to that observed. E_s for association would very probably be positive, since there is a change from solvation of two species, one a relatively small single ion, to solvation of a large triple-ion. Moreover, E_s would be small in comparison to $b/2$ and therefore, the use of exp ($b/2 - 3 - E_s/kT$) would not have a large effect on k and, if anything, would exaggerate the trend towards greater dissociation with large ions since the magnitude of the exponential term would be smaller. It should be noted, however, that E_s would be larger in the smaller ion case and this effect, while small, would offset the general trend towards greater association for the smaller ion predicted.

The basis of the derivation of eq. 4 provides some insight into the trend of change in k with ion size and suggests a possible modification of the expression to account for the trend. The triple-ion dissociation constant is an inverse function of the collision volume of the ion pair and the Boltzmann factor associated with the energy change upon association (6):

$$k^{-1} \propto [\text{collision volume}][e^{b/2}]$$

Thus as ion size increases: (a) the collision volume increases and triple-ion dissociation decreases; (b) working in the opposite direction, the energy released upon association decreases and the triple-ion dissociation increases. Obviously, the general trend in Table 4 shows that collision volume is predominant and the exponential factor has a smaller effect than allowed for in the Fuoss expression.

The Boltzmann factor is determined assuming the ions in the contact ion-pair have unit charge; however, mutual polarization will result in a net reduction in charge. Allowance for this effect reduces the sharp fall-off in the exponential term with increasing ion size and the volume factor becomes predominant in determining k. Estimation of the partial ionic charge on the ions in an ion-pair may be made by considering the relative electronegativities of the cation and anion (16). No experimental value for the electronegativity of the $[CF_3CO_2]$ group is available in the literature but the comparable acid strengths of HO_2CCF_3 and HCl and comparable electronegativities of Cl and the average of the atoms making up the $[CF_3CO_2]$ group, suggest that the electronegativity of Cl should be a fair approximation. The partial charges, $e^{b/2}$ factors and k from this calculation are listed in Table 4. It may be seen that consideration of partial charge reproduces the relative order of k observed experimentally. The observed and theoretical k differ in magnitude, but better agreement would be achieved if the entropy change in both solute and solvent and the enthalpy change upon dissociation were considered since these would have the effect of making the exponential term smaller and, thus, k larger. Completely satisfactory agreement would also require improvements in the treatment of the electrical conductivity data such as allowance for different triple-ion dissociation constants, k_+ and k_-, use of a conductance equation other than the Limiting Law, consideration of the variation in "a" with concentration and evaluation of the ratio, Λ_T^0/Λ^0.

Conclusion

The dissociation behavior of triple-ions in trifluoroacetic acid is, in general, opposite to that of their respective ion-pairs; that is, the triple-ions formed with the smaller cation are more dissociated. That this is so is readily seen by comparing Λ at comparable concentrations in the triple-ion region for different solutes in Table 1. A plot of Λ *vs.* c for acetates in acetic acid from data in the literature (3, 17) shows analogous behavior. For trifluoroacetic acid, at the two ends of the scale of ion size (LiO_2CCF_3 and $CsB(O_2CCF_3)_4$), in terms of the Fuoss expression for k (eq. 4), the Boltzmann factor predominates and the solute triple-ions containing Li are less dissociated than those of Na with the larger cation; similarly, the triple-

ions of CsO_2CCF_3 are less dissociated than those of $CsB(O_2CCF_3)_4$, which has the larger anion. However for the remaining solutes, excluding SbF_5 which is an acid and not readily compared to the others, the size of the solute species and their collision probability predominates; thus, the triple-ions containing the larger cation are the least dissociated.

Some Mixtures of Carbon Tetrachloride with Several *n*-Alkanes: Enthalpies and Energies of Mixing[1]

JAMES M. BERRYMAN[2] AND E. L. HERIC[3]

Department of Chemistry, University of Georgia, Athens, Georgia 30601

Received June 14, 1971[4]

Molar enthalpies of mixing for the five *n*-alkanes from pentane through nonane with carbon tetrachloride at 298.15 K have been measured. The maximum values are, with increasing chain length, 295, 315, 339, 373, and 417 J. Energies calculated from the enthalpies are compared with the lattice theory of mixtures. The comparison is also extended through hexadecane, using previously reported results.

Nous avons mesuré les enthalpies molaires de mélange de cinq *n*-alcanes, du pentane au nonane, avec le tétrachlorure de carbone à 298.15 K. Avec la longueur de chaîne croissante, les valeurs maximales sont, 295, 315, 339, 373 et 417 J. Nous comparons les énergies calculées à partir des enthalpies avec la théorie des réseaux de mélanges. Nous étendons la comparaison à l'hexadécane au moyen de résultats publiés antérieurement.

Introduction

Previous workers have considered Guggenheim's lattice theory of mixtures (1) for binary systems of *n*-alkanes and a dissimilar common second component. For example, Gainey and Young (2) found that the activity coefficients of benzene at infinite dilution in the alkanes from *n*-C_5 through *n*-C_{32} were adequately explained by this approach. Vesely (3) reported, however, that the theory agreed to a degree with experimental molar energies of mixing of cyclohexane with *n*-alkanes which ranged from very good to semi-quantitative as the chain length increased from *n*-C_6 to *n*-C_{16}.

Everett and Swinton (4), commented in 1963 on possible "genuine departures" of their results from lattice theory behavior. The theory continues to be examined, both in its originally intended application to *r*-meric mixtures and in extensions to nonhomologous mixture components.

We report here molar enthalpies of mixing of carbon tetrachloride with the *n*-alkanes from *n*-C_5 through *n*-C_9. (For brevity in this paper we shall label a carbon tetrachloride–*n*-alkane system by identifying only the alkane.) Molar energies of mixing have been calculated therefrom, and the lattice theory has been applied to these data, as well as to the results of others from *n*-C_6 through *n*-C_{16} (5–7). This represents the extent to which the theory may reasonably be considered now relative to these systems.

Experimental Section

Calorimetric Apparatus

The design of the calorimeter was essentially the same as that of Adcock and McGlashan (8). Two liquids are mixed under mercury so that no vapor phase is present. The temperature was followed with a ten-junction copper–constantan difference couple and a reflecting galvanometer. The heater was constructed of about 40 cm of B and S No. 38 constantan wire wound noninductively onto a glass bell. The amount of heat introduced was determined by measuring the voltage drop across the calorimeter heater, the current through the heating circuit, and the time of heating. A Leeds and Northrup K-1 potentiometer and one circuit of an L and N x_1–x_2 recorder were used for the voltage measurements. A 1-ohm standard resistor, another K-1 potentiometer, and the other circuit of the recorder were used to measure the current.

Procedure

The two liquids were mixed as previously described (8). Typically the total mixture volume was 1 to 2 ml. A measured amount of heat was added as soon as possible after mixing to compensate for, as nearly as possible, the heat absorbed on mixing. The heat capacity of the loaded calorimeter was then determined by measuring the temperature rise caused by the addition of another measured quantity of heat. This heat capacity was used to correct for the off-balance of the opposing heat effects occurring during the simultaneous mixing and heater operation. Possible errors of the design have been described (8).

The calorimeter was tested with the system benzene + carbon tetrachloride at 298.15 K. Larkin and McGlashan summarized heats of mixing for this system reported prior

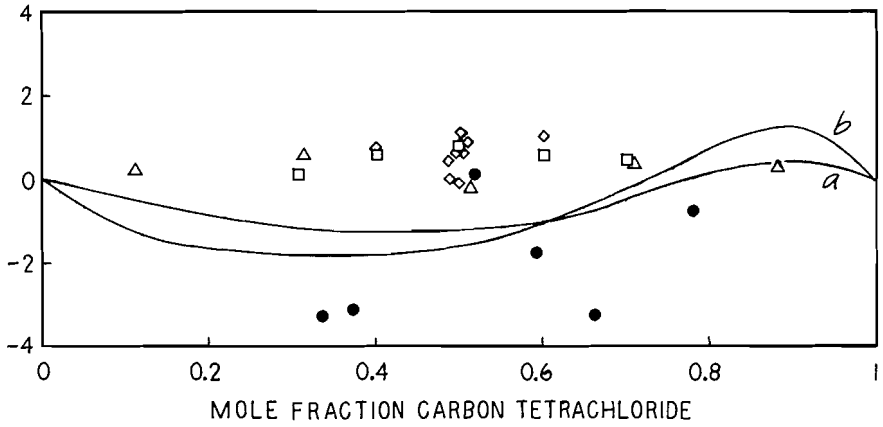

FIG. 1. Deviations (J mol^{-1}) of heats of mixing of carbon tetrachloride + benzene at 298.15 K from the values of Larkin and McGlashan (9). ●, this work; □, Larkin and McGlashan, added in proof in ref. 9; ◇, Larkin and Scott (10); △, Lewis and Johnson (11). Curves are the smoothed results reported in (*a*), ref. 12 and (*b*), ref. 13.

to their own work (9). The latter is generally several J mol^{-1} higher than prior work. In Fig. 1, our calibration results are compared with those of Larkin and McGlashan, and with other values subsequently reported for this system (10–13). Our results fall somewhat below the others, although the disagreement is not considerable. It may be due to incomplete mixing, which is a hazard of the calorimeter design. A smooth curve through our calibration results shows that $(\Sigma d^2/n)^{1/2}$ is 1.2 J mol^{-1}, where d is the difference between a smoothed H^E and the corresponding unsmoothed value, and n is the number of results.

Materials

All of the components were purified by double distillation through a four-foot Vigreux column at atmospheric pressure over CaH_2. The middle third of the product of each distillation was recovered. The final product was tested for reactivity with mercury. No color change on the mercury surface was evident after 48 h of stirring in contact with the final product.

The refractive indices of the compounds were determined at 298.15 K with a Bausch and Lomb Precision Refractometer with the Na-D line. For carbon tetrachloride the value was 1.45729 (lit., 1.45704 (14)), and for benzene, 1.49760 (lit., 1.49792 (15)). For the *n*-alkanes in order of increasing chain length, the values were 1.35457, 1.37216, 1.38495, 1.39521, and 1.40304 (lit., 1.35472, 1.37226, 1.38511, 1.39505, and 1.40311 (15)). A gas chromatogram was also obtained for each liquid and no significant amounts of impurities were detected.

Results and Discussion

Experimental H^E at 298.15 K are listed in Table 1. They were fitted by the method of least-squares to

$$[1] \quad \frac{H^E}{x_1 x_2} = A + B(x_1 - x_2) + C(x_1 - x_2)^2 + \ldots$$

with a digital computer. Each datum was statistically weighted on the basis of the uncertainty in the product $x_1 x_2$ (16). Two coefficients were sufficient to fit each system, although more might be required with measurements of greater precision and over a greater range of mixture compositions. The values of the coefficients and the standard deviations are given in Table 1. Throughout this work x_1 is the mole fraction of carbon tetrachloride.

Table 1 shows that the quality of H^E data in the alkane systems is considerably less than what would be predicted from the calibration results. Several factors may account for this. (*1*) The calorimeter design, in which stirring results from the turbulence during the rise of the less dense through the more dense liquid, is decreasingly effective as the viscosities of the alkanes increase with increasing chain length. (*2*) Extrapolation of the time-temperature curves is increasingly uncertain as H^E grows larger with greater alkane chain length. (*3*) Manipulation of the shorter-chained alkanes involves risk of error through their high volatility.

Experimental H^E were also fitted to a volume fraction equation analogous to eq. 1. This also required two coefficients and yielded essentially the same percent deviation as eq. 1.

Present results are briefly compared with previous values in Table 2, all smoothed with with eq. 1. Tabular, rather than graphical, comparison has been used to provide a more incisive basis for noting the effect of these disagreements

*For the systems in order of increasing chain length, the coefficients of eq. 1 as A, B J mol^{-1} ± standard per cent deviation in H^E are: 1168, 108, 2.4; 1257, 152, 4.1; 1339, 341, 2.5; 1458, 593, 4.2; 1576, 799, 3.1.

on lattice theory calculations below. The systems *n*-C_5 and *n*-C_9 have not previously been reported.

In the *n*-C_6 system present results, within experimental error, agree with those of Bissell *et al.* (6) up to $x_1 \sim 0.6$ and with those of Jain *et al.* (5) beyond. For *n*-C_7, present results and those of Bissell agree up to $x_1 \sim 0.75$ and are generally greater than those of Jain *et al.* For this system the results of Vilcu and Stanciu (7) agree so poorly with the other three sources that that work was excluded from further consideration here. For *n*-C_8 present results agree with those of Jain *et al.* up to $x_1 \sim 0.8$. In summary, while there are some regions of agreement between the three data sources retained, there are significant differences.

From lattice theory with the zeroth approximation (1),

$$[2] \qquad U^E = x_1 x_2 ru/(x_1 + x_2 r)$$

where U^E is the molar energy of mixing at constant volume, r is a molecular size ratio, and u is the interaction energy parameter. U^E have been calculated from H^E with Scatchard's equation (17)

$$[3] \qquad U^E = H^E - T\alpha V^E/\beta$$

where T is absolute temperature, α the thermal expansion coefficient, β the isothermal compressibility, and V^E the molar excess volume of mixing. For mixtures, α and β were obtained with

$$[4] \qquad \alpha = \phi_1'\alpha_1 + (1 - \phi_1')\alpha_2$$

§Obtained with a procedure described in text.

[5] $$\beta = \phi_1'\beta_1 + (1 - \phi_1')\beta_2$$

where α_i and β_i are those of the pure components and

[6] $$\phi_1' = x_1V_1/(x_1V_1 + x_2V_2)$$

is the volume fraction (ideal). V_i is the molar volume of pure component *i*. V_i, α_i, and β_i, and V^E at equimolarity are given in Table 3. U^E for the present work are given in Table 1. $T\alpha V^E/\beta$ increases with alkane chain length, becoming 158 and 198 J mol^{-1} for the *n*-C_{12} and *n*-C_{16} systems, respectively, at equimolarity.

The uncertainty in $T\alpha V^E/\beta$ in the seven systems is largely due to that in V^E values, which in some instances can only be estimated. Alternative values of β_i for *n*-C_6 (21) and *n*-C_8 (20), differing from those in Table 3 by about 10^{-5} atm^{-1} and of apparently equal dependability, exist, but they lead to conclusions agreeing with those given below.

For the *n*-C_6 and *n*-C_{16} systems V^E were calculated from equations given by Heric and Brewer (24)

[7] $$V^E = x_1x_2[A' + B'(x_1 - x_2) + C'(x_1 - x_2)^2 + \ldots]$$

For the *n*-C_7, *n*-C_8, and *n*-C_{12} systems V^E reported by Jain *et al.* (25) were smoothed with eq. 7. Bissell *et al.* (6) have also reported V^E for the systems of *n*-C_6 and *n*-C_7. Their results for the latter are in good agreement with those of Jain *et al.*, but for the former are over 0.1 ml mol^{-1} at equimolarity below values reported in the above two sources.

V^E have not been reported for the systems of *n*-C_5 and *n*-C_9. These were estimated by a procedure adapted from Desmyter and van der Waals (26), who found that for *n*-alkane + *n*-alkane mixtures V^E at equimolarity were linearly related to a function of the chain lengths of the components n_i and n_i', $[1/(n_i + 1) - 1/(n_i' + 1)]^2$. The plot is also linear for the present type of system from *n*-C_6 through *n*-C_{16}, using the combined equimolar data of Heric and Brewer (24) and Jain *et al.* (25), with $n_i = 1$ for carbon tetrachloride and n_i' as the alkane chain length. For the eight systems plotted, equimolar V^E are randomly distributed about the least-squares line, with $[\sum d^2/n]^{1/2} = \pm 0.03$ ml/mol, where d is the deviation of equimolar V^E for the n systems. A' for use in eq. 7 were obtained from this plot for the systems of *n*-C_5 (extrapolation) and *n*-C_9 (interpolation).

B' values for these two systems were obtained with a plot B' *vs.* alkane chain length in the systems from *n*-C_6 through *n*-C_{12}. Over this range B' is distributed randomly about a monotonic curve increasing with alkane chain length, with $[\sum d^2/n]^{1/2} = \pm 0.15$ ml mol^{-1} in B values. This is equivalent to a maximum effect of ± 0.01 ml mol^{-1} in V^E. These procedures yield $V^E = x_1x_2$ [0.20] and $V^E = x_1x_2[1.56 + 0.51\ (x_1 - x_2)]$ for the *n*-C_5 and *n*-C_9 systems, respectively.

We estimate that the uncertainty in V^E at equimolarity is no greater than ± 0.03 ml mol^{-1} for the systems from *n*-C_5 through *n*-C_{16}, and is generally less. This produces an uncertainty in $T\alpha V^E/\beta$ at equimolarity which varies from about 6 to 10 J mol^{-1} over the range of alkanes listed in Table 3.

In calculating r and u from U^E and x in eq. 2, we have followed the method of Everett and Swinton (4), which is iterative. Values of r are adjusted to obtain the parameter u independent of concentration. It has been shown (4, 27) that u varies linearly with $\phi_1 = x_1/(x_1 + x_2 r)$ for r values near that sought. Thus the "best" r is that for which $du/d\phi_1 = 0$ in the linear plot of $du/d\phi_1$ *vs.* r. From the best r value, the mean value of u is obtained with eq. 2. $du/d\phi_1$, the r for which $du/d\phi_1 = 0$, and the mean value of u were all obtained here using the method of least-squares.

Values of r and u and their uncertainties, for both the present data and those of the two previous works (5, 6) are given in Table 4, along with the ratio of molar volumes of each component pair. The data of Bissell *et al.* (6) exhibit the least uncertainty in r and u, and they indicate almost the same values of r and of u in the *n*-C_6 and *n*-C_7 systems. The data of Jain *et al.* (5) show the greatest scatter, but indicate a trend of increasing r and decreasing u with increasing chain length. In treating Jain *et al.*'s results we have omitted several data which were statistically atypical in a system. The trend of r and u in Jain *et al.*'s results is confirmed by our data, although there is significant difference between the two works.

Table 4 shows that r from our work change from equality with to greater than the ratio of molar volumes as chain length increases; that is, as the difference between the component molar volumes increases. This trend is continued in the work of Jain *et al.* for the *n*-C_{12} and *n*-C_{16} systems. Cutler and Morrison (27) found $r = 1.79$ for the system methane + propane, which exceeded the ratio of molar volumes by 0.1. An increase in r with increasing chain length is plausible, but the increasing rate of change of r is less easily justified. The true rate may actually be considerably less at the longest chain length, because the available data in the *n*-C_{16} system covers a range of ϕ_1 of only about 0.3. This is undesirably small for the method used to determine r and u.

Williamson and Scott (28) have shown that treatment of mixtures of homologs with lattice theory leads to equivalent relations obtained through van der Waals theory. Although lattice theory is extended here to non-homologous pairs, if u is considered to be related to the difference between the cohesive energy densities of a component pair, a concept which has received prominent attention in van der Waals

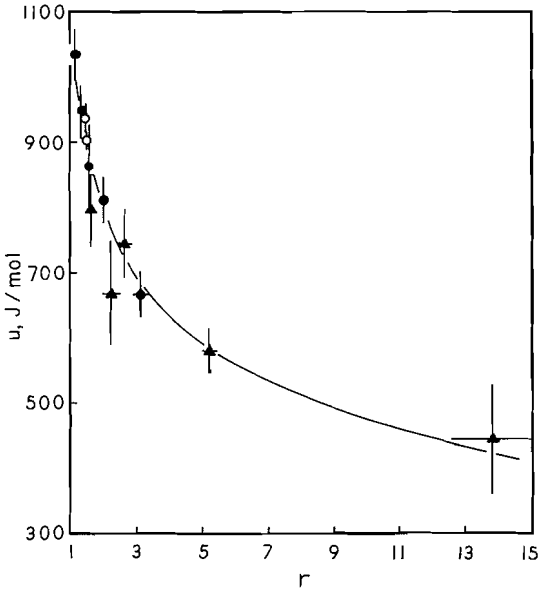

FIG. 2. The variation of u with r in eq. 2. ●, this work; △, Jain *et al.* (5); ○, Bissell *et al.* (6).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

theories (29), then a decrease of u with increasing alkane chain length is tenable. The cohesive energy density of n-C_{16} is less than that of carbon tetrachloride, and it decreases for n-alkanes with decreasing chain length.

The relation between u and r is plotted in Fig. 2. The curve has been drawn by inspection through our results from n-C_5 to n-C_9 and extended through Jain *et al.*'s results for n-C_{12} and n-C_{16}. The scatter of points for the systems n-C_6, n-C_7, and n-C_8, for which more than one data source is available, shows the sensitivity of u and r toward differences in the heats of mixing shown in Table 2. Conclusions which can be drawn from Fig. 2 must clearly be considered tentative. Whereas Jain *et al.*'s data and our own include a considerable range of chain length, they are of lesser precision than those of Bissell *et al.*, whose data treat only two adjacent alkanes. Moreover systematic errors in the data for any of the systems can have a considerable effect on the r and u values there. Resolution of the questions raised by Fig. 2 must await highly precise measurements of H^E and V^E for this series of systems. Studies such as that of Vesely (3), where the total concentration range was observed, represent a much more stringent test of the theory than those like that of Gainey and Young (2), where the concentration range was restricted.

Synthesis and Structural Investigation of *cis*-8-Oxabicyclo[4.3.0]nonan-3-ols

KOICHI KIMOTO, TA-YAN LEONG, TAKESHI IMAGAWA, AND MITUYOSI KAWANISI[1]

Department of Industrial Chemistry, Kyoto University, Kyoto, Japan 606

Received March 2, 1972

A variety of methods of synthesis of hitherto unknown isomeric *cis*-8-oxabicyclo[4.3.0]nonan-3-ols were studied, and the best method for obtaining *cis*-8-oxabicyclo[4.3.0]nonan-3β-ol (**2**) was hydroboration of *cis*-8-oxabicyclo[4.3.0]non-3-ene (**1**). *cis*-8-Oxabicyclo[4.3.0]nonan-3α-ol (**3**) could be obtained highly stereoselectively by the hydrogenation of *cis*-8-oxabicyclo[4.3.0]nonan-3-one (**4**) over platinum oxide in an acidic medium. The configurations of **2** and **3** were deduced mainly from the chemical and spectral similarity with the known *cis*-bicyclo[4.3.0]nonan-3-ols. The preferred conformations of the two isomeric alcohols were discussed in terms of i.r. as well as n.m.r. spectroscopy using paramagnetic shift reagents. There is almost no difference in the coordination abilities of europium ions with the alcoholic and ethereal oxygen atoms in these compounds.

Des méthodes variées de synthèse des *cis* oxa-8 bicyclo[4,3,0] nonanols-3 isomères, inconnus jusqu'ici, ont été étudiées et la meilleure méthode pour obtenir le *cis* oxa-8 bicyclo[4,3,0] nonanol-3β (**2**) est l'hydroboration du *cis* oxa-8 bicyclo[4,3,0] nonène-3 (**1**); le *cis* oxa-8 bicyclo[4,3,0] nonanol-3α (**3**) peut être obtenu de façon hautement stéréosélective par hydrogénation du *cis* oxa-8 bicyclo[4,3,0] nonanone-3 (**4**), en présence de l'oxyde de platine en milieu acide. Les configurations de **2** et **3** ont surtout été déduites à partir des propriétés chimiques et spectrales similaires aux *cis* bicyclo[4,3,0] nonanols-3 connus. Les conformations préférentielles des deux alcools isomères ont été discutées à partir des données de la spectroscopie i.r. et de la r.m.n. utilisant les chélates de terres rares. Il n'y a pratiquement aucune différence dans la coordination des ions europium avec les atomes d'oxygène des groupes alcool ou éther pour ces composés.

Canadian Journal of Chemistry, **50**, 3805 (1972)

In connection with the studies of steroids, there have been many reports on the studies of synthesis and stereochemistry of bicyclo[4.3.0]-nonanes (1, 3). However, in the field of their oxa-analogs (8-oxabicyclo[4.3.0]nonanes) (2), research has not been so active. In order to gain an insight into the properties of the compounds in which a methylene group of the five-membered ring in bicyclo[4.3.0]nonanes is replaced by an oxygen atom, the synthesis of the hitherto unknown alcohols, *cis*-8-oxabicyclo[4.3.0]nonan-3β-ol (**2**)[2] and *cis*-8-oxabicyclo[4.3.0]nonan-3α-ol (**3**) has been undertaken (see Scheme 1). The configurations of the resulting alcohols **2** and **3** were deduced from the stereochemical consideration similar to the determination of the configurations of *cis*-bicyclo[4.3.0]nonan-3-ols (3) and cyclohexanols (4).

Granger *et al.* had determined the conformations of bicyclo[4.3.0]nonan-3-ols with i.r. and n.m.r. spectroscopic methods (3). In the present investigation we have employed additionally the recently developed technique of n.m.r. paramagnetic shift reagent which enabled us to deduce the preferred conformations of **2** and **3** in more detail, as well as to certify the configurational assignment.

Results and Discussion

(a) Syntheses and Configurations

As shown in Table 1, hydroboration of **1** with diborane gave mainly **2**, but hydroboration with diisopinocamphenylborane did not improve the ratio of **2**. Lithium aluminum hydride (LAH) reduction of the epoxide of **1**[3] obtained by the reaction of **1** with *m*-chloroperbenzoic acid also gave **2** as major product. The reduction of **4** with sodium in ethanol yielded mainly **2** whereas reduction with LAH afforded the isomer **3** predominantly. Compound **3** was obtained stereoselectively by the hydrogenation of **4** over platinum oxide in acetic acid with a small amount of hydrochloric acid. Summarizing these results, the hydroboration of **1** with diborane seems to be the method of choice for the synthesis of isomer **2**, and the hydrogenation

[1]To whom correspondence should be addressed.

[2]A hydroxyl group oriented *cis* to the angular hydrogens at C-1 and -6 is termed β; the *trans* orientation is termed α.

[3]Formation of epoxide of **1** was confirmed by i.r., and the ring opening of the epoxide was immediately effected without further purification (see Experimental). This epoxide was described in the literature (5) without isolation.

*Percentage of ratio of alcohols **2** and **3** was determined by g.l.c. analysis, conversion in all cases was 100%.
†DICB stands for diisopinocamphenylborane.
‡MCPBA stands for *m*-chloroperbenzoic acid and LAH stands for lithium aluminum hydride.
§Oxymercuration of **1** was described in ref. 6 without a specific ratio.
‖No hydrochloric acid was added during hydrogenation.

of **4** in an acidic medium provides the most convenient route to **3**.

It is generally accepted that the reduction of cyclohexanone derivatives with sodium in alcohol yields the more stable alcohols whereas hydrogenation in an acidic medium gives the less stable alcohols (4). Judging from the above tendency and from the agreement of the results of the reduction of **4** with those of *cis*-bicyclo-[4.3.0]nonan-3-one (3) (Table 2), it can be safely stated that the hydroxyl group of **2** is *trans* to the five-membered ring, that is, it has a β-configuration and that of **3** has an α-configuration. From this close resemblance in stereochemical relationships, there seems to be no difference in the reactivities of the ketones in reductions even when one methylene group of the five-membered ring is substituted by an oxygen atom.

During the hydroboration of **1**, chiefly due to the steric hindrance of the methylene groups in the five-membered ring, and probably due, to a certain extent, to the direct participation (6), if any, of the ethereal oxygen orbitals towards the C_3—C_4 double bond, **2** should be formed predominantly as the boron atom attacks preferably from the *exo*-face, and actually the

result was as expected. This steric hindrance also accounts for the higher yield of **2** in the reductive ring opening of the epoxide of **1**. The hydroboration with the bulky diisopinocamphenylborane is unexpectedly lower in stereoselectivity than that with diborane, and the reason for this is not clear yet.

(b) Nuclear Magnetic Resonance Studies Using the Shift Reagent, Eu(DPM)$_3$.

The lanthanide complex-induced n.m.r. shift effect has become a valuable aid for the structural analysis of organic molecules having substituents with lone-pair electrons (7). To obtain conformational evidence, we have applied this technique to the n.m.r. study of the isomers of *cis*-8-oxabicyclo[4.3.0]nonan-3-ols (**2** and **3**), which are bifunctional compounds with two coordination sites[4] (8) (see Figs. 1 and 2).

The relationship between the variation of chemical shifts (δ_E) and $Eu(DPM)_3$/substrate (molar ratio) and the shift parameters, the *S* values[5] (9) for the two isomers of **2** and **3** is shown in Figs. 3 and 4, demonstrating the linearity between δ_E and $Eu(DPM)_3$/substrate for different protons in both isomers.

The linearities even at a high concentration of 1.2 molar ratio for the carbinyl protons and the four methylene protons adjacent to the oxygen atom of the five-membered rings indicate that there is no great difference in the equilibrium constants of complex formation for the alcoholic and the ethereal oxygen atoms.

Since Sanders and Williams (10) reported

[4]One of the referees has recommended the more recently developed shift reagent, tris-(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione)-europium(III), $Eu(fod)_3$, because of its superior complexing properties for ethers (22). As expected, we obtained the following three results: (*i*) the signals of the carbinyl proton (H-3) and the α-protons of ether (H_7 and H_9) overlapped in all molar ratios of $Eu(fod)_3$/substrate, (*ii*) the other signals showed a pattern similar to the case of $Eu(DPM)_3$, (*iii*) the gradients of the signals shifted by $Eu(fod)_3$ are *ca.* 1.6 times greater than those of signals shifted by $Eu(DPM)_3$.

[5]*S* represents the shift parameters and is defined in (9) as $\delta_E = \delta + S \cdot Eu(DPM)_3$/substrate, where δ is the chemical shift in the uncomplexed substrate.

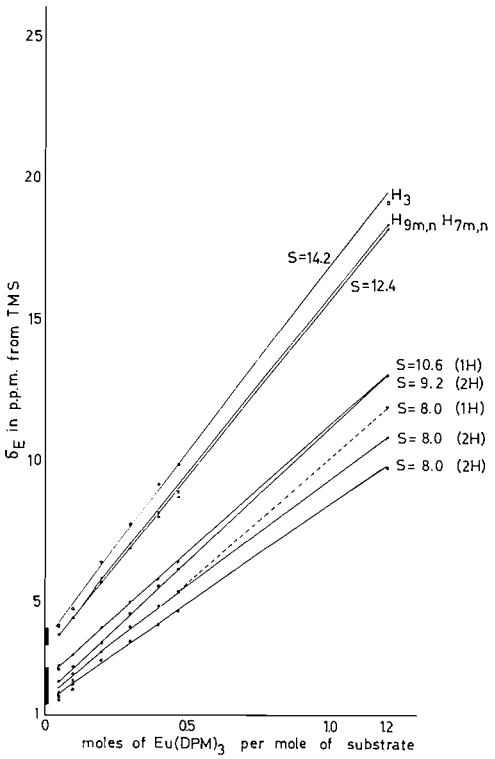

FIG. 3. Variation of chemical shift with molar ratio of Eu(DPM)$_3$/substrate for **2** in $CDCl_3$ solution.

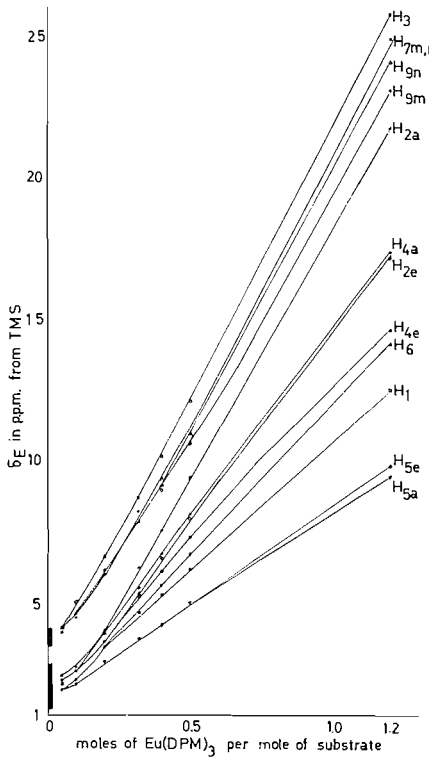

FIG. 4. Variation of chemical shift with molar ratio of Eu(DPM)$_3$/substrate for **3** in $CDCl_3$ solution.

that the gradients for RCH_2OH and RCH_2OCH_2R are $20 \sim 25$ and 10 (in CCl_4), respectively, it is generally accepted that the carbinyl protons are shifted much more than the protons situated α to the ethereal oxygen atom; however, no qualitative competition experiment in this respect has ever been reported. Hart and Love (11) reported the gradients, ΔEu values of $25 \sim 29$ for the α protons of cyclic ethers (probably in $CDCl_3$). This contradiction demonstrates the difficulty of comparing the gradients directly from one compound to another. As examples of intramolecular competition, there are two reports: Farid *et al.* indicated that the ethereal oxygen and not the sterically hindered hydroxyl group is involved in complex formation (12); whereas on the other hand, judging from the n.m.r. charts in Horton and Thomson's report (13) on carbohydrates, we can deduce that complex formation occurs mainly at the hydroxyl group, although the compound contains two ethereal oxygen atoms.

We have carried out an intermolecular competitive experiment on an equal molar mixture of tetrahydrofuran and cyclohexanol and the results are shown in Fig. 5. The $S_{-CH-OH}/S_{-CH-O-CH-}$ for the mixture is 1.19 and is compatible with the average values of **2** and **3** (1.16 and 1.14 respectively), indicating a similar degree of competitive coordination for the two sites in these three cases.

We could obtain a reasonably satisfactory linear relationship between S values and the values of $r_A^{-2} + r_E^{-2}$ (where r_A stands for the distance of the proton from the alcoholic oxygen atom and r_E represents the distance of the proton from the ethereal oxygen atom) (Table 3) for the protons of **3***a*,[6] but not **3***b*. Unfortunately, however, the tentatively assigned S and $r_A^{-2} + r_E^{-2}$ for **2***a* and *b* both displayed a fairly good linearity and the differentiation between **2***a* and *b* as the preferred conformation is impossible.

[6]Even if the value of a/b for $a \cdot r_A^{-2} + b \cdot r_E^{-2}$ is changed, the linearity cannot be improved.

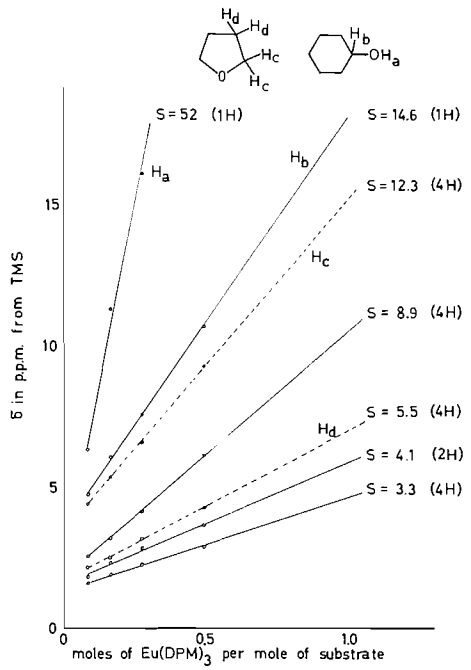

FIG. 5. Variation of chemical shift with molar ratio of $Eu(DPM)_3$/substrate and *S*-values for an equal molar mixture of cyclohexanol and tetrahydrofuran in $CDCl_3$. Dotted lines represent protons of tetrahydrofuran, solid lines represent protons of cyclohexanol.

However, these satisfactory r–S relationships show clearly that the equilibrium constants of complex formation for the alcoholic oxygen atom and the ethereal oxygen atom with the shift reagent are almost equal.

The spectral pattern for H_{2a} of **3** is clearly discernible in Fig. 2. The spacings of the four-line multiplet indicate the coupling constants of $J_{1,2a} \sim J_{3,2a} \sim J_{2e,2a} = ca.$ 12 Hz. These values clearly indicate that the cyclohexanol ring in **3** adopts a regular chair conformation and the hydroxyl group exists in an equatorial arrangement. When the $Eu(DPM)_3$/substrate (molar ratio) is increased to 0.5, in the case of **3**, the spectral pattern of $H_{7m,n}$ and $H_{9m,n}$[7] are simplified to such an extent that analysis becomes possible. The signals of H_{9n} and H_{9m} feature the AB portion ($J_{AB} = 8.9$ Hz) of the ABX system and the approximately calculated values (14) of $J_{AX} = 4.9$ Hz, (A = H_{9n}, X = H_1); $J_{BX} = 1.9$ Hz (B = H_{9m}, X = H_1) are obtained.[8] Judging from the molecular model with a conformation of **3***a* as shown in Fig. 6, the dihedral angles between the hydrogen C-1 and the hydrogens m,n at C-9 are nearly 90 and 30°, respectively. The above

[7]A hydrogen atom oriented *trans* to the angular hydrogens at C-1 and -6 is termed m; the *cis* orientation is termed n. Refer to Figs. 1 and 2 for a detailed description.

For personal use only.

coupling constants are in good agreement with the values calculated according to the Karplus equation (16) with the above angles.

On the other hand, in the case of **2**, even when the concentration of the shift reagent is increased to 1.2 equiv, the degeneracy of signals, except those of the carbinyl proton and the methylene protons adjacent to the ethereal oxygen atom, cannot be altered (Fig. 3); that is, three clusters of signals consisting of three protons, three protons, and two protons each are shifted together as groups.

Based on the $r_A^{-2} + r_E^{-2}$ in Table 3, the groups of complex multiplets are tentatively assigned in the order of chemical shifts as follows: (H_{5a}, H_{2a}, H_{2e}); (H_{4a}, H_{4e}, H_1); (H_6, H_{5e}).

These assignments are partially supported by irradiation at the signals of the carbinyl proton causing remarkable changes in both the three-proton multiplets and none in the two-proton multiplet, although the decoupling experiments in other cases are rendered difficult by the inherent degeneracies of the signals.

(c) Conformations

To determine the axial or equatorial nature of protons adjacent to the hydroxyl or the acetate moieties, it is helpful to observe the half-band widths of the proton signal. The half-band widths of the carbinyl protons of **2** and **3** cannot be observed directly owing to the overlapping with the signals of the protons α to the ethereal oxygen, but the widths of the respective acetates of **2** and **3** are observed to be 14 and 17 Hz, respectively, indicating the equatorial arrangement of the acetoxy groups in both acetates.

The half-band widths of the carbinyl protons (H_3) of **2** and **3** are observed, however, after addition of the n.m.r. shift reagent as described earlier, the values being about 16 and 17 Hz, respectively. These band widths would seem to confirm that the preferred conformations for **2** and **3** are **2***a* and **3***a* in Fig. 6, when we consider additionally the information[9] about the total ring-systems of **2** and **3** described in the previous section.

The i.r. spectra of CCl_4 solutions of **2** and **3** (Table 2) show absorptions due to the stretching vibration ν_{C-O-} at 1025, 1009, and 987 cm^{-1} for compound **2** and at 1020, 993 cm^{-1} for compound **3**, respectively. When the stronger intensities of the equatorial bands are compared with those described for bicyclo[4.3.0]nonan-3-ols (3), the above conformational assignments are further supported. The i.r. spectra of highly diluted solutions of **2** and **3** indicate no intramolecular hydrogen bonding resulting from the hydroxyl group and the ethereal oxygen; therefore, a boat form or a skewed boat form stabilized by intramolecular hydrogen bonding might be excluded.

These conclusions on conformational assignments are consistent with the deduction using the concept of conformational analysis as described for *cis*-bicyclo[4.3.0]nonan-3-ols by Dauben and Jiu (1*b*).

[9]Although the evidence for **2** might be less convincing than that for **3**, the conclusion will not be unchanged in light of the fact that the *r*–*S* relationships for **2** were not obtained in terms of its boat or skewed boat conformations.

Experimental

The i.r. spectra were recorded on a Shimadzu IR-27C spectrometer with the exception of the investigation of the intramolecular hydrogen-bonding spectra which were run on a Shimadzu IR-27G spectrometer using CCl_4 solutions of various concentrations from 0.01–0.002 *M* in a cell of 1 cm in path length. The n.m.r. spectra were determined on a JEOL C-60H spectrometer using tetramethylsilane as an internal standard, and $CDCl_3$ as solvent. Tris(dipivalomethanato)europium(III), $Eu(DPM)_3$, was prepared in a manner similar to that of Eisentraut and Sievers (17), and had a m.p. 189.5–190° (lit. m.p. 190–191° (18)). The g.l.c. analyses and separations were carried out on a Shimadzu GC-4APT using a 3 m × 3 mm column with 15% polyethyleneglycol on 60/80 Chromosorb W operating at 150° with a He flow rate of 40 cc/min. For preparative t.l.c., a 1.0 mm thickness of Merck GF-254 Silica Gel was employed with the solvent system of diethyl ether–benzene (50:50). Microanalyses were performed by Mrs. K. Fujimoto of our laboratory. Mass spectra were recorded with a Hitachi RMS-4 mass spectrometer with a nominal ionizing energy of 70 eV, and a source temperature of 150 °C. All melting points and boiling points were uncorrected.

Reaction of cis-8-Oxabicyclo[4.3.0]non-3-ene (1)

(a) Hydroboration with Diborane

Diborane generated by adding a solution of 14 g of $BF_3 \cdot Et_2O$ in 25 ml of diglyme to 1.9 g of sodium borohydride in 50 ml of diglyme was passed during 75 min into a stirred solution of 5.9 g of **1** (19) in 50 ml of THF, cooled in an ice bath. The solution was then left for 75 min at room temperature, excess diborane was decomposed with water (15 ml), and 15 ml of 3 *N* sodium hydroxide was added, and subsequently, 15 ml of 30% hydrogen peroxide was added dropwise. The reaction mixture was stirred for an additional hour at room temperature and extracted with dichloromethane. After evaporation of the solvent, distillation yielded 4.2 g of a mixture of **2** and **3**, b.p. 115°/9 mm; the isomeric ratio of **2** to **3** was shown to be 86:14 by g.l.c.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(b) Hydroboration with Diisopinocamphenylborane

Hydroboration with diisopinocamphenylborane was carried out with 6.8 g of **1** according to the method of Brown *et al.* (20), and 5.8 g of a mixture of **2** and **3** was obtained, the isomeric ratio of which was shown to be 75:25 by g.l.c.

*(c) Reaction of **1** with m-Chloroperbenzoic Acid Followed by Reduction with Lithium Aluminum Hydride (LAH)*

A solution of 5.4 g of 85% *m*-chloroperbenzoic acid in 120 ml of dry chloroform was added dropwise to a stirred solution of 3 g of **1** in 50 ml of dry chloroform. The reaction mixture was stirred overnight at room temperature. The solution was then washed twice with 100 ml of 10% sodium sulfite solution, twice with 100 ml of 5% sodium bicarbonate solution, and finally with saturated sodium chloride solution, and dried (Na_2SO_4). Chloroform was driven off at reduced pressure, and the i.r. of the reaction product (3.2 g) showed no absorption of olefin, but bands at 3008 and 810 cm^{-1}, confirming the presence of epoxide. G.l.c. analysis also showed that the starting material **1** had disappeared; however, it was impossible to determine the isomeric ratio of the epoxide under the above-mentioned g.l.c. condition, and the following reaction with LAH was carried out without further purification of the epoxide. The solution of 3.2 g of the above epoxide in 50 ml of dry ether was added dropwise to a stirred slurry of LAH in 50 ml of ether, and the mixture was stirred overnight at room temperature. Aqueous hydrochloric acid (10%) was added to destroy the excess hydride, the aqueous phase extracted with ether, and dried (Na_2SO_4). On concentration, 2.44 g of a mixture of **2** and **3** was obtained, which was shown by g.l.c. to have an isomeric ratio of 85:15.

*(d) Reduction of cis-8-Oxabicyclo[4.3.0]nonan-3-one (**4**)*

The ketone (**4**) was prepared by oxidizing the mixture of **2** and **3** obtained in the hydroboration (with diborane) of **1**. A solution of 2.84 g of a mixture of **2** and **3** in a small volume of dichloromethane was oxidized with chromium trioxide–pyridine complex as described by Ratcliffe and Rodehorst (21) to yield 1.68 g of **4**, b.p. 118–119°/19 mm, i.r.: 1718, 1710, 1060, 1035 cm^{-1}; n.m.r.: (CCl_4) δ 4.03–3.22 (4H, m), 2.84–1.34 (8H, m); *m/e*: 140 (M^+, 10%), 82 (100%).

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.63. Found: C, 68.66; H, 8.83.

A solution of **4** (200 mg) in 10 ml of ether was added dropwise to a stirred slurry of 70 mg of LAH in 10 ml of ether. The mixture was stirred overnight at room temperature, dilute hydrochloric acid was added to destroy excess hydride, the aqueous phase was extracted with ether, and dried (Na_2SO_4). The solvent was removed and the alcohols **2** and **3** were formed in the ratio of 15:85 and no trace of **4** could be detected.

*(e) Hydrogenation of **4** over Platinum Oxide*

A sample (100 mg) of **4** in 5 ml of glacial acetic acid was added to 50 mg of platinum oxide in 10 ml of glacial acetic acid, three drops of concentrated hydrochloric acid was added, and hydrogenation was carried out under a normal atmosphere of hydrogen at room temperature. A rapid uptake of hydrogen occurred and the theoretical amount of hydrogen was absorbed in 20 min. The reaction mixture was neutralized with aqueous sodium bicarbonate, extracted with ether, and dried (Na_2SO_4). Analysis of the reaction product with g.l.c. showed that **3** was obtained at an isomeric ratio of over 98%. This method was employed to obtain a pure sample of **3** by separating the trace of **2** with preparative t.l.c. (*vide infra*).

*(f) Reduction of **4** with Sodium in Ethanol*

A solution of 32 mg of **4** in 10 ml of absolute ethanol was placed in a flask fitted with a reflux condenser and 175 mg of small pieces of sodium were added to maintain reflux. After the addition of sodium was finished, the reaction mixture was refluxed for an additional hour, then cooled and acidified with 10% aqueous hydrochloric acid. Ethanol was removed under diminished pressure and the aqueous phase extracted with ether, and dried (Na_2SO_4). Analysis of the reaction product with g.l.c. showed that the isomers **2** and **3** were formed in a ratio of 61:39.

*Preparation of Pure Specimens of **2** and **3***

Pure samples of **2** and **3** were isolated from the reaction mixtures obtained in methods (*a*) and (*e*), respectively, purified after separation by preparative t.l.c. and g.l.c., and showed the following properties.

Compounds **2** and **3**: i.r. and n.m.r. spectral data: shown in Table 2; *m/e* for **2**: 142 (M^+, 9%), 124 ($M^+ - 18$, 47%), 79 (100%); *m/e* for **3**: 142 (M^+, 5%), 124 ($M^+ - 18$, 30%), 69 (100%).

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found for **2**: C, 67.35; H, 9.65. **3**: C, 67.37; H, 10.17.

Acetate of **2**: i.r.: (neat) 1741, 1245, 1060, 1020 cm^{-1}: n.m.r.: (CCl_4) δ 5.12–4.66 (m, *w*/2: 14 Hz, 1H), 4.04–3.33 (m, 4H), 2.64–1.14 (m, 11H); *m/e*: 184 (M^+, 2%), 141 ($M^+ - 43$, 30%), 124 ($M^+ - 60$, 30%), 43(100%).

Acetate of **3**: i.r.: (neat) 1756, 1742, 1255, 1236, 1083, 1050, 1034, 1016 cm^{-1}; n.m.r.: (CCl_4) δ 5.01–4.52 (m, *w*/2: 17 Hz, 1H), 3.91–3.40 (m, 4H), 2.51–1.09 (m, 11H); *m/e*: 184 (M^+, 2%), 141 ($M^+ - 43$, 25%), 124 ($M^+ - 60$, 28%), 43 (100%).

*Decoupling Experiments for the Nuclear Magnetic Resonance Spectral Assignment of **3***

Decoupling experiments were done with a Varian HA-100 spectrometer operating at a 100 MHz field in the frequency-swept and tetramethylsilane (TMS) locked mode.

The spectrum of **3** shows a one-proton multiplet at δ 9.10 assignable to the carbinyl proton (H_3) and two AB portions of ABX systems at δ 8.15 ~ 9.05 (sharp 2 × 6 lines) due to the four methylene protons adjacent to the oxygen of the five-membered ring.

Decoupling on H_3 resulted in changes of the one-proton quartet centered at δ 6.95 into a broad triplet, of the complex two-proton multiplet at δ 5.7 ~ 6.6 into a more complex but sharper multiplet, and of the broad multiplet at δ 5.58 into a relatively sharper pattern.

Irradiation at the center of the six-line pattern (AB portion of ABX system) centered at δ 8.87 made the broad triplet at δ 5.24 relatively narrower, and double irradiation at the other AB portion of ABX system changed the six-line multiplet at δ 4.87 into a five-line multiplet.

Then, the complex multiplet (two protons) at δ 3.55 ~ 4.20 which showed no change on these three decoupling experiments is assignable to H_{5a} and H_{5e} (refer to formula in Fig. 2).

Double irradiation (to cover the wide resonance frequencies) at the multiplets of H_{5a} and H_{5e} at δ 3.55 ~ 4.20 changed the broad triplet at δ 5.24 into a relatively narrower quartet, which was assignable to H_6, and the two-proton

multiplet at δ 5.7 ~ 6.6 into a much broader and featureless pattern, which might be due to H_{4a} and H_{4e}. Accordingly, the signals at δ 6.95 and 5.58 may be assignable to H_{2a} and H_{2e}, respectively, based on their signal widths (base-line; 40 and 30 Hz, respectively), and on the spacing of 11.8 Hz for the quartet at δ 6.95.

On irradiation on H_6, the six-line pattern at δ 8.87 collapsed to a broad AB pattern of the case where δ_{AB} is small relative to J_{AB}; therefore this AB pattern is ascribed to H_{7m} and H_{7n}. On irradiation on the six-line multiplet at δ 4.87 now assignable to H_1, the six-line multiplet at δ 8.26–8.70 was changed into an AB quartet, which is due to H_{9m} and H_{9n}.

The authors are grateful to Prof. H. Nozaki for help and encouragement.

Chemical Reactions of Methane in a Triboelectric Discharge

W. G. ALCOCK, E. J. HAYWARD, B. MILE, AND B. WARD

Shell Research Ltd., Thornton Research Centre, P.O. Box 1, Chester CH1 3SH, England

Received March 27, 1972

Methane can be converted into C_2 hydrocarbons and hydrogen in a triboelectric discharge arising from the intermittent contacting of mercury with a glass surface. The discharge is a result of the accumulation of high densities of static charge at the interface by the transfer of electrons from the mercury to the glass. Excited species with energies up to 20 eV above their ground states have been detected by spectroscopic examination of the discharge. The effects of physical parameters such as surface area and surface nature on the triboelectrification process have been examined. Both the area and nature of the solid surface influence the extent of breakdown and discharge. The rates of conversion are virtually invariant with pressure from 760 to 200 Torr, but at 200 Torr they increase sharply before gradually falling off again as the pressure is further reduced. This behavior is explained in terms of the opposite effects of pressure on the electrical breakdown of the gas and on the rates of the chemical reactions accompanying the discharge. The pressure at which the rise in yield occurs has been used to estimate the production of an average static charge density of 2 e.s.u. cm^{-2} by contact electrification at a mercury/glass interface. The effects of inert gases and oxygen have also been studied and the results of these experiments together with a comparison of the products formed in other decomposition processes suggest that CH_2 and CH_3 are important intermediates in the triboprocess occurring in methane.

On peut convertir le méthane en hydrocarbures C_2 et en hydrogène au moyen d'une décharge triboélectrique provenant du contact intermittent du mercure avec une surface de verre. La décharge est le résultat d'une accumulation de charge statique de forte densité à l'interface provoquée par le transfert d'électrons du mercure au verre. Nous avons détecté des espèces excitées possédant des énergies allant jusqu'à 20 eV au-dessus de leur état fondamental, au moyen d'un examen spectroscopique de la décharge. Nous avons examiné des effets de paramètres physiques, tels la grandeur et la nature de la surface sur le procédé de triboélectrification. Ces deux facteurs influent sur la brisure et la décharge. Les vitesses de conversion sont virtuellement indépendantes de la pression de 760 à 200 Torr, mais à 200 Torr, elles augmentent brusquement avant de retomber graduellement lorsqu'on diminue de plus la pression. On explique ce comportement en termes d'effets antagonistes de la pression sur la brisure électrique du gaz et sur les vitesses des réactions chimiques accompagnant la décharge. Nous avons utilisé la pression à laquelle augmente le rendement pour estimer la production d'une densité de charge statique moyenne de 2 u.s.e. cm^{-2} par électrification de contact à une interface mercure/verre. Nous avons aussi étudié les effets de gaz inertes et d'oxygène et les résultats de ces expériences, combinés à une comparaison des produits formés dans d'autres procédés de décomposition, suggèrent que CH_2 et CH_3 sont d'importants intermédiaires dans la triboélectrification du méthane.

Canadian Journal of Chemistry, **50**, 3813 (1972)

Introduction

The term 'triboluminescence' describes the emission of light when certain materials are rubbed, or otherwise intermittently contacted. A particularly vivid example in which heat is converted, via mechanical motion, into light is the sporadic flashing and sparking of a glass/mercury diffusion pump during operation. More generally, it seems that photons are emitted whenever mercury moves along the surface of an insulating material.

The luminescence is a result of a weak gas discharge which itself must result from the generation of high electric fields by the movement of mercury over an insulating material such as glass. These high fields probably arise from the transfer of ions or electrons across the mercury/glass interface, followed by the separation of the statically charged surfaces (1).

Spectroscopic examinations of the light emitted when mercury moves over quartz or glass surfaces in the presence of inert gases at various temperatures and pressures have been made by de Walden (2), Ikenoue and Sasada (3), Dybwad and Mandeville (4), and Schoen (5). The results indicate that excited species with energies up to 20 eV above the ground state are produced by the simple mechanical agitation of liquid mercury in glass vessels.

Since the strength of most chemical bonds is below 8 eV, the production of species with 20 eV excess energy during the triboprocess should result in appreciable chemical change when complex molecules rather than inert

gases are present in the system. For this reason we decided to investigate tribodischarging in the presence of methane. Initial experiments showed that methane could be converted into C_2 and C_3 hydrocarbons and hydrogen in a tribodischarge, and here we report a detailed study of some of the factors that influence the rates of conversion.

There were no reported studies of the chemical aspects of triboluminescence when we started our investigations but very recently Johnson *et al.* (6), and de Paoli and Strausz (7) have briefly reported their observations of such chemical changes in a range of compounds.

Experimental

Two types of reactor were used which we refer to as the 'bubbler' reactor and the 'rotator' reactor. In the bubbler reactor, methane was circulated continuously through a vertical glass column (packed and unpacked) containing some 600 g of mercury. Teflon stopcocks were used in the circulating system, which was grease-free. In the simpler but less efficient rotator reactor the movement of surfaces was achieved by rotating a cylindrical glass vessel containing methane and a pool of mercury (200 g). Rotation speeds of 150 r.p.m. were used giving a linear velocity of 3100 cm/min at the mercury edge.

Since the triboprocess is likely to be very surface-dependent, a rigorous procedure was adopted for cleaning the glassware both in the rotator and in the bubbler experiments. This involved washing with permanganic acid, 100-volume hydrogen peroxide, and distilled water, followed by drying at 120 °C and pumping on a high vacuum line for 12 h.

Samples were withdrawn from both reactors into a gas syringe by using a serum cap which was isolated from the reaction systems except for the time of sampling. The gases were analyzed by g.l.c., a Porapak T column being used for hydrocarbon analysis and a molecular sieve 5A column for hydrogen.

A Hilger Medium Raman Spectrograph was used to make spectroscopic measurements with the bubbler. The spectra were photographed using an exposure of about 2 days and were calibrated with the spectral lines from a mercury arc.

Results

Spectroscopic Studies

The spectra observed from different gases confirm the results of Schoen and unequivocally demonstrate that highly excited species can be formed by simple mechanical agitation of mercury in glass vessels. A new feature was the observation of a CH emission (431.2 nm, $^2\Delta \rightarrow {}^2\pi$) with methane which provides striking evidence for the decomposition of methane. Interestingly, the triboluminescence spectrum from methane differs from that observed in a spark discharge (8) at atmospheric pressure in that emission from C_2 was not observed. One can infer from this that the conditions in a triboelectric discharge are not identical with those in a spark discharge.

Chemical Studies

(a) Products and Time Dependence

Simple agitation of mercury in either reactor at ambient temperatures results in the conversion of methane into acetylene, ethylene, ethane, hydrogen and traces of C_3 hydrocarbons. The yield of hydrogen corresponded closely to that expected from its concurrent production with the C_2 hydrocarbons, *i.e.*

$$[H_2] = [C_2H_6] + 2[C_2H_4] + 3[C_2H_2]$$

Similar products and product ratios were observed by de Paoli and Strausz (7) in their experiments at 10 Torr.

The growth curves for the production of C_2 hydrocarbons depend on the type of reactor used and on other factors discussed below but Fig. 1 for the rotator at 200 Torr gives the general shape of such curves for unpacked reactors. It can be seen that the rates of conversion decreased with increasing time. C_3 hydrocarbons were present in small amounts but were not produced during the early stages of reaction.

(b) Reactor Material

The effect of the nature of the surface of the reactor material was examined by using reactors made of different materials. Although the differences found were small, the order of efficiency was quartz > Pyrex > nylon. No reaction occurred in a steel reactor. Pyrex vessels were used in all the other experiments described here.

(c) Surface Area

In the unpacked bubbler reactor the intermittent contacting between the mercury and the glass is small. If the triboprocess is dependent on the making and breaking of the mercury/glass interface then any way of increasing this interface should increase the rate of decomposition of methane. The simplest way of increasing the contact area is to pack the reactor. The best packing material was found to be that of Pyrex helices of 3 mm diameter; this had a large

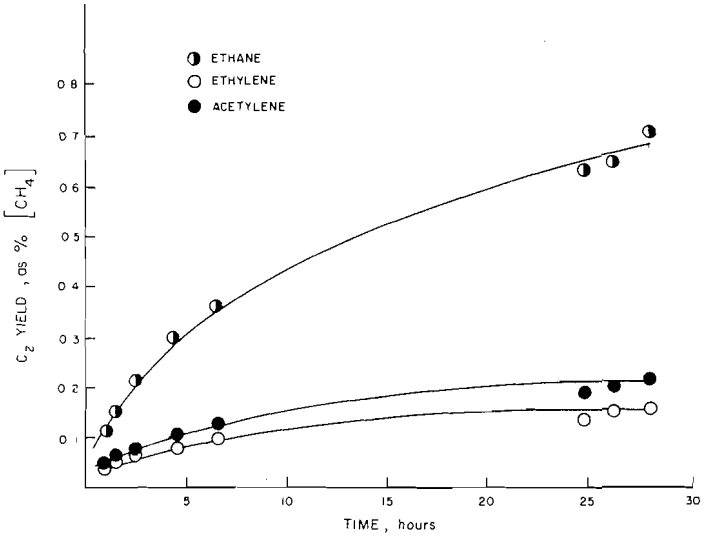

FIG. 1. C_2 hydrocarbon formation in rotator, CH_4 pressure = 200 Torr.

surface area and did not impede the flow of mercury, and vigorous agitation could be seen to be occurring. With this packing the rates of C_2 production increased approximately four-fold as illustrated in Fig. 2. Unlike the case of the unpacked reactor the rates of conversion did not fall off after a few hours operation but were maintained even after 200 h. It is probable that the fall-off in rates is due to the contamination of the glass surface. The agitation of the packing scours and keeps the surface free from contaminant. Indeed, with a packing of 5-mm diameter spheres distinct bands of contaminant built up only where the packing was not rubbing against the reactor wall.

(d) Pressure Effects

The rotator was used for detailed studies of the effect of pressure. The results for the initial rates of production of C_2 hydrocarbons are shown in Fig. 3. Despite some scatter in the results (due probably to the difficulty of obtaining reproducible surface conditions in the reactor) it is clear that the effect of pressure is not simple and monatonic but complex, the most significant feature being the sharp rise in rates as the pressure was reduced below 200 Torr. Many experiments were carried out in the region of 200 Torr to show that there was indeed a very sharp change, almost a discontinuity in behavior, at this pressure. Below 200 Torr there was a more gradual fall-off in rates. A similar discontinuity at 200 Torr was also found in experiments with the bubbler reactor.

(e) Gas Additives

We have used the rotating vessels to study the effect of the addition of helium, argon, krypton, xenon, nitrogen, and oxygen to methane at a total pressure of 200 Torr. The results are summarized in Table 1.

Discussion

The present results show that methane, characterized by its extremely low reactivity, can be decomposed and converted into higher hydrocarbons at room temperature by the simple mechanical agitation of mercury against glass and other insulator surfaces. The results are most conveniently discussed in terms of two aspects of the triboprocess; (*a*) the excitation process involving the conversion of mechanical into electrostatic energy; and (*b*) the chemical reactions occurring in the gas discharge arising from this excitation. The overall chemical changes and the effects of experimental conditions result from the interaction of these two aspects.

Excitation Mechanism

It is probable that the reactions are initiated by excited species produced in the gas discharge. The occurrence of the discharge shows that high electric fields of several 1000 V/cm must be

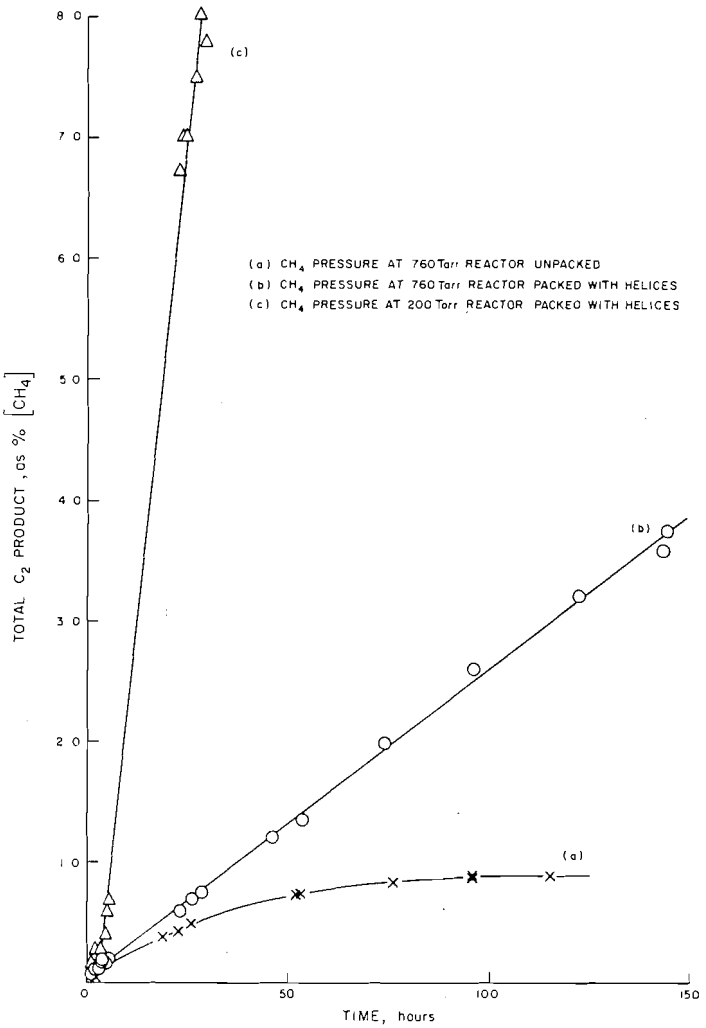

FIG. 2. Production of C_2 hydrocarbons in bubbler reactor.

created as mercury makes intermittent contact with the glass surface. Three mechanisms for the creation of such high fields are possible in the circumstances of the present experiments, contact, frictional, and spray electrification (9). Our results show that contact and/or frictional electrification are the predominant mechanisms for the following reasons.

(*a*) The rates of production of C_2 hydrocarbons depend on the reactor material. Thus there was a definite decrease in rate in the series quartz, Pyrex, and nylon, and no conversion at all occurred in the stainless-steel reactor even though bubble and spray formation must have taken place. Such effects can only be explained in terms of a mechanism involving liquid/solid interactions.

(*b*) The fall-off in the rates of conversion with time found in the case of the rotator and unpacked bubbler experiments is probably associated with the build-up of deposits on the vessel surfaces. This again shows that it is the liquid/solid interaction that is the most important.

(*c*) The use of a sinter to break up the gas stream, though leading to more bubble formation and disintegration, did not increase the efficiency of the bubbler. Furthermore, no spray or droplets were produced in the rotator and

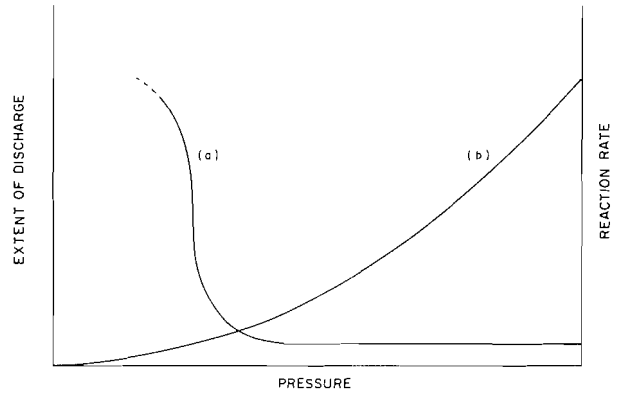

FIG. 4. Possible effects of pressure on (*a*) extent of discharging and (*b*) rate of chemical reaction.

the increasing conductivity along this series as expected, since an increase in surface conductivity will result in the accumulation of lower surface charge densities. However, other factors such as the potential depth of the electron traps in the insulator and the topology of the energy barrier to electron transfer also change along the series and these also will be important.

The Effect of Pressure

The complex dependence of the rate on the methane pressure is probably due to the result of the opposite effects of pressure on the two stages of the triboprocess; (*1*) initiation of the discharge; and (*2*) the reactions occurring in the discharge.

Consider first the effect of pressure on the breakdown of the gas. The field created by the separation of the mercury and glass will be proportional to the charge density, σ, on the two surfaces. Because one of the surfaces is a non-conductor, and further because the electron traps will be localized, there will be some spread in the value of the charge density and hence in the value of the field, E. At any one pressure, discharges will only occur near those sites where the critical breakdown field at this pressure is exceeded.

At high pressures very few sites will have fields sufficiently high to allow discharge to occur. No great change will take place on decreasing the pressure until the breakdown field required corresponds to the field created by the majority of sites. Further reduction in pressure will allow those sites with fields lower than the average to discharge. These changes are represented schematically by curve *a* of Fig. 4.

Consider now the effect of pressure on the rate of formation of C_2 hydrocarbons. Although no detailed mechanism can be formulated at present it is reasonable to assume that the rates of the reactions producing C_2 hydrocarbons will increase with increase in pressure. A second-order pressure dependence is shown in curve *b* of Fig. 4 for the purpose of discussion.

The overall influence of pressure on the yield of C_2 hydrocarbons will be the resultant of these two effects. The sharp discontinuity in the experimental curve occurs at that pressure of methane whose breakdown field corresponds to the field produced by most of the surface sites. The value of the pressure at which the discontinuity occurs can be used to give an order of magnitude estimate of the average charge density. The value of the breakdown field for methane at 200 Torr is estimated (10) to be 6800 V cm^{-1}. If the two surfaces are planar the field is given by $E = 4\pi\sigma/\varepsilon_0$ and thus $\sigma = E\varepsilon_0/4\pi$, where ε_0 is the dielectric constant for methane (4π will be replaced by different constants for different geometries). The value of σ so calculated is approximately 2 e.s.u. cm^{-2}, which is close to that found by other, more direct, methods (1, 11). The maximum number of surface sites will be given by the number of atoms in the surface (12) (10^{15} cm^{-2}) and hence if one electron is transferred to each site the

X-rays (50 kV)	760	100	14	Very small	14

*Ratios of the C_2 products are essentially unchanged down to 0.05% decomposition of CH_4.

maximum charge density will be 5×10^5 e.s.u. cm^{-2}. The value of 2 e.s.u. cm^{-2} shows that very few surface sites are charged.

Addition of Inert Gases

Inert gases were added to the methane in order to determine whether energy transfer and sensitization could affect the rates of production of C_2 hydrocarbons. The addition of 10% of inert gas to methane did not result in any pronounced change in the C_2 hydrocarbon yields or affect the product distribution significantly (Table 1). This shows that charge transfer from inert gas ions or excitation by long-lived metastable states of the inert gases (*e.g.* He^3S) are not effective at the 10% level.

In the case of a 1:1 mixture of the inert gases and methane at 200 Torr total pressure there are significant and specific effects on the rate of C_2 production. Consideration of the ionization potentials and the ionization cross-sections of the inert gases and methane allows at least a phenomenological explanation of the effect of the inert gas additives to be given. The cross-sections for electronic excitation will probably be of a similar magnitude and follow the same order as those for ionization.

The absence of any real effect in the case of helium can probably be attributed to the much smaller cross-section of helium compared with that of methane.

There is a real increase in rates in the presence of argon which is probably associated with two factors: (*1*) the cross-section for argon is close to that for methane; and (*2*) argon has a metastable state, ^3S, at 11.55 eV above the ground state. Indeed, the argon does have a significant effect on the product distribution (the acetylene yield is doubled with respect to that of ethane) and this could arise because ionized or excited argon favors those routes which lead to acetylene.

The progressive increase in rates, argon < krypton < xenon, correlates with the increase in cross-section in this series. If is of interest that the ionization potential of xenon is below that of methane, since this suggests that the first excited state of the xenon ion with energy of 13.43 eV may be an important participant (13).

Possible Reaction Intermediates

The present results allow some conclusions to be drawn about the relative importance of intermediates such as radicals, ions or carbenes in the triboprocess.

Radicals

Oxygen produces a dramatic reduction in the ethane yield but is almost without effect on the ethylene and acetylene yields (Table 2). The C_3 yields are also reduced to near zero. This shows that ethane is produced principally from intermediates not involved in producing ethylene and acetylene. The reaction between radicals and oxygen (*e.g.*, $CH_3 + O_2 + M \rightarrow CH_3O_2$) is known to be very fast so that the decrease in ethane yield in the presence of oxygen indicates that methyl radical combination could be an important source of ethane. The localized nature of the discharge will favor radical–radical reactions. The fall in yield of the C_3 hydrocarbons also indicates that they are formed by free radical reactions. The absence of any large effect in the case of ethylene and acetylene shows that these products are formed via non-radical intermediates.

Ions

In the X-ray radiolysis (14) and vacuum u.v. photolysis (58.4 nm (15, 16)) the products are considered to arise from the reactions of the intermediates CH_4^+, CH_3^+, and $C_2H_3^+$. Since the product distribution from these processes (Table 2) is so different from that found in the present work under similar conditions, it is unlikely that these intermediates are important in the triboprocess. The participation of the CH_5^+ cannot be excluded but Field and Munson (17) have shown that this ion does not react rapidly with methane.

Carbenes

Mahan and Mandal (18), Ausloos and Lias (19) (photolysis at 123.6 nm), and Manton and Tickner (20) (15 eV electron irradiation), all suggest that singlet methylene (ground or excited state) may be an important precursor of the C_2 hydrocarbons in these cases. If this conclusion is correct the similar product distribution found in the triboprocess suggests that methylene may participate here also. The absence of any effect of oxygen on the yields of ethylene and acetylene is evidence for the formation of these hydrocarbons from a precursor that does not react appreciably with oxygen. Singlet methylene satisfies this requirement and the following reactions of this species can explain most of the present results.

$$CH_2 + CH_4 \rightarrow C_2H_6^*$$
$$C_2H_6^* \rightarrow C_2H_4 + H_2$$
$$\rightarrow C_2H_2 + 2H_2$$
$$\rightarrow 2CH_3$$
$$C_2H_6^* + M \rightarrow C_2H_6 + M$$

Methylene could be produced by electron excitation or by a recombination process:

$$CH_4 \xrightarrow{e} CH_4^* \rightarrow CH_2 + H_2$$
$$CH_4^+ + e \rightarrow CH_4^* \rightarrow CH_2 + H_2$$

Acetylene could also be produced from the reaction of C (^{1}D) atoms with methane (22),[1]

$$C(^1D) + CH_4 \rightarrow C_2H_2 + H_2$$

though we suspect that the relatively small effect of oxygen on the acetylene yield suggests that carbon atom reactions are not important in this system (23).

The C_3 hydrocarbons were not produced during the early stages of the triboprocess and are thus most likely to result from secondary reactions of the C_2 hydrocarbons.

The polarographic behavior of the lead ion in the presence of excess DTPA was studied over the pH range 2–10. Three different polarographic waves can be distinguished. The wave occurring at the most negative potentials and highest pH values is assigned to an irreversible reduction of $PbHA^{2-}$. The kinetic current treatment gives the results

$$PbHA^{2-} \underset{k \leqslant 8.7 \times 10^{8}\ M^{-1}\ s^{-1}}{\overset{k \geqslant 8.7 \times 10^{4}\ s^{-1}}{\rightleftharpoons}} PbA^{3-} + H^{+}$$

The wave occurring at intermediate potentials and pH values is also assigned to an irreversible reduction of $PbHA^{2-}$. The kinetic current treatment gives the results

$$PbHA^{2-} \underset{k = 2.6 \times 10^{4}\ M^{-1}\ s^{-1}}{\overset{k = 0.79\ s^{-1}}{\rightleftharpoons}} PbA^{3-} + H^{+}$$

Protonation is assumed to occur at different coordination sites. In the former case it occurs at the center carboxyl group; in the latter case it occurs at a terminal nitrogen atom. The reversible wave occurring at the most positive potentials and lowest pH values can be interpreted in either of two ways

$$Pb^{2+} + H_2A^{3-} \underset{k = 1.5 \times 10^{6}\ M^{-1}\ s^{-1}}{\overset{k = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}}{\rightleftharpoons}} PbHA^{2-} + H^{+}$$

$$Pb^{2+} + H_2A^{3-} \underset{k = 1.6 \times 10^{4}\ s^{-1}}{\overset{k = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}}{\rightleftharpoons}} PbH_2A^{-}$$

For the stability constant we obtained $\log K_{PbA} = 19.1$. All values above were obtained at 25° and an ionic strength of 0.2.

Nous avons étudié le comportement polarographique de l'ion plomb en présence d'un excès de DTPA, sur une gamme de pH de 2–10. On a pu distinguer trois vagues polarographiques différentes. La vague se produisant aux potentiels les plus négatifs et aux valeurs les plus élevées de pH est assignée à une réduction irréversible de $PbHA^{2-}$. Le traitement de courant cinétique donne les résultats suivants

$$PbHA^{2-} \underset{k \leqslant 8.7 \times 10^{8}\ M^{-1}\ s^{-1}}{\overset{k \geqslant 8.7 \times 10^{4}\ s^{-1}}{\rightleftharpoons}} PbA^{3-} + H^{+}$$

La vague située aux valeurs de pH et de potentiel intermédiaires est aussi assignée à une réduction irréversible de $PbHA^{2-}$. Le traitement de courant cinétique permet d'obtenir

$$PbHA^{2-} \underset{k = 2.6 \times 10^{4}\ M^{-1}\ s^{-1}}{\overset{k = 0.79\ s^{-1}}{\rightleftharpoons}} PbA^{3-} + H^{+}$$

On suppose que la protonation se produit à différents sites de coordination. Dans le premier cas, elle se produit en groupement carboxyl central; dans le dernier cas, à l'atome d'azote terminal.

[1]We thank the National Research Council of Canada for financial support of this work.

La vague réversible située aux potentiels les plus positifs et aux pH les plus bas peut s'interpréter de deux façons différentes

$$Pb^{2+} + H_2A^{3-} \underset{k = 1.5 \times 10^{6}\ M^{-1}\ s^{-1}}{\overset{k = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}}{\rightleftharpoons}} PbHA^{2-} + H^{+}$$

$$Pb^{2+} + H_2A^{3-} \underset{k = 1.6 \times 10^{4}\ s^{-1}}{\overset{k = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}}{\rightleftharpoons}} PbH_2A^{-}$$

Nous obtenons pour la constante de stabilité log $K_{PbA} = 19.1$ Toutes les valeurs précédentes ont été obtenues à 25° et à une force ionique de 0.2. [Traduit par le journal]

Introduction

Information on the thermodynamics and kinetics of equilibria between metal ions and aminopolycarboxylic acids in aqueous solution is of importance from both a theoretical viewpoint and because of the wide use of aminopolycarboxylic acids in analytical applications. In favorable circumstances the polarographic method can be used to obtain such information and has been applied, for example, to the study of solutions of Cd^{2+} with NTA (1, 2), with EDTA (3), and with TTHA (4). In this paper we describe a systematic study of solutions of Pb^{2+} with diethylenetriaminepentaacetic acid (DTPA) by the polarographic method. These results complement and extend those obtained in our earlier proton magnetic resonance study of this system (5).

Experimental

DTPA (J. T. Baker) was recrystallized from hot water, dried, weighed, and dissolved in distilled water containing sufficient sodium hydroxide to affect solution. This was made up to a sufficient volume to give a 0.01 *M* stock solution. A stock solution of Pb^{2+} was prepared from lead nitrate (Fisher Scientific Co.). Chloroacetic acid – chloroacetate buffers were used for the p*H* range 2–4 and acetic acid – acetate buffers for the range 4–8. Sodium perchlorate was used to adjust the ionic strength of the test solution to 0.2. Triton X-100 was obtained from Rohm and Hass. All solutions were stored in polyethylene bottles. Test solutions were prepared by taking appropriate aliquots of the stock, buffer and sodium perchlorate solutions, then diluting to nearly the volume required. The p*H* was measured (Radiometer type PH28 p*H* meter calibrated at p*H* = 2.00, 4.01, and 6.86 with Beckman buffers), then adjusted by addition of sodium hydroxide or perchloric acid as required. The solution was then made up to its final volume with distilled water.

The test solutions were placed in one arm of an H-cell (6) immersed in a water thermostat, deoxygenated with nitrogen, and polarograms recorded with a Sargent model XXI polarograph. The potential of the dropping electrode was recorded against a saturated calomel electrode contained in the other arm of the H-cell. When accurate potential measurements were required a Rubicon type B precision potentiometer was used.

Capillary characteristics were measured at open circuit at a number of mercury heads (corrected for the interfacial tension at the mercury drop). For the most frequently used conditions the characteristics were: $h = 50$ cm, $h_{corr} = 48.4$ cm, $m = 1.733$ mg/s, $t = 5.02$ s, $m^{2/3}t^{1/6} = 1.887$; $h = 60$ cm, $h_{corr} = 58.4$ cm, $m = 2.071$ mg/s, $t = 4.20$ s, $m^{2/3}t^{1/6} = 2.064$; $h = 70$ cm, $h_{corr} = 68.4$ cm, $m = 2.396$ mg/s, $t = 3.63$ s, $m^{2/3}t^{1/6} = 2.217$; where the symbols have their conventional meanings.

Results

In the p*H* range 2–4 polarograms of solutions containing Pb(II) and DTPA exhibited strong maxima. These maxima could be suppressed by the addition of small amounts of gelatin or Triton X-100. Detailed studies showed the latter compound to perform better as a maximum suppressor than the former. Figure 1 shows the effect of various concentrations of Triton X-100 on the polarograms of a 1:2, Pb(II):DTPA solution at p*H* = 4.0. Low concentrations of Triton X-100 suppress the maximum and reveal that at least three waves are present in the polarogram. Higher concentrations of Triton X-100 shift the waves to more negative potentials and reduce the heights of the waves. Triton X-100 (up to 0.003%) had little effect on the reduction of free Pb^{2+} other than to suppress the maximum. Above p*H* = 4 the addition of a maximum suppressor was unnecessary.

Figure 2 shows the effect of addition of increasing amounts of DTPA added to a given amount of Pb^{2+} at p*H* = 4.0. As the DTPA concentration increases the height of the original wave decreases and a second wave appears at more negative potentials. Polarograms obtained at higher ligand concentrations show a third

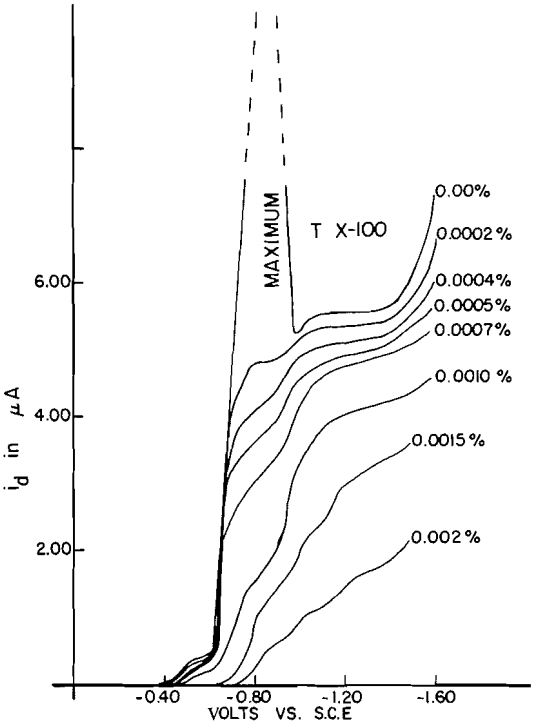

FIG. 1. Effect of Triton X-100 on the polarogram. Experimental conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 2.0×10^{-3} M; pH = 4.0; h = 60 cm; t = 4.20 s; μ = 0.2; T = 25°.

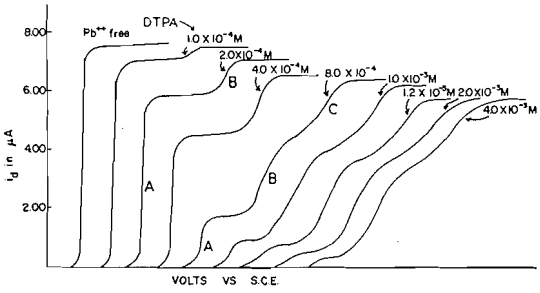

FIG. 2. Effect of DTPA concentrations on the polarograms. Experimental conditions: [lead] = 1.0×10^{-3} M; pH = 4.0; h = 60 cm; t = 4.20 s; μ = 0.2; T = 25°; Triton X-100 = 0.0001%. (For clarity, successive polarograms are displaced along the abscissa.)

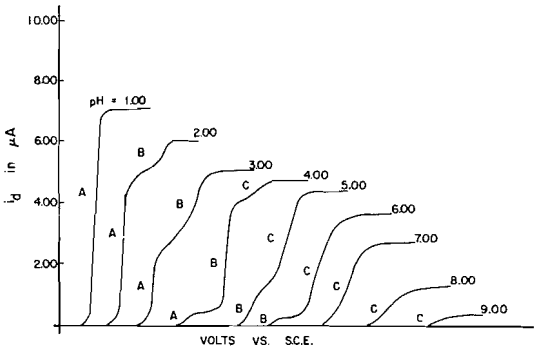

FIG. 3. Effect of pH on the polarograms. Experimental conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 2.0×10^{-3} M; h = 60 cm; t = 4.20 s; μ = 0.2; T = 25°; Triton X-100 = 0.0001% (pH ≤ 4.0), 0% (pH > 4.0). (For clarity, successive polarograms are displaced along the abscissa.)

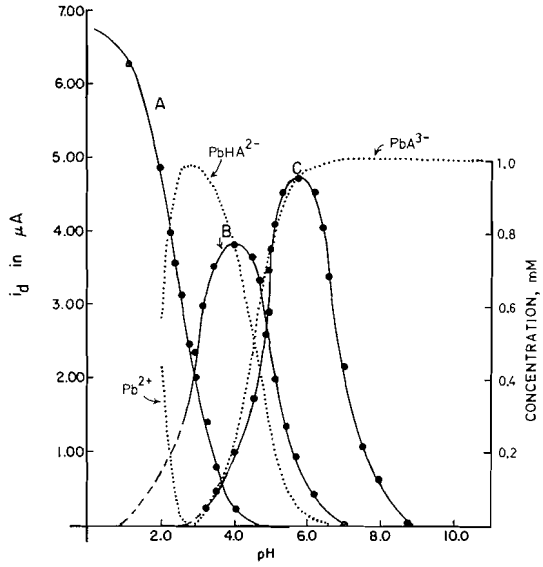

FIG. 4. Limiting currents of waves A, B, and C as a function of pH (solid line) and calculated concentrations of lead-containing species (dotted line). Conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 2.0×10^{-3} M; h = 60 cm; t = 4.20 s; μ = 0.2; T = 25°.

wave, at yet more negative potentials. In subsequent discussion the three waves will be referred to as waves A, B, and C, respectively. As the concentration of ligand is increased, the height of wave A decreases, but wave A is still detectable up to the highest ligand concentrations shown. The heights and positions of the three waves were strongly pH dependent, as verified by studies on solutions with metal:ligand concentration ratios of 1:2 and 1:8. Results obtained for the 1:2 ratio are shown in Figs. 3, 4, and 5.

The characteristics of the three waves are summarized in Table 1. It is appropriate to recall the following properties of polarographic waves: (i) for a reversible two-electron reduction at 25°

a reciprocal slope of -29.5 mV for the plot of $\log \{i/(i_l - i)\}$ *vs.* E is required. An irreversible reduction will give a value numerically greater than 29.5 mV; (*ii*) for a diffusion controlled reduction $i_l \propto h_{corr}^{1/2}$, whereas for a kinetically controlled reduction i_l is independent of h_{corr}; (*iii*) diffusion controlled waves typically have wave height temperature coefficients of about 1.5%/°C. Kinetically controlled reduction waves usually have temperature coefficients significantly greater than this. Table 1 allows the following conclusions about the waves to be drawn:

Wave A

This wave changes from a diffusion controlled to a kinetically controlled reduction wave as the pH increases, *e.g.* at p$H = 4.00$ when i_l was less than 10% of the total diffusion current its properties resemble those of a kinetic wave. The electrochemical reduction step is however reversible.

Waves B and C

At small wave heights, *e.g.* at p$H = 6.0$ and p$H = 7.0$, respectively, the properties of these waves are consistent with those of irreversible, kinetically controlled reduction waves.

Supplementary Studies

To supply data required for the mathematical interpretation of the characteristics of wave A, the diffusion currents and half-wave potentials of the lead ion were measured in solutions identical to those of the test solutions except that they did not contain DTPA. The values of the half-wave potentials in the buffer solutions are shown in Fig. 5.

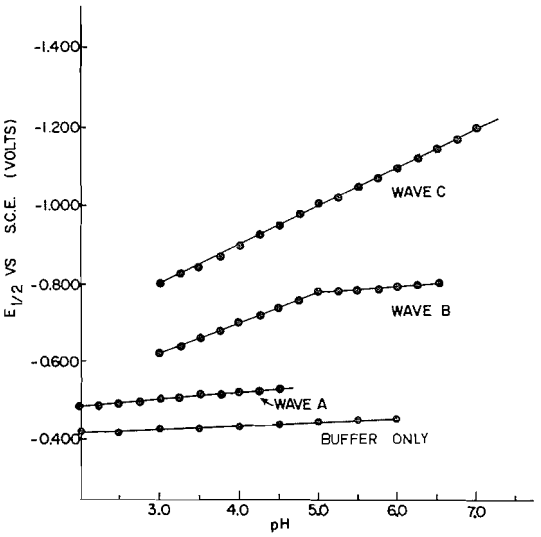

FIG. 5. Half-wave potentials of waves A, B, and C as a function of pH, and of free lead in the same buffer. Conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 2.0×10^{-3} M; $h = 60$ cm; $t = 4.20$ s; $T = 25°$; $\mu = 0.2$.

Discussion

The polarographic method of determining formation constants from half-wave potentials requires a reversible electron-transfer electrode reaction. Hence only wave A could yield information of this type. Although waves B and C could not be used to obtain formation constants the waves can be analyzed by the kinetic wave treatment (see Appendix 2) to obtain data on the rates of chemical equilibria in the solutions. The species in solution can be deduced from equilibrium constant data and are shown in Fig. 4 using the values $K_{PbA} = 10^{18.9}$, $K^{H}_{PbHA} = 10^{4.52}$ (7), where DTPA is represented by H_5A, and allowing for the complexing effect of the buffer. (Throughout this paper, published equilibrium constants are used without any attempt to correct for effects of ionic strength. We used a constant ionic strength of 0.2 throughout.) The waves are discussed in order of increasing complexity of interpretation, *i.e.* in reverse order.

Wave C

Potentiometric (7) and n.m.r. (5) measurements on solutions containing Pb^{2+} and DTPA have been interpreted by the existence of pH dependent equilibria involving the complex species $PbHA^{2-}$ and PbA^{3-} in solution. When p$H > 6$, in presence of excess DTPA, the only metal-containing species present in solution in significant concentration is PbA^{3-}. If this species is non-reducible at the dropping mercury electrode, this would account for the disappearance of all reduction waves when p$H > 9$. The assumption that wave C is due to the reduction of $PbHA^{2-}$ results in a successful application of the kinetic wave theory. We can write the reactions as

$$PbHA^{2-} \underset{k_p}{\overset{k_d}{\rightleftharpoons}} PbA^{3-} + H^+ \quad \text{(rate determining)}$$

$$PbHA^{2-} + Hg + 2e^- \rightleftharpoons Pb(Hg) + HA^{4-} \quad \text{(fast when mean limiting current reached)}$$

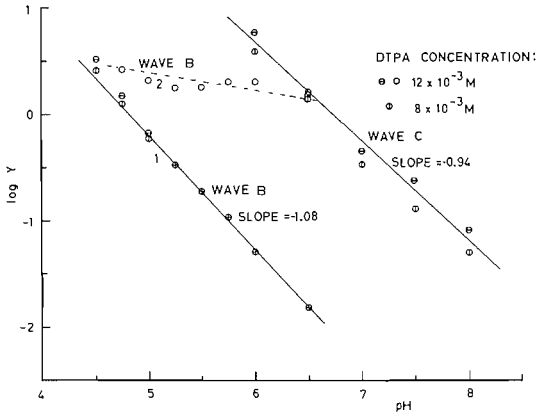

FIG. 6. Test of kinetic current theory for waves B and C. Wave B: 1 (solid line), $\log Y = \{\log i_l/(i_d - i_l)\} + \log \alpha_{PbA(H)}$. Wave B: 2(broken line), $\log Y = \log \{i_l/(i_d - i_l)\} + \log \alpha_{PbHA(H)}$. Wave C: $\log Y = \log \{i_l/(i_d - i_l)\}$. Conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 2.0×10^{-3} M, and 8.0×10^{-3} M; $h = 60$ cm; $t = 4.20$ s; $\mu = 0.2$; $T = 25°$.

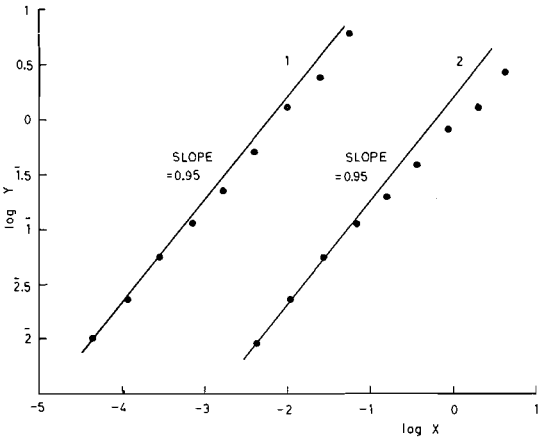

FIG. 7. Test of kinetic current theory for wave A. Plot 1: $\log Y = \log\{i_l/(i_d - i_l)\} + \log\{1 + (i_l C_M \alpha_{H_2A(H)})/(i_d C_L \alpha_{PbHA(H)})\}$; $\log X = \frac{1}{2}\{\log \alpha_{Pb(B)} + \log \alpha_{H_2A(H)}\} - \log \alpha_{PbHA(H)} - \text{pH}$. Plot 2: $\log Y = \log \{i_l/(i_d - i_l)\} + \log \{1 + (i_l C_M \alpha_{H_2A(H)})/(i_d C_L \alpha_{PbH_2A(H)})\}$; $\log X = \frac{1}{2}\{\log \alpha_{Pb(B)} + \log \alpha_{H_2A(H)}\} - \log \alpha_{PbH_2A(H)}$. Conditions: [lead] = 1.0×10^{-3} M; [DTPA] = 8.0×10^{-3} M; $h = 60$ cm; $t = 4.20$ s; $\mu = 0.2$; $T = 25°$.

For this reaction (see appendix 2) a plot of $\log\{i_l/(i_d - i_l)\}$ *vs.* pH should yield a straight line with slope = -1.0 (see eq. A2.2). This is verified in Fig. 6 where the value of $i_d = 5.4$ μA (the maximum value of the sum of the heights of wave B and wave C) was used at $t = 4.2$ s. We return to discussion of this reaction after some discussion of wave B.

Wave B

The reaction that was expected to produce this wave was:

$$\underset{\text{reducible}}{PbH_2A^-} \underset{k_p}{\overset{k_d}{\rightleftharpoons}} PbHA^{2-} + H^+ \quad \text{(rate determining)}$$

provided that the equilibrium concentration of PbH_2A^- is insignificant. In fact, potentiometric (7) and n.m.r. (5) studies have failed to detect the species PbH_2A^- when p$H > 2$ suggesting that its concentration in solution never exceeds an upper limit of about 5–10% of other complex species, *i.e.* $K^H_{PbH_2A} \leqslant 10^{2.0}$. Thus, $[PbH_2A^-]$ should certainly be insignificant at pH = 5–6.5. Equation A2.4 given as a solution to the above reaction scheme must be modified to include the pH dependence of $[PbHA^{2-}]$ to give

$$[1] \qquad \frac{i_l}{i_d - i_l} = \frac{0.886\ [H^+]}{\alpha_{PbHA(H)}} \sqrt{k_p t K^H_{PbH_2A}}$$

where $\alpha_{PbHA(H)} = 1 + K^H_{PbHA}/[H^+]$ (see eq. A1.6). A plot of $\log\{i_l/(i_d - i_l)\} + \log \alpha_{PbHA(H)}$ *vs.* pH is shown in Fig. 6. A straight line with a slope of -1.0 should be obtained but the observed slope (-0.15 approx.) is significantly different from this. The reaction scheme

$$\underset{\text{reducible}}{PbH_2A^-} \rightleftarrows PbHA^{2-} \rightleftarrows PbA^{3-}$$

where the equilibria involve reactions of comparable rates was also considered. The solution to this problem has been given by Koutecky (8). It was found that wave B did not correspond to this reaction scheme. The only reaction that was found to give a satisfactory response to the kinetic wave theory was

$$\underset{\text{reducible}}{PbHA^{2-}} \underset{k_p}{\overset{k_d}{\rightleftharpoons}} PbA^{3-} + H^+ \quad \text{(rate determining)}$$

as for wave C. The corrected form of eq. A2.2 is

$$[2] \qquad \frac{i_l}{i_d - i_l} = \frac{0.886\ [H^+]}{\alpha_{PbA(H)}} \sqrt{k_p t K^H_{PbHA}}$$

A plot of $\log\{i_l/(i_d - i_l)\} + \log \alpha_{PbA(H)}$ *vs.* pH has a slope close to -1.0 (see Fig. 6). The implication of this result is that the protonated complex giving rise to wave B has a different structure from the protonated complex giving rise to wave C.

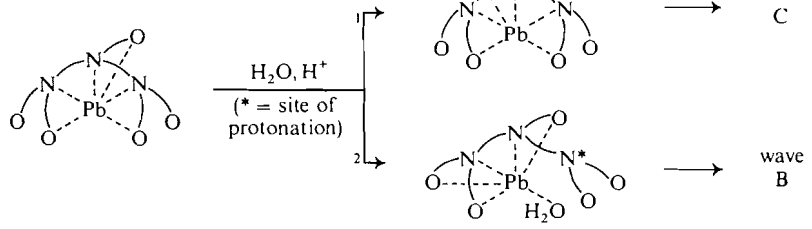
Interpretation of Waves B and C

Application of the kinetic wave theory to these waves leads to rate expressions of the same kinetic form, namely, rate $= k_p[PbA^{3-}][H^+]$, with different values of k_p for each wave. Thus, the waves can be interpreted as the reduction of protonated complexes of different structures. The slower protonation reaction leads to the more readily reduced complex. Previously, we have interpreted the structure of PbA^{3-} from n.m.r. studies (5) and suggest that the present observation can be explained by the scheme



This scheme makes no implication as to the rate-determining steps in what are certainly multi-step reactions. The slow step in each reaction is likely to be the breakage of the appropriate metal ligand bond, and entry of a water molecule into the coordination shell of the metal ion; this is followed by rapid proton transfer equilibria. Protonation of the ligating atoms would block their reentry into the coordination shell. The lability of the metal–water bonds in the protonated complexes would provide an opportunity for electron transfer to occur at the electrode surface.

Although reaction 1 is assumed to be much faster than reaction 2 the equilibrium constant is such that its product is not detectable by the n.m.r. studies, *i.e.* the measured equilibrium constant $K^H_{PbHA} = 10^{4.52}$ (7) corresponds to that for reaction 2 and the corresponding equilibrium constant for reaction 1 will be smaller than this. If we assume an upper limit of $10^{4.0}$ for this equilibrium constant then the wave C data lead to a lower limit for reaction 1 for k_p of 8.7×10^8 l mol^{-1} s^{-1} and an upper limit for k_d of 8.7×10^4 s^{-1}. For reaction 2, using the wave B data, we obtain $k_p = 2.6 \times 10^4$ l mol^{-1} s^{-1} and $k_d = 0.79$ s^{-1}. Furthermore, it is reasonable to expect reaction 2 to be slower than reaction 1 because more extensive reorganization of the coordination shell of the metal ion is necessary. In addition, in aminopolycarboxylate complexes the metal–oxygen bonds are more labile than the metal–nitrogen bonds (see ref. 5 and references therein).

Wave A

Wave A is due to a reversible electrochemical reduction. Its height is much greater than expected from the equilibrium concentration of uncomplexed Pb^{2+} (see Fig. 4). Wave A can be explained by the reduction of uncomplexed Pb^{2+} produced by a rate determining dissociation of its DTPA complex in the diffusion layer. Application of the kinetic current treatment in the pH region where the equilibrium concentration of Pb^{2+} is insignificant, *i.e.* when p$H \geqslant 3$ (Fig. 4) shows that the major contribution to production of wave A under kinetic control conditions comes from the sequence:

$$\underset{\text{reducible}}{Pb^{2+}} + H_2A^{3-} \rightleftarrows PbH_2A^- \rightleftarrows PbHA^{2-} + H^+$$

where it is not possible to determine mathematically which reaction is rate determining. If the reaction $PbHA^{2-} + H^+ \rightarrow PbH_2A^-$ is rate determining, followed by a rapid dissociation of PbH_2A^- at the electrode surface to give free Pb^{2+}, the reaction reduces to

$$\underset{\text{reducible}}{Pb^{2+}} + H_2A^{3-} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} PbHA^{2-} + H^+$$

The species Pb^{2+}, H_2A^{3-}, and $PbHA^{2-}$ also participate in other equilibria. After applying the necessary corrections (see appendix 1) to eq. A2.6 the expected limiting current for wave A

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is given by

$$[3]\quad \left(\frac{i_l}{i_d - i_l}\right)\left(1 + \frac{i_l}{i_d}\cdot\frac{C_M}{C_L}\cdot\frac{\alpha_{H_2A(H)}}{\alpha_{PbHA(H)}}\right)^{1/2} = \frac{0.886\,[H^+]}{\alpha_{PbHA(H)}}\sqrt{\frac{k_2 t \alpha_{Pb(B)}\alpha_{H_2A(H)}}{K_{eq}C_L}}$$

where C_L is the overall concentration of ligand not bound up in complex formation, and C_M is the overall concentration of metal. Hence, a plot of log (l.h.s.) *vs.* $\frac{1}{2}(\log \alpha_{Pb(B)} + \log \alpha_{H_2A(H)}) - \log \alpha_{PbHA(H)} - pH$ should yield a straight line with a slope = 1.0. This plot is shown in Fig. 7.

Alternatively, if the rate determining step in supplying Pb^{2+} to the electrode surface is dissociation of PbH_2A^- the reaction reduces to

$$\underset{\text{reducible}}{Pb^{2+}} + H_2A^{3-} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} PbH_2A^-$$

$$K^{Pb}_{PbH_2A} = k_3/k_4$$

The expected limiting current for wave A is given by

$$[4]\quad \left(\frac{i_l}{i_d - i_l}\right)\left(1 + \frac{i_l}{i_d}\cdot\frac{C_M}{C_L}\cdot\frac{\alpha_{H_2A(H)}}{\alpha_{PbH_2A(H)}}\right)^{1/2} = \frac{0.886}{\alpha_{PbH_2A(H)}}\sqrt{\frac{k_4 t \alpha_{Pb(B)}\alpha_{H_2A(H)}}{K^{Pb}_{PbH_2A}C_L}}$$

This equation was obtained by modifying eq. A2.9 to allow for participation by Pb^{2+}, H_2A^{3-}, and PbH_2A^{2-} in other equilibria. A plot of log (l.h.s.) *vs.* $\frac{1}{2}(\log \alpha_{H_2A(H)} + \log \alpha_{Pb(B)}) - \log \alpha_{PbH_2A(H)}$ should yield a straight line with a slope = 1.0. To test this plot, values $\alpha_{PbH_2A(H)}$ are required. These were calculated using an upper limit, discussed earlier, for $K^{H}_{PbH_2A}$ of $10^{2.0}$. Use of this value does not greatly affect values of $\alpha_{PbHA(H)}$ when $pH \geqslant 2.5$, as used in the previous test plot. The plot is shown in Fig. 7. The two plots shown in Fig. 7 are very similar in form because $\alpha_{PbHA(H)} = [H^+]K^{Pb}_{PbH_2A}\alpha_{PbH_2A(H)}$. The slopes of the plots at the high pH end are close to the required value of 1.0 but deviations occur at the low pH end, where uncertainties in data used in calculating α functions probably lead to greater inaccuracies, and the conditions desired for true kinetic currents hold less rigorously.

Approximate rate constants for these reactions were calculated using the data for pH = 4.50. For the first case, using eq. A2.6 to evaluate $K_{eq} = 10^{4.5} \times 10^{18.9} \times 10^{-8.7} \times 10^{-10.5} = 10^{4.2}$, we obtain $k_2 = 1.5 \times 10^6$ l mol^{-1} s^{-1} and $k_1 = 2.5 \times 10^{10}$ l mol^{-1} s^{-1}. For the second case, using eq. A2.9 to evaluate $K^{Pb}_{PbH_2A} = 10^{2.0} \times 10^{4.5} \times 10^{8.9} \times 10^{-8.7} \times 10^{-10.5} = 10^{6.2}$ as an upper limit, we obtain $k_4 = 1.6 \times 10^4$ s^{-1} (lower limit) and $k_3 = 2.5 \times 10^{10}$ l mol^{-1} s^{-1} (not dependent on value of $K^{Pb}_{PbH_2A}$). If the first case is rate determining then a higher value for k_4 is implied. If the second case is rate-determining then a higher value for k_2 is implied. We suggest that the slow step in each case would be the breakage of a metal–ligand bond as the complex further unwraps after the first metal–nitrogen bond is broken. In the first case breakage of the second metal–nitrogen bond (probably that involving the center nitrogen atom) is rate-determining; in the second case breakage of the third metal–nitrogen bond is rate-determining.

Calculation of Equilibrium Constants

Since wave A corresponds to a reversible reduction of lead ions the half-wave potentials may be used for the calculation of equilibrium constants. For a reversible diffusion-controlled reduction of a metal complex the dependence of the half-wave potential on the stability constant has been given (9), and for a 1:1 metal:ligand complex at 25°, simplifies to

$$[5]\quad E^c_{1/2} = E^s_{1/2} - \frac{0.0591}{n}\log K_{app}C^0_L$$

where $E^c_{1/2}$ and $E^s_{1/2}$ are the half-wave potentials of the complex and simple ions, respectively, K_{app} is the apparent stability constant of the complex under the prevailing conditions, and C^0_L is the concentration of ligand at the electrode surface. For a kinetically controlled reversible reduction at 25 °C $E^c_{1/2}$ is related to $E^k_{1/2}$, the measured half-wave potential of the kinetic wave (10) by

$$[6]\quad E^c_{1/2} = E^k_{1/2} + \frac{0.0591}{n}\log\frac{i_l}{i_d}$$

where i_l is the limiting kinetic current. Also

$$C^0_L = C_L + C_M\cdot\frac{i_l}{i_d}$$

where C_L is the free ligand concentration and C_M is the overall metal ion concentration.

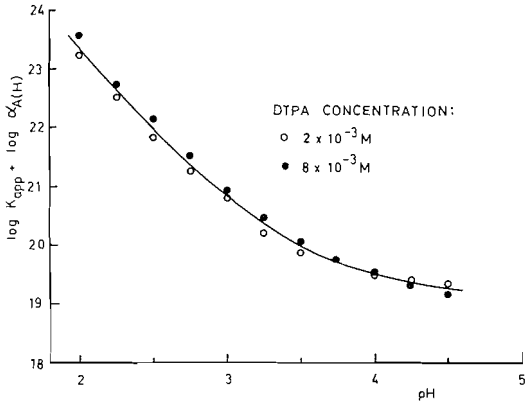


Fig. 8. Values of $\log K_{app} + \log \alpha_{A(H)}$ as a function of pH. Conditions: [lead] = 1.0×10^{-3} M: [DTPA] = 2.0×10^{-3} M and 8.0×10^{-3} M; $h = 60$ cm; $t = 4.20$ s; $\mu = 0.2$; $T = 25°$.

Combining and rearranging eqs. 1 and 2 we obtain

$$[7] \quad \log K_{app} = \frac{n}{0.0591}(E^{k}_{1/2} - E^{s}_{1/2}) - \log \frac{i_l}{i_d} - \log C^{0}_{L}$$

Values of $\log K_{app}$ were calculated from the wave A data (Fig. 5) over the pH range 2.0–4.5. The effect of the buffer on half-wave potentials is cancelled out by taking $E^{s}_{1/2}$ as the value for the free lead ion in the same buffer at the same pH.

Using the methods of appendix 1 it is now readily shown that

$$[8] \quad K_{app} = K_{PbA}\alpha_{PbA(H)}/\alpha_{A(H)}$$

or

$$[9] \quad \log K_{app} + \log \alpha_{A(H)} = \log K_{PbA} + \log \alpha_{PbA(H)}$$

If we assume that a series of protonated complexes is possible then using the methods of appendix 1, it can be shown that

$$[10] \quad \alpha_{PbA(H)} = [1 + 10^{\log K^{H}_{PbHA} - pH} + 10^{\log K^{H}_{PbH_2A} + \log K^{H}_{PbHA} - 2pH} + \ldots]$$

an expression which is convenient for graphical interpretation. In Fig. 8, $\log K_{app} + \log \alpha_{A(H)}$ is plotted against pH. Assuming that singly, doubly, and triply protonated complexes are possible the best fit to the experimental data was obtained from

$$[11] \quad \log K_{app} + \log \alpha_{A(H)} = 19.10 + \log (1 + 10^{4.05 - pH} + 10^{7.45 - 2pH} + 10^{10.20 - 3bH})$$

which gives $\log K_{PbA} = 19.10$, $\log K^{H}_{PbHA} = 4.05$, $\log K^{H}_{PbH_2A} = 3.40$, and $\log K^{H}_{PbH_3A} = 2.75$. The first of these equilibrium constants is in good agreement with the literature value (7) used earlier and supports our interpretation of wave A. The other values are inaccurate since other reliable evidence (5, 7) fails to detect doubly and triply protonated complexes when p$H \geqslant 2$. Reasons for the failure of the polarographic method here are not obvious but may be associated with the necessity to use a maximum suppressor when p$H < 4.0$.

Appendix 1

Use of Alpha Coefficients

The nature of the solutions studied in this report is complex. Several species participate in many side reactions and to simplify the equations used in other parts of the paper we have adopted the use of alpha coefficients introduced by Schwarzenbach (11) and further described by Ringbom (12). For example, for a ligand L which can complex with a metal but also participate in various side reactions we have

$$[A1.1] \quad \alpha_L = \frac{[L']}{[L]}$$

where [L] denotes the concentration of the free active form of the ligand in solution and [L′] denotes the concentration not only of the free ligand but also all the concentrations of the complexing agent not bound to the metal. Thus, for DTPA, which can be represented as H_5A, we can write

$$[A1.2] \quad \alpha_{A(H)} = ([A^{5-}] + [HA^{4-}] + [H_2A^{3-}] + [H_3A^{2-}] + [H_4A^{-}] + [H_5A])/[A^{5-}]$$

where $\alpha_{A(H)}$ is a coefficient accounting for the influence of the side reaction between A^{5-} and H^{+} on the reaction between A^{5-} and the metal

ion. Equation A1.2 can be rewritten as

$$[A1.3]\quad \alpha_{A(H)} = 1 + \frac{[H^+]}{K_5} + \frac{[H^+]^2}{K_4K_5} + \frac{[H^+]^3}{K_3K_4K_5} + \frac{[H^+]^4}{K_2K_3K_4K_5} + \frac{[H^+]^5}{K_1K_2K_3K_4K_5}$$

where K_1, K_2, K_3, K_4, and K_5 are the successive ionization constants of DTPA. Values of $\alpha_{A(H)}$ were calculated using the following values of the ionization constants: $pK_1 = 1.92$, $pK_2 = 2.66$, $pK_3 = 4.34$, $pK_4 = 8.67$, $pK_5 = 10.50$, which are an average of literature values (12–15). If required, values of $\alpha_{HA(H)}$, $\alpha_{H_2A(H)}$, etc. can be obtained by similar methods.

Metal ions which are not complexed to L may be involved in complex formation reactions with buffer components, and we can write

$$[A1.4]\quad \alpha_{M(B)} = \frac{[M^{z+}] + [MB]}{[M^{z+}]} = 1 + \frac{[MB]}{[M^{z+}]}$$

where [MB] represents the sum of concentrations of complexes between buffer and metal ions. For a buffer containing the components of a monobasic acid, such as acetic or chloroacetic acid, equation A1.4 becomes

$$[A1.5]\quad \alpha_{M(B)} = 1 + K_{MB}[B^-] = 1 + \frac{K_{MB}C_B}{(1 + [H^+]K_a^{-1})}$$

where K_{MB} is the stability constant of the complex of the metal ion with B^-, K_a is the ionization constant of HB, and C_B is the overall concentration of the buffer. Values of $\alpha_{M(B)}$ can usually be found from tabulated values (12) or calculated from published equilibrium constants (16).

Complexes between metal ions and complexing agent may also exist in a number of protonated forms, and we can write, for example

$$[A1.6]\quad \alpha_{MHL(H)} = \frac{[ML] + [MHL] + [MH_2L] + \ldots}{[MHL]}$$

which can be rewritten

$$[A1.7]\quad \alpha_{MHL(H)} = \frac{1}{[H^+]K^H_{MHL}} + 1 + [H^+]K^H_{MH_2L} + \ldots$$

where

$$K^H_{MHL} = \frac{[MHL]}{[ML][H^+]}$$

and

$$K^H_{MH_2L} = \frac{[MH_2L]}{[MHL][H^+]} \quad \text{etc.}$$

Expressions for $\alpha_{ML(H)}$, $\alpha_{MH_2L(H)}$ can be obtained by similar methods.

Appendix II

Treatment of Polarographic Kinetic Currents

The theoretical treatment of polarographic kinetic currents was developed and described in numerous publications, mainly by Koutecky, and by Koryta, and by Brdicka. References to this work are contained in reviews by Brdicka, Hanus, and Koutecky (17) and by Koryta (18). The equations summarized below can be derived from those in the former review.

The reaction

$$[A2.1]\quad \underset{\text{reducible}}{MHA^{2-}} \underset{k_p}{\overset{k_d}{\rightleftharpoons}} MA^{3-} + H^+$$

where k_d and k_p are the overall proton dissociation and protonation rate constants, respectively, belongs to reaction scheme III*a* (17). Under kinetic control conditions the relationship of the mean limiting current, i_l, to the mean current, i_d, expected for a diffusion controlled process is given by

$$[A2.2]\quad \frac{i_l}{i_d - i_l} = 0.886[H^+]\sqrt{k_p t K^H_{MHA}}$$

where t is the drop time, and

$$K^H_{MHA} = \frac{[MHA^{2-}]}{[MA^{3-}][H^+]} = \frac{k_p}{k_d}$$

Similarly, for the reaction

$$[A2.3]\quad \underset{\text{reducible}}{MH_2A^-} \underset{k_p}{\overset{k_d}{\rightleftharpoons}} MHA^{2-} + H^+$$

$$[A2.4]\quad \frac{i_l}{i_d - i_l} = 0.886[H^+]\sqrt{k_p t K^H_{MH_2A}}$$

where

$$K^H_{MH_2A} = \frac{[MH_2A^-]}{[MHA^{2-}][H^+]} = \frac{k_p}{k_d}$$

A reaction of the type

$$[A2.5]\quad \underset{\text{reducible}}{M^{2+}} + H_2A^{3-} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} MHA^{2-} + H^+$$

belongs to the reaction scheme V*a* (17). The solution is

$$[A2.6]\quad \left(\frac{i_l}{i_d - i_l}\right)\left(1 + \frac{[MHA^{2-}]}{[H_2A^{3-}]}\cdot\frac{i_l}{i_d}\right)^{1/2} = 0.886[H^+]\sqrt{\frac{k_2 t}{K_{eq}[H_2A^{3-}]}}$$

where the equilibrium constant is given by

$$[A2.7]\quad K_{eq} = K^H_{MHA}K_{MA}K_4K_5$$

A reaction of the type

$$[A2.8]\quad \underset{\text{reducible}}{M^{2+}} + H_2A^{3-} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} MH_2A^-$$

leads to the result

$$[A2.9]\quad \left(\frac{i_l}{i_d - i_l}\right)\left(1 + \frac{[MH_2A^-]}{[H_2A^{3-}]}\cdot\frac{i_l}{i_d}\right)^{1/2} = 0.886\sqrt{\frac{k_4 t}{K^M_{MH_2A}[H_2A^{3-}]}}$$

where the equilibrium constant, $K^M_{MH_2A}$, is given by

$$[A2.10]\quad K^M_{MH_2A} = \frac{[MH_2A^-]}{[M^{2+}][H_2A^{3-}]} = K^H_{MH_2A}K^H_{MHA}K_{MA}K_4K_5$$

The Master Equation for the Dissociation of a Dilute Diatomic Gas. VII. Vibration–Dissociation Coupling in an Expansion Nozzle

N. I. LABIB, D. L. S. MCELWAIN, AND H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received February 16, 1972

The normal-mode approach to the solution of the vibration–dissociation coupling problem for a dilute diatomic gas, which was described in Part III of this series, has been extended to the treatment of recombination in a steady supersonic nozzle expansion. This method of solution did not suffer from the familiar instabilities associated with parasitic eigenvalues which have so far impeded solution of this problem. We report a calculation on $H + H + M \rightarrow H_2 + M$ (*without* V–V coupling) yielding simultaneously the temperature, density, velocity, and the populations of *each individual* vibrational level from 3900–1500 °K which was completed with acceptable accuracy along the zero-streamline in a few minutes of computer time.

In the absence of V–V coupling effects, although grossly distorted vibrational population distributions were found, the populations were always monotonic with vibrational quantum number; however, it was possible to generate absolute overpopulations of one vibrational state with respect to another by simulating vibrational coupling effects.

The main conclusions of the calculation are that under these conditions (*i*) the rate constant for recombination is the normal phenomenological recombination rate constant; (*ii*) the vibrational relaxation time τ_{vib} appears to vary over several orders of magnitude depending on the approximation used to define the vibrational energy content, but if a proper measure of the vibrational energy is used, τ_{vib} can be correlated with the second eigenvalue of the relaxation matrix, and is therefore the same as that which would have been found in a shock-tube measurement.

Nous avons étendu l'approche du mode normal à la solution du problème de couplage dissociation–vibration d'un gaz diatomique dilué, décrit dans la partie III de cette série, à la solution de recombinaison dans une expansion constante de gicleur supersonique. Cette méthode de solution ne souffre pas des instabilités inhérentes aux valeurs propres parasites qui nuisent habituellement à trouver la solution de ce problème. Nous rapportons un calcul de $H + H + M \rightarrow H_2 + M$ (*sans* couplage V–V) aboutissant à la température, la densité, la vitesse et les populations de chaque niveau vibrationnel *individuel*, de 3900–1500 °K, complété avec une précision acceptable le long de la ligne zéro pendant un court temps d'ordinateur.

Nous constatons qu'en l'absence de couplage V–V, que les populations sont toujours monotones avec le nombre quantique vibrationnel, quoique apparaissent certaines distortions dans les distributions des populations vibrationnelles; il est toutefois possible de susciter des surpopulations absolues d'un état vibrationnel par rapport à un autre en simulant des effets de couplage vibrationnel.

A partir de ce calcul, nous concluons principalement que sous ces conditions (*i*) la constante de vitesse de recombinaison est la constante de vitesse de recombinaison phénoménologique normale; (*ii*) le temps de relaxation vibrationnel τ_{vib} semble varier sur plusieurs ordres de grandeur, dépendant de l'approximation utilisée pour définir la quantité d'énergie vibrationnelle, mais si on utilise une mesure appropriée de l'énergie vibrationnelle, τ_{vib} peut être relié à la deuxième valeur quantifiée de la matrice de relaxation et par conséquent est le même que celui qui aurait été trouvé au moyen d'une mesure dans des tubes de choc.

Canadian Journal of Chemistry, **50**, 3832 (1972)

Introduction

The problems associated with the calculation of vibration–dissociation coupling in a gas flowing at supersonic speeds are well known, and have been well documented (1, 2 and references therein). Briefly, the internal (vibrational) relaxation times are very much shorter than the chemical relaxation time, but in order to obtain an accurate numerical solution of the problem it is necessary to use an integration step length which is short compared to the fastest of the internal relaxation times, which means that integrations spanning chemically interesting relaxation times are prohibitive in computer time (2, 3). The differential equations are said to be stiff, and the system of equations is said to have parasitic eigenvalues (2). In Part III of this series (3), we described a method of integration which overcame these difficulties in the special case of a highly dilute diatomic gas (*i.e.* one in which there is no vibration–vibration coupling) and the method was shown to give accurate results in the simple example of a vibration–dissociation relaxation taking place at constant

volume and constant temperature. In this paper we describe the extension of this method to the coupling of the vibration–dissociation relaxation and the gas dynamic equations of flow. Hitherto, this has been impossible because of the difficulties noted above: many calculations have been performed (4–6) but they all fall into one of two broad general classes. The first are calculations in which, following on from the early work of Lighthill (7) and Freeman (8), there is proper coupling between the dissociation rate and the flow but the vibrations of the molecule are all assumed to be in equilibrium with each other, in the sense that the vibrational population distribution is Boltzmann for some temperature which is not the local translational temperature. There has been some suspicion (devastatingly confirmed by the results of our calculations below) that this could be a poor assumption, and at least one calculation (9) has been done in which the vibrational population distribution is described by two effective temperatures, one for the lower vibrational levels and another for the higher vibrational levels. Unfortunately, the all too ready acceptance by experimenters (10) of the elegant harmonic-oscillator result that a system of oscillators will relax through a series of Boltzmann distributions (11) has impeded a proper interpretation of the experimental results; the application of this concept to anharmonic oscillators should be eradicated from such discussions as quickly as possible. The second class consists of calculations in which the dissociation is ignored *i.e.* there is coupling between the flow and the vibrational degree of freedom only: these calculations have become quite sophisticated recently because of interest in lasers, and the equations include terms representing V–V coupling between both like and unlike molecules and radiation coupling (12 and references therein): it is usually assumed in these calculations that as far as T–V transfers are concerned only nearest-neighbor transitions occur (12), which is moderately acceptable (13); however, the concept of conservation of vibrational quanta in V–V collisions clearly cannot be justified for anharmonic molecules with any significant degree of vibrational excitation (14), except on grounds of convenience.

The analysis in this paper is concerned *only* with the solution of the vibration–dissociation–gasdynamic flow problem, and for this reason the numerical experiment is a somewhat artificial one in several respects; it is therefore to be regarded only as the first step towards the complete solution of the vibration–dissociation–gasdynamic flow problem for a real system. We begin by assuming, as in our previous calculations (3, 13), that we have a mixture consisting of He and H_2 in 1000 to 1 proportions, and that only T–V transitions occur with transition probabilities given as a function of temperature by eq. III(1) (a Roman numeral prefix denotes an equation taken from an earlier paper in this series). In order to avoid the problems associated with integrating through the throat of the nozzle from the reservoir (5, 15), when the gas flow changes from subsonic to supersonic, our calculation begins with the gas already in the divergent section of the nozzle, flowing with a slightly supersonic velocity. The initial conditions are taken to be $[He] = 3.5 \times 10^{19}$ atoms cc^{-1}, $[H_2] + \frac{1}{2}[H] = 3.5 \times 10^{16}$ molecules cc^{-1}, with the system at complete thermodynamic equilibrium at 3900 °K, moving at a velocity of $U = 4.0 \times 10^5$ cm s^{-1}; the nozzle parameters are those used previously by Emanuel and Vincenti (16) with the integration beginning at $x_0 = 1.651$ cm, about 1 mm from the throat which is located at $x = 1.55$ cm. The reasons for choosing these initial conditions are as follows. At 3900 °K, H_2 is almost completely dissociated ($\alpha \approx 0.96$) whereas at 1500 °K at equilibrium at the same density, it is almost completely recombined ($\alpha < 10^{-4}$); hence this is an interesting temperature range, at least as far as chemical disequilibrium is concerned. The initial choice of thermodynamic equilibrium at 3900 °K is simply a matter of convenience: since the velocity is only just sonic (Mach number ≈ 1.08)[1] the populations will not be grossly different from those in the reservoir. Thus, not only is equilibrium at 3900 °K convenient, but it is moderately realistic, and in fact for our purposes any arbitrary initial distribution could have been chosen. The other feature of our

[1]To the extent that even ignoring the vibrational relaxation problem altogether the NASA (Lewis Research Center) General Chemical Kinetics Computer Program prints out flags to warn that one is too near the singularity at the sonic point (17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

initial conditions is that they correspond to an enormously fast initial rate of temperature change, of about 10^4 °K per cm (or 4×10^9 °K per s!): the advantage of this choice is that it is possible, in an hour or so's computer time, to integrate the necessary equations of flow by Runge–Kutta methods and span a temperature drop of about 200 °K, thereby providing a valuable check on our own method which takes much longer steps; we well appreciate that under these conditions a real flow would not be ideal, that the assumption of quasi-one-dimensional flow is unrealistic, that boundary-layer separation would occur, and so on. However, once it is established that the parasitic eigenvalue problem can be overcome, all of these features can be accommodated in future calculations.

Brute-Force Integration: Nineteen Equations

In Parts II and III of this series (13, 3) it was shown that using an asymptotic expansion technique, it was possible to take integration steps as much as 10^6 larger than is possible with conventional *e.g.* Runge–Kutta methods: in those calculations however, both the temperature and therefore the transition probabilities were regarded as constants, independent of time. In order to check on the accuracy of our technique when the gas was considered to be flowing, and therefore the temperature and the transition probabilities were changing with time, we felt it was necessary to perform an integration by standard techniques, and extending over as large a temperature range as possible. Our choice of initial conditions, as noted above, meant that a 200 °K range was accessible without consumption of inordinate amounts of computer time, thereby providing a valuable direct check on our results: otherwise, only circumstantial evidence of accuracy, such as conservation, rate constants, entropy production, etc., would be available, and would have to suffice.

We consider a mass element m of gas, having an initial density ρ_0, and containing a total number of particles N of which N_{He} are helium atoms, N_H are hydrogen atoms and N_{H_2} are hydrogen molecules, with $\frac{1}{2}N_H + N_{H_2} = N^0_{H_2}$; it will be a convenient notation to write $\rho_0/\rho_x = V_x$. Our previous formulation of the master equation for H_2 was in terms of changes taking place in 1 cc (3, 18), but must now be recast to refer to changes taking place within the mass element, whatever its density may be. The N_i now represent the number of molecules in vibrational state i, with N_n the number of dissociated molecules ($N_H = 2N_n$) in the mass element m; a tilde, *e.g.* $\tilde{N}_i$, implies the equilibrium value of N_i for the translational temperature and the density at the point in question. The probabilities of endothermic processes are assumed to be given by eq. III(1), with P_{ji} being the probability per collision of a transition from state i to state j, and $\bar{P}_{ni}$ being the probability per collision of a direct dissociation from state i: probabilities of deactivation processes are related to those of the activation processes by the usual detailed-balancing relationships, which now become

$$P_{ij}\tilde{N}_j = P_{ji}\tilde{N}_i$$

$$\bar{P}_{in}\tilde{N}_n^2/V_x = \bar{P}_{ni}\tilde{N}_i$$

If $Z_{1,1}$ is the number of collisions *per cc* per second when there is one helium atom and one hydrogen molecule in that cc, then the master equation for the mass element m is

$$[1]\quad \frac{dN_i}{dt} = \frac{(Z_{1,1})N_{He}}{V_x} \times \left\{ \sum_{j=0}^{14} (P_{ij}N_j - P_{ji}N_i) + \bar{P}_{in}N_n^2/V_x - \bar{P}_{ni}N_i \right\} \qquad i = 0, 1, \ldots, 14$$

$$[2]\quad \frac{dN_n}{dt} = \frac{(Z_{1,1})N_{He}}{V_x} \sum_{j=0}^{14} (\bar{P}_{nj}N_j - \bar{P}_{jn}N_n^2/V_x)$$

These sixteen equations have to be solved simultaneously with the equations of flow of the gas, and here we follow standard procedures for the description of quasi-one-dimensional flow (2, 4–12, 15, 16). We have first the Bernoulli equation

$$[3]\quad H = E + PV + \tfrac{1}{2}mU^2 = \text{stagnation enthalpy} = \text{constant}$$

or in differential form

$$[3']\quad dE + PdV + VdP + mUdU = 0$$

second, the mass-conservation equation

$$[4]\quad \rho UA = \text{constant}$$

where A is the cross-sectional area of the nozzle,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

or in differential form

$$[4'] \qquad d\rho/\rho + dU/U + dA/A = 0$$

and third, the momentum-conservation equation for quasi-one-dimensional flow

$$[5] \qquad -\rho U dU = dP$$

After considerable algebraic manipulation (19), and assuming the perfect-gas laws, one can reduce these three equations to one of the form

$$[6] \quad dE + \frac{kTN}{(mU^2 - kTN)} \times \{mU^2 dA/A - kN dT - kT dN\} = 0$$

Now consider the conservation of energy

$$[7] \quad E = N_{He}\varepsilon^{He}_{trans} + N_{H_2}(\varepsilon^{H_2}_{trans} + \varepsilon^{H_2}_{rot} + \varepsilon^{H_2}_{vib}) + N_H(\varepsilon^{H}_{trans} + \tfrac{1}{2}D_0)$$

where ε denotes an average energy per molecule, and all internal energies are measured with respect to $H_2(v = 0)$. Using the gas laws, it is a simple matter to assign values to the ε_{trans} terms, and $N_{H_2}\varepsilon^{H_2}_{vib}$ is just

$$\sum_{i=0}^{14} \varepsilon_i N_i$$

where the ε_i are the vibrational energy levels assumed for the molecule (13). However, since we chose to use the *experimental* equilibrium constant (20), one cannot maintain strict conservation and assume that the rotational energy of H_2 is simply the kinetic-theory value of $N_{H_2}kT$, as we have noted previously (13), but one has to make a correction which becomes more severe as the temperature becomes higher (21). Thus, denoting for the moment the rotational energy per molecule by R_{H_2} and remembering that the rotational specific heat (dR_{H_2}/dT) is not exactly equal to k, one finds after extensive manipulation (19) that dE can be eliminated between [6] and the differential form of [7] to give

$$[8] \qquad \frac{dT}{T} = \frac{\dfrac{dN}{N} - \dfrac{2\bar{\varepsilon}_u}{kT}\dfrac{dA}{A} + \left\{\dfrac{2\bar{\varepsilon}_u}{kT} - 1\right\}\left\{-\dfrac{1}{2}\dfrac{D_0}{kT}\dfrac{dN_H}{N} - \dfrac{3}{2}\dfrac{dN}{N} - \dfrac{R_{H_2}}{kT}\dfrac{dN_{H_2}}{N} - \sum_i \dfrac{\varepsilon_i}{kT}\dfrac{dN_i}{N}\right\}}{\left\{\dfrac{2\bar{\varepsilon}_u}{kT} - 1\right\}\left\{\dfrac{3}{2} + \dfrac{1}{k}\left(\dfrac{dR_{H_2}}{dT}\right)\dfrac{N_{H_2}}{N}\right\} - 1}$$

where $\bar{\varepsilon}_u$ is the mean (per particle) kinetic energy of the flow *i.e.*

$$\bar{\varepsilon}_u = mU^2/2N$$

In order to avoid cancellation difficulties in the numerical evaluation of the rotational heat capacity, one has to write

$$[9] \qquad K_c = K^* e^{-D_0/kT}$$

where, as was noted above, K_p (from which K_c is derived) is tabulated in the JANAF Tables every 100 °K; thus, before proceeding K^* was fitted to a fifth-order polynomial in T. Then

$$R_{H_2} = \left[\frac{3kT}{2} - \frac{\sum_{i=0}^{14} \varepsilon_i e^{-\varepsilon_i/kT}}{Q^{H_2}_{vib}(T)} - kT^2\frac{d \ln K^*}{dT}\right]$$

follows from the standard relationship between K_c and the relevant partition functions $Q(T)$: thus

$$\frac{dR_{H_2}}{dT} = \left[\frac{3k}{2} - \frac{1}{Q^{H_2}_{vib}(T)}\cdot\frac{d}{dT}\left(\sum_{i=0}^{14} \varepsilon_i e^{-\varepsilon_i/kT}\right) + \frac{\sum_{i=0}^{14} \varepsilon_i e^{-\varepsilon_i/kT}}{\{Q^{H_2}_{vib}(T)\}^2}\cdot\frac{dQ^{H_2}_{vib}(T)}{dT} - \frac{2kT\, d \ln K^*}{dT} - \frac{kT^2\, d^2 \ln K^*}{dT^2}\right]$$

If one inspects eq. 8, it is written in a completely dimensionless form. The normal procedure is to solve the equations, advancing x, the distance down the nozzle, for which the quantity dA/A is always specified by the polynomial (16) describing the nozzle shape. The terms in dN_H/N, dN_{H_2}/N,

dN_i/N, and therefore dN/N change only as the result of vibrational and chemical relaxations embodied in the sixteen eqs. 1 and 2, and it is therefore convenient to convert these equations into distance-dependent instead of time-dependent ones by substituting dx/U for dt, *viz.*

$$[1x] \qquad \frac{dN_i}{dx} = \frac{(Z_{1,1})N_{He}}{UV_x}\left\{\sum_{j=0}^{14}(P_{ij}N_j - P_{ji}N_i) + \bar{P}_{in}N_n^2/V_x - \bar{P}_{ni}N_i\right\} \qquad i = 0, 1, \ldots, 14$$

$$[2x] \qquad \frac{dN_n}{dx} = \frac{(Z_{1,1})N_{He}}{UV_x}\sum_{j=0}^{14}(\bar{P}_{nj}N_j - \bar{P}_{jn}N_n^2/V_x)$$

Common practice at this stage is to construct one more differential equation, *e.g.* by substituting $-P\,dV$ for dE (from equations [3′] and [5] into [6] whence

$$[10] \qquad \frac{d\rho}{\rho} = \left\{\frac{dT}{T} + \frac{dN}{N} - \frac{2\bar{\varepsilon}_u}{kT}\frac{dA}{A}\right\}\Big/\left(\frac{2\bar{\varepsilon}_u}{kT} - 1\right)$$

giving eighteen equations in all, *i.e.* (1x], [2x], [8], and [10] which can be solved simultaneously using the auxiliary algebraic eq. [4] to find U. However, for the normal-mode solution which we describe below, this procedure is inadequate because one cannot regard U as being constant over the very large steps used in that method: therefore, one more equation is needed for a complete solution, *viz.*

$$[11] \qquad \frac{dt}{dx} = \frac{1}{U}$$

Thus, to set up the standard test-solution, these nineteen equations were solved by a fifth-order Runge–Kutta procedure (22), paying considerable attention to conservation. For example, at each of the six points within the fifth-order Runge–Kutta routine, new transition probabilities were calculated according to eq. III(1), a new value of K^* was calculated, new rotational heat contents and heat capacities were generated, and so on. The result was that even with the very rapid rates of change that exist in this system, a calculation covering the temperature range 3900–3710 °K was achieved in about 2 h of computer (IBM360/50) time, in which both the stagnation enthalpy and the total number of H atoms (*i.e.* H_2^0) were conserved to 13 decimal places. This solution was used as the standard against which to test the normal-mode procedure described below; discussion of the results will be deferred until the comparison of the two methods has been described.

Normal-mode Integration: Five Equations

Following exactly our previous derivation (3), the sixteen eqs. 1 and 2 can be transformed, at constant mass instead of at constant volume, to the sixteen normal-mode equations analogous to III(9a) and III(9b)

$$[12] \qquad \frac{d\Psi_i}{dt} = D_i\Psi_i(t) + \Gamma_i\Phi_n^2(t)$$

$$[13] \qquad \frac{d\Phi_n}{dt} = \frac{\tilde{N}_n^{1/2}}{V_x}\left\{V_x\sum_{i=0}^{14}\Gamma_i\Psi_i(t) + \Gamma_n\Phi_n^2(t)\right\}$$

where the capital-letter symbols refer to the mass element m, as opposed to the lower case symbols used previously to describe the relaxation at constant volume ($V = 1$). As before,

$$[14] \qquad \Psi_i = \sum_{j=0}^{14}\tilde{S}_{ij}\tilde{N}_j^{-1/2}N_j \qquad i = 0, 1, \ldots, 14$$

$$[15] \qquad \Phi_n = \tilde{N}_n^{-1/2}N_n$$

i.e., eq. III(10); note the omission of a tilde from the $\tilde{S}_{ij}$ in ref 3. Then, transcribing the derivation of the asymptotic expansion solution, eqs. III(13) and III(14) to constant-mass but variable-volume, we have

$$[16] \qquad \frac{d\Psi_{n-1}}{dt} = D_{n-1}\Psi_{n-1}(t) + \Gamma_{n-1}\Phi_n^2(t)$$

$$[17] \qquad \frac{d\Phi_n}{dt} = \frac{\tilde{N}_n^{1/2}}{V_x}\left\{\sum_{i=0}^{13}V_x\Gamma_i[\Psi_i(t_0) - \Gamma_iD_i^{-1}\Phi_n^2(t_0)]\,e^{D_i(t-t_0)} + V_x\Gamma_{n-1}\Psi_{n-1}(t) + \left[\Gamma_n - V_x\sum_{i=0}^{13}\Gamma_i^2D_i^{-1}\right]\Phi_n^2(t)\right\}$$

Finally, we form [16x] and [17x] by multiplying the right hand sides of [16] and [17] by U^{-1}, and changing the denominators on the left-hand sides to dx instead of dt. It is implicit in writing equations [16x] and [17x], and attempting to solve them simultaneously by Runge–Kutta

methods with [8], [10], and [11], that we must know the eigenvalues D_i and the eigenvectors S_{ij} of the relaxation matrix at every integration step. Once it has been established that large steps can be taken, these can probably be calculated as and when needed for the density and temperature in question, as already described (3), and we hope to undertake a shock-wave calculation where the temperature change is less violent by this approach in the near future. However, since part of our testing procedure in this work was to compare solutions for the same distance x obtained by using a variety of step-lengths, it would have been prohibitive to calculate the D_i and the S_{ij} anew each time. Hence, the d_i and s_{ij} for the initial density ρ_0 (*i.e.* $N_{He} = 3.5 \times 10^{19}$ atoms cc^{-1}; $N^0_{H_2} = 3.5 \times 10^{16}$ molecules cc^{-1}) were calculated every 100° from 1500 to 4000 °K: then each element of s_{ij} and the d_i were fitted to an eighth-order polynomial in T, d_{n-1} being treated separately like the equilibrium constant (eq. 9) because of its very rapid change with T; nevertheless, four sets of polynomials had to be used to give adequate representation, covering the ranges 4000–3000, 3200–2500, 2600–2000, and 2200–1500 °K respectively. Thus, to obtain the correct values at the density in question for the quantities in eqs. 16 and 17 from the corresponding values interpolated for the same temperature, but at density ρ_0, one needs the following scaling

$$D_i = d_i/V_x$$
$$\Gamma_i = \gamma_i/V_x^{3/2}$$
$$\Gamma_n = \gamma_n/V_x$$
$$S_{ij} = s_{ij}$$

The five equations [8], [10], [11], [16x], and [17x] can now be solved by a fifth-order Runge–Kutta procedure: hence, instead of generating transition probabilities and detailed-balancing relationships at each point within the integration, the D_i, Γ_i, etc. have to be generated from the standard sets of polynomials already stored in the machine.

It is important to realize that eqs. 16 and 17 are not exact. Two terms have been omitted (19), one in $d\tilde{N}_i/dT$ and the other in dS_{ij}/dT. In other words, [16] and [17] are only correct (as were III(13) and III(14)) if the temperature does not change during the step. By ignoring these two terms, we are implying that the $\tilde{N}_i$ and the S_{ij} do not change appreciably across each integration step. Clearly, then, we are not going to be able to take the very large steps characteristic of our earlier work (3), but making use of the exact solution found by the nineteen-equation method, can find how big a step-length is possible whilst still retaining acceptable accuracy.

Results

(a) Comparison of the Two Methods

For the particular flow chosen as the subject of the calculation described in this paper, the longest integration step that was possible with the nineteen-equation method whilst maintaining stability, conservation of particles, and conservation of stagnation enthalpy (eq. 3) was about 10^{-5} cm *i.e.* 2×10^{-11} s; this is more-or-less consistent with the fact that the largest eigenvalue of the relaxation matrix is always of the order of 10^{11} s^{-1} (2, 3). The five-equation method was then used over the same temperature range and with a step-length of 8×10^{-5} cm there was agreement at 3711 °K as follows: stagnation enthalpy, 10 decimal places; flow parameters, 8 decimal places; atom concentration, 8 decimal places; ground vibrational state population, 5 decimal places; topmost vibrational state population, 4 decimal places. Our interpolations of d_i, K^*, s_{ij}, etc. are not consistent with each other and with the assumed transition probabilities to better than 10 decimal places, hence, about 10 figures is the best agreement that would be possible. For convenience, therefore, the total hydrogenic population was readjusted after each integration cycle to be exactly $N^0_{H_2} = 3.5 \times 10^{16}$ molecules. Integrations were then continued down to about 3000 °K with a variety of step-lengths 8, 64, 128, and 256×10^{-5} cm, and thence down to 1500 °K in steps of 256×10^{-5} cm. At 2000 °K the stagnation enthalpy still agreed with the initial starting value to 7 decimal places, but the agreement deteriorated towards 1500 °K due to increasing inaccuracy in the eigenvectors S_{ij} at the lower temperatures. From our experiments with varying step-length, we conclude that using the longest step, which is 256 times as long as that allowed in the nineteen-equation method, the

*Equilibrium populations denoted by $\tilde{N}$ refer to thermodynamic equilibrium at the stated temperature, not to an "equilibrium" calculation, see text.

final accuracies on the population distributions are: atoms, 5–6 figures; ground vibrational state, 4 figures; topmost vibrational state, 2 figures, the latter quantity always being the most sensitive to error (23). However, since the population distributions observed are so very non-Boltzmann, 2-decimal place accuracy on the topmost level is a very considerable advance on previous assumptions of an effective vibrational temperature which could place the topmost level at 1500 °K perhaps seven or eight orders of magnitude different from what we find, depending upon how closely the vibrational temperature followed the translational temperature. In our earlier calculations (3), in which the temperature did not change, we found it was possible to take very large steps whilst still maintaining excellent accuracy on all populations. The poorer performance of the method described here is due in the main to the neglect of the terms in $d\tilde{N}_i/dT$ and dS_{ij}/dT noted above: the step length of 256×10^{-5} cm corresponds to a temperature drop of about 20 °K at early times in the flow; the S_{ij} are very insensitive to temperature, but the $\tilde{N}_i$, particularly $\tilde{N}_n$ the number of dissociated molecules, change appreciably over a 20° range. From the evidence available, it would appear that the present five-equation approximation will be highly satisfactory for integrations in which there is a change of not much more than (say) 1° over the integration cycle. Smaller errors arise from the imperfections in interpolating the d_i, etc., also noted above: for example, one of the thermodynamic quantities monitored in the flow was the total entropy, which rose gradually from 9.28810582 cal deg^{-1} g^{-1} 3900 °K to 9.28810858 cal deg^{-1} g^{-1} at 1500 °K, but with discernible steps when the polynomials were changed at 3000, 2500, and 2000 °K; the entropy was calculated as described previously (13, 19). Had there been no non-equilibrium effects present, the flow would have been isentropic (24) and the smallness of the observed increase is due to the fact that the mixture is quite dilute in H_2. In a previous paper (13) we examined successive time derivatives of the

entropy, but in this approximate calculation, the accuracy of the total entropy is too low for us to derive any meaningful information on the higher derivatives and on monotonicity.

(b) Population Distributions

The principal gasdynamic quantities for the flow are tabulated at 100° intervals in Table 1. In the sixth and seventh columns we compare the actual atom population and the value it would have at equilibrium at the listed temperature; likewise for molecules in columns eight and nine. Note that the equilibrium populations are *not* the populations that would have been obtained in an "equilibrium" calculation, since through the energy conservation relationships, the temperature would have been altered slightly. Nevertheless, they are quite close to what would have been obtained in such a calculation, as are the flow parameters (17), since the mixture is very dilute in H_2. It is clear that on this time scale, the recombination reaction appears to be almost frozen, which is to be expected under the chosen conditions.

Table 2 shows the evolution of the vibrational population distributions at 100° intervals: at the same time, Table 2 also shows what would be the equilibrium vibrational population distribution based on the same number of ground-state molecules (figures underlined). Comparison of the actual and equilibrium values reveals immediately that down to about 2000 °K, states $v = 1$ and $v = 2$ remain very closely coupled to the ground state, $v = 0$, but that by 1500 °K, $v = 2$ is no longer coupled to $v = 0$, and $v = 1$ is beginning to depart strongly from the equilibrium value. On the other hand, the topmost vibrational levels remain in very close equilibrium with the free atoms: this is not immediately obvious from the data presented in Table 2, where N_{14} appears to be changing much more rapidly than N_H; however, when one allows for the density change which is occurring in the flow, the mass-action ratio n_H^2/n_{14} hardly changes at all throughout the calculation.

The sudden onset of freezing of successive vibrational levels is shown very clearly in Table 2: if we use as a rough-and-ready criterion for freezing that the actual population is about three (or more) times what it would be if it were in equilibrium with N_0 at the list temperature, then one can see that levels $v = 11, 12, 13$, and 14 suddenly freeze between 3700 and 3500 °K; at 3700 °K, no actual value exceeds the equilibrium value by as much as a factor of two, whereas at 3500 °K, the topmost four levels have clearly failed to remain in any sort of rough equilibrium with the ground state. As time goes on, more and more levels freeze suddenly, so that at 3000 °K, $v = 8$ and above are no longer strongly coupled to the ground-state population, at 2500 °K, $v = 6$ and above are frozen, at 2000 °K the freezing point is around $v = 3$ or 4, and at 1500 °K, the first vibrational level is about to freeze. An interesting second-order effect occurs for $v = 6$, 7, 8, and 9 around 2100 °K, and by 1500 °K has spread to levels $v = 4$ to 10 inclusive; these levels were originally much more strongly coupled to the ground state than to the atoms but, these levels having failed to keep step with the ground-state population, now become somewhat better coupled to the atoms than to the ground state, and their populations begin to rise again.

It is interesting that the initial onset of freezing takes place at and around $v = 11$, which is about the position where we have previously suggested that a bottleneck occurs with the particular set of transition probabilities used in this calculation (3). However, as the flow progresses, the freezing point moves to progressively lower vibrational levels, thereby amplifying our earlier conclusion (27) that any vibrational bottleneck is basically a very complex manifestation.

(c) Generating Population Inversions

It seems likely that if, under these severe conditions, one cannot generate a vibrational population inversion, then one is not going to be able to do so in this temperature range if only T–V processes are allowed. This statement refers, of course, to gross vibrational populations (there may be overpopulations of optically coupled J-substates, as is often discussed in treatments of nozzle lasers (12, 25)); also, H_2 is homonuclear and will not radiate, but the behavior of heteronuclear molecules will not be very different (26) unless atom exchange reactions are important. It is, however, possible to generate an absolute vibrational overpopulation by simulating V–V processes in our flow. As we noted above, our method of solution is applicable only to T–V processes, and V–V processes cannot be properly included; however, their

Table 2. Comparison of the computed vibrational population distribution (n.b. the underlined figures represent that would be in equilibrium with the actual number calculation)

effect can be surmized as follows. We consider a distribution such as that occurring in the middle of Table 1: we actually chose 2490 °K for this calculation. It is considered that *from this point on*, the heat-bath molecules M have the special property that they can deactivate H_2 in state i to H_2 in state j with high probability (*e.g.*, because M now has some degree of freedom which can be excited and which is closely resonant with $(\varepsilon_i - \varepsilon_j)$) and that the excitation transferred to M is rapidly degraded to heat: thus $P_{ji} = 0.5$ was substituted for the normal value, with P_{ij} following from detailed-balancing. The calculation was then continued by the nineteen-equation method, since such a change in one specific pair of transition probabilities is sufficient to change both the d_i and the s_{ij}. The general effect is to depress the population of state i and augment state j: it is obviously not possible to overpopulate state j with respect to state $(j-1)$ because of the large numbers involved, but it may be possible to depopulate state i by this wide-open channel to the extent that N_{i+1} would exceed N_i, and this is in fact the case. Three examples were examined. One was across the bottleneck (3, 27) with $P_{2,11} = 0.5$ and this generated a small overpopulation of state $v = 12$ with respect to $v = 11$. In a second experiment, $P_{2,5}$ was set equal to 0.5, but there was no overpopulation of $v = 6$ with respect to $v = 5$, presumably because $v = 2$ and $v = 6$ are slightly too closely coupled by T–V processes. However, with $P_{2,6} = 0.5$, a significant overpopulation of $v = 7$ with respect to $v = 6$ was observed. Before switching on the V–V simulation, N_7 and N_6 were 1.32×10^{10} and 2.26×10^{10} molecules respectively, but after quite a short time ($\sim 2 \times 10^{-9}$ s), a strong reversal to $N_7 = 1.15 \times 10^{10}$ molecules and $N_6 = 5.64 \times 10^9$ molecules had developed. Whilst this is no more than an illustrative calculation, it is clear that under the right conditions, such overpopulations should occur in simple nozzles, since if the "V–V" process had been switched on from the beginning of the flow, the overpopulation would have been more marked than is shown here.

(d) The Rate Constant for Recombination

We have already shown (3) that under non-flowing conditions, the rate constant for recombination $k_{r,M}$ can be found from the smallest eigenvalue d_{n-1} of the relaxation matrix by eqs. III(21) and III(22) *viz.*

$$[18] \quad k_{r,M} = K_c^{-1} k_{d,M} = -K_c^{-1}[M]^{-1} d_{n-1}$$

where $k_{d,M}$ is the dissociation rate constant. The quantity d_{n-1} is used at every step throughout the five-equation method, and it is therefore a simple matter to say what the true recombination rate constant should be at any instant. From the transition probabilities that were assumed together with the calculated population distribution function, it is also possible to write down the recombination flux by eq. II(11*b*) (analogous to eq. 2 but in n_i (per cc) instead of N_i) and obtain the phenomenological rate constant for recombination via

$$[19] \quad (Z_{1,1})[M] \sum_{j=0}^{n-1} \{\bar{P}_{jn} n_n^2 - \bar{P}_{nj} n_j\} = k_{r,M}[M]\left\{(2n_n)^2 - K_c \sum_{j=0}^{n-1} n_j\right\}$$

At very early times, when the system is not very far from the 3900 °K equilibrium distribution, the results are inaccurate because of severe cancellation in the left-hand side of eq. 19. However, once the temperature has fallen 200–300°, the cancellation difficulties subside, and thereafter, all the way down the flow, the values of $k_{r,M}$ calculated by eq. 18 and by eq. 19 agree excellently, as shown in Table 3 (note also that there are small "kinks" in the agreement at 3000 and 2500 °K where the eigenvalue and eigenvector polynomials were changed). Hence, since our nozzle flow is an extremely severe one, generating grossly non-Boltzmann distributions, we regard this result as conclusive evidence that the recombination rate constants measured in nozzle flows should agree with those deduced from shock-wave dissociation measurements via the rate-quotient law.

(e) The Vibrational Relaxation Time

There has been considerable discussion recently over the question as to whether the vibrational relaxation time measured in an expanding flow (*i.e.* in deactivation) is the same as that measured in excitation in a shock wave (10, 28, 29). These experimental flows are very much more complicated than that described in this paper, being dominated by V–V transitions,

and perhaps plagued by impurity effects (28). Nevertheless, an examination of the vibrational relaxation time in our flow may throw some light on the interpretation of the experimental findings. The standard experimental approach is to assume that a vibrational temperature can be defined, and then an attempt is made to measure it. This has been done in some cases (*e.g.* CO) by the measurement of direct emission intensity from the $0 \leftarrow 1$ transition (30, 31) which can be interpreted to yield the ratio N_1/N_0. This ratio can be used to define a vibrational temperature which, if it can be assumed to represent the complete vibrational population distribution, gives the mean vibrational energy content of the molecule ε_{vib}. In other cases, reversal measurements have been made (10, 32): the resulting vibrational temperature is less easy to define, but is clearly characteristic of some part of the upper-level population distribution of the molecule. One can also conceive, in principle, of other possible methods of measuring population ratios of pairs of levels, and so we have taken a general approach in examining the problem, that of taking the data in Table 2 and for each value of T, calculating the effective vibrational temperature from the population ratio of *every possible pair* of levels. Early in the flow, the calculated temperatures do not depart disastrously from the translational temperature. For example, at 3700 °K, N_0 taken together in turn with each other N_i gives temperatures rising monotonically from 3711 °K (from N_1/N_0) to 3870 °K (from N_{14}/N_0). However, once pairs of high levels are used, the discrepancy is larger, and the trend is no longer monotonic, with N_{12}/N_{11} yielding the highest apparent vibrational temperature of 4455 °K. Towards the end of the calculation, however, below $T = 2100$ °K, the situation has become very exaggerated, with some population ratios, *e.g.* N_8/N_7, yielding "temperatures" of around 10 000 °K. Then each value of $(T_{vib})_{ij}$ was used to generate a vibrational energy content ε_{vib} on the assumption that equilibrium existed amongst all the vibrational levels. By repeating the calculation for adjacent points in the flow (usually one step upstream or down-

stream), values for $d\varepsilon_{vib}/dt$ were established, since the velocity U was also known. Hence the vibrational relaxation time τ_{vib} follows by substitution in the standard equation (24, 33)

$$[20] \qquad -\frac{d\varepsilon_{vib}}{dt} = \frac{\varepsilon_{vib} - \tilde{\varepsilon}_{vib}}{\tau_{vib}}$$

where $\tilde{\varepsilon}_{vib}$ would be the vibrational energy content at equilibrium at the bath temperature T. In many of the cases, of course, this cannot be done since as we have just noted, if i and j are both high, $(T_{vib})_{ij}$ rises as the gas cools, giving *negative* values of $(\tau_{vib})_{ij}$.

It is however possible to solve eq. 20 exactly for τ_{vib} since our solutions for each value of T contain all the populations N_i, all the dN_i/dt, and of course the ε_i are given. Values of τ_{vib} calculated in this way are listed in Table 3, where they are compared with the quantity $-d_{n-2}^{-1}$, which we have previously identified (3) as the vibrational relaxation time that should be observed in the perfect shock-wave experiment; the comparison requires of course that the τ_{vib} be scaled by ρ_x/ρ_0 so that they refer to the same density as do the d_{n-2}. It can be seen that the agreement is remarkably good, and in our view, the fact that the two columns of numbers do not coincide more precisely arises from the limited accuracy of our solutions a long way down the flow. The basic reason for this agreement seems to be that the highly overpopulated vibrational levels are strongly coupled to the atoms, but that their contribution to ε_{vib} is only of the order 0.1% of the total vibrational energy content; on the other hand, those molecules which contain the bulk of the vibrational energy, *i.e.* $i(=v) = 1, 2, 3$, and 4 have $(T_{vib})_{0i} \approx T$, and so eq. 20 may be expected to hold reasonably well. It would have been interesting to continue on to lower temperatures still, but we cannot yet generate satisfactory eigenvectors S_{ij} below 1500 °K.

The question then arises, do any of the non-negative values of $(\tau_{vib})_{ij}$ calculated from population ratios give the correct vibrational relaxation time? The answer appears to be yes; if $(\tau_{vib})_{ij}$ is calculated from N_1/N_0, it appears to be consistently about 20% too low, or if it is calculated from the ratio N_2/N_0 it is usually within 2–3% of the correct answer (this statement only holds above 2000 °K, since below that, $v = 2$ and then $v = 1$ begin to freeze, thereby making the population ratios meaningless as "temperature"). However, using other ratios N_i/N_0, $(\tau_{vib})_{ij}$ rapidly diverges from the correct answer to something about 10^3 too long, and then may become negative as described above. In the current terminology (28, 29), $\phi \approx 10^{-3}$, which is considerably smaller than anything so far found experimentally. However, using N_i/N_j ratios where neither i nor j is zero, much faster relaxation times are also calculated, the fastest in our particular calculation being $\phi \approx 20$ which is similar to some of the controversial experimental values (29). This occurred when the system was not very far from equilibrium and when both levels used to define $(T_{vib})_{ij}$ were above the bottleneck, *i.e.* $i,j \geqslant 10$ and $T > 3800$ °K. Thus it would seem that the derived value of ϕ is rather sensitive to any imperfection there may be in the representation of the non-equilibrium vibrational population distribution by a "vibrational temperature", and whilst this result is only valid in the T–V regime, it does point to a possible source of difficulty in the more general case.

(f) Future Calculations

It should be possible in the foreseeable future to extend this method to the study of the vibrational activation and dissociation of a dilute diatomic gas as it flows at hypersonic speed over an aerodynamically interesting object, obtaining population distributions at least as reliable as those found in this work. Here again, assumptions of vibrational equilibrium can be rejected for the first time. If better accuracy is required than was achieved in this calculation, it will follow automatically if the change in temperature per integration step is reduced. This will be acceptable where temperature changes are small, but for a proper treatment of very large and rapid temperature changes, it will be necessary to modify eqs. 12 and 13 to include terms dS_{ij}/dT and $d\tilde{N}_n/dT$. That will leave, apart from the problem of calculating transition probabilities which we have argued (3, 13) is not crucial, the problem of including V–V coupling in such calculations; until such time as this can be achieved, it seems that we will have to rely on perturbation simulations applied to the T–V solutions, such as that described in section (*c*) above, together with a large measure of insight

Préparation simple et configuration de dérivés des bicyclo[3.3.1]nonanol-2 ones-9 *endo* et *exo*. Utilité de la fonction trichloro-2,2,2 éthoxycarbonyle comme groupe protecteur d'aldols

D. GRAVEL, S. RAHAL,[1] ET A. REGNAULT[2]

Département de Chimie, Université de Montréal, C.P. 6128, Montréal, Québec

Reçu le 2 mars 1972

Des modes de préparation simples et efficaces de paires d'épimères *endo* et *exo* en série bicyclo[3.3.1]nonanol-2 one-9 sont décrits. La configuration de chacun des isomères est établie par voie spectroscopique et par corrélation chimique. Il est montré que le groupe trichloro-2,2,2 éthoxycarbonyle peut être employé pour protéger ces aldols et que leur régénération n'entraîne aucune épimérisation.

Simple and efficient preparations of some *endo* and *exo* epimeric pairs in the bicyclo[3.3.1]nonan-2-ol-9-one series are described. The configuration of each isomer is established spectroscopically and by chemical correlation. It is shown that the 2,2,2-trichloroethoxycarbonyl group may be used to protect these aldols and that regeneration of the latter does not give rise to epimerization.

Introduction

Depuis la parution en 1961 des travaux de Murray *et al.* (1), les dérivés bicyclo[3.3.1]-nonanes ont connu une période très féconde des points de vue synthèse, mécanismes réactionnels, et analyse conformationnelle. A l'examen des travaux, on remarque que la paire d'isomères: *endo* (**1***a*) et *exo* (**2***a*), quoique préparée plusieurs fois (2–8) n'a été séparée qu'une seule fois (7) sur une base préparative et ce par une méthode laborieuse impliquant: chromatographie, cristallisation, et sublimation.

En relation avec des travaux en cours dans notre laboratoire, nous avons mis au point deux méthodes simples d'obtention de quantités importantes des paires d'isomères *endo* et *exo*: **1**, **2** et **3**, **4**. Etant donné l'importance de ces paires d'épimères dans l'étude de la réactivité du système bicyclo[3.3.1]nonane nous rapportons ici les détails de préparation ainsi que les preuves de structure.

Résultats et discussion

La méthode de Allan *et al.* (6) a été empruntée pour préparer le mélange des alcools **1***a* et **2***a*. L'analyse par c.p.g. montra que le céto–alcool *exo* (**2***a*) est formé à 40% et que le céto–alcool *endo* (**1***a*) constitue 60% du mélange. Ces proportions sont en accord avec celles trouvées par Kraus *et al.* (7) ainsi que par Dean *et al.* (5).

Au cours de notre étude, nous avons remarqué que lorsqu'on acétalise le mélange des céto–alcools **1***a* et **2***a*, les proportions relatives de ces deux isomères se trouvent *inversées*. De plus, ce qui s'avère très utile, ces deux isomères sont faciles à séparer: l'isomère *exo* (**4***a*) étant très soluble dans l'hexane.

L'acétal–alcool *endo* (**3***a*), montre en r.m.n. le proton carbinolique comme un massif centré à 4.1 p.p.m., largeur à la mi-hauteur ($L_{\frac{1}{2}}$): 24 Hz; l'isomère *exo* (**4***a*) présente ce proton à 4.15 p.p.m. avec un $L_{\frac{1}{2}}$ de 5 Hz, conformément à la stéréochimie postulée (7). D'autre part, le spectre i.r. de solutions diluées de chaque épimère montre: pour l'*endo* (**3***a*): une bande fine à 3625 cm^{-1} (OH libre) alors que l'*exo* (**4***a*) présente une bande large à 3530 cm^{-1}, indiquant un pont hydrogène intramoléculaire (3). Finalement, les tosylates **3***b* et **4***b* ont été préparés et seul le tosylate **4***b* conduit à l'oléfine **5** (9) con-

firmant la position axiale du groupement hydroxyle dans **4***a* (3).

La méthode exposée plus haut permet donc d'une façon simple d'obtenir les isomères *endo* et *exo* du bicyclo[3.3.1]nonanol-2 one-9 mais bloqués sous forme d'acétal. Etant donné qu'il n'est pas possible de débloquer celui-ci sans isomériser l'alcool en position 2, nous avons mis au point une seconde méthode d'obtention des alcools mais cette fois en modifiant la fonction hydroxyle du mélange.

Celle-ci consiste à préparer le dérivé trichloro-2,2,2 éthoxycarbonyle (**1***b* + **2***b*) (10) du mélange des céto–alcools qui, par trituration dans le *n*-hexane, laisse précipiter l'isomère *exo* (**2***b*). Par chromatographie simple du résidu, on obtient l'isomère *endo* (**1***b*). Contrairement à l'acétalisation qui favorisait l'isomère *exo* par équilibration, la formation des dérivés "*carbonates*", conserve le rapport *endo–exo* (60:40) du mélange de départ.

Comme dans le cas précédent, l'isomère *exo* (**2***b*) présente en r.m.n. à 5.25 p.p.m. un singulet, dû au proton carbinolique ayant un $L_{\frac{1}{2}}$ de 7 Hz alors que l'isomère *endo* (**1***b*) montre à 4.80 p.p.m. un massif ayant un $L_{\frac{1}{2}}$ de 30 Hz. Une corrélation de configuration de chacun des isomères fut apportée en les transformant respectivement en alcool *endo* (**1***a*) et *exo* (**2***a*) décrits par Kraus *et al.* (7). La transformation se fait dans de l'acide acétique glacial en présence de poudre de zinc. Le céto–alcool *exo* (**2***a*) obtenu a le point de fusion et les propriétés spectroscopiques décrits (7).[3] De même, l'alcool *endo* (**1***a*) possède des propriétés spectroscopiques décrites (7).

Enfin, il est important de noter que la réaction est stéréospécifique ce qui suggère l'application de ce dérivé comme groupe protecteur de la fonction aldol.

Partie éxperimentale

Les points de fusion, déterminés à l'aide d'un appareil "Buchi", ne sont pas corrigés. Les spectres i.r. ont été pris dans le chloroforme sur un spectrophotomètre "Beckman" modèle IR-8. Les spectres de r.m.n. ont été pris dans le $CDCl_3$, sauf indication contraire, sur un spectromètre "Jeol" de 60 MHz modèle C60-H. Les déplacements chimiques ($-\delta$) sont exprimés en p.p.m. et la référence interne est le TMS. Les analyses par c.p.g. ont été faites sur un appareil "Varian Aerograph", modèle 90 P. Colonne: 6 pd. × 1/4 po., adsorbant: 10% U.C.W. 98 sur diatoport 80–100 S. Température: 170°. Les indices de réfraction ont été mesurés à l'aide d'un réfractomètre "Abbé" de la compagnie Karl–Zeiss. Les analyses élémentaires ont été confiées à "Midwest Microlab Inc.", Indianapolis, Indiana.

*Bicyclo[3.3.1]nonanol-2 one-9 (**1***a* + **2***a*) (6)*

Un mélange de 31 g (0.20 mol) d'(oxo-2 cyclohexyl)-3 propanal (6), 45 ml de Rexyn 101 et 150 ml d'eau distillée est porté à reflux pendant 2–3 h. Après extraction à l'éther la masse gommeuse obtenue est recristallisée d'un mélange acétate d'éthyle–*n*-hexane. Le solide obtenu (22–25 g, 73–83%, litt. (6) 90–95%) est un mélange de **1***a* et **2***a*. I.r.: 1720, 3450, et 3640 cm^{-1}. R.m.n. 3.2 singulet, (échangeable avec D_2O); 4.1 p.p.m. massif (protons carbinoliques).

*Analyse par c.p.g. du mélange des épimères (**1***a* + **2***a*)*

(A) Ethers silylés (11)

Un mélange de 10 mg des épimères, 1 ml de pyridine, 0.2 ml d'hexaméthyldisilazane, et 0.1 ml de triméthylchlorosilane est agité 30 s, puis laissé reposer pendant 1 h. Résultat: le rapport *endo*:*exo* est de 60:40.

(B) Acétates

Un mélange de 10 mg des épimères, 5 gouttes de pyridine, 2 ml d'acide acétique, et 4 ml d'anhydride acétique est mis à reflux pendant 1 h. Le mélange est laissé à reposer 1 h. Résultat: le rapport *endo*:*exo* est de 60:40.

*Ethylènedioxy-9,9 bicyclo[3.3.1]nonanol-2 endo (**3***a*) et exo (**4***a*)*

Une solution de 15.4 g (0.10 mol) de bicyclo[3.3.1]-nonanol-2 one-9 (**1***a* + **2***a*), 12.5 g (0.20 mol) d'éthylène glycol, 0.05 g d'acide *p*-toluène sulfonique dans 150 ml de benzène est refluée jusqu'à élimination de 1.8 ml d'eau. Après le traitement habituel et distillation, un liquide visqueux est isolé (19 g). Celui-ci traité par 150 ml d'hexane permet de précipiter 7.2 g (36.4%) de cristaux d'acétal–

[3]Ce céto–alcool fut aussi isolé en bas rendement par Martin *et al.* (3) lors de la réduction d'une énol–lactone bicyclique appropriée.

alcool *endo* (**3***a*): p.f. 101–102° (hexane). I.r.: 1000, 1100, et 3640 cm^{-1}.

Anal. calc. pour $C_{11}H_{18}O_3$: C, 66.66; H, 9.09. Trouvé: C, 66.74; H, 9.18.

L'huile résiduelle, distillée, donne 11 g (55.6%) d'acétal-alcool *exo* (**4***a*): p.f. 34–35°. I.r.: 1010, 1110, et 3520 cm^{-1}.

Anal. calc. pour $C_{11}H_{18}O_3$: C, 66.66; H, 9.09. Trouvé: C, 66.59; H, 9.06.

Etude de dilution en i.r. des épimères **3***a et* **4***a*

L'appareil utilisé est un spectrophotomètre Perkin-Elmer modèle 621. Résultats: isomère *endo*, pour $c = 0.15$ *M* (cellules 0.2 mm): bande OH libre à 3625 cm^{-1}, bande OH lié de 3250 à 3550 cm^{-1} et non symétrique. Pour $c = 0.15 \times 10^{-2}$ *M* (cellules 2 cm): bande OH libre à 3625 cm^{-1} seulement. Isomère *exo*, pour $c = 0.15$ *M*: bande OH lié intramoléculairement à 3530 cm^{-1}, et bande OH lié intermoléculairement chevauchant la précédente et allant jusqu'à 3250 cm^{-1}. Pour $c = 0.15 \times 10^{-2}$ *M*: bande OH lié intramoléculairement à 3530 cm^{-1} seulement.

*(Trichloro-2,2,2 éthoxycarbonyl)-oxy-2 bicyclo[3.3.1]nonanone-9 endo (***1***b) et exo (***2***b) (10)*

Dans 20 ml de pyridine on agite pendant une nuit à température ambiante 1 g (0.065 mol) de céto-alcool (**1**a et **2**a), et 3 g (0.14 mol) de chloroformiate de trichloro-2,2,2 éthyle. Le mélange est dilué dans 20 ml d'eau et extrait à l'éther. Celle-ci est lavée, séchée, et évaporée pour donner 3.2 g d'une huile. Triturée dans le *n*-hexane, cette huile donne 0.9 g de cristaux qui après recristallisation dans un mélange acétate d'éthyle–hexane donnent 0.8 g (38%) de produit *exo* (**2***b*). P.f.: 110–111°. I.r.: 1730 et 1750 cm^{-1}.

L'huile restante (2.3 g) est chromatographiée sur gel de silice, en éluant avec du *n*-hexane; les premières fractions donnent un solide blanc issu du réactif. Les fractions suivantes, éluées avec 5% d'acétate d'éthyle dans l'hexane, contiennent 1.2 g (56%) d'une huile limpide qui est le produit *endo* (**1***b*). I.r.: 1720 et 1750 cm^{-1}.

*Bicyclo[3.3.1]nonanol-2 one-9 endo (***1***a) et exo (***2***a) (10)*

Une portion de 1 g de dérivé *exo* (**2***b*) est agitée à la température ambiante avec un même poids de poudre de zinc dans 10 ml d'acide acétique pendant 2 h. Après filtration, la solution est reprise par du chloroforme, lavée à l'eau, séchée, et évaporée. Le résidu est un solide cotonneux qui, après recristallisation dans un mélange *n*-hexane–acétate d'éthyle donne 400 mg (85%) d'alcool *exo* (**2***a*). P.f.: 175–176° (litt. (7) 175–176°). I.r.: 955, 1720, et 3450 cm^{-1}. R.m.n. (CCl_4): 3.25, singulet (1 H) échangeable avec D_2O; 4.3 p.p.m. singulet élargi (1H).

Le même procédé est utilisé pour le dérivé *endo* (**1***b*), sauf que l'agitation dure une nuit. Le résidu obtenu est une huile qui cristallise partiellement mais qui, sublimée à 150° sous 0.5 Torr donne 320 mg (70%) d'alcool *endo* (**1***a*). P.f.: 199–200° (litt. (7) 192–193.5°). I.r.: 1050 et 1700 cm^{-1}. R.m.n. (CCl_4): 3.9 p.p.m., massif (1H).

*p-Toluènesulfonates des éthylènedioxy-9,9 bicyclo[3.3.1]nonyl-2 endo (***3***b) et exo (***4***b) (12)*

Une solution de 2 g (0.01 mol) d'acétal-alcool (**3***b*) ou (**4***b*) dans de la pyridine (20 ml) est traitée par 2.20 g de chlorure de *p*-toluènesulfonyle pendant une nuit à 0°. Après traitement habituel, le tosylate *endo* (**3***b*) est obtenu sous forme d'un solide blanc. Rendement 88%. P.f.: 100–101° (*n*-hexane). I.r.: 1040, 1120, 1180, 1350 et 1600 cm^{-1}. R.m.n.: 2.46, singulet (3H); 3.90, singulet (4H); 4.90, massif (1H), et 7.60 p.p.m., quadruplet déformé (4H).

Anal. calc. pour $C_{18}H_{24}O_5S$: C, 61.36; H, 6.82; S, 9.09. Trouvé: C, 61.20; H, 7.02; S, 9.39.

Le tosylate *exo* (**4***b*) est obtenu sous forme d'un solide blanc qui se décompose avec le temps; rendement 60%. P.f.: 79–80° (pentane). I.r.: 1040, 1130, 1180, 1360, et 1600 cm^{-1}. R.m.n. 2.46, singulet (3H); 3.94, singulet (4H); 4.75, singulet élargi (1H), et 7.60 p.p.m., quadruplet déformé (4H).

*Ethylènedioxy-9,9 bicyclo[3.3.1]nonène-2 (***5***)*

Une solution de 1.30 g (0.004 mol) de tosylate *exo* (**4***b*) dans 25 ml d'éthanol en présence d'éthylate de sodium (0.17 g de Na dans 25 ml d'éthanol absolu) est chauffée à reflux pendant 2 h. Le mélange est extrait au *n*-hexane, et la phase organique est lavée à l'eau séchée et évaporée pour donner l'oléfine **5** (9) sous forme d'huile incolore avec un rendement de 67%. I.r.: 1040, 1120, et 1650 cm^{-1}. R.m.n.: 3.87, singulet (4H), et 5.5 p.p.m., massif (2H).

Nous remercions tout particulièrement le Conseil National de Recherches du Canada pour l'aide financière apportée à D.G. sous forme d'octroi de recherche et l'Agence Canadienne de Développement International pour une bourse d'étude accordée à S.R. Notre reconnaissance s'adresse également à Mme M. Bernard pour sa collaboration lors de l'étude de dilution en i.r. Enfin, nous remercions le Dr R. J. Wells de nous avoir fourni des détails supplémentaires sur la cyclisation en présence de résine acide.

Photooxidation and Decarboxylation of Tyrosine Studied by E.P.R. and C.I.D.N.P. Techniques

MICHA TOMKIEWICZ,[1] ROBERT D. MCALPINE,[2] AND MICHAEL COCIVERA

Department of Chemistry, University of Guelph, Guelph, Ontario

Received June 21, 1972

The photooxidation of deoxygenated solutions of tyrosine in water at p*H* 8.5–12.6 has been studied at room temperature using e.p.r. spectroscopy. By means of e.p.r., four radicals were detected during irradiation with the full spectrum of a Hg–Xe arc lamp. These were identified as the tyrosyl radical, CO_2^- and two radicals derived from dopa. A tentative mechanism suggested for CO_2^- formation involves the reaction of tyrosine with the hydrated electron, which has been ejected from another tyrosine molecule in one of its excited electronic states. A mechanism similar to the one proposed for the photooxidation of phenol has been suggested for the formation of the radicals derived from dopa. Support for this mechanism is provided by the observation of proton nuclear spin polarization during irradiation.

La photooxydation des solutions desoxygénées de tyrosine dans l'eau, à des p*H* de 8.5–12.6, a été étudiée à la température ambiante au moyen de la spectroscopie r.p.e. Quatre radicaux ont été détectés pendant l'irradiation par la totalité du spectre d'arc de la lampe Hg–Xe. Ils ont été identifiés aux radicaux tyrosyle, CO_2^- et deux dérivés du dopa. Une tentative pour expliquer le mécanisme de la formation de CO_2^- fait intervenir la réaction de la tyrosine avec l'électron hydraté, éjecté d'une autre molécule de tyrosine dans un de ses états électroniques excités. Un mécanisme, semblable à celui proposé dans la photooxydation du phénol, a été suggéré pour la formation des radicaux dérivés du dopa. A l'appui de ce mécanisme, la polarisation de spin nucléaire du proton a été observée durant l'irradiation. [Traduit par le journal]

Introduction

The use of e.p.r. spectroscopy to detect radical intermediates resulting from the irradiation of aromatic amino acids has been mainly confined to the solid state (1). Without the use of special techniques, such as ENDOR (Electron Nuclear Double Resonance), the broad nature of solid state e.s.r. lines makes the identification of hyperfine interactions difficult. However, in the liquid state, molecular motion tends to sharpen the lines of the spectrum, and isotropic hyperfine coupling constants can be obtained to a high degree of precision. Often the details of the hyperfine structure of a radical spectrum are sufficient to assign the structure of the radical. One additional motivation for carrying out liquid phase studies is the fact that variables, such as p*H*, ionic strength, and concentrations may be more easily controlled in liquid than in solid state. We have undertaken an e.p.r. study of the irradiation of tyrosine and several related compounds in water solution using the full spectrum (quartz optics) of a 1000 W mercury–xenon high pressure lamp. Subsequently, we will attempt to extend these studies to polypeptides.

Since tyrosine is a building block of polypeptides and proteins, it is our hope that information about the photochemistry of this and other aromatic amino acids will lead to some understanding of u.v. irradiation processes in the larger molecules. Tyrosine consists of a phenol attached to an alanine residue. Consequently, in this article, we will show that most of the photochemical oxidation of tyrosine in basic solution, and in the absence of molecular oxygen, may be understood in terms of the known photochemical oxidation of phenol, a study which has been carried out in this laboratory (2). Under the conditions described, the tyrosyl radical **1**, and an *o*-benzosemiquinone **2** derived from dopa can be detected. The formation of these radicals can be understood in terms of photoelectron ejection via an excited state of tyrosine (3) followed by a hydroxide ion attack on the tyrosyl radical to form dopa, which is subsequently further oxidized to the *o*-benzosemiquinone radical **2**. Additional evi-

2

dence in favor of this mechanism was obtained from the n.m.r. spectrum of the solution obtained during irradiation. Under these conditions nuclear spin polarization, which is consistent with the proposed mechanism, is obtained.

Experimental

Solutions of 10^{-2} *M* L-tyrosine (Cyclo Chemical Co.) were irradiated at various p*H* values between 8.5–12.6, in the microwave cavity of a Varian E-12 e.p.r. spectrometer. The irradiation consisted of the full spectrum of a Hanovia 1000 W mercury–xenon lamp using quartz optics. Closed, continuous flow systems were used as described previously (2*b*). Solutions were maintained oxygen free by passing nitrogen (Canox) or argon (Canox) through the reservoir of the flow system. For several experiments the nitrogen gas was replaced by N_2O (Canox).

In a few experiments tyrosine α-d_1, or tyrosine α-d_1, *o*-d_2 (both prepared specially for us by Merck, Sharpe and Dohme, Montreal) were irradiated in the place of tyrosine.

N.m.r. studies were carried out on a Varian HA100 spectrometer which was equipped with a special probe which allowed the n.m.r. spectrum to be observed during irradiation. The details have been described previously (2*b*).

Results and Discussion

Electron Paramagnetic Resonance Spectroscopy

Figure 1 illustrates the e.p.r. spectrum obtained during irradiation of a deoxygenated solution of 0.01 *M* tyrosine in water at p*H* 11 and room temperature. For this spectrum, the flow rate was 5 ml/min. Variation in the flow rate (5–20 ml/min) has very little effect on the absolute, but no effect on the relative intensities of the lines. Variation in the p*H* affects both the absolute and the relative intensities of the lines. Maximum absolute intensities occur around p*H* 11.4. Below p*H* 8.5 and above p*H* 12.6, the radicals could not be detected at the flow rates employed (5–20 ml/min).

The spectrum in Fig. 1 can be analyzed as a superposition of the spectra of four radicals. In the first (*g*, 2.0041), the hyperfine interactions involve six protons in equivalent sets 2:2:1:1 with coupling constants 6.15, 1.5, 15.4, and 0.4 G, respectively. Borg and Elmoro (4) have observed the same spectrum with less resolution during chemical oxidation of tyrosine in alkaline water. They did not observe the 0.4 G splitting. They assigned this spectrum to the tyrosyl radical with the ortho and meta protons having the coupling constants 6.5 and 1.5 G, respectively. They suggested that the CH_2-protons were unequivalent due to hindered rotation with one having a coupling constant of 15.4 G and the other having one too small to resolve. They base this conclusion on the fact that these protons appear to be equivalent in acidic water solutions but become unequivalent again when a NH_2- or a COOH-proton is substituted by a bigger

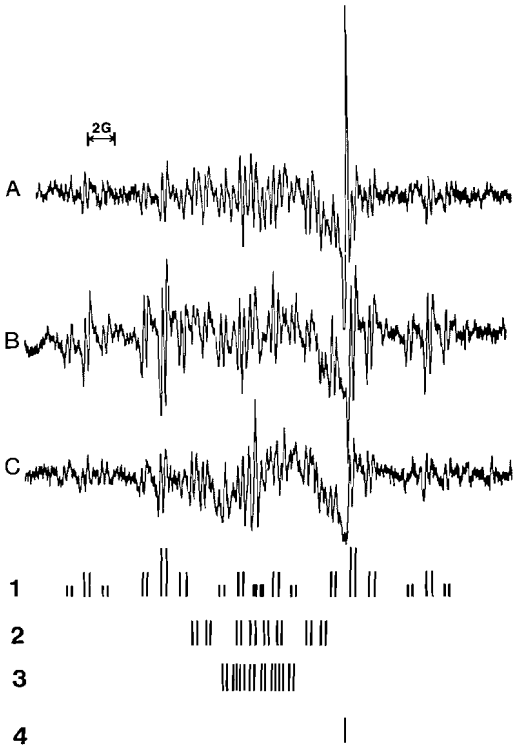

FIG. 1. (A) E.p.r. spectrum obtained during the irradiation of a deoxygenated water solution of 0.01 *M* tyrosine at p*H* 11 and ambient temperature. Flow rate is 5 ml/min. (B) E.p.r. spectrum under the same conditions as part A except the solution is saturated with N_2O. (C) E.p.r. spectrum under the same conditions as part B except the solution contains 1 *M* methanol.

*α, β are defined relative to the —COOH group.
†o, m are defined relative to the —OH group.
‡The β hydrogens are assumed to undergo hindered rotation.
§The assignments of hyperfine constants for the three unequivalent ring protons of radicals 2 and 3 cannot be specified with the present information.

group. While we agree that hindered rotation probably is responsible for the occurrence of a doublet rather than a triplet splitting due to the methylene protons, we prefer to assign the doublet splitting to both methylene protons rather than to one of them. Thus, although a triplet is expected, a doublet is observed because the hindered rotation occurs at a rate which broadens the central line to the extent that it cannot be detected. This alternating linewidth effect has been observed for a number of radicals (5). Thus, according to our interpretation, the hyperfine coupling constant for the methylene protons is 7.7 G. Support for this interpretation is the fact that these methylene protons have a coupling constant of 7.8 G when the tyrosyl radical is formed under conditions in which hindered rotation is unimportant and the triplet is observed (4). Additional evidence in favor of this assignment is given below.

To obtain a more conclusive assignment of the hyperfine interactions, we have repeated our experiments using two types of partially deuterated tyrosine: tyrosine o-d_2,α-d_1 and tyrosine α-d_1. These were obtained under the same conditions as Fig. 1. The effect of the deuteration on the spectra of the other radicals will be discussed below. The spectrum for radical **1** obtained from tyrosine o-d_2,α-d_1 indicates that the two equivalent protons with the hyperfine constant of 6.15 G observed in Fig. 1 have been replaced by two deuterons. Furthermore, the 0.4 G splitting has disappeared. The absence of the 0.4 G splitting occurred for tyrosine α-d_1, also. These results indicate that the 6.15 G splitting is due to the ortho-protons and the 0.4 G splitting is due to the α-CH-proton. To check the possibility that the aliphatic side-chain has undergone an elimination reaction to give the phenoxyl radical derived from *p*-hydroxycinnamic acid, we have studied the irradiation of this acid under the same conditions. We detected the phenoxyl radical derived from this acid with the following hyperfine coupling constants for the α-H, β-H, *o*-H, and *m*-H, respectively: 0.35, 8.2, 1.4, and 6.4 G. Thus since the doublet splitting due to the β-H of this radical is about half the value of 15.4 G observed for the β-H of the tyrosyl radical, this alternative is unlikely. Combining these conclusions with those made in the previous paragraph, the assignment of the hyperfine coupling constants for tyrosyl radical are given in Table 1.

Since we feel that the second and third radicals are closely related, we will discuss them together. The spectrum for the second radical in Fig. 1 can be analyzed in terms of four doublet splittings with values of 5.30, 3.55, 1.12, and 0.32 G, and $g = 2.0021$. The third radical also has a spectrum which can be analyzed in terms of four doublet splittings having values of 1.55, 3.70, 0.91, and 0.39 G, and $g = 2.0021$. We suggest that the second and third radicals have structures **2** and **3**, respectively. As can be seen,

3

3 is the conjugate base of **2**. As in the case of the tyrosyl radical, the observation of a doublet rather than a triplet splitting for the CH_2-protons of **2** and **3** is explained in terms of hindered rotation at a rate which broadens the central line of the triplet to the extent that it cannot be detected. The spectra for these radicals obtained from tyrosine o-d_2,α-d_1 exhibited broad lines with insufficient detail for an adequate analysis. This result is not unexpected since deuteration at the ring should cause overlap of lines. On the other hand, the spectra for radicals **2** and **3** obtained from tyrosine α-d_1 are identical to the spectra in Fig. 1, indicating the absence of a measurable hyperfine interaction for the α-CH proton. The assignments of the hyperfine coupling constants are given in Table 1. These assignments are arbitrary, and the choice of the largest splitting for the methylene protons is made to be consistent with the similar assignment made for the tyrosyl radical.

Another reason for the choice of **2** and **3** is that the relative concentrations of these radicals depend on the pH of the solution. From this pH dependence, the pK_a value for the acid dissociation of **2** is determined to be about 12.4. This value can only be considered approximate since it is based on measurements at only seven pH values ranging from 9.6 to 12.6. Gorton and Jameson (6) have obtained a value of 13.4 for the same acid dissociation step involving the corresponding diamagnetic molecule, dopa (3-[3,4-dihydroxyphenyl]alanine). Thus, the pK_a value appears to decrease when an electron is removed from dopa. A decrease is not unexpected since Carrington and Smith (7) have found a similar but larger effect for pyrogallol.

Additional support for the assignment of **2** and **3** is the fact that L-dopa forms these radicals, also, as can be seen in Fig. 2. The spectrum given in Fig. 2 is obtained in water at pH 11 in the absence of irradiation. If the solution is made acidic, the radicals cannot be detected. Oxidation of L-dopa by molecular oxygen seems unlikely since the same spectrum was observed, also, in a static solution which had been evacu-

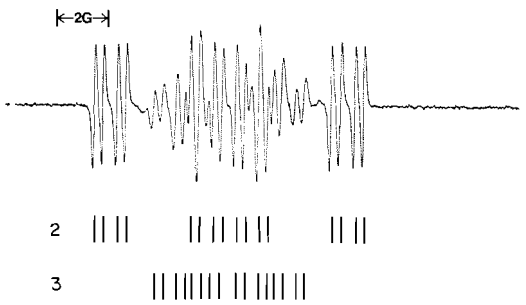

FIG. 2. E.p.r. spectrum of a deoxygenated water solution of L-dopa at pH 11 in the absence of irradiation. The intensity of the spectrum is enhanced during irradiation and no additional signals are observed.

ated to 2 μ Hg. This degassed solution was prepared by dissolving L-dopa in water after the evacuation had been completed. At this pressure, the concentration of O_2 in water is about 10^{-9} M whereas the concentration of radicals is about 10^{-5} M. As a result, we believe that dopa is being oxidized by a small amount of its corresponding o-quinone which is present as an impurity. Upon irradiation, no new radicals are observed, but the concentrations of **2** and **3** are increased. Thus, in the absence of molecular oxygen, oxidation of L-dopa beyond its corresponding o-benzosemiquinone cannot be detected. A similar result was obtained for o- and p-hydroquinone (2*b*).

Borg (8) has studied the oxidation of dopa in alkaline water using $K_3Fe(CN)_6$ as an oxidizing agent. Apparently his experiment involved air-saturated solutions, and he observed a radical different from **2** and **3**. As a check, we have repeated his experiment under anaerobic conditions. The resultant spectrum is identical to Fig. 2.

We have ruled out the possibility of ring formation via nitrogen addition to the phenyl ring (9) because no nitrogen hyperfine interaction is observed. Furthermore, lactone formation (10) would result in structures which are not consistent with the observed hyperfine interactions. Thus, we suggest structures **2** and **3**.

The fourth radical observed during the irradiation of tyrosine solution has a spectrum consisting of one line as indicated in Fig. 1. The g factor, which is 2.0001, is very close to the one determined (11) for CO_2^- (2.0003). The mech-

anism for the formation of this radical seems to involve the hydrated electron because the resonance line is not observed when the solution is saturated with N_2O, as indicated in Fig. 1B. N_2O is a good scavenger of the hydrated electron via reaction 1 (12). Tyrosine is known to react

$$[1] \qquad N_2O + e^-_{aq} \rightarrow N_2 + OH^- + OH$$

with the hydrated electron (13) also, although the details of the reaction have not been specified. Thus, it is possible that CO_2^- is formed via a reaction between the hydrated electron and tyrosine. The presence of N_2O reduces the extent of this reaction by competing for the hydrated electron. The possibility that the CO_2^- radical disappears because it reacts directly with N_2O is ruled out because of the results obtained by Neta *et al.* (12). These workers generated CO_2^- by two different reactions as indicated in eqs. 2 and 3. In eq. 3 the OH radical

$$[2] \qquad CO_2 + e^-_{aq} \rightarrow CO_2^-$$

$$[3] \qquad HCO_2^- + OH \rightarrow CO_2^- + H_2O$$

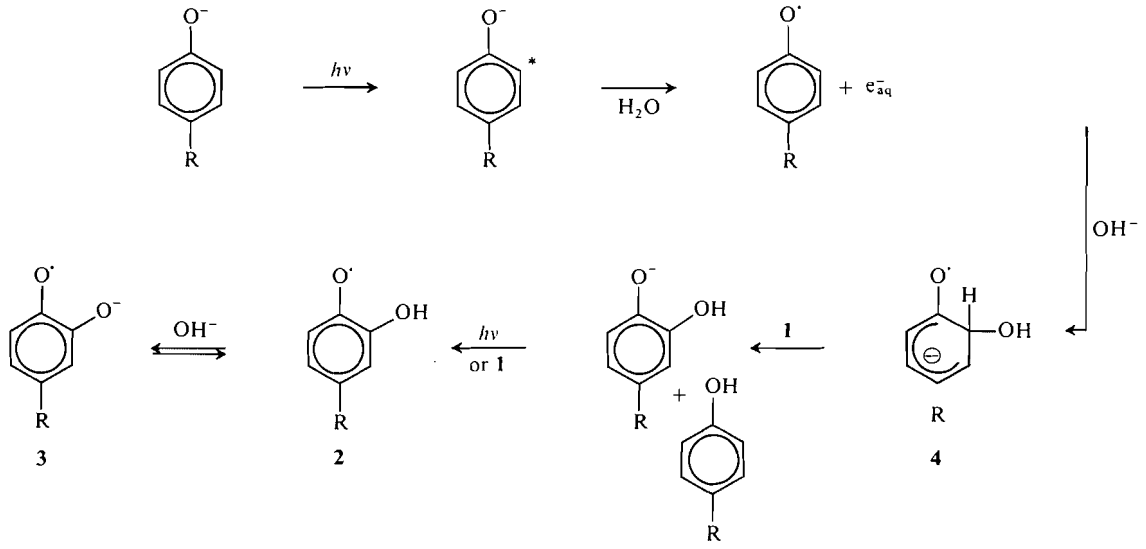
is formed by reacting N_2O with the hydrated electron according to eq. 1. Consequently, N_2O was present in the system when reaction 3 was used to generate CO_2^-. The rate of decay of CO_2^- was found to be the same whether reaction 2 or 3 was used to generate the radical. This result indicates that N_2O does not affect the lifetime of CO_2^-. Thus, we conclude that the N_2O results indicate that the hydrated electron is involved in the formation of CO_2^-. A possible reaction path is depicted by eq. 4. It is interesting to note that we were unable to detect CO_2^- during the irradiation of 3-[*p*-hydroxyphenyl]propionic acid under the same conditions. Apparently an α-amino group facilitates the decarboxylation.

$$[4] \qquad \underset{\text{dianion}}{\text{Tyrosine}} + e^-_{aq} \xrightarrow[H_2O]{} \text{Tyramine} + CO_2^- + OH^-$$

Comparison of Fig. 1A with 1B indicates that the presence of N_2O enhances the concentrations of radicals **1**, **2**, and **3**. Since the reaction of N_2O with the hydrated electron results in the formation of the OH radical (eq. 1), much of the enhancement is probably due to the reaction of this radical with the anions of tyrosine and dopa to form **1**, **2**, and **3**. This conclusion is based on the fact that addition of 1 *M* methanol to the tyrosine–N_2O solution causes the enhancement to disappear (compare Fig. 1C with 1A). Methanol is known to be a scavenger of the OH radical (14). That methanol is scavenging this radical under these conditions is confirmed by the observation of the CH_2OH radical.

The presence of 0.1 *M* H_2O_2 in a solution of tyrosine at p*H* 11 causes an enhancement in the concentration of radicals **1**, **2**, and **3** during irradiation. The enhancement is smaller for **1** than for the other radicals. Most likely several reactions are responsible for these enhancements. First, OH, which is formed from the irradiation-induced cleavage of H_2O_2, could add to the phenyl ring of tyrosine to form **2** and **3** since OH addition to the phenyl ring has been observed in studies of phenol (13*a*, 15). Second, the reaction of the OH radical (16) and H_2O_2 (17) with the hydrated electron would result in a slower rate of removal of **1**, **2**, and **3** via recombination with the hydrated electron. Third, OH may react with tyrosine to form **1** (13*a*). With our present results, it is not possible to decide on the importance of each of these reactions.

However, in the absence of N_2O, H_2O_2, and O_2, we feel that the addition of the OH radical to the phenyl ring is not an important path in the formation of **2** and **3** because the addition of methanol to the solution has little effect on the intensity of the spectrum observed under these conditions. Therefore, we propose the mechanism depicted by Scheme 1 for the formation of **1**, **2**, and **3**. In this scheme, R represents the allanyl group ($CH_2CHNH_2COO^-$). The tyrosine dianion absorbs a photon and subsequently ends up in an electronic excited state from which an electron is ejected to form **1** in its ground state. These steps are consistent with the formation of the hydrated electron observed during the flash photolysis of tyrosine and other substituted phenols (3, 18). Although the excited state involved has not been determined for tyrosine, Joschek and Grossweiner (18) have suggested that the electron ejection step for phenol involves a charge-transfer-to-solvent state which is produced via an excited singlet state. The next step in Scheme 1 is the addition of the hydroxide ion to the phenyl ring to form **4** from which a hydrogen atom is removed by **1** to form tyrosine and the dianion of dopa. The



SCHEME 1

oxidation of dopa to form **2** may be accomplished either with **1** or with a photon; we cannot distinguish between these steps with our results. These steps are identical to the ones proposed to explain the oxidation of phenol to *o*- and *p*-benzosemiquinone (2) under similar conditions. In the case of phenol, the oxidation proceeds beyond *o*- and *p*-benzosemiquinone to oxy- and dioxybenzosemiquinone. Finally, as indicated in Scheme 1, we suggest that the equilibration between **2** and **3** occurs after the electron has been removed from dopa because the pK_a for dopa (6) is larger than the one for **2**. However we do not mean to imply that only **2** is formed from dopa.

As just mentioned, the photooxidation of dopa does not proceed as far as the photooxidation of phenol under the same conditions. For example at p*H* 12, oxy- and dioxybenzosemiquinone can be detected during the irradiation of phenol (2) but not during the irradiation of tyrosine. The manner in which the side-chain inhibits further oxidation is not clear at this time.

Nuclear Magnetic Resonance Spectroscopy

We have studied the irradiation of tyrosine in deoxygenated water by means of proton n.m.r. spectroscopy, also, and the results support the mechanism given in Scheme 1. In these experiments, an evacuated solution of 10^{-2} *M* tyrosine in D_2O at p*H* 11 is irradiated in the n.m.r. probe. Because tyrosine is sparingly soluble in water, its concentration could not be increased significantly above 10^{-2} *M* under these conditions. Consequently, the n.m.r. lines due to the protons of tyrosine could not be detected with our spectrometer. As a result, the spectrum of the D_2O solution in the absence of irradiation consists of one line due to a small amount (0.2%) of HDO present in the solvent. During irradiation, this line changes from absorption to emission as can be seen in Fig. 3. This emission indicates that the HDO-proton is spin polarized, *i.e.* the populations of the nuclear spin states differ from those expected for a Boltzmann distribution. Nuclear spin polarization has been observed for a number of systems involving radical reactions (19), and a rather convincing body of evidence is available to indicate that the nuclear spin polarization occurs via a radical pair. Since this phenomenon has been discussed in detail elsewhere (19), a general presentation of the mechanism for nuclear spin polarization is unnecessary in this paper. Instead, we will show only that the observed nuclear spin polarization is qualitatively consistent with the mechanism proposed in Scheme 1. The mechanism proposed to explain the spin polarization of the HDO-proton is given in Scheme 2 which simply describes some of the steps in Scheme 1 in more detail. In

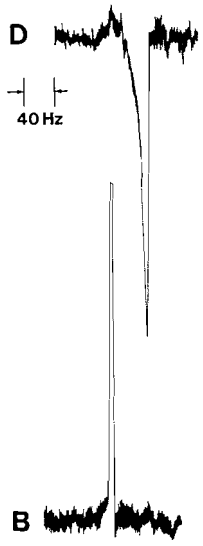

FIG. 3. The n.m.r. line of the HDO-proton for a deoxygenated D_2O solution of 0.01 *M* tyrosine at p*H* 11 and ambient temperature; B: before irradiation, D: during irradiation. The field strength increases from left to right. The shift in the HDO line during irradiation is due to local heating of the sample.

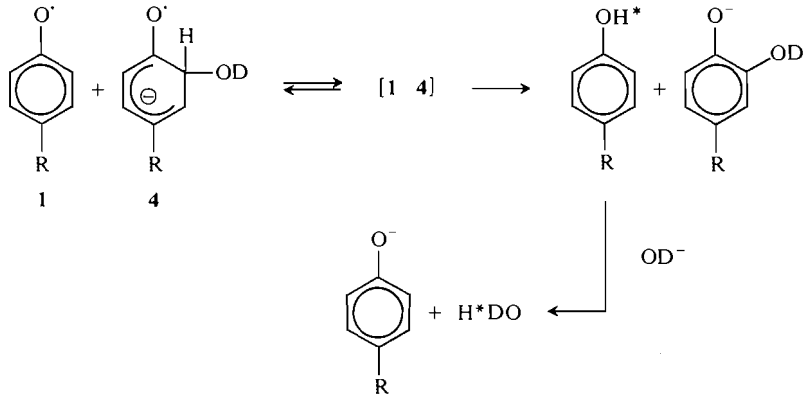
Scheme 2, **1**, and **4**, which start out as non-interacting radicals in the bulk, diffuse together to form a radical pair symbolized as [**1** **4**]. The radicals in the radical pair can diffuse apart or undergo a disproportionation reaction to form tyrosine and dopa having nuclear spin polarization. The proton of interest is the tyrosine OH-proton which is labelled with an asterisk. The removal of this proton by OD^- to form HDO is probably more rapid than its spin relaxation rate. This conclusion is based on the rate constant for reaction of phenol with OH^- (20). Thus, Scheme 2 provides a mechanism for the observed spin polarization of the HDO-proton.

The HDO-proton is polarized in the same manner during the irradiation of phenol under the same conditions (2). The mechanism used to explain this polarization is identical to Scheme 2. For this system, it was possible to present additional evidence in favor of Scheme 2. Because of the close similarity between the results for phenol and tyrosine it seems reasonable that they would be oxidized via the same mechanism under these conditions.

Thus according to Scheme 1, after tyrosine has been oxidized to the tyrosyl radical **1**, it can act as an oxidizing agent for subsequent oxidation to dopa and **2** or **3**. In other words, once the tyrosyl radical is formed no other oxidizing agent is needed to form dopa. It will be interesting to determine if enzymatic oxidation of tyrosine can be accomplished in the same manner. In addition, this work is being extended to other aromatic amino acids and to polypeptides containing tyrosine to determine the feasibility of investigating the irradiation of proteins using these techniques.

Finally, in Scheme 1, the formation of the hydrated electron is suggested, but a mechanism for its disappearance has not been discussed. The e.p.r. and n.m.r. results give us no information concerning the reaction of this species. Probably it disappears by way of various paths which do not alter the mechanism proposed in Scheme 1. For example, the hydrated



SCHEME 2

electron could combine with any of the observed radicals or react with water.

We are grateful to Dr. M. Fujimoto for allowing the use of the e.p.r. spectrometer and to the referee for pointing out the alternating linewidth effect. This work has been supported in part by the Petroleum Research Fund administered by the American Chemical Society, the Department of University Affairs (Ontario), and the Defence Research Board of Canada.

Phosphonitrilic Chloride — The Dehydration of Amides to Nitriles

JOHN C. GRAHAM[1] AND DAVID H. MARR
Hooker Chemical Corporation, Research Center, Grand Island, N.Y. 14072

Received June 12, 1972

Phosphonitrilic chloride is found to dehydrate amides to nitriles rapidly and in high yields. A mechanism for the dehydration is proposed.

Le chlorure de phosphonitrile convertit les amides en nitriles, par une réaction de deshydratation rapide, avec de bons rendements. Un mécanisme pour cette réaction a été proposé.

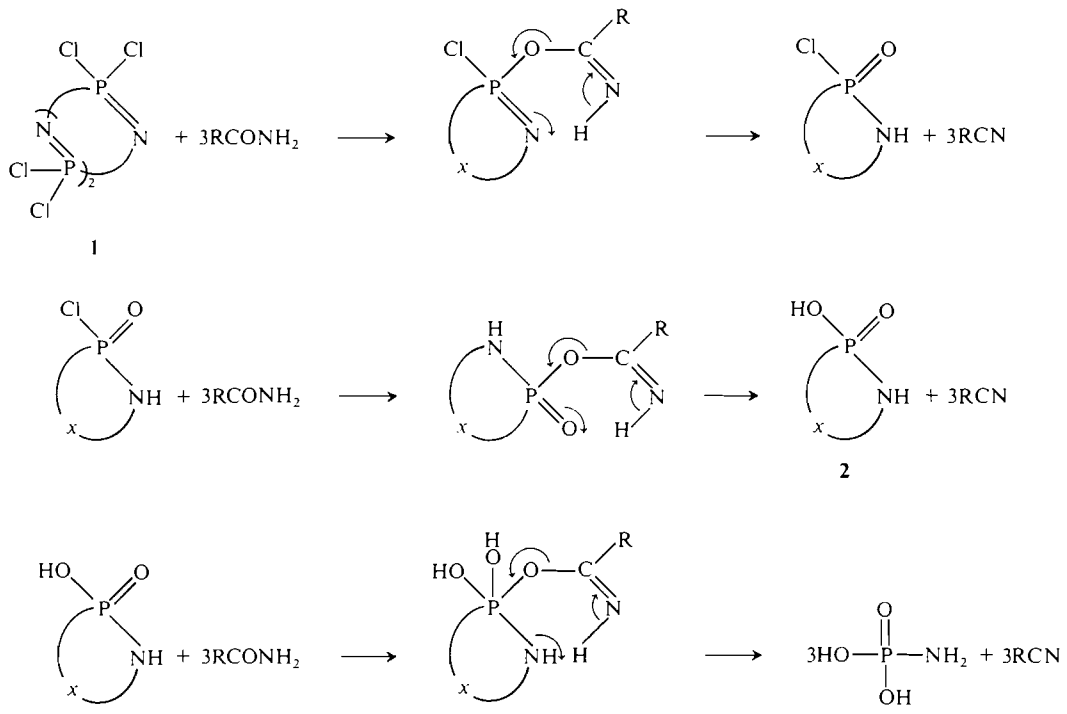
[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3857 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The dehydration of amides to nitriles has been accomplished by a variety of agents (1). Many of these have been summarized recently (2). We have found that 1,1,3,3,5,5-hexachlorocyclophosphazatriene (**1**), commonly called phosphonitrilic chloride can also be used to convert amides to nitriles rapidly and in excellent yields.[2] Ideally, the reaction is carried out on a mixture of the amide and **1** at temperatures above 100 °C and the nitrile distilled from the reaction mixture on formation. Although in our investigations we preferred a 1:3 mole ratio of **1** to amide, we found in many cases that a ratio of 1:6 could be used, and in the case of acetamide, a 1:12 mole ratio was effective.

In addition to the nitrile, an amorphous, hy-

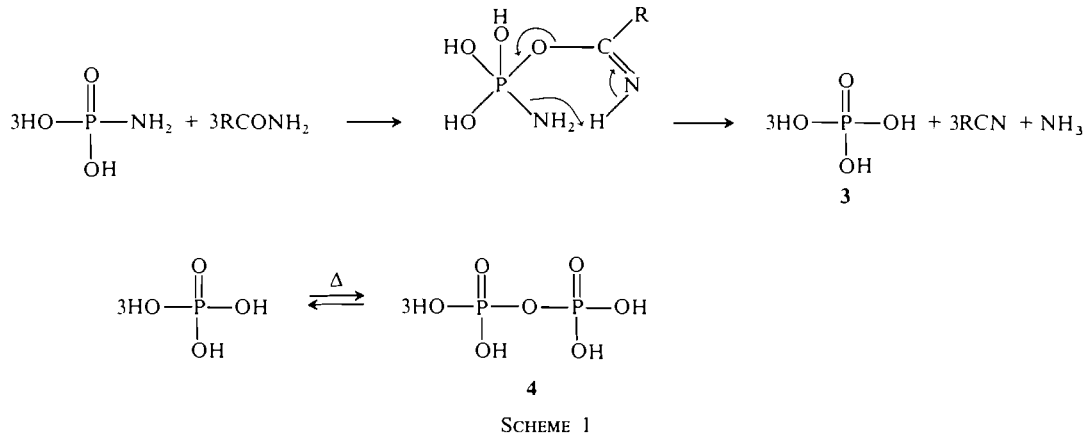


1

2

[1]Author to whom all correspondence should be addressed.

[2]The high amide to $(PNCl_2)_3$ ratios employed, combined with minimum handling difficulties, makes this reagent competitive with other commonly employed dehydrating agents. Although pure **1** is expensive, **1** admixed with higher cyclic and linear material is inexpensive and commercially available (5). Dehydration reactions using this mixture gave similar results.



SCHEME 1

groscopic, water-soluble material is recovered. ^{31}P n.m.r. analysis of this amorphous residue gave singlets at +11.0 and 0.0 p.p.m. relative to H_3PO_4. The former is consistent with pyrophosphoric acid (**4**) (3) or its monoammonium salt and the latter signal has been assigned to pyrophosphimic acid ($HOPO_2NHPO_2OH$) or its monoammonium salt. It is important to note that the absence of orthophosphoric acid (**3**) was established by the addition of authentic material. The proposed trimetaphosphimic acid intermediate (**2**) was not observed (3, 4). Neutralization of the amorphous residue with aqueous sodium hydroxide followed by evaporation yielded $Na_4P_2O_7$ as evidenced by X-ray diffraction.

Discussion

The discovery of $Na_4P_2O_7$ in the neutralized residue and the ^{31}P n.m.r. singlet at 0.0 p.p.m. indicative of pyrophosphimic acid suggests the reaction path outlined in Scheme 1.[3] Preliminary investigations regarding the mechanism of the dehydration have shown the intermediate phosphorous moieties to be better dehydrating agents than **1**. In controlled reactions using various ratios of **1** to acetamide, the theoretical amount of excess **1** was recovered based on a mole equivalent ratio of 1:12. The results are summarized in Table 1. This is not surprising since sulfonic acid amides (SO_3HNH_2) (6) as well as alkyl phosphates and phosphoramides (which are similar to the intermediates proposed for this reaction) are known to dehydrate amides in good to excellent yields. This dehydration reaction has been applied to a number of amides and appears to be quite general except for α-chloroacetamide which did not react and hydroxyamides which yield, not unexpectedly, high molecular weight materials via nucleophilic displacement of chloride (7). The results are summarized in Table 2.

Sonobe (8) has proposed a mechanism for the reaction of ammonium salts of carboxylic acids with $(PNCl_2)_x$ to form nitriles and acid chlorides, based on the nucleophilic attack of the salt on $(PNCl_2)_x$. This proposal is analogous to those of Bezman and Reed (9) and Caglioti *et al.* (10) for the reaction of sodium salts of carboxylic acids with $(PNCl_2)_x$ where nitriles and anhydrides are isolated. However, at the temperatures involved in Sonobe's investigation, it is likely that the ammonium carboxylates are converted to amides which then react as outlined in Scheme 1. Consequently, in light of the present work, it appears that at least two mechanistic pathways may be involved; the

[3]A referee has pointed out that a more logical first step in the mechanism involves nucleophilic attack by nitrogen instead of oxygen. However, a number of investigators have established that amides behave as weak nucleophiles with oxygen as the most reactive site (excellent reviews on this aspect can be found in ref. 2*a*, Chapts. 3 and 13). This argument cannot in itself preclude the possibility of intramolecular rearrangements which would lead to the same intermediate obtainable directly from nucleophilic attack by nitrogen. Similar rearrangements are well-documented in the field of amide chemistry, but in this instance, the 4-centered intermediate required for the rearrangement would be in direct competition with the 6-centered intermediate postulated in step 2 of Scheme 1. Intuitively, the authors favor the latter.

reaction of ammonium carboxylates directly with $(PNCl_2)_x$ to yield nitrile, acid chloride, and anhydride or first its conversion to the amide with subsequent reaction via Scheme 1 to give solely the nitrile. Since the source of nitrilic nitrogen is different for the two pathways, ^{15}N labeling experiments should resolve this question.

Experimental

Trimeric phosphonitrilic chloride $(PNCl_2)_3$ was obtained by distillation of a commercially obtainable material, m.p. 112–114° (lit. 112–113°) (11).

Commercially available chlorobenzene was used as the solvent. Identification of compounds was by i.r. and n.m.r. techniques. Boiling points and melting points were used where applicable. Two methods were used in the synthetic approach as follows.

Method A

The amide and phosphonitrilic chloride were heated in a flask to above the boiling point of the nitrile. Almost immediately, the nitrile began to distill with liberation of HCl and after 30 min, the required amount of nitrile had been recovered. Gas chromatographic analysis showed the nitrile to be extremely pure with no anomalous peaks.

Method B

The amide and phosphonitrilic chloride were dissolved or suspended in a suitable solvent such as chlorobenzene. The mixture was then heated at reflux for a few hours. The mixture in the flask was filtered and the nitrile recovered from the filtrate by evaporation of the solvent or from the filtered solid by dissolving the solid nitrile in a suitable solvent and filtering off the inorganic residue.

Nuclear Magnetic Resonance Analysis

The ^{31}P n.m.r. chemical shifts of saturated aqueous solutions were obtained on a Varian HA-100 spectrometer operating at 40.5 MHz with baseline stabilization. An external capillary of 85% H_3PO_4 was used as a reference and chemical shifts were obtained by interpolation between reference and sample side bands. Calibration was provided by the known sideband separation in Hz. An average of five separate determinations were taken and the values obtained are estimated to be accurate to ± 0.5 p.p.m.

The authors wish to thank the Hooker Chemical Corporation for permission to publish this work.

Kinetics of the Anation Reaction of Nickel(II) and 1,10-Phenanthroline in Ethanol

M. L. SANDUJA AND W. MACF. SMITH

Department of Chemistry, Queen's University, Kingston, Ontario.

Received June 13, 1972

The kinetics of formation of the monophenanthroline complex of nickel(II) in ethanol has been studied using stopped-flow methods over the temperature range 7 to 35 °C. Tetrabutyl ammonium perchlorate in concentration 0.044 *M* does not affect the rate appreciably, sodium perchlorate at the same concentration depresses the rate significantly. Most measurements were made in the absence of electrolytes other than nickel perchlorate and a trace of perchloric acid. The second order rate constant is not significantly dependent on the nickel(II) concentration over a four-fold change in value indicating that the concentration of encounter pairs is small relative to the concentration of the free reactants. The rate constant at 25 °C ($31 \times 10^3\ M^{-1}\ s^{-1}$) is consistent with a dissociative interchange mechanism and the rate constant for ethanol exchange on nickel. However, the value of $\Delta H^{\ddagger}$ for the overall reaction (15.9 ± 1.0 kcal mol^{-1}) is about 5 kcal mol^{-1} higher than that reported for ethanol exchange.

Nous avons étudié la cinétique de formation du complexe monophénanthroline du nickel(II) dans l'éthanol au moyen de méthodes à débit arrêté, dans un domaine de température de 7 à 35 °C. Le perchlorate de tétrabutyl ammonium en concentration de 0.044 *M* n'affecte pas appréciablement la vitesse; le perchlorate de sodium, par contre, à la même concentration ralentit cette vitesse de façon significative. La plupart des mesures ont été effectuées sans d'autres électrolytes que le perchlorate de nickel et une trace d'acide perchlorique. La constante de vitesse d'ordre deux ne dépend pas de la concentration de nickel(II) de façon significative pour un changement de la valeur par un facteur de quatre, indiquant que la concentration de paires voisines est petite relativement à la concentration des réactifs libres. La constante de vitesse à 25 °C ($31 \times 10^3\ M^{-1}\ s^{-1}$) est conciliable avec un mécanisme d'échange dissociatif et avec la constante de vitesse d'échange d'éthanol sur le nickel. Toutefois la valeur de $\Delta H^{\ddagger}$ pour la réaction globale (15.9 ± 1.0 kcal mol^{-1}) est environ de 5 kcal mol^{-1} plus élevée que celle rapportée pour l'échange d'éthanol.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3861 (1972)

Kinetic behavior in the anation reactions of nickel(II) in the hydroxylic solvents water (1) and methanol (2) is consistent with a dissociative interchange (I_d) (3) mechanism [1].

$$[1]\qquad \begin{aligned} NiS_6^{2+} + L &\overset{K_0}{\rightleftharpoons} NiS_6^{2+}.L \\ NiS_6.L^{2+} &\xrightarrow{k} NiS_5L^{2+} + S \end{aligned}$$

where NiS_6^{2+} represents the solvated nickel ion and NiS_6^{2+}. L the encounter complex and L is the entering ligand which is represented here as neutral and monodentate and k is the rate constant for collapse of the encounter complex which in the case of an I_d mechanism relates to the rate constant for solvent exchange on nickel(II). For reactions of nickel(II) with bidentate ligands the reaction involving the first solvent molecule appears to be rate controlling (4) although formation of the final product involves replacement of two solvent molecules. If the concentration of the encounter complex is close to the equilibrium value and is substantially less than those of the free reactants, the overall rate of reaction would be second order with rate constant $k_f = kK_0$. However, Bennetto and Caldin (5) consider that the results of investigations on the reactions of nickel(II) with 2,2′-bipyridyl and 2,2′,2″-terpyridyl in a variety of solvents, predominantly non-hydroxylic, are not consistent with a simple I_d mechanism. Also, the data of Langford and Tsiang (6) on the reaction of $Ni(DMSO)_6^{2+}$ with thiocyanate and murexide imply a value for the rate constant which is less than anticipated on the basis of an I_d mechanism if a value of K_0 of the order expected from the Fuoss–Eigen equations (8) is assumed to apply. Cock, Cottrell, and Boyd (9) on the basis of their results on the reactions of 2,2′,2″-terpyridyl with $Ni(DMSO)_6^{2+}$ and a species they believe to be $[Ni(terpy)Cl(DMSO)_2]^{2+}$ consider that the mechanisms are of I_d character although the values obtained for the rate constants are substantially less than anticipated on the basis of commonly accepted interpretations.

To expand information about the as yet unresolved kinetic behavior of nickel(II) in various classes of solvents we are investigating the reactions of nickel(II) in ethanol, a hydroxylic

solvent relating to the commonly used solvents water and methanol. The rate of ethanol exchange on nickel(II) has been investigated by Breivogel (10) but studies of other anation reactions in this solvent do not appear to have been reported. Although the ionizing power of this solvent is greater than implied by simple electrostatic considerations and its dielectric constant (11), complications in interpreting data due to outer ion pairing between reactant and nonreactant species and to corresponding uncertainties in the nature of the ion environment may be expected when ligands are charged. However, the reaction between nickel(II) and phenanthroline, upon which we report here, involves an uncharged ligand, a large association constant, a probable lack of sensitivity on ionic strength and in consequence complications associated with ion pairing involving reactant and nonreactant species should not be serious.

Experimental

Hydrogen chloride was of electronic grade from Matheson of Canada. Anhydrous nickel chloride of analytical grade from Alfa-Inorganics and silver perchlorate of reagent grade from G. Frederick Smith were heated at 100 °C under reduced pressure over phosphorus pentoxide for 48 h before use. Absolute ethanol was subjected to standard purification procedures with magnesium turnings and iodine (12) and the middle fraction from distillation with a Widmer column was stored in colored bottles in a dry box and used within a few days of preparation. All other substances were of reagent grade from Fisher Scientific Company, G. Frederick Smith or British Drug Houses and apart from drying over silica gel or drierite were subjected to no further purification.

The preparation and transfer of solutions were carried out in a dry box under an atmosphere of dry nitrogen, and freshly prepared solutions were used in all kinetic runs. Nickel chloride, silver perchlorate, sodium perchlorate, and tetrabutyl ammonium perchlorate, stored in vacuum desiccators were transferred to the dry box for weighing at the time of their use in the preparation of solutions. All glassware used for measurement or storage of solutions was dried at 115 to 120 °C for several hours prior to use. Solutions of nickel perchlorate were prepared from solutions of nickel chloride and silver perchlorate of known concentrations with the precipitated silver chloride removed by filtration through a glass frit. The nickel content of the nickel chloride solution was estimated using EDTA and murexide as indicator (13, 14). Perchloric acid solution was prepared from ethanolic solutions of known concentrations of hydrogen chloride and silver perchlorate. The solution of perchloric acid was tested for the presence of excess silver ion by addition of a little hydrogen chloride solution to some test solution and was standardized using B.D.H. standard sodium hydroxide solution.

Spectrophotometric measurements relating to equilibria were made with a DK1 spectrophotometer. Kinetic measurements were made using a model D-150 Durrum–Gibson stopped-flow spectrophotometer with thermostatic control of the solution maintained to ± 0.1 °C. The oscilloscope traces of transmission against time which were photographed were the overlay of the traces of four or five kinetic runs carried out with the same reactant solutions under given conditions. Near $\lambda 295$ mμ the extinction coefficient of the complex is in optimal excess over that of phenanthroline and light of this wavelength was used to monitor the course of the reaction.

The majority of kinetic runs was made at a concentration of nickel(II) of 2.0×10^{-3} M and a concentration of phenanthroline of 2.0×10^{-5} M but some measurements were made over the ranges of 1.0×10^{-3} to 8.0×10^{-3} M in nickel(II) and 2.0×10^{-5} to 5.0×10^{-5} M in phenanthroline to check the order of the reaction. To avoid possible complications associated with the solvolysis of nickel(II) ions, a trace of perchloric acid was added to all solutions to a concentration 4×10^{-7} M. A further four-fold increase in acidity yielded no significant change in rate. The spectrophotometric properties of the slightly acidified solution of phenanthroline were identical with those of solutions of the free base, implying that at the concentration of acid used in the kinetic runs the phenanthroline is substantially all in the basic form. At higher acidities there is an increase in optical density of the solutions at wavelengths less than $\lambda 360$ mμ, with a nearly five-fold increase in absorbance occurring, to reach a plateau where presumably monoprotonated phenanthrolinium ion is the dominant species. Some kinetic runs were made with solutions containing tetrabutyl ammonium perchlorate or sodium perchlorate but in the majority of runs no electrolyte beyond nickel perchlorate and the trace of perchloric acid were added and the values of the kinetic parameters reported below are based on measurements on solutions in which there was no electrolyte additional to nickel perchlorate and the trace of perchloric acid. That reaction was substantially complete is attested by the independence of the change in optical density over the course of a run on nickel(II) concentration when it was varied four-fold at constant phenanthroline concentration. Measurements at 25 °C using as solvent the center cut of absolute ethanol which had been distilled through a Widmer column yielded results which were not significantly different from those obtained using ethanol subjected to treatment with magnesium and iodine prior to distillation. However, the addition of 0.6 wt. % of water was found to increase the rate by a factor of almost two with the implied rate constant greater than those applying to purely ethanolic or purely aqueous solvents.

In interpreting our data we have provisionally assumed that the rate controlling step in the formation of the complex is the formation of a monodentate intermediate. If an interchange mechanism is dominant and the concentration of encounter pairs is small relative to that of the reactants, the relation [2] should apply where NiL^{2+} represents NiS_4L^{2+}.

$$[2] \quad \frac{d}{dt}[NiL^{2+}] = kK_0[Ni^{2+}][L] = k_f[Ni^{2+}][L]$$

As the nickel(II) was present in substantial excess over phenanthroline the reaction should be pseudo first order, and as the phenanthroline exists almost entirely as the free

base and the change in absorbance (A) of the solution is proportional to the concentration of the complex (NiL) formed, the slope of the plot of log $(A - A_\infty)$ against time is identifiable with $-k_f[Ni]_0/2.303$ where $[Ni]_0$ represents the initial concentration of nickel(II) which remains essentially at this value throughout the course of the run.

Results and Discussion

Values for the rate constants k_f with a summary of the conditions to which they apply are given in Table 1. Each value for k_f is the mean of several estimates, and each estimate is derived from a record of transmission against time which was the overlay of the records of four or five runs. Included with the value for k_f is the standard error associated with the estimates (three to five in number unless otherwise indicated). Under the heading I are values obtained from the relation $I = \frac{1}{2}\sum c_i z_i^2$ where c_i is the initial concentration of the ions assuming that the electrolytes are completely dissociated and z_i is the ionic charge number. In view of the possibility of significant ion association these values may not accurately summarize the ionic environmental conditions existing in solutions.

It is apparent that the influence of tetrabutyl ammonium perchlorate on rate is barely significant but that sodium perchlorate has a significant effect. If ion pairing between nickel(II) ion and perchlorate ion is occurring to a significant degree, the kinetic activity of the ion pairs must be close to that of free nickel(II) ion. The depressive effect of sodium ion was unexpected but is possibly associated with the formation of associates between sodium ion and phenanthroline. The near independence of rate constant on concentration of reactants implies that the concentration of encounter pairs (NiS_6.Phen) is low relative to the concentration of free phenanthroline. Otherwise a fall-off in rate constant with increase in the concentration of nickel(II) would be expected. A plot of $\log k_f/T$ *vs.* $1/T$ based on data applying to $[Ni(II)] = 2 \times 10^{-3}$ M and $[Phen]_0 = 2 \times 10^{-5}$ M is presented in Fig. 1. The values of the kinetic parameters implied by this plot are $\Delta H^{\ddagger} = 15.9 \pm 1.0$ kcal mol^{-1} $\Delta S^{\ddagger} = 15.4 \pm 3.2$ cal deg^{-1} mol^{-1}.

If, as we are provisionally assuming, the formation of a monodentate complex is rate controlling and if an interchange mechanism is dominant and the concentration of encounter pairs is not marked then $k_f = kK_0$. The value for the first order rate constant for ethanol exchange on nickel(II) at 25 °C has been reported as 6.6×10^4 sec^{-1} (10) and on the basis of an interchange model $k = k_f/K_0$ should relate closely to this value. The value for K_0 implied by the Fuoss relation (7) for non-interacting encounter pairs is dependent only on the value of a, the distance between centers of the members of an encounter pair. We assume that the value applicable to this reaction in ethanol is somewhat larger than the value 5 Å which has been assumed for reaction in water and 6 Å which has been assumed for reaction in methanolic solutions (2). For a value

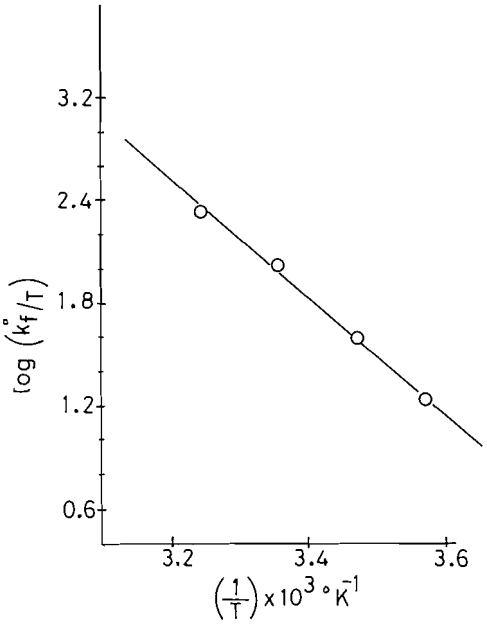

FIG. 1. Modified Arrhenius plot for the reaction of nickel(II) with 1,10-phenanthroline in ethanol.

of $a = 7$ Å, K_0 (Fuoss) is 0.87 M^{-1}, for $a = 9$ Å it is 1.84 M^{-1}. The corresponding values of k are then 3.4×10^4 s^{-1} and 1.6×10^4 s^{-1} which may be compared with the value 6.6×10^4 s^{-1} for the first order rate constant (k_{ex}) for ethanol exchange on nickel(II). In view of the possibility of some attractive interaction between the nickel(II) ion and phenanthroline the above estimates of K_0, which are based on an application of the Fuoss relation which assumes no interaction, may be somewhat low and the values for k correspondingly high. Taken in isolation our data for 25 °C suggest the applicability of the dissociative interchange mechanism. The value of $\Delta H^{\ddagger}$ of 15.9 kcal mol^{-1} for the overall reaction does differ significantly from the value for $\Delta H^{\ddagger}$ of 10.8 kcal mol^{-1} which has been reported for ethanol exchange on nickel (10) and it is improbable that the difference of 5 kcal mol^{-1} would be attributed to ΔH^0 for the formation of the encounter complex. However, in view of the range of values for $\Delta H^{\ddagger}$ for solvent exchange which have been reported for other processes (*e.g.* for the exchange of dimethyl sulfoxide on nickel(II) values ranging from 6.2 to 13.1 kcal mol^{-1} have been reported (9, 15)) we suggest that a mechanism which is essentially dissociative interchange is an acceptable interpretation for the reaction between nickel(II) and phenanthroline in ethanol on the basis of presently available evidence.

Bennetto and Caldin (5) consider that mechanisms such as I_d are too simplistic to describe the behavior of ligand substitution reactions in a variety of solvents and present a model in which the change in structural features in the solvent zones surrounding the reacting species as well as the breaking of the metal–solvent bond on the cation are specifically influential in controlling the magnitude of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the overall process. In this model a difference between the values of $\Delta H^{\ddagger}$ for solvent exchange and for foreign ligand entry may occur even when there is little direct interaction between the entering ligand and the cation up to the attainment of the transition state. They suggest that a ligand which loosens the bulk solvent structure will lead to values of $\Delta H^{\ddagger}$ (and $\Delta S^{\ddagger}$) which are higher than those for solvent exchange. This in turn implies a dependence of kinetic character on ligand type which in fact is not very marked for the reactions of nickel(II) in water and methanol. For reactions in water they suggest that the structural "stiffness" of water confers on the liquid an ability to preserve its structure during the attainment of the transition state, that little net structural work is done for a variety of ligands and consequently there is little ligand specificity and $\Delta H^{\ddagger}$ would be about the same for solvent exchange and foreign ligand entry. The degree to which there is ligand specificity in the various anation reactions of nickel(II) in ethanol and how such specificity, if any, relates to solvent structure must await the results of further investigation.

Isotopic Studies of the Metal–Ligand Bond. Part I. Further Spectroscopic Studies of Copper Ethylenediamine Complexes: Copper–Nitrogen Vibrations

G. W. RAYNER CANHAM AND A. B. P. LEVER
Department of Chemistry, York University, Toronto, Ontario

Received June 6, 1972

Confirmation of the far infrared (500–200 K) spectroscopic assignments of the metal–ligand vibrations in the complexes $Cu(N-N)_2X_2$ and $Cu(N-N)X_2$((N–N) = ethylenediamine, symmetric and asymmetric *N,N*-dimethyl- and *N,N*-diethylethylenediamine, X = Cl, Br, NO_3) has been obtained from copper isotopic substitution measurements. Extension of the series Cu(ethylenediamine)$_2X_2$ has provided some exceptions to the straight line correlation between $[\nu(Cu—N)]^2$ and mean electronic d–d band energy. These are discussed.

A l'aide de mesures de la substitution d'isotopes du cuivre, on a confirmé les attributions spectroscopiques infrarouges lointaines (500–200 K) des vibrations métal–groupe coordiné dans les complexes $Cu(N-N)_2X_2$ et $Cu(N-N)X_2$((N–N) = éthylènediamine, *N,N*-diméthyléthylènediamine et *N,N*-diéthyléthylènediamine symétriques et asymétriques, X = Cl, Br, NO_3). L'extension de la série Cu(éthylènediamine)$_2X_2$ a fourni quelques exceptions à la corrélation en ligne droite entre $[\nu(Cu-N)]^2$ et l'énergie de bande d–d électronique moyenne. Celles-ci sont discutées. [Traduit par le journal]

Introduction

Previous studies (1, 2) have indicated a relationship between values of a far infrared vibrational band and the d–d band envelope maximum for series of copper(II) ethylenediamine complexes. This infrared absorption was assigned as predominantly a metal–nitrogen stretching mode for the copper (1, 2) and related cobalt (1, 3) and nickel (1, 3) complexes. Metal isotopic substitution is now well established as a means of identifying asymmetric metal–ligand vibrations (4), thus the principle was applied to the conclusive identification of most of those vibrations which were predominantly copper–nitrogen in character.

It had been observed that the complex $Cu(en)_2(NO_3)_2$ was an exception to the straight line correlation (1). To elucidate this observation, spectroscopic studies of the series $Cu(en)_2X_2$ were extended to the anions NO_2^-, N_3^-, NCS^-, $SeCN^-$, SO_4^{2-}, HgI_4^{2-}, and $Hg(SCN)_4^{2-}$.

Experimental

^{65}CuO and ^{63}CuO were obtained from Oak Ridge National Laboratory, Tennessee. *N,N'*-Diperdeutero-methylethylenediamine was prepared by the method of Johnson and Bailey (5); however, the initial synthesis of the tosylate was performed by the Schotten–Baumann procedure. N-Deuteration was undertaken as described previously (1). Mass spectrometry was used to check the isotopic purity of the deuterated ligand.

TABLE 1. Copper analyses and bibliography

Complex	% Cu Found	% Cu Calcd.	Reference
$Cu(en)_2[Hg(SCN)_4]$	10.3	10.3	36
$Cu(en)_2(HgI_4)$	7.1	7.1	37
$Cu(en)_2SO_4$	22.6	22.7	—
$Cu(en)_2(N_3)_2$	21.7	21.5	38
$Cu(en)_2(NO_2)_2$	23.0	23.0	39
$Cu(en)_2(SeCN)_2$	15.85	16.1	39
$[Cu(en)_2(NCS)]ClO_4$	18.4	18.6	24

Anion exchange methods were employed for the isolation of the complexes $Cu(en)_2X_2$ with X as N_3^-, NO_2^-, $SeCN^-$, HgI_4^{2-}, and $Hg(SCN)_4^{2-}$. $Cu(en)_2(NCS)(ClO_4)$ was prepared from the reaction of stoichiometric quantities of $Cu(en)_2(SCN)_2$ and $Cu(en)_2(ClO_4)_2$ in aqueous methanol. All the complexes have been reported previously. Copper analyses (to ensure purity) and references are presented in Table 1.

Far infrared spectra were obtained with a Beckman IR-12 instrument using high density polythene plates with petroleum jelly as a mulling agent. Slow, repeated scanning enabled isotopic shift measurements, accurate to within ±0.3 K. A Cary 14 spectrophotometer was utilized for transmittance electronic spectroscopic studies.

Results and Discussion

In a recent review, Durig and Wertz (6) reported a profusion of values of ν(M—N) for ethylenediamine complexes. They concluded that the vibration lay between 400 and 600 K.

*Natural copper contains 69% ^{63}Cu and 31% ^{65}Cu; this will lead to some broadening in the spectra and to *underestimation* of the isotopic shift. Some isotopically pure ^{63}Cu data are cited in Table 3.
†Bands in parentheses are too broad or too weak for accurate determination of isotopic shift.

Subsequent values of ν(M—N) obtained range from 360 K (M = Lanthanide) (7) through 400, 320 K (M = Cu) (1, 2) to 518, 470 K (M = Pt) (8) and 570, 550 K (M = Pt, Pd) (9–11). A recent normal coordinate analysis suggested that four bands above 200 K in ethylenediamine complexes have metal–ligand character (12). In the case of $Cu(en)_2(SCN)_2$, the absorptions at 472 and 412 K were assigned as ν(Cu—N) and those at 330 and 230 K as (N—Cu—N) deformations (12).

Assignments of the low energy ligand bands themselves are not definitive (13–15). Isotopic substitutions of $enH_2.2X$ lead to the assignments; C—N torsion at 331 K and C—C—N deformation at 244 K (15). On complexation, the former appears to become only weakly active (1, 12), and the latter adopts the character of a ring mode (12). The greatest uncertainty concerned the CH_3 torsional mode in the *N*-alkylated ethylenediamines. This particular vibration has been assigned to bands between 280 and 180 K in other systems (16–19). On a deductive basis the band at about 300 K in the *N*-alkyl ethylenediamine hydrochlorides was ascribed to the methyl vibration (14); however the same authors did not assign any absorption to this vibration in the corresponding metal complexes (9). Subsequently the vibration was reported to be between 280 and 320 K (13). Considerable shifting or inactivation of this mode upon coordination has been reported in the case of *N*-methyl imidazole (20).

Table 2 shows the results of ^{65}Cu isotopic substitution for the series of bis(ethylenediamine) copper(II) chlorides and nitrates, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

their alkylated congeners. In addition some deuteration studies are included. Values in parentheses indicate bandwidths too great for observation of shifts. In each case two or more bands were shifted by measurable amounts. (NOTE: Because of the inherent limitations of the metal isotopic shift method, we do not exclude the possibility of metal–ligand contributions to other vibrations.) According to the Teller Redlich direct product rule (21), shifts of up to 3 K are expected for the metal–ligand vibrations; values of up to 2.5 K are observed, indicative of a substantial contribution of metal–ligand character.

For the ethylenediamine complexes, the two bands previously assigned as ν(Cu—N) (1) were found to be isotopically sensitive, thereby confirming the assignments. The alkyl substituted complexes in each case have bands at ca. 300 K and ca. 380 K which shift, and correspond to the isotopically sensitive bands at ~330 and 410 K in the non-alkylated complexes. Previously the 300 K band was assigned to a CH_3 torsional vibration. The complexes Cu(asym-Me_2en)$_2$-$(NO_3)_2$ and Cu(sym-Et_2en)$_2(NO_3)_2$ also have metal sensitive bands at 439 and 433 K respectively, which appear to correspond to the ν(Cu—N)(*b*) of Omura *et al.* (12). Apparently in these complexes there is a ν(Cu—N) contribution (small in the other complexes studied) to this basically ring breathing mode (9). Earlier (1) it had been supposed that the sensitivity of certain of the ring vibrations towards deuteration implied possible coupling between these modes and the metal–nitrogen vibrations. It now appears that with the exception of the two compounds indicated above, such coupling does not occur to any appreciable extent. Presumably there is coupling between the ring modes and some N—H vibrations. Discussion of assignments of the few other bands where shifts are observed would be purely speculative at this time.

The above assignments cast doubt on the position of the CH_3 torsional mode. To clarify the matter, perdeuteromethyl and deuteronitrogen sym-dimethylethylenediamines were prepared. The 298 K band of the ligand hydrochloride shifts 15 K upon N-deuteration and 25 K upon methyl deuteration. The methyl torsional mode is expected to shift considerably upon deuteration (19), thus the 300 K band in the alkylated ethylenediamines is more likely to be a skeletal mode. The bands in the 2:1 *complexes* could generally be correlated with their non-deuterated congeners on the basis of band shapes and relative intensities. All but one of the medium to strong bands in the CD_3 substituted complexes showed shifts in energy of 10–20 K, confirmatory evidence of the vibrational coupling in these systems. The exception, the band at 300 K, appeared unshifted. That this band does not shift upon methyl or nitrogen (1) deuteration and yet is the most strongly affected by metal isotopic substitution (1, 3) would indicate that it is a relatively "pure" Cu—N vibration. The CH_3 torsional mode itself would appear to be below 200 K.

Isotopic substitution data for the 1:1 complexes are shown in Table 3. Isotopically pure ^{63}Cu complexes were prepared in two cases to maximize isotopic shift values obtained. Although assignments are more tentative, in that both ν(Cu—Cl) and ν(Cu—N) vibrations appear in the same region and are both sensitive to copper isotopic substitution, meaningful conclusions may be drawn. The lower energy metal–nitrogen and the metal–chlorine stretching vibration both lie close to 300 cm^{-1}; they are generally distinguished by the following criteria: (*i*) in the corresponding bromo complex the ν(Cu—N) vibration should lie at approximately the same energy whilst the ν(Cu—Cl) vibration will, of course, disappear, and be replaced by a lower energy ν(Cu—Br) vibration, with ν(Cu—Br)/ν(Cu—Cl) ≃ 0.77 (22), (*ii*) upon methyl or nitrogen deuteration the ν(Cu—N) vibration should be more affected than the ν(Cu—Cl) vibration. Coupling between the Cu—Cl and Cu—N vibrations undoubtedly occurs such that the distinction drawn above may be somewhat arbitrary. Considering the limiting *cis*-CuN_2X_2 structure, two ν(Cu—X) are to be expected (23); however, as previously reported (2), only one is conclusively identified in this series.

Previous assignments of the copper–nitrogen bands (2) appear, in general, to be correct though with the reclassification of the CH_3 torsion as predominantly a copper–nitrogen mode.

Having confirmed the assignments of the metal–ligand vibrations, a further study of the

†δ(SCN).

relationship between the electronic and vibrational bands (1, 2) was undertaken.

The series of $Cu(en)_2X_2$ complexes was extended to include the terminal anions NCS^-, N_3^-, and NO_2^- and the bridging SO_4^{2-}, HgI_4^{2-}, $Hg(SCN)_4^{2-}$, and SCN^- (this last complex, $[Cu(en)_2NCS]ClO_4$ has been shown to have N-bridging thiocyanate and ionic perchlorate groups (24)). Spectroscopic data are shown in Table 4. A plot of ν_{d-d} against $[\nu(Cu—N)]^2$ (higher energy band, near 400 K) gave a poorer correlation than previously reported (1) (coefficient of variation, 2.85%); a plot of ν_{d-d} against $[\nu(Cu—N)]^2$ (lower energy band, near 330 K) yielded comparatively better agreement (coefficient of variation, 2.16%). There appears to be a similar correlation between the ν_{d-d} band and the lower energy ν(Cu—N) vibration, near 300 K, in the sym-dimethylethylenediamine complexes but no such correlation is observed with the other substituted ethylenediamines (1). In these circumstances the lower energy correlation will not be pursued.

There seems little doubt that the correlation of $[\nu(Cu—N)]^2$ (higher energy) with ν_{d-d} is valid. Indeed the correlation has now been extended to the copper tetraammine complexes (25) and to the charge transfer spectra of the ethylenediamine complexes (26). However, as indicated above, there are a number of apparent excep-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tions to this correlation. These may arise through the difficulty in accurately assessing the in-plane crystal field transition energy.

An approximation in the previous work (1) was to take the maximum of the d–d band envelope as a measure of the in-plane bond strength (*i.e.*, the transition $x^2 - y^2 \leftarrow xy$) (23). Single crystal studies of the $Cu(en)_2X_2$ series (27) show one transition to be dominant in the spectrum, namely, $x^2 - y^2 \leftarrow xz,yz$. The $x^2 - y^2 \leftarrow xy$ transition lies close to, or under, this band and cannot generally be accurately located. Variations in intensity and position of each component will diminish the accuracy of the approximation used, and may well explain the poorer correlation found for this extensive series.

The sulfate complex is intriguing in that the position of the d–d band maximum is considerably lower than that expected for such a conventionally weak ligand. By previous arguments (1) such a ligand should lead to a strong in-plane field. The crystal structures of $Cu(NH_3)_4SO_4$ (28) and Cu(1,3-diaminopropane)$_2SO_4$ (29) both show considerable inequalities in the Cu—O bond distances. The low energy of the band might thus be explained by loss of center of symmetry of the CuN_4O_2 chromophore, causing a bathochromic shift similar to, but of course smaller than, observed upon addition of 1 mol of ammonia to $Cu(en)_2X_2$ complexes (30). This explanation, unfortunately, does not hold for the nitrate complex as the copper–oxygen bond lengths are identical within experimental error (31).

The azide complex is interesting in that two equal intensity components of $\nu(N{\equiv}N)$ are observed at 2030 and 2007 K. Before dismissing this as a solid state effect, it is worth noting that a similar phenomenon has been observed in *trans* bis-azide complexes of platinum, both in the solid state and in solution (32). A splitting of this order has been found for non-centrosymmetric molecules (33).

The assignment of $\delta(SCN)$ in $Cu(en)_2(SCN)_2$ to the band at 484 K rather than that at 475 K (34) is preferable by comparison with the isomorphous selenocyanate complex (35).

Conclusion

The vibrations of the complexes $Cu(en)_2X_2$ and $Cu(en)X_2$ and of the alkylated ethylenediamine congeners at *ca.* 300–300 K and *ca.* 380–420 K are metal isotope sensitive. These bands are assigned as predominantly copper–nitrogen in character.

In those cases where the relationships between ν_{d-d} and vibrational bands do not appear to be valid, this may arise because of the difficulty in locating the $x^2 - y^2 \leftarrow xy$ transition.

We thank Miss M. F. Rushton for valuable preparative assistance and the National Research Council of Canada for financial support.

Identification and Thermal Stability of Copper(I) Sulfate

KIM VO VAN AND FATHI HABASHI

Department of Mining and Metallurgy, Laval University, Quebec 10, Quebec

Received May 10, 1972

Anhydrous Cu_2SO_4 was prepared and its X-ray diffraction pattern was established. Differential thermal analysis, thermogravimetric analysis, and X-ray diffraction methods were used to study the effect of heating in different atmospheres. The formation of Cu_2SO_4 as an intermediate in chemical processes has been discussed.

Le sulfate cuivreux anhydre a été préparé et son spectre de diffraction de rayons-X établi. L'analyse thermique différentielle, l'analyse thermogravimétrique et les méthodes de diffraction de rayons-X ont été utilisées pour étudier l'effet de la chaleur sous des atmosphères différentes. La formation de Cu_2SO_4 comme intermédiaire dans des processus chimiques a été discutée. [Traduit par le journal]

Introduction

While extensive literature exists for $CuSO_4$, very little is known about Cu_2SO_4 (1). Druce and Fowles (2) reported that Cu_2SO_4 was formed during the dissolution of metallic Cu in hot concentrated H_2SO_4 (2). Schenck (3) concluded from vapor pressure measurements on the system Cu_2S–$CuSO_4$ at 300–500 °C the possible formation of Cu_2SO_4 according to the equation

$$Cu_2S + 4CuSO_4 \rightarrow 3Cu_2SO_4 + 2SO_2$$

Cu_2SO_4 was identified indirectly by quenching the samples in water and filtering; the appearance of metallic copper was indication of the presence of Cu_2SO_4 since it disproportionates in water according to:

$$Cu_2SO_4 \xrightarrow{H_2O} Cu + CuSO_4$$

Recent work (4) showed that Cu_2SO_4 is formed during the reduction of $CuSO_4$ by H_2.

$$2CuSO_4 + 2H_2 \rightarrow Cu_2SO_4 + SO_2 + 2H_2O$$

Cuprous ion can be readily formed in aqueous sulfate solutions (1). For example, metallic copper dissolves in $CuSO_4$ solution in absence of air to form Cu^+ ions. $CuSO_4$ solutions can be reduced by SO_2 or CO under pressure at about 90 °C to generate Cu^+. However, it is not possible to crystallize Cu_2SO_4 from aqueous solutions. The present investigation was undertaken to acquire more information on anhydrous Cu_2SO_4.

Experimental

Preparation and Identification of Cu_2SO_4

The starting material for preparing Cu_2SO_4 is Cu_2O. Reagent grade Cu_2O was not suitable for this purpose because it contained CuO. Therefore, Cu_2O was freshly prepared from Fehling's solution (5). The other method described by Brauer (6) and involving the reduction of cupric acetate by hydrazine was not convenient because Cu_2O obtained was extremely fine powder and was difficult to wash. The purity of Cu_2O was ascertained by X-ray diffraction and thermogravimetric analysis.

Cu_2SO_4 was then prepared according to Recoura's method (7) by the reaction of Cu_2O with dimethyl sulfate:

$$Cu_2O + (CH_3)_2SO_4 \rightarrow Cu_2SO_4 + (CH_3)_2O$$

Cu_2SO_4 so prepared was washed with ether and dried at 60 °C in a stream of argon for 24 h; it was pale beige in color. According to Recoura, this material disproportionates in water to give metallic copper and pure cupric sulfate solution in equimolecular amounts, thus indicating that copper existed in the cuprous form. Because of its sensitivity to moisture it was stored in a desiccator. Reaction of Cu with hot concentrated H_2SO_4 did not yield any Cu_2SO_4 as claimed by Druce and Fowles (2).

Since the X-ray diffraction pattern of Cu_2SO_4 is not described in the literature, we present it in Table 1 as obtained by powder diffractometry counter method from the sample we prepared. Two hours were needed for obtaining a diffractogram. The diffractogram showed the presence of $CuSO_4$, the amount of which was estimated from thermogravimetric analysis in argon to be 25% as described later. The presence of $CuSO_4$ in the sample seems to be inherent to the method of preparation and not due to deterioration by exposure to the air, because a sample exposed to the air for 10 h contained the same amount of $CuSO_4$ as a freshly prepared sample and no metallic copper.

Studies on Cu_2SO_4

Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were used to study the effect of heating Cu_2SO_4 in different atmospheres. The DTA instrument was a Stanton model Standata 6-25 with stainless steel sample holder; weight of sample was about 200 mg. The TGA instrument was a Fisher Series 100 TGA System; weight of sample was about 20 mg. In both instruments a continuous gas flow was maintained, and a heating rate of 10 °C/min was used.

38.88	1.23	2

Samples of $CuSO_4.5H_2O$ were heated in both DTA and TGA apparatus and the thermograms so obtained were compared. Since the sample in DTA apparatus is in intimate contact with the thermocouple, the temperatures at which dehydration and decomposition take place were considered precise enough for calibrating the TGA.

Reaction products were identified by interrupting the heating of samples under investigation at a certain temperature and examining the residue by X-ray powder diffractometry. Sulfur dioxide liberated during the tests was detected by absorption in KI solution acidified by 1% HCl and containing starch as indicator. The solution was continuously titrated during a test by KIO_3 solution to maintain a constant color (8).

Results and Discussion

Heating in Argon

The TGA thermogram presented in Fig. 1 shows that the first decomposition takes place at about 300 °C followed by two other overlapping steps at about 560 and 650 °C. DTA curves shown in Fig. 2, however, revealed peaks at 400, 610, 720, and 805 °C. SO_2 produced in this case was first detected at 350 °C. Heating was interrupted at different temperatures (marked *a* to *e* in Fig. 2) in the DTA instrument and the samples obtained were examined by X-ray diffraction. The products identified by this method are shown in Table 2. It can be concluded from this information that the drifting of the base line in the endothermic region in DTA curve starting at about 220 °C may be attributed to the partial decomposition of Cu_2SO_4 according to

$$Cu_2SO_4 \rightarrow Cu + CuSO_4$$

The first stage of decomposition then follows the following reaction

$$3Cu_2SO_4 \rightarrow 2CuSO_4 + 2Cu_2O + SO_2$$

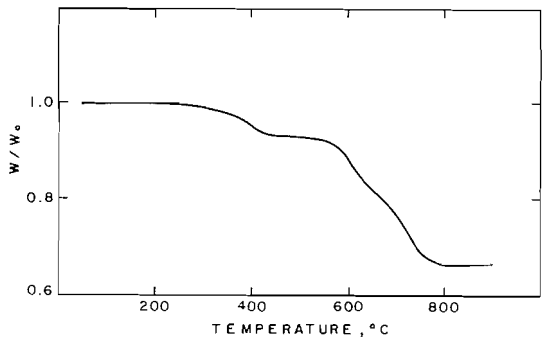

FIG. 1. TGA curve showing the decomposition of Cu_2SO_4 in argon. Heating rate 10 °C/min, gas flow 80 ml/min.

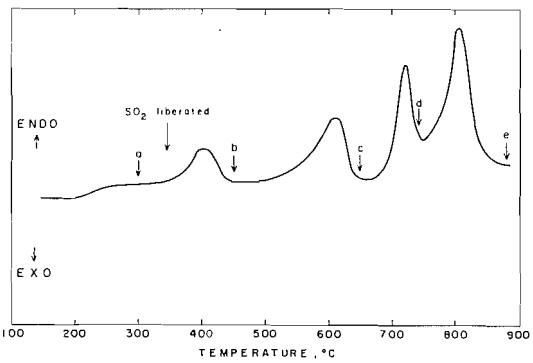

FIG. 2. DTA curve showing the decomposition of Cu_2SO_4 in argon. Heating rate 10 °C/min, gas flow 80 ml/min. Letters *a* to *e* indicate the temperatures at which heating was interrupted and samples obtained were examined by X-ray diffraction (see Table 2).

TABLE 2. Identification of products of decomposition of Cu_2SO_4 in argon by X-ray diffraction

Point on DTA curve	Temperature of interruption in DTA (°C)	Product		
		Major	Minor	Trace
a	300	Cu_2SO_4	$CuSO_4$	Cu
b	450	$CuSO_4$, Cu_2O	—	Cu
c	650	$CuO.CuSO_4$, Cu_2O	—	Cu
d	740	$CuO.CuSO_4$, CuO	—	Cu
e	880	CuO	—	Cu

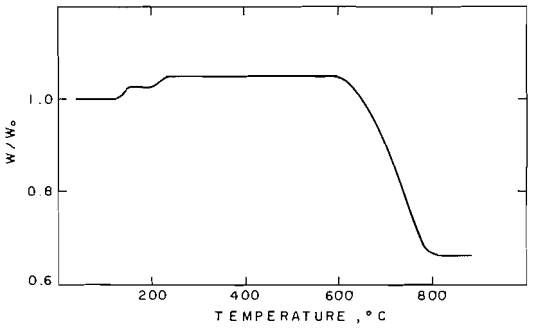

FIG. 3. TGA curves showing the behavior of Cu_2SO_4 when heated in air. Heating rate 10 °C/min, gas flow 100 ml/min. Letters *a* to *d* indicate the temperatures at which heating was interrupted and samples obtained were examined by X-ray diffraction (see Table 3).

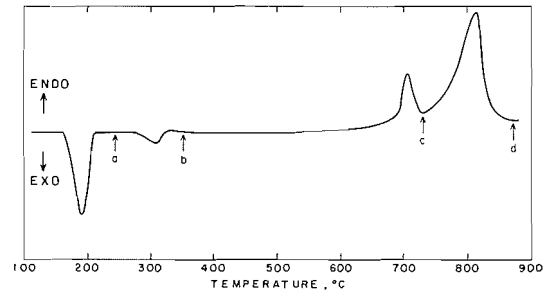

FIG. 4. DTA curves showing the behavior of Cu_2SO_4 when heated in air. Heating rate 10 °C/min, gas flow 100 ml/min.

The weight change according to this equation is 9.6% while data in Fig. 1 indicate 7.2%. The discrepancy between these two values is due to the presence of $CuSO_4$ in the sample which remains undecomposed in the low temperature range. The amount of $CuSO_4$ in the sample can be calculated as 25% of its weight.

TABLE 3. Identification of products of decomposition of Cu_2SO_4 in air by X-ray diffraction

Point on DTA curve	Temperature of interruption in DTA (°C)	Product		
		Major	Minor	Trace
a	250	$CuSO_4$, Cu_2O	—	—
b	350	$CuSO_4$, CuO	—	—
c	740	$CuO.CuSO_4$, CuO	—	—
d	880	CuO	—	—

Data in Table 2 suggest that the above reactions are followed by

$$4CuSO_4 + Cu_2O \rightarrow 3CuO.CuSO_4 + SO_2$$

$$CuO.CuSO_4 + Cu_2O \rightarrow 4CuO + SO_2$$

$$CuO.CuSO_4 \rightarrow 2CuO + SO_2 + \tfrac{1}{2}O_2$$

which correspond to the last three DTA peaks in Fig. 2. The liberation of SO_2 in each step was confirmed.

Heating in Air

Figure 3 shows the TGA curves for the behavior of Cu_2SO_4 when heated in air. It can be seen that there are two steps indicating a weight increase at 120 and 200 °C, and a loss in weight at 600 °C. Figure 4 shows the DTA curves for the same process. It can be seen that the first two reactions are exothermic while the last two are endothermic. X-ray diffraction analysis after each step (Table 3) and the percentage change in weight conform to the following reaction scheme

$$2Cu_2SO_4 + \tfrac{1}{2}O_2 \rightarrow 2CuSO_4 + Cu_2O$$

$$Cu_2O + \tfrac{1}{2}O_2 \rightarrow 2CuO$$

$$2CuSO_4 \rightarrow CuO.CuSO_4 + SO_2 + \tfrac{1}{2}O_2$$

$$CuO.CuSO_4 \rightarrow 2CuO + SO_2 + \tfrac{1}{2}O_2$$

These reactions can therefore be assigned to the DTA peaks in Fig. 4.

Heating in H_2

Figure 5 shows that the change in weight during reduction by H_2 is gradual in the temperature range 120 to 340 °C. X-ray diffraction analysis of residues obtained when heating was interrupted at 250 °C showed the presence of $CuSO_4$ and Cu. It seems that reduction takes place according to the equation

$$Cu_2SO_4 + 2H_2 \rightarrow 2Cu + SO_2 + 2H_2O$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

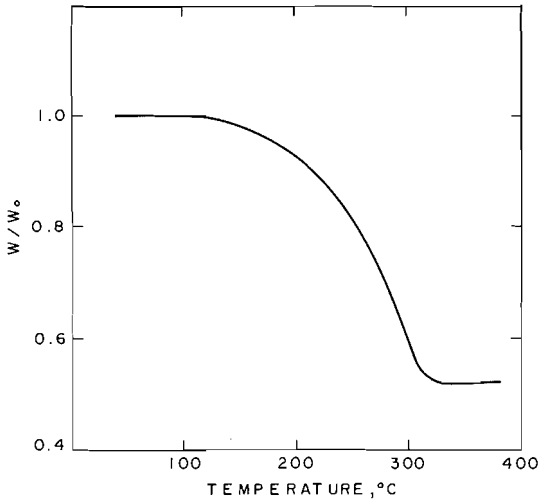

FIG. 5. TGA curves showing the reduction of Cu_2SO_4 by H_2. Heating rate 10 °C/min, gas flow 360 ml/min.

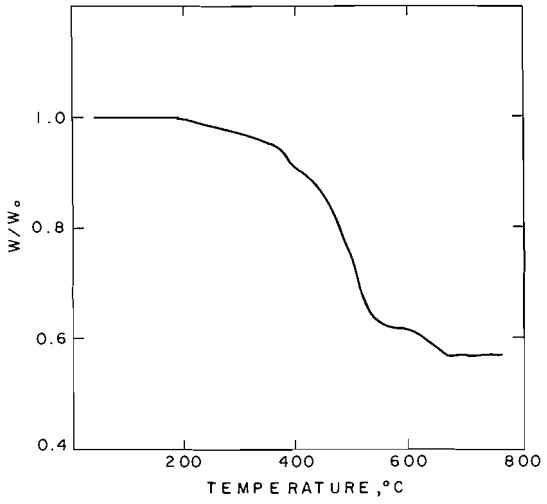

FIG. 6. TGA curves showing the reduction of Cu_2SO_4 by CO. Heating rate 10 °C/min, gas flow 100 ml/min.

and the H_2O vapor liberated reacts with the remaining Cu_2SO_4 to form Cu and $CuSO_4$

$$Cu_2SO_4 \xrightarrow{H_2O} CuSO_4 + Cu$$

$CuSO_4$ is then reduced to Cu_2SO_4

$$2CuSO_4 + 2H_2 \rightarrow Cu_2SO_4 + SO_2 + 2H_2O$$

These three reactions proceed simultaneously until all Cu_2SO_4 is reduced to Cu. DTA curves did not yield any significant data because the heat liberated or absorbed is the sum of the above reactions.

Heating in CO

Figure 6 shows the TGA curve for reduction by CO. In the temperature range 200 to 400 °C the behavior is the same as in the case when heating in argon. At 400 °C, X-ray diffraction revealed the presence of $CuSO_4$ and Cu_2O, *i.e.*, the following reaction takes place

$$3Cu_2SO_4 \rightarrow 2CuSO_4 + 2Cu_2O + SO_2$$

Above 400 °C, $CuSO_4$ is reduced in two steps, namely to Cu_2O then to Cu as follows (4)

$$2CuSO_4 + 3CO \rightarrow Cu_2O + 2SO_2 + 3CO_2$$
$$3Cu_2O + 3CO \rightarrow 6Cu + 3CO_2$$

Conclusions

Anhydrous Cu_2SO_4 can be readily prepared in about 75% purity by the action of dimethyl sulfate on Cu_2O; the remaining 25% is $CuSO_4$. The material is fairly stable in dry air at room temperature but decomposes rapidly in presence of moisture or on heating. In air or in H_2, decomposition starts at 120 °C while in argon or in CO decomposition takes place at 200 °C. It is doubtful that Cu_2SO_4 can exist above 300 °C under any circumstances.

A Conformational Study of Lysergic Acid and *iso*-Lysergic Acid Dialkylamides by Proton Magnetic Resonance Spectroscopy

K. BAILEY

Research Laboratories, Health Protection Branch, Department of National Health and Welfare, Ottawa, Canada K1A 0L2

AND

A. A. GREY

Ontario Research Foundation, Sheridan Park, Ontario

Received May 19, 1972

The 220 MHz p.m.r. spectra of the dimethylamides of D-lysergic acid (**3**) and D-*iso*-lysergic acid (**4**) are reported. Extensive use of double resonance experiments and the presence of four long-range coupling constants provide an unambiguous assignment for the conformation of **3** in $CDCl_3$. Its D ring is shown to exist in a half-chair form in which the 8-β amide function is pseudo-equatorial. Its epimer essentially exists in the other half-chair form with a pseudo-equatorial 8-α amide function. Data from the p.m.r. spectra of a series of *N*,*N*-dialkylamides of these acids are also presented.

The spectrum of protonated **3** at 23 °C shows two forms of the 6-NCH_3 and 8-$CON(CH_3)_2$ groups but only one for the epimer **4**.

Les spectres de r.m.n. à 220 MHz des diméthylamides de l'acide D-lysergique (**3**) et de l'acide D-*iso*-lysergique (**4**) sont rapportés. L'usage extensif de la double résonance et la présence de quatre constantes de couplage à longue distance ont permis d'attribuer sans ambiguité la conformation de **3** dans le $CDCl_3$. On a montré que le cycle D de ce dernier existe sous la forme demi-chaise dans laquelle la fonction amide-8β est pseudoéquatoriale. Son épimère existe essentiellement sous l'autre forme demi-chaise avec la fonction amide-8α pseudo-équatoriale. Les données des spectres de r.m.n. d'une série de *N*,*N*-dialkylamides de ces acides sont également présentés. Le spectre de **3** sous forme protonée à 23 °C montre deux formes pour les groupes NCH_3-6 et $CON(CH_3)_2$-8 alors que l'épimère **4** n'en donne qu'une. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3876 (1972)

Introduction

Interest in possible similarities in the mode of action of LSD, tryptamines, and the hallucinogenic phenylethylamines (1–5) prompted us to study the solution conformation of LSD and other amides (**3–12**) of lysergic and *iso*-lysergic acids (**1** and **2**) (6) by p.m.r. spectroscopy (7). Stoll *et al.* (8) have presented evidence that ring D in both acids is in a ψ-chair form, the carboxyl function being equatorial in lysergic acid and axial in the *iso*-acid.

Experimental

The p.m.r. spectra of **3** and **4** were obtained on a Varian HR-220 spectrometer (Canadian 220 MHz n.m.r. centre, Ontario Research Foundation, Sheridan Park, Ontario). Double resonance experiments were carried out under track-field sweep decoupling conditions with a Wavetek, Model 101, voltage-controlled generator calibrated to the sweep widths of the spectrometer recorder. Other spectra were obtained on Varian A 60-A and XL-100 spectrometers.

The synthesis employed (9) gives a mixture of the isomeric amides of both acids, column chromatography on alumina readily separating the faster-running lysergamide from the *iso*-lysergamide (10). The p.m.r. spectral assignments in Table 1 are based primarily on chemical shift values and are supported by the decoupling experiments described below.

*Measured at 220 MHz, with internal TMS, additional data in Table 1. J Values are first order, in Hz.

Results and Discussion

The assignment of signals other than those in Table 1 was not attempted with homologues higher than N,N-dimethyl, because the NCH_2-multiplets (doubled for every compound because of the partial double-bond character of the amide C—N link) extensively overlap multiplets derived from the basic ergoline system. The methyl resonances from compounds **3** and **4** provided the minimum interference and their spectra were determined at 220 MHz. The results are shown in Tables 2 and 3. Axial and equatorial positions are indicated parenthetically by a and e respectively and the designation α or β is made with respect to the proton at C-5 being termed β; see conformations **I**–**III**.

D-*Lysergic Acid Dimethylamide (3)*

The pertinent 220 MHz spectra are reproduced in Figs. 1 and 2. Double irradiation of the H_2 resonance at 6.86 p.p.m. (11) affected only the multiplet at 2.68 p.p.m. ($J = 1.6$ Hz). The magnitude of the coupling is typical of a *cisoid*-allylic coupling (12) and must involve H_2 and H_4 where the estimated dihedral angle $\theta_{2,4\alpha}$ between these hydrogens measures about 80°. The magnitude of geminal coupling constants adjacent to a π bond system is also known to be orientation dependent (12, 13). The observed −14.8 Hz splitting in $H_{4\alpha}$ at 2.68 p.p.m. therefore is also consistent with an estimated $\theta_{2,4\alpha} = 80°$ where the indole π-bond lobes are more or less aligned with $H_{4\alpha}$ and are expected to exert

a near-maximum effect on J_{gem}. The well defined geometry for $H_{4\beta}$ necessitates that its resonance be deshielded relative to $H_{4\alpha}$ by virtue of its almost planar orientation with the aromatic B ring while showing a very small (0.5 Hz) $J_{2,4\beta}$ allylic coupling. Indeed, $H_{4\beta}$ is 0.86 p.p.m. to low field of $H_{4\alpha}$ and displays only two observable couplings of 5.5 and −14.8 Hz, the latter being $J_{4\alpha,4\beta}$.

Models indicate that the methine hydrogen $H_{5\beta}$ is rigidly fixed by virtue of its bridgehead position at C-5 which is at the puckered end of the half-chair ring C. This unique arrangement places H_5 above the aromatic ring plane of rings A and B with C_5—H_5 bond more or less perpendicular to these as well as to the olefinic double bond in ring D: an ideal position for allylic coupling with H_9. Double resonance experiments on H_9 at 6.36 p.p.m. clearly reduce the heavily coupled multiplet at 3.40 p.p.m. to an eight-line pattern with splittings of 11.4, 5.5, and 3.8 Hz. The former two are those observed in $H_{4\alpha}$ and $H_{4\beta}$ respectively, allowing the assignment of H_5 at 3.40 p.p.m. In addition, $H_{5\beta}$ is uniquely situated at a bridgehead position which is attached to nitrogen which permits an assessment of its environment with respect to the nitrogen lone pair of electrons (14); methine hydrogens in structurally related fragments which are *gauche* to the nitrogen lone pair are deshielded by about 0.6–0.8 p.p.m. relative to those oriented *trans*-axially which are found at ~3.2 p.p.m. The observed chemical shift of $H_{5\beta}$ at 3.20 p.p.m. suggests it to be the latter with the N-lone pair directed in a *trans*-axial relationship with H_5. Such an arrangement can only be realized if ring D exists in that half-chair conformation in which C-5, -10, -9, and -8 are more or less in the same plane. Carbon-7 is above this plane on the same side as H_5; the heterocyclic nitrogen and its lone pair are directed below.

The remaining 3.8 Hz splitting associated with $H_{5\beta}$ can be related to the broad unresolved multiplet at 3.98 p.p.m. This resonance is transformed on double irradiation at 6.36 p.p.m. (H_9) into a symmetrical first-order eight-line multiplet of splittings J = 3.5, 10.5, and 5.0 Hz.

The larger couplings are also found in the mutually coupled (J_{gem} = −11.2 Hz) signals at 2.89 and 3.08 p.p.m. respectively. The analysis of the $H_{8\alpha}$, $H_{7\alpha}$, $H_{7\beta}$ subsystem indicates that $J_{7\beta,8\alpha}$(a–a) = 10.5, $J_{7\alpha,8\alpha}$(e–a) = 5.2, and $J_{7\alpha,7\beta}$ (*gem*) = (−)11.3 Hz. The common 3.8 Hz coupling between H_5 and H_8 is a homoallylic long-range interaction (13) which clearly portrays their relative orientations with each other and the olefinic double bond. For appreciable coupling, both dihedral angles involved for maximum σ–π overlap (15) must approach 90°. The dihedral angles $\theta_{5,9}$ and $\theta_{8,9}$ measured from models in the conformation depicted in Fig. 1 are 90 and 75° respectively. The latter is of such magnitude as to expect a small vicinal coupling between the sp^2–sp^3 bonded hydrogens on C-9 and -8. Its presence is responsible for the unresolved appearance of the unperturbed $H_{8\alpha}$ resonance at 3.98 p.p.m.

The only remaining unaccounted coupling is evident in $H_{7\alpha}$ at 3.08 p.p.m. This multiplet also loses a coupling of about 1 Hz on irradiating H_9 and is compatible with a long-range W coupling between H_9 and H_7. These are more or less in one plane because of the half-chair conformation imposed on ring D. A self-consistent analysis could not be obtained if the other ψ-chair form (compare conformation **II**) were present to any great extent.

The spectrum of **3** measured in C_6D_6 gave chemically shifted resonances (16) as summarized in Table 2, where $\Delta = \delta(CDCl_3) - \delta(C_6D_6)$. Consideration of the data for H_5, H_7, H_8, and 6-NCH_3 suggests that the rotameric conformation of the amide function is possibly as shown in conformation **I**.

These results support conformation **I** proposed by Chothia and Pauling (17) for LSD, and for lysergic acid by Stoll *et al.* (8) at least in the solvents considered here.

iso-Lysergic Acid Dimethylamide (4)

The pertinent 220 MHz n.m.r. spectra are reproduced in Figs. 3 and 4. In $CDCl_3$, the dimethylamide singlets overlap with those of H_4 and H_7 but are preferentially shifted upfield in C_6D_6 thereby allowing the complete coupling data for the ring hydrogens to be extracted. The assignments were confirmed by double resonance experiments in $CDCl_3$ solution.

The assignments of $H_{4\alpha}$, $H_{5\beta}$, and $H_{8\beta}$ follow arguments similar to those presented for **3**; however, the identification of $H_{7\alpha}$ and $H_{7\beta}$ in the *iso*-compound is less clear. Conformations **II** and **III** represent **4** with ring D in a ψ-chair form

in which $H_{8\beta}$ is axial and equatorial, respectively. The 6-NCH_3 is considered equatorially displaced for minimum steric interaction in both conformers, only the 7 and 8 hydrogens interchange their axial or equatorial positions.

Consideration of the ψ-chair form illustrated in conformation **II** shows that only one realistic assignment can be made. The resonance at 2.86 p.p.m. is attributed to $H_{7\beta}$ (equatorial) with $J_{7\beta,8\beta}$(e–a) = 5.2 Hz while that at 3.18 p.p.m. to $H_{7\alpha}$ (axial) with $J_{7\alpha,8\beta}$(a–a) = 7.5 Hz.[1] The geminal coupling $J_{7\alpha,7\beta} = (-)12.1$ Hz is common to both resonances. The observed slight sharpening of the proposed $H_{7\beta}$ resonance at 2.86 p.p.m. on double irradiation of the olefinic H_9 at 6.36 p.p.m. may be ascribed to a long-range W coupling as was observed in **3**. Since the 6, 7, 8, 9 system possesses almost the same relative geometry to that of **3** in conformation **I**, similar vicinal couplings constants are expected in this 7, 8 subsystem. The smaller 7.5 Hz *trans*-axial vicinal coupling constant appears to be anomalous compared to that in **3**; however, it is not unlike that obtained from a similar arrangement found in shikimic acid (19) and other systems (20) which display $J_{aa} = 6.2$–8.4 Hz in half-chair conformations.

The alternative conformer, **III**, can be assigned as follows: $H_{7\alpha}$ (equatorial) at 2.86 p.p.m. and $H_{7\beta}$ (axial) at 3.18 p.p.m. with $J_{7\alpha,8\beta}$(e–e) = 5.2, $J_{7\beta,8\beta}$(a–e) = 7.5 Hz. Molecular models suggest that $\theta_{7\alpha,8\beta} = 80$ and $\theta_{7\beta,8\beta} = 40°$. An interchange of assignments for the 7-hydrogens forces an unrealistic set of J_{vic} which does not conform with the general view of the Karplus relationship. As before, this assignment also accounts for the decoupling of the equatorial $H_{7\alpha}$ while irradiating H_9. The fact that only one of these H_7 protons shows an observable long-range coupling does not negate the possibility of a dynamic equilibrium between conformations **II** and **III**, since the averaging process is expected to reduce $J_{7,9}$ perhaps making it too small to detect in the signal at 3.18 p.p.m. Rough calculations from coupling constants expected in frozen conformations ($J_{ae} = 5.3$, $J_{aa} = 10.4$ Hz in **II** (see **3**); $J_{ae} = 3$–4, $J_{ee} = 1.5$–3.0 Hz in **III**) for the observed $J_{7,9}$ couplings indicate that **II**:**III** $\simeq 2:1$ if $H_{7\beta}$ is at 2.86 and $H_{7\alpha}$ is at 3.18, but self-consistent results cannot be obtained with the reverse assignment. Although the case here is less clear than for the lysergamides, the analysis thus supports conformation **II** for the *iso*-lysergamides in the solutions examined here.

The solvent-shift Δ values suggest that the amide–carbonyl bond is directed as shown in **II** (pointing towards the $H_{4\alpha}$ bond projection). Comparing the chemical shifts of **3** and **4**, H_9, 6-NCH_3, and Δ6-NCH_3 are very similar and indicate that the anisotropic amide group disposition with respect to H_9 and 6-NCH_3 is much the same on epimerization at C-8 (the conformations **I**, **II**, and **III** all satisfy this condition.)

Spectra of **3** and **4** in $CDCl_3$ with an added excess of trifluoracetic acid were not very useful because of the complexities of protonation at different sites, peak broadening, and poor resolution. However, the amide **3** clearly displayed two protonated forms (21) at 23 °C for each of its methyl groups and the complex aromatic region; each amide methyl group displayed a doublet ($\delta = 3.0$ and 3.2 p.p.m., $J = 10$ Hz) and the two $CH_3\overset{+}{N}H$ doublets at 3.05 and 3.10 p.p.m. ($J_{CH_3\overset{+}{N}H} = 4.8$ Hz) collapsed to singlets on irradiation of the broad $\overset{+}{N}H$ peaks at 9.91 and 10.05 p.p.m. The amide **4** displayed only one doublet for each of its CH_3 groups, the doublet $CH_3\overset{+}{N}H$ ($J = 5$ Hz) collapsing on irradiation of the $\overset{+}{N}H$ at 9.21 p.p.m.

Conclusion

The D ring of the *N*,*N*-dimethylamide of D-lysergic acid and its 8-epimer exist in different conformations in $CDCl_3$. The gross stereochemical features of these amides are essentially the same in that the N_6-methyls as well as the *N*,*N*-dimethylamide groups are in pseudo-equatorial positions. The different biological activities of the two series of amides may be in part

[1]This analysis stems from a generalization of the Karplus equation (18) that when both vicinal coupling constants are greater than about 5 Hz in a $—CH_2—CH_x—$ system where the geminal "dihedral" angle is 120°, then H_x must lie outside the *gem* protons. The only conformation consistent with this is that shown in conformation **II** and possibly the less favored boat form in which both 6-NCH_3 and the amide group assume pseudo-equatorial positions. However, J_0 values required to calculate J's from estimated dihedral angles are unrealistic, see ref. 19.

due to the relative orientation of the 6-nitrogen lone pair of electrons. In LSD, the latter is *trans*-axial to $H_{5\beta}$ and on the concave α-face while for the *iso*-compounds, it is essentially *gauche* and on the β-face of the molecule.

Spectra at 60 MHz were determined by Mr. H. W. Avdovich using a Varian A 60-A, Department of National Health and Welfare, Health Protection Branch, Research Laboratories, Ottawa; at 100 MHz on a Varian XL-100 through the courtesy of Dr. G. Buchanan, Department of Chemistry, Carleton University, Ottawa; and at 220 MHz with a Varian HR-220 at the Canadian 220 MHz n.m.r. Centre. Mlle. D. Verner and Monsieur D. Legault of the Department of National Health and Welfare are thanked for assistance in the preparation and purification of the amides examined.

A New Synthesis of 5-Phenyl-2,3-dihydro- and 2,3,4,5-Tetrahydro-1*H*-2-benzazepin-1-ones

K. ACKERMAN,[1] D. E. HORNING, AND J. M. MUCHOWSKI[2]
Bristol Laboratories of Canada, Candiac, Quebec

Received June 26, 1972

It was shown that 3-phenyl-3-(2-aminoethyl)phthalide (**6**, R = H) and its *N*-methyl analog (**6**, R = CH_3) existed in the amino lactone form in solution at room temperature. In the absence of solvents, however, these compounds underwent a spontaneous transformation into the 5-phenyl-2,3,4,5-tetrahydro-1*H*-2-benzazepin-1-ones (**8**, R = H, CH_3) which suffered dehydration in sulfuric acid with the formation of 5-phenyl-2,3-dihydro-1*H*-2-benzazepin-1-ones (**9**, R = H, CH_3).

This benzazepine synthesis can be considered to be analogous to the known (12–15) conversion of 1-aminomethylphthalides (**11**) to 4-hydroxy-3,4-dihydroisocarbostyrils (**13**).

Il a été montré que la phényl-3 (amino-2 éthyl)-3 phtalide (**6**, R = H) et son analogue *N*-méthyle existent en solution sous forme d'aminolactone à la température ambiante. En l'absence de solvants cependant, ces composés subissent une transformation spontanée en phényl-5 tétrahydro-2,3,4,5-1*H*- benzazépine-2 ones-1 (**8**, R = H, CH_3) qui se déshydratent en milieu sulfurique en formant des phényl-5 dihydro-2,3-1H- benzazépine-2 ones-1 (**9**, R = H, CH_3).

Cette synthèse de benzazépine peut être considérée comme l'analogue de la conversion (12–15) connue des aminométhyl-1 phtalides (**11**) en hydroxy-4 dihydro-3,4 isocarbostyryles (**13**).

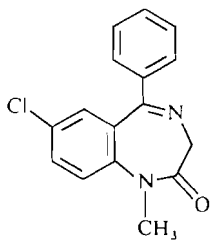
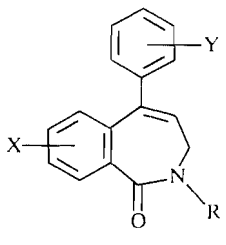
Canadian Journal of Chemistry, **50**, 3886 (1972)

In connection with a synthetic program the purpose of which was to prepare compounds structurally related to Diazepam[3] (**1**) we required a method whereby certain 4-aryl-2,3-dihydro-1*H*-2-benzazepin-1-ones (**2**) would be available in large quantities. The Schmidt or Beckmann expansions of 4-aryl-1-tetralones, which in principle might provide access to precursors of the above compounds, are in practice of little synthetic value because of the predominant formation of 5-aryltetrahydro-1-benzazepin-2-ones (2). With the possible exception of the acid-catalyzed cyclization of the acid chlorides of *o*-carboxycinnamonitriles (4), the other known 2-benzazepin syntheses (3, 5–7) did not appear to be readily adaptable to the preparation of **2** or derivatives thereof.



1



2

It occurred to us that a straightforward synthesis of compounds of type **2** might be based on an intramolecular variant of the aminolysis of esters. An examination of Dreiding models revealed that the benzobicyclo[3.2.1] transition state (intermediate (?), see ref. **8**, pp. 1164–1166) **7** (Scheme 1) would be especially favorable. Therefore, to test the feasibility of the above approach, the anion generated from 3-phenylphthalide (**3**), using sodium hydride in dimethylformamide (9), was alkylated with 2-(tetrahydropyran-2-yloxy)ethyl bromide and the product thus obtained was hydrolyzed to the alcohol **4**, (X = OH). The bromo compound **4** (X = Br), prepared from the alcohol and phosphorous tribromide, was converted without purification to the azide **5**, which was subjected to catalytic reduction in 2-propanol solution. If this solution was diluted with ether and then treated with gaseous hydrogen bromide, the amino lactone **6** (R = H) was isolated as its stable hydrobromide salt. If the solvent was

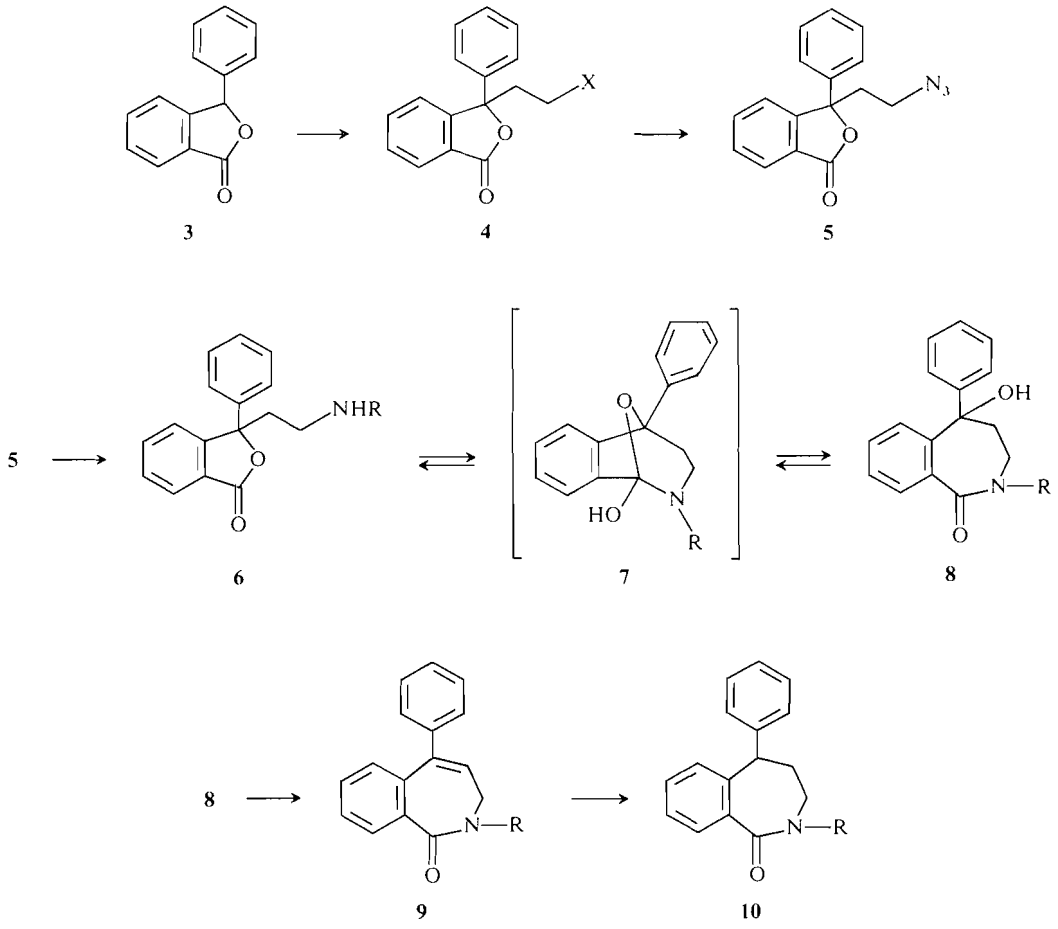

SCHEME 1

removed, however, an oil (strong i.r. band at 1765 cm^{-1}) was obtained, which underwent a spontaneous transformation into a crystalline, non-basic compound, isomeric with the starting material, and having an intense absorption at 1672 cm^{-1} in the i.r. spectrum. The 2-benzazepin-1-one structure **8** (R = H) was assigned to this compound on the basis of its spectral properties (see Table 1) and on the chemical evidence cited below. Solution of the above alcohol in concentrated sulfuric acid at 0°, and subsequent quenching of the reaction with ice, resulted in the formation of 5-phenyl-2,3-dihydro-1*H*-2-benzazepin-1-one (**9**, R = H). The structure of this substance was strongly supported by the n.m.r. spectrum, and fully substantiated by palladium-catalyzed hydrogenation to the tetrahydro derivative **10** (R = H) identical to the minor product[4] obtained from the Schmidt expansion of 4-phenyl-1-tetralone (2).

The process depicted by formulae **6** → **8** → **9** was also applicable when the amine function in **6** was secondary. Thus, the methyl amine **6** ($R = CH_3$), prepared by alkylation of the iminophosphorane **4** ($X = N^-P^+(C_6H_5)_3$) with methyl iodide followed by aqueous acidic hydrolysis of the phosphiniminium salt (10), rearranged when neat to the hydroxy lactam **8** ($R = CH_3$), which underwent dehydration in the expected manner to the olefin **9** ($R = CH_3$). The last-mentioned compound was identical to the product obtained by *N*-alkylation of the sodium salt of **9** (R = H) with methyl iodide.

The compounds represented by structures **6**

[4]We thank Dr. I. Monkovic of these laboratories for providing us with a specimen of this compound.

and **8** can be considered as the reactant and the product in an ester aminolysis reaction (see ref. 11, p. 330). They may also be regarded as the two extreme forms of a ring chain tautomeric equilibrium (see ref. 8, pp. 802–805). In either case, **6** and **8** ought to be interconvertible. After 24 h at room temperature a chloroform solution of **6** (R = H) showed neither diminution of the integrated intensity of the i.r. carbonyl absorption at 1765 cm^{-1}, nor the presence of the lactam tautomer ($\nu_{(C=O)} = 1672\ cm^{-1}$). Removal of the solvent gave an oil which was soon converted to the crystalline hydroxylactam **8** (R = H) as described previously. When a solution of the lactam in various solvents was heated, a rapid reversion to the amino lactone took place; indeed, even the most rapid recrystallization of this compound did not prevent considerable conversion to the lactone tautomer. The compounds in the *N*-methyl series displayed essentially the same behavior as the parent members.

When this study was completed, we became aware of the work of Ullyot *et al.* (12–14) and Szeki (15),[5] which demonstrated that the liberation of 1-aminomethylphthalides (**11**, Scheme 2) from their salts (2 or 3 equiv of hot sodium hydroxide was used) resulted in the formation of stereoisomeric mixtures of 3-alkyl-3,4-dihydroisocarbostyrils (**13**) which were dehydratable with hot, concentrated sulfuric acid to 3-alkylisocarbostyrils (**14**).[6] On the basis that the above reaction occurred more readily[7] in the presence of an excess of alkali, Ullyot *et al.* (12, 13) concluded that the reaction was base-catalyzed and proceeded through the open chain intermediate (**15**) which cyclized to **13** with the loss of an hydroxide ion. We suggest that this intermediate is unlikely in view of the observations described herein, and of the known mechanisms of ester aminolysis (ref. 11, p. 330) and amide hydrolysis (ref. 11, pp. 327–329).

Experimental

The melting points were recorded in a Gallenkamp melting point apparatus and are not corrected. The i.r. spectra were measured with a Unicam SP-200G i.r. spectro-

[5]We are grateful to a referee for directing our attention to references 13–15.

[6]The benzazepine synthesis described herein must therefore be considered to be an extension of the observations of these investigators.

[7]The cyclization also occurred in the absence of an external base, but at a rate 1/3 to 1/5 of that in the presence of alkali.

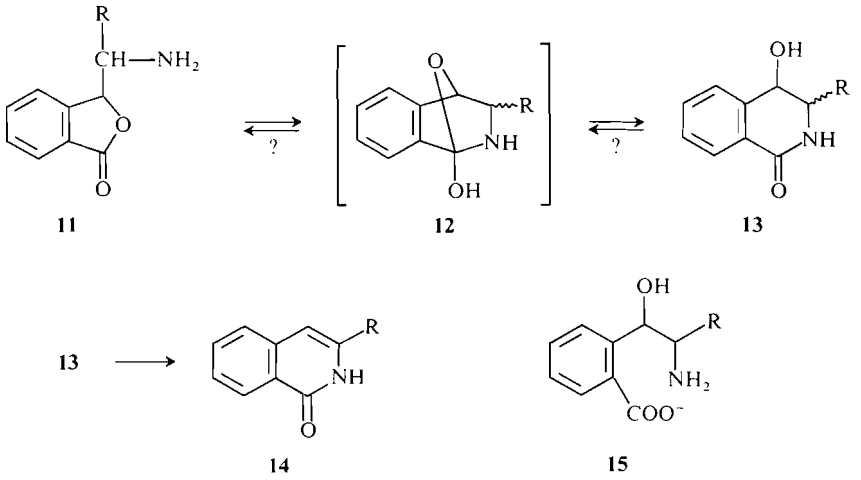

SCHEME 2

photometer. The n.m.r. spectra were recorded with a Varian A-60A spectrometer and are expressed in p.p.m. (δ) from internal tetramethylsilane.

The tetrahydropyranyl ether of bromoethanol was prepared according to the method of Parham and Anderson (16). 3-Phenylphthalide was prepared from 2-benzoylbenzoic acid by the method of Mole (17).

*3-Phenyl-3-(2-hydroxyethyl)phthalide (**4**, X = OH)*

A 55% dispersion of sodium hydride in mineral oil (3.50 g) was washed free of the carrier with petroleum ether (b.p. 30–60°), layered with anhydrous DMF (400 ml), and then 3-phenylphthalide (15.73 g, 75 mmol) was added. The mixture was heated to 50° in an atmosphere of dry nitrogen until hydrogen evolution had ceased (45 min), the solution was then cooled to room temperature and the tetrahydropyranyl ether of 2-bromoethanol (16.8 g, 80 mmol) was added. After stirring at room temperature for 7 h, the solution was poured into a large amount of cold water, the product was extracted into benzene, the extract was washed well with water and dried over sodium sulfate. The solvent was removed *in vacuo* and the residual oil was dissolved in a solution made up of methanol (180 ml) and 10% hydrochloric acid (20 ml). After 10 min at reflux temperature the solution was concentrated to a small volume *in vacuo*, the residue was diluted with water, and the mixture was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The alcohol was obtained as a very viscous oil in quantitative yield. A small portion was twice evaporatively distilled at 130°/0.005 mm. A satisfactory analysis could not be obtained, but the n.m.r. spectrum (See Table 1) indicated a purity of at least 95%.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.10; H, 5.69.

*3-Phenyl-3-(2-azidoethyl)phthalide (**5**)*

The crude alcohol from above (7.82 g, 30.8 mmol) was treated, in a dropwise manner with stirring at 0°, with phosphorous tribromide (9.5 g, 35.1 mmol). The cooling bath was removed, and after 18 h at room temperature and 1 h on a steam bath, the oil was treated with a large amount of ice–water. The product was extracted into benzene, the extract was washed with sodium carbonate solution (100 g/l), then with water, and finally it was dried over sodium sulfate. Removal of the solvent *in vacuo* left an oil (6.83–7.52 g, 70–77%) the i.r. spectrum (neat) of which was devoid of absorptions in the 3600–3200 cm^{-1} region but which had a strong band at 1772 cm^{-1}. This material partially decomposed on distillation and therefore it was used in the next step without purification.

The crude bromo compound (3.31 g, 10.5 mmol) in dimethylsulfoxide (80 ml), was mixed with a solution of sodium azide (6.3 g, 97 mmol) in water (30 ml), and the resultant was heated on a steam bath for 92 h. The solution was poured into a large amount of water, and the product was extracted into ethyl acetate. The extract was washed well with water, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil (2.52–2.84 g, 86–97%) had strong i.r. absorptions (neat) at 2105 and 1768 cm^{-1}, and was used without purification.

*3-Phenyl-3-(2-aminoethyl)phthalide hydrobromide (**6**, R = H)*

A solution of the above azide (8.00 g, 28.7 mmol) in 2-propanol (250 ml) containing 10% palladium-on-charcoal (800 mg), was hydrogenated at room temperature and a hydrogen pressure of 55 p.s.i.g. for 1.5 h. The catalyst was removed by filtration through Celite and the filtrate was concentrated to a volume of *ca.* 50 ml, diluted with ether, and dry hydrogen bromide was bubbled into the solution. The solid was collected by filtration and crystallized from 2-propanol–ether. There was obtained a solid (8.7 g, m.p. 113–116°) which after crystallization from 2-propanol had m.p. 116–118°. The elemental analysis and the n.m.r. spectrum (DMSO-d_6) showed that the salt crystallized with 0.75 mol of 2-propanol.

Anal. Calcd. for $C_{16}H_{15}NO_2$:HBr:0.75 C_3H_8O:C, 57.80; H, 5.85; N, 3.69. Found: C, 57.46; H, 6.09; N, 3.69.

*5-Phenyl-5-hydroxy-2,3,4,5-tetrahydro-1H-2-benzazepin-1-one (**8**, R = H)*

If the 2-propanol solution obtained from the reduction

of the azide was evaporated to dryness there was obtained an oil (i.r. (neat) bands at 1765 and 1672 cm^{-1}) which solidified on standing. After 14 h the residue was slurried with benzene and the insoluble solid (71–82% yield), m.p. 129–134° was collected by filtration. A small specimen was rapidly crystallized from acetonitrile to give compound **8** with m.p. 145–147°.

Anal. Calcd. for $C_{16}H_{15}NO_2$: C, 75.87; H, 5.97; N, 5.53. Found: C, 76.13; H, 6.00; N, 5.55.

*3-Phenyl-3-(2-methylaminoethyl)phthalide (**6**, R = CH_3)*

The crude azide **5** (4.94 g, 17.6 mmol) described previously, in dry benzene (130 ml), containing triphenylphosphine (4.62 g, 17.6 mmol) was heated at reflux temperature for 1.5 h. To the cooled solution was added methyl iodide (5.0 g, 35.2 mmol), and reflux temperature was maintained for an additional 2 h. The solvent was removed *in vacuo*, glacial acetic acid (50 ml) and 48% hydrobromic acid (50 ml) were added to the residue, and boiling under reflux was resumed (2.5 h). The solution was concentrated to a small volume *in vacuo*, ice–water was added to the residue, and the mixture was extracted with benzene. The aqueous phase was made basic with sodium carbonate solution (200 g/l), the product was extracted into benzene, the extract was dried and evaporated to a small volume (10–20 ml) *in vacuo*. The solution was diluted with ether and the hydrobromide salt was formed in the usual manner. The salt was crystallized from acetonitrile to give material (3.7 g), m.p. 176–177°.

Anal. Calcd. for $C_{17}H_{17}NO_2$: HBr: C, 58.63; H, 5.21; N, 4.02. Found: C, 58.64; H, 5.13; N, 4.10.

*2-Methyl-5-phenyl-5-hydroxy-2,3,4,5-tetrahydro-1H-2-benzazepin-1-one (**8**, R = CH_3)*

If the benzene solution from the above experiment, containing the secondary amine, was evaporated *in vacuo*, an oil remained (i.r. bands at 1766 and 1636 cm^{-1}) which completely solidified after 24 h. The solid was slurried with ether and collected by filtration. The product, m.p. 136–138°, was obtained in 61% yield. One crystallization from benzene gave material with m.p. 140–141°.

Anal. Calcd. for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24. Found: C, 76.43; H, 6.30; N, 5.29.

*5-Phenyl-2,3-dihydro-1H-2-benzazepin-1-one (**9**, R = H)*

Crystalline 5-phenyl-5-hydroxy-2,3,4,5-tetrahydro-1*H*-2-benzazepin-1-one (**8**, 1.2 g, 4.84 mmol) was added all at once at 0° with efficient stirring to concentrated sulfuric acid (40 ml). After 25 min, solution of the solid had been achieved and this was poured slowly with good stirring onto a large amount of ice. The solid was collected by filtration, dried, and then crystallized from benzene. The product **9** (R = H, 795–861 mg, 70–76%) was obtained in two crops, m.p. 230–233° and 227–230°. One additional crystallization gave material with m.p. 233–235°.

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.67; H, 5.57; N, 5.95. Found: C, 81.37; H, 5.67; N, 5.66.

*2-Methyl-5-phenyl-2,3-dihydro-1H-2-benzazepin-1-one (**9**, R = CH_3)*

(a) By Dehydration of the Corresponding Tetrahydro Alcohol

The dehydration was performed in the same manner as described above for the *N*-unsubstituted compound. Crystallization of the crude product from hexane: benzene (2:1) gave the product (60–64%) in two crops, m.p. 136–137.5° and 131–133°. After recrystallization and then sublimation at 110°/0.001 mm the product had m.p. 136.5–138°.

Anal. Calcd. for $C_{17}H_{15}NO$: C, 81.90; H, 6.06; N, 5.62. Found: C, 81.98; H, 6.02; N, 5.72.

(b) By Alkylation of 5-Phenyl-2,3-dihydro-1H-2-benzazepin-1-one with Methyl Iodide

A 55% suspension of sodium hydride in mineral oil (110 mg) was washed free of the carrier with hexane, layered with dry DMF (15 ml), and cooled with stirring to 0°. The unsubstituted lactam (353 mg) was added all at once, the cooling bath was removed, and when gas evolution was complete, methyl iodide (675 mg, 4.8 mmol) was added. The solution was stirred at room temperature under a slight positive pressure of nitrogen for 18 h, then diluted with water, and extracted with benzene. The extract was dried, evaporated *in vacuo*, and the residue was crystallized from hexane: benzene (2:1). The product **9** (R = CH_3, 283 mg, 76%), m.p. 136–138° was identical in every respect (i.r., n.m.r., mixed melting point) to the product obtained in method (*a*).

*5-Phenyl-2,3,4,5-tetrahydro-1H-2-benzazepin-1-one (**10**, R = H)*

A solution of 5-phenyl-2,3-dihydro-1*H*-2-benzazepin-1-one (**9**, R = H, 235 mg, 1 mmol) in glacial acetic acid (37 ml) containing 60% perchloric acid (1.5 ml) and 10% palladium-on charcoal (50 mg) was hydrogenated at room temperature and an initial hydrogen pressure of 59 p.s.i.g. ($2\frac{1}{4}$ h). The catalyst was removed by filtration through Celite, the filtrate was diluted with water, the product (195 mg) was collected by filtration and dried. After crystallization from benzene:hexane it had m.p. 224–225° (undepressed on admixture with an authentic specimen) and was identical in all respects with the minor product of the Schmidt rearrangement on 4-phenyl-1-tetralone (reported (2) m.p. 226–228°).

The Conformation of Racemic 4,6-Dimethyl Trimethylene Sulfite by Gas Phase Electron Diffraction

FRANK J. MUSTOE AND J. LAWRENCE HENCHER
Department of Chemistry, University of Windsor, Windsor, Ontario

Received December 21, 1971[1]

The molecular geometry of the racemate *trans*-4,6-dimethyl trimethylene sulfite has been studied in the gas phase by electron diffraction. Six trial conformations were examined by least squares fitting of the intensity data. A significance test applied to the fits obtained for each of the six static models tested indicate that the best single representation of the molecule has a chair conformation, although a mixture containing other conformations could not be definitely eliminated. It was not possible to conclusively discriminate between an axial or an equatorial S=O bond, although the axial position is favored. The following bond distances (r_g values) and angles were determined: C—H = 1.119 ± 0.020, C—C = 1.505 ± 0.014, C—O = 1.413 ± 0.013, S=O = 1.480 ± 0.022, S—O = 1.622 ± 0.009 Å; ∠CCO = 111.1 ± 1.3, ∠OS=O = 116.7 ± 1.4, ∠COS = 114.1 ± 1.0, ∠OSO = 100.7 ± 2.0°. The following angles were assumed to be tetrahedral: ∠CCC, ∠HCH, ∠CCH. The errors are estimated to be at the 95% confidence level. The molecular parameters are in agreement with those of trimethylene sulfite.

La géométrie moléculaire du *trans* diméthyl-4,6 triméthylène sulfite racémique a été étudiée en phase gazeuse par diffraction électronique. Six conformations ont été testées par la méthode des ajustements aux moindres carrés sur les données des intensités. Un test significatif appliqué aux ajustements obtenus sur chacun des six modèles statiques montre que l'unique et la meilleure représentation de la molécule possède une conformation chaise, bien qu'un mélange d'autres types de conformations n'ait pu être écarté définitivement. Il n'a pas été possible de trancher de façon concluante entre une liaison S=O axiale ou équatoriale, malgré une position axiale favorisée. Les valeurs suivantes pour les distances et les angles ont été déterminées: C—H = 1.119 ± 0.020, C—C = 1.505 ± 0.014, C—O = 1.413 ± 0.013, S=O = 1.480 ± 0.022, S—O = 1.622 ± 0.009 Å; ∠CCO = 111.1 ± 1.3, ∠OS=O = 116.7 ± 1.4, ∠COS = 114.1 ± 1.0, ∠OSO = 100.7 ± 2.0°. Les angles suivants ont été supposés tétrahédraux: ∠CCC, ∠HCH, ∠CCH. Les erreurs ont été estimées à 5%; les paramètres moléculaires sont en accord avec ceux du triméthylène sulfite.

Introduction

The considerable controversy in recent literature prompted this study of a dimethyl substituted six-membered cyclic sulfite in which steric interactions might be expected to play an important role in determining the conformation. The early literature of trimethylene sulfite and its derivatives is mainly concerned with the orientation of the exocyclic oxygen atom (1–6), although equilibrium mixtures of conformers are suggested (7, 8). The positioning of the exocyclic oxygen has since been shown to be axial in solution studies (9–12), in X-ray diffraction of solid crystals (13, 14), and in the gas phase by electron diffraction (15).

The first isomers of trimethylene sulfite substituted in the 4- and 6-positions were isolated by Lauterbur *et al.* (3) who, on the basis of i.r. and n.m.r. spectra assigned the racemic isomer a chair form with equatorial S=O. Overberger *et al.* (8) concluded from temperature dependance of the n.m.r. and i.r. spectra that a conformational mixture of chair forms (S=O axial and S=O equatorial) was present with S=O axial predominating. From spectral studies and dipole moments, Wucherpfennig (16) proposed a mixture of twist and perhaps chair forms. A previous spectral study (17) of the analogous racemic 4,6-diisopropyl trimethylene sulfite was in favor of the twist form. Wyn-Jones and coworkers (18–21) have used ultrasonic techniques to study various sulfites and have concluded that anancomeric equilibria of inverting chair conformations are present. Finally, Wood and Miskow (22) favor a distorted chair or flexible form for the racemic isomer and have reinterpreted the ultrasonic results to agree with that viewpoint (23, 24).

Experimental

A gas chromatographically pure sample of the racemic compound was provided by Dr. M. H. Miskow (23).

[1]Revision received August 15, 1972.

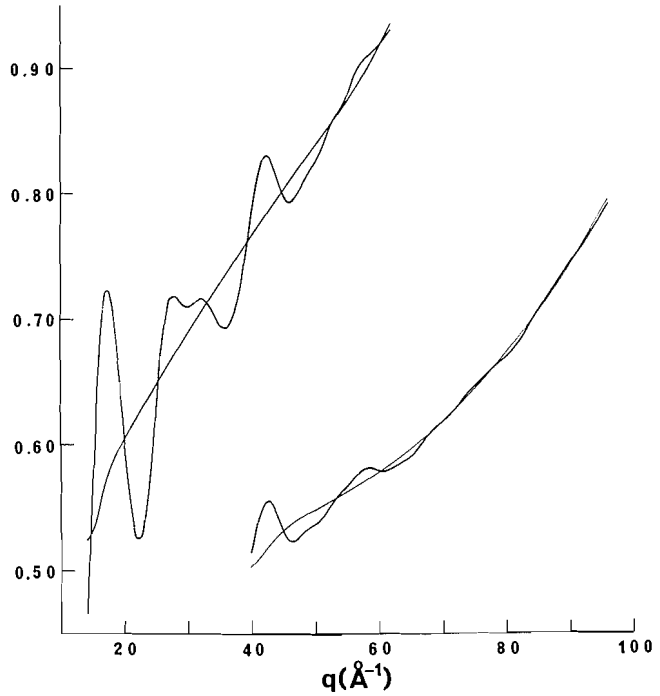

FIG. 1. The experimental intensity and background curves for racemic 4,6-dimethyl trimethylene sulfite, data set I.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Sectored electron diffraction photographs were recorded on the Cornell apparatus (25). A suitable vapor pressure was obtained with the sample at a temperature about 10 °C lower than that of the nozzle which was at 130 °C as measured by an attached thermocouple. Optical densities as a function of radial position were obtained with a digitized microphotometer (27). The data reduction procedure was that of Bauer and co-workers (26, 27), using the Hartley modification to the least square procedure (28) and a weight matrix that includes the first off-diagonal terms (29). Anharmonicity corrections were made for bonded atom pairs (30).

Results

Experimental relative intensities of four plates were obtained, covering the ranges $q = 14$–96 Å^{-1} (data set I) and $q = 6$–93 Å^{-1} (data set II), where $q = (40/\lambda) \sin(\theta/2)$, λ is the electron wavelength, and θ the scattering angle. Both sets of data have been placed in the Depository of Unpublished Data[2], and the intensities for data set I are plotted with the refined backgrounds in Fig. 1.

Six conformations, described using Hilderbrandt's algorithm (31), were tested against the experimental reduced intensity $(\pi/10)(qM_{expt}(q))$ by the method of least squares. The conformations were labelled **A** through **F** and are presented in Fig. 2. A larger drawing of model **A** with numbered atoms is shown in Fig. 3. The endocyclic carbon atoms and their attached hydrogen atoms were positioned routinely by means of C—C, C—H, and $\angle$CCH = $\angle$CCC = $\angle$HCH. The endocyclic oxygens were positioned by means of C—C, C—O, $\angle$CCC, $\angle$CCO and the angle τOCC (*e.g.* the nonvalence angle between C_4—C_5 and C_6—O_1. A value of zero for τOCC would correspond to these oxygens lying in the plane formed by $C_4C_5C_6$). The position of the sulfur atom was obtained using the distance $C_5 \ldots S_2$ (parameter C ... S) and angle $H_1C_5S_2$ (parameter $\angle$SCH). This ensures that both S—O lengths are equivalent and conveniently allows the boat or chair conformations to be determined primarily by the value of $\angle$SCH. The twist forms were obtained by rotating the C—O bonds against each other by means of τOCC (See Fig. 2). Due to the complexity of the molecule it was assumed

[2]Both sets of data are available at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

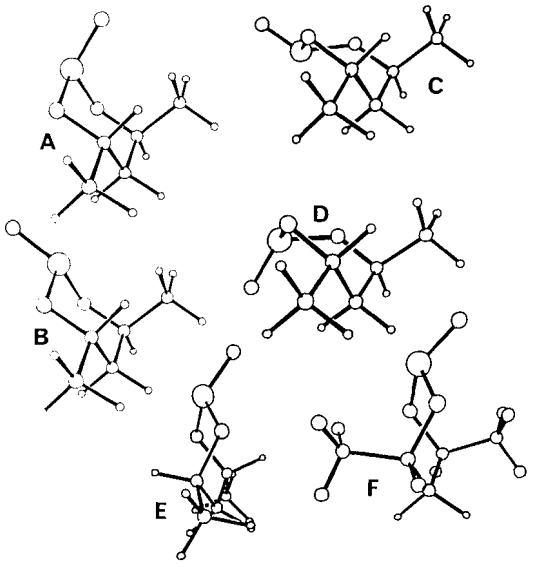

FIG. 2. The six different conformations analyzed by least square fitting of the reduced experimental molecular scattering curve.

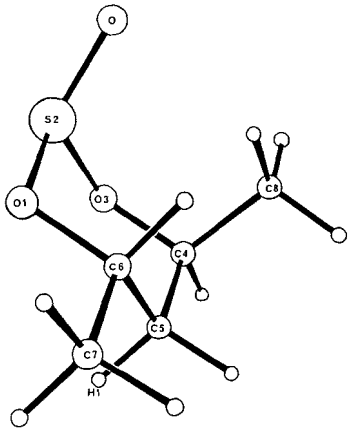

FIG. 3. The conformation, with numbered atoms, for model A.

that all CCH, HCH, and CCC angles were tetrahedral, and that the endo- and exocyclic CCO angles were equivalent.

The selection of initial parameter values for

C-8									0.0

*These are r_g values, in Å.

†The *lij* values presented in this table were determined during previous least squares analysis and were constrained during the later stages of refinement. Mean square amplitudes involving hydrogen were as follows: C—H = 0.080; H... H = 0.120; with geminal C or O atom = 0.100; with all other heavy atoms = 0.150; all long H... H distances = 0.200. All values are in Å.

‡The conformation and designation of the atoms corresponds to Fig. 3. The distances presented above were calculated for this conformation using the parameter values listed for data set I in Table 1.

least squares refinement was straight forward for the bond lengths and valence angles. However, initial values of ∠SCH, C... S, and τOCC had to be found by trial and error in order that the redundant parameters ∠COS, ∠OSO, and S—O would have reasonable starting values, as calculated from the interatomic distance matrix. In order to test each conformation it was necessary to attempt a refinement of as many parameters as possible, although under these conditions large correlation coefficients were found between the parameters and convergence was difficult to obtain.

Radial distribution curves were calculated using a value of 0.0025 for the Degard damping constant. Only the contributions due to C—H and S—O were clearly resolved. By fitting the intensity curves we find two solutions for each of the chair models, placing the S—O distance at 1.62 Å. The parameter values obtained when both sets of data were treated independently for the preferred chair form of model **A** are given in Table 1. The corresponding interatomic distances and mean square amplitudes of vibration for the heavy atoms are given in Table 2 and the correlation coefficients between the parameters in this solution are listed in Table 3. Some of the parameters are highly correlated, and although convergence was not obtained, the parameter values were oscillating with amplitudes less than the given uncertainties.

The alternate form of model **A**, again refined independently from the two sets of data, gave valence parameter values in close agreement with each other, and within the errors given for the preferred model, with the exceptions of ∠OS=O, ∠COS, and ∠OSO. For these respective parameters we determined the values 107.9, 117.9, and 106.9° from data set I ($R = 0.0846$) and 108.6, 118.3, and 106.1° from data set II ($R = 0.0986$). Although the fit to data set II for this form is better than that given in Table 1, it is not significantly so (32, 33), and the values for ∠OS=O are smaller than expected.

A similar result was obtained for model **B**, the chair form with equatorial S=O bond, although the best fits to both data sets were obtained with parameter values similar to those discussed above for the alternate form of model **A**. These results are presented in Table 4. On comparing

Tables 1 and 4 it is evident that the differences in the chair forms are due largely to the parameters ∠SCH and τOCC. Transferring the parameters given in Table 1 as an initial structure for model **B**, we find that allowing the valence and conformational determining parameters to vary results in solutions with valence parameters as given in Table 1, within the given errors, with the exception of ∠OSO. Data sets I and II yield values of 92.4 and 91.0° respectively for ∠OSO, values which are approximately 10° less than the similar angle determined in trimethylene sulfite (13, 15) and 2,2′-dichloro trimethylene sulfite (14).

The boat forms **C** and **D** were analyzed using data set I only. The best fits obtained for these conformations had *R* values of 0.1878 and 0.2186 respectively, and the hypothesis that they were significant compared to A was rejected at the 99% confidence level (32, 33). Partially twisted boat conformations did not successfully refine, hence the completely twisted forms **E** and **F** were assumed by constraining the sulfur atom to the position shown in Fig. 2 by means of ∠SCH = 125.25°. Model **E** was analyzed using data set I only and refined to a set of valence parameter values consistent with those of Table 1, ($R = 0.1701$) but was likewise re-

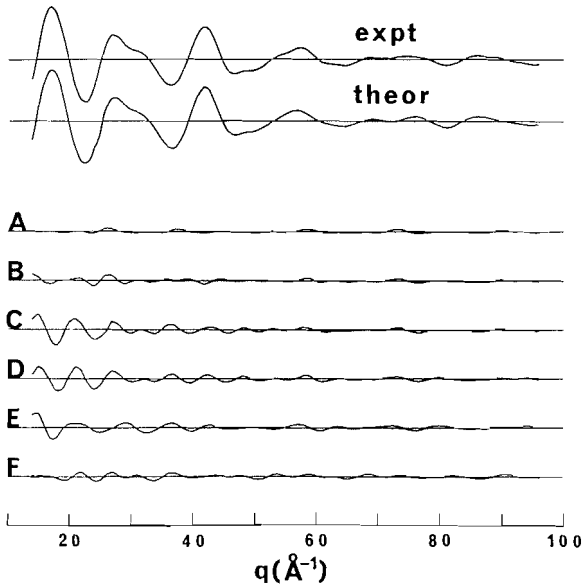

FIG. 4. The reduced experimental molecular scattering curve, the corresponding theoretical curve calculated for model A, and the difference curves (experimental – theoretical) for models **A** through **F**, data set I.

jected. Model **F** was analyzed using both data sets, ($R = 0.1101$ for set I and $R = 0.1469$ for set II) and was also rejected at the 99% confidence level (32, 33).

The experimental reduced intensity $(\pi/10)(qM_{expt}(q))$ is compared with $(\pi/10)(qM_{theor}(q))$ for **A** in Fig. 4 along with the difference curves for **A** through **F**. The corresponding radial distribution curves calculated from the reduced intensity curves are presented in Fig. 5 for the region of structural interest. The full experimental radial distribution curve is compared with that calculated for model A in Fig. 6.

Discussion

While the analyses of the two sets of data are consistent in that the parameter values obtained for models **A**, **B**, and **F** are the same, within calculated errors, the normalized standard deviations for models **A** and **B** are not consistent: for data set I the lowest value for R is given by model **A**, the chair form with axial S=O bond, while for data set II the lowest value for R is given by model **B**, a chair form having different ring valence angles than those of model **A**, with an equatorial bond. However, the R factor ratio

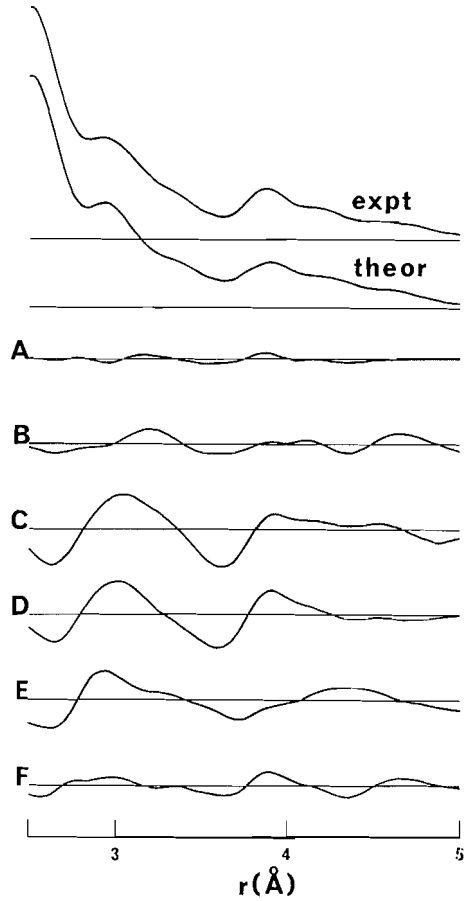

FIG. 5. The experimental radial distribution function in the region of structural interest, together with the corresponding theoretical function for model **A** and the difference curves (experimental – theoretical) for models **A** through **F**.

$0.0746/0.0646 = 1.155$ for the two fits to data set I does not allow us to statistically reject the hypothesis that model **B** is an acceptable solution at the 1% level of significance for this data (32, 33).

We tested the tetrahedral constraint on ∠CCC for model **A** and data set I. Using the parameters of Table 1 as an initial model, we found a minimum ($R = 0.0585$) with the exocyclic ∠CCC = 111.1° and the endocyclic angle = 106.6°. As a second test we constrained ∠CCC at 110.5° and obtained a fit with $R = 0.0704$. In both cases the other parameters were unchanged, within the estimated errors, and the addition of ∠CCC to the varied parameters, or the change in the value of the constraint, does not make a

*Bond lengths in Å, angles in degrees. The mean square amplitudes of vibration are given in parentheses.

significant difference to the fit obtained. We therefore conclude that ∠CCC might well be a degree or so larger than tetrahedral.

A more serious constraint in our analysis was the use of the same mean square amplitudes of vibration for all the models. The mean square amplitudes given in Table 2 are certainly not unique, and we would expect different results depending on the values used. However, it is beyond the capabilities of our experiment to determine the non-bonded amplitudes for this molecule, so we have assumed a reasonable set of values and admit that an alternate set might give an improved fit to any of the models tested, although it is highly unlikely that the rejected models would become statistically significant.

The parameter values for models **A** and **B** are again listed and compared with the values in trimethylene sulfite (13, 15) and 2,2′-dichlorotrimethylene sulfite (14) in Table 5. The errors given for the two models in the present work are three times the calculated uncertainties and are estimated to be at the 95% confidence level and to include systematic errors. It can be seen that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

model **A** agrees reasonably well with the electron diffraction results for the unsubstituted molecule, while model **B** compares more favorably with the X-ray results, particularly in that ∠COS is much larger than ∠OS=O. This is an unexpected trend, and we note that in model **A** the peak in the radial distribution curve just less than 4 Å is due to the exocyclic oxygen to carbon distances. When this oxygen is placed in the equatorial position, as in model **B**, it is precisely these distances which change the most. It is therefore reasonable to assume, as Naumov and co-workers have pointed out (15), that the ∠OS=O would tend to become much smaller than that determined for an axial S=O model in an effort to make these distances the same as before.

In summary, the electron diffraction data are not consistent with a static boat, or fully twisted conformation for racemic 4,6-dimethyl trimethylene sulfite. Although the available evidence favors a chair form with an axial S=O bond, the equatorial form, or mixture of conformers, could not be definitely eliminated.

We extend our thanks to Professor S. H. Bauer for the use of experimental facilities, and to Dr. M. H. Miskow for providing a sample of the compound. The financial support of the National Research Council of Canada is gratefully acknowledged.

Cancentrine. IV. Acetolysis Products of Cancentrine Methiodide

R. RODRIGO AND R. H. F. MANSKE
Department of Chemistry, University of Waterloo, Waterloo, Ontario
AND
V. SMULA, D. B. MACLEAN, AND L. BACZYNSKYJ
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 2, 1972

Treatment of cancentrine methiodide with boiling acetic anhydride in the presence of sodium acetate gave two highly unsaturated products formed in rearrangement reactions. One of the products retained all the original carbon and both nitrogen atoms of cancentrine while the other formed with loss of three carbon atoms and one nitrogen atom. The structures of the two compounds were deduced through analysis of their p.m.r. spectra and through comparison of their p.m.r. and u.v. spectra with those of model compounds synthesized in this study. A mechanism for the formation of the rearrangement products is proposed and discussed.

Le traitement du méthyliodure de la cancentrine par l'anhydride acétique bouillant, en présence d'acétate de sodium, conduit à deux produits hautement insaturés issus de réactions de réarrangement. L'un des produits conserve tous les atomes de carbone originaux et les deux atomes d'azote de la cancentrine tandis que l'autre perd trois atomes de carbone et un d'azote. Les structures des deux composés ont été déduites à partir de leurs spectres r.m.n. et par comparaison de leurs spectres r.m.n. et u.v. avec ceux de composés modèles synthétisés au cours de cette étude. Un mécanisme pour la formation de produits réarrangés a été proposé et discuté. [Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The structure of cancentrine (**1**) a novel dimeric alkaloid from *Dicentra canadensis* Walp. was recently determined by a combination of physical and chemical methods (1). One of the first items of chemical evidence obtained concerning its structure came from the reaction of cancentrine methiodide with acetic anhydride and sodium acetate. We now report the results of our investigation of this acetolysis reaction and the structures of the products obtained.

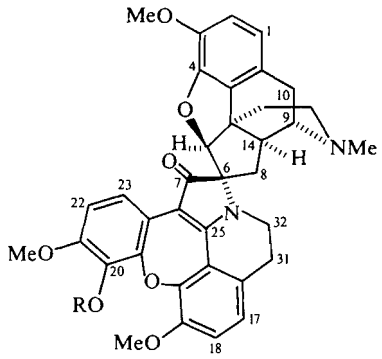
Cancentrine methiodide, when refluxed with acetic anhydride and sodium acetate for *ca.* 48 h, produced two compounds to which we assign structures **3** and **4**. The i.r. spectrum of **3** lacked the characteristic carbonyl absorption of cancentrine and its derivatives at 1660 ± 5 cm^{-1} but had strong absorption at 1765 cm^{-1} indicative of a phenyl acetate. The u.v. spectrum was complex and bore no similarity to the now familiar spectra of cancentrine and its derivatives. The mass spectrum of **3** provided little structural information but had intense ions at *m/e* 615 (58),[1] 573 (44), 531 (100), and 43 (50). The mass of the molecular ion at *m/e* 615 corresponds in composition to $C_{37}H_{29}NO_8$ (h.r.m.s.) and this formula was confirmed by elemental analysis of **3**. The ions at *m/e* 573 and 531 arise from the successive loss of ketene from the molecular ion and merely indicate the presence of two acetate groups in the molecule.

The p.m.r. spectrum of **3**, to be examined in detail later, confirmed the presence of two phenyl acetate groups and also indicated that the molecule contained three methoxyl groups and ten aromatic protons. Besides these absorptions there were two triplets of two protons each, centered at 2.92 and 4.16 δ constituting an A_2X_2 system (confirmed by decoupling).

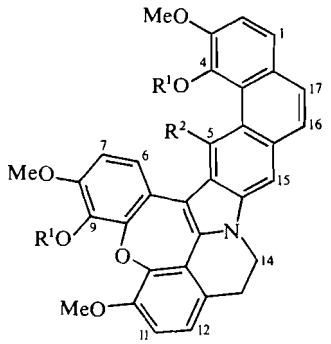
Compound **3** upon hydrolysis with potassium hydroxide and methylation with diazomethane yielded a pentamethoxy compound **5** with the expected p.m.r. properties. The mass spectrum of **5** had the molecular ion at *m/e* 559 (100) corresponding in mass to the formula, $C_{35}H_{29}NO_6$ (h.r.m.s.) and an intense *m/2e* ion at 279.5 but nothing else of significance.

Thus it was clear from the preliminary data on **3** that extensive changes have taken place in the reaction of the methiodide with acetic anhydride – sodium acetate. These changes may

[1]Ion intensities are in parentheses.



1 R = H
2 R = Ac



3 R′ = Ac; R^2 = H
4 R′ = Ac; R^2 = $CH_2CH_2N(Me)Ac$
5 R′ = Me; R^2 = H

be summarized as follows: (*i*), the carbonyl group and the characteristic chromophore of cancentrine of which it was a part had been destroyed; (*ii*), extensive aromatization had taken place; and (*iii*), cancentrine, $C_{36}H_{34}N_2O_7$, had been converted to the equivalent of $C_{33}H_{25}NO_6$ (*i.e.* **3** less two acetyl groups) in the overall process indicating that the elements of C_3H_9NO had been lost in the conversion. A search was therefore launched for other products of the reaction and *N*-methylethanolamine was successfully isolated from the aqueous extract after a prior saponification, and characterized as its chloroaurate. Since the acetolysis had been carried out with cancentrine methiodide this result meant that an *N*-demethylation had also been effected under the conditions. Such *N*-demethylations of quaternary metho salts by acetate ion have been studied (2) in many systems. These findings suggested the presence of a morphine-like moiety in cancentrine because the loss of the *N*-methyl ethanamine bridge (C_3H_7N) and a suitably placed oxygen function (as the equivalent of H_2O) is normally observed during the acetolysis of most morphine alkaloids (3). Meanwhile the structure of cancentrine was established by other methods (4) so that it was possible to proceed with the investigation of the structures of **3** and **4**.

The aromatic region of the p.m.r. spectrum of **3** determined at 220 MHz showed the presence of four AB quartets and two singlets (Fig. 1). One of the singlets at extremely low field (9.90 δ in **3** and 10.26 δ in **5**) is crucial to the structural arguments subsequently presented for both **3** and **4**. Previous studies of the p.m.r. spectra of condensed polycyclic benzenoid aromatic systems have shown that "bay" protons absorb at unusually low fields due to ring current effects and/or a variety of local influences. Some of the latter possibilities that have been explored are mutual van der Waals interactions, deshieldings due to σ-bond anisotropies, and electric field effects (5 and references therein). In any event, the 4- and 5-protons of phenanthrene (**6**) resonate at *ca.* 8.7 δ (5) while the 14-hydrogen of benz(*a*,*j*)anthracene (**7**) appears at 9.97 δ (6). This prompted the idea that the low field proton of **3** is in a similar environment. Cancentrine *O*-acetate (**2**) contains three pairs of ortho aromatic protons which appear as AB quartets in its p.m.r. spectrum (1); the presence of a fourth AB quartet in the product is easily accounted for by aromatization at the 9,10 position of **2**. Thus structure **3** can be derived for the first acetolysis product, the singlets at 9.90 and 7.72 δ being ascribed to C-5 and -15 protons, respectively, and the $—CH_2—CH_2—$ unit at C-13, -14 being responsible for the A_2X_2 system. The structure is supported by the detection of significant nuclear Overhauser effects (n.O.e.) in the C-5 proton when the acetate methyl groups of **3** (14%) and the *O*-methyl groups of **5** (18%) were saturated.

The second acetolysis product **4** had the molecular formula $C_{42}H_{38}N_2O_9$ (h.r.m.s., elemental analysis) which is greater than **3** by C_5H_9NO. This suggests the presence of an acetylated *N*-methylethanamine side chain in **4**.

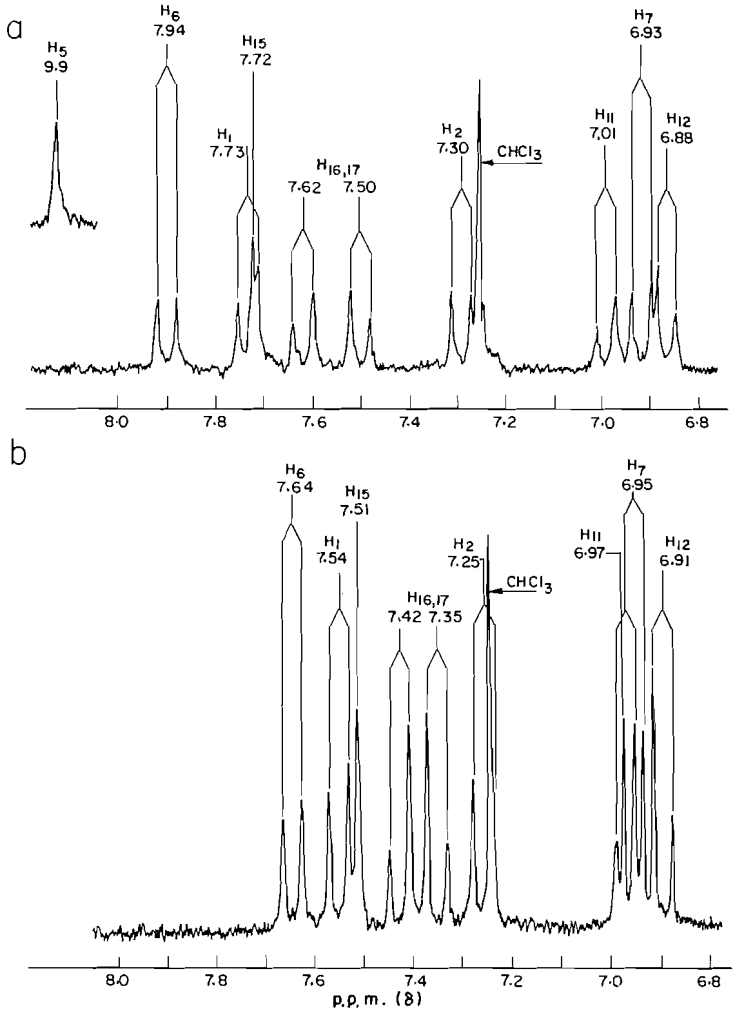

FIG. 1. The aromatic region of the 220 MHz p.m.r. spectrum of (*a*) **3**, (*b*) **4** (at 95°).

The mass spectrum of **4** contained ions corresponding to the presence of precisely such a structural unit as well as two *O*-acetyl groups. Thus there were ions at *m/e* 714 (12), 672 (20), 630 (42), 544 (50), 542 (100), 100 (11), 86 (10), and 44 (36). These correspond to M^+, $[M - CH_2CO]^+$, $[M - 2 \times CH_2CO]^+$, $[M - 2 \times CH_2CO - CH_2N(Me)Ac]^+$, $[M - 2 \times CH_2CO - CH_2N(Me)Ac - 2H]^+$, $[CH_2CH_2N(Me)Ac]^+$, $[CH_2{=}N^+MeAc]$, and $[CH_2{=}\overset{+}{N}HMe]$ respectively. Again, as in **3** there were no significant fragments corresponding to the fission of the ring system. The i.r. spectrum, in accord with the foregoing evidence, showed absorption corresponding to the presence of phenyl-acetate (1765 cm^{-1}) and amide (1630 cm^{-1}) carbonyl groups.

The room temperature p.m.r. spectrum of **4** was very complex. The spectrum was dramatically simplified however when determined at higher temperature. This behavior is attributable to conformational isomerism, and complete coalescence of peaks due to the various conformers takes place only at about 95° indicating that a considerable barrier to rotation about the C—N bond exists in this compound. Similar behavior has been observed before, in a related phenanthrene **8** (7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

The spectrum of **4** (at 95°) had seven three-proton singlets, six of which were readily assigned to three *O*-methyl (3.88, 3.94, and 3.96 δ) two *O*-acetyl (2.26 and 2.44 δ), and one *N*-acetyl group (2.15 δ). The other singlet at unusually high field (1.30 δ) was tentatively attributed to the *N*-methyl group. The p.m.r. spectrum also indicated the presence of eight aliphatic and nine aromatic protons. The aromatic region of the spectrum was very similar to that of **3** with the significant exception that it lacked the low field singlet of the latter (Fig. 1).

The ethanamine side chain was therefore placed at C-5 and in a model of **4** so constructed it is found that the *N*-methyl group is forced into the shielding zone of the aromatic system accounting for its unusually high chemical shift.

It is possible to assign the signals in the aromatic regions of the p.m.r. spectra of **3** and **4** by comparison with the spectra of phenanthrene (5) and cancentrine-*O*-acetate (1). In both compounds every aromatic signal had been unambiguously assigned.

Thus signals in the dibenzoxepine part of **3** and **4** are assigned by comparison with cancentrine-*O*-acetate (**2**) and signals of the phenanthrene part by comparison with phenanthrene (**6**). The results are recorded in Table 1. Good qualitative correspondence is found for the signals of the phenanthrene part of **3** and **4** with **6** when allowance is made for the increasing substitution of the phenanthrene moiety in the order **6** < **3** < **4**. The assignment of the resonances of H_{16} and H_{17} in **3** and **4** is based on the small separation between them ($\Delta\nu = 0.12$ and 0.07 p.p.m. respectively). In many phenanthrenes the corresponding H_9 and H_{10} protons have identical chemical shifts and appear in the spectra as two-proton singlets (5). There is excellent agreement between the values for H_{11} and H_{12} of **3** and **4** with the corresponding values of H_{18} and H_{17} of **2**. However, discrepancies are found in the resonances of H_6 and H_7. The reasons for these are not immediately apparent but must be related to the serious crowding that occurs in this region of the molecules of **3** and **4**.

The formation of **3** and **4** from cancentrine methiodide is rationalized in Scheme 1. The first step is *O*-acetylation of the enaminoketone for which a precedent exists (8). The *N*-demethylation is also included at this stage for convenience. This is followed by the key ring-expansion step for which there are two *a priori* possibilities. Thus migration of the C_5—C_6 bond with loss of a C-8 proton may take place leading ultimately to **3** (and **4**), or alternatively, migration of the C_6—C_8 bond with loss of a C-5 proton can lead through similar intermediates to **9**. Structure **3** is supported by the p.m.r. data discussed above but most notably by the detection of a strong n.O.e. (32%) between the signals at 9.90 and 7.94 δ assigned to H_5 and H_6 respectively. Structure **9** is clearly excluded by this observation. The reason for the preferred migration of C_5—C_6 may lie in the geometry of the transition state for this step. $H_{8\alpha}$ is much closer to being *trans* and coplanar to the C_5—C_6 bond than $H_{5\alpha}$ is to the C_6—C_8 bond. There is a further point of interest about this reaction. The retention of the ethanamine side chain during acetolysis has no precedent in the chemistry of morphinan, promorphinan, and related alkaloids with the sole exception of the acetolysis of two closely related compounds, sinomeninone (**10**) and 1-bromosinomeninone (**11**). In these instances both products **12** and **13** were formed from **10**, and **14** and **15** from **11** (9). The location of the second acetoxy group in **13**

SCHEME 2

and **15** was not absolutely certain but position C-6 was preferred over C-7 on the basis of some color reactions. The acetolysis of morphine alkaloids containing a C_4—C_5 oxide bridge is believed to involve concerted ring opening of the bridge and *trans*-elimination of the ethanamine side chain (3). In all such cases no retention of the side chain has been observed. In the case of promorphinan compounds that do not possess an oxide bridge the loss of the side chain obviously cannot take place in this way. It is therefore proposed that in the acetolysis of cancentrine methiodide the presence of the second nitrogen atom induces opening of the oxide ring independently of the loss of the side chain by stabilizing the incipient carbonium ion thus leading to both products **3** and **4**. Moreover, this nitrogen atom is in a situation exactly analogous to the oxygen of the carbonyl group at C-7 of sinomeninone. A companion mechanism is proposed for the acetolysis of sinomeninone to emphasize these similarities (Scheme 1).

The second acetolysis product, **4**, is an isomer of compound **16** that would result from a thebenine rearrangement (3) and we therefore wish to propose the name "isothebenine" rearrangement for the process leading to **4**. Indeed the evidence adduced thus far in support of the structure of **4** does not rigorously exclude the alternative structure **16**. The synthesis of model compounds **17** and **18** which correspond to the ring systems of **3** (**4**) and **16**, respectively, was therefore undertaken in order that the u.v. and p.m.r. comparisons could be made. The syntheses (Scheme 2) starting from the dihydrodibenzoxepinone (**21**) and 2-amino-9,10-dihydrophenanthrene (**19**) and 2-aminophenanthrene (**24**), respectively, made use of the Fischer indole procedure for completing the fusion of the two tricyclic halves. It had previously been observed that in the Skraup synthesis with **19** ring closure occurs at C-3 whereas with **24** the same procedure produces ring closure at C-1 (10). In this case therefore **22** is expected to yield **23**, and **26** to give **18** when subjected to the conditions of the Fischer indole synthesis.

The u.v. spectra of **3**, **4**, and **17** were very similar. There were only slight shifts in the absorption maxima which were qualitatively consistent with the degree of substitution of the chromophore in the three compounds. The u.v. spectrum of **18** was substantially different (Fig. 2).

The p.m.r. spectrum of **17** was very complex but showed the presence of singlets at 7.93, 9.39, and 10.86 δ. The latter signal was relatively broad and D_2O exchangeable. It is therefore assigned to the indole proton. The signal at

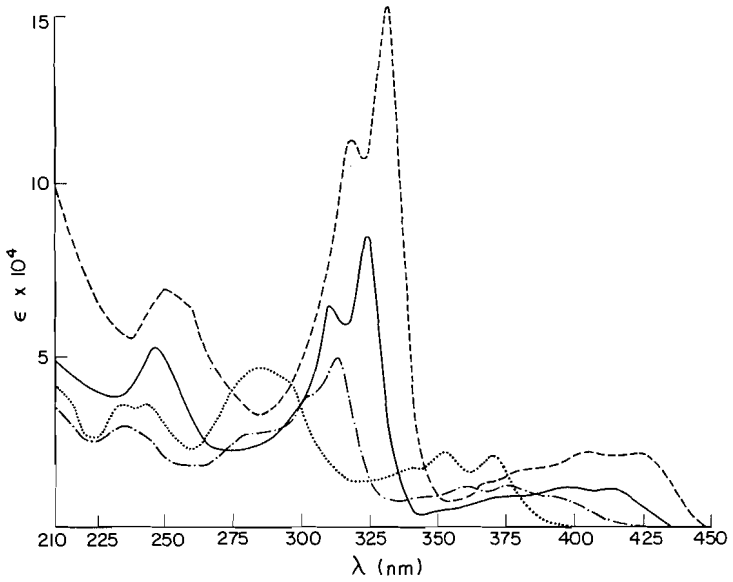

FIG. 2. The u.v. and visible spectra of **3** (——), **4** (----), **17** (·-·-·-), and **18** (·····) in ethanol solution.

9.39 δ is attributed to the C-5 proton which is in a "bay" situation like H_5 in **3** (9.9 δ) and H_{14} in **7** (9.97 δ). The singlet at 7.93 δ is assigned to H_{14} in **17** because of its close correspondence to H_8 in **6** (7.88 δ). The p.m.r. spectrum of **18**, also very complex, contained no singlets, except for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the indole proton appearing at 11.3 δ and similarly exchangeable with D_2O. There were two other complex but well-separated regions of absorption in the spectrum, 7.10–7.95 δ and 8.45–8.85 δ. The latter (four protons) may be ascribed in part to the "bay" protons H_{14} and H_{15}, since protons in a similar environment in **27** (8.50 δ) and **28** (8.80 δ) appear at similar frequencies (11). The rest of the absorption in the region must be due to H_4 and H_5 of the phenanthrene system.

It is clear that much of the foregoing argument is based upon the previously described de-shielding influences to which protons in a "bay" situation in polycyclic aromatic compounds are exposed. The comparisons made may be validated by an examination of the p.m.r. spectra of **29** and **30** which are related to the systems **17** and **18**, respectively, but lack the oxygen bridge which forces the latter systems into near planarity. In these cases it may be expected that the phenyl substituents of the indole will no longer be coplanar with the rest of the aromatic system and significant changes should be observed in their p.m.r. spectra. These compounds were synthesized by a procedure identical with that described before (Scheme 2) using desoxybenzoin (**31**) in place of the dihydrodibenzoxepinone **21**.

The p.m.r. spectrum of **29** again showed the expected singlets due to H_5 and H_8. The latter appears at 8.00 δ and corresponds well with H_{14} in **17** (7.93 δ). However, the H_5 absorption in **29** is found at 8.95 δ, an upfield shift of 0.44 p.p.m. from its position in **17**, and this must represent the decrease in deshielding at H_5 due to non-coplanarity of the 6-phenyl substituent with the rest of the aromatic system.

The spectrum of **30** also had the two regions of absorption at 7.10–7.95 and 8.50–8.85 δ just like that of **18**. The significant difference however between the two spectra was that the latter region now only integrated for two protons and not four as in the case of **18**. These two protons can be assigned to H_4 and H_5 of the phenanthrene system and once more it appears that the non-coplanarity of the C_8-phenyl substituent with the rest of the aromatic system is responsible for the upfield shift of protons (H_{14} and H_{15} in **18**) now no longer in a "bay" situation.

Experimental

Methods

Melting points were determined in a Fisher Mel-Temp apparatus and are uncorrected. Mass spectra were recorded on a CEC 21-110B double focussing mass spectrometer. Accurate mass measurements were made either by the peak matching technique (12) or by recording spectra on photo plates (13). In both cases appropriate peaks of perfluorokerosene were used for reference (14). The p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ (unless otherwise stated) and added TMS was used as the internal locking signal. Chemical shifts were measured relative to TMS using a V315 frequency counter incorporated in the instrument and are reported in p.p.m. (δ) from TMS. Double irradiation was achieved by employing a Hewlett Packard 201C audiogenerator at the desired frequency. The 220 MHz spectra of **3** and **4** were determined at the Canadian 220 N.M.R. Centre at Sheridan Park, Ontario. A Beckmann IR10 spectrometer was used to record the i.r. spectra and a Cary 14 spectrophotometer was used for the u.v. spectra.

The Acetolysis of Cancentrine Methiodide

Cancentrine methiodide (1.767 g) and anhydrous sodium acetate (4.6 g) were refluxed in acetic anhydride (75 ml) for 48 h under nitrogen. The liquids were removed *in vacuo*, water added, and the mixture extracted with chloroform. The chloroform extracts were dried ($MgSO_4$) and the solvent removed. The residue was purified on a silica gel column. Elution of the column with benzene–acetone (2.5%) yielded **3** (245 mg) crystallized from methanol, m.p. 269°. The u.v. spectrum: λ_{max} (EtOH) 246, 310, 324, 369, 397, and 415 nm; log ε_{max} 4.72, 4.81, 4.94, 3.97, 4.06, and 4.03 respectively. The i.r. spectrum: ν_{max} ($CHCl_3$) 1765 cm^{-1}. The 220 MHz p.m.r. spectrum: 2.52(s) 3H, and 2.55(s) 3H, 2 × OAc; 3.07 (t) 2H and 4.32 (t) 2H (J_{AX} = 6.0 Hz), $—CH_2—CH_2$; 3.67 (s) 3H, 3.70 (s) 3H, 3.78 (s) 3H, 3 × OMe, 6.8–9.9, 10H see text for analysis.

Anal. Calcd. for $C_{37}H_{29}NO_8$ (mol. wt 615.189): C, 72.20; H, 4.74; N, 2.28. Found (615.189 (h.r.m.s.)): C, 72.50; H, 4.94; N, 2.24.

Elution of the silica gel column with chloroform–methanol (2%) yielded **4** (408 mg) crystallized from methanol, m.p. 198°. The u.v. spectrum: λ_{max} (EtOH) 250, 256 (sh), 318, 332, 384, 406, and 424 nm; log ε_{max} 4.84, 4.83, 5.06, 5.19, 4.24, 4.34, and 4.34, respectively. The i.r. spectrum: ν_{max} ($CHCl_3$) 1765 and 1630 cm^{-1}. The 220 MHz p.m.r. spectrum (95°): 1.3 (s) 3H, *N*-Me; 2.15 (s) 3H, *N*-Ac; 2.26 (s) 3H, and 2.44 (s) 3H, 2 × OAc; 2.97 (m) 4H, 3.77 (m) 2H, 4.45 (br.m) 2H; 3.88 (s) 3H, 3.94 (s) 3H, and 3.96 (s) 3H, 3 × OMe; 6.8–7.7, 9H see text for analysis.

Anal. Calcd. for $C_{42}H_{38}N_2O_9 \cdot \frac{1}{2}H_2O$ (mol. wt. 714.258): C, 69.69; H, 5.43; N, 3.87. Found (714.255 (h.r.m.s.)): C, 69.73; H, 5.73; N, 4.16.

The aqueous phase after chloroform extraction was basified with 10% sodium hydroxide and the mixture distilled in a slow current of nitrogen into dilute hydrochloric acid. The distillate was evaporated to dryness and the residue dissolved in a small volume of water and added to a solution of gold chloride in 2 *N* hydrochloric acid. Yellow crystals (18 mg) separated out m.p. 143° (lit. 145–146° (15)).

Anal. Calcd. for $C_3H_{10}ONAuCl_4$: C, 8.69; H, 2.43; N, 3.38. Found: C, 8.78, 8.76; H, 2.11, 2.30; N, 3.43, 3.78.

Hydrolysis and Methylation of ***3***

Compound **3** (58 mg) and potassium hydroxide (1.5 g) were refluxed for 4.5 h with methanol–*n*-butanol (30 ml, 2:1). The solution was saturated with carbon dioxide and the solvent removed *in vacuo*. Water was added and the mixture extracted with dichloromethane. The latter extract was treated with excess ethereal diazomethane at room temperature for 2 days and a fresh batch of ethereal diazomethane added and the mixture allowed to stand again for 4 days. The solvents were removed and the product purified by chromatography on silica gel (benzene–acetone, 17:3), and crystallized from ethanol–ligroin, m.p. 216–218° (18 mg). The u.v. spectrum: λ_{max} (EtOH) 247, 310, 323, 368, 392, and 405–415 nm; log ε_{max} 4.90, 4.97, 5.07, 4.24, 4.32, and 4.28 respectively. The i.r. spectrum: no absorption between 1600 and 1800 cm^{-1}. The p.m.r. spectrum: 2.94 (t), 2H and 4.20 (t), 2H ($J_{AX} = 6.0$ Hz), $-CH_2-CH_2-$; 3.77 (s) 3H, 3.82 (s) 3H, 3.86 (s) 3H, 3.88 (s) 3H, and 3.96 (s) 3H, 5 × OMe; 6.6–7.6 (9H aromatic), and 10.26 (s) 1H.

Mol. Wt. Calcd. for $C_{35}H_{29}NO_6$: 559.199. Found (h.r.m.s.): 559.197.

*2-Hydrazino-9,10-dihydrophenanthrene (****20****)*

An ice-cold, magnetically stirred suspension of 2-amino-9,10-dihydrophenanthrene hydrochloride (16) (5.172 g) in aqueous hydrochloric acid (40 ml, 20%) was diazotized by the dropwise addition of aqueous sodium nitrite (1.7 g in 3.5 ml). The stirring was continued for 1 h and a small amount of urea added to decompose the excess nitrous acid (until negative to starch-iodide paper). The yellow solution of the resulting diazonium salt was treated in the cold (−5 to 0°) with a solution of stannous chloride ($SnCl_2 \cdot 2H_2O$ 10.3 g) in the minimum quantity of concentrated hydrochloric acid and the stirring continued for 2 h. The precipitated hydrochloride of **20** was filtered, washed with cold water, and crystallized from ethanol–ether, m.p. 218–220°.

Anal. Calcd. for $C_{14}H_{15}N_2Cl$: C, 68.14; H, 6.13. Found: C, 68.13; H, 6.00.

The hydrochloride was treated with 10% aqueous sodium hydroxide and the solution extracted with benzene. The benzene extracts were dried (NaOH) and the solvent removed to yield a red-brown solid (4.50 g).

Preparation of ***17***

To a suspension of the hydrazine **20** (601 mg) in absolute ethanol (10 ml) there was added the dihydrodibenzoxepinone **21** (17) (560 mg) in absolute ethanol (5 ml) and glacial acetic acid (1 ml). The mixture was heated on a steam bath for 10–15 min and the solvent was then removed under reduced pressure. The hydrazone so obtained was dissolved in 1-butanol (10 ml) and the solution was heated to reflux for 20 min while hydrogen chloride gas was bubbled through the mixture. The deposition of ammonium chloride indicated the progress of the reaction. The mixture was washed twice with water, made basic with ammonium hydroxide, rinsed again with water, dried ($MgSO_4$), and evaporated to yield crude **23** (1.182 g). Purification was effected on a silica gel column using benzene–petroleum ether (60°) (1:1) as eluant affording pure **23** (523 mg), crystallized from methanol, m.p. 278–280°.

The pure indole **23** (62 mg) with Pd/C (40 mg of 5%) in naphthalene (720 mg) was heated under dry nitrogen at 220–230° for 3 h. The cold mixture was then dissolved in acetone, filtered, and evaporated. The excess of naphthalene was sublimed off under vacuum to leave crude **17**. Purification of the residue by chromatography on a silica gel plate developed with benzene–petroleum ether (2:1) afforded pure **17** (51 mg), crystallized from ethanol–ether, m.p. 198–200°. The u.v. spectrum: λ_{max} (EtOH) 234, 241(sh), 283(sh), 303(sh), 313, 343, 359, 371, and 391(sh) nm; log ε_{max} 4.47, 4.44, 4.44, 4.57, 4.69, 3.94, 4.06, 4.08, and 3.96, respectively.

Mol. Wt. Calcd. for $C_{28}H_{17}NO$: 383.131. Found: (h.r.m.s.) 383.129.

*2-Hydrazinophenanthrene (****25****)*

2-Aminophenanthrene (18) (993 mg) was converted to 2-hydrazinophenanthrene (900 mg) by the same procedure as that employed in the preparation of **20**; M.p. of hydrochloride (from methanol) 176–178°.

Anal. Calcd. for $C_{14}H_{13}N_2Cl$: C, 68.71; H, 5.35; N, 11.45. Found: C, 68.45; H, 4.99; N, 11.63.

Preparation of ***18***

The hydrazine **25** (293 mg) was treated with the dihydrodibenzoxepinone (**21**) (284 mg) in the manner described above to yield the hydrazone **26** which was subjected to the Fischer-indole conditions as before to yield **18** (348 mg). The product was purified by preparative t.l.c. on silica gel (benzene–ligroin, 3:1), crystallized from methanol, and recrystallized from benzene m.p. 260–262°.

The u.v. spectrum: λ_{max} (EtOH) 235, 243, 284, 292(sh), 336(sh), 352 and 369 nm; log ε_{max} 4.56, 4.55, 4.67, 4.65, 4.21, 4.33 and 4.32, respectively.

Mol. Wt. Calcd. for $C_{28}H_{17}NO$: 383.131. Found (h.r.m.s.): 383.133.

Preparation of ***29***

The procedure was identical to that employed in the preparation of **17**. Thus 2-hydrazino-9,10-dihydrophenanthrene **20**, (100 mg) was treated with desoxybenzoin **31** (52 mg) to yield the hydrazone which was subjected to the Fischer-indole process to give the corresponding indole (67 mg) which was dehydrogenated as before to **29** (56 mg). The product was purified by preparative t.l.c. (silica gel, benzene–ligroin, 3:1) and crystallized once from ethanol and then twice from ligroin. M.p. 224–225°. The u.v. spectrum: λ_{max} (EtOH) 234, 281(sh), 309, 347(sh), 361, and 380 nm; log ε_{max} 4.63, 4.63, 4.91, 4.15, 4.28, and 4.25 respectively.

The molecular formula was determined by h.r.m.s.

Mol. Wt. Calcd. for $C_{28}H_{19}N$: 369.152. Found (h.r.m.s.): 369.154.

Preparation of ***30***

The procedure was identical to that employed in the preparation of **18**. Thus, 2-hydrazinophenanthrene, **25** (116 mg) was treated with desoxybenzoin, **31** (109 mg) to yield the hydrazone which was subjected to the Fischer-indole process to give the indole **30** (169 mg). The product was purified by preparative t.l.c. (silica gel, benzene–ligroin, 3:1) and crystallized from ethanol–ligroin, M.p. 184–186°.

The u.v. spectrum: λ_{max} (EtOH) 241, 269(sh), 281, 291(sh), 341, 350, and 370 nm; log ε_{max} 4.62, 4.68, 4.73, 4.68, 4.39, 4.37, and 4.33 respectively.

Mol. Wt. Calcd. for $C_{28}H_{19}N$: 369.152. Found (h.r.m.s.): 369.153.

Appendix

Systematic names for the ring systems prepared in the study are as follows:

3 (**4**): 9,10-dihydrobenzo[2,3][1]benzoxepino-[6,5,4-*ghi*] phenanthro[3,2,-*b*]indolizine;

17: 10*H*-dibenz[2,3:6,7]oxepino[4,5-*b*]naphth-[1,2-*f*]indole;

18: 7 *H*-dibenz[2,3,:6,7]oxepino[4,5-*b*]naphth-[2,1-*e*]indole;

29: 8*H*-naphth[1,2-*f*]indole;

30: 7*H*-naphth[2,1-*e*]indole.

The names of **3**, (**4**), **17**, and **18** were kindly provided by Dr. Kurt L. Loening, Director of Nomenclature, Chemical Abstracts Service, Columbus, Ohio.

The systematic names were not used in the text because comparison of corresponding protons of ring systems with different numbering might be confusing to the reader.

We wish to thank the National Research Council of Canada for financial support.

Ruthenium and Arsenic Electrode Potentials in Fused LiCl–KCl Eutectic

T. FOLKMAN AND JAMES A. PLAMBECK

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 1, 1972

Electrode potentials of the Ru(III)/Ru(0) and As(III)/As(0) systems were measured in dilute solutions of the ionic species in fused LiCl–KCl eutectic at 450 °C. Standard molar electrode potentials of these couples of -0.107 ± 0.007 V and -0.460 ± 0.017 V against a standard molar platinum electrode were calculated. The As(V)/As(III) potential was found to be beyond the potential range of the melt.

Les potentiels électrochimiques des systèmes Ru(III)/Ru(0) et As(III)/As(0) ont été mesurés à 450 °C en solutions diluées des ions dans l'eutectique LiCl–KCl fondu. Les potentiels normaux molaires, par rapport au potentiel de l'electrode de platine normale à l'échelle molaire, ont été calculés à -0.107 ± 0.007 V et -0.460 ± 0.017 V. Le potentiel electrochimique du système As(V)/As(III) se trouve outre le domaine des potentiels utilisables du mélange fondu LiCl–KCl.

Canadian Journal of Chemistry, **50**, 3911 (1972)

Introduction

The oxidation states and potentials of most metals have been established in one of the fused halide systems, but arsenic and ruthenium have not yet been extensively studied. No data exist regarding the behavior of arsenic in fused alkali halides. Fung and Johnson (1) studied Ru(III) in the fused LiCl–KCl melt spectrophotometrically and reported a stable $RuCl_6^{3-}$ species in the melt. They report the Ru(III) species to be electrochemically inactive. Spectral measurements on Ru(III) have also been made in this solvent by Suzuki and Tanaka (2), who confirm the species as $RuCl_6^{3-}$.

In this work we report standard potentials of the As(III)/As(0) and Ru(III)/Ru(0) couples in a form compatible with an extensive review of redox potentials in this melt (3).

Experimental

Apparatus

Potentials were measured with a Model 3440A digital voltmeter (Hewlett–Packard) and metal ions were generated using a Model IV coulometric current source (E. H. Sargent and Co.).

The electrolytic cell and glassware preparation procedure used has been previously described (4). The outer glass jacket was heated with a vertical tube furnace equipped with a 59344 Lindberg-Hevi-Duty temperature controller. The temperatures were recorded using a calibrated chromel–alumel thermocouple and the above digital voltmeter.

Solvent

The solvent used was prepared from certified reagent grade LiCl (Fisher Scientific Co.) and KCl (J. T. Baker Chem. Co.) made up as the LiCl 59 mole%–KCl 41 mole% eutectic. The method of purification used was that of Maricle and Hume (5).

Electrodes

For the reduction of Ru(III), purified ruthenium chloride, $RuCl_3 \cdot xH_2O$ (Fisher Scientific Co.) was used. For the oxidation of arsenic, 99.999 + % pieces (lot #08058, Alfa Inorganics, Inc.) connected to a gold wire were used. Gold was used in both cases because arsenic and ruthenium do not alloy with it at these temperatures (6).

Counter electrodes used in coulometric generation were 0.120 × 12 in. carbon rods (AGKSP spectrographic graphite electrodes, National Carbon Co. Div. of Union Carbide) connected to copper leads inside the furnace but above the melt. Standard potential measurements were made against a Pt(II)/Pt electrode (4). All electrodes were dried before entering the melt and each was kept in a separate fritted-glass compartment.

Procedure

The cell was maintained under a slight positive pressure of dry argon to prevent contamination by water vapor. The procedure for arsenic was similar to that described previously for rhodium (4) with additional precautions due to the toxicity of $AsCl_3$. The procedure for ruthenium differed; a weighed amount of $RuCl_3 \cdot xH_2O$ was added to the solvent and Ru(III) plated cathodically on a gold wire. Stable potentials were obtained within a few minutes after cessation of the current and agitation of the electrode to stir the contents of the compartment. This procedure, which is less satisfactory than anodic oxidation, was necessary due to the authors' inability to obtain proper coherent metallic ruthenium.

The potentials reported in this paper are with reference to the Pt(II) (1.0 *M*), LiCl–KCl/Pt standard molar platinum electrode (s.m.p.e.) of Laitinen and Liu (7) and the calculations were as outlined in that paper. They conform to the I.U.P.A.C. "Stockholm" sign convention.

Results and Discussion

Arsenic (III)/Arsenic(0) Couple

A total of 13 concentration–potential data points were taken at 450 ± 4 °C in two separate experiments. Stable potentials were not obtained at concentrations of As(III) lower than about 1×10^{-3} *M*. At concentrations above 1×10^{-2} *M*, bubbles of $AsCl_3$ became noticeable and continuous negative drifting of the potentials was observed. For the points in the concentration range 10^{-3} to 10^{-2} *M*, the slope of a Nernst plot corresponded to 3.1 electrons. Using a three-electron slope and each individual point, the mean standard potential (molarity scale) of the As(III)/As(0) couple was calculated to be -0.460, standard deviation ± 0.017 V, with respect to the s.m.p.e. This corresponds to values of -0.465 and -0.495 V, with the same standard deviation, on the molal and mole fraction scales, respectively.

Attempts to further oxidize As(III) by replacing the arsenic metal in the compartment with a carbon rod and continuing anodization were unsuccessful; chlorine evolution occurred. This indicates that the As(V)/As(III) potential is beyond the range of the melt. An attempt to cathodize arsenic into solution was also unsuccessful.

There are no literature data with which the arsenic potential measured here is directly comparable, but the standard potentials of the analogous antimony and bismuth couples (7–9) are both -0.635 V on the same scale. A value for arsenic some 150 mV more positive is reasonable.

Ruthenium(III)/Ruthenium(0) Couple

In four separate experiments, a weighed amount of the solid ruthenium trichloride was added to a compartment in the melt, a gold wire was inserted, and ruthenium metal cathodically deposited on the gold using the coulometer. An adherent dark plate, which became silver-shiny after polishing, was obtained. Stable potentials were always obtained a few minutes after completion of the deposition and stirring with Ru(III) concentrations greater than 1×10^{-3} *M*, and a total of 27 such measurements were made.

The ruthenium content of the compartments was analyzed by the method of Ayres and Young (10). Analysis of the ruthenium chloride by the method of Gilchrist and Wichers (11) showed that it contained three to four waters of hydration which were not removable by evacuation or by treatment with HCl gas, and a significant fraction of the ruthenium was not platable, remaining in the compartment as black insoluble material, presumably an oxide or mixed oxide chloride. After correction for this loss, the standard electrode potential of the Ru(III)/Ru(0) couple was calculated as -0.1065, standard deviation ± 0.0067 V against s.m.p.e. In view of the approximate three-electron Nernst slope obtained in these runs, especially those in which the amount of added $RuCl_3$ (and hence water) was comparatively low, it is felt that a value of -0.107 ± 0.007 V against s.m.p.e. is realistic for this couple. This corresponds to values of -0.112 and -0.142 V, with the same standard deviation, on the molal and mole fraction scales, respectively.

The authors are grateful to the National Research Council of Canada for support of this work by an Operating Grant. This work is taken in part from a report of T. Folkman, submitted in partial fulfillment of the requirements for a B.Sc. Honours degree, University of Alberta. The authors are indebted to J. T. Chapman for preliminary studies of ruthenium.

P.M.R. Spectroscopy of Trimethylsilyl Derivatives of Hydroxy Acids

GUY GORDON STUDDY DUTTON, NORMAN FUNNELL AND KELLY BLAIR GIBNEY[1]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 24, 1972

P.m.r. spectroscopy at 60 MHz of trimethylsilyl ethers and esters, prepared from hydroxy acids, gives well resolved sharp singlets in the range τ 9.8–9.9. These signals may be used to determine the ratio of hydroxyl to carboxyl groups in a molecule. Measurements may be made directly on fractions isolated by gas–liquid chromatography. The influence of the solvent on the resolution is demonstrated.

La spectroscopie r.m.n. (60 MHz) des éthers et esters triméthylsilyl, derivés des acides hydroxylés, donne des pics bien résolus (τ 9.8–9.9). On peut utiliser ces signaux pour déterminer le rapport entre les groupements hydroxyles et carboxyles dans une molécule. On peut faire les mesures directement sur les fractions isolées par chromatographie en phase gaseuse. L'influence du solvant sur la résolution des pics est démontrée.

Trimethylsilyl derivatives have been prepared from many different types of compounds and the silylation reaction has been reviewed (1). These derivatives are commonly prepared mainly for the purpose of separations by gas–liquid chromatography and also for mass spectrometry (1). In contrast to the wealth of literature available on these two applications of trimethylsilyl derivatives much less has been reported on the physical properties of such compounds and, in particular, their uses in p.m.r. spectroscopy.

We have shown recently that the protons of the $—OSi(CH_3)_3$ group in trimethylsilyl ethers give a sharp singlet in the range τ 9.8 and that non-equivalent ethers have distinct chemical shifts (2). Thus, the trimethylsilyl ether of glycerol gives two such singlets (integral ratio 1:2), and the derivatives of methyl α-D-galactopyranoside and of α-D-glucopyranose give four and five well resolved signals of equal magnitude, respectively. Carboxylic acids readily form trimethylsilyl esters and thus hydroxy acids give derivatives which are both trimethylsilyl ethers and esters. The present note shows how p.m.r. spectroscopy of these derivatives may be used to determine the relative numbers of carboxyl and hydroxyl groups per molecule and, in certain cases, the absolute number.

Trimethylsilyl (TMS) derivatives were prepared by reaction of the hydroxy acid in pyridine with hexamethyldisilazane (HMDS) alone or with the addition of chlorotrimethylsilane. Figure 1 shows the p.m.r. spectrum (60 MHz) in carbon tetrachloride of the derivative of citric acid ($HOOC—CH_2—C(OH)(COOH)—CH_2-COOH$) which forms a triester (TMS ester) monoether (TMS ether). Figure 1 utilizes two scales: the signals due to the TMS esters and ethers are shown in Hz downfield from tetramethylsilane (TMS), which was used as internal standard, while those due to the methylene protons are shown on the τ scale (TMS, τ 10). The former were obtained at a sweep width of

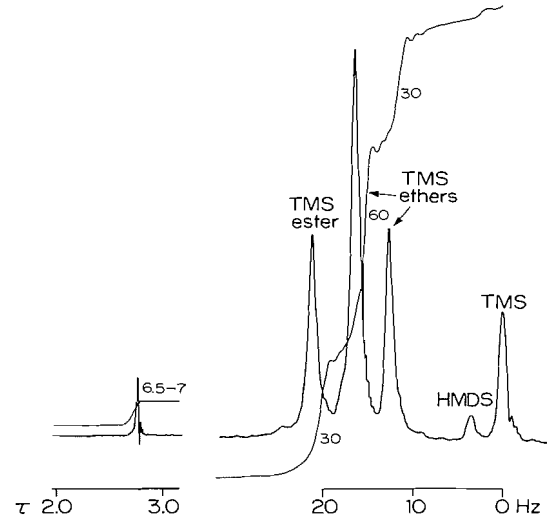

FIG. 2. Gallic acid. P.m.r. spectrum at 60 MHz, as Fig. 1.

100 Hz and the latter at 500 Hz. A small peak due to residual hexamethyldisilazane is also visible. The expanded scale clearly shows that hydroxyl and carboxyl groups are present in the ratio of 1:3. When the spectrum is run at a sweep width of 500 Hz the TMS ether and TMS ester signals are not clearly resolved but are sufficiently well separated from the hexamethyldisilazane and internal standard signals to permit integration and thus comparison with the integral due to the methylene protons. Values of 86:9 (arbitrary units) were obtained in this manner; in Fig. 1 the methylene integral has been increased proportionately to accord with the expanded scale. Figure 2 represents the spectrum, similarly presented, for gallic acid (3,4,5-trihydroxybenzoic acid). Table 1 shows the other compounds studied and gives, in Hz downfield from tetramethylsilane, the chemical shifts of the TMS ether and TMS ester peaks.

In certain cases the resolution of the trimethylsilyl ether signals was better in benzene than in carbon tetrachloride (2) and the effect of solvent was therefore studied for the derivatives of hydroxy acids. To illustrate this Fig. 3 shows the high field portion of the spectra, obtained in different solvents, of the derivative of malic acid. In benzene (Fig. 3*A*) all three signals, although resolved, have similar chemical shifts and in pyridine (Fig. 3*B*), the TMS ester

TABLE 1. Chemical shifts of trimethylsilyl ethers and esters

Acid	Chemical shift (Hz)* TMS ether	TMS ester	Solvent
Malonic	—	20.0	pyr.
Succinic	—	17.0	pyr.

*Hz downfield from internal tetramethylsilane (60 MHz).

signals are barely distinguished. In chloroform (Fig. 3*C*) the signal due to the TMS ether is well separated from those of the esters but these, in turn, are poorly resolved. Of the solvents studied carbon tetrachloride (Fig. 3*D*) appears to give the best results. The change in chemical shift of the HMDS signal in the different solvents may also be seen.

It should be noted that these spectra were all obtained at 60 MHz. When working with compounds containing only hydroxyl groups, *e.g.* carbohydrates, it was necessary to run spectra at 100 MHz in order to resolve the four or five TMS ether signals obtained (2).

When a hydroxyl or a carboxyl group is converted to the corresponding trimethylsilyl derivative one proton is effectively replaced by nine protons. The advantage of this in behaving as a built-in signal multiplier and thus permitting p.m.r. spectra to be obtained on small quantities of material, such as individual fractions isolated by gas–liquid chromatography, has been previously illustrated and discussed and is not here repeated (2). The choice of compounds used in this note was influenced by the fact that acids of the tricarboxylic acid cycle have been separated by g.l.c. of their trimethylsilyl derivatives (3–5) and difficulty has been reported in achieving complete silylation of aromatic hydroxy acids (ref. 1, p. 161). The method is clearly extendable, as an aid in structural elucidations and particularly where separations are made by g.l.c. to other naturally occurring hydroxy acids or such acids obtained in degradation studies, for example, urinary acids (6) and alkaline degradation products of flavonoids

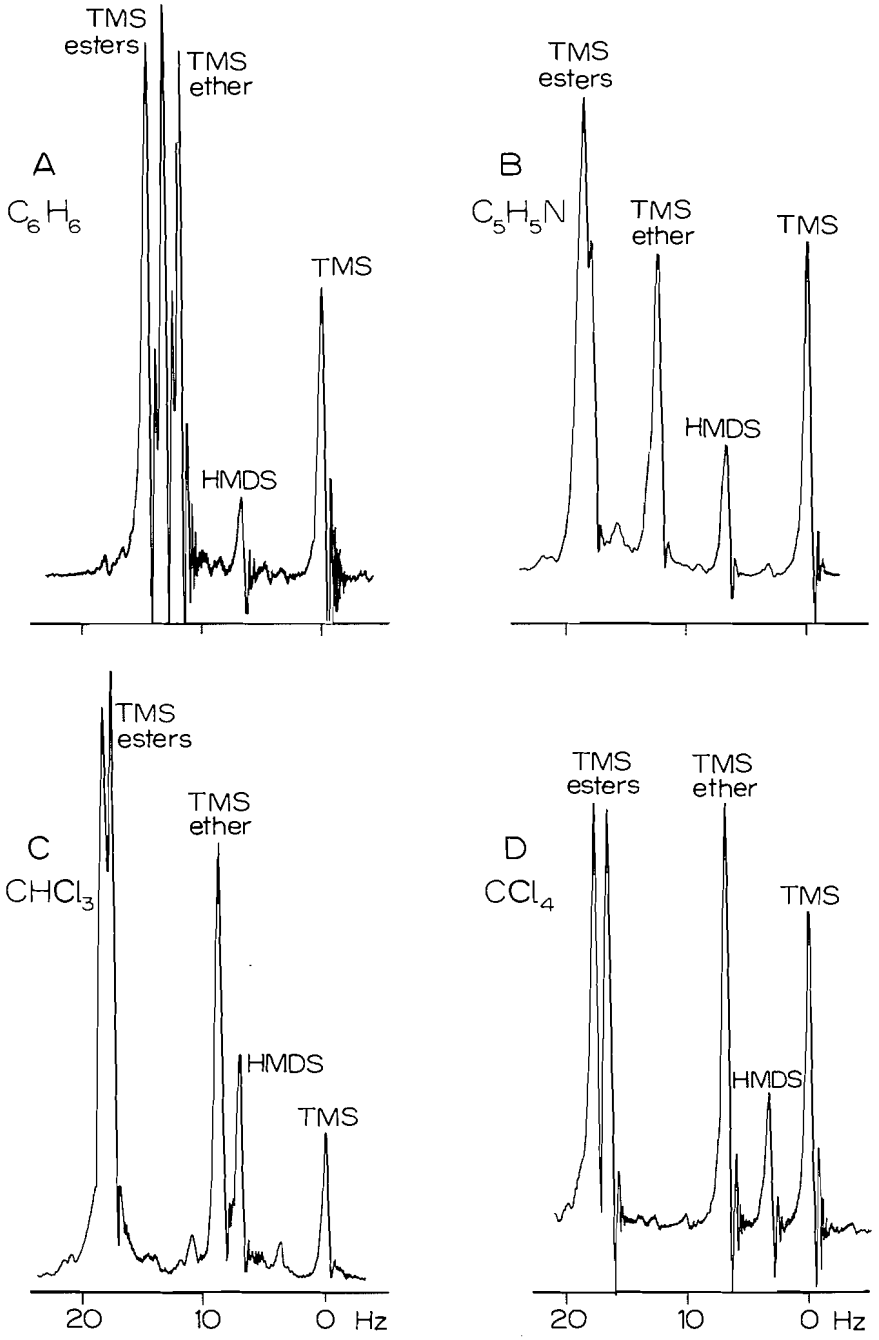

FIG. 3. Malic acid. P.m.r. spectra at 60 MHz in *A*, benzene; *B*, pyridine; *C*, chloroform; *D*, carbon tetrachloride. High field portion only shown (as Fig. 1).

(7). Measurement of the TMS ester and TMS ether signals affords a convenient check on the completeness of trimethylsilylation of hydroxy acids and the former signal may also be used as a means of following the kinetics of hydrolysis of such esters.

Experimental

Trimethylsilylation

The acid (10–50 mg) was dissolved in pyridine (1 ml); for some acids this required several hours of warming at 45°. When solution was complete hexamethyldisilazane (1 ml) was added and the solution was heated at 45° for a further 1–2 h. These conditions gave fully trimethylsilylated derivatives for all the acids used in the present study except for gallic and citric acids. For these compounds chlorotrimethylsilane (0.1 ml) was added in addition to the hexamethyldisilazane and the solution was heated under reflux and protected from moisture for 1 h. Solvents and excess reagents were removed *in vacuo* by an oil pump. Evaporation using a water aspirator gave variable results for the TMS ester signals due, presumably, to hydrolysis. The residual syrups were dissolved in the solvents indicated for p.m.r. measurements.

P.m.r. Spectroscopy

Spectra were obtained on a Varian T60 instrument using a sweep width of 500 Hz. The high field portion was re-run at a sweep width of 100 Hz. Tetramethylsilane (TMS) was used as an internal standard (τ, 10).

We thank Phyllis Watson for running the spectra and Beatrix Krizsan for the drawings. The continued financial support of the National Research Council of Canada and the award of an NRCC scholarship to N.F. are gratefully acknowledged.

Location of Energy Barriers. V. Scaling the Energy-Surface for AB + CD → AC + BD

D. S. PERRY AND J. C. POLANYI

Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received July 19, 1972

In order to make use of the sliding-mass analogy for AB + CD four-center exchange reactions it is necessary to know how to scale the "diagnostic" potential-energy surface. This note describes the method of scaling, and exemplifies it for the case of $H_2 + I_2$.

Afin de pouvoir utiliser l'analogie de la masse glissante pour les réactions d'échange à quatre centres de type AB + CD, on doit savoir graduer la surface "diagnostique" d'énergie potentielle. Cette communication décrit la méthode de graduation et donne l'exemple dans le cas de $H_2 + I_2$.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3916 (1972)

The dynamics of four-center exchange reactions AB + CD → AC + BD continue to be the subject of considerable experimental and theoretical interest (for a review, see ref. 1). Three classical trajectory calculations have been reported (2–4); another is being readied for publication (5). In trajectory studies of three-atom exchange reactions, A + BC → AB + C, the analogue of the sliding mass on a scaled and skewed surface has assisted notably in the interpretation of the findings.[1] The path of the sliding mass can be pictured, hence the solution of the equations of motion for collinear reaction can often be rationalized. As a predictive device the method must be used with caution. Its success depends upon the extent to which a collinear (1D) trajectory can be regarded as being representative of the outcome of a statis-

Canadian Journal of Chemistry, **50**, 3916 (1972)

The dynamics of four-center exchange reactions AB + CD → AC + BD continue to be the subject of considerable experimental and theoretical interest (for a review, see ref. 1). Three classical trajectory calculations have been reported (2–4); another is being readied for publication (5). In trajectory studies of three-atom exchange reactions, A + BC → AB + C, the analogue of the sliding mass on a scaled and skewed surface has assisted notably in the interpretation of the findings.[1] The path of the sliding mass can be pictured, hence the solution of the equations of motion for collinear reaction can often be rationalized. As a predictive device the method must be used with caution. Its success depends upon the extent to which a collinear (1D) trajectory can be regarded as being representative of the outcome of a statis-

[1]For a description of the scaling and skewing appropriate to collinear reaction A + BC → AB + C, see ref. 6.

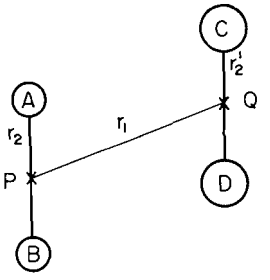

FIG. 1. Coordinate system.

tical group of trajectories in 3D. Most of the trajectory work up to the present has been concerned with potential-energy hypersurfaces that to some degree favor collinear reaction (for a review, see ref. 7). For potential-energy surfaces of this type the collinear surface constitutes a useful "diagnostic" cut through the hypersurface (for a review, see ref. 8).

In a 3D trajectory study of the effect on the dynamics of reactions $AB + CD \rightarrow AC + BD$ of changes in barrier location, it has been found that the potential-energy surface for coplanar rectangular reaction constitutes an instructive diagnostic-cut through the full hypersurface $U(r_{AB},r_{AC},r_{AD},r_{BC},r_{BD},r_{CD})$. It is important to bear in mind, however, that the diagnostic cut in this case gives a still more restricted view of the hypersurface than for the three-center reaction (3).

Consider the coplanar collision of AB + CD in Fig. 1; P and Q are the centers-of-mass of AB and CD. The reagents approach along r_1 and the products separate along $r_2(=r_2')$. The kinetic energy can be written

$$[1] \qquad T = T_{AB} + T_{CD} + T_{AB,CD} = \tfrac{1}{2}(\mu_{AB}\dot{r}_2^2 + \mu_{CD}\dot{r}_2^2 + \mu_{AB,CD}\dot{r}_1^2)$$

where

$$\mu_{AB} = \frac{m_A m_B}{m_A + m_B}$$

$$\mu_{CD} = \frac{m_C m_D}{m_C + m_D}$$

$$\mu_{AB,CD} = \frac{(m_A + m_B)(m_C + m_D)}{m_A + m_B + m_C + m_D}$$

We wish to make an analogy with a sliding mass, whose kinetic energy is

$$[2] \qquad T = \tfrac{1}{2}(\dot{x}^2 + \dot{y}^2)$$

The transformation of coordinates is therefore given by

$$[3] \qquad \begin{pmatrix} r_1 \\ r_2 \end{pmatrix} = \begin{pmatrix} \left(\dfrac{(m_A + m_B)(m_C + m_D)}{m_A + m_B + m_C + m_D}\right)^{-1/2} & 0 \\ 0 & \left(\dfrac{m_A m_B}{m_A + m_B} + \dfrac{m_C m_D}{m_C + m_D}\right)^{-1/2} \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}$$

$$[4] \qquad = \begin{pmatrix} b & 0 \\ 0 & a \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}$$

where a and b are mass-dependent constants. Since r_1 depends only on x, and r_2 on y the Cartesian coordinates, x and y, already provide a "diagonalized" representation of $T(r_1,r_2)$. This result merely constitutes a particular example of a general principle due to Jepsen and Hirschfelder (9),[2] namely that any coordinate system, for n particles, which is analogous to a dangling "mobile" will have the property of expressing the relative kinetic energy without cross-terms.

[2]Their diagonalization applies to motion in 3D.

The constants b and a in eq. 4 correspond to the "scaling factors" required in order that the motion of a sliding mass $T(x,y)$ (eq. 2) shall represent $T(r_1,r_2)$ (eq. 1). The significant parameter is the scaling ratio, $S = b/a$. If $S > 1$ then the exit valley of the energy-surface (along r_1) must be plotted on a larger scale, *i.e.* it must be stretched relative to the entry valley. If $S < 1$ the converse distortion must be applied. It is evident that for the equal-mass case, for example $H_2 + H_2$ studied in ref. 2, $S = 1$. The saddle point configuration for this reaction was square, that is to say it was located symmetrically on the

$r_1 = r_2$ diagonal of the coplanar rectangular cut through the potential-energy hypersurface.

Barrier-location has an important bearing on the relative effectiveness of reagent translation and vibration in carrying the system over an energy-barrier; barriers with their crests in the approach coordinate are most-effectively surmounted if the reagents are translationally-excited, conversely barriers with their crests in the retreat coordinate are best surmounted if the reagents have vibration (10, 11). These generalizations regarding the effect of barrier-location are best applied to the location of the barrier on a scale diagnostic energy-surface (11).

It is evident from the preceding discussion that the surface for $H_2 + H_2$ needs no scaling ($S = 1$), consequently the symmetrical location of the barrier-crest, mid-way between the approach and retreat coordinates, leads to the expectation that both reagent translation and reagent vibration will be effective in bringing about reaction. The 3D trajectory calculations of Morokuma *et al.* (2) showed that this was the case.[3]

The effects of "early" and "late" energy-barriers (characterized as "surface I" and "surface II", respectively) have been explored in a 3D trajectory study of hypothetical reactions $AB + CD \rightarrow AC + BD$ (3). The diagnostic surface was the potential-energy surface for reaction through coplanar rectangular configurations. Specimen coplanar trajectories, computed numerically for the equal-mass case, were shown superimposed on the diagnostic energy surfaces I and II (Fig. 2 of ref. 3). Despite the lack of skewing or scaling, the trajectories could be understood, *qualitatively*, in terms of the path expected for a sliding point-mass. In fact the unskewed unscaled surface, as has been shown here, is the surface that causes the sliding mass to mimic the motions involved in coplanar rectangular reaction, $AB + CD \rightarrow AC + BD$.

It should be noted that the sliding-mass analogy for $AB + CD$ was developed here on the assumption that $r_{AB} = r_{CD}$ and $r_{AC} = r_{BD}$ throughout the course of the reactive encounter. In reality the vibration of AB and CD may be out of phase, and so may that of AC and BD; the configuration of the four atoms could deviate from a parallelogram for this reason (if not for others). This did occur in the trajectories recorded in Fig. 2 of ref. 3 (the mean of r_{AB},r_{CD} and the mean of r_{AC},r_{BD} was plotted). Nonetheless the sliding mass analogy retained its value as a qualitative guide to the behavior of the reacting system.

It is important to consider the effect of changing mass-combination on the barrier location. A barrier that is symmetrically-placed on the unscaled surface could be rendered significantly asymmetric on the scaled surface. For reactions $A + BC \rightarrow AB + C$ the two extremes of scaling were achieved for $L + HH$ (L symbolizes a light atom, H a heavy atom), and $H + HL$. The former gave $S \gg 1$ (extended exit valley), the latter $S \ll 1$ (extended entry valley). The corresponding mass-combinations for the exchange reaction $AB + CD \rightarrow AC + BD$ are (eq. 3) $LL + HH$ and $HL + HL$. If $L = 1$ a.m.u., $H = 80$ a.m.u., then $LL + HH$ has $S = 4.5$, $HL + HL$ has $S = 0.22$. (By contrast the other two possible combinations of these atomic masses have for $LL + HL$, $S = 1.2$, and for $HH + HL$, $S = 0.9$.)

It may be significant that the most extreme scaling should apply to the mass combinations appropriate to the celebrated reaction $H_2 + I_2 \rightarrow 2HI$ and its reverse. Noyes (13) has suggested that for the $H_2 + I_2$ reaction H_2 may approach so rapidly that the iodine atoms have insufficient time to separate as r_1 decreases. Trajectory calculations indicate the existence of special behavior due to a kinematic effect (termed the "light atom anomaly") when atomic hydrogen collides with molecular halogens; this has been interpreted as being due to the approach of H before the halogen atoms can separate (14). In the case of $H_2 + I_2$, for which there is a substantial energy-barrier, Noyes suggested that the rapid approach of H_2 might allow too little time for an interaction to occur that could lead to reaction. Reagent vibration, it was felt, would also fail to give rise to bimolecular exchange; instead it would dissociate I_2 (13).

Consideration of the probable path of a sliding mass on an appropriately scaled surface could perhaps shed some light on the effects postulated by Noyes. It should be pointed out, however, that our previous success in using the

[3]For recent, novel, experiments indicative of a requirement for vibrational excitation in the reaction $H_2 + D_2$, see ref. 12.

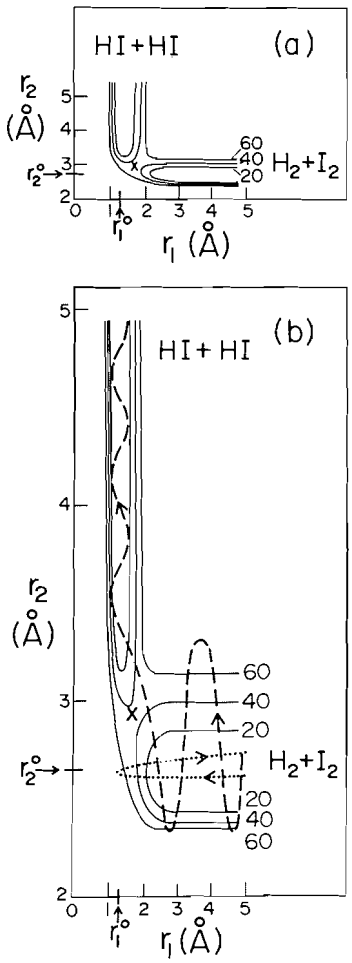

FIG. 2. (*a*) A planar rectangular (or trapezoidal) "cut" through the H_2I_2 potential-energy hypersurface obtained by Raff *et al.* (15). The contours are in kcal mol^{-1}, × is the location of the barrier crest. (*b*) The same surface drawn with scaling appropriate to the $H_2 + I_2$ mass combination. The dashed line is a hypothetical coplanar rectangular reactive trajectory with the reagent energy present as vibration. The dotted line indicates schematically the contrasting non-reactive case, in which the reagent energy is present as translation.

coplanar rectangular cut through the potential-energy surface for AB + CD as a diagnostic device was for a case (3) in which the equilibrium internuclear separations were identical ($r_1^0 = (r_1^0)'$; $r_2^0 = (r_2^0)'$), the normal force constants in the two bonds were the same ($f_1^0 = (f_1^0)'$; $f_2^0 = (f_2^0)'$), and there was no reagent rotation (the effect of reagent rotation was examined only for the case A + BC (11)). In the case of $H_2 + I_2$ reaction these restrictions will not apply.

Figure 2(*a*) shows the semi-empirical potential-energy surface obtained by Raff *et al.* for the $H_2 + I_2$ reaction (15).[4] The crest of the 42 kcal mol^{-1} energy barrier is almost symmetrically located along the reaction coordinate, since the extension in the bonds being formed and those being broken is very similar; $r_1^{\ddagger} - r_1^0 = 0.4$ Å and $r_2^{\ddagger} - r_2^0 = 0.3$ Å. Figure 2 shows the effect of applying the appropriate scaling factor, $S = 5.7$, to this $H_2 + I_2$ surface. The crest of the barrier is shifted significantly into the exit valley to give $(r_2^{\ddagger} - r_2^0)_S/(r_1^{\ddagger} - r_1^0)_S \sim 4$ (the subscript S indicates that these are *distances* measured along the scaled surface).

On the basis of our earlier model studies (3) using the mass-combinations $LL + LL$ and $LL + HH$ ($L = 1$ a.m.u., $H = 35$ a.m.u., corresponding to hydrogen and chlorine) we would anticipate (*a*) that the reactive cross-section would be detectable ($\gtrsim 0.1$ Å^2) only when the reagent energy significantly exceeded the barrier height, (*b*) that reagent vibration would be essential for barrier-crossing in the reaction $H_2 + I_2 \rightarrow 2HI$, and, by contrast, reagent translation for the reverse reaction. In each case the "disfavored" degree of freedom (translation in the former case, vibration in the latter) would further enhance the cross-section, provided that the essential threshold energy of the favored degree of freedom was present.

The first of these anticipations is based on the fact that for *both the mass-combinations* used in the model calculations on AB + CD, on both types of surface, a reagent energy of almost double the classical barrier height was required in order to obtain significant reaction. A further (25%) reduction in cross-section was noted for the unequal mass case $LL + HH$ compared with the equal mass case $LL + LL$. The latter reduction in cross-section has also been observed for the case of three-atom exchange reaction $L + HH$, as compared with $H + HL$ (11) and $H + LH$ (16). This mass-dependant reduction in cross-section is probably con-

[4]The coordinate r_1 in ref. 15 and Fig. 2 is that shown in Fig. 1. The coordinate r_2 in ref. 15 and Fig. 2 is the separation between the centers-of-mass of the two product molecules, HI. Since $m_I \gg m_H$ this means that r_2 is virtually identical to that shown in Fig. 1.

nected with the fact that the sliding mass-point (on a surface of type I *or* II) must find its way from a broad entry valley into a narrow lateral exit valley; see Fig. 2(*b*). The second of these anticipations ((*b*) above) is based on the fact that the scaled surface for $H_2 + I_2$ (Fig. 2(*b*)) is of type II, *i.e.* the barrier crest is displaced toward the exit valley. A pair of purely hypothetical trajectories have been sketched in Fig. 2(*b*) to indicate the anticipated behavior.

A recent detailed Monte Carlo study of the bimolecular reaction $H_2 + I_2$ confirms the first of these anticipations but not the second (4). The reaction cross-section was found to exhibit a threshold 10 kcal mol^{-1} in excess of the 42 kcal mol^{-1} potential-energy barrier for H_2 $(v = 0) + I_2$ $(v = 0)$. If one quantum of vibrational excitation $(E(v = 1) - E(v = 0) = 11.9$ kcal $mol^{-1})$ was introduced into the H_2, the threshold collision energy dropped from $T = 52$ kcal mol^{-1} to $T = 38.4$ kcal mol^{-1}, *i.e.* the *total* reagent energy at threshold for H_2 $(v = 1) + I_2$ $(v = 0)$ was reduced by only 1.7 kcal mol^{-1}, to 50.3 kcal mol^{-1}. For H_2 $(v = 2) + I_2$ $(v = 0)$ the *total* reagent threshold energy rose again to 58.9 kcal mol^{-1}. Vibration instead of being notably more efficient than translation in promoting reaction is at first marginally more efficient and then significantly less efficient. For the reasons already indicated $(r_1^0 \ll (r_1^0)', f_1^0 \gg (f_1^0)'$, and perhaps the rapid rotation of H_2) the scaled diagnostic surface based on coplanar rectangular reaction appears, on the present evidence, to be insufficiently representative of the actual reaction dynamics to assist more than marginally in the interpretation of the findings for the reaction $H_2 + I_2$. Our previous model studies on surfaces with early and late barriers, combined with the discussion of the sliding-mass analogy presented here, strongly suggest that there will be reactions $AB + CD \rightarrow AC + BD$ (less pathological than $H_2 + I_2$) for which the coplanar rectangular diagnostic cut can serve as an aid to interpretation.

Thiohydantoins. XII. Secondary Deuterium Isotope Effects in the Acid- and Base-catalyzed Hydrolysis of 1-Acetyl-5,5-dimethyl-2-thiohydantoin

WAYNE I. CONGDON[1] AND JOHN T. EDWARD
Department of Chemistry, McGill University, Montreal, Quebec

Received June 7, 1972

The rates of hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin and of 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin in acid and base over the temperature range 11–58 °C have been measured. For the A-1 hydrolysis in 96.3% sulfuric acid, k_H/k_D decreased from 1.31 at 10.8° to 1.05 at 58.1°; these results accord with the proposed mechanism. For A-2 hydrolysis in 39.6% sulfuric acid and for base-catalyzed hydrolysis in dilute sodium hydroxide, k_H/k_D *vs.* temperature passed through a minimum at about 40 and 25° respectively. Some possible reasons for the temperature effect are discussed.

On a observé les vitesses de l'hydrolyse de l'acétyl-1 diméthyl-5,5 thiohydantoïne-2 et de l'acétyl-1-d_3 diméthyl-5,5 thiohydantoïne-2 dans les solutions acides et basiques entre les températures 11–58 °C. Pour l'hydrolyse A-1 en acide sulfurique de 96.3%, k_H/k_D decroisse de 1.31 à 10.8° à 1.05 à 58.1°, en accord avec autres réactions de mécanisme semblable. Cependant, pour l'hydrolyse A-2 en acide sulfurique de 39.6% et pour l'hydrolyse en hydroxide de sodium dilué, k_H/k_D *vs.* température passe par un minimum. On discute des causes possibles pour cet effet.

Canadian Journal of Chemistry, **50**, 3921 (1972)

Possible mechanisms for the hydrolysis of 1-acyl-2-thiohydantoins in aqueous acid (*1*) and base (2) have been derived from a consideration of several well-established criteria (acidity effects, entropies of activation, Hammett $\rho\sigma$ relations, etc.). It accordingly became of interest to consider yet another criterion, that of secondary deuterium isotope effects. For this reason, we synthesized 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin (**1**), and compared its rates of hydrolysis to acetic acid-d_3 (**2**) and 5,5-dimethyl-2-thiohydantoin (**3**) in aqueous acid and alkali with the corresponding rates for the protio-compound (see eq. 1). We report below (in order) the results for hydrolysis in 96.3% sulfuric acid, in dilute sodium hydroxide, and in 39.6% sulfuric acid, since this probably represents the order of increasing complexity of mechanisms. Rates were determined in a large excess of acid or base, and rate constants k are pseudo-first-order constants for the disappearance of the 1-acyl-2-thiohydantoin.

In 96.3% sulfuric acid $k_H/k_D > 1$ (Table 1) and increased as the temperature was lowered; extrapolation to $-22°$ indicated that the isotope effect at this temperature would be roughly that found by Bender and Feng (3) for the hydrolysis of acetyl chloride in 10% aqueous acetone. Bender and Feng advance reasons for believing that hydrolysis of acetyl chloride under these conditions proceeds by a rate-determining ionization to chloride ion and acylium ion (CH_3CO^+ or CD_3CO^+). The secondary isotope effects support this view: the formation of carbonium ions is known to be retarded by β-deuterium substitution (4), although there is no unanimity on the explanation. Hyperconjugation (4, 5) and steric effects (6) have been invoked, and in very

TABLE 1. The effect of temperature on the pseudo-first-order rates (k) of hydrolysis of 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin and 1-acetyl-5,5-dimethyl-2-thiohydantoin

Reaction conditions	Temperature (°C)	k for 1-CH_3 (10^4 s^{-1})	No. of runs	k for 1-CD_3 (10^4 s^{-1})	No. of runs	k_H/k_D	Average error
96.3% sulfuric acid	10.8	1.15± 0.04	2	0.88±0.03	2	1.31	0.10
	20.1	3.11± 0.04	2	2.57±0.04	2	1.22	0.03
	35.5	24.20± 0.60	3	21.30±0.60	3	1.14	0.05
	49.6	124.00± 4.00	3	114.00±2.40	3	1.08	0.05
	58.1	266.00±12.00	3	235.00±7.30	3	1.05	0.08
39.6% sulfuric acid	11.0	7.15± 0.03	3	7.52±0.12	3	0.95	0.02
	25.3	26.00± 0.04	2	28.10±0.19	2	0.93	0.01
	35.5	54.70± 0.43	3	56.70±0.86	3	0.96	0.02
	49.6	170.00± 7.22	5	150.00±1.54	2	1.13	0.06
$pH = 11.95$ $\mu = 0.55$	11.0	3.65± 0.02	2	3.64±0.13	3	1.00	0.04
	25.3	12.90± 0.04	3	13.20±0.02	2	0.97	0.004
	49.6	95.80± 0.93	3	98.30±0.83	3	0.97	0.02
	58.1	177.00± 2.10	3	177.00±1.30	3	1.00	0.02

aqueous solutions the latter effects may be manifest in altered entropies of activation (7). The increase in the isotope effect as the temperature is lowered is in line with calculations by Miller (8). These results support the A-1 mechanism already advanced for the hydrolysis of 1-acyl-2-thiohydantoins in concentrated sulfuric acid (1).

Halevi and Margolin (9) found that k_H/k_D for the hydrolysis of ethyl acetate-d_3 in dilute aqueous sodium hydroxide varied with temperature, going through a minimum ($\sim$0.90) at about 25°. We found evidence for a similar but very much smaller, effect of temperature on the alkaline hydrolysis of 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin; the effect is scarcely greater than experimental error (see Table 1).

Thornton (10) suggested that Halevi and Margolin's results might be explained by a change of mechanism with temperature. However, this would lead to a non-linear Arrhenius plot; this we do not observe for the hydrolysis of 1-acetyl-5,5-dimethyl-2-thiohydantoin in alkaline solution (or in the two concentrations of acid). Halevi and Margolin point out that the secondary isotope effect observed by them (and observed by others in highly aqueous solutions) is probably caused by small differences in energy and entropy of solvation, resulting from isotopic differences in average charge distribution. In the hydrolysis of 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin certain special steric effects should additionally be considered, which would preferentially destabilize the protio compound (2). Hence the data displayed in Table 1 can be considered as compatible with (if not convincing evidence for) a similarity in mechanism for the two reactions, both involving formation of a tetrahedral intermediate.

The A-2 acid hydrolysis of esters, in contrast to their alkaline hydrolysis, is relatively unaffected by the electronic effects of changing substitution in the acyl moiety, the effect of the substituent on the preequilibrium protonation being counterbalanced by its effect on the rate of the subsequent attack by a water molecule (11). Consequently, we might expect steric and solvation effects to become predominant in the hydrolysis of 1-acetyl-d_3-5,5-dimethyl-2-thiohydantoin in 39.6% sulfuric acid, which has been shown to proceed most probably by A-2 mechanism (1). However, it is difficult to guess in what direction steric effects caused by the greater "size" of the CH_3 group (6) should operate because of the possibility of destabilization of the ground state by interference between methyl and sulfur (2). In the event, the isotope effect proved to be temperature dependent and k_H/k_D showed a minimum at about 25° (Table 1). The isotope effect is close to that found by Halevi and Margolin for the alkaline hydrolysis of methyl acetate in dilute aqueous solution. This is interesting, because solvation effects in 39.6% sulfuric acid should be quite different

from those in water (12). While we can offer no plausible explanation, the difference in isotope effects for the hydrolysis in 39.6 and in 96.3% acid points to a difference in mechanism, in agreement with arguments based on other criteria (1).

Experimental

Acetic anhydride-d_6 and acetic acid-d_4 were purchased from Stohler Isotope of Canada and used in the general procedure of Johnson and Nicolet (13) for the preparation of 1-acyl-2-thiohydantoins. 1-Acetyl-5,5-dimethyl-2-thiohydantoin was characterized by m.p. (uncorrected) 186–187 °C, in agreement with Carrington (14), and by n.m.r. (3H-singlet at 7.33 and 6H-singlet 8.5 τ). 1-Acetyl-d_3-5,5-dimethyl-2-thiohydantoin had the same m.p. and n.m.r. spectrum, except that the peak at 7.33 τ was missing. Both compounds in water showed the same u.v. absorption spectrum. Experimental methods for following the hydrolysis and for working-up the data have been described (1, 2).

A New Photochemical Reaction of Unconjugated Thioketones[1,2,3]

JAMES J. WORMAN,[4] MASON SHEN, AND PATRICK C. NICHOLS
Department of Chemistry, South Dakota State University, Brookings, South Dakota 57006

Received April 5, 1972

Tetramethyl-3-thio-1,3-cyclobutanedione (**1**) and tetramethyl-1,3-cyclobutanedithione (**6**) react with oxygen in the presence of light to yield tetramethyl-1,3-cyclobutanedione (**2**). A mechanism involving singlet oxygen is suggested. 1,3-Diphenyl-2-propanethione (**3**) undergoes accelerated dimerization in the presence of visible radiation to yield tetrabenzyl-1,3-dithietane (**4**).

La tétraméthylthio-3 cyclobutanedione-1,3 (**1**) et la tétraméthylcyclobutanedithione-1,3 (**6**) réagissent avec l'oxygène en présence de lumière pour conduire à la tétraméthylcyclobutanedione-1,3 (**2**). Un mécanisme faisant intervenir l'oxygène singulet est suggéré. La diphényl-1,3 propanethione-2 (**3**) subit une dimérisation accélérée en présence de radiation visible pour conduire au tétrabenzyldithiétane-1,3 (**4**).

Canadian Journal of Chemistry, **50**, 3923 (1972)

In a continuing attempt to understand the chemical differences between unconjugated ketones, imines and thioketones, (1) we have investigated the photochemistry of compounds containing the thiocarbonyl chromophore. There were no documented photochemical reports in the literature concerning this unconjugated chromophore until adamantanethione very recently (2) was shown to dimerize and add to alkenes probably through an $n \rightarrow \pi^*$ triplet state.

A New Photochemical Reaction of Unconjugated Thioketones[1,2,3]

JAMES J. WORMAN,[4] MASON SHEN, AND PATRICK C. NICHOLS
Department of Chemistry, South Dakota State University, Brookings, South Dakota 57006

Received April 5, 1972

Tetramethyl-3-thio-1,3-cyclobutanedione (**1**) and tetramethyl-1,3-cyclobutanedithione (**6**) react with oxygen in the presence of light to yield tetramethyl-1,3-cyclobutanedione (**2**). A mechanism involving singlet oxygen is suggested. 1,3-Diphenyl-2-propanethione (**3**) undergoes accelerated dimerization in the presence of visible radiation to yield tetrabenzyl-1,3-dithietane (**4**).

La tétraméthylthio-3 cyclobutanedione-1,3 (**1**) et la tétraméthylcyclobutanedithione-1,3 (**6**) réagissent avec l'oxygène en présence de lumière pour conduire à la tétraméthylcyclobutanedione-1,3 (**2**). Un mécanisme faisant intervenir l'oxygène singulet est suggéré. La diphényl-1,3 propanethione-2 (**3**) subit une dimérisation accélérée en présence de radiation visible pour conduire au tétrabenzyldithiétane-1,3 (**4**).

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3923 (1972)

In a continuing attempt to understand the chemical differences between unconjugated ketones, imines and thioketones, (1) we have investigated the photochemistry of compounds containing the thiocarbonyl chromophore. There were no documented photochemical reports in the literature concerning this unconjugated chromophore until adamantanethione very recently (2) was shown to dimerize and add to alkenes probably through an $n \rightarrow \pi^*$ triplet state.

We wish to report the first example of an unconjugated thioketone reacting photochemically with oxygen. Tetramethyl-3-thio-1,3-cyclobutanedione (**1**) (3) when irradiated in isopropyl alcohol at wavelengths >400 nm in the presence of oxygen gave tetramethyl-1,3-cyclobutanedione (**2**) and most likely sulfur monoxide (eq. 1). The reaction was complete in 3 days and there was no evidence for the formation of a dimer even in the absence of oxygen. It would appear the resulting dimer is structurally unfavorable in this case.

Dibenzyl thione (**3**) photochemically does give tetrabenzyl-1,3-dithietane (**4**) in quantitative yield (eq. 2). This dimerization also occurs in the dark but is definitely accelerated by light. These results are consistent with those reported on the dark reactions of cyclohexanethione (4), in which it was shown that the ground state reaction possessed both ionic and free radical character.

In an attempt to determine the mechanism for the photochemical reaction of the monothione (**1**) with oxygen we encountered once again the importance of singlet oxygen. Because the reaction occurs in the absence of a dye photosensitizer it might be suggested that the reaction proceeds via the triplet $n \rightarrow \pi^*$ state of the thione and triplet oxygen to give a cyclic intermediate (**5**), which then collapses to give the desired products. Our kinetic data obviate this pathway. The reaction is first order in monothione, at low concentration of **1** (0.01–0.1 *M*), and yet the rate decreases dramatically at high concentrations of **1** (1 *M*). This suggests a competitive excited state reaction, photochemical quenching, or substantially decreased oxygen solubility. We are hypothesizing that the excited state thione itself photosensitizes the formation of singlet oxygen from triplet oxygen in a spin forbidden process (5). Singlet oxygen then reacts with ground state thione to give the cyclic intermediate (**5**) which collapses to give

[3] 
1 5

the products (eq. 3). Ground state thione (**1**) does react in the dark with singlet oxygen generated thermally (6) to give the same products. This reaction occurs at a faster rate than the photochemical reaction and this is consistent with our hypothesis. A mechanism similar to ours has been shown to occur in the dye-photosensitized photooxygenation of 4*H*-pyran-4-thiones and 4*H*-thiopyran-4-thiones (7).

We examined the photochemistry of tetramethyl-1,3-cyclobutanedithione (**6**) under identical conditions to those used for the monothione (**1**) and the same products resulted (eq. 4). Experimental evidence suggests that there is no transannular participation in the dithione (**6**) or in (**1**) (8). We feel therefore that the presence of the carbonyl chromophone has no significant effect when irradiation is carried out on (**1**) at wavelengths greater than 400 nm.

Although only a few examples are present in the literature, it would appear that simple unconjugated thioketones are to some extent unlike their oxygen or nitrogen analogs. The thiones absorb light and react through an

[4] 
6 2

$n \rightarrow \pi^*$ state to add to alkenes or dimerize in the absence of alkenes if the spirothietane is sterically favorable. A third reaction results in the formation of ketones by reaction of the excited state thione with oxygen.

The mechanisms of these reactions are somewhat aberrant. We are presently investigating the feasibility of the monothione (**1**) acting as a dye type photosensitizer for the production of singlet oxygen.

Experimental

Melting points are uncorrected. The i.r. spectra were recorded with a Perkin–Elmer 521 grating i.r. spectrometer. Visible and u.v. spectra were run on a Beckman DK-2A ratio recording spectrophotometer. The n.m.r. spectra were obtained from a Varian A-60A instrument. Samples were dissolved in CCl_4 solution using tetramethylsilane as the internal standard. Molecular weight data were obtained by use of a Mechrolab Model 301A vapor phase osmometer. Samples were run as solutions in benzene. Mass spectra were run on both the Varian CH-5 and CEC-103-C mass spectrometers at the University of Wyoming, Laramie, Wyoming. Vapor phase chromatography was performed on an Aerograph Autoprep Model A-700 using 30% SE30 on 45/60 Chrom-P. The aluminum column dimensions were 3/8 in. × 20 ft and the operating temperature was 100 °C. Analytical v.p.c. was performed on a Beckman GC-2A using 15% SE-30 on 45/60 Chrom-P. The dimensions of the column were 1/4 in. × 10 ft and the operating temperature was 160 °C. Chemical analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

*Tetramethyl-3-thio-1,3-cyclobutanedione (**1**) and Tetramethyl-1,3-cyclobutanedithione (**6**)*

The procedure used here was a modification of the one described by Elam and Davis (3).

To 210 g (1.50 mol) of tetramethyl-1,3-cyclobutanedione (**2**) (Aldrich Chemical Co.) dissolved in 500 ml of pyridine was added 150 g (0.67 mol) of phosphorus pentasulfide (Fisher Scientific Co.) and the mixture refluxed for 40 min. After cooling to room temperature the pyridine was decanted and saved. The remaining solid was heated to boiling with 125 ml of fresh pyridine and once again decanted. The combined pyridine solutions were distilled rapidly without fractionating *in vacuo* (35–50 mm Hg). The pyridine was then removed *in vacuo* (30 mm Hg) by fractional distillation until the temperature reached 60 °C. The resulting residue was extracted with 150 ml of warm hexane and then cooled to 20 °C. At this point the majority of unreacted **2** would crystallize. The compound was collected on a Büchner and washed with hexane to remove the last traces of red color. The mother liquor and the hexane washings were combined and distilled and a fraction collected at 160–170 °C. This heavy red liquid was subjected to column chromatography on silicic acid (Matheson Coleman and Bell) with hexane as the eluting solvent. Column dimensions were 80 cm long × 3 cm diameter and the column was packed about half full. After 1 h, three distinct layers appeared. The layers were collected, solvent evaporated, and the compound identified.

Tetramethyl-1,3-cyclobutanedithione (**6**), the first layer, was an orange solid, m.p. 123–125° (lit. 124–125°) (3); i.r.: 1460, 1256, and 1075 cm^{-1}; n.m.r.: 1.40 δ (12H, S); visible and u.v. absorptions in hexane, λ_{max} 227 (ε 21 600), 298 (409), 500 nm (22.4); *m/e* 172; yield 10%.

Tetramethyl-3-thio-1,3-cyclobutanedione (**1**), the second layer, was a red solid, m.p. 57–58° (lit. 57–58°) (3); i.r.: 1800, 1700, 1450, 1290, and 1125 cm^{-1}; n.m.r.: 1.33 δ (12H, S); visible and u.v. absorptions in hexane, λ_{max} 228 nm (ε 8700), 270 (300), 318 (100), and 520 nm (9.65); *m/e* 156; yield 50%.

The third layer was unreacted tetramethyl-1,3-cyclobutanedione.

*Photolysis of Tetramethyl-3-thio-1,3-cyclobutanedione (**1**)*

A solution of **1**, 0.096 *M* in isopropyl alcohol was irradiated through a Kimax sleeve using a 250 W R40/3 Westinghouse lamp. The reaction was followed by u.v. spectroscopy and v.p.c. There was no apparent reaction after 10 days.

Any oxygen stream was introduced and after 3 days the monothione **1** had completely reacted. The hexane solution was evaporated to give a white solid which was purified by sublimation. The compound was identical in all respects to that of an authentic sample of tetramethyl-1,3-cyclobutanedione (**2**); yield 75%.

The effluent oxygen stream from the photoreaction was trapped using 100 ml of 1% sodium hydroxide. The excess sodium hydroxide was neutralized with hydrochloric acid and the solution titrated with iodine to indicate the presence of sodium sulfite, thus the presence of SO_2 in the oxygen stream.

A second method for the detection of sulfur dioxide was to precipitate and identify barium sulfite from a portion of the non-neutralized sodium hydroxide solution.

The photolysis was carried out in hexane and in carbon tetrachloride and the times for complete reaction were 5 and 1 days respectively.

*Reaction of Tetramethyl-3-thio-1,3-cyclobutanedione (**1**) with Singlet Oxygen*

Tetramethyl-3-thio-1,3-cyclobutanedione (**1**), 0.10 *M* in isopropyl alcohol was placed in a 250 ml separatory funnel and 50 ml of 5.25% sodium hypochlorite solution (Hilex) was placed in another separatory funnel. Both funnels were attached to a 250 ml three-neck flask containing 50 ml of 30% hydrogen peroxide (J. T. Baker) which was being stirred magnetically. The sodium hypochlorite solution was added slowly and completely, followed by the dropwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

addition of the monothione **1** solution. The reaction was complete in 5 min. The gas evolving from the reaction was trapped using 100 ml of 1% sodium hydroxide. A positive analysis for SO_2 was obtained as described above. The diketone **2** was obtained by evaporation of the isopropyl alcohol, yield 90%.

There was no apparent reaction (by visible spectroscopy or v.p.c.) when the monothione **1** was added separately to hydrogen peroxide or to sodium hypochlorite solution.

Photolysis of Tetramethyl-1,3-cyclobutanedithione (6)

A 0.10 *M* solution of the dithione **6** in hexane was irradiated under identical conditions as reported for the monothione **1**. Sulfur dioxide and the diketone **2** were identified as reported above. The reaction was complete in 3 days.

1,3-Diphenyl-2-propanethione (3)

Modified procedure of Mayer and Berthold (9).

To 27.2 g (0.10 mol) of 2,2-diethoxy-1,3-diphenylpropane (10) was added 0.05 g of *p*-toluenesulfonic acid. Hydrogen sulfide gas was passed through the solution for 8 h or until the solution was a consistent brilliant red. The solution was evaporated *in vacuo* to remove excess ketal, hydrogen sulfide, and ethanol. The condensate was a viscous red liquid, n.m.r.: 4.17 (4H, S), 7.19 δ (10H, m), visible absorptions in cyclohexane, λ_{max} 510 nm (ε 10); *m/e* 226, P + 2 228 (1 sulfur).

Tetrabenzyl-1,3-dithietane (4)

1,3-Diphenyl-2-propanethione (**3**) was irradiated using direct sunlight and a Pyrex container. The red color began to disappear and a white precipitate began to form after 2 h. The red color was completely gone after 2 days. The solution was filtered with solution and the precipitate washed with ethanol and acetone. The crude product was then recrystallized from carbon tetrachloride collected and dried in an oven at 120° for 24 h; m.p. 247–248°; i.r.: 3080, 3050, 3025, 2925, 2900, 2825, 1947, 1880, 1810, 1765, 1600, 1577, 1488, 1449, 1426, 1379, 1321, 1309, 1211, 1172, 1150, 1141, 1075, 1039, 1025, 1000, 992, 982, 970, 954, 911, 900, 879, 850, 827, 808, 752, 740, 702, 690, 608, 590, 565, 510 and 460 cm^{-1}; n.m.r.: 7.25 δ (20H, S); *m/e* 452 P + 2 454 (2 sulfur); v.p.o. 442 g/mol.

Anal. Calcd. for $C_{30}H_{28}S_2$: C, 79.59; H, 6.23. Found: C, 79.18; H, 6.39.

1,3-Diphenyl-2-propanethione (**3**) will also dimerize in the dark to give tetrabenzyl-1,3-dithietane (**4**) but the reaction is not nearly complete even after 8 days.

AND

R. G. KIDD

Department of Chemistry, University of Western Ontario, London 72, Ontario

Received December 17, 1968[2]

The ^{39}K chemical shifts in a number of aqueous electrolyte solutions have been determined. These arise from the overlapping of the outer electron orbitals of the anion and cation during random ionic collisions. The magnitudes of the chemical shifts are shown to be directly proportional to the effectiveness of this overlap interaction.

Nous avons déterminé les déplacements chimiques du ^{39}K dans différentes solutions électrolytiques aqueuses. Ceux-ci proviennent du recouvrement des orbitales des électrons externes de l'anion et du cation lors de collisions ioniques aléatoires. Nous avons montré que l'importance de ces déplacements chimiques est directement proportionnelle à cette interaction de recouvrement.

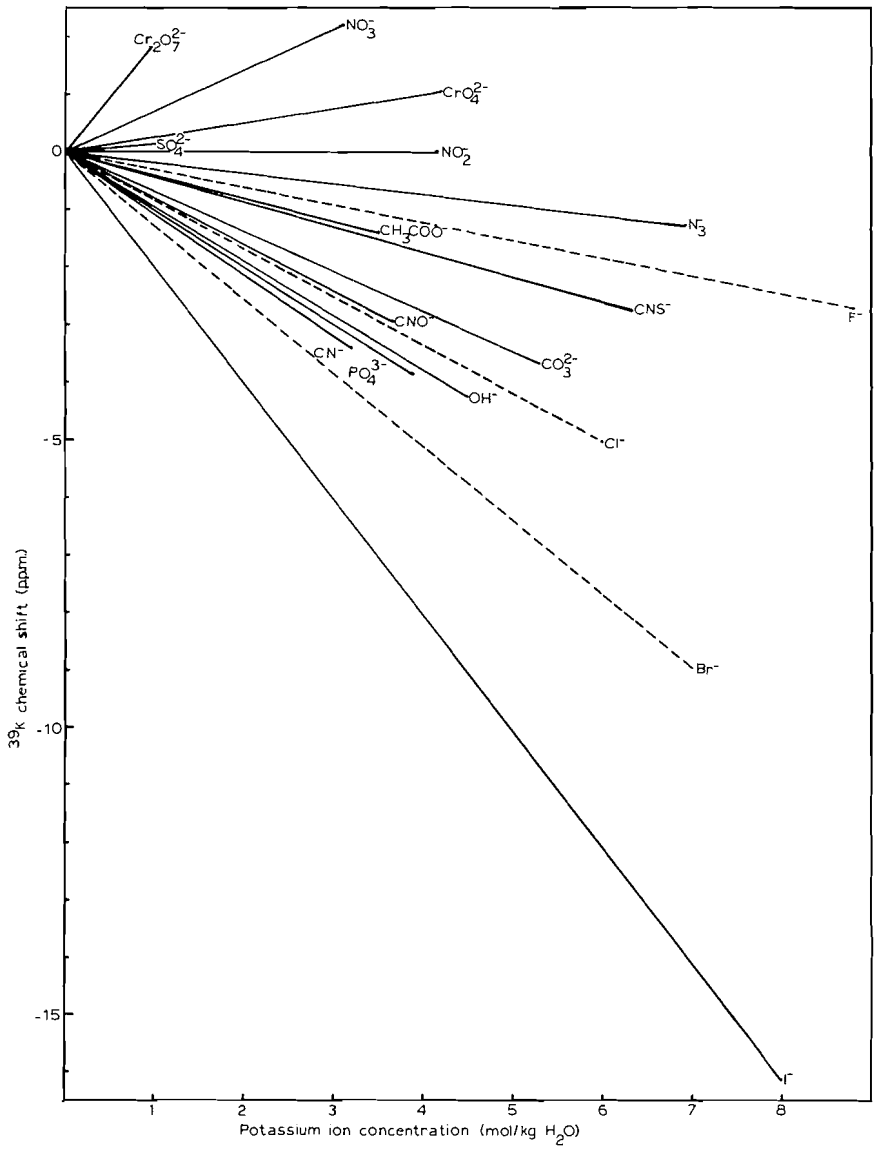

FIG. 1. Anion dependence of ^{39}K chemical shifts in aqueous solutions. The solid lines are the results of our study while the broken lines are from ref. 8.

The dynamic state of electrolyte solutions has been the subject of a great deal of interest amongst n.m.r. spectroscopists (1–4). Most of these studies have monitored the ^1H or ^{17}O chemical shift of the solvent water while systematically varying the constituent ions. As a continuation of our studies of cation–solvent interactions by ^{23}Na n.m.r. (5), we now wish to report a study of cation–anion interactions in aqueous solutions by ^{39}K n.m.r.

In order to isolate the cation–anion interactions, a common cation (K^+) and solvent (H_2O) were used throughout while only the nature of the anion was varied. The ^{39}K n.m.r. spectrum of each of the aqueous solutions of a number of different potassium salts thus investigated consisted of a single line. The position of this line was found to be dependent on both the nature of the anion and concentration of the salt. This dependence is illustrated in Fig. 1. The

slope of each line, δ/c, is defined as the "concentration shift" for that particular ion and is the parameter which is most useful in correlating the ^{39}K chemical shifts with known properties of the ions. The concentration shifts are listed in column 2 of Table 1.

All the salts used were AR grade and in most cases these were recrystallized and dried under a partial vacuum with heating. A Varian HR-60 NMR Spectrometer, equipped with the Varian V4200-B wide line accessories, operating at 2.800 MHz was employed. The sample was contained in a 15 mm i.d. cylindrical Pyrex tube fitted with a concentric 6 mm i.d. cylindrical insert for the 7.47 m aqueous KI reference solution. The ^{39}K chemical shifts for each of the electrolyte solutions at infinite dilution are approximately the same, *i.e.* $\delta_0 = 15.20 \pm 0.56$ p.p.m. (column 3, Table 1). The contribution of bulk susceptibility differences to the chemical shift were calculated and these were found to be small and to affect each concentration shift approximately equally (columns 4 and 5, Table 1). In this case then little is to be gained from this correction and only the uncorrected values will be considered further. Chemical shifts were determined at 0.5 m intervals from potassium ion concentrations of 0.5 m to the solubility limit of the salt.

Chemical shifts of alkali metal resonances in alkali metal halide crystals have been best accounted for in terms of the overlapping of the outer electron shells of the oppositely charged ions (6). Since these orbitals are fully occupied, a strong, short-range repulsive force arises due mainly to the Pauli exclusion principle. This results in an increase in the paramagnetic shielding of the nucleus (7) and the resonance is thus shifted to a lower magnetic field. Identical reasoning has been employed (1, 8, 9) to interpret the chemical shifts of the ions in alkali metal halide solutions. Short-range repulsive interactions occur during the random cation–anion collisions which distort the spherical symmetry of the electron distribution and a downfield shift of the resonance results. The larger the halide ion, the larger was the cation paramagnetic shift that was found. This was interpreted as being due to an increased collision probability (8).

The results of this study, however, indicate quite the opposite dependence of cation chemical shift on anion size. Instead, the order of the anions, arranged in the order of their ability

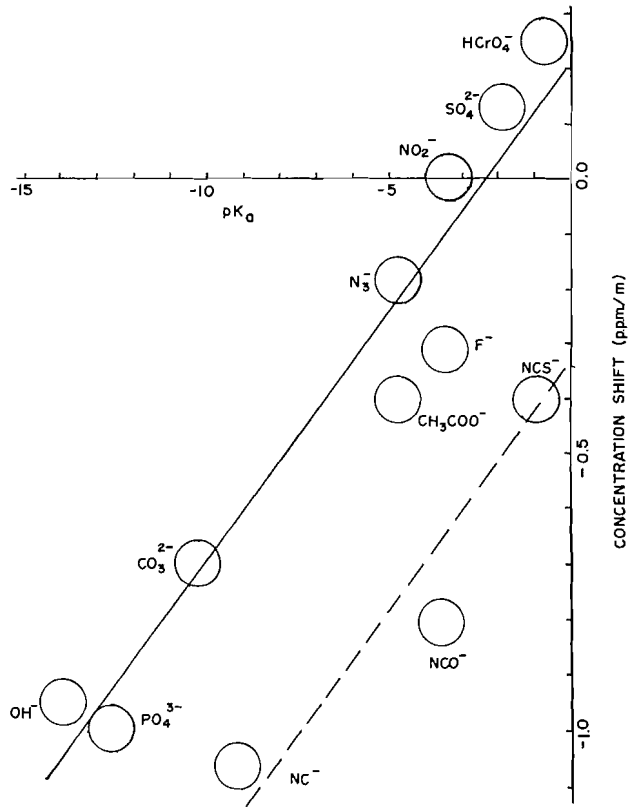

FIG. 2. Correlation of ^{39}K concentration shifts with the basicities of the counterions. The pK_a is the negative $\log_{10}$ of the association constant for the equilibrium which exists between the anion and its parent monoprotic acid. It is inversely proportional to the basicity of the anion.

to increase the paramagnetic shielding, (*i.e.*, $I^- > Br^- > CN^- > PO_4^{3-} > OH^- > Cl^- > CNO^- > CO_3^{2-} > CNS^- > CH_3COO^- > F^- > N_3^- > NO_2^- = H_2O > SO_4^{2-} > CrO_4^{2-} > NO_3^- > Cr_2O_7^{2-}$) bears a striking resemblance to the *nephelauxetic series* (10). The common feature of the two series is the ability of the constituent ions to effect overlap between themselves and a central metal ion. Furthermore, there exists a correlation of the concentration shifts with the basicities of the interacting species (Fig. 2) which is similar to what was found in the earlier ^{23}Na work (5). The greater availability of the electrons on the more basic anions results in a proportionately greater perturbation of the spherical symmetry of the outer electron cloud of the potassium ion. The magnitude of the paramagnetic shift caused by the induction of a net orbital angular momentum in the vicinity of the nucleus is thus a measure of the strength of the cation–anion interaction. The upfield shift of the ^{39}K resonance produced by some anions simply indicates that the overlap interaction between these anions and K^+ is weaker than the water $-K^+$ overlap interaction. The pseudo-halogen ions fall well off the regression line for the other anions in Fig. 2. This is probably because these anions are the only ones among the group studied which have two potential non-identical sites for coordination to the metal ion. Because the second coordination site in these anions depends largely upon a π-type interaction, this additional coordinating ability will not be reflected in the pK_a which reflects only the ability to coordinate protons.

The financial assistance of the National Research Council of Canada throughout the course of this research is gratefully acknowledged.

Isomérisation des épisulfures

KRZYSZTOF JANKOWSKI ET RONALD HARVEY

Département de chimie, Université de Moncton, Moncton, Nouveau-Brunswick

Reçu le 2 mai 1972

La stéréoisomérisation de quelques épisulfures a été realisée par le traitement avec le thiocyanate de potassium en DMF ou en milieu éthanol–eau. La stéréoisomérisation a été suivie par r.m.n.

Stereoisomerisation of some episulfides was observed using the reaction of potassium thiocyanate in DMF or water–ethanol. The stereoisomerisation was followed by n.m.r.

Canadian Journal of Chemistry, **50**, 3930 (1972)

En continuant les travaux précédents (1, 2) sur l'isomérisation des époxydes, nous avons démontré que l'isomérisation peut également être réalisée sur les épisulfures (3). En effet les épisulfures, par exemple, stéroidaux (3–6) ou sur le cyclohexane ayant la stéréochimie voulue ont été synthétisé en une étape. La réaction de l'isomérisation est facilement contrôlée par r.m.n. La différence entre les déplacements chimiques des protons α et β du noyau thiranique des épisulfures isomères reste constante.

La comparaison de la stéréochimie de l'hydroxy-3 épithio-1,2 cyclohexane[1] de départ avec le produit obtenu après le chauffage avec le thiocyanate de potassium (en solution éthanol–eau ou DMF) révèle qu'en partant d'un produit *cis* (**1***c*) (l'hydroxyle et le cycle thiranique *cis*) on obtient le produit *trans* (**1***t*) majoritaire (l'hydroxyle et le cycle thiranique *trans*). En partant d'un mèlange d'épisulfures *cis* et *trans*, on obtient un mélange mais de rapport *cis*/*trans* renversé. Finalement en partant d'un *trans*-hydroxy-3 épithio-1,2 cyclohexane (**1***t*) on obtient le *cis*-hydroxy-3 épithio-1,2 cyclohexane (**1***c*) majoritaire. La série de l'acétoxy-3 épithio-1,2 cyclohexane (*trans* **2***t* et *cis* **2***c*) donnent les résultants semblables (voir tableau 1).

Le controle par r.m.n. de la stéréoisomérisation est basé sur le déplacement chimique des signaux observés pour les protons du noyau thiranique. Nous observons que le signal pour les protons thiraniques des épisulfures *trans* est déplacé vers un champ plus bas par rapport aux épisulfures *cis*. Par exemple, pour le *trans*-hydroxy-3 épithio-1,2 cyclohexane (**1***t*) ce signal est à 3.60 p.p.m. et pour l'isomère *cis* (**1***c*) il est à 3.15 p.p.m. Le $\Delta\delta$ *trans*/*cis* de 0.45 p.p.m. a également été observé pour la série acétoxy-3. Il faut admettre que dans la série méthyle-3 épithio-1,2 cyclohexane cette différence n'est que de 0.06 p.p.m. seulement (les spectres enrégistrés dans les mêmes conditions) (3). Les diphenyl-1,2 épithio-1,2 éthane (épisulfure de stilbène) *trans* et *cis* donnent les signaux des protons thiraniques à 3.98 et 4.40 p.p.m. respectivement, ce que fait une différence de 0.42 p.p.m. (7). Les constantes de couplage sont de $J_{23} \approx 5$ Hz pour les épisulfures *cis* et $J_{23} \approx 0$ Hz pour les épisulfures *trans*. Ces valeurs s'accordent avec des calculs théoriques

†Échange D_2O.

(l'équation de Karplus (8)). Il est bon de noter que ces produits représentent des systèmes conformationellement homogènes.

Les épisulfures **1***c* et **1***t* d'une part et **2***c* et **2***t* de l'autre, donnent le spectre de masse qui se compose de pics a *m/e* identique mais de l'intensité différente. Les ions moléculaires sont d'une intensité de 7–12%. Les produits *cis* démontrent les ions 100% provenant de l'ionisation du soufre tandis que les produits *trans* démontrent les ions 100% provenant de l'ionisation de l'oxygène.

Partie éxperimentale

Les spectres de r.m.n. ont été enrégistrés à l'aide de spectrophotomètres Varian A-60 et EM-300 en $CDCl_3$ (concentration 5%); les spectres de masse-Varian EM-600. Les points d'ébullition n'ont pas été corrigés. Les époxydes ont été obtenus par nous mêmes (2). Nous avons utilisé deux méthodes pour l'obtention des épisulfures à partir des époxydes: (*a*) l'action de thiocyante de potassium (par exemple, l'époxyde *trans* donne l'épithio *cis*); (*b*) l'action de la thiourée en milieu H_2SO_4 (par exemple, l'époxyde *cis* donne l'épithio *cis*) (7). Seuls les produits racémiques ont été employés.

Episulfuration des époxydes

Méthode a

L'époxyde (1 mol) est ajouté en deux portions à une solution de thiocyanate de potassium (1.25 mol) dans 100 ml d'eau et 75 ml d'éthanol (ou 175 ml de DMF). Après avoir laissé au repos pendant 3–4 h la solution est vigoureusement agitée pendant 36 h à la température de la pièce dans l'obscurité. Le produit est extrait à l'éther, lavé avec une solution de chlorure de sodium à 10%, séché puis le solvant évaporé *in vacuo*. Le produit est purifié par distillation.

Méthode b

L'époxyde (1 mol) est agité avec de l'eau (50 ml), de l'acide sulfurique (3 equiv), et de la thiourée (3 mol) à la température de la pièce. La solution résultante est agitée 12–24 h et le sulfate est filtré et lavé avec de l'éther, pour ensuite être suspendu dans l'eau. Cette dernière suspension est rendue alcaline (p*H* 9) avec du carbonate de sodium et agitée pour 30 min. L'épisulfure est extrait avec de l'éther puis purifié par distillation.

Isomérisation des épisulfures

L'épisulfure (1 mol) est ajouté à une solution de thiocyanate de potassium dans un mélange éthanol–eau (1:1) (ou dans la diméthylformamide); cette solution est chauffée à reflux et agitée vigoureusement pour 24 h. Le produit est extrait à l'éther, lavé avec une solution de chlorure de sodium à 5%, séché, et le solvant évaporé sous vide. Le produit pur est obtenu par distillation. Le résidue (20–40%) est composé des goudrons sulfurés.

In the process of abbreviating the Experimental section, the description of the conversion of the alcohol (**31**) to tricyclovetivene (**1***a*) was shortened in a way which made it misleading and in apparent contradiction to a statement in the Theoretical part.

The full description of the experiment should read as follows:

Conversion of the Alcohol (**31**) *to Tricyclovetivene* (**1***a*)

A solution of the "natural" alcohol (**31**) (90 mg) in acetic anhydride (0.7 ml) and pyridine (0.7 ml) was heated to 120 °C for 60 h. After cooling, the reaction mixture was chromatographed on a silica gel column (light petroleum ether) to give the starting alcohol (56 mg) and a mixture of exocyclic and endocyclic olefins (25 mg, 92% based on the starting material consumed) in a ratio of 3.5:1 which was established by analytical g.l.p.c. (15 ft × 1/4 in. column of 30% SE-30 at 225 °C).

The mixture of olefins was then separated by preparative g.l.p.c. to yield a peak fraction of pure "natural" tricyclovetivene (**1***a*) (7.5 mg) as an oil, homogeneous in t.l.c. All analytical data (i.r., n.m.r., mass, t.l.c., and g.l.c.) for "natural" tricyclovetivene were superimposable with those of natural tricyclovetivene.

By the same method synthetic alcohol (**31**) (5.6 mg) was converted to racemic tricyclovetivene (**1***a*) (1.5 mg.).

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.1878. Found (mass spectroscopy): 204.1876.

The remaining recorded data (i.r. and g.l.c.) were completely identical to those of natural tricyclovetivene.

Solvation of the Sodium Ion. Quadrupolar Broadening of the ^{23}Na Nuclear Magnetic Resonance

R. D. GREEN[1] AND JOHN S. MARTIN

Department of Chemistry, The University of Alberta, Edmonton, Alberta T6G 2G2

Received May 28, 1971[2]

Sodium ion preferentially forms long lived complexes with dimethylsulfoxide or *N,N*-dimethylformamide, in mixtures of either of these solvents with either ethanenitrile or propanone. No long lived complexes are observed in solvent mixtures of water or methanol with ethanenitrile or propanone.

L'ion sodium forme de préférence des complexes d'une longue durée de vie avec le diméthylsulfoxyde et le *N,N*-diméthylformamide, dans des mélanges d'un des solvants précédants avec l'éthanenitrile ou le propanone. Il ne forme pas des tels complexes dans des mélanges de l'eau ou le méthanol avec le diméthylsulfoxyde ou le propanone.

Canadian Journal of Chemistry, **50**, 3935 (1972)

Of several spectroscopic methods which have been used to determine the nature of the microscopic environment of ions in solution, one of the more successful has been nuclear magnetic resonance. This usually involves deducing the influence of the ions on the solvent from the change in the solvent ^{1}H or ^{17}O spectrum as a salt is added (1). A complementary approach is to observe the nuclear shielding (2, 3) or linewidth (4–6) of the ion's nucleus as a function of solvent composition. This method has the advantage of allowing observation of small concentrations of ions without masking of the spectral changes by the bulk of the solvent.

The linewidth of the ^{23}Na nuclear resonance in solutions of sodium salts is usually determined by nuclear relaxation by coupling of the nuclear quadrupole, eQ, to transitory field gradients. These may arise from two mechanisms.

(*1*) If no persistent solvation complexes form, and neighboring molecules undergo unrestricted motion, then the reorientation of the electric dipoles of molecules near an ion will lead (7) to a linewidth dependence of the form

$$[1] \qquad \Delta\nu \propto (T_2)^{-1} \propto \left(\frac{eQ}{\hbar}\right)^2 \frac{\mu^2}{r_0^5} N\tau_s$$

where N is the number density of solvent molecules, μ is the solvent molecule dipole moment, and r_0 the distance of closest approach. τ_s, the solvent reorientation correlation time, is usually proportional to the viscosity.

(*2*) If sodium ions are involved in complexes of significant lifetime, then the net electric field gradient in the complex, eq, on thermal reorientation leads to a linewidth dependence (8) of the form

$$[2] \qquad \Delta\nu \propto (T_2)^{-1} \propto \left(\frac{e^2qQ}{\hbar}\right)^2 \tau_c$$

In this case, τ_c is the reorientation correlation time of the complex.

In a mixed solvent, if no complexes form, the first mechanism should yield linewidths intermediate between those in the two pure solvents, unless there are anomalies in the viscosity.

On the other hand, if long-lived complexes form involving a total of n solvent molecules (n

[1]Present address: Department of Chemistry, University of Malaya, Kuala Lumpur, Malaysia.

[2]Revision received July 20, 1972.

TABLE 1. ^{23}Na linewidths in 0.2 *M* solutions of $NaClO_4$, and observed viscosities of solvents at 302 K

Solvent	Linewidth (Hz)	Viscosity $\times 10^4$ (kg $m^{-1} s^{-1}$)	Dipole moment (D)	Donor number (ref. 12)
Propanone	26.8 ± 0.7	2.3	2.9	17
Ethanenitrile	25.0 ± 1.0	2.7	4.0	14
Water	25.3 ± 0.4	8.2	1.8	18
Dimethylsulfoxide	54.3 ± 1.7	19.5	3.9	30
N,N-dimethylformamide	41.7 ± 1.3	7.7	3.8	27

usually being of the order of six), we have contributions to the linewidth from all complexes present of the general formula $NaS_mS'_{n-m}^{+}$ where S and S′ are the two solvents. If the mean lifetime τ_l of a complex is in the range $\tau_c \ll \tau_l \ll T_2$, where T_2 is the relaxation time of a nucleus in that complex (8, 9), the width of the single observed line will be a population-weighted average of the linewidths of all complexes at equilibrium.

Of all possible complexes involving dissimilar solvents, the symmetric ones ($m = 0$ or n) should produce minimum linewidth, since the net field gradient will be small (it is zero for octahedral symmetry). The field gradient and linewidth contributions should increase to a maximum for some mixed complex containing both solvents. Consequently, the possibility exists of a maximum appearing in the curve of linewidth *vs.* concentration when a second solvent is added, if the second mechanism is significant.

Such observations are particularly interesting in the cases of alkali metal ions, whose solvation shells are too labile for their nature and composition to be determined. We have measured the linewidth of the ^{23}Na resonance in 0.2 *M* sodium perchlorate solutions in several pure and mixed solvents. The spectra were obtained at 15.86 MHz, using dispersion mode. The linewidths reported are the separations between the turning points of the signals. Viscosities of the pure and mixed solvents were measured by standard methods (10) using an Ostwald viscosimeter calibrated with water and benzene at ambient probe temperature (302 K).

Table 1 gives observed linewidths of ^{23}Na in several pure solvents. It is apparent that the linewidths do not correlate simply with either viscosity or dipole moment. However, dimethylsulfoxide and *N,N*-dimethylformamide, both strongly basic solvents of relatively high viscosity, produce the greatest linewidths. It has been shown (11) that $NaClO_4$ exhibits no significant ion pairing in these solvents, so interionic contributions to the linewidth should be negligible.

Ideally, to study mixed solvent systems, one would dissolve the salt in an "inert" solvent, S, and monitor the linewidth of the ion's resonance as small quantities of a second solvent, S′, are added. If persistent complexes form as S molecules are displaced by S′ molecules in the solvation shell, the linewidth would increase, pass through a maximum corresponding to the presence of asymmetric complexes, and ultimately decrease to the value characteristic of solvation entirely by S′.

The most nearly "inert" solvents which afford adequate solubility of sodium perchlorate are ethanenitrile (CH_3CN) and propanone (CH_3COCH_3). They appear not to interact strongly with sodium ion; the small change of linewidth between ethanenitrile and propanone occurs uniformly as the composition is varied.

There is no evidence of persistent complexes with water or methanol. The addition of small quantities of either of these solvents to an ethanenitrile solution produced no significant change in the sodium linewidth. This appears to confirm the previous finding (5, 9) that no persistent hydrates of sodium occur in mixed solvents. This is particularly interesting in view of the observation by Bloor and Kidd (2) that water preferentially solvates sodium ion in ethanenitrile–water systems. Thus, it appears that relaxation in these systems is entirely by the first of the two mechanisms discussed previously.

On the other hand, when dimethylsulfoxide or *N,N*-dimethylformamide is added to $NaClO_4$ in ethanenitrile, the linewidth, as shown in Fig. 1, increases rapidly with added solvent S′ con-

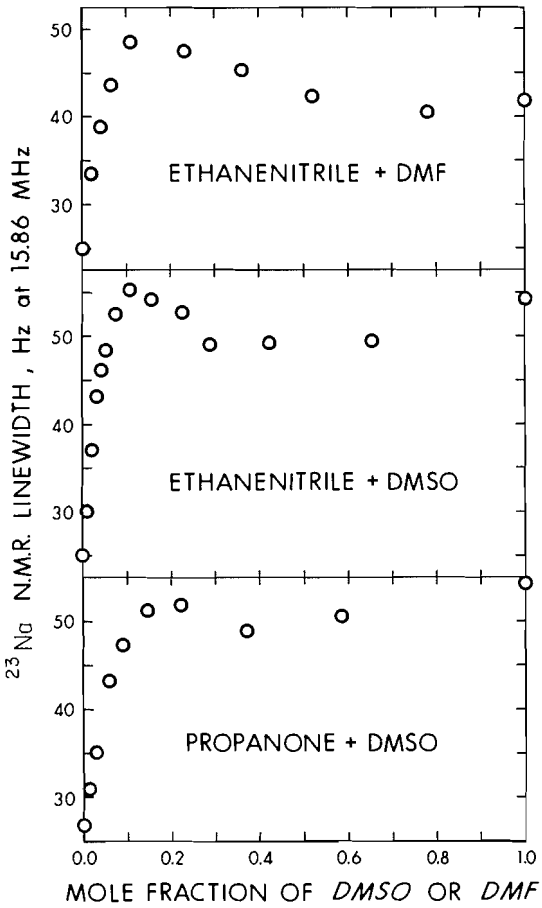

FIG. 1. Variation of ^{23}Na linewidth with solvent composition.

centration, reaching a maximum at a ratio $[S']/[Na^+]$ of about 10 to 15. On further addition of DMSO or DMF, the linewidth decreases again and passes through a slight minimum before reaching the value appropriate to solvent S'. Similar behavior is observed when DMSO is added to $NaClO_4$ in propanone. The linewidth maximum occurs at higher DMSO concentration, but the form of the curve is much the same. The measured viscosities of these solvent pairs showed no corresponding features. A smooth, monotonic variation of viscosity with composition was observed in all cases, with no maxima or minima.

The observed quadrupolar broadening of the ^{23}Na resonance and its dependence on solvent composition have several implications with regard to sodium ion solvation. The maxima in the linewidth curves of systems involving DMSO and DMF imply that the second relaxation mechanism is operative, and thus that complexes of these solvents with Na^+ have lifetimes significantly longer than their reorientation correlation times. It is also evident from the curves of Fig. 1 that the mixed solvation shells, which occur in the neighborhood of the linewidth maxima, predominate when DMSO or DMF is the minor constituent of the mixed solvent. This is evidence that DMSO and DMF preferentially solvate sodium ion, in competition with ethanenitrile or propanone.

Thus dimethylsulfoxide and *N*,*N*-dimethylformamide appear to form complexes which are thermodynamically more stable than those of the other solvents with sodium ion. These complexes also appear to have a significantly greater lifetime when DMSO or DMF is in the solvation shell. This experiment affords no evidence for persistent solvation by ethanenitrile, propanone, water, or methanol. These observations are in accord with the basicities of the various solvents, as measured by their Gutmann donor numbers (12) given in Table 1. The most basic solvents, DMSO and DMF, form the most stable and long-lived complexes with sodium ion.

The Vacuum Ultraviolet Photolysis of Cyclopentanone

ALFRED A. SCALA AND DANIEL G. BALLAN
Department of Chemistry, Worcester Polytechnic Institute, Worcester, Massachusetts 01609

Received March 23, 1972

In the vacuum ultraviolet photolysis of cyclopentanone, the major modes of fragmentation of the electronically excited ketone are:

[6]  → $CO + (CH_2)_4$ → A: $2C_2H_4$; B: C_4H_8

[8] → $CH_2 + CO + C_3H_6$

[4] → $H + C_5H_7O$

[5] → $H_2 + C_5H_6O$

The sum of the quantum yields for reactions A and B is 0.87 at 147.0 nm and these reactions become less important as the incident energy is increased. A pressure study at 147.0 nm of the partitioning of the tetramethylene diradical between paths A and B indicates that the ratio k_A/k_B is approximately 8. The quantum yield for reaction 8 is only 0.02. The remainder of the decomposition of cyclopentanone is accounted for by reactions 4 and 5, which appear to become more significant as the incident energy increases. The mechanisms for reactions 6 and 8 are best interpreted in terms of diradicals of structure $(CH_2)_n$ where $n = 1$, 3, and 4. The lack of non-acyl σ-cleavage at 147.0 nm is an indication that the absorption of energy occurs at the carbonyl group.

Dans la photolyse ultraviolet sous vide de la cyclopentanone les modes de fragmentation majoritaire pour la cétone électroniquement excitée sont:

[6]  → $CO + (CH_2)_4$ → A: $2C_2H_4$; B: C_4H_8

[8] → $CH_2 + CO + C_3H_6$

[4] → $H + C_5H_7O$

[5] → $H_2 + C_5H_6O$

La somme des rendements quantiques pour les réactions A et B est de 0.87 à 147.0 nm et celle-ci deviennent moins importantes lorsque l'énergie incidente augmente. L'étude sur la pression à 147.0 nm du partage du diradical tétraméthylène entre les voies A et B, indique que le rapport k_A/k_B est approximativement de 8. Le rendement quantique pour la réaction 8 n'est que de 0.02. Le restant de la décomposition de la cyclopentanone est expliqué par les réactions 4 et 5 qui apparaissent plus importantes lorsque l'énergie incidente croît. Les mécanismes des réactions 6 et 8 sont interprétés de la meilleure façon par les diradicaux de structure $(CH_2)_n$ où $n = 1$, 3, et 4. L'absence de clivage σ non acyle à 147.0 nm est une indication que l'absorption d'énergie a lieu sur le groupe carbonyle. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3938 (1972)

Introduction

The near ultraviolet photochemistry of cyclopentanone has been extensively investigated and is characterized by reactions 1–3 (for a review, see refs. 1 and 2)

[1]  → $CH_2CH(CH_2)_2CHO$

[2] → $CO + 2C_2H_4$

[3] → $CO + c\text{-}C_4H_8$

At 313 nm reaction 1 is the major reaction, while reactions 2 and 3 occur to about the same extent as reaction 1. Lee (3) has shown that in the benzene sensitization of cyclopentanone reaction 1 is the result of triplet energy transfer while reactions 2 and 3 occur by way of singlet energy transfer. Dunion and Trumbore (4) have shown that in the liquid phase γ-radiolysis of cyclopentanone, the first excited triplet state ($n-\pi^*$)

is the precursor in reaction 1. The present study was undertaken with the expectation that on the basis of product analysis and by making use of cyclopentanone-α-d_4 we would be able to establish some of the primary processes which occur when cyclopentanone is photolyzed in the gas phase with vacuum ultraviolet radiation.

Experimental

The experimental procedures were essentially the same as those used in the vacuum ultraviolet photolysis of cyclohexanone (5). Cyclopentanone obtained from Matheson Coleman Bell was purified by distillation on a thirty theoretical plate spinning band column. Only the middle 1/5, which was outgassed by several trap-to-trap distillations, was used in these experiments and no impurities were discernable by gas chromatography using both diisodecyl phthalate and Poropak Q-S columns. Cyclopentanone-α-d_4 was obtained from Merck, Sharp and Dohme, Ltd., of Canada. It was outgassed and passed through a column of Linde molecular sieves, type 13X. After this treatment, the only discernable impurity was *ca.* 1% of 4-pentenal. According to the mass spectral cracking pattern of cyclopentanone-α-d_4, it contained about 12% cyclopentanone-α-d_3. In calculating the isotopic compositions of the ethylenes formed during photolysis, corrections have been made to compensate for the presence of cyclopentanone-α-d_3. No correction was made in calculating the hydrogen isotopic compositions.

Results

The product distributions obtained when cyclopentanone is photolyzed at 147.0, 123.6, and 106.7–4.8 nm, both in the presence and absence of nitric oxide, are given in Table 1. The conversion in most experiments was 0.1–0.05%. However, even changes by a factor of 10 in the conversion had little effect on the relative yields of the products. The only noticeable effect was a slight increase in the ethane, propane, and butane yields at higher conversions. In Table 2 are the isotopic compositions of the ethylene and hydrogen formed when cyclopentanone-α-d_4 is photolyzed at 147.0 and 123.6 nm. Isotopic compositions were not determined at 106.7–4.8 nm because the low intensity of the argon lamp made the accumulation of enough products for this analysis almost impossible. It can be reported however that the isotopic compositions of both the ethylene and the hydrogen formed in the γ-radiolysis are similar to those reported in Table 2.

In addition to the results reported above, a number of high pressure photolyses were conducted at 147.0 nm in order to determine if 4-pentenal was a product at these energies. In none of these experiments was any 4-pentenal observed, even at conversions as high as 2%. In a further attempt to increase the pressure and stabilize any 4-pentenal which might be formed and undergo secondary decomposition, cyclopentanone was photolyzed in the solid phase at 77 °K. In this case also no 4-pentenal was observed. The analysis for 4-pentenal was capable of detecting as little as a quantum yield of

0.025 of this compound. The ratios C_2H_4/c-C_4H_8 and 1-C_4H_8/c-C_4H_8 observed in these high pressure experiments are presented in Fig. 1. When cyclopentanone was photolyzed in the presence of 2% added ethylene the yields of ethane, propane, and butane relative to carbon monoxide were increased by factors of 2.1, 3.1, and 8.4, respectively. Except for a 20% reduction in the yield of 1-butene, the yields of other products were essentially unchanged. When the xenon photolysis was conducted in the presence of 25% hydrogen sulfide, the methane yield increased from 1.5 in the absence of hydrogen sulfide, to 4.3 relative to carbon monoxide. The quantum yields reported in Table 1 for 123.6 and 106.7–4.8 nm are based upon the measured ionization efficiencies for cyclopentanone of 0.28 and 0.23, respectively. These ionization efficiencies were determined as previously described using the well established ionization efficiencies of nitric oxide as the standard (6). The quantum yield of CO at 147.0 nm is based upon carbon dioxide actinometry (7).

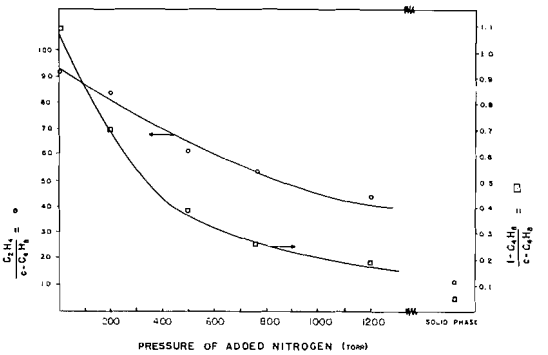

FIG. 1. The dependence of the ratios C_2H_4/c-C_4H_8 and 1-C_4H_8/c-C_4H_8 upon the pressure of added nitrogen at 147.0 nm.

Discussion

There is no evidence to the occurrence of reaction 1 in the vacuum ultraviolet photolysis of cyclopentanone. This observation is consistent with previous work which has shown that intramolecular rearrangements do not occur in

[1]  $\rightarrow$ $CH_2=CHCH_2CH_2CHO$

the vacuum ultraviolet photolysis of ketones (5, 8, 9). Although the possibility exists that 4-pentenal is formed and undergoes secondary decomposition, this is unlikely since no trace of 4-pentenal was ever observed, even when 1.5 atmospheres of nitrogen was present to collisionally deactivate the 4-pentenal. The effectiveness of nitrogen in stabilizing vibrationally excited cyclobutane can be seen in Fig. 1.

From the product distributions given in Table 1 it may be seen that ethylene is by far the most abundant hydrocarbon product and that the ratio C_2H_4/CO is very close to 2.0 as required by reaction 2. As the incident energy increases, the importance of ethylene diminishes and the C_2H_4/CO ratio becomes less than 2. The divergence of the quantum yield of carbon monoxide from unity is the result of the occurrence of reactions 4 and 5 which become more important

[4]  $\rightarrow$ $H + C_5H_7O$

[5] $\rightarrow$ $H_2 + C_5H_6O$

as the incident energy increases. These reactions are not observed in the near ultraviolet photolysis of cyclopentanone, since hydrogen is not a product. If sizeable fractions of the C_5H_7O and C_5H_6O produced in reactions 4 and 5 do not undergo secondary decomposition to produce carbon monoxide, then the difference between the carbon monoxide quantum yield and unity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

should be reflected in the hydrogen yield. This is in fact what is observed, as the incident energy is increased the quantum yield of carbon monoxide decreases, while the quantum yield of hydrogen increases. A similar observation has been made in the vacuum ultraviolet photolysis of cyclohexanone (5).

At 123.6 and 106.7–4.8 nm ion–molecule reactions may also contribute to the production of hydrogen. The divergence of the ratio C_2H_4/CO from 2.0 at these wavelengths indicates that reactions are occurring which do not produce two molecules of ethylene and a molecule of carbon monoxide. This is also indicated by the slight increases in the C_3 and C_4 products when the incident energy is sufficient to ionize cyclopentanone. The elucidation of the detailed photolytic mechanism at 123.6 and 106.7–4.8 nm is more difficult than at 147.0 nm because although approximately 25% of the incident photons result in ionization we have not been able to clearly demonstrate the occurrence of any ion–molecule reaction.

The photolytic mechanism at 147.0 nm is best interpreted in terms of the initial decomposition of the excited cyclopentanone to carbon monoxide and a tetramethylene diradical. The major reaction products as well as the pressure de-

[6]  $\rightarrow$ CO + $(CH_2)_4$

pendence of the products (Fig. 1) is then determined by the secondary reactions of the tetramethylene diradical as shown in Scheme 1.

$$(CH_2)_4 \longrightarrow 1\text{-}C_4H_8^* \rightleftharpoons CH_3 + CH_2CHCH_2$$
$$\xrightarrow{k_d} 2\text{-}C_2H_4$$
$$\underset{}{\overset{k_c}{\rightleftharpoons}} c\text{-}C_4H_8^* \xrightarrow[(M)]{} c\text{-}C_4H_8$$

SCHEME 1

At 147.0 nm reaction 6 occurs with a quantum yield of 0.87. The postulation of a tetramethylene diradical is consistent with our interpretation of the vacuum ultraviolet photolysis of cyclohexanone in terms of a pentamethylene diradical. The slight reduction in the ethylene quantum yield observed when 5% nitric oxide is added to the ketone is attributed to the inefficient scavenging of the diradical by nitric oxide. This hypothesis is consistent with the following observations: cyclobutane is a product and it is also inefficiently scavenged by nitric oxide; the trimethylene diradical which must be the precursor of the cyclopropane formed in this system and in the photolysis of cyclohexanone (5) is also slightly scavenged by nitric oxide in both of these systems. McKnight, Lee, and Rowland (10) have observed that the triplet trimethylene diradical produced by the addition of methylene to ethylene is scavenged slightly by oxygen.

Scheme 1 explains the greater susceptibility of the 1-butene to nitric oxide scavenging by the secondary decomposition of vibrationally excited 1-butene to methyl and allyl radicals, a relatively large fraction of which will recombine to form 1-butene (11). The pressure dependence of the $C_2H_4/c\text{-}C_4H_8$ and $1\text{-}C_4H_8/c\text{-}C_4H_8$ ratios shown in Fig. 1 are the result of the decomposition of vibrationally excited cyclobutane. Both the solid phase photolysis and the isotopic composition of the ethylene produced in the photolysis of cyclopentanone-α-d_4 indicate that at most 20% of the ethylene produced in a 7.0 Torr photolysis arises by way of the decomposition of a vibrationally excited cyclobutane molecule. This result would indicate that the ratio k_d/k_c is approximately 8. Considering the likelihood that the tetramethylene diradical is produced with excess vibrational energy this estimate is in good agreement with the experimental results of Gerberick and Walters (12) on the thermal isomerization of *cis*- and *trans*-1,2-dimethylcyclobutane, which respectively indicate this ratio to be 4.6 and 2.8 and with the calculated value of O'Neal and Benson (13) which is 1.9.

The preference of the tetramethylene diradical to undergo cleavage to two molecules of ethylene compared to the preference of the trimethylene diradical to undergo cyclization

[7] $(CH_2)_4 \rightarrow 2C_2H_4$

rather than cleavage is due in part to the more favorable entropy of cyclization of the trimethylene diradical, but mainly to the less favorable enthalpy for the cleavage of the trimethylene to ethylene and methylene (14). The trimethylene diradical shows no tendency to undergo fragmentation in thermal systems and little tendency to undergo this reaction when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

it is produced in the vacuum ultraviolet photolysis of cyclohexanone (5). The trimethylene diradical is an intermediate in the present system since it is necessary to include reaction 8 in the mechanism in order to account for the presence of cyclopropane and propylene among the

[8]  $\rightarrow CH_2CO + (CH_2)_3$

products. The intermediacy of the trimethylene diradical in a number of reactions is well documented (10, 13, 15). Although reaction 8 indicates the production of ketene, at these energies any ketene produced will certainly decompose to methylene and carbon monoxide. Both the total C_3H_6 yield and the C_1 yield indicate that reaction 8 accounts for approximately 3% of the carbon monoxide. If we make the assumption that reaction 8 occurs entirely by way of initial cleavage of the α–β σ bond, we can still conclude that non-acyl σ bond cleavage is certainly a relatively unimportant reaction. Since α–β σ cleavage, which should be statistically favored by a factor of 2 over β–β' σ cleavage, is unimportant and since non-acyl σ cleavage should be a relatively nonselective reaction, we therefore conclude that initial β–β' σ cleavage reaction 9 is insignificant and does not contribute to the production of ethylene. Since

[9]  $\rightarrow CO + 2C_2H_4$

1

non-acyl σ cleavage reactions are expected to be more important at higher energies, it seems justified to conclude that **1** which has been suggested as a possible intermediate in reaction 2 is not a source of ethylene in the near ultraviolet photolysis of cyclopentanone (16).

The methylene produced by the decomposition of the ketene formed in reaction 8 probably inserts into the cyclopentanone, followed by the decomposition of a fraction of the methylcyclopentanone to produce methyl radicals and cyclo-

[10] $CH_2 +$  $CH_3^* \rightarrow CH_3 + C_5H_7O$

pentanonyl radicals. The minor contribution of reaction 8 is also indicated by the fact that when the xenon photolysis is conducted in the presence of 25% hydrogen sulfide the methane yield is still only 4.3% of the carbon monoxide yield. Hydrogen sulfide has been shown to be an efficient scavenger of methylene, resulting in the production of methane (15*e*).

The small amounts of acetylene and allene present in the 147.0 nm photolysis products, probably result from the unimolecular decomposition of vibrationally excited C_2H_4 and C_3H_6. These reactions are consistent with the insensitivity of these products to the presence of nitric oxide. The dramatic increase in the yields of both C_2H_2 and C_3H_4 at 106.7–4.8 nm we believe may be due to a proton transfer reaction between $C_2H_3^+$ and $C_3H_5^+$ and cyclopentanone as shown in reaction 11, where R is either C_2H_2 or C_3H_4. The $C_2H_3^+$ and $C_3H_5^+$ ions account

[11] $RH^+ + K \rightarrow R + KH^+$

for 4 and 12% of the total ionization in the 70 eV mass spectrum of cyclopentanone (17, 18). Since the appearance potentials of these ions formed from cyclopentanone are not known, it is not possible to say with certainty that reaction 11 does occur.

The remaining products, methane, ethane, propane and butane are clearly formed in free radical reactions as demonstrated by their almost complete scavenging by nitric oxide. These products can be accounted for by the usual abstraction, disproportionation, and combination reactions of methyl and ethyl radicals. That ethyl radicals originate by hydrogen atom addition to ethylene is demonstrated by the observation that the yields of ethane, propane, and butane are increased by factors of 2.1, 3.1, and 8.4, respectively, when 2% ethylene is added to the ketone prior to photolysis at 147.0 nm. The isotopic compositions of the hydrogen formed in the photolysis of cyclopentanone-α-d_4 as well as the effect of nitric oxide on the hydrogen yield indicate that a sizeable fraction of the hydrogen is produced from hydrogen atoms.

The results of the present study clearly indicate that diradicals are intermediates in the photolysis of cyclopentanone in the vacuum ultraviolet. The broad applicability of diradical intermediates in explaining many experimental

observations on cyclic compounds has been demonstrated by Benson (14). Another interesting aspect of the present study is the insignificance of non-acyl carbon–carbon σ cleavage, particularly at 147.0 nm. This result requires that even at these energies most of the energy is absorbed in the carbonyl group. This is consistent with McMurry's assignment of the 150 nm absorption band of ketones to the $\pi-\pi^*$ transition (19).

We would like to express our sincere appreciation to Dr. Peter Ausloos for his gracious gift of a number of the deuterated compounds which were necessary to complete this study. This research was supported by the U.S. Atomic Energy Commission (AT(30-1)-3945).

Crystal Structure of a New Form of $Cu_3V_2O_8$

ROBERT D. SHANNON[1] AND CRISPIN CALVO
Institute of Materials Research, McMaster University, Hamilton, Ontario

Received June 30, 1972

A new form of $Cu_3V_2O_8$ was prepared at 30 kbar and 900 °C. The unit cell has dimensions $a = 6.2493(9)$, $b = 7.9936(9)$, $c = 6.3776(10)$ Å, $\beta = 111.49(1)°$, and the space group is $P2_1/c$. The crystal structure, refined by least-squares to a final $R = 0.054$, using 848 reflections, is similar to that of $Mg_3V_2O_8$. Chains of edge-shared M2 octahedra run along the c axis at about $y = \pm 1/4$ with M1 octahedra sharing two edges with the M2 octahedra. These octahedral networks at about $y = \pm 1/4$ are linked by corner-shared V–O tetrahedra. The distortion from the $Mg_3V_2O_8$ structure can be explained on the basis of the Jahn–Teller effect in which four of the octahedral Cu—O distances shorten to 1.93–1.99 Å and two Cu—O distances lengthen to 2.3–2.6 Å.

Nous avons préparé une nouvelle forme de $Cu_3V_2O_8$, à 30 kbar et 900 °C. La maille a les dimensions suivantes: $a = 6.2493(9)$, $b = 7.9936(9)$, $c = 6.3776(10)$ Å, $\beta = 111.49(1)°$; le groupe spatial est $P2_1/c$. La structure cristalline, raffinée par moindres carrés jusqu'à une valeur finale de $R = 0.054$ au moyen de 848 réflexions, est semblable à celle de $Mg_3V_2O_8$. Les chaînes d'octaèdres M2 à arêtes communes suivent l'axe des c, à environ $y = \pm 1/4$; les octaèdres M1 partagent deux arêtes avec les octaèdres M2. Ces réseaux octàdriques, aux environs de $y = \pm 1/4$, sont reliés par des tetraèdres V–O à coins communs. La distortion de la structure de $Mg_3V_2O_8$ peut s'expliquer en se basant sur un effet Jahn–Teller où quatre distances octaédriques Cu—O raccoursissent jusqu'à 1.93–1.99 Å et deux distances Cu—O allongent jusqu'à 2.3–2.6 Å.

Canadian Journal of Chemistry, **50**, 3944 (1972)

Introduction

Brisi and Molinari (1) reported the preparation of a variety of copper vanadates having the composition nCuO:V_2O_5 where $n = 1$, 2, 3, 4, and 5. Fleury (2, 3) confirmed the compositions with $n = 1$, 2, 3, and 5 but was unable to prepare $Cu_4V_2O_9$. Fleury found $Cu_3V_2O_8$ to decompose at 780 °C. We were interested in $Cu_3V_2O_8$ and $Cu_5V_2O_{10}$ because they are examples of vanadates containing a large percentage of the highly electronegative cation Cu^{2+}. Such compounds were expected to show average V—O distances greater than vanadates containing highly electropositive cations, *e.g.* Li_3VO_4, Ca_2VO_4Cl, and $Ca_3V_2O_8$. Although we were not able to prepare crystals of the $Cu_3V_2O_8$ phase reported by Brisi and Molinari (1) we were able to stabilize a new form of $Cu_3V_2O_8$ at elevated pressures. In this paper we report the synthesis and crystal structure of this new form of $Cu_3V_2O_8$, and compare the structure with that of other compounds having the stoichiometry $M_3V_2O_8$ where M = Co, Ni, Zn, and Mg.

Experiments

Stoichiometric quantities of spectrographic grade CuO and V_2O_5 (Johnson–Matthey) were carefully mixed and heated in air at 700 °C for 24 h. The product was identified as the $Cu_3V_2O_8$ prepared by Brisi and Molinari. This material was heated at a temperature of 900 °C and a pressure of 30 kbar for 2 h and quenched according to a procedure described earlier (4). Small irregular crystals with a dark red color were obtained. Powder diffraction patterns obtained from these crystals indicated a phase different from the starting material. Although the majority of the crystals were badly twinned, a crystal suitable for the structure determination was eventually obtained. The space group was found from precession photographs to be $P2_1/c$. X-Ray powder diffraction photographs were taken with a Hägg–Guinier camera using a KCl internal standard. The d values were obtained using λ (CuKα_1) = 1.54051 Å and a (KCl) = 6.2531 Å. Cell dimensions determined by least squares refinement are $a = 6.2493(9)$, $b = 7.9936(9)$, $c = 6.3776(10)$ Å, $\beta = 111.49(1)°$ at $T = 20$ °C. Other crystal data are: formula wt. = 420.50, $Z = 2$, $d_x = 4.66$ g/cc. Differential thermal analysis performed on the starting material showed two endotherms on heating, one at 500 °C and one at 725°. Apparently there is a phase transition at 500° followed by decomposition at 725 °C. Because of this phase transition at 500 °C it is not possible to say whether the phase reported in this paper is indeed a high-pressure phase or a high-temperature polymorph.

A single crystal of irregular shape and approximate dimensions, 0.19 × 0.14 × 0.18 mm was used to obtain the intensity data. Intensities were collected on a Syntex automatic diffrometer using MoKα radiation, a graphite monochromator ($2\theta = 12°$) and a scintillation detector. Reflections were scanned in the 2θ–θ mode at variable rates from 2.0°–24.0°/min, depending on the peak count, through an angle of 2° plus the α_1–α_2 separation. Background counts were made at the extremes of each scan for

times equal to the peak count. The $\bar{1}30$ reflection was chosen as an internal standard and monitored every 50 reflections. No significant deviation in its intensity was noted. The average deviation in intensity of the 60 $0kl$ pairwise equivalent reflections measured was approximately 9% with about 10% of these deviating by as much as 25%. These variations are to be anticipated from the shape of the crystal and imply some systematic error. A total of 848 independent reflections were measured of which 710 were observed. A reflection was considered to be unobserved if the intensity was less than three times the standard deviation of the background $\sigma^2 = \sigma^2_{peak} + \sigma^2_{B1} + \sigma^2_{B2}$. The maximum 2θ was 60°. The intensities were corrected for Lorentz and polarization factors and for absorption assuming a sphere of radius 0.008 cm ($\mu r = 1.18$) using X-ray 67 Program System for X-ray Crystallography written by J. M. Stewart, University of Maryland and adapted to the CDC 6400 computer by H. D. Grundy.

The positions of the metal atoms were obtained from $h0l$ and $0kl$ Patterson projections and the knowledge that Cu(1) must be in a special position. Electron density difference maps were used to locate the four oxygen atoms. Cu(1) was placed at the origin and all other atoms in equipoint 4e. Several cycles of refinement using the full-matrix least squares program CUDLS (5) reduced

$$\omega R = \left\{ \frac{\sum \omega ||F_o| - |F_c||^2}{\sum \omega |F_o|^2} \right\}^{1/2}$$

to 0.109, with isotropic temperature factors. At this stage the isotropic U values were 0.008 for both Cu ions, 0.005 for V, and 0.010, 0.009, 0.009, and 0.009 for O(1), O(2), O(3) and O(4), respectively. A Cruickshank weighting scheme was used in which $\omega = (9.95 - 0.303|F_o| + 0.0141|F_o|^2)^{-1}$. The weights ω were chosen so as to make $\omega||F_o| - |F_c||^2$ independent of the variation in F_o. Unobserved reflections were assigned a maximum possible intensity of 3σ and these were given zero weight if $F_c < F_o$. Further refinement using anisotropic temperature factors and the secondary extinction coefficients calculated according to Zachariasen (6) reduced R to 0.054 and ωR to 0.067 for all reflections. The standard deviation of a reflection of unit weight was 1.00. The last cycle of refinement had a maximum shift over error of 0.02 and an average of 0.004. The secondary extinction parameter refined according to the method of Larson (7) was found to be $c = 3.11 \times 10^{-7}$. Scattering factors for neutral Cu, V, and O were taken from Cromer and Waber (8) with real and imaginary anomalous dispersion terms given by Cromer (9). Table 1 lists the observed and calculated structure factors[2] and Table 2 lists the atomic coordinates with anisotropic temperature factors.

Results and Discussion

Figure 1 shows a perspective view of $Cu_3V_2O_8$ looking along the c axis. The structure is similar to that of $Ni_3V_2O_8$ (10, 11), $Co_3V_2O_8$ (11, 12),

[2]Table 1 is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

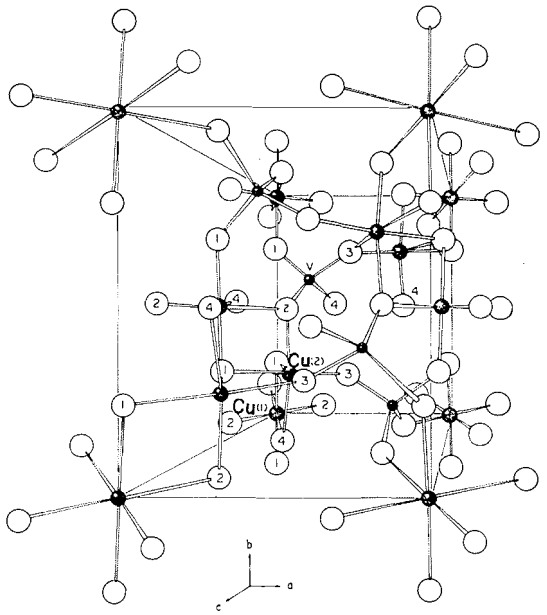

FIG. 1. Perspective view of $Cu_3V_2O_8$ along the c axis. Solid black spheres are V, shaded spheres are Cu, and open spheres are O.

$Zn_3V_2O_8$ (13), and $Mg_3V_2O_8$ (14). These structures are characterized by chains of edge-shared M(2) octahedra running along the a axis near $y = 1/8$, $z = 1/4$ and $y = 3/8$, $z = 3/4$ as shown in Fig. 2a. The M(1) octahedra are situated at $y = 0$, $z = 0$ and $y = 1/2$, $z = 1/2$ and each shares 2 edges with the M(2) octahedra. The network of octahedra containing M(2) ions at $y = 1/8$ is linked to the network of octahedra at $y = 3/8$ by corner-sharing V—O tetrahedra.

In $Cu_3V_2O_8$ the same network of Cu—O octahedra linked by V—O tetrahedra can be seen. The chains of edge-shared octahedra run along the c axis approximately at $y = 1/4$ and 3/4 (see Figs. 1 and 2b). However the Jahn–Teller effect typical of Cu^{2+} which frequently results in four short bonds and two longer bonds has distorted the structure, reducing the symmetry from $Cmca$ to $P2_1/c$. Figure 2b shows the relationship between the two unit cells. The approximate corresponding cell dimensions are $Cu_3V_2O_8$: $a \cos\beta = 5.8$, $b = 8.0$, $c = 6.4$ Å; $Mg_3V_2O_8$: $b/2 = 5.7$, $c = 8.3$, $a = 6.1$ Å. Table 3 contains pertinent bond lengths and angles for $Cu_3V_2O_8$. The octahedra in $Mg_3V_2O_8$ (14) are relatively undistorted: around Mg(1), 2.034 Å ×

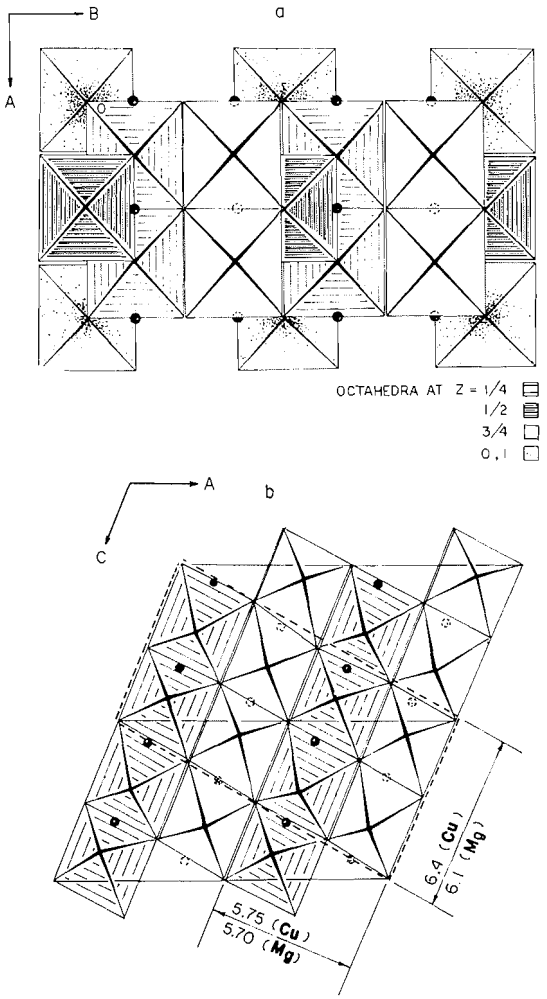

FIG. 2 (*a*) An *ab* projection of $Mg_3V_2O_8$ showing the arrangement of the MgO_6 octahedra. Small spheres represent V atoms. (*b*) An *ac* projection of 4 unit cells of $Cu_3V_2O_8$ showing an octahedral arrangement similar to that of $Mg_3V_2O_8$. The dotted line corresponds to one unit cell of $Mg_3V_2O_8$. Only the edge-shared octahedra at about $y = 1/4$ and 3/4 are shown.

2 and 2.130 Å × 4 and around Mg(2), 2.022 Å × 2, 2.135 Å × 2, and 2.118 Å × 2. In $Cu_3V_2O_8$ the octahedra are greatly distorted: around Cu(1), 1.912 Å × 2, 1.978 Å × 2, and 2.595 Å × 2 and around Cu(2) 1.931, 1.962, 1.967, 1.988, 2.288, and 2.640 Å. The oxygen ions around both Cu(1) and Cu(2) in approximate (201) planes of $Cu_3V_3O_8$ have shortened whereas the oxygen atoms perpendicular to (201) have lengthened. This results in $b(Cu_3V_2O_8) < c(Mg_3V_2O_8)$ and a shortening along a 110 diagonal of $Mg_3V_2O_8$.

The CuO_6 groups sharing an edge have the axially elongated Cu—O bonds nearly parallel. If $Cu_3V_2O_8$ were to crystallize in the $Mg_3V_2O_8$ structure these bonds would necessarily lie parallel to the *c* axis of $Mg_3V_2O_8$ in order that the 2/*m* site symmetry at cation (1) be preserved. However, in $Cu_3V_2O_8$ we find that these elongated bond lengths run parallel to $a + 2c$ rather than the *b* axis. In this manner O(1), which is the only oxygen atom bonded to three Cu ions and the vanadium ion, can reduce its bond strength whereas in the $Mg_3V_2O_8$ structure a comparable weakening of the bonds to this over-bonded oxygen atom cannot occur.

The VO_4 tetrahedron is distorted with distances varying from 1.670 to 1.795 Å. These variations, however, are consistent with distances anticipated from a consideration of the number and strength of cation bonds to each anion. Baur (15) has demonstrated this relationship for a number of tetrahedral oxyanions and Gopal (16) has extended this to vanadates. Gopal (16) derived a relation for tetrahedrally-coordinated V^{5+}, $d(V^{5+}—O) = 1.384 + 0.1602\ p_0$, where p_0 = the sum of electrostatic bond strengths around oxygen. Using the slope of this line and a mean V^{5+}—O value from Shannon and Calvo (17) to calculate V—O distances according to Baur's procedure, we have listed in Table 4 observed and predicted V—O distances in $Cu_3V_2O_8$. Note that his prescription arbitrarily redistributes the valency units so that short Cu—O bond lengths contribute twice as much as do the longer ones. The agreement between observed and calculated distances is rather poor.

Using the relations:

$$[1] \qquad s_{Cu^{2+}} = 0.333\left(\frac{2.084}{R}\right)^{5.3}$$

$$[2] \qquad s_{V^{5+}} = 1.25\left(\frac{1.714}{R}\right)^{5.1}$$

derived from a number of Cu- and V-containing oxides (18) to calculate the strengths of Cu—O bonds and determining the V—O bond strengths as the difference between 2.0 and the sum of the Cu—O bond strengths, there is a fairly good correlation between V—O lengths calcu-

[1] $$s_{Cu^{2+}} = 0.333\left(\frac{2.084}{R}\right)^{5.3}$$

[2] $$s_{V^{5+}} = 1.25\left(\frac{1.714}{R}\right)^{5.1}$$

†Values in parentheses are average bond strengths calculated from s = valence/coordination no.

lated from eq. 2 and the observed V—O lengths. Table 5 lists the results of the calculation of bond strength sums around all atoms using (*1*) eqs. 1 and 2, and (*2*) using Pauling's system (results given in parentheses) which takes average cation coordination number only into account. Using the analytical expressions 1 and 2, the Pauling electrostatic valence rule is satisfied with an average deviation of about 4% from the ideal values of 2.0 for Cu^{2+}, 5.0 for V^{5+}, and 2.0 for O^{2-}.

The mean V—O distance of 1.725 Å agrees well with the value of 1.721 ± 0.012, the grand mean derived from 21 other well-refined vanadate structures (17). The effective ionic radius of V^{5+} in $Cu_3V_2O_8$ (0.365 Å) obtained by subtracting an appropriate oxygen radius (19) is significantly larger than that obtained from Li_3VO_4 (0.337 Å) (17), $Ca_3V_2O_8$ (0.335 Å) (20), Ca_2VO_4Cl (0.327) (21), and KVO_3 (0.344 Å) (22). In ternary $M_xV_yO_z$ systems this behavior can be correlated with the relative strengths of the M—O bonds. Because individual V—O distances show a strong correlation with the total strength of the M—O bonds (see column 4 in Table 4) it is not surprising to find that the average V—O distance is similarly affected. Thus, stronger bonds such as Cu^{2+}—O (as estimated from electronegativity or electrostatic bond strength criteria) result in longer average corrected V—O distances than weaker bonds such as Li—O, Ca—O, or K—O.

The thermal ellipsoid for all the atoms, shown in Table 6, are remarkably similar. The maximum amplitudes range from 0.100 to 0.136 Å and the minima lie between 0.040 and 0.069 Å. These maxima lie in the direction of the long bond Cu—O bonds for the copper

Coordination Compounds of Indium. Part XIX[1]. Ligand Exchange Studies with Indium(III) Complexes of Trifluoromethyl-β-diketonates

MRS. G. M. TANNER, D. G. TUCK,[2] AND E. J. WELLS

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received, March 7, 1972

The ligand exchange reaction between InL_3 con plexes ($L = CF_3.CO.CH.CO.R^-$ anion; R = methyl, *i*-butyl, phenyl, 2-naphthyl, and 2-thienyl) and excess free ligand (HL) has been studied in the solvents di-isopropyl ketone, acetonitrile, benzene, and dimethylsulfoxide. Studies of the lifetimes of the reactants as obtained from their ^{19}F n.m.r. line-widths show that the exchange is first order in InL_3 concentration, but zero order in free ligand concentration. The coalescence temperature for the collapse of the n.m.r. ^{19}F chemical shift between free and complexed ligand (~50 Hz) yields ΔG^* for the exchange. The results are in agreement with the known stereochemical properties of indium(III) complexes. The rate-controlling process in the exchange is identified as the rotation of one monodentate ligand about a partial double bond prior to intramolecular proton transfer to a second monodentate ligand.

La réaction d'échange de ligand entre les complexes de InL_3 (L = anion $CF_3.CO.CH.CO.R^-$; R = méthyle, isobutyle, phényle, naphtyl-2, et thiényl-2) et un excès de ligand libre (HL) a été étudiée dans les solvants di-isopropylcétone, acétonitrile, benzène, et diméthylsulfoxyde. Les durées de vie des réactants, obtenues à partir des largeurs de raies RMN du ^{19}F, montrent que l'échange est du premier ordre par rapport à la concentration en InL_3 et d'ordre zéro par rapport au ligand libre. La température de coalescence du déplacement chimique du ^{19}F entre le ligand libre et le ligand complexé (~50 Hz) conduit à ΔG^* pour l'échange. Les résultats sont en accord avec les propriétés stéréochimiques connues pour les complexes du l'indium(III). Le processus contrôlant la vitesse de l'échange à été identifié à la rotation d'un ligand monodentate autour d'une double liaison partielle avant le transfert intramoléculaire de proton à un second ligand monodentate.

Introduction

In recent years, a number of papers have appeared on the kinetics and mechanism of the exchange reactions between metal chelate complexes of various β-diketonates and the free ligand. In some experiments (1, 2), the ligand has been labelled with ^{14}C radioactive tracer, in which case the final separation of ligand and complex is a critical experimental step. Alternatively, differences in the proton magnetic resonance spectra of free and complexed ligand can be utilized in these kinetic studies (3), and both diketonate and organometal–acetylacetonate (4) complexes have been investigated in the latter way.

We now report the results of ^{19}F n.m.r. studies of ligand exchange between chelates of indium(III) and ligands of the type $CF_3.CO.CH_2.CO.R$ in a number of organic solvents. Indium complexes were selected in order to extend the knowledge of the stereochemistry of the coordination complexes of this element (5) to include kinetic systems. Use of the partially fluorinated diketones allows the ^{19}F resonances of free and complexed ligand to be used to explore the exchange; the fact that the ^{19}F chemical shifts are significantly larger than in the analogous proton experiments is of some advantage in this respect. The availability of a group of these diketonates allowed a range of complexes with varying substituents R to be investigated; InL_3 complexes with R = methyl, *i*-butyl, phenyl, 2-naphthyl, 2-furyl, and 2-thienyl were prepared and studied. The compound R = 2-thienyl is the well-known analytical reagent TTA (thenoyltrifluoroacetone), which leads to some interesting comparisons between the present results and previous reports of mixed chelate–neutral donor complexes of TTA and tri-*n*-butyl phosphate with trivalent metal cations (6, 7).

Experimental

Preparative

In a typical procedure, indium metal (0.62 g) was dissolved in concentrated nitric acid and the solution evaporated to give indium trinitrate hydrate (8). This was dissolved

in water, the p*H* of the solution adjusted to 6, a solution of TTA (3.2 g) in chloroform added, and the two-phase mixture refluxed for 2 h. Evaporation of the separated chloroform phase yielded a pink solid which was recrystallized from chloroform–petroleum ether as white needles. This procedure yielded the compounds listed in Table 1; reactions were also carried out in this way with the R = 3-pyridyl diketone, but we were unable to obtain the expected crystalline indium complex.

Indium analysis was by titration against EDTA, using pyridine-2-azo-4-resorcinol as indicator (9). Molecular weights were obtained from the parent peak in the mass spectrum, using a Hitachi Perkin–Elmer RMU-6E instrument operating in the single focussing mode at an excitation energy of 80 V, and a sample temperature of 250 °C. Analytical results are given in Table 1.

Nuclear Magnetic Resonance Studies

All ^{19}F n.m.r. spectra were obtained in standard capped 5 mm sample tubes with a Varian A56/60 spectrometer, operating at an oscillator frequency of 56.4 MHz. Resonance frequencies were measured with reference to an external standard of liquid trichlorofluoromethane (see Table 1).

Temperature variation experiments were carried out over the range −40 to 100 °C, unless otherwise restricted by the physical properties of the solvent. Sample temperatures were determined by the usual proton shift n.m.r. thermometers using methanol or ethylene glycol separations at 60 MHz, and are believed to be accurate to within 2 °C. Solutions for the temperature dependence studies contained the InL_3 complex at concentrations in the range 0.4–0.7 *M* (depending on solubility, molecular weight, etc.), and an exactly threefold concentration of free ligand, in order to maintain the nuclear exchange process between chemically shifted sites of identical nuclear population (10, 11).

Solvents

Solvents were Reagent Grade materials. Acetonitrile was distilled from phosphorus pentoxide before use.

In addition to the solvents shown in Table 2, we also investigated 1-propanol and nitromethane. With the former, the compounds proved insufficiently soluble for meaningful spectra to be recorded. With nitromethane, results could only be obtained with $In(CF_3.CO.CH.CO.CH_3)_3$; insolubility again prevented investigation of the other complexes.

Results and Discussion

Theory

For an exchange in a system at equilibrium

$$[1] \qquad aA + bB \underset{k}{\overset{k}{\rightleftharpoons}} aA + bB$$

the average lifetime τ_A of a single reactant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molecule A is given by (12)

$$[2] \qquad \tau_A^{-1} = \frac{1}{[A]} \cdot \frac{d[A]}{dt} = k[A]^{a-1}[B]^b$$

An exactly analogous equation gives τ_B. In the slow exchange limit (τ_A^{-1}, $\tau_B^{-1} \ll 2\pi\Delta\nu_{AB}$), the width of the n.m.r. resonance line due to A (or some group characteristic of A) is simply related to τ_A^{-1}, and hence can yield the order of the reaction.

Experiments of this type reported below establish that the overall order of reaction in the exchange systems studied is unity. In this case, the reciprocal lifetime of one of the species is just the rate constant k. For chemical exchange of equivalent nuclei between two distinct sites of equal nuclear population, and equal transverse relaxation rates R_2 separated by a chemical shift difference $\Delta\nu = \Delta\omega/2\pi$ Hz, coalescence of the individual site resonances occurs when the chemical exchange rate constant k (s^{-1}) reaches the value (13, 14)

$$[3] \qquad k_c = \Delta\omega/\sqrt{2} = \sqrt{2}\pi\Delta\nu$$

which occurs at a temperature T_c, the coalescence temperature. Thus the observation of the temperature dependence of the n.m.r. spectrum, together with independent measurement of the chemical shift parameters, leads to the chemical exchange rate k_c at the single temperature T_c. This information, together with the well-known Eyring rate equation based on the assumptions of the theory of absolute reaction rates (15, 16)

$$[4] \qquad k_c = \kappa \frac{\boldsymbol{k}T_c}{h} \exp\left(-\Delta G^{\ddagger}/RT_c\right)$$

or

$$[5] \qquad \Delta G^{\ddagger} = RT_c \ln \frac{hk_c}{\kappa \boldsymbol{k} T_c}$$

allows the determination of the activation parameter $\Delta G^{\ddagger}$. In eqs. 4 and 5, the transmission coefficient κ may be arbitrarily assigned the value 0.5 without introducing appreciable error; $\boldsymbol{k}$ is the Boltzmann constant, and the other symbols have their usual significance. A feature of eq. 4 is that for the conditions used in the present work the derived values of $\Delta G^{\ddagger}$ are quite insensitive to errors in both T_c and $\Delta\nu$. Thus for T_c in the region of 330 °K, an error of $\pm 10°$ in T_c introduces an error of only ± 0.5 kcal mol^{-1} in a derived $\Delta G^{\ddagger}$ of about 15 kcal mol^{-1} (*i.e.*, $\sim 3\%$ error); similarly an error of $\pm 20\%$ in the measurement of $\Delta\nu$ leads to an error of ± 0.12 kcal mol^{-1} in $\Delta G^{\ddagger}$ at the same temperature. This might seem to imply that $\Delta G^{\ddagger}$ cannot be measured with any certainty by this technique, but in fact the coalescence method can only be used for $\Delta G^{\ddagger}$ values in the limited range of approx. 8–18 kcal mol^{-1}, and within this range the results are quite reliable.

While $\Delta G^{\ddagger}$ alone is less informative than independent measurements of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, the above simple method, where applicable, obviates the notorious problems associated with n.m.r. determinations of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ independently (11). For a comparative study of exchange in related systems, or of the solvent dependence of a common exchange process, one may expect that little is lost by consideration of $\Delta G^{\ddagger}$ alone.

^{19}F n.m.r. *Lifetime Measurements*

As noted above, the order of the exchange reaction can be established by following the life-times of the individual species as a function of reactant concentration, measuring the n.m.r. line widths below coalescence (eq. 2). We chose to investigate the reaction order for the system $In(tfac)_3$/Htfac in di-isopropyl ketone (Htfac = 1,1,1-trifluoromethyl-2,4-pentadione; **1**, R = CH_3), since in this case the ^{19}F resonances are well-resolved below coalescence at the temperature of the probe of the n.m.r. spectrometer, with $\Delta\nu$ at 36 °C = 50 Hz. It is worth noting here the contrast between the ^{19}F and ^1H spectra. The ^1H spectrum of Htfac in carbon tetrachloride consists of sharp singlets at 132 (CH_3) and 353 Hz (γ—CH) downfield from internal TMS; for $In(tfac)_3$ these frequencies are 136 and 352 Hz, while a 3:1 mixture of Htfac and $In(tfac)_3$ show singlets at 133 and 352 Hz. The ^{19}F spectra clearly give rise to more reliable data over a convenient temperature range than could be the case in studies of proton resonances in such systems.

The results reported in Table 2*a* show the ^{19}F line-width for $In(tfac)_3$ and Htfac as a function of the amount of solid complex added to a solution containing a constant quantity of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ligand. Since the volume changes involved in this case are small the results establish that τ_{Htfac} is a linear function of the complex concentration within experimental error. The only point which deviates from a linear plot is that for the highest InL_3 concentration; here the spectral line for the complex is broad, and non-Lorentzian, overlapping significantly with the free ligand peak, so that the slow exchange limit approximation is not valid.

The half-width of the ^{19}F resonance of the complex in Table 2*a* is sensibly constant. A similar result was obtained in experiments using constant amounts of $In(tfac)_3$ and varying quantities of added ligand. For 0.31 mmol $In(tfac)_3$ and 0.27, 0.55, and 1.04 mmol Htfac at 36 °C, the complex line-widths were 11.5, 12.5, and 12.5 Hz; similarly with 0.22 mmol $In(tfac)_3$, and 0.27, 1.15, and 2.57 mmol Htfac the line-widths were 12.5, 13.0, and 12.5 Hz, so that the line-width is sensibly constant at 36 °C at 12.5 ± 0.5 Hz. A final series of measurements at 42 °C gave the results in Table 2*b*, which show that the line-width for tfac is inversely dependent on [Htfac]; the line-width for $In(tfac)_3$ is once again constant within experimental error. The two expressions for the average life-times are then

$$[6] \qquad \tau_{tfac}^{-1} = k[\text{Htfac}]^{-1}\,[\text{complex}]^{1}$$

$$[7] \qquad \tau_{complex}^{-1} = k[\text{Htfac}]^{0}\,[\text{complex}]^{0}$$

and the rate law for the exchange in di-isopropyl ketone must be of the form

$$[8] \qquad R = k[InL_3]^{1}\,[HL]^{0}$$

It is important in terms of the subsequent discussion to emphasize that the experiments just described were with concentrations similar to those used in the $\Delta G^{\ddagger}$ determinations, and that the range of mole ratios studied spanned the condition $[InL_3] = 3[HL]$ used in those measurements.

Finally we note that since the stability constants of the InL_3 species studied are all very similar, and since the pK_a values of the individual ligands fall within a small range (5.8–6.7) (17), a rate law of the same form, and hence a similar mechanism, should apply in all the InL_3/HL systems studied in the present work.

Experimental Free Energies of Activation

Table 3 shows the experimentally observed coalescence temperatures for a number of complex–ligand systems in a variety of solvents, together with the relevant changes in the ^{19}F resonance frequency between the complex and the free ligand. In a number of systems, complete coalescence of the complex and ligand resonance peaks could not be observed because of limitations imposed by the boiling point of the solvent, but in some of these cases it was possible to estimate an approximate coalescence temperature. Since the calculation of $\Delta G^{\ddagger}$ from $\Delta\nu$ (eq. 3) involves T_c predominantly in a linear term (see above), the errors introduced in this way are not large. With solutions in dimethylsulfoxide (dmso), separate complex and free ligand resonances could not be observed in the available temperature range (*i.e.* even down to the freezing point of the solvent, 18.5 °C), and the chemical shift $\Delta\nu$ was therefore estimated from separate solutions of the individual species in dmso. This procedure may introduce some small errors because of possible differences in the bulk susceptibilities of the two solutions being compared, but the values for solutions are in any case estimated upper limits, so that these susceptibility problems can be neglected. We can also neglect errors which might arise from possible changes in $\Delta\nu$ on changing the temperature from ambient (say 36 °C) to T_c; as emphasized above, the derived values of $\Delta G^{\ddagger}$ are relatively insensitive to errors in $\Delta\nu$.

Solubility restrictions prohibited meaningful measurements in a number of cases (see Experimental). The only complex–ligand pair that could be investigated in nitromethane was for the ligand $CF_3.CO.CH_2.CO.CH_3$, for which we estimate $T_c \sim 110°$ (the b.p. of CH_3NO_2 is 101°); $\Delta\nu$ is 47 Hz, leading to an approximate value of 17.9 kcal mol^{-1} for $\Delta G^{\ddagger}$.

Reaction Mechanism

The results obtained show that rapid ligand exchange occurs in all the InL_3/HL systems studied in the present work. We base our discussion of the mechanism of the reaction on the scheme originally proposed by Adams and Larsen (3) for ZrL_4 and HfL_4 systems, and subsequently adopted by other workers (1, 2, 4).

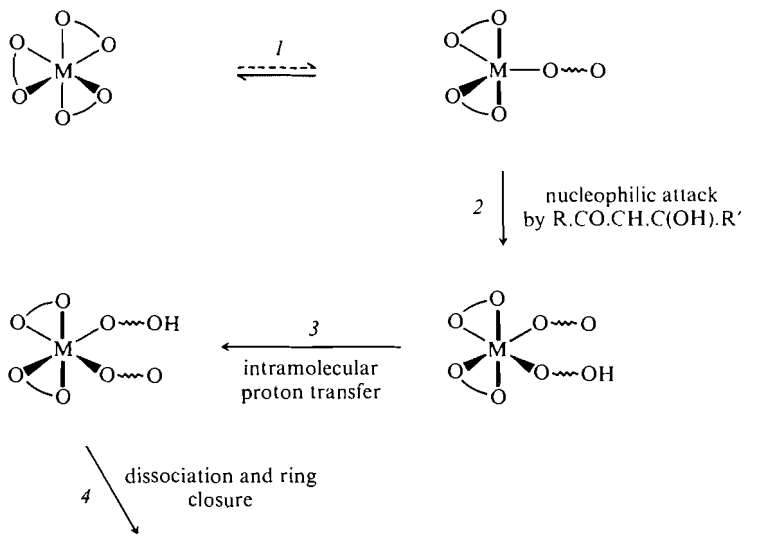
*Asymmetric peak at coalescence.
†Insufficient solubility for measurement.

For a six coordinate complex, the reactions are:



The diketone form of the free ligand does not undergo exchange (3). Various pieces of evidence support different aspects of this scheme for InL_3 complexes.

(*A*) In the light of the known stereochemical behavior of indium(III) complexes, a mechanism requiring a change of coordination number is readily acceptable. Coordination numbers of two, three, four, five, and six have been reported (5, 18), and both preparative work, and studies of solutions in aqueous and non-aqueous solvents (5, 19, 20), have shown that four, five, and six-coordinate neutral and anionic species may co-exist, and readily interchange. The high rate of exchange at the coalescence temperature ($k_c \sim 10^2$ s^{-2}) is in keeping with the known tendency of indium(III) complexes to establish the appropriate equilibrium situation very rapidly in solution (5).

(*B*) The thermodynamic stability of the InL_3 complexes (17) argues against any mechanism involving complete dissociation into free ligand and a charged or neutral residue. At the same time, coordination numbers greater than six are rare for indium(III), so that a dissociative step of some sort must be assumed (*i.e.* step 1). Fay and Piper (21) have reported studies of intramolecular rearrangements in a number of ML_3 chelate complexes, including $In(tfac)_3$, and conclude that such reactions require a five-coordinate intermediate with one monodentate ligand, in equilibrium with the normal tris-chelated form (*i.e.* equilibrium 1 above). This equilibrium is very fast, with ΔG^* for $In(tfac)_3$ below 11.0 kcal mol^{-1}. Fay and Piper were not able to obtain n.m.r. evidence to establish the existence of significant concentrations of the five-coordinate species, and the spectrum of $In(tfac)_3$ was a sharp singlet at all temperatures down to their temperature limit of -57 °C.

We have confirmed this result for the following $In(CF_3.CO.CH.CO.R)_3$ complexes in $CDCl_3$: R = 2-thienyl to -50°; R = 2-furyl to -37°; R = *i*-butyl to -43°; R = *t*-butyl to -25°, and for $In(acac)_3$ to -56°. These temperatures represent limits set by freezing or solubility factors, and do not imply that multiplets appear at lower temperatures. Such results, together with the extensive studies by Fay and Piper (21) show that the rapid formation of a five-coordinate intermediate is a likely step in the intermolecular exchange mechanism. Equally, because of its rapidity, this cannot be the rate-controlling step in the intermolecular process at issue here.

(*C*) An interesting piece of supporting evidence for one aspect of this mechanism comes from work on the crystal structure of $[(Meen)_2Cu(CF_3.CO.CH.CO.CF_3)_2]$, where Meen = $(CH_3)_2NC_2H_4NH_2$ (22). In this molecule, the copper atom is six-coordinate, with two bidentate *N,N*-dimethylethylenediamine ligands and two monodentate hexafluoropentane-2,4-dionate ligands; the non-coordinated oxygens of the latter are each hydrogen-bonded to a hydrogen atom of an amino group. This structure confirms that monodentate diketonate ligand can indeed exist, and it seems reasonable that such a structure could be involved in the exchange mechanism described above. The bond lengths show that delocalization is important in the O—C—C—C—O system of the monodentate dionate ligand.

While the general scheme receives support, the present results are in marked contrast with those of Adams and Larsen (3) in one important respect, namely, reaction orders. These authors found that the rate of exchange was first order in both ML_4 and HL, and identified the rate-controlling step as the loss of the monodentate ligand from the ML_5 intermediate (M = Hf or Zr). The analogous process in the above scheme (step 4) cannot be rate-controlling in the InL_3/HL system, and in fact the only step which would give the correct order if rate-controlling is step 3, the intramolecular proton transfer reaction between the two monodentate ligands. The barrier here is presumably not the transfer itself, but the rotation of the monodentate ligand required to bring the —C—OH group of one ligand into the correct orientation with the C=O group of the other. Such a rotation will be hindered by the partial double bond character of the O—C—C—C—O system (see (*C*) above). The free energies of activation of 15–20 kcal mol^{-1} (Table 3) are in keeping with this argument, since such values are typical of the activation barrier to rotation in various well-studied simple carbonyl systems; E_a = 14–16 kcals mol^{-1} for *N,N*-dimethyl carbamyl chloride (23–26), and 18.3 kcal mol^{-1} in the analogous fluoride (27); $\Delta G^{\ddagger}$ is 18 kcal mol^{-1} at room temperature in dimethyl trifluoroacetamide, 17.3 in dimethyl acetamide, and 14.8 in dimethyl benzamide (28), and near 20.5 kcal mol^{-1} in dimethyl formamide (24, 29).

Effects of Solvent, and of the Group R

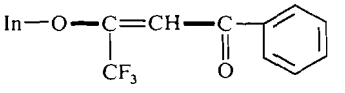
The results in Table 3 indicate that the order of increasing $\Delta G^{\ddagger}$ of the various ligands in the four solvents used is: dimethylsulfoxide < di-isopropyl ketone < acetonitrile < benzene, so that $\Delta G^{\ddagger}$ increases with decreasing ability of the solvent to act as a hydrogen-bond acceptor. In terms of the intramolecular hydrogen transfer mechanism proposed above, we conclude that the transfer is facilitated by hydrogen-bonding of the transition state to the solvent. This could result from the solvent acting as a protonating bridge from the enol unidentate ligand to the keto unidentate ligand, reducing the strict orientation requirements, or from a lowering of the rotation barrier of the enol form by H-bonding to the solvent.

There is no apparent dependence of the $\Delta G^{\ddagger}$ values on the stability constants (K_1) for the InL_3 complexes, nor on the pK_a values of the parent ligands (17). This is not surprising, since $\Delta G^{\ddagger}$ must involve not only pK_a, but also important $\Delta S^{\ddagger}$ terms such as those for the solvation of the species in question.

We note finally in this respect that in detailed studies of the $In(tfac)_3$/Htfac/di-isopropyl ketone systems, the addition of solvent saturated with water caused no significant change in the ^{19}F n.m.r. spectrum. This result is in contrast to the very marked effect of traces of water found by Adams and Larsen (3) in the $Hf(tfac)_4$/Htfac/benzene system.

Other Studies

Attempts were made to confirm the reaction scheme set out earlier for $In—O_6$ complexes by some further experiments, in which we examined the u.v./visible spectra of InL_3 (R = phenyl) species in solution, arguing that if monodentate diketonate groups containing an aromatic substituent are present, light absorption by a highly conjugated system such as



might be observed. We could find no detectable light absorption by solutions in organic solvents such as chloroform or methanol, nor were any n.m.r. signals additional to those of the free ligand and the complex detected on cooling solutions of 3:1 mixtures to −55 °C.

The synergistic extraction of iron(III) and cobalt(III) with mixtures of acetylacetone (acac) and tri-octylphosphine oxide (TOPO) has been discussed in terms of mixed $[M(acac)_3TOPO]$ complexes, implying one monodentate acetylacetone ligand (7). We therefore examined solutions of InL_3 (R = phenyl) in the presence of added TOPO, but again no light absorption could be detected. We therefore conclude that the steady-state concentration of complexes containing monodentate ligand in such systems is extremely small.

Synthesis and Reactions of Strained Hydrocarbons Possessing Inverted Carbon Atoms. Tetracyclo[3.3.1.1^{3,7}.0^{1,3}]decanes

R. E. PINCOCK, J. SCHMIDT, W. B. SCOTT, AND E. J. TORUPKA

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 26, 1972

Tetracyclo[3.3.1.1^{3,7}.0^{1,3}]decane (*i.e.*, 1,3-dehydroadamantane or DHA) and its 5,7-dimethyl derivative may be synthesized from the corresponding 1,3-dibromoadamantane compounds with sodium–potassium alloy in ether or heptane. These highly strained cyclopropyl compounds are very reactive towards free radical and electrophilic reagents. They homopolymerize 140–160° to thermally resistant, insoluble materials and spontaneously copolymerize with oxygen in solvents at room temperature. Reaction with bromine in ether at −70° yields an intermediate bromoadamantyloxonium tribromide which decomposes to 1-bromo-3-ethoxyadamantane on warming. Other rapid reactions of these strained 1,3-dehydroadamantanes are reported.

La tétracyclo[3.3.1.1.^{3,7}0^{1,3}]décane (c'est-à-dire le déhydro-1,3 adamantane ou DHA) et son dérivé diméthyl-5,7 peuvent être synthétisés à partir des dibromo-1,3 adamantanes correspondants par traitement à l'alliage sodium–potassium dans l'éther ou l'heptane. Ces composés cyclopropyles hautement tendus sont très réactifs envers les radicaux et les réactifs électrophiles. Une homopolymérisation se produit à 140–160° avec formation de matériaux thermorésistants et insolubles; en présence d'oxygène dans les solvants et à la température ambiante, il y a copolymérisation spontanée. La réaction avec le brome à −70° dans l'éther conduit à l'intermédiaire tribromure de bromoadamantyloxonium qui se décompose par chauffage en bromo-1 éthoxy-3 adamantane. D'autres réactions rapides de ces déhydro-1,3 adamantanes tendus sont raportées.

Introduction

Many properties of cyclopropyl compounds and small ring polycyclic compounds can be related to the presence of hybridized carbon atoms possessing high p-character in the constrained C—C bonds. It is of interest to further increase the constraints at bridgehead atoms by incorporating more short bridges between atoms in small rings. This could possibly lead to even greater p-character at the bridgeheads of a polycyclic ring system and to new reactivity characteristics. This possibility has been considered with some hypothetical compounds, *e.g.*, tricyclo[2.2.2.0]octane (1–4), and some special reactivity has been demonstrated in related tricyclo[3.2.1.0]octane compounds **1** (3). This latter ring structure possesses an internal C—C cyclopropyl bond which is essentially formed by sigma bonding of two p-orbitals. The configuration of carbon at the bridgehead may be termed "inverted" (3) since, with respect to the plane defined by three of the attached atoms (see dotted lines in diagram of structure **2**), the quaternary bridgehead atom lies on the opposite side from the fourth attached atom.

1

2

We present here the synthesis and some reactions of two readily accessible compounds of this type,[1] tetracyclo[3.3.1.1^{3,7}.0^{1,3}]decane (**4**, Y = H) and its 5,7-dimethyl derivative, (**4**, Y = CH_3) commonly named 1,3-dehydroadamantanes or DHA's. These compounds are highly reactive in unusual ways and they may be used to form various derivatives of adamantane including polymeric materials.

Results and Discussion

Preparations

A relatively inconvenient preparation of 1,3-dehydroadamantane has been briefly described in a communication (6). The reaction of 1,3-dibromoadamantane (**3**; X = Br, Y = H) with Na–K alloy in refluxing heptane (6) was sensitive to reaction conditions. The reaction sometimes refused to start unless various additives were present. It is not clear whether traces of

[1]Crystallographic data show that 1,3-dehydroadamantanes possess inverted carbon atoms at the bridgeheads (5).

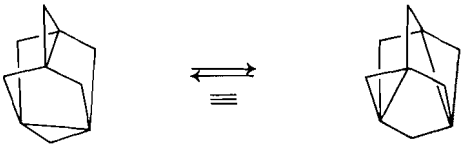
3 4

water (perhaps "cleaning" the surface of the alloy) were necessary for reaction to occur, but, in any case, addition of small amounts of *t*-butyl alcohol or hexamethylphosphoramide promoted rapid reaction. The DHA **4** (Y = H) produced was always accompanied by some adamantane. It was separately shown that the alloy reduces DHA slowly in heptane solvent, and rapidly in hexamethylphosphoramide, to adamantane.

Dehydroadamantane may be separated in small quantities from the heptane solvent by g.l.p.c. However, for larger scale preparations, ether as a solvent is more convenient. This allows isolation of DHA by evaporation of solvent followed by vacuum sublimation. The dimethyldehydro derivative **4** ($Y = CH_3$) was produced from the corresponding dibromide **3** ($X = Br$, $Y = CH_3$) in a similar manner. Some physical characteristics of DHA have been previously reported (6); a comparison of chemical shifts of the cyclopropyl hydrogens of dimethyl–DHA (1.47 δ) with those of DHA (1.66 δ) showed an upfield shift just as predicted by additivity factors of -0.10 for each CH_3 group on the adamantane ring structure (7). On the other hand, all the hydrogens on the DHA structure are greatly affected by the anisotropic field of the cyclopropyl ring so that no simple relationship of n.m.r. spectra with those of adamantanes is possible. For example, the chemical shift difference of the two C-4 hydrogens in dimethyldehydroadamantane is 0.59 p.p.m. whereas no difference shows up in dimethyladamantane itself. Even the C-6 hydrogens of dimethyladamantane, which lie in the plane of the cyclopropyl group but farthest from the cyclopropyl system, are 0.77 p.p.m. lower field than the corresponding hydrogens in dimethyladamantane. This is consistent with "aromatic" ring current effects extending from the cyclopropyl ring across the inside of the DHA skeleton.

Homopolymerization of cyclopropyl compounds is relatively rare, but examples with bicyclobutanes have recently been published (8). DHA, which dissolves readily in common solvents, does not melt when heated but transforms at *ca.* 130–160° to a white polymeric solid, 1,3-polyadamantane. This material is insoluble in all solvents tried including high boiling hydrocarbons, amides, and alcohols. Differential scanning calorimetry of this polymer showed no phase transformations to 500° and the polymer appeared quite thermally stable. Samples held in air yellowed slowly at 400° but remained essentially white under nitrogen for $\frac{1}{2}$ h at this temperature. 1,3-Poly-5,7-dimethyladamantane, prepared by heating molten monomer, m.p. 44–45.5°, showed similar thermal characteristics and lack of solubility.

Polyadamantane possesses a structural relationship to polymethylene in that the four bridgehead positions of adamantane have the same symmetry as methane. 1,3-Polyadamantane is then an analog in which a 1,3-$C_{10}H_{14}$ unit takes the place of a $—CH_2—$ unit in polymethylene. This analogy points to a similar formal relationship of the diamond structure to an adamantane polymer formed by bonding $C_{10}H_{12}$ units at all four bridgehead positions. Such 1,3–5,7-polyadamantane network would be formed by polymerization of double-dehydroadamantane, **5** (pentacyclo[3.3.1.$1^{3,7}$.$0^{1,3}$.$0^{5,7}$]-



5 5

decane). This compound is also of interest with regards to expected high strain and the possibility of interaction of the internal cyclopropyl bonds leading to a new type of valence tautomerization. Unfortunately, attempts to prepare double-DHA **5** have so far been unsuccessful: 1,3,5,7-tetrabromoadamantane (**3**, X = Y = Br) reacts with Na–K alloy at room temperature in ether to give only DHA as the major detectable product. If double-dehydroadamantane is an intermediate, it is rapidly reduced by the sodium–potassium alloy with apparent hydrogen transfer from the solvent. 1,3,5-Tribromoadamantane similarly gives DHA as the major product accompanied by bromoadamantane and adamantane.

†The first figure is the rate constant of the reaction while under the influence of inhibitor, the second figure is the rate constant after all inhibitor was consumed.

‡Inhibitor used reacted directly with DHA in the absence of oxygen.

Free Radical Reactions of Dehydroadamantane

In the absence of oxygen, DHA is thermally quite stable with a half-life of *ca.* 4 h at 0.08 *M* in *n*-octane at 195°. However, exposure of such solutions to air causes loss of DHA in a few hours at room temperature with precipitation of polyperoxyadamantane. This material, explosion point 146–180°, is only partially soluble in benzene and the most insoluble fraction analyzed for close to a 1:1 copolymer with oxygen $(—O—C_{10}H_{14}—O—)_x$. Reduction of the polymer with LAH gave 1,3-dihydroxyadamantane as the major product.

For a formally saturated hydrocarbon, such a rapid reaction with oxygen is unusual and gives rise to the following questions: how is the copolymerization with oxygen initiated at such low temperatures and what is the relative contribution of free radical propagation steps in the overall loss of DHA? Under 1 atm of oxygen the rate of oxygen uptake of DHA was measured at 22° in heptane, octane, and *p*-xylene, with and without various inhibitors present. Without inhibitors the rate of oxygen consumption is first order in DHA with a half-life of *ca.* 90 min in heptane or octane and *ca.* 35 min in xylene. No induction period for oxygen uptake was apparent.

In the presence of inhibitors no precipitation of insoluble polymer occurred and, as shown in Table 1, there was a decreased rate of oxygen consumption. With 0.1 to 4.0 mol ratio of 2,6-di-*t*-butyl-*p*-cresol to DHA the rate was decreased to about one-fourth that of the uninhibited reaction, and as long as sufficient inhibitor was present the reaction remained first order in DHA (with $k = 3.76 \pm 0.35 \times 10^{-5}\ s^{-1}$ at 22° in octane). Those inhibitors which did not react directly with DHA (see Table 1) also decreased the rate of loss of DHA

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

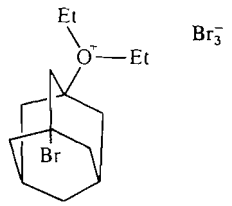
down to about the same spontaneous rate of oxygen uptake. The molar ratio of oxygen to DHA consumed was approximately 1.25. If the reaction exclusively formed long-chain polymers of the type $(—O—C_{10}H_{14}—O—)_x$ the ratio would be 1; if all the peroxyradicals were stopped immediately by hydrogen transfer the product would be $HOO—C_{10}H_{14}—OOH$ and the ratio would be 2. A ratio of only 1.25 indicated that some oligomers were forming even in the presence of inhibitors. If the oligomers were of the type $HO(—O—C_{10}H_{14}—O—)_xOH$, x would average out to four.

The small difference between the inhibited and uninhibited rate of oxygenation and the O_2/DHA ratio indicate that the polymerization chain length is short (*ca.* 3–4 units) and that direct loss of DHA by free radical formation, rather than chain propagation, is a major reaction. The absence of an induction period and the nearly identical rate of oxygenation with various inhibitors suggests that DHA is a direct source of free radicals. Perhaps the high activation energy for ring opening of unencumbered cyclopropanes (9), is reduced in the especially strained DHA cyclopropyl group so that spontaneous ring opening near room temperature is possible, *i.e.*, $DHA \rightleftarrows \cdot C_{10}H_{14} \cdot \xrightarrow{O_2}$ peroxy radicals. In the absence of a free radical scavenger, a rapid ring closure back to DHA would be encouraged by the polycyclic structure. If oxygen is completely effective in trapping out any diradical present, the value of $k_{obs} = 3.7 \times 10^{-5}\ s^{-1}$ is the maximum possible rate constant in octane for formation of the diradical from DHA. A direct reaction of dehydroadamantane with oxygen, *i.e.*, $DHA + O_2 \rightarrow$ peroxy radicals, seems less likely but cannot be eliminated at present. However, radical character of DHA is further indicated by rapid reactions, in the absence of oxygen, with both galvinoxyl radical and with *p*-quinone to give dark, uncharacterized products.

Ionic Addition Reactions of Dehydroadamantane

Dehydroadamantanes react extremely rapidly with electrophilic reagents; for example, in heptane at room temperature acetic acid adds immediately to give 1-adamantyl acetate. Other 1-adamantyl esters may be similarly prepared under mild conditions. Halogenation of DHA in heptane rapidly produces 1,3-dihalo compounds. However, at low temperatures ($-70°$) in ether, the uptake of bromine by DHA occurs immediately but does not directly yield the 1,3-dibromide. A flocculent, lemon-yellow precipitate is formed which, after washing with fresh ether at $-70°$, may be decomposed at room temperature to yield 30% of 1,3-dibromoadamantane. The major product (68%) was identified as 1-bromo-3-ethoxyadamantane by its n.m.r. spectrum and by conversion to 1,3-dibromide with HBr/H_2SO_4. Formation of ethoxy product indicates an oxonium tribromide structure **6** for the yellow precipitate. The initial



6

addition of bromonium ion to the cyclopropyl ring of DHA leads to a tertiary carbonium ion stabilized by bonding with ether and then precipitation as the tribromide. If the yellow complex is allowed to decompose in CCl_4, 1 mol of bromine is liberated for every mole of DHA used in the preparation. The complex decomposes in ethanol/K_2CO_3, acetone/KI, or acetone/NaCN solutions to give only the 1-bromo-3-ethoxyadamantane. In acetone/water/H_2SO_4 the complex yields 1-bromo-3-hydroxyadamantane (60%) accompanied by 30% of the 1-bromo-3-ethoxy product.

A freshly prepared solution of the complex in acetone at $-65°$ shows a low field quartet ($J = 7$ Hz) at 5.19 δ. This is 1.8 p.p.m. downfield from a corresponding quartet for the methylene group next to oxygen in 1-bromo-3-ethoxyadamantane and is just as expected for an oxonium ion structure (10). Cleavage of the salt at the tertiary center occurs to about 60% in acidic solution, but bases like K_2CO_3, KI, or NaCN cleave an ethyl group from the complex to give rise to bromoethoxyadamantane. A similar complex is obtained by iodination of DHA in ether at $-70°$; decomposition of the dark red precipitate at room temperature gave 1-iodo-3-ethoxyadamantane. Other types of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ionic additions which occur readily with dehydroadamantane are reaction with methanol/BF_3 to give 1-methoxyadamantane, with benzene/$AlCl_3$ to give predominately 1-phenyladamantane, and with $Hg(OAc)_2$ followed by $NaBH_4$ to give 1-hydroxyadamantane in low yields.

It is apparent that 1,3-dehydroadamantanes are much more reactive than simple cyclopropyl compounds and that the weak 1,3-bond readily undergoes free radical or electrophilic attack. Similar reactivity has been shown with tricyclic-[3.2.1.0] structures (3, 4). Although 1,3-dehydroadamantanes are basically a larger [3.3.1.0] ring system, they still show the high reactivity which seems associated with an inverted carbon at a bridgehead. More quantitative knowledge of relative stabilities and strains can perhaps be attained by thermochemical methods.

Although explicit theoretical suggestions concerning the hybridization of bridgehead atoms in the DHA system have not been made, the reactivity is distinctive enough to suggest an increased p-character in the central cyclopropyl bond over that in a simple cyclopropyl compound. As suggested (2) for related compounds, considerable electron density lies in the region of space most exposed to external attack, the backside of the 1,3-bridgehead bond of the inverted carbon atoms. This promotes attack by electrophilic reagents, while low-lying unoccupied orbitals aid reactions with electron donors and free radical reagents. As both free radical and ionic electrophilic reagents easily react with dehydroadamantanes under mild conditions, they may be quite synthetically useful in forming a variety of adamantyl derivatives and polymers.

Experimental

Adamantane, 1-bromoadamantane, and 1-hydroxyadamantane were obtained from commercial sources. 1,3-Dimethyladamantane and 1,3-dihydroxy-5,7-dimethyladamantane were kindly supplied by Sun Oil Company, Philadelphia, Pa.

General Procedure for the Preparation of Dehydroadamantanes

A typical procedure is the preparation of 5,7-dimethyldehydroadamantane (**4**, $Y = CH_3$).

To 1.0 g of 1,3-dibromo-5,7-dimethyladamantane in 50 ml of ether under nitrogen was added 0.83 g of Na–K alloy (1:5 w/w). The alloy was dispersed by high speed stirring, 25 μl of *t*-butanol and/or hexamethylphosphoramide was added, and the mixture stirred until completion of the reaction (*ca.* 2 h). The appearance of product was monitored by g.l.p.c. using a Carbowax 20M (10% on Chromosorb W) column. The gas inlet, stirrer, and condenser were replaced by a vacuum sublimation assembly of the cold finger type. The diethyl ether was removed under vacuum at autogenous temperatures. A Dry Ice – acetone mixture was then placed in the cold finger and the product sublimed at about 0.5 mm pressure and 25–30°. The yield was 0.35 g (78%) with a ratio of **4**, ($Y = CH_3$) and **3** ($X = H$, $Y = CH_3$) of 1:1. Better ratios of products were often obtained; careful monitoring of the reaction progress can aid prevention of further reduction of **4** to **3** ($X = H$). 1,3-Dichlorides may be used in the preparations; use of 1,3-dichloro-5,7-dimethyladamantane gave 75% yields of the dehydroadamantane derivative and dimethyladamantane (ratio 10:1).

Compound **4** ($Y = CH_3$) was purified by g.l.p.c. and had m.p. 44.0–45.5° (sealed capillary). N.m.r. δ (degassed benzene): singlet 0.91 methyl groups, doublet $J = 10$ Hz 1.01, four of the hydrogens of type C-4, doublet $J = 10$ Hz, 1.60, four other hydrogens at C-4 positions, broad multiplet 1.47, two hydrogens of C-2, singlet 1.92, two hydrogens of C-6. I.r. spectrum (cm^{-1}) in CCl_4: 3030 shoulder, 2900, 1445, 1360, 1280, 890. The absorptions at 3030, 1280 and 890 rapidly disappear in several minutes. Rapid reaction with oxygen also prevented obtaining of consistent C and H analyses.

A similar preparation of 1,3-dehydroadamantane using 1.0 g of 1,3-dibromoadamantane, 0.52 g of Na–K alloy, and 25 μl of hexamethylphosphoramide in 50 ml of ether over 5 h gave after sublimation 0.35 g (77%) of a 9:1 DHA:adamantane mixture.

The physical characteristics of dehydroadamantane **4** ($Y = H$) have been reported (6).

Similar reactions using 1,3,5-tribromo- or 1,3,5,7-tetrabromoadamantane in ether or heptane gave dehydroadamantane with adamantane (ratio *ca.* 8:1) in isolated yield of 40–72%. Some monobromoadamantane was also present. Di-, tri-, and tetrabromoadamantanes and 1,3-dibromo-5,7-dimethyladamantane were made by $AlBr_3$-catalyzed brominations of adamantane or dimethyladamantane (11).

Polymers

Bulk polymerization was effected by heating 1,3-dehydroadamantane overnight at 140° in a sealed vial. The material remained solid throughout the polymerization. At 160° polymerization was complete in *ca.* 10 min. Vacuum sublimation removed the adamantane leaving only a white solid polymer which did not melt to 330°.

Anal. Calcd. for $C_{10}H_{14}$: C, 89.49; H, 10.51. Found: C, 89.31; H, 10.43.

I.r. spectrum (cm^{-1}) as a Nujol mull: 2930, 2640, 1440, 1340, 1000, and 960.

Molten dimethyldehydroadamantane was polymerized similarly at 90–145° to give material with generally the same physical characteristics as polyadamantane. X-ray powder diffraction patterns showed no lines, only halos indicating non-crystallinity.

Anal. Calcd. for $C_{12}H_{18}$: C, 88.82; H, 11.18. Found: C, 88.94; H, 11.19.

The polymeric materials were insoluble in all common solvents. Differential scanning colorimetry showed no transitions up to 500°. Under nitrogen the samples remained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

visibly unchanged; under air, the samples darkened at temperatures above 400°.

Copolymerization with oxygen occurs simply on dissolving dehydroadamantane in pentane at room temperature. The white precipitate was washed with benzene and dried. When heated it exploded at 140–180°. The material was partially soluble in benzene and the benzene insoluble fraction was analyzed.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 72.55; H, 8.28.

Another fraction, more soluble in benzene, was analyzed giving 70.68% C and 8.37% H corresponding to roughly $HO(OC_{10}H_{14}O)_{10}OH$. A suspension of the polyperoxide was refluxed with LAH in ether for 12 h. The predominate product (*ca.* 80–90%) was 1,3-adamantanediol identified by g.l.p.c. comparisons with authentic samples.

Addition Reactions

Hydration

Addition of dilute sulfuric acid to a solution of dehydroadamantane in THF immediately yields 1-hydroxyadamantane (90 ± 5%) by g.l.p.c. comparisons with an authentic sample.

Methanolysis

To 1,3-dehydroadamantane (0.6 g) in 10 ml of methanol and 20 ml of ether under nitrogen at room temperature was added 0.2 ml of boron trifluoride etherate. After 2 min, 0.2 ml of water was added and the solution dried with Na_2SO_4. G.l.p.c. comparisons with authentic solutions of 1-methoxyadamantane showed that 90% yields were obtained together with 6% of an unidentified by-product. Authentic 1-methoxyadamantane was prepared by refluxing 1-hydroxyadamantane with 40 ml of methyl iodide, 10.8 g of sodium hydride and 75 ml of ether for 24 days. Addition of ethanol, then water, followed by extraction and distillation gave, in 69% yields, 1-methoxyadamantane, b.p. 95–100°/1.4 mm.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.91. Found: C, 79.56; H, 10.94.

N.m.r. δ (CCl_4): singlet 3.12 methyl group, broad singlet 2.11 three bridgehead hydrogens, and unresolved multiplet 1.67 for 12 CH_2 hydrogens.

Mercuric Acetate Oxidation

A solution of 1.35 g of $Hg(OAc)_2$ in 4 ml of water was added to 0.58 g of DHA in 4.3 ml of THF. After *ca.* 3 min, 4 ml each of 3 *N* NaOH and 1 *N* $NaBH_4$ were added successively and the mixture stirred 5 min before work-up. G.l.p.c. analysis showed that 47% of 1-hydroxyadamantane and *ca.* 9% of 1,3-dihydroxyadamantane was produced. The largest percentage of the several unidentified by-products was *ca.* 18%.

Phenylation

A solution of 0.67 g of DHA in 300 ml of benzene was treated with 2.0 g of $AlCl_3$ at 60° for 10 min. The reaction mixture was cooled and worked-up by normal extractions. 1-Phenyladamantane (40% yields) was identified by g.l.p.c. comparisons with authentic compound. Polymeric material was also produced and was formed in larger amounts in more concentrated solutions.

Ester Formation

Stirring 0.14 g of DHA with 0.3 g of *p*-nitrobenzoic acid in 25 ml of ether under nitrogen for 6 h gave 82% of 1-adamantyl-*p*-nitrobenzoate, m.p. 182–183°, characterized by its reported n.m.r. spectrum (7).

Anal. Calcd. for $C_{17}H_{19}O_4N$: C, 67.75; H, 6.32; N, 4.65. Found: C, 67.62; H, 6.41; N, 4.63.

Halogenation

The iodination product of DHA has been reported (6). 5,7-Dimethyldehydroadamantane immediately decolorizes iodine in ether at room temperature or lower and yields 1,3-diiodo-5,7-dimethyladamantane which, after crystallization from CCl_4, gave m.p. 102–103.2°.

Anal. Calcd. for $C_{12}H_{18}I_2$: C, 34.64; H, 4.36; I, 61.00. Found: C, 34.66; H, 4.68; I, 61.58. N.m.r. δ ($CDCl_3$); singlets at 0.85 for the methyl hydrogens, 1.34 for two hydrogens β to the methyl groups, 2.30 for eight hydrogens β to both CH_3 and iodine, and 3.11 for the two hydrogens β to both iodines. In benzene, corresponding singlets occurred at δ 0.42, 0.75, 1.88, and 3.0.

To a rapidly stirred solution of 0.17 g of DHA in 25 ml of ether at −70° was added dropwise *ca.* 0.7 g of bromine. A flocculent, lemon-yellow precipitate was instantly formed. The solvent was removed with a pipet after centrifugation. The precipitate was washed at −70° with several portions of ether until the supernatant was colorless. The suspension from similar preparations was treated with various reagents and then decomposed by bringing to room temperature. In 250 ml of ether with 4 g K_2CO_3 a 28% yield of 1,3-dibromoadamantane was obtained together with 68% of 1-bromo-3-ethoxyadamantane. These compounds were separated by chromatography on Woelm grade I neutral alumina. 1-Bromo-3 ethoxyadamantane, m.p. 39.5–41.5° (sealed tube), was reacted with 47% HBr in H_2SO_4 to give 1,3-dibromoadamantane.

Anal. Calcd. for $C_{12}H_{19}OBr$: C, 55.70; H, 7.34; Br, 30.83. Found: C, 55.50; H, 7.21; Br, 30.79.

N.m.r. δ (benzene): quartet (J = 7 Hz) 3.18 for —CH_2O— hydrogens, singlet 2.29 for two hydrogens β to EtO and Br, unsymmetrical doublet 2.03 for four hydrogens β to Br; unresolved multiplet 1.79 for two hydrogens at bridgeheads, unsymmetrical doublet 1.47 for four hydrogens β to EtO, poorly resolved triplet 1.17 for two hydrogens δ to both substituents, and triplet (J = 7 Hz) 1.06 for three hydrogens of CH_3.

The precipitated yellow complex in 95% ethanol with powdered K_2CO_3, or acetone–potassium iodide, or acetone–sodium cyanide gave only 1-bromo-3-ethoxyadamantane as shown by g.l.p.c. analysis. In acetone – 10% water the complex decomposed on warming to yield 22–33% of the bromoethoxy compound and 61–43% of 1-bromo-3-hydroxyadamantane, m.p. 157–158° (sealed tube). This compound was purified by sublimation at 70°/1 mm and characterized by its n.m.r. spectrum and by base-promoted ring opening to 3-methylene-bicyclo[3.3.1]nonanone-7 (12).

Anal. Calcd. for $C_{10}H_{15}BrO$: C, 51.96; H, 6.54; Br, 34.57. Found: C, 52.00; H, 6.60; Br, 34.90.

N.m.r. δ (benzene): singlet 2.17 for two hydrogens β to OH and Br, doublet (J = 3 Hz) for four hydrogens β to Br, broad multiplet 1.75 for two hydrogens at bridgehead, unsymmetrical doublet (J = 3 Hz) 1.35 for four hydrogens β to OH, singlet 1.19 for OH, triplet (J = 3 Hz) 1.08 for two hydrogens δ to OH and Br.

Addition of a solution of iodine in ether to DHA in ether at −70° gave a dark red precipitate which was dissolved in

acetone containing solid NaCN and stirred at $-70°$ for 24 h. After warming to room temperature, chromatography on Woelm neutral alumina gave 1-iodo-3-ethoxyadamantane, m.p. 35–37° (sealed tube).

Anal. Calcd. for $C_{12}H_{19}OI$: C, 47.07; H, 6.25; I, 41.45. Found: C, 47.29; H, 6.33; I, 41.31.

N.m.r. δ (benzene): similar to the 1-bromo-3-ethoxy compound above, the corresponding absorptions are quartet ($J = 7$ Hz) 3.17, singlet 2.57, unsymmetrical doublet 2.25, singlet with a lower-field broad shoulder 1.59 (total of six hydrogens), unresolved multiplet 1.35, and triplet ($J = 7$ Hz) 1.05.

The yellow precipitate prepared from 0.157 g of DHA was washed with ether at $-70°$ to remove unbound bromine and decomposed in 50 ml of CCl_4. After dilution to 100 ml the solution was compared spectrophotometrically to a freshly prepared standard solution of bromine in CCl_4. The absorbance at 415 mμ corresponded to 0.9 mol of bromine released per mol of DHA. Because of instability the yellow complex did not give consistent C and H analyses.

The n.m.r. spectrum at *ca.* $-65°$ of the complex in deuterioacetone showed a quartet at 5.19 δ ($J = 7$ Hz) for four hydrogens, a quartet at 3.37 ($J = 7$ Hz) for residual diethyl ether, a singlet at 3.07 for two hydrogens, a broad singlet at 2.59 for six hydrogens, a broad singlet at 2.36 for four hydrogens, a triplet-like absorption at 1.71 for eight hydrogens, and a triplet at 1.10 for residual ether. On warming to $-25°$ the complex decomposes as indicated by the loss of absorptions, especially the prominent low field quartet. Less well defined peaks arise in positions expected for product.

Kinetic Measurements

The volume of oxygen taken up by DHA in rapidly stirred solutions was measured in a simple constant pressure apparatus. Plots of

$$\log (\Delta V_\infty/(\Delta V_\infty - \Delta V_t))$$

against time, where ΔV_∞ is the total volume taken up and ΔV_t is the volume taken up at time t, were straight lines to over two half-lives. Rate constants were obtained from 2.303 times the slope of the plots. With the higher concentration of inhibitors (see Table 1), the plots were also straight lines, while at lower concentrations the curve separated into a straight inhibited portion and another largely straight portion of greater slope (corresponding to some radical chain reaction).

Support of this work by the National Research Council of Canada is gratefully acknowledged.

Sterically Hindered Aromatic Compounds. V. Solvolysis of *p*-Methyl-, 2,4,6-Trimethyl-, and 2,4,6-Tri-*t*-butylbenzyl Chloride. Effect of Solvent and α-Deuterium Substitution

L. R. C. BARCLAY, J. R. MERCER, AND J. C. HUDSON

Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received June 7, 1972

Rates, activation parameters, and kinetic α-deuterium isotope effects are reported for solvolysis of *p*-methylbenzyl chloride in 80% trifluoroethanol–water, and in ethanol–water and *t*-butyl alcohol–water of varying solvent compositions. The α-deuterium isotope effect in trifluoroethanol–water ($k_H/k_D = 1.14$ per D) indicates approximately limiting behavior. Results in the other solvents ($k_H/k_D = 1.04$–1.08) indicate considerable nucleophilic participation by solvent in the transition state. 2,4,6-Trimethylbenzyl chloride gave $k_H/k_D = 1.09$ in 80% ethanol–water but $k_H/k_D = 1.16$ in 80% trifluoroethanol–water. 2,4,6-Tri-*t*-butylbenzyl chloride showed k_H/k_D effects of 1.13–1.15 in *t*-butyl alcohol–water and 1.15–1.16 in ethanol–water. The higher kinetic isotope effects for solvolysis of these trialkylbenzyl chlorides are discussed in terms of steric hindrance to nucleophilic participation by solvent. N.m.r. chemical shifts give evidence for steric compression of the benzylic protons in 2,4,6-tri-*t*-butylbenzyl chlorides.

Les vitesses, les paramètres d'activation, et les effets isotopiques sur la cinétique du deutérium α sont rapportés pour la solvolyse du *p*-méthylbenzyle chlorure dans les systèmes trifluoroéthanol 80%–eau et éthanol–eau, *t*-butanol–eau de compositions variables. L'effet isotopique de deutérium α dans le trifluoroéthanol–eau ($k_H/k_D = 1.14$ par D) correspond approximativement à un comportement limite. Les résultats dans les autres solvants ($k_H/k_D = 1.04$–1.08) indiquent une participation nucléophile considérable du solvant dans l'état de transition. Le triméthyl-2,4,6 benzyle chlorure donne un $k_H/k_D = 1.09$ dans l'éthanol 80%–eau mais 1.16 dans le trifluoroéthanol 80%–eau. Le tri-*t*-butyl-2,4,6 benzyle chlorure donne des valeurs de k_H/k_D de 1.13–1.15 dans le *t*-butanol–eau et 1.15–1.16 dans l'éthanol–eau. Les effets isotopiques sur la cinétique les plus élevées dans la solvolyse de ces trialkylbenzyle chlorures sont interprétés en fonction de l'empêchement stérique à la participation nucléophile du solvant. Les déplacements chimiques en r.m.n. fournissent la preuve d'une compression stérique des protons benzyliques dans les tri-*t*-butyl-2,4,6 benzyle chlorures.

Introduction

Our previous publication in this series (1) reported on the effect of the proximity and size of alkyl substituents on the solvolysis of substituted benzyl chlorides in 80% ethanol–water. In the 2,4,6-trialkylbenzyl chlorides, the solvolytic behavior of 2,4,6-tri-*t*-butylbenzyl chloride was of particular interest. This compound exhibited an unexpected high reactivity and an abrupt increase in the entropy of activation (ΔS^*) term. These results were rationalized in terms of steric acceleration in the S_N1 mechanism for solvolysis of this compound.

The main purpose of the present investigation was to apply α-deuterium kinetic isotope effects as a probe for establishing with more certainty the mechanism of solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride. The two bulky *o*-*t*-butyl groups in this chloride place rather severe steric restrictions on the solvation of its transition state. The compound might prove to be an interesting model system for testing ideas of specific solvation or solvent sorting in solvolysis using binary solvent mixtures (2). Thus it was also desirable to determine the effect of different solvent systems on the activation parameters, kinetic isotope effects, and product compositions. It was desirable to find some ground state properties in the sterically hindered benzyl chlorides that indicate more directly the steric effect. The n.m.r. chemical shifts of the benzylic protons are examined in this regard.

Experimental

(a) Preparations

p-Methylbenzyl-α-d_2 Chloride

p-Methylbenzyl-α-d_2 alcohol was prepared by reduction of methyl *p*-toluate with lithium aluminum deuteride according to the procedure used to prepare *p*-methylbenzyl alcohol (1). The crude labelled alcohol was converted into *p*-methylbenzyl-α-d_2 chloride by treatment with thionyl

TABLE 1. Major mass spectral peaks of 2,4,6-trimethylbenzyl chloride and -α-d_2 chloride

	Peak	Relative intensity	Assignment
2,4,6-Trimethyl-benzyl chloride	168	17	M^+ (parent mass)
	133	100	M − Cl
2,4,6-Trimethyl-benzyl-α-d_2 chloride	170	17	M^+ (parent mass)
	135	100	M − Cl

TABLE 2. Solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride and -α-d_2 chloride in 80% *t*-butyl alcohol–water at 70.05°

Compound	Rate constants ($k_1 \times 10^3$ s^{-1})	Average	% deviation
2,4,6-Tri-*t*-butyl-benzyl chloride	2.267	2.26_1[a]	0.23
	2.255		
	2.262		
	2.262		
2,4,6-Tri-*t*-butyl-α-d_2 chloride	1.773	1.78_1[a]	0.34
	1.785		
	1.787		
	1.781	($k_H/k_D = 1.26_9$)	

[a]In reproducibility checks, average rate constants of 2.249×10^{-3} s^{-1} for 2,4,6-tri-*t*-butylbenzyl chloride and 1.778 for the α-d_2 chloride were obtained ($k_H/k_D = 1.26_5$).

chloride (1). The percent deuterium in the methylene group of this *p*-methylbenzyl-α-d_2 chloride was estimated from its n.m.r. spectrum to be approximately 95%.

2,4,6-Trimethylbenzyl-α-d_2 Chloride

2,4,6-Trimethylbenzyl-α-d_2 alcohol was prepared by reduction of mesitoic acid with lithium aluminum deuteride. The alcohol was converted into the chloride by chlorination with thionyl chloride (1). The n.m.r. spectrum of this 2,4,6-trimethylbenzyl-α-d_2 chloride showed that substitution of benzylic hydrogen for deuterium was essentially complete. This conclusion was confirmed by comparative mass spectroscopic analyses of the labelled and the ordinary chlorides. The data for the major peaks in the spectra and their assignments are summarized in Table 1.

2,4,6-Tri-t-butylbenzyl Chloride and -α-d_2 Chloride

The synthesis and spectroscopic analyses of 2,4,6-tri-*t*-butylbenzyl chloride and -α-d_2 chloride were described earlier (1).

(b) Solvents

The binary solvents were prepared by mixing accurately measured volumes of triply distilled, deionized water and freshly fractionated anhydrous alcohols. Trifluoroethanol (Eastman Chemicals) was purified by the method of Shiner and coworkers (3) and the fraction boiling at 73.4–74.5° used.

(c) Kinetic Measurements

Kinetic measurements were made by the precision conductance method using stirred cells as described previously (1). The data were treated as before and a computer used to calculate the rate constants by means of a least squares program. High accuracy was required to determine the α-deuterium kinetic isotope effects. Computer plots of the first order rate constants were examined for linearity. In all cases the correlations were 0.999. The standard deviations between the four rate constants measured simultaneously in four conductivity cells were less than 1% and usually less than 0.5%. A sample of the data for solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride and α-d_2 chloride is outlined in Table 2.

(d) Product Analysis

Attempts were made to determine the product composition of solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride by v.p.c. Test runs were made on this chloride and the corresponding alcohol on Carbowax, Apiezon and silicon columns at various temperatures. Some decomposition of these compounds during v.p.c. analysis was always observed. The cyclization product, 1,1-dimethyl-4,6-di-*t*-butylindane, reported earlier (4) was produced during the v.p.c. analysis. The product analyses were, therefore, carried out using the n.m.r. method as before (1).

Results and Discussion

(a) Solvolysis of p-Methylbenzyl Chloride

p-Methylbenzyl chloride has been extensively investigated both with regard to solvolytic activation parameters (5–7) and precision α-deuterium kinetic isotope effects (3, 8). This compound was selected as a convenient *reference system* for our studies. It provides a convenient comparison of our rate constants, activation parameters, and α-deuterium isotope effects with reported literature values. At the same time it was desirable to study the variation of these solvolytic data with different alcohol–water binary solvent systems.

(1) Rates and Activation Parameters

The first order rate constants and activation parameters for solvolysis of *p*-methylbenzyl chloride in various binary solvent mixtures are given in Table 3. The rate constant and activation parameters for 45% ethanol–water are in good agreement with the data reported by Hyne and coworkers (6). There was an increase in rates

TABLE 3. Rates and activation parameters of solvolysis of *p*-methylbenzyl chloride in binary solvents

Solvent	Temperature (°C)	Rate ($k_1 \times 10^5$ s^{-1})	ΔE^* (kcal/mol)	ΔS^* (e.u./mol)
80% Ethanol–water[a]	44.89	0.728	21.0	−18.2
	60.09	3.31		
45% Ethanol–water (0.203 mol fraction ethanol)	22.44	0.933[b]	20.7[b]	−13.4[b]

	70.05	1.45		

[a]Results taken fron ref. 1.
[b]Rate constant calculated from results at higher temperatures. Under these conditions, reported results (6) were $k_1 = 0.917$, $\Delta E^* = 20\,830$ cal/mol, $\Delta S^* = -13.1$.
[c]TFE = trifluoroethanol.
[d]TBA = *t*-butyl alcohol.

on going from 80% ethanol–water (or 80% *t*-butyl alcohol–water) to the more highly ionizing binary mixtures of 45% ethanol–water or 80% trifluoroethanol–water. There was an increase in the ΔS^* term of the order of 3–5 e.u. in these more highly ionizing solvent mixtures. Various factors could contribute to variations in activation parameters with such changes in solvent composition. Some of these factors are:

(i) Changes in ground state solvation

Arnett and coworkers (9) provided convincing evidence and arguments for the importance of solvation effects on the ground states as indicated in endothermic maxima behavior of the partial molal heats of solution for a variety of salts and nonelectrolytes. These extrema were limited to the behavior of solutes in the region of high water content of binary solvents (above 0.8 mol fraction H_2O). On the more alcoholic side of these solvent–solute effects, where our measurements are concerned, the situation may be "unmanageably complex" (9) but it should be acknowledged that such effects may play an, as yet, unpredictable role.[1]

[1]A referee points out that initial state solvation differences have a significant kinetic effect with reference to one chosen standard only if the transition state differences are significantly less; a reasonable expectation in the high water range where quasi-aqueous structure is maintained. Conversely in the high alcohol range, one might expect that ground state solvation effects would not have a significant effect.

(ii) Specific solvation of the transition state

p-Methylbenzyl chloride exhibited a very large change in entropy of activation in ethanol–water solvolysis, as the alcohol content of the medium was increased (7) ($\Delta\Delta S = 15.0$ e.u. in the range of 0.00–0.125 mol fraction ethanol). This was interpreted in terms of changes in specificity of solvation or solvent sorting; that is, differences in the activation parameters can be related to variations in specific demand for selective solvation of the ionic transition state by the more polar component (water) in the binary solvent system. It was further argued that, in the case of *p*-methylbenzyl chloride, "the greatest unmixing of the solvent must take place in order to achieve persistence of specific hydration of the transition state as ethanol is added to the solvent" (7). These observations were made in low alcohol content (0.00–0.203 mol fraction ethanol) of the binary solvent mixtures. We recently extended the Hyne hypothesis on specific solvation in an attempt to account for the variation in activation entropy for solvolysis of other alkyl- and phenylbenzyl chlorides in 80% ethanol–water (1).

Specific solvation effects may also in part account for variations in activation parameters shown for *p*-methylbenzyl chloride (Table 3) during changes in the high alcohol content of solvent mixtures. For example, the larger $-\Delta S^*$ values for 80% alcohol(s)–water could, in part,

TABLE 4. α-Deuterium isotope effects in solvolysis of *p*-methylbenzyl chloride in mixed solvents

Solvent	Temperature (°C)	Rate ($k_1 \times 10^5$ s^{-1}) α-H_2 compound	Rate ($k_1 \times 10^5$ s^{-1}) α-D_2 compound	k_H/k_D	k_H/k_D corrected[a]	k_H/k_D[d] per D
80% Ethanol–water	70.05	7.08	6.56	1.07_9	1.08_4	1.041
50% Ethanol–water	45.04	7.04[b]	6.12	1.15	1.16	1.077[b]
80% TFE–water	60.09	36.2	28.4	1.28	1.29	1.136[c]
80% TBA–water	70.05	1.45	1.32	1.10	1.11	1.054
60% TBA–water	70.05	8.77	7.65	1.15	1.16	1.077

[a]The deuterated compound contained approximately 5.4% benzylic hydrogens, ratios were corrected for complete deuteration.
[b]Shiner and coworkers (3) reported $k_H = 6.999 \times 10^{-5}$ s^{-1} and isotope effect per D = 1.080 at 45° in 50% ethanol–water.
[c]Reported values (3) for k_H/k_D (per D) were 1.140 in 70% TFE–water and 1.145 in 94% TFE–water at 25°.
[d]$(k_H/k_D)^{1/2}$. The third decimal is retained only for comparison purposes.

be a consequence of more solvent "unmixing" required to maintain specific hydration of the transition state in the higher alcohol–water mixtures. This effect is not so noticeable for 80% trifluoroethanol–water. This is understandable because trifluoroethanol is itself a very effective ionizing medium (8). These arguments relating activation parameters to specific solvation effects are admittedly very qualitative and incomplete. They have ignored in this instance the important changes in the structuring of solvent molecules that must take place as the composition of the binary mixture is changed.

(iii) Nucleophilic participation by solvent

Nucleophilic covalent participation by solvent at the reaction site generally will raise the $-\Delta S^*$ value. The ΔS^* parameter together with heat capacities of activation (ΔC_p^*) have been used to give an indication of mechanism for solvolysis (10). These parameters are of doubtful value to diagnose mechanisms in mixed solvents.

In view of the multiplicity of factors affecting activation parameters, it was highly desirable to use other criteria also, notably kinetic isotope effects, as a probe to study the mechanism of solvolysis of hindered benzyl chlorides.

(2) α-Deuterium Isotope Effects

α-Deuterium secondary isotope effects are well recognized as providing a criterion for the mechanism of solvolytic reactions (11). Solvent influences *per se* on α-D effects are small (12), so these effects provide one of the most definitive criteria for the extent of nucleophilic involvement by solvent in the transition state. Shiner and Fisher indicated that α-D effects provide the "best probe" for the degree of nucleophilic attachment (13), although there may be limitations in their use in detecting nucleophilic participation by solvent near the limiting end of solvolysis (14). From highly accurate conductivity rate measurements, Shiner and coworkers (3, 13) were able to place an upper limit of $k_H/k_D = 1.15$ per deuterium for chlorides (including *p*-methylbenzyl-α-d_2 chloride) for S_N1 solvolysis.

Our kinetic isotope effects data for *p*-methylbenzyl-α-d_2 chloride are given in Table 4. Our rate constant in 50% ethanol–water and kinetic isotope effects in this solvent and in trifluoroethanol–water are in very good agreement with the results of Shiner and coworkers (3). The k_H/k_D values were in the range 1.04–1.08 per deuterium for solvolysis in ethanol–water, and *t*-butyl alcohol–water. The magnitude of the isotope effect was rather sensitive to the alcohol content of the binary solvent mixture, at least in these high alcohol content ranges. On the other hand, in 80% trifluoroethanol–water, a solvent system of low nucleophilic power and high ionizing capacity, the isotope effect ($k_H/k_D = 1.14$) approaches that for limiting behavior as observed under similar conditions by Shiner and coworkers (3). The lower kinetic isotope effects in ethanol–water and *t*-butyl alcohol–water indicate that there is undoubtedly considerable nucleophilic participation by solvent (S_N2), especially in the 80% alcohol–water mixtures. We showed earlier (1) that the solvolysis rates in 80% ethanol–water for para and meta *t*-butyl, phenyl, and *p*-methylbenzyl chloride correlated well in a linear free energy relationship provided that σ^+ constants were used. This was taken as evidence that an S_N1

80% TFE–water	30.06	1078	797	1.35_3[a]	1.163

[a]Results from two different runs by different investigators. The third decimal point is retained only for comparison purposes.

mechanism applied throughout the series. The present α-deuterium isotope effect shows that this conclusion was not justified. There is considerable nucleophilic participation by solvent, even in 50% ethanol–water, for solvolysis of *p*-methylbenzyl chloride according to the isotope effect (1.08). Thus the solvolyses of other monosubstituted benzyl chlorides examined earlier (1) in ethanol–water most certainly have a significant amount of bimolecular nucleophilic component as well. It appears that the α-deuterium isotope effects provide a much more sensitive and definitive measure of nucleophilic participation by solvent, at least for solvolysis of substituted benzyl chlorides, than do activation parameters or linear free energy relationships.

(b) Solvolysis of 2,4,6-Trimethyl- and 2,4,6-Tri-t-butylbenzyl Chloride

We earlier reported (1) that solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride in 80% ethanol–water gave an abrupt increase in the entropy of activation term compared to other mono- and trialkylbenzyl chlorides, such as *p*-methylbenzyl chloride or 2,4,6-trimethylbenzyl chloride. The results were interpreted in terms of steric hindrance to solvent reorganization at the reaction center due to the two ortho-*t*-butyl groups. It was desirable to study the α-deuterium isotope effect on solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride relative to this effect for typical mono and trialkylbenzyl chlorides such as *p*-methyl- and 2,4,6-trimethyl-. In this way we hoped to determine the degree of nucleophilic participation by solvent when the —CH_2Cl group has two *t*-butyl groups in close proximity.

(1) Solvolysis of 2,4,6-Tri-t-butylbenzyl Chloride in t-Butyl Alcohol–Water

Solvolysis results on 2,4,6-tri-*t*-butylbenzyl chloride in *t*-butyl alcohol–water (Table 5) show again the abrupt increase in entropy of activation (compare ΔS^* in 80% *t*-butyl alcohol–water for *p*-methylbenzyl chloride, Table 3). This is in agreement with the reported results in ethanol–water (1) and is probably due to steric hindrance to solvation. The sizable difference in ΔS^* for 2,4,6-tri-*t*-butylbenzyl chloride in 60% *t*-butyl alcohol–water could be due to a temperature dependance effect on ΔS^* and/or some specific solvation effect as the alcohol content of the medium is changed.

(2) α-Deuterium Isotope Effects

α-Deuterium isotope effects for solvolysis of 2,4,6-trimethylbenzyl chloride in 80% ethanol–water and 80% trifluoroethanol–water are given in Table 6. The results in 80% ethanol–water

TABLE 7. α-Deuterium isotope effects in solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride

Solvent	Temperature (°C)	Rate ($k_1 \times 10^5$ s^{-1}) Undeuterated	Rate ($k_1 \times 10^5$ s^{-1}) α-D_2 compound	$k_H/k_{\alpha-D_2}$	k_H/k_D per D
80% Ethanol–water	44.89	298	225	1.32	1.149
80% Ethanol–water	45.04	243	181	1.34	1.158
80% TBA–water	70.05	226	178	1.27	1.127
80% TBA–water	60.01	78.8	61.3	1.29	1.136
60% TBA–water	45.15	106	79.6	1.33	1.153

average $k_H/k_D = 1.09$ per deuterium.[2] This is somewhat higher than the α-D effect on *p*-methylbenzyl chloride under these conditions. It is apparent that solvolysis of neither of these compounds approaches limiting behavior (requiring an α-D effect of 1.15) in 80% ethanol–water. In other words there is a significant nucleophilic participation by solvent in the solvolysis of these compounds in ethanol–water, although somewhat less in the case of 2,4,6-trimethylbenzyl chloride.

The α-deuterium isotope effect for 2,4,6-trimethylbenzyl chloride in 80% trifluoroethanol–water ($k_H/k_D = 1.16$) actually exceeded the "upper limit" established by Shiner and Fisher for solvolysis of benzyl chlorides (13). The isotope effects for 2,4,6-tri-*t*-butylbenzyl chloride (Table 7) are also of considerable interest. The values in 80% *t*-butyl alcohol – water (1.13–1.14) indicate that solvolysis in this medium was approaching the limiting character. The results in 60% *t*-butyl alcohol – water and in 80% ethanol–water of 1.15 and 1.16 respectively are unusually high for such solvents. Unfortunately the reaction rate for solvolysis of this chloride in trifluoroethanol–water was too fast for accurate measurement in our apparatus, even at lower temperatures.

These somewhat higher values of isotope effects in the range of 1.15–1.16 for 2,4,6-trimethyl- and 2,4,6-tri-*t*-butylbenzyl chloride are of interest, especially in view of some recent publications on the magnitude of α-deuterium isotope effects (13, 14). Our results are not of the high accuracy of those of Shiner and coworkers. Nevertheless, some preliminary suggestions to account for the high values are in order. One possibility would be to attribute the enhanced isotope effects to a steric contribution due to different nonbonded interactions between the deuteriums of the benzylic group and the hydrogens of the benzylic group, and the di-ortho alkyl groups. The case for a steric contribution to secondary isotope effects has been made by Bartell (15). However, a number of inadequacies have been pointed out in the steric explanation (12) and later calculations have shown the steric contribution to be only a small fraction of the isotope effect (16). There is the possibility of such a direct steric effect in the case of the isotope effect in solvolysis of 2,4,6-tri-*t*-butylbenzyl chloride because of the very close proximity of the two ortho *t*-butyl groups to the deuteriums or hydrogens in the benzylic group. On the other hand, it is unlikely that this is a satisfactory explanation for the results in the case of trimethylbenzyl chloride in 80% trifluoroethanol–water. It seems more reasonable to attribute the higher isotope effects for 2,4,6-trimethyl- and 2,4,6-tri-*t*-butylbenzyl chloride to steric inhibition of nucleophilic participation by solvent in the solvolysis. This means that the reactions would approximate more closely the "free" carbonium ion mechanism. The 2,4,6-tri-*t*-butylbenzyl system provides an interesting model for further work in this field. In particular it is an interesting substrate for studying the magnitude of the α-deuterium isotope effect for different leaving groups under conditions of limiting behavior.

(3) Product Analysis

Comparative product analyses results from solvolysis of trimethyl- and tri-*t*-butylbenzyl

[2]It appears from these data that our results are not sufficiently accurate to detect small differences in k_H/k_D due to temperature effects. The isotope effect is reported (3) to decrease by approximately 0.005 per D for a 20° rise in temperature.

2-Methyl-4,6-di-*t*-butyl-	5.16	0.34
2,4,6-Tri-*t*-butyl-	4.72	0.78
Toluene	7.72	
2-Methyl-4,6-di-*t*-butyltoluene	7.68[c]	0.04
2,4,6-Tri-*t*-butyltoluene	7.37[c]	0.35

[a]Chemical shifts were measured in carbon tetrachloride containing tetramethylsilane.
[b]$\Delta\tau$ values refer to the chemical shift difference (downfield) relative to the benzylic hydrogens of benzyl chloride or the methyl hydrogens of toluene.
[c]τ values are for the aryl methyl group at position 1.

chloride in ethanol–water and in *t*-butyl alcohol–water are summarized in Table 8. As reported in Part IV of this series (1), the products are the expected corresponding alcohols and ethers. These were obtained in similar amounts in the cases of solvolysis in ethanol–water. The most significant result was obtained in the case of the solvolysis product from tri-*t*-butylbenzyl chloride in *t*-butyl alcohol–water, which was only the corresponding alcohol, there being none of the ether formed. This is an interesting example of the effect of "solvent sorting" on product formation. It appears that the bulky nucleophile (*t*-butyl alcohol) in this case is excluded from the competition with water for the reaction center by the steric requirements of the two ortho-*t*-butyl groups. Despite the usual high reactivity of this chloride, it failed to react with pure *t*-butyl alcohol even after heating at 70° for 98 h. The steric inhibition of ether formation did not appear to be important in the case of solvolysis in isopropyl alcohol–water. In this case, both ether and alcohol were formed.[3]

(c) Compression Chemical Shifts of Hindered Benzylic Protons

It was desirable to discover some ground state property of our hindered 2,4,6-trialkylbenzyl chlorides which might relate to the solvolysis data, especially the "steric acceleration" (1) and limiting behavior of 2,4,6-tri-*t*-butylbenzyl chloride. Protons in a highly congested environment of closely situated C—H bonds are known to undergo low field n.m.r. chemical shifts (17, 18). These so-called compression shifts have been attributed to intramolecular van der Waals-type forces (18) and it is possible that they may give some indication of the degree of steric compression in the ground state of tri-*t*-butylbenzyl compounds.

The downfield compression shifts of benzylic protons in hindered trialkylbenzyl chlorides summarized in Table 9 support the idea of steric congestion in 2,4,6-tri-*t*-butylbenzyl chloride (1). This chloride showed the largest downfield chemical shift of the benzylic protons relative to benzyl chloride. The compression shift does not occur in 2,4,6-trimethylbenzyl chloride. *p*-*t*-Butylbenzyl chloride showed nearly the same chemical shift as benzyl chloride. This indicates that the electronic effect of a *t*-butyl influences the chemical shifts of the benzylic protons comparatively slightly and such effects could be ignored in this qualitative discussion. The compression shift was also exhibited in the methyl

[3]Reaction of 2,4,6-tri-*t*-butylbenzyl chloride with anhydrous isopropyl alcohol yielded the corresponding isopropyl ether in high yield.

For personal use only.

group of 2,4,6-tri-*t*-butyltoluene (Table 9). The shift was considerably less than for the tri-*t*-butylbenzyl chloride. This is presumably due to the smaller size of the aryl—CH_3 group in contrast to the —CH_2Cl group with resulting lower steric congestion in the former.

Free Radicals by Mass Spectrometry. XLV. Ionization Potentials and Heats of Formation of C_3H_3, C_3H_5, and C_4H_7 Radicals and Ions[1]

F. P. LOSSING

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 15, 1972

Using an energy-resolved electron beam, appearance potentials for $C_3H_3^+$, $C_3H_5^+$, and $C_4H_7^+$ fragment ions from hydrocarbons of formula C_3H_4, C_3H_6, C_4H_6, C_4H_8, and C_5H_{10} have been measured. In each case the fragment appears to have a common structure, corresponding to $\Delta H_f(C_3H_3^+) = 256 \pm 2$ kcal/mol, $\Delta H_f(C_3H_5^+) = 226 \pm 2$ kcal/mol, and $\Delta H_f(C_4H_7^+) = 206 \pm 2$ kcal/mol. Ionization potentials have been measured for propargyl radical (8.68 V), methallyl radical (7.54 V), and 2-methylallyl radical (7.89 V). Corresponding ionic heats of formation are propargyl 281 ± 3 kcal/mol, methallyl 204 ± 3 kcal/mol, and 2-methylallyl 211 ± 5 kcal/mol. The $C_3H_3^+$ fragment ion is 25 kcal/mol more stable than propargyl ion, and is almost certainly cyclopropenyl ion. Ionization potentials for propyne, allene, cyclopropene, 1- and 2-butyne, and fifteen isomers of formula C_nH_{2n} have also been measured by monoenergetic electron impact.

En utilisant un faisceau d'électrons d'énergie résolue, les potentiels d'apparition des ions fragments $C_3H_3^+$, $C_3H_5^+$, et $C_4H_7^+$ à partir des hydrocarbures de formule C_3H_4, C_3H_6, C_4H_6, C_4H_8 et C_5H_{10}, ont été mesurés. Dans chaque cas le fragment semble posséder une structure commune correspondant à $\Delta H_f(C_3H_3^+) = 256 \pm 2$ kcal/mol, $\Delta H_f(C_3H_5^+) = 226 \pm 2$ kcal/mol, et $\Delta H_f(C_4H_7^+) = 206 \pm 2$ kcal/mol. Les potentiels d'ionisation ont été mesurés pour les radicaux propargyle (8.68 V), méthallyle (7.54 V), et méthyl-2 allyle (7.89 V). Les chaleurs de formation ionique correspondantes sont, pour le propargyle 281 ± 3 kcal/mol, le méthallyle 204 ± 3 kcal/mol et le méthyl-2 allyle 211 ± 5 kcal/mol. L'ion fragment C_3H_3 est plus stable de 25 kcal/mol que l'ion propargyle et correspond très certainement à l'ion cyclopropenyle. Les potentiels d'ionisation pour le propyne, l'allène, le cyclopropène, les butyne-1 et -2 et pour quinze isomères de formule C_nH_{2n} ont été mesurés par impact électronique monoénergétique. Introduction

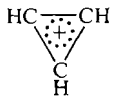
Positive ions of mass 55 ($C_4H_7^+$), mass 41 ($C_3H_5^+$), and mass 39 ($C_3H_3^+$) are generally prominent features in the mass spectra of hydrocarbons. Although these ionic species and their uncharged free radical counterparts have been frequently studied by mass spectrometric methods, the structural identities and heats of formation of the ions are by no means well-established, as revealed by a recent data compilation (1). The $C_3H_3^+$ ion, in particular, has been the subject of considerable speculation, in view of the possibility that it could have the cyclopropenyl structure



This structure is of special interest, as reviewed by Krebs (2), since it is the smallest aromatic system (3) on the basis of the $(4n + 2)$ π-electron rule, where in this case $n = 0$. The great stability predicted (3) on these grounds has been confirmed experimentally (4–6).

Mass spectral studies on $C_3H_3^+$ formation from deuterium-labelled propyne (7) and 1,3-butadiene (8) have shown that these processes involve complete randomization of H-atoms. The earlier mass spectrometric work on $C_3H_3^+$ attempted to distinguish between cyclo-$C_3H_3^+$ and propargyl ion $HC \equiv \overset{+}{C}CH_2$ on the basis of appearance potentials of $C_3H_3^+$ fragment from hydrocarbons (7–9) including cyclopropene (10), combined with the ionization potential of propargyl radical (11). Although the evidence pointed to a common structure for all $C_3H_3^+$ fragment ions, the data did not permit a clear differentiation between the energies of the two structures. In the present work improved measurements of appearance potentials and of the ionization potential of propargyl radical show that the $C_3H_3^+$ fragment ion from hydrocarbons is at least 1 eV more stable than an ionized propargyl radical, and is therefore almost certainly a cyclopropenyl ion.

Assignment of the allyl structure to the

$C_3H_5^+$ fragment ion seems to have been more-or-less taken for granted. Alternative structures such as cyclopropyl ion or propenyl ($CH_3\overset{+}{C}=CH_2$) ion lack resonance stabilization and are consequently appreciably less stable. An earlier electron impact study (12) showed that the $C_3H_5^+$ fragment ion from six C_4H_8 isomers had nearly the same heat of formation, and one which was close to that for allyl ion. In the present work these appearance potentials have been more precisely re-determined using a monoenergetic electron impact method, and compared with a revised value for ΔH_f (allyl$^+$) (13). There seems from this to be no doubt that the $C_3H_5^+$ fragment ion is in all cases an allyl ion, regardless of the structure of the parent molecule.

Similarly, the heat of formation of $C_4H_7^+$ ion as a fragment from thirteen C_4H_8 and C_5H_{10} isomers is investigated in the present work. Again a common ionic structure appears to be involved. Comparison with the heats of formation and the re-measured ionization potentials for methallyl and 2-methyl allyl radicals suggest that the first of these structures is favored.

In addition to the fragment ion measurements, the molecular ionization potentials for selected C_3, C_4, and C_5 hydrocarbons have also been obtained by monoenergetic electron impact.

Experimental

Measurements of ionization efficiency curves for fragment ion formation and for direct ionization of propargyl, methallyl, and 2-methyl allyl radicals were carried out using an electron energy selector, ionization chamber, ion extractor, and quadrupole mass filter previously described (14). The energy dispersion in the electron beam was about 0.07 V at half-maximum. The free radicals were produced by pyrolysis of suitable compounds at pressures of about 10^{-3} Torr in a fused-silica capillary furnace (11).

Propargyl iodide was prepared from a commercial sample of the bromide by reaction with sodium iodide in acetone. After separation the iodide was purified by bulb-to-bulb distillation at reduced pressure. Propargyl methyl nitrite ($HC{\equiv}CCH_2CH_2ONO$) was prepared from 3-butyn-1-ol through reaction with $NaNO_2$ and H_2SO_4. The nitrites $CH_3CH{=}CHCH_2CH_2ONO$ and $CH_2{=}C(CH_3)CH_2CH_2ONO$, and cyclopropyl methyl nitrite, were prepared similarly from the corresponding alcohols.

Cyclopropene was prepared by the method of Closs and Krantz (15). A propylene impurity was removed by bulb-to-bulb distillation at $-130°$.

Cyclopropylcarbonyl peroxide $\triangleright\text{—}\overset{O}{\overset{\|}{C}}\text{—OO—}\overset{O}{\overset{\|}{C}}\text{—}\triangleleft$ was prepared from cyclopropylacetyl chloride by the method of Sheldon and Kochi (16). After purification it was a white solid apparently stable indefinitely at 20°, and easily sublimed at 30°.

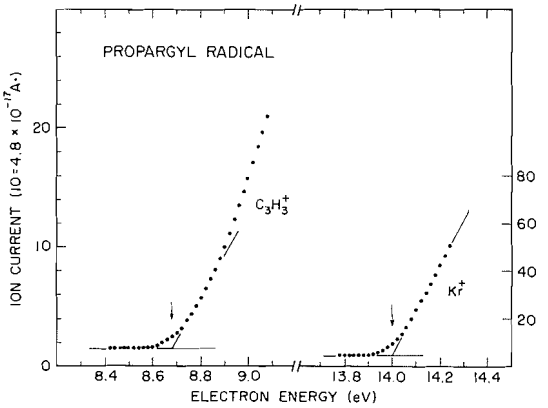

FIG. 1. Ionization efficiency curves for propargyl radical and for krypton standard.

The hydrocarbon samples employed were commercial samples of high purity. The heats of formation at 25° were taken from Cox and Pilcher (17) except for methylcyclopropane (5.7 kcal/mol), ethylcyclopropane (0.7 kcal/mol), and 1,1-dimethylcyclopropane (−1.9 kcal/mol) from Benson and O'Neal's data compilation (18).

Results and Discussion

Propargyl Radical and Ion

In an earlier measurement of the ionization potential, the propargyl radical was produced by the thermal decomposition of propargyl iodide at 1000°–1100° (11). In the present work a better yield was obtained at a much lower temperature by the thermal decomposition (19) of propargyl methyl nitrite.

$$HC{\equiv}CCH_2CH_2ONO \rightarrow HC{\equiv}CCH_2CH_2\dot{O} + NO$$

$$HC{\equiv}CCH_2CH_2\dot{O} \rightarrow HC{\equiv}C\dot{C}H_2 + CH_2O$$

The ionization efficiency curve for propargyl radical is shown in Fig. 1, along with that of krypton for energy calibration. The average of several determinations gave 8.68 V for the ionization potential of this radical. This is appreciably higher than the earlier result of 8.25 V (11), contrary to the usual experience that the older measurements with low energy resolution gave values which were several tenths of a volt too high. Repeat measurements in the original apparatus on propargyl radical from pyrolysis of propargyl iodide, propargyl bromide, and propargyl methyl nitrite all gave ionization potentials of 8.8–8.9 V, consistent with the present results but not with 8.25 V. It

would appear that the voltage scale calibration must have been in error in the earlier work.

$C_3H_3^+$ Fragment Ion

Recent energetics data on $C_3H_3^+$ fragment ions, from the present work and from photoionization studies (20–22) are shown in Table 1. The earlier electron impact results are not included. Typical curves for $C_3H_3^+$ ion production are shown in Figs. 2 and 3. The photoionization data and the present results are in excellent agreement, giving $\Delta H_f(C_3H_3^+) = 256$ kcal/mol with an uncertainty of about ±2 kcal/mol. This value, which is nearly identical with that recommended by Franklin *et al.* (1) will be too high by the difference between the "thermal" shift (23) and the "kinetic" shift (24), which may amount to 2–3 kcal/mol. In this respect it is worth noting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

from Table 1 that H-loss from C_3H_4 molecules gives $\Delta H_f(C_3H_3^+)$ about 3 kcal/mol higher than does CH_3-loss from C_4H_6, indicating a slightly larger kinetic shift for H-atom loss. This heat of formation almost certainly refers to a common ionic species which can be formed with little or no excess energy from parent ions of widely different structure. The identity of this ion, as mentioned above, has been much discussed, the two most probable configurations being cyclopropenyl and propargyl. A third possible $C_3H_3^+$ structure, methylethynyl $CH_3C{\equiv}C^+$, would have a much higher heat of formation than the propargyl ion, since the neutral radical, unlike propargyl, will not possess resonance stabilization. In addition, the ionization potential for $CH_3C{\equiv}\dot{C}$ radical would be much higher than for propargyl radical.[2]

One can estimate $\Delta H_f(HC{\equiv}CCH_2^+)$ from the ionization potential of the radical and a recent measurement of its heat of formation, $\Delta H_f(HC{\equiv}C\dot{C}H_2) = 80.7$ kcal/mol (25). Adding $IP(HC{\equiv}C\dot{C}H_2) = 8.68$ V gives $\Delta H_f(HC{\equiv}CCH_2^+) = 281$ kcal/mol. This is 25 kcal/mol higher than the heat of formation of the common $C_3H_3^+$ species, which clearly rules out the $HC{\equiv}CCH_2^+$ structure for this fragment ion, at least near the dissociation threshold. It seems probable, therefore, that the $C_3H_3^+$ fragment is a cyclopropenyl ion, even when extensive skeletal rearrangement is necessary. The loss of identity of H-atoms in the dissociative ionization of propyne (7) and 1,3-butadiene (8) would be most easily understood on this basis. The formation of cyclo-$C_3H_3^+$ ion appears to be analogous to the well-known dissociative ionization of benzyl derivatives (26), which detailed labelling experiments have shown to involve an easily-scrambled $C_7H_8^+$ precursor dissociating to symmetrical cycloheptatrienyl cation (tropylium). In this case the loss of positional identity has been demonstrated for both H-atoms (26) and C-atoms (27).

Although the present results indicate that $\Delta H_f = 256$ kcal/mol should be attributed to the cyclopropenyl ion, a much lower heat of formation, < 200 kcal/mol, has been proposed (28, 29) to account for the appearance of $C_3H_3^+$ ion as a result of chemi-ionization in shock-tube oxidation of hydrocarbons. However, an alternative mechanism consistent with $\Delta H_f(C_3H_3^+) \sim 256$ kcal/mol has been suggested (22). Evidence for a lower value comes also from observations of $C_3H_3^+$ ion which is formed in an ion-molecule reaction in butadiene (30):

$$C_4H_6^+ + C_4H_6 \rightarrow C_3H_3^+ + C_5H_9$$

For this proposed CH_3-transfer reaction to be exothermic $\Delta H_f(C_3H_3^+)$ would have to be < 240 kcal/mol, which is not consistent with the present result.

Finally, it should be noted that the appearance potential data for $C_3H_3^+$ ion are concerned only with the identity of the ions produced at minimum energies in the region of the dissociation limit. It is possible that at higher energies $C_3H_3^+$ fragment ions with less stable structures, such as propargyl ion, can be formed, which may have lifetimes before isomerization long enough to be of importance in ion-molecule reactions or in metastable transitions. It may be that there are two stable structures for $C_3H_3^+$ fragment ions as has been proposed (31) to explain fine structure in the metastable transition

$$C_3H_5^+ \rightarrow C_3H_3^+ + H_2$$

There is no supporting evidence for this from appearance potentials, however; the divergence in $\Delta H_f(C_3H_3^+)$ values found in the literature (1, 7) almost certainly can be explained on the basis of the well-known difficulties in measuring appearance potential thresholds by low energy-resolution methods. It might be noted also that photoionization curves for $C_3H_3^+$ fragment from 1,2-butadiene and allene (21) show no indication of a second upward break in the region of ~ 25 kcal/mol above the threshold, which would correspond to formation of $HC{\equiv}CCH_2^+$ ion. There are upward breaks at 1.8 V and 1.5 V, respectively, above the thresholds, but these correspond to breaks at the same energies for both parent ions and for other peaks, suggesting the onset of formation of an excited state of the parent ion (21), rather than a new species of $C_3H_3^+$ fragment ion.

$C_3H_5^+$ Fragment Ion

The appearance potentials obtained for $C_3H_5^+$ ion from C_3H_6 and C_4H_8 isomers are listed in

[2]Note that from $\Delta H_f(HC{\equiv}C^+) = 399$ kcal/mol and $\Delta H_f(HC{\equiv}\dot{C}) = 112$ kcal/mol (1) one obtains $IP(HC{\equiv}\dot{C}) \simeq 12.4$ V. This is 2–3 V higher than the ionization potential of any hydrocarbon radical of the form $R{-}\dot{C}H_2$.

Table 2, together with literature electron impact data (12, 32, 33), which is generally 0.2–0.4 V higher. No photon impact data is available. The ionization efficiency curves for these processes were all of the same general form already reported (13) for $C_3H_5^+$ ion production from propylene. Heats of formation for $C_3H_5^+$ derived from these appearance potentials are also listed in Table 2, and provide further support for the value of $\Delta H_f(C_3H_5^+) = 226$ kcal/mol found earlier (13). As noted in this reference, the heat of formation of allyl ion of known structure is also 226 kcal/mol as derived from $\Delta H_f(\text{allyl}) + \text{IP(allyl)}$. The alternative structure for $C_3H_5^+$, the cyclopropyl ion, has a heat of formation considerably higher than this, as estimated below from the same relationship. Although the heat of formation of cyclopropyl radical is known, 61 ± 3 kcal/mol (34), the ionization potential is not known; an earlier measurement (33) refers almost certainly to cyclopropyl radicals which had largely isomerized to allyl radicals. An attempt was made in the present work to measure the ionization potential of cyclopropyl radical on radicals of mass 41 produced by the thermal decomposition of cyclopropylcarbonyl peroxide (16) at a relatively low furnace temperature, around 250°, with a contact time of 1 ms. The ionization efficiency curves for $C_3H_5^+$ were found, however, to be almost exactly superimposable on those for allyl radical obtained from the pyrolysis of allylmethyl nitrite (13). Either all the cyclopropyl radicals are rapidly isomerized to allyl at this temperature, or the ionization potential of cyclopropyl radical is higher than that of allyl, and the threshold for ionization of any cyclopropyl radicals retaining their identity is obscured by allyl ions. It can be assumed, however, either from calculation (35) or from naïve consideration of cyclopropyl ion as a "secondary" alkyl ion, that its ionization potential will be about the same as, or a few tenths of a volt lower than, that of allyl radical. Assuming, then, that IP(cyclopropyl) > 7.8 V one obtains $\Delta H_f(\text{cyclopropyl}^+) > 241$ kcal/mol, clearly larger than $\Delta H_f(\text{allyl}^+)$.

It appears therefore that the minimum energy path for $C_3H_5^+$ production from all the compounds in Table 2 corresponds to allyl formation with little or no excess energy required, even when extensive skeletal rearrangements are necessary. Although the only $C_4H_8^+$ isomer which can dissociate to allyl ion and CH_3 by a simple bond rupture without rearrangement is the parent ion of 1-butene, the minimum energy dissociation path is not lower for this than for the other isomers. This is consistent with the findings of Meisels *et al.* (12) that complete skeletal randomization occurs in $C_3H_5^+$ production from 1-butene at energies close to the dissociation threshold. Regardless of which isomer one starts with, whenever the total energy content reaches the level of $\Delta H_f(\text{allyl}^+) + \Delta H_f(CH_3)$ (*i.e.* 226 + 34 kcal/mol or 11.27 V), these products can be formed. This implies a facility for isomerization which appears at first sight to be at odds with evidence from ion–molecule studies that various $C_4H_8^+$ isomeric ions lose their identity relatively slowly (36–39).

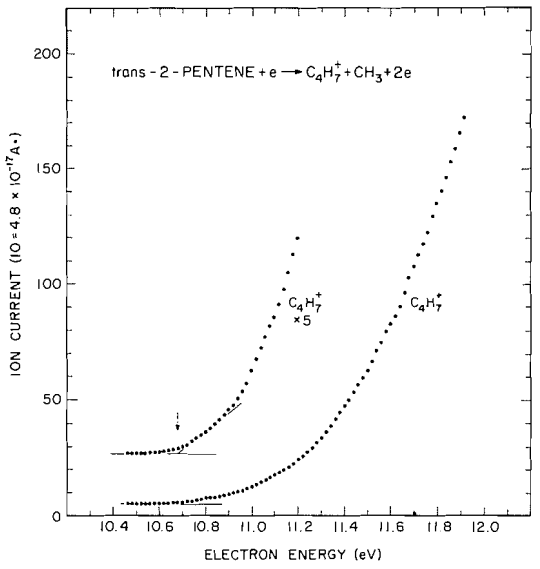

FIG. 4. Ionization efficiency curve for $C_4H_7^+$ fragment ion from *trans*-2-pentene.

In the present experiments, however, we are concerned only with reaction rates along the minimum energy path for dissociation, for which the time-scale will be considerably longer than for isomerization (12). Moreover, as a result of an unusually small ion draw-out potential, the ion residence time in the present apparatus is quite long, around 3×10^{-5} s. This favors the detection of low-energy processes, and reduces the kinetic shift associated with the detectable threshold for dissociation.

The formation, at higher electron energies, of $C_3H_5^+$ fragment ions having a structure other than allyl, which is retained long enough to undergo ion-molecule reactions, cannot of course be ruled out on the basis of the present work.

$C_4H_7^+$ Fragment Ion

The appearance potentials for $C_4H_7^+$ fragment ion from five C_4H_8 isomers and eight C_5H_{10} isomers are listed in Table 3. A few electron impact values are available from the literature (32, 33, 40), but no photoionization results have appeared. The efficiency curves for $C_4H_7^+$ were generally of the form shown in Fig. 4, having no significant structural features other than a low probability near the onset and curving strongly upward over a 1-V interval. The thresholds were not well-defined, so the appearance potentials in Table 3 are probably uncertain to at least ± 0.1 V. Corresponding ionic heats of formation are also given in Table 3, from

which it appears that the $C_4H_7^+$ fragment ion from all these isomers has a common structure, with $\Delta H_f = 206 \pm 2$ kcal/mol. The most probable structures are the two allylic forms corresponding to the resonance stabilized free radicals $CH_3\dot{C}HCH{=}CH_2$ and $CH_2{=}C(CH_3)\dot{C}H_2$. To clarify this point these two radicals were generated thermally by the pyrolysis of the appropriate nitrites RCH_2ONO and their ionization efficiency curves were obtained. The ionization potentials, which are about 0.2 V lower than earlier measurements (41), are given in Table 3. Taken with the heat of formation of $CH_3\dot{C}HCH{=}CH_2$ (methallyl) radical, 30.2 kcal/mol (42), the ionization potential gives 204 kcal/mol for the heat of formation of this ion, with an estimated uncertainty of ± 3 kcal/mol. No heat of formation is available for $CH_2{=}C(CH_3)\dot{C}H_2$ radical, but an estimate can be made on the assumption that the bond dissociation energy $D(CH_2{=}C(CH_3)CH_2{-}H) \sim$ 85 kcal/mol, *i.e.* lower than D(allyl—H) = 88 kcal/mol (43) but not as low as $D(CH_3CH{=}CHCH_2{-}H) = 82.5$ kcal/mol (42). This estimate gives $\Delta H_f(CH_2{=}C(CH_3)CH_2) \sim 28.6$ kcal/mol and an ionic heat of formation of 211 kcal/mol for this structure, with an estimated uncertainty of ± 5 kcal/mol. Taking into account a presumed kinetic energy shift in the appearance potential, these values suggest that the $C_4H_7^+$ ion at the energy threshold has more probably the non-branched form, regardless of the structure of the parent ion. Evidently the situation is similar to that for allyl and cyclopropenyl ions, in that isomerization leads to complete loss of parent ion identity on the time-scale involved in dissociation near the energy threshold.

It is interesting to note that for each of the C_4H_8 isomers in Tables 2 and 3, the appearance potentials for the $C_3H_5^+$ and the $C_4H_7^+$ fragment ions are equal within the experimental error; the largest difference, 0.09 V, is found for cyclobutane. It is doubtful if any special significance should be attributed to this fact, other than that, by coincidence, the heats of formation of the two sets of products $C_3H_5^+ + CH_3$ and $C_4H_7^+ + H$ are nearly identical. The exact coincidence of the appearance potential curves for $C_3H_5^+$ and $C_4H_7^+$ from cyclobutane, from the threshold up to 50 V, and the resulting insensitivity of the ratio $C_3H_5^+/C_4H_7^+$ to internal energy, have been noted by Hughes and Tiernan (37).

Molecular Ionization Potentials

The ionization potentials of allene, propyne, cyclopropene, and 1- and 2-butyne, as measured by monoenergetic electron impact, are given in Table 4, together with values obtained by photoionization (PI) and photoelectron spectroscopy (PS) (21, 22, 44–47). The ionization efficiency curves for allene and cyclopropene molecular ions are shown in Figs. 2 and 3, respectively. The allene curve has a short segment at the foot, which appears also in the photoionization curve (21). The cyclopropene curve shows no resolvable structure, but is slightly curved over the first 0.2 V. The agreement of the data for these molecules is satisfactory, except possibly for allene.

The ionization potentials obtained for C_nH_{2n} isomers are given in Table 5, along with photo-

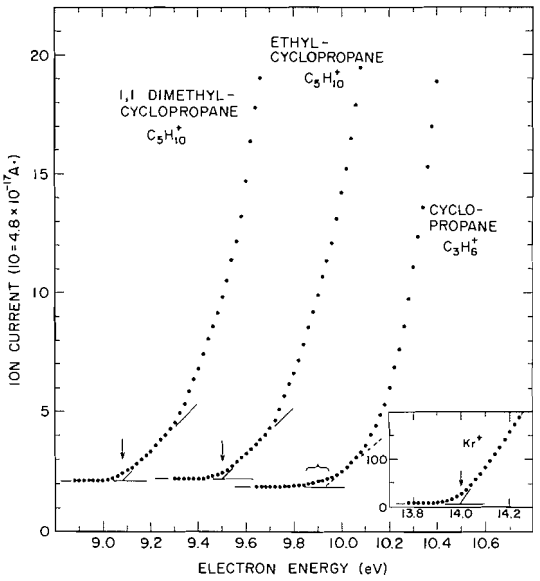

FIG. 5. Ionization efficiency curves for parent ions of 1,1-dimethylcyclopropane, ethylcyclopropane, and cyclopropane. The latter has a nearly asymptotic threshold, corresponding to a low probability for the adiabatic ionization process.

ionization and photoelectron spectroscopy values from the literature (44–50). The ionization efficiency curves were generally of the shape shown by 1,1-dimethylcyclopropane and ethylcyclopropane in Fig. 5, with a moderately abrupt onset, exhibiting possibly a short linear section, as for the latter compound. The curve for cyclopropane itself (Fig. 5) was more nearly asymptotic in shape, and the 9.93 V reported is undoubtedly only an upper limit for the adiabatic ionization potential. The agreement of the data is satisfactory, with the possible exception of cyclopropane and cyclobutane. It is interesting to note that the ionization potential of cyclopropane is lower than that of cyclobutane, which is in turn lower than that of cyclopentane. Methyl- and ethylcyclopropane have essentially the same ionization potential, rather surprisingly lower than that of 1-butene, while 1,1-dimethylcyclopropane is even lower by about 0.4 V, as might be expected from the double substitution.

Structure of Radicals Produced by γ-Radiolysis. Part 2. Radicals Derived from 5-Membered Alicyclic Molecules

RON E. LINDER AND A. CAMPBELL LING[1]

Department of Chemistry, West Virginia University, Morgantown, W.V. 26506

Received December 29, 1971[2]

Data are presented for the results of γ-radiolysis on cyclopentane, methyl cyclopentane, cyclopentene, and cyclopentadiene, held as solutes in adamantane matrices. Data from this particular matrix isolation technique are in accord with liquid phase studies for cyclopentane and cyclopentene, and indicate that tertiary hydrogen loss occurs in methyl cyclopentane, and that cyclopentadiene yields at least three radicals. Two of the radicals derived from cyclopentadiene have been identified as the C_5H_5· entity with five equivalent protons, and the allylic-type radical formed by hydrogen atom addition to molecular C_5H_6.

Les résultats de la radiolyse γ du cyclopentane, méthycyclopentane, cyclopentène, et cyclopentadiène, retenus comme solutés dans des matrices adamantane, sont présentés. Cette technique particulière d'isolement par matrice donne des résultats en accord avec ceux de la phase liquide pour le cyclopentane et cyclopentène, et montre que la perte de l'hydrogène tertiaire se produit dans le méthylcyclopentane tandis que le cyclopentadiène conduit au moins à trois radicaux. Parmi ceux ci deux ont été identifiés: c'est l'entité C_5H_5· avec cinq protons équivalents et le radical de type allylique formé par addition d'hydrogène atomique sur C_5H_6 moléculaire. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3982 (1972)

Introduction

As part of an investigation involving radiolysis of five-membered heterocyclic molecules it was felt that data from equivalent alicyclic compounds would prove useful. Cyclopentane has been studied previously by Fessenden and Schuler (1) in the liquid phase using continuous flow radiolytic production techniques below room temperature and by Fischer (2) using chemical generation in the liquid phase. The major radical was shown to be that resulting from C—H bond cleavage with a structure that is either planar or rapidly inverting in a "chair–boat" vibration analogous to that undergone by cyclohexane. In this context, it is interesting to note that the cyclohexyl radical resulting from radiolysis of cyclohexane does *not* exhibit four equivalent protons at the β-position relative to the unpaired electron and cannot be planar (1). Ohnishi and Nitta (3) have shown that radiolysis of cyclopentadiene as a crystalline solid at 77 °K leads to the production of two different radicals, one of which was identified as the C_5H_5· radical with five equivalent protons, but the second radical could not be identified from the observed e.s.r. spectrum. Similarly, Kuri and co-workers (4) obtained a broad, and poorly resolved, e.s.r. spectra following radiolysis of cyclopentadiene at 77 °K and assigned it to two different radical species, one of which was probably the C_5H_5· radical. Pyrolysis experiments on ferrocene were shown to lead to the production of C_5H_5· radicals (5), although radiolysis and photolysis of metallocene solutes in glassy 2-methylpentane matrices at 77 °K gave no evidence for C_5H_5· radical production (6). However, photolysis of cyclopentadiene itself as a crystalline solid at 77 °K does lead to C_5H_5· generation, but no other radical (7). Analogously, photolysis of a dilute solution of hexachloro-cyclopentadiene in carbon tetrachloride in a flow system leads to the production of C_5Cl_5· radicals and no others (8). In contrast to these predominantly solid phase studies, Krusic and Kochi (9) studied the chemical generation of C_5H_5· from cyclopentadiene in the liquid state at low temperature. E.s.r. data for the γ-radiolysis of cyclopentene in adamantane has now been reported by Wan and co-worker (10).

Experimental

Cyclopentane (CP), cyclopentene (CPE), methyl cyclopentane (MCP), cyclopentadiene dimer, and adamantane, were obtained from commercial sources in the purest grade available and used as received. Cyclopentadiene (CPDE) was prepared from its dimer by standard distillation procedures, collected at −78 °C, degassed, and stored at −78 °C on a vacuum line. Incorporation of CP, CPE, and MCP, into the adamantane matrix was done by multiple recrystallization of adamantane crystals from small aliquots (*ca.* 25 ml) of solvent (CP, CPE, and MCP, respectively), using fresh portions of the solvent each time (3–4 repetitions). Incorporation of CPDE into adamantane required a slightly different technique due to the risk of dimerization at room temperatures and above. Adamantane was recrystallized from methyl cyclohexane[3] to remove solvent impurities contained in the cavity on receipt from the vendor. It was transferred to a container on the vacuum line and degassed, using an ice-bath to restrict sublimation. Freshly prepared CPDE from its storage reservoir (at 195 °K) on the vacuum line was transferred to the adamantane vessel using liquid N_2 to condense the vapor and allowing the reservoir to warm to 273 °K. The container with adamantane was allowed to warm from 77 to 273 °K, thus permitting the adamantane to dissolve in the CPDE liquid. After 60 min the CPDE was transferred out of the adamantane container to a new vessel, and fresh CPDE transferred into the adamantane from the reservoir. Using standard vacuum line techniques and controlling the temperature with ice, Dry-Ice, and liquid N_2, the adamantane was thoroughly washed four to five times with CPDE monomer, where at no time was the temperature allowed to exceed 0 °C for liquid CPDE monomer, so curtailing dimer formation. All adamantane samples containing the requisite solute were dried in an oven at *ca.* 35–40 °C for 15 min, and then irradiated at room temperature in a Pyrex tube utilizing a ^{60}Co source (dose rate 3.5×10^{16} eV g^{-1} min^{-1} via Fricke solution dosimetry). Irradiated adamantane samples containing solute were transferred to quartz e.s.r. tubes and monitored at room temperature using a Varian E-3 e.s.r. spectrometer (typically; 0.5–50 mW power, 0.5–2.0 G modulation amplitude, 16 min scans at 3390 ± 100 G). Saturation effects were noted for radicals derived from CPDE as low as 10 mW, typical γ-doses were *ca.* 10^{18} eV g^{-1}, radical lifetimes varied widely but were all in excess of 2 h. Particularly for radicals derived from CPDE, serious degeneration of the low power spectrum was noted after only 90–120 min. Re-irradiation of the same adamantane sample invariably led to shorter lifetimes, more rapid degeneration, and poorer resolution, of the observed e.s.r. spectrum. Computer simulations of e.s.r. spectra were carried out by a modified program supplied by Quantum Chemistry Program Exchange[4] utilizing an IBM-360/75 computer system and Cal-Comp Plotter accessory.

[3]Recrystallization of adamantane from methyl cyclohexane followed by γ-radiolysis in the usual manner does not lead to any recognizable e.s.r. spectrum attributable to methyl cyclohexane itself. The only noted feature is a broad singlet, typical of polycrystalline e.s.r. studies, and characteristic of 1-adamantyl radicals, rather than of 2-adamantyl radicals which lead to distinctly different signals (11). It is interesting to note that sublimation techniques do *not* necessarily lead to adamantane samples free from impurities. A very characteristic e.s.r. spectrum is obtained by radiolysis of adamantane directly from samples supplied by the vendor. This characteristic spectrum persists even after sublimation, and is attributed to trapped solvent molecules used in the synthesis of adamantane originally.

Results and Discussion

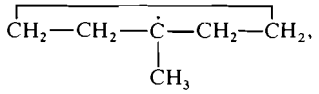
Experimental spectrum, stick spectrum, and computer simulated spectrum for γ-irradiated MCP are shown in Fig. 1. Low power and high power e.s.r. spectra of γ-irradiated cyclopentadiene together with the spectrum obtained from γ-radiolysis of cyclopentene are shown in Fig. 2. Hyperfine coupling constants for the radicals studied are shown in Table 1. Resolution of spectra using adamantane as the trapping matrix is adequate for unambiguous assignments (line widths in the range 0.8–3.0 G), but line widths in general are inferior to those obtained in the liquid state (*e.g.*, 0.08 G (9), 0.5 G and less (1, 12).[5]

Cyclopentane and Cyclopentene

These data from the solid state at room temperature agree well with that previously recorded for low temperature liquid phase studies (see Table 1). In the case of CP, temperature dependent studies in adamantane matrices between 77 and 373 °K proved ambiguous, and did not resolve the question of whether the radical was planar or undergoing vibratory inversion through the ring center.

Methyl Cyclopentane

Data obtained are consistent with tertiary hydrogen loss as previously postulated for alkane molecules (13). The e.s.r. spectrum being assigned to a radical



coupling constants are given in Table 1. Again,

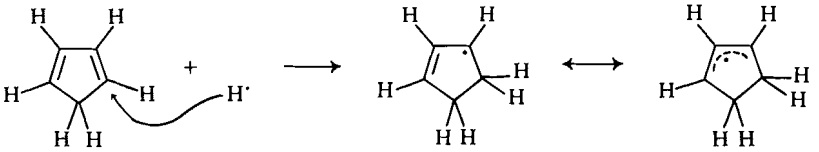
temperature dependent studies were unable to answer the question as to whether the radical is planar, or rapidly inverting at room temperature.

Cyclopentadiene

The experimental data are given in Table 1 and in Fig. 2. Power saturation experiments demonstrated that above approximately 20 mW, the e.s.r. spectrum of one radical could be enhanced significantly at the expense of others. The spectrum obtained at 32 mW is shown in Fig. 2*a*, and exhibits a well defined sextet with intensities close to the theoretical 1:5:10:10:5:1 required for five equivalent protons, and a coupling constant of 6.1 ± 0.1 G. The significant features of the underlying spectrum, both at high power and low power, are matching sets of doublets to the outside of the sextet. This is characteristic of the spectrum obtained from the radiolysis of cyclopentene, as demonstrated by the published spectrum of Wan and co-worker (10) and the experimentally obtained spectra in this work (displayed in Fig. 2*c*). Comparison on a peak-by-peak basis, via direct overlay of one spectrum on top of the other, shows complete agreement between the cyclopentenyl spectrum and the peaks in the low-power observed spectrum from cyclopentadiene. However, this low-power spectrum displays more peaks than can be accounted for by the sum of the cyclopentadienyl spectrum and the cyclopentenyl spectrum. There are, therefore, *at least* three radicals produced by γ-radiolysis of cyclopentadiene in adamantane matrices. Both of these observed and assigned radicals can be accounted for simply; the cyclopentadienyl radical $C_5H_5\cdot$ by loss of a hydrogen atom from the $-CH_2-$ group in the five-membered ring, and the cyclopentenyl allylic structure

by addition of a hydrogen atom to a molecule of cyclopentadiene at one of the double bonds (as shown in the scheme below).



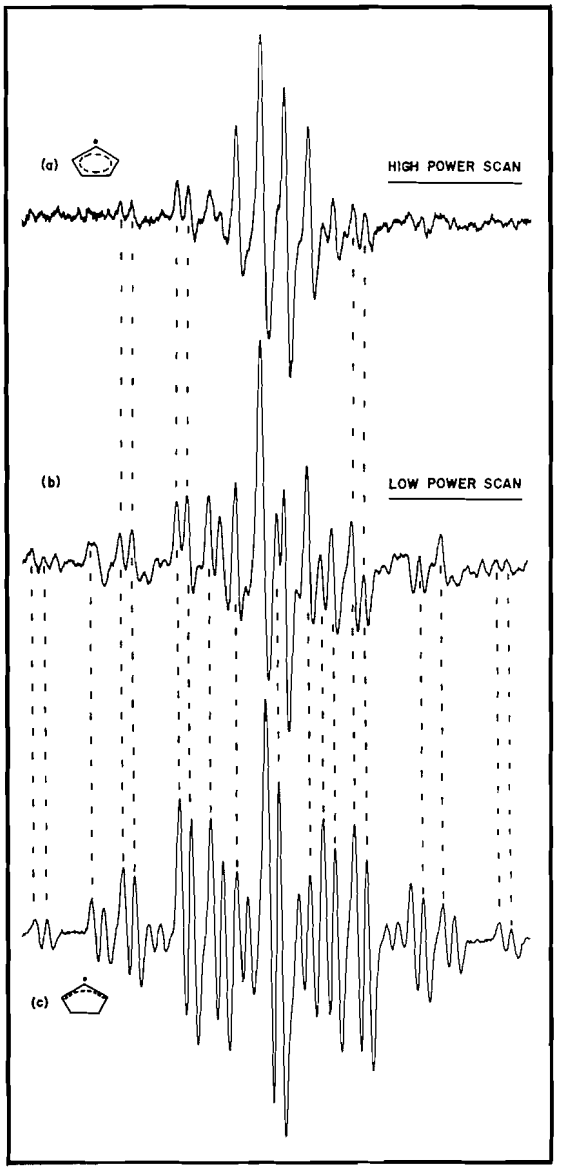


FIG. 2. Experimental e.s.r. spectra for γ-irradiated cyclopentadiene and cyclopentene in adamantane matrices at room temperature: (*a*) high power spectrum of cyclopentadiene (32 mW); (*b*) low power spectrum of cyclopentadiene (2 mW); (*c*) spectrum of the allylic-type radical derived from cyclopentene in adamantane (2 mW).

It is tempting to assign the third radical to the structure $\overset{\cdot}{C}H_2—CH_2—CH—CH_2—CH_2$ (*i.e.*, the cyclopentyl radical) corresponding to hydrogen atom addition at the other end of the double bond, but there are insufficient data from the e.s.r. spectrum to support this hypothesis. Hydrogen atom addition to alkenes in conventional matrices is well documented, and Wan[6] reports that γ-radiolysis of cyclooctatetraene in adamantane leads to two radicals, one of which can be explained by hydrogen atom addition to one of the double bonds in this molecule. Finally, in an attempt to elucidate further the mode of decay of adamantane isolated species, the rate of decay of the sextet attributed to the $C_5H_5\cdot$ radical was determined over a period of 110 h at room temperature. Radical concentrations, as measured by the height of the high-field central line of the sextet, were determined for fourteen different times between 0 and 110 h. Plots of concentration against time (correlation coefficient 0.979_2), log (concentration) against time (correlation coefficient 0.980_2), and concentration^{-1} against time (correlation coefficient 0.979_2), were all reasonably linear, with a half-life for the radical species of *ca.* 142 h at room temperatures. It is not possible, therefore, to draw any meaningful conclusions concerning the order of the kinetic rate, since data spanned less than one half-life for the process.

Adduct Intermediates in the Side-chain Nitration of 1,4-Dimethylnaphthalene

ALFRED FISCHER AND ALAN LESLIE WILKINSON
Department of Chemistry, University of Victoria, Victoria, British Columbia

Received June 5, 1972

cis and *trans* isomers of 1,4-dimethyl-4-nitro-1,4-dihydro-1-naphthyl acetate (**1**) have been isolated from a mixture of 1,4-dimethylnaphthalene and nitric acid in acetic anhydride by quenching at −40°. At room temperature only 1-methyl-4-nitromethylnaphthalene (**4**) is obtained. The conversion of 1,4-dimethylnaphthalene to **4** and of the *cis* (**1***a*) and *trans* (**1***b*) adducts to **4**, by nitric acid in acetic anhydride, has been followed by n.m.r. 1,4-Dimethyl-4-nitro-1,4-dihydro-1-naphthyl nitrate (**5**) appears to be the immediate product from nitration of 1,4-dimethylnaphthalene in acetic anhydride, methylene chloride, or nitromethane. In acetic anhydride **5** is converted into **1**. Decomposition of **1** in acetic acid gives 1,4-dimethyl-2-naphthyl acetate and some **4**. The formation of **4** in this reaction is suppressed by urea.

Les isomères *cis* et *trans* de l'acétate de diméthyl-1,4 nitro-4 dihydro-1,4 naphtyl-1 (**1**) ont été isolés d'un mélange de diméthyl-1,4 naphtalène et d'acide nitrique dans l'anhydride acétique, après trempage à −40°. A la température ambiante, seul le méthyl-1 nitrométhyl-4 naphtalène (**4**) est obtenu. La conversion par l'acide nitrique dans l'anhydride acétique, du diméthyl-1,4 naphtalène en **4** et des adduits *cis* (**1***a*) et *trans* (**1***b*) en **4**, a été suivie par r.m.n. Le nitrate de diméthyl-1,4 nitro-4 dihydro-1,4 naphtyl-1 (**5**) apparait être le produit immédiat lors de la nitration du diméthyl-1,4 naphtalène dans l'anhydride acétique, chlorure de méthylène ou nitrométhane. Dans l'anhydride acétique, **5** est transformé en **1**. La décomposition de **1** dans l'acide acétique donne l'acétate de diméthyl-1,4 naphtyl-2 et un peu de **4**. La formation de **4** dans cette réaction est supprimée par l'urée. [Traduit par le journal]

Introduction

There are a number of reported cases of abnormal electrophilic substitution reactions in which substitution occurs in the side-chain of alkyl derivatives of aromatic and heteroaromatic compounds. For example, hexamethylbenzene gives pentamethylbenzyl halide on halogenation under electrophilic conditions (1) and 2,3-dimethylbenzothiophene gives the 2-nitromethyl derivative on reaction with nitric acid in acetic anhydride (2). It seems likely, and has been well established in at least some of the examples (3), that these reactions involve as the first step the normal nuclear electrophilic attack to generate the expected σ-complex (phenonium ion). However, the mechanism by which the σ-complex is converted into the side-chain substitution product has not been established in any of the examples, although almost every report of this type of abnormal substitution includes a speculative mechanism. Formation of 1-methyl-4-nitromethylnaphthalene on nitration of 1,4-dimethylnaphthalene is clearly an example of this type of abnormal substitution.

Nitration of 1,4-dimethylnaphthalene in acetic anhydride, nitromethane, aqueous suspension (4), and in methylene chloride (5) gives 1-methyl-4-nitromethylnaphthalene (**4**). Davies and Warren (6) isolated a pale yellow crystalline substance, m.p. 47–48°, when nitration was carried out in acetic anhydride at −10° using equimolar amounts of nitric acid and 1,4-dimethylnaphthalene. They suggested on the basis of its u.v. spectrum that this compound was 1,4-dimethyl-5-nitronaphthalene, and that it was an intermediate in the formation of **4**. Subsequently Robinson (7) pointed to the absence of the 310–350 nm band expected for a nitronaphthalene in the u.v. spectrum of the yellow substance, and he suggested that it had structure **2**. He also suggested the mechanism outlined in Scheme 1 for the conversion of 1,4-dimethylnaphthalene into **4**. Formation of acetyl nitrate adducts, of which **1** is an example, has been observed from a variety of aromatic compounds on reaction with nitric acid in acetic anhydride (8). In particular, the formation has been reported (8*d*), of 1,4-adducts from some tetracyclic naphthalene derivatives, which are closely related to **1**. However, none of the intermediates, including **1**, depicted in Scheme 1 have been isolated and characterized. Indeed, considering the ambiguity as to the structure of Davies and Warren's yellow compound, none

a *cis*
b *trans*

2 3 4

SCHEME 1

of the intermediates in Scheme 1 can be properly claimed to have been detected. We now report the investigation of the reaction between nitric acid and 1,4-dimethylnaphthalene in acetic anhydride at −40°, and the detection and isolation of a pair of diastereoisomeric adducts corresponding to structure **1**.

Results and Discussion

Nitration in acetic anhydride of 1,4-dimethylnaphthalene, both at room temperature and at −40°, with the product being isolated by extraction after pouring the reaction mixture onto ice, gave only 1-methyl-4-nitromethylnaphthalene. However, when nitration was carried out at −40° and the reaction mixture was quenched with ammonia at that temperature the diastereoisomeric adducts **1***a* and *b* were formed as the major reaction products, together with **4** and small amounts of 1,4-dimethyl-2-nitronaphthalene and other substances. The diastereoisomers **1***a* and *b* were separated from each other and from the other constituents of the product mixture by low temperature chromatography on alumina.

The structures of the adducts were unambiguously established by their spectra. The presence of the nitro and acetoxy groups was revealed by the i.r. spectra and supported by the mass spectra. The loss of the low field α-naphthyl proton n.m.r. absorption, and the appearance of the E_2 and B bands in the u.v. spectrum in the regions characteristic of the benzenoid system rather than at the longer wavelengths characteristic of a naphthalenic system, is consistent with adduct formation. The n.m.r. spectra also showed that the adducts each contain four aromatic protons and two vinylic protons. It follows that addition must have occurred to the disubstituted rather than the unsubstituted ring. The two vinylic protons exhibited a 10 Hz coupling and must therefore be *cis* and adjacent as in structure **1**.

The *cis* configuration was assigned to **1***a* and the *trans* to **1***b* on the basis of their dipole moments which are 3.54 and 3.79 D, respectively. The difference between the two moments is small but, since the measurements were made under the same conditions and the compounds are of close structural similarity, the conclusion that **1***b* has a larger dipole moment than **1***a* should be valid. The calculated moments are 3.34 (*cis*) and 4.10 (*trans*), for a planar cyclohexadiene ring, and 3.43 (*cis*) and 3.82 (*trans*), for a boat cyclohexadiene ring with equal populations of the two conformations of each isomer. The isomer of lower measured dipole moment was thus assigned the *cis* configuration.

Both **1***a* and *b* decomposed slowly ($t_{\frac{1}{2}} \simeq 45$ min) in acetic acid at 30° and gave as the main product 1,4-dimethyl-2-naphthyl acetate and a lesser amount of the side-chain nitration product **4**. In the presence of urea the formation of **4**, from **1***b*,[1] was completely suppressed and only the acetate was formed, the rate of decomposition being unaffected.

Isolation of **1***a* and *b* allowed a systematic study of the reaction of each with nitric acid in acetic anhydride and made it possible to interpret the behavior of 1,4-dimethylnaphthalene. At −60° 1,4-dimethylnaphthalene was converted into a species which absorbed in the vinylic region and which, like **1**, exhibited a 10 Hz coupling between the vinyl protons and did not absorb in the α-naphthyl proton region. This species was neither **1***a* nor *b*, since both the vinyl protons and the aromatic protons absorbed at lower fields than in either of these

[1]The effect of urea was not investigated in the case of **1***a*. In the absence of urea, **1***a* gives only 15% of **4** whereas **1***b* gives 35% of **4**.

5

adducts. The general similarity of the spectra indicates that it was an adduct similar in structure to **1***a* and *b* and we suggest that it was the nitronium nitrate adduct **5**. At −40° the adducts **1***a* and *b* appeared, their olefinic protons absorbing at higher fields but with the same 10 Hz coupling. At −10° the olefinic peaks of **1***a* and *b* declined and were eventually replaced by the methylene peak of the nitromethyl compound **4**. Simultaneously the low field absorption of the α-naphthyl protons of **4** appeared. At 25° the only prominent peaks were those of **4**.[2] Smaller amounts of other unidentified components were formed at various times but at no stage were there any major peaks observed which could be attributed to the exocyclic diene **2** postulated by Robinson (7). This does not rule out the possibility of **2** being an essential intermediate in the reaction but does imply that if **2** is formed it is more reactive than other intermediates in the sequence.

Both **1***a* and *b* interconverted and formed the species assumed to be the nitronium nitrate addition compound **5** when reacted with nitric acid in acetic anhydride at −30°. The conversion of either isomer to **5** was more rapid than the interconversion of the isomers and **1***b* reacted more rapidly than **1***a*. In both cases an equilibrium concentration ratio of **1***a*:**1***b* = 3.5:1 was reached.

The reaction between 1,4-dimethylnaphthalene and nitric acid in the absence of acetic anhydride was investigated in deuterated methylene chloride and deuterated nitromethane. In methylene chloride the characteristic vinylic AB pattern ($J = 10$ Hz) appeared when the temperature was raised to −40°, and it is presumed the diastereoisomeric nitronium nitrate adducts **5** formed. The aliphatic methyl groups, which in acetic anhydride were obscured by the anhydride methyl proton peak, were observed. The isomeric ratio indicated by these was 6:1. At −20° the adducts began to be converted to the nitromethyl compound **4** and another unidentified transient species. At 25° **4** remained as the major reaction product. Similar behavior was observed in nitromethane.[3]

It is clear that the acetyl nitrate adducts **1** are formed during the side-chain nitration of 1,4-dimethylnaphthalene. It is not possible to demonstrate that these are necessary intermediates since they are in equilibrium with the initially formed nitronium nitrate adducts and it may be the latter that are converted directly to the next intermediate in the sequence rather than the former. Formation of **4** as the minor constitutent of the product when decomposition of the adducts **1***a* and *b* was carried out in acetic acid suggests that the shift of the nitro group from the ring to the side-chain is an intermolecular process. The higher yields of **4** obtained when decomposition occurred in the original nitrating mixture are attributed to the greater amount of nitric acid present (as acetyl nitrate) which can compete more effectively, for the precursor to **4**, with the process leading to the naphthyl acetate.[4] Further support for the conclusion that the **1** → **4** process is intermolecular is provided by the observation that urea suppressed the formation of **4** from the decomposition of **1***b*, presumably because the urea competed effectively for the released nitric acid.

Decomposition of the acetyl nitrate adducts from *o*-xylene (8*a*), 1,2,3-trimethylbenzene (8*b*), indane (8*c*), and tetralin (8*d*), occurs by loss of nitrous acid and leads to the appropriate aryl acetate. Decomposition of the *p*-xylene adduct (8*b*) gives, via loss of nitrous acid and an intramolecular rearrangement, 1,4-dimethyl-2-phenyl acetate. The acetate group must migrate in order for the ring to rearomatize. In the case of the adduct of 1,4-dimethylnaphthalene rearomatiz-

[2]Normally the nitric acid was in excess of the hydrocarbon but some runs were made using excess hydrocarbon and **4** was again the predominant product.

[3]Suzuki and Nakamura (5) have investigated the nitration of 1,4-dimethylnaphthalene in methylene chloride. They claim to have observed addition products but do not give the structure of these. They include **5** as an intermediate in a proposed sequence for the formation of 1-methyl-4-nitromethylnaphthalene. Their suggested mechanism is essentially analogous to Robinson's mechanism (Scheme 1).

[4]No naphthyl acetate was isolated from the nitration reaction in acetic anhydride carried out under conditions under which the adducts decomposed. As indicated, the amount of naphthyl acetate which would form under the conditions would not be large and any which did form would react further with the excess nitric acid present.

ation occurs in two ways: loss of nitrous acid and (probably intramolecular) migration of the acetoxy group to give the naphthyl acetate and loss of acetic acid and (intermolecular) migration of the nitro group to give **4**.

Experimental

U.v. spectra were determined on a Unicam SP 700 spectrometer. I.r. spectra were determined on a Beckman IR 20 spectrometer calibrated with polystyrene. N.m.r. spectra were determined on Varian HA-60-IL, and Perkin–Elmer R12A spectrometers with tetramethylsilane as internal standard unless specified otherwise. Mass spectra were determined on a Perkin–Elmer Hitachi RMU-7 spectrometer. Molecular weights were determined in methylene dibromide using a Perkin–Elmer Hitachi Model 115 molecular weight apparatus. Micro-analyses were by Mr. M. Yang, Simon Fraser University, Burnaby, B.C. Melting points are uncorrected. Nitric acid was purified by distilling fuming acid (300 cm^3) at 1 mm from urea (10 g) and sulfuric acid (500 cm^2). Alumina was deactivated with 3% of 10% acetic acid.

Nitration of 1,4-Dimethylnaphthalene in Acetic Anhydride

A cold solution of nitric acid (11 g, 0.26 mol) in acetic anhydride (55 cm^3) was added slowly with stirring to a solution of 1,4-dimethylnaphthalene (20 g, 0.13 mol) in acetic anhydride (25 cm^3) cooled in solid carbon dioxide–acetone. The mixture was allowed to warm to −40° and maintained at that temperature for 30 min. It was then cooled in solid carbon dioxide–acetone, ether (100 cm^3) was added, and ammonia condensed into the solution. Excess ammonia was removed with an aspirator, more ether added, and the mixture poured onto ice. The combined etheral layer and ether extract of the aqueous layer was dried over magnesium sulfate and the ether subsequently evaporated at 14°. The n.m.r. spectrum of the residue (18.2 g) indicated that 30% of the starting material had been reacted, the product consisting mainly of acetyl nitrate adduct with some side-chain nitro compound and considerably smaller amounts of other compounds. Chromatography on alumina at −40° and elution with ether–pentane mixtures gave **1***a* (1.8 g) in the 75% ether fraction and a mixture (3.2 g) of **1***a* and *b* in the 100% ether fraction. Recrystallization of the residue of the 75% ether fraction from ether–pentane gave *cis-1,4-dimethyl-4-nitro-1,4-dihydro-1-naphthyl acetate* (**1***a*), m.p. 61–62°, u.v. (95% ethyl alcohol) 219 (ε 610), 262 nm (shoulder, ε 119 m^2 mol^{-1}); i.r. (Nujol) 1738 and 1239 ($OCOCH_3$), 1538 and 1344 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 8.31 (s, 3, 1-CH_3), 8.04 (s, 3, $OCOCH_3$), 7.93 (s, 3, 4-CH_3), 4.03 (nq, 1, J = 10.3 Hz, 2-*H*), 3.80 (nq, 1, J = 10.3 Hz, 3-*H*), 2.58 p.p.m. (m, 4, C_6H_4); mass spectrum (70 eV) *m/e* (relative intensity) 215.109 (5, $M - NO_2$: $^{12}C_{14}{}^1H_{15}{}^{16}O_2$ requires 215.107), 214 (15), 201.076 (10, $M - CH_3CO_2H$: $^{12}C_{12}{}^1H_{11}{}^{14}N^{16}O_2$ requires 201.079), 184 (7), 173 (72), 172 (82), 157 (47), 156 (100), 155 (95), 141 (90).

Anal. Calcd. for $C_{14}H_{15}NO_4$ (M_r 261): C, 64.36; H, 5.79. Found (262): C, 64.41; H, 5.79.

Chromatography of the residue from the 100% ether fraction and recrystallization of the residue of the new 100% ether fraction gave *trans-1,4-dimethyl-4-nitro-1,4-dihydro-1-naphthyl acetate* (**1***b*), m.p. 91–92°; i.r. (Nujol) 1748 and 1231 ($OCOCH_3$), 1542 and 1344 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 8.39 (s, 3, 1-CH_3), 8.05 (s, 3, 4-CH_3), 7.99 (s, 3, $OCOCH_3$), 3.89 (nq, 1, J = 10.3 Hz, 2-*H*), 3.66 (nq, 1, J = 10.3 Hz, 3-*H*), 2.57 p.p.m. (m, 4, C_6H_4); *m/e* 215.111 ($M - NO_2$: $^{12}C_{14}{}^1H_{15}{}^{16}O_2$ requires 215.107).

Anal. Calcd. for $C_{14}H_{15}NO_4$ (M_r 261): C, 64.36; H, 5.79; N, 5.36. Found (266): C, 64.18; H, 5.98; N, 5.18.

The residue from the 25% ether fraction of the original column gave an unknown compound, m.p. 43°, which decomposed before identification. The decomposition product was also present in the 10% ether fraction and these were combined and chromatographed. The residue of the fraction eluted with 8% ether–pentane from this new column was a mixture of two nitronaphthalenes in a 5:1 ratio. *1,4-Dimethyl-2-nitronaphthalene*, the major component, was crystallized and had m.p. 67–68°; i.r. (CCl_4) 1538 (NO_2), 1369, 1351, 887, 873 cm^{-1}; n.m.r. (CCl_4) τ 7.35 (s, 3, 4-CH_3), 7.29 (s, 3, 1-CH_3) 2.52 (s, 1, 3-*H*), 2.50 (m, 2, 6-*H* and 7-*H*), 2.01 p.p.m. (m, 2, 5-*H* and 8-*H*); mass spectrum (70 eV) *m/e* (relative intensity) 201.081 (100, M_r ($^{12}C_{12}{}^1H_{11}{}^{14}N^{16}O_2$) = 201.079), 184 (97), 171 (22, M − NO), 156 (84), 129 (81), metastable peaks were observed at 168.5, 132.3, and 106.7 corresponding to the successive losses of OH, CO, and HCN in the sequence 201 → 184 → 156 → 129 and confirm the presence of adjacent nitro and methyl groups (9). The sixth fraction of this column gave *1,4-dimethyl-2,3-dinitronaphthalene*, m.p. 260°; i.r. (Nujol), 1540 (NO_2), 1361, 1331, 861, 760, 735 cm^{-1}; n.m.r. ($CDCl_3$) τ 7.30 (s, 6, 1-CH_3 and 4-CH_3); 2.15 (m, 2, 6-*H* and 7-*H*), 1.90 (m, 2, 5-*H* and 8-*H*); mass spectrum (70 eV) *m/e* (relative intensity) 246 (100, M_r ($^{12}C_{12}{}^1H_{10}{}^{14}N_2{}^{16}O_4$) = 246), 229 (41, M − OH), 201 (18), 199 (22, $M - HNO_2$), 198 (21), 155 (26), 154 (44, $M - (NO_2)_2$), 153 (50), 152 (41), metastable peak at 213.2 for 246 → 229 (loss of OH). The highly symmetric n.m.r. spectrum is consistent with the 2,3-dinitro isomer rather than with any other dinitro 1,4-dimethylnaphthalene.

When the initial reaction mixture was worked-up by pouring it onto ice and extracting the product with carbon tetrachloride the only product isolated was 1-methyl-4-nitromethylnaphthalene, m.p. 105° (107° (4)); i.r. (CCl_4) 1561 (NO_2), 1368 cm^{-1}; n.m.r. ($CDCl_3$) τ 7.39 (s, 3, CH_3), 4.26 (s, 2, CH_2), 2.60 (m, 4, 2-*H*, 3-*H*, 6-*H*, 7-*H*), 2.08 (m, 2, 5-*H* and 8-*H*); mass spectrum (70 eV) *m/e* (relative intensity) 201 (3, M_r ($^{12}C_{12}{}^1H_{11}{}^{14}N^{16}O_2$) = 201), 156 (17), 155 (100, $M - NO_2$) 153 (9), 128 (6).

Attempts were made to isolate **1** by pumping the acetic anhydride off the reaction mixture at < −10° but in each case n.m.r. showed that the initially formed adduct **1** was converted into **4**.

Nuclear Magnetic Resonance Study of the Nitration of 1,4-Dimethylnaphthalene

A solution of the hydrocarbon (50 mg, 0.32 mmol) in acetic anhydride (0.13 cm^3) was put into an n.m.r. tube and frozen. A solution of nitric acid (29 mg, 0.46 mmol) in acetic anhydride (0.6 cm^3) was added to the cold tube and the tube placed in the probe of the spectrometer at −60°. The spectrometer was locked on the absorption peak of the acetic anhydride methyl group. The temperature of the probe was raised in 10° increments and the spectrum taken several times at each temperature. A similar procedure was used to investigate the reaction of the adducts **1***a* and *b* with nitric acid

TABLE 1. Measured and calculated dipole moment values

‡Calculated assuming a planar hexadiene ring.
§Calculated assuming a boat hexadiene ring with equal populations of each conformer and free rotation about the C—O bond.
‖Calculated assuming a boat hexadiene ring with equal populations of each conformer and free rotation about the C—O bond in both *trans* conformers and in that *cis* conformer with an equatorial acetate group.

in acetic anhydride and also the nitration of 1,4-dimethylnaphthalene in methylene chloride-d_2 and nitromethane-d_3.

Decomposition of the Acetyl Nitrate Adducts of 1,4-Dimethylnaphthalene

Decomposition was followed by n.m.r. 1,4-Dimethyl-2-naphthyl acetate was isolated from the product mixture, m.p. 70–71°; i.r. (CCl_4) 1766 and 1208 ($OCOCH_3$) 1468, 1169, 1082 cm^{-1}; n.m.r. (CCl_4) τ 7.78 (s, 3, $OCOCH_3$), 7.66 (s, 3, 1-CH_3), 7.42 (s, 3, 4-CH_3), 3.18 (s, 1, 3-*H*), 2.68 (m, 2, 6-*H* and 7-*H*), 2.19 p.p.m. (m, 2, 5-*H* and 8-*H*); the methyl groups were assigned from the weak coupling to the 3-H which broadened the 4-CH_3, and to a smaller extent the 1-CH_3, singlets: the relative heights of the 4-CH_3, 1-CH_3, and acetate CH_3 singlets were 59:64:100. On irradiation of the 3-*H* the coupling was reduced and the 4-CH_3 and 1-CH_3 peak heights increased and became more nearly equal at 76:77:100; mass spectrum (70 eV) *m/e* (relative intensity) 214 (20, M_r ($^{12}C_{14}{}^{1}H_{14}{}^{16}O_2$) = 214), 173 (14), 172 (100), 157 (12), 128 (13), 43 (5). **1***a* gave 15% of **4** and 85% of the acetate. **1***b* gave 35% of **4** and 65% of the acetate.

Dipole Moment Measurements and Calculations

Measurements were made in benzene solution following the procedure described previously (8*c*). Dreiding models of the *cis* and *trans* adducts **1***a* and *b* suggest that there are two rigid boat forms which are interconvertible by a ring flip. However, the planar nature of the 1,4-cyclohexadiene ring seems to be well established (10). Dipole moments were calculated for both planar and boat forms and both sets of calculations predicted the *trans* isomer to have the larger moment. The calculations assume that (*i*) the group moment of the C—$OCOCH_3$ fragment is the same as the dipole moment of methyl acetate (1.70 D) with the moment orientated at 66° to the C—O bond with the negative end towards carbon, the acetoxy group is in the *s-trans* configuration and there is free rotation about the C—O bond; (*ii*) the group moment of the C—NO_2 fragment is the same as the dipole moment of nitromethane (3.01 D) directed along the C—N bond with the positive end towards carbon; (*iii*) contributions from the other groups to the overall dipole moment are negligible; (*iv*) the C—O and C—N bonds are coplanar; (*v*) the angle between 1,4-diaxial bonds in the boat forms is 10°; (*vi*) each pair of boat conformers is populated equally; (*vii*) in the planar forms the angle between the exterior pair of bonds at 1-C (and at 4-C) is 108°. Dipole moments are given in Table 1.

The assumption that there is free rotation about the C—O bond is likely to fail in the case of the *cis* diaxial boat form where in one orientation the diaxial $OCOCH_3$ and NO_2 groups would be brought into close proximity. Accordingly the calculations were repeated assuming that only that rotamer was allowed in which the $OCOCH_3$ group was remote from the NO_2 group. This raised the moment calculated for the *cis* form from 3.43 to 3.52 D but did not vitiate the conclusion that the *trans* form has the higher dipole moment.

We thank the National Research Council of Canada and the University of Victoria for financial support.

The Synthesis of 17β-(4(5)imidazolyl)-5α-androstane-3β,11β-diamine: a Water Soluble Steroid with a Potentially Catalytic Substituent

J. PETER GUTHRIE

Department of Chemistry, University of Western Ontario, London, Ontario

Received June 12, 1972

The title compound, **9**, has been synthesized in an eight-step process, starting with corticosterone (**1**). The Weidenhagen reaction on **1** converted the 17-$COCH_2OH$ to an imidazole. Reduction with lithium–ammonia–methanol gave 17β-(4(5)-imidazolyl)-5α-androstane-3β, 11β-diol (**3**) which could be selectively oxidized to the 3β-ol, 11-one, which was then converted to the oxime and hydrogenated to the 3β-ol, 11β-amine, **6**. Oxidation of the 3β-ol to the 3-one, oximation and sodium–propanol reduction gave **9**.

Le produit **9** a été synthétisé en huit étapes en partant de la corticostérone (**1**). La réaction de Weidenhagen sur **1** convertit le $COCH_2OH$-17 en un imidazole. La réduction par le lithium–ammoniac–methanol conduit à l'(imidazolyl-4(5))-17β 5α-androstane diol-3β,11β (**3**), qui peut être oxydée sélectivement en ol-3β one-11, cette dernière étant transformée ensuite en oxime puis hydrogénée en ol-3β amine-11β **6**. L'oxydation du ol-3β en one-3, l'oximation et la réduction par le sodium dans le propanol donnent **9**.

Introduction

There has been considerable interest (1–13) in the study of enzyme models which show both substrate binding and catalytic properties. Such compounds can provide information bearing on two questions of crucial importance to the development of a full understanding of enzymic catalysis: (*1*) the requirements for non-covalent binding of substrate from aqueous solution (14); (*2*) the orientational requirements for efficient catalysis (15–19). The latter question has traditionally been investigated using intramolecular systems (15, 20, 21), but suffers from the limitation that if the reaction is very rapid, the reactive form of the compound must be generated in solution; already cases are known where even stopped flow techniques are barely adequate to follow the kinetics of the intramolecular reaction (22). Thus it would be preferable to study questions of orientation by looking at reactions of two compounds held together in a non-covalent complex, provided that complex formation was favorable, so that reaction occurred only within the complex, *and* provided that complex formation was specific enough that one could be assured of the orientation of the two molecules within the complex. This should be attainable if one uses relatively large, rigid molecules.

As a step towards the goals outlined above, I wish to report the preparation of 17β-(4(5)-imidazolyl)-5α-androstane-3β,11β-diamine (**9**), which was designed to be water-soluble at p*H* below 10, by virtue of the two amino groups, and to have a quasi-equatorial imidazolyl group, which can act as a catalyst for the hydrolysis of active esters. The steroid nucleus provides a large rigid framework, and has the additional advantage that one can draw upon the immense body of synthetic chemistry performed on steroids. With two ionic substituents, micelle formation should not occur (23). The α surface of **9** is unhindered, and available for hydrophobic binding.

Discussion

The approach used for the preparation of **9** is outlined in Schemes 1 and 2. Corticosterone (**1**) was smoothly converted in excellent yield into 11β-hydroxy-17β-(4(5)-imidazolyl)-4-androsten-3-one (**2**) using a procedure based on the imidazole synthesis devised by Weidenhagen and co-workers (24). The stereochemistry at C-5 was established by reduction of **2** using lithium–ammonia–methanol, to give the diol **3**. This reduction is expected to give the 5α-isomer; the stereochemistry was proved unambiguously by comparison of the ^{13}C n.m.r. spectrum (25) of the corresponding dione **10** with the ^{13}C spectra of the known compounds 5α- and 5β-pregnane-3,11,20-trione. The signal from the 19-methyl carbon is strikingly dependent on the stereochemistry at C-5 (25).

Oxidation of the 11β-hydroxyl was expected

to be much faster than for the 3β-hydroxyl, on the basis of the kinetic studies of Rocek *et al.* (26). In fact, selective oxidation of **3** to **4** was readily achieved. Crude **4**, containing traces of **3** and **10** (t.l.c. analysis), was converted, via its oxime, **5**, to the 11β-amine by hydrogenation with PtO_2 in acetic acid. This hydrogenation proved to be very slow, requiring high pressure, prolonged reaction time, and large amounts of catalyst. However, the desired 11β-amino compound could be obtained in modest yield. Metal hydride reduction, which would also be expected to give the 11β-amine could not be employed because **5** was insoluble in solvents compatible with $LiAlH_4$. That the stereochemistry was indeed 11β is shown by the n.m.r. spectrum, since the methyne signal attributed to the hydrogen on C-11 has the width expected for an equatorial hydrogen.

Finally, the alcohol at C-3 was converted to an amino group, again by way of an oxime. However, since in this case the *equatorial* amine was desired, it was necessary to use sodium–propanol as the reducing agent. Ordinarily the sequence from **6** to **9** was carried out without purifying intermediates, and **9** was crystallized as the trishydrochloride. The n.m.r. spectrum showed a new signal at 3.20 δ, $\Delta\nu_{\frac{1}{2}} = 20$ Hz attributed to the C-3 proton with the width expected for the equatorial amino group.

The overall synthesis requires purifications at only three stages, **3**, **6**, and **9**. Further optimization is almost certainly possible; however the synthesis as reported here makes **9** available in gram quantities, by a route which gives complete control of stereochemistry. Compound **9** is indeed water soluble, to better than 0.1 *M*, at p*H* 8, where the imidazole group is free to act as a nucleophile.

Active esters of 3-(2-naphthyl)-propionic acid (**12**) and 3-(3-phenanthryl)-propionic acid (**13**) react more rapidly with **9** than with imidazole, and the rate enhancement is larger for derivatives of **13**, as would be expected, since the binding area is larger for **13**. Details of these studies of the catalytic properties of **9** will be published shortly.

Experimental

Materials and Methods

Mallinckrodt 2847 silicic acid was used for column chromatography and Camag silica gel was used for t.l.c. Proton n.m.r. spectra were recorded on a Varian HA100. ^{13}C n.m.r. spectra were recorded on a Varian XL100 with noise decoupling of protons; methyl groups were identified by recording off-resonance decoupled spectra. Imidazole-containing compounds were detected using diazotized sulfanilic acid (Pauly reagent (27)).

11-Hydroxy-17β-(4(5)-imidazolyl)-4-androsten-3-one (2)

Corticosterone (**1**) (Sigma Chemical Corp., m.p. 180–183°) (10 g, 28.9 mmol) was dissolved in 800 ml warm 95% ethanol; to this was added 50 ml formalin (Shawinigan, 37% CH_2O) and a solution of 12 g $Cu(OAc)_2 \cdot H_2O$ (60 mmol) in 30 ml water plus 174 ml concentrated ammonia. The solution was refluxed for 3 h, at which time the solution had turned from blue to green, and t.l.c. (80:20, $CHCl_3$:CH_3OH) showed that the reaction was over. The reaction mixture was allowed to cool and then worked-up by partitioning between saturated aqueous sodium chloride and ethyl acetate. The combined ethyl acetate extracts (total volume about 2 l) were dried over Na_2SO_4, and then evaporated to dryness. The residue was extracted with 46 ml of hot methanol, made alkaline with ammonia, and brought to saturation with water. The first crop was 5.44 g. The residue was extracted with methanol till no more Pauly positive material dissolved. These extracts and the crystallization mother liquors were pooled and evaporated. Similarly using 23 ml of hot methanol a second crop of 2.11 g was obtained. The process was repeated to give 1.89 g in the third crop. Total yield of crude product: 9.43 g (92%). Recrystallization from methanol–water (with a few drops of concentrated ammonia added) gave material of m.p. 177° (dec.); n.m.r. (as HCl salt) δ (D_2O), 0.76 (C-18 methyl), 1.37 (C-19 methyl), 4.30 ($\Delta\nu_{\frac{1}{2}} = 9$ Hz, C-11 methine), 5.58 (singlet, —C*H*=C), 7.14, 8.46 (C—H protons of the imidazolium ring).

Anal. Calcd. for $C_{22}H_{30}N_2O_2 \cdot CH_3OH$: C, 71.46; H, 8.86; N, 7.24. Found: C, 71.33; H, 8.78; N, 7.32.

17β-(4(5)-Imidazolyl)-5α-androstane-3β,11β diol (3)

A solution of **2** (9 g, 25.4 mmol) in 100 ml methanol was added to 1000 ml of liquid ammonia (giving a turbid suspension). To the stirred suspension was added in portions over 2 h, 15 g lithium metal. The solution was allowed to evaporate overnight under nitrogen. The residue was partitioned between ethyl acetate and saturated aqueous sodium chloride, and the combined ethyl acetate extracts were evaporated to dryness. The residue was dissolved in 250 ml of methanol, cooled, and filtered. Repeated concentration of filtrates led to further crops, giving a total of 4.9 g, 13.8 mmol, 54%. Chromatography of the mother liquors on silicic acid, and crystallization of fractions rich in **3** gave a further 0.583 g, making a total of 5.52 g or 61%. Recrystallization of **3** from methanol–water–ammonia gave material of m.p. 263.5–267.5°; n.m.r. (as HCl salt) δ (D_2O): 0.67 (C-18 methyl), 0.94 (C-19 methyl), 3.50 ($\Delta\nu_{\frac{1}{2}} = 21$ Hz, C-3 methine), 4.25 ($\Delta\nu_{\frac{1}{2}} = 8$ Hz, C-11 methine), 7.11, 8.40 (C—H protons of the imidazolium ring).

Anal. Calcd. for $C_{22}H_{34}N_2O_2$: C, 73.71; H, 9.55; N, 7.82. Found: C, 73.67; H, 9.45; N, 7.72.

3β-Hydroxy-17β-(4(5)-imidazolyl)-5α-androstan-11-one (4)

Crude **3**, (4.50 g, 12.5 mmol) was dissolved in a mixture of 23 ml water and 5.7 ml 6 *N* H_2SO_4. To this was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

225 ml glacial acetic acid. The solution was stirred in an ice bath and 4.3 ml of Jones reagent (2 *M* in CrO_3, 3.3 *M* in H_2SO_4) was added. After 10 min stirring, analytical t.l.c. (80:20 $CHCl_3$:CH_3OH) showed that only traces of starting material remained. Sodium acetate, 4.5 g, in methanol was added to neutralize the excess mineral acid, and the solution was evaporated to dryness. The residue was taken up in water, basified with 50 ml concentrated ammonia, and extracted with ethyl acetate. The extracts were washed with water and the aqueous wash solution was extracted with ethyl acetate. Evaporation of the combined ethyl acetate fractions gave 3.72 g of crude product (10.4 mmol, 84%). Recrystallization of **4** from methanol–water–ammonia gave material of m.p. 301–303°; n.m.r. (as HCl salt) δ (D_2O): 0.41 (C-18, methyl), 0.89 (C-19 methyl); 3.48 ($\Delta\nu_{\frac{1}{2}} = 25$ Hz, C-3 methine), 7.13, 8.40 (C—H protons of the imidazolium ring).

Anal. Calcd. for $C_{22}H_{32}N_2O_2$: C, 74.12; H, 9.05; N, 7.86. Found: C, 74.21; H, 8.88; N, 7.96.

*17β-(4(5)-Imidazolyl)-11-oximido-5α-androstan-3β-ol (**5**)*

Crude **4** (3.73 g, 10.5 mmol) and hydroxylamine hydrochloride, 3.7 g, in refluxing anhydrous pyridine, 25 ml, were allowed to react for 24 h. The reaction mixture was cooled, and poured into 50 ml of water; 1 *N* sodium hydroxide solution was added until the p*H* was 12. The resulting suspension was stirred until the product solidified to a fine powder, and then filtered; yield 3.64 g, 93%.

*11β-Amino-17β-(4(5)-imidazolyl)-5α-androstan-3β-ol (**6**)*

Crude **5**, 5.68 g, in glacial acetic acid, 100 ml, with 5.2 ml of 3 *N* HCl and 2.0 g PtO_2 was hydrogenated at 800 p.s.i. for 48 h. The hydrogenation was twice interrupted and 1.0 g PtO_2 and 2.6 ml 3 *N* HCl were added; after each addition hydrogenation was continued at 1800 p.s.i. for 48 h. After filtering off the catalyst, the solution was evaporated to dryness, taken up in methanol, and adsorbed into 10 g of silicic acid. This material was placed on a column of 60 g of silicic acid, poured in ether. The column was developed with 20% methanol in ether, then 20% 1 *M* ammonia in methanol – 80% ether, then 30% methanolic ammonia, then 40%, finally 100% 1 *M* ammonia in methanol. Elution was followed by t.l.c. Three major bands eluted: 2.50 g of a by-product of unknown constitution, 2.98 g of **6**, and 0.55 g of a more polar material. The n.m.r. of **6** (as HCl salt) δ (D_2O): 0.72 (C-18 methyl), 0.98 (C-19 methyl), 3.18 ($\Delta\nu_{\frac{1}{2}} = 18$ Hz, C-3 methine), 4.02 ($\Delta\nu_{\frac{1}{2}} = 10$ Hz, C-11 methine), 7.34, 8.64 (C—H protons of the imidazolium ring).

*11β-Amino-17β-(4(5)-imidazolyl)-5α-androstan-3-one (**7**)*

Chromatographically purified **6** (0.400 g) was dissolved in 40 ml 6 *N* H_2SO_4. To the stirred solution was added 0.35 ml Jones reagent. After 1 h, an analytical t.l.c. was run to check on the extent of reaction; an appropriate amount of Jones reagent was added and the process was repeated. Reaction was stopped when the ratio of 3-keto to 3-hydroxy-steroid was about 10:1 (attempting to carry the reaction to completion incurs excessive loss of material through over-oxidation). The solution was transferred to a separatory funnel, and basified by the addition of 25 ml of concentrated ammonia solution. Ice was added to cool the solution, which now showed the pink color of ammonia Cr(III) complexes. The solution was extracted four times with 100 ml portions of ethyl acetate; the organic layers were filtered and evaporated to dryness, giving 0.261 g, 67%. Compound **7** was converted to its hydrochloride salt and crystallized from methanol – *n*-propanol; n.m.r. (as HCl salt) δ (D_2O): 0.71 (C-18 methyl), 1.15 (C-19 methyl), 3.94 ($\Delta\nu_{\frac{1}{2}} = 11$ Hz, C-11 methine), 7.13, 8.34 (C—H protons of the imidazolium ring).

Anal. Calcd. for $C_{22}H_{35}N_3OCl_2 \cdot H_2O$: C, 59.18; H, 8.35; N, 9.41. Found: C, 58.87; H, 8.20; N, 9.31.

*17β-(4(5)-Imidazolyl)-3-oximido-5α-androstan-11β-amine (**8**)*

Crude **7** (0.742 g, 2.09 mmol) and 0.75 g of hydroxylamine hydrochloride in 7 ml dry pyridine were heated at *ca.* 90° for 1 h, cooled, poured into 21 g of ice, basified with sodium hydroxide (to p*H* 12), and extracted with ethyl acetate; yield, 0.707 g, 91%.

*17β-(4(5)-Imidazolyl)-5α-androstane-3β,11β-diamine (**9**)*

Crude **8**, 1.16 g, was dissolved in 140 ml refluxing *n*-propanol, under nitrogen. Sodium metal, 4.5 g, was added in portions. After all the sodium was consumed, t.l.c. showed no remaining **8**. The solution was cooled, concentrated to 50 ml, and then poured into 100 ml half-saturated aqueous sodium chloride solution. This solution was extracted with four portions of ethyl acetate and the combined organic layers were washed with saturated sodium chloride solution, filtered and evaporated to give 1.13 g of crude product. This crude material was converted to its hydrochloride which was crystallized from methanol – *n*-propanol to give 0.674 g of trishydrochloride. A second crop, 0.128 g, was obtained from the mother liquor. The yield of crystallized product was 55%; n.m.r. (as HCl salt) δ (D_2O): 0.73 (C-18 methyl), 0.98 (C-19 methyl), 3.20 ($\Delta\nu_{\frac{1}{2}} = 20$ Hz, C-3 methine), 4.00 ($\Delta\nu_{\frac{1}{2}} = 10$ Hz, C-11 methine), 7.40, 8.71 (C—H protons on imidazolium ring).

Anal. Calcd. for $C_{22}H_{39}N_4Cl_3 \cdot H_2O$: C, 54.60; H, 8.54; N, 11.58; Cl, 21.98. Found: C, 54.73; H, 8.76; N, 11.63; Cl, 22.88.

*17β-(4(5)-Imidazolyl)-5α-androstane-3,11-dione (**10**)*

Crude **3** from lithium–ammonia–methanol reduction of 1 g of **2** was oxidized with excess Jones reagent in 90% acetic acid. The solution was treated with water and concentrated ammonia and then extracted with ethyl acetate. The organic layer was extracted four times with 1 *M* HCl, the aqueous extracts were basified with concentrated NH_3, and then extracted five times with ethyl acetate. Evaporation of the combined ethyl acetate extracts gave 619 mg of crude product, m.p. 230–233°. Two recrystallizations from methanol–water gave material with m.p. 232.5–235°; n.m.r. (on HCl salt) δ (D_2O): 0.46 (C-18 methyl), 1.14 (C-19 methyl), 7.30, 8.61 (C—H protons of the imidazolium ring). ^{13}C n.m.r., δ (pyridine): 11.2, C-19; 14.2, C-18.

Anal. Calcd. for $C_{22}H_{30}N_2O_2$: C, 74.54; H, 8.53; N, 7.90. Found: C, 74.35; H, 8.54; N, 7.89.

*17β-(4(5)-Imidazolyl)-4-androstene-3,11-dione (**11**)*

Compound **2** (2 g, 5.7 mmol) in a mixture of 10 ml H_2O, 1.9 ml 3 *M* HCl and 50 ml acetic acid was cooled to 6° and treated with 2.9 ml Jones reagent in two portions. After 10 min 1 ml of isopropanol was added to destroy excess oxidant. The reaction mixture was poured into 500 ml of water, neutralized with Na_2CO_3, and extracted repeatedly with methylene chloride. The combined extracts were

evaporated to dryness and crystallized from hot methanol, giving 0.929 g of product. After recrystallization from methanol–water–ammonia, this material had m.p. 152–155° (dec.); n.m.r. (on HCl salt) δ (D_2O): 0.47 (C-18 methyl), 1.32 (C-19 methyl), 5.67 (—C*H*=C, C-4), 7.14, 8.40 (C—H protons of the imidazolium ring). ^{13}C n.m.r., δ (pyridine): 17.2, C-19; 14.2, C-18.

Anal. Calcd. for $C_{22}H_{28}N_2O_2 \cdot CH_3OH$: C, 71.89; H, 8.38; N, 7.34. Found: C, 71.53; H, 8.41; N, 7.41.

5α- and 5β-Pregnane-3,11,20-triones

These compounds were prepared from 4-pregnene-3,11,20-trione (Sigma) by hydrogenation and separated by crystallization following the procedure of Schmitt *et al.* (28). 5α-pregnane-3,11,20-trione had m.p. 208–215° (lit. m.p. 212–216° (29)); ^{13}C n.m.r., δ (pyridine): 11.1 (C-19) and 14.3 (C-18) p.p.m. 5β-Pregnane-3,11,20-trione had m.p. 155–156° (lit. m.p. 158–160° (30)); ^{13}C n.m.r., δ (pyridine): 14.3 (C-18) and 22.5 (C-19) p.p.m.

Financial support from the National Research Council of Canada, and the University Research Council of the University of Western Ontario is gratefully acknowledged. I wish to thank Dr. J. B. Stothers of this Department for the ^{13}C n.m.r. spectra.

The synthesis of four RS diastereoisomeric analogs of acetylcholine based on 2-amino-4-*t*-butylcyclohexanol is described. Preferred conformations of these derivatives, their intermediates, and analogs lacking a *t*-butyl substituent, are assigned on the basis of 1- and 2-methine and other p.m.r. characteristics. In general, major deviations from preferred chair conformations arise only in quaternary salts which require an axial trimethylammonium group. Certain p.m.r. signals of *t*-2-amino-*c*-4-*t*-butylcyclohexanol (base and hydrochloride) and *t*-2-dimethylamino-*t*-5-*t*-butylcyclohexanol hydrochloride are duplicated at 30°, a result attributed to a slow interconversion of conformational isomers.

La synthèse de quatre analogues RS diastéréoisomères de l'acétyl choline à partir de l'amino-2 *t*-butyl-4 cyclohexanol est décrite. Les conformations préférentielles de ces dérivés, leurs intermédiaires et les analogues où manque le substituant *t*-butyle, sont attribuées à partir de la r.m.n. du méthine-1 et -2 et des autres caractéristiques. En général, les déviations majeures aux conformations chaises préférentielles se produisent pour les sels quaternaires qui font intervenir un groupe triméthyl-ammonium axiale. Certains signaux r.m.n. du *t*-amino-2-*c*-*t*-butyl-4 cyclohexanol (base et chlorhydrate) et du chlorhydrate de *t*-diméthylamino-2 *t*-butyl-5 cyclohexanol sont dédoublés à 30°, résultat qu'on attribue à une interconversion lente entre les isomères de conformation. This work forms part of our studies of the stereochemistry of muscarinic agonists and their antagonists (1–3). There is considerable interest in the influence of the relative orientations of the acetoxy and trimethylammonium functions of acetylcholine (ACh) upon cholinergic activity and to this end cyclic analogs of ACh based on cyclopropane (4), cyclobutane (5), cyclohexane (6), and decalin (7) have been examined. An extension of work upon six-membered ring analogs to those incorporating a *t*-butyl substituent was considered of value because the isomers **1***b* provide a greater range of N—C—C—O dihedral angle variations than is found in the corresponding disubstituted cyclohexyl derivatives **1***a*.

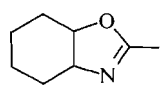
1

a R = H
b R = *t*-Bu

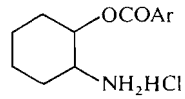
[1]Present address: School of Pharmacy, Liverpool Polytechnic, Byron Street, Liverpool, England L3 3AF.

Synthesis

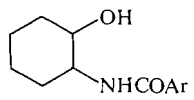
The 2-dimethylaminocyclohexanol precursors of *trans* **1***a* and *b*[2] (N^aO^a series) were prepared via the *N*-benzyl derivatives **3** rather than directly from the epoxide **2** and dimethylamine. The sequence **2** through **5** (Scheme 1) avoided the need for pressure reactions and facilitated separation of positional isomers (fractional crystallization of the *N*-tosyl derivative of **4***b* and the 5-*t*-butyl analog was readily achieved, monitored by p.m.r. spectroscopy). This route also provided the primary amine **4***a* which could be converted to the *cis* analog by an



6



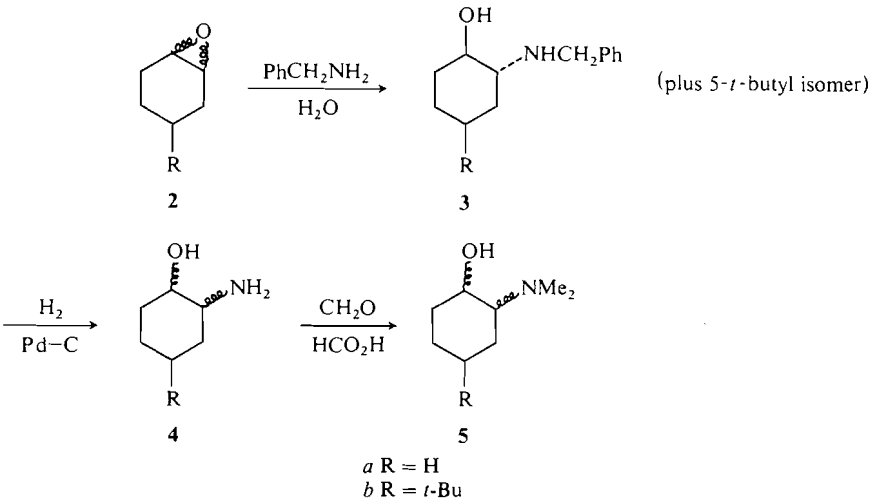
7



8

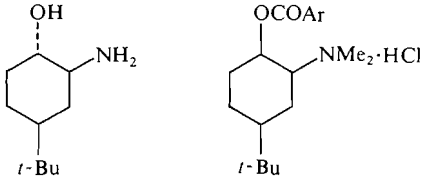
Ar = *p*-$NO_2 \cdot C_6H_4$

[2]Following Sicher *et al.*, (8), the configurations of **1***b* and analogs are conveniently represented by the symbols N^aO^a, N^eO^e, N^eO^a, and N^aO^e denoting N and O axial or equatorial substituents in a cyclohexane chair anchored by equatorial *t*-butyl at C-4.



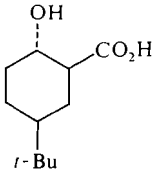
SCHEME 1. *Note*: Configuration is not specified in **4** and **5** so that these structures may serve generally.

inversion procedure (9). The intermediate *cis* oxazoline, **6** (from *N*-*p*-nitrobenzoyl **4***a* and thionyl chloride), and the derived ester hydrochloride **7** and amide **8**, all proved more resistant to acid hydrolysis than was anticipated from the literature (9); high yields of *cis* 2-aminocyclohexanol followed treatment of **7** or **8** with hot ethanolic potash.[3] In the similar inversion of *t*-2-amino-*t*-4-*t*-butylcyclohexanol **9**, the final hydrolysis step was performed on the



dimethylamino ester salt **10** (N^eO^a) in which O to N acyl migration was blocked. The aminocyclohexanol **9** (N^eO^e) was obtained from *t*-4-*t*-butylcyclohexanol-*t*-2-carboxylate **11** by the method of Sicher *et al.* (8); the acid **11** was made conveniently by carbethoxylation of 4-*t*-butylcyclohexanone. The aminocyclohexanol **14** (N^aO^e) was obtained from 4-*t*-butylcyclohexene following a literature method used for the decalin analog (7) (see Scheme 2).

[3]Inversion of *trans* **4***a* via the acetamide followed by acid hydrolysis has recently been recommended as the best procedure for this interconversion (10).



The aminocyclohexanols **4** etc. were *N*,*N*-dimethylated with formaldehyde and formic acid and the resultant tertiary amines acetylated with acetyl chloride. Most of the acetates formed methiodide salts without difficulty; exceptions were the N^aO^e analog **1***b*, isolated as a tosylate, and the N^aO^a derivative **1***b* which was deliquescent. The N^eO^a acetate methiodide **1***b* was made by treating the corresponding cyclohexanol methiodide with acetic anhydride and pyridine.

Stereochemistry

Information about the conformation of the cyclohexyl derivatives **5** and related compounds has been obtained chiefly from the dimensions of the 1- and 2-H methine p.m.r. signals (Table 1). While the 1-H signals were resolved in all spectra and lowest field in esters as a result of the acylation shift (11), isolated 2-H signals were largely confined to spectra of quaternary ammonium salts. The four combinations of vicinal coupling possible for the methine protons of 1,2-disubstituted cyclohexanes are shown

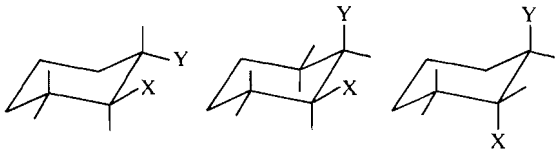
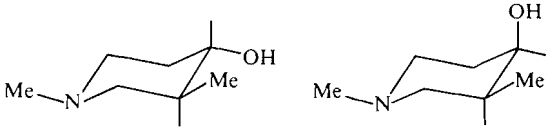
SCHEME 2

below together with their ranking in terms of



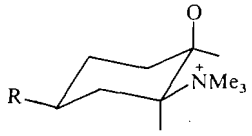
2aa + 1ae > 1aa + 2ae(X) > 2ea + 1ee(Y) ≅ 2ee + 1ea

outer line separations based on ^3J values for six-membered alicycles (12). Model values for the 2aa,1ae and 2ea,1ee types were provided by the 4-H methine signals of derivatives of the *t*- and *c*-3-methyl-4-piperidinols **15** and **16** respectively (1*a*). Some of the present cyclohexyl



15 16

derivatives themselves provided model spectra when there was little doubt of their preferred conformation; examples are the N^eO^e derivatives (2aa, 1ae type) and N^eO^a quaternary ammonium salts **17** (1-H: 2ea,1ee; 2-H: 1aa,2ae



17

type) where the *N*-substituent is markedly larger than the oxygen function. No model was available for the 2ee,1ea type but it is reasonable to assume that signal dimensions in these cases would be similar to or slightly narrower than those of the 2ea,1ee type.

The applicability of first order treatment of model methine resonances and those under investigation could not be judged even when a well resolved methine signal was obtained (Fig. 1*a*) because the 3- and 6-methylene resonances were not resolved. Signal dimensions therefore had to be gauged by measuring the separations of terminal lines (b.w.*)(13) or widths at half the maximum height ($w_{1/2}$) (14). Difficulties arose when outer lines could not be identified with certainty (*cf.* Figs. 1*b* and *c*) while $w_{1/2}$ values were unreliable standards for signals of pronounced asymmetry (*cf.* Figs. 1*d* and *e*). Full base widths (b.w.) are recorded in Table 1 but they provide only very approximate yardsticks because the extremes of a resonance band are generally ill-defined. The appearance of a 1aa,2ae methine signal was characteristic, forming a pair of humps at low amplitude as a result of the single aa exceeding the two ae couplings (Fig. 1*f*). Methine signal dimensions for the model compounds are summarized in Table 2. For 2aa,1ae signals measurements of terminal line separations were possible in all cases and these values (confined to a narrow range) provide a better criterion than the $w_{1/2}$ values which vary from 12 to 21.5 Hz although most lie in the upper end of this range. For the 1aa,2ae type, a $w_{1/2}$ value near 18 Hz together with the characteristic signal appearance seems a reliable standard, while most of the 2ea,1ee signals display $w_{1/2}$ values close to 8 Hz.

In the conformational analyses which follow, conclusions reached on the basis of 1- and 2-methine signal dimensions are corroborated by chemical shift data on these and other proton groups. Generally axial (a) are higher field than equatorial (e) methine resonances in cyclohexane derivatives by about 0.5 p.p.m. (15) and the same order of difference holds for the present

All signals recorded at 100 MHz, sweep width 250 Hz, and in DMSO-d_6 unless otherwise stated.

derivatives as is clear, for example, from δ 1-H values for **18** (axial 1-H) and **19** (equatorial 1-H) (Δ 0.38 p.p.m.). When the OH (or OCOMe) substituent is axial, the resonance of an axial 2-H proton is not significantly higher field than an equatorial 2-H signal because of the deshielding influence of the oxygen function in this orientation (16).

	18	**19**
δ_{1-H}	5.0	5.38
		in DMSO-d_6

The polar solvents deuterium oxide (D_2O) and deuterated dimethylsulfoxide (DMSO-d_6) were mostly employed in these studies; with certain exceptions (discussed below) changes in solvent had little influence upon the dimensions of 1- and 2- p.m.r. signals and, by inference, solute conformation.

For personal use only.

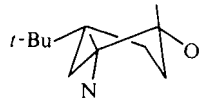
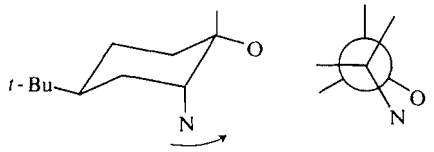
methylamino analog **5***b* is that expected of an axial proton (no. 22) and the 1-H chemical shift (δ 3.73, base in $CDCl_3$–TFA) is consistent with that of an axial proton deshielded by an adjacent axial ammonium function ($\delta_{1\text{-H}}$ for *trans* 2-dimethylaminocyclohexanol in the same solvent is 3.60). The 2-H signal (δ 3.5 in D_2O) is distinctly lower field than that of axial 2-H in *trans* **5***a* and *b* (nos. 5 and 14). In the spectrum of the N^aO^e acetate hydrochloride of **5***b*, in DMSO-d_6 both 1-H and 2-H signals have typically axial $w_{1/2}$ values (no. 24). Chemical shifts of the 1- and 2-protons ($\delta_{1\text{-H}}$ 5.07, $\delta_{2\text{-H}}$ 3.59) are both close to those of the axial methine signals of N^eO^e **5***b* acetate hydrochloride ($\delta_{1\text{-H}}$ 4.92, $\delta_{2\text{-H}}$ 3.5 in DMSO-d_6). Conformations most consistent with this evidence are either a skew-boat of type **24** in which the *N*- and *O*-substituents have

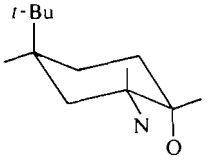


24

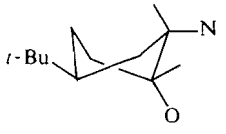


25

pseudo equatorial orientations or a flattened chair (**25**) in which the H—C_1—C_2—H dihedral angle approaches zero with a concomittant increase in $^3J_{H_1H_2}$ (12). Evidence indicative of significant populations of such conformations is also found from p.m.r. data upon N^aO^e **5***b* hydrochloride in DMSO-d_6 and the acetate salt in D_2O (nos. 22 and 24). A flattened chair has previously been proposed as a preferred conformational form in this series for N^aO^e **5***b* free base on the basis of i.r. studies (17). In the spectrum of the methiodide of N^aO^e **5***b* (no. 23) $w_{1/2}$ for the 1-H resonance approaches the typical equatorial value and $\delta_{1\text{-H}}$ (4.4 p.p.m.) is close to equatorial 1-H in spectra of *cis* **5***a* and N^eO^a **5***b* methiodides (nos. 10 and 18). The 2-H signal is obscured but its chemical shift (δ 3.5) corresponds with that of axial 2-H of the same model compounds. Similar results are obtained for the N^aO^e acetate methotosylate (no. 25); both 1- and 2-H signals are well resolved with the methiodides (nos. 12 and 20) serving as the appropriate models. Conformations of the two N^aO^e methiodides favored on the basis of the p.m.r. evidence are the inverted chair **26** and the



26

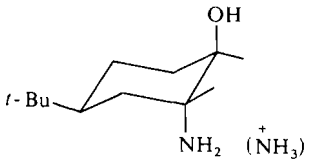


27

skew-boat **27**; the former is unlikely because of its axial *t*-butyl substituent but the latter is a reasonable formulation since there are precedents for *t*-butylcyclohexyl derivatives with skew-boat geometry (18).

(4) N^aO^a Series

Magnitudes of $w_{1/2}$ for 1- and 2-H methine signals of *t*-2-amino-*c*-4-*t*-butylcyclohexanol establish **28** as the preferred conformations of



28

both base and hydrochloride form (nos. 26 and 27); in confirmation, the chemical shifts of these protons are both significantly lower field of the signals of corresponding axial protons of model analogs (nos. 13 and 2 respectively). The methine signal dimensions are distinctly smaller than those of the 2ea,1ee type (Table 2) as anticipated from the generally smaller values of $^3J_{ee}$ compared with $^3J_{ea}$ coupling (12); the sum of the ^3J values is about 9 Hz and the signal a near-symmetrical quartet (Figs. 1*g* and *h*). The dimensions of these signals provide no evidence of contributions from skew-boat forms (like **29**) identified as present in solutions of N^aO^a **4***b*

29

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from i.r. studies (19). It is noted, however, that the methine "quartets" are superimposed on broad bands of low but distinct intensity and particularly clear in the spectrum of N^aO^a **4***b* hydrochloride (Fig. 1*h*). These bands are attributed to skew-boat species, probably stabilized by intramolecular hydrogen bonds (19);[5] the rate of interconversion of such forms with N^aO^a conformers (intermolecular bonded and/or solvated molecules) must be slow on the n.m.r. time scale because distinct rather than averaged methine signals are observed. Clearer evidence on this point follows from p.m.r. studies of *t*-2-dimethylamino-*t*-5-*t*-butylcyclohexanol hydrochloride (the N^aO^a 5-*t*-butyl isomer of **5***b*) because chemical shift differences between conformers are greater. Distinct NH (δ 10.4 major, 9.6 minor) and OH (δ 5.77 minor, 5.36 major) signals were apparent in DMSO-d_6 (absent after D_2O) while major and minor 1- and 2-H signals were also present. The two OH signals merged together when the temperature was raised and formed a broad band at 80–90° (other signals were poorly resolved at higher temperatures). In one spectrum at 30°, both signals showed coupling to the 1-H proton ($^3J = 4$ Hz for the higher and 5.5 Hz for the lower field signal); this is good evidence that both signals are due to sec-OH of the cyclohexanol derivative. In $CDCl_3$ at 30° duplicate $\overset{+}{H}N\ Me_2$ (doublets $^3J = 5$ Hz, δ 5.02 major, 4.88 minor) and *t*-Bu (δ 0.96 major, 0.92 minor) signals were clear and minor 1-H and 2-H multiplets could be assigned with reasonable confidence. Further conformational studies of these compounds will be reported elsewhere.

Methine p.m.r. data likewise support N/O *trans* diaxial orientations as the favored conformations of hydrochlorides of the corresponding dimethylaminocyclohexanol **5***b* and derived acetate in D_2O (nos. 28 and 30). The 1- and 2-methine signals of the alcohol salt are 0.3 to 0.5 p.p.m. to lower field of the appropriate axial signals of *trans* 2-dimethylaminocyclohexanol hydrochloride (no. 5). The fact of the chemical shift difference between equatorial 2-H in no. 30 and axial 2-H in no. 7 being less than expected for an *a*–e pair, is accounted for by the known shielding influence of an axial acetyl substituent upon the equatorial proton of an adjacent carbon atom in six-membered saturated rings (16). When D_2O is replaced by DMSO-d_6 as solvent for the N^aO^a hydrochloride **5***b*, the $w_{1/2}$ value of the 2-H resonance increases from 8 to 14.5 Hz while the 1-H signal is little changed (no. 28). This result is evidence that the cyclohexane ring is flattened in a similar manner to that proposed for some of the N^aO^e analogs (see **25**), whence $^3J_{2,3}$ but not $^3J_{1,2}$ couplings increase in magnitude. The 1-H resonance of the methiodide of N^aO^a **5***b* resembles the axial 1-H signals of methiodides of *trans* **5***a* and N^eO^e **5***b* in both dimensions and chemical shift (nos. 6, 15, and 29); the 2-H signal is poorly resolved but its chemical shift correlates with $\delta_{2\text{-H}}$ of the same two standards. Hence the skew-boat **29** is probably the chief contributor to the conformational equilibrium of N^aO^a **5***b* methiodide. The 1-H p.m.r. signal of the N^aO^a acetate methiodide **1***b* was of the equatorial type in spectra recorded in DMSO-d_6, D_2O, and $CDCl_3$ (no. 31), and chemical shift values confirm this assignment (*cf.* nos. 8, 16 (axial 1-H), and 12, 20, 25 (equatorial 1-H); $\delta_{1\text{-H}}$ for no. 12 in D_2O is 5.62). The $w_{1/2}$ values of the 2-H signal in these solvents are also indicative of an equatorial orientation but the dimensions of the signals (all are well resolved four-line resonances of b.w.* near 20 Hz) invalidate a genuine equatorial assignment as in nos. 26 and 27. Hence the preferred conformation of N^aO^a **1***b* iodide is probably a flattened chair of the type **25** with an axial rather than equatorial acyl substituent, and analogous to that of N^aO^a 3-dimethylamino-2-acetoxy-*trans*-decalin methiodide (methine signal $w_{1/2}$ values 8 (2-H) and 10 Hz (3-H)) the solid state conformation of which is known (7).

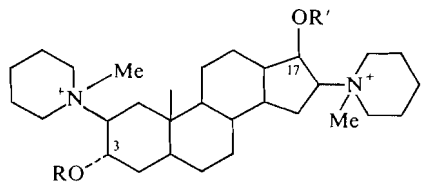
Differences in chemical shift and extent of $^3J_{HCOH}$ coupling between the methiodides *trans* **5***a*/N^eO^e **5***b* (δ 5.5, $^3J = 5$ Hz and δ 5.48, $^3J = 4.8$ Hz respectively) and *cis* **5***a*/N^eO^a **5***b* (δ 5.18, $^3J = 4.0$ and δ 5.2, $^3J \sim 3.0$ Hz respectively) are typical of those seen between e- and a-O*H* signals in six-membered alicylic sec-alcohols examined in DMSO-d_6 (1*a*, 21). The fact that the p.m.r. features of O*H* in the N^eO^e **5***b* methiodide (δ 5.2, $^3J = 3.8$ Hz) correspond with the axial type seems to support the skew-boat conformation **27** proposed for this salt. The applicability of such data to non-chair con-

[5]Intramolecular hydrogen bonding occurs in amino-alcohol hydrochlorides as well as in the corresponding free bases (20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formations is doubtful however, since the O*H* signal of the N^aO^a **5***b* methiodide combines an axial type chemical shift (δ 5.21) with a $^3J_{HCOH}$ value (4.8 Hz) typical of an equatorial group.

It follows from this conformational study that chair conformations (probably flattened somewhat by the *t*-butyl substituent) are preferred for most of the aminoalcohols **5***b* and their acetates. Apart from the case of N^aO^e **5***b* acetate hydrochloride, major deviations arise in formally N^a derivatives only when the 2-substituent is a fully methylated onium group; in this form its steric demands are comparable with those of *t*-butyl. A precedent for the skew-boat forms proposed for methiodides of the N^aO^e and N^aO^a series is that of ring A of the bisquaternary steroid **30***a* (pancuronium iodide) in the solid state as established by X-ray crystallography (22). The 3- and 17-methine signals overlap in the spectrum of the diacetate **30***a*,



30
a R = R′ = COMe
b R = COMe; R′ = H

but the 3-H signal of the monoacetate **30***b* (dacuronium iodide) in DMSO-d_6 is resolved at δ 5.15 as a typical axial-type resonance ($w_{1/2}$ 20.5, b.w. 35 Hz). N^aO^a forms of **30** are seriously destabilized by 1,3-diaxial interactions between onium and angular methyl groups, a factor absent in the N^aO^a acetate methiodide **1***b* which does not prefer a skew-boat conformation.

The muscarinic activities and other pharmacological properties of the ACh analogs **1** will be reported elsewhere.

Experimental

Melting points (uncorrected) were taken in a Thomas–Hoover capillary apparatus. Hydrochloride and methiodide salts were recrystallized from ethanol–ether unless otherwise stated. Petroleum ether refers to the 30–60° b.p. fraction. P.m.r. spectra were recorded on Varian HA-100 or A-60D spectrophotometers in $CDCl_3$ or DMSO-d_6 (TMS internal standard) or D_2O (DSS internal or TMS external standard) at the ambient temperature. I.r. spectra were recorded (Nujols mulls) on a Beckman IR-10 instrument.

cis- and trans-2-Dimethylaminocyclohexanol and Derivatives

A mixture of cyclohexene oxide (100 g), benzylamine (109 g) and water (15 ml) was heated under reflux for 5 h, then cooled and extracted with ether. The dried (Na_2SO_4) extract was evaporated and the residue recrystallized from ligroin to give *trans*-2-benzylaminocyclohexanol (205 g), m.p. 71–73° (lit. (23) 73°). A mixture of the benzylaminoalcohol **3***a* (205 g), palladium-on-carbon (20 g, 10%), and ethanol (300 ml) was stirred with hydrogen at room temperature and pressure until uptake of gas ceased. The product was filtered and the filtrate concentrated; the residue on distillation gave *trans*-2-aminocyclohexanol (110 g), b.p. 111–112°/17 mm, m.p. 65° (base), 177° (hydrochloride), (lit. (24) b.p. 102–107°/9 mm, m.p. 68° (base), 176–177° (hydrochloride)). The *trans*-dimethylamino alcohol **5***a*, b.p. 91–92°/17 mm, m.p. 186° (hydrochloride) (lit. (25) b.p. 78–80°/11 mm, m.p. 186–188° (hydrochloride)), was obtained from **4***a* by the reported method; it was converted to the corresponding acetate *hydrochloride*, m.p. 187–189°, by stirring with an equimolar proportion of acetyl chloride in toluene for 1 h.

Anal. Calcd. for $C_{10}H_{20}ClNO_2$: C, 54.21; H, 9.03. Found: C, 54.38; H, 9.04.

It formed a methiodide, m.p. 148–149°.

Anal. Calcd. for $C_{11}H_{22}INO_2$: C, 40.38; H, 6.78. Found: C, 40.27; H, 6.75.

Literature reports of the m.p. of this methiodide are inconsistent: 210–211° for monohydrate (26), 134–135° (25), 161–165° hygroscopic (6). Our material was anhydrous and its m.p. was little changed when the salt was crystallized from ethanol–ether containing water.

The *cis-p*-nitrobenzoyl ester hydrochloride **7**, m.p. 231–233° (dec.) (lit. (9) 230–232°), and the *cis-p*-nitrobenzamide **8**, m.p. 173–175° (as lit. (9)), were obtained by the reported methods. The amide **8** (13.1 g) in ethanolic potash (300 ml, 5%) was heated under reflux for 36 h. The cooled mixture was filtered, the filtrate concentrated and the residue extracted with ether. The dried (Na_2SO_4) ether was evaporated to leave *cis*-2-aminocyclohexanol (5.2 g, 90%), m.p. 74–75° (lit. (24) 72–73°). Similar treatment of the ester hydrochloride **7** (3 g) gave the same aminoalcohol (1 g, 87%). *cis*-2-Dimethylaminocyclohexanol, b.p. 102–104°/17 mm, m.p. 42–44° (base), 183–184° (hydrochloride) (lit. (25) b.p. 95–97°/15 mm, m.p. 40–42° (base), 182–183° (hydrochloride)), was converted to the corresponding acetate *hydrochloride*, m.p. 137–138°, by the method described for the *trans*-isomer.

Anal. Calcd. for $C_{10}H_{20}ClNO_2$: C, 54.21; H, 9.03. Found: C, 54.50; H, 8.98.

It formed a methiodide, m.p. 182–184° from methanol–ether (lit. 182–183° (26), 185–186° (25)).

cis-2-Benzylaminocyclohexanol, m.p. 62–63° (base), 245–246° (hydrochloride) (lit. (23) 67° (base), 248–250° (hydrochloride)), was prepared by treating *cis* **4***a* in ether with benzyl chloride and K_2CO_3 at the reflux temperature.

N^aO^a Series

c-4-t-Butyl-t-2-benzylamino- (3b) and t-5-t-Butyl-t-2-benzylaminocyclohexanol

Peracetic acid (40%) (FMC Corporation) (22 g) con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

taining a small amount of sodium acetate was added dropwise to a stirred mixture of 4-*t*-butylcyclohexene (13.8 g) (8) and Na_2CO_3 (32 g) in methylene chloride (200 ml) cooled in ice–water. The mixture was stirred at room temperature until it gave a negative test with moist starch–iodide paper; further 40% peracetic acid (3 g) was then added and the mixture stirred for a further 24 h (positive test maintained). The filtered solution was evaporated and the residue distilled to give the epoxide mixture **2***b* (12.5 g), b.p. 80–94°/16 mm (lit. (8) 78–80°/9 mm). A mixture of the epoxides (**2***b*) (12 g), benzylamine (8.4 g), and water (10 ml) was heated under reflux for 24 h. The product was extracted with ether and the ether dried (Na_2SO_4) and evaporated; the residue was distilled to give the benzylaminocyclohexanol **3***b* and the 5-*t*-butyl analog (14.5 g), b.p. 146–150°/2 mm, δ (DMSO-d_6): 0.83 (s, *t*-Bu), 3.7 (s, CH_2N). These gave a hydrochloride mixture, m.p. 150–160° from *n*-hexane, δ ($CDCl_3$): 0.83, 0.87 (s, *t*-Bu) which on repeated fractional crystallization from ethanol, ether, and *n*-hexane gave the *c-4-t-butyl isomer* **3***b hydrochloride*, m.p. 185–186° (19 g from 122 g mixture), δ ($CDCl_3$): 0.83 (s, *t*-Bu).

Anal. Calcd. for $C_{17}H_{28}ClNO$: C, 68.55; H, 9.48; N, 4.7. Found: C, 68.41; H, 9.43; N, 5.0.

Treatment of **3***b* hydrochloride (3 g) with acetyl chloride (5 ml) in chloroform (50 ml) (3 h at reflux) gave the corresponding *acetate* of 3*b* hydrochloride (2.9 g), m.p. 232–233°, δ (DMSO-d_6): 5.14 (m, $w_{1/2}$ 8 Hz, 1-H), 4.2 (bs, CH_2Ph), 3.28 (m, 2-H), 1.98 (s, OCOMe), 0.82 (s, *t*-Bu).

Anal. Calcd. for $C_{19}H_{30}ClNO_2$: C, 67.1; H, 8.8; N, 4.1. Found: C, 67.3; H, 8.97; N, 3.9.

t-2-Amino-c-4-t-butylcyclohexanol

A mixture of the benzylaminocyclohexanols **3***b* and isomer (26 g), palladized carbon (2.6 g, 10%), and ethanol (75 ml) containing a few ml water, was stirred with hydrogen at room temperature and pressure until gas absorption ceased. The product was filtered and the filtrate evaporated to give a mixture of aminocyclohexanols N^aO^a **4***b* and isomer. The mixture from 46.5 g of **3***b* and isomer in benzene (120 ml) was stirred for several hours with tosyl chloride (32.1 g) in benzene (120 ml), and aqueous sodium hydroxide (29 ml, 10%). The solid which formed was collected, washed with water, and recrystallized twice from 95% ethanol to give the *N*-tosyl derivative of N^aO^a **4***b* (24.5 g), m.p. 190–191° (lit. (8) 192–193°), δ (DMSO-d_6): 0.72 (s, *t*-Bu). The mother liquors were evaporated and the residue recrystallized first from benzene and then from ethanol to give the *N*-tosyl derivative of the 5-*t*-butyl analog of N^aO^a **4***b* (18 g), m.p. 176°, (lit. (17) 178–178.5°), δ (DMSO-d_6): 0.80, (s, *t*-Bu). The *N*-tosyl derivative of N^aO^a **4***b* (5.7 g) was treated with sodium (2 g) in liquid ammonia (120 ml) as reported (8), and gave the crude aminocyclohexanol N^aO^a **4***b* (2.2 g), m.p. 108–109° from ethyl acetate–petroleum ether, hydrochloride, m.p. 237–238° from ethanol–ether (lit. (8) 108.5–109.5° (base) and 239–240° (hydrochloride)). The amino alcohol N^aO^a **4***b* hydrochloride (1.9 g), m.p. and mixed m.p. 236–238°, was also obtained by hydrogenolysis of **3***b* hydrochloride (3 g) in ethanol (10 ml) with palladized carbon (0.3 g, 10%) as catalyst. Treatment of the *N*-tosyl derivative of the 5-*t*-butyl analog of N^aO^a **4***b* with Na–NH_3 similarly gave *t*-2-amino-*t*-5-*t*-butylcyclohexanol.

c-4-t-Butyl-t-2-dimethylaminocyclohexanol (5b) and Corresponding Acetate

A mixture of the aminoalcohol N^aO^a **4***b* (0.85 g), formalin (6 ml), and formic acid (4 g, 88%) was heated under reflux for 24 h. The product was evaporated under reduced pressure, the residue treated with water, re-evaporated and then made alkaline (NaOH) and extracted with ether. The dried extract (Na_2SO_4) was evaporated and the residual base acidified with ethanolic HCl and diluted with ether; N^aO^a **5***b* hydrochloride, m.p. 186–187° separated on storage at 5°.

Anal. Calcd. for $C_{12}H_{26}ClNO$: C, 61.1; H, 11.1; N, 5.9. Found: C, 61.33; H, 11.25; N, 6.02.

The base formed a methiodide, m.p. 197–198°.

Anal. Calcd. for $C_{13}H_{28}INO$: C, 45.7; H, 8.2. Found: C, 45.82; H, 8.35.

A mixture of N^aO^a **5***b* (1 g), liberated from the hydrochloride, acetyl chloride (1.2 g), and benzene (25 ml) was heated under reflux for 8 h and then evaporated. The residue in ethanol was diluted with ether when N^aO^a **5***b acetate hydrochloride* (1 g) separated, m.p. 183–184° from ethanol–ether, ν_{max} 1750 cm^{-1} (C=O).

Anal. Calcd. for $C_{14}H_{28}ClNO_2$: C, 60.52; H, 10.16. Found: C, 60.42; H, 10.08.

The **5***b* acetate hydrochloride, m.p. and mixed m.p. 182°, was also obtained by reductive methylation of the acetate of N^aO^a **4***b* (mixture of the ester hydrochloride (1 g), formalin (1.25 ml), ethanol (60 ml), and palladized carbon (1 g) stirred with hydrogen until gas absorption ceased). The **4***b* acetate was obtained by catalytic debenzylation of **3***b* acetate hydrochloride (1.5 g) using palladized carbon (1 g, 10%) as catalyst. It had m.p. 254–256° (dec.), δ (DMSO-d_6): 4.95 (m, $w_{1/2}$ 8 Hz, 1-H), 3.35 (m, $w_{1/2}$ 8.5 Hz, 2-H), 2.02 (s, OCOMe), 0.84 (s, *t*-Bu).

N,N-Dimethylation of *t*-2-amino-*t*-5-butylcyclohexanol was similarly performed to yield the *hydrochloride* of the N^aO^a *5-t-butyl analog* of **5***b*, m.p. 212°.

Anal. Calcd. for $C_{12}H_{26}ClNO$: C, 61.1; H, 11.1; N, 5.9. Found: C, 61.33; H, 11.25; N, 6.02.

A mixture of the N^aO^a base **5***b* (1 g) and acetic anhydride (10 ml) was stirred at room temperature for 4 days and then concentrated; the residue was stirred with acetone (5 ml) and methyl iodide (2 g) for 2 days. The solvents were removed and the residual salt recrystallized twice from acetone–benzene to give N^aO^a **1** iodide (0.8 g), m.p. 43–46° (approximate only because of hygroscopic nature), ν_{max} (in $CHCl_3$) 1745 cm^{-1} (C=O).

Anal. Calcd. for $C_{15}H_{30}INO_2$: C, 47.0; H, 7.9. Found: C, 47.38; H, 8.2.

N^aO^c Series

c-4-t-Butyl-t-2-carbomethoxyaminocyclohexyl Iodide (12)

Silver cyanate (47 g) and iodine (50.7 g) were added portionwise to a cold (−40°) solution of 4-*t*-butylcyclohexene (27.7 g) in ether (500 ml). After the addition the mixture was stirred at room temperature for 48 h when it formed a greenish yellow slurry. The mixture was filtered and the filtrate mixed with methanol (50 ml) and heated under reflux for 6 h and the reddish-brown solution left overnight. The solution was washed with aqueous sodium sulfite (150 ml, 10%) and then with water and finally dried (Na_2SO_4). Ether and unreacted 4-*t*-butylcyclohexene were removed by distillation and the residue cooled when a pale yellow solid (10 g) separated. A second crop (5 g) formed when the filtrate was diluted with methanol (few ml) and the combined crops were recrystallized twice from chloroform–methanol to give the acyclic urethane **12** (14 g), m.p.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

154–155°, ν_{max} 3260, 3120 cm^{-1} (NH), 1700 cm^{-1} (C=O), δ ($CDCl_3$): 5.17, 4.6, 4.1 (broad bands $w_{1/2}$ 17.5, 6.5 and 14.5 Hz, respectively 1-H, 2-H, NH) 3.7 (s, OMe), 0.9 (s, *t*-Bu).

Anal. Calcd. for $C_{12}H_{22}INO_2$: C, 42.49; H, 6.53. Found: C, 42.18; H, 6.37.

*t-4-t-Butyl-c-2-aminocyclohexanol (**14**)*

The acyclic urethane **12** (5 g) was heated in an oil bath at 150° under reduced pressure (0.01 mm) for 20 min. The yellow residue was recrystallized from ethyl acetate to give colorless crystals of the *cyclic urethane* **13** (2 g), m.p. 140–142° (lit. (8) 145–146°), ν_{max} 3220, 3120 cm^{-1} (NH), 1750 cm^{-1} (C=O), δ ($CDCl_3$): 5.92 (NH), 4.63, 4.12 (broad bands, 1-H and 2-H), 0.87 (s, *t*-Bu).

Anal. Calcd. for $C_{11}H_{19}NO_2$: C, 66.96; H, 9.7. Found: C, 67.16; H, 9.62.

A mixture of cyclic urethane **13** (1.3 g) and 1 *N* potassium hydroxide in 10% aqueous ethanol (100 ml) was heated under reflux for 12 h. The ethanol was distilled and the residue extracted with chloroform which was dried (Na_2SO_4) and evaporated to give the aminocyclohexanol **14** (0.9 g), m.p. and mixed m.p. 112–113° (lit. (8) 112–113°); its m.p. was depressed to 85–86° when mixed with authentic *c*-4-*t*-butyl-*c*-2-aminocyclohexanol (samples kindly supplied by Dr. M. Tichý). It gave a hydrochloride, m.p. 242–244° (lit. (27) 249–250°).

Anal. Calcd. for $C_{10}H_{12}NO$ (base): C, 70.12; H, 12.36. Found: C, 70.39; H, 12.23.

t-4-t-Butyl-c-2-dimethylaminocyclohexanol and Derivatives

A mixture of the aminoalcohol **14** (9.5 g), formalin (75 ml), and formic acid (50.3 g, 88%) was heated under reflux for 24 h and treated as described for the isomer N^aO^a **5***b* to give the crude dimethylaminoalcohol (11.2 g), isolated as a *hydrochloride*, m.p. 190–192°.

Anal. Calcd. for $C_{12}H_{26}ClNO$: C, 61.1; H, 11.1; N, 5.9. Found: C, 61.2; H, 10.98; N, 5.80.

A mixture of N^aO^e **5***b* hydrochloride (5.7 g), chloroform (100 ml) and acetyl chloride (10 ml) was heated under reflux for 3 h. The solvents were evaporated and the residue recrystallized from ethanol–ether to give the corresponding *acetate hydrochloride* (5.8 g), m.p. 146–148°, ν_{max} 1745 cm^{-1} (C=O).

Anal. Calcd. for $C_{14}H_{28}ClNO_2$: C, 60.5; H, 10.1; N, 5.0. Found: C, 60.63; H, 10.02; N, 5.2.

The alcohol N^aO^e **5***b* with excess of methyl iodide in ether gave a *methiodide*, m.p. 160–162° from ethanol–ether.

Anal. Calcd. for $C_{13}H_{28}INO$: C, 45.7; H, 8.2; N, 4.1. Found: C, 45.79; H, 8.32; N, 4.06.

A mixture of the N^aO^e **5***b* acetate (0.42 g), methyl tosylate (0.28 g) and acetone (30 ml) was heated under reflux for 7 days. The solvent was evaporated and the residue dried in a vacuum desiccator over concentrated sulfuric acid for 2 days, then dissolved in acetone and diluted with ether. The oil which separated solidified on storage at 5° and this solid (0.56 g) was recrystallized from acetone–ether to give the *methyl tosylate* of N^aO^e **1***b*, m.p. 61–64° (hygroscopic), ν_{max} 1740 cm^{-1} (C=O), 700–600 cm^{-1} (SO_3).

Anal. Calcd. for $C_{22}H_{37}NO_5S$: C, 61.8; H, 8.72. Found: C, 61.76; H, 8.87.

Treatment of the acetate base with methyl iodide gave oils which could not be purified.

N^eO^e Series

4-t-Butyl-2-carbethoxycyclohexanone

Sodium hydride dispersion (12 g) (freed from mineral oil by several rinses with benzene) was mixed with benzene (120 ml) and diethyl carbonate (23.6 g). The mixture was heated to reflux and then 4-*t*-butylcyclohexanone (15.4 g) in benzene (50 ml) added over a period of 4 h. When addition was complete the mixture was kept at reflux for a further 1.5 h until gas evolution ceased (detected by a mercury trap connected to the condenser). Then glacial acetic acid (20 ml), followed by ice–cold water (100 ml) was added, the benzene separated and the aqueous phase extracted with more benzene. The combined benzene was washed with water and dried (Na_2SO_4). The benzene and excess of diethylcarbonate were removed under water-pump pressure and the residue distilled to give a fraction, b.p. 90–115°/1 mm. This was redistilled to give an isomeric mixture of the *2-carbethoxycyclohexanones* (16 g), b.p. 99°/0.8 mm, ν_{max} 1745 and 1725 cm^{-1} (C=O of keto form), 1655 and 1615 cm^{-1} (enol), δ (CCl_4): 4.17, 4.05 (q, OCH_2), 1.37, 1.3 (t, CH_3), 0.92, 0.87 (s, *t*-Bu) (paired signals of equal intensities).

Anal. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.8. Found: C, 69.24; H, 10.03.

*t-4-t-Butylcyclohexanol-2-t-carboxylate (**11**)*

A mixture of the previous ester (22.6 g), sodium borohydride (1.89 g), and ethanol (250 ml) was stirred for 4 h (ice bath); it was then acidified to p*H* 4–6 by addition of dilute hydrochloric acid and the solvent evaporated. The residue in ether was dried (Na_2SO_4) and the ether evaporated to give a mixture of the ethyl ester of **11** and other isomers (21 g). An analytical sample distilled at 86°/0.05 mm.

Anal. Calcd. for $C_{13}H_{24}O_3$: C, 68.38; H, 10.58. Found: C, 68.41; H, 10.34.

The ethyl esters so obtained (12 g) were treated with sodium methoxide in methanol followed by 50% aqueous sodium hydroxide as reported (8) to give the cyclohexane carboxylic acid **11** (7 g), m.p. 144–145° from acetone (lit. (8) 146–147°).

*t-2-Amino-t-4-t-butylcyclohexanol (**9**)*

The carboxylic acid **11** was methylated with diazomethane or dimethylsulfate–Na_2CO_3 in methanol to give the methyl ester of **11**, m.p. 76–77.5° (lit. (8) 79–80°). By reported procedures (8) the ester was successively converted to the corresponding acid hydrazide, m.p. 178–179° (lit. 177–178°), the cyclic urethane, m.p. 112–115° (lit. 124–125°), and the 2-aminocyclohexanol **9**, m.p. 93–94° from ethyl acetate–petroleum ether (lit. 94.5–95.5°).

t-4-t-Butyl-t-2-dimethylaminocyclohexanol and Derivatives

The aminocyclohexanol **9** (10.5 g) was treated with formalin (83 ml) and formic acid (45.6 ml, 88%) in the usual manner to give the N^eO^e 2-dimethylaminocyclohexanol **5***b* (12 g) isolated as a *hydrochloride*, m.p. 216–217.5°.

Anal. Calcd. for $C_{12}H_{26}ClNO$: C, 61.1; H, 11.1; N, 5.9. Found: C, 61.27; H, 11.09; N, 6.0.

Treatment of the base (2.5 g) with acetyl chloride (6 ml) and chloroform (30 ml) (1.5 h at reflux) gave the acetate hydrochloride of N^eO^e **5***b*, m.p. 231–232.5° from chloroform–ether.

Anal. Calcd. for $C_{14}H_{28}ClNO_2$: C, 60.5; H, 10.1; N, 5.0. Found: C, 60.08; H, 9.94; N, 4.95.

The same isomer of **5***b* formed a *methiodide*, m.p. 237.5–238.5°.

Anal. Calcd. for $C_{13}H_{28}INO$: C, 45.75; H, 8.27. Found: C, 45.52; H, 8.0.

This methiodide (3 g) was heated under reflux with acetic anhydride (25 ml) for 2 h; on cooling the N°O° *acetate* **1** *methiodide* separated, m.p. 193–194°, from ethanol–ether, ν_{max} 1745 cm^{-1} (C=O).

Anal. Calcd. for $C_{15}H_{30}INO_2$: C, 47.0; H, 7.88; N, 3.6. Found: C, 47.20; H, 7.84; N, 3.9.

N°O° Series

c-4-t-Butyl-c-2-dimethylaminocyclohexanol and Derivatives

p-Nitrobenzoyl chloride (0.92 g) in warm benzene (25 ml) was added to a suspension of the aminocyclohexanol **9** (0.85 g) in water (50 ml) followed by 5% aqueous sodium hydroxide (4 ml). The whole was stirred for several hours, then the solid collected, washed, and recrystallized from 95% ethanol to give the *N-p*-nitrobenzoyl derivative of **9** (1 g), m.p. 176°, ν_{max} 3310, 3210 (OH, NH), 1630 cm^{-1} (C=O), δ (DMSO-d_6): 4.7 (d, J = 4.5 Hz, OH) absent after D_2O.

Anal. Calcd. for $C_{17}H_{24}N_2O_4$: C, 63.75; H, 7.5. Found: C, 63.80; H, 7.69.

A mixture of the amide (10 g) so obtained and thionyl chloride (125 ml) was stirred at room temperature for 2 days. Excess of reagent was evaporated under reduced pressure and the residual crude oxazoline heated under reflux with aqueous hydrochloric acid (75 ml, 10%) and ethanol (75 ml). The product was concentrated and extracted with chloroform; this extract was evaporated and the residual crude ester hydrochloride (a 4-*t*-butyl analog of **7**) treated with formalin (100 ml), formic acid (50 ml, 88%), and solid potassium hydroxide (4 pellets). This mixture was heated under reflux for 4 days then evaporated, made alkaline with aqueous potassium hydroxide, and extracted with benzene. The filtered extract was shaken with 10% aqueous hydrochloric acid and the aqueous phase plus solid in suspension extracted with chloroform. The chloroform extract was evaporated to give the *dimethylamino ester hydrochloride monohydrate* **10** (11.9 g), m.p. 208–212° from chloroform–ether, ν_{max} 3400 (H_2O), 1720, 1730 (CO), δ (DMSO-d_6): 8.38 (s, $C_6H_4NO_2$), 5.7 (m, $w_{1/2}$ 7 Hz, 1-H), 2.8 (s, NMe_2), 0.93 (s, *t*-Bu).

Anal. Calcd. for $C_{19}H_{29}ClN_2O_4H_2O$: C, 56.65; H, 7.7; N, 6.96. Found: C, 56.42; H, 7.54; N, 7.28.

A mixture of the ester hydrochloride **10** (1.6 g), potassium hydroxide (2.8 g), ethanol (50 ml), and water (20 ml) heated under reflux for 18 h and then concentrated under reduced pressure. The residue was diluted with water (50 ml) and extracted with benzene. The N°O° dimethylaminocyclohexanol **5***b* (0.6 g) recovered from the extract was isolated as a *hydrochloride*, m.p. 224° from ethanol–ether.

Anal. Calcd. for $C_{12}H_{26}ClNO$: C, 61.1; H, 11.1. Found: C, 60.90; H, 11.20.

It formed a *methiodide*, m.p. 238–239°.

Anal. Calcd. for $C_{13}H_{28}INO$: C, 45.7; H, 8.2; N, 4.1. Found: C, 45.22; H, 8.24; N, 3.97.

A mixture of the methiodide of N°O° **5***b* (1 g), acetic anhydride (1 ml) and pyridine (2 ml) was stirred at room temperature for 28 h, then evaporated under reduced pressure. The residue was washed with ether and then stored in a vacuum desiccator over concentrated sulfuric acid. The partially solid product was dissolved in acetone then diluted with ether and stored at 5°. The solid which separated was recrystallized from acetone to give the N°O° acetate methiodide **1**, m.p. 222–223°, ν_{max} 1740 cm^{-1} (C=O).

Anal. Calcd. for $C_{15}H_{30}INO_2$: C, 47.0; H, 7.8; N, 3.6. Found: C, 47.5; H, 7.60; N, 3.60.

The authors thank the Medical Research Council of Canada for financial support, Dr. D. S. Savage for samples of dacuronium and pancuronium iodides, and Mr. Ih Chu, M.Sc. for assistance in final stages of the synthetic work.

A Model Compound for Anhydroryanodol

BRIAN G. BROWNLEE, PAK-TSUN HO, and K. WIESNER
Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received July 17, 1972

The synthesis of the acetoxy lactone **17** by a method potentially suitable for anhydroryanodine is described.

In the course of the synthesis several mechanistically unusual reactions were observed. One of them was an attack of Cl^+ on an exocyclic double bond in a benzobicycloheptane system from the *endo* side. Another was a S_N2 type displacement of chlorine by chloride or acetate ions in a six-membered ring.

La synthèse de l'acétoxy lactone **17** par une méthode pouvant convenir à celle de l'anhydroryanodine est décrite.

Au cours de cette synthèse, plusieurs réactions inhabituelles quant au mécanisme ont été observées. L'une d'entre elles est l'attaque de Cl^+ sur la double liaison exocyclique d'un système benzobicycloheptane par la face *endo*. L'autre concerne le déplacement de type S_N2 d'un chlore par des ions chlorure ou acétate dans un cycle à six membres. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 4013 (1972)

Introduction

The structure and absolute stereochemistry of anhydroryanodol portrayed by the formula **I** was proposed by us in 1962 (*1*), and in 1966 we deduced (*2a*) the structure of its parent compound ryanodine **II**. When a year later **II** was finally corroborated by X-ray crystallography (*2b*),[1] it became clear to all our critics that the original proposal **I** was in fact correct in every detail. As our laboratory was committed to the development of synthetic methods for various types of diterpene alkaloids we had no plans to synthesize ryanodine or its derivatives. It was only when we realized that the methods developed by us for the synthesis of songorine (*3*) could be readily adapted to the synthesis of **I** that we decided to perform a model study (*4*) to this end.

Scheme 1 (**III** → **IV** → **V** → **VI**) formed the backbone of our plan. In the present communication we wish to describe the synthesis of compound **VI** by an expansion of this scheme, which in its original form did not work.

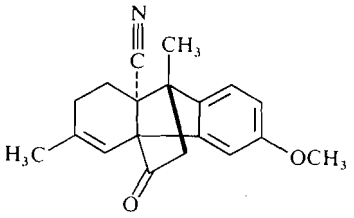
VII



VIII

The failure of the original proposal was due to the fact that the one step rearrangement **IV** → **V** did not take place as planned.

However, in a second generation synthesis now under way the rearrangement **VII** → **VIII** was just accomplished in an almost quantitative yield.

Discussion

The starting material for the synthesis was benzonorbornadiene (5). A Diels–Alder reaction of this compound with an excess of butadiene gave the crystalline adduct **1** in a yield of 76%.

The n.m.r. spectrum of **1** contained a two-proton multiplet at $\tau = 4.12$ p.p.m. for the vinylic hydrogens. The mass spectrum of **1** had a molecular ion at *m/e* 196. The most intense peak was at *m/e* 116 corresponding to a reverse diene addition. At this point the stereochemistry of compound **1** was assumed on the basis of precedent (6), at a later stage conclusive stereochemical evidence will be presented.

Hydroboration of **1** gave the alcohol **2** as a mixture of epimers. Jones oxidation of this mixture yielded the single crystalline ketone **3** in a crude yield of 99%. Bromination of **3** with pyridine hydrobromide perbromide in acetic acid gave an oily mixture from which the crystalline bromoketone **4** was isolated in a yield of 52%. The i.r. carbonyl absorption of **4** was shifted by 25 cm^{-1} to higher wave numbers with respect to the position of the carbonyl maximum in the i.r. of **3** (1715 cm^{-1}). Such a shift indicates a conformation of the bromine in which this substituent is coplanar with the carbonyl group (7). The hydrogen deshielded by the bromine atom appeared in the n.m.r. spectrum of **4** as a doublet ($J = 12$ Hz) at $\tau = 5.3$ p.p.m. This is in agreement with the dihedral angle of about 180° between the two hydrogens marked by asterisks in formula **4**. If we assume that the preferred conformation of the ring is a boat, then the above data are in agreement with the configuration portrayed in the formula **4**.

Dehydrobromination of **4** in boiling pyridine gave an 80% yield of the crystalline unsaturated ketone **5***a*. The u.v. spectrum of **5***a* had an absorption maximum at 236 nm ($\log \varepsilon = 4.19$) and the i.r. displayed a band at 1675 cm^{-1} for the α,β-unsaturated ketone function. A one-proton singlet at $\tau = 4.0$ p.p.m. in the n.m.r. spectrum of the product further confirmed the structure **5***a* assigned to it.

On reflux with methanolic sodium hydroxide compound **5***a* was converted into an equilibrium mixture (2:8) of the starting material and the epimer **5***b* (8). The u.v. maximum of **5***b* (253 nm, $\log \varepsilon = 4.15$) was shifted significantly to high wavelength. This is undoubtedly due to orbital overlap between the α,β-unsaturated ketone and the benzene ring made possible by the stereochemistry of **5***b* but not present in **5***a*. Further support for the configuration of **5***b* came from the n.m.r. spectrum of this compound. A one-proton multiplet at $\tau = 8.8$–9.5 p.p.m. was located upfield from all proton resonances in both **5***b* and *a*. The molecular model of **5***b* shows clearly that the hydrogen marked with the arrow (in **5***b*) is located in the shielding region of the benzene ring.

Treatment of the conjugated ketone **5***a* with methylmagnesium bromide in ether gave in high yield a mixture of two crystalline epimers (3:1) represented by the formula **6**. When this mixture was heated with dilute hydrochloric acid in aqueous tetrahydrofuran a new crystalline alcohol was formed in a yield of 53%. We, of course, hoped that under these conditions the initially formed delocalized allylic carbonium ion would further delocalize by participation of the benzene ring and yield ultimately **7***b*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

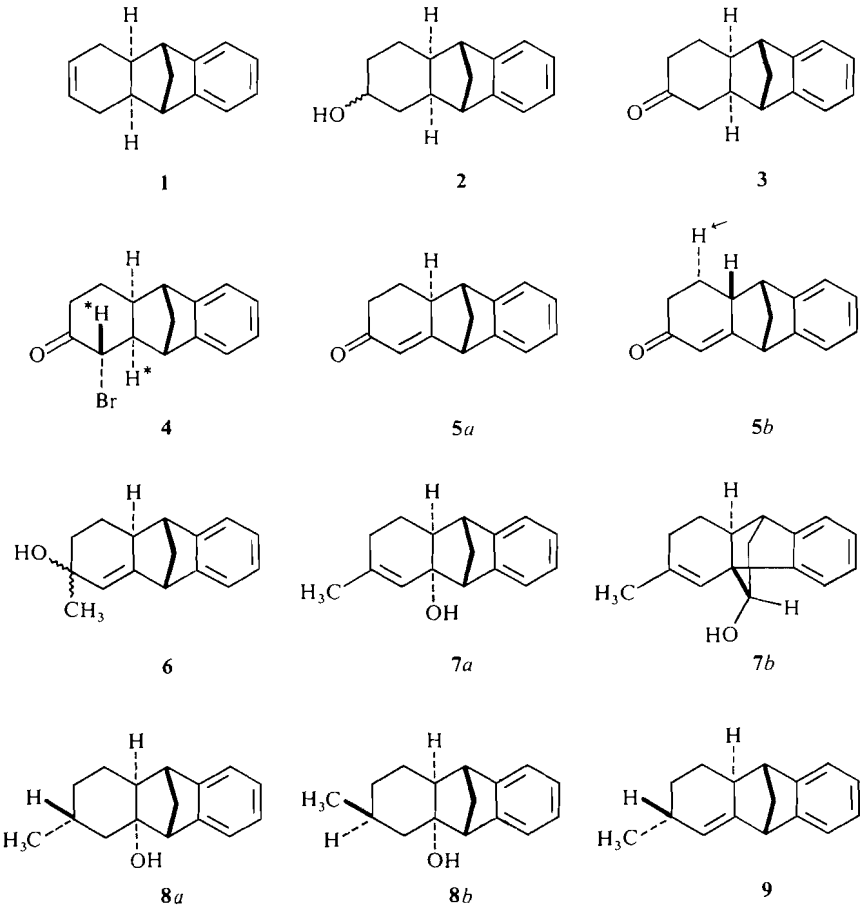
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



However, it soon became clear that the product of the reaction was, in fact, 7*a*. After many changes of experimental conditions and leaving groups attempts to achieve a reaction of the type **6** → 7*b* were abandoned and the synthesis was continued with 7*a*.

The n.m.r. spectrum of compound 7*a* was in agreement with the formula (see Experimental) and the tertiary nature of the hydroxyl was corroborated by its resistance to oxidation.

The configuration of the hydroxyl is probably as shown in formula 7*a*. The epimeric configuration involves considerable strain and the product was obtained under equilibriating conditions. Moreover, no spectral anomalies were found to indicate orbital overlap between the double bond and the benzene ring.

Hydrogenation of compound 7*a* with palladium on calcium carbonate gave two crystalline epimeric products **8***a* (55%) and *b* (23%). The epimer **8***a* showed in the n.m.r. spectrum a methyl doublet ($\tau = 8.92$ p.p.m., $J = 6$ Hz) at lower field than the epimer **8***b* ($\tau = 9.00$ p.p.m., $J = 6$ Hz). This seems to indicate an interaction between the hydroxyl and methyl group in compound **8***a* and consequently the configurations of the two products were assigned preliminarily as shown. The higher R_f value of **8***a* as compared to **8***b* in t.l.c. led to the same conclusion.

Dehydration of the alcohol **8***a* with thionyl chloride in pyridine gave the compound **9** as an unstable oil. A broad one-proton singlet at $\tau = 4.38$ p.p.m. in the n.m.r. spectrum of this product indicated the presence of a trisubstituted double bond.

When the olefin **9** was subjected to the action of *N*-chlorosuccinimide in glacial acetic acid, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

highly crystalline compound **10** was isolated in a yield of 48%. This acetoxy-chloro-derivative could be assigned a structure possessing the rearranged carbon skeleton on the basis of the following data. The mass spectrum had molecular ion peaks at *m/e* 306 and 304 in the ratio 1:3 as calculated for $C_{18}H_{21}ClO_2$. The base peak was at *m/e* 183 corresponding to a loss of HCl and $CH_3—CO_2—\underset{|}{CH}—CH_2—$. The n.m.r. spectrum of **10** had a one-proton doublet (J = 3.5 Hz) at $\tau = 5.12$ p.p.m. for the hydrogen deshielded by chlorine, a one-proton quartet (ABX) at $\tau = 5.27$ p.p.m. for the hydrogen deshielded by the acetoxy group, and a broad one-proton singlet at $\tau = 6.86$ p.p.m. for a lone bridgehead hydrogen. The acetoxy group was assigned the *exo* configuration on mechanistic grounds in view of the known preference for *exo* attack of solvent on bridged benzo bicycloheptane carbonium ions. On the other hand the configuration of the chlorine was assigned only on the basis of the small coupling constant (in the n.m.r. spectrum) of the hydrogen unshielded by this substituent.

As a matter of fact we have expected the chlorine to have the opposite configuration (as in **12**) since this epimer could be formed by a fully concerted attack of Cl^+ and acetic acid on **9** with simultaneous rearrangement. However, the fragmentation of compound **10** discovered subsequently corroborated unambiguously the configuration of this product. Treatment of the acetoxychloride **10** with methanolic sodium hydroxide gave the unstable oily aldehyde **11**. This material showed absorption peaks in the i.r. at 2710 and 1730 cm^{-1} in agreement with the presence of the aldehyde group. A u.v. absorption maximum at 255 nm ($\log \varepsilon = 4.27$) indicated the conjugation of the double bond and the benzene ring. The n.m.r. spectrum contained a one-proton triplet (J = 1 Hz) at $\tau = 0.25$ p.p.m. for the aldehyde hydrogen, a one-proton multiplet at $\tau = 4.15$ p.p.m. for a vinylic hydrogen, a one-proton quartet (apparent J = 7 Hz) at τ = 6.30 p.p.m. for the benzylic hydrogen, and a two-proton double triplet (J = 6 and 1 Hz) at $\tau = 7.60$ p.p.m. for the methylene group adjacent to the aldehyde carbonyl.

The facile formation of the aldehyde **11** from **10** and the subsequent finding that the epimer **12** only hydrolyzes to the corresponding chloroalcohol under the same conditions clearly defines the configuration of the chlorine in both compounds.

Treatment of **10** with an excess of lithium chloride in dimethylformamide gave the crystalline compound **12**. The mass and n.m.r. spectra of this material (see Experimental) have shown that it is a diastereoisomer of **10**. The only significant difference in the spectral properties of both diastereoisomers may be seen in the n.m.r. spectrum. The hydrogen unshielded by the chlorine in compound **12** gives a one-proton doublet (J = 10.5 Hz) typical for *trans* diaxial splitting. Thus, compound **12** was produced by a chlorine–chlorine displacement with inversion of configuration and the spectral data combined with the fragmentation of the epimer **10** provide rigorous evidence of the entire stereochemistry for all products involved.[2] Treatment of the acetoxychloride **10** with tetraethylammonium acetate in DMF at 120° yielded the crystalline diacetate **13** by a displacement of the chlorine with inversion of configuration. The n.m.r. of compound **13** had a one-proton doublet at τ = 4.55 p.p.m. (J = 10 Hz) for the proton deshielded by the acetate and adjacent to the methyl group. As in compound **12** (and in ryanodine) this splitting is characteristic for the *trans* diequatorial stereochemistry of the acetoxy and methyl groups.

Selective hydrolysis of **13** gave the crystalline acetoxy alcohol **14** in a yield of 64%.

Oxidation of this product by the Jones reagent yielded quantitatively the crystalline ketone **15**. The i.r. spectrum of **15** had a carbonyl band at 1745 with a shoulder at 1735 cm^{-1}. The n.m.r. showed a one-proton doublet (J = 10 Hz) at $\tau = 4.72$ p.p.m. for the hydrogen deshielded by the acetate and an acetate methyl singlet at $\tau = 7.73$ p.p.m. Hydrolysis of the acetoxy ketone **15** gave the crystalline alcohol **16** which was prepared to characterize the carbonyl absorption of the keto group. Compound **16** showed in the i.r. spectrum as expected a single carbonyl band at 1735 cm^{-1} in agreement with a ketone in a five-membered ring.

[2]The doublet of the hydrogen unshielded by chlorine in compound **12** is exactly the same as the doublet of the proton unshielded by the ring-carbon oxygen in various ryanodine derivatives *cf.* ref. 1.

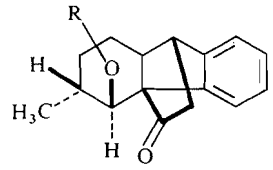
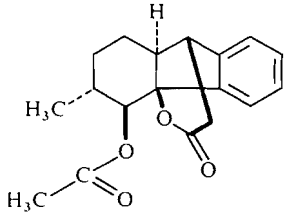
13 R = $C(=O)CH_3$
14 R = H



15 R = $C(=O)CH_3$
16 R = H



17

Finally, a Baeyer–Villiger oxidation of the acetoxy ketone **15** gave the crystalline lactone **17** in a yield of 67% (based on consumed starting material).[3] The mass spectrum of lactone **17** had a molecular ion at $m/e = 300$ ($C_{18}H_{20}O_4$). The base peak was at $m/e = 196$ ($C_{15}H_{16}$) for the loss of acetic acid and CO_2. The i.r. spectrum had carbonyl absorptions at 1735 and 1720 cm^{-1} for the ester and Δ-lactone functions. The n.m.r. spectrum had a one proton doublet ($J = 10$ Hz) at $\tau = 4.78$ p.p.m. for the hydrogen deshielded by the acetoxyl, a one-proton multiplet at $\tau = 6.7$ p.p.m. for the bridgehead hydrogen, a one-proton doublet ($J = 4$ Hz) at $\tau = 7.18$ p.p.m., and a one-proton doublet ($J = 2$ Hz) at $\tau = 7.3$ p.p.m. for the two hydrogens adjacent to the lactone carbonyl, a three-proton singlet at $\tau = 7.70$ p.p.m. for the acetate methyl, and a three-proton doublet ($J = 6.5$ Hz) for the secondary *C*-methyl. The alternative structure in which the oxygen and the carbonyl groups of the lactone are interchanged is ruled out since it would show the presence of two hydrogens deshielded by the lactone oxygen.

[3]Experiments involving the construction of the anhydroryanodine lactone by a Baeyer–Villiger oxidation of a bicyclo(2.2.1)heptanone derivative were conducted with an entirely different system by P. Cavanagh and K. Wiesner in 1965.

The same construction of the lactone is also envisaged in the synthetic approach of P. Deslongchamps (9).

Experimental

Preparation of the Diels–Alder Adduct **1**

Benzonorbornadiene (5) (8.6 g), hydroquinone (0.1 g), and excess butadiene (25 ml, measured at −70 °C) in dry benzene (100 ml) were heated to 200–220 °C for 40 h in a steel bomb. Evaporation of solvent and volatile by-products left 24 g of crude product which was purified by chromatography on silica gel (720 g). Elution with petroleum ether (b.p. 30–60 °C, 10 l) removed unwanted by-products from the column. Elution with petroleum ether–benzene (9:1, v/v) gave 9.0 g (76%) of **1**, homogeneous by t.l.c. Recrystallization from ethanol three times gave pure material as colorless plates m.p. 62–63 °C.

Anal. Calcd. for $C_{15}H_{16}$ (mol. wt. 196): C, 91.78; H, 8.22. Found (196 (mass spectroscopy)): C, 91.37; H, 8.21.

N.m.r. ($CDCl_3$)τ: unresolved multiplet (2H) 4.12 (vinylic hydrogens), unresolved multiplet (2H) 7.03 p.p.m. (bridgehead hydrogens).

Hydroboration of **1** *to* **2**

The olefin **1** (9.1 g) in dry tetrahydrofuran (100 ml) was stirred 2 h under a dry nitrogen atmosphere with a solution of borane in tetrahydrofuran (1 *M*, 17 ml). Excess borane was decomposed by dropwise addition of water (15–20 drops). Sodium hydroxide solution (2.5 *M*, 5.6 ml) was added and the organoborane was oxidized by addition of 30% hydrogen peroxide (5.6 ml) in small portions at a rate sufficient to maintain a temperature of 40–50 °C in the reaction mixture. After 1 h the solution was poured into ice-water (500 ml) and extracted with three portions of methylene chloride (100 ml). The aqueous phase was rendered slightly acidic with dilute hydrochloric acid to facilitate separation of the organic phase. The combined methylene chloride extracts were washed with water (100 ml), dried over anhydrous magnesium sulfate, and evaporated to give 9.2 g (92%) of a mixture of epimeric alcohols **2**. A small portion of the material was purified by crystallization from ether–hexane and preparative t.l.c. and had m.p. 120–130 °C.

Anal. Calcd. for $C_{15}H_{18}O$ (mol. wt. 214): C, 84.07; H, 8.47. Found (214 (mass spectroscopy)): C, 83.72; H, 8.46.

For personal use only.

I.r. (CCl_4): 3620 cm^{-1} (hydroxyl); n.m.r. ($CDCl_3$)τ: several peaks 5.7–6.5 (H—C—O), broad singlet (2H) 7.10 p.p.m. (bridgehead hydrogens).

Oxidation of Alcohol **2** *to Ketone* **3**

Jones' reagent (10 ml) was added dropwise to a well-stirred, ice-cold solution of alcohol **2** (8.56 g) in acetone (100 ml). The acetone solution was decanted from precipitated chromium salts into 500 ml of ice-water and extracted with three portions of methylene chloride (100 ml). The precipitated chromium salts were dissolved in water and the solution was extracted with methylene chloride (50 ml). The combined methylene chloride extracts were washed with dilute sodium chloride solution, dried over anhydrous magnesium sulfate, and evaporated to give 8.4 g (99%) of crude ketone **3**. After three recrystallizations from carbon tetrachloride–hexane (1:2, v/v), the pure material had a m.p. 134–134.5 °C.

Anal. Calcd. for $C_{15}H_{16}O$ (mol. wt. 212): C, 84.87; H, 7.60. Found (212 (mass spectroscopy)): C, 84.81; H, 7.48.

I.r. (CCl_4): 1715 cm^{-1} (ketone); n.m.r. ($CDCl_3$)τ: broad singlet (2H) 6.93 p.p.m. (bridgehead hydrogens).

Preparation of Bromoketone **4**

The ketone **3** (4.25 g) was dissolved in glacial acetic acid (100 ml). Pyridine hydrobromide perbromide (6.7 g) was added in small portions to the stirred solution. After 0.25 h the solution was poured into ice-water (600 ml) and extracted with three portions of chloroform (100 ml). The combined extracts were washed with water (100 ml), dried over anhydrous magnesium sulfate, and evaporated to give an oil which still contained some acetic acid. This was conveniently removed by azeotropic distillation with two portions of benzene (25 ml). The yield of thick yellow oil was 5.70 g. Analysis by t.l.c. showed this material to consist of three components (approximate ratio, 60:30:10).

This oil was dissolved in hot carbon tetrachloride (15 ml) and the solution was diluted with hexane. Upon cooling there was deposited 3.00 g (52%) of crystalline bromoketone **4**, m.p. 120–132 °C. Material of this purity was used in the subsequent step. Further recrystallizations gave pure material, m.p. 136–137.5 °C.

Anal. Calcd. for $C_{15}H_{15}BrO$ (mol. wt. 290 and 292): C, 61.86; H, 5.19; Br, 27.45. Found (290 and 292 (mass spectroscopy)): C, 61.51; H, 4.88; Br, 30.24.

I.r. (CCl_4): 1740 cm^{-1} (ketone); n.m.r. ($CDCl_3$)τ: doublet (J = 12 Hz, 1H) 5.30 (BrC—H), broad singlet (1H) 6.40 (bridgehead hydrogen), broad singlet (1H) 6.81 p.p.m. (bridgehead hydrogen).

Preparation of α,β*-Unsaturated Ketone* **5***a*

The bromoketone **4** (9.0 g) was heated under reflux with dry pyridine (100 ml) for 6 h. The cooled reaction mixture was poured into ice-water (1000 ml) containing concentrated hydrochloric acid (120 ml), and extracted with two portions of methylene chloride (200 ml). The combined extracts were washed once with dilute hydrochloric acid, dried over anhydrous magnesium sulfate, and evaporated to give 5.7 g of crude product. Chromatography on a column of neutral alumina (175 g, activity grade II) gave 5.2 g (80%) of pure **5***a* eluted with benzene. For analysis, the material was recrystallized from ether–hexane to a m.p. of 99–100 °C.

Anal. Calcd. for $C_{15}H_{14}O$ (mol. wt. 210): C, 85.67; H, 6.71. Found (210 (mass spectroscopy)): C, 85.35; H, 6.67.

I.r. (CCl_4): 1675 cm^{-1} (α,β-unsaturated ketone); u.v. (EtOH): λ_{max} 236 nm (log ε 4.19); n.m.r. ($CDCl_3$)τ: broad singlet (1H) 4.00 (vinylic hydrogen), broad singlet (1H) 6.06 (bridgehead hydrogen), broad singlet (1H) 6.76 p.p.m. (bridgehead hydrogen).

Isomerization of **5***a* *to* **5***b*

The α,β-unsaturated ketone **5***a* (0.210 g, 1.00 mmol) and 1% sodium hydroxide in 90% aqueous methanol were heated to reflux under nitrogen. Analysis by t.l.c. showed the appearance of a new compound **5***b* of lesser mobility. After 30 h it appeared that equilibrium had been obtained (ratio of **5***a* to *b* about 1:5). The reaction mixture was poured into ice-water and extracted with two portions of ether (25 ml). The ether extracts were washed twice with water (25 ml), saturated sodium chloride solution (25 ml), then combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 0.204 g of an oily mixture of α,β-unsaturated ketones **5***a* and *b*. This mixture was separated by preparative t.l.c. on silica gel using hexane–ether 1:1 (v/v). Recovered starting material (0.024 g) had m.p. 89–95 °C and i.r. and n.m.r. spectra identical to authentic **5***a*. The new isomer **5***b* was obtained as a colorless oil (0.140 g).

Mol. Wt. Calcd. for $C_{15}H_{14}O$: 210. Found (mass spectroscopy): 210.

The entire mass spectra of **5***a* and *b* were practically identical.

I.r. (CCl_4): 1675 cm^{-1} (α,β-unsaturated ketone); u.v. (EtOH): λ_{max} 253 nm (log ε 4.15); n.m.r. ($CDCl_3$)τ: doublet (J = 2.5 Hz, 1H) 4.05 (vinylic hydrogen), broad singlet ($w_{1/2h}$ = 3.5 Hz, 1H) τ = 6.03 (bridgehead hydrogen), broad singlet ($w_{1/2h}$ = 7.5 Hz, 1H) 6.56 (bridgehead hydrogen), multiplet (1H) 8.8–9.5 p.p.m. (methylene hydrogen shielded by aromatic ring).

Preparation of Tertiary Allylic Alcohol **6**

A solution of unsaturated ketone **5***a* (2.0 g) in dry ether (80 ml) was added dropwise (0.5 h) to a stirred solution of excess methyl-magnesium bromide (30 mmol) in dry ether (50 ml) under a dry nitrogen atmosphere. The reaction mixture was stirred for 3 h at room temperature and 2 h at reflux. The reaction mixture was cooled (ice-bath) and poured into cold 5% ammonium chloride solution (100 ml). The ether layer was separated, washed with ice-water (100 ml), saturated sodium chloride solution (100 ml), and dried briefly over anhydrous magnesium sulfate. Removal of the solvent *in vacuo* at 20–25 °C gave 2.0 g (93%) of **6** as a waxy, white solid. This material appeared as a 3:1 mixture when examined by t.l.c. on silica gel using pentane–ether (1:1, v/v) as developing solvent.

A portion (100 mg) of this mixture was separated by preparative t.l.c. There was obtained 63 mg of the isomer of higher mobility as white needles m.p. 112–114 °C (stage preheated to 100 °C).

Anal. Calcd. for $C_{16}H_{18}O$: C, 84.92; H, 8.02. Found: C, 84.75; H, 7.69.

I.r. (CCl_4): 3610, 3450 (hydroxyl); 1675 cm^{-1} (—CH=C<); n.m.r. ($CDCl_3$)τ: broad singlet (1H) 4.48 (vinylic hydrogen), broad singlet (1H) 6.31 (bridgehead hydrogen), broad

singlet (1H) 6.90 (bridgehead hydrogen), singlet 8.55 (hydroxyl), and singlet 8.70 p.p.m. (C—CH_3).

The isomer of lower mobility (19 mg) was obtained as a slightly waxy material, m.p. 121–123 °C (stage preheated to 115 °C).

Anal. Calcd. for $C_{16}H_{18}O$: C, 84.92; H, 8.02. Found: C, 84.67; H, 7.71.

I.r. (CCl_4): 3610, 3450 (hydroxyl); 1675 cm^{-1} (—HC=C<); n.m.r. ($CDCl_3$)τ: broad singlet (1H) 4.46 (vinylic hydrogen), broad singlet (1H) 6.30 (bridgehead hydrogen), broad singlet (1H) 6.86 (bridgehead hydrogen), singlet 8.44 (hydroxyl), and singlet 8.77 p.p.m. (C—CH_3).

Rearrangement of Alcohol **6** *to Alcohol* 7*a*

The alcohol **6** (2.94 g) was dissolved in tetrahydrofuran (130 ml) and to this solution was added 0.02 *N* hydrochloric acid (130 ml). The solution was stirred at room temperature for 18 h, diluted with saturated sodium chloride solution and extracted twice with ether (200 ml). The combined ether extracts were washed with two portions of saturated sodium chloride solution (250 ml) and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 3.0 g of a thick oil which was chromatographed on silica gel (120 g). Elution with 5–10% ether in petroleum ether (b.p. 30–60 °C) removed less polar material. Pure 7*a* was eluted with 20–25% ether in petroleum ether. The yield was 1.55 g (53%). Two recrystallizations from ether–hexane gave an analytical sample as white needles m.p. 82.5–83 °C.

Anal. Calcd. for $C_{16}H_{18}O$ (mol. wt. 226): C, 84.92; H, 8.02. Found (226 (mass spectroscopy)): C, 85.38; H, 7.95.

I.r. (CCl_4): 3610, 3560 (hydroxyl), and 1670 cm^{-1} (—HC—C<); n.m.r. ($CDCl_3$)τ: broad singlet (1H) 4.34 (vinylic hydrogen), unresolved multiplet (1H) 6.95 (bridgehead hydrogen), unresolved multiplet (1H) 7.10 (bridgehead hydrogen), doublet ($J = 1$ Hz) 8.25 (vinylic —CH_3), and singlet 8.92 p.p.m. (hydroxyl).

Hydrogenation of Alcohol 7*a to the Dihydro Alcohols* **8***a and b*

The allylic alcohol 7*a* (1.55 g) was hydrogenated in absolute ethanol (150 ml) with 10% palladium on calcium carbonate (1.5 g) for 12 h. The product (1.56 g) was a mixture of two compounds which could be separated by chromatography on silica gel (75 g). Epimer **8***a* (0.860 g, 55%) was eluted with 5% ether in petroleum ether (b.p. 30–60 °C). Elution with 6% ether in petroleum ether gave 0.157 g of a mixture of **8***a* and *b*, and epimer **8***b* (0.365 g, 23%) was eluted with 10% ether in petroleum ether.

In a small-scale experiment using 0.200 g of 7*a*, 20 ml of ethanol and 0.20 g of catalyst there was obtained, after purification by preparative t.l.c., 0.115 g (57%) of **8***a* as long white needles m.p. 51–53 °C, and 0.073 g (36%) of **8***b* as fine white needles m.p. 99–101 °C.

After sublimation epimer **8***a* had m.p. 52–53 °C.

Anal. Calcd. for $C_{16}H_{20}O$ (mol. wt. 228): C, 84.18; H, 8.83. Found (228 (mass spectroscopy)): C, 84.11; H, 8.67.

After sublimation epimer **8***b* had m.p. 102–103 °C.

Anal. Calcd. for $C_{16}H_{20}O$ (mol. wt. 228): C, 84.18; H, 8.83. Found (228 (mass spectroscopy)): C, 83.93; H, 8.73.

I.r. (CCl_4): 3630, 3575 cm^{-1} (hydroxyl); n.m.r. ($CDCl_3$)τ: unresolved multiplet (2H) 7.04 (bridgehead hydrogens), doublet ($J = 6$ Hz) 9.00 p.p.m. (C—CH_3).

Dehydration of **8***a to Olefin* **9**

The alcohol **8***a* (1.14 g) dissolved in dry pyridine (25 ml) was cooled to −10 °C (methanol–ice bath) and treated with excess thionyl chloride (0.50 ml, 0.82 g). The reaction mixture was stirred 1 h at −10 °C and then warmed to 25–30 °C. The excess thionyl chloride and most of the pyridine were removed by water aspirator suction. The residue was treated with ice-water (50 ml) and extracted with ether (50 ml and 25 ml). The ether extracts were washed four times with water (50 ml), saturated sodium chloride solution (50 ml), then combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 1.05 g of a pale-yellow oil showing 15–20% of impurities in the n.m.r. spectrum.

A small sample was purified by preparative t.l.c. on silica gel (hexane as solvent) to give pure **9** as a colorless oil.

Mol. Wt. Calcd. for $C_{16}H_{18}$: 210. Found (mass spectroscopy): 210.

Preparation of Rearranged Chloro-acetate **10**

The olefin **9** (2.13 g of crude material of about 80% purity) was dissolved in glacial acetic acid (25 ml) and treated with *N*-chlorosuccinimide (1.07 g). The reaction mixture was stirred 3 h at room temperature and most of the acetic acid was removed *in vacuo*. The residue was treated with ice-water and extracted with ether (100 ml and 50 ml). The ether extracts were washed with three portions of water (50 ml), saturated sodium chloride solution (50 ml), combined, and dried over anhydrous magnesium sulfate. The solvent was evaporated and traces of acetic acid were removed from the residue by azeotropic distillation with two portions of benzene (25 ml). The yield of crude product was 2.77 g. Chromatography on silica gel (80 g) and elution with benzene removed less polar impurities. Elution with benzene–ether (9:1, v/v) gave 1.73 g of **10**. Pure **10** m.p. 158–159 °C was obtained by crystallization from ether–hexane. The yield was 1.45 g (48% based on **8***a*).

Anal. Calcd. for $C_{18}H_{21}ClO_2$ (mol. wt. 304 and 306): C, 70.92; H, 6.94; Cl, 11.63. Found (304 and 306 (mass spectroscopy)): C, 71.00; H, 6.94; Cl, 11.72.

Preparation of Acetoxychloride ***12***

A solution of acetoxychloride **10** (0.155 g) and lithium chloride (0.105 g, dried at 160°) in dry *N*,*N*-dimethylformamide (DMF) (5 ml) was stirred for 24 h at 140–145 °C under a nitrogen atmosphere. The cooled reaction mixture was poured into ice-water (100 ml) and extracted with ether (50 ml and 25 ml). The ether extracts were washed with two portions of water (50 ml), saturated sodium chloride solution (50 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the ether gave 0.27 g of a colorless oil which still contained some DMF. Analysis by t.l.c. showed the presence of a small amount of starting material. This oil was subjected to preparative t.l.c. on silica gel using benzene–chloroform (1:1, v/v) and the resulting solid product was crystallized from ether–hexane to give 64 mg (41%) of pure acetoxychloride **12** as white needles m.p. 125–126.5 °C. The analytical sample obtained after one recrystallization had m.p. 125.5–126.5 °C.

Anal. Calcd. for $C_{18}H_{21}ClO_2$ (mol. wt. 304 and 306): C, 70.92; H, 6.94; Cl, 11.63. Found (304 and 306 (mass spectroscopy)): C, 70.95; H, 6.93; Cl, 11.65.

I.r. (KBr): 1730 (ester carbonyl), 1235, 1035, 1030 cm^{-1} (ester —C—O—); n.m.r. ($CDCl_3$): multiplet (1H) 2.43 (aromatic hydrogen); doublet (3H) 2.90 (aromatic hydrogens); quartet, X portion of ABX (1H) 5.03 (secondary acetate); doublet ($J = 10.5$ Hz, 1H) 5.80 (—CHCl—); broad doublet (1H) 6.82 (bridgehead hydrogen); singlet (3H) 7.92 (acetate methyl); doublet ($J = 6.5$ Hz, 3H) 8.85 p.p.m. (C—CH_3).

Saponification of Compound ***12*** *to the Corresponding Chloroalcohol*

The acetoxychloride **12** (78 mg) was dissolved in methanol (4.5 ml) and 10% sodium hydroxide solution (0.5 ml) was added. The solution was stirred under nitrogen for 24 h at room temperature. The methanol was removed *in vacuo*, ice-water (25 ml) was added to the residue, and the product was extracted into ether (two portions of 20 ml). The ether extracts were washed with two portions of water (25 ml), saturated sodium chloride solution (25 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 66 mg of a colorless oil. Purification by preparative t.l.c. ($CHCl_3$) gave 50 mg (77%) of the pure chloroalcohol as a colorless oil homogeneous by t.l.c.

Mass spectrum: parent ion less HCl at *m/e* 226; i.r. (CCl_4): 3600 cm^{-1} (hydroxyl); n.m.r. ($CDCl_3$)τ: multiplet (1H) 2.50 (aromatic hydrogen); multiplet (3H) 2.92 (aromatic hydrogens); doublet ($J = 10.5$ Hz, 1H) 5.66 (—CHCl—); quartet, X portion of ABX (1H) 5.85 (secondary alcohol); multiplet (1H) 6.84 (bridgehead hydrogen); doublet ($J = 7$ Hz, 3H) 8.84 p.p.m. (C—CH_3). The material was characterized by oxidation to the corresponding ketone. The chloroalcohol (50 mg) in acetone (2 ml) was oxidized at 0 °C with Jones' reagent. The acetone solution was poured into ice-water (25 ml) and extracted with ether (two portions of 10 ml). The ether extracts were washed with two portions of water (10 ml), saturated sodium chloride solution (10 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 49 mg of a white solid. After preparative t.l.c. ($CHCl_3$) and crystallization of the product from ether–hexane, the pure chloroketone (45 mg, 91%) was obtained as white needles, m.p. 147–147.5 °C. The analytical sample had m.p. 147.5–148 °C after one recrystallization.

Anal. Calcd. for $C_{16}H_{17}ClO$ (mol. wt. 260 and 262): C, 73.70; H, 6.57; Cl, 13.59. Found (260 and 262 (mass spectroscopy)): C, 73.83; H, 6.63; Cl, 13.59.

I.r. (KBr): 1735 cm^{-1} (ketone in five-membered ring); n.m.r. ($CDCl_3$)τ: multiplet (1H) 2.25 (aromatic hydrogen), multiplet (3H) 2.85 (aromatic hydrogens), doublet ($J = 10$ Hz, 1H) 6.05 (—CHCl—), multiplet (1H) 6.73 (bridgehead hydrogen), doublet ($J = 6$ Hz, 3H) 8.89 p.p.m. (C—CH_3).

Preparation of the Diacetate ***13***

The acetoxychloride **10** (0.183 g), tetraethylammonium acetate (0.57 g, five-fold excess), and dry DMF (6 ml) were heated to 120–125 °C for 18 h under a dry nitrogen atmosphere. The cooled reaction mixture was poured into ice-water (150 ml) and extracted with ether (50 ml and 25 ml). The ether extracts were washed with two portions of water (50 ml), saturated sodium chloride solution (50 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 0.182 g of a brown oil. The pure diacetate **18** was isolated by preparative t.l.c. ($CHCl_3$) and crystallization of the product from hexane. The yield of white needles, m.p. 147–148 °C, was 63 mg (32%).

Anal. Calcd. for $C_{20}H_{24}O_4$ (mol. wt. 328): C, 73.14; H, 7.37. Found (328 (mass spectroscopy)): C, 73.48; H, 7.61.

I.r. (KBr): 1735 (acetate carbonyl), 1240, 1220, 1045, 1035, 1020 cm^{-1} (acetate —C—O—); n.m.r. ($CDCl_3$)τ: doublet ($J = 10$ Hz, 1H) 4.55 (secondary acetate); quartet, X portion of ABX (1H) 5.00 (secondary acetate); multiplet (1H) 6.82 (bridgehead hydrogen); singlet (3H) 7.86 (acetate methyl); singlet (3H) 7.91 (acetate methyl); doublet ($J = 6$ Hz, 3H) 9.05 p.p.m. (C—CH_3).

Partial Hydrolysis of Diacetate ***13*** *to Monoacetate* ***14***

The diacetate **13** (0.108 g) was dissolved in 90% aqueous methanol containing 0.2% sodium hydroxide (10.0 ml, 1.5 equiv of NaOH). The reaction mixture was stirred at room temperature and the course of the reaction was followed by t.l.c. (benzene–methanol 19:1, v/v). As the starting material was consumed a product of intermediate R_f (monoacetate) appeared, followed more slowly by a product of low R_f (diol). After 12 h the reaction mixture was poured into ice-water (100 ml) and extracted with ether (25 ml and 20 ml). The ether extracts were washed with two portions of water (25 ml), saturated sodium chloride solution (25 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 0.100 g of a colorless oil. Separation by preparative t.l.c. gave 24 mg of recovered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

starting material, 60 mg (64%) of monoacetate **14** as a white solid homogeneous by t.l.c., and 12 mg of the material of low R_f (diol) as a white solid. The monoacetate crystallized from hexane as slender needles m.p. 169–169.5 °C.

Anal. Calcd. for $C_{18}H_{22}O_3$ (mol. wt. 286): C, 75.49; H, 7.74. Found (286 (mass spectroscopy)): C, 75.88; H, 7.65.

I.r. (CCl_4): 3610 (hydroxyl), 1740 (acetate carbonyl), 1230 cm^{-1} (—C—O—); (KBr): 3490 (hydroxyl), 1710 (acetate carbonyl), 1260 cm^{-1} (—C—O—); n.m.r. ($CDCl_3$)τ: doublet ($J = 10.5$ Hz, 1H) 4.45 (secondary acetate); multiplet, X portion of ABX, sharpened by D_2O exchange (1H) 6.00 (secondary alcohol); broad singlet (1H) 6.87 (bridgehead hydrogen); singlet (3H) 7.79 (acetate methyl); doublet ($J = 6.5$ Hz, 3H) 9.05 p.p.m. (C—CH_3); the signal for the hydroxyl proton was obscured by signals from the methylene protons and its presence could only be inferred from a decrease in the integrated peak area for signals in the range τ 7.3–8.1 after D_2O exchange.

The diol was identified by conversion to the diacetate **13** in a 96% yield by acetylation with acetic anhydride in pyridine for 5 days at 50 °C.

*Oxidation of the Monoacetate **14** to the Acetoxyketone **15***

The monoacetate **14** (68 mg) dissolved in acetone (4 ml) was oxidized at 0 °C with Jones' reagent (0.1 ml) for 0.25 h. The reaction mixture was poured into ice-water (100 ml) and extracted with ether (20 and 10 ml). The ether extracts were washed with two portions of water (25 ml), saturated sodium chloride solution (25 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 66 mg (98%) of acetoxyketone **15** as a white solid homogeneous by t.l.c. (benzene–methanol 19:1, v/v). The acetoxyketone crystallized from hexane as white needles, m.p. 146–147 °C.

Mol. Wt. Calcd. for $C_{18}H_{20}O_3$: 284.1413. Found (mass spectroscopy): 284.1407.

I.r. (CCl_4): 1745 with a shoulder at 1735 cm^{-1} (carbonyl), 1240, 1030 cm^{-1} (acetate —C—O—); (KBr): 1735 with a shoulder at 1725 (carbonyl), 1240, 1040 cm^{-1} (acetate —C—O—); n.m.r. ($CDCl_3$)τ: doublet ($J = 10$ Hz, 1H) 4.72 (secondary acetate), multiplet (1H) 6.62 (bridgehead hydrogen), singlet (3H) 7.73 (acetate methyl), doublet ($J = 6$ Hz, 3H) 9.07 p.p.m. (C—CH_3).

*Hydrolysis of the Acetoxyketone **15** to the Hydroxyketone **16***

The acetoxyketone **15** (30 mg) was hydrolyzed (3 days) in boiling 1 *N* hydrochloric acid in 90% aqueous methanol (3 ml). The cooled reaction mixture was diluted with ice-water (50 ml) and extracted with ether (20 and 10 ml). The ether extracts were washed with two portions of water (25 ml), saturated sodium chloride solution (25 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 28 mg of a white solid. The hydroxyketone **21** (22 mg, 86%) was isolated by preparative t.l.c. ($CHCl_3$) as a white solid m.p. 100–102 °C.

Mol. Wt. Calcd. for $C_{16}H_{18}O_2$: 242. Found (mass spectroscopy): 242.

I.r. (CCl_4): 3530 (hydroxyl), 1735 cm^{-1} (ketone in five-membered ring); (KBr): 3500 (hydroxyl), 1720 cm^{-1} (ketone); n.m.r. ($CDCl_3$)τ: multiplet (1H) 2.32 (aromatic hydrogen); multiplet (3H) 2.80 (aromatic hydrogens); multiplet (2H) 6.30–6.53 (secondary alcohol and hydroxyl) changing to a doublet ($J = 9$ Hz, 1H) 6.40 (secondary alcohol) after D_2O exchange; multiplet (1H) 6.60 (bridgehead hydrogen); doublet ($J = 6$ Hz, 3H) 8.90 p.p.m. (C—CH_3).

*Baeyer–Villiger Oxidation of Acetoxyketone **15** to Acetoxylactone **17***

The acetoxyketone **15** (58 mg), sodium acetate (0.10 g), acetic acid (1.5 ml), and 28% peracetic acid in acetic acid (0.5 ml, ten-fold excess) were stirred in the dark for 90 h. Analysis by t.l.c. (benzene–methanol 19:1, v/v) showed some starting material and a new component of lower R_f (ratio about 1:1). The reaction mixture was poured into ice-water (100 ml) containing sodium bisulfite (0.5 g) and extracted with ether (20 and 10 ml). The ether extracts were washed with three portions of water (25 ml), saturated sodium chloride solution (25 ml), combined and dried over anhydrous magnesium sulfate. Evaporation of the solvent and removal of remaining acetic acid from the residue by azeotropic distillation with benzene (2 ml) gave 62 mg of a colorless oil. This oil was fractionated by preparative t.l.c. to give recovered starting material (27 mg) and acetoxylactone **17** (22 mg, 67% based on reacted starting material) as a white solid m.p. 183–185 °C. Crystallization from ether–hexane gave 17 mg of white needles m.p. 187–188 °C. The analytical sample crystallized from absolute ethanol as white rhombs m.p. 189 °C.

Anal. Calcd. for $C_{18}H_{20}O_4$ (mol. wt. 300): C, 71.98; H, 6.71. Found (300 (mass spectroscopy)): C, 72.08; H, 6.62.

I.r. (KBr): 1735, 1720 (ester and lactone carbonyls), 1255, 1240, 1220, 1210, 1030 cm^{-1} (—C—O—); n.m.r. ($CDCl_3$)τ: doublet ($J = 10$ Hz, 1H) 4.78 (secondary acetate), multiplet (1H) 6.70 (bridgehead hydrogen), doublet ($J = 4$ Hz, 1H) 7.18 and doublet ($J = 2$ Hz, 1H) 7.30 (methylene group adjacent to lactone function), singlet (3H) 7.70 (acetate methyl), doublet ($J = 6.5$ Hz, 3H) 9.03 p.p.m. (C—CH_3).

We wish to thank the National Institutes of Health, Bethesda, Maryland, and the National Research Council of Canada for a grant in support of this investigation.

The Chromyl Chloride Oxidation of α-Pinene[1]

FRANK WILLIAM BACHELOR AND UKKEN OUSEPH CHERIYAN
Department of Chemistry, The University of Calgary, Calgary, Alberta, T2N 1N4

Received June 22, 1972

The oxidation of α-pinene with chromyl chloride has been investigated and 11 compounds amounting to 81% of the total reaction have been isolated and identified. Besides a small amount of recovered α-pinene these compounds have been found to be products of acid-catalyzed rearrangement (bornyl chloride, borneol, and limonene); products of allylic oxidation (myrtenal, myrtenol, and verbenone); and products of oxidative addition–rearrangement (pinocamphone, pinocarveol, campholenaldehyde, and pinol). In addition, *p*-cymene was isolated which may arise from several oxidation sequences. The isolation of optically active pinol suggests that at least part of the oxidation of α-pinene is initiated by attack of the chromyl chloride on the same side of the double bond as the dimethyl substituted bridge. An attack by a positive chromium atom on the double bond is ruled out by a deuteration study.

L'oxydation de l'α-pinène par le chlorure de chromyle a été étudiée; onze composés correspondant à 81% de la réaction totale ont été isolés et identifiés. En plus d'une petite quantité d'α-pinène retrouvée, ces composés proviennent de réarrangement acido-catalysé (chlorure de bornyle, bornéol, et limonène), d'oxydation allylique (myrtenal, myrtènol, et verbènone) et de réarrangement d'addition oxydante (pinocamphone, pinocarvéol, campholènaldéhyde, et pinol). On a isolé de plus du *p*-cymène qui pourrait provenir de plusieurs séquences d'oxydation. L'isolement du pinol optiquement actif laisse penser qu'une partie au moins de l'oxydation de l'α-pinène a été initiée par une attaque du chlorure de chromyle sur la même face de la double liaison que le pont diméthyle substitué. L'attaque par un atome de chrome positif sur la double liaison a été écartée par une étude de deutériation. [Traduit par le journal]

Canadian Journal of Chemistry, 50, 4022 (1972)

The oxidation of monoterpenes by chromyl chloride has been an exercise in futility as far as obtaining controlled reactions or identification of products. These reactions lead to a multitude of compounds which result not only from oxidation but from acid-catalyzed rearrangements and often compounds which arise from conditions in the work-up procedure and are not the results of the chromyl chloride reagent at all (see refs. 1 and 2 for reviews of this reaction).

We have reinvestigated the oxidation of α-pinene (**1**) with chromyl chloride with the hope that some modification of the procedure might lead to a more useful reaction and also to attempt to throw some light on the mechanism of the reaction or reactions involved. We have not achieved the former to any practical degree but an investigation of the products has given some clues as to possible mechanisms for this oxidation.

The first treatment of α-pinene with chromyl chloride was by Henderson and coworkers (3, 4) who reported only that among other products there was produced a saturated aldehyde, an unsaturated ketone, and a chlorinated oil. Work done some 50 years later by Okuda (5) identified as the major product *d*-pinocamphone (**2**) and some isocamphenilanaldehyde (**3**). No further work has been reported. The original workers were undoubtedly handicapped by impure α-pinene. Okuda reported that he started with commercial material and, considering that gas chromatography was not yet available in 1951, it is also probable that his α-pinene was not pure.

The standard procedure for oxidizing olefins with chromyl chloride was to add either one or two molar equivalents of chromyl chloride to the olefin which produced a precipitate of a complex. The complex was then added to cold water and the products isolated either by steam distillation or ether extraction of the aqueous mixture. Later variations include adding the complex to aqueous sodium bisulfite solution which reduces any higher oxidation states of chromium still remaining. Both of these methods have obvious drawbacks, the first being a highly acidic solution which still contains a strong oxidizing agent, and the second contains a nucleophile which readily opens epoxides, a long sought for intermediate in chromyl chloride oxidations. Considering the penchant of monoterpenes to rearrange under acidic conditions, it is not surprising that a large number of components are found in these reactions, many of which are artifacts from work-up conditions.

We have modified the work-up procedure by adding the complex formed, together with the reaction solvent in which much of the complex is still soluble, to an ice-cold 10% sodium bicarbonate solution. This avoids subsequent acid-catalyzed rearrangements, nucleophilic substitutions, or opening of epoxides and the excess oxidizing agents are relatively weak in such alkaline media. Using this procedure we have been able to reduce the number of components from over 30 distinguishable peaks in a gas chromatograph to 11 readily separable and identifiable components. In addition to these, there is still some 19% of the reaction products which has not been identified. This is mostly polymeric material and probably represents products from allylic oxidations. Only a small amount (6%) of α-pinene is recovered from the reaction.[2]

The products of this reaction can be classified into three groups: those from non-oxidative rearrangements, products of allylic oxidation, and products from oxidation by addition followed by rearrangement. These products and their percentages of the total material are listed in Table 1. All of these compounds were identified by comparison with authentic specimens or by the preparation of derivatives.

TABLE 1. Yields and relative retention times of products from treatment of α-pinene with chromyl chloride

Product	r.r.t.*	Yield†
Bornyl chloride (**5**)	6.6	13.5
Pinocamphone (**2**)	10.0	11.4
Pinol (**14**)	4.2	9.4
Myrtenol (**10**)	42.6	9.4
α-Pinene (**1**)‡	1.0	6.3
Campholenaldehyde (**13**)	9.0	6.3
p-Cymene (**7**)	3.3	5.8
Verbenone (**8**)	27.3	5.6
Pinocarveol (**12**)	20.0	4.2
Borneol (**6**)	25.3	4.2
Myrtenal (**9**)	17.6	3.5
Limonene (**4**)	2.3	3.1
Unidentified polymer	—	18.8

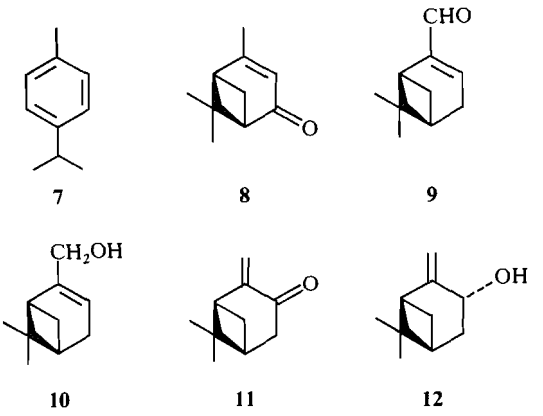
*Relative retention time compared to α-pinene on a 6 ft × 1/8 in. column packed with 20% Carbowax 20M on chromosorb W at a temperature of 90 °C.

†Percentages calculated from areas under the analytical g.l.c. curves, and based on distillable material. The 18.8% polymer represents the non-distillable residue.

‡Recovered unreacted.

Three products were isolated which had the same oxidation state as α-pinene: limonene (**4**), bornyl chloride (**5**), and borneol (**6**). The formation of these products is undoubtedly catalyzed by the hydrochloric acid or intermediate chromium acids formed by the allylic oxidations. The formation of bornyl chloride is straight-forward and is a normal rearrangement product from the action of hydrochloric acid on α-pinene (6). Limonene is also a known rearrangement product from the treatment of α-pinene with strong acids (7), so that it is not too surprising to find it in this medium. Subsequent oxidation of limonene with 1 equiv of chromyl chloride gives primarily *p*-cymene (**7**) (1), also a component of this reaction. The presence of borneol is somewhat more difficult to explain. It certainly does not arise from solvolysis of bornyl chloride during the aqueous work-ups because this reaction does not lead to borneol (8). The most logical explanation would appear to be that the protonated intermediate from α-pinene reacts with some chromium

[2]It has been suggested that perhaps some of the products could arise by the basic conditions of the work-up. We have found no noticeable differences in the products from work-up with bicarbonate or carbonate, with the exception of the epoxide. We believe that the products here reported are those resulting from the reaction of chromyl chloride and its intermediates followed by hydrolysis of these products with water, and that none of them result from nucleophilic attack or elimination caused by the weak bases used here. These products are also those found in bisulfite work-ups.



7 8 9

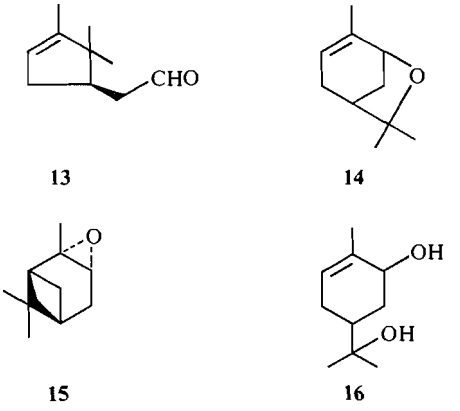
10 11 12

oxide species to give an ester which is subsequently hydrolyzed. All three of these compounds are optically active, bornyl chloride and borneol showing essentially no racemization. The limonene formed is about 50% racemic. This implies a high degree of concertedness to these rearrangements in contrast to other reactions which give, for example, racemic limonene (*7a*).

A possible alternative to the proton-catalyzed formation of these products would be attack on the double bond by a positive chromium ion. In order to check this possibility, a chromyl chloride α-pinene complex was decomposed with D_2O. Should any chromium–carbon bond be present it would be broken and the chromium atom would be replaced by deuterium. Isolation and examination of the bornyl chloride formed showed no incorporation of deuterium. This rules out the attack of any species other than a proton as the initiator for these rearrangements.

Three products from allylic oxidation of α-pinene were obtained. These were verbenone (**8**), myrtenal (**9**), and myrtenol (**10**). These arise from straightforward oxidations of α-pinene in a process which is presumably related to the Etard reaction (9). The nature of these products speaks strongly against the proposals of Stairs *et al.* (10) and Nenitzescu and coworkers (11) both of whom proposed that the α,β-unsaturated carbonyl compounds formed in chromyl chloride oxidations of olefins could arise from the elimination of HCl from an α-chloroketone. This rather unlikely process would yield α,β-unsaturated derivatives of pinocamphone (**2**) but none of these products are found. Although we searched for a chloroketone we were unable to detect any, nor was any pinocarvone (**11**) found.

Finally, the products which result from oxidative attack on the double bond were found to be pinocamphone (**2**), pinocarveol (**12**), campholenaldehyde (**13**), and pinol (**14**). All of these are the products from initial attack on the C-2 position of α-pinene followed by rearrangements. One is tempted to invoke the intermediacy of pinene oxide (**15**) in the formation of these products since all four of them are known to be formed from the oxide from reaction conditions which could be simulated during the oxidation. The rearrangement of oxides to the corresponding ketones with Lewis acids is a common preparative procedure (12). Acid-catalyzed opening of the epoxide also readily leads to pinocarveol (**12**) (13). The treatments of α-pinene oxide with zinc bromide (14) or *p*-toluenesulfonic acid (15) are both known to give campholenaldehyde (**13**) along with other products including *p*-cymene (**7**).



13 14

15 16

The formation of pinol (**14**) is of more than passing interest since it is approximately one-quarter optically active. Pinol may be obtained from α-pinene oxide by heating with water (16) or by treating it with acids (17). These two methods go through an intermediate, sobrerol (**16**), which is optically inactive in both cases. Pinol can also be obtained by treating *cis*-1,2-pinane glycol (**17**) (18) or *trans*-1,2-pinane glycol (**18**) with aqueous oxalic acid (19). From the latter compound optically active pinol was produced. An examination of the formation of

SCHEME 1

pinol from these two glycols suggests that the *cis*-glycol (**17**) or pinene oxide probably go through the allylic carbonium ion (**19**). This intermediate also would explain the formation of optically inactive sobrerol (**16**). From the *trans*-glycol (**18**), the C_2-hydroxyl group is on the same side of the ring as the migrating bridge in the carbonium ion intermediate (**20**) and can react directly to give optically active pinol. These reactions are depicted in Scheme 1. All of this implies that in order to produce optically active pinol from a pinene derivative the oxygen function at C-2 must be *cis* to the rearranging bridge. Therefore, the chromyl chloride must be attacking the double bond of α-pinene from both sides. This appears to be the first example of a reagent attacking the α-pinene double bond *cis* to the dimethyl substituted bridge.

In contrast to the report by Okuda (5) that isocamphenilanaldehyde (**3**) is formed by the action of chromyl chloride on α-pinene, we were unable to detect any in our reactions. This compound is a natural oxidation product of camphene and is characteristic of the chromyl chloride oxidation of terminal olefins (2). We can only suppose that his α-pinene was contaminated with camphene or, more likely, that camphene was produced from α-pinene in the aqueous work-up and subsequently oxidized.

In spite of the similarity of the oxidation products from chromyl chloride and the rearrangement products from α-pinene oxide, we do not believe that this is a major pathway in the formation of these products. Although it may well be formed to some extent, and probably is, several other intermediates or transition states could readily explain all of the results. We are in the process of examining these possibilities in simpler systems.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. N.m.r.'s were run on a Varian A-60 and are reported in τ values relative to internal tetramethylsilane. Mass spectra were run on a Varian-MAT CH-5 mass spectrometer. Analytical gas chromatography was carried out on a Hewlett–Packard Biomedical 402 gas chromatographic instrument using a 6 ft glass column packed with 20% Carbowax 20M on chromosorb W. Preparative gas chromatography was carried out using a Varian Aerograph 90-P gas chromatograph using an 8 ft column, 3/8 in. diameter, packed with 20 or 30% Carbowax 20M on chromosorb W. Optical rotations were measured on a Durrum–Jasco ORD-UV/5 spectropolarimeter.

α-Pinene

Commercially available α-pinene (99+% pure) obtained from Aldrich Chemical Co. was distilled through a Nester–Faust annular Teflon distillation column. The distillate was shown to be better than 99% pure by analytical gas chromatography.

Chromyl Chloride

Chromyl chloride (Alfa Inorganics) was purified by passing a stream of dry nitrogen through it to expel any dissolved hydrogen chloride or chlorine. It was then freshly distilled before each oxidation.

Solvents

Methylene chloride was used throughout in these experiments and was purified by drying over anhydrous calcium chloride and distillation.

Oxidation of α-Pinene with Chromyl Chloride

α-Pinene (136 g, 1 mol, $[\alpha]_D^{25}$ +34.4, neat) was dissolved in 2 l of freshly distilled methylene chloride and cooled in

TABLE 2. Column chromatogram of crude oxidation mixture from chromyl chloride on α-pinene

Fraction	Solvent	Solvent ratio	Material eluted (g)
1	Hexane		5.2
2	Hexane–Benzene	19:1	9.9
3	Hexane–Benzene	3:1	4.8
4	Hexane–Benzene	1:1	7.8
5	Hexane–Benzene	1:3	8.1
6	Benzene		6.5
7	Benzene–Chloroform	1:1	10.1
8	Chloroform		13.8

an ice–salt bath to 0 to −5 °C. To this was added dropwise, with stirring, chromyl chloride (160 g, 1 mol) in 1 l of methylene chloride over a period of 6 h. Without isolation, the complex was decomposed by adding it, with vigorous stirring, to 1600 ml of 10% sodium bicarbonate solution containing 500 g of crushed ice. The mixture was placed in a large separatory funnel and ether was added until two clearly separable layers were obtained. The lower aqueous layer was removed, saturated with sodium chloride, and exhaustively extracted with ether. The combined ether extracts were washed with water and dried over anhydrous magnesium sulfate. The solvents were removed by distillation on a steam bath and the last traces were removed by distillation through a spinning band column. The residue amounted to 102 g of crude products.

The crude product (80 g) was fractionated by chromatography on silica gel (2.4 kg, Hopkins and Williams, column diameter, 9 cm) and eluted successively with 10 l of each solvent mixture (see Table 2).

Isolation of p-Cymene and Limonene

The solvent was removed from fraction 1 *in vacuo*. The residue showed two major peaks on analytical g.l.c. with relative retention times (r.r.t.) of 2.3 and 3.3 with respect to α-pinene. These two compounds were separated by preparative g.l.c. (20% Carbowax 20M, column temperature 140 °C). These were found to be limonene (r.r.t. 2.3) $[\alpha]_D^{25}$ +62.5 ($c = 1$, $CHCl_3$), lit. (20) $[\alpha]_D^{25}$ +111.6 (methanol), and *p*-cymene (r.r.t. 3.3) by comparison of their i.r. and n.m.r. spectra with authentic specimens.

Isolation of Bornyl Chloride

Removal of solvent from fraction 2 *in vacuo* left a liquid which showed two major peaks on analytical g.l.c. One of these peaks corresponded to α-pinene (r.r.t. 1) and the second had an r.r.t. of 6.6. Separation of this second component by preparative g.l.c. (20% Carbowax 20M, column temperature 140 °C) yielded a white solid, m.p. 130–131 °C, $[\alpha]_D^{25}$ +31.2 ($c = 0.28$, $CHCl_3$), lit. (20), m.p. 132 °C, $[\alpha]_D^{25}$ +30.96 (ethanol); n.m.r. ($CDCl_3$) 5.82 (1 H, d, $J = 3$ Hz each doublet split into a quartet, $J < 1$ Hz), 9.08 (3 H, s), 9.12 (6 H, s). The i.r. and n.m.r. spectra of this compound were identical to a synthetic sample of bornyl chloride.

Isolation of Campholenaldehyde

Removal of solvent from fraction 3 yielded a yellow oil which, on distillation at 20 mm, gave a colorless liquid. This was found to contain two major components with r.r.t.'s of 6.6 and 9.0 on analytical g.l.c. The former corresponds to bornyl chloride. The compound with r.r.t. 9.0 was collected by preparative g.l.c. (30% Carbowax 20M, column temperature 160 °C). This compound showed prominent bands in the i.r. ($CHCl_3$) at 2725, 1740, 1390, and 1370 cm^{-1}. N.m.r. ($CDCl_3$) 0.24 (1 H, t), 5.2 (1 H, m), 8.3 (1 H, m), 8.98 (3 H, s), 9.2 (3 H, s). A mass spectrum showed a molecular ion at *m/e* 152. The i.r. and n.m.r. spectra of this compound were superimposable on those of an authentic sample of campholenaldehyde.

Isolation of Pinocamphone

The residue after removal of solvent from fraction 4 was distilled at reduced pressure (20 mm). This yielded a colorless liquid which showed only one major component on analytical g.l.c. with r.r.t. 10.0. Purification of this component by preparative g.l.c. (30% Carbowax 20M, column temperature 160 °C) yielded a colorless liquid with the following spectral properties: $[\alpha]_D^{25}$ +28° ($c = 0.18$, $CHCl_3$), lit. (21) $[\alpha]_D^{25}$ +22.5; i.r. 1715, 1390, 1375 cm^{-1}; n.m.r. (CCl_4) 8.66 (3 H, s), 8.97 (3 H, d, $J = 7$ Hz), 9.1 (3 H, s) (see ref. 22).

Semicarbazide hydrochloride (1 g) and sodium acetate (1.5 g) were dissolved in 100 ml of H_2O. To this was added a few drops of the above compound and the mixture shaken. A white precipitate started to appear after about 1 h. The reaction mixture was kept overnight and the crystalline derivative was collected by filtration. Recrystallization from ethanol yielded white crystals, m.p. 226–227 °C, lit. (21) 227 °C, for the semicarbazone of *d*-pinocamphone.

Isolation of Pinol and Myrtenal

Analysis of the residue obtained after removal of the solvent from fraction 5 showed that it contained two major components with r.r.t.'s of 4.25 and 17.6 on analytical g.l.c. The two compounds were obtained pure by preparative g.l.c. (20% Carbowax 20M, column temperature 140 °C).

The compound with r.r.t. 4.25 was a colorless liquid with the following spectral properties: $[\alpha]_D^{25}$ +8.3 ($c = 0.24$, $CHCl_3$); i.r. (CCl_4) 3015, 1380, 1370, 1215, 1115, 1010 cm^{-1}; n.m.r. ($CDCl_3$) 4.78 (1 H, m), 5.98 (1 H, d), 8.27 (3 H, q, $J = 1$ Hz), 8.68 (3 H, s), 8.79 (3 H, s). The mass spectrum showed a molecular ion at *m/e* 152, lit. for pinol (19), $[\alpha]_D^{25}$ +34.8°.

A dibromide was prepared by dissolving 10 drops of the compound in CCl_4 and adding a dilute solution of bromine in the same solvent dropwise until a permanent yellow color was obtained. On addition of water a pale yellow solid precipitated which was collected by filtration and recrystallized from benzene–chloroform, m.p. 92–93 °C, lit. (23) 94 °C. The molecular weight was found to be 312 by mass spectral analysis.

The compound with r.r.t. 17.6 showed the following spectral properties: i.r. (film) 2720, 1690, 1385, 1370 cm^{-1}; n.m.r. (CCl_4) 0.72 (1 H, s), 3.43 (1 H, m, $J = 1$ Hz), 8.62 (3 H, s), 9.22 (3 H, s). The i.r. and n.m.r. spectra were identical to that of an authentic specimen of myrtenal.

Isolation of Borneol and Verbenone

Removal of solvent from fraction 6 left a viscous brown liquid. Two grams of this residue was absorbed on a column of silica gel (100 g, Hopkins and Williams, column diameter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2.8 cm) and eluted with 1:1 benzene–hexane. The column was eluted with 1.5 l of this solvent and removal of the solvent yielded 1.5 g of a viscous yellow liquid. This contained two major components by analytical g.l.c. with r.r.t.'s 25.3 and 27.3. These were separated by preparative g.l.c. (30% Carbowax 20M, column temperature 170 °C).

The compound with r.r.t. 25.3 was a white solid, m.p. 206–207 °C; $[\alpha]_D^{25}$ +31.6 ($c = 0.21$, $CHCl_3$); i.r. (CCl_4) 3640, 3510, 1385, 1375, 1055 cm^{-1}; n.m.r. (CCl_4) 6.02 (1 H, d, $J = 4$ Hz, each doublet split into a quartet, $J < 1$ Hz), 8.5 (1 H, s, exchanges with D_2O), 9.12 (9 H, s). These spectra were identical to those of an authentic specimen of borneol.

The compound with r.r.t. 27.3 was initially a colorless liquid which turned yellow on standing. It had the following spectral properties: i.r. (CCl_4) 1690, 1390, 1380, 1040, 870 cm^{-1}; n.m.r. (CCl_4) 4.38 (1H, m), 7.98 (3 H, q), 8.48 (3 H, s). These spectra were identical to those of an authentic sample of verbenone obtained from the Glidden–Durkee Co. of Jacksonville, Florida.

Isolation of Pinocarveol and Myrtenol

The solvent was removed from fraction 7 and 2 g of the residue was absorbed on silica gel (100 g, Hopkins and Williams, column diameter 2.8 cm) and eluted with benzene. Elution with 1.5 l of solvent yielded 1.3 g of a viscous yellow oil. Analysis by analytical g.l.c. showed that it was a mixture of two major compounds with r.r.t.'s 20.0 and 42.6, and a minor component with r.r.t. 25.3. The components were separated by preparative g.l.c. (30% Carbowax 20M, column temperature 160 °C).

The compound with r.r.t. 20.0 had the following spectral properties: i.r. (CCl_4) 3614, 3490, 1645, 1385, 1370, 1020, 995, and 865 cm^{-1}; n.m.r. (CCl_4) 5.08 (1 H, d, $J < 1$ Hz), 5.25 (1 H, d, $J < 1$ Hz), 8.5 (1 H, s, exchanges with D_2O), 8.71 (3 H, s), 9.37 (3 H, s). These spectra were identical to those of authentic *trans*-pinocarveol.

The compound with r.r.t. 42.6 was a viscous liquid with the following spectral properties: i.r. (film) 3330, 3040, 1375, 1365, 1060, 890, 800 cm^{-1}; n.m.r. (CCl_4) 4.6 (1 H, m), 6.11 (2 H, s), 7.37 (1 H, s, exchanges with D_2O), 8.7 (3 H, s), 9.15 (3 H, s). These spectra were identical with those of authentic myrtenol.

Analysis of Fraction 8

This fraction was semi-solid and failed to yield any pure compounds.

Quantitative Estimations of Constituents from Oxidation of α-Pinene with Chromyl Chloride

The percentages of the constituents from oxidation of α-pinene with chromyl chloride were estimated by measuring the area of the peaks from analytical g.l.c. chromatography of the crude residue. It was assumed that the sensitivity of the detector was proportional to the amount of compound present, however, it is recognized that this is not necessarily true. All peaks were sufficiently resolved to calculate areas. Unidentified and nonvolatile material accounted for 18.8% of the total residue.

Bornyl Chloride

Bornyl chloride was prepared by the method of Frankforter and Frary (6) and yielded a gas chromatographically pure compound, m.p. 130–131 °C.

Myrtenol and Myrtenal

A mixture of myrtenol and myrtenal was prepared by the oxidation of α-pinene with selenium dioxide according to the procedure of Dupont and Zacharewics (24). The myrtenal was separated by treatment with aqueous sodium bisulfite and the myrtenol extracted with ether. The myrtenal was recovered from the aqueous solution by treating with 8% sodium hydroxide and extraction with ether.

Attempted Isolation of Isocamphenilinaldehyde

The crude oxidation product of α-pinene (15 g) was agitated for 1 h with 100 ml of 20% sodium bisulfite solution and the unreactive components removed by extraction with ether. The aqueous layer was then treated with 100 ml of 8% sodium hydroxide solution and was exhaustively extracted with ether. The ether extracts were combined, dried over anhydrous magnesium sulfate, and the solvent removed by distillation. A colorless liquid (1.2 g) remained. Analytical g.l.c. showed only two components present with r.r.t.'s 9.0 and 17.6. Preparative g.l.c. of this mixture showed these components to be campholenaldehyde and myrtenal respectively.

Examination of Deuterium Incorporation into Bornyl Chloride on Work-up of the α-Pinene–Chromyl Chloride Complex with D_2O

α-Pinene (13.6 g, 0.1 mol) dissolved in 200 ml of dry methylene chloride was cooled in an ice–salt bath to 0 to −5 °C. A solution of chromyl chloride (15.5 g, 0.1 mol) in 125 ml of methylene chloride was added dropwise with stirring over a period of 1 h. The reaction was stirred for an additional 10 min and then decomposed by adding with stirring to a mixture of 10 g of anhydrous sodium carbonate in 20 ml of deuterium oxide (99.7% D_2O). The products were exhaustively extracted with ether, the ether extracts combined, dried over anhydrous $MgSO_4$, and the solvent removed by distillation to yield 10.5 g of crude products.

The crude product mixture was fractionally distilled under reduced pressure (20 mm) and the fraction boiling at 85–95 °C collected for analysis. This fraction contained most of the bornyl chloride produced in this reaction. Purification of the bornyl chloride was accomplished by preparative gas chromatography.

A mass spectral analysis of the pure bornyl chloride showed no significant increase in the *m/e* 173 peak corresponding to the incorporation of one deuterium atom, over that of normal isotopic bornyl chloride.

We wish to thank Dr. E. E. von Rudloff for samples of pinocarveol and campholenaldehyde. We also wish to thank The University of Calgary for a University of Calgary Dissertation Fellowship (UOC) and the National Research Council of Canada for financial support.

Reactions of Ozonides. IX. A Radioisotopic Dilution Study of Ozonide Methanolysis

DUNDAPPA R. KERUR AND DENNIS G. M. DIAPER

Department of Chemistry and Chemical Engineering, Royal Military College of Canada, Kingston, Ontario

Received October 5, 1971[1]

A radioisotopic dilution study indicates that no significant amounts of $HOOCH(OCH_3)-(CH_2)_9-{}^{14}CO_2CH_3$ are produced by reacting  with methanol.

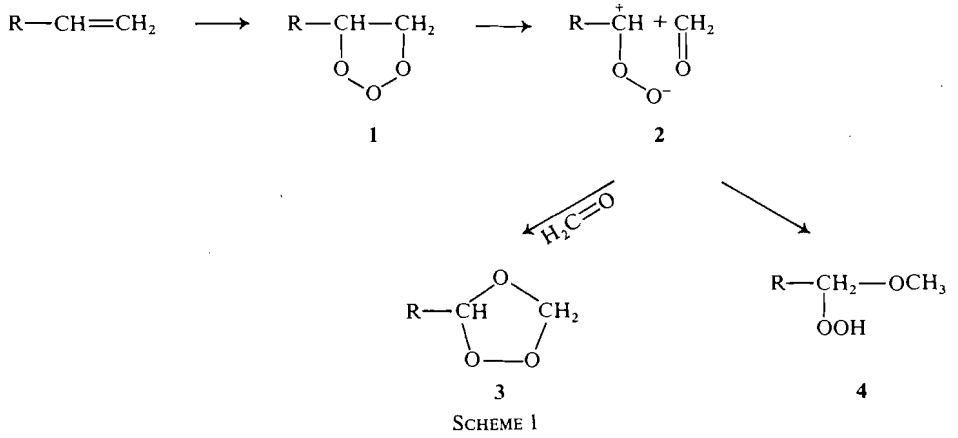
Une étude par dilution radioisotopique montre que des quantités non importantes de $HOOC(OCH_3)-(CH_2)_9-{}^{14}CO_2CH_3$ sont formées dans la réaction de  avec le méthanol.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 4029 (1972)

A key intermediate in the Criegee mechanism for the ozonolysis reaction is the zwitterion **2** which is produced by cleavage of the primary ozonide **1** (1, 2). Among other reactions, the zwitterion may react with a carbonyl component to form an ozonide **3**, or if a reactive solvent such as methanol is present, the corresponding methoxyhydroperoxide **4** may be produced (see Scheme 1).

While investigating the thermal breakdown of 1-hexene ozonide, Razumovskii and Yurev (3) noted that prolonged holding of the ozonide in methanol at ordinary temperatures did not convert it to the methoxyhydroperoxide. However, thermal decomposition of either the ozonide in methanol or the methoxyhydroperoxide gave similar product distribution. On the basis of their observations, they proposed that at low temperatures, equilibrium in solution between ozonide, zwitterion, and carbonyl fragment was on the side of the ozonide. But with rising temperatures, equilibrium was shifted to the opposite direction leading to fragmentation of the ozonide. The zwitterion thus formed



SCHEME 1

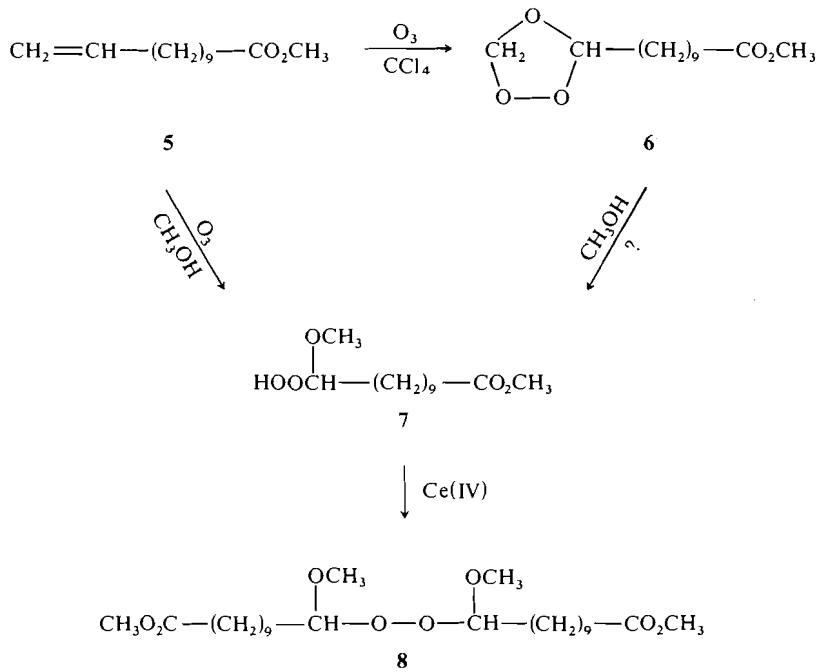

SCHEME 2. Structures **5*** and **6*** represent compounds where the ester function is $^{14}CO_2CH_3$.

reacted with methanol to give the methoxyhydroperoxide which in turn eliminated a molecule of water to produce a methyl ester.

Pryde *et al.* (4), in a study of pyrolytic decomposition of selected ozonolysis products, proposed that an ozonide in the presence of methanol and hydrogen ion produced an ester via a methoxyhydroperoxide. In their investigation, they ozonized 1-decene in water emulsions, conditions under which one would expect formulation of some hydroxyhydroperoxide in addition to the ozonide.

Neither pure ozonides nor pure methoxyhydroperoxides were used in the two reports just cited. Only gross reaction mixtures obtained after ozonation were employed.

In our own experience, methyl 10-undecenoate ozonide (5) could be recovered unchanged and in good yields after prolonged dissolution in methanol at room temperature.

Recently, Criegee and Korber (6) have recorded the fragmentation of several ozonides by methanol. Depending on the substitution pattern on the trioxolane ring, acids and aldehydes or ketones have been identified.

If methanolysis of the ozonide ring proceeds through the methoxyhydroperoxide, failure to isolate this product (3) is explicable by (*a*) rapid further reaction giving the ester, or (*b*) failure to interrupt the reaction before completion of the sequence: ozonide, methoxyhydroperoxide, ester. If on the other hand, methanolysis of the ozonide ring is a concerted process (6) without a methoxyhydroperoxide intermediate, failure to isolate methoxyhydroperoxide products of ozonide methanolysis is also explicable. Sensitivity of detection of methoxyhydroperoxide can be greatly increased using an isotopic dilution method, and the present study was undertaken using this analytical method. Methanolysis of an ozonide and the corresponding methoxyhydroperoxide were performed under comparable conditions to obtain some idea of the relative rates of reaction.

The results support the proposed methanolysis mechanism (6) of ozonide and indicate that intermediate formation of methoxyhydroperoxide plays a negligible part (see Scheme 2).

Experimental

Counting of radioactive samples was done on a Nuclear–Chicago counter.

A Coleman Model 33 Carbon–Hydrogen Analyzer was used for microanalyses.

I.r. spectra were recorded on a Perkin–Elmer Infracord spectrophotometer.

N.m.r. spectra were recorded on a Varian A-60A model spectrometer. Tetramethylsilane was used as internal reference.

"Baker Analyzed" reagent grade silica gel powder was used for column chromatography.

T.l.c. was performed on Eastman Chromagram sheets without fluorescent indicator. T.l.c. plates (20 × 20 cm, 100 μ thick) were made on a Shandon Unoplan leveller using silica gel powder containing 5% calcium sulfate.

Two spray reagents were employed in this work. One was a 3% solution of potassium iodide in 5% aqueous acetic acid. The other was prepared by dissolving 1 g of 2,4-dinitrophenyl hydrazine (DNP) in 7.5 ml of concentrated sulfuric acid and diluting the solution to 250 ml with 95% ethanol.

Petroleum ether refers to the fraction boiling between 30 and 60°.

Ceric ammonium nitrate (ammonium hexanitrato cerate) was obtained from the A. Frederick Smith Chemical Co., Columbus, Ohio.

Methyl 11-dodecenoate (**5**), b.p. 138–154° at 4 mm pressure, was prepared by carbonation of undecenylmagnesium bromide and subsequent esterification. Methyl carboxyl-^{14}C-11-dodecenoate (**5***) was similarly prepared using $^{14}CO_2$. Barium carbonate-^{14}C (specific activity 5.0 mCi/mmol) from New England Nuclear Corp., Boston, Massachusetts was used to generate the radioactive carbon dioxide.

*Methyl-carboxyl-^{14}C-11-dodecenoate Ozonide (**6***)*

A solution of methyl carboxyl-^{14}C-11-dodecenoate (**5***) in carbon tetrachloride was treated with a stream of ozone–oxygen at ice-water temperature. The reaction mixture was evaporated and the residue was chromatographed on a silica gel column using 5% ether in petroleum ether as eluant. Fractions were tested for purity by t.l.c. using a potassium iodide–acetic acid spray. Fractions which contained pure ozonide as evidenced by single spots were pooled and evaporated. The ozonide isolated had a specific activity of 220.20 ± 0.69 counts/min mg. N.m.r. spectrum of a similarly prepared non-radioactive sample has been described by us before (5).

Methyl 11-Hydroperoxy-11-methoxyundecanoate (7)

A solution of methyl 11-dodecenoate (**5**) in methanol was ozonized at ice-water temperature. The residue after evaporation was purified on a silica gel column using 50% ether in petroleum ether as eluant.

N.m.r. spectrum of an undiluted sample showed peaks at δ 1.32 (chain CH_2), triplet centered at 2.28 $\left(-CH_2-C(=O)-O\right)$, 3.45 ($-OCH_3$), 3.63 $\left(-C(=O)-OCH_3\right)$, and multiplet between 4.67–4.85 p.p.m. (—O—CH—O—).

In a cognate preparation for methyl 10-hydroperoxy-10-methoxydecanoate the yield of purified product was 74.2%.

*Di(methyl 11-methoxyundecanoate) Peroxide (**8**)*

To a solution of methyl 11-hydroperoxy-11-methoxyundecanoate (**7**) in methanol, solid ceric ammonium nitrate was added at room temperature until a slight orange color persisted. Dilution of the reaction mixture with ether led to separation of a white precipitate. The ether layer was extracted with aqueous sodium bicarbonate and the excess alkali was removed by repeated washing with water. After drying over anhydrous sodium sulfate, the ether solution was evaporated to obtain the diperoxide. It was purified by silica gel column chromatography using 50% ether in petroleum ether. Its i.r. spectrum showed no hydroxyl peak.

N.m.r. spectrum of a carbon tetrachloride solution showed peaks at δ 1.32 (chain CH_2), triplet centered at 2.27 $\left(-CH-C(=O)-O\right)$, 3.24 ($-OCH_3$), 3.62 $\left(-C(=O)-OCH_3\right)$, and triplet centered at 4.27 p.p.m. (—CH).

In a cognate preparation of di(methyl 10-methoxydecanoate) peroxide, the yield of purified material was 77.3%. Due to premature detonation of this diperoxide in the combustion tube, no satisfactory elemental analysis could be obtained.

Anal. Calcd. for $C_{24}H_{46}O_8$: C, 62.31; H, 10.02. Found: C, 62.66, 63.33, 63.20, 62.99; H, 11.09, 10.77, 10.73, 9.29.

It gave a single spot thin layer chromatogram.

In general, the radioactive ozonide **6*** was heated in about 5 ml of methanol for varying periods of time. If necessary, the alcohol was evaporated and the residue was diluted with a measured quantity of unlabelled methoxyhydroperoxide (**7**). The latter was isolated by column or thin layer plate chromatography and submitted to radioactive counting. Further details are listed in Table 1.

In order to facilitate additional purification of the isolated methoxyhydroperoxide it was converted to a diperoxide using ceric ammonium nitrate (8). The diperoxide was subjected to fractionation on an Eastman Chromagram sheet and the major regions of the chromatogram were examined for radioactivity. Details concerning purification of the diperoxide are listed in Table 2.

Stability Studies of Representative Methoxyhydroperoxides

The following experiments were conducted to assess the stability of the methoxyhydroperoxide involved in this study.

Methyl 10-hydroperoxy-10-methoxy-nonanoate (250 mg) was dissolved in 5 ml of methanol and the solution was refluxed vigorously on a steam bath for 1 h. N.m.r. and i.r. spectra of the residue obtained after evaporation of the reaction mixture were identical with those of unheated samples. A peak at 2.9 μ due to the —OH of the hydroperoxy group and a multiplet between δ 4.65–4.85 p.p.m. confirmed that not all of the methoxyhydroperoxide had been destroyed on refluxing.

Similarly, 9-hydroperoxy-9-methoxynonane was submitted to the same treatment as described above. In general, the i.r. and n.m.r. spectra were similar to those of unheated samples. I.r. investigation revealed the presence of an —OH group at 2.8–2.9 μ. In addition, a small peak due to $-C(=O)-$ absorption at 5.8 μ could be observed indicating some decomposition of the methoxyhydroperoxide to carbonyl bearing compounds. N.m.r. revealed the presence of $-OCH_3$ peak at δ 3.48 p.p.m. and absorption due to —O—CH—O— was centered in a multiplet around δ 4.70 p.p.m.

Quantitative assay by i.r. spectroscopy using the carbonyl peak at 5.8 μ and methyl nonanoate as standard revealed that at the end of 1 h refluxing, only 2.8% of the methoxyhydroperoxide had decomposed. Although results varied

with different samples in no case did we observe extensive decomposition of the methoxyhydroperoxide after refluxing it for 1 h.

Results and Discussion

After short reflux periods of the radioactive ozonide in methanol, t.l.c. (5% methanol in petroleum ether, $KI-CH_3CO_2H$ spray) revealed considerable amounts of unreacted ozonide together with a blank region at the point of spotting. Further refluxing reduced the intensity of the ozonide spot but showed two additional clear spots slightly above the origin. DNP spray revealed a yellow ozonide spot on the top, a yellow spot in the middle and two blank spots, one at the origin and another slightly above it.

When column chromatography was attempted, methanol was evaporated on a rotary evaporator and the residue was diluted with unlabelled methoxyhydroperoxide (**7**).[2] When thin layer plates were used, the methoxyhydroperoxide was added directly to the cooled reaction mixture and the solution was streaked across the plate. Any unreacted ozonide which was faster moving than the methoxyhydroperoxide was removed by elution with 5% methanol or ether in petroleum ether. In one experiment, refluxing of 250 mg of the ozonide for 1 h left behind 43 mg of it unreacted. To expedite collection of the methoxyhydroperoxide after removal of the ozonide, in some cases 50% ether in petroleum ether was used for elution purposes.

The methoxyhydroperoxide which was used for counting showed several impurities. On careful t.l.c. these were easily discernible with either of the spray reagents. A small amount of

[2]The stability of this methoxyhydroperoxide is such that it could have been refluxed together with the ozonide. But such a procedure only aggravated the problems encountered in its recovery and subsequent purification. The heat stability of methoxyhydroperoxides of this type is in sharp contrast to the stability of α-alkoxy-α-hydroperoxyacetophenones reported by Bailey and Chang (9). Obviously in the latter case, the $-\overset{\overset{O}{\|}}{C}-$ function adjacent to the hydroperoxy group exerts a decidedly destabilizing effect.

immovable material registered as a blank circle around the original point of spotting. On extended standing, a blank area developed on top of the methoxyhydroperoxide spot. These impurities could not be eliminated even after extensive attempts at purification. Repeated fractionation on a silica gel column (Table 1, expt. 3) led to continuous lowering of specific activity after each purification. There was thus none or only negligible amounts of ^{14}C labelled methoxyhydroperoxide formed during the reaction. The methoxyhydroperoxide assayed was obviously contaminated with ^{14}C bearing impurities and these were progressively being removed on repeated column chromatography.

It was thus deemed advisable to convert the methoxyhydroperoxide to a derivative which was produced by it alone and not by any of the impurities. Conversion to a diperoxide by action of ceric ammonium nitrate seemed appropriate.

From 475 mg of crude methoxyhydroperoxide (specific activity 104 ± 0.49 counts/min mg, expt. 4 in Table 1) after treatment with ceric ammonium nitrate and dilution with 49.1 mg of unlabelled diperoxide **8**, a total of 426.7 mg of impure diperoxide was obtained. It registered a specific activity of 58.73 ± 0.31 counts/min mg. Elution with 50% ether in petroleum ether on a silica gel column yielded 259.3 mg of nonperoxidic material, specific activity 50.54 ± 0.22 counts/min mg and 67.4 mg of partially pure diperoxide, specific activity 43.89 ± 0.51 counts/min mg.

The diperoxide on further careful examination by t.l.c. revealed the presence of impurities. With iodide spray, these usually showed up as blank spots crowning the diperoxide region and as a blank smear extending from the point of origin to the diperoxide spot. The diperoxide was therefore submitted to further fractionation (Table 2). About 22 mg of it was streaked across an Eastman Chromogram sheet and developed in 50% ether in petroleum ether. Spraying with $KI-CH_3CO_2H$ spray revealed a brown streak due to the diperoxide and a blank area adjacent to it on the top. The sheet was cut into three portions, one covering the diperoxide region, another covering the blank area on top, and a third covering the area from the point of streaking to the diperoxide region. The adsorbent layer from these cuttings was scraped off and washed thoroughly with ether. The ether solutions were evaporated and specific activities of the residues were determined.

The blank area on top of the chromatogram yielded about 5 mg of material with a specific activity of 77.36 ± 0.74 counts/min mg. The diperoxide region gave 16.6 mg of material with a specific activity of 2.34 ± 0.2 counts/min mg. The third fraction covering the region from the point of streaking to the diperoxide zone gave 1.6 mg of material which was nonradioactive. The concentration of radioactivity in the nonperoxidic region as opposed to only minor amounts in the diperoxide region again indicates that under the experimental conditions employed, no substantial amounts of ozonide were converted to the methoxyhydroperoxide. Indeed, Criegee and Korber (6) have drawn attention to the fact that the mechanism of fragmentation of ozonides by alcohols is similar to the cleavage of ozonides by alkalis as proposed by Kornblum and de la Mare (10).

Because the ozonide methanolysis route proposed by Razumovskii and Yurev (3) ozonide → methoxyhydroperoxide → ester makes only a negligible ($\not> 1\%$) contribution, the arguments of these authors concerning ozonide–zwitterion equilibria are not supported.

The authors wish to thank Prof. S. N. Naldrett of this Department for the use of counting facilities. Financial support through Defence Research Board Grant No. 9530-17 is gratefully acknowledged.

Deuterium Isotope Effects in the Oxidation of 2,3-Dimethyl-2-butene via the Bromohydroperoxide, by Singlet Oxygen and by Triphenyl Phosphite Ozonide[1,2]

KARL R. KOPECKY AND JOHAN H. VAN DE SANDE[3]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received June 2, 1972

The partially deuterated alkenes $(CH_3)_2C{=}C(CD_3)_2$ (**1***b*) and $CH_3CD_3C{=}CCH_3CD_3$ (**1***c*) were prepared and converted to the corresponding allylic hydroperoxides by the routes shown in the title. Two bromohydroperoxides were formed from **1***b* in a 1.6:1 ratio with the major isomer having the OOH group on the carbon bearing the CH_3's. On treatment with base at 0° this mixture formed two allylic hydroperoxides in a 2.2:1 ratio with the major isomer having the OOH group on the carbon bearing the CD_3's, showing migration of the OOH group. This isomer predominated in a 1.4:1 ratio when **1***b* was oxidized with singlet oxygen at 15 or −52° and in a 1.6:1 ratio when **1***b* was oxidized with triphenyl phosphite ozonide at −70°. Under the same conditions C—H bond breaking also predominated in the oxidation of **1***c*, by 2.1:1 via the bromohydroperoxide, by 1.4:1 with singlet oxygen, and by 1.3:1 with triphenyl phosphite ozonide. Migration of the OOH group in the reaction of the bromohydroperoxide of **1***b* does not occur by way of a 1,2-dioxetane. A perepoxide may be the intermediate. Neither perepoxides nor 1,2-dioxetanes are involved in the singlet oxygen oxidation of **1***b* and *c*. At −70° the triphenyl phosphite ozonide oxidations do not proceed by way of these intermediates, either, or by way of singlet oxygen. The intermolecular deuterium isotope effect in the singlet oxygen oxidation of both *cis*- and *trans*-2,3-diphenyl-2-butene was found to be 1.1.

Les alcènes partiellement deutériés $(CH_3)_2C{=}C(CD_3)_2$ (**1***b*) et $CH_3CD_3C{=}CCH_3CD_3$ (**1***c*) ont été préparés puis convertis en hydropéroxydes allyliques correspondants, selon le schéma exposé dans le titre de ce mémoire. Deux hydropéroxydes bromés sont obtenus à partir de **1***b* dans le rapport 1.6:1, l'isomère prépondérant ayant le groupe OOH sur le carbone portent du CH_3. Par traitement basique à 0°, ce mélange conduit à deux hydropéroxydes allyliques, dans le rapport 2.2:1; avec l'isomère possédant le groupe OOH sur le carbone du CD_3, en majorité, montrant ainsi la migration du groupe OOH. Cet isomère prédomine dans le rapport 1.4:1 lorsque **1***b* est oxydé par l'oxygène singulet à 15 ou −52° et dans le rapport 1.6:1 lorsque cette oxydation est effectuée par l'oxyde de la triphénylphosphite à −70°. Dans les mêmes conditions, la cassure de la liaison C—H prédomine aussi dans l'oxydation de **1***c*, dans le rapport 2.1:1 via le bromohydropéroxyde, 1.4:1 dans le cas de l'oxygène singulet, et 1.3:1 avec l'ozonide de la triphénylphosphite. La migration du groupe OOH dans la réaction du bromohydropéroxyde de **1***b* ne se produit pas par l'intermédiaire du dioxétane-1,2. Une perépoxyde serait l'intermédiaire. Ni les perépoxydes, ni les dioxétanes-1,2 n'interviennent dans l'oxydation par l'oxygène singulet de **1***b* et *c*. A −70° les oxydations par l'ozonide de la triphénylphosphite ne passent pas par ces intermédiaires, ni par oxygène singulet. L'effet isotopique intermoléculaire de deutérium dans l'oxydation par l'oxygène singulet des *cis* et *trans* diphényl-2,3 butène-2 a été trouvé égal à 1.1.

Introduction

β-Halohydroperoxides derived from a variety of tetrasubstituted ethylenes are converted rapidly at 0° by base to allylic hydroperoxides in good to excellent yields (1, 2). The reaction sequence shown in Scheme 1 represents an alternate synthesis of allylic hydroperoxides which are usually prepared by the oxidation of alkenes with singlet oxygen (3). Indeed, essentially the same distributions of products are formed from the β-halohydroperoxides of 1,2-dimethylcyclohexene (1) and 2-methyl-3-(4-methoxyphenyl)-2-butene (2*b*) as are formed by the oxidation of these alkenes by singlet oxygen.

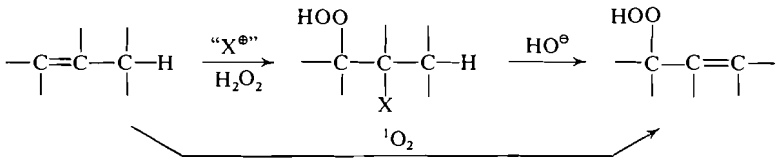
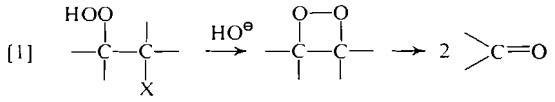


SCHEME 1

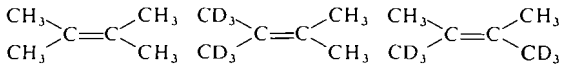
However, the formation of allylic hydroperoxides from β-halohydroperoxides is not a general reaction. In sharp contrast to the results outlined above no trace of allylic hydroperoxides could be found among the products of reaction, under similar conditions, between base and a number of less highly substituted ethylenes. A variety of products is formed (1). Carbon–carbon bond cleavage occurs in some cases (1, 4) which indicates that cyclic peroxides may be formed as intermediates, eq. 1. Trimethyl-



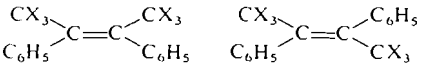
[1]

1,2-dioxetane (5, 6) and 3-methyl-3-phenyl-1,2-dioxetane (6) have been isolated recently from such reactions and are cleaved to carbonyl compounds on heating. No such cleavage products have yet been observed in the reactions between the β-halohydroperoxides of tetrasubstituted ethylenes and base.

The present study was made in an attempt to distinguish between the several possible mechanisms that could be envisaged for the transformation of β-halohydroperoxides to allylic hydroperoxides and, in particular, to determine if the transformation also involves 1,2-dioxetanes as intermediates. In addition, it was of interest to determine whether this reaction and the reaction between singlet oxygen and tetrasubstituted ethylenes have common intermediates as well as common products. Two partially deuterated 2,3-dimethyl-2-butenes, 1,1,1-trideuterio-2-methyl-3-trideuteriomethyl-2-butene (**1***b*) and 2,3-bis(trideuteriomethyl)-2-butene (**1***c*) were prepared. The intramolecular deuterium isotope effects were determined for the conversion of these alkenes to allylic hydroperoxides by the routes (*1*) reaction between their β-bromohydroperoxides and base, (*2*) by oxidation with singlet oxygen generated by a variety of sensitizers and from the hydrogen peroxide–



1*a* **1***b* **1***c*



cis-**2** *trans*-**2**

a X = H *a* X = H
b X = D *b* X = D

sodium hypochlorite reactions (3*b*), and (*3*) by oxidation with triphenyl phosphite ozonide (7). Also, *cis*- and *trans*-1,1,1,4,4,4-hexadeuterio-2,3-diphenyl-2-butene (*cis*- and *trans*-**2***b*) were prepared and the intermolecular deuterium isotope effects in the singlet oxygen oxidation of *cis*- and *trans*-2,3-diphenyl-2-butene (*cis*- and *trans*-**2***a*) were determined.

Results

Preparation of the Deuterated Alkenes

The syntheses of the deuterated alkenes **1***b*, **1***c*,[4] and *cis*- and *trans*-**2***b* are outlined in Schemes 2, 3, and 4, respectively.[5] The deuterated methyl hydroxyisobutyrate (Scheme 2) was prepared by addition of deuterium cyanide to hexadeuterioacetone followed by hydrolysis of the resulting product and then treatment of the hydroxy acid so obtained with diazomethane.

[4]Although only the *cis* isomer of **1***c* is shown as the product of the reaction sequence, nearly equimolar amounts of the *cis* and *trans* isomers undoubtedly are formed (8).

[5]In principle, a simpler route to **1***b* would involve addition of trideuteriomethylmagnesium iodide to an ester of isobutyric acid followed by dehydration of the resulting alcohol. However, in numerous exploratory experiments dehydration of 2,3-dimethyl-2-butanol by various methods in the absence of strong acid produced mainly 2,3-dimethyl-1-butene and only small amounts of the desired internal alkene. Acid-catalyzed dehydration of the alcohol gives predominantly the internal alkene, but extensive isotopic exchange would have occurred in the dehydration of the appropriate partially deuterated alcohol (9).

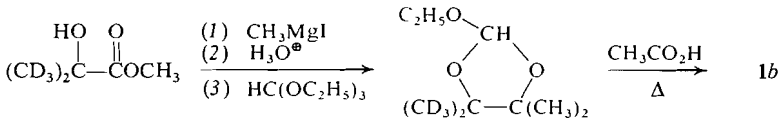
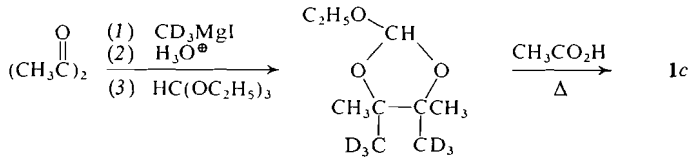
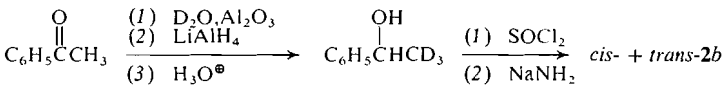


SCHEME 2



SCHEME 3



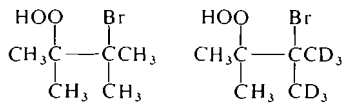
SCHEME 4

Only two points concerning the reactions will be made here. We found the preparation and subsequent decomposition (without isolation) of the orthoformate ester derivative of 2,3-dimethyl-2,3-butanediol to be a more convenient route (10) for the preparation of 2,3-dimethyl-2-butene (**1***a*) than the preparation and decomposition of the thionocarbonate derivative (11). Also, 2,2,2-trideuterioacetophenone could be prepared quickly and on a large scale by passing a solution of acetophenone through a long column of alumina pretreated with deuterium oxide.

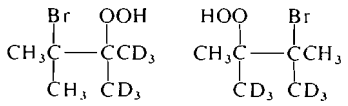
Mass spectral analysis (12) at low ionizing voltage (9.5–12 eV) showed that the trideuteriomethyl groups of **1***b* are 99.4% deuterated, those of **1***c* are 95.3% deuterated, and those of *cis*- and *trans*-**2***b* are 92% deuterated. Analysis of the $M^{\oplus} - CX_3$ (X = H or D) region of the mass spectrum taken at 70 eV of **1***b* and *c* showed that very little, if any, exchange of deuterium between the CD_3 and the CH_3 groups had occurred during the preparation of these materials.

Isotope Effect in Elimination of Hydrogen Bromide from 3-Bromo-2,3-dimethyl-2-butyl Hydroperoxide

The alkenes **1***b* and *c* were converted to the bromohydroperoxides, **3***b* + *c* and **3***d*, respectively, by adding 1,3-dibromo-5,5-dimethylhydantoin (dibromantin) to solutions of the alkenes and excess 98% hydrogen peroxide in ether at −40° and then allowing the temperature to rise to 0° (1). The two products from **1***b*, 3-bromo-4,4,4-trideuterio-3-trideuteriomethyl-2-methyl-2-butyl hydroperoxide (**3***b*) and 3-



3*a* **3***b*



3*c* **3***d*

bromo-1,1,1-trideuterio-2-trideuteriomethyl-2-butyl hydroperoxide (**3***c*) were formed in unequal amounts. The material containing the hydroperoxy group on the carbon bearing the CH_3 groups, **3***b*, made up 61.5% of the product mixture. The product ratio was determined from the n.m.r. spectrum (CCl_4) of the product mixture by comparing the area of the signal at τ 8.57, due to the CH_3 groups of **3***b*, with the area of the signal at τ 8.20, due to the CH_3 groups of **3***c*. The assignments are made on the basis that a bromine atom causes a greater deshielding of β-protons than does a hydroxyl or an alkoxy group (13) and that the hydroperoxy group causes a deshielding similar in magnitude to that of the latter groups. For example, the n.m.r.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

4 5 6

spectra (CCl_4) of 3-chloro-2,3-dimethyl-2-butyl hydroperoxide (**4**) and 3-chloro-2,3-dimethyl-2-butanol (**5**) show signals for the methyl groups at τ 8.38 and 8.60, and at τ 8.36 and 8.69, respectively (1), and the *gem*-dimethyl groups of 3-bromo-2-methoxy-2,3-dimethylbutane (**6**), prepared by the addition of dibromantin to **1***a* in methanol, absorb at τ 8.26 and 8.67.

Freshly prepared samples of the bromohydroperoxides **3***b* + *c* and **3***d* were converted to allylic hydroperoxides by allowing them to react at 0° for 6 h with a five-fold excess of sodium deuteroxide in methanol-d_4, eqs. 2 and 3. Benzene was added as an internal standard so as to be able to obtain material balances for the reactions. A material balance was also obtained in this way for the conversion of the undeuterated bromohydroperoxide **3***a* to 2,3-dimethyl-3-hydroperoxy-1-butene (**7***a*) under similar conditions, eq. 4. The reaction mixtures were analyzed directly by n.m.r. spectroscopy. The relative intensities of the signals at τ 8.70, due to the CH_3 groups attached to the carbon bearing the hydroperoxy group, and at τ 8.22, due to the allylic CH_3 group, of the allylic hydroperoxides were measured by careful integration and the ratios **7***c*/**7***b* and **7***d*/**7***e* were determined as described in the Experimental. Integration of methanolic solutions of **7***a* made from freshly prepared samples of **3***a* gave area ratios for the peaks at τ 8.70 and 8.22 of 2.02 ± 0.06 to 1.00, so no corrections were applied to the area ratios obtained from the runs using the deuterated bromohydroperoxides. However, this area ratio was somewhat larger than 2.0 to 1.0 when samples of **3***a* which had been stored for several weeks at 5° were used to prepare solutions of **7***a*. It was found that this was due to the formation of some 2,3-epoxy-2,3-dimethylbutane whose n.m.r. absorption in methanol solution is almost superimposable upon that of the *gem*-dimethyl group of **7***a*, see below.

The results in Table 1 show that in each case conversion to allylic hydroperoxide is essentially quantitative. Furthermore, it is clear that in the case of the bromohydroperoxides **3***b* and *c* a shift of the hydroperoxy group occurs during the reaction. The compound with the hydroperoxy group on the carbon bearing the CH_3 groups, **3***b*, predominates in the starting mixture while in the product mixture the compound with the hydroperoxy group on the carbon bearing the CD_3 groups, **7***c*, predominates. Clearly, the reaction does not proceed by a direct elimination of the elements of HBr or DBr. In this case the product ratio, **7***c*/**7***b* would have been the same as the ratio, **3***c*/**3***b*, of the starting materials, namely, 0.63. The actual product ratio, **7***c*/**7***b*, is about 2.2.

Further evidence that a C—H or C—D bond is not broken in the rate-determining step of the elimination was obtained by carrying out the elimination reactions on the mixture of **3***b* and *c* with less than one equivalent of base. The relative amounts of **3***b* and *c* remaining at various conversions were determined by n.m.r.

*Sufficient 0.55 *N* NaOD was added in each case to 0.11 *M* solutions of 3*b* + *c* to give the conversions shown.

†Measured by n.m.r. spectroscopy from relative peak heights of the signals at τ 8.19 of 3*c* and at τ 8.58 of 3*b*. The ratio of 3*b*/3*c* formed from 1*b* as determined by integration of these signals is 1.6.

‡Measured by n.m.r. spectroscopy from relative peak heights (normalized) of signals of 7*c* at τ 8.22 and of 7*b* at τ 8.70. On complete conversion this ratio is 2.2 as measured by integration of these signals (Table 1).

spectroscopy. The results in Table 2 show that the two bromohydroperoxides 3*b* and *c* both react at essentially the same rate. The ratio, 3*b*/3*c*, changes hardly at all up to 57% reaction. Isotope effects, k_H/k_D, of from 5–9 have been found in a variety of base-promoted elimination reactions of alkyl bromides (14). Thus, if the C—H or C—D and C—Br bonds were being broken simultaneously in the reaction of 3*b* and *c* then 3*c* should be consumed more rapidly than 3*b*, in contrast to what is observed.

The product ratio, 7*c*/7*b*, even at 31% conversion, shows that a migration of the hydroperoxy group has occurred. The ratios of 7*c*/7*b* given in Table 2 differ from those given in Table 1 because the former were determined from the relative peak heights of the signals due to the CH_3 groups of 7*c* and *b*. It was necessary to use the less accurate peak height method of analysis because the absorption of the allylic CH_3 group of 7*c* was too near that of the CH_3 groups at τ 8.20 of the starting material 3*c* for accurate integrations of the signals to be made.

The results suggest that 3*b* and *c* are converted by base to the same reactive bromine-free intermediate which can then lose either a proton or deuteron equally well, except for an isotope effect, to give the allylic hydroperoxides 7*b* and *c*.

The results obtained from the reaction between 3*d* and base are consistent with this. The major product of the reaction is 7*d*, formed by loss of hydrogen bromide, rather than 7*e*, formed by loss of deuterium bromide, and the product ratio, 7*d*/7*e*, is essentially the same as the ratio, 7*c*/7*b*, of products obtained from the mixture of 3*b* and *c*, Table 1.

The results above were obtained before it was discovered that some 2,3-epoxy-2,3-dimethylbutane was formed under these conditions from samples of 3*a* which had been stored for some time. As a result of the method of analysis of the reaction mixtures the ratios, 7*c*/7*b* and 7*d*/7*e*, given in Table 1 are minimum and maximum values, respectively. For example, had 5% of epoxide actually been present in the reaction mixtures obtained from 3*b* + *c* and 3*d*, the corrected value for the ratio, 7*c*/7*b*, would be 2.6 and that for the ratio, 7*d*/7*e*, would be 1.8.

It is not known how much epoxide was formed during reaction of the deuterated bromohydroperoxides with base, but the amounts formed, if any, are probably quite small because fresh samples of the deuterated bromohydroperoxides were used so the ratios, *7c*/*7b* and *7d*/*7e*, are uncorrected. Barely detectable amounts, less than 1%, of epoxide were formed from fresh samples of *3a*, while a maximum of about 12% was formed from some of the older samples of *3a*, see below.

Spectroscopic Search for an Intermediate

At the time that these results were obtained it was thought that the intermediate formed during the conversion of the β-bromohydroperoxide, *3a*, to the allylic hydroperoxide, *7a*, might be tetramethyl-1,2-dioxetane (**8**), eq. *5a*. The

[5a] 
8

formation of **8** from *3a* would be consistent with evidence which was accumulating (1, 4, 15) which suggested that 1,2-dioxetanes were formed in reactions between other suitably substituted hydroperoxides and base. Attempts were made to detect **8** by following the reaction between *3a* and base in methanol between −17.5 and −37.5° by n.m.r. spectroscopy in the thermoregulated probe of a 100 MHz n.m.r. spectrometer. The reaction is rapid enough so that it can be monitored conveniently in this way at temperatures as low as −40°, Table 3. The rate of disappearance of *3a* obeyed second order kinetics over the first 50–60% of reaction during which the reactions were followed.

Besides absorptions for starting material *3a* and product *7a*, a new absorption, a sharp singlet, appeared about 3 Hz downfield from the absorption of the *gem*-dimethyl group of the allylic hydroperoxide and increased in intensity as the reaction progressed until about 40% reaction, after which the intensity of this signal remained constant. It was determined that this signal was due to a compound having 12 equivalent protons by careful integration of the starting material and products before and during reaction using tetramethylsilane as internal standard. The signal was shown to be due to

TABLE 3. Rate of reaction between 3-bromo-2,3-dimethyl-2-butyl hydroperoxide (*3a*) and hydroxide ion in methanol*

−37.5	0.22	0.83	1.0
−27.5	0.15	0.82	1.7
−17.5	0.23	0.58	3.5

*At −17.5° $\Delta H^{\ddagger}$ = 6.9 kcal/mol, $\Delta S^{\ddagger}$ = −47 e.u. for disappearance of *3a*.

2,3-epoxy-2,3-dimethylbutane by comparing the chemical shift of authentic material in methanol solution at the temperatures used and by peak enhancement on addition of small amounts of authentic material to reaction mixtures at low temperatures. About 12% of the epoxide was formed from the samples of bromohydroperoxide used for the rate studies. These samples had been stored for several weeks at 5°. When fresh samples of *3a* were used in the reaction the signal due to the epoxide was barely detectable; less than 1% was formed. The epoxide presumably is formed from the corresponding bromohydrin which may be formed by the slow decomposition of the bromohydroperoxide, *3a*.

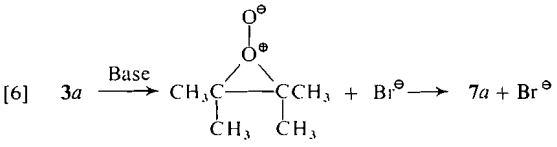
No signals other than those due to *3a*, *7a*, and the epoxide could be detected above τ 8 in the n.m.r. spectrum of the reacting mixtures at low temperature. Careful integration indicated that there was no significant absorption other than those due to *3a* and *7a* at around τ 8.20.

Authentic tetramethyl-1,2-dioxetane (**8**) was prepared some time after these experiments were carried out (5). It is not converted to *7a* by base in methanol even in the presence of added bromide ion and in methanol solution it shows absorption at τ 8.53, so that it clearly is not the intermediate which is formed in the reaction between *3a* and base.

There are two other routes involving symmetrical intermediates that appear to be plausible by which the allylic hydroperoxide may be formed from *3a*. One route is fragmentation of the anion of *3a* to give the alkene **1***a*, singlet oxygen, and bromide ion followed by reaction between **1***a* and singlet oxygen, eq. *5b*. This

[5b] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

route to the formation of **7***a* can be ruled out on two grounds. First, the reaction between singlet oxygen and **1***a* is not a diffusion controlled reaction (16) so that a significant amount of the singlet oxygen would be deactivated before it could react and the conversion of **3***a* to **7***a* by this route could not be quantitative. In fact, the yield is essentially quantitative. Second, if the reaction between **3***a* and base proceeded as in eq. 5*b* the singlet oxygen oxidation of the deuterated analogs of **1***a*, *b*, and *c* would give the same distributions of products as are obtained from the reactions of **3***b* + *c* and **3***d* with base. As is shown below, the actual product distributions are quite different from each other.



9

The remaining plausible route, and one which we have not yet ruled out, for formation of **7***a* from **3***a* proceeds by way of the perepoxide **9**, eq. 6. Attempts to trap the intermediate **9** with added azide ion have been unsuccessful. A reaction between **3***a* and base in 40% water – 60% CD_3OD saturated with sodium azide (about 0.4 *N*) at 0° formed **7***a* exclusively as judged by the n.m.r. spectrum of the solution after reaction.

Intramolecular Isotope Effects in the Singlet Oxygen and Triphenyl Phosphite Ozonide Oxidation of 2,3-Dimethyl-2-butene

The partially deuterated alkenes **1***b* and *c* were oxidized in methanol to the corresponding mixtures of allylic hydroperoxides with singlet oxygen generated by dye photosensitization (3) and by the reaction between sodium hypochlorite and hydrogen peroxide (3*a*, 3*b*, 17). Mixtures of allylic hydroperoxides were produced whose compositions were analyzed directly by n.m.r. spectroscopy, as described above for the bromohydroperoxide reactions, after extraction into ether and subsequent complete removal of the ether under reduced pressure or after preparative isolation. In these oxidations the allylic hydroperoxides formed by loss of hydrogen rather than deuterium from carbon predominate only to a slight extent. The product ratios, expressed as isotope effects, k_H/k_D, in Table 4 show only a small variation with the source[6] of singlet oxygen and temperature. Indeed, all the values of k_H/k_D for the singlet oxygen oxidations are within 8% of 1.40.[7] The variations of k_H/k_D with temperature and solvent, which are undoubtedly present, are too small to be distinguishable in these experiments. However, the method of product analysis used is accurate enough to show clearly that the observed isotope effects in the singlet oxygen oxidations of the unsymmetrically deuterated alkene **1***b* and the symmetrically deuterated alkene **1***c* differ by no more than 8%. It is also clear that there is a significant difference between the ratios of allylic hydroperoxides formed in these oxidations of **1***b* and *c* and the ratio of allylic hydroperoxides formed by the reactions between base and the bromohydroperoxides of **1***b* and *c*, Table 1, even when the photooxygenation was carried out in the presence of base at −52° (run 8, Table 4). This shows that if any intermediates are formed in the singlet oxygen oxidation of the alkenes **1***b* and *c* they must be different from the intermediates formed in the reactions between base and the bromohydroperoxides of these alkenes.

Triphenyl phosphite ozonide (23) has been shown to oxidize **1***a* to the allylic hydroperoxide **7***a* at −30° and to decompose to triphenyl phosphate and singlet oxygen at −15° (27). It was suggested that **1***a* was oxidized by the singlet oxygen released. In an attempt to distinguish between this mode of oxidation and

[6]A variety of sensitizers was used in order to test the then recent suggestion (18) that sensitizers with high triplet state energies produced more $^1\Sigma_g^+$ than $^1\Delta_g$ oxygen molecules and that these had different reactivities. The suggestion was made to explain the observed (19) sensitizer dependence of product distribution in oxidation of cholest-4-en-3β-ol. It has since been shown that this variation in product distribution is probably due to a direct reaction between sensitizer and substrate which competes with the singlet oxygen ($^1\Delta_g$) reaction and produces a different product (20), and that $^1\Sigma_g^+$ oxygen molecules are deactivated so rapidly by solvent that no reaction with substrate could take place (21).

[7]It has been reported briefly that isotope effects of 1.2 to 2.1 were obtained in the singlet oxygen oxidation of **1***b*, *c*, and 2,2,6,6,2′,2′,6′,6′-octadeuteriocyclohexylidenecyclohexane, unpublished work cited in ref. 22.

NOTE ADDED IN PROOF: These results have now been published (55) and those for **1***b* and *c* are in excellent agreement with the results presented here.

a possible direct reaction between the alkene **1***a* and the ozonide, the alkenes **1***b* and *c* were allowed to react with the triphenyl phosphite ozonide at −28° in dichloromethane and the products isolated. The isotope effect in each case is not significantly different from those observed in the oxidations of these alkenes by singlet oxygen generated by unambiguous routes. The oxidations with triphenyl phosphite ozonide were repeated[8] at −70° after it was shown that there is a direct reaction between the ozonide and **1***a* at this temperature which produces **7***a* (24). The reactions were carried out in duplicate with each alkene at the same time. The difference in isotope effects between the two alkenes is somewhat larger in the reactions at −70° than it is at −28° and we feel that at −70° this difference is greater than the probable experimental error of about 8%.

[8]We thank Dr. J.-Y. Ding for performing these experiments.

Intermolecular Deuterium Isotope Effects in the Singlet Oxygen Oxidation of cis- and trans-1,2-Dimethylstilbene

The intramolecular isotope effects in the singlet oxygen oxidation of **1***b* and *c* are quite small. This is not unexpected in view of the high reactivity of **1***a* toward singlet oxygen (16, 25). The energy of activation for the reaction between singlet oxygen and **1***a* is reported to be 0.5 kcal/mol (25*c*). A brief study was made to determine whether the magnitude of the isotope effect would be greater in the oxidation of a less reactive alkene than it is in the oxidation of **1***b* and *c*. The dimethylstilbenes, *cis*- and *trans*-**2***a*, were chosen as substrates for this study as they are readily prepared and were expected to be less reactive toward singlet oxygen than is **1***a*. This expectation was substantiated qualitatively by finding that the methylene blue photosensitized oxidation of 0.014 mol of *cis*-**2**, the more reactive of the two isomers, required 2 h while the oxidation, under identical conditions, of

0.012 mol of **1***a*, required 45 min. After reduction of the intermediate hydroperoxide a 48% yield of 2,3-diphenyl-3-butene-2-ol (**10**) was isolated from the oxidation of *cis*-**2***a*, eq. 7.

[7] *cis*-**2***a* $\xrightarrow[(3)\ NH_4Cl]{(1)\ {}^1O_2,\ (2)\ LiAlH_4}$ $CH_3C(OH)(C_6H_5)C(=CH_2)C_6H_5$

10

In a competitive oxidation (25*a*) it was found that *cis*-**2***a* was about 10 times as reactive as *trans*-**2***a* toward singlet oxygen, in agreement with a previous report that *cis*-**2***a* is more reactive than *trans*-**2***a* (26).

The intermolecular isotope effects in the singlet oxygen oxidations were determined by oxidizing mixtures of *cis*-**2***a* and *cis*-**2***b* and of *trans*-**2***a* and *trans*-**2***b* to partial completion in methanol. The unreacted alkenes were isolated by column chromatography. The composition of the initial and final mixtures of alkenes was determined by mass spectrometry using an ionizing voltage of 9.5 eV. The mass spectrometric analysis of weighed mixtures of *cis*-**2***a* and *b* and of *trans*-**2***a* and *b* reproduced the synthetic ratios to within 2% so it is felt that the isotope effects determined in this way should be accurate to within about 10% or less. The isotope effects, Table 5, are even smaller than those obtained in the singlet oxygen oxidations of **1***b* and *c*. Also, they are the same for both *cis*- and *trans*-**2***a* even though *trans*-**2***a* is less reactive than *cis*-**2***a* toward singlet oxygen.

Discussion

Conversion of **3** *to* **7**

The product distribution observed in the conversion of the mixture of **3***b* + *c* to **7***b* + *c* indicates that migration of the hydroperoxy group occurs in the reaction. This migration cannot occur by fragmentation to singlet oxygen and alkene followed by recombination, eq. 5, or by way of tetramethyl-1,2-dioxetane (5). This appears to leave, as a result of this process of elimination, formation and subsequent reorganization of the perepoxide **9** as the pathway for migration of the hydroperoxy group. The perepoxide **9** must be a short-lived species, at least in the reaction medium used, as attempts to detect it by n.m.r. spectroscopy at temperatures as low as −37° gave no evidence for its existence. Attempts to trap **9** with azide ion also failed. Under the reaction conditions used **9** could be converted to **7** either by an intramolecular reorganization or by reaction with base.

Although the intermediate under discussion has been formulated as a perepoxide the migration of the hydroperoxy group in the present system can also be formulated as proceeding by way of a pair of rapidly interconverting open chain zwitterions, eq. 8, in which case the

[8] $CH_3C(O^{\ominus})(O)C(CH_3)_2C^{\oplus}H_2 \rightleftharpoons$ **9** $\rightleftharpoons CH_3C^{\oplus}(O)C(CH_3)_2O^{\ominus}$

perepoxide would represent a transition state or an intermediate between the two zwitterions.

Evidence that such open chain zwitterions do not play a role in the conversion of bromohydroperoxides to allylic hydroperoxides comes from the reaction between base in methanol and 3-bromo-3-methyl-2-(4-methoxyphenyl)-2-butyl hydroperoxide (**11**), eq. 9, in which migration of the hydroperoxy group also clearly occurs. A mixture of the allylic hydroperoxides **12** and **13** is formed in a 6.3:1 ratio (2*b*). One would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[9] 
11 12 13

Ar = 4-Methoxyphenyl

expect such a great difference in the stabilities of the two possible open chain zwitterions that might be derived from **11** that **12** should be the exclusive product. A perepoxide intermediate might be more likely to lead to the observed product distribution.

The perepoxides derived from **3** and **11** must form allylic hydroperoxides by a process with a very low activation energy and which may be concerted. This would account for the relatively small magnitude of the isotope effect observed in the conversion of **3** to **7** and the perhaps smaller than expected ratio of **12**:**13** formed from **11**. If the perepoxides rearranged in an intramolecular, concerted reaction the carbon, hydrogen, and oxygen atoms involved in the hydrogen transfer could not be colinear. This would also result in the formation of products with little discrimination as discussed below for the singlet oxygen reactions. In fact, if the perepoxide reaction is concerted the transition state geometry for this reaction must resemble quite closely that of the singlet oxygen reaction.

Until recently there appeared to be no authentic examples of compounds which had structures and which gave reactions analogous to those of **9**. Now, two classes of such "strained dipolar species" have been characterized definitively: the episulfoxides (28) and the aziridine *N*-oxides (29). When suitably substituted these materials rearrange thermally at relatively low temperatures to give allylic sulfenic acids and allylic hydroxylamines, respectively. Further, aziridine *N*-oxides do not rearrange to the four-membered ring compounds, 1,2-oxazetidines (29). In these respects the behavior of the proposed intermediate **9** parallels that of the above materials very closely.

It is possible to compare the neighboring group effect of the hydroperoxy anion with that of the oxide ion in the 2,3-dimethyl-3-bromo-2-butyl system. Because the bromohydroperoxide **3***a* is stable in neutral methanol for several days, at least, the perepoxide **9** must be formed from the conjugate base of **3***a*. Since no evidence was obtained for the formation of any of the dioxetane **8**, cyclization by the neighboring hydroperoxy anion with participation of the disubstituted oxygen to give **9** is at least 50 times faster than is cyclization with participation of the anionic oxygen to give **8**. This is the reverse of what occurs in the reactions between base and 3-bromo-2-methyl-2-butyl hydroperoxide (5) and 1-chloro-2-methyl-2-propyl hydroperoxide (30) in which only 1,2-dioxetanes are formed initially. Apparently, in a system such as **3***a* where a tertiary halide is to be displaced by the hydroperoxy anion, only a small amount of nucleophilic assistance is required so that the inherently more favorable cyclization to form a three-membered ring can compete effectively with the cyclization to form a four-membered ring. Even so, the disubstituted oxygen atom of the hydroperoxy anion is a much less effective neighboring group than is the oxide ion in the present system. From the observation, that in the reaction between base and samples of **3***a* which were contaminated with bromohydrin, epoxide formation was essentially complete by the time 50% of **3***a* had been consumed together with the estimate that the pK_a's of **3***a* ($pK_a \approx 13$ (31)) and the corresponding bromohydrin ($pK_a \approx 18$ (32)) differ by about five pK_a units, it can be reckoned that cyclization of oxide ion to epoxide is 10^4–10^6 times as fast as cyclization of hydroperoxy anion to **9**.

Mechanism of Singlet Oxygen Oxidation

Three mechanisms have been proposed for the oxygenation of alkenes to allylic hydroperoxides by singlet oxygen: (*1*) formation and subsequent reorganization of a perepoxide intermediate which was initially proposed to account for the large rate enhancement caused by increasing substitution of the double bond by alkyl groups (25*a*, 33); (*2*) formation and subsequent reorganization of a 1,2-dioxetane which was proposed when cleavage products were observed in photooxygenation of indene (34); (*3*) a concerted reaction in which the C—O

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and C—H bonds are formed simultaneously in a cyclic transition state. This latter mechanism was proposed to explain the geometric requirements of the photooxygenation reactions in steroids (35) and the lack of solvent and substituent effects on product distribution (3*a*, 3*b*, 36). Intervention of 1,2-dioxetanes as intermediates in the conversion of alkenes to allylic hydroperoxides by singlet oxygen can be disregarded as a general phenomenon as it has been shown that trimethyl- and tetramethyl-1,2-dioxetane are not converted to allylic hydroperoxides even when treated with base (5). The results of the present study certainly provide no evidence against a concerted mechanism and provide strong evidence that perepoxides are not formed in this reaction.

The perepoxide mechanism had appeared to receive experimental support when it was reported that photooxygenation of **1***a* and of 1,2-dimethylcyclohexene in the presence of azide ion resulted in the formation of high yields of hydroperoxy azides (37). It was suggested that azide ion trapped perepoxides formed by reaction of singlet oxygen with these alkenes. It has now been shown (38) that the formation of hydroperoxy azides is a radical reaction which has nothing to do with the allylic oxygenation reaction. Furthermore, the present work shows that the perepoxide derived from **7***a* cannot be trapped by azide ion anyway under reaction conditions similar to those which gave hydroperoxy azides from **1***a* (37).

Evidence has existed for some time that supports strongly a concerted mechanism for the singlet oxygen oxygenation of alkenes. It is difficult to explain the conformational requirements of the allylic hydrogen which is to be removed by singlet oxygen (35) and the complete lack of reactivity of norbornene, methylenecyclopentene, and methylenecyclohexane towards singlet oxygen (39) in terms of either a dioxetane or a perepoxide mechanism without invoking an extremely unlikely reversible formation of these species. Such arguments have been made already (22).[9]

The magnitudes of the deuterium isotope effect in the photooxygenation of **1***b* and *c* and of **2***a* and *b* might appear to be rather small for a reaction in which a C—H or a C—D bond is broken in the rate determining step. There can be several reasons for this small isotope effect. The reaction has a very small energy of activation so that a large isotope effect is not to be expected. In the transition state for the concerted reaction, it is unlikely that the oxygen, hydrogen, and carbon atoms involved in the hydrogen transfer are colinear. It has been pointed out that in such a situation the isotope effect should be smaller than for a process in which all these atoms can be colinear (41). Finally, it is theoretically possible to have small and even inverse isotope effects for reactions in which hydrogen is transferred from carbon to oxygen (42).

Oxygenation by Triphenyl Phosphite Ozonide

The isotope effects observed on oxygenation of **1***b* and *c* by triphenyl phosphite ozonide at $-70°$ in methylene chloride are quite similar to those observed on oxygenation of **1***b* and *c* by singlet oxygen at $-52°$ in methanol which indicates that a perepoxide intermediate cannot be involved. Also, it has been shown that singlet oxygen does not intervene in the triphenyl phosphite ozonide oxygenation at low temperatures (24) so that still another mechanism is required for oxygenation by this reagent. This reaction gives a higher proportion of the product of C—H bond breaking with **1***b* than with **1***c* which suggests the formation of a transition state or intermediate in which the oxygen is bonded more strongly to the carbon bearing the CD_3 groups of **1***b* than to the other carbon atom than is the case in the singlet oxygen reaction. The difference in isotope effects between **1***b* and *c* is quite small, however, and may not be outside experimental error although it is reproducible.

It is remarkable that there are so many different routes for the conversion of **1***a* to **7***a*.

Experimental

General

Boiling points and melting points are uncorrected. The latter were taken on a Gallenkamp melting point apparatus. I.r. spectra were taken on Perkin–Elmer Model 421 and 337 spectrophotometers and only characteristic absorption bands are cited. Refractive indices were measured on a Bausch and Lomb Abbe-34 refractometer. N.m.r. spectra were determined in carbon tetrachloride and with tetra-

[9]The argument made against a perepoxide intermediate in terms of *syn* and *anti* isomers (22) probably is not valid. These would undoubtedly interconvert rapidly by inversion about the tricoordinated oxygen atom (40).

For personal use only.

methylsilane as internal standard, unless otherwise noted, using Varian analytical spectrometers Models A-60 and HR-100. Abbreviations used in reporting the n.m.r. spectra are b, broad; s, singlet; d, doublet; m, multiplet. Gas chromatography was carried out on an Aerograph A-90-P3 gas chromatograph using a 5 ft × 1/4 in. stainless steel column packed with 20% SF-96 on 60/80 Chromosorb P. Mass spectra were obtained on an A.E.I. MS-2-H mass spectrometer. Organic extracts were dried with magnesium sulfate unless otherwise indicated. Elemental analyses were performed by Mrs. Darlene Mahlow of this Department.

All preparations of β-bromohydroperoxides were carried out behind shields. Apparatus containing these compounds was manipulated with the aid of tongs and hands were protected with heavy canvas gloves.

Materials

Deuterium oxide (99.8 atom %D) and acetone-d_6 (99.5 atom %D) were obtained from Merck, Sharp & Dohme of Canada, Ltd.

Deuteriosulfuric acid was prepared by the addition of anhydrous sulfur trioxide to deuterium oxide.

Trideuterioiodomethane (96.5 atom %D) was prepared by pyrolysis of perdeuteriotrimethyloxosulfonium iodide obtained by isotopic exchange of the undeuterated salt with deuterium oxide (43).

Perdeuterioacetone Cyanohydrin (3,3,3-Trideuterio-2-trideuteriomethyl-2-hydroxypropanenitrile)

The synthesis was patterned after the procedure used for the preparation of acetone cyanohydrin (44). A solution of 28 ml deuteriosulfuric acid in 79 ml of deuterium oxide was added to a cooled (ice-bath) solution of 25 g (0.39 mol) of acetone-d_6 and 22 g (0.45 mol) sodium cyanide in 48 ml deuterium oxide at such a rate as to keep the temperature of the reaction mixture below 15°. The solution was stirred for 15 min after the addition was complete and then continuously extracted with ether for 36 h. The dried ether extract was freed of solvent and the residue distilled to give 32 g (93%) of product, b.p. 78–80° (17 mm), n_D^{25} 1.3966 (lit. (44) for acetone cyanohydrin, b.p. 78–82° (15 mm), n_D^{19} 1.4002); i.r. ($CHCl_3$): 2400 to 2700, 2250 cm^{-1}; n.m.r. (neat) no absorption from τ 0–10.

Methyl 3,3,3-Trideuterio-2-trideuteriomethyl-2-hydroxyproponoate

Perdeuterioacetone cyanohydrin was hydrolyzed using a modification of the procedure for the hydrolysis of a related cyanohydrin (45). A solution of 32.5 g (0.35 mol) of the cyanohydrin and 35 ml concentrated hydrochloric acid in 14 ml water was heated at 95° for 2 h. Sodium sulfate, 12 g, was then added and the mixture cooled to −15°. The resulting mixture was filtered and both the precipitate and the filtrate were extracted continuously with ether for 2 days. The extracts were combined, dried, and a small sample of 3,3,3-trideuterio-2-trideuteriomethyl-2-hydroxypropanoic acid, m.p. 75–76° (lit. (46) for 2-methyl-2-hydroxypropanoic acid, m.p. 79°), was isolated from a portion of the extracts; i.r. ($CHCl_3$): 2500 to 3600, 2230, 1730 cm^{-1}; n.m.r. ($CDCl_3$): τ 3.24 (s).

The remainder of the extracts was treated with 0.4 mol diazomethane in ether at 0°. Excess diazomethane was destroyed by addition of acetic acid in small portions. Removal of solvent and distillation of the residual oil gave 33.0 g (74%) of product, b.p. 133–134° (710 mm), n_D^{25} 1.4069 (lit. (47) for methyl 2-methyl-2-hydroxypropanoate, b.p. 137–139° (760 mm), $n_D^{19.3}$ 1.4112); i.r. ($CHCl_3$): 3250 to 3600, 2230, 2210, 1745 cm^{-1}; n.m.r. τ 6.31 (s, 3.10H), 6.67 (s, 1.0H).

3-Methyl-1,1,1-trideuterio-2-trideuteriomethyl-2,3-butanediol

A solution of 33 g (0.27 mol) of the above ester in 150 ml ether was added to a solution of methylmagnesium iodide prepared from 26.4 g (1.1 mol) magnesium and 200 g (1.45 mol) iodomethane in 1 l ether. The reaction mixture was stirred 4 h after the addition was complete and then poured into a mixture of ice and 1.1 mol hydrochloric acid. The ether layer was separated and the aqueous layer continuously extracted with ether for 2 days. The combined ether extracts were dried thoroughly, first with magnesium sulfate, then with molecular sieves (4 A) and finally poured through a column (4 × 20 cm) of molecular sieves. The solution was concentrated and the residue distilled to give 20 g (88%) of colorless oil, b.p. 164–167° (710 mm) (lit. (48) for pinacol, b.p. 172°); n.m.r.: τ 7.23 (s, 2.0H), 8.82 (s, 6.10H).

1,1,1-Trideuterio-2-trideuteriomethyl-3-methyl-2-butene (1b)

The procedure (10) for the preparation of 2,3-dimethyl-2-butene was adapted. This reaction gave a poor yield of product if the pinacol was not dried thoroughly as described. The above deuterated pinacol, 27.0 g (0.218 mol) was heated with 32.2 g (0.218 mol) of freshly distilled ethyl orthoformate under a 10 cm Vigreux column for 10 h after which the slow distillation of ethanol ceased. Two drops of acetic acid were added and the mixture was heated at 175° until no more product distilled (8 h) into the ice-cooled receiver. The product was redistilled to give 10.9 g (54%) of an oil, b.p. 69.5–70.5° (710 mm) (lit. (49) for 2,3-dimethyl-2-butene, b.p. 73°); i.r. (CCl_4): 2250, 2180, 2060 cm^{-1}; n.m.r.: τ 8.40 (s). Mass spectral analysis (12) at 12 eV, mol % d_n: 0.51 d_3, 0.10 d_4, 2.5 d_5, 96.88 d_6. The mass spectrum taken at 70 eV had the following peaks in the $M^{\oplus} - CX_3$ (X = D or H) region, *m/e* (% relative intensity): 69 (2), 70 (5), 71 (6), 72 (100), 73 (11), 74 (6), 75 (93), 76 (5).

2,3-Bis(trideuteriomethyl)-2,3-butanediol

A solution of 28 g (0.33 mol) dry, freshly distilled 2,3-butanedione in 200 ml ether was added at a rate to maintain mild reflux to a solution of trideuteriomethyl magnesium iodide prepared from 120 g (0.83 mol) trideuterioiodomethane and 18 g (0.75 mol) magnesium in 1500 ml ether contained in a Morton flask. High speed stirring was used during the addition and for 8 h afterwards. Work-up and drying of the product was carried out as described above for the preparation of the other deuterated pinacol to give 34 g (79%) of product, b.p. 163–168° (710 mm); n.m.r.: τ 6.49 (s, 2.0H), τ 8.78 (s, 6.1H).

In exploratory runs using undeuterated materials the yield of pinacol was found to be 30% or less when ordinary stirring was used in the Grignard reaction.

2,3-Bis(trideuteriomethyl)-2,3-dimethyl-2-butene (1c)

This reaction was carried out as described for the preparation of 1*b*. From 34 g (0.28 mol) of the above pinacol and 41 g (0.28 mol) ethyl orthoformate 14 g (56%) of product was obtained, b.p. 69–70.5° (710 mm); i.r. (CCl_4): 2235,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2180, 2130, 2060 cm^{-1}; n.m.r.: τ 8.41 (s). Mass spectral analysis (12) at 9.5 eV, mol % d_n: 0.31 d_2, 0.77 d_3, 3.09 d_4, 18.4 d_5, 77.43 d_6. The mass spectrum taken at 70 eV had the following peaks in the $M^+ - CX_3$ (X = D or H) region, *m/e* (% relative intensity): 67 (2), 68 (2), 69 (4), 70 (9), 71 (16), 72 (100), 73 (11), 74 (22), 75 (79), 76 (3).

cis- and trans-1,2-Bis(trideuteriomethyl)-stilbene (cis- and trans-2b)

The adsorbed water on 300 g basic alumina was replaced by deuterium oxide with a series of exchanges (50) which involved heating the alumina to 200° under 1 mm pressure followed by cooling and shaking the alumina with 18 g deuterium oxide. This process was repeated until the moisture collected on heating the alumina contained 0.4% protium (four exchanges). The resulting alumina was placed into two long (5 ft × 17 mm) chromatography columns and a solution of 30 g acetophenone in pentane was passed through the columns. The methyl group of the recovered acetophenone was 93% deuterated as determined by n.m.r. spectroscopy. Treatment of this material with lithium aluminum hydride in ether and hydrolysis of the reaction mixture gave 2,2,2-trideuterio-1-phenylethanol in 91% yield, b.p. 97–98° (18 mm), n_D^{25} 1.5245 (lit. (51) for 1-phenylethanol, b.p. 103–104° (20 mm), n_D^{25} 1.5251). This product was treated with a 5% excess of thionyl chloride in benzene to give 2,2,2-trideuterio-1-chloro-1-phenylethane in 90% yield, b.p. 76–77° (13 mm), n_D^{25} 1.5235 (lit. (52) for 1-chloro-1-phenylethane, b.p. 75° (14 mm), n_D^{19} 1.5275), and then converted to the deuterated 1,2-dimethylstilbenes, *cis-* and *trans-***2***b*, with sodium amide using the procedure described (53) for the preparation of the undeuterated analogs. The products were fractionally crystallized from methanol. Samples of both isomers were obtained in pure form as determined by g.c. and n.m.r. spectroscopy, *cis-***2***b*, m.p. 63–64°, *trans-***2***b*, m.p. 103–104° (lit. (53) for *cis-***2***a*, m.p. 65–66°, *trans-***2***a*, m.p. 105–106°); i.r. (CCl_4): *cis-***2***b*, 2230, 2210, 2115, 2060 cm^{-1}, *trans-***2***b*, 2230, 2210, 2110, 2060 cm^{-1}; n.m.r.: *cis-***2***b*, τ 3.09 (s), *trans-***2***b*, τ 2.50 (s); mass spectral analysis (12) at 9.5 eV, mol % d_n: *cis-***2***b*, 0.17 d_0, 0.14 d_1, 0.09 d_2, 0.90 d_3, 6.45 d_4, 30.68 d_5, 61.60 d_6; *trans-***2***b*, 0.07 d_0, 0.03 d_1, 0.09 d_2, 0.90 d_3, 6.65 d_4, 30.80 d_5, 61.47 d_6.

*2,3-Diphenyl-1-butene-3-ol, (**10**)*

A solution of 3 g (0.013 mol) of *cis-***2***a* (53) in 30 ml methanol was photooxidized at 14° using methylene blue as sensitizer in the apparatus previously described (1). Oxygen uptake became very slow after 2 h when 350 ml (112%) had been consumed. The solution was poured into 100 ml ice-water and the resulting mixture extracted twice with 50 ml ether. The combined extracts were washed with water and with saturated aqueous sodium chloride solution. After drying, the ether solution was added to a stirred slurry of 0.5 g lithium aluminum hydride in 25 ml ether. The mixture was heated under reflux for 30 min and then hydrolyzed with 15% potassium hydroxide. The precipitate was stirred several times with ether and the combined ether solutions dried and concentrated. The residue was distilled to give 1.5 g (48%) of a colorless oil, b.p. 101–104° (0.1 mm), n_D^{25} 1.5809; i.r. ($CHCl_3$): 3560, 3300–3500, 3060, 1640, 905 cm^{-1}; n.m.r.: τ 2.5–3.2 (m, 10.4H), 4.55 (d, J = 1.5 Hz, 0.94H), 4.82 (d, J = 1.5 Hz, 1.01H), 8.05 (s, 0.90H), 8.40 (s, 2.80H).

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.67; H, 7.19. Found: C, 85.63; H, 7.00.

3-Bromo-2,3-bis(trideuteriomethyl)-2-butyl Hydroperoxide (3d)

This material was prepared from the corresponding deuterated alkene **1***c*, 98% hydrogen peroxide, and 1,3-dibromo-5,5-dimethylhydantoin according to the procedure described for the preparation of 3-bromo-2,3-dimethyl-2-butyl hydroperoxide (**3***a*) (1), m.p. 90–92° (lit. (1) for **3***a*, m.p. 93–94°); i.r. (CCl_4): 3550, 3200–3500, 2250 and 2160 cm^{-1}; n.m.r.: τ 2.4 (bs, 0.90H), 8.20 (s, 3.0H), 8.57 (s, 3.0H). Iodometric titration indicated that **3***d* contained 97.0% of the theoretical amount of active oxygen.

3-Bromo-4,4,4-trideuterio-3-trideuteriomethyl-2-methyl-2-butyl Hydroperoxide (3b) and 3-Bromo-1,1,1-trideuterio-2-trideuteriomethyl-3-methyl-2-butyl Hydroperoxide (3c)

A mixture of **3***b* and *c* was prepared from the corresponding alkene **1***b* by the procedure described for the preparation of **1***a* (1), m.p. 91–93°; i.r. (CCl_4): 3550, 3200–3500, 2240, 2130 cm^{-1}; n.m.r.: τ 2.1 (bs), 8.20 (s), 8.53 (s). The ratio of the areas of the latter signals was 1:1.60 as determined by careful integration. From four integrations the average ratio of the areas of the corresponding signals in the spectrum of the undeuterated compound **1***a* was 1.00 ± 0.02. Iodometric titration indicated that the mixture of **3***b* and *c* contained 97.4% of the theoretical amount of active oxygen.

*2-Bromo-2,3-dimethyl-3-methoxybutane (**6**)*

To a stirred solution of 5 g (0.06 mol) **1***a* and 9.6 g (0.3 mol) of methanol in 50 ml ether at −40° was added 8.1 g (0.03 mol) of 1,3-dibromo-5,5-dimethylhydantoin in small portions over 10 min. The resulting mixture was allowed to warm to 23° and then was shaken four times with 50 ml water. The organic layer was dried and concentrated and the residue distilled to give 9.2 g (79%) of colorless oil, b.p. 75–77° (15 mm), which crystallized on standing. The solid was recrystallized from methanol to give 7.3 g white needles, m.p. 71–73°; n.m.r.: τ 6.70 (s, 3.0H), 8.26 (s, 6.0H), and 8.67 (s, 6.1H).

*Material Balance and Rate of Reaction Between Base and **1**a*

Material Balance

A methanol solution 0.39 *M* in **1***a* and 0.25 *M* in benzene was made up and the areas of the n.m.r. signals due to benzene and to the methyl groups of **1***a* were carefully measured. Three n.m.r. tubes were prepared at −70° with one part of this solution and two parts of a 1.22 *M* solution of sodium hydroxide in methanol. The tubes were sealed and individual tubes were warmed to −19, 2, and 25°. After standing for 28 h, long enough for complete reaction to occur at −19°, the areas of the n.m.r. signals due to benzene and to the methyl groups of the product allylic hydroperoxide **7***a* were carefully measured. The results are given in Table 1.

Reaction Rates

Volumetric solutions of **1***a* and tetramethylsilane and of sodium hydroxide in methanol were prepared. Aliquots of these solutions were transferred to n.m.r. tubes at −78° and mixed. The tubes were placed in the temperature con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

trolled probe of the 100 MHz n.m.r. spectrometer. The areas of the signals due to the *gem*-dimethyl group on the carbon bearing the hydroperoxy group of the starting material **1***a*, the *gem*-dimethyl group of product **7***a*, and tetramethylsilane were determined periodically. The apparent second order rate constants for the disappearance of **1***a* were determined from the slopes of plots of $1/(a-b)\ln b(a-x)/a(b-x)$ *vs.* time (54) where a and b represent the initial concentrations of hydroxide ion and **1***a*, respectively, and x is the instantaneous concentration of **1***a*. Reactions were followed to *ca.* 60% completion and the plots gave good straight lines. The results are given in Table 3.

Reaction between Deuterated Bromohydroperoxides **3***b* + *c and* **3***d and Base*

To n.m.r. sample tubes at $-70°$ were added 0.15 ml of a solution made from 0.07 g deuterated bromohydroperoxide, 0.018 g benzene, 1.0 ml methanol-d_4, and 0.30 ml of a solution made from 0.038 g sodium, 0.046 g deuterium oxide, and 2.0 ml methanol-d_4. The contents of the tubes were mixed at $-70°$ and then the tubes were placed in an ice bath for 6 h. The relative amounts of the deuterated allylic hydroperoxides were determined by integration of the n.m.r. signals at τ 8.2 (allylic CH_3) and 8.7 (*gem*-CH_3's). The ratio, **7***c*/**7***b*, was obtained by dividing twice the area of the signal at τ 8.2 by the area of the signal at τ 8.7. To account for the fact that the trideuteriomethyl groups of **1***c* were only 95.3% deuterated the ratio, **7***d*/**7***e*, was obtained using the expression

$$\frac{\text{area at } \tau 8.7}{\text{area at } \tau 8.2} = \frac{3a(100-y)+0.14a(100-y)+3ay+0.14ay}{3a(100-y)+0.141ay} = \frac{314}{2.86y}$$

where a is the area due to one proton and y is the % **3***d* in the product mixture. The results are given in Table 1.

Photosensitized Oxidation of the Deuterated Alkenes **1***b and c*

The photosensitized oxidation of the alkenes **1***b* and *c* was carried out using the apparatus previously described (1). In preparative reactions, a solution of 1 g (0.01 mol) of the alkene and 15 mg methylene blue in 25 ml methanol was irradiated at 14° until oxygen uptake became very slow (*ca.* 45 min, *ca.* 120% oxygen uptake). The solution was then poured into 100 ml ice-water and the resulting mixture extracted with ether, 3 × 50 ml. The combined ether extracts were dried and concentrated and the residual oil distilled. From **1***b* there was obtained 0.65 g (48%) of a mixture of the deuterated allylic hydroperoxides **7***b* and *c*, b.p. 57–59° (17 mm); n_D^{29} 1.4375 (lit. (1) for **1***a*, b.p. 55° (12 mm); n_D^{20} 1.4428). From the oxidation of **1***c* there was obtained 0.70 g (56%) of a mixture of the deuterated allylic hydroperoxides **7***d* and *e*, b.p. 58–60° (17 mm), n_D^{29} 1.4379.

A series of oxidations with various sensitizers was carried out in the same apparatus using solutions 0.044 *M* in alkene **1***b* or *c*. The solutions were irradiated for 15 min, long enough for complete reaction to occur. For the runs at $-52°$ the solutions were cooled by blowing cold nitrogen gas through the jacket of the apparatus. The temperature of the solution was checked just before and just after irradiation. One oxidation of **1***b* was carried out at $-52°$ in the presence of 0.83 *M* sodium hydroxide. This reaction mixture was kept at $-65°$ for 1.5 h after irradiation and then warmed to 0° over a 2 h period before work-up. After irradiation the reaction mixtures were worked-up as described above, except that the ether extracts were concentrated to a film under reduced pressure. Carbon tetrachloride (2 ml) was then added and the resulting solution was again concentrated to a film under reduced pressure. The residue was taken up in 0.5 ml carbon tetrachloride and the relative amounts of the deuterated allylic hydroperoxides were determined as described for the reaction between the deuterated bromohydroperoxides and base. In the analysis of the product of oxidation of the undeuterated alkene **1***a* carried out in this way, it was found that the ratio of twice the area of the signal at τ 8.2 divided by the area of the signal at τ 8.7 was 1.01 ± 0.03 so no correction was applied to the results obtained from deuterated materials which are given in Table 4.

Oxidation of the Deuterated Alkenes **1***b and c with Triphenyl Phosphite Ozonide*

A stream of ozone was introduced into a solution of 2.2 g (0.007 mol) of redistilled triphenyl phosphite in 40 ml methylene chloride at $-75°$ until a blue color persisted in the solution. Excess ozone was flushed out with a stream of nitrogen and a solution of 0.6 g (0.006 mol) of deuterated alkene **1***b* or *c* in 5 ml methylene chloride was added. The resulting solution was mixed and then allowed to stand at $-28°$ for 2.5 h. The methylene chloride was removed through a short fractionating column and the residue was distilled to give the corresponding allylic hydroperoxides. From **1***b* there was obtained 0.36 g (49%) of product, b.p. 50–56° (12 mm), n_D^{25} 1.4398, and from **1***c* 0.28 g (40%) of product, b.p. 49–53° (15 mm), n_D^{25} 1.4395. The composition of each mixture was determined as in the photooxidation reactions.

These reactions were repeated later at lower temperatures. One-milliliter solutions 0.4 *M* in triphenyl phosphite ozonide and 0.2 *M* in deuterated alkene, made up as described above, were allowed to stand at $-70°$ for 4 h (24) and then analyzed directly by n.m.r. spectroscopy at 100 MHz. A run with undeuterated alkene **1***a* was made under these conditions and it was found on n.m.r. analysis that twice the area of the signal at τ 8.2 divided by the area of the signal at τ 8.7 was 1.05 ± 0.03. The results shown in Table 4, runs 11, 12, 21, and 22, are corrected for this.

*Deuterium Isotope Effects in Photosensitized Oxidation of cis- and trans-1,2-Dimethylstilbene (cis- and trans-***2***a)*

A solution of 0.520 g (2.5 mmol) of *trans*-1,2-dimethylstilbene (*trans*-**2***a*) (53) and 0.534 g (2.5 mmol) of *trans*-1,2-bis-(trideuteriomethyl)-stilbene (*trans*-**2***b*) in 40 ml methanol was prepared. Solvent was removed from an aliquot of this solution and the residue analyzed by mass spectrometry at 9.5 eV. The remainder of the solution, after addition of 15 mg methylene blue, was irradiated at 14° in the apparatus described (1) until 49% of *trans*-**2***a* had been consumed as determined by n.m.r. spectroscopy. The reaction mixture was then worked-up as described for the preparation of 2,3-diphenyl-1-butene-3-ol above. The concentrated residue obtained from the lithium aluminum hydride reduction was

absorbed on a 1 cm × 15 cm column of basic alumina. Elution of the column with 50 ml pentane and removal of the pentane from the element left the mixture of unreacted alkenes of which the relative amounts of deuterated and undeuterated materials were determined by analysis (12) of the parent region of the mass spectrum taken at 9.5 eV. There were only traces of ions formed with *m/e* ratios below those of the parent ions at this voltage. The isotope effect, k_H/k_D, was calculated from the relative amounts of the alkenes remaining (25*b*, 27). The same procedure was used in the oxidation of mixtures of *cis*-**2***a* and *cis*-**2***b*. The results are presented in Table 5.

*Relative Rates of Photosensitized Oxidation of cis- and trans-1,2-Dimethylstilbene (cis- and trans-***2***a)*

A solution of 0.253 g *cis*-**2***a*, 0.251 g *trans*-**2***a*, 0.204 g bibenzyl, and 15 mg methylene blue was made up in 40 ml methanol and analyzed by g.c. (165°). Solvent was removed from an aliquot and the residue analyzed by n.m.r. spectroscopy. The methanol solution was irradiated in the apparatus described (1). Aliquots were removed after 25, 30, and 35 min and analyzed by g.c. The hydrocarbons remaining in each aliquot were isolated using the procedure described in the intermolecular isotope effect experiments, above, and their relative amounts also determined by n.m.r. spectroscopy. The relative rates of oxidations, k_{cis}/k_{trans}, were calculated from the relative amounts of materials remaining (25*b*, 27), and were determined at 25, 30, and 35 min to be 9, 11, and 13 by g.c. analysis and 6, 7, and 8 by n.m.r. spectroscopic analysis.

*Reaction between 2,3-Dimethyl-3-bromo-2-butyl Hydroperoxide (***3***a) and Base in the Presence of Azide Ion*

To a heterogeneous mixture of 9.5 mg (0.24 mequiv) of sodium hydroxide and 35.7 mg (0.55 mequiv) of sodium azide in 1.0 ml of 40:60 water–methanol-d_3 solution at 0° was added 25 mg (0.13 mmol) of **3***a*. The resulting mixture was allowed to stand at 0° for 6 h with occasional shaking and then filtered. The n.m.r. spectrum of the filtrate was identical to that from a reaction carried out under identical conditions in the absence of sodium azide. There was no evidence for the formation from **3***a* of any material in addition to the allylic hydroperoxide **7***a*.

This work was supported in part by a grant from the National Research Council of Canada.

Correlation of π,π^* Triplet Energy of some Cyclic α,β-Unsaturated Ketones with Electroreduction Potentials[1]

RAFIK O. LOUTFY

Received July 14, 1972

The half-wave reduction potentials, $E_{1/2}$'s, of some cyclic enones have been determined in acetonitrile. A linear free-energy relationship was obtained between $E_{1/2}$ and the lowest π,π^* triplet state of the enones studied. This correlation enabled an estimate to be made of the triplet energy of the cyclohexenone, which was found to be ~70 kcal/mol.

Nous avons déterminé les potentiels de réduction de demi-vague $E_{1/2}$ de quelques énones cycliques dans l'acétonitrile. Nous obtenons une relation linéaire de l'énergie libre entre $E_{1/2}$ et l'état triplet π,π^* des énones considérées. Cette corrélation rend possible l'estimation de l'énergie du triplet de la cyclohexanone, soit ~70 kcal/mol. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 4050 (1972)

Cyclic enones (α,β-unsaturated ketones) undergo a variety of photochemical reactions (1–3). Generally most of them, such as cycloaddition, rearrangement, and H-abstraction proceed via triplet states (1, 2 and references therein). Correlation of the energy of the lowest triplet state with physical parameters are therefore of great interest.

In previous reports (4, 5), we demonstrated the existence of a linear free-energy relationship between the n,π^* triplet energy of some benzophenones, thiobenzophenones, aromatic, and aliphatic ketones and aldehydes and the corresponding reduction half-wave potentials, $E_{1/2}$'s. Expansion of the above relationship to include cyclic enone's π,π^* triplet states may bring better understanding of the reactivity of this system and provide a correlation which could be utilized to estimate the triplet energy of compounds of known electrochemistry. Such correlation is illustrated in Fig. 1.

The reduction of all cyclic enones in acetonitrile at the dropping mercury electrode exhibited two a.c. waves, which is in general agreement with that reported by Wawzonek and others (6, 7). The first a.c. wave is of interest in this study. Therefore, the following discussion will mainly pertain to it. The procedure used for the polarographic measurements was the same as described previously (4).

The acceptance of a single electron in a reversible reduction results in the formation of the corresponding radical anion. It is well established that the electron normally enters the lowest unoccupied π molecular orbital and the potential at which the molecule is reduced should thus be related to the energy of π^* level. Hence, the triplet excitation energy can simply be given as

$$[1] \qquad E_{^3(\pi,\pi^*)} = \varepsilon_\pi - \varepsilon_{\pi^*} - J_{\pi,\pi^*} - E_{\text{c.i.}}$$

where ε_π and ε_{π^*} are the energies of the π bonding and anti-bonding orbital respectively. The term J_{π,π^*} represents the appropriate exchange integral, and $E_{\text{c.i.}}$ is the term resulting from the configuration interaction (a second order perturbation term). The latter two terms for first approximation can be assumed constant throughout the series, and therefore, can be neglected. Thus, one would expect a linear relationship between the π,π^* triplet energy of

[1]NRCC No. 12887.

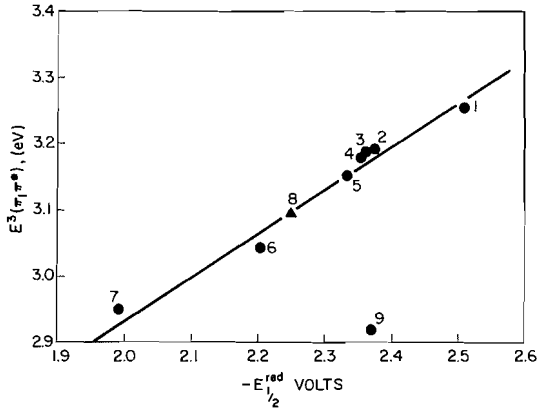

FIG. 1. A plot of $E_{3(\pi,\pi^*)}$ of cyclic enones and the corresponding $E_{1/2}$'s.

TABLE 1. Half-wave potentials and π,π^* triplet energies of some cyclic enones

	Compounds	$E_{3(\pi,\pi^*)}$ eV	$-E_{1/2}$, V (± 0.005 V)
1	Bicyclo[3.3.0]oct-5-en-2-one	3.25*	2.51
2	Cholestenone	3.19†	2.38
3	Cyclopentenone	3.184‡	2.36
4	Testosterone propionate	3.18†	2.35
5	Tricyclo [3.3.2.$0^{1,5}$]dec-3-en-2-one	3.15§	2.33
6	4-Acetoxytestosterone acetate	3.04†	2.20
7	4-Chlorotestosterone acetate	2.95†	1.99
8	Cyclohexenone	(3.08)	2.25
9	4-Methyltestosterone acetate	2.92†	2.37

*Reference 12.
†Reference 13.
‡Reference 14.
§It was predicted that the $^3(\pi,\pi^*)$ of this compound is not more than one kcal/mol above the lowest $^3(n,\pi^*)$, the triplet energy of the latter being 71.6 kcal/mol; see ref. 15.

cyclic enone and the corresponding $E_{1/2}$'s if the energy of the highest occupied MO(π-orbital) is the same throughout the series, or if it is a constant function of π^* level energy.

The location of the main peak of the singlet or triplet (n,π^*) band of α,β unsaturated ketones appears to be displaced to a shorter wavelength by alkyl substitution. For example, in the case of cyclohexenone, one α or β alkyl substituent caused a hypsochromic shift of about $\sim$6 nm (8). This probably means that alkyl substitution on the ethylenic bond raises the energy of the π^* orbital, since the non-bonding orbital is considered to be practically unaffected. Similarly, electron withdrawing substituents would lower the energy of the π^* orbital. On the other hand, alkyl substitution at α or β positions would cause bathochromic shifts of the $^1(\pi,\pi^*)$ band. In steroid system the magnitude of the shift per an α-alkyl and β-alkyl substitution are about 10 and 12 nm respectively (9, 10). This must indicate therefore, that alkyl substitution raises the energy of both π and π^* orbital, where the effect on the ε_π is more pronounced than on ε_{π^*}.

The $E_{1/2}$ data for the cyclic enones studied are shown in Table 1. The compounds studied can be divided into two groups: (*a*) cyclic enones, where cyclopentenone represents the parent compound; (*b*) those where cyclohexenone is the parent compound. In both cases alkyl substitutions at α and/or β position render reduction more difficult, while electron withdrawing groups lower $E_{1/2}$ as predicted. The state correlation is emphasized by a plot of half-wave potentials *vs.* triplet energies which is presented in Fig. 1 with a slope of 0.7. From the previous discussion, it is obvious that the energy of the π-orbital for these cyclic enones is not constant. This linear free energy relationship, therefore, indicates that the change of energy of the π orbital on substitution should be a function of that for the π^* orbital.

This is not, however, surprising since a set of empirical rules for determining the effect of a substituent on the position of the first $^1(\pi,\pi^*)$ band of cyclic enones has been proposed by Woodward (9) and Fieser and Fieser (10) which implies that substitution at the α or β position of cyclic enones causes a systematic shift of both π and π^* orbital.

The triplet energy of cyclohexenone can be estimated, using the relationship in Fig. 1, and it was found to be $\sim$70 kcal/mol which is in very good agreement with the predicted value of 68 kcal/mol reported by de Mayo *et al.* (11).

The deviation of 4-methyl testosterone acetate from the linear correlation obtained, represents a case where the relation between the energy of π and π^* orbital breaks down due to the marked effect of the second-CH_3 group on the π^*-orbital energy (8).

In conclusion, the existence of correlation between the $^3(\pi,\pi^*)$ energy of cyclic enones and $E_{1/2}$'s indicates the presence of useful and meaningful relations between the spectroscopic and electrochemical properties of molecules.

Triplet Charge Transfer Complex between Excited Electron Acceptor and Ground State Electron Donor[1]

RAFIK O. LOUTFY

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

AND

RAOUF O. LOUTFY

Chemistry Department, University of Guelph, Guelph, Ontario

Received July 14, 1972

The half-wave reduction and oxidation potentials, $E_{1/2}$'s, of carbonyl compounds and amines, respectively, are used to estimate the location of triplet charge transfer states (CT). A linear free-energy relationship between the calculated CT triplet energies and the corresponding carbonyl molecules triplet energies was obtained. It has also been found that the free energy change (ΔF) for CT complex formation correlate with the triplet carbonyl quenching rate constant k_q.

Nous utilisons les potentiels d'oxydation et de réduction de demi-vague, $E_{1/2}$, de carbonyls et d'amines pour estimer les endroits où se trouvent les états triplets de transfert de charge (CT). Nous obtenons une relation linéaire d'énergie libre entre les énergies de triplet CT calculées et les énergies de triplets correspondants pour les molécules de carbonyles. Nous trouvons aussi que le changement d'énergie libre (ΔF) pour la formation de complexes CT est en accord avec la constante de vitesse d'amortissement du triplet carbonyl k_q.

Canadian Journal of Chemistry, **50**, 4052 (1972)

In recent years there has been much activity on the subject of quenching of excited aromatic and aliphatic ketones by amines (1–5). It appears to be generally accepted that phosphorescence quenching and photoreduction of the excited carbonyl molecule by amines involved charge transfer (c.t.) complex formation (4, 5). However, several aspects remain unclear: (*1*) the absence of phosphorescence emission from the c.t. state; (*2*) the position of the complex maximum emission frequency; and (*3*) factors influencing the formation of the c.t. complex.

In a large number of cases it has been possible

Canadian Journal of Chemistry, **50**, 4052 (1972)

In recent years there has been much activity on the subject of quenching of excited aromatic and aliphatic ketones by amines (1–5). It appears to be generally accepted that phosphorescence quenching and photoreduction of the excited carbonyl molecule by amines involved charge transfer (c.t.) complex formation (4, 5). However, several aspects remain unclear: (*1*) the absence of phosphorescence emission from the c.t. state; (*2*) the position of the complex maximum emission frequency; and (*3*) factors influencing the formation of the c.t. complex.

In a large number of cases it has been possible

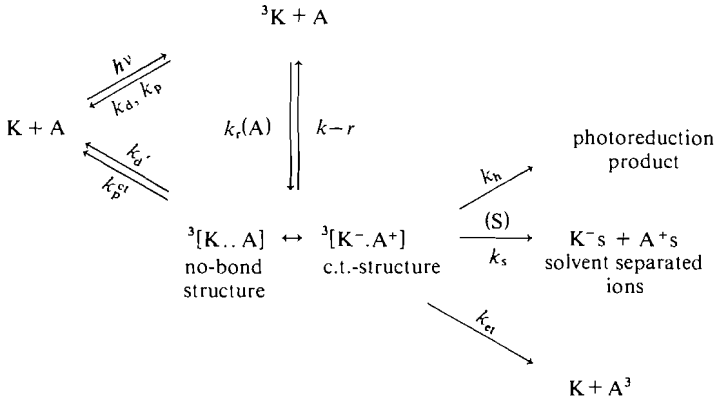

SCHEME I

to observe the formation of the electronically excited singlet c.t. state of aromatic hydrocarbon and amine complexes (6–9). On the other hand, little is known about the lowest triplet excited c.t. state particularly of ketone–amine complexes. In this report, from the polarographic oxidation and reduction potentials measured in acetonitrile, the energies of the triplet c.t. states were estimated and correlated with the experimental triplet quenching rate constants.

Quenching of excited carbonyl groups by amines with low ionization potentials can be described by Scheme 1, where K and A stand for the ketone and amine respectively. $(K^+ \cdot A^-)$ represents the initially formed charge-transfer state, which may undergo proton transfer and electron redistribution to give the photoreduction product by a reaction which proceeds with a rate k_h (1–3 and references therein). Furthermore, when there is sufficient energy gain through solvation, the excited c.t. state may readily dissociate into ions, with rate k_s. The excited c.t. complex may also undergo intercombinative conversion to a triplet state (with rates $k - r$ and/or k_{et}), or be deactivated to the ground state (k_d'). The latter possibility has been discussed in detail by Kuz'min and Guseva (7). Finally, radiative deactivation of the excited c.t. complex competes with all the previously mentioned deactivation processes. In general, radiationless deactivation of the triplet c.t. complex is predominant, and even more pronounced in polar solvents (7) which makes the observation of phosphorescence emission from that state in fluid media rather difficult. In a rigid matrix where all diffusion processes are suppressed there should be greater chance of observing the emission.[2]

The energy of the charge-transfer state is expressed (11) as

$$[1] \qquad E_{c.t.} = I_A - A_K - C - \Delta$$

I_A represents the ionization potential of donor, A_K the electron affinity of the acceptor; $C = e^2/\varepsilon r$ is the columbic interaction between the positive and negative ions, and Δ is an interaction term (12). MacColl (13) suggested that the polarographic reduction half-wave potential ($E_{1/2}^{red}$) is directly related to the electron affinity (eq. 2). Similarly, the oxidation half-wave potential ($E_{1/2}^{oxid}$) is related to I_A (eq. 3) (14),

$$[2] \quad E(K^-/K) \simeq E_{1/2}^{red} = A_A + \Delta E_{K^-}(s) - K$$

$$[3] \quad E(A/A^+) \simeq E_{1/2}^{oxid} = I_D + \Delta E_{A^+}(s) - K$$

where $E(K^-/K)$ and $E(A/A^+)$ represent the standard reduction and oxidation potential which can be taken as equal to $E_{1/2}^{red}$ and $E_{1/2}^{oxid}$, respectively. $\Delta E_{K^-}(s)$ and $\Delta E_{A^+}(s)$ are the differences in free energy of solvation of the neutral molecule and ion, these are almost equal for the systems studied. K is a constant which depends on the reference cell (14). Substituting for the values of I_A and A_k in eq. 1, the following useful form can be derived:

$$[4] \quad E_{c.t.} = [E(A/A^+) - E(K^-/K) - C] - \Delta$$

The half-wave potentials for the compounds studied were obtained from cathodic sweeps

[2]Recently emission from excited states of EDA-complexes of benzophenone with aromatic amines at 77 °K was observed (10).

§This value is in very good agreement with the emission maximum observed recently by Arimitsu and Tsubomura (10).

of the a.c. wave; the procedure for the measurement is the same as that described in ref. (15). The data are given in Table 1 along with the oxidation half-wave potentials of the donors, which were obtained from the literature.

From eq. 4 the energy of the ^{3}c.t. state can be determined if the term Δ is known. This term represents the difference in the energy of formation of c.t. complex in the excited ($\Delta E_{K^-A^+}$) and ground state (ΔE_{KA}) (12). Since no c.t. complex formation was observed in the ground state between ketones and amines the latter term can be neglected. In other words $\Delta = \Delta E(K^-A^+)$ which should be a function of $(E(A/A^+) - E(K^-/K))$. Indeed, from Weller's results (16), a linear relationship between Δ and $[E(D/D^+) - E(A^-/A)]$ has been found, where

$$[5]\quad \Delta = (0.65 \pm 0.06)[E(A/A^+) - E(K^-/K)] - (13.0 \pm 1.3)$$

From this relation Δ's for our systems can be calculated, and the results are given in Table 2. Using the experimentally measured $E_{1/2}^{red}$ of the ketones, the $E_{1/2}^{oxid}$ of *N,N*-dimethyl aniline and the calculated values of Δ the triplet energy of the c.t. complex can be obtained using eq. 4. The data are listed in Table 2.

The calculated ^{3}c.t. energies are about 5000 cm^{-1} to the red of the molecular phosphorescence, compatible with the results obtained for fluorescent quenching of aromatic hydrocarbons by *N,N*-dimethyl aniline (17).

Interestingly, a linear free-energy relationship between the carbonyl molecule triplet energy

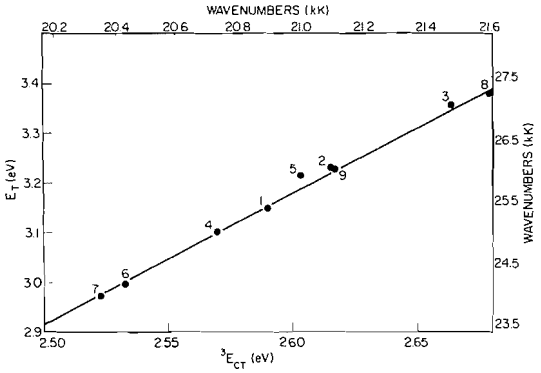

FIG. 1. A plot of the carbonyl compounds triplet energies E_T's *vs.* the corresponding triplet energy of c.t. complex of *N*,*N*-dimethylaniline with : *1*, formaldehyde; *2*, acetaldehyde; *3*, acetone; *4*, benzaldehyde; *5*, acetophenone; *6*, benzonitrile; *7*, acrolein; *8*, benzonitrile; and *9*, *s*-triazine.

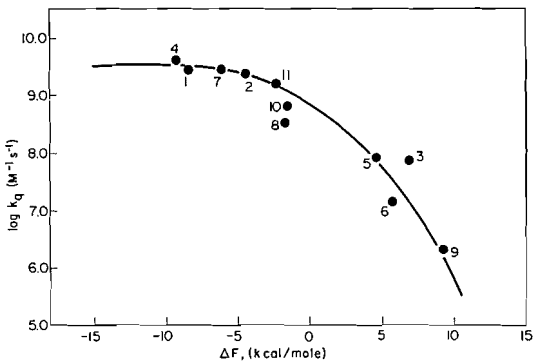

FIG. 2. Plot of the quenching rate constant *vs.* the free energy change (ΔF) of the reaction of triplet: benzophenone with: *1*, *N*,*N*-dimethylaniline; *2*, triethylamine; *3*, *t*-butylamine; *4*, *N*,*N*-dimethyl-*p*-tolylamine; *5*, phenylmethylsulfide, acetophenone with *6*, *N*-butylmercaptane, acetone with *7*,*N*,*N*-dimethylaniline; *8*, triethylamine; *9*, *t*-butylamine and fluorenone with *10*, *N*,*N*-dimethylaniline; *11*, *N*,*N*-dimethyl-*p*-tolylamine.

(E_T) and the corresponding triplet c.t. complex energy was obtained (Fig. 1). The slope of the plot was found to be slightly larger than 2. These results are in very good agreement with those of Azumi and McGlynn (11). These authors found a linear correlation between ($I_D - A_A$) and the singlet energy of the aromatic hydrocarbon excimer with a slope greater than 2.

The free-energy change, ΔF, for charge transfer formation in a triplet excited state may be represented by eq. 6 (16):

$$[6]\quad \Delta F = E(A/A^+) - E(K^-/K) - \frac{e^2}{\varepsilon r} - {}^3\Delta E_{0,0}$$

In the present application the calculated ΔF for triplet ketone–amine, ether, sulfide and thiol c.t. formation are listed in Table 3 along with the experimental quenching rate. From a plot of the calculated ΔF *vs.* the triplet quenching rate constant (Fig. 2) we obtained a curve similar to that reported earlier by Weller and co-worker (18) for the singlet state in which k_q tended to level off at $\Delta F < -4$ kcal/mol. Cohen and co-worker (5*b*) recently applied eq. 2 for a special case,

where he used common acceptor. In such case, $E(K^-/K)$ and $^3\Delta E_{0,0}$ are constant and ΔF depend only on oxidation potential of the donor or the ionization potential can be used if the solvation energy differences between the various donors are small.

In conclusion, the correlation obtained between the triplet energy of organic carbonyl molecules and the estimated triplet energy of carbonyl molecule–amine c.t. complexes indicates the existence of a direct and useful relation which could be utilized coupled with the electrochemical data to predict the energy of ^{3}c.t. complexes.

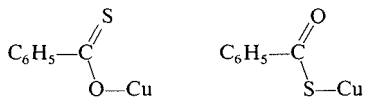
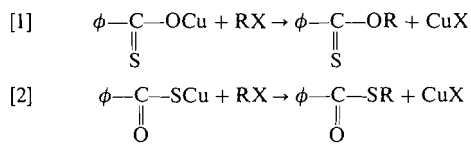
Introduction

In a recent article Nair and Nair (1) concluded, chiefly on the basis of infrared measurements, that in cuprous thiobenzoate, copper is linked to the oxygen, rather than to the sulfur, as in **1**. This article prompted an investigation



1 **2**

on the potential usefulness of this salt for the direct synthesis of thionbenzoate esters by reaction with aliphatic and aromatic halides according to reaction 1. All the presently avail-



ϕ = phenyl; R = alkyl or aryl; X = halogen

able methods for thionesters are indirect (2, 3). If, however, **2** should prove to be the correct structure of cuprous thiobenzoate, thiolbenzoate esters should result instead, according to reaction 2. Since thiolesters, by acid or alkaline hydrolysis, always yield a carboxylic acid and a thiol (2), the formation of thiolbenzoates with cuprous thiobenzoate would afford a simple two-step method for the synthesis of aromatic and aliphatic thiols and polythiols starting from the corresponding halides.

Results and Discussion

The reaction of cuprous thiobenzoate with the following organic halides has been studied: bromobenzene, fluorobenzene, *p*-iodotoluene, *p*-chlorobenzoic acid, *o*-iodobenzoic acid, iodomethane, 1,2-dichlorotetrafluorocyclobut-1-ene, 1-bromopropane, and 2-chloroethanol. Apparently, cuprous thiobenzoate is not as versatile as cuprous thiophenolate and aliphatic mercaptides (4, 5) in displacing halogens from organic substrates. In fact, only *o*-iodobenzoic acid and iodomethane reacted. However, thiolbenzoates were obtained rather than thionbenzoates.

Iodomethane failed to react in alcohol at reflux temperature. However, when two molar equivalents of pyridine per mole of cuprous thiobenzoate was added, methyl thiolbenzoate formed with 90% yield. Its infrared and mass spectra are identical with those of an authentic sample of *S*-methyl thiobenzoate prepared from benzoyl chloride and methyl mercaptan. When one half molar equivalent of pyridine was used, the yield dropped to 50%. In both cases a small amount of ethyl benzoate was present in the crude product.

The reaction of *o*-iodobenzoic acid with cuprous thiobenzoate proceeded smoothly and quantitatively in absence of pyridine with formation of a thioester. Its infrared spectrum shows a band at 1682 cm^{-1} ($\nu C{=}O$) consistent with a thiolbenzoate structure (6). The high-resolution mass spectrum of the thioester (molecular ion at *m/e* 258, elemental composition $C_{14}H_{10}O_3S$) has the base peak at *m/e* 105 ($C_7H_5O^+$), and shows two intense rearrangement ions at *m/e* 122 ($C_7H_6O_2^{+\cdot}$) and *m/e* 136 ($C_7H_4OS^{+\cdot}$). These fragments are consistent with a thiolbenzoate structure only. Chemical confirmation was obtained by alkaline hydrolysis which afforded benzoic acid and diphenyl disulfide 2,2′-dicarboxylic acid (after $FeCl_3$ oxidation).

In cases in which the halogen compound failed to react, the starting material was recovered along with the following: ethyl benzoate, dibenzoyl disulfide, benzoic acid, thiobenzoic acid, hydrogen sulfide, and cuprous sulfide. These are products of decomposition of the copper salt and were all present each time the reaction was unsuccessful, except in the case of 1,2-dichlorotetrafluorocyclobut-1-ene, where ethyl benzoate was the only identifiable product.

The formation of thiolesters, instead of the thionesters one would expect on the basis of Nair and Nair's conclusion (1), does not necessarily settle the problem of the structure of the salt. The formation of *S*-thiobenzoates can be explained if one admits the existence of an equilibrium mixture of the two tautomeric forms **1** and **2**, the latter reacting much faster than the former (3).

The behavior of cuprous thiobenzoate is somewhat reminiscent of that of cuprous benzylmercaptide, *t*-butylmercaptide, and xanthate (5); namely, with certain substrates it decomposes before the reaction temperature is reached. Unlike cuprous benzylmercaptide (7), the thiobenzoate fails to react with 1,2-dichlorotetra-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fluorocyclobut-1-ene, even in the presence of pyridine.

On the basis of the above experiments, it appears that cuprous thiobenzoate has a good potential for the synthesis of *S*-thioesters from halides. However, its usefulness is limited to the reaction with aliphatic and activated aromatic iodides.

Experimental

General Conditions

The i.r. spectra were recorded on a Beckman IR 5A instrument, and were calibrated with polystyrene. The mass spectra were determined on a CEC 21-110B double-focusing spectrometer (ionizing energy 70 eV). Accurate mass measurements were made by the peak-matching method using a perfluorokerosene reference. Gas-liquid chromatographic separations were performed with a 240 cm × 6 mm column packed with Chromosorb W coated with 20% Silicone SE-30, and with a 420 cm × 6 mm column packed with Chromosorb W coated with 15% Triton X305. The instrument was a 5750 Hewlett–Packard equipped with a thermal conductivity cell. The reactions were carried out in alcohol or alcohol–pyridine.

Methyl Thiolbenzoate

Two grams (0.01 mol) of cuprous thiobenzoate was suspended in 20 ml of ethanol and 1.6 ml (0.02 mol) of pyridine, and the mixture was heated to mild reflux. Methyl iodide (3.55 g, 0.025 mol) was added, and heating continued for 45 min with magnetic stirring. The reaction mixture was then poured into ice-water containing 2 ml of concentrated hydrochloric acid, and extracted with chloroform. After drying, evaporation of the solvent afforded 1.44 g of crude methyl thiolbenzoate which was contaminated with 5% of ethyl benzoate, as calculated by peak area measurement of the gas chromatogram. Therefore, the actual yield was 90%.

2-(Benzoylthiol)benzoic Acid

Two grams (0.01 mol) of cuprous thiobenzoate and 2.48 g (0.01 mol) of *o*-iodobenzoic acid were heated at gentle reflux in 20 ml of ethanol for 90 min with stirring. The color of the suspended solid changed from brick-red to tan in 45 min. No pyridine was added as the change in color was indicative of reaction. An excess of alcohol was added, and the suspension was filtered hot through a 2 cm layer of Celite 245. The crude material (2.50 g) was recrystallized from ethanol; m.p. 160–161° (Fisher–Johns, uncorrected). This compound has not been previously reported in the literature. Its i.r. spectrum (Nujol) shows bands at 2500 ~ 2800(w), 1698(sh), 1682(s), 1585(m), 1418(m), 1316(m), 1292(w), 1212(m), 1185(m), 1152(w), 1059(w), 963(w), 910(s), 800(m), 772(m), 748(s), 697(m), 687(s), 648(w), 639(m) cm^{-1}. In the mass spectrum, the ten most intense peaks (*m/e*) are (percentage of the base peak and elemental composition in parentheses): 50(9%, $C_4H_2^{+\cdot}$), 51(21%, $C_4H_3^+$), 77(57%, $C_6H_5^+$), 105(100%, $C_7H_5O^+$), 106(9%, $C_6{}^{13}CH_5O^+$), 108(9%, $C_6H_4S^{+\cdot}$), 122(18%, $C_7H_6O_2^{+\cdot}$), 136(37%, $C_7H_4OS^{+\cdot}$), 153(3%, $C_7H_5O_2S^+$), 258(3%, $C_{14}H_{10}O_3S^{+\cdot}$). All the above elemental compositions are the result of accurate mass measurements.

The author thanks Dr. John M. Ruth, Entomology Research Division, A.R.S., U.S. Department of Agriculture, Beltsville, Maryland, for the mass spectral measurements, and Mr. Vincent P. Flanagan of this laboratory for the gas–liquid chromatographic separations.

Mention of brand or firm names does not constitute an endorsement by the Department of Agriculture over others of a similar nature not mentioned.

The Preparation and Paramagnetic Susceptibility of β-MnSe

RITCHIE MACLAREN MURRAY, BRIAN CHARLES FORBES, AND ROBERT DONALD HEYDING
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 25, 1972

A procedure is given for the preparation of β-MnSe by precipitation from solution. The cubic B3 zinc blende type structure has a unit cell dimension of 5.88 ± 1 Å. The magnetic susceptibility obeys the Curie–Weiss law above 110 °K with $C = 3.64 \pm 14$ and $\theta = 444 \pm 13$, equivalent to an effective moment of 5.40 μ_B.

Un mode opératoire est donné pour la préparation du β-MnSe par précipitation à partir d'une solution. La structure cubique B3 du type zinc blende possède une maille élémentaire de dimension égale à 5.88 ± 1 Å. La susceptibilité magnétique obéit au-dessus de 110 °K, à la loi de Curie–Weiss avec $C = 3.64 \pm 14$ et $\theta = 444 \pm 13$ ce qui équivaut à un moment effectif de 5.40 μ_B. Introduction

Although manganese sulfide and selenide normally crystallize with the B1 rock salt structure, metastable zinc blende (B3) and wurtzite (B4) modifications have been prepared (1, 2). Baroni prepared β-MnSe (B3) by treating a solution of manganese acetate with hydrogen selenide (2). The hexagonal B4 modification, γ-MnS, was obtained from an ammoniacal solution of manganese chloride or sulfate. Both modifications transformed rapidly to the B1 α-MnSe form when dried.

α-MnSe is antiferromagnetic with a Néel temperature T_N between 145 and 170 °K (3–5). Observation of the magnetic transformation is complicated by a phase transition at *ca.* 245 °K which is sluggish and gives rise to hysteresis effects in the magnetic susceptibility. The low temperature phase has the hexagonal nickel arsenide ($B8_1$) structure (5, 6). The additional neutron diffraction lines observed by Sirota and Makovetskii at 115 °K and believed to be due to a B3 zinc blende type phase (7) are almost certainly due to the formation of the $B8_1$ phase. Baroni's modifications, β- and γ-MnSe, do not appear to be associated with low temperature equilibrium transformations in α-MnSe as had been suggested earlier (3).

In general the addition of H_2Se to any divalent manganese solution produces α-MnSe rather than the metastable forms. Control of the p*H* during the addition of H_2Se is of considerable importance in determining the form of the precipitate. In this Note a recipe for the preparation of β-MnSe is given, and the magnetic properties of this modification are recorded.

Experimental

β-MnSe may be prepared as follows: A solution 0.74 *M* in NaOAc and containing 10 mmol of manganese acetate is outgassed on a vacuum line and exposed at 298 °K to 7 mmol of hydrogen selenide at *ca.* 0.5 atm. The gas dissolves rapidly, and a precipitate begins to appear after 2 h. The reaction is complete in 12 h. The product, a finely divided brown powder, is recovered on a sintered disc under nitrogen, washed with water and ethanol, also under nitrogen, finally washed with ether and air dried. The yield is about 50% of theoretical.

Selenium precipitates at the same time, sometimes in an amorphous form, and may constitute as much as 15% by weight of the total precipitate. Some of this contaminant can be removed by extraction with carbon disulfide.

Traces of γ-MnSe may also appear. Larger quantities may be obtained by increasing the $Mn(OAc)_2$ concentration by a factor of two, but this polymorphic form was never more than a minor constituent in any of the precipitates we recovered, regardless of the recipe.

Magnetic susceptibilities were determined from 85 to 450 °K in a Curie apparatus at field gradients of 19.5, 22, and 23.5×10^6 Oe cm^{-1} (8). The susceptibility of α-MnSe was redetermined using a specimen prepared by direct interaction between the elements in the usual way. Products were identified by Debye–Scherrer X-ray powder diffraction patterns using copper radiation and a nickel screen between specimen and film.

Results and Discussion

The powder diffraction pattern of β-MnSe is given in Table 1. The unit cell dimension, 5.88 ± 1 Å, agrees well with Baroni's value of 5.82 Å obtained by electron diffraction. The manganese–selenium distance in four-coordinated

TABLE 1. X-Ray powder diffraction pattern of β-MnSe cubic, $F\bar{4}3m$, B3 zinc blende, $a = 5.88 \pm 1$ Å Cu K_α radiation, Ni filter, Al screen, $\lambda = 1.5418$ Å I/I_M from integrated Debye Scherrer films

d (Å)	I/I_M	hkl
3.36	100	111
2.99	7	200
2.07	68	220
1.79	43	311
1.47	5	400
1.347	10	331
1.199	12	422
1.131	7	511
1.040	3	440
0.994	7	531
0.930	3	620
0.824	4	551
0.788	6	642

β-MnSe (2.54 Å) is 7% shorter than the interionic distance in six-coordinated α-MnSe (2.73 Å). A similar difference is observed in the manganese–sulfur distance in α- and β-MnS (1). In both systems the molar volume of the β form is 24% greater than that of the α form.

β-MnSe is stable at room temperature and requires no special storage precautions. On heating in a sealed ampoule, transformation to the α form takes place relatively slowly, and at the same time the elemental selenium present in the product reacts with the monoselenide to form the diselenide, $MnSe_2$. The transformation and reaction are complete in 3 days at 625 °K.

The results of the susceptibility studies are summarized in Fig. 1 and in Table 2. Hysteresis in the susceptibility behavior of α-MnSe was again observed below 250 °K. The susceptibility

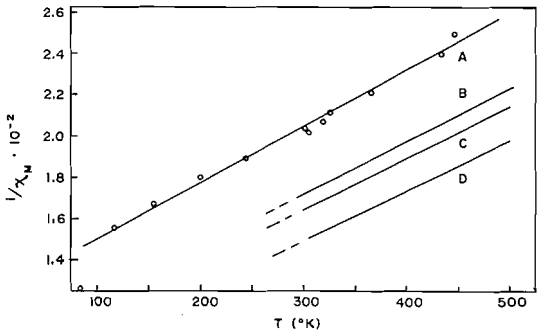

FIG. 1. Paramagnetic susceptibilities of MnSe: *A*, β-MnSe, corrected for 15 weight % Se in sample; *B*, α-MnSe, prepared by direct combination of the elements; *C*, α-MnSe, ref. 12; *D*, α-MnSe, ref. 13.

of β-MnSe obeys the Curie–Weiss law above 110 °K. Positive deviation from the law below 110 °K may indicate the onset of magnetic ordering, but because of the temperature limit of 85 °K in our balance this possibility could not be confirmed. It is surprising that a magnetic transformation does not occur above 110 °K, since the Néel temperature of the corresponding sulfide, β-MnS (~160 °K), is greater than that of α-MnS (~130 °K) (9).

Like the other monsulfides and selenides of manganese, the effective Bohr magneton number, p_{eff}, of β-MnSe is less than expected for a d^5 ion assuming spin only contributions. The exception is γ-MnS, which according to data given by Corliss *et al.*, has an effective moment of 6.15 μ_B (9), and all three dichalcogenides have moments greater than the theoretical value (11).

The susceptibility constants of β-MnSe above

The Synthesis of 1-Benzyl-2-carbomethoxy-3,3-dimethyl Aziridine and its Ring Opening with Excess Acids

CASIMIR BERSE AND PIERRE BESSETTE
Department of Chemistry, Université de Montréal, Montreal, Quebec

Received June 27, 1972

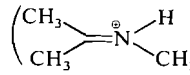
The synthesis of 1-benzyl-2-carbomethoxy-3,3-dimethyl aziridine and its ring opening with various excess acids such as hydrogen chloride, acetic, propionic, and thioacetic acids and benzyl mercaptan are herein described.

La synthèse du benzyl-1 méthoxycarbonyl-2 diméthyl-3,3 aziridine et de ses ouvertures, par différents acides en excès tels que: le chlorure d'hydrogène, les acides acétique, propionique, et thiolacétique, et par le benzyl mercaptan, est décrite.

Canadian Journal of Chemistry, **50**, 4061 (1972)

In our attempt to synthesize penicillamine via the aziridine route (1), the preparation and reactions of 1-benzyl-2-carbomethoxy-3,3-dimethylaziridine (**2**) were undertaken. Due to the failure, in our case, of the synthesis of such a highly substituted aziridine by the methods of Cromwell and Huisgen (2, 3), the use of triphenylphosphine dibromide (4) on methyl *N*-benzyl-β-hydroxyvalinate (**1**) was attempted and permitted the formation of aziridine (**2**), b.p. 95–100°/0.05 mm, yield 76%.

Reaction of aziridine (**2**) with anhydrous hydrogen chloride in benzene at 25 °C gave a white solid identified as methyl 3-benzylamino-2-chloro-3-methylbutyrate hydrochloride (**3**), m.p. 174–175°; yield 87%. Structure **3** was differentiated, from its possible 2-benzylamino-3-chloro-isomer, by the fact that its mass spectrum showed a large fragment at *m/e* 148



When aziridine **2** was heated at reflux in benzene with acetic acid, the product obtained was methyl 2-(*N*-benzylacetamido)-3-methylcrotonate (**4***a*); b.p. 133–136°/0.15 mm; yield 41%. The n.m.r. of product **4***a* showed a marked non-equivalence between the two methyls on the double bond which appeared as two singlets at τ (CCl_4) 8.60 and 7.90. To distinguish the

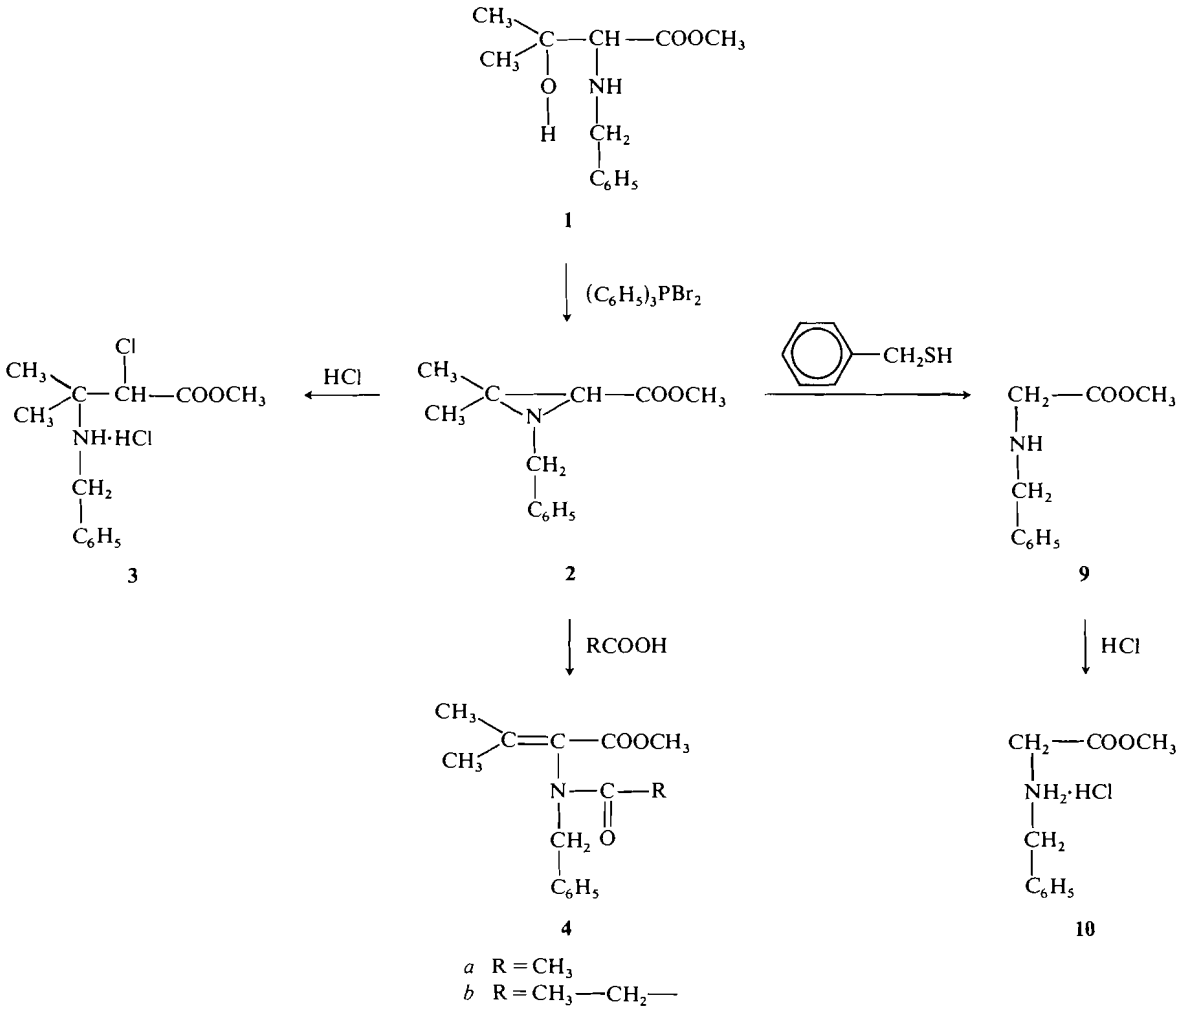
The n.m.r. of product **4***a* showed a marked non-equivalence between the two methyls on the double bond which appeared as two singlets at τ (CCl_4) 8.60 and 7.90. To distinguish the

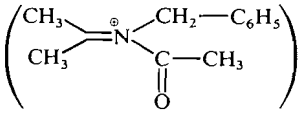


SCHEME 1

two methyl groups from the acetamido group at τ (CCl_4) 8.20, the methyl 2-(*N*-benzylpropionamido)-3-methylcrotonate (**4***b*) was prepared. Product **4***b* showed an almost identical spectrum, except that the singlet of the acetamido group was replaced by a triplet and a quadruplet at τ (CCl_4) 8.97 and 8.00 (Scheme 1).

In the case of reaction of aziridine (**2**) with thioacetic acid in benzene at 25 °C, at least four products could be obtained depending upon the concentration of thioacetic acid used.

At low concentration of thioacetic acid, two products were obtained: (*i*) methyl 3-methyl-2-thioacetoxycrotonate (**5**), b.p. 65–70°/0.05 mm, yield (23%), and (*ii*) methyl 3-(*N*-benzylacetamido)-3-methyl-2-thiobutyrate (**6**), yield (54%), whose mass spectrum showed a high peak at *m/e* 190



Product **6** which is unstable was further proved by acetylation with acetyl chloride to give a white solid identified as methyl 3-(*N*-benzylacetamido)-3-methyl-2-thioacetoxybutyrate (**7**), m.p. 118–119°, yield (56%).

Use of higher concentration of thioacetic

computer. Elemental analyses were performed by Midwest Microlab. Inc., Indianapolis, Indiana.

Methyl N-Benzyl-β-hydroxyvalinate (1)

To a solution of *N*-benzyl-β-hydroxyvaline (6) (4.005 g, 0.0179 mol) in methanol (50 ml) an ethereal solution of diazomethane was added. The solution was evaporated *in vacuo* and chromatographed on silica gel and eluted with ether–hexane (50:50 v/v) to give product **1**; yield 3.715 g (87%), b.p. 104–106°/0.05 mm Hg. I.r. bands (CCl_4) at 3540, 3360 and 1735 cm^{-1}; τ (CCl_4): 8.96 and 8.80 (6H, singlet), 7.35 (2H, hump), 7.00 (1H, singlet), 6.36 (5H, singlet and AB system for $—CH_2—$ of benzyl, $J = -10$ Hz), 2.76 (5H, singlet).

Anal. Calcd. for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.08. Found. C, 65.88; H, 8.35.

1-Benzyl-2-carbomethoxy-3,3-dimethylaziridine (2)

To a 0 °C cooled solution of triphenylphosphine (7.62 g, 0.0282 mol) in acetonitrile (50 ml) a solution of bromine (4.45 g, 0.0282 mol) in acetonitrile (30 ml) was added dropwise under stirring. The addition finished, product **1** (6.61 g, 0.0279 mol) in acetonitrile (40 ml) was added dropwise during 1/2 h. To the solution obtained, triethylamine (5.69 g, 0.0564 mol) in acetonitrile (40 ml) was added during 1/2 h. The solution was stirred at 0 °C for 2 h and an additional 2 h at 20 °C.

Triethylamine hydrobromide was filtered off. The solution was concentrated *in vacuo* and ether (100 ml) was added. Triphenylphosphine oxide was filtered off, and the ethereal solution evaporated *in vacuo*. The oily residue was chromatographed on silica gel and eluted with ether 20%/hexane to give pure aziridine **2**; yield 4.63 g (76%); b.p. 95–100°/0.05 mm Hg; i.r. bands (CCl_4) at 3090, 3050, 2980, 1750, 1725, 1600 cm^{-1}; τ (CCl_4): 8.75 (6H, singlet), 8.04 (1H, singlet), 6.43 (3H, singlet), 6.34 (2H, singlet (broad)), 2.76 (5H, multiplet).

Anal. Calcd. for $C_{13}H_{17}NO_2$: C, 71.20; H, 7.81. Found: C, 70.99; H, 7.89.

Methyl 3-Benzylamino-2-chloro-3-methylbutyrate Hydrochloride (3)

Product **2** (0.330 g, 0.00151 mol) in anhydrous benzene (5 ml) was bubbled at 20 °C with anhydrous hydrogen chloride for 5 min. The solution was stirred for 2 h. The white solid was filtered and recrystallized in a dichloromethane/ether mixture.

Product **3**, 0.384 g (87%); m.p. 174–175°; i.r. bands (Nujol) at 2740, 2360, 1755, 1740, and 1565 cm^{-1}; τ (D_2O): 8.40 and 8.32 (6H, singlet), 6.07 (3H, singlet), 5.65 (2H, singlet), 5.20 (2H, DHO singlet), 4.82 (1H, singlet), 2.47 (5H, singlet).

Anal. Calcd. for $C_{13}H_{19}NO_2Cl_2$: C, 53.43; H, 6.55. Found: C, 53.14; H, 6.84.

Methyl 2-(N-Benzylacetamido)-3-methylcrotonate (4a)

Product **2** (0.324 g, 0.00148 mol) and acetic acid (2.00 g, 0.033 mol) in benzene (10 ml) were heated at reflux for 14 h. Benzene was evaporated *in vacuo* and ether (50 ml) added. The solution was washed with 5% sodium carbonate dried on magnesium sulfate and chromatographed on silica gel and eluted with ether 40%/hexane.

Product **4***a*, 0.156 g (45%); b.p. 133–135°/0.15 mm Hg; i.r. bands (CCl_4) 2960, 1720, 1665, 1640; τ (CCl_4): 8.60 (3H, singlet), 8.20 (3H, singlet), 7.90 (3H, singlet), 6.45 (3H, singlet), 5.11 and 5.97 (2H, doublet, $J_{gem} = -14$ Hz), 2.78 (5H, singlet).

Anal. Calcd. for $C_{15}H_{19}NO_3$ (mol. wt. 261.1364): C, 69.32; H, 7.34. Found (261.1361 (mass spectrum)): C, 69.75; H, 7.30.

Methyl 2-(N-Benzylpropionamido)-3-methylcrotonate (4b)

Prepared as **4***a*. Reaction of product **2** (0.333 g, 0.00152 mol) with propionic acid (2.79 g, 0.0377 mol) was followed by chromatography on silica gel and pure product **4***b* 0.152 g (37%) was obtained. I.r. bands (CCl_4) at 3000, 2960, 1720, 1665 and 1635 cm^{-1} (shoulder); τ (CCl_4): 8.97 (3H, triplet, $J = 7.5$ Hz), 8.65 (3H, singlet), 8.00 (2H, quadruplet, $J = 7.5$ Hz), 7.91 (3H, singlet), 6.47 (3H, singlet), 5.09 and 5.99 (2H, AB system, $J_{gem} = -14$ Hz) 2.80 (5H, singlet).

Anal. Calcd. for $C_{16}H_{21}NO_3$: C, 69.79; H, 7.68. Found: C, 69.50; H, 7.62.

Methyl 3-Methyl-2-thioacetoxycrotonate (5) and Methyl 3-(N-Benzylacetamido)-2-mercapto-3-methylbutyrate (6)

To a solution of aziridine **2** (0.345 g, 0.00158 mol) in benzene (3 ml) a solution of thioacetic acid (0.360 g, 0.0047 mol) in benzene (3 ml) was added dropwise. The solution was stirred at 20 °C for 2 h and then evaporated *in vacuo*. The yellow oil was chromatographed on silica gel and eluted first with ether 20%/hexane to give **5** and then with ether 50%/hexane to give **6** which gave a positive test for the mercapto group.

Product **5**, 0.070 g(23%); b.p. 65–70°/0.05 mm; i.r. bands (CCl_4) at 2970, 1720, and 1700 cm^{-1} (shoulder); τ (CCl_4): 7.97 (3H, singlet), 7.75 (3H, singlet), 7.68 (3H, singlet), 6.31 (3H, singlet).

Anal. Calcd. for $C_8H_{12}O_3S$: C, 51.04; H, 6.42. Found: C, 50.72; H, 6.41.

Product **6**, 0.250 g (54%); i.r. bands (CCl_4) at 2970, 2350, 1730, and 1650 cm^{-1}; τ (CCl_4): 8.50 (6H, singlet), 8.02 (3H, singlet), 7.7 (1H, broad), 6.30 (3H, singlet), 5.42 (2H, singlet), 5.02 (1H, doublet (broad)), 2.75 (5H, multiplet). Mass spectrum: fragments at *m/e* 277, 190, and 148.

Methyl 3-(N-Benzylacetamido)-3-methyl-2-thioacetoxybutyrate (7)

To a solution of product **6** (0.050 g, 0.00017 mol), and acetyl chloride (0.014 g, 0.00017 mol) in benzene (0.5 ml), a solution of triethylamine (0.018 g, 0.00017 mol) in benzene (0.5 ml) was added dropwise. The solution was stirred at 25 °C for 24 h. The triethylamine hydrochloride was filtered off and the solution evaporated and the residue was crystallized in an ether–hexane mixture.

Product **7**, 0.032 g (56%), m.p. 117–118°; i.r. bands ($CHCl_3$) at 2970, 1730, 1700, and 1645 cm^{-1}; τ ($CDCl_3$): 8.54 (6H, singlet), 8.01 (3H, singlet), 7.68 (3H, singlet), 6.32 (3H, singlet), 5.45 (2H, singlet), 4.42 (1H, singlet), 2.74 (5H, singlet).

Anal. Calcd. for $C_{17}H_{23}NO_4S$: C, 60.51; H, 6.87. Found: C, 60.45; H, 6.66.

3-Benzyl-5-methoxycarbonyl-4,4-dimethyl-2-(2′-thioxopropylidene)thiazolidine (8)

To a stirred solution of aziridine **2** (0.844 g, 0.00386 mol)

thioacetic acid (3.00 g, 0.040 mol) was added dropwise during 10 min. The solution was stirred 1/2 h and excess thioacetic acid was evaporated *in vacuo*. The red oil obtained was chromatographed on silica gel and eluted with ether 10%/hexane, ether 20%/hexane, and ether 30%/hexane to give product **5**, 0.319 g (43%), **8**, 0.161 g (12%), and **7**, 0.144 g (11%), respectively.

Products **5** and **7** were identified by comparison of their spectra, t.l.c., b.p., and m.p., which proved identical in every way to those obtained earlier.

Product **8** had the following characteristics: m.p. 175–177°; i.r. bands ($CHCl_3$) at 2960, 1735, 1500 cm^{-1}; τ ($CDCl_3$): 8.58 and 8.48 (6H, singlet), 7.48 (3H, singlet), 6.20 (3H, singlet), 6.01 (1H, singlet), 5.40 (2H, singlet), 3.58 (1H, singlet), 2.60 (5H, singlet). Mass spectrum: *m/e* 335 (two sulfurs, P + 2/P = 12%); u.v. (EtOH 95%): λ 235 (ε 25 000); λ 288 (ε 5200).

Anal. Calcd. for $C_{17}H_{21}NO_2S_2$: C, 60.86; H, 6.33. Found: C, 60.61; H, 6.35.

*Methyl N-Benzylglycinate Hydrochloride (**10**)*

Product **2** (0.266 g, 0.00192 mol), benzylmercaptan (1.80 g, 0.0121 mol), and toluene (2 ml) were heated at reflux for 20 h. The solution was then chromatographed on silica gel and eluted first with hexane to get rid of the unreacted mercaptan and then with ether–hexane (50–50 v/v). The fraction was evaporated and ether (25 ml) added. The ethereal solution was saturated with hydrogen chloride and the precipitate crystallized in a dichloromethane–ether mixture.

Product **10**, 0.045 g (17%), m.p. 127–128 °C (lit. (5) 128°), fused m.p. with an authentical sample, 127–128 °C; i.r. bands (CH_2Cl_2) at 3100–2200 (broad), 1750 and 1560 cm^{-1}; τ (D_2O): 6.22 (3H, singlet), 6.00 (2H, singlet), 5.70 (2H, singlet), 5.20 (2.7H, singlet DHO), 2.50 (5H, singlet).

Oxidation of *p*-Dimethylaminobenzaldehyde Semicarbazone. Novel Conversion of an Aromatic Aldehyde to an Aroyl Cyanide

PETER KNITTEL AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 31, 1972

Oxidation of the semicarbazone of *p*-dimethylaminobenzaldehyde with lead tetraacetate affords *p*-dimethylaminobenzoyl cyanide. Probable intermediates are an iminooxadiazoline and an iminooxirane.

L'oxydation de la semicarbazone de la *p*-diméthylaminobenzaldéhyde par le tetraacétate de plomb conduit au cyanure de *p*-diméthylaminobenzoyle. Les intermédiaires probables sont un iminooxadiazoline et une iminooxirane. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 4066 (1972)

Oxidative cyclization of carbohydrazones (1) and semicarbazones (2) of ketones with lead tetraacetate (LTA) appears to be a general method for the synthesis of the 2-imino-Δ^3-1,3,4-oxadiazoline ring system, eq. 1.

Corresponding derivatives of aldehydes have

[1] 
R^1, R^2 = alkyl or aryl; R^3 = alkyl, aryl or $N{=}CR^1R^2$

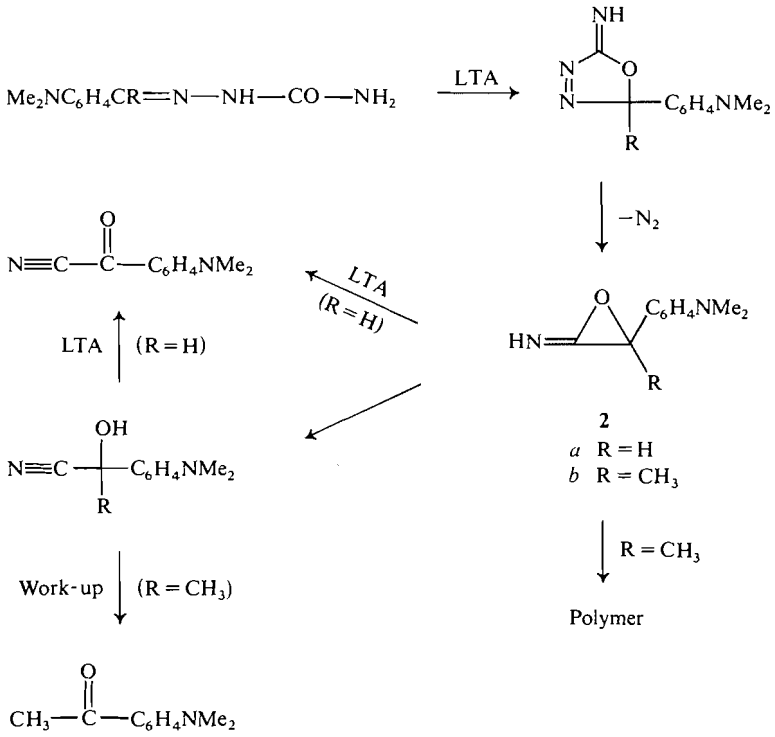
also been cyclized (3–7) but ring closure is followed by tautomerization; aminooxadiazoles being the products isolated, eq. 2. We wish to

[2] 
report a novel, efficient conversion of an aromatic aldehyde to an aroyl nitrile (ArCHO → ArCO(CN)) through oxidation of its semicarbazone.

p-Dimethylaminobenzaldehyde semicarbazone (5.0 g, 0.024 mol) in 300 ml of methylene chloride at 0° under pure nitrogen was stirred for 2 h with LTA (10 g, 0.023 mol). Addition of more LTA (12 g, 0.027 mol) and further stirring for 2 h at 0°, followed by addition of water (500 ml), filtration through Celite, separation, and drying of the organic layer gave a greenish-brown solid (3.7 g) which was recrystallized from alcohol and sublimed (100°, 10^{-2} Torr) to afford *p*-dimethylaminobenzoyl cyanide (**1**) as a yellow solid (3.0 g, 71%), m.p. 170–171°, lit. (8) m.p. 170°. Analyses, spectra, and molecular weight consistent with the assigned structure were obtained. Treatment of **1** with aqueous alkali lead to its dissolution with loss of the yellow color. Acidification afforded *p*-dimethylaminobenzoic acid, m.p. 240–242°, lit. (9) m.p. 242.5–243.5°; i.r. and n.m.r. spectra identical with those of an authentic sample. The residual aqueous solution gave a strong Prussian blue test for cyanide ion (10).

Formation of **1** can be rationalized in terms of cyclization of the semicarbazone to the 2-imino-Δ^3-1,3,4-oxadiazoline which, instead of tautomerizing, loses nitrogen to form the iminooxirane **2***a*. The latter may be oxidized to **1**, either by

[3]



direct action of LTA, or by prior isomerization to aldehyde cyanohydrin, which is then oxidized by LTA, eq. 3.

The same treatment of the semicarbazone of *p*-dimethylaminoacetophenone gave *p*-dimethylaminoacetophenone (*ca.* 15%) and a polymer. With $R = CH_3$ (eq. 3), oxidation of both the iminooxirane and the cyanohydrin is stopped and polymerization, a very facile reaction of α-lactones (11, 12), appears to compete with cyanohydrin formation.

Semicarbazones of benzaldehydes substituted with groups (*e.g.* CH_3O) of lower donor capability than NMe_2 give very little, if any, aroyl nitrile but lead instead to aminooxadiazoles (eq. 2) and their oxidation products. Furfural semicarbazone also follows the latter course.

Work aimed at isolation of iminooxiranes from this novel route is in progress.

The Photocyclization of Aromatic Thioketones[1]

R. LAPOUYADE[2] AND P. DE MAYO

Photochemistry Unit, The University of Western Ontario, London, Ontario

Received August 16, 1972

Certain aromatic thioketones, having an adjacent vacant *peri* position to the thiobenzoyl group cyclize on irradiation. This rearrangement, unknown in the ketonic series, leads to thiophane derivatives.

Certaines thiocétones aromatiques ayant, par rapport au groupe thiobenzoyle, une position *péri* adjacente vacante se cyclisent par irradiation. Ce réarrangement, inconnu en série cétonique conduit à des dérivés du thiophane. [Traduit par le journal]

Although the photochemistry of aromatic ketones has been studied at very great length, the corresponding thioketones have received very little attention. Such photochemical reactions as have been reported have been concerned, essentially, with cycloaddition (1–3) or reduction (3*a*, 4). We wish to report here a new class of reaction which does not fall into these categories and which has presently (5) no equivalent in the ketonic series.

Aromatic thiones so far described have a lowest n,π^* triplet state (6). In connection with attempts to prepare an aromatic thione with a lowest energy state other than triplet n,π^* lowest in energy, we have prepared a number of substances having an aromatic nucleus substituted by a thiobenzoyl grouping, *i.e.* of the general formula Ar·CS·C_6H_5 (**1**). These substances were prepared from the corresponding ketones by the classical reaction with hydrogen chloride and hydrogen sulfide.[3]

We have observed that irradiation of these substances having a vacant *peri* position to the thiocarbonyl function leads to chemical reaction. With light of wavelength >520 nm, cyclization occurred to give derivatives of thiophane. For instance, in benzene or acetonitrile solution **1**, Ar = 1-naphthyl, 1-pyrenyl, 6-chrysenyl, and 3-perylenyl, gave compounds **2**–**5**, respectively. The yields of crystallized products were of the order of 60%. In contrast, the similar irradiation of **1**, Ar = 2-naphthyl which does not have a free *peri* position, did not lead to any product over comparable time periods.

The carbon skeletons of the products were shown by desulfurization to the benzylic derivatives. In all cases the benzylic hydrogen was detectable in the n.m.r. spectrum, and there was the corresponding loss of one aromatic proton signal. In the case of **2**, the corresponding sulfone was identical in properties with that described in the literature (7). Irradiation of **1**, Ar = 1-naphthyl in acetonitrile solution containing deuterium oxide leads to complete incorporation of one deuterium atom at the benzylic position as indicated by the disappearance of this proton signal from the n.m.r. spectrum. This indicates that the required hydrogen transfer can be intermolecular and suggests the intermediacy of ionic species which would be more in keeping with a reacting singlet state. In keeping with this it was found impossible to quench the photochemical reaction of **1**, Ar = 1-naphthyl by the addition of perylene ($E_T \sim 36$ kcal/mol) which has a triplet below that of the naphthyl derivative ($E_T \sim 39$ kcal/mol[4]).

It is interesting to note that ketonic substances corresponding to these thioketones would be expected to have π,π^* lowest singlets (or, in the case of the naphthalene derivatives very close-lying states which would be expected

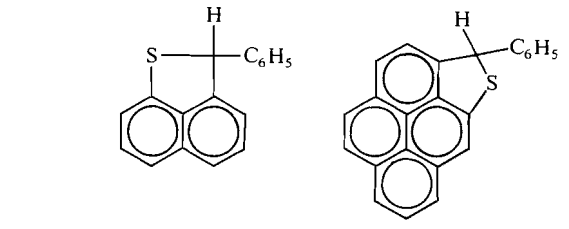
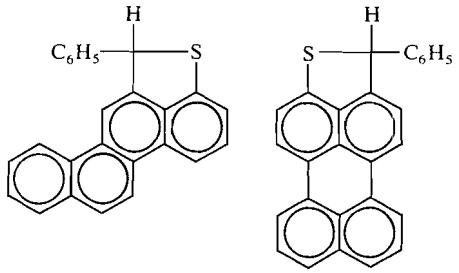
[3]The preparation of the substances and their spectroscopic properties will be reported in full in the complete report. Proper analyses have been obtained for all new substances.

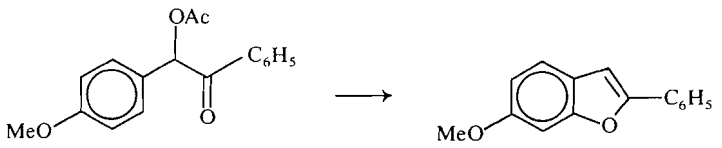
[4]From the emission in EPA at 77 °K.



2 3



4 5



6

to modify chemical behavior). The thioketones, in contrast all have lowest n,π^* singlet states (6*b*). When an aromatic carbonyl group is in the correct spatial relationship and does have the n,π^* singlet state lowest, as in **6**, it does behave appropriately.[5] For these conditions to be met the benzoyl group cannot be directly attached to the aromatic nucleus.

The mechanism of the reaction is under study, but the quantum yields appear to be low. The 1-naphthyl derivative, for instance, reacts with $\Phi \sim 10^{-3}$ depending on the solvent. This may be because of the ready reversibility of an intermediate in which the new C—S bond is already formed. If this is so this decay process is essentially a chemical self-quenching mode.

[5]Reference 8. It is not certain what state is involved in this reaction since the reaction of **6** is quenched with piperylene, but not that of related substances.
