Collisional Deactivation Rates of Electronically Excited Molecular Ions. II

G. I. MACKAY AND R. E. MARCH

Department of Chemistry, Trent University, Peterborough, Ontario

Received July 5, 1971

Total deactivation rate constants have been determined for $N_2^+(B^2\Sigma_u^+)$ and the $(A^2\Pi_u)$ and $(B^2\Sigma_u^+)$ states of CO_2^+ with a number of quenchers. The energy specific total deactivation rate constant is compared to the total radiative lifetime of the excited species. A particular novelty of the technique is that it does not require a complete knowledge of the formation modes for the excited species. The results are compared with theoretical values obtained from the ion-induced dipole model. Individual deactivation rate constants are presented for $N_2^+(B^2\Sigma_u^+)$ ions in the $v = 0$, 1, and 2 vibrational levels quenched by N_2, O_2, H_2, and CO_2; and for the $(A^2\Pi_u)$ and $(B^2\Sigma_u^+)$ states of CO_2^+ quenched by CO_2, N_2, O_2, NO, and H_2. Charge transfer is the most probable mode of deactivation except in the CO_2^+–H_2 reactions where H-atom abstraction is more probable.

Les constantes de vitesse de désactivation totale ont été déterminées pour $N_2^+(B^2\Sigma_u^+)$ et pour les états $(A^2\Pi_u)$ et $(B^2\Sigma_u^+)$ de CO_2^+ avec un certain nombre d'accepteurs. L'énergie spécifique correspondant à la constante de vitesse de désactivation totale est comparée à la durée de vie radiative totale des espèces excitées. Une nouveauté particulière de la technique est qu'elle ne nécessite pas une connaissance complète des modes de formation des espèces excitées. Les résultats sont comparés avec les valeurs théoriques issues du modèle ion-dipôle induit. Les constantes de vitesse de désactivation sont données individuellement pour les ions $N_2^+(B^2\Sigma_u^+)$ dans les niveaux vibrationnels $v = 0$, 1 et 2, piégés par N_2, O_2, H_2 et CO_2; et pour CO_2^+ dans les niveaux $(A^2\Pi_u)$ et $(B^2\Sigma_u^+)$, piégés par CO_2, N_2, O_2, NO et H_2. Le transfert de charge est le mode de désactivation le plus probable sauf pour le système CO_2^+–H_2 où l'arrachement de l'hydrogène est plus probable.

Canadian Journal of Chemistry **50**, 1 (1972)

Thermal energy positive ion–neutral deactivation rate constants have been determined for electronically excited molecular ions, produced in a high energy electron beam. Deactivation rate constants are presented for the ground vibrational level ($v = 0$) of the $N_2^+(B^2\Sigma_u^+)$ ion and for the $v = 1$ and $v = 2$ levels, and for electronically excited molecular ions of carbon dioxide deactivated by carbon dioxide, oxygen, nitrogen, nitric oxide, and hydrogen.

The acquisition of ultraviolet spectra of Mars from the flyby flights of Mariners 6 and 7 has led to a renewed interest in the photochemistry of carbon dioxide. The Martian dayglow spectrum consists of a variety of emission features associated with CO_2^+, CO, O, C, and H. This paper is concerned partially with loss processes of excited CO_2^+ ions which may be either of atmospheric interest or of relevance to the CO_2 atmospheric laser.

Experimental

A differentially pumped beam of electrons, accelerated to 20 keV through an orifice 0.022 in. in diameter, was directed into a cylindrical observation chamber located in a flow system. The beam which was perpendicular to the direction of flow was maintained by adjustment of the filament voltage at a constant current of approximately 1 mA. The current was measured by a Faraday cup grounded through a Keithley 601 electrometer. The flow rate of each component was determined initially from the decrease in pressure of a known volume of gas; a calibrated McLeod gauge was used for the total pressure. An image of the slit of the spectrometer at a magnification of unity was formed along the axis of the beam using a combination of lens and front-surfaced mirror. Direct observation of the first negative system (1N) of nitrogen and the $(\tilde{B} \rightarrow \tilde{X})$ and $(\tilde{A} \rightarrow \tilde{X})$ systems of carbon dioxide was made with a SPEX 1700-II Czerny-Turner spectrometer equipped with a 100 mm × 100 mm grating (1200 lines/mm)

blazed at 3000 Å. The spectra were scanned in the first order. The beam diameter was 0.15 cm. The signal was detected with an EMI 6256S photomultiplier, amplified with an Ortec 486 Amplifier–Pulse Height Analyzer coupled with an Ortec 441 Linear Ratemeter and recorded with a Speedomax W Azar Recorder. The signal intensity was taken as the integrated area of an entire vibrational band.

Results and Discussion

Electronically excited molecular ions are produced by electron impact, as the beam traverses the gas filled observation chamber. Those states from which radiative transitions are allowed were monitored spectroscopically. The effects of secondary electron excitation are small at the pressures used here (0.1–1 Torr). With nitrogen the following bands of the N_2 IN system were monitored; the (0,0) band at 3914 Å, the (1,2) band at 4236 Å, and the (2,4) band at 4597 Å. The essential features of the carbon dioxide electron impact induced fluorescence spectrum arise from the ($A^2\Pi_u$) and ($B^2\Sigma_u^+$) states of the carbon dioxide ion, CO_2^+.

$CO_2^+(\tilde{B}^2\Sigma^+ \rightarrow \tilde{X}^2\Pi_g)$

Emission of a very strong double-peaked band (1) at 2875–2905 Å is due to the $CO_2^+(B^2\Sigma_u^+ \rightarrow \tilde{X}^2\Pi_g)$ transition. The excitation potential of this band is around 18.0 eV. The high intensity of this band (as compared with other possible bands in the same system) suggests that there is very little vibration in the upper state. This may be due to the operation of the Franck–Condon principle in the excitation process, since the values of the rotational constant B of the CO_2 ground state, the $CO_2^+(B^2\Sigma_u^+)$ state and the $CO_2^+(X^2\Pi_g)$ state are almost equal ($B = 0.381$, 0.379, and 0.350 cm^{-1}, respectively (2)) and the molecule is linear in all three states.

$CO_2^+(\tilde{A}^2\Pi_u \rightarrow \tilde{X}^2\Pi_g)$

The band spectrum appearing in emission in the region 2900–4300 Å (and often referred to as the Fox, Duffendack and Barker (3) system) has been identified (4) as a $^2\Pi$–$^2\Pi$ transition of CO_2^+. The system is composed of two sub-bands corresponding to the ($^2\Pi_{3/2} \rightarrow {}^2\Pi_{3/2}$) and ($^2\Pi_{1/2} \rightarrow {}^2\Pi_{1/2}$) transitions. The band sequence at 3247–3275 Å, which was found to be free of overlapping nitrogen bands, is due to (v_1', v_1'') transitions with $v_2' = v_2'' = v_3' = v_3'' = 0$ and it was possible to resolve the (2,0) and (3,1) transitions in each of the sub-bands. The (2,0) band of the ($^2\Pi_{3/2u} \rightarrow {}^2\Pi_{3/2g}$) transition is situated on the short wavelength side of the sequence and since all bands are degraded towards the red, a band-width of 6 Å was isolated free from overlappings. The remaining bands of the sequence overlap other bands lying at longer wavelengths, *i.e.* the (2,0) band of the ($^2\Pi_{1/2u} \rightarrow {}^2\Pi_{1/2g}$) transition is overlapped by the (2,0) band of the ($^2\Pi_{3/2u} \rightarrow {}^2\Pi_{3/2g}$) transition and, in turn, overlaps the (3,1) band of the ($^2\Pi_{1/2u} \rightarrow {}^2\Pi_{1/2g}$) transition which overlaps the (3,1) band of the ($^2\Pi_{3/2u} \rightarrow {}^2\Pi_{3/2g}$) transition. The extent of overlap of the last three bands described above was estimated to be less than 10%. When a correction for this overlap was applied to the data, it had little effect due to the similarity of the self-deactivation rate constants.

For a single gas, A, the steady state equation for the intensity of a given band, I is of the form

$$[1] \qquad \frac{1}{I} = \frac{1}{k_1 c[\mathrm{A}]} + \frac{k_3}{k_1 k_2 c}$$

where c is the electron beam current, k_1 is related to the cross-section for formation of an excited ion, k_2 is the reciprocal of the lifetime τ of the radiative transition, and k_3 is the deactivation rate constant for parent molecules. A plot of I^{-1} *vs.* $[\mathrm{A}]^{-1}$ yields $k_3 = (\text{intercept}/\tau\ \text{slope})$.

In the presence of added quencher and at constant total pressure, P, the intensity of a given band I_q is of the form

$$[2] \qquad \frac{1}{I_q} = \frac{(k_2 + k_4)P}{k_1 k_2 c[\mathrm{A}]} + \frac{(k_3 - k_4)}{k_1 k_2 c}$$

where k_4 is the quencher deactivation rate constant. Thus from a plot of I_q^{-1} *vs.* $[\mathrm{A}]^{-1}k_4$ may be evaluated provided that the lifetime of the radiative state is known. The experimental uncertainty in the reported value for k_2 is reflected directly in this evaluation of k_4. A summary is given in Table 1 of the lifetimes of the $N_2^+(B)$ and $CO_2^+(A)$ and (B) states reported in the past seven years.

The method outlined above is particularly convenient for flow systems with calibrated flow rates in that it offers the advantage over the treatment of, for example, Brown and Miller (5) in that it obviates the evaluation of k_1. Population of the observed radiative states by collision induced cascade processes from higher vibrational levels may well occur in these systems. It has been assumed here that k_1 is a total rate con-

stant for all pressure dependent production processes for the radiative state. The linearity of the subsequent plots of I^{-1} *vs.* $[A]^{-1}$ demonstrates the constancy of k_1 over the pressure range and justifies the assumption of negligible cascade population. The population of the excited states by electronic transitions from higher energy levels does not appear likely. Such transitions populating the states under observation would be accompanied by emissions comparable in intensity to those observed. No such emissions have been reported in the literature. Other electronic states of N_2^+ other than $N_2^+(B)$ have been identified, but these states combine only with ground state $N_2^+(X)$. Both the $CO_2^+(A^2)$ and (B^2) states combine only with ground state $CO_2^+(X^2)$.

The polarization theory of ion–molecule collisions (6, 7) predicts a collision rate constant (collisions referring to orbiting collisions) which is given by $k_c = 2\pi e(\alpha/\mu)^{1/2}$ where e is the electronic charge, α is the polarizability of the molecule, and μ is the reactant pair reduced mass. It is convenient to compare the total deactivation rate constant with k_c as the ratio affords a measure of the reaction efficiency *i.e.* the probability of a reactive encounter per orbiting collision. While it is recognized that the induced dipole model was not intended to describe reactions of electronically excited ions and their quenching the model does provide a form of reference for these results. The rotational temperature as determined from the R branch of the N_2^+IN (0,0) band varied only between 308–320 °K over the pressure range 1–0.05 Torr, thus as translational–rotational equilibrium is attained rapidly, the kinetic energy of the ions will be thermalized.

In brief the present technique is restricted to those molecules which may be ionized on electron impact to an excited ion energy level from which radiative transfer can be observed. Charge transfer may then occur with a quencher molecule which has an ion energy level (or levels, wherein multiple pathways will be available) which is at a lower energy than the level initially excited (including vibrational energy). In Fig. 1 are shown the ion energy levels of the species studied in this work. It is readily seen that charge transfer is exothermic for H_2, O_2, NO, and CO_2, with $N_2^+(B)$, and for H_2, O_2, N_2, NO, and CO_2 with $CO_2^+(A^2)$ and (B^2), provided that the final ion states produced are those shown in this figure. The only exception is in the CO_2^+–H_2 reactions where it appears (8) that hydrogen-

atom abstraction to produce CO_2H^+ ions is more probable. It is also apparent that while charge transfer of vibrationally "cool" $O_2^+(X)$ with N_2 is highly endothermic, charge transfer of $O_2^+(B)$ with N_2 (to produce $N_2^+(X)$) is highly exothermic and that measurement of its rate is possible from observation of the oxygen (IN) system. This work will be reported later.

Nitrogen

A summary of the self-quenching rate data for nitrogen is given in Table 2 and the results are shown graphically in Fig. 2. The radiative lifetimes of the $v' = 0$ and $v' = 1$ levels were taken as 58.6 ± 5 and 62.5 ± 5 ns, respectively (11), while that of the $v' = 2$ level was taken as 70 ± 5 ns (12). On the addition of quencher (CO_2, O_2 or NO), it was possible to measure the deactivation rates for the $N_2^+(B)$ $v' = 0$ and 1 levels only due to overlap of a quencher band with the $N_2^+(2,4)$ band. With hydrogen as quencher individual rate constants were obtained for $v' = 0$, 1, and 2 of $N_2^+(B)$. The results are presented in Table 3. The values presented in Tables 2 and 3 are mean values from several determinations; the variation in the mean indicates the spread presented by individual runs in which the experimental error was not greater than 5%.

The rate constants for the deactivation of $N_2^+(B)$ in $v' = 0$ and 1 by nitrogen are in good agreement with our earlier published values (16), and the variation in each value is somewhat diminished. The relative ratio for the $v' = 0$, 1, and 2 levels is presented with more certainty than the given variations would tend to indicate. The values for $k_{3,v'=0}$ and $k_{3,v'=2}$ are virtually the same, but $k_{3,v'=1}$ is appreciably lower. k_3 may be regarded as the sum of electronic and vibrational quenching constants for the $v' = 1$ and 2 levels, but can represent only the electronic quenching constant for the $v' = 0$ level, *i.e.* $k_{3,0}$.

0.2471 eV; $N_2^+(X^2{}_g^+)$ 0.2697 eV), we may assume that vibrational quenching is relatively slow and that the observed value of $k_{3,1}$ represents mainly electronic quenching. Calo and Axtmann (18) have shown that in the deactivation of the $C^3\Pi_u$ state of nitrogen by ground state nitrogen molecules the ratio of electronic quenching cross-sections for the $v' = 0$ and $v' = 1$ levels ≈ 1.5 which is in agreement, albeit fortuitously, with the ratio for $k_{3,0}/k_{3,1}$ obtained here for $N_2^+(B)$. The diminution of the deactivation rate constant for $N_2^+(B)_{v'=1}$ as shown in Fig. 2 is not limited to deactivation by nitrogen molecules. We reported earlier (16) that the rate constant for deactivation of $N_2^+(B)$ by nitric oxide is decreased by a factor of 3 on the acquisition by the ion of a single vibrational quantum. However, in the quenching by nitric oxide it was not possible, due to overlapping of bands, to determine the rate constant for deactivation of the $N_2^+(B)$ $v' = 2$ level. It would be of interest to know in this system whether or not the rate constant for $v' = 2$ is comparable to that for $v' = 0$. Deactivation of $N_2^+(B)$ by molecular hydrogen exhibits the same minimum in the deactivation rate constant at $v' = 1$, and deactivation with molecular oxygen also shows diminution of the rate for $v' = 1$ relative to $v' = 0$. Of particular interest in aeronomy is the appreciable enhancement of the deactivation rate of the excited nitrogen ion by molecular oxygen compared to that of the ground state ion (15).

Hydrogen-atom abstraction from H_2 by positive ions has been shown previously to be a rapid reaction when exothermic. In this work we made no attempt to determine the nature of the products of the reaction of $N_2^+(B)$ with hydrogen, but assumed that the excitation of the ion would not cause any departure from the pathway proposed by Moran and Friedman (19), in which the hydride ion is formed.

[3] $$N_2^+ + H_2 \rightarrow N_2H^+ + H$$

Chupka and Russell (20) have shown that NH_3^+ in higher vibrational states reacts less efficiently with NH_3 to produce NH_4^+ while vibrational excitation has virtually no effect on the NH_3^+–H_2O reaction. Both reactions are exothermic.

In contrast, the rate constant for deactivation of $N_2^+(B)$ by carbon dioxide is greater than the corresponding constant with nitrogen or nitric oxide and fails to exhibit any difference in activity between the $v' = 0$ and $v' = 1$ levels for $N_2^+(B)$. The values obtained here, and shown in Table 3, agree well with the value reported by Ferguson and co-workers (13) for deactivation of the ground state ion $N_2^+(X)$ by carbon dioxide. In each case the deactivation rate constant approaches the collision rate constant, k_c. The conclusions which may be drawn at this stage are as follows:

(*i*) That when the charge transfer rate of ground state N_2^+ with diatomic molecules is slow (relative to the maximum value which is taken here as k_c), electronic excitation of the ion will lead to enhancement of the charge transfer rate (though mindful of the distinction between deactivation and charge transfer and in particular that the rate of the latter process must be equal to or less than that of the former process).

(*ii*) That electronic excitation of N_2^+ does not lead to any diminution of the overall deactivation rate in comparison to that of the ground state ion when charge transfer of the ground state ion is rapid as was observed with H_2 and CO_2.

(*iii*) Deactivation by diatomic molecules of $N_2^+(B)$ ions possessing a single vibrational quantum appears to proceed generally at a rate which is slower by a factor of 2–3 in comparison to the respective rate for ions in the zeroth vibrational level. This effect on $N_2^+(B)_{v'=1}$ was observed with nitrogen, hydrogen, oxygen, and nitric oxide. No such effect was observed with carbon dioxide. One is thus led to speculate that the first quantum of vibrational energy in the $N_2^+(B)$ ion which is large in comparison to other vibrational quanta in nitrogen decreases the probability of a reactive encounter with a diatomic molecule. This effect was non-existent with a polyatomic molecule possessing several modes of vibration. Exhibition of this effect in the $N_2^+(B)$–H_2 reaction was somewhat surprising in view of Moran and Friedman's proposal concerning hydride formation in which the total number of vibrational modes would be increased.

(*iv*) Deactivation by diatomic molecules (N_2 and H_2) of $N_2^+(B)$ ions with two vibrational quanta appears to proceed at a rate which is comparable to that for ions in the zeroth vibrational level and to the collision rate.

Carbon Dioxide

The self-quenching rate constants shown in Table 4 are the least accurate due to the requirement of the evaluation of the intercept from the plot of I^{-1} *vs.* $[CO_2]^{-1}$. A relatively small change in slope can produce a large change in the intercept and hence there is a relatively large uncertainty in the value for k_5. However, two points may be made here. (*i*) That within the stated uncertainty limits the data can be interpreted as following the trend previously observed that ions in high electronic states are deactivated more rapidly than those in lower electronic states. (*ii*) That the deactivation rate constants appear to exceed the collision rate constant. Thus the self-quenching reaction for carbon dioxide may be yet another example for which the ion-induced dipole model is inadequate for the explanation of reactions of excited ions.

CO_2^+–O_2

The quenching constants for this reaction are shown in Table 5. The value for the $CO_2^+(B)$ state is more accurate than that for the $CO_2^+(A)$ state. Thus we are able to report with some certainty that deactivation of the $CO_2^+(B)$ state by O_2 proceeds at a rate in excess of that predicted by the ion-induced dipole model. A similar observation has been reported by Giomousis and Stevenson (7) for the reaction of O_2 with H_2^+ and D_2^+ ions, and although their values lack some precision as the ion residence times were not measured, the O_2 reactions were unique in that the experimental rate constants exceeded the theoretical value (k_c) by a factor ~ 2. Thus it appears that the ion-induced dipole model is not applicable generally to O_2 reactions possibly due to the polarizability tensor of oxygen which is not isotropic.

It is of interest to note in this series of reactions of carbon dioxide ions with molecular oxygen that a linear relationship appears to exist between the logarithm of the deactivation rate constant and the energy of the ion.

CO_2^+–N_2

In Table 5 we report the deactivation rate constants for the $CO_2^+(\tilde{A})$ and $CO_2^+(\tilde{B})$ ions with N_2. The energetic ion is deactivated at an enhanced rate in comparison to the less energetic ion.

‡An interpolation, see Discussion.

An attempt was made to determine the effect of vibrational excitation in the $CO_2^+(\tilde{A})$ ion on the deactivation rate with nitrogen. The bands selected were the (2,0) and (3,1) of the $\Pi_{1/2}$ system and the (2,0) and (3,1) of the $\Pi_{3/2}$ system which overlap each other as discussed above. A common lifetime was assumed. It was found that within each of these systems the $v_1 = 2$ state was deactivated at a slightly enhanced rate ($\sim$30–40%) in comparison to the $v_1 = 3$ state. The $\Pi_{3/2}$ system exhibited a similar enhancement ($\sim$50–60%) in comparison to the $\Pi_{1/2}$ system. The effect is small and may not be real.

CO_2^+–NO

The $CO_2^+(\tilde{A} \rightarrow \tilde{X})$ system is overlapped by emission from nitric oxide molecules excited by the electron beam. The deactivation rate constant for the $CO_2^+(\tilde{B})$ state ion is given in Table 5 along with the value obtained by Ferguson and co-workers (17) for charge transfer from the ground state ion. Again in this series the excited ion ($\tilde{B}$) is deactivated at an enhanced rate compared to the ground state ion but somewhat less than the collision rate. On the assumption that a similar relationship exists in the CO_2^+–NO system as in the CO_2^+–O_2 system one may

estimate that the deactivation rate constant for $CO_2^+(\tilde{A})$ by NO is $26 \pm 5 \times 10^{10}$ l s^{-1}.

It should be emphasized that the data obtained for the $CO_2^+(\tilde{B})$ ion are more accurate than for the $CO_2^+(\tilde{A})$ ion due to the high intensity of the double peaked emission from the $CO_2^+(\tilde{B})$ ion in a spectral region free from background interference and overlap.

The experimental uncertainties for the rate constants quoted in Table 5 include an uncertainty of $\pm 10\%$ from the value of the lifetime, thus the relative value of a given rate constant to another is somewhat more accurate than the quoted uncertainties would indicate.

Studies of β-Diketone Complexes of Rhenium. I. Trispentane-2,4-dionatorhenium(III) and Tris(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)rhenium(III)

W. D. COURRIER, W. FORSTER, C. J. L. LOCK,[1] AND G. TURNER
Institute for Materials Research, McMaster University, Hamilton, Ontario

Received July 7, 1971

Pure samples[2] of $Re(hfac)_3$ and $Re(acac)_3$ have been prepared and their physical properties studied by ultraviolet–visible and infrared spectroscopy, mass spectrometry, magnetic susceptibility measurements, and X-ray diffraction. The compounds are monomeric and the physical properties may be explained if the rhenium atom sits in an essentially octahedral ligand field. $Re(hfac)_3$ has a hexagonal unit cell and the acetylacetone complex adopts the monoclinic cell of the α-form of the three typical crystal structure types which Astbury (1) observed for trispentane-2,4-dionatometal(III) compounds. The properties observed for trispentane-2,4-dionatorhenium(III) differ from those reported previously (2, 3). The difficulties experienced in obtaining pure $Re(C_5H_7O_2)_3$ were caused by the ease with which the material is oxidized.

On a préparé des échantillons purs[2] de $Re(hfac)_3$ et $Re(acac)_3$ et étudié leurs propriétés physiques par la spectroscopie ultraviolette–visible et infrarouge, la spectrométrie de masse, des mesures de susceptibilité magnétique et la diffraction de rayons-X. Les composés sont monomériques et on peut expliquer les propriétés physiques si l'atome de rhénium se trouve dans un champ de ligand essentiellement octaédrique. $Re(hfac)_3$ possède une maille hexagonale et le complexe acétylacétone adopte la maille monoclinique de forme α des trois genres de structure cristalline typiques que Astbury (1) a observé pour les composés trispentane-2,4-dionatométalliques. Les propriétés observées pour le trispentane-2,4-dionatorhénium(III) diffèrent de celles rapportées précédemment (2, 3). Les difficultés rencontrées pour obtenir le $Re(C_5H_7O_2)_3$ pur furent causées par la facilité avec laquelle le matériel est oxydé.

Canadian Journal of Chemistry, **50**, 8 (1972)

Introduction

Tris(pentane-2,4-dionato)rhenium(III) was first described in 1960 (2, 3). We attempted to prepare some crystals of the material for X-ray diffraction studies, but had great difficulty isolating any solid. The products usually obtained by us were tars. In 1969 (4) a different method was described for the preparation of tris(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)-rhenium(III) in which the sodium salt of the β-diketone and rhenium trichloride were destructively distilled. This suggested an alternative preparation for $Re(C_5H_7O_2)_3$ which is described herein. As the properties of the material we obtained were so different from those of the material described previously we have made extensive physical measurements on our compound with the dual purpose of contrasting it with previous work and showing that our material was really $Re(C_5H_7O_2)_3$. No physical measurements of $Re(C_5F_6HO_2)_3$ have been described previously so we have made a set of measurements on this compound, similar to those for $Re(C_5H_7O_2)_3$.

Experiments

Carbon and hydrogen analyses were performed by Alfred Bernhardt Microanalytisches Laboratorium, West Germany. Infrared spectra were recorded for solid samples ground into a mull with Nujol. The Nujol had been dried by refluxing with phosphorus pentoxide followed by vacuum distillation. The mull samples were mounted between potassium bromide or polyethylene plates and spectra were recorded on Perkin–Elmer 337 and 301 spectrometers. X-Ray diffraction photographs of powdered samples were recorded on a Debye–Scherrer camera. Samples were sealed inside quartz tubes and nickel-filtered copper radiation was used for recording the photographs. Line intensities were measured from the powder photographs using a Joyce–Loebl microdensitometer.

The densities of the compounds were measured using a float – no float technique in aqueous $ZnBr_2$ solutions which had been vacuum degassed. For $Re(acac)_3$ we had up to 10 min to do the measurements before significant decomposition occurred. The extent of decomposition was checked by dissolving the crystals in diethyl ether after the measurement since the oxidation products are insoluble in ether.

Electronic spectra were recorded for methylene chloride solutions in matched 1 cm silica cells on a Cary 14 spectrometer. Mass spectra were recorded on a Consolidated Electrodynamics Corp. Mass Spectrometer Model 21-110B.[3]

Measurements of magnetic susceptibility were made by the Gouy method. The apparatus used is described in detail elsewhere (5).

Tris(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)rhenium(III)

A finely ground mixture of sodium hexafluoroacetylacetonate and dichloro(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)bis(triphenylphosphine)rhenium(III) (6) (2:1 by weight) was heated *in vacuo* for 12 h at 110 °C. The product, which sublimed from the mixture, was collected in a cold trap (solid carbon dioxide – acetone or liquid nitrogen). In a typical experiment 3.0 g of the mixture gave 0.45 g of dark purple crystals (yield 40%).

Anal. Calcd. for $C_{15}H_3F_{18}O_6Re$: C, 22.3; H, 0.40. Found: C, 22.7; H, 0.61.

Tris(pentane-2,4-dionato)rhenium(III)

(*a*) A finely ground mixture of sodium acetylacetonate and dichlorobis(pentane-2,4-dionato)rhenium(IV) (6, 7) (2:1 by weight) was heated *in vacuo* (10^{-4} mm Hg) for 24 h at 175 °C. The product collected just outside the hot zone as dark red crystals. In a typical experiment 3 g of mixture gave 0.4 g of crystals (yield 38%).

Anal. Calcd. for $C_{15}H_{21}O_6Re$: C, 37.4; H, 4.39. Found: C, 37.1; H, 4.48.

Best yields were obtained when an excess of sodium acetylacetonate was used and when the sodium acetylacetonate had been recrystallized from methanol/benzene and the dichlorobis(pentane-2,4-dionato)rhenium(IV) from dichloromethane before use.

(*b*) $Re(acac)_3$ may be prepared in a similar manner to the above using dichloropentane-2,4-dionatobis(triphenylphosphine)rhenium(III) (6) as the starting material. The sublimed product was contaminated with triphenylphosphine and was purified by recrystallization from a very carefully deoxygenated anhydrous ether/hexane mixture.

Results and Discussion

The existence of $Re(acac)_3$ and $Re(hfac)_3$ was clearly demonstrated from the analyses and the mass spectral results for the two compounds. In both cases the parent ions were observed in relatively high intensities. The mass spectral results are presented in Tables 1 and 2. It is apparent that the mass spectra of the two compounds are quite different, the main difference being the transfer of fluorine atoms to the metal for $Re(hfac)_3$. This difference is hardly surprising since the Re—F bond is likely to be fairly strong, whereas Re—H (the analogous bond for the acetylacetone case) is not likely to be formed very readily.

The $Re(hfac)_3$ breakdown pattern is of interest since it is quite unlike that of $Cr(hfac)_3$ (see Table 1). This difference might indicate that the mechanism of breakdown is quite different for the two compounds. The presence of the L_2ReO^+ ion may be caused by C—O bond fission and elimination of a C_5HF_6O fragment. This type of mechanism has been suggested by Bancroft *et al.* (11) for $Ti(acac)_3$ and $V(acac)_3$ and related to the tendency of titanium and vanadium to form the MO^{2+} grouping. Many compounds of rhenium(V) containing the ReO grouping are known and a similar mechanism may apply to $Re(hfac)_3$.

It is possible, however, that despite the differences in breakdown pattern, the mechanism of breakdown may be the same. We have suggested possible breakdown schemes in Fig. 1. They are based on the suggestion by Bancroft *et al.* (9) that the initial process involves "fission of one M—O bond followed by a rotation of part of the ligand about the 2,3 C—C bond, which brings the halogens close to the metal atom. In a presumed concerted process the metal–fluorine bond is formed and a neutral species, such as CF_2, is eliminated". The differences in the

spectra of $Re(hfac)_3$ and $Cr(hfac)_3$ are assumed to arise because of subsequent steps. McDonald and Shannon (10) have related the stable valences of the metal to the observed mass spectra of several acetylacetonates, and Bancroft *et al.* (11) explained the spectra of $Ti(acac)_3$ and $V(acac)_3$ in terms of oxidation to Ti(IV) and V(IV), respectively. In addition they showed that in $Cr(acac)_3$ the Cr(III) state was particularly stable. Thus the absence of stable peaks of the type L_nMF^+, $L_nMF_2{}^+$, LMF_2O^+ for chromium is not unusual since their presence would imply oxidation of the Cr(III). The metastable ions $L_nMF(C_4F_3O_2H)^+$ decompose directly to L_nM^+. For rhenium, however, Re(IV), Re(V), and Re(VII) states are more stable than monomeric Re(III) species, particularly in the presence of fluoro- or oxo-groups so that decomposition of the initial ion to give ions of the type shown above is to be expected.

The mass spectrum of $Re(acac)_3$ has been compared with those of $M(acac)_3$ (M = Ti, V, Cr, Mn) in Table 2. The results for rhenium show considerable similarity to those for vanadium,

Not assigned	$p-218$	17	—	—	—	—
MO^+	$p-281$	—	34	—	—	—

the only significant difference being a somewhat greater tendency to form MO groups rather than MOH groups. As with $Re(hfac)_3$ oxidation to Re(IV) is to be expected, since it has been shown (8) that Re(III) compounds such as $Re(acac)Cl_2[P(C_6H_5)_3]_2$ are readily oxidized to very stable Re(IV) compounds like $Re(acac)_2Cl_2$. In addition $Re(acac)_3$ is very easily oxidized (*vide infra*).

The data from the electronic spectra of both rhenium compounds are given in Table 3. Attempts to assign the observed bands to specific electronic transitions for the d^4-system developed by Kamimura *et al.* (12) have been unsuccessful. The magnitudes of the extinction coefficients of the bands are more characteristic of absorptions arising from charge transfer processes than from d–d transitions.

Both rhenium compounds show essentially temperature independent paramagnetism over the temperature range 80–290 °K. This behavior is like that observed previously for Re(III) in a close to octahedral environment (13) and the magnitude of the magnetic susceptibility lies in the range $1200–1900 \times 10^{-6}$ c.g.s. units observed previously. Like previous workers we find that the value of the spin-orbit coupling constant ζ_{5d} calculated using conventional magnetic relationships (13) is approximately 4500 cm^{-1}, nearly twice the free ion value of 2500 cm^{-1}.

The infrared spectra of $Re(acac)_3$ and $Re(hfac)_3$ are reported in Table 5. Raman spectra were not obtained as solid samples absorbed the laser light, melted, and volatilized. No signal could be obtained from solutions because of absorption.

The assignments of the vibrational transitions for $Re(acac)_3$ and $Re(hfac)_3$ were made by comparison with previous work.

The vibrational spectra of metal acetylacetonates have been extensively studied (14–23) and bands at 1365, 1274, 1190, 1022, 780, 652, 620 cm^{-1} for $Re(acac)_3$ correspond to bands reported previously for similar compounds and for

which there is unanimity of assignment. Bands at 1545, 1530, 1515, 1420, 1380 cm^{-1} correspond to bands reported previously, but over which there has been some controversy. The assignment we have used is based on the more recent analyses of spectra (21–23). The three highest bands are at somewhat lower energies than usual (27). The band at 1530 cm^{-1} may arise from splitting of one of the neighboring bands or more probably from a C—H out of plane vibration coupled either with the infrared inactive CH out-of-plane vibration (23) or CO stretch (14), since it has been shown that the band (when observed) disappears on deuteration (23). No assignment has been made previously of the band at 910 cm^{-1}, although calculations show a C—CH_3 stretch may occur near this value (14). It is also possible that this band may arise from a small amount of oxidation product, since strong absorptions for Re=O stretches occur in this region (28). The band at 614 cm^{-1} is probably a C—C(C)—O out-of-plane bend (14, 15, 17). The assignment of the remaining bands is a matter of some controversy. Gillard *et al.* (17) have shown that there should be three M—O stretches in this region of which two should be strong and three bands have been reported for $Fe(acac)_3$ at 433, 415, and 298 cm^{-1}.

Unfortunately, the stretches are necessarily very metal sensitive and may shift considerably from the above frequencies. Typical ranges for these bands are 420–480, 390–450, and 290–390 cm^{-1}(14–21, 23) and on this basis we have assigned the bands at 321, 401, and 444 cm^{-1} to M—O stretches. The first two bands are also observed for $Re(hfac)_3$, but no band is observed near 444 cm^{-1}. Another band of comparable strength occurs at 418(1) cm^{-1} for both compounds, but is unlikely to be an Re—O stretch, since a medium-strong metal-insensitive band at 420 ± 10 is observed in nearly all acetylacetone complexes (37) and Nakamoto *et al.* (24) have shown that for the series $M(C_5H_7O_2)_2$, $M(C_5H_4F_3O_2)_2$, and $M(C_5F_6HO_2)_2$(M = Ni, Cu) the intensity of the M—O stretch in these compounds drops markedly as hydrogen is substituted for fluorine, almost disappearing for the hexafluoroacetylacetone complexes. The source of the assignment of the remaining bands is indicated in the table.

The vibrational spectra of metal hexafluoroacetylacetonates have been studied less extensively. The assignments for $Re(hfac)_3$ are based on comparisons with the work of Nakamoto *et al.* (24) and Morris *et al.* (25) and are incomplete. Nevertheless, one feature of the spectrum is particularly interesting and this is that the highest frequency bands of $Re(hfac)_3$ are nearly identical in energy to those of $Re(acac)_3$. This is in complete contrast to the results of Nakamoto *et al.* (24) which show a strong shift to higher energies of the C=O and C=C stretches when CH_3 is substituted by CF_3 in metal β-ketoenolates. Nakamoto *et al.* postulated that the effect is caused by the inductive effect of the fluorine atoms which causes strengthening of the C=O and C=C bonds and a decrease in the MO bond strength.

Morris *et al.* (25) noticed in their studies on $M(hfac)_3$ and $M(hfac)_2.1$ or $2H_2O$ compounds that there were two groups of CO stretching frequencies and related these to the charge/radius ratio of the central metal, assuming an ionic model (q/r 2.2–2.6, ν(CO) = 1650 cm^{-1}; q/r 4–6, ν(CO) = 1610 cm^{-1}). $Re(hfac)_3$, with q/r for Re(III) roughly 5.4, does not fit this simple relationship. Nevertheless, we feel the picture is capable of extension. The covalent bond strength will be related to q/r, and we feel that it is the strength of the MO bond, in particular the π bond, (pπO—dπM) which is related to the position of ν(CO). Following the argument of Nakamoto *et al.* (24), we have a competitive process for the electrons associated with the MO bond. The shift of electron density will depend on the ability of the metal to attract the electrons relative to the fluorine atoms. The greater this ability (reflected in greater MO π bond strength), the less will be the upward shift of ν(CO). The importance of this π bonding (pπO→dπM donation) has already been commented on by Cotton and Holm (29) in explaining the electronic spectra and Hester and Plane (20) the Raman spectra of metal acetylacetonates. If the explanation is correct, one would expect a parallel effect to be observed for corresponding acetylacetonates as is the case. Indeed, Holtzclaw and Collmann (30) and West and Riley (31) have already related the position of ν(CO) to the stability constants of metal acetylacetonates; the lower the energy, the greater is the stability constant. Nakamoto (27) has criticized this relationship; nevertheless, as is shown in Fig. 2, there is a broad correlation between ν(CO)

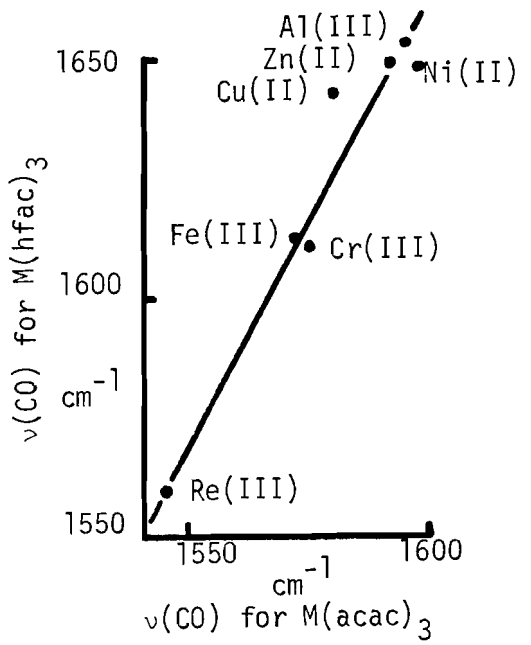

FIG. 2. The relationship between ν(CO) in $M(acac)_3$ and $M(hfac)_3$.

stretching frequencies for corresponding metal acetylacetonates and hexafluoroacetylacetonates, as would be expected from the above model.

Whether a direct relationship can be drawn between π-bond strength and ν(CO) remains a matter of conjecture. Nakamoto has pointed out (27) a measure of the MO bond strength is the MO force constant. The bands we have assigned to ν(ReO) do not shift much from $Re(acac)_3$ to $Re(hfac)_3$, as expected, but our assignment is not unambiguous. Detailed force constant calculations of a number of compounds will be necessary to test the relationship suggested.

The X-ray powder diffraction patterns of both rhenium compounds were recorded primarily for identification purposes and to see whether the compounds were isomorphous with known $M(acac)_3$ and $M(hfac)_3$ compounds. The data are presented in Table 6.

The data for $Re(acac)_3$ can be indexed in terms of a monoclinic cell, $a = 14.10(1)$ Å, $b = 7.52(1)$ Å, $c = 16.56(1)$ Å, and $\beta = 99.15(5)°$, space group $P2_1/c$, $Z = 4$, $D_{calcd} = 1.85$ g cm^{-3}, $D = 1.92$ g cm^{-3}. Thus the compound has the α-form of the three common unit cells for $M(acac)_3$ compounds first noted by Astbury (1). A comparison of the powder pattern of $Re(acac)_3$ with that for $Ir(acac)_3$ (32) shows a fair similarity between the intensities of the corresponding lines, and good agreement is shown with the calculated intensities which were obtained by placing rhenium atoms at coordinates found for

*Calculated using rhenium atoms only at coordinates given for Mn in $Mn(acac)_3$ (33). Monoclinic cell, $a = 14.10(1)$ Å; $b = 7.52(1)$ Å; $c = 16.56(1)$ Å; $\beta = 99.15(5)°$, $P2_1/C$, $Z = 4$, $D_{calcd} = 1.85$ g cm^{-3}, $D_m = 1.92$ g cm^{-3}.

manganese in $Mn(acac)_3$ (33), and applying appropriate Lorenz-Polarization and multiplicity corrections (see Table 6). A calculation of the residual $R = \Sigma\|F_o| - |F_c\|/\Sigma F_o$ using this data without refinement gave $R = 0.21$, suggesting that $Re(acac)_3$ and $Mn(acac)_3$ are structurally similar as well as isomorphous. It should be noticed that our indexing differs significantly from that proposed for $Ir(acac)_3$, for which some indices are used which are forbidden by the systematic absence requirements of the space group.

The powder data for $Re(hfac)_3$ can be indexed in terms of a hexagonal unit cell with $a = 18.44(1)$ Å, $c = 12.13(1)$ Å, $Z = 6$, $D_{calcd} = 2.25$ g cm^{-3}, $D_m = 2.26$ g cm^{-3}. These data show a very close relationship to those reported for $Ir(hfac)_3$ and $Rh(hfac)_3$ (34), where for iridium $a = 18.2$ Å, $c = 6.16$ Å and for rhodium $a = 18.27$ Å, $c = 6.175$ Å. The iridium and rhodium compound parameters were derived from powder data. Our powder data also would indicate a *c* axis length one half of what we have reported. However, single crystal measurements (35) show very weak superstructure spots indicating the powder *c*-axis length should be doubled. It is probable that all three compounds are isomorphous. At present the single crystal data are inadequate to give full structural details. From the small amount of data for the *hk*0 zone it is possible to say that the $Re(hfac)_3$ units are monomeric and have a threefold axis. Patterson synthesis showed rhenium atoms at (0,0,0), 1/3,2/3,*Z*, and 2/3,1/3,*Z* and subsequent Fourier synthesis located the oxygen atoms, which are in a six-fold array around the rhenium atom in projection. There is no evidence of polymerization. However, there are considerable problems in refinement of data containing information along the *c*-axis. This may be caused by disorder of left-handed and right-handed molecules or a form of "microtwinning" similar to that reported by Beurskens and Cras (36).

Now that we have prepared $Re(acac)_3$ and examined its properties it is easy to understand why it was so difficult to prepare. Unlike $Re(hfac)_3$, $Re(acac)_3$ is extremely susceptible to oxidation. If a sample of $Re(acac)_3$, prepared in a dry box and handled with precautions to exclude air, is used for infrared spectroscopy the spectrum

*Observed value.
†Calculated value.

described in Table 5 is obtained. If the containing plates are opened in air for a few seconds, and then closed and the spectra recorded, extra bands in the 800–1000 cm^{-1} region are observed, which we postulate are caused by Re=O or Re—O—Re groups. The nature of the oxidation is complex since the frequency and number of bands in the 800–1000 cm^{-1} region depend on the time of exposure to air. A complex pattern is also observed if a solution of $Re(acac)_3$ is allowed to stand in air. The purple solution soon turns red and eventually brown after a few hours. These reactions can be speeded-up considerably by bubbling oxygen through the solution. Solid $Re(acac)_3$ becomes brown on standing and ether-insoluble. $Re(hfac)_3$ is much more stable to oxidation and can be handled in air at room temperature for hours with little sign of decomposition. However, both the solid and solutions can be oxidized if they are heated for any length of time in air. Again, reaction is much more rapid in an atmosphere of oxygen.

Comparison of the chemical and physical properties of $Re(acac)_3$ and those of the compound described previously (3), suggest that the two compounds are different. Some properties are compared in Table 7. Since our compound has been shown to be $Re(acac)_3$, we suggest that the previous description of $Re(acac)_3$ was incorrect. In light of our results we suspect that the sample described previously was at least partly oxidized.

Formation des dérivés *N*- et *C*-substitués au cours de l'alkylation de l'indol-2(3*H*)-one

ILONA GRUDA

Département de chimie–biologie, Université du Québec à Trois-Rivières, Trois-Rivières, Québec

Reçu le 27 juillet 1971

The alkylation of indol-2(3*H*)-one (oxindole) and of some of its mono and dialkyl derivatives has been investigated.

Chromatographic methods for preparative separation and quantitative determination of the five compounds formed in the reaction between oxindole and benzyl chloride in the presence of a base are reported.

A kinetic approach to these reactions shows that in unsubstituted indol-2(3*H*)-one the 3-position is twice as reactive as the 1-position. In the already 3-monosubstituted compound the reactivity of the 3-position is about 30 times greater than that of the 1-position.

On a étudié l'alkylation de l'indol-2 (3*H*)-one et de quelques uns de ses dérivés mono et dialkylés.

On rapporte des méthodes chromatographiques pour la séparation préparative et la détermination quantitative des cinq composés formés au cours de la réaction entre l'oxindole et le chlorure de benzyle en présence d'une base.

Une approche cinétique dans le cas de ces réactions nous montre que pour l'indol-2 (3*H*)-one, la position 3 est deux fois plus réactive que la position 1. Pour le composé qui est déjà mono-substitué en position 3, la réactivité de la position 3 est environ trente fois plus grande que celle de la position 1.

Canadian Journal of Chemistry, **50**, 18 (1972)

La réaction de l'alkylation directe de l'indol-2(3*H*)-one (oxindole) et de ses dérivés a fait l'object d'un certain nombre de publications (1–9).

Les résultats obtenus sont assez contradictoires. Ainsi certains auteurs (4, 5) affirment que l'introduction d'un substituant sur le carbone 3 de l'oxindole n'est possible que dans le cas d'un composé déjà 3-monosubstitué. D'autres, (1, 3, 6, 7) par contre, ont démontré que l'alkylation directe de l'oxindole et des *N*-alkyloxindoles était facile et que les produits obtenus étaient principalement des dérivés 3,3-disubstitués. Certains auteurs ont réussi également à isoler des dérivés 1,3,3-trisubstitués (3, 7).

D'après les résultats de la plupart des auteurs il semblerait que, en général, la réaction de l'oxindole avec des halogénures actifs tels que les halogénures d'allyle, de benzyle ou de carbalkoxyméthyle dans un milieu homogène mène uniquement à des produits polysubstitués tandis que la monosubstitution n'a lieu qu'avec des halogénures peu actifs ou dans un milieu hétérogène.

Dans une étude approfondie Daisley et Walker (9) ont démontré récemment que dans un milieu hétérogène le *N*-méthyloxindole réagit avec de différents halogénures en donnant des mélanges de produits mono- et disubstitués. La réactivité de l'azote n'a pas été étudiée par ces auteurs.

En ce qui concerne les voies réactionnelles de l'alkylation directe de l'oxindole et de ses dérivés alkylés les résultats décrits jusqu'à présent sont assez fragmentaires.

Le schéma 1 montre les voies possibles menant au produit 1,3,3-trisubstitué.

D'après les produits principalement obtenus (CC et NCC) par la plupart des auteurs, on aurait pu conclure que la voie oxindole $\xrightarrow{k_1}$ C $\xrightarrow{k_2}$ CC $\xrightarrow{k_3}$ NCC est la voie dominante avec $k_1 \ll k_2$, $k_3 < k_2$, et k_4 et $k_7 \simeq 0$. Ceci laisserait supposer une réactivité beaucoup plus grande du carbone 3 que de l'azote dans une attaque nucléophile. Par contre, Wenkert et Blossey (2) obtiennent dans la réaction entre l'oxindole et l'iodure d'éthyle 3 fois plus de produit *N*-substitué que de produit substitué sur le carbone et ne constatent pas la présence de dérivés polysubstitués.

Donc d'après ces auteurs $k_4 > k_1$ et $k_1 \gg k_2$, $k_4 \gg k_5$. Le but de ce travail a été d'examiner les étapes de l'alkylation de l'oxindole et de comparer la réactivité nucléophile de l'azote et du carbone 3.

SCHÉMA 1

Résultats et discussion

Le système réactionnel représenté dans le schéma 1 semble trop complexe pour qu'on puisse déterminer les constantes de vitesse. Il faut indiquer en outre que chaque réaction du schéma est en réalité composée de deux réactions (eq. 1).

Il fallait donc envisager l'étude du problème d'une façon approchée.

Le système choisi dans ce travail était: l'oxindole, le chlorure de benzyle et une base (NaOH ou $NaOC_2H_5$) dans le rapport 1:1:1, dans l'éthanol. En séparant le mélange après la réaction par chromatographie sur colonne on a isolé six composés: l'oxindole et ses produits de substitution N, C, NC, CC, NCC, donc tous les produits du schéma 1. Leur structure a été établie par l'analyse élémentaire et les spectres i.r. et confirmée par comparaison avec les mêmes composés synthétisés par d'autres méthodes.

Afin d'étudier le cours de la réaction on a utilisé la c.p.v. quantitative.

Les résultats sont représentés par les figs. 1 et 2.

Il en résulte que l'agent électrophile attaque simultanément l'azote et le carbone 3 de l'oxindole, le rapport des produits formés étant N/C = 1/2 au début de la réaction. Ce rapport change par la suite à cause de la formation des dérivés polysubstitués.

La forme des courbes dans les fig. 1 et 2 suggère que l'accumulation rapide du produit CC est dûe à une grande réactivité de C et éventuellement à une diminution de la réactivité de l'azote causée par les substituants sur le carbone 3.

Pour vérifier cette hypothèse on a étudié le cours de réactions suivantes:

[*a*] N + chlorure de benzyle

[*b*] C + chlorure de benzyle

[1]

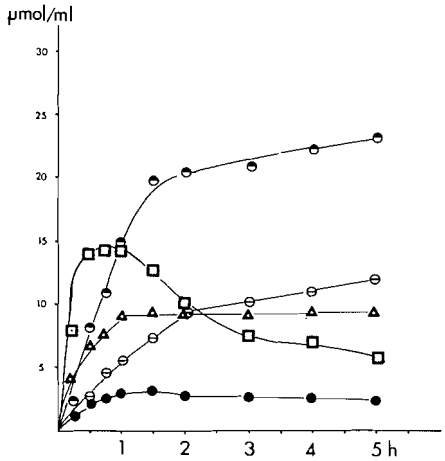

FIG. 1. Oxindole + chlorure de benzyle + $NaOC_2H_5$ (1:1:1); concentrations, 230 μmol/ml; température, 40° -●-. 3,3-Dibenzyloxindole; -□-, 3-benzyloxindole; -△- l-benzyloxindole; -⊖-, 1,3,3-tribenzyloxindole; -●-, 1,3-dibenzyloxindole.

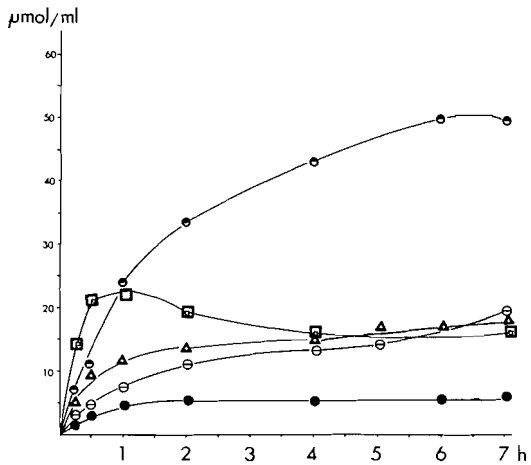

FIG. 2. Oxindole + chlorure de benzyle + NaOH (1:1:1); concentrations, 230 μmol/ml; température, 40°. -●-, 3,3-Dibenzyloxindole; -□-, 3-benzyloxindole; -△-, l-benzyloxindole; -⊖-, 1,3,3-tribenzyloxindole; -●- 1,3-dibenzyloxindole.

[c] NC + chlorure de benzyle

[d] CC + chlorure de benzyle

En effectuant les réactions *a*, *b*, et *c* dans l'atmosphère ambiante on constate sur le chromatogramme l'apparition de produits qui ne furent pas détectés auparavant dans la réaction à partir de l'oxindole. Un de ces composés a été

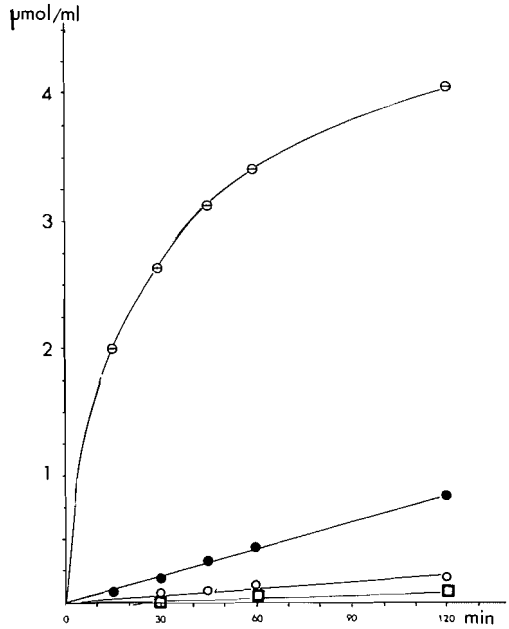

FIG. 3. Formation du 1,3,3-tribenzyloxindole, -⊖-, À partir du 1,3-dibenzyloxindole (10 μmol/ml); -●- à partir du l-benzyloxindole (10.7 μmol/ml); -○-, à partir du 3,3-dibenzyloxindole (10 μmol/ml); -□-, à partir du 3-benzyloxindole (10.7 μmol/ml).

isolé et identifié comme étant un dérivé du dioxindole ce qui est en accord avec les observations de Ghosal et Dutta (10) qui obtinrent différents 3-phényldioxindoles en introduisant l'oxygène dans une solution alcaline des oxindoles correspondants. Les essais suivants pour ces réactions furent donc menés dans l'atmosphère de l'azote.

Les résultats sont représentés dans la fig. 3 et les tableaux 1, 2, 3,[1] et 4.

Il en résulte que les composés NC et NCC ne se forment pratiquement qu'à partir de N.

On peut donc déduire que:

$$(1) \qquad C \xrightarrow{k_2} CC \xrightarrow{k_3} NCC \qquad k_2 \gg k_3$$

$$(2) \qquad N \xrightarrow{k_5} NC \xrightarrow{k_6} NCC \qquad k_6 \gg k_3$$

$$(3) \qquad C \xrightarrow{k_7} NC \qquad k_7 \cong 0$$

[1]On peut remarquer dans le tableau 3 une baisse considérable de la quantité du substrat dans les premières minutes de la réaction. Cette baisse est accompagnée de l'apparition d'un produit inconnu dont la quantité diminue par la suite proportionnellement à la quantité de NCC formé. L'étude de ce produit est en cours.

On en vient donc à conclure que l'expression $r = (N + NC + NCC)/(C + CC)$ peut être considérée avec une certaine approximation comme mesure de la réactivité relative de l'azote et du carbone 3, surtout au début de la réaction quand les différences en concentration de NC et CC ne sont pas encore trop grandes.

Les valeurs de r calculées à partir des résultats des figs. 1 et 2 sont représentées dans le tableau 5.

Comme on voit le carbone 3 de l'oxindole est environ deux fois plus réactif que l'azote. Cette différence en réactivité est beaucoup plus prononcée dans le cas des dérivés de l'oxindole substitués en 3. Le tableau 6 montre que la vitesse de la transformation $CC \rightarrow NCC$ (V_n) est environ 30 fois plus faible que la vitesse de la transformation $NC \rightarrow NCC$ (V_c). Autrement dit $r' = V_n/V_c \cong 1/30$.

Cette différence considérable entre r et r' n'est expliquable que partiellement par la croissance de la réactivité du carbone 3 dans les dérivés 3-substitués. Si on compare la vitesse des transformations $N \rightarrow NC$ et $NC \rightarrow NCC$ (tableaux 1 et 3) on aperçoit que la différence en réactivité entre les composés N et NC n'est que de l'ordre de 3–5. Il faut donc admettre qu'il existe un autre facteur responsable de la valeur basse de r', notamment une diminution de la réactivité nucléophile de l'azote par les substituants en carbone-3. Cela est dû probablement à une plus importante délocalisation du doublet libre de l'azote (structure **2**) dans les composés 3,3-disubstitués en comparaison avec les dérivés non ou monosubstitués formant les ions énolates dans lesquels est favorisée la structure **4** (éq. **3**).

Partie expérimentale

Les points de fusion, non corrigés, ont été pris sur un appareil Mettler FPI.

Les c.p.v. analytiques ont été effectuées sur un Varian Aerograph 1700. Les spectres i.r. ont été déterminés au moyen d'un appareil Unicam SP 200 G.

L'oxindole provient de chez Baker, Baker Grade; le chlorure de benzyle, Fisher Scientific, Reagent Grade.

(A) Partie préparative

Benzylation de l'oxindole

A 2.0 g (0.015 mol) d'oxindole dissous dans 20 ml d'éthanol on ajoute une solution de 0.6 g (0.015 mol) de NaOH dans 80 ml d'éthanol et 1.9 g (0.015 mol) de chlorure de benzyle dissous dans 7 ml d'éthanol. On chauffe ce mélange à reflux pendant 4 h. Après avoir refroidi la solution on l'acidifie (HCl), évapore sous vide, ajoute 25 ml de benzène, essore le NaCl et évapore la solution à sec sous vide.

On obtient ainsi 3.4 g d'une huile jaune foncé qu'on dissout par la suite dans une quantité minimale de benzène et sépare sur une colonne de 100 g de gel de silice. L'élution avec un mélange benzène–hexane (2:1) donne 0.49 g de 1,3,3-tribenzyloxindole, rendement, 8.1%; p.f., 116.4° (éthanol). Spectres i.r. (CCl_4): 1708 cm^{-1} ($\nu_{(C=O)}$).

L'élution avec le benzène donne 0.169 g de 1,3-dibenzyloxindole, rendement 3.6%; p.f., 100.0° (éthanol).

Anal. calc. pour $C_{22}H_{19}NO$: C, 84.34; H, 6.04; N, 4.47. Trouvé: C, 83.95; H, 6.31; N, 4.46.

Spectres i.r. (CCl_4): 1708, 1712 cm^{-1} ($\nu_{(C=O)}$).

Dans les fractions benzéniques suivantes on trouve 0.217 g de 1-benzyloxindole, rendement, 6.5%; p.f., 75.5° (éthanol).

Anal. calc. pour $C_{15}H_{13}NO$: C, 80.72; H, 5.83; N, 6.28. Trouvé: C, 80.93; H, 6.06; N, 6.35.

Spectres i.r. (CCl_4): 1705, 1715 cm^{-1} ($\nu_{(C=O)}$). Ce produit est identique avec le 1-benzyloxindole obtenu à partir de la 1-benzylisatine (8).

L'élution avec le mélange benzène–chloroforme (2:1) donne 0.95 g de 3,3-dibenzyloxindole, rendement, 20.2%; p.f., 204.2° (éthanol).

Spectres i.r. (CCl_4): 1704, 1728 ($\nu_{(C=O)}$); 3445, 3190 cm^{-1} ($\nu_{(N-H)}$).

L'élution avec le chloroforme donne 0.435 g de 3-benzyloxindole, rendement, 13%; p.f., 132° (éthanol).

Anal. calc. pour $C_{15}H_{13}NO$: C, 80.72; H, 5.83; N, 6.28. Trouvé; C, 80.94; H, 5.91; N, 6.49.

Spectres i.r. (CCl_4): 1702, 1724, 1730 ($\nu_{(C=O)}$) 3448, 3200 cm^{-1} ($\nu_{(N-H)}$).

Il est identique avec le 3-benzyloxindole synthétisé par la réduction du 3-benzylidènoxindole avec le $NaBH_4$ (11).

En continuant l'élution avec le chloroforme on obtient 0.778 g (39%) d'oxindole.

Synthèse du 1,3-dibenzyloxindole à partir du 3-benzylidènoxindole

A une solution de $NaOC_2H_5$ (à partir de 0.8 g de Na) dans 50 ml d'éthanol ou ajoute 7.1 g (0.032 mol) de 3-benzylidènoxindole; on ajoute alors par portions 15.2 g (0.12 mol) de chlorure de benzyle et porte le mélange à reflux pendant 15 h. On évapore à sec sous vide, reprend le résidu par du benzène, lave avec de l'eau, sèche la solution benzénique sur le $MgSO_4$ anhydre. Après avoir chassé le solvant on dissout le résidu dans 150 ml d'éthanol à 50% et réduit par le $NaBH_4$. Une fois la réduction terminée on concentre sous vide et reprend par du benzène.

On sépare la solution dans le benzène sur une colonne de gel de silice.

L'élution par le benzène donne 4 g (40%) de 1,3-dibenzyloxindole, p.f., 92°, après une cristallisation dans l'éthanol, p.f., 99.8°.

L'élution par le chloroforme donne 3.2 g de 3-benzyloxindole.

1,3-Dibenzyldioxindole

A une solution de 0.276 g (0.00088 mol) de 1,3-dibenzyloxindole on ajoute 1.2 g (0.009 mol) de chlorure de benzyle et 17 ml d'une solution 0.05 *M* de NaOH dans l'éthanol. On chauffe à 40° pendant 5 h, acidifie avec du HCl, évapore à sec, ajoute du benzène, essore le NaCl et sépare la solution benzénique sur une colonne de 12 g de gel de silice.

Eluant avec du benzène on obtient le 1,3,3-tribenzyloxindole. Le chloroforme élue 0.12 g de 1,3-dibenzyldioxindole, p.f., 170°, après une cristallisation dans l'éthanol, p.f., 178.5°, lit. (12) p.f., 176–177°.

Anal. calc. pour $C_{22}H_{19}NO_2$: C, 80.24; H, 5.77; N, 4.26. Trouvé: C, 79.89; H, 6.08; N, 4.48.

Spectres i.r. (CCl_4): 1710 ($\nu_{(C=O)}$), 3560 cm^{-1} ($\nu_{(O-H)}$)

(B) Partie analytique

On chauffe une solution de l'oxindole ou d'un de ces dérivés mono- ou disubstitués, du chlorure de benzyle et de la base (le NaOH ou le $NaOC_2H_5$) en agitant sur un bain thermostaté. Les concentrations de chaque produit sont données dans les graphiques et les tableaux.

On prélève les échantillons aux temps indiqués, les acidifie, chasse le solvant, ajoute du benzène, essore le NaCl et ajuste le volume de la solution avec du benzène. On injecte ensuite des échantillons de 5–20 μl sur une colonne de c.p.v.

On utilise les colonnes de 10% Versamide 900 (3 ft × 1/8 in.) avec un programme 200→300° 15°/min, *T*(det.), 320°; *T* (inj.), 310°, N_2 30 cm^3/min, ou bien les colonnes de 10% SE 30 (5 ft × 1/8 in.) avec un programme 170→320° 10°/min, autres conditions identiques. Les temps de retension avec le Versamide: oxindole, 3.5; 1-benzyloxindole, 5.8; 3-benzyloxindole, 8; 1,3-dibenzyloxindole, 10.7; 3,3-dibenzyloxindole, 12.7; 1,3,3-dibenzyloxindole, 16.3 min; avec le SE-30: oxindole, 2.2 min; 1-benzyloxindole, 8; 3-benzyloxindole, 9; 1,3-dibenzyloxindole, 13.6; 3,3-dibenzyloxindole, 14.1; 1,3,3-tribenzyloxindole, 18 min.

On calcule la quantité de chaque dérivé à partir des hauteurs des pics, après avoir calibré l'appareil avec un mélange des composés purs. On répète la calibration quelques fois durant la journée. L'erreur estimée de la méthode: 10%.

Dans les réactions menées dans l'atmosphère de l'azote on introduit ce gaz après l'avoir saturé en éthanol à la température de l'eau du robinet.

Ce travail a été partiellement financé par une subvention du Conseil National de Recherches du Canada.

Kinetics of Proton Transfer Reactions of Carbon Acids. II.[1] Reaction of Di-(4-nitrophenyl)methane with Alkoxide Bases

A. JARCZEWSKI[2] AND K.T. LEFFEK
Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received July 12, 1971

The second-order rate constants have been measured over a range of temperatures for the proton-transfer reactions from di-(4-nitrophenyl)methane to ethoxide, isopropoxide, and *t*-butoxide ions in solvents consisting of the corresponding alcohols containing 10% toluene by volume. The activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ have been calculated and an interpretation of them is given in terms of solvation effects during the activation process. A comparison between the activation parameters for proton transfers and E2 olefin-forming β-elimination reactions is made and discussed with respect to transition state character of the latter reactions.

On a mesuré les constantes de vitesse de second ordre à plusieurs températures pour les réactions de transfert de proton du di-(4-nitrophényl)méthane aux ions éthoxyde, isopropoxyde et butoxyde tertiaire dans des solvants consistant en les alcools correspondants contenant 10% de toluène par volume. On a calculé les paramètres d'activation $\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$ et on les interprète en termes d'effets de solvation durant le procédé d'activation. On fait une comparaison entre les paramètres d'activation pour les transferts de proton et les réactions E2 de formation d'oléfine par élimination-β et on discute par rapport au caractère d'état de transition de ces dernières réactions.

Canadian Journal of Chemistry, **50**, 24 (1972)

Introduction

The kinetics of proton-transfer reactions between substituted methanes and bases in organic solvents have been studied by Caldin and co-workers (1–4). This paper presents part of a systematic study of the activation parameters of this type of reaction.

The addition of sodium alkoxide to di-(4-nitrophenyl)methane in alcohol yields a violet colored solution. The reaction is presumed to be a reversible proton-transfer by analogy with the reaction with tri-(4-nitrophenyl)methane, which has been investigated in detail (2) and also from the fact that neutralization of the basic solution with deuterated hydrochloric acid yields a colorless solution from which the original di-(4-nitrophenyl)methane can be recovered, deuterated on the aliphatic carbon atom. Some work has been carried out by Shapiro *et al.* (5) on the formation of anion radicals from di-(4-nitrophenyl)methane and hydroxyl ions in non-hydroxylic solvents. In some cases the colored solution yielded an e.p.r. signal and in others it did not, but in all cases the appearance of the color preceded the appearance of the e.p.r. signal. It is, therefore, concluded that the second-order rate constant corresponding to the appearance of the color is the k_2 of eq. 1.

$$[1] \quad (NO_2C_6H_4)_2CH_2 + \bar{O}Alk \overset{k_2}{\rightleftarrows} [(NO_2C_6H_4)_2CH]^- + HOAlk$$

The anion has a maximum absorption at about 530 nm, hence the velocity of the reaction may be conveniently followed spectrophotometrically.

Results and Discussion

Optical density measurements were made on equilibrium mixtures for solutions containing a constant concentration of the substrate and various concentrations of sodium ethoxide. These are given in Table 1. From eq. 1 the expression for the equilibrium constant may be written as eq. 2, since the concentration of

$$[2] \quad \frac{K}{[C_2H_5OH]} = K' = \frac{[A^-]}{[C_2H_5O^-]([AH]-[A^-])}$$

ethoxide is in large excess over that of the anion. AH is the substituted methane and A^- its anion. Substitution of the anion concentration by the optical density (o.d.) and molar

absorptivity (ε) according to de Beer's Law leads (4) to eq. 3.

[3] $$[AH]/(o.d.) = 1/K'\varepsilon[\bar{O}C_2H_5] + 1/\varepsilon$$

The results of Table 1 plotted in the form of [AH]/(o.d.) *vs.* $1/[\bar{O}C_2H_5]$ give a good straight line, which demonstrates the validity of de Beer's Law for the anion and also the form in which eq. 1 is written. Although these results may be used to evaluate ε for the anion and K' for the system, it is not possible to do so to a good precision because the intercept of the graph, equal to $1/\varepsilon$, contains a large percentage uncertainty which also appears in K' which is calculated from the slope of the graph (slope = $1/K\varepsilon$). However, the values obtained are $\varepsilon \sim$ 11 000 l mol^{-1} cm^{-1} and $K' \sim$250 l mol^{-1}.

The kinetic measurements were made using a large excess of base and first-order rate constants were calculated using eq. 4 (see Experimental) derived from the equilibrium shown in eq. 1. These are shown in Table 2 for the reaction with ethoxide, isopropoxide, and *t*-butoxide in solvents consisting of the corresponding alcohol containing 10% toluene by volume. These rate constants were measured at a number of temperatures between 0 and 50 °C. The slope of the graph of the first order rate constant against the base concentration is the second order rate constant k_2 of eq. 1. The values of k_2, which were actually obtained by a least squares computation, are given in Table 3 together with their standard deviations. These second order rate constants were fitted to the transition state theory equation ($\log_{10} k_2$ *vs.* $1/T$) by a second least squares computation and the resulting activation parameters are shown in Table 4, with their standard deviations. Within the limits of the experimental precision the activation parameters for the ethoxide and isopropoxide reactions are the same but those for the tertiary butoxide attack show a lower enthalpy of activation which is compensated by a much more negative entropy of activation.

Caldin (6) has discussed the interpretation of energies of activation of some aromatic nitrocompounds, including the proton-abstraction from 2,4,6-trinitrotoluene by ethoxide ion in ethanol containing 1% toluene. This particular reaction gave a $\Delta H^{\ddagger}$ of 13.0 kcal mol^{-1} and a $\Delta S^{\ddagger}$ of -5.6 cal mol^{-1} deg^{-1}. Other measurements of the activation parameters for proton-abstraction by ethoxide in ethanolic solvents gave results of the same order of magnitude, *i.e.* for 4-nitrobenzyl cyanide (4), $\Delta H^{\ddagger} = 8.57$ kcal mol^{-1}, $\Delta S^{\ddagger} = -0.6$ cal mol^{-1} deg^{-1} and for tri(4-nitrophenyl)methane (2), $\Delta H^{\ddagger} = 11.6$ kcal mol^{-1}, $\Delta S^{\ddagger} = -11.1$ cal mol^{-1} deg^{-1}. Thus the result of approximately 10 kcal mol^{-1} for the enthalpy of activation for the ethoxide and isopropoxide reactions is within the range of typical proton abstraction reactions.

Enthalpies of Activation

Caldin's discussion (6) was made in terms of the four factors which contribute to the activation energies of bimolecular reactions in solution which had been recognized much earlier by Polanyi and co-workers (7, 8), *i.e.* bond breaking and making, non-bonded repulsions, electrostatic interactions, and solvation changes. It was concluded that the reorganization of solvent molecules could account for the major part of the activation energy. The point of interest of the results in Table 4 is, therefore, whether the enthalpies and entropies of activation confirm or cast doubt upon Caldin's conclusions.

When the reagent is changed from ethoxide ion to *t*-butoxide ion with each reaction run in its conjugate acid solvent, the reagent ($\bar{O}Bu$) becomes larger and more strongly basic and the solvent becomes less well able to facilitate ionization and solvate ions. Thus, the ethoxide ion is strongly solvated in ethanol, whereas the larger, more basic *t*-butoxide ion is less strongly solvated in *t*-butanol. Cram has suggested (9) that potassium *t*-butoxide at concentrations above 0.01 *M* in *t*-butanol exists as ion-pairs.

40.0	1.02	1.73_5	2.98	5.28

Therefore, it is probable that there is a qualitative difference in the initial state of the reagent between ethoxide and *t*-butoxide which should appear as a quantitative difference in the activation parameters even though both reactions exhibit the same type of second-order kinetics. If a major part of the activation energy is the breaking down of a strong solvation shell around the ethoxide ion in ethanol, then the enthalpy of activation for *t*-butoxide attack should be smaller since its solvation shell is weaker, and the more so if it does indeed exist predominantly in an ion-paired state.

Entropies of Activation

The activation entropies shown in Table 4 are all negative but of larger magnitude than those for the other proton-transfers quoted above. Such entropies of activation indicate a marked increase in the order of the system during the

activation process. This will result automatically for any bimolecular reaction, but if the activation parameters are to be interpreted on the basis of a major contribution from solvation effects, then it must be assumed that the transition states for these reactions have more solvent molecules tied down than do the corresponding initial states. For the ethoxide reaction a strongly solvated initial state contains ethanol molecules hydrogen-bonded to the negatively charged oxygen atom. In the transition state the negative charge is dispersed partly onto the carbon atom of the incipient carbanion with the whole entity solvated by an ethanol sheath which must contain a lot of solvent–hydrogen-bonded interaction and a much reduced ethanol-ethoxide interaction. Thus, it is possible to have more solvent molecules constrained in the transition state than in the initial state, with a concomitant decrease in entropy.

The much larger entropy of activation encountered with the *t*-butoxide reaction may result from the ion-pair state of sodium *t*-butoxide in *t*-butanol. The weak solvation of the initial state becomes stronger on activation by a mechanism analogous to that postulated for the ethoxide reaction. In addition, a strong solvation shell must form around the sodium ion since it will become a more independent entity as the negative charge is dispersed between the oxygen and carbon atoms. Such an explanation would predict that the entropy of activation for the *t*-butoxide attack in *t*-butanol should be largely independent of the structure of the substrate molecule. Caldin and Hyde[3] have found $\Delta S^{\ddagger} = -35$ cal mol^{-1} deg^{-1} for tri-(4-nitrophenyl)methane under almost the same conditions as the present work, which is essentially the same as our value in Table 4. On the other hand for the ethoxide attack in ethanol the entropies of activation are quite different; -11 cal mol^{-1} deg^{-1} for tri-(4-nitrophenyl)methane and -21 cal mol^{-1} deg^{-1} for di-(4-nitrophenyl)methane.

It is concluded that the major part of the observed activation parameters may be satisfactorily interpreted in terms of solvation effects in a manner consistent with the earlier treatment of Caldin (6) by using arguments similar to those used by others in discussions of solvation effects, particularly those of Robertson in his review of the characteristics of solvolysis reactions of alkyl halides and sulfonates in water (10).

Comparison with β-Elimination Reactions

It is of interest to compare the above proton abstraction reactions with olefin-forming β-eliminations which involve the removal of a halide with its bonding electrons from an α-carbon atom and also the removal of a proton from the β-carbon atom of an alkyl halide to yield an olefin. Of the three main mechanisms possible, E1, E2, and E1cB, the E2 is by far the most common. The unimolecular elimination from the conjugate base of the alkyl halide (E1cB) would involve the initial formation of a carbanion followed by rapid loss of halide. This mechanism seems to be quite rare for reactions which produce simple olefins (11, 12). Since the first step is a proton transfer, the activation parameters of an E1cB reaction might be expected to be similar to those in Table 4 under certain mechanistic conditions. The conditions are that the carbanion intermediates should decompose to olefins at roughly the same rate as they re-protonate to form the original molecule, so that the first proton-abstraction step would play a major role in controlling the rate of the overall reaction. This type of E1cB mechanism merges smoothly into an E2 process as the rate at which the carbanion decomposes to olefin is increased in relation to the re-protonation step (13). Thus, the E2 reaction may have a symmetrical transition state with equal amounts of β-carbon–hydrogen and α-carbon–halogen bond breaking, or the transition state may be unsymmetrical, either E1-like with more carbon–halogen bond breaking or E1cB-like with more carbon–hydrogen bond breaking. Such different transition states have been postulated several times (12–15) and correlated with kinetic isotope effects (15–17).

Despite the fact that Cristol *et al.* (18) estimated that the energy required to form a sym-

metrical E2 transition state was lower than that required for a carbanion transition state by 7 to 14 kcal mol^{-1} for a molecule with no resonance stabilization of the carbanion, it seems reasonable to postulate, in the light of the results in Table 4, that an increase in carbanion character in the transition state of an E2 reaction would be accompanied by a decrease in ethalpy of activation, for molecules in which some amount of stabilization of the carbanion is to be expected. The reduction in the enthalpy of activation is achieved by a reduction in the energy contribution from the stretching of the carbon–halogen bond. This postulate may be used to interpret some activation parameter changes which have been observed, *e.g.* with β-phenylethyl tosylate and bromide undergoing E2 reactions with ethoxide in ethanol and *t*-butoxide in *t*-butanol. For the bromide $\Delta H^{\ddagger}$ falls from 20.4 to 13.0 kcal mol^{-1} while $\Delta S^{\ddagger}$ changes from −6.8 to −25.0 cal mol^{-1} deg^{-1} on changing from ethoxide to *t*-butoxide (19, 20). A very similar change is also found for the tosylate (19). These parameters might reasonably be interpreted as an indication that the elimination reaction with *t*-butoxide is going through a transition state with more carbanion character than that of the ethoxide reaction. The bromide shows a primary β-deuterium isotope effect (k_H/k_D) of between 7 and 8 (20) for both the ethoxide and tertiary butoxide, and also the same Hammett ρ-value (19), indicating that the reacting proton is symmetrically placed between the carbon atom and the base in this transition state (21). Thus, any difference in the transition states of the two reactions must lie in the amount of stretching of the carbon-bromine bond. It may be possible, therefore, to deduce the character of an E2 transition state, for particular types of substrate molecules, from the magnitude of the activation parameters.

Examples of the E1cB mechanism may be found in the future by first studying the proton-transfer reaction and then adjusting the structure of the formed carbanion so that it has the correct stability and also the ability to eliminate a halogen or some other group at an appropriate rate. An example, using essentially this approach, has been reported recently (22).

Experimental

Materials

Di-(4-nitrophenyl)methane was prepared by adding diphenylmethane (75 g) slowly to a vigorously stirred solution of concentrated nitric acid (390 g) and concentrated sulfuric acid (470 g) maintained at −10 to −15 °C. Stirring was continued for 45 min keeping the temperature below −10°, after which the solution was poured into an excess of ice-water. The yellow precipitate which formed was filtered off and washed successively with water, methanol, and diethyl ether. The nitro compound was recrystallized from benzene several times yielding yellow needles m.p. 183–185° (lit. 183° (23)).

Ethanol was purified by refluxing with potassium hydroxide and silver nitrate to remove the aldehydes (24), then dried by the method of Lund and Bjerrum (24). Traces of bases were finally removed by redistilling with a little 2,4,6-trinitrobenzoic acid (24).

2-Propanol was dried for several days over Drierite, then with calcium hydride. After heating under reflux with stannous chloride, the 2-propanol was fractionally distilled.

t-Butanol was dried over calcium hydride and then fractionally distilled from dibutylphthalate.

Toluene was dried with sodium metal and fractionally distilled.

Equilibrium Measurements

The o.d. measurements were made on a Unicam SP800 Spectrophotometer, fitted with a constant-temperature bath to control the temperature of the cell block.

Kinetic Measurements

Alkoxide stock solutions were prepared in the alcohols containing 10% toluene by volume, by dissolving clean sodium metal in the solvents in flasks protected from absorption of moisture and carbon dioxide from the atmosphere. The solutions were stored under nitrogen. The concentrations of the alkoxide solutions were determined by titration against standard HCl solutions, using methyl orange as the indicator.

For the ethoxide and isopropoxide reactions the velocities were observed using a Durrum-Gibson stopped-flow spectrophotometer with a Kel-F flow system and an optical cell of 2 mm light-pathlength. The instrument was fitted with a constant-temperature system which maintained the reservoir, in which the drive syringes of the apparatus are immersed, at the temperatures quoted in Table 2 to ±0.03 °C.

The concentrations in the ethoxide reaction were chosen so that the traces showing transmittance *vs.* time, which were displayed on a Tektronix 564 storage oscilloscope screen, covered the range of 80–100% transmittance. Several runs under identical reaction conditions were displayed on the screen consecutively then this was photographed with a Polaroid camera. The photographs were enlarged and the first-order rate constants were calculated by the Guggenheim method (25) assuming that the transmittance was proportional to the substrate concentration.

For the isopropoxide reaction, it was not convenient to work in the 80–100% transmittance range, so in this case the color change was monitored over a wider transmittance range and converted to absorbance before calculation of the rate constants.

The *t*-butoxide reaction was followed on the Unicam SP 800 spectrophotometer by scanning at a fixed wavelength of 530 nm against time. The absorbance values were read directly from the chart paper and the first-order rate constants were again calculated by the Guggenheim method.

Diffusion of some Hydrocarbons in Air: a Regularity in the Diffusion Coefficients of a Homologous Series[1]

ROBERT W. ELLIOTT[2] AND HARRY WATTS

Research Department, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received March 17, 1971

Diffusion coefficients in air at 298.2 °K and 1 atm pressure are reported for ethane, ethene, ethyne, cyclopropane, propene, propadiene, propyne, butane, 1-butene, 2-methylpropene, *cis*-2-butene, *trans*-2-butene, 1,3-butadiene, 1-butyne, 2-methylbutane, 2,2-dimethylpropane, cyclopentane, and 1-pentene.

A linear relationship, valid for alkanes and alkenes, has been found between the diffusion coefficient and the reduced molecular weight of the members of a homologous series and air.

Diffusion coefficients calculated by ten prediction equations were generally lower than those observed.

Les coefficients de diffusion dans l'air à 298.2 °K et sous une pression de une atmosphère sont rapportés pour l'éthane, l'éthène, l'éthyne, le cyclopropane, le propène, le propadiène, le propyne, le butane, le butène-1, le méthyl-2 propène, le butène-2 *cis*, le butène-2 *trans*, le butadiène-1,3, le butyne-1, le méthyl-2 butane, le diméthyl-2,2 propane, le cyclopentane et le pentène-1.

Une relation linéaire, valable pour les alcanes et les alcènes, existe entre le coefficient de diffusion et la masse moléculaire réduite des membres d'une série homologue et l'air.

Les coefficients de diffusion, calculés à partir de dix équations de prédiction, sont généralement plus bas que ceux observés.

Canadian Journal of Chemistry, **50**, 31 (1972)

Introduction

Measurements of gaseous diffusion coefficients are of great value for both theoretical and practical reasons. The detailed kinetic theory of gases relates the diffusion coefficient in a binary mixture to the intermolecular forces acting between the diffusing species (1). In principle, it is possible to calculate a diffusion coefficient from intermolecular forces. However, knowledge of intermolecular forces is far from complete; hence data necessary for this calculation must be obtained from measurements of some other property, such as viscosity, which can also be related to intermolecular forces. Alternately, data on diffusion coefficients may be used to give information on intermolecular forces (2). The practical need in engineering design for reasonable values of diffusion coefficients has produced a rash of semi-empirical prediction equations. Most of these are soundly based on theory, but have been forced to empiricism because of our incomplete knowledge of intermolecular forces.

Dichotomy of interest has divided diffusion coefficient measurements into two groups, those aimed at gaining greater understanding of intermolecular forces, and those aimed at obtaining data on systems of practical importance. Most studies of gaseous diffusion have been fragmentary and few systematic investigations of related systems have been made. Recent notable exceptions have been the investigations of noble gas mixtures by Van Heijningen, Harpe, and Beenakker (2) and the diffusion of 147 compounds in air by Lugg (3).

In this paper we report the results of a systematic investigation of the diffusion of some hydrocarbons in air. These results have revealed a regularity in the diffusion coefficients of a homologous series that has apparently not been previously observed.

Experimental

The apparatus and experimental techniques have been described previously (4, 5). All data were corrected to 1 atm pressure and 25 °C as before. In an attempt to refine techniques two possible sources of experimental error were investigated. Previously it had been considered that the effect of small atmospheric pressure fluctuations would be negligible from the point of view of their effect upon the magnitude of the diffusion coefficient. However, if the atmospheric pressure fell steadily during an experiment the rate of loss of diffusing gas from the cell would be enhanced, due to expansion of the cell contents, and if it rose steadily during an experiment the rate of loss would be lowered, due to contraction of the cell contents. If this effect were significant, then experiments performed with a steady pressure

TABLE 1. Diffusion coefficients at 298.2 °K

Compound	Infrared frequency (cm^{-1})	No. of data	Diffusion coefficients in $cm^2\ s^{-1}$	
			Experimental	Calculated
Ethane	2950	6	0.1531±0.0038	0.1453
Ethene	3123	6	0.1655±0.0021	0.1543
Ethyne	3307	5	0.1457±0.0015	0.1597
Cyclopropane	1028	6	0.1277±0.0012	0.1219
Propene	2953	6	0.1318±0.0017	0.1204
Propadiene	1969	6	0.1392±0.0018	0.1160
Propyne	3346	6	0.1316±0.0011	0.1236
Butane	2965	8	0.1021±0.0013	0.0981
1-Butene	2969	6	0.1092±0.0016	0.1019
2-Methylpropene	2963	6	0.1072±0.0032	0.1000
cis-2-Butene	3036	6	0.1087±0.0013	0.1011
trans-2-Butene	961	6	0.1131±0.0012	0.1091
1,3-Butadiene	3110	6	0.1158±0.0018	0.1039
1-Butyne	3340	6	0.1163±0.0020	0.0945
2-Methylbutane	2967	6	0.0935±0.0020	0.0876
2,2-Dimethylpropane	2957	6	0.0877±0.0021	0.0883
Cyclopentane	2967	6	0.0919±0.0025	0.0920
1-Pentene	2967	6	0.0958±0.0011	0.0926

drop would give diffusion coefficients showing positive deviations from the mean of a set and those performed with a steady pressure increase would show negative deviations. Statistical analysis of experiments in which these conditions obtained showed no such systematic trend in the diffusion coefficients. We therefore conclude that any effect of small systematic atmospheric pressure changes during an experiment is negligible.

The frequencies of the i.r. absorption bands used to follow concentration changes in the diffusion cell lay near the OH stretching vibration frequency of water, consequently changes in atmospheric humidity during an experiment might effect the results due to changes in atmospheric absorbance in the reference beam of the i.r. spectrophotometer used to follow concentration changes in the cell. Consequently the relative humidity of the room was measured during experiments. Analysis of results showed no trend in diffusion coefficient with humidity.

Materials

The compounds studied were pure grade (99 mol% or better) and were obtained from the following sources: ethane, propene, *n*-butane, 2-methylpropene, 1-butene, *cis*-2-butene, *trans*-2-butene, 1,3-butadiene, 2-methylbutane, 1-pentene, and cyclopentane (95 mol%), Phillips Petroleum Company; ethyne, cyclopropane, propadiene, propyne, 1-butyne, and 2,2-dimethylpropane, Matheson of Canada, Ltd.; ethylene, Imperial Oil, Limited.

Results and Discussion

Table 1 gives the mean observed diffusion coefficients in air of the compounds studied together with their root-mean-square deviations, the number of data obtained, and the i.r. frequency used to follow concentration changes of the diffusing gas. Inspection of the data reveals some systematic trends. The diffusion coefficients of the alkenes, ethene, propene, 1-butene, and 1-pentene, are all higher than those for the corresponding alkanes. Propane and *n*-pentane were determined previously (5) and have the values 0.1144 ± 0.0015 and 0.0856 ± 0.0035 $cm^2\ s^{-1}$, respectively. Propadiene and 1,3-butadiene have higher diffusion coefficients than the corresponding alkenes. The values for cyclopropane and cyclopentane are both higher than the respective straight chain alkanes quoted above. Lugg (3) reported that the diffusion coefficients of chain isomers of many substituted alkanes was in the order *iso* > *n*. This order is observed with pentane but not with butane. Beatty (6) observed that the binary diffusion coefficient for the system 2,2-dimethylpropane–pentane was higher than the self diffusion coefficient of pentane; consistent with this we find the diffusion coefficients in air to be ordered 2,2-dimethylpropane > pentane. We also note a significant difference between the *cis* and *trans* isomers of 2-butene.

Diffusion coefficients were calculated from the detailed kinetic theory equation (1) as in previous work (4, 7) and from nine other prediction equations using modified versions of the computer programmes of Jarvis and Lugg (8). The equations used are named in order of decreasing accuracy of their predictions, together with the root-mean-square deviations in $cm^2\ s^{-1}$ of the predicted from our experimental results: Wilke–Lee (9), ±0.0087; Slattery-Bird (10),

±0.0092; the kinetic theory equation (1), ±0.0105; Chen–Othmer (11), ±0.0106; Fuller, Schettler, and Giddings (12), ±0.0122; Hirschfelder, Bird, and Spotz (13), ±0.0141; Othmer–Chen (14), ±0.0147; Andrussow (15), ±0.0202; Gilliland (16), ±0.0220; and Arnold (17), ±0.0414. In general, all of these equations predicted diffusion coefficients lower than the experimental values, and none was completely successful in arranging the diffusion coefficients of isomers in the correct order. Indeed the equations of Gilliland (16), Andrussow (15), and Fuller, Schettler, and Giddings (12) are unable to distinguish between isomers at all!

If good data for its use were available, the kinetic theory equation should be superior to the other equations because of its sound theoretical basis. In our calculations we used tabulated values of the Lennard–Jones potential parameters for the hydrocarbons obtained from viscosity measurements (1), where available; where these data were not available they were estimated from critical properties listed by Kudchadkar, Alani, and Zwolinski (18) by the method of Stiel and Thodos (19). Where critical properties were not available they were estimated by standard methods (19). Potential parameters for the mixture were calculated from those for the pure components as before (7) using the Hudson–McCoubrey combining rules (20) and ionization potentials as follows: ethane, ethene, ethyne, propene, propadiene, propyne, 1-butene, 1,3-butadiene, and 1-butyne from Herzberg (21), butane, 2-methylpropene, *cis*-2-butene, *trans*-2-butene from Bernecker and Long (22), 2-methylbutane, 2,2-dimethylpropane, and cyclopentane from Lorquet (23), cyclopropane from Cermak (24), and 1-pentene from Honig (25). It is probably this estimation of data that causes the kinetic theory equal ion to be slightly inferior to the Wilke–Lee and Slattery–Bird equations for the present systems.

In Fig. 1 are plotted the observed diffusion coefficients against the reduced molecular weight of each system, defined by

$$[1] \qquad \mu = \frac{M_A M_H}{M_A + M_H}$$

where M_A is the mean molecular weight of air and M_H is the molecular weight of the hydrocarbon. Data for the *n*-alkanes and *n*-alkenes

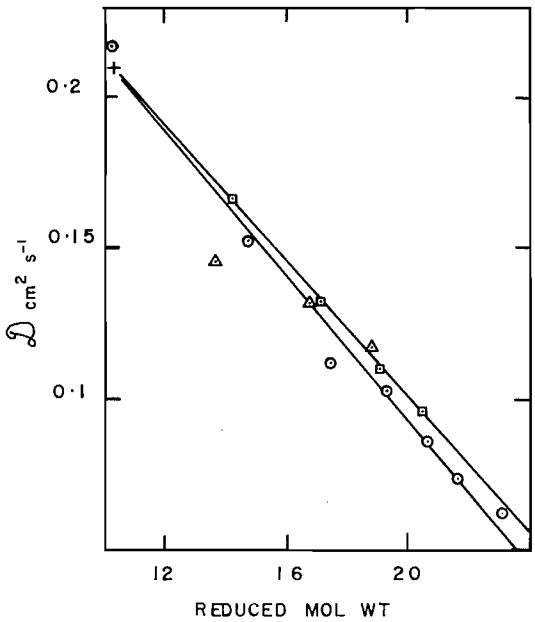

FIG. 1. Linear plots of diffusion coefficient in air at 25 °C against reduced molecular weight for the diffusion of *n*-alkanes, ⊙; *n*-alkenes, ⊡; and *n*-alkynes, △. The intersection of lines for alkanes and alkenes is marked +.

gave good straight lines. A least square fit to the equation:

$$[2] \qquad \mathcal{D} = m\mu + c$$

gave values for the slope m, intercept c, intercept on the μ axis, correlation coefficients, and standard deviations of experimental value of $\mathcal{D}$ from the fitted line listed in Table 2. The probability of obtaining these values of the correlation coefficients by chance alone is less than 0.01, indicating that the data are well represented by a linear relationship (26). To increase the number of data used in this calculation we included our previous values for methane (4) and propane (5) and Lugg's values for hexane and octane (3).

The intercepts of these lines on the reduced molecular weight axis are very close to the mean molecular weight of air, 28.967. This is consistent with the limit of $\mu \to M_A$ as $M_H \to \infty$, and the expectation that $\mathcal{D} \to 0$ as $M_H \to \infty$.

Figure 1 shows that the lines for the *n*-alkanes and *n*-alkenes intersect close to the point for methane. This would imply that, as far as diffusion is concerned, methane can be regarded as the first member of the alkene series. No

TABLE 2. Values for least squares fit to eq. 3

Hydrocarbon	m	c	μ axis intercept	Standard deviation	Correlation coefficients
n-alkanes	0.3344	−0.01206	27.73	0.0062	−0.9945
n-alkenes	0.3261	−0.01130	28.85	0.001	−0.9996

linear correlation was observed with the alkynes but our data are insufficient to draw any conclusion about the trend of diffusion coefficient with reduced molecular weight in this series.

The kinetic theory equation can be written in the form

$$[3] \qquad \mathscr{D}_{12} = \frac{bT^{3/2}}{\mu^{1/2}\sigma_{12}^{2}\Omega(T^*)}$$

where T is the absolute temperature and $\Omega(T^*)$ is a collision integral at a reduced temperature of $T^* = kT/\varepsilon_{12}$ and ε_{12} and σ_{12} are molecular interaction parameters characteristic of a 1–2 interaction; b is a constant, and k is the Boltzmann constant. The implications of eqs. 2 and 3 are that $\sigma_{12}^{2}\Omega(T^*)$ varies in a systematic, but not simple, way with reduced molecular weight for a homologous series. The discovery of this regularity in diffusion coefficients points to the need for further experimental work on other homologous series and to the need for further theoretical work. Analysis of literature data, now in progress, indicates that the linear variation of diffusion coefficient with reduced molecular weight is a general phenomenon for other classes of compounds (27).

We suggest that our linear relationship may be used for the empirical prediction of diffusion coefficients and predict the following for $\mathscr{D}$ in $cm^2\ s^{-1}$: heptane, 0.0635; nonane, 0.0495; decane, 0.0442. We might expect that the value for heptane in air would be reliable because it is an interpolated value and it will be interesting to see if future measurement bears out these predictions.

FOR ERRATA SEE V.50 #1 1972 P.1

The i.r. and Raman spectra of liquid and crystalline SiH_4 and SiD_4–SiH_4 mixtures have been recorded. The spectra show striking changes when the crystal undergoes the solid–solid phase transition. Phase I is disordered. Possible site, and factor groups for the low temperature crystalline phase are proposed.

Les spectres i.r. et Raman de SiH_4 et de mélanges SiD_4–SiH_4 dans la phase liquide et les deux phases cristallines furent enregistrées. Les spectres sont profondément modifiés au point de transition solide–solide. La phase I est désordonnée. On propose certains groupes de site et certains groupes facteurs possibles pour la phase cristalline de basse température.

Canadian Journal of Chemistry, **50**, 35 (1972)

Introduction

It is well known that the analysis of vibrational spectra may lead to the determination of the site and factor groups, of crystals, although such an analysis is seldom sufficient to allow a unique choice of space group (1–4). This method is particularly useful with solids which are not well suited for diffraction studies, as is the case with molecules containing light atoms or when single crystals cannot be obtained. Solid methane, which provides a typical example of this, has received considerable attention, although some doubt still remains about the structure of its low-temperature phases (5–8). Monosilane (SiH_4) appeared to be another compound appropriate to this kind of study. The solid (m.p. 88 °K) is known to exhibit a λ-type phase transition at 63.75 °K (9), but no crystallographic data are as yet available on either solid phase. Clusius (10) has observed that the high-temperature phase (phase I) is weakly optically anisotropic, whereas phase II is strongly birefringent. This suggests that solid SiH_4, at least in its low-temperature modification, has a non-cubic crystal structure.

Vibrational spectra of silane in both the gas (11) and condensed phases (12–15) have been previously reported. However, previous works on the solid were not performed in the best of experimental conditions. The i.r. spectrum of McKean and Chalmers (13), believed to be that of the solid in its phase II, was recorded at a temperature very close to the transition point, and our results indicate that phase II was not always attained in that previous work. In the two other reported studies (12–14), the solid samples were prepared by direct deposition of the gas on a cold window. Preliminary experiments from our part indicated that spectra thus obtained were usually not reproducible, and were often very different from one another, even when attempts were made to anneal the solid deposits. We have therefore carefully rerun the i.r. spectra and recorded the Raman spectra of liquid and solid SiH_4, the solid samples being grown from the melt. In addition, studies were performed on solutions of SiD_4 in SiH_4 in order to gather information on the site symmetry (16) in the solid phases of silane.

Experimental

The SiH_4 (semi-conductor grade) used in our experiments was obtained from the Matheson Co. and used without purification. The SiD_4, from Merck, Sharp, and Dohme of Canada, Ltd., was analyzed by mass spectrography and found to contain ~4 at.% H. This material, although suitable for obtaining the spectra of SiD_4 diluted in SiH_4, could not be used for obtaining the spectra of pure solid SiD_4.

The mid-infrared spectra (400–4000 cm^{-1}) were recorded on a Perkin–Elmer Model 125 prism-grating spectrometer calibrated with references at the I.U.P.A.C. tables (17). Far-infrared spectra (10–400 cm^{-1}) were obtained with a Michelson interferometer (Research and Industrial Instruments Co., model FS–720) coupled to a Fourier transform computer (model FTC–100). The frequency accuracy for both instruments is probably close to 0.5 cm^{-1} in the regions of interest. A conventional variable temperature liquid helium cryostat supplied by Andonian Associates was used

for the i.r. experiments. The gaseous mixtures were prepared in a Pyrex system previously evacuated to a pressure lower than 1×10^{-6} mm Hg. The samples were prepared by condensing the pure gas, or the appropriate isotopic mixtures, to the liquid between two circular windows sealed off into a closed compartment by means of indium gaskets. The window material was either sapphire ($\nu > 2000$ cm^{-1}), germanium (400–2000 cm^{-1}), or crystalline quartz ($\nu < 200$ cm^{-1}). Germanium windows are known to distort i.r. band shapes because of its high refractive index; however, this effect was found to be unimportant in our study. The crystals, slowly grown from the liquid, always yielded reproducible spectra. The rate of cooling at the freezing and solid transition temperatures was of the order of one half of a degree per hour. Reproducible spectra were always obtained when the samples were repeatedly cycled through the transition temperatures. The sample thickness was ~1 micron for pure SiH_4 and ~50 microns for the isotopic mixtures in the mid-infrared, whereas very thick films (~2 mm) were needed in the far-infrared.

The Raman spectra, obtained with two different sets of spectrometers and cryostats, were identical except that better resolution was achieved with the more powerful laser source. One of the two spectrometers consisted of a Spex Model 1400 double monochromator with a Spectra Physics Model 125 He–Ne laser operated at ~70 mW, an ITT (FW-130) phototube, and direct current amplification. The other instrument contained a Jarrell–Ash Model 25–100 double monochromator with a Coherent Radiation Laboratory Model 52–A argon ion laser operated at 100–800 mW, an ITT (FW-130) phototube, and photon counting detection system. Both instruments were calibrated using Ne and Kr discharge lamps and the frequency accuracy is estimated at ± 0.5 cm^{-1} for sharp peaks. The Pyrex cells for Raman studies, 8 mm in diameter, were either fixed at the base of a commercial Andonian cryostat and cooled by a flow of helium gas, or directly dipped into liquid helium in an all-glass cryostat. In this latter technique, appreciable scattering of the laser beam occurred from frozen particles of N_2, O_2, and CO_2 which gathered around the sample cell at the bottom part of the cryostat. Since very little change was observed in the spectra when the temperature was lowered from the solid I–solid II transition point to 4.2 °K, most experiments were performed with the Andonian cryostat, at a temperature of ~40 °K. The samples studied were usually quite transparent in the high-temperature phase but shattered upon cooling to phase II.

Results and Discussion

The SiH_4 molecule (of T_d symmetry) has four normal modes of vibration, of which all are Raman active but only the two F_2 vibrations are infrared active. Although it was relatively easy to obtain the $\nu_1(A_1)$, $\nu_2(E)$, and $\nu_3(F_2)$ bands in the Raman spectra of the liquid and solid, no band could be detected in the $\nu_4(F_2)$ region, even when very wide slits were used. This implies that the ν_4 band in the Raman spectrum of silane is at least 500 times weaker than the ν_1 band. Similarly, the ν_2 band was not found in the i.r. spectrum, even with samples 50 times thicker than those used for the study of the gas-phase allowed fundamentals. As for ν_1, it was impossible to check for its i.r. activity in the liquid and solid I, since its frequency is almost identical to that of ν_3 which gives a very strong absorption band. This makes the assignment of the observed bands in the ν_1–ν_3 region particularly difficult in SiH_4 in phase II.

A. Infrared and Raman Spectra of Liquid and Solid I Silane

The i.r. and Raman spectra of liquid and solid I SiH_4 are reproduced in Fig. 1 and measured frequencies and bandwidths are listed in Table 1. Polarization studies of the ν_3–ν_1 bands in the liquid show that the observed band cannot be entirely extinguished, the ~10% residual intensity indicating frequency overlapping and possible partial mixing of the two modes.

The vibrational spectra of solid SiH_4 in phase I are quite similar to those of the liquid, except for a slight narrowing of the bands in the solid. The frequency shifts from the liquid to phase I are also very small (less than 2 cm^{-1}), as can be seen in Table 1. The large bandwidths indicate that the molecules are being subjected to a great variety of fields in these two phases. It is likely that molecular rotation is only partially hindered, even in phase I, and that orientational disorder therefore prevails in the solid. A similar situation was encountered in CH_4, CD_4, and CF_4 in their high-temperature solid phase (5, 7, 18). An identical conclusion can be deduced from the vibrational spectra of SiD_4 in a solution of 1.8% SiD_4 in SiH_4 (see Fig. 2 and Table 2). The ν_4 region of that spectrum was not investigated although it is obvious that it should show some spectral activity. However, it would not yield additional information. The far-infrared spectrum of liquid SiH_4 and that of the solid in phase I (Fig. 3) also point to the plasticity of the high-temperature solid phase of this compound.

B. Spectra of SiD_4–SiH_4 Isotopic Solutions in Phase II

The vibrational frequencies of SiD_4 being sufficiently different from those of SiH_4, the vibrational modes of this molecule should be largely uncoupled from those of the SiH_4 host molecules in an isotopic solution. The i.r. spectrum of a 1% solution, and the Raman spectrum

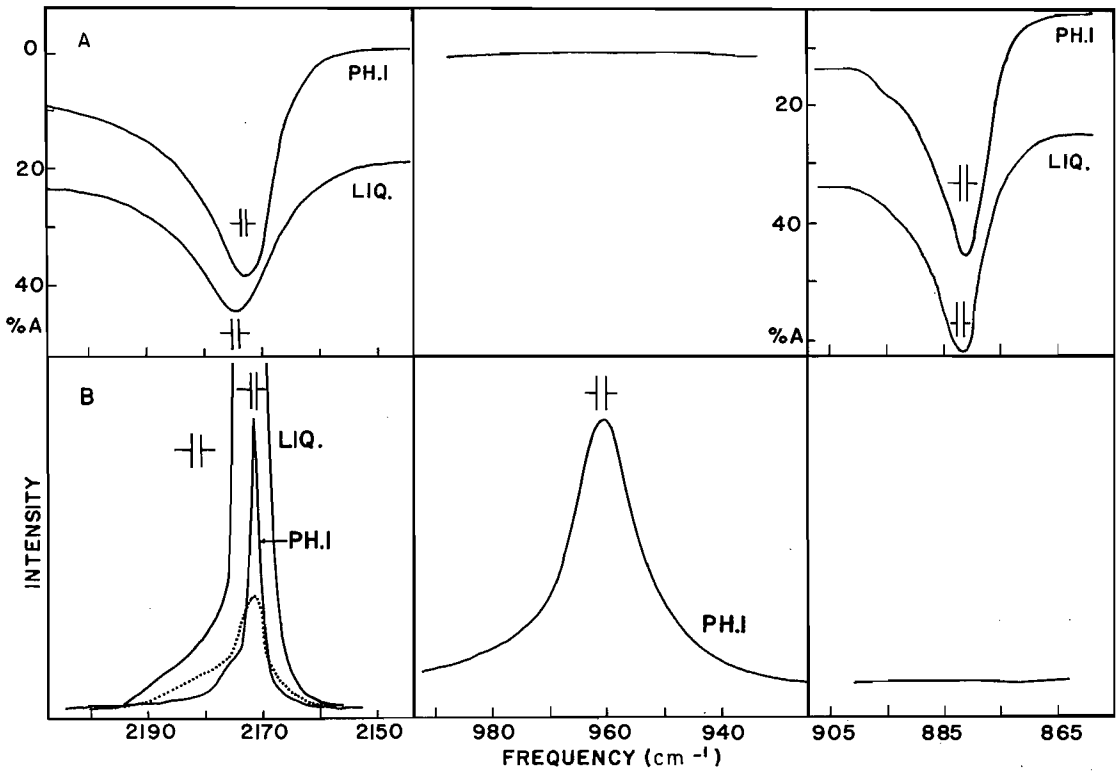

FIG. 1. (*A*) Infrared spectra of a ~1 micron thick sample of (*a*) liquid (98 °K) and (*b*) solid in phase I (77 °K) SiH_4. (*B*) Corresponding Raman spectra, with laser beam polarized perpendicular (—) and parallel (...) to spectrometer axis.

of a 1.8% solution of SiD_4 in SiH_4 in phase II are reproduced in Fig. 4. Vibrational frequencies and bandwidths are given in Table 2. Only the two gas-phase F_2 modes were detected in each case. McKean and Chalmers (13) have reported an intense ν_1 absorption band for GeH_4 and SnH_4 isolated in a SiH_4 matrix in phase II, whereas in the present study the ν_1 band of SiD_4 was not observed. The different sizes of guest and host molecules used in the previous investigation, and possibly crystal imperfections resulting from rapid deposition of the gaseous mixtures, are probably responsible for this discrepancy. The splitting into three components of the ν_4 band of SiD_4 in solution in SiH_4 in phase II has already been reported by Shrinivasan and Wilde (14).

The Raman spectrum is particularly informative in this case since all the fundamentals are active, yielding one, two, and three components for the gas phase A_1, E, and F_2 vibrations, respectively (the weak Raman bands between ν_1 and ν_3 (Fig. 4) of SiD_4 arise from impurities of partially deuterated silane). The site splitting of the degenerate vibrations of SiD_4 in solution in SiH_4

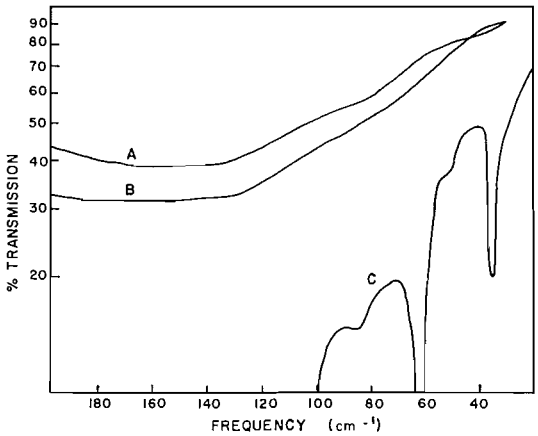

FIG. 3. Far-infrared spectra of a 2 mm thick sample of SiH_4;(*A*) liquid at 98 °K, (*B*) solid in phase I at 77 °K, and (*C*) solid in phase II at ~15 °K.

in phase II proves the absence of threefold or higher symmetry axis at the site in this solid. Acceptable site symmetries are then limited to the following: D_2, C_{2v}, C_2, C_s and C_1. In addition, the observation of a singlet for the A_1 mode proves that only one set of equivalent sites is occupied in the crystal.

The apparent i.r. inactivity of the ν_1 vibration of SiD_4 in SiH_4 in phase II suggests a D_2 site symmetry since, among the groups cited above, this is the only one in which a totally symmetric vibration would be infrared inactive. However, as will be shown below, a site of D_2 symmetry fails to account for the multiplicity of bands in the spectra of the pure solid and has to be rejected. We therefore surmise that the ν_1 vibration of SiD_4 in SiH_4 in phase II should be weakly i.r. active, and has not been observed because of its very low intensity.

C. Spectra of Pure SiH_4 in its Solid Phase II

The i.r. spectrum of pure SiH_4 in its low-temperature modification is reproduced in Fig. 5 and measured frequencies are listed in Table 1.

The ν_3 and ν_4 bands reproduced here were

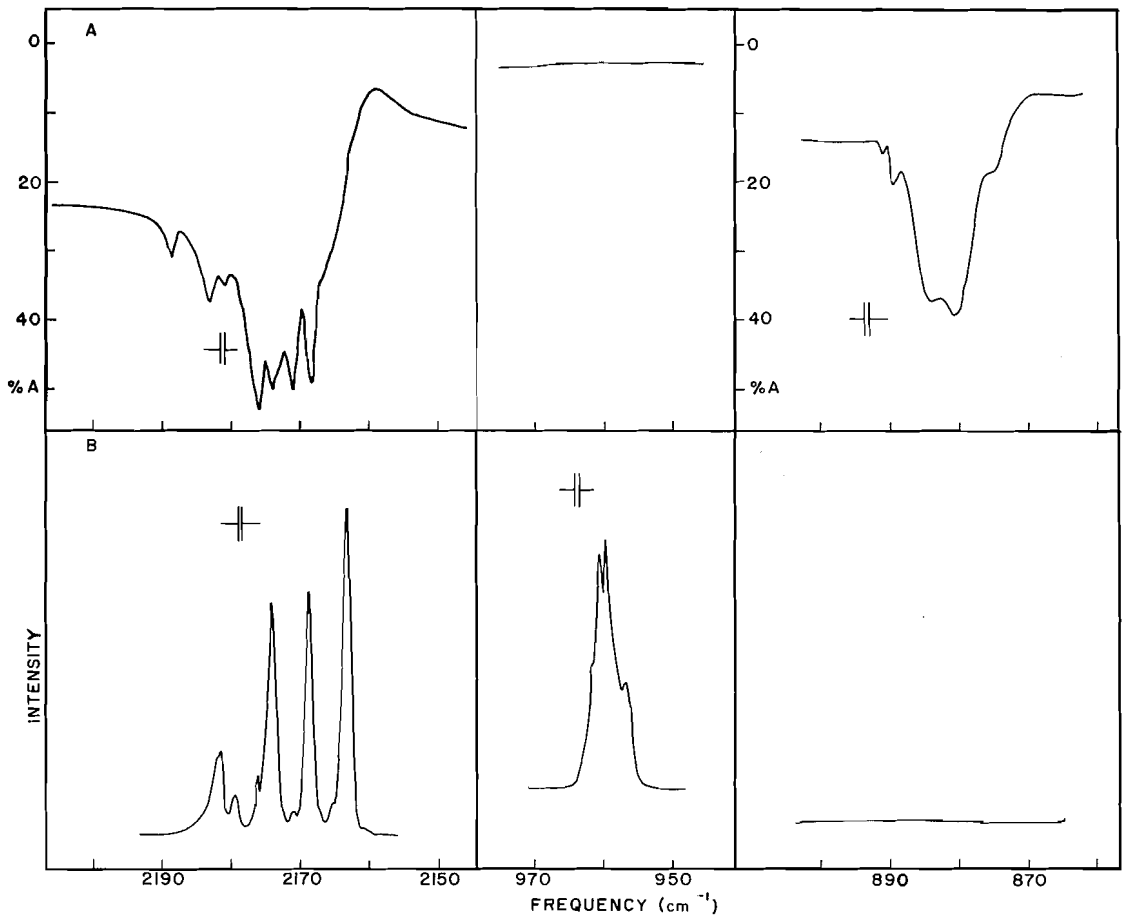

FIG. 5. (*A*) Infrared spectrum of a 1 micron thick sample of pure SiH_4 in phase II at ~10 °K. (*B*) Raman spectrum at ~40 °K.

obtained with different samples, such that their relative intensity is not meaningful. When the same sample thickness was used in both regions, these two bands had almost equal intensities. Seven resolved components and two shoulders on the low frequency side of the main features are seen in the ν_3 region, whereas a complicated structure is also observed in the ν_4 region. As in the liquid or in the solid in phase I, ν_2 could not be detected, even with very thick films.

The far-infrared spectrum of solid SiH_4 in its phase II at ~15 °K is reproduced in Fig. 3. Two sharp peaks are observed at 35 and 61 cm^{-1}, together with two much weaker bands at 53 and 85 cm^{-1}. The strong absorption at higher frequencies is believed to be caused by reflection of the incident beam by crystal defects in the very thick samples used. The far-infrared spectrum of solid SiH_4 is of little help in elucidating the crystal structure of the low-temperature modification of this compound. The narrowness of the observed peaks, together with their location close to the Debye frequency, 69 cm^{-1} (10, 19), suggest that they arise from translational modes. The librational modes are probably located at higher frequencies and were not observed in this study. A similar situation was encountered in CH_4 in its solid phase II (7).

The Raman spectrum of SiH_4 in phase II at ~40 °K is shown in Fig. 5 and measured frequencies are collected in Table 1. At least seven bands are resolved in the ν_3–ν_1 region and four components are present in the ν_2 region. Although it is impossible to assign all the lines

individually in both type of spectra, the multiplicity of components for the observed fundamentals indicates that there are at least two molecules per primitive cell in this solid.

D. Silicon Isotope Effects

Natural silicon contains 92.28% of ^{28}Si, 4.67% of ^{29}Si, and 3.05% of ^{30}Si. The ν_3 gas vibrational frequencies of the three corresponding silane molecules are 2189.16, 2187.63, and 2186.19 cm^{-1}, respectively (11). Isotopic shifts are expected to be smaller for ν_4 and almost negligible for ν_1 and ν_2 in the condensed states. Observed bands of SiD_4 in SiH_4 cannot be explained by an isotopic effect since their relative intensities are not appropriate and their spacings are not as expected. Thus, it is believed that the main bands are due to the most abundant isotopic variety, the other species mainly contributing to bandwidths. However, some weak features or shoulders, particularly in the ν_3–ν_1 region of the spectra of the pure solid, could result from the presence of the less abundant varieties.

E. Crystal Structure of SiH_4 on Phase II

Possible site symmetries for SiH_4 in phase II (D_2, C_{2v}, C_2, C_s, and C_1) have been deduced above from the i.r. and Raman spectra of mixed isotopic crystals. The multiplicity of bands in the i.r. and Raman spectra of the pure crystal may now be used to search for acceptable factor groups. This can be accomplished by selecting, amongst the super-groups of these site groups, those compatible with the number of components observed in the spectra of the pure crystal. This somewhat tedious process is straightforwardly carried out using standard group theoretical procedures (2, 3). Basic assumptions are that only one set of equivalent sites is occupied (the opposite would be exceptional in a molecular crystal), and that all the observed components are due to the site and coupling effects only.

Among the groups cited above, the D_2 site group can readily be discarded since, for any appropriate factor group, ν_1 should be infrared inactive and ν_3 is predicted to give three components whereas seven resolved peaks (and two shoulders) are observed in the ν_3–ν_1 region of the infrared spectrum (Fig. 5). The C_{2v} site group can also be rejected since it predicts a maximum of four infrared-active components in the ν_3–ν_1 region, and a maximum of three in the ν_4 region (five are observed). As for the C_2 and C_s sites, for which a maximum of 6 and 7 infrared-active components are respectively predicted in the ν_3–ν_1 region, they can be tentatively eliminated, in as much as the weak band at 2181.2 cm^{-1} and the shoulders at 2167 and 2162 cm^{-1} in the i.r. spectrum are assumed to be genuine components of the ν_1 and ν_3 fundamentals. Finally, if the site symmetry is C_1, a maximum of 3 and 9 infrared components is predicted for ν_1 and ν_3, respectively, which could certainly account for the multiplicity of bands in the ν_3–ν_1 region of the infrared spectrum. It is therefore likely that the molecules occupy general positions of the unit cell in SiH_4 in phase II. Speculating further, it is possible that the three intense peaks in the ν_3–ν_1 region of the Raman spectrum are all due to ν_1, since this mode is expected to be appreciably more intense than ν_3. If this is the case, acceptable crystals systems are then limited to tetragonal (factor groups: S_4, C_4, C_{4h}), trigonal (factor groups: C_{3v}, D_3, D_{3d}) or hexagonal (factor groups: C_{3h}, C_6, C_{6h}). Further elimination would be possible by determining whether or not the crystal is piezoelectric.

The frequency coincidence of many of the i.r. and Raman bands in the ν_3–ν_1 region suggests a non-centrosymmetric crystal structure. However, in such a case a longitudinal component, or a shoulder extending to the longitudinal frequency, should have been observed on the high-frequency side of ν_3 in the Raman spectrum. Using the relation of Haas and Hornig (20), the known value of $\partial\mu/\partial Q$ for ν_3 in gaseous SiH_4 (21), the crystal density (22), and an assumed index of refraction of 1.3, it is found that the longitudinal frequency associated to ν_3 should be about 17 cm^{-1} above that of the transverse mode. No feature unambiguously attributable to a longitudinal mode is found in our Raman spectrum, but this cannot be taken as a proof that the crystal is centrosymmetric.

Electron Spin Resonance of γ-Irradiated Taurine

G. LIND AND R. KEWLEY[1]

Department of Chemistry, Queen's University, Kingston, Ontario

Received July 19, 1971

The 9.5 GHz electron spin resonance (e.s.r.) spectra of single crystal and powder samples of γ-irradiated taurine, $H_3\overset{+}{N}CH_2CH_2SO_3^-$, have been recorded. Overlapping spectra from three distinct radicals are present. The first of these is the species SO_3^- with an isotropic *g*-value of 2.0035 and a ^{33}S hyperfine coupling tensor with principal values 135.2, 99.2, and 97.9 G. The second radical is a π-electron species with the unpaired electron mainly on carbon and exhibiting hyperfine interaction from at least four protons, probably $H_3\overset{+}{N}CH_2CH_2$ or $H_3\overset{+}{N}CH_2CHSO_3^-$, and with principal *g*-values 2.0021, 2.0027, and 2.0034. The third radical has principal *g*-values 2.0024, 2.0056, and 2.0097 and principal values of the ^{33}S hyperfine tensor of 49.6, 9.1, and 1.2 G. The proposed structure for this radical is $H_3\overset{+}{N}CH_2CH_2SO_2$.

Les spectres de résonance paramagnétique électronique (r.p.e.) à 9.5 GHz de l'état cristallin et de poudre de la taurine $H_3\overset{+}{N}CH_2CH_2SO_3^-$ irradiée aux rayons-γ sont rapportés. On observe un recouvrement de spectres de trois radicaux distincts. Le premier est l'espèce SO_3^- avec une valeur de *g* isotropique de 2.0035 et des tenseurs hyperfins du ^{33}S de 135.2, 99.2 et 97.9 G. Le second radical est une espèce à électron π ayant l'électron non pairé principalement sur le carbone et les interactions hyperfines pour au moins quatre protons, probablement $H_3\overset{+}{N}CH_2CH_2$ ou $H_3\overset{+}{N}CH_2CHSO_3^-$, ont des valeurs de *g* de 2.0021, 2.0027 et 2.0034. Le troisième radical a des valeurs de *g* de 2.0024, 2.0056 et 2.0097 et les tenseurs hyperfins du ^{33}S sont de 49.6, 9.1 et 1.2 G. La structure proposée pour ce radical est $H_3\overset{+}{N}CH_2CH_2SO_2$.

Canadian Journal of Chemistry, **50**, 43 (1972)

Introduction

In the past detailed electron spin resonance (e.s.r.) studies have been made of a number of radicals produced by irradiation of amino-acids and amino-acid derivatives (1–4). As is well known the most common product is the type of radical formed by loss of a hydrogen atom from a carbon atom adjacent to a carboxyl group. In a few cases detachment of an NH_2 group may occur and in sulfur-containing amino-acids a C—S or S—S bond may break; for example, when the radical $HOOCCH(NH_3^+Cl^-)CH_2S$ is formed during the γ-irradiation of L-cystine hydrochloride (5). Except for a qualitative study in which the e.s.r. spectrum of a single crystal was reported but no *g*-values given (6), no work appears to have been done on the naturally occurring amino-acid taurine, $H_2NCH_2CH_2SO_3H$. It was therefore considered worthwhile to carry out a careful study of the e.s.r. spectrum of this substance with a view to discovering how this amino-acid is broken down by γ-irradiation.

[1]On sabbatical leave until August 31, 1972 at Department of Chemistry, Rice University, Houston, Texas 77001.

Experimental

Commercial taurine from the Nutritional Biochemicals Corporation was used without further purification. Single crystals were grown easily by slow evaporation from aqueous solution. Such crystals were reported to be monoclinic with space group $P2_1/c$ and having the greatest length along the *a*-axis (7). For the $P2_1/c$ space group there should be two magnetically distinct sites for each molecule in the crystal. This is seen to be the case when the e.s.r. spectra are well resolved. From the angular dependence of the spectra on magnetic field direction and by examining the shape of the crystal there was no difficulty in identifying the axes of the crystal used.

The crystal had a tabular appearance with the *a*-axis lying along the largest dimension as expected. The *b*-axis is perpendicular to the largest face and to the *a*-direction. The *c'*-axis was chosen to be in the largest face at 4° 12′ to the crystal *c*-axis and perpendicular to *a* and *b* in a right-handed cartesian system, see Fig. 1. The magnetic field was rotated around the *a*, *b*, and *c'* axes as well as around the two axes in the *ac'* plane at 45 and 135° from *c'* towards *a*, $\beta = 45$ and 135° in Fig. 1.

The single crystal and also a powder sample were irradiated for periods from 5 min to 3 h at a γ-ray dosage of 5.7×10^{17} eV/g min in a ^{60}Co Gammacell (A.E.C.L.) at room temperature. No change in the character of the e.s.r. spectrum, other than an increase in intensity, was noticed in this time range. Neither the unirradiated powder nor the unirradiated single crystal gave an e.s.r. signal. Further details of the experimental procedure have been given earlier (8).

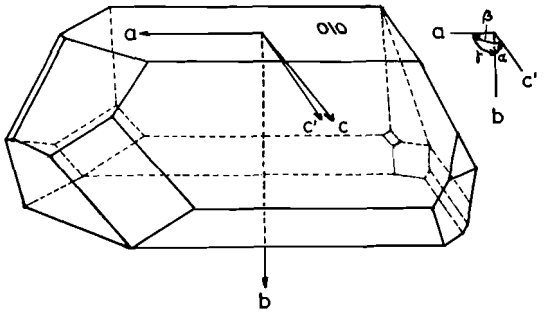

FIG. 1. The form of the taurine single crystal and the choice of reference axes. The c'-axis is at 90° to the a-axis and at 4° 17′ from the c-axis.

Results and Discussion

(1) Single Crystal

The e.s.r. spectrum of a single crystal of γ-irradiated taurine shows the presence of four different radical species, see Fig. 2.

(*A*) The e.s.r. spectrum of the first radical (radical A) is a single line of width 2 G. This line is masked over a wide range of orientations by the more intense spectrum of radical C. described below, but seems to have an almost isotropic **g**-tensor with $g = 2.0035$. There is an unidentified bump on the high field side of the line at a distance of about 5 G and with intensity about 1/7 of the line itself. There is no way of finding out if there is a corresponding bump on the low field side as there is no orientation where such a line would be far enough separated from the radical C spectrum.

The single line is thought to be the e.s.r. spectrum of the species SO_3^-. This radical could be produced with the scission of only one covalent bond provided that taurine consists of the "zwitterion" form, $H_3\overset{+}{N}CH_2CH_2SO_3^-$. Two bonds would have to break for SO_3^- to be formed from the molecular form of taurine, $H_2NCH_2CH_2SO_3H$. Thus it is considered that the "zwitterion" structure is the more accurate representation for the solid. This question was left undecided by the X-ray work (7). There are several earlier reports describing e.s.r. spectra following irradiation of molecules containing one or more $-SO_3^-$ groups and in which the radical SO_3^- was identified, with an isotropic **g**-tensor having $g = 2.004$ (9–11). In the present study at high gain and modulation amplitude the four weak isotopic lines due to $^{33}SO_3^-$ in 0.76% natural abundance were observed. The same downfield shift of the ^{33}S hyperfine pattern relative to the single line of the ^{32}S spectrum was found as that reported by Chantry *et al.* (10). This effect is expected if second order terms are retained in the derivation of the line positions from the spin Hamiltonian (12). For a typical spectrum, for example at the orientation $H_0 \| a (\gamma = 0°)$, the downfield shift was 2.6 G for the outer ^{33}S lines ($M_I = \pm 3/2$) and 6.1 G for the inner lines ($M_I = \pm 1/2$). The unidentified bump seen close to the single ^{32}S line seems to manifest itself in the ^{33}S pattern as a peak on the high field side of the high field line ($M_I = -3/2$) at most orientations. There is also a similar peak on the low field side of the low field line ($M_I = +3/2$) but no such peaks associated with the inner lines ($M_I = \pm 1/2$). At present the significance of these bumps is not understood.

The principal values of the $^{33}SO_3^-$ **A**-tensor are given in Table 1 and agree very well with those reported by Chantry *et al.* (10). The tensor shows cylindrical symmetry and all three elements must have the same sign, otherwise the atomic ^{33}S anisotopic coupling ($2B$) of 56 G would be exceeded. The spin densities at sulfur calculated from the principal **A**-tensor elements are $\rho_S^s = 0.11$ and $\rho_S^p = 0.43$.

Chantry *et al.* (10) calculated the angle between the direction corresponding to the largest **A**-tensor element of SO_3^- and the two distinguishable C—S bonds in the host crystal of $K_2CH_2(SO_3)_2$ and obtained the values 7 and 53°. They considered it unlikely that the SO_3^- fragment would be grossly displaced from its position prior to irradiation and therefore selected the angle 7° as the one through which the SO_3^- axis moves on irradiation. However, in the present case the angle between the direction for the largest **A**-tensor element (135.2 G) and the C—S bond in unirradiated taurine is 56 and 85° for the two different magnetic sites. This indicates a surprisingly large change in orientation for the SO_3^- species, which may be due to hydrogen bonding forces in taurine which would not be important in $K_2CH_2(SO_3)_2$.

(*B*) The second radical (radical B) has a spectrum of many lines which is typical of a π-electron species with the unpaired electron located primarily at a carbon atom but able to undergo hyperfine interactions with nearby protons. This spectrum is about 1/10 of the intensity of that of radical A. In this radical there

$H_3\overset{+}{N}CH_2CH_2{}^{33}SO_2$	$A_1 = 49.6\ (1.5)$ G	$(0.593 \mp 0.454 \quad 0.666)$
	$A_2 = 9.1\ (1.5)$ G	$(0.577 \pm 0.815 \quad 0.042)$
	$A_3 = 1.2\ (1.5)$ G	$(0.562 \mp 0.360 \quad -0.745)$

are at least four protons interacting with the unpaired electron. These protons may be attached to both nitrogen and carbon, although no ^{14}N hyperfine splitting was noticed. An unambiguous identification of this radical has not been possible but it is thought to be either the $H_3\overset{+}{N}CH_2CH_2$ residue, from the loss of SO_3^-, or $H_3\overset{+}{N}CH_2CHSO_3^-$. At all orientations the middle part of this spectrum was completely overlapped by the spectra of radicals A and C so only the wings of spectrum B could be studied. Attempts to remove the spectra of radicals A and C by heating were not successful. Although the elements of the several proton **A**-tensors could not be determined the principal *g*-values (Table 1) are those of a typical carbon-centered π-radical. It should be noted that the proximity of the sulfur in an $-SO_3^-$ group, attached to the carbon in question would not be expected to be reflected in the **g**-tensor values since in the radical $CH(SO_3^-)_2$ the principal values are 2.0033, 2.0025, and 2.0019 (9).

The angle between the direction corresponding to the **g**-tensor element 2.0021 (Table 1, radical B), which should be that for the axis of the carbon 2p orbital, and the direction of the C—C bonds in the undamaged taurine crystal is calculated to be 79°, which confirms the π-electron nature of radical B. There appears to be only one magnetically distinct site as regards the **g**-tensor of this radical, within the limits of experimental error.

(*C*) The spectrum of radical C is a single line of width 3.5 G when the magnetic field is in the *ab* or *ac'* plane. There is also on each side of this line a bump at a distance of about 6 G and of about 1/20 of the intensity. These bumps appear to follow the movement of the main line with change of orientation of the crystal. These extra peaks have not yet been explained. The **g**-tensor of radical C is noticeably anisotropic (Table 1), which results in the appearance of two lines, from the two magnetically inequivalent sites, at most orientations in the *bc'* plane. The principal **g**-tensor elements indicate that the radical is one in which the unpaired electron is at least partially on a sulfur atom.

At high gain and modulation amplitude further lines were seen which can be assigned to the ^{33}S isotopic form of the radical. Only the two outer lines of the hyperfine pattern could be observed for each magnetic site. The **A**-tensor is anisotropic (Table 1) and the direction of the largest principal value (49.6 G) coincides well with the direction of the smallest principal value 2.0024 of the **g**-tensor which would be the direction of the p-orbital containing the odd electron for a radical of the π-electron type.

For several reasons it was thought initially that radical C might be the species SO_2^-. The observed principal *g*-values (Table 1) are close to 2.0018, 2.0103, and 2.0055 observed by Atkins *et al.* for SO_2^- in irradiated potassium metabisulfite, $K_2S_2O_5$, (13). The a_{iso} for the radical C of 20.0 G, assuming all three ^{33}S **A**-tensor elements to be of like sign, and the a_{iso} for SO_2^- of 14.2 G (13) are also quite similar. Also no

resolved proton hyperfine splitting was found at any orientation in the spectrum of radical C. On the other hand the similarity in the g-values is by no means conclusive evidence since the $S_2O_2^-$ observed in X-irradiated $Na_2S_2O_3 \cdot 5H_2O$ by Morton (14) also has g-values similar to those of SO_2^-, 2.0083, 2.0050, and 2.0030. Furthermore in e.s.r. studies of irradiated solids it is unusual to find a radical formed by breakage of two covalent bonds, which would be required if the C—S and S---O bonds break as SO_2^- is formed from $H_3\overset{+}{N}CH_2CH_2SO_3^-$. There are, however, a number of instances in which an oxy-radical is produced by loss of an O^- from an oxy-ion. The formation of $S_2O_2^-$ from $S_2O_3^{2-}$ cited above is one example. Others occur in the formation of SeO_3^- from SeO_4^{2-} (15) and the formation of AsO_3^{2-} from AsO_4^{3-} (16). So although SO_2^- cannot be ruled out we consider an alternative possibility to be more likely. This is the radical $H_3\overset{+}{N}CH_2CH_2SO_2$.

Radicals of the type RSO_2 have been observed previously in γ-irradiated sulfones and polysulfones and in γ-irradiated hydrocarbon polymers on exposure to SO_2 gas (17–19). The typical RSO_2 e.s.r. spectrum for a powder was reported to be a peak of width 3–5 G showing no resolved proton hyperfine structure (19), indicating that the odd electron is located mainly on sulfur. This spectrum is similar in appearance to that of radical C in both taurine single crystal and powder. The g-values for RSO_2 type radicals were estimated as $g_\perp = 2.002$ and $g_\parallel = 2.005$ from the spectra in amorphous matrices (19), which are somewhat lower than the principal g-values of radical C. For both $H_3\overset{+}{N}CH_2CH_2SO_2$ and RSO_2 type radicals the electronic environment at sulfur should not be markedly different from that in the SO_2^- radical, the lone pair of electrons on sulfur in SO_2^- being replaced by the C—S bonding pair in $H_3\overset{+}{N}CH_2CH_2SO_2$ and RSO_2.

The calculated spin densities at sulfur in $H_3\overset{+}{N}CH_2CH_2SO_2$, assuming all three principal **A**-tensor elements to be of the same sign, are $\rho_S^s \simeq 0.02$ and $\rho_S^p \simeq 0.54$, showing that the radical is of the π-electron type with the unpaired electron concentrated mainly in a sulfur 3p-orbital. This is supported by the calculation of the angle between the principal **g**-value 2.0024, $A_1 = 49.6$ G, direction and that of the C—S bond in the undamaged structure. The result obtained is 86.5°, using the atom parameters of Sutherland and Young (7).

The lack of any proton hyperfine splitting in the spectrum of $H_3\overset{+}{N}CH_2CH_2SO_2$ requires some explanation. The accepted formula for the isotropic splitting of β-protons when an unpaired electron is located at an α-carbon atom is (20)

$$a_H = B_0 + B_2 \cos^2 \theta$$

where θ is the angle between the plane defined by $C_\alpha C_\beta H_\beta$ and the symmetry axis of the C_α 2p-orbital and $B_2 \gg B_0$ with $0 < B_0 < 3.5$ G (21). The calculated angles θ between the $g = 2.0024$ principal direction and the S—C—H_1 and S—C—H_2 planes, where the designations H_1 and H_2 are taken from the X-ray study (7), are respectively 19.5 and 39.5°. Using the simplified formula

$$a_H = A_0 \cos^2 \theta$$

with $A_0 \simeq 9$ G as given by Kurita and Gordy (5) for the isotropic β-proton splitting when the unpaired electron is located at an α-sulfur atom, we arrive at the values $a_{H_1} = 8.0$ G and $a_{H_2} = 5.3$ G. However the observed spin density at sulfur in $H_3\overset{+}{N}CH_2CH_2SO_2$ is only about 50% so it may well be that the β-proton splittings are of the same magnitude as the line width and were therefore not detached.

(*D*) In addition to the spectra of the radicals discussed in *A*, *B*, and *C* above there is an unexplained feature (*D*) consisting of an orientation dependent, broad line of width 8 G, see Fig. 2.

(2) Powder

The e.s.r. spectrum of γ-irradiated taurine powder fully confirms the results of the single crystal study, see Fig. 3. The observed pattern is an overlapping of the single g-value powder spectrum of SO_3^- with the three g-value powder spectrum of $H_3\overset{+}{N}CH_2CH_2SO_2$. These g-values are shown in Table 2 and agree very closely with the corresponding ones in Table 1. The spectrum of the π-electron species radical B, $H_3\overset{+}{N}CH_2CH_2$ or $H_3\overset{+}{N}CH_2CHSO_3^-$, is much less intense and lies beneath the other two overlapping patterns. At higher gain and modulation amplitude the

^{33}S lines in natural abundance for both SO_3^- and $H_3\overset{+}{N}CH_2CH_2SO_2$ were observed, see Fig. 4, yielding the additional confirmatory data of Table 2.

The Pyrolysis of Tetramethyltin

R. P. JOHNSON AND S. J. W. PRICE
Chemistry Department, University of Windsor, Windsor 11, Ontario
Received July 29, 1971

The pyrolysis of tetramethyltin has been studied in a toluene carrier flow system from 803–941 °K using total pressures of 10.6 to 52.4 mm. Contact times varied from 0.49 to 13.8 s and the amount of decomposition from 1.35–98.7%. The progress of the reaction was followed by measuring the amount of methane, ethane, ethylene, and ethylbenzene formed. No appreciable heterogeneous reaction was detected and the first order rates constants appear to have been determined at the high pressure limit. The quantity of undecomposed alkyl was also measured and was found to be in agreement with the product analysis if four methyl radicals are released for each molecule undergoing reaction.

Least squares analysis gives

$$\log_{10} k/\mathrm{s} = 15.7 - (64\,500/2.3\,RT)$$

with an estimated uncertainty in E of ± 1 kcal mol^{-1}. The activation energy should be a good approximation to $D[(CH_3)_3Sn—CH_3]$.

La pyrolyse du tétraméthyl étain a été étudiée dans un système à courant porteur de toluène entre 803 et 941 °K et en utilisant des pressions totales de 10.6 à 52.4 mm. Les temps de contact varient entre 0.49 et 13.8 s et le degré de décomposition de 1.35 à 98.7%. L'avancement de la réaction est suivie en mesurant la quantité formée de méthane, d'éthane d'éthylène et d'éthylbenzène. Aucune réaction hétérogène appréciable n'a été détectée et les constantes de vitesse du premier ordre semblent avoir été déterminées à la limite des hautes pressions. La quantité d'alkyle non décomposée est également mesurée et est en accord avec l'analyse du produit si quatre radicaux méthyles sont libérés pour chaque molécule subissant la réaction.

L'analyse par la méthode des moindres carrés donne:

$$\log_{10} k/\mathrm{s} = 15.7 - (64\,500/2.3\,RT)$$

l'incertitude estimée sur E étant de ± 1 kcal mol^{-1}. L'énergie d'activation devrait être une bonne approximation à $D[(CH_3)_3Sn—CH_3]$.

Canadian Journal of Chemistry, **50**, 50 (1972)

Introduction

Two previous investigations of the pyrolysis of tetramethyltin have been reported. The first investigation (1) showed approximately first order kinetics and gave $k = 8.3 \times 10^{21}$ exp $(-82\,400/RT)$ s^{-1}. A later investigation reported the overall decomposition was 3/2 order and gave an activation energy of 75.9 kcal mol^{-1} (2). The suggested mechanism explained the observed order but leads to the conclusion

[1] $$Sn(CH_3)_4 \rightarrow Sn(CH_3)_3 + CH_3$$

that $E_1 = 121$ kcal mol^{-1}. Neither investigation is satisfactory.

A related alkyl, dimethyltindichloride, has been studied in a toluene carrier system similar to that used in the present investigation (3). The decomposition was first order and homogeneous. For reaction 1*a* the Arrhenius equation obtained

[1*a*] $$(CH_3)_2SnCl_2 \rightarrow CH_3SnCl_2 + CH_3$$

was $k = 3.3 \times 10^{13} \exp(-56\,100/RT)$ s^{-1}. However, no allowance was made for the methyl radicals which combine with benzyl to form ethylbenzene. Based on our experience with other alkyls we would estimate that full analysis would have led to approximately $k = 2 \times 10^{14}$ exp $(-58\,000/RT)$ s^{-1}. This activation energy should be approximately equal to $D[CH_3Cl_2Sn—CH_3]$. Thermochemical results (4, 5) then lead to $D[Cl_2Sn—CH_3] = 32$ kcal mol^{-1}. The mean bond dissociation energy in tetramethyltin is 55 kcal mol^{-1} (4, 5) some 10 kcal stronger than the mean of the two Sn—C bonds in dimethyltindichloride. $D[(CH_3)_3Sn—CH_3]$ might be expected to be somewhat greater than $D[CH_3Cl_2Sn-CH_3]$ but not to the extent suggested by the two previous studies of this tetramethyl compound.

Experimental

Materials

(*a*) Toluene from sulfonic acid (Eastman Organic X325) was prepared for use by refluxing over sodium under vacuum and then degassing by bulb-to-bulb distillation.

*P runs in packed reaction vessel.
†Prerun, duration of alkyl flow, postrun.

(*b*) Tetramethyltin was purchased from Alfa Inorganics [No. SN-145]. The vapor pressure curve was checked against that of Bullard and Haussman (6) and found to correspond. Refractive index and specific gravity measurements also agreed with literature values (1).

Apparatus

The experiments were carried out using the same system previously used in studying the decomposition of dimethylmercury in a benzene carrier (7). The gaseous products were analyzed using a Perkin–Elmer 154 gas chromatograph equipped with a 1/4 in. × 6 ft silica gel column. The column was maintained at 80 °C and a helium flow rate of 20 cc/min was used. The liquid products condensed along with the toluene in an acetone – Dry Ice trap were analyzed using a Perkin–Elmer model 800 gas chromatograph equipped with a 150 ft × 0.02 in. inside diameter Golay Column coated with poly(propylene glycol) (isothermal operation at 60 °C, flow rate N_2 carrier 10 cc/min).

The contact times used in the toluene carrier flow system were selected to minimize both thermal equilibrium and diffusion errors (8, 9). The unpacked reaction vessel had a volume of 171 cc. The packed reaction vessel had a volume of 117 cc and a surface-to-volume ratio 17 times that of the unpacked vessel. Before use both vessels were treated with boiling concentrated nitric acid and vacuum baked without rinsing.

Results and Discussion

Selected[1] experimental results are given in Table 1. They may be discussed in terms of the following mechanism.

[1] $Sn(CH_3)_4 \rightarrow Sn(CH_3)_3 + CH_3$

[2] $Sn(CH_3)_3 \rightarrow Sn(CH_3)_2 + CH_3$

[3] $Sn(CH_3)_2 \rightarrow Sn(CH_3) + CH_3$

[4] $Sn(CH_3) \rightarrow Sn + CH_3$

[5] $CH_3 + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + CH_4$

[6] $2CH_3 \rightarrow C_2H_6$

[7] $CH_3 + C_6H_5CH_2 \rightarrow C_6H_5C_2H_5$

[8] $2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$

[9] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[10] $C_2H_5 \rightarrow C_2H_4 + H$

[11] $H + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H_2$

[12] $H + C_6H_5CH_3 \rightarrow C_6H_6 + CH_3$

It is apparent from the results that the bulk of the methyl radicals are removed by reactions 5 and 7. The small yields of ethylene seem somewhat higher than might be expected from reactions 9 and 10. This may be due to reaction 13.

[13] $C_6H_5C_2H_5 \rightarrow C_6H_6 + C_2H_4$

In a conditioned reaction vessel this reaction should be completely negligible under the conditions of temperature, pressure, and residence time used in the present work (10). However, as shown in reference 10 reaction 13 is extremely sensitive to the nature of the surface and may be catalyzed by the tin released in the present reaction.

TABLE 3. Effect of pressure on k_1

T (°K)	P (mm)	% decomposition		k_1 (s^{-1})
		Product analysis	Residual alkyl analysis	
866	52.4	79.6	76.1	0.214
866	40.6	93.7	94.8	0.201
866	23.9	89.5	—	0.221
867	14.9	34.6	38.0	0.211
867	10.6	25.3	25.3	0.210

In Tables 2, 3, and 4 a comparison is shown between the percent decomposition based on products analysis (assuming four CH_3 are released for each molecule undergoing reaction 1) and the percent decomposition calculated from the undecomposed alkyl. The basic agreement over a wide range of decomposition (approximately 13%–90%) indicates that each time reaction 1 occurs it is followed in rapid sequence by reactions 2, 3, and 4 or some equivalent processes. Rate constants have therefore been calculated from the usual first order equation

$$k = \frac{2.303}{t_c} \log \frac{1}{1-x}$$

where t_c is the average residence time in the reaction zone and the fraction decomposed, x, is given by

$$x = \frac{\text{moles } CH_4 + \text{moles ethylbenzene} + 2\,(\text{moles } C_2H_6 + C_2H_4)}{4\,(\text{moles } Sn(CH_3)_4 \text{ used})}$$

To the extent that reaction 12 occurs the value of x calculated in this way will be too high. However, even if reaction 13 is completely negligible the maximum contribution of reaction 12 is 0.3 × moles C_2H_4 (11). Any correction for reaction 12 is therefore negligible.

The results in Table 2 show the reaction follows first order kinetics. For a molecule as complex as $Sn(CH_3)_4$ no unimolecular pressure effects were expected at the temperatures and pressures used. The limited tests shown in Table 3 are in agreement with this expectation. Although most of the contact times used conform to the recommendations of Mulcahy and Pethard (9) a significant number of runs were done with $t_c/P < 0.5$. However, the results in Table 4 indicate that even at $t_c/P = 0.28$ no significant change in k_1 has occurred.

The Arrhenius plot for k_1 is shown in Fig. 1. It is clear that within the limits of the experimental method the extent of heterogeneous decomposition of the alkyl is undetectably small except for a very small contribution at the lowest temperatures used. The Arrhenius equation obtained by least squares analysis of the runs in the unpacked vessel is $k = 4.7 \times 10^{15} \exp(-64\,500 \pm 1\,000/RT)\ s^{-1}$. The activation energy should be a good approximation to

$D[(CH_3)_3Sn—CH_3]$. Thus $D_1 = 64.5 \pm 1$ kcal mol^{-1}. This value is in fair agreement with a value derived from a combination of mass spectral and thermochemical data (12) 66.5 kcal mol^{-1} (actually 67.5 as calculated by Lappert *et al.* (12) but this is based on $\Delta H_f^0(CH_3) =$ 34.8 kcal mol^{-1}). The kinetic energy of the fragments ion is expected to be no more than 0.05 eV but even this would lower D_1 to about 65.3 kcal mol^{-1}. It is difficult to estimate the probable error limits on this value but ± 2 kcal is probably a fair guess. The extent of agreement with the present results for D_1 is therefore well within the combined experimental error.

Although no further quantitative conclusions can be reached it is interesting to speculate on the relative magnitudes of D_1, D_2, D_3, and D_4 and how they relate to the proposed mechanism. From previous studies in our laboratory (3, 13–16) it seems reasonable to assign the following approximate values

$$A_2 = 10^{15}\ s^{-1}$$

$$A_3 = 10^{14}\ s^{-1}$$

Then in order to establish reaction 1 as rate controlling we arbitrarily set $5k_1 = k_2 = k_3 = k_4$. At approximately the middle of our temperature range, 850 °K, $k_1 = 0.126$. Therefore $k_2 = k_3 = k_4 = 0.630$ and $E_2 = 59$ kcal mol^{-1}. This should be close to D_2 at the temperature and pressures used. Similarly, $E_3 = 55$ kcal mol^{-1} but due to unimolecular pressure effects, D_3 is probably about 4 kcal greater than E_3. Thus D_3 is approximately 59 kcal mol^{-1}. Since $(D_1 + D_2 + D_3 + D_4) = 220$ kcal, $D_4 = 37.5$ or again estimating the effect of pressure on E_4, E_4 should be approximately 34 kcal mol^{-1}. This leads to $A_4 = 8.5$ s^{-1}. Because of the way the calculation has been done these values of E_4 and A_4 are probably a reasonable estimate of minimum values. Based on experience with methylindium A_4 might be as large as 10^{11} s^{-1} (15). This would set an approximate maximum value of $E_4 = 43.5$ kcal mol^{-1}. If E_3 is not changed then E_2 could now be as low as 49 kcal mol^{-1}. In relation to E_1 this would be more in line with the relative E_1 and E_2 values for dimethyltindichloride. Therefore values of $D_1:D_2:D_3:D_4 = 65:49:59:47$ kcal mol^{-1} would be consistent with the proposed mechanism and the experimental evidence that is available. However, the whole process used to reach this conclusion is extremely speculative and the results obtained are at best an indication that decomposition by simple consecutive release of methyl radicals is plausible.

We are indebted to Professor Lappert who supplied a prepublication copy of his paper "Bonding Studies of Compounds of Boron and the Group IV Elements, Part VI".

The Photodecomposition of an Analogue of DDT

H. J. Liu, P. J. Silk, and I. Unger

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received July 22, 1971

The photodecomposition of 1,1,1-trichloro-2,2-bis(5′-chloro-2′-methoxyphenyl)ethane (MPA) has been carried out both in solution and solid phase with exciting light > 300 nm. The major products of the solid phase photolyses are HCl and 1,1-dichloro-2,2-bis(5′-chloro-2′-methoxyphenyl)ethylene (MPE), 5,5′-chloro-2,2′-methoxybenzophenone (MPO), 1,1-dichloro-2,2-bis(5′-chloro-2′-methoxyphenyl)ethane (MPD), and 1-chloro-2,2-bis(5′-chloro-2′-methoxyphenyl)ethane (MPC). In liquid phase and in the presence of O_2 the photodecomposition yields many products, the major ones, in addition to HCl, being MPE, MPD, MPC, and MPO. In the absence of O_2 in liquid phase only HCl, MPD, MPC, and MPE were observed. In the O_2 free photolysis MPD and MPC are produced in larger quantity than MPE. A preliminary investigation has shown that MPE irradiated at $\lambda > 300$ nm also photodecomposes. A check carried out by the Canada Department of Agriculture indicates that MPA is a pesticide although it may not be as effective as DDT.

La photodécomposition du trichloro-1,1,1 bis(chloro-5′ méthoxy-2′ phényl)-2,2 éthane (MPA) a été menée à bien à la fois en solution et en phase solide, avec une lumière excitatrice >300 nm. Les produits principaux de la photolyse en phase solide sont HCl et le dichloro-1,1 bis(chloro-5′ méthoxy-2′ phényl)-2,2 éthylène (MPE), le chloro-5,5′ méthoxy-2,2′ benzophénone (MPO), le dichloro-1,1 bis(chloro-5′ méthoxy-2′ phényl)-2,2′ éthane (MPD), et le chloro-1 bis(chloro-5′ mèthoxy-2′ phényl)-2,2 éthane (MPC). En phase liquide et en présence d'O_2 la photodécomposition donne de nombreux produits; en plus de HCl, les produits majoritaires sont le MPE, MPD, MPC, et MPO. En l'absence d'O_2 et en phase liquide on observe uniquement la présence d'HCl, MPD, MPC, et MPE. Dans la photolyse en l'absence d'O_2, le MPD et le MPC sont formés en plus grande quantité que le MPE. Des recherches préliminaires ont montré que le MPE. Des recherches préliminaires ont montré que le MPE irradié à $\lambda > 300$ nm subit également une photodécomposition. Des recherches entreprises par le Département d'Agriculture du Canada montrent que le MPA est un pesticide bien qu'il ne soit pas aussi efficace que le DDT.

Canadian Journal of Chemistry, **50**, 55 (1972)

Introduction

The persistence of DDT, and related chlorinated pesticides, in the environment is due to two reasons: (*a*) they do not absorb appreciably in the solar spectrum, and (*b*) they resist degradation by microorganisms. A technique to overcome the former difficulty has been suggested by Miller and Narang (1), who showed that absorption by a variety of aromatic amines in the presence of DDT resulted in the decomposition of DDT, and postulated that the reaction occurred via a charge transfer from the amine to DDT. Since intramolecular energy transfer has been shown to occur in a variety of systems such as naphthalene–anthracene (2), naphthalene–benzophenone (3), and benzene–olefin (4–6) and since DDT may be thought of as consisting of three distinct moieties (the two chlorophenyl groups and the chlorinated ethane moiety), then an alternative procedure to that described by Miller and Narang would be to produce a bathochromic shift in DDT by a suitable modification in the chlorophenyl part of the molecule with the expectation that the resulting molecule may exhibit intramolecular sensitized decomposition. We report here the results of such a study.

Experimental

(1) Equipment and Materials

Infrared spectra were determined using a Perkin–Elmer grating Infra-Red Spectrophotometer, Model 457. Ultraviolet spectra were determined either on a Perkin–Elmer 402 UV-Visible Spectrophotometer, or an Hitachi EPS-3T Spectrophotometer. The n.m.r. spectra were recorded on a Varian T-60 NMR spectrometer; tetramethylsilane was used as an internal standard. Mass spectra were recorded using an Hitachi Perkin–Elmer RMU-6D Mass Spectrometer. Melting points were determined on a Kofler hot-stage apparatus and are uncorrected.

The photolyses were performed using a 1 KW Hanovia high-pressure xenon–mercury lamp contained in a Schoeffel housing, air-cooled to a temperature of 110 °C. Radiation from the lamp was filtered using two Corning 0-54(0160) filters, each being 2.1 mm thick and with an exact wavelength cut-off at 300 nm. Solution and solid phase photolyses were performed in cylindrical quartz cells (5 × 1 cm). The cells were always placed 20 cm from the focusing device of the lamp housing.

The v.p.c. was performed either on a Hewlett–Packard 7620A Chromatograph equipped with a flame ionization and a thermal conductivity detector, or a Varian Aerograph, Model 705 equipped with a flame ionization detector. Helium was used as a carrier gas throughout Columns for

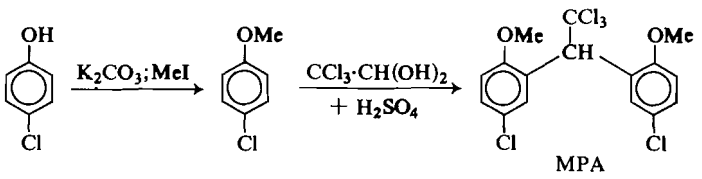

SCHEME 1

the HP were either 4 or 6 ft long constructed from 1/8 in. stainless-steel. Liquid phases used were DC-200 (12500-cnstk), OV-17, or QF-1, on Chromosorb Q (100/120 mesh) at 10% w/w loading. Column temperature was 210° with a helium flow-rate of ~60 ml/min. The column used for the Varian Aerograph was 10 ft × 1/4 in. stainless-steel packed with 5% w/w QF-1 on Chromosorb W (60/80 mesh). The injectors and detectors on both instruments were maintained at 230 and 260 °C, respectively. Sample introduction was by Hamilton Precision syringes, solid samples being injected as benzene solutions through self-sealing rubber septa. "On-column" injection was used throughout.

Cyclohexane used for solution photolyses and u.v. spectra was fluorometric grade obtained from Harleco and was used without further purification. A standard cyclohexane solution of MPA (4g/l) was used for all photolyses.

(2) Preparation of MPA

MPA was prepared by the overall reaction sequence shown in Scheme 1.

p-Chloroanisole was prepared in 98% yield by reacting *p*-chlorophenol with methyl iodide in the presence of potassium carbonate under an atmosphere of nitrogen. This was done at room temperature and the reaction mixture was stirred overnight. The mixture was then poured into water and the product was extracted with chloroform. The extract was dried with magnesium sulfate, filtered, and concentrated to yield *p*-chloroanisole.

The general method of preparing 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) was adapted (7) for the synthesis of MPA. Chloral hydrate crystals (23 g) and *p*-chloroanisole in a round-bottomed flask (1 l) were warmed in a water bath until all crystals were dissolved. The solution was cooled and concentrated sulfuric acid (270 ml) was slowly added. After stirring at room temperature for 3 h, the mixture was poured into cold water (1 l), filtered through a sintered-glass funnel and washed with water (3 × 500 ml). The solid was then stirred with 100 ml of 2% sodium carbonate solution and washed with distilled water followed by absolute ethanol (3 × 25 ml). The residue was dried in an oven at 70 °C. The MPA produced in this way was in 69% yield; crude m.p. 142–143 °C; ethanol recrystallized product m.p. 146–147 °C; i.r. ($CHCl_3$) 1600 cm^{-1} (benzene); n.m.r. ($CDCl_3$) τ 2.23 (d, 2 Hz, 2H, $=C-CH=C-$, Cl), 2.80 (d of d, 2 and 8 Hz, 2H, $-CH=CH-CCl=$), 3.24 (d, 8 Hz, 2H, $-CH=C(OCH_3-)$), 3.67 (s, 1H, $>CH-CCl_3$), and 6.17 (s, 6H, $-OCH_3$); mass spectrum: M^+ 412 (with peaks at 414, 416, 418, 420 in the ratio corresponding to five Cl atoms in the molecule (8)); u.v.: (C_6H_{12}) λ_{max} 289 nm. No impurities were detected, by v.p.c., in the recrystallized MPA.

(3) The Preparation of Photolysis Products for Comparison Purposes

(a) Synthesis of MPE

MPE was synthesized in 98% yield by the alkaline dehydrochlorination of MPA the method being adapted from a similar procedure (9). To a solution of MPA (4 g) in 95% ethanol (50 ml) was added 50 ml of a 5% sodium hydroxide solution. The mixture was then refluxed and stirred for 3 h. The mixture was then cooled and then alcohol mostly removed by placing the mixture under vacuum in a rotary evaporator. The product was then extracted with ether, washed with water (3 × 50 ml), and the ethereal solution dried over magnesium sulfate overnight. The solution was filtered and the ether removed from the extract on the rotary evaporator. The crude product was then recrystallized from hot absolute ethanol and dried in an air-oven at 70 °C; v.p.c., (6 ft DC-200, HP, at 200 °C, benzene) showed the material to have a purity of 98%. The spectral data for MPE and MPD are given in the Results section of this paper.

(b) Synthesis of MPD

Two general methods were adopted:

(*i*) MPD was produced in >90% yield by the photolysis of pure MPA in cyclohexane in the absence of $O_2(N_2)$ at λ > 300 nm (see Table 1). The cyclohexane was then evaporated from the solution and the product recrystallized in absolute ethanol.

(*ii*) MPD was also produced in ~10% yield from a Clemmensen reduction (7) of MPA along with three other products, MPC, $R_2-CH-CH_3$ (n.m.r.), and a rearranged product (9). The n.m.r. ($CDCl_3$) on the mixture indicates τ 3.85 (d, 7 Hz, 2H, $>CH-CH_2Cl$)(10), α-proton triplet obscured by other compounds present including $>CH-CH_3$ (n.m.r. ($CDCl_3$) τ 8.53 (d, 4 Hz, 3H, $>CH-CH_3$), 5.25 (q, 4 Hz, $>CH-CH_3$)) and MPD.

(c) Synthesis of MPO

Several methods of producing MPO from MPE were attempted. These included oxidation with IO_4^-/MnO_4^- in K_2CO_3 and IO_4^-/OsO_4. Both were unsuccessful in that they produced MPO in very low yield, 99% of MPE being recovered from the starting material. MPO was finally produced in ~10% yield by the oxidation of MPE in acetone by Jones' reagent (7, 9) ($CrO_3 + H_2SO_4$) the product being extracted into ether and dried with magnesium sulfate. MPO was not separated from MPE and was used as such in benzene solution for v.p.c. analysis using peak-matching techniques (in two different columns) for comparison with photolysis samples; i.r. (Nujol mull) 1715 cm^{-1} (ν C=O); n.m.r. ($CDCl_3$) similar to MPE, no other proton containing impurities present.

Results and Discussion

The absorption spectra of *p,p'*-DDT, **1**, methoxychlor, **2**, and MPA, **3**, are given in Fig. 1. It is interesting to compare the spectra of the above molecules with the published spectrum of 1,1-diphenyl-2,2,2-trichloroethane (**4**) (11). The π,π^* absorption (12) of **4** begins at about 275 nm and exhibits six clearly discernible vibrational bands. On substituting a chlorine atom for an H atom in the para position, thus forming *p,p'*-DDT **1**, the absorption is red shifted by about 6 nm and some of the structure begins to disappear. Similarly substituting an MeO group in the para position of **4**, to yield methoxychlor **2**, produces a red shift of approximately 10 nm and eliminates most of the vibrational bands. The addition of both Cl and MeO to **4**, to give MPA **3** results in a bathochromic shift of about 30 nm, and the almost total disappearance of vibrational structure.

The photolysis of MPA was carried out in solution (cyclohexane solvent) in the presence and absence of O_2, by bubbling either O_2 or N_2 through the solution prior to and during photolysis. Photolysis was performed on MPA, with filtered light $\lambda > 300$ nm and in direct sun-

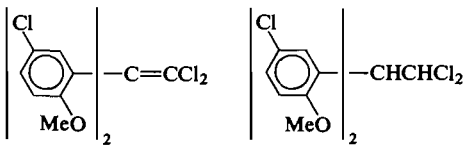
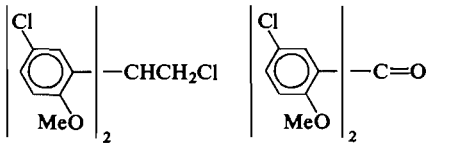
light. The results of these experiments are summarized in Table 1. The major products of photolysis are MPE **5**, MPD, **6**, MPC, **7**, MPO, **8**, and HCl. These molecules were identified by the following means.



5 **6**



7 **8**

In solution photolysis in cyclohexane (both in O_2 and N_2) a small quantity of a white solid was precipitated. This solid, collected from several photolysis experiments was found to be identical, spectrally, with MPE, prepared by the alkaline dehydrochlorination of MPA. White solid; m.p. 164–165 °C; i.r. ($CHCl_3$) 1600 cm^{-1}; n.m.r. ($CDCl_3$) τ 6.16 (s, 6H, —OCH_3); ratio of 2 × (—OCH_3): aromatic protons, 1:1; mass spectrum: M^+ 376 (with peaks at 378, 380, 382, 384 in ratio corresponding to four Cl atoms in the molecule (8)); u.v. (C_6H_{12}) λ_{max} 295.5 and 214 nm; MPD was isolated in a similar way from the photolyses of MPA (C_6H_{12}) under N_2. Again the spectral properties of the product isolated from the photolysis was identical to synthesized MPD; mass spectrum: M^+ 378 (peaks at 380, 382, 384 ratio corresponding to four Cl atoms in the molecule); n.m.r. ($CDCl_3$) τ 6.16 (s, 6H,—OCH_3), 4.80 (d, 6 Hz, 1H, $\rangle$CH—$CHCl_2$), 3.79 (d, 6 Hz, 1H, $\rangle$$CH$—$CHCl_2$); AB system of α,β-ethane protons (10), aromatic protons, see synthesis of MPA; ratio 2 × (—OCH_3) + α,β ethane protons : aromatic protons 4:3; some impurities evident from n.m.r. spectrum. In the case of MPC and MPO, together with other photolysis products, v.p.c. peak matching (retention times) was employed as a method of identification. Two different columns (DC-200, QF-1) were used in retention time matching to ensure proper identification of the products. A standard solution (benzene) of MPA, MPD, MPC, MPE, and MPO was prepared in order to provide a peak matching reference before and after each analysis of photolyzed material. HCl gas, evolved from *all* photolyses both in solution and from the solid, was identified by collecting the gas (~2 cm pressure) *in vacuo* in a 10 cm i.r. gas cell from various photolysis experiments. The typical i.r. spectrum of gaseous HCl was obtained.

Inspection of the data in Table 1 shows that MPE, MPD, and MPC are formed in both liquid and solid phase, in the absence as well as in the presence of O_2. Trace quantities of MPO and higher molecular weight compounds are produced only in the presence of O_2. MPE and MPC are formed in small amounts and their production does not appear to be dependent on photolysis time. MPD is produced in large quantities, its concentration is dependent on irradiation time and it may have an induction period. Our experimental results show that π,π^* absorption in MPA leads to photodecomposition in the chloroethane part of the molecule. In view of the fact that intramolecular energy transfer is known to occur much more efficiently than intermolecular energy transfer (2, 3, 13) it is possible that MPA photodissociation occurs via intramolecular sensitization. While our data do not permit any conclusions about the mechanism of the reaction, the knowledge that photodecomposition of DDT (14–16), carried out at exciting wavelengths ranging from 280–250 nm, proceeds via a free radical mechanism, (C—Cl bond cleavage occurs from both the ethane and the aromatic parts of the molecule with the latter being favored at shorter wavelengths) suggests that MPA photolysis occurs via a mechanism similar to the photolysis of DDT at high wavelengths. This contention is supported by the fact that the major products in the DDT photolysis (16), are analogous to the products of MPA photolysis. At the same time since molecular elimination of HCl is known to occur in the photolysis of chlorinated hydrocarbons (17, 18), it is possible that MPE results from such a reaction. Since MPE has a large extinction coefficient in the 300 nm region ($\simeq 7.5 \times 10^3$) it is possible that it undergoes secondary photolysis, one or more of the observed products could conceivably be due to

this reaction. Further work, which should elucidate the mechanism of photodecomposition of MPA, is underway in our laboratory.

Two other points are also worth noting; a preliminary investigation shows that MPE dissociates when excited by light of $\lambda > 300$ nm, MPA has been shown by the Canada Department of Agriculture (Fredericton, New Brunswick Experimental Station) to have pesticidal properties.

We wish to thank professors G. P. Semeluk and Z. Valenta for many valuable discussions. We are indebted to Mr. D. Pond of the Canada Department of Agriculture, Fredericton for carrying out the toxocological tests on MPA. We thank Mr. J. Addison and Mr. M. Chalmers for technical assistance. We are grateful for financial aid for this project from the University of New Brunswick Research Fund.

Vapor Phase Catalytic Transformations of Terpene Hydrocarbons in the $C_{10}H_{16}$ Series. I. Isomerization of α-Pinene over Alumina[1]

A. STANISLAUS[2] AND L. M. YEDDANAPALLI
Department of Chemistry, Loyola College, Madras, India

Received April 1, 1971

The isomerization of α-pinene in the vapor phase over alumina catalysts of varying acid strength has been studied. The isomerization proceeds via two parallel paths, one giving bi- and tricyclic products such as camphene, β-pinene, tricyclene, and bornylene and the other giving rise to monocyclic compounds such as dipentene, terpinolene, α-terpinene, γ-terpinene, *p*-cymene, and *p*-menthene. Dependence of the distribution of reaction products on space time reveals that camphene, β-pinene, tricyclene, dipentene, and terpinolene are the primary products. The acid strength of alumina catalysts has a remarkable influence on the selectivity ratio of bi- and tricyclic to monocyclic products, the strong acid sites favoring the formation of monocyclic products. From the study of the reactions of camphene and tricyclene over the same catalysts under similar conditions it has been concluded that the decrease in the selectivity ratio with increasing acid strength of the catalysts is mainly due to the further isomerization of the bi- and tricyclic compounds to monocyclic products which takes place only on the strong acid sites.

L'isomérisation de α-pinène en phase vapeur sur catalyseurs d'alumine d'acidité variable a été étudiée. L'isomérisation procède par deux voies parallèles, l'une donnant des produits bi et tricycliques tels que le camphène, le β-pinène, le tricyclène et le bornylène et l'autre permettant d'obtenir des composés monocycliques tels que le dipentène, le terpinolène, l'α-terpinène, le γ-terpinène, le *p*-cymène et le *p*-menthène. La relation entre la distribution des produits de réaction et du temps de contact révèle que le camphène, le β-pinène, le tricyclène, le dipentène et le terpinolène sont des produits primaires. L'acidité des catalyseurs d'alumine a une influence notable sur le rapport de sélectivité: produits bi et tricycliques sur produits monocycliques; les sites fortement acides favorisent la formation de produits monocycliques.

Canadian Journal of Chemistry, **50**, 61 (1972).

Introduction

Alumina has been used as a catalyst and catalyst support in this laboratory for the vapor phase catalytic transformations of terpene compounds (1–5). Studies (6, 7*a*) on the nature of the active sites of alumina have revealed that aluminas can vary widely in their activity for skeletal and double bond isomerization reactions depending upon the strength of acid sites on their surface. A survey of literature reveals that a systematic investigation of the isomerization of α-pinene over alumina catalysts of varying acid strength in vapor phase has not been carried out. The influence of the acid strength of alumina on the rate and the distribution of products of the isomerization of α-pinene was, therefore, studied and the results of such studies are presented in this paper.

[1]This investigation is dedicated to the memory of Professor L. M. Yeddanapalli who died on June 6, 1970.

[2]Present address: Department of Chemistry & Chemical Engineering, Royal Military College of Canada, Kingston, Ontario.

Experimental

(1) Materials

α-Pinene was obtained from the first quality Indian turpentine oil supplied by the Government Turpentine and Rosin Company Ltd., Bareilly, India, by fractionation using a 5 ft column packed with stainless steel helices (containing 20 theoretical plates) at reduced pressure (10 mm Hg). The purity was found to be better than 99% by gas chromatographic analysis.

Camphene: Pure camphene (BDH) was further fractionated and the liquid distilling at 158–159 °C/760 mm was collected and stored in brown bottles. By gas chromatographic analysis the purity was established to be better than 99%.

Tricyclene: Tricyclene (99% pure) generously gifted by Hercules Powder Company, U.S.A., was used without further purification.

Alumina A was prepared by hydrolyzing aluminum isopropoxide with water. The precipitated aluminum hydroxide was filtered with a Buckner funnel, washed thoroughly with distilled water, cut into cakes, and dried at 120 °C for 24 h. The material was then activated at 500 °C in a stream of dry air for 24 h. The activated material was crushed into a powder and then pelletized to give 4 × 4 mm cylindrical pellets.

Aluminas B, C, and D were prepared by doping alumina A with appropriate amounts of sodium carbonate solution to give 0.6, 1.0, and 1.5% by weight of sodium in the catalysts, respectively.

TABLE 1. Acid strength distribution of alumina catalysts

Catalyst	*n*-Butylamine mequiv/g		
	pK_a < -5.7	pK_a -3.0 to -5.7	pK_a* 3.3 to -3.0
Alumina C	0.0	0.24	0.0
Alumina A	0.19	0.05	0.01
Alumina E	0.21	0.20	0.00

*Compared to sulfuric acid water system acid sites having pK_a values in the three ranges 3.3 to -3.0, -3.0 to -5.7, and -5.7 and less are 3×10^{-4} to 48% H_2SO_4, 48 to 72% H_2SO_4, and stronger than 72% H_2SO_4, respectively.

Alumina E was prepared by impregnating alumina A with appropriate amounts of HF acid (40% E. Merck) to give 5% by weight of HF in the catalyst. The activation of these catalysts were carried out in a manner similar to that employed in the preparation of alumina A.

The distribution of acid strengths in aluminas A, C, and E was determined by the *n*-butylamine titration method (*7b*). The results are summarized in Table 1. Pure alumina appears to have a continuous distribution of acid strength although most of the acidity is strong ($pK_a < -5.7$). The treatment with HF increases acid sites having pK_a values -3.0 to -5.7 considerably. On the other hand addition of 1% sodium to pure alumina results in the removal of all strong acid sites.

(2) Apparatus and Procedure

The reactions were carried out in a fixed bed flow type reactor. Five grams of alumina (4 × 4 mm cylindrical pellets) was placed in a Pyrex reaction tube of 25 cm long and 3 cm internal diameter. Above the catalyst bed Pyrex glass beads (4 mm diameter) were placed to a height of 5 cm. The tube was inserted into the furnace (a cylindrical steel tube of internal diameter 4 cm coated with thin layer of asbestos and wound uniformly with the nichrome wire) and heated electrically to the requisite temperature. α-Pinene was passed over the catalyst using a constant feed-rate syringe pump that could be operated at different feed rates.

The products of the isomerization were analyzed by gas chromatography using a Perkin–Elmer Vapor Fractometer Model 154-D with a thermal conductivity cell detector. Hydrogen was used as the carrier gas. Perkin–Elmer Column K consisting of 2 m column of Carbowax on Chromosorb was used. The column temperature for the best resolution within a reasonable time was found to be 115 °C with the hydrogen inlet pressure of 15 psig and flow rate of 112 cc/min. For the identification of different peaks in a chromatogram, retention times for the different compounds were found by introducing pure substances gifted generously by Hercules Powder Company, U.S.A.

For quantitative analysis exactly reproducible quantities of synthetic mixtures containing the different compounds in varying proportion were introduced and calibration curves relating the concentration with the peak heights were drawn. Since the peaks obtained were sharp and symmetrical, peak heights were used as a measure of concentration without any serious error. Initial experiments in which both peak heights and the total areas were compared using mixtures of known concentrations, gave identical results. Therefore, in subsequent work all analyses were based on comparison of peak heights.

Results and Discussion

Isomerization of α-Pinene

Effect of Sodium

Figure 1 shows the influence of sodium content of the catalyst on the distribution of products resulting from the isomerization of α-pinene. As can be seen from Fig. 1, a change in the sodium content of the catalyst markedly changes the distribution of products. With increasing amount of sodium in the catalyst the concentrations of camphene and dipentene in the product are increased at the expense of α- and γ-terpinenes. With a catalyst containing 1.5% sodium the isomerization product contained only camphene, tricyclene, dipentene, β-pinene, and terpinolene, the concentrations of the other products being reduced to zero.

Addition of sodium ions to pure alumina reduces the strength of its surface acidity (Table 1). A catalyst impregnated with 1% sodium has lost all the strong acid sites having pK_a values less than -5.7 originally present in pure alumina. It has been shown by a number of workers (*7a*, 8) that aluminas containing only weak acid sites do not promote secondary reactions. Based on this fact it may be concluded that camphene, tricyclene, β-pinene, dipentene, and terpinolene (the only products obtained from α-pinene over a catalyst containing 1.5% sodium) are the primary products of the isomerization of α-pinene.

Effect of Space–Time[3]

Figures 2, 3, and 4 illustrate the effect of space–time on the distribution of the reaction products over aluminas A, C, and E, respectively. As can be seen from Fig. 2, the concentrations of camphene, dipentene, terpinolene,

[3]Space–time = 1/WHSV; WHSV = the number of grams of α-pinene passed per gram of the catalyst per hour.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

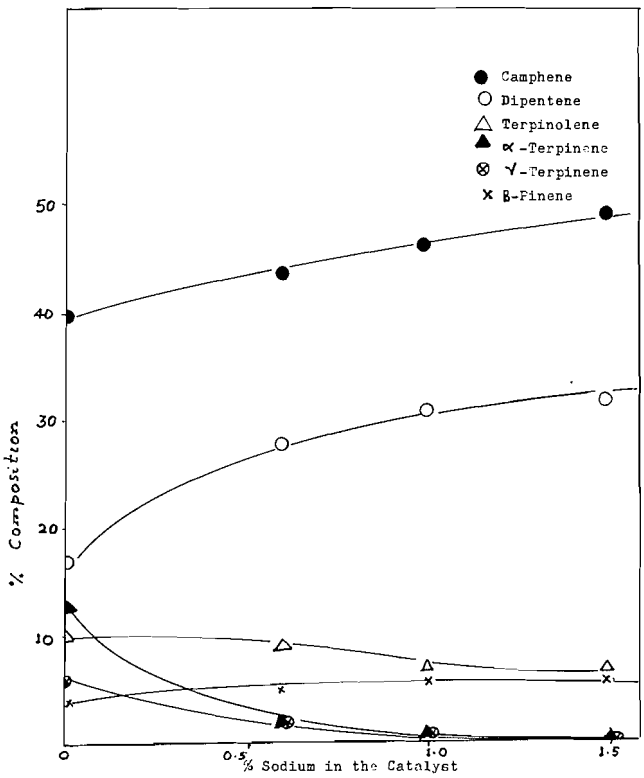

FIG. 1. Effect of sodium on the distribution of products of isomerization of α-pinene; temperature, 210 °C; WHSV, 1.

β-pinene, and tricyclene reach a maximum at a relatively low space–time and then fall rapidly with further increase in space–time. Also the rate of formation of camphene is appreciably faster. The concentrations of α- and γ-terpinenes increase with increasing space–time, the amount of α-terpinene being much higher than that of γ-terpinene. At high space–times, *p*-cymene and *p*-menthenes are formed and their concentrations continue to increase with space–time. Essentially the same reaction pattern is presented in Figs. 3 and 4. These results indicate that camphene, β-pinene, dipentene, tricyclene, and terpinolene are the primary isomerization products of α-pinene. α- and γ-terpinenes, and *p*-cymene and *p*-menthenes are secondary and tertiary products, respectively.

Carber *et al.* (9) from the results of their study of the kinetics of isomerization of α-pinene in the liquid phase in presence of cobalt molybdenite catalysts have shown that camphene and dipentene are the primary products. The results of the present investigation show that in addition to these two products, β-pinene, terpinolene, and tricyclene are also formed in the primary step.

Dipentene and terpinolene which are formed in the first step undergo subsequently a double bond isomerization to α- and γ-terpinenes. The terpinenes are then converted to *p*-cymene and *p*-menthene by disproportionation or by direct dehydrogenation. This is in accordance with the results of Hunter and Brogden (10) who from their studies of the kinetics of isomerization of dipentene in the presence of silica gel in the liquid phase showed that dipentene undergoes isomerization to α- and γ-terpinenes which are then converted to *p*-cymene and *p*-menthenes at high contact times.

β-Pinene can isomerize similarly over acid catalyst giving α-pinene, camphene, tricyclene, dipentene, and terpinolene (11). Camphene has been reported to yield tricyclene and bornylene in an equilibrium composition of 73% camphene, 24% tricyclene, and 3% bornylene in the presence of alumina catalysts (12). The decrease

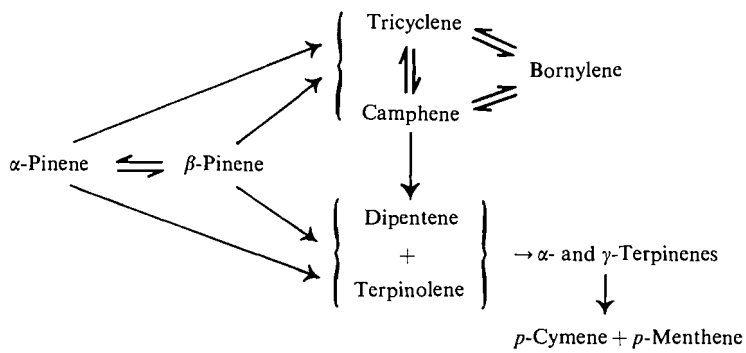

SCHEME 1

in concentration of camphene at high space–times after a maximum at a relatively low space–time over strongly acidic aluminas shows that camphene undergoes further reaction over these catalysts.

The sequence shown in Scheme 1 may, therefore, be proposed for the isomerization of α-pinene.

Isomerization of Camphene and Tricyclene

The reactions of camphene and tricyclene were studied separately under similar conditions of the isomerization of α-pinene in order to obtain further support to the kinetic sequence proposed for the isomerization of α-pinene.

Table 2 gives the results obtained from the reactions of camphene over different alumina

Alumina E	49	46	40	14

catalysts. As can be seen from Table 2 the extent of camphene undergoing isomerization increases from 24 to 49% in going from the weakly acidic sodium doped alumina to the strongly acidic HF treated alumina. It appears also from Table 2 that over weakly acidic sodium doped catalyst (alumina C) camphene does not undergo conversion to monocyclic products but undergoes isomerization to only tricyclene and bornylene. Over strongly acidic HF treated alumina (alumina E) it undergoes ring opening giving monocyclic products which include dipentene, terpinolene, α- and γ-terpinenes, *p*- and *m*-cymenes and menthenes.

Another notable feature of the results presented in Table 2 is that the concentration of tricyclene in the product decreases and that of monocyclic products increases with increasing acid strength. Thus the concentration of tricyclene decreases from 90 to 46% and that of monocyclics increases from 0 to 40% in going from the weakly acidic sodium doped alumina (alumina C) to the strongly acidic HF treated alumina (alumina E).

Table 3 presents the results obtained by subjecting tricyclene to isomerization over various alumina catalysts. The amount of tricyclene undergoing reaction increases from 77 to 87%

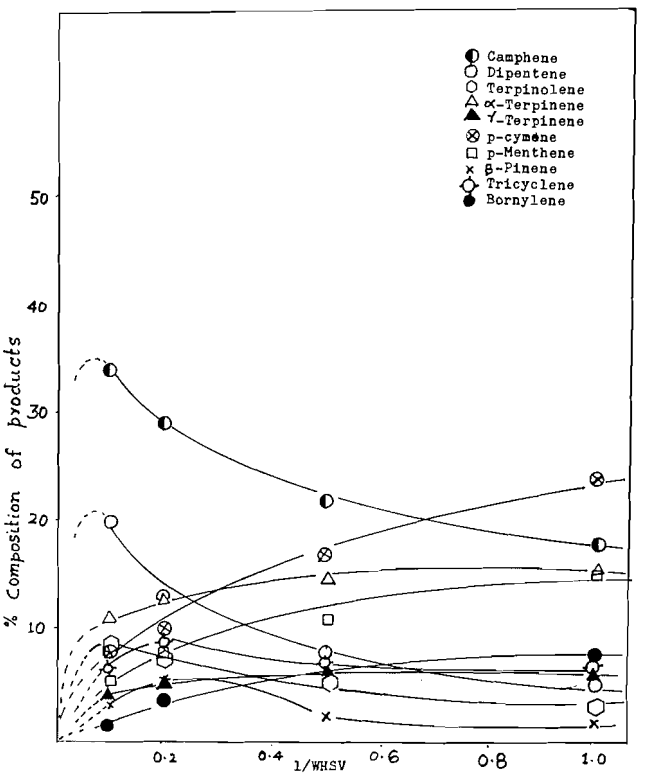

FIG. 4. Isomerization of α-pinene over alumina E. Influence of space–time; temperature, 235 °C.

TABLE 3. Isomerization of tricyclene. Catalyst type and reactivity; temperature, 250 °C; WHSV, 1

Catalyst	% tricyclene reacted	% composition of the products

Alumina A	80	85	7	8
Alumina E	87	40	45	15

in going from the weakly acidic sodium containing alumina to the HF treated alumina having strong acid sites. Also over the sodium doped alumina tricyclene does not undergo conversion to monocyclic products, but isomerizes to give only camphene and bornylene. In going from sodium doped alumina to HF treated alumina catalyst the amount of camphene in the product decreases from 96 to 40% while that of monocyclic products increases from 0 to 45%.

A comparison of the results in Tables 2 and 3 shows that for a given catalyst at constant temperature and space velocity, tricyclene is more reactive than camphene. Thus, while 80% of tricyclene undergoes reaction over alumina A at 250 °C, only 32% of camphene reacts under similar conditions. This is not surprising in view of the greater strain in the molecule of tricyclene.

The following conclusions can be drawn from these results: (*1*) Over weakly acidic sodium doped catalyst both camphene and tricyclene undergo interconversion but do not isomerize to monocyclic products. (*2*) The extent of interconversion decreases with increasing acid strength. (*3*) Strong acid sites are necessary for

the conversion of camphene and tricyclene to monocyclic products. (*4*) Tricyclene is more reactive than camphene.

The effect of pyridine on the reaction was studied with a view to ascertaining whether only the strong acid sites of the catalysts are involved in the conversion of camphene and tricyclene to monocyclic products. The reactions were carried out over HF treated alumina and pure alumina catalysts. The results obtained for camphene are presented in Table 4. The corresponding results for tricyclene are given in Table 5.

It is seen that pyridine, apart from reducing the activity of the catalyst for total isomerization, brings out marked decrease in the proportion of monocyclic products formed from both camphene and tricyclene. In the case of pure alumina the added pyridine (5% by weight) is sufficient to neutralize all strong acid sites and completely suppress the formation of monocyclic products. In the case of HF treated alumina the concentration of monocyclic products decreases from 47 to 15% by the addition of the same amount of pyridine. In this case the amount of pyridine added is probably not sufficient to neutralize all the strong acid sites. These results support the conclusion that strong acid sites are involved in the conversion of camphene and tricyclene to monocyclic products.

The effect of space–time on the isomerization of camphene and tricyclene over pure alumina and HF doped alumina has been studied in an attempt to arrive at the sequence of the reaction steps. The compositions of the products formed from camphene and tricyclene over HF treated alumina (alumina E) are plotted in Figs. 5 and 6 respectively, as a function of space–time.

As can be seen from Fig. 5 the amount of tricyclene formed from camphene reaches a maximum and falls rapidly with increasing space–time. Thus tricyclene is formed in the rapid initial stage and undergoes further isomerization to monocyclic products whose concentrations in the product increase with increasing space–time.

Starting with tricyclene (Fig. 6) the amount of camphene produced falls steadily with space–time after a maximum at low space–time region.

These results indicate that camphene and tricyclene undergo isomerization to monocyclic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

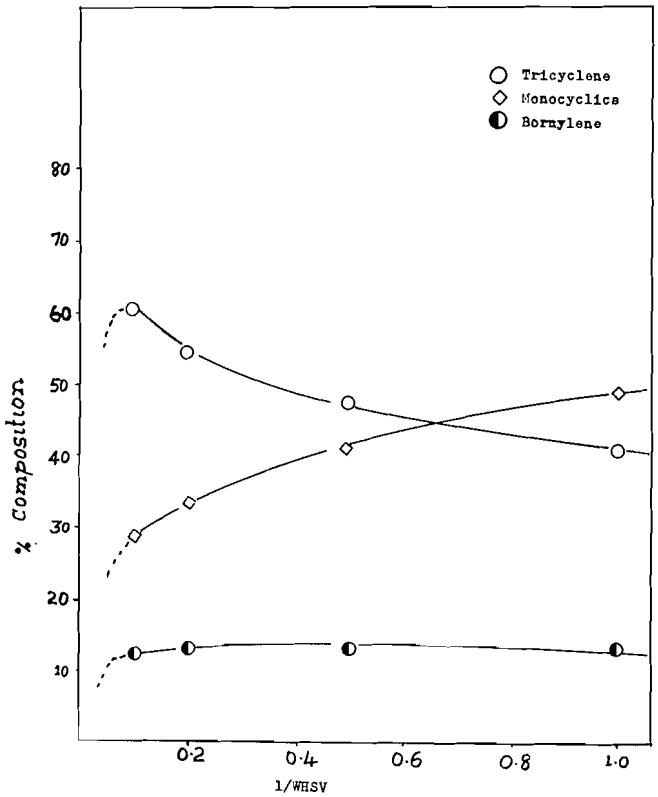

FIG. 5. Isomerization of camphene over alumina E. Influence of space–time; temperature, 250 °C.

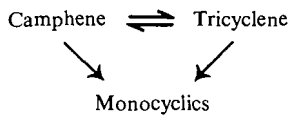
products and interconversion simultaneously over acid catalysts (see Scheme 2).



SCHEME 2

The change in the composition of monocyclic products with space–time is shown in Fig. 7. It is evident from Fig. 7 that the concentrations of dipentene and terpinolene in the product decrease while those of α- and γ-terpinenes increase with space–time. This indicates that dipentene and terpinolene are the first to be formed which then undergo double bond isomerization to α- and γ-terpinenes. At higher contact times *p*-cymene and menthene are formed. In general, the change in the composition of monocyclic products is similar to that observed in the case of the isomerization of α-pinene. The complete sequence of the reactions of camphene and tricyclene over alumina E may, therefore, be written as Scheme 3.

These results confirm the kinetic sequence suggested for the isomerization of α-pinene over strongly acidic alumina catalysts.

Mechanism of Isomerization of α-Pinene over Alumina

It has been well established that alumina surface contains both Bronsted and Lewis acid sites. Several mechanisms have been proposed for the isomerization of olefins over solid acid catalysts. These include the carbonium ion theory of Whitmore (13) and hydrogen switch mechanism of Turkevich and Smith (14). In recent years Pines and Haag (15) have proposed that the isomerization proceeds through an intermediate π-complex of the olefin and a proton from the catalyst. All these mechanisms assume proton addition to the olefin double bond accompanied by a subsequent or simultaneous proton elimination from another part of the carbonium ion thus formed.

Carbonium ions on the surface of solid acid catalysts have been identified by Leftin and Hermana (16).

Osaki and Kimura (17) have suggested a proton donor–acceptor mechanism for butene isomerization over solid acid catalysts, either the Bronsted acid sites on the surface of the catalysts or the carbonium ions formed by the adsorption of olefins on Lewis acid sites serving as proton donors.

The isomerization of α-pinene over alumina catalysts will be interpreted in terms of carbonium ions adsorbed on the surface of the catalyst.

The isomerization of α-pinene proceeds via two parallel directions one giving bi- and tricyclic products (camphene, β-pinene, and tricyclene) and the other giving rise to monocyclic products (dipentene, terpinolene, α-terpinene, and γ-terpinene).

The direction of the reaction is determined by the nature of orientation of α-pinene molecule to the surface of the catalyst. α-Pinene can be adsorbed on the catalyst surface in three ways, as shown by structures **1**, **2**, and **3**.

In type **1** adsorption the acid site acts on the double bond on the side away from the *gem-*

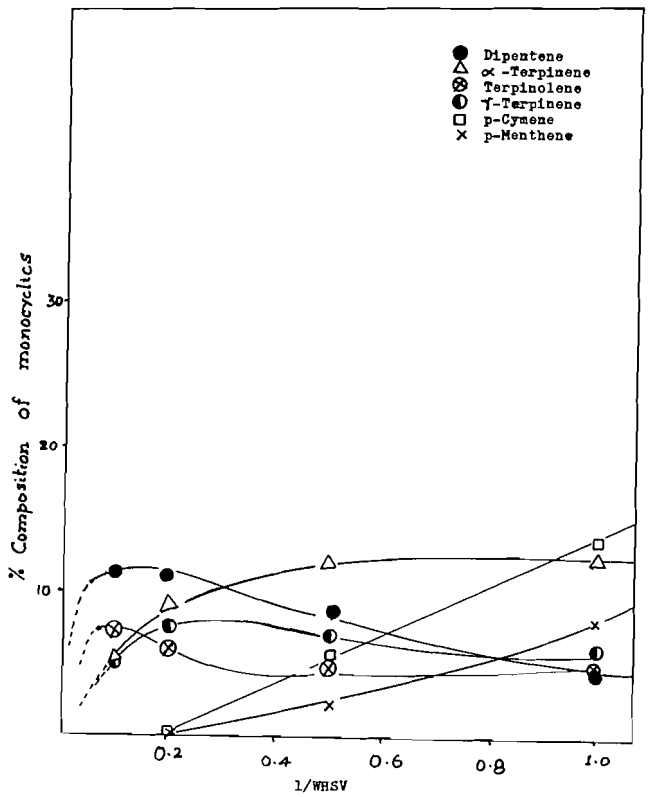

FIG. 7. Isomerization of camphene over alumina E. Influence of space–time on the distribution of monocyclic products; temperature, 250 °C.

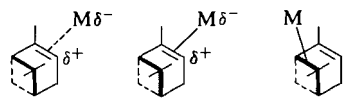


(M is an acid site in the catalyst surface)

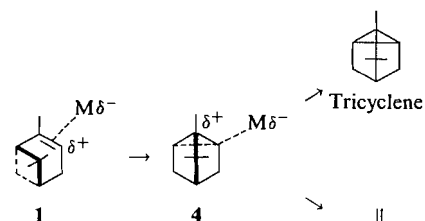
dimethyl group because of its bulkiness. This mode of adsorption is sterically favored.

In type **2** the acid site acts on the double bond from the side of the *gem*-dimethyl group. This mode of adsorption is sterically unfavorable.

In type **3** the cyclobutane ring of α-pinene is attached to the acid site. This mode of adsorption will be favored within the pores of the catalyst.

According to Rudakov (18) if the double bond of α-pinene molecule is directed towards the surface of the catalyst bi- and tricyclic compounds are formed, while if the four-membered ring is directed towards the catalyst surface monocyclic products are formed.

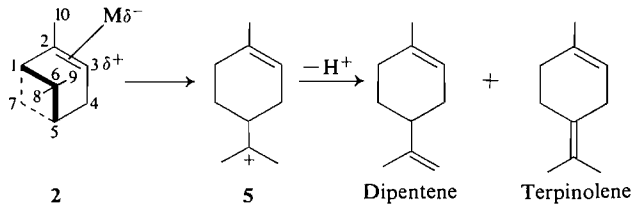
Thus type **1** and **2** mode of adsorption must lead to the formation of bi- and tricyclic products. But due to steric reasons only the mode of adsorption corresponding to **1** can give rise to these products.



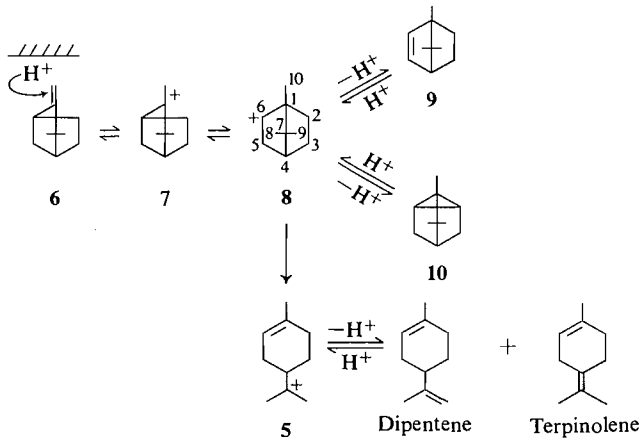
SCHEME 4

The formation of camphene and tricyclene from **1** can be represented by Scheme 4. The surface complex **1** is converted into camphene through the nonclassical ion **4**. This intermediate nonclassical ion is similar to that occurring in the well known isobornylchloride –

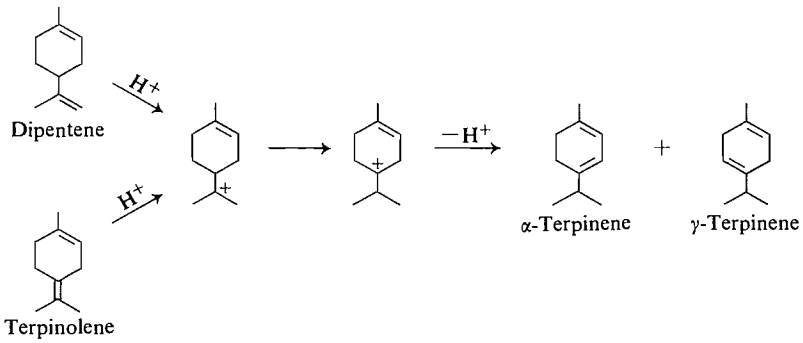
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 5



SCHEME 6



SCHEME 7

camphene interconversion. Analogous conversion from **2** is sterically hindered.

The formation of dipentene and terpinolene from α-pinene involves the bond rearrangements shown in Scheme 5. The bond between C-6 and -1 is ruptured resulting in the formation of the classical carbonium ion **5** which on subsequent proton elimination gives dipentene and terpinolene. The rupture of the C_6—C_1 bond of α-pinene molecule is favored by type **2** and **3** adsorptions.

The formation of dipentene and terpinolene from camphene and tricyclene may be represented by Scheme 6. The catalyst surface interacts with the double bond of camphene molecule (**6**) resulting in the formation of the carbonium ion (**7**). This carbonium ion rearranges to another carbonium ion (**8**) which with the elimination of a proton from C-5 forms bornylene (**9**). Elimination of a proton from C-2 results in the formation of tricyclene (**10**). Over strong acid sites the carbonium ion (**8**) re-

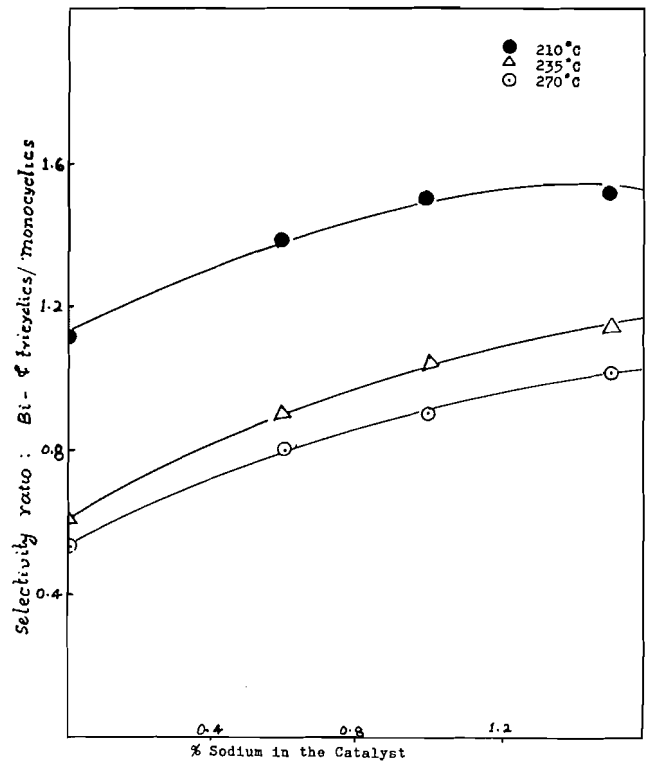

FIG. 8. Isomerization of α-pinene. Influence of sodium on the selectivity ratio.

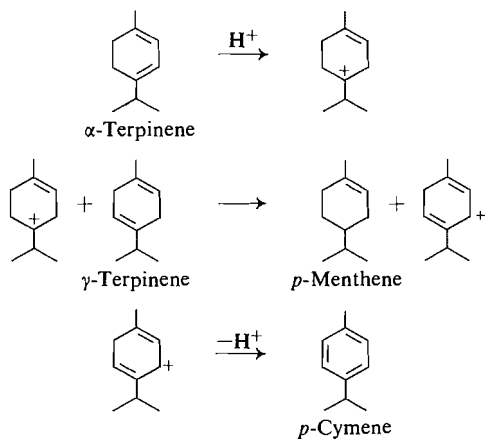

SCHEME 8

arranges to the monocyclic carbonium ion (**5**) by breaking of C_1—C_7 bond. Removal of a proton from **5** leads to the formation of dipentene and terpinolene.

α- and γ-terpinenes are formed from dipentene and terpinolene by further double bond isomerization as shown in Scheme 7.

p-Cymene and menthene are probably formed from α- and γ-terpinenes by disproportionation or hydrogen exchange (Scheme 8).

It has been shown by Tung and McInninch (19) that Lewis acid sites of alumina can catalyze dehydrogenation and hydrogenation reactions. *p*-Cymene may also be formed by direct dehydrogenation of α-terpinene by the Lewis acid sites of alumina (Scheme 9).

The Lewis acid site abstracts a hydride ion from α-terpinene molecule generating a carbonium ion. This then loses a proton to an adjacent oxide ion forming the dehydrogenated compound (*p*-cymene). The hydrogen liberated in this process may hydrogenate α- and γ-terpinenes to *p*-menthene.

Influence of Acid Strength of the Catalyst on the Selectivity Ratio

The influence of sodium on the selectivity ratio of bicyclic to monocyclic products is shown in Fig. 8. It is evident that the selectivity ratio increases with increasing sodium content

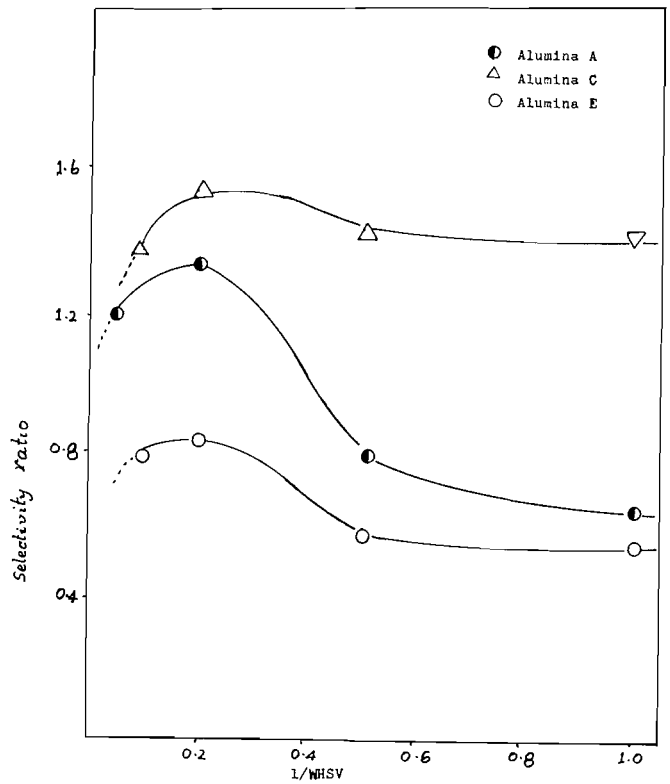

FIG. 9. Isomerization of α-pinene. Influence of space–time on the selectivity ratio; temperature, 235 °C; WHSV, 1.

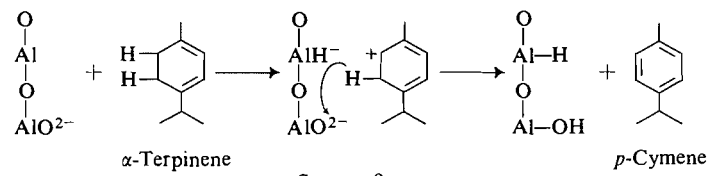

SCHEME 9

of the catalyst. This means that the rates of the two paths of the reaction one giving bi- and tricyclics (camphene, β-pinene, and tricyclene) and the other giving monocyclics (dipentene and terpinolene) depend on the sodium content or in other words the acidic strength of the catalyst. This may be due to three factors which may act separately or jointly depending on the conditions:

(*1*) The strong acid sites of the catalyst may cause an increase in the type **2** adsorption despite the steric hinderance and thus lead to the formation of more monocyclics.

(*2*) The strong acid sites of the catalyst may cause further isomerization of bicyclic products to monocyclics and thus bring about an increase in the amount of monocyclics.

(*3*) The substance (sodium or HF) added to the catalysts, in order to decrease or increase their acid strength may modify the structure and texture of the catalyst. The changes in the texture of the catalyst may affect the nature of orientation of the molecules to the surface. The narrow pores of alumina and modified alumina catalysts can act as a pseudo-solvent (20). Within the narrow pores an attack on the cyclobutane ring may take place leading to the formation of monocyclics.

Rudakov and Ivanova (21) have recently shown that the course of the reaction (in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

liquid phase) does not depend on the pore structure of the catalyst.

The acid strength of the catalyst is, therefore, the major factor in deciding the course of the reaction. The next question to answer is whether the strong acid sites of alumina cause the observed change in the selectivity ratio by mechanism *1* or *2*.

The results of the influence of contact time on the selectivity ratio (Fig. 9) suggest that mechanism *2* is mainly operative.

Over strongly acidic alumina catalysts the selectivity ratio of bicyclic to monocyclic products increases, reaches a maximum and then decreases rapidly with increasing contact time. On the other hand over weakly acidic sodium doped alumina there is not much fall in the selectivity ratio after reaching the maximum even at high contact times. This means that over catalysts having strong acid sites further conversion of the bi- and tricyclic products (camphene and tricyclene) to monocyclic products occurs. This is further supported by the results of the study of the reaction of camphene and tricyclene over various alumina catalysts under similar conditions. Mechanism *1* may also contribute partly to the formation of monocyclic products by favoring type **2** adsorption on the strong acid sites.

We wish to thank the Council of Scientific and Industrial Research for financial help.

Chlorocuprate(II) and Chlorocobaltate(II) Salts of the Aminodiphenylphosphonitrileaminodiphenylphosphonium Ion

R. M. CLIPSHAM[1] AND M. A. WHITEHEAD[2]

Department of Chemistry, McGill University, The Royal Institution for the Advancement of Learning, P.O. Box 6070, Montréal 110, Québec

Received April 22, 1971

Two new compounds $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[CoCl_4]$ and $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2][CoCl_4]CH_2Cl_2$ have been isolated, and characterized by spectrometry, as examples of the general series of quaternary amine transition metal chloride salts. Three other compounds containing the same cations, with empirical formulae, $CuP_2N_3C_{25}H_{32}OCl_3$ (**1**), $CuP_2N_3C_{24}H_{28}Cl_3$ (**2**), and $Cu_3P_4N_6C_{50}H_{64}O_2Cl_8$ (**3**) have been isolated and studied by spectrometry. The formulae $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[Cu_2Cl_6]$ and $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[Cu_2Cl_6]$. $2CH_3OH$ are proposed for (**2**) and (**1**) by comparison with the cobalt compounds, and interpretation of the electronic structure. These compounds were produced during attempts to synthesize mixed ring compounds of (PN) and (SN) units.

Deux nouveaux composés $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[CoCl_4]$ et $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2][CoCl_4]CH_2Cl_2$ ont été isolés et caractérisés par spectrométrie; ils appartiennent à la série générale des sels des chlorures des métaux de transition et des amines quaternaires. Trois autres composés contenant les mêmes cations, et ayant pour formule empirique, $CuP_2N_3C_{25}H_{32}Cl_3$ (**1**), $CuP_2N_3C_{24}H_{28}Cl_3$ (**2**) et $Cu_3P_4N_6C_{50}H_{64}O_2Cl_8$ (**3**) ont été isolés et étudiés par spectrométrie. Les formules $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[Cu_2Cl_6]$ et $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]_2[Cu_2Cl_6]$. $2CH_3OH$ ont été proposées pour les composés (**2**) et (**1**), par comparaison avec les composés du cobalt et par l'interprétation de la structure électronique. Ces composés ont été fabriqués pendant l'essai de synthèse de composés à cycle mixte des unités (PN) et (SN).

Canadian Journal of Chemistry, **50**, 75 (1972)

Introduction

In the course of research into the possibility of producing mixed rings containing PN and SN units (1), the cation $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]^+$ was studied. Models of the cation, showed that the amino groups could be oriented "*cis*" or "*trans*" with no "visible" preference. For a "*trans*" orientation, formation of a linear chain would be more likely than the formation of a ring. (Preliminary X-ray analysis of the molecular structure published subsequent to these studies confirms a "*trans*" orientation (2).) Coordination of both amino groups of a single molecule to an appropriate transition metal atom would lock the NPNPN skeleton into a ring structure, and this chelate could then react with a suitable sulfur compound to substitute a sulfur atom for the metal and form a mixed ring. The positive charge of the phosphonitrile could hinder coordination to another positively charged species. To minimize this possibility, initial chelate formation attempts were made with copper(II) salts. When crystalline solids were isolated, reactions with other transition metal salts were also investigated. Only copper(II) and cobalt(II) chloride compounds were obtained. Subsequent characterization of these indicated they were not the chelates desired, but salts containing the phosphonitrile cations and cobalt(II) or copper(II) chloride anions.

*$L^+ = [NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]^+$.

Experimental

All starting materials were reagent grade. The Cu(II) and Co(II) chlorides were dried Fisher reagent grade salts, $CuCl_2 \cdot 2H_2O$ and $CoCl_2 \cdot XH_2O$, and were kept at 120 °C for several hours and stored over silica gel.

Aminodiphenylphosphonitrileaminodiphenylphosphonium Chloride

$[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]Cl$ was prepared from the controlled ammonolysis of diphenyltrichlorophosphorane in chloroform solution (3). Diphenyltrichlorophosphorane was prepared by chlorination of diphenylchlorophosphine in controlled ratio in carbontetrachloride.

Reactions of Aminodiphenylphosphonitrileaminodiphenylphosphonium Chloride with Transition Metal Halides

Initial attempts to use other salts of copper(II), the nitrate, sulfate, and bromide, in a similar preparation to that for compounds of the phosphonitrile and copper(II) chloride, were unsuccessful; only copper(II) chloride in either dried or hydrated form resulted in "complex" formation. This was also found for cobalt(II) salts. Similar preparative attempts were unsuccessful for hydrated chlorides of iron(III), iron(II), chromium(III), nickel(II), and anhydrous zinc(II) chloride. No other preparative method was tried.

Copper(II) Compounds[3]

A, ($CuLCl_3 \cdot CH_3OH$): crystallized from methanol solution; 2.0 g (0.0044 mol) LCl and 0.57 g (0.0042 mol) dried $CuCl_2$ were added to enough methanol to just dissolve the combined substances, and the green solution warmed to 60 °C. Then anhydrous diethylether was added slowly, until the point of cloudiness. The solution was allowed to stand until red-green plates formed, which were filtered, washed with a mixture of methanol and ether, and stored in methanol atmosphere. A slight excess of LCL must be present for reprecipitation from methanol.

B, ($CuLCl_3$): prepared by heating powdered samples of A at 100 °C until constant weight, or by precipitation from acetonitrile or methylene chloride as for A. Yellow-gold needles or plates precipitated from orange solution and were filtered, washed in a mixture of solvent and ether, then in ether to dry, and stored over silica gel. A slight excess of LCL must be present for reprecipitation from methylene chloride or acetonitrile.

C, ($Cu_3L_2Cl_8 \cdot 2CH_3OH$): precipitated from methanol as for A, using a 1:2 molar ratio of LCL:dried $CuCl_2$. Red needle clusters obtained were filtered, washed in a methanol–ether mixture, and stored in methanol atmosphere. The substance lost methanol when heated to 100 °C, but the product did not melt sharply. From i.r. analysis, it was a mixture of B and another substance which was not anhydrous copper(II) chloride.

Cobalt(II) Compounds

D, (CoL_2Cl_4): precipitated from methanol solution of LCl and dried $CoCl_2$ as for A (1:1 molar ratio). Royal blue diamonds formed which were filtered, washed with a mixture of methanol and ether, then ether to dry, and stored over silica gel.

E, ($CoL_2Cl_4 \cdot CH_2Cl_2$): precipitated from methylene chloride solution as for A (1:1 molar ratio). Turquoise needles or plates were obtained and stored over silica gel at room temperature without decomposition from loss of methylene chloride. When heated above 90 °C, E lost methylene chloride to become D.

The analytical results for these molecules are given in Table 1.

Copper(II) and Cobalt(II) Chlorides of Aminodiphenylphosphonitrileaminodiphenylphosphonium Ion

The phosphonitrile cation, $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]^+$, is designated L^+, and the phosphonitrile chloride as LCl. The copper compounds are referred to as A, B, and C;

[3]Empirical formulae: $L = P_2N_3C_{24}H_{24}$. The phosphonitrile cation is referred to as L^+ and the chloride as $LCl \equiv [NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]Cl$.

and the cobalt compounds as D and E, following the outline and formulae in the experimental section.

There has been one report of complex chelate formation (52), $[N_6P_6(NMe_2)_{12}Cu^{II}Cl]^+$ Cu^ICl_2, but none from phosphonitrile chlorides; however, a blue compound, $Cu(NH(C_6H_5)_2PNP(C_6H_5)_2NH)_2$ (m.p. 178–180 °C with decomposition), prepared from methanol solution of the ionic phosphonitrile and $CuCl_2 \cdot 2H_2O$, has been reported (4). After treatment with sodium methoxide, a green precipitate was obtained which became the copper compound on hydrolysis. It was insoluble in water and could be crystallized from polar organic solvents or benzene.

When compounds are formed by an amino group nitrogen atom coordinating to copper(II) or cobalt(II) halides, they usually contain polymeric distorted octahedral copper(II), and octahedral or tetrahedral cobalt(II) in a non-ionic structure (5–8). Cobalt(II) halides form complex ionic compounds for some ligands, particularly at low metal : ligand ratios, where the cations are ligand-coordinated cobalt(II) ions and the anions are tetrahedral tetrachlorocobaltate(II) (9). Similar behavior occurs for copper(II) halides (10, 11).

The donor properties of positively charged ligand quaternary amines and phosphines have been studied (11–14), and it has been suggested that a positive charge on a ligand does not necessarily prevent its coordination to a positively charged metal ion, but may stabilize unusual stoichiometries and structures. Tetracoordinate cobalt(II) and nickel(II) complexes containing monoquaternized ditertiary phosphines have been reported with stoichiometry $MX_2 \cdot \P X$, where ¶ is the monocharged phosphonium ion. Although these compounds are supposed to contain non-ionic monomeric transition metal species, they have high thermal stabilities and low solubilities in non-polar solvents, which has been attributed to high lattice energies from interaction of polar $\P^{\delta+}$–$MX_3^{\delta-}$ sites of neighboring units.

On the other hand, there are many examples of ionic compounds containing bulky quaternary amine (15, 16) or other cations (17) and transition metal halide anions, including tetracoordinate copper(II) and cobalt(II) chlorides (16, 18–21).

From the solubility, conductivity, and melting point characteristics, and the similarity of their electronic spectra to those of anionic copper(II) and cobalt(II) chlorides, it was concluded that the compounds prepared could be ionic compounds with $\P^{\delta+}MX_3^{\delta-}$ structure. However, the pseudo-tetrahedral "polarized" phosphonium $MX_2\P X$ structure might occur.

Physical and Chemical Properties

The compounds were soluble in polar, and insoluble in non-polar organic solvents. In aqueous solution, or in wet organic solvents, decomposition occurred with formation of the phosphonitrile chloride and octahedral aquo copper(II) or cobalt(II) ions. Decomposition also occurred in pyridine, with formation of the phosphonitrile chloride and copper(II) or cobalt(II) pyridine complexes.

The solid state copper(II) compounds exhibited color changes on variation of temperature. For example, B changed from brown, through gold, to yellow as the temperature was lowered from the melting point, 430 °K, to 77 °K. The change was gradual, with no evidence of a sharp transition. Single crystals of all the copper(II) compounds were pleochroic: viewed in one direction, plates of A appear green-brown, while in perpendicular view, they are deep red.

TABLE 2. *g*-Values from electron paramagnetic resonance measurements for some copper(II) chloride compounds

	Compound*	*g*-Value† 294 °K	*g*-Value† 124 °K
A	$CuLCl_3 \cdot CH_3OH$	2.098	2.092
B	$CuLCl_3$	2.107	2.113
C	$Cu_3L_2Cl_8 \cdot 2CH_3OH$	2.096	2.094
	Dried $CuCl_2$	2.096	2.089

*Empirical formulae, $[NH_2(C_6H_5)_2PNP(C_6H_5)_2NH_2]^+ = L^+$; polycrystalline.

†A varian spectrometer, V4500-10A was used for these measurements on both the solid state and solution. Samples were contained in dried, sealed quartz tubes 4 mm diameter. The limit of error in the *g*-value is ±0.005 from 3 measurements per sample for duplicate samples. No signal was detected for A, B, or C in any solvent.

Conductance measurements indicated B was more ionic than the phosphonitrile chloride (22) in nitrobenzene. However, solvation occurred to a varying extent for all compounds. For each metal ion, the same solution spectrum was obtained for all compounds, and because of their insolubility in solvents with low coordination (23), no further conductance studies were attempted.

Spectrometric Results

(1) ^{35}Cl Nuclear Quadrupole Resonance (1): Solid samples of all molecules were scanned through 9–54 MHz. No interactions were detected.

(2) Electron Paramagnetic Resonance: See Table 2.

(3) Infrared Spectra: Few changes in solid state or solution spectra occur on compound formation. Those which are observed are minor shifts or "splitting" of bands assigned to phosphonitrile amino or P—NH_2 group vibrations, which could be attributable to a solvent shift or crystal packing effect (24).

(4) Ultraviolet, Visible, and Near-infrared Spectra: Dried $CuCl_2$ and $CoCl_2$ were insoluble in methylene chloride or nitromethane. All cobalt(II) and copper(II) compounds were soluble in both solvents, and in the absence of moisture no changes in their solution spectra occurred during periods of 2 h. Tables 3, 4, and 5.[4]

Discussion

1. *Empirical Formulae*

From solution i.r. spectra of A and C, the molecules are probably methanolates.

[4]Footnote to Tables 3, 4 and 5: Solution spectra were obtained using matched silica cells of 10 mm path length on a Beckman D.U. manual spectrometer, or a Unicam SP 800 recording spectrometer (13 500 – 47 500 cm^{-1}), and on the former, or a Perkin–Elmer 350 spectrophotometer (4 000–16 800 cm^{-1}), solvent permitting. Solid state spectra were obtained using Nujol mulls on Whatman no. 1 filter paper strips held in place by matched silica cells (26); a strip painted with Nujol was used as a reference. The spectra are qualitative since values of molar extinction coefficient cannot be calculated. However, this technique is as reproducible as reflectance measurements on powdered samples, and as useful for solid state spectra where samples can be ground sufficiently fine to make a good mull suspension.

Melting point characteristics of A, C, and E also indicate these compounds are solvates. From a comparison of the analytical results (Table 1) the empirical formulae for A, B, and C are $CuLCl_3 \cdot CH_3OH$, $CuLCl_3$, and $Cu_3L_2Cl_8 \cdot 2CH_3OH$, respectively; and A and C are methanolates rather than hydrates. Empirical formulae concluded for D and E are less certain. Infrared spectra indicate neither is a methanolate. Low percent oxygen values for both compounds are also evidence that neither is a methonalate nor a hydrate. From its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

analysis, E is most likely a solvate of methylene chloride, with the empirical formula $CoL_2Cl_4 \cdot CH_2Cl_2$; comparing spectral characteristics and other behavior with E, the empirical formula of D is CoL_2Cl_4.

2. Cobalt(II) Compounds; Ionic Type $[L]_2[CoCl_4]$

Solid state and solution electronic spectra for D and E indicate that the cobalt(II) species in both is tetracoordinate (Table 3). Comparison of the solid state spectra of D and E suggests that the latter contains a more distorted ligand arrangement. That is, the minor shifts in band shape observed are similar to those expected for a more "solvolyzed" structure (27). Given the empirical formula, CoL_2Cl_4, for D, the possibilities which must be considered for the solid state structure are: (*a*), $[CoL_2^{4+}][Cl^-]_4$; (*b*), a eutectic mixture of $CoLCl_3$ and LCl; and (*c*), $[L^+]_2[CoCl_4^{2-}]$; in a crystal lattice which is ionic ((*a*) or (*c*)) or pseudoionic (*b*). Possibility (*a*) is least likely because of the high formal charge of the cobalt cation, and can be ruled out because the major spectral changes which would be expected on solution do not occur. The electronic spectrum of pseudotetrahedral $CoCl_3$¶ where ¶ is a monoquaternized phosphine cation, has been described as very similar to that of tetrahedral $CoCl_4^{2-}$ (12). Thus, the electronic spectral evidence is consistent with either (*b*) or (*c*). Possibility (*b*) is less likely on the basis of i.r. spectra, since the solid state spectrum would then be a superposition of unchanged phosphonitrile chloride and the pseudotetrahedral complex spectra. This is not observed. Therefore the most likely structure for D is a lattice of phosphonitrile cations, and somewhat distorted tetrahedral $CoCl_4^{2-}$ anions. E can then be considered as a solvate containing methylene chloride "of crystallization", which further distorts the solid state $CoCl_4^{2-}$ anions from a strictly tetrahedral arrangement. A pentacoordinate cobalt(II) arrangement for E is not likely by comparison of its electronic spectrum with that reported for pentacoordinate arrangements (11). The relatively strong band expected at $\simeq 10\,500$ cm^{-1} is not observed.

3. Copper(II) Compounds; Ionic Type $[L]_2[Cu_2Cl_6]$

From the similarity to the cobalt compounds in their i.r. spectra and solubility, and the qualitative conductivity of B, the copper compounds are also ionic and possibly contain analogous copper(II) chloride anions. The same preparative system was used for monoalkylammoniumtetrachlorocuprates(II) (28) and acetamidinium tetrachlorocuprate(II) (29), which is chemical evidence for the ionic formulation as well as for the possible presence of tetracoordinate copper(II) anions.

Several tetracoordinate copper(II) chloride anions are known, and there is X-ray structural evidence for the existence of the types: discrete distorted tetrahedral, $CuCl_4^{2-}$ (20, 31–32); trigonal bipyramidal, $CuCl_5^{3-}$ (33), square planar ("long"-bonded, tetragonally distorted octahedral), $CuCl_4^{2-}$; and dimeric square planar, $Cu_2Cl_6^{2-}$ (34, 35). Electronic d–d bands and some charge-transfer bands observed for compounds containing these anions have been used to differentiate between possible arrangements. From comparison of the spectrum of B (or A, Table 4) with the spectra for these types (Table 6), it is apparent that neither is tetrahedral nor trigonal bipyramidal as the d–d bands occur at too high energies. The solid state electronic spectrum of A indicates the copper absorbing species is very similar to that which exists in methylene chloride in the absence of excess chloride ion, so that the copper species in compound A is probably a "solvated" form of that in B. Both solids probably contain square planar, or distorted square planar anions.

Thermochromic and pleochroic behavior similar to that observed for A, B, and C has been noted for solid state compounds containing tetragonal copper(II) chloride anions, either approximately square planar (29, 39–41), or distorted square planar, $Cu_2Cl_6^{2-}$ (38), and cited as evidence for the existence of this arrangement (29). However, dichroism has also been noted for compounds containing discrete flattened tetrahedral anions (19, 42). Thus, it is likely that the use of such behavior as a diagnostic tool is invalid.

The empirical formulae of A and B or C indicate that a discrete tetracoordinate anion arrangement, analogous to that proposed for D and E, does not occur, and that A and B, at least, are probably similar to the dimeric square planar compounds (Table 6).

The presence of a band at 18 500 – 18 800 cm^{-1} has been used to distinguish between dimeric

($Cu_2Cl_6^{2-}$) and discrete ($CuCl_4^{2-}$) square planar arrangements being indicative of the former (38). On the "dimer" band basis, however, A (and C) should be considered to contain $Cu_2Cl_6^{2-}$ ions, and B should not. This is unlikely, considering the ease with which B and A can be interconverted in the solid state. It is more probable that a dimeric arrangement exists for both A and B, and the "dimer" band does not indicate the $Cu_2Cl_6^{2-}$ arrangement, but the distortion from square planar symmetry.

The possibility remains that instead of a lattice of discrete anions, a pseudotetrahedral system occurs, MX_2¶X as for the quaternary phosphines (11–14). Since the electronic spectra of the phosphines (11–14) resemble those of tetrahedral cobalt(II) and nickel(II) species, a pseudotetrahedrally coordinated metal ion structure has been proposed (11–14). A similar quaternary phosphine of copper(II) would be even more distorted from this arrangement, and might possess the d–d band spectra observed for A and B. However, the cobalt(II) and nickel(II) halides required rigorously anhydrous preparative conditions, as well as excess halide ion, quite different conditions from those used to prepare the copper(II) and cobalt(II) phosphonitrile compounds. Consequently, it is preferable to formulate B and A as the ionic compounds $[L^+]_2[Cu_2Cl_6^{2-}]$ and $[L^+]_2[Cu_2Cl_6^{2-}]\cdot 2CH_3OH$.

The Copper(II) Compound, $Cu_3L_2Cl_8\cdot 2CH_3OH$

The solid state electronic spectrum of C suggests that two forms of copper(II) could be present: both tetragonally distorted from square planar, one more so than the other. It is possible that C is a methanolate containing trimeric anionic groups $Cu_3Cl_8^{2-}$, analogous to the dimeric structures proposed for A and B. Such a compound would have a similar solid state electronic spectrum to A, with smaller components from copper(II), in a completely bridged environment. The latter would also be derived from square planar symmetry and this is consistent with the electronic spectrum of C. Considering the changes in the infrared spectra of the phosphonitrile cation, on replacement of the Cl^- counterion by $Cu_2Cl_6^{2-}$, similar changes to those observed would be expected on replacement of the Cl^- by $Cu_3Cl_8^{2-}$. The crystal structure of a compound containing molecules with a related trimeric structure, $Cu_3Cl_6(CH_3CN)_2$, has been reported (43). Melting point behavior of C indicates that, on drying, decomposition occurs, so that the remaining substance is not a single compound. Thus, instead of discrete $Cu_3Cl_8^{2-}$ ions, C may contain a more complex ionic structure, involving three-dimensional bridging to form infinite chains, which decomposes on loss of methanol to a mixture containing units of B.

Further Evidence

Electron Paramagnetic Resonance: *g*-Values from e.p.r. measurements on polycrystalline samples of A, B, and C and dried copper(II) chloride are almost the same, and within the accuracy of measurement the paramagnetism is

temperature independent (Table 2). The average g-value is 2.10 ± 0.01, within the range for an "unpaired" copper(II) electron in a complex molecule. However, this does not rule out the dimeric anion arrangement. No anomalies in the magnetic susceptibility of $CsCuCl_3$ due to exchange interactions have been observed down to 80 °K (44), and g-values from e.p.r. measurements at room temperature on other compounds containing $Cu_2Cl_6^{2-}$ dimers are similar to those for square planar (40) or trigonal bipyramidal (45) chloride anion arrangements, and lie within the "normal" range.

Metal-Chlorine Vibrational Stretching Modes: Some assignments for copper(II) and tetrahedral cobalt(II) chloride anions for solid state measurements are shown in Table 7 in comparison with tentative assignments for the ionic phosphonitrile prepared. Assignments of bands at 304 and 290 cm^{-1} to cobalt(II) chloride stretching modes agrees with those reported for tetrahedral tetrachlorocobaltate(II) compounds (47). Considering that the anion arrangement for D is flattened tetrahedral in the solid state, it is likely that two bands in the expected region are observed. Thus, the ionic structures suggested for D and E are substantiated. If B contains dimeric $Cu_2Cl_6^{2-}$ anions, a third band (attributable to a bridging chloride mode) should occur at lower energy, though the limits of measurement may have precluded its observation. The positions of the bands which are observed, 315 and 300 cm^{-1}, suggest that the arrangement for B could be tetragonally distorted square planar. At most, it can be concluded that these assignments are consistent with other evidence in support of the ionic structures proposed.

Chelate Formation for Aminodiphenylphosphonitrileaminodiphenylphosphonium Ion Reassessed

Initially, it was considered that the positive charge repulsion hindrance to chelation or coordination via the amino groups might not prevent formation of covalent bonds with a positive transition metal ion. Based on the observation of a single ^{31}P n.m.r. interaction and only a single broad interaction attributable to the nitrogen hydrogen atoms, the phosphorus atoms are equivalent, and the positive charge can be considered as delocalized over the PNP portion of the skeleton (49).

The recent preliminary crystal structure report (50) indicates a possible reason for the non-occurrence of chelation or coordination. The phosphorus–nitrogen interatomic distances for the PNP portion are equal and short (1.57 Å), comparable with those of cyclic phosphonitriles, as expected for a delocalized multiple bonding system. However, the phosphorus–nitrogen distance for the P—NH_2 bonds are also short (1.65 Å) compared with that usually considered as the single bond value (1.78 Å). They are of the order calculated for a phosphorus–nitrogen "pure" double bond (1.64 Å) (51). This is evidence for a π_s-type bond system involving the whole phosphorus–nitrogen skeleton (51). Thus, the amino group lone-pairs must be even

less "available" for donation to any external acceptor site. This substantiates the proposal of ionic structures for the copper(II) and cobalt(II) compounds prepared. It also indicates that formation of a covalent bond to a sulfur atom, for example, through an addition mechanism, would require substantial rearrangement of the charge distribution for the phosphonitrile, possibly resulting in a destabilized skeleton. This might favor chain polymerization, thus contributing to the problem of obtaining an experimental compromise between conditions necessary for reaction and also favorable to intramolecular cyclization.

Isotope Effects and Hydrogen Yields in the Radiolysis of H_2O–D_2O Mixtures at Very High Dose Rates[1]

A. W. BOYD, C. WILLIS,[2] AND G. C. LALOR[3]

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received April 15, 1971

Total hydrogen yields and their isotopic ratios have been measured in the single pulse, high dose rate radiolysis of H_2O–D_2O mixtures and acidic, basic, and nitrous oxide solutions. The yield from D_2O is $\sim 11\%$ lower than in H_2O at 7×10^{27} eV g^{-1} s^{-1}. In acid solutions the yields from H_2O and D_2O are the same within 5%. This yield, $G(H_2) = 1.15 \pm 0.05$ has been used to derive a value of $k_{H+OH} = 2.5 \pm 0.3 \times 10^{10}$ M^{-1} s^{-1}.

Using the literature values for primary yield data and for the reaction rate constants, values of α have been determined for the various hydrogen forming processes by computer calculation. We obtain values for hydrogen formation of $\alpha_{spur} = 2.1 \pm 0.1$, $\alpha_{e+e} = 6.0 \pm 0.1$, α_{H+H} (effective) $= 3.2 \pm 0.1$, and α_{e+H} (effective) $= 1.3 \pm 0.2$. Detailed consideration of the mechanisms involved suggest that there are little or no isotopic preferences in H + H and e + H reactions.

Les rendements totaux en hydrogène et leurs rapports isotopiques ont été mesurés par radiolyse à un seul faisceau et à vitesse à haute dose de mélanges H_2O–D_2O et de solutions acides, basiques et de solutions d'oxyde nitreux. Le rendement à partir de D_2O est de environ 11% plus faible que dans H_2O à 7×10^{27} eV g^{-1} s^{-1}. En solutions acides, les rendements à partir de H_2O et D_2O sont les mêmes à 5% près. Ce rendement, $G(H_2) = 1.15 \pm 0.05$ a été utilisé pour obtenir une valeur de $k_{H+OH} = 2.5 \pm 0.3 \times 10^{10}$ M^{-1} s^{-1}.

En utilisant les valeurs de la littérature pour les données des rendements primaires et pour les constantes de vitesse de réaction, des valeurs de α ont été déterminées pour les nombreux procédés de formation de l'hydrogène par calculateur électronique. Nous obtenons des valeurs pour la formation de l'hydrogène $\alpha_{spur} = 2.1 \pm 0.1$, $\alpha_{e+e} = 6.0 \pm 0.1$, α_{H+H} (effectif) $= 3.2 \pm 0.1$ et α_{e+H} (effectif) $= 1.3 \pm 0.2$. Une analyse détaillée des mécanismes impliqués permet d'avancer qu'il y a peu de préférences ou des préférences non isotopiques dans les réactions H + H et e + H.

Canadian Journal of Chemistry, **50**, 83 (1972)

Introduction

Isotope effects in hydrogen formation in the radiolysis of H_2O–D_2O mixtures can be divided into three classes: (*a*) isotope effects in the spur processes leading to molecular and atomic hydrogen, (*b*) isotope effects in the bimolecular reactions of e_{aq}^- and H atoms which form hydrogen, (*c*) isotope effects in other reactions involving e_{aq}^- and H atoms which do not directly form hydrogen. The reactions of importance in these three classes are

(*a*)

[1] $H_2O \rightsquigarrow H_2$ } spur processes

[2] $H_2O \rightsquigarrow H$ }

(*b*)

[3] $e^- + e^- \rightarrow H_2 + 2OH^-$

[4] $e^- + H \rightarrow H_2 + OH^-$

[5] $H + H \rightarrow H_2$

(*c*)

[6] $e^- + H_3O^+ \rightarrow H + H_2O$

[7] $OH + H_2 \rightarrow H + H_2O$

[8] $H + OH \rightarrow H_2O$

[9] $H + H_2O_2 \rightarrow OH + H_2O$

[10] $H + O_2 \rightarrow HO_2$

[11] $H + HO_2 \rightarrow H_2O_2$

[12] $H + OH^- \rightarrow e^-$

Reactions of e^- and OH, other than those producing H atoms, are not included in (*a*) and (*c*), as these species rapidly equilibrate with the bulk solvent whereas H atoms do not. A comprehensive review of isotope effects has been given by Anbar and Meyerstein (1).

The isotope effect in reaction 1, α_1, has been shown to be 2.2 ± 0.2 (1) for a variety of conditions in low linear energy transfer (l.e.t.) radiolysis.[4] Values of $\alpha_2 = 2.6 \pm 0.2$ (1) have been determined from the radiolysis of solutions of radical scavengers where conversion of e^- to

H atoms (reaction 6) is suppressed. By addition of a deuterated compound from which H atoms can abstract, reaction 13, the isotope effect in

[13] $\quad H(\text{or } D) + RD \rightarrow HD(\text{or } D_2) + R\cdot$

reaction 2 can be derived from the ratio of HD to D_2 in the hydrogen produced. Since H atoms are not in equilibrium with the bulk solvent and since they all must undergo reaction 13, any isotope effect in reaction 13 itself will not be reflected in the ratio of HD to D_2.

The most important reaction in class *c* is [6]. The isotope effect in this reaction, $\alpha_6 = 3.5 \pm 0.3$, has been determined in the same way as α_2 by irradiating acidic solutions of RD in H_2O–D_2O mixtures (1). Results from both radiolysis and photodetachment are in good agreement (2, 3).

Since all other contributions to the hydrogen yield are completely suppressed by the addition of radical scavengers the measurement of α_1 is unambiguous. The derivation of α_2 and α_6 depend upon both the contribution of these and that of reaction 1 to the hydrogen yield but these contributions can be determined with good precision. Values of α_1, α_2, and α_6 should then be meaningful. The determination of α_3, α_4, and α_5 is more complex. Not only are the contributions of these reactions often uncertain but also they reflect isotope effects in other reactions.

Anbar and Meyerstein have reported determinations of α_3 by studying the reactions of electrons produced by photodetachment (4) and by radiolysis (5). In the former paper (4) they obtained values of α_3 of 3.9 ± 0.2, 4.7 ± 0.2, and 5.5 ± 0.2 for 25, 50, and 75% D_2O in H_2O, but state their values to be lower limits. The uncertainty is due to reactions of OH radicals with the hydrogen formed (reaction 7). In the latter paper (5) they irradiated solutions of 0.1 *M* CD_3OH in H_2O–D_2O mixtures at pH = 14 and a dose rate of $\sim 4 \times 10^{23}$ eV g^{-1} s^{-1}. Under these conditions all the OH radicals react with the CD_3OH and the H atoms are converted to e^- (reaction 12). Their measured α value, 3.4 to 3.7, was corrected for the contribution of α_1 ($G_{H_2} = 0.45$) by assuming the yield from reaction 3 was $\frac{1}{2}(G_e + G_H - G_{H_2O_2}) = 1.2$, giving $\alpha_3 = 4.6 \pm 0.2$. This neglects the reactions of e^- with O_2, CO_2, and other electron scavenging impurities which may be significant at their dose rates. Thus their radiolytic values of α_3 should also be considered as lower limits.

Using the same system they also derived values of α_4 and α_5 (5). They report α_4(effective) $= 1.5 \pm 0.3$ using rough estimates of the contributions of reactions 1, 3, 4, and 5 to the total hydrogen yield. This should be considered an effective value because isotope effects in the formation of H atoms are not taken into account.

Under their conditions, at p$H = 1.1$, all e^- form H atoms by reaction 6. A value of α_5(effective) $= 3.5 \pm 0.2$ was obtained by assuming the contribution of reaction 5 to the total hydrogen yield to be $\frac{1}{2}(G_e + G_H) = 1.6$. This means that all the H atoms formed disappear by reaction 5. Therefore any isotope effect in reaction 5 cannot be reflected in the results. What is then being measured is a weighted mean of α_2 and α_6.

From the above discussion it is obvious that further work on the determination of α_3, α_4, and α_5 is desirable.

We have previously shown (6) that single pulse irradiations of pure H_2O at dose rates of 10^{26} to 10^{28} eV g^{-1} s^{-1} give hydrogen yields with $G(H_2) \approx 1$. These are made up of the molecular hydrogen yield and the reactions outside the spurs of e^- and H. They are in agreement with computer calculations (7) of the yields from rate constant and primary yield data. These computer calculations also give the contributions of the various reactions. In this paper we describe the determination of hydrogen yields and H/D separation factors in the irradiation of H_2O–D_2O solutions under the above conditions. By combining the measured values of the isotopic composition with the calculated contributions we can estimate α_1, α_3, α_4, and α_5.

Experimental

Irradiations

As in ref. 6, the irradiations were done with a Febetron 705.[5] Pure H_2O, D_2O, and H_2O–D_2O mixtures and solutions containing N_2O were irradiated in the stainless steel cells described in ref. 6. The acidic and basic solutions were irradiated by putting 2 to 3 ml of solution in the 75 ml quartz cells used for irradiation of gases (8). Quartz cells filled with liquid shatter when irradiated with high intensity electron pulses (6). With this partial filling technique only one cell was shattered in 25 irradiations.

Dosimetry

Previously, good agreement was obtained between experimental yields (based on calorimetric dosimetry (9)) and

calculated yields for hydrogen from water for single pulses from 0.1 to 8.0 Mrad per pulse giving dose rates of 10^{26}–10^{28} eV $g^{-1}s^{-1}$ (6). In the present work the hydrogen from H_2O was used to determine the absorbed dose in H_2O–D_2O mixtures. The energy absorbed per unit volume of D_2O was taken to be the same as that for light water. The increase in density in going from H_2O to D_2O compensates almost exactly for the decrease in stopping power per gram.

Analyses

The volume of radiolytic gas, non-condensible at 77 °K, was measured by conventional vacuum line techniques using a McLeod gauge. The H_2, HD, and D_2 ratios and total hydrogen content of this gas were determined by mass spectrometry.

The mass spectrometers were calibrated with known mixtures of H_2, HD, and D_2. Mixtures for the range 20–95% H were prepared by equilibrating appropriate mixtures of H_2 and D_2 on a platinum filament at 900–930 °C.

Most of the work reported here was obtained using a CEC-21-130[6] mass spectrometer. To obtain an accurate value of the isotopic composition of the hydrogen samples, we used essentially three different mass spectrometers, the CEC-21-130 and a CEC-21-614[6] with either a type 614-1 or a 614-2 cycloid tube. The radiolytic hydrogen from a mixture of equal volumes of H_2O and D_2O was compared using these instruments to a standard mixture of approximately the same composition (H_2:HD:D_2::1.0:0.8:0.2) at the same inlet pressure. In these determinations, standard mixtures and radiolytic samples were analyzed alternately.

The radiolytic samples containing very low deuterium concentrations were compared with a standard hydrogen mixture containing 120.9 p.p.m. D. This was used to attempt to correct for both memory effects of the mass spectrometer and also for the contribution of H_3^+ to the $m/e = 3$ peak. Again pressures of the standard were matched to those of the samples and standard and sample were analyzed alternately. For radiolytic samples containing very high deuterium concentrations, comparison was made with a standard deuterium sample of 99.682% isotopic purity. Both H_2 and D_2 standards were originally analyzed by conversion to water and determining the isotopic content of the water by infrared analysis. Although the errors at both low and high deuterium concentrations were significantly reduced by these standardizations, the remaining errors are much larger than those for intermediate concentrations. Further reductions in these errors could only be made by using a large range of low and high deuterium standards. This was not done because of the difficulty of obtaining these standards.

The precision of the measured total hydrogen yields depends only on the reproducibility of the experimental techniques as basically a comparative measurement was involved. Exchange in the mass-spectrometer does not significantly affect the hydrogen to nitrogen, oxygen sensitivities. Overall errors should be less than ±2%. The errors involved in the α value determinations are much more difficult to assess but should be less than ±5% over most of the range of composition.

Materials

Both the H_2O (isotopic D content 150 p.p.m.) and D_2O (isotopic purity 99.58 and 99.949%) were pre-irradiated and triply distilled. Gases non-condensible at 77 °K were removed by several freeze–pump–thaw cycles. The N_2O was McDuff medical grade and was also freed of gases non-condensible at 77 °K. The acidic and basic solutions were prepared by diluting "acculute" standard solutions (Anachemia Chemicals) of 2 *N* H_2SO_4 and 2 *N* NaOH with appropriate H_2O–D_2O mixtures, making corrections for the isotopic dilution introduced by the solutes.

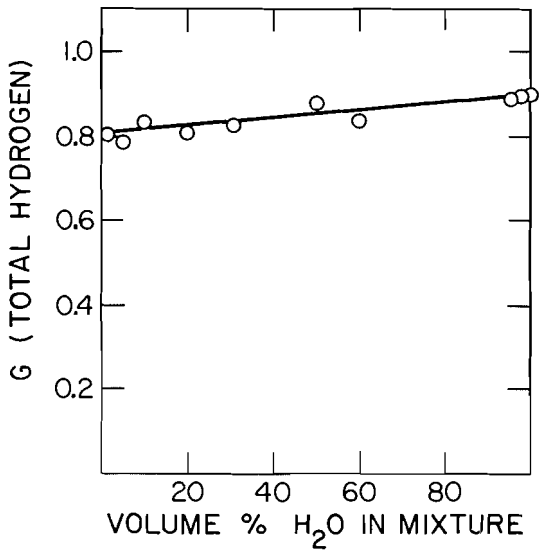

FIG. 1. Total hydrogen yield from H_2O–D_2O mixtures at 7×10^{27} eV g^{-1} s^{-1}.

Results

Pure H_2O–D_2O Mixtures

The total yield of hydrogen (H_2, HD, and D_2) from single pulse irradiations of 3.5×10^{20} eV g^{-1} (7×10^{27} eV g^{-1} s^{-1}) as a function of H_2O concentration is shown in Fig. 1. The yield from pure H_2O at this dose rate and dose per pulse is $G(H_2) = 0.90$ (6). This decreases to $G(D_2) = 0.81$ for pure D_2O.

The values of $\alpha = (H/D)_{\text{radiolytic hydrogen}}/(H/D)_{H_2O-D_2O\text{ solution}}$ and $K = (HD)^2/(H_2)(D_2)$ (radiolytic hydrogen) as a function of H_2O concentration at dose rates of 7×10^{27} and 5×10^{26} eV g^{-1} s^{-1} are shown in Figs. 2 and 3, respectively. The uncertainties in the α values at both high and low H_2O concentrations are due to the mass spectrometric exchange discussed above. Values for *K* are given only for intermediate concentrations where exchange does not contribute significantly. The values of *K* obtained, 3.7–3.8, are higher than the calculated equilibrium value at room temperature, 3.25 (1), but

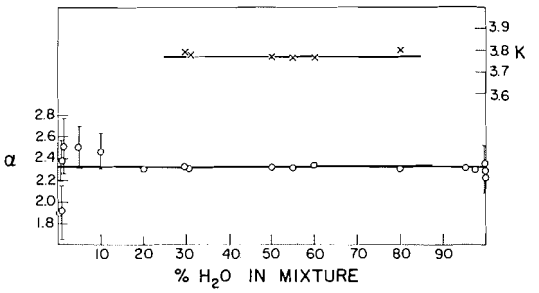

FIG. 2. α and K values in the radiolysis of H_2O–D_2O mixtures at 7×10^{27} eV g^{-1} s^{-1}. The uncertainties are represented by the circles or by the error bars.

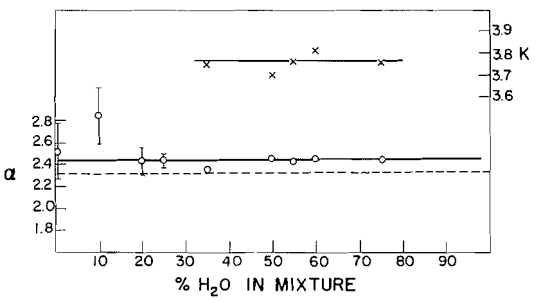

FIG. 3. α and K values in the radiolysis of H_2O–D_2O mixtures at 5×10^{26} eV g^{-1} s^{-1}. --- line from 7×10^{27} eV g^{-1} s^{-1}.

are close to a value of 4.0 expected on a statistical basis. As can be seen in Fig. 3, the α value at 5×10^{26} eV g^{-1} s^{-1} is significantly higher than that at 7×10^{27} eV g^{-1} s^{-1}.

The α value obtained using three different mass spectrometers and a 50 mol% H_2O–D_2O mixture are given in Table 1. The agreement between the α values obtained using the three different mass spectrometers is most satisfactory and gives confidence in the accuracy of the measurements, at least for 50:50 mixtures.

H_2O–D_2O–N_2O Mixtures

At 7×10^{27} eV g^{-1} s^{-1} the addition of N_2O up to 0.05 M has little effect on the hydrogen yield (6) from H_2O. The effect of N_2O on the hydrogen yield from mixtures of H_2O and D_2O is shown in Fig. 4 and the effect of N_2O on α and K for the same mixtures is shown in Fig. 5 both for a dose rate of 5×10^{26}.

H_2O–D_2O with H_2SO_4 or NaOH

The effect of pH on α in the irradiation of mixtures of equal volumes of H_2O and D_2O is shown in Fig. 6. The dose and dose rate in these

irradiations are estimated to be 7×10^{19} eV g^{-1} and 1×10^{27} eV g^{-1} s^{-1}, respectively.

Figure 7 shows the dependence of measured α values on concentration of H_2O for 0.2 *N* H_2SO_4 solutions. The total measured yield of hydrogen from these samples gave $G(H_2)_{total} = 1.15 \pm 0.05$ over the whole range of H_2O–D_2O concentrations.

Discussion

Hydrogen Yields from H_2O and D_2O

In our previous paper on the high dose rate radiolysis of liquid water (6) we obtained good agreement between measured values and those calculated from primary yield and reaction rate constant data. From the present work, as shown in Fig. 1, in going from pure H_2O to pure D_2O there is a decrease in the total hydrogen yield of $\sim 11\%$ at the highest dose rate of 7×10^{27} eV g^{-1} s^{-1}.

The yields of the primary radiolytic species in H_2O and D_2O and the rate constants for the reactions of these species that are important at Febetron dose rates are listed in Tables 2 and 3. The yield of hydrogen calculated with the values in these tables and the computer program, WR 16 of Schmidt (7), for the single pulse irradiations at 7×10^{27} eV g^{-1} s^{-1} is $G(H_2) = 0.90$ for both H_2O and D_2O.

The accuracy of the results obtained with the computer program is dependent on the values of the rate constants and primary yields used. It is also dependent on the applicability of calculations based on a homogeneous distribution of reactants to the high dose rate situation when reactions take place while the spurs expand, an essentially non-homogeneous situation. We have already discussed this (6) and concluded that, for pure systems, the calculated final yields should not be seriously in error. As stated the precision of the measured yields is estimated to be within $\pm 2\%$. The difference between the measured value of $G(D_2) = 0.81$ and the calculated value of $G(D_2) = 0.90$ is most probably due to errors in the values used for the primary yields and rate constants. The errors in the experimental primary yield data seem to be much less than for the rate constant data. To determine the effect of uncertainties in the latter we have calculated hydrogen yields for various values of the rate constants of the most important reactions. The results of these are shown in Table 4. Changes of 20% in a few of these rate constants will reduce the calculated value of $G(D_2)$ to the observed value and, within the precision of the rate constant data, it is easy to obtain calculated yields which agree with our experimental data. Any choice of values for these rate constants to give $G(D_2) = 0.8$ is somewhat arbitrary. We used the following values for H_2O and D_2O for the important reactions which are listed in Table 4: $k_{3H} = k_{3D} = 4.5 \times 10^9$; $k_{4H} = 2.5 \times 10^{10}$, $k_{4D} = 2.0 \times 10^{10}$; $k_{5H} = 1.0 \times 10^{10}$, $k_{5D} = 8.0 \times 10^9$; $k_{6H} = 2.2 \times 10^{10}$; $k_{6D} = 1.7 \times 10^{10}$; $k_{8H} = 2.5 \times 10^{10}$, $k_{8D} = 2.4 \times 10^{10}$; $k_{14H} = 3.0 \times 10^{10}$, $k_{14D} = 2.8 \times 10^{10}$; $k_{15H} = k_{15D} = 1.2 \times 10^{10}$; $k_{16H} = 1.43 \times 10^{11}$, $k_{16D} = 1.23 \times 10^{11}$; $k_{17H} = 5.0 \times 10^9$, $k_{17D} = 4.0 \times 10^9$. All have units l mol^{-1} s^{-1}; suffix H signifies H_2O, D signifies D_2O. The only values which are different by more than the present uncertainty in the value for H_2O are k_{6D} and k_{16D} but these are in line with experimentally observed differences, see Table 3.

In 0.2 *N* acid solutions we find $G(H_2)_{total} = 1.15 \pm 0.05$ in both H_2O and D_2O. This value

α *Values for* H_2O–D_2O *Mixtures*

General

Our experimental observations of the isotope effects in hydrogen formation consist of α values for five different systems. These are listed in Table 5. As shown in Figs. 2, 3, and 7 these values appear to be independent of H_2O concentration from <10 to >90% H_2O in D_2O.

The hydrogen from water irradiated under our conditions results from four processes

[1] $H_2O \rightsquigarrow H_2$

[3] $e^- + e^- \rightarrow H_2$

[4] $e^- + H \rightarrow H_2$

[5] $H + H \rightarrow H_2$

In H_2O or D_2O solutions the contributions of each of these to the hydrogen yield can be calculated with the computer program within the accuracy of the data in Tables 2 and 3.

As we have discussed in (6) the non-homogeneous part of the reaction sequence leads to errors in the calculations for other than pure water but for limiting conditions these errors are small. In the following discussion we shall consider in turn the N_2O, the acidic, and the basic solutions. The α values for the individual reactions thus obtained will be applied to the mixtures of "pure" D_2O–H_2O. To calculate the effective contributions from mixtures we shall use the calculations for D_2O and H_2O and take the mean.

N_2O Solutions

For conditions identical to those of the present experiments the effective rate constant for reaction 25 was shown to be $2 \times 10^9\ M^{-1}\ s^{-1}$ (6).

[25] $N_2O + e^- \rightarrow N_2 + OH + OH^-$

Using this value the calculated effect of 0.05 *M* N_2O in both H_2O and D_2O is to reduce the total contribution of reactions 3, 4, and 5 to the hydrogen yield to less than 10%. The reduction in [5] is due to the increased concentration of OH radicals in the system and the consequent increase in the reaction H + OH. The calculation is supported by the measured reduction of the total hydrogen yield in N_2O solutions to $G(H_2) \approx 0.45$, which is paralleled by the reduction in the measured α values. Since

$$\alpha_{\text{measured}} = \alpha_1 f_1 + \alpha_3 f_3 + \alpha_4 f_4 + \alpha_5 f_5$$

where $f\alpha$ is the fractional contribution to the hydrogen yield of reaction [*a*],

[26] $$\alpha_1 = \frac{2.11 - 0.1\,(\text{mean effective } \alpha \text{ for [3], [4], and [5]})}{0.9}$$

Assuming that the mean α for [3], [4], and [5] is 2 ± 1 we have $\alpha(\text{spur}) = 2.1 \pm 0.1$. This is in good agreement with previous work (1).

Acidic Solutions

In acid solutions the electron reacts with H_3O^+ giving H atoms and under limiting conditions hydrogen is formed only by reactions 1 and 5. Using the calculated contributions of these two reactions to the hydrogen yield an effective value for α_5 can be obtained

[27] $$\alpha_5(\text{effective}) = \frac{2.82 - 0.37(2.1)}{0.63} = 3.24 \pm 0.06$$

Relating this effective α value to the isotope effects in reaction 5 is complex. The H atoms reacting in reaction 5 are produced both by reactions 2 and 6, each of which has a large isotope effect, $\alpha_2 = 2.6$ and $\alpha_6 = 3.5$. Since H atoms are not in equilibrium with the bulk solvent, their initial concentration will differ from the H_2O/D_2O ratio by the weighted mean of α_2 and α_6, which for acid solutions is $\overline{\alpha_{2,6}} = 3.3$. The observed effective α value is a function of this initial ratio and of the true isotope effects in reactions 5 and also in reaction 8.

Reaction 5 can be written

[5*a*] $H + H \rightarrow H_2$

[5*b*] $H + D \rightarrow HD$

[5*c*] $D + D \rightarrow D_2$

(4)	$e^- + H$	0.236	0.325	0.331	0.188	0.314	0.316
(5)	H+H	0.021	0.089	0.104	0.014	0.067	0.081

so that,

[28] $$\alpha_5(\text{true}) = \frac{2k_{5a}[H]^2 + k_{5b}[H][D]}{2k_{5c}[D]^2 + k_{5b}[H][D]} [H]/[D] = \frac{2k_{5a}[H]/[D] + k_{5b}}{2k_{5c} + k_{5b}[H]/[D]}$$

Since under our pulsed conditions we do not have stationary state kinetics the above equation cannot be directly applied. What we have done is to compare our experimental values of α in acid solutions with the computer calculated values based on assumed rate constants. We have assumed H and D atoms are produced from H_2O–D_2O 0.2 *N* acid mixtures with an isotope effect of $\overline{\alpha_{2,6}} = 3.3$ and that $k_{5a} = 1.0 \times 10^{10}$ M^{-1} s^{-1}, $k_{5b} = 1.8 \times 10^{10}$ M^{-1} s^{-1}, $k_{5c} = 0.8 \times 10^{10}$ M^{-1} s^{-1}, $k_{8H} = 2.5 \times 10^{10}$ M^{-1} s^{-1}, $k_{8D} = 2.0 \times 10^{10}$ M^{-1} s^{-1}, and $k_{17} = 0.5 \times 10^{10}$ M^{-1} s^{-1}. The value of k_{5b} is taken as twice the average of k_{5a} and k_{5c}. The value of α in acid solutions calculated from these data is 2.74 ± 0.02 over the concentration range in Fig. 7. (The calculated α_5 value will be dependent on the ratio of H_2O to D_2O unless $k_{5a} \approx k_{5c} \approx 0.5k_{5b}$.) Exact agreement with the experimental value of $\alpha = 2.82$ can be obtained by increasing $\overline{\alpha_{2,6}}$ to 3.5. These results imply that there is little isotopic preference in reaction 5.

Alkaline Solutions

The limiting condition in which all the hydrogen atoms are converted to electrons cannot be obtained at our dose rates. The computer calculations indicate however that at p$H = 12$, reaction 6 is completely suppressed and even at p$H = 14$ less than 10% of H atoms react via [12]. Since inhomogeneities will reduce the effective concentration of OH^-, the limiting condition can be considered to be where e and H are not interconverted and react in proportion to their primary yields. Assuming this to be the limiting condition the computer calculated contributions of reactions 1, 3, 4, and 5 are given in Table 6. We have not taken into account the uncertainty which exists at high p*H* due to the ionization of the OH radical.

From these values using values for α_1 and α_5 we can derive relationships between α_3 and α_4 for H_2O and D_2O, respectively. For H_2O

[29] $$\alpha_{\text{measured}} = 0.55\alpha_1 + 0.193\alpha_3 + 0.236\alpha_4 + 0.021\alpha_5$$

Taking α_5(effective) (p*H* 14) $= \overline{\alpha_{2,6}}$(p*H* 14) $= \alpha_2 = 2.6$, $\alpha_{\text{measured}} = 2.70$, and $\alpha_1 = 2.1$

[30] $$\alpha_3 = 7.72 - 1.22\alpha_4$$

Similarly for D_2O

[31] $$\alpha_3 = 7.05 - 0.94\alpha_4$$

"Pure" H_2O–D_2O Mixtures

For pure H_2O and D_2O the calculated contributions to the hydrogen yields at low (LDR) and high dose rates (HDR) are given in Table 6. The relationships between α_3 and α_4 for the four sets of conditions are:

H_2O

[32] HDR $\alpha_3 = 10.87 - 3.49\alpha_4$

[33] LDR $\alpha_3 = 10.41 - 2.96\alpha_4$

D_2O

[34] HDR $\alpha_3 = 8.76 - 2.57\alpha_4$

[35] LDR $\alpha_3 = 8.43 - 2.16\alpha_4$

In all four expressions α_5 has been taken to be $\overline{\alpha_{2,6}}$ (p*H* 7) = 3.1.

Calculation of α_3 and α_4

Assuming effective values of α_3 and α_4 do not vary between p*H* 7 and p*H* 14 eq. 30 can be com-

bined with eq. 32 or eq. 33 and eq. 31 with eq. 34 or eq. 35 to obtain four sets of values. The averages of these four sets are

$$\alpha_3(\text{effective}) = 5.98 \pm 0.07$$
$$\alpha_4(\text{effective}) = 1.28 \pm 0.19$$

This value of $\alpha_3 = 6.0$ should be a "true" value. Electrons are solvated in less than 20 ps (14) and equilibration of the solvent shell with the bulk solvent should be very rapid. The relatively high value of α_3, particularly since $k_{3H} \simeq k_{3D}$, is generally considered (4) to be due to preferential decomposition of the solvated dimer $(e_{aq}^-)_2$ transition state to form light hydrogen. A similar argument is used to explain $\alpha_6 = 3.5$ but it is by no means certain that a solvated complex is formed in reaction 4.

It has been proposed (15) that reaction 4 takes place via a hydride mechanism involving formation of H^- and reaction of this with the solvent to give hydrogen as in reaction 36.

[36] $$H^- + H_2O \rightarrow H_2 + OH^-$$

Also it has been demonstrated that reaction 36 has no isotope effect.

Accepting this mechanism reaction 4 can be written

[4*a*] $$e + (H)_{solvent} + H \rightarrow H_2$$
[4*b*] $$e + (H)_{solvent} + D \rightarrow HD$$
[4*c*] $$e + (D)_{solvent} + H \rightarrow HD$$
[4*d*] $$e + (D)_{solvent} + D \rightarrow D_2$$

Assuming there is no true isotope effect in reaction 4, *i.e.* $k_{4a} = k_{4b} = k_{4c} = k_{4d}$ and that $[H]/[D] = \overline{\alpha_{2,6}}\ (H/D)_{solvent}$ and $(H)_{solvent}/(D)_{solvent} = (H/D)_{solvent}$ for stationary state conditions,

[37] $$\alpha_4(\text{effective}) = \frac{2\overline{\alpha_{2,6}}(H/D)_{solvent} + \overline{\alpha_{2,6}} + 1}{2 + (1 + \overline{\alpha_{2,6}})(H/D)_{solvent}}$$

The terms $(H)_{solvent}$, $(D)_{solvent}$ in reactions 4*a* to 4*d* refer to the solvent with which the H^- ion will react on its formation. If

$$\overline{\alpha_{2,6}} = 1$$

then

$$\alpha_4(\text{effective}) = 1 \text{ at any ratio of } H_2O/D_2O$$

but taking

$$\alpha_{2,6} = 3.0$$

as the approximation mean of the values at p*H* 7 and p*H* 14, eq. 37 becomes

[38] $$\alpha_4(\text{effective}) = \frac{2 + 3(H/D)_{solvent}}{1 + 2(H/D)_{solvent}}$$

This equation indicates that α_4 will vary between 2 and 1.5 over the total range of H_2O concentration for this ideal steady state condition. Under our conditions the variation would presumably be reduced and be within our experimental uncertainty.

Our experimentally derived value of $\alpha_4 = 1.3 \pm 0.2$ is close to the value given by eq. 38 and implies that in reaction 4 as well as reaction 5 the true isotope effect is very small and the observed effective α values are due to isotope effects in precursor reactions.

We can compare our values of α_3 and α_4 to those obtained in previous work. Our value of $\alpha_3 = 6.0$ is higher than the value of Anbar and Meyerstein (4, 5) of about 4.6 but as we discussed in the introduction, their value should properly be considered a lower limit. Also our value of $\alpha_4(\text{effective}) \simeq 1.3 \pm 0.2$ for p*H* 7 and 14 is not too different from the value found by these workers (5) ($\alpha = 1.5 \pm 0.3$).

Conclusions

Our value of $\alpha_1 = 2.1 \pm 0.1$ is in good agreement with the values obtained at low dose rates. Since the previous values of α_3 were lower limits the fact that our value $\alpha_3 = 6.0 \pm 0.1$ is higher is not unexpected. Our observed effective α values for reactions 4 and 5 are in good agreement with previous work. From our treatment of the kinetics of these reactions it is suggested that there is little or no isotopic preference in these reactions. The fairly high effective α values in these reactions are attributed to isotope effects in the formation of H atoms.

We thank Mr. W. M. Thurston, General Chemistry Branch, CRNL for providing the standardized hydrogen, deuterium, and D_2O samples and Mr. W. J. Olmstead, also of the General Chemistry Branch, for his extensive help in preparing reliable H_2:HD:D_2 standards and his help and advice in our mass spectrometric calibrations.

We are also very grateful to Dr. J. W. Fletcher, Physical Chemistry Branch, CRNL, for many helpful discussions which greatly enhanced our understanding of the subject in preparing the manuscript.

The Crystal and Molecular Structure of 3-Chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idose

F. W. B. EINSTEIN AND K. N. SLESSOR

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received August 4, 1971

The crystal and molecular structure of 3-chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idose has been determined from three dimensional X-ray data collected by counter methods. The structure was refined by full-matrix least-squares techniques to a conventional *R* factor of 5.7% for the 817 observed reflections. The compound crystallizes in the orthorhombic space group $P2_12_12_1$ with four molecules in a cell of dimensions $a = 9.744(6)$, $b = 26.76(2)$, $c = 5.403(3)$ Å.

The structure analysis has served to confirm the site of halogenation and that it occurs stereospecifically. The conformation of the furan ring is an envelope arrangement with C(4) displaced from the mean plane.

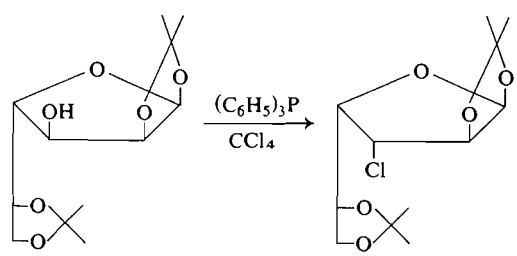
La structure cristalline et moléculaire du 3-chloro-3-déoxy-1,2;5,6-di-*O*-isopropylidène-β-D-idose a été déterminée à partir des données tridimensionnelles de rayons-X obtenues par des méthodes de comptage. La structure a été affinée par moindres carrés (matrice complète) jusqu'à un facteur d'accord $R = 5.7\%$ pour 817 réflexions observées. Le composé cristallise dans le système orthorhombique groupe d'espace $P2_12_12_1$, avec quatre molécules dans une maille de dimensions $a = 9.744(6)$, $b = 26.76(2)$, $c = 5.403(3)$ Å.

La détermination de la structure a servi à confirmer le site de l'halogénation ainsi que le fait de sa stéréospécificité. La conformation du noyau du furanne est un arrangement en enveloppe avec le C_4 déplacé par rapport au plan central.

Canadian Journal of Chemistry, **50**, 93 (1972)

Introduction

It has been found that some procedures (1, 2) for halogenation of sugars have resulted in the rearrangement of the acetal linkage. In order to both establish unequivocally the position of chlorination in the triphenylphosphine/carbon tetrachloride (TPP/CCl_4) reaction (3) with 1,2;5,6-di-*O*-isopropylidene-β-D-talose (**1**), and also to examine the detailed conformation of the molecule we have determined the crystal structure of the title compound (**2**).



1 **2**

Experimental

Compound **2** was prepared by reacting 1,2;5,6-di-*O*-isopropylidene-β-D-talose with TPP/CCl_4 (3). Colorless needle-shaped single crystals suitable for diffraction studies were obtained by recrystallization from petroleum ether (b.p. 30–60°). Weissenberg photographs of the nets *hk*0–*hk*2 inclusive using CrKα radiation together with precession photographs of the zones *h*0*l*, and 0*kl* using MoKα radiation, showed systematic absences for *h*00: $h = 2n + 1$, 0*k*0: $k = 2n + 1$, 00*l*: $l = 2n + 1$. This combined with the Laue group *mmm*, indicated unambiguously the space group $P2_12_12_1$.

Crystal Data

$C_{12}H_{19}ClO_5$ f.w. = 278.7

Orthorhombic, $a = 9.744(6)$, $b = 26.76(2)$, $c = 5.403(3)$ Å, $V = 1408.8$ Å^3, ρo 1.27 g cm^{-3}, $Z = 4$, ρc 1.31 g cm^{-3}, 22 °C, μ(MoKα) = 2.9 cm^{-1}, λMoKα = 0.7107 Å.

Two crystals were used to provide the diffraction data; the crystal used for intensity measurements had dimensions 0.14 × 0.11 × 0.51 mm. The direction of greater elongation (*c* axis) was parallel to Φ. Cell constants were determined using MoKβ radiation $\lambda = 0.63225$ Å by applying a least-squares fit to 12 high angle reflections (the numbers in parentheses are the estimated standard errors).

Reflection intensities for the unique set of intensity data were manually measured using a Picker 4 circle goniostat equipped with our own semiautomation. Niobium filtered MoKα radiation was used in conjunction with a scintillation detector and pulse-height analysis. Measurements were made using a 1.5° take-off angle with a symmetrical θ–2θ scan of 1.6° width (carried out at a rate of 2°/min). Background counts of 24 s were measured at both scan limits. Of the 1119 intensities recorded in the range $0° < 2\theta < 45°$, 817 were above 1.8σ and were considered as observed reflections ($\sigma = \sqrt{N}$ where *N* is the scan count plus the total of both background counts). Three standard reflections were measured at least every 90 min and their intensities decreased steadily during the data collection. A decrease in crystal size, and a decrease in overall scale of approximately 20% during data collection can both be attributed to sublimation.

*Origin defining.
†Enantiomorph defining.
‡Variable.

Coincidence losses were shown to be negligible by measurement of all outstanding and some intermediate intensity reflections at low incident beam strength. No absorption corrections were made; the maximum error in F^2 which can result would be less than 1%. Lorentz and polarization factors were applied to give structure factors in the usual way.

Structure Determination

It was intended to solve the structure using three dimensional Patterson superposition techniques, however, after an examination of the sharpened Patterson function it became clear that there was considerable overlap and the chlorine–chlorine vectors were in doubt. Examination of the final coordinates shows vectors falling on or near lines of *mm* symmetry.

The structure was solved using the tangent refinement procedure (4, 5). One enantiomorph defining and three origin determining reflections were chosen together with an additional reflection of variable sign. These are shown in Table 1. *R*-Karle (4) was 0.18 for the correct sign (0) and 0.25 for the incorrectly signed (π) reflection.

Two electron density Fourier maps were computed (one for each sign of the variable), each map was phased on the signed structure factors of the 128 largest phased *E*'s. Seventeen of the 18 non-hydrogen atoms of the molecule were located in the correctly signed map.

Full-matrix least-squares refinement of all the non-hydrogen atoms commenced with $R = 0.34$ and proceeded with isotropic temperature factors to $R = 0.15$. Electron-density difference maps indicated anisotropic motion and, at a later stage, the position of the hydrogen atoms. The final refinement was computed allowing all non-hydrogen atom parameters to vary. Hydrogen atoms were given thermal motion parameters one unit larger than the atom to which they were bonded. The final value of $R = 0.057$.

All the variables introduced were justified by improved agreement meeting Hamilton's criterion (6). A constant weighting scheme was used with $\sigma F = 1.3$ until the final three cycles of refinement. At this point down-weighting of the weak reflections was indicated by an analysis of $\omega\Delta^2$ as a function of $\sin\theta/\lambda$, $|F_0|$, and h, k, and l. The final weighting scheme was such that $\sigma F = 1.14$ for $F_0 \geq 12.0$ and $\sigma F = 3.95/(F_0)^{1/2}$ for $F_{obs} < 12.0$. The error of fit $[\Sigma\omega(|F_0| - |F_c|)^2/(N_o - N_v)]^{1/2}$ where $N_o - N_v$ = number of observations − number of variables, was 0.92 (indicating the assigned standard errors were slightly too large). No trends in $\omega\Delta^2$ were present in an analysis of structure factor agreement after refinement was completed. The final value of $\omega R(\Sigma\omega(|F_0| - |F_c|)^2/\Sigma|F_0|^2)^{1/2}$ was 0.049.

from the variance–covariance matrix. No corrections to bond lengths for anisotropic thermal motion were made. A table listing $|F_o|, |F_c| = (A^2 + B^2)^{1/2}$, and α for each measured reflection can be obtained from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa K1A 0S2. (Accidentally unobserved reflections are indicated as $-\sigma/2$ in place of $|F_o|$.) Figure 1 shows the packing of the molecules within the unit cell, viewed down the *c* axis.

The major programs used are listed in ref. 8, in addition the NRCC Tangent Refinement Program was used in the structure solution. Calculations were carried out at the Simon Fraser University Computing Centre on an IBM 360/50.

Discussion

The crystal structure analysis has shown (Table 3) that there are no significant intermolecular interactions; while this is an advantage in eliminating any conformational changes which may result from hydrogen bonding, it has also permitted a larger amount of thermal motion (with a corresponding decrease in accuracy). The bond lengths and angles show chemically expected variations and are close to accepted values.

Two major structural features are important in this molecule and both are related to the method of preparation of this chloro sugar (3). Firstly, the site of halogenation is clearly at C(3), confirming that substitution of chlorine for hydroxyl took place without rearrangement of the acetal functions. Several closely related reagents (1, 2) have been shown to effect halogenation only after extensive rearrangement of the acetal blocking groups. Clearly such rearrangements are not involved in the chlorination of 1,2;5,6-di-*O*-isopropylidene-β-D-talofuranose. Secondly, the configuration about C(3) shows that replacement of the hydroxyl in the talofuranose derivative occurred stereospecifically and with inversion to give the idofuranose derivative. had indicated this to be the case but this crystal structure determination settles the point unambiguously.

Conformations of five-membered rings, especially those containing oxygen atoms, are of considerable interest since the furan ring is a component of the biologically important nucleotides and nucleic acids. Extensive X-ray crystal structural studies have shown the furan ring in nucleotides adopts a conformation with either carbon atoms 2 and/or 3 out of the plane of the ring (9), in keeping with earlier suggestions that such a ring puckering would be the most stable (10, 11). The structure of 3-chloro-3-deoxy-1,2;5,6-di-*O*-isopropylidene-β-D-idofuranose (**2**) is clearly of interest in this respect since it contains three five-membered rings, one of which is a furan ring (C(1)—C(2)—C(3)—C(4)—O(4)). Inspection of the molecular structure and Table 4 shows the furan ring conformation as an envelope with carbon atom four displaced from the mean plane of C(1), C(2), C(3), and O(4), ^4V in Hall's designation (12), and quite out of keeping with previous suggestions (10, 11). A similar furanose conformation was found for the crystal structure of 6-azido-5,6-dideoxy-5-iodo-1,2-*O*-isopropylidene-β-L-idofuranose (**3**) (13). However, a recent communication (14) revealing the crystal structure of the methyl ester of 1,2,3,5-tetra-*O*-acetyl-β-D-galactofuranuronate (**4**) to be one in which C(1) is displaced in from the mean plane (^1V) suggests the *cis* fused 1,2-*O*-isopropylidene ring is not responsible for this apparently anomalous behavior. Recent n.m.r. studies (15) indicate that position of substitution is an important criterion in the conformational preference of furanose rings in solution.

The conformation of the two remaining five-membered dioxolane rings are most difficult to describe since they adopt twist conformations to different extents. Table 4 describes equations of planes formed by atoms in these rings. The 1,2-*O*-isopropylidene ring is the less twisted of two with the dihedral angle O(1)—C(1)—C(2)—O(2) being 4.1(7)° with C(8) being displaced in an *exo* fashion from the fused ring system. This is in keeping with recent n.m.r. spectroscopic work (15) and the two other crystal structures (**3** and **5**) reporting this structural feature (13, 16). The 5,6-*O*-isopropylidene ring is twisted to a great extent, the dihedral angle O(5)—C(5)—C(6)—O(6) being 25.2(9)°. Again, this agrees well with n.m.r. (15) and the only other structure (16) reporting this molecular arrangement, **5**.

Dielectric and Association Behavior of 1-Propanol, 2-Propen-1-ol, and 2-Propyn-1-ol in Non-polar Solvents

G. E. RAJALA AND J. CROSSLEY

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received August 31, 1971

Dielectric constants and losses of 1-propanol, 2-propen-1-ol, and 2-propyn-1-ol in *p*-xylene, and 1-propanol and 2-propen-1-ol in cyclohexane have been measured at up to 10 frequencies in the range 1–145 GHz at 25 °C. The low frequency dielectric constants have also been measured at 2 MHz. An analysis in terms of two relaxation times has been obtained for each system. The short relaxation times are relatively independent of the alcohol, its concentration, and the solvent. Conversely, the longer relaxation times lengthen with increased alcohol concentration, lengthen in the order 2-propyn-1-ol, 2-propen-1-ol, 1-propyn-1-ol and are considerably shorter in *p*-xylene than in cyclohexane.

On a mesuré les pertes et les constantes diélectriques du 1-propanol, du 2-propène-1-ol, et du 2-propyne-1-ol dans le *p*-xylène et celles du 1-propanol et du 2-propène-1-ol dans le cyclohexane, jusqu'à dix fréquences dans la région de 1–145 GHz à 25 °C. On a aussi mesuré les constantes diélectriques à basse fréquence à 2 MHz. On a obtenu une analyse en termes de deux temps de relaxation pour chaque système. Les temps de relaxation courts sont relativement indépendants du type d'alcool utilisé, de sa concentration et du solvant. D'autre part, les temps de relaxation longs augmentent avec la concentration en alcool, cette augmentation se faisant dans l'ordre suivant: 2-propyne-1-ol, 2-propène-1-ol, 1-propyne-1-ol; ils sont considérablement plus courts dans le *p*-xylène que dans le cyclohexane.

Introduction

In dilute solution the microwave absorption of aliphatic alcohols may be characterized by two relaxation times (1–4). The high frequency process is undoubtedly due to the rotation of hydroxyl groups about their C—O bonds. Reorientation of monomers and low polymers, together with —OR groups in polymers, has received strong support as the most likely mechanism for the longer relaxation time. The magnitude of this relaxation time, its weight factor, and the apparent dipole moment are sensitive to the alcohol chain length, its concentration, the basicity of the solvent, and the steric environment of the hydroxyl group. At higher alcohol concentrations a third low frequency process, which is responsible for almost the entire absorption of pure liquid *n*-alkanols, emerges (5).

Recently the dielectric properties of pure liquid 2-propen-1-ol and 2-propyn-1-ol have been measured (6), at frequencies less than 500 MHz, and the results compared with those previously reported for 1-propanol (7). It was considered that the unsaturation in alkenols and alkynols may enhance molecular interactions not possible in alkanols. Very little difference was in fact observed for the equilibrium dielectric constants and their temperature dependence, and the dielectric dispersion of 2-propen-1-ol was typical of the monoalkanols. However, the Arrhenius activation parameters for 1-propanol and 2-propen-1-ol differed significantly. The high frequency relaxation processes were not examined, and liquid 2-propyn-1-ol could not be cooled sufficiently to bring its main dispersion into their frequency range.

One of us (4) has examined the disassociating effect of electron donor solvents on alkanols by dielectric relaxation measurements. We decided to investigate the effect of solute–solute interactions on the two high frequency relaxation processes of alcohols by measuring 1-propanol, 2-propen-1-ol and 2-propyn-1-ol in solution, in the microwave region at 25 °C.

Experimental

The apparatus and procedure for determining the dielectric constant and loss at the frequencies (up to 10 in the range 1–145 GHz) employed in this study have been described previously (8–10).

Materials

1-Propanol and 2-propen-1-ol were dried over calcium hydride and fractionally distilled under reduced pressure. 2-Propyn-1-ol, which polymerizes on standing, was dried over calcium hydride, distilled under reduced pressure, and finally purified by molecular distillation and stored under

vacuum. This alcohol is insoluble in cyclohexane and tends to polymerize when allowed to stand in *p*-xylene solution. All the measurements on each 2-propyn-1-ol solution were made in a single day. There was no evidence of polymerization during that time and the static dielectric constants were the same before and after the microwave measurements.

Cyclohexane and *p*-xylene were dried over and distilled from sodium.

Results

Cole–Cole plots (11) for all the systems were unsymmetrical (Fig. 1) and it was possible to analyze each set of dielectric data for two relaxation times τ_2 and τ_3, their weight factors C_2 and C_3 respectively, and the high frequency dielectric constant ε_∞. The computer method used to obtain the analyses has been described previously (3). The errors involved in the measurements and analyses have been discussed elsewhere (12).

As before (3) apparent dipole moments μ were calculated using the Onsager equation.

The experimental dielectric constant and loss values have been placed in a depository.[1] Static dielectric constants ε_0, very high frequency dielectric constants ε_∞, relaxation times τ_2 and τ_3, weight factors C_2, and apparent dipole moments μ are presented in Table 1.

[1]Copies of material in the depository may be obtained from: Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Discussion

The dielectric dispersions for all the solutions examined can not be represented by either a single Debye relaxation or a Cole–Cole distribution. The complex plane plots are obviously unsymmetrical and analyses in terms of two relaxation times give a satisfactory representation of the experimental data. The relaxation times, shown in Table 1, are consistent and compare favorably with values obtained previously for monohydric alkanols in non-polar solvents (1–4).

The short relaxation times τ_3 are very similar to those reported for phenols (13, 14) and other alcohols, as the pure liquids (5) or in solution (1–4). They are relatively independent of the alcohol and the solvent, and are probably associated with the reorientation of —OH dipoles about their C—O bonds. This process is the predominant mechanism in very dilute solution (15). For 2-propen-1-ol and 2-propyn-1-ol an additional fast relaxation process, involving the rotation of $—C{=}CH_2$ and $—C{\equiv}CH$ groups about their C—C bonds, is possible (16). However, the dipole component perpendicular to the axis of rotation for these groups, and thus the contribution to the absorption, is very small compared to that for the —OH group. In addition, it is anticipated that the relaxation times for —OH, $—C{=}CH_2$, and $—C{\equiv}CH$ group rotations would be very similar.

The possible origins of the relaxation time τ_2 have been discussed in detail elsewhere (1, 17). Its magnitude and weight factor are dependent upon the alcohol size, its concentration, and the solvent. Figure 2 shows the concentration dependence of τ_2 for 1-propanol, 2-propen-1-ol, and 1-butanol (4) in cyclohexane (2-propyn-1-ol is insoluble in cyclohexane). It is apparent that τ_2 decreases in the order 1-butanol, 1-propanol, 2-propen-1-ol in all concentrations. The longer values for 1-butanol are consistent with Johari and Smyth's (18) hypothesis that, in dilute solution, monomer reorientation is the major mechanism responsible for τ_2. However, l-propanol and 2-propen-1-ol are essentially the same shape and size and the considerably shorter τ_2 values for the latter must, in some way, be due to the olefinic linkage. In *p*-xylene solution τ_2 decreases in the order 1-propanol, 2-propen-1-ol, 2-propyn-1-ol, *i.e.* with increased multiple bond character of the terminal carbon–carbon bond. Also, as noted previously (4), the τ_2 values in cyclohexane are longer than those in *p*-xylene solution at similar concentrations. The low frequency relaxation process τ_1, which is responsible for almost the entire absorption of pure liquid *n*-alkanols (5), has been detected above about 0.15 mol fraction and undoubtedly makes some contribution at lower concentrations (1). The absence of any dielectric loss data at frequencies below 1 GHz did not allow us to observe τ_1 or to analyze our data for three relaxation times. It is probable that our τ_2 values contain some contribution from τ_1 and the slopes (Fig. 2) do appear to increase sharply above about 0.08–0.1 mol fraction alcohol.

The dipole moments of 1-butanol and 1-propanol in cyclohexane are almost the same but, at concentrations less than 0.12 mol fraction, they are significantly smaller than those for 2-propen-1-ol. In *p*-xylene the dipole moments of 1-butanol (3), 1-decanol (4), 1-propanol, 2-propen-1-ol, and 2-propyn-1-ol are similar and relatively independent of concentration. The dipole moment of a monomeric alkanol in the gaseous phase is about 1.7 D. In dilute solution alcohol self association predominantly involves the formation of small weakly polar multimers, with increased concentration association into larger highly polar multimers becomes progressively more important and the dipole moments of *n*-alkanols increase markedly with increased concentration (2). Electron donor solvents, such as *p*-xylene have a disassociating effect on alcohol multimers (19). At those concentrations where weakly polar multimers are the most important associated species, the dipole moments increase with increased solvent basicity and are smallest in inert solvents, such as cyclohexane, in which alcohol self association is the most extensive. Conversely, when highly polar multimers are predominant the dipole moments decrease with increased solvent basicity, and are largest in inert solvents (4). The dipole moment of 1-propanol in cyclohexane increases with increased alcohol concentration, which indicates that large highly polar multimers become progressively more important. For 2-propen-1-ol the dipole moment in cyclohexane shows only small changes in this concentration range which suggests that association into large multimers is less extensive than for 1-propanol.

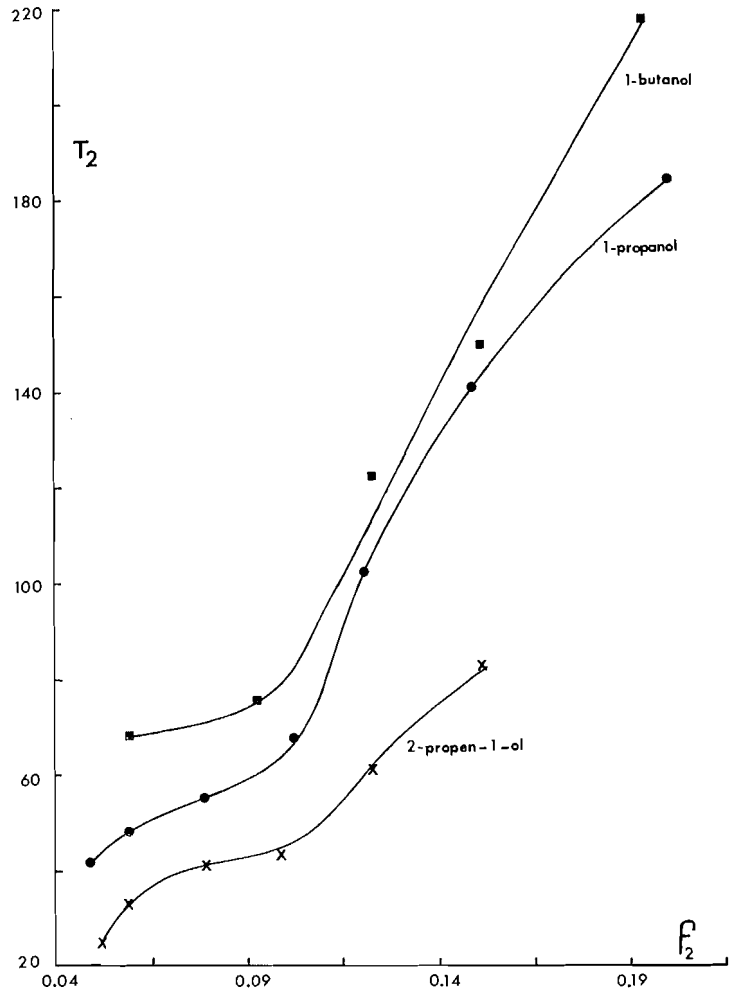

FIG. 2. Relaxation time τ_2 (ps) at 25 °C for 1-butanol, 1-propanol, and 2-propen-1-ol in cyclohexane.

The differences in the dielectric properties of 1-propanol, 2-propen-1-ol, and 2-propyn-1-ol are somewhat analogous to those observed for an alkanol in an inert and an electron donor solvent. In both situations an alternative to the O—H···O type of molecular interaction is probably responsible. For 2-propen-1-ol and 2-propyn-1-ol interactions involving the hydroxyl group and the unsaturated carbon–carbon bond and/or the terminal hydrogen atoms may provide additional molecular interactions which are not possible for 1-propanol. The shorter τ_2 values and larger dipole moments observed for the unsaturated alcohols suggest that such interactions are not negligible. This disassociating effect appears to be greatest for 2-propyn-1-ol which has the most acidic terminal hydrogen atom, and is most evident in the relatively inert cyclohexane. Interactions between the hydroxyl hydrogen atoms and the π-electrons of the solvent are possible for all three alcohols in *p*-xylene.

Selectivity in NBS Bromination. I. The Reaction of Methyl Enol Ethers of Cyclohexane-1,3-diones. A Reexamination

D. V. C. AWANG,[1] A. VINCENT, W. L. WILSON, AND H. W. AVDOVICH
Department of National Health and Welfare, Tunney's Pasture, Ottawa, Canada K1A OL2

Received May 19, 1971

The n.m.r. spectral analysis utilising solvent- and $Eu(DPM)_3$-induced chemical shifts demonstrates that the reaction of *N*-bromosuccinimide with the methyl enol ethers of cyclohexane-1,3-dione and dimedone leads to bromine substitution at the carbon atom allylic to the olefinic bond, and not at the olefinic site or α to carbonyl, respectively, as previously claimed.

Par l'utilisation en r.m.n. des déplacements chimiques induits par les solvants et $Eu(DPM)_3$, il est prouvé que la réaction entre le *N*-bromosuccinimide et l'éther méthyl énolique de la cyclohexanedione-1,3 conduit à une substitution par le brome sur le carbone allylique à la double liaison, et non pas sur le site oléfinique ou en α du carbonyle, comme cela avait été respectivement annoncé.

Canadian Journal of Chemistry, **50**, 104 (1972)

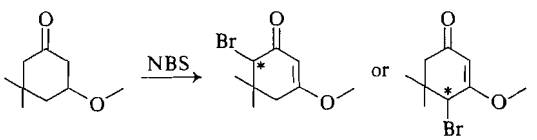
The remarkable antibacterial activity of tetracyclines has been imputed to their characteristic A-ring (1), whose salient chemical features are represented by cyclohexane-1,3-diones bearing carbamoyl and dimethylamino substituents at the 2- and 4-positions, respectively. One of the general approaches to synthesis of model compounds for study of structure–activity relationships and stability factors involves derivatization of 1,3-diones; carbamoylation at the 2-position of 1,3-diones, unsubstituted at that site, can readily be achieved (1, 2), but functionalization of the 4-position is not so easily accomplished.

Bromination of cyclohexane-1,3-dione, dimedone, and monoenolates of 5-phenylcyclohexane-1,3-diones using *N*-bromosuccinimide (NBS) under radical-promoting conditions leads to substitution at the 2-position (3). It has been reported, however (4), that the methyl enol ether of dimedone, 3-methoxy-5,5-dimethylcyclohex-2-enone (**1**), undergoes substitution at the 6-position upon reaction with NBS under similar conditions. In the case of the enolates of symmetrical cyclohexane-1,3-diones, the question of whether substitution occurs at the 4- or 6-position, although a matter of some fundamental significance,[2] does not jeopardize the potential

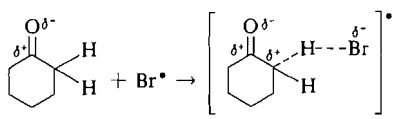


1 **2** **3**

of the synthetic plan, since hydrolysis of both 4- and 6-bromoenolates would lead to 4-bromo-1,3-dione; but the answer may be of crucial importance to the application of any synthetic scheme which involves this bromination step in the derivatization of *unsymmetrical* cyclohexane-1,3-diones. Arakawa (4) has based his conclusion that **2** rather than **3** is the product of NBS reaction with **1** on what appears to be rather tenuous *chemical* evidence: easy condensation of the bromination product with nitrogen bases and ready reaction with Brady's reagent were thought to be indicative of an α-haloketone, as was formation of an "osazone"[3] rather than a tris(2,4-dinitrophenylhydrazone) upon treatment of the initially formed bromohydrazone[3]

[1]To whom correspondence should be addressed.

[2]The bromine atom, which is the chain-carrying species in NBS allylic bromination is a strong acceptor radical (5). The passivity of cyclohexanone towards NBS in the presence of cyclohexene is imputed to polar factors affecting the stability of the transition state for hydrogen abstraction: the carbonyl dipole militates against the development of positive charge at the α carbon.



While the same rationale can be expected to apply to the case of simple α,β-unsaturated ketones, the effect of polar substituent groups on the selectivity of bromine substitution in such systems cannot be readily surmised.

[3]The detailed structures of the "osazone" and bromohydrazone were not elucidated.

with an excess of Brady's reagent. Arakawa's decision seemed unjustified, since the relative reactivity of α'- and γ-brominated α,β-unsaturated ketones was not considered, and since it has been established unequivocally by n.m.r. spectral analysis (6) that NBS bromination of cyclopent-2-enone leads to substitution at the 4-position.[4] Also, the claim by Arakawa and Irie (3) that monoenolates of cyclohexane-1,3-dione yield 2-bromo derivatives upon reaction with NBS appeared enigmatic, in face of the claimed dimedone enol ether result. Because of these apparent inconsistencies, and the possible theoretical and synthetic implications a re-examination of these reactions was undertaken.

The n.m.r. spectral analysis of the product of reaction of NBS with **1** establishes that bromine substitution takes place at carbon atom 4 rather than at carbon atom 6, yielding **3** instead of **2** as previously claimed (4); similar examination of the product of NBS reaction of isophorone confirms, as expected, the conclusion by earlier workers (8) that substitution occurs at the 4-position. The reaction of NBS with the methyl enol ether of cyclohexane-1,3-dione also leads to substitution at the 4-position, rather than at the 2-position as formerly reported (3).

The disposition of bromine in the products of the NBS reaction is clear from a consideration of the solvent-induced chemical shifts (Table 1) observed in the n.m.r. spectrum on passing from dilute solution in carbon tetrachloride to dilute solution in benzene ($\Delta = \delta(CCl_4) - \delta(C_6H_6)$ p.p.m.); the signs and magnitudes of the observed shifts are in accord with the generalization that the signals of protons lying behind a reference plane, perpendicular to the αC—CO—α'C plane through the carbonyl carbon atom, suffer positive shifts whereas those of protons in front of the plane undergo negative shifts and those of protons close to the plane exhibit very small and variable shifts (10). The downfield shifts induced by trifluoroacetic acid (TFA) ($\Delta = \delta(CDCl_3) - \delta(TFA)$ p.p.m.) also support these assignments, on the premise that protonation of carbonyl oxygen predominates.

The structures indicated by the solvent shift observations eminently satisfy the data (Table 2) available from reagent shift studies employing $Eu(DPM)_3$, if one assumes complexation of the shift reagent at the carbonyl oxygen (11).

It seems clear from this work that substitution of the methoxyl group for the C-3 hydrogen of cyclic 2-enone systems[6] does not promote a departure from the general rule that radical bromination by NBS effects substitution at the carbon atom allylic to the olefinic bond.

Experimental

The n.m.r. spectra were recorded on a Varian A-60A spectrometer operated at an ambient probe temperature of 40 ± 2 °C. The i.r. spectra were obtained using a Perkin–Elmer Model 621 spectrophotometer.

Materials

Dimedone, 1,3-cyclohexanedione, and isophorone were obtained commercially. The latter liquid was purified by vacuum distillation. The enol ethers were prepared by methylation of the diones using methanol – sulfuric acid according to the procedure of Arakawa and Irie (3).

General Bromination Procedure

NBS brominations were conducted in the standard manner (12) employing a 100 W, Photoflood No. 2 lamp to maintain reflux of carbon tetrachloride while providing a catalytic radiative source. Irradiation was halted as soon as it was estimated, visually, that the NBS had been consumed. The reaction product was quickly cooled, succinimide filtered off and the filtrate concentrated.

The n.m.r. analysis of the filtrates indicated that better than 95% conversion to product was achieved in all cases.

Bromination products were purified by preparative t.l.c. on silica gel GF_{254} using benzene–ether (9:1). Satisfactory microanalyses were obtained for all products.

4-Bromo-5,5-dimethyl-3-methoxycyclohex-2-enone (3)

Compound **3** had m.p. 87–88° (lit. (4) 90–91°); i.r. ($CHCl_3$) ν 1645 (C=O), 1600 (C=C), 1150 (C—O—C) cm^{-1}.

6-Bromo-5,5-dimethyl-3-methoxycyclohex-2-enone (2)

The product of hydrolysis of **3** (13) was treated with ethereal diazomethane to yield ethers **2** and **3** in a 3:2 ratio. Compound **2** was obtained by preparative t.l.c., as described above, in the form of an oil which resisted attempts at crystallization. Its i.r. spectrum showed characteristic absorption at ν 1650 (C=O), 1600 (C=C), 1150 (C—O—C) cm^{-1}.

4-Bromo-3-methoxycyclohex-2-enone

This compound was obtained as an oil and showed characteristic i.r. absorption at ν 1650 (C=O), 1600 (C=C), 1160 (C—O—C) cm^{-1}.

[4]There is also chemical evidence which supports the direction of substitution of cyclopenten-2-ones (6*a*, 7) as well as for isophorone (8) but Hafner and Goliasch (9) have assigned the wrong structure to the product of NBS bromination of cyclopenten-2-one on the basis of observed chemical transformation.[5]

[5]See commentary in ref. 6*a*.

[6]An examination of conformationally labile acyclic enone systems and of the theoretical implications of selective bromination of such systems is in progress.

†The signal at lower field, due to the protons allylic to the olefinic bond, is of appreciably greater line-width than that of the protons α to carbonyl, presumably because of coupling of C-4 protons with the vinylic proton.

‡The doublet character of the two high-field components of the 6 H AB quartet and the corresponding splitting of the 4H proton signal suggests long-range W-coupling between two quasi-equatorial protons and therefore, a quasi-axial conformation for the bromine substituent. The spectra of the other bromination products are complicated by allylic coupling and do not lend themselves as readily to such detailed analysis.

6-Bromo-3-methoxycyclohex-2-enone

A methylene chloride solution of 4-bromo-3-methoxycyclohex-2-enone stored for 3 days in the refrigerator underwent isomerization[7] to produce a 1:1 ratio of 4-bromo and 6-bromo isomers, also separated by preparative t.l.c. The latter isomer showed characteristic i.r. absorption at ν 1650 (C═O), 1590 (C═C), 1155 (C—O—C) cm^{-1}.

The authors are grateful to Mr. H. Séguin of NRCC for the elemental microanalyses and to Mr. J. C. Ethier for recording of the i.r. spectra.

Structure of Grandiflorenic Acid

F. PIOZZI,[1] S. PASSANNANTI,[1] M. L. MARINO,[1] AND V. SPRIO[2]
Institute of Organic Chemistry, University of Palermo, Palermo, Italy
Received July 13, 1971

Grandiflorenic acid is determined to be structure **2**, (−)-kaura-9(11),16-dien-19-oic acid.

L'acide grandiflorénique a la structure **2**, l'acide (−)-kaura-9(11),16-diène-19-oique.
Canadian Journal of Chemistry, **50**, 109 (1972)

We wish to present definitive evidence concerning the structure of grandiflorenic acid, extracted from the acid fraction of the resin of *Espeletia grandiflora* Humb. et Bonpl. (Compositae). This fraction also contains grandiflorolic acid, whose structure elucidation we have already reported (1) and (−)-kaur-16-en-19-oic acid (2). The neutral fraction of the resin contains (−)-kaur-16-ene, (−)-kaur-16-en-19-ol, and (−)-kaur-16-en-19-al (2).

Grandiflorenic acid $C_{20}H_{28}O_2$ contains two double bonds (as proved by perbenzoic acid titration and by selective hydrogenation to dihydro-grandiflorenic acid $C_{20}H_{30}O_2$ and tetrahydro-grandiflorenic acid $C_{20}H_{32}O_2$) in the form of an exocyclic methylene group (confirmed also by formation of formaldehyde upon ozonolysis) and of a trisubstituted C=CH— system, as indicated by n.m.r. and i.r. data. The n.m.r. spectrum of grandiflorenic acid also reveals the occurrence of two tertiary methyls; the i.r. spectrum of methyl grandiflorenate has the typical band at 1147 cm^{-1} for an axial $COOCH_3$ group. Physical constants of tetrahydro-grandiflorenic acid agree with those reported (3) for 16β-(−)-kauran-19-oic acid (**3**); the identification is confirmed by direct comparison (mixed m.p., g.l.c., m.s.) with a sure specimen of **3** prepared from a sample of (−)-kaur-16-en-19-oic acid, and by lithium aluminum hydride reduction to the known (4) 16β-(−)-kauran-19-ol (**4**). This identification is confirmed also by comparison with a specimen of **4**.

On the basis of such evidence, we had tentatively suggested (5) the structure **1** for grandiflorenic acid, although the alternative structure **2** could not be ruled out.

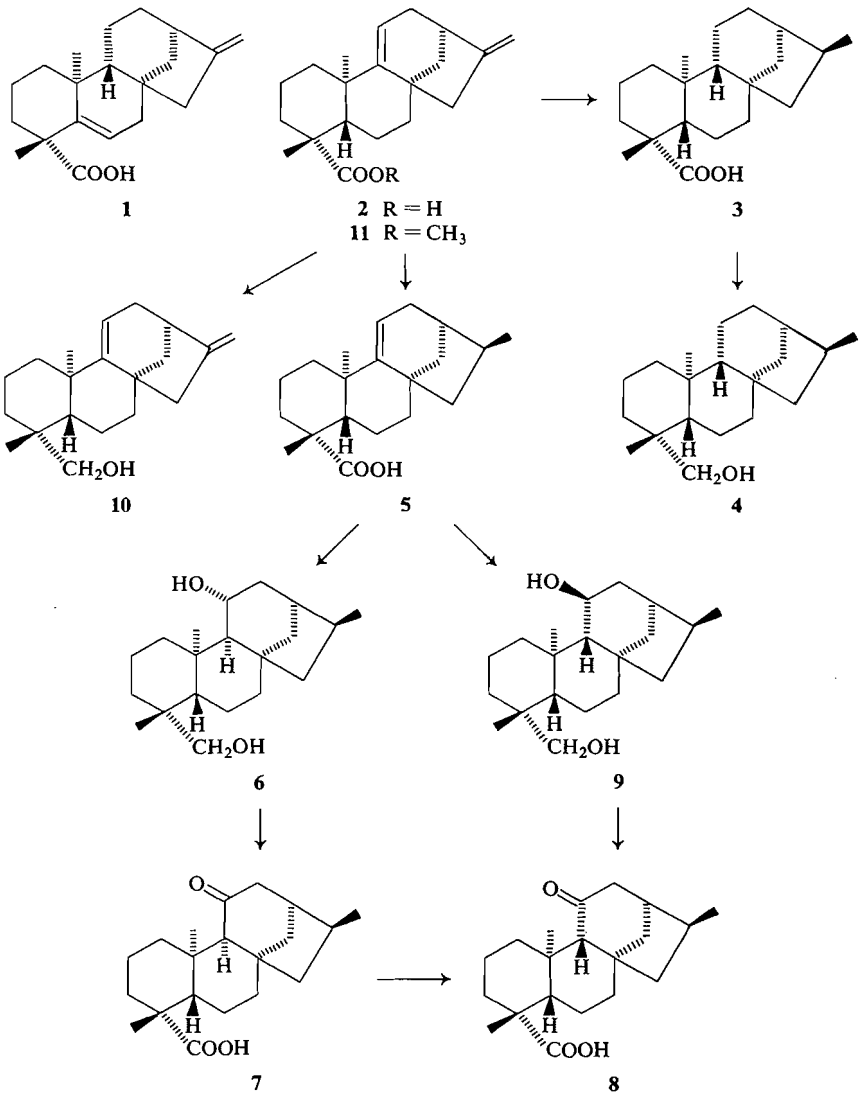
Grandiflorenic acid was isolated concurrently by Kloss (6) from the related species *Espeletia schultzii* Wedd. After comparison of his experimental results with those we had communicated, Kloss suggested structure **1**: however, his considerations, based on mass spectra, seemed to us to be not probative.

Grandiflorenic acid is clearly identical with "S 1 acid", extracted by Brieskorn and Pöhlmann (7) from *Espeletia schultzii* Wedd. These workers preferred the structure **2** on the basis of results similar to ours and of two other considerations: (*a*) the acid does not decarboxylate easily, while a β,γ-unsaturated acid such as **1** should do so; (*b*) the sequence ozonization, lithium aluminum hydride reduction – selenium dehydrogenation of the dihydro-acid, gives 1,5-dimethylnaphthalene.

Our own more recent results demonstrate the correctness of formula **2**.

Comparative determinations[3] of pK_{MCS}* gave 8.49 for grandiflorenic acid, 8.53 for dihydro-grandiflorenic acid, and 8.66 for tetrahydro-grandiflorenic acid.[4] These results can be rationalized only by assuming that in the three products there are three 1,3-interactions with a 4α-COOH (calcd. 8.50 for three and 8.25 for two 1,3-interactions). The small increment in the pK_{MCS}* when passing from the dihydro-acid to the tetrahydro-acid seems to us not sufficient to postulate the formation of an additional

[1]Faculty of Sciences.
[2]Faculty of Pharmacy.
[3]By the courtesy of Professor W. Simon, E. T. H., Zürich.
[4]Brieskorn and Pöhlmann (7) reported pK_{MCS}* 8.70 for their tetrahydro-acid.



1,3-interaction. Hence the double bond cannot be at position 5,6.

The comparison of the n.m.r. chemical shift values for 4β-CH_3 and 10α-CH_3 indicates that 4β-CH_3 is not substantially shifted when passing from grandiflorenic to dihydro- and thence to tetrahydro-acid: 1.25, 1.24, and 1.22 δ respectively. On the contrary, the 10α-CH_3 is shifted moderately upfield: 1.03, 1.00, and 0.94 δ respectively. The same results are observed for methyl grandiflorenate and methyl tetrahydrograndiflorenate: 4β-CH_3 1.16 and 1.16 δ, 10α-CH_3 0.92 and 0.82 δ respectively. Such behavior agrees with the presence of a 9,11-double bond as in **2**, but is less likely in the case of a 5,6-double bond as in **1**.

Hence, the most probable structures are **2** for grandiflorenic acid and **5** for dihydro-grandiflorenic acid.

Hydroboration–oxidation of dihydro-grandiflorenic acid gives as main product a $C_{20}H_{34}O_2$ diol whose n.m.r. spectrum shows a complex multiplet at 4.07 δ for the —C*H*OH— proton. This signal is an apparent sextet with three coupling constants of 10.50, 9.75, and 6.75 Hz. Chromic oxidation of the diol affords a

$C_{20}H_{30}O_3$ ketoacid, having pK_{MCS}* 8.66: this result definitively excludes the occurrence of a keto group at C-6, because it is known (4) in the case of 6-keto-(−)-kaur-16-en-19-oic acid that hydrogen bonding of the carboxyl with the keto group at C-6 increases the pK_{MCS}* to 9.25. Therefore the carbonyl of the present ketoacid must be at C-11.

The three coupling constants reported for the diol can be interpreted as belonging to axial–axial, axial–axial, and axial–equatorial couplings. These relationships can be fulfilled only by structure **6** with a 9α-H configuration, deriving from *cis*-addition from the least hindered α side of the 9,11-double bond. A similar result has been reported (8) recently in the hydroboration of an abietane skeleton with a 9,11-double bond. Hence, our ketoacid has the structure **7** with 9α-H configuration. This product can be epimerized easily by base to the more stable 9β-H derivative **8**. The o.r.d. and c.d. have been obtained for **7** and **8**. The Cotton effect is positive for both products but is rather weak in **7** and more intense in **8**.

Hydroboration of **5** gives also as a minor product the isomeric diol **9**. In its n.m.r. spectrum 11α-H appears as a broad signal at 3.89 δ with $w_{1/2} = 6.5$ Hz, as can be foreseen for equatorial–equatorial, equatorial–equatorial, and equatorial–axial relationships. Jones oxidation of **9** affords as expected the ketoacid **8**.

Lithium aluminum hydride reduction of grandiflorenic acid affords the dienol $C_{20}H_{30}O$ described by Kloss (6). On the basis of previous evidence, this product must be assigned the structure **10**, (−)-kaura-9(11),16-dien-19-ol.

The above reported results allow us to assign grandiflorenic acid the structure **2**.

Experimental

Melting points (capillary tubes) are uncorrected. The i.r. spectra were measured on a Perkin–Elmer Infracord 137, Nujol mull; n.m.r. spectra, C-60 H Jeol, TMS internal standard with $\delta = 0$; m.s., Hitachi Perkin–Elmer RMU-6D, 70 eV (courtesy of Dr. A. Selva, Institute of Chemistry, Politechnic of Milano); g.l.c. analyses, 1440 Varian Aerograph with flame ionization detector, carrier gas N_2, columns 1% GE XE 60 at 180° or 3% SE 30 at 200°; $[\alpha]_D^{20°}$, Perkin–Elmer 141 polarimeter.

Extraction

The resin, collected from trees growing at Pàramo de Guadalupe, Bogotà, Colombia at 3400 meters above sea level, is dissolved in ether and extracted with 3% sodium hydroxyde solution; the latter is acidified and extracted with ether. The acidic fraction obtained is chromatographed on silica gel with benzene – ethyl acetate, eluting in the order: pure grandiflorenic acid, a mixture of grandiflorenic and (−)-kaur-16-en-19-oic acid, pure grandiflorolic acid. No trace of acetyl-grandiflorolic acid (= "S 2 acid" of Brieskorn and Pöhlmann (7)) is present.

Grandiflorenic Acid (2)

The pure acid has m.p. 158–160° (from ethyl acetate then from methanol); $[\alpha]_D^{20°}$ +38° (ethanol; *c*, 1.02).

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39. Found: C, 79.65; H, 9.35.

The i.r.: 1695 (COOH), 1655 and 876 (C=CH_2), 810 cm^{-1} (C=CH); n.m.r. ($CDCl_3$): 1.03 and 1.25 (s, *t*-CH_3), 4.80 and 4.90 (C=CH_2), 5.26 (t of 3 Hz, C=C*H*—CH_2), ~10 δ (broad, COOH); m.s.: 300 *m/e* (M^+), 285 (M-15), 239 (M-15-46); TNM test: positive; determination of pK_{MCS}*: found 8.49.

Methyl grandiflorenate (**11**) is obtained by treatment of the acid with ethereal diazomethane and is purified by chromatography on neutral alumina eluting with cyclohexane: uncrystallizable viscous oil, one component by t.l.c. and g.l.c. The i.r. (liquid): 1725 ($COOCH_3$), 1655 and 877 (C=CH_2), 1147 (axial $COOCH_3$ on C-4), 810 cm^{-1} (C=CH); n.m.r. (CCl_4): 0.92 and 1.16 (s, *t*-CH_3), 3.62 (s, $COOCH_3$), 4.76 and 4.89 (C=CH_2), 5.21 δ (t of 3 Hz, C=C*H*—CH_2). Titrations with perbenzoic acid: 2.20 and 2.10 double bonds (two determinations).

Methyl grandiflorenate (**11**) (150 mg) is reduced with excess of lithium aluminum hydride in ether solution (6 h reflux); the isolated product is chromatographed on silica gel (eluent benzene – ethyl acetate 9:1) and crystallized from cyclohexane: (−)-kaura-9(11),16-dien-19-ol (**10**) has m.p. 114–115°, $[\alpha]_D^{20°}$ +43° (ethanol; *c*, 0.38); i.r.: 3330 (OH), 1655 and 877 (C=CH_2), 810 cm^{-1} (C=CH); n.m.r. ($CDCl_3$): 0.95 and 1.03 (s, *t*-CH_3), 3.62 and 3.83 (q, $J_{AB} = 11$ Hz, axial CH_2OH on C-4), 4.78 and 4.89 (C=CH_2), 5.16 δ (t of 3 Hz, C=C*H*—CH_2); m.s.: 286 *m/e* (M^+), 271 (M-15), 255 (M-31). Kloss (6) reported m.p. 114–115°, $[\alpha]_D^{20°}$ +45°, and identical m.s.

Dihydro-grandiflorenic Acid (5)

A sample of grandiflorenic acid (200 mg) in methanol solution is hydrogenated on PtO_2 (20 mg) at room temperature (H_2 absorbed corresponding to 1.02 double bonds after 1 h): m.p. 166–168° (from aqueous ethanol); $[\alpha]_D^{20°}$ +43° (ethanol; *c*, 0.30); i.r.: 1695 (COOH), 815 cm^{-1} (C=CH); n.m.r. ($CDCl_3$): 0.98 (d, $J = 6$ Hz, *s*-CH_3), 1.00 and 1.24 (s, *t*-CH_3), 5.17 δ (t of 3 Hz, C=C*H*—CH_2); m.s.: 302 *m/e* (M^+), 287 (M-15), 241 (M-15-46); TNM test: positive; determination of pK_{MCS}*: found 8.53.

Transformation of samples of the dihydro-acid into its methyl ester (not characterized) and g.l.c. determinations indicate that the crude acid is a 80:20 mixture of 16β-CH_3 and 16α-CH_3 epimers; the crystallized acid contains ~85% of the 16β-CH_3 epimer.

Tetrahydro-grandiflorenic Acid (3)

A sample of grandiflorenic acid (200 mg) in ethanol solution is hydrogenated on 10% Pd–C at room temperature (H_2 absorbed corresponding to 1.98 double bonds after 24 h): m.p. 209–210° (from methanol); $[\alpha]_D^{20°}$ −80° (ethanol; *c*, 0.44); i.r.: 1690 cm^{-1} (COOH); n.m.r. ($CDCl_3$): 0.94 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1.22 (s, t-CH_3), 0.99 δ (d, $J = 6$ Hz, s-CH_3); m.s.: 304 m/e (M^+), 289 (M-15), 243 (M-15-46); TNM test: negative; determination of pK_{MCS}*: found 8.66.

Transformation of samples of the tetrahydro-acid into its methyl ester and g.l.c. determinations indicate that the crude acid is a 80:20 mixture of 16β-CH_3 and 16α-CH_3 epimers. The crystallized acid contains only the pure 16β-CH_3 epimer. This finding agrees with common assumption that catalytic hydrogenation of the exocyclic double bond of (−)-kaur-16-ene derivatives gives mainly 16β-CH_3 epimers.

The characteristics of the crystallized acid agree sufficiently with those reported (3) for 16β-(−)-kauran-19-oic acid, *i.e.* m.p. 210–214° and $[\alpha]_D^{20}$ −68°. Direct comparison with a sure sample, prepared by hydrogenation of (−)-kaur-16-en-19-oic acid extracted (2) from *Espeletia grandiflora* and having m.p. 209–211°, shows no depression at mixed m.p., identical m.s., identical retention volume as methyl ester at g.l.c. (crossed injection).

A sample of the crystallized acid is then methylated and reduced with lithium aluminum hydride: the product has m.p. 146–147° (from aqueous ethanol), in agreement with m.p. 148–150° reported (4) for 16β-(−)-kauran-19-ol (**4**). Direct comparison with a sure specimen, prepared from sure 16β-(−)-kauran-19-oic acid and having m.p. 147–148°, shows no depression at mixed m.p. and identical retention volume at g.l.c. (crossed injection).

Hydroboration of **5**: *Diol* **9** *and Diol* **6**

A solution of **5** (250 mg) in anhydrous tetrahydrofuran (100 ml) is added at 0° with sodium borohydride (3 g) and boron trifluoride etherate (6 ml). After 24 h, water (30 ml), 3 *N* sodium hydroxide (15 ml) and hydrogen peroxide (30% solution, 15 ml) are added dropwise. Repeated ether extractions afford a solid residue that is chromatographed on silica gel (50 g; eluent benzene – ethyl acetate 9:1, 10 ml fractions): fractions 80–90 yield 10 mg of diol **9**, fractions 100–145 give 150 mg of diol **6**.

The first product has m.p. 158–160° with pseudo m.p. 70° (from cyclohexane); m.s.: 306 m/e (M^+), 288 (M-18), 275 (M-31), 257 (M-18-31); n.m.r. ($CDCl_3$): 0.88 and 0.97 (s, t-CH_3), 1.11 (d, $J = 6.5$ Hz, s-CH_3), 3.44 and 3.69 (q, $J_{AB} = 11$ Hz, axial CH_2OH), 3.89 δ (broad, $w_{1/2}$ 6.5 Hz, 11α-H). These data are consistent with the structure **9** of 16β-(−)-kauran-11β,19-diol.

The second product has m.p. 57–58° (from cyclohexane), $[\alpha]_D^{20}$ −27° (ethanol; *c*, 0.35); m.s.: same peaks as **9** but with different intensities; n.m.r. ($CDCl_3$): 1.00 and 1.08 (s, t-CH_3), 1.01 (d, $J = 6.5$ Hz, s-CH_3), 3.57 and 3.93 (q, $J_{AB} = 11$ Hz, axial CH_2OH), 4.07 δ (six-line pattern, $J_{ax,ax} = 10.50$, $J_{ax,ax} = 9.75$, $J_{ax,eq} = 6.75$ Hz, 11β-H). In the n.m.r. spectrum ($CDCl_3$) of its diacetate (not characterized) the latter signals are shifted downfield: 3.88 and 4.18 (q_{AB}, CH_2OAc), 5.00 δ (six-line pattern, 11β-H). Such data support the structure **6** of 16β,9α-(−)-kauran-11α,19-diol.

Oxidation of Diol **6**: *Ketoacid* **7**

The diol (100 mg) is oxidized with Jones reagent at 0°; after usual work-up, the crude ketoacid is chromatographed on silica gel (eluent benzene – ethyl acetate 9:1), obtaining 40 mg of **7**, m.p. 210° (from benzene–cyclohexane); $[\alpha]_D^{20}$ −68° (ethanol; *c*, 0.19); m.s.: 318 m/e (M^+), 300 (M-18), 285 (M-18-15), 274 (M-44), 272 (M-18-28), 257 (M-18-28-15), 229 (257-28); determination of pK_{MCS}*: found 8.66; o.r.d. (ethanol; *c*, 0.19; 27°): $[\alpha]_{400}$ −140, $[\alpha]_{330}$ +40 (peak), $[\alpha]_{270}$ −1200° (sh); c.d.[5]: 330 (sh), 320 (sh), 309 ($\Delta\varepsilon$ +0.65), 303 ($\Delta\varepsilon$ +0.65), 292 nm (sh).

The product (examined as methyl ester, uncharacterized) is pure by g.l.c.

A sample of the ketoacid **7** (20 mg) is dissolved in 10% methanolic potassium hydroxide (5 ml) and refluxed 1 h: the epimeric ketoacid **8** has m.p. 187–188°. The product (examined as methyl ester, not characterized) is pure by g.l.c.: it differs from **7** but is identical with the product obtained by oxidation of **9** (see below); also mixed m.p. shows no depression, i.r. and m.s. are identical.

Oxidation of Diol **9**: *Ketoacid* **8**

Jones oxidation of the diol (20 mg) gives the ketoacid **8** (8 mg), m.p. 186–187° (from cyclohexane); $[\alpha]_D^{20}$ +32° (ethanol; *c*, 0.14); m.s.: almost identical peaks as in **7**, but with different intensities; o.r.d. (ethanol; *c*, 0.14; 27°): $[\alpha]_{400}$ +190, $[\alpha]_{326}$ +1460 (peak), $[\alpha]_{282}$ −1880 (trough), $[\alpha]_{255}$ −1560° (peak); c.d.: 330 (sh), 320 (sh), 309.5 ($\Delta\varepsilon$ +2.37), 304 (sh), 294 nm (sh). The product (examined as methyl ester, uncharacterized) is pure by g.l.c. and different from **7**.

Vapor Phase Catalytic Transformations of Terpene Hydrocarbons in the $C_{10}H_{16}$ Series. II. Aromatization of α-Pinene over Chromia–Alumina[1]

A. STANISLAUS[2] and L. M. YEDDANAPALLI
Department of Chemistry, Loyola College, Madras, India

Received April 1, 1971

The aromatization of α-pinene in the vapor phase over chromia gel and chromia–alumina catalysts prepared from aluminas of different acidity has been studied. The acidity of alumina support has a remarkable influence on the composition of the aromatics resulting from the dehydrogenation of α-pinene. Over weakly acidic chromia–alumina doped with 1% sodium catalyst, α-pinene is aromatized to *p*-cymene, 1,2,4- and 1,2,3-trimethylbenzenes with traces of toluene and xylenes, whereas over the strongly acidic chromia – pure alumina and chromia–alumina containing 5% HF catalysts it gives considerable amount of *m*-cymene, toluene, and tetramethylbenzenes. A satisfactory mechanism to explain the formation of these compounds is offered.

L'aromatisation de l'α-pinène en phase vapeur sur catalyseurs gel de chrome et chrome–aluminium préparés à partir d'alumine d'acidité différente a été étudiée. L'acidité du support d'alumine a une influence notable sur la composition des produits aromatiques résultant de la déshydrogénation de l'α-pinène sur un catalyseur chrome–alumine faiblement acide dopé par 1% de sodium, l'α-pinène s'aromatise en *p*-cymène et en benzènes triméthylés en 1,2,4- et 1,2,3 avec des traces de toluène et de xylènes tandis que, sur des catalyseurs chrome–alumine pure faiblement acide et chrome–alumine contenant 5% HF, on obtient une quantité considérable de *m*-cymène, de toluène et de benzènes tétraméthylés. Un mécanisme satisfaisant pour expliquer la formation de ces composés est offert.

Canadian Journal of Chemistry, **50**, 113 (1972)

Introduction

Chromia–alumina has been used extensively as a catalyst for dehydrogenation and aromatization studies. It has been shown recently that the alumina influences the catalytic properties of chromia–alumina catalysts and that the products resulting from such aromatization reactions depend to a great extent upon the type of alumina (1–3). The present study was undertaken in order to determine the effect of different types of alumina in chromia–alumina catalysts upon the aromatization of α-pinene. Chromia gel, chromia–alumina doped with 1% sodium, chromia – pure alumina, and chromia–alumina containing 5% hydrogen fluoride were used as catalysts.

Experimental

Materials

α-Pinene: First quality Indian turpentine oil supplied by the Government Turpentine and Rosin Company Ltd., Bareilly, India, contains 50% carene, 40% α-pinene, and 10% β-pinene. α-Pinene was obtained from this oil by fractionation using a 5 ft column packed with stainless steel helices (containing 20 theoretical plates) at reduced pressure (10 mm Hg). The purity was found to be better than 99% by gas chromatographic analysis.

Catalysts

Chromia Gel

Hydrated chromium nitrate (Rideal) (100 g) and ammonium acetate (33 g) were dissolved in water (625 ml). The solution was heated to boiling for a brief interval and cooled to room temperature. A solution of ammonium hydroxide (*d.* 0.885; 90 ml) in water (250 ml) was then added with stirring and the whole slowly warmed on a water bath, where upon a strong, homogeneous jelly was obtained. This jelly was cut into cubes and partially dried at 50 to 60 °C for 12 h. The cubes were then washed by decantation with distilled water until the nitrate and ammonium ions were completely removed. The cubes were then activated at 50 to 60 °C to a hard black vitreous material which before use was raised slowly in temperature with further elimination of water and finally held over 12 h at 400 °C.

Chromia–Alumina A

It was prepared by impregnating alumina A (prepared by hydrolyzing aluminum isopropoxide with water) with requisite amount of chromic acid solution to give 6% chromium in the catalyst. It was dried at 120 °C for 24 h, made into pellets (4 × 4 mm), and calcined at 500 °C for 24 h.

Chromia–Alumina C

It was prepared by impregnating alumina C (prepared by doping alumina A with appropriate amount of sodium carbonate solution to give 1% sodium in the catalyst) with requisite amount of chromic acid solution to give 6% chromium in the catalyst. It was dried at 120 °C for 24 h, made into pellets (4 × 4 mm), and calcined at 500 °C for 24 h.

[1]This investigation is dedicated to the memory of Professor L. M. Yeddanapalli who died on June 6, 1970.

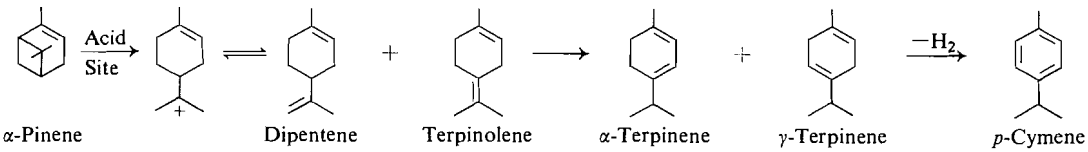

SCHEME 1

Chromia–Alumina E

It was prepared by impregnating alumina E (obtained by doping alumina A with appropriate amount of HF acid to give 5% by weight of HF in the catalyst) with requisite amount of chromic acid solution to give 6% chromium in the catalyst. The method of activation of the catalyst was similar to that employed in preparing chromia–alumina A.

Apparatus and Procedure

Apparatus, procedure and analytical techniques were essentially the same as described in paper I of these series (9).

Results and Discussion

Table 1 summarizes the data on the rate and distribution of products of aromatization of α-pinene over the different chromia–alumina catalysts at 390 °C. The results obtained at 425 and 460 °C are given in Tables 2 and 3, respectively. It appears from these tables that there is a marked change in the distribution of products as the acid strength of alumina support is increased. In the case of chromia–alumina prepared from weakly acidic sodium doped alumina, the aromatic fraction contains mainly *p*-cymene with small amounts of *m*-cymene, toluene, and xylenes and trimethylbenzenes. Over the strongly acidic HF treated chromia–alumina catalyst the concentration of *m*-cymene, toluene, and xylenes are increased. In addition to these tetramethylbenzenes are also formed.

The formation of *p*-cymene from α-pinene under aromatizing conditions is well known (4–6) (see Scheme 1). Breaking of the cyclobutane ring to give *p*-menthadienes followed by dehydrogenation is the mechanism proposed by these authors to explain the formation of *p*-cymene from α-pinene. Chromia–alumina and chromia catalysts are poly functional catalysts. They contain two types of sites, one catalyzing the isomerization and the other dehydrogenation reactions. The isomerization activity is associated with the acidity of the catalysts whereas the dehydrogenation activity is associated with Cr(II) and Cr(III) ions. In the formation of *p*-cymene first α-pinene is isomerized on the acid sites to dipentene and terpinolene. The dipentene and terpinolene undergo further isomerization to α- and γ-terpinenes which are then dehydrogenated to *p*-cymene.

The production of 1,2,3- and 1,2,4-trimethylbenzenes may be explained by assuming that the hydrogen liberated in the formation of *p*-cymene acts upon the unreacted portion of α-pinene to form 1,1,2,3- and 1,1,2,5-tetramethylcyclohexanes by breaking the bonds III and IV by hydrogenolysis followed by dehydrogenation and demethanation as shown in Scheme 2. Ipatieff and Pines (6) have proposed a similar mechanism to explain the formation of 1,2,3- and 1,2,4-trimethylbenzenes from pinane during dehydrogenation over Pt–alumina.

TABLE 4. Isomerization of *p*-cymene over alumina catalysts; temperature, 460 °C; WHSV, 1

Catalyst	% *m*-cymene
Alumina C	0
Alumina A	6
Alumina E	13

Tetramethylbenzenes, *m*-cymene, and toluene are formed only when the catalyst contains strong acid sites. The tetramethylbenzenes are probably formed by skeletal isomerization of 1,1,2,3- and 1,1,2,5-tetramethylcyclohexanes to 1,2,3,4-, 1,2,3,5-, and 1,2,4,5-tetramethylcyclohexanes followed by dehydrogenation.

Skeletal isomerization may be interpreted in terms of a carbonium ion mechanism involving the strong acid sites of alumina. The saturated hydrocarbons 1,1,2,3- and 1,1,2,5-tetramethylcyclohexanes could form the corresponding cyclohexyl carbonium ion either by partial dehydrogenation to the corresponding tetramethylcyclohexenes followed by proton exchange or by a direct hydride ion removal from the saturated compound. The carbonium ion thus formed would give through a methide migration, isomerized cyclohexyl carbonium ion which would then aromatize to the corresponding tetramethylbenzenes. Such skeletal isomerization preceding aromatization over chromia–alumina catalysts having strong intrinsic acidity have been reported by Pines and Chen (3).

m-Cymene is formed by the isomerization of *p*-menthadienes to *m*-menthadienes over strong acid sites and subsequent dehydrogenation or directly from *p*-cymene by isomerization. The latter view is supported by the fact that *p*-cymene itself undergoes isomerization to *m*-cymene over strongly acidic HF treated alumina as shown in Table 4. Similar isomerizations involving xylenes have already been reported by Pines and Covini (7) over strongly acidic molybdena–alumina catalysts. Cracking of the isopropyl group of both *p*- and *m*-cymenes on the strong acid sites results in the formation of toluene.

It also appears from Tables 1, 2 and 3 that both the weakly acidic sodium doped and strongly acidic HF treated chromia–alumina are more active than chromia – pure alumina for aromatization of α-pinene. The high activity of chromia–alumina catalyst prepared from sodium doped alumina may be explained on the basis of the fact that alkali metal ions doped on chromia–alumina promote the dehydrogenation activity of the catalyst by neutralizing the strong acid sites of alumina and thus preventing the undesirable side reactions leading to the formation of alkyl cyclopentenes which act as poisons for dehydrogenation sites (8). The high aromatization activity of chromia–alumina–HF catalyst can be explained as follows. Camphene and tricyclene are formed from α-pinene in the primary isomerization step to an extent of 30–40%. Strong acid sites are necessary for the conversion of camphene to monocyclics (9) and consequently its aromatization will be favored by only catalysts possessing strong acid sites. Since HF treated chromia–alumina contains a large number of such strong acid sites, it can cause the further isomerization of camphene to menthadienes which are then dehydrogenated to *p*-cymene.

Effect of Pyridine

From the results of the influence of acidic strength of alumina in chromia–alumina catalysts on the distribution of products of the aromatization of α-pinene it was concluded that strong acid sites are necessary for the formation of tetramethylbenzenes, *m*-cymene, and toluene. Selective poisoning of these sites by bases like pyridine was employed to verify the validity of this conclusion. At low partial pressures pyridine should get adsorbed preferentially on the stronger acid sites than on the weaker acid sites.

α-Pinene in presence of varying amounts of pyridine was subjected to aromatization over chromia–alumina E and the results are summarized in Table 5. It appears from Table 5 that the yield of aromatics is decreased by the addition of pyridine to the reactant. In the absence of pyridine 72% of aromatics are obtained whereas in the presence of 5% by weight of pyridine the yield of aromatics is only 48%. Among the aromatics the concentrations of *m*-cymene, tetramethylbenzenes, and toluene are decreased by pyridine supporting the conclusion that the formation of these compounds involves strong acid sites. The concentration of camphene in the products is increased by the addition of pyridine. This shows that in the presence of pyridine camphene formed from α-pinene in the primary isomerization step does not undergo

Base-catalyzed Deuteration of Tricarbonylchromium Complexes[1]

M. ASHRAF[2]
Department of Chemistry, Queen's University, Belfast, N. Ireland

Received June 16, 1971

Hydrogen–deuterium exchange in tricarbonylchromium complexes of anisole, ethylbenzoate, and *N,N*-dimethylaniline has been studied for solutions in ethanol-*O*-d_1, containing sodium ethoxide. The extent of deuteration has been estimated mass spectroscopically and the position of deuteration by n.m.r. spectroscopy. In this kinetically controlled reaction ortho-substitution has been found to be predominantly preferred in case of anisole complex, whereas random substitution was observed (n.m.r.) for ethylbenzoate complex. The results are interpreted in terms of chelative, inductive, mesomeric, and steric effects of the substituents.

L'échange hydrogène–deutérium dans les complexes du chrome tri-carbonyle de l'anisole, de l'éthylbenzoate et de la *N,N*-diméthyl aniline a été étudié pour des solutions dans l'éthanol-*O*-d_1, contenant de l'éthylate de sodium. Le domaine de deutération a été estimé par spectroscopie de masse et la position de deutération par spectroscopie r.m.n. Dans cette réaction contrôlée cinétiquement la substitution en ortho a été trouvée prédominante dans le cas du complexe de l'anisole tandis qu'une substitution annexe a été observée par r.m.n. pour le complexe de l'éthylbenzoate. Les résultats sont interprétés en termes de chélation, d'induction, de mésomérie et d'effets stériques des substituants.

Canadian Journal of Chemistry, **50**, 118 (1972)

Introduction

The ability of a tricarbonylchromium group to stabilize a negative charge on or adjacent to a benzene ring has been shown by the ease of nucleophilic displacement of chloride and fluoride ions from tricarbonyl(chloro- and fluorobenzene)chromiums and in the increased acid strength of tricarbonyl(benzoic acid)chromium relative to that of benzoic acid (1). Russian workers (2) have shown that when a solution of tricarbonyl(benzene)chromium in ethanol-*O*-d_1 containing sodium ethoxide is heated for 20 h at 100° almost half of the hydrogen is replaced by deuterium. They also found that the tendency of hydrogen atoms to undergo protophilic hydrogen–deuterium exchange in the aromatic ring was very much greater in tricarbonyl(toluene)chromium than in toluene (3).

We have extended this work by studying the degree and nature of hydrogen-deuterium exchange reactions in tricarbonylchromium complexes of anisole, ethylbenzoate, and *N,N*-dimethylaniline.

Results and Discussion

Deuteration of Tricarbonyl(anisole)chromium

When a solution of tricarbonyl(anisole)-chromium was heated for 24 h at 100° appreciable decomposition occurred and *ca.* 14% of the anisole complex was recovered. The amount

of hydrogen–deuterium exchange was estimated by comparison of the mass spectrum of the deuterated sample with that of tricarbonyl(anisole)chromium. The parent molecular ion was not used for measuring the amount of deuterium incorporation because of the difficulties associated with chromium isotopes. Instead the peaks associated with the anisole ion, *m/e* 108 were used. The spectra were obtained with a beam energy of 70 and 12 eV and the results are shown in Table 1. The average of these results indicated that the deuterated sample contained 24.5% of molecules with no deuterium, 38.5% with 1D, 24% with 2D, and 7.6% with 3D.

The n.m.r. spectrum of tricarbonyl(anisole)-chromium ($CDCl_3$) at 100 MHz showed the aromatic protons as well resolved signals at τ 4.46 (triplet, meta), 4.90 (doublet, ortho), and 5.14 (triplet, para) with the methoxy protons at τ 6.34, in agreement with a published spectrum (4). The deuterated sample had a similar spectrum with two distinctions. The meta-triplet, $J = 6$ Hz was now a five-line multiplet consisting of the original triplet together with a doublet, $J = 6$ Hz, also centered at τ 4.46. The integral was now in the ratio 1.9 meta:1.25 ortho:0.9 para:3 methoxy protons, suggesting a deuterium exchange of 5% of the meta, 38% of the ortho and 10% of the para hydrogen atoms. These results are in agreement with an independent Russian study which was published during the course of this work (5).

Deuteration of Tricarbonyl(ethylbenzoate)-chromium

The deuteration of tricarbonyl(ethylbenzoate)chromium, as described in the Experimental recovered only *ca.* 7% of the ester complex from the ethereal extract of the reaction mixture. However, the aqueous layer on acidification afforded tricarbonyl(benzoic acid)chromium (*ca.* 46%). The amount of deuterium incorporation in both substances was measured using the peaks associated with ethylbenzoate and benzoic acid ions, *m/e* 150 and 122 respectively. No correction was used for oxygen isotopes. The relevant spectra for both of these complexes, obtained with an ionizing voltage

of 70 and 12 eV, are given in Table 1. The average of these results indicated *ca.* 5% of molecules with no deuterium, 14% with 1D, 27% with 2D, 29% with 3D, 18% with 4D, and 7% with 5D in the ethylbenzoate complex, while the corresponding percentages in the benzoic acid complex were 26, 14, 25, 23, 11, and 3% for the molecules containing 0D to 5D respectively. The rather large variation of deuterium incorporation in these compounds might be due to the hydrolysis of the ester complex partly during the course of the reaction (due to some moisture content) and partly during work-up of the hot reaction mixture.

The n.m.r. spectrum of tricarbonyl(ethylbenzoate)chromium in $CDCl_3$ at 100 MHz showed well resolved signals at τ 8.64 (triplet, methyl), 5.65 (quartet, methylene), 4.74 (triplet, meta), 4.47 (triplet, para, $J = 6.0$ Hz), and 3.90 (doublet, ortho, $J = 6.5$ Hz). In the case of the deuterated sample the spectrum was very different in the aromatic region. The meta-triplet now appeared as a five-line multiplet centered on τ 4.74, the para-proton as a partially resolved multiplet on 4.47, and the ortho-protons as a well resolved triplet on 3.9, suggesting that deuteration occurred on all available positions. The integral intensity was now in the ratio 1 meta:0.6 para:0.8 ortho:2 methylene:3 methyl protons indicating that 50% of the meta, 40% of the para, and 60% of the ortho protons had been exchanged by deuterium.

The n.m.r. spectrum of the tricarbonyl(benzoic acid)chromium in CD_3COCD_3 showed signals at τ 4.39 (triplet, meta), 4.11 (triplet, para), and 3.74 (doublet, ortho). The n.m.r. spectrum of the deuterated sample was almost identical to the deuterated sample of the ester complex as regarded the coupling pattern of the signals. The signals were, however, centered on the same positions as that of the undeuterated acid complex. The integrated intensities in the deuterated sample of the benzoic acid complex were in the ratio 1.0 meta:0.6 para:1.0 ortho suggesting an exchange of 50, 40, and 50% protons from the meta, para, and ortho positions respectively. This ratio is slightly different from that in the ester complex. This could again be explained by hydrolysis of some of the ester complex giving the complexed benzoate ion which would not be expected to exchange readily.

Attempted Deuteration of Tricarbonyl-(N,N-dimethylaniline)chromium

When the deuteration of tricarbonyl(*N*,*N*-dimethylaniline)chromium was now attempted under conditions similar to previous reactions, *ca.* 18% of the complex was recovered. The mass spectrum of this sample showed no enhancement of various peaks as compared with starting material. The n.m.r. spectrum of the recovered sample was also identical to the undeuterated sample with no difference in the integral intensities of various protons.

The results of the deuteration of the anisole complex indicate that the exchange reaction must be predominantly kinetically controlled and that the exchange of ortho-protons is kinetically preferred over that of the meta- or para-protons. The metallation of anisole with *n*-butyllithium has been reported to give exclusive (99.9%) ortho-substitution (6). The high selectivity in metallation reflects the relative thermodynamic stability of the isomeric lithiated anisoles, whereas the preference for ortho-substitution in this work reflects a lower transition state energy for proton abstraction from the ortho-position. However, in analogy with the metallation reaction it would appear that inductive and possibly chelative effects of the methoxy group can stabilize the transition state leading to ortho-deuteration.

The kinetically controlled deuterium exchange reaction of tricarbonyl(ethylbenzoate)-chromium gives an almost statistical exchange pattern of ortho:meta:para. The carboxyethyl group can withdraw electrons by both inductive and mesomeric effects, and thus help stabilize a negatively charged transition state in any position. Possibly slightly higher deuteration may be expected at the ortho- and para-positions of this compound but results give marginal support for this suggestion.

Tricarbonyl(*N*,*N*-dimethylaniline)chromium should be comparatively more susceptible to hydrogen–deuterium exchange reaction because of strongly electron-withdrawing power of $Cr(CO)_3$ group. Moreover, electronegative nitrogen could also activate the ortho-hydrogens inductively. But no deuteration takes place even in the chromium complex of *N*,*N*-dimethylaniline. This could be due to weak inductive effect of nitrogen as compared with oxygen in anisole. It is also possible that flanking methyl

groups of *N,N*-dimethylamino group inhibit sterically the exchange of ortho-protons.

In conclusion, the base-catalyzed hydrogen-deuterium exchange reactions in these tricarbonylchromium complexes can be rationalized by considering the well-known inductive, mesomeric, and steric effects of the substituents.

Experimental

Spectra

Mass spectra were determined with an AE1 MS9, using the heated inlet system and operating at 70 and 12 eV. The n.m.r. spectra were recorded for $CDCl_3$ and CD_3COCD_3 solutions (as specified) containing TMS as internal standard using a Varian HA 100 spectrometer.

Materials

Tricarbonylchromium complexes of anisole had m.p. 85–86° (lit. 86–87° (1)) and that of *N,N*-dimethylaniline, m.p. 143–144° (lit. 145.8–146.5° (1)). Tricarbonyl(ethyl-benzoate)chromium, m.p. 52–53° from ether–light petroleum, was prepared by the method of Nicholls and Whiting (1).

Anal. calcd. for $C_{12}H_{10}CrO_5$: C, 50.3; H, 3.5. Found: C, 50.1; H, 3.5.

Ethanol-*O*-d_1, was prepared by the method of Shiner and Smith (7).

Deuteration of Tricarbonyl(anisole)chromium

A solution of tricarbonyl(ethyl benzoate)chromium (0.4 g) in ethanol-*O*-d_1 (100 ml) was placed in a thick-walled glass tube and sodium ethoxide, prepared from sodium (2.0 g), added under a nitrogen atmosphere. The solution was flushed well with nitrogen, the tube sealed and heated at 100° for 24 h. The cooled reaction mixture was poured into ice water and the product (55 mg) isolated in benzene. One crystallization from light petroleum gave tricarbonyl-(anisole)chromium (34 mg), m.p. 86–87°.

Another reaction on an identical scale which was heated for 24 h recovered tricarbonyl(anisole)chromium (68 mg, 17%). The mass spectrum indicated that *ca.* 15% of mono-deuteration had taken place and n.m.r. spectrum showed that this had occurred mainly in the ortho-position (see Discussion).

Deuteration of Tricarbonyl(ethyl benzoate)chromium

A solution of tricarbonyl(ethyl benzoate)chromium (0.4 g) and sodium ethoxide in ethanol-*O*-d_1 (100 ml) was heated similar to the anisole complex. After 26 h the solvent was removed on the water-bath and the hot residue poured in water. The ethereal extract gave the yellow oil (0.112 g) which on crystallization from ether–light petroleum provided only small amount (30 mg) of the ester complex, m.p. 50–51°.

The aqueous layer on acidification and routine extraction gave crude tricarbonyl(benzoic acid)chromium (0.164 g). Crystallization from ether–light petroleum afforded the acid complex (0.135 g), m.p. 195–196° (dec.) (lit. 194° (1)).

Attempted Deuteration of Tricarbonyl(N,N-dimethylaniline)chromium

A solution of tricarbonyl(*N,N*-dimethylaniline)chromium (0.4 g) and sodium ethoxide, in ethanol-*O*-d_1 (80 ml) was heated as already described. Work-up after 24 h recovered the complex (73 mg, 18%), which on crystallization from ether–light petroleum afforded the complex (49 mg), m.p. 143–146° (dec.).

A repeat experiment on an identical scale gave the complex (53 mg).

The author wishes to thank Dr. W. R. Jackson and Dr. J. Grimshaw of this Department for their helpful discussion. Thanks are also due to Mr. T. G. Kee who performed a section of the experimental work. The award of a visiting studentship from this University is also acknowledged.

Stereochemistry of some Altersolanol B Derivatives and their Correlation with Bostrycin[1]

M. GORDON, A. STOESSL, AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario and the Research Institute, Canada Department of Agriculture, London, Ontario

Received August 25, 1971

The results of a complete analysis of the proton spectra of altersolanol B acetonide indicate that this compound exists preferentially in the half-chair conformation corresponding to that favored by the parent pigment in the solid state, as shown by previous X-ray studies. In contrast, the triacetate derivative apparently adopts the alternative half-chair conformation.

Les résultats d'une analyse complète r.m.n. de l'altersolanol B acétonide indique que ce composé existe préférentiellement sous la forme demi-chaise correspondant à celle favorisée par le pigment de base dans l'état solide, comme l'ont montré de précédentes études rayons-X. En revanche, le dérivé triacétate adopte apparemment la conformation demi-chaise alternative.

Canadian Journal of Chemistry, **50**, 122 (1972)

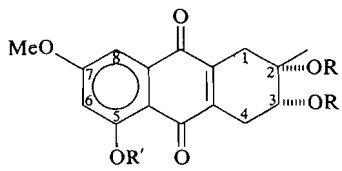
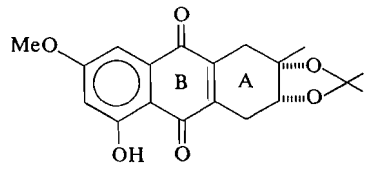
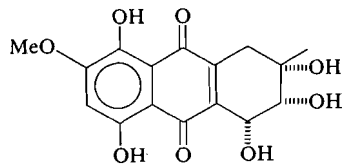
In an earlier paper on some metabolites of *Alternaria solani* (1), structures were proposed for altersolanol B (**1**, R = R′ = H), its triacetate (**1**, R = R′ = Ac) and isopropylidene (**2**) derivatives. To confirm the assigned structures and to obtain information bearing on the probable conformations of these materials, a complete analysis of the proton spectrum of acetonide **2** was undertaken. In the interim Noda *et al.* (2) reported the results of their structural study of bostrycin (**3**), a closely related tetrahydroanthraquinone pigment. These authors found that treatment of hydrogenation products of **3** with *p*-bromobenzoyl chloride in pyridine yielded a crystalline ester which was subsequently hydrolyzed in these laboratories to give altersolanol B as judged by t.l.c. and u.v. spectra. X-Ray diffraction results for the *p*-bromobenzoate **1** (R = H, R′ = *p*-BrC_6H_4CO) were presented by Takenaka *et al.* (3). As a further check on the correspondence between the two pigments a sample of acetonide **2** was treated with *p*-bromobenzoic anhydride in tetrahydrofuran containing some γ-dimethylaminopyridine to yield an acetonide ester. Upon removal of the isopropylidene group, the resulting *p*-bromobenzoate was compared to an authentic sample of the degradation product obtained by Noda *et al.* (2) and found to be identical by m.p., mixture m.p., i.r. and u.v. spectra and specific rotation. Consequently, the structures originally proposed are undoubtedly correct but the question of preferred conformation remained.



1



2



3

In addition to the methyl proton absorptions, the high field region of the proton spectrum of **2** consists of two overlapping AB patterns one of which is part of an ABX system; since the two AB patterns are long-range coupled a better description of the spin system may be ABMNX. To

analyze this portion of the spectrum the LAOCOON III program was utilized with spectra obtained at 60 and 100 MHz. Since the amount of material was limited, time-averaging was employed to obtain spectra having suitable S/N ratios. The averaged results of these analyses are listed in Table 1. The acetonide methyl protons absorb at δ 1.22 and 1.37 while the quaternary methyl protons appear at δ 1.46; the *gem*-dimethyl absorptions are readily identified since each appears as a quartet ($J = 0.6$ Hz) due to mutual long-range coupling. The relatively small shift between the *gem*-dimethyl protons offers strong evidence that these groups do not lie close to the double bond of the B-ring, *i.e.*, this acetonide does not exist in a boat conformation analogous to that found for altersolanol A acetonide (4).

The lowest field pattern, readily assigned to the C-3 proton, has the typical appearance of the X-absorption for an ABX spin system; there is no evidence of coupling between the X proton (C-3 H) and the C-1 methylene protons. The sum of the vicinal coupling constants, $J_{AX} + J_{BX}$, is obtained directly from the X-pattern and the value of 6.5 Hz indicates the absence of a *trans*-diaxial interaction. This observation rules out the alternative boat conformation for the A-ring in which the acetonide grouping is in a pseudo-equatorial orientation. The intensity of the X pattern increases by 14% upon simultaneous irradiation of the δ 1.46 methyl protons; this nuclear Overhauser enhancement confirms the *cis* relation of X with respect to the quaternary methyl.

On the basis of the foregoing it follows that the A-ring exists in a half-chair conformation for which there are two possibilities, **4** and **5**. To illustrate the relative orientations of the ABX protons in each of these conformations, Newman projections along the C_3—C_4 bond are shown

6 7

as **6** and **7**, respectively. Since **4** requires an essentially *trans*-diaxial disposition of the X proton with respect to one of the vicinal protons and the vicinal couplings are 4.3 and 2.4 Hz it appears that **5** is the preferred conformation. The dihedral angles between vicinal protons in this form are approximately 75 and 45°, which are consistent with the observed couplings. It is interesting that the geminal coupling constants for the C-1 and -4 methylene groups differ slightly, -17.3 and -17.9 Hz, respectively. This difference may be taken to indicate that the C-4 protons are more symmetrically disposed relative to the double bond than the C-1 methylene protons (5) which suggests a slight warping of half-chair **5**. There remains the assignment of the long-range, homoallylic couplings. Since it is generally found that protons lying near the plane of the π-system in the HC—C=C—C—H fragment exhibit small coupling constants while diaxial protons are the most strongly coupled nuclei in such systems (6), the following assignments may be made: $J_{1a',4a'}$ 2.2; $J_{1e',4a'}$ 1.3; $J_{1a',4e'}$ 0.2; and $J_{1e',4e'}$ 0.9 Hz. The chemical shifts of the methylene protons are consistent with these assignments in that the pseudo-axial protons are significantly shielded relative to their pseudo-equatorial counterparts.

On the basis of the X-ray diffraction results for the *p*-bromobenzoate of altersolanol B, it follows that the preferred conformation for the parent pigment, in the solid state, is also the half-chair form corresponding to **5**. Although we have been unable to complete the analysis of the

spectrum of altersolanol B triacetate (**1**, R = R′ = Ac), the absorption of the C-3 proton is distinctively the X-portion of an ABX system in which $(J_{AX} + J_{BX}) = 10.5$ Hz, significantly larger than that found for the acetonide. This finding strongly suggests that altersolanol B triacetate preferentially exists in the alternative half-chair conformation in which the C-3 proton is *trans*-diaxial with respect to one of the vicinal protons as in **6**.

The correlation with the *p*-bromobenzoyl derivative of bostrycin establishes **1** (R = R′ = H) as a representation of the absolute stereochemistry of altersolanol B. It is most probable that altersolanol A, a cometabolite of altersolanol B, will have the same configuration at C-2 and -3. Therefore, the absolute stereochemistry of altersolanol A is the mirror image of that depicted in an earlier communication (4).

Experimental

Nuclear Magnetic Resonance Spectra

The proton spectra were obtained with Varian HA-60 and HA-100 instruments using dilute solutions in $CDCl_3$. To increase the sensitivity, time-averaged spectra were collected using a Varian C-1024 device; in each case 100–200 scans over sweep widths of 100–500 Hz were employed. Spectral analysis was accomplished using the LAOCOON III program of Bothner-By and Castellano with the University of Western Ontario 7040 computer. Comparisons of the observed spectra with those calculated were aided by generating the latter using a plot program kindly supplied by Dr. Castellano in conjunction with the Cal-Comp plotter of the University of Western Ontario computer center. The precision of the chemical shifts and coupling constants is judged to be ±0.05 Hz; both 60 and 100 MHz spectra were fitted with an overall r.m.s. error of 0.05.

Altersolanol B 5-p-Bromobenzoate

Altersolanol B acetonide (35 mg; 0.104 mmol) in tetrahydrofuran (1.5 ml) was added to an ice-cold suspension of *p*-bromobenzoic anhydride (153 mg; 0.40 mmol) in a solution of 4-dimethylaminopyridine (48 mg; 0.40 mmol) in tetrahydrofuran (2.5 ml), which was then allowed to warm to room temperature. After gentle shaking during 2 h, the clear solution was poured on ice (10 ml), sodium hydrogen carbonate solution (5%, 2 ml) was added, and the solution extracted with ethyl acetate (3 × 10 ml). After washing with dilute sodium hydrogen carbonate, water, ice-cold *N*/10 hydrochloric acid, and repeatedly with water, the extracts were dried, filtered, and evaporated *in vacuo*. The bright yellow band obtained on preparative t.l.c. of the residue (silica gel (Camag DF-5), with ether–petroleum ether (b.p. 37–67°)–acetic acid (30:70:2) as irrigant) was eluted. A little more of the same material was obtained by irrigating a band, which had remained at the origin, with methanol–chloroform–acetic acid (10:90:2). The combined product was crystallized and recrystallized from ether, to give altersolanol B acetonide-5-*p*-bromobenzoate (12.6 mg); m.p. 209–212°; λ_{max} 375, 340, 284 (sh), 266 (sh), and 252 nm (log ε 3.24, 3.30, 4.23, 4.48, and 4.49).

To a solution of the acetonide 5-*p*-bromobenzoate (8.6 mg) in chloroform (1 ml)–methanol (1.8 ml) was added aqueous hydrochloric acid (0.2 ml 1 *N*). After 22 h at room temperature, the solution was evaporated *in vacuo* and the product recrystallized from ethanol. It was identical with an authentic specimen of the *p*-bromobenzoate derived from bostrycin by m.p., mixture m.p., i.r. spectrum (in $CHCl_3$), u.v. spectrum (λ_{max} 375, 340, 281 (sh), and 248 nm (log ε 3.19, 3.30, 4.18, and 4.47). Both specimens exhibited the same specific rotation ($[\alpha]_D^{23}$ +23°; *c*, 0.40 in $CHCl_3$).

We thank Dr. T. Noda for a generous gift of bostrycin and its *p*-bromobenzoate derivative; Mr. G. Rock and Miss P. M. Pellitt for valuable technical assistance; and Dr. S. Castellano, Carnegie-Mellon University, for kindly supplying the plotter program. The financial support of the National Research Council of Canada is gratefully acknowledged.

The Adsorption of Alkylchlorosilanes on Quartz Crystal Surfaces

G. M. KHAN
Institute of Chemistry, University of Islamabad, Rawalpindi, Pakistan

Received June 29, 1971

The piezogravimetric method has been used to study the adsorption of dimethyl and trimethylchlorosilanes on quartz crystal surfaces by varying the mode of treatment. The nature of the resulting low-energy surfaces has been discussed in the light of the extent of adsorption of *n*-hexane and water, calculated at different relative pressures, from their isotherms. The results obtained permit the conclusion that after the adsorption of silanes at 240 °C, the modified surface may be described as close-packed methyl surface, impenetrable to *n*-alkane and water vapor.

La méthode piézogravimétrie a été utilisée pour étudier l'adsorption des diméthyl et triméthylchlorosilanes, sur des surfaces en cristaux de quartz, en modifiant les modes de traitement. La nature des surfaces à faible énergie ainsi obtenues a été discutée à la lumière du degré d'adsorption en *n*-hexane et eau, calculé à différentes pressions relatives, à partir de leurs isothermes. Les résultats obtenus permettent de conclure qu'après l'adsorption des silanes à 240 °C, la surface modifiée peut être décrite comme étant une surface méthylée très tassée, impénétrable aux *n*-alkanes et à la vapeur d'eau.

Introduction

The ability of alkylchlorosilanes to chemisorb onto many high energy surfaces, and convert them to low energy ones, is well-known. Most of the previous work has been concerned, for technological reasons, with glass substrates. Glass differs from quartz in the well-known sense that the very term 'glass' implies a measure of uncertainty; the type of glass, and its mode of preparation, needs to be specified. The term 'quartz' is more precise, particularly when a certain modification, and crystal cut are specified. Nevertheless, glass and quartz crystals possess some features in common. With particular respect to the chemisorption of alkylchlorosilanes, the critical feature concerns the number and distribution of residual hydroxyl groups on the surface, these being dependent both upon the basic nature of the substrate and upon the history of its pretreatment.

Surface hydroxyl groups, or residual adsorbed water molecules upon glass or quartz surfaces must obviously play a predominant role in the chemisorption of alkylchlorosilane vapors to which they are exposed. Presently available information in the literature is helpful, but not definitive (1–3). There are, for example, indications that not all of the hydroxyl groups are removed during the vapor phase adsorption of trichloroalkylsilanes on hydrated porous glass samples at room temperature (2, 3). The findings from the present studies fall into the same class; they are indicative, rather than definitive.

Experimental

The core feature of the piezogravimetric method is that a suitably chosen quartz crystal, capable of resonating at its characteristic frequency between two exciting electrodes, be coupled with an auxiliary device for measuring frequency shifts at various pressures of the adsorbate vapor, at equilibrium with the adsorbent phase, in an accurately temperature controlled cell. The vacuum system and circuits used in this work have been described, in detail, elsewhere (4). However, for convenience, Fig. 1 is given here which shows the details of the experimental cell and the quartz crystal mounting assembly.

Before use, the cell, stainless steel components, and the crystal assembly were treated with chromic acid – sulfuric acid mixture followed by repeated rinsing with triply-distilled water. Prior to each set of observations, the cell with crystal assembly was heated at 240 °C and the vacuum line was thoroughly baked at 80 °C for about 48 h. Special attention was paid to the purity of the adsorbate sample of *n*-hexane obtained from Matheson Coleman and Bell Co. (U.S.A.), listed as being of chromatoquality, which was further dried thoroughly by passing through molecular sieve and finally degassed by trap-to-trap distillation and repeated freezing and thawing in vacuum. The water used as adsorbate was, of course, triply-distilled, and the alkylchlorosilanes were kindly provided by Dr. A. C. Lowe (5). They had been purified by trap-to-trap distillation under grease-free conditions.

The crystal assembly mounted in the experimental cell and connected to the oscillator was placed in the air-stirred constant temperature thermostat and the whole system was evacuated for a period of about 24 h, till the system had attained a full stability shown by a constant value of the resonant frequency. As the temperature of the adsorbate

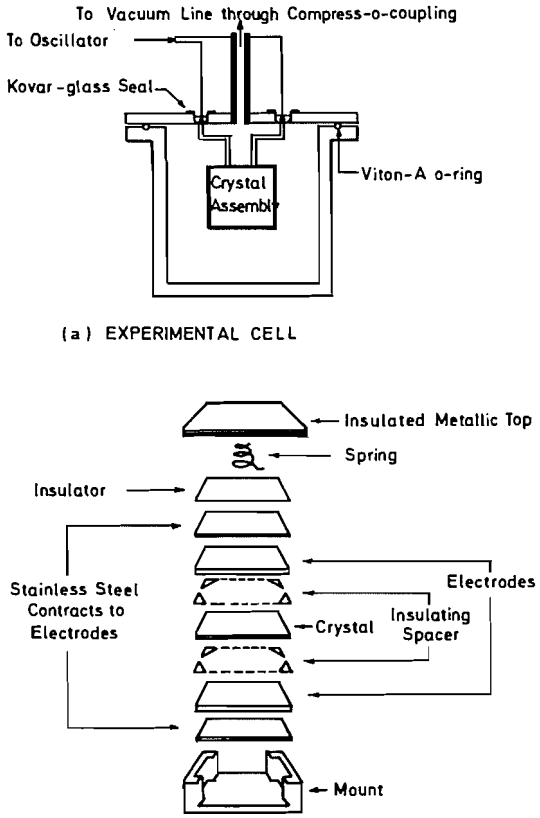

FIG. 1. The schematic diagram of (*a*) the experimental cell, (*b*) the quartz crystal mounting assembly.

vapor differed from that of the quartz surface, the former was preheated in a preliminary thermostating compartment before admitting it into the cell. At each run the vapor was introduced gradually by increasing the pressure in small steps. Following the introduction of vapor, the frequency was monitored as a function of time over a period of about 30 min for each run until equilibrium had been attained. After the determination of a particular isotherm, the system was outgassed till a stable value for the resonant frequency was obtained again.

Three AT-cut crystals, A, B, and C have been used during these studies. Their apparent (geometric) available areas for adsorption and their masses are shown in Table 1, which also summarizes the treatments to which the crystals were submitted and the designations given to each treated surface.

Crystal A cleaned and mounted in standard fashion, and stable to the extent shown in Table 2, was placed in the experimental cell and outgassed as mentioned before. It was named surface 'A' and the adsorption of *n*-hexane and water vapors was studied on this surface. The experimental system was outgassed hard, at 200 °C, and surface 'AS2' prepared by adsorbing $(CH_3)_2SiCl_2$ on the crystal at 26.7 °C. The process was monitored by measuring the change in crystal frequency. When the latter approached constancy, excess silane was removed by the pump. The stability of this coated crystal is also shown in Table 2, and appeared to be somewhat better than the uncoated crystal. The term 'S2' is simply a convenient notation for dichloromethylsilane. After adsorption studies on 'AS2' surfaces above, the experimental cell was outgassed and heated to 160 °C for about 5 h before being allowed to cool. The adsorption of *n*-hexane and water vapor was studied on the resulting surface termed 'AS2H'.

Crystal B, essentially similar to A, was coated with $(CH_3)_2SiCl_2$ by exposure to the vapor at 240 °C for approximately 8 h and the adsorption of *n*-hexane and water vapor was studied on the resulting surface termed 'BS2HA'. The surface 'CS3HA' was prepared in the same manner as 'BS2HA' except that crystal 'C' was coated with $(CH_3)_3SiCl$ by exposure to the vapor under the same conditions and the adsorption studies of *n*-hexane and water vapor were studied as mentioned before.

Results and Discussion

Figures 2 and 3 show the observed extent of adsorption measured by the change in frequency, $\Delta\nu$, for *n*-hexane and of water vapor in comparative form for these different surfaces as a function of pressure. As expected, the extent of adsorption was always highest upon the clean quartz surface 'A'. Of more interest, adsorption decreases in passing from the 'AS2' surface,

TABLE 1. Nomenclature of the surfaces (all crystals used were AT-cut)

Crystal	Apparent area used for adsorption (cm^2)	Mass (g)	Treatment	Designation of surface

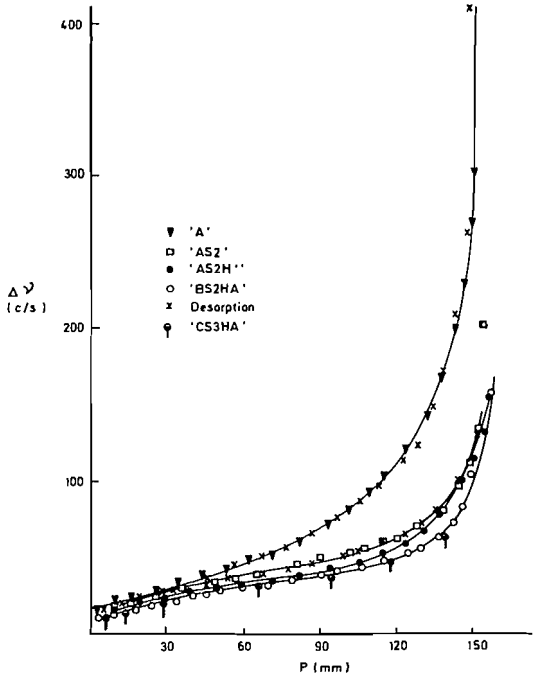

FIG. 2. Extent of *n*-hexane adsorption on 'A', 'AS2', 'AS2H', 'BS2HA', and 'CS3HA' at 26.7 °C.

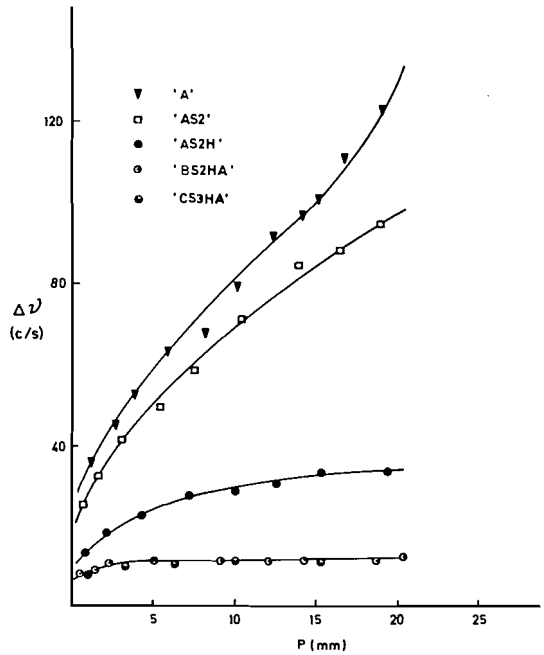

FIG. 3. Extent of water adsorption on 'A', 'AS2', 'AS2H', 'BS2HA', and 'CS3HA' at 26.7 °C.

through the 'AS2H', 'BS2HA', and 'CS3HA'. The differences between the 'AS2H' and 'BS2HA' surfaces are smaller than those found for the 'AS2' surface, but are sufficiently large as to indicate a marked difference between a heat-cured surface prepared by silane deposition at 26.7 °C, followed by heating at 160 °C, and the surface prepared by deposition at 240 °C.

From Fig. 2, the adsorption of *n*-hexane on the 'AS2' surface is not too dissimilar from the behavior found for the 'AS2H', 'BS2HA', and 'CS3HA' surfaces. This presumably reflects the size of the adsorbate molecule as compared with the possibility of its penetrating the surface layer. For the smaller water molecule (see Fig. 3), there is a much greater spread in the extent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of adsorption upon the three coated surfaces, adsorption on 'AS2' now tending towards the values found for the clean quartz surface. This must mean that water molecules can penetrate through gaps in the silane layer deposited at 26.7 °C. These gaps are reduced in number or diameter by subsequent curing at 160 °C, and still further by deposition at 240 °C.

From a practical point of view it is clear that when a silane layer is deposited upon a quartz surface under moderate conditions, the resulting surface is more hydrophilic than when the same surface is heated prior to exposure to water vapor, or when the initial silane deposition is conducted at elevated temperature. Whether heat is necessary to bond the silane layer fully to the surface, either during the initial act of deposition, or subsequently, and the mode of such treatments, are matters upon which the present studies can give no clear guide, although it should be noted that Armstead and Hockey have shown that reactions between methylchlorosilanes and silica surfaces are completed in 1 h at temperatures in excess of 280 °C. In the present studies, the use of curing temperature around 240 °C, for periods of approximately 8 h would suggest similar completion.

The author wishes to express his thanks to the National Research Council of Canada for support of this work, and to the Department of Chemistry, University of Victoria, Victoria, British Columbia for providing necessary research facilities, and Professor A. C. Riddiford for his guidance throughout this work.

An Aromatic Amine—1,3,5-Trinitrobenzene σ-Complex

E. BUNCEL AND J. G. K. WEBB

Department of Chemistry, Queen's University, Kingston, Ontario

Received September 7, 1971

Interaction between aniline and the 1,3,5-trinitrobenzene–methoxide ion adduct **1** in DMSO solution results in spectral changes which are characteristic of σ-complex formation, the first such case involving an aromatic amine.

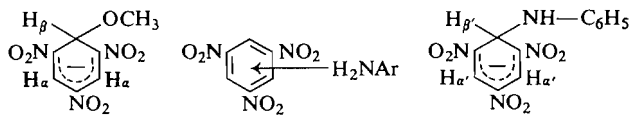
L'intéraction entre l'aniline et le produit d'addition trinitro-1,3,5 benzène–ion méthylate **1**, en solution dans le DMSO, provoque des modifications spectrales caractéristiques de la formation d'un complexe σ. Ce cas est le premier qui implique une amine aromatique.

Canadian Journal of Chemistry, **50**, 129 (1972)

The interaction between aromatic polynitro compounds and a variety of anionic reagents is now well established to give rise to covalently bonded adducts, generally called Meisenheimer or σ-complexes (1). The relevance of such complexes in nucleophilic aromatic substitution has been discussed (1). The 1,3,5-trinitrobenzene–methoxide ion adduct **1**, for instance, has been characterized through n.m.r., visible, and i.r. spectroscopy. σ-Complex formation between polynitro aromatics and primary or secondary aliphatic amines is likewise established (2, 3). In contrast, the interaction between aromatic amines and polynitro aromatics which has been characterized hitherto (4, 5) is the weaker electron-donor–acceptor type of interaction (6, 7), leading to charge transfer complexes which can be represented by **2**. The presumed lack of formation of σ-adducts with aromatic amines could be rationalized on the ground of their very much weaker basicity in comparison with aliphatic amines.

We have now obtained evidence which is strongly indicative of the formation of a σ-complex between 1,3,5-trinitrobenzene and aniline. The complex appears to be formed in the interaction between aniline and adduct **1** in dimethylsulfoxide (DMSO) solution. The characterization involves n.m.r. and visible spectroscopy.

The substance **1**, prepared (8) as the potassium salt from 1,3,5-trinitrobenzene and potassium methoxide, showed in the n.m.r. spectrum in DMSO-d_6 signals (quoted downfield in p.p.m. from tetramethylsilane as internal standard) at 8.57 (doublet, J 1.2 Hz), 6.25 (unresolved triplet), and 3.30 (singlet), corresponding respectively to the H_α, H_β, and OCH_3 proton resonances. Addition of aniline in DMSO-d_6 (the initial solution concentrations being *ca.* aniline, 0.5 M; **1**, 0.4 M) resulted in spectral changes with time as follows. A spectrum taken 10 min after mixing exhibited the H_α, H_β, and OCH_3 absorptions due to **1**, a multiplet centered at 6.9 p.p.m. due to the ring protons of aniline and a broad signal at 4.9 p.p.m. due to the amino protons of aniline; in addition there were present a small peak upfield by 0.1 p.p.m. from H_α and assigned to H'_α of **3**, a doublet 0.4 p.p.m. upfield from H_β, interpreted as half the NH—H'_β AB quartet expected for **3**, and peaks due to methanol at 4.1 and 3.2 p.p.m. The spectrum obtained



1 **2** **3**

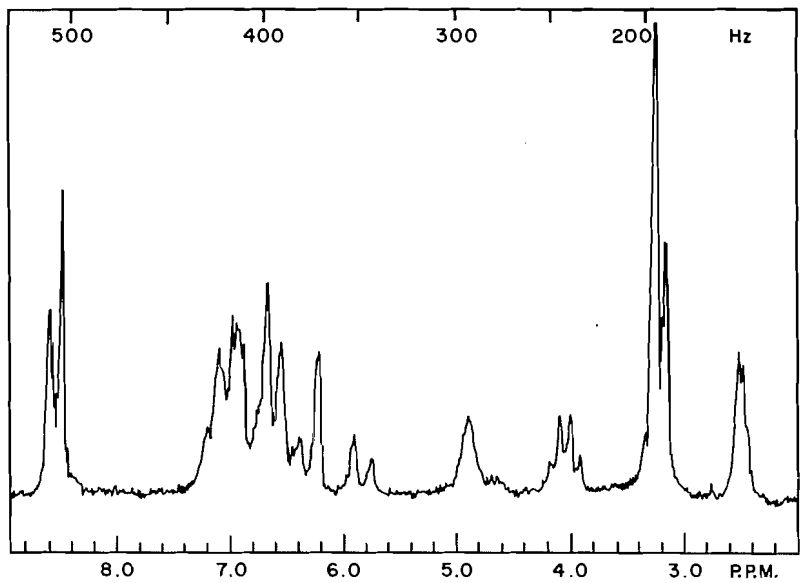


FIG. 1. The n.m.r. spectrum at 60 MHz for reaction of TNB–methoxide ion σ-complex with aniline in DMSO taken after 75 min.

after 75 min is shown in Fig. 1 and exhibits further development of the H_α' signal at the expense of H_α and a clearer emergence of the NH—H_β' quartet. The NH_2 signal has become correspondingly diminished and the methanol signals increased. The multiplet at 2.5 p.p.m. represents residual DMSO-d_5 in the solvent. A spectrum taken after 26 h shows these changes to be substantially complete. Addition of a small amount of D_2O to the solution results in a collapse of the NH—H_β' quartet into a single slightly broadened peak at 6.30 p.p.m. as a result of deuteration of NH, and at the same time a sharp OH signal at 4.00 p.p.m. is produced. Thus the n.m.r. assignments for the σ-adduct **3** are: H_α' 8.45, H_β' 6.30, NH 5.88 p.p.m., J(NH—H_α') 8.8 Hz. Isolation of the complex in the pure state has not yet been found feasible.

The reaction between aniline and **1** in DMSO was also followed by visible spectroscopy. Using the solution prepared for the n.m.r. measurements, 0.05 ml aliquots were withdrawn periodically, diluted to 5 ml with DMSO, and the spectra taken in a 0.1 mm cell. Reaction was thus seen to be accompanied by a decrease in the 427 and 509 nm absorptions characteristic of **1** and the growth of peaks at 443 and 520 nm due to product formation. Reasonably tight isobestic points were maintained for interconversion of the two absorbing species. These spectral characteristics of the reaction product, *i.e.* twin absorptions with the higher energy maximum being more intense, are typical of σ-complexes in the trinitrobenzene series (1, 9).

Thus the n.m.r. and visible spectral characteristics observed in the interaction of aniline with adduct **1** are fully in accord with formation of σ-complex **3**. In continuation, it should be of interest to determine whether substituents in the aryl amine moiety can lead to useful information concerning structural characteristics of these σ-complexes. Systematic studies, through kinetic and thermodynamic measurements, are underway to investigate this possibility. The detailed mechanism for formation of **3** should then also be clarified.

Support of this research by the National Research Council of Canada is gratefully acknowledged.

Aqueous Solutions of Nonpolar Compounds. Heat-Capacity Effects[1]

R. D. WAUCHOPE[2] AND R. HAQUE

Department of Agricultural Chemistry and Environmental Health Sciences Center, Oregon State University, Corvallis, Oregon 97331

Received July 19, 1971

The method of Clarke and Glew has been used to obtain estimates of the precision of measurement of the thermodynamic functions for the solution of hydrocarbons, the noble gases, and inert diatomic gases in water. In some cases, the precision of the data is such that a statistically significant value for the temperature coefficient of the heat-capacity change for the solution process is obtained. Comparison with the theory of Némethy and Scheraga shows that their calculations of heat-capacity changes at 25 °C are better than previously believed, but that their prediction of a positive temperature coefficient for this quantity is in contradiction with most data.

On a utilisé la méthode de Clarke et Glew pour obtenir des estimés de la précision des mesures des fonctions thermodynamiques dans le cas de solutions d'hydrocarbures, de gaz nobles et de gaz diatomiques inertes dans l'eau. Dans quelques cas, la précision des données est telle qu'on obtient une valeur statistiquement significative pour le coefficient de température du changement de capacité calorifique pour le procédé de solution. Une comparaison avec la théorie de Némethy et Scheraga montre que leurs calculs de changement de capacité calorifique à 25 °C sont plus valables qu'on le croyait antérieurement, mais que leur prédiction d'un coefficient de température positif pour cette quantité est en contradiction avec la plupart des données.

Canadian Journal of Chemistry, **50**, 133 (1972)

Introduction

The aqueous solubility of nonpolar compounds plays a major role in explaining the behavior of such chemicals in various phases of the environment. Theories of the effects of water-structure on solubility, some quite elegant (1–8), have been advanced which account for most of the unusual properties of aqueous solutions of nonpolar species, but the large partial molar heat capacities observed for these solutes are difficult to predict from theory (8). The analysis of this problem is pivotal in the understanding of these solutions, and in understanding the biochemical effects for which these solutions have served as models (4, 9, 10). We have reviewed the best solubility data from the literature to determine how much is known from experiment. In particular, since the heat-capacity change for the solution process is a second derivative quantity requiring precise solubility *vs.* temperature data for its determination, we wished to know the limits of error with which this quantity has been determined for various nonpolar solutes, and, if possible, its dependence on temperature.

The calculation of thermodynamic functions from equilibrium constant data involves "curve fitting" to a model temperature function. Much of the solubility data for nonpolar solutes has been correlated using the Valentiner equation (11, 12) where K_s

$$[1] \qquad \ln K_s = AT^{-1} + B \ln T + C$$

is the solubility at temperature T. For accurate

solubility data, however, covering a wide range of temperatures, eq. 1 fails and an equation which describes functional dependence of ΔC_p on T is needed. Himmelblau (13) used an expression of the form

$$[2] \quad A(\log K_s)^2 + BT^{-2} + CT^{-1} \log K_s + D \log K_s + ET^{-1} - 1 = 0$$

to fit gas solubilities up to near the critical point of water, but for solubilities in the region of room temperature a simple expansion of the heat capacity in powers of T has been sufficient for most data (14, 15), giving an expression of the form

$$[3] \quad \ln K_s = AT^{-1} + B \ln T + C + DT + ET^2 + \ldots$$

Glew (14) fitted the data for methane to the four-term form of eq. 3, obtaining a linear temperature coefficient of ΔC_p for the solution process. On the other hand, Franks *et al.* (16) found that a simple power series in T fitted the data for benzene better than eq. 3.

Clarke and Glew (17) have derived a general family of equations to describe the temperature dependence of equilibrium constants. These are equivalent in functional form to eq. 3 but allow the unbiased estimate of the standard errors of the derived thermodynamic functions. A stepwise least-squares regression fit to successively higher-order variables in T is performed, and standard statistical tests (17, 18) allow an objective decision to be made as to whether $d\Delta C_p/dT$ or higher-order derivatives of ΔC_p are significantly different from zero. In the present paper the method of Clarke and Glew has been applied to the available solubility data because of its generality and because it provides estimates of the precision with which the thermodynamic functions have been determined.

Sources and Treatment of the Data

Sources of data are listed in Table 1 in approximate order of decreasing internal precision, as estimated from the present curve-fitting procedure. In several cases, independent investigations of a solute have been made of near-equal

precision, and each is shown. For methane, a solute which has been studied many times, only the data of Morrison and Billett (19) are presented: Glew (14) previously analyzed these and other data with results in substantial agreement with ours.

Unsmoothed solubility data from the various sources were all converted (29) to Henry's law coefficients,

$$[4] \qquad K_T\,(\text{atm}) = f_s/X_s$$

where f_s is the fugacity of the solute over a saturated solution of mole fraction X_s. The standard free energy of solution at temperature T is then calculated from

$$[5] \qquad \Delta G_T^0\,(\text{cal/mol}) = RT \ln K_T$$

and the standard enthalpy, etc., of solution are obtained through standard thermodynamic relations from the temperature dependence of $\ln K_T$. All standard thermodynamic functions thus refer to the process

$$[6] \qquad \text{gas, 1 atm, } T \rightarrow \text{soln, } X_s = 1, T$$

in which the effects of solute condensed state are removed, allowing a comparison of "hydration" effects only (30). For liquids and solids, f_s was taken to be the saturation vapor pressure of the pure solute, neglecting the effects of water dissolution in the solute phase. Vapor pressures for the liquid hydrocarbons and naphthalene were taken from the compilation by Dreisbach (31); the data of Bradley and Cleasby (32) were used for the other solid hydrocarbons. No corrections were made for the small expansion of the aqueous phase with dissolution of the solute; according to Weiss (15), the effect for nitrogen and argon is approximately 0.14% but for most solutes this quantity, and its dependence on temperature, is not known.

Eley (34) suggested that comparisons of thermodynamic functions for the dissolution of nonpolar solutes in water should be made at 4 °C, where the entropy and enthalpy of cavity formation is at a minimum. However, most of the data in Table 1 span ranges near room temperature, and the usual comparison at 25 °C seemed more appropriate. Furthermore, very accurate studies (20–22, 24) of argon, nitrogen, and oxygen showed complicated temperature dependences of the solubility near 4 °C; thus, for purposes of comparison with the other solutes, data points in this low-temperature region were deleted, as shown in Table 1. A stepwise regression program based on the model of Clarke and Glew (17) was written for the Oregon State University CDC 3300 computer,[3] and tested with the data of Feates and Ives (33) with results identical to those obtained by Clarke and Glew.

Results and Discussion

Table 2 gives the calculated standard thermodynamic functions and errors obtained from the Clarke and Glew procedure. All data sets required at least a three-constant or Valentiner-type, equation representation, and some, as shown required four or five constants. In the four and five constant cases, a linear and quadratic dependence of ΔC_p^0 on temperature, respectively, is assumed. Rejection of fourth and fifth terms was arbitrarily made if standard statistical tests (17, 18) indicated a 20% or greater probability that the improvement in fit was due to chance.

The relationships between the standard free energies, enthalpies, and entropies of solution for the inert gases and hydrocarbons are shown in Fig. 1, plotted against molecular volumes. The results for the solid hydrocarbons will be presented elsewhere[4] but they are included in Table 2 since the present study has allowed an estimate of the precision of that data. Miller and Hildebrand (35) have discussed the trends for the entropies of the gases, and those authors' values for molecular volumes have been used to relate the volumes of methane and the smaller gases. Volumes for the hydrocarbons were taken from the data used by McAuliffe (36). Plots based on molecular surface area (35) or second virial coefficient (13) show similar trends. From Fig. 1 we find (*a*) a smaller volume for H_2 and a larger one for O_2 are required to bring them "in line" with the other small gases; (*b*) helium appears to belong to the left of neon; (*c*) based on McAuliffe's (36 and references therein) molar volume data, a comparison of benzene with the paraffin hydrocarbons indi-

cates that the enthalpy of solution for the aromatic species is more negative than for similar-sized paraffin molecules, and differences in the entropies of solution for the two types are less than previously stated.[4]

Examination of Table 2 shows that ΔC^0_p at 25 °C does increase with molecular size as has been stated (2, 4), but that the major increase occurs in the methane–butane region, with fairly constant values near 50 cal/deg mol below and 80–100 cal/deg mol above this region, respectively. Finer comparisons are made difficult by the variety of temperature intervals of the source data, and perhaps by other complications in the temperature dependence of ΔC^0_p. Regressions based on eq. 3 give non-comparable results when the data for different solutes are taken over different temperature ranges. Thus, there is little consistency in the last column of Table 2, and this may be due to wild oscillation of $d^2\Delta C^0_p/dT^2$, as suggested by the plot of ΔC^0_p *vs.* T given by Franks *et al.* (16) for benzene.

Nevertheless, some agreement between compounds is seen for the first derivative of ΔC^0_p at 25 °C; most of the entries in the fifth column of Table 2 are negative, and eight compounds, having data over similar temperature intervals, have values between −0.5 and −1.5 cal/deg^2 mol. A single value of −0.5 cal/deg^2 mol was assumed for these eight solutes (this "low"

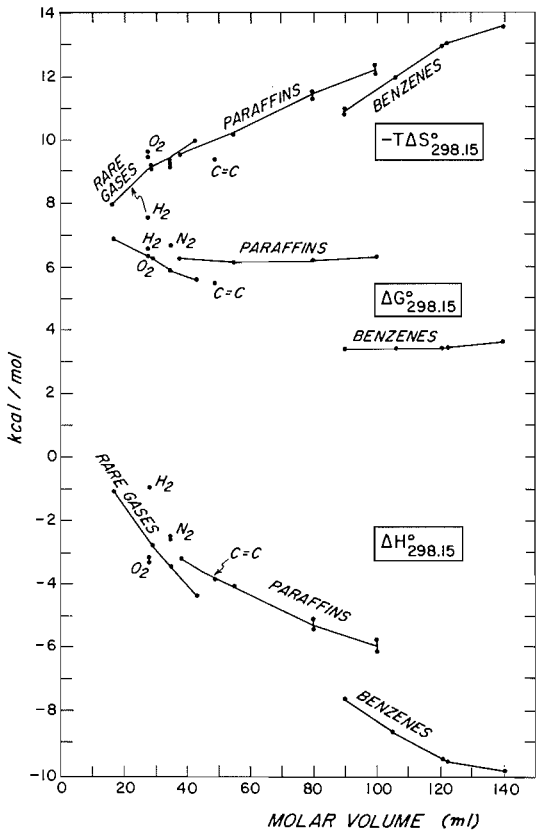

FIG. 1. Standard thermodynamic function changes for solution of gaseous compounds in water at 298.15 °K, as a function of molar volume.

average for $d\Delta C_p^0/dT$ takes into account the near-zero value which is indicated by the very accurate nitrogen and argon data, and is also closer to the values obtained by Glew (14) for methane). The values for ΔC_p^0 obtained from the three-constant step of the regression procedure, which are associated with the mid-point temperature of the data, were corrected to 25 °C using this value. The results are shown in Table 3. This assumption of a common *linear* dependence of ΔC_p^0 on temperature is doubtless an oversimplification, but it provides a first-approximation correction to ΔC_p^0 for differences in temperature range and the relation of the other solutes to the paraffins is seen. We believe these "corrected" values to be the best available for comparison with the predictions of theory. The theory of Némethy and Scheraga (4) is seen to calculate ΔC_p^0 values better than they themselves had thought, at 25 °C. However, their prediction of a positive temperature dependence of ΔC_p^0 does not agree with experiment.

NOTE ADDED IN REVISION

After submission of this study for publication, a paper by Alexander, Hill, and White (37) appeared, in which the Clarke and Glew method was used to analyze the benzene solubility data, and much of the gas solubility data, cited in the present work. In most cases their results confirm ours in detail. However, a

consistent error appears to exist in their analyses of the nitrogen, argon, and oxygen data of Klots and Benson (22), as their reported values for the standard free energy of solution at 298.16 °K yields a Henry's constant which is 0.59 that reported by Klots and Benson in all three cases.

Theoretical Anisotropic Hyperfine Tensors in Neutral Radicals

H. R. FALLE[1] AND M. A. WHITEHEAD
Department of Chemistry, McGill University, Montréal, Québec

Received December 23, 1970[2]

Anisotropic hyperfine tensors were calculated for C—H, (C—CH_3), allyl, and perinaphthenyl. In the McConnell and Strathdee theory, the anisotropic proton tensor depends primarily on the STO exponent chosen for the $2p_\pi$ carbon atom orbital. By decreasing the exponent ζ_π from the normal Slater value to ~1.3, the effect of σ-spin density in the C—H bond could be taken into account. However, this reduction in ζ_π yields too small a value for $\langle r^{-3} \rangle$, which governs the anisotropic ^{13}C tensor. Contributions to the anisotropic proton and ^{13}C hyperfine tensors are discussed, and the results compared with recent *ab initio* calculations, as well as single-crystal and liquid crystal data.

Les tenseurs anisotropiques hyperfins ont été calculés pour les groupements C—H, C—CH_3, allyle et perinaphthényle. Dans la théorie de McConnell et Strathdee, le tenseur anisotropique du proton dépend en premier de l'exposant STO choisi pour l'orbitale de l'atome de carbone $2p_\pi$. En faisant décroître l'exposant ζ_π à partir de la valeur normale de Slater approximative de 1.3, l'effet de la densité σ-spin dans la liaison C—H a pû être prise en compte. Cependant, cette réduction du ζ_π amène à valeur trop petite pour $\langle r^{-3} \rangle$ qui gouverne le tenseur anisotropique du carbone 13. Les contributions aux tenseurs anisotropiques hyperfins du proton et du carbone 13 sont discutées et les résultats comparés avec les récents calculs *ab initio*, ainsi que les données des cristals unique et d'un cristal liquide.

Introduction

The use of nematic liquid crystals as solvents in e.p.r. studies of π-electron free radicals (1–4) has provided valuable qualitative information: for example, confirmation of negative spin densities in perinaphthenyl (2). However, certain quantitative descriptions have been more difficult because of inaccuracies in the theoretical anisotropic hyperfine tensors. This difficulty is evident from the calculations of anisotropic proton tensors in perinaphthenyl (4).

McConnell and Strathdee (5) have calculated the anisotropic hyperfine tensor components for a proton bonded to a sp^2 hybridized carbon atom. Comparison with experimental results for isolated C—H fragments shows that the dominant contribution to the anisotropic proton tensor comes from the dipolar interaction between the proton and the unpaired electron in the $2p_\pi$ carbon atom orbital (5, 6). Calculation of the anisotropic hyperfine tensor for a proton in a delocalized π-electron radical requires the summation of contributions which are proportional to the unpaired π-spin densities borne by the constituent atoms (1, 7, 8). In the case of perinaphthenyl, calculations were found to agree with experiment when only the adjacent and the two nearest-neighbor π-spin density contributions were included (2). However, it was also found that, although contributions from carbon atoms further removed were significant, the inclusion of all the π-contributions in the radical led to a large discrepancy between theory and experiment (4).

The observations above were based on calculations which employed a Slater $2p_\pi$ carbon atom orbital

$$[1] \qquad \varphi(2p_\pi) \sim r \exp(-\zeta_\pi r)$$

with exponent ζ_π equal to 1.59 or 1.63, and which also neglected the effect of unpaired spin density in the σ-orbitals. The σ-spin density in the C—H bond of course gives rise to the isotropic proton coupling and, in fact, is quite substantial; in $HC(CO_2H)_2$ for example, it is roughly 5% of the π-spin density (9). Modification of the carbon orbital functions should obviously have a considerable effect on the π- and σ-contributions to the anisotropic proton tensor calculated for the hypothetical molecular fragment $\rangle\dot{C}$—H. However, it is noteworthy that the outcome obtained with Hartree–Fock ^5S carbon valence-state functions (10) is not very different from *ab initio* calculations which used a minimal basis set of Slater orbitals (6). Clearly, the inclusion

[1]Postdoctoral Teaching Fellow, McGill University, 1967–1969. Present address: Cookridge High Energy Radiation Research Centre, Cookridge Hospital, LEEDS LS16 6QB, England.

For personal use only.

of the σ-contributions only serves to increase the discrepancy between theory and experiment. On the other hand, allowance can be made for the effect of σ-spin density when the exponent ζ_π is reduced to 1.3 (10).

In order to enquire further into the disparity between the theoretical and experimental results, we have undertaken calculation of the anisotropic hyperfine tensors in perinaphthenyl with the following Slater-type (STO) atomic orbital functions:

(*A*) The STO exponents obtained from s.c.f. calculations of atomic screening constants were used; for the carbon atom $2p_\pi$ orbital, $\zeta_\pi = 1.5679$ (11).

(*B*) Using a valence-state model, the charge density dependence of the isotropic hyperfine coupling in C—H has been evaluated and STO exponents given as a function of the spin density, $\rho_{\pi\pi}$, in the $2p_\pi$ orbital; for unit $\rho_{\pi\pi}$, $\zeta_\pi = 1.5387$ (12). For the cases in which the π-spin density differs from unity, we have employed the equation

$$[2] \qquad \zeta_\pi = 1.2969 + 0.2418\rho_{\pi\pi}^2$$

This expression gives a close approximation to the results of Kay and Silverstone, except that ζ_π should be 1.2929 when $\rho_{\pi\pi}$ is zero.

(*C*) For the purpose of comparison, we have included the valence-state integral *n* minimal STO derived for alternant hydrocarbon ground-states (13). The closed-shell $2\rho_\pi$ exponent has the same value as a neutral radical with $\rho_{\pi\pi} = 0$, namely $\zeta_\pi = 1.2929$.

(*D*) Chang, Davidson, and Vincow (14, 15) have done extensive *ab initio* calculations concerning the isotropic hyperfine interactions in C—H and CH_3, employing in particular a minimal STO basis set with exponents optimized by minimization of the s.c.f. energy. The optimized $2p_\pi$ orbital exponent is $\zeta_\pi = 1.46$ (15).

While the calculated anisotropic proton tensor is most dependent on the $2p_\pi$ orbital exponent (6), the isotropic hyperfine coupling shows a significant dependence on the hydrogen 1s orbital exponent ζ_h (15). In the optimized basis set D, $\zeta_h = 1.19$ whereas a ζ_h of unity was employed in cases *A*, *B*, and *C*. Orthogonalized 2s orbitals were used in all the above cases.

In the next section, we shall review the theories of isotropic and anisotropic hyperfine interactions in the C—H fragment. The foregoing STO functions will then be applied to the calculation of the anisotropic proton tensor for C—H and for the allyl radical, in order to provide a background for the similar calculations on perinaphthenyl. The anisotropic β-proton hyperfine tensor for a freely rotating methyl group will also be included.

The C—H Fragment

The total hyperfine coupling for the proton in the trigonal fragment $\rangle$C—H is comprised of two parts; the anisotropic electron–nucleus dipolar interaction and the isotropic contact interaction (16, 17). Following the treatment by McConnell and Strathdee (5), the spin Hamiltonian for the anisotropic dipolar interaction can be written in the form

$$[3] \qquad \mathscr{H}_d = \boldsymbol{S}\cdot[-K\boldsymbol{\tau}]\cdot\boldsymbol{I}$$

where the constant K is $g\beta(\gamma/h)$ in the notation of atomic units, and takes the value 533.53 MHz a.u.[3] The tensor $\boldsymbol{\tau}$ is given by

$$[4] \qquad \boldsymbol{\tau} = \int\rho(\boldsymbol{r})\mathbf{T}\mathrm{d}v$$

in which $\rho(\boldsymbol{r})$ is the unpaired spin density distribution function, and

$$[5] \qquad \mathbf{T} = (r^{-3})[\mathbf{U} - 3\boldsymbol{rr}(r^{-2})]$$

U is the unit tensor and $\boldsymbol{r}$ is the vector position of the electron. When the complete molecular wave function is described in terms of a set of atomic orbitals $\{\phi_\lambda\}$, the spin density function has the form

$$[6] \qquad \rho(\boldsymbol{r}) = \sum_{\lambda\mu}\rho_{\lambda\mu}\phi_\lambda^*\phi_\mu$$

It follows from [4] and [6] that

$$[7] \qquad \boldsymbol{\tau} = \sum_{\lambda\mu}\rho_{\lambda\mu}\langle\phi_\lambda|\mathbf{T}|\phi_\mu\rangle$$

The spin density function can be separated into π- and σ-contributions

$$[8] \qquad \rho(\boldsymbol{r}) = \rho^\pi(\boldsymbol{r}) + \rho^\sigma(\boldsymbol{r})$$

and we can subsequently write

$$[9] \quad \boldsymbol{\tau} = \boldsymbol{\pi} + \boldsymbol{\sigma} = \sum_{\pi\pi'}\rho_{\pi\pi'}\langle\phi_{\pi'}|\mathbf{T}|\phi_\pi\rangle + \sum_{\sigma\sigma'}\rho_{\sigma\sigma'}\langle\phi_{\sigma'}|\mathbf{T}|\phi_\sigma\rangle$$

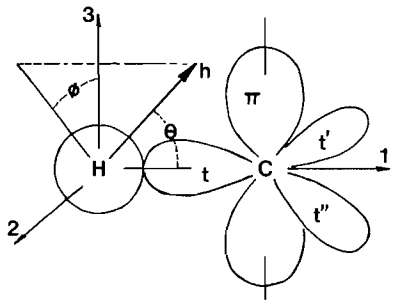

FIG. 1. The angles θ and ϕ define the direction of the external magnetic field h with respect to the principal axes $i = 1, 2, 3$ of the proton hyperfine tensor for C—H (5)

For the C—H fragment, the π-contribution to τ is simply

$$[10] \qquad \boldsymbol{\pi} = \rho_{\pi\pi}\langle\pi|\mathbf{T}|\pi\rangle$$

where $\rho_{\pi\pi}$ is the unpaired spin density in the $2p_\pi$ orbital π. When localized sp^2 hybrid orbitals, t, t', and t'' as in Fig. 1, are used to represent the σ-orbitals in C—H, the σ-spin density matrix is diagonal. By symmetry, the spin densities in the orbitals t' and t'' will be equal, though not necessarily the same as the spin density in t. The σ-contribution to τ can then be written

$$[11] \quad \boldsymbol{\sigma} = \rho_{\sigma\sigma}\langle t|\mathbf{T}|t\rangle + \rho_{\sigma'\sigma'}[\langle t'|\mathbf{T}|t'\rangle + \langle t''|\mathbf{T}|t''\rangle]$$

The established explanation for the isotropic hyperfine coupling in $\rangle$C—H is the finite unpaired spin density $\rho^\sigma(\boldsymbol{r}_H)$ at the proton, due essentially to configuration interaction (16, 17). To first-order (18),

$$[12] \quad \rho^\sigma(\boldsymbol{r}_H) = -2[\langle\sigma\pi|e^2/r|\pi\sigma^*\rangle/\Delta E]\sigma(\boldsymbol{r}_H)\sigma^*(\boldsymbol{r}_H)$$

Neglecting overlap and writing the bonding and antibonding orbitals as $\sigma = (t + h)/\sqrt{2}$ and $\sigma^* = (t - h)/\sqrt{2}$, respectively, [12] reduces to

$$[13] \quad \rho^\sigma(\boldsymbol{r}_H) = (K_{\pi t} - K_{\pi h})[|t(\boldsymbol{r}_H)|^2 - |h(\boldsymbol{r}_H)|^2]$$

in which the exchange interaction term is

$$[14] \quad (K_{\pi t} - K_{\pi h}) = (-1/2\Delta E)[\langle t\pi|\pi t\rangle - \langle h\pi|\pi h\rangle]$$

ΔE is the $\sigma \rightarrow \sigma^*$ one-electron excitation energy, t is the carbon sp^2 hybrid orbital and h the hydrogen 1s orbital. The orbital densities $|h(\boldsymbol{r}_H)|^2$ and $|t(\boldsymbol{r}_H)|^2$ are obtained by evaluating the square of h and t at the proton; in the axis system in Fig. 1,

$$[15] \qquad t = \sqrt{1/3}(2s) - \sqrt{2/3}(2p_\sigma)$$

The magnitude of the $\pi - \sigma$ exchange interaction $(K_{\pi t} - K_{\pi h})$, and hence the magnitude of the isotropic hyperfine coupling a, depends on the unpaired spin density in the orbital π. The McConnell relation

$$[16] \qquad a/\rho_{\pi\pi} = (8\pi/3)K\rho^\sigma(\boldsymbol{r}_H) = Q$$

assumes the same direct proportionality, between the isotropic proton coupling and the π-spin density, for all C—H type bonds in π-radicals. For neutral aromatic radicals, Q generally lies in the vicinity of -80 MHz (7, 17, 19) whereas -64 to -76 is quoted as the "experimental" range of Q for the fragment $\rangle$C—H (14). Now the unpaired σ-spin density in h is opposite in sign and, to first-order, equal in magnitude to that in the orbital t forming the C—H bond (16, 17). It follows that a reasonable estimate of the σ-spin density in t can be derived from the isotropic proton coupling on substitution into the equation

$$[17] \quad \rho_{\sigma\sigma} = a/\{(8\pi/3)K[|t(\boldsymbol{r}_H)|^2 - |h(\boldsymbol{r}_H)|^2]\}$$

If the three trigonal orbitals in the C—H fragment are assumed equivalent, that is to set $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$, then the principal components of the σ-contribution to τ can be reformulated from [11] as

$$[18] \qquad \sigma_{ii} = \rho_{\sigma\sigma}r^{-3}V(3\cos^2\theta - 1)$$

Similarly, the π-contribution to τ can be written

$$[19] \quad \pi_{ii} = \rho_{\pi\pi}r^{-3}[P(3\cos^2\theta - 1) + Q(1 - \cos 2\phi)]$$

The carbon–hydrogen internuclear distance is r a.u. (the atomic unit of distance is 52.9167 pm). The subscripts i refer to the axis system 1, 2, 3 and the angles θ and ϕ define the direction of the external magnetic field h, in Fig. 1. The terms V, P, and Q involve the parameter $a = \zeta r(5, 20)$ and are reproduced below for the standard STO functions $\varphi(2s) \sim r\exp(-\zeta r) \sim \varphi(2p)$.

TABLE 1. Anisotropic proton hyperfine tensor components (in MHz), calculated for the hypothetical >Ċ—H fragment, assuming $r_{C-H} = 2.05$ a.u.

STO function	Anisotropic principal component
A, s.c.f. screening constants (11)	$A'_{11} = 41.99\ \rho_{\pi\pi} + 145.2\ \rho_{\sigma\sigma} + 74.4\ \rho_{\sigma'\sigma'}$ $A'_{33} = -3.60\ \rho_{\pi\pi} - 72.6\ \rho_{\sigma\sigma} - 54.6\ \rho_{\sigma'\sigma'}$
B, Valence-state (unit $\rho_{\pi\pi}$) STO (12)	$A'_{11} = 40.30\ \rho_{\pi\pi} + 147.3\ \rho_{\sigma\sigma} + 74.8\ \rho_{\sigma'\sigma'}$ $A'_{33} = -2.58\ \rho_{\pi\pi} - 73.7\ \rho_{\sigma\sigma} - 54.6\ \rho_{\sigma'\sigma'}$
D, *ab initio* C—H optimized STO (14)	$A'_{11} = 35.72\ \rho_{\pi\pi} + 181.5\ \rho_{\sigma\sigma} + 91.4\ \rho_{\sigma'\sigma'}$ $A'_{33} = +0.15\ \rho_{\pi\pi} - 90.7\ \rho_{\sigma\sigma} - 61.4\ \rho_{\sigma'\sigma'}$
Hartree–Fock ^{5}S valence-state (10) ($r_{C-H} = 2.0$ a.u.)	$A'_{11} = 42.3\ \rho_{\pi\pi} + 144.3\ \rho_{\sigma\sigma} + 77.4\ \rho_{\sigma'\sigma'}$ $A'_{33} = -3.1\ \rho_{\pi\pi} - 72.2\ \rho_{\sigma\sigma} - 56.8\ \rho_{\sigma'\sigma'}$

$$[20]\quad V = 3 + \frac{9}{a^2} - e^{-2a}\left(\frac{16a^5}{9} + \frac{8a^4}{3} + \frac{19a^3}{3} + 12a^2 + 18a + 21 + \frac{18}{a} + \frac{9}{a^2}\right)$$

$$[21]\quad P = 1 - \frac{9}{a^2} + e^{-2a}\left(a^3 + 4a^2 + 10a + 17 + \frac{18}{a} + \frac{9}{a^2}\right)$$

$$[22]\quad Q = \frac{9}{2a^2} - e^{-2a}\left(a^3 + 3a^2 + 6a + 9 + \frac{9}{a} + \frac{9}{2a^2}\right)$$

(The correction made by Pitzer *et al.* (20) on the McConnell and Strathdee form of V essentially entails examination of the dipolar interaction in the region of the nucleus which requires introduction of the term $-(16a^5/9)\ e^{-2a}$. The terms P and Q are not affected since the proton lies in the nodal plane of the orbital π). Hence, the principal components of the anisotropic hyperfine tensor for the proton in >Ċ—H will be given by

$$[23]\quad A'_{ii} = K(\pi_{ii} + \sigma_{ii})$$

The total hyperfine tensor is of course $\mathbf{A} = a\mathbf{U} + \mathbf{A}'$, and $A'_{22} = -A'_{11} - A'_{33}$.

Numerical values of the principal components of the anisotropic proton tensor for the C—H fragment are listed in Table 1, in terms of the requisite spin densities. Provided that Q is known and that $\rho_{\sigma'\sigma'}$ can be related to $\rho_{\sigma\sigma}$, comparisons between experimental and theoretical values of the $A'^{(H)}_{ii}$ can be made. In order to obtain the results in Table 2, we have assumed a Q of -80 MHz and have taken $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$. An experimental estimate of the anisotropic proton tensor for C—H is now required with which to assess these rather wide-ranging results. To do this, we have selected the single-crystal data in Table 3, and have expressed the anisotropic principal components in terms of the corresponding isotropic coupling. The principal components of the total proton tensor in these radicals, and hence $a = (1/3)\sum A_{ii}$, are all negative in sign (16, 21). By taking the ratios A'_{ii}/a for each radical, as in Table 3, Q remains an unknown. The "experimental" principal components $A'^{(H)}_{ii}$ for the fragment >Ċ—H were subsequently derived from the averages $\langle A'_{ii}/a \rangle$ assuming two values of Q.

*From Vincow *et al.* (6).

As indicated by the results in Table 1, the σ-spin density terms cannot be satisfactorily included under *A*, *B*, or the Hartree–Fock case. Comparison of Tables 2 and 3 shows that when the σ-contributions are included, assuming $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$, the closed-shell function *C* provides the closest agreement between theory and experiment. Although the anisotropic proton tensor components are over-estimated by *A* and *B*, this can be compensated for, as in *C*, by

a decrease in the effective nuclear charge on the carbon atom. The magnitudes of the *ab initio* optimized orbital exponents for carbon are smaller than the standard Slater exponents and hence, the former give correspondingly better agreement (6). It should be noted that as $\rho_{\pi\pi}$ tends to zero, the outcome for B approaches that obtained with C. An estimate of the effectiveness of the approximations embodied by [11] and [17] can be gained by comparing the results under D with the *ab initio* based $A'^{(H)}_{ii}$ calculated by Vincow *et al.* (6). Thus the σ-contributions obtained following the above approximations are roughly two-thirds the magnitudes of those derived by incorporating the complete σ-spin density matrix; the π-contributions should of course be the same.

Although the most important consideration in the foregoing calculations is certainly the form of the carbon STO functions, there are other factors which should be mentioned. One, which has a bearing on the magnitude of Q, is the sensitive dependence of the isotropic proton coupling on the hydrogen 1s orbital exponent (14). Chang *et al.* (16) have found that the use of $\zeta_h = 1.0$ along with the optimized STO exponents yielded a more reasonable proton coupling than $\zeta_h = 1.19$, whereas the latter led to a better total s.c.f. energy. However, when ζ_h under D is changed from 1.19 to unity, as in Table 4, the σ-spin density contributions to the $A'^{(H)}_{ii}$ become larger. That is, although an increase in ζ_h is reflected in a Q of increased magnitude (14), the accompanying increase in $|a|$ and $|h(\mathbf{r}_H)|^2$ would leave the $\rho_{\sigma\sigma}$ derived from [17] comparatively unchanged. Changes in carbon–hydrogen bond length have a significant effect but variations within the normal range of r_{C-H}, like changes in ζ_h and Q, would be difficult to assess. Other calculations have shown that small changes in bond-angle and hybridization do not markedly affect either the anisotropic σ-contributions (31) or the magnitude of Q (32).

Also from Table 4, a change in Q from the more or less arbitrary value of −80 to the −66.5 MHz calculated for the fragment $C'_2\dot{C}$—H (33) has a relatively small effect. In fact, setting $\rho_{\sigma'\sigma'}$ equal to zero has more effect on the theoretical $A'^{(H)}_{ii}$ than the change in Q. On the basis of theoretical results, the difference between $\rho_{\sigma'\sigma'}$ and $\rho_{\sigma\sigma}$ in the C—H fragment is small (33). However, contributions to the anisotropic proton tensor from the orbitals t' and t'' might be at least partially cancelled by unpaired spin density in the trigonal orbitals of contiguous carbon atoms. To gauge this possibility, we have included the two extra orbitals forming the C′—C bonds in $C'_2\dot{C}$—H; the spin density in these two extra orbitals was assumed equal to $-\rho_{\sigma\sigma}$. The effect is not large, but could conceivably be more significant in an odd-alternant radical such as allyl.

At this point, it will be useful to calculate the anisotropic proton tensors for the allyl radical,

	42.0	−39.0	−3.0	$\rho_{\sigma'\sigma'} = 0$
	44.9	−40.1	−4.8	$\rho'_{\sigma'\sigma'} = -\rho_{\sigma\sigma}$
	43.6	−39.4	−4.2	$Q = -66.5$
	52.2	−43.1	−9.0	$\zeta_h = 1.00$
	44.3	−38.2	−6.0	$r_{C-H} = 2.10$
	42.3	−39.0	−3.4	$Q = -62.5$
	49.1	−42.5	−6.6	From ref. 6

*The basic parameters were $Q = -80$ MHz, $\rho_{\pi\pi} = 1$, $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$, $\zeta_h = 1.19$ and $r_{C-H} = 2.05$ a.u.

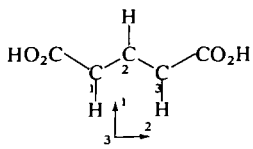

FIG. 2. Molecular axis system *1*, *2*, *3* for the allyl-type fragment observed in x-irradiated glutaconic acid (8).

since it is in many respects similar to perinaphthenyl. Heller and Cole (8) have shown that X-ray irradiation of a single crystal of glutaconic acid yields the allyl-type radical in Fig. 2, and have demonstrated conclusively the positive sign of the isotropic coupling for proton 2. The experimental anisotropic proton tensor principal components and isotropic couplings in MHz were found to be

$$\begin{aligned} A_{ii}'^{(H_1,H_3)} &= 27.7,\ -27.3,\ -0.3 \\ a^{(H_1,H_3)} &= -35.7 \\ A_{ii}'^{(H_2)} &= 0.0,\quad 5.0,\ -5.0 \\ a^{(H_2)} &= 12.0 \end{aligned} \qquad [24]$$

and it was noted that the principal axes for protons 1 and 3 were slightly different. Since the unpaired electron is delocalized, mainly within a three carbon π-orbital (8), significant contributions to the anisotropic tensor for a given proton arise from spin density associated with the neighboring carbon atoms in addition to contributions from the adjacent carbon atom. The complete π-spin density contribution for the proton in position k will be given by

$$\boldsymbol{\pi}^{(k)} = \sum_{ij} \rho_{ij}^{\pi} \langle \pi^{(i)} | \mathbf{T}^{(k)} | \pi^{(j)} \rangle \qquad [25]$$

McConnell (34) has calculated the atomic orbital π-spin density matrix for allyl using the self-consistent unrestricted wave function given by Berthier (35) and found, after elimination of the quartet spin component,

$$\rho_{ij}^{\pi} = \begin{bmatrix} 0.609 & -0.005 & -0.345 \\ -0.005 & -0.185 & -0.005 \\ -0.345 & -0.005 & 0.609 \end{bmatrix} \qquad [26]$$

If, for the moment, the off-diagonal elements of ρ_{ij}^{π} are neglected, then [25] becomes

$$\boldsymbol{\pi}^{(k)} = \sum_{i} \rho_{ii}^{\pi} \langle \pi^{(i)} | \mathbf{T}^{(k)} | \pi^{(i)} \rangle \qquad [27]$$

where the various contributions are by definition not in the same axis system. The transformation of a tensor in an axis system, *a*, *b*, *c* into another system α, β, γ is given by (16)

$$\boldsymbol{T}_{\alpha\beta} = \sum l_{\alpha a} T_{ab} l_{b\beta} \qquad [28]$$

where $l_{\alpha a}$ is the direction cosine between the axes α and *a*. In calculating the proton tensors, each of the carbon atoms of allyl was considered as an isolated sp^2 hybridized fragment. Equation 27 was used to calculate the π-contributions and, except as outlined below, σ-spin density

contributions were confined to the $>\dot{C}—H$ portion containing the proton in question. Now the two sites of large positive π-spin density which flank the negative $\rho_{\pi\pi}$ site could affect the σ-contribution for proton 2 to the extent that the approximation $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$ loses validity. Two possibilities have been entertained in this regard: one is to set $\rho_{\sigma'\sigma'}$ equal to zero and consider only the σ-spin density in the C—H bond, whereas the other effectively considers the fragment $C'_2\dot{C}—H$. In the latter case, the σ-spin densities in the trigonal orbitals forming the C′—C bonds are derived from the isotropic couplings of the protons bonded to the respective carbon atoms. As can be seen from the results in Table 5, the differences between these choices for proton 2 are quite small.

The results for allyl under *B* were obtained using the expression [2] for the sites with $\rho_{\pi\pi} > 0$; for the negative $\rho_{\pi\pi}$ site, ζ_{π} was assigned the closed-shell value from *C*. The σ-spin density terms showed little overall change with $\rho_{\pi\pi}$ and so the case *C* STO functions were also used to derive the σ-terms in this instance. The carbon-hydrogen and carbon–carbon bond lengths used were 2.05 and 2.65 a.u., respectively, and all bond angles were 120°. The anisotropic tensor calculated for proton 2 is diagonal in the molecular axis system *1*, *2*, *3* in Fig. 2, whereas the angle between the axis corresponding to the positive principal component of $\mathbf{A}'^{(H_1)}$ and the axis *1* is $\cong 1°$. The agreement between the calculated principal components in Table 5 and the experimental values [24] is reasonable for proton 2 but less so for protons 1 and 3.

The anisotropic hyperfine tensor component which is perpendicular to the molecular plane is the one essential to the discussion of the liquid-crystal results for perinaphthenyl. Hence, it is worthwhile to consider the breakdown of the various contributions to the $A'^{(H)}_{33}$ in the allyl radical, and also to gauge the importance of terms arising from the off-diagonal elements of ρ^{π}_{ij}. The sum of the off-diagonal π-contributions to the $A'^{(H)}_{33}$ are given in Table 6, along with the various diagonal π- and σ-terms. The off-diagonal contributions were approximated (8) as being of the order of $\langle r^{-3}\rangle\rho^{\pi}_{ij}\langle i|j\rangle$, where $\langle i|j\rangle$ represents the overlap between $2p_{\pi}$ atomic orbitals on centers *i* and *j*; from benzene, $\langle 1|2\rangle = \langle 2|3\rangle = 0.260$ and $\langle 1|3\rangle = 0.039$ (36). In effect, we have thus considered point-dipoles of magnitude $\rho^{\pi}_{ij}\langle i|j\rangle$ located midway between carbon atoms *i* and *j* at the distances *r* from the proton concerned. The magnitude of the sum of the off-diagonal contributions for proton 1 is small compared with the in-plane anisotropic components, but significant when compared with the diagonal contributions to $A'^{(H_1)}_{33}$; for proton 2, the off-diagonal terms contribute

roughly 10% of the total $A_{33}^{\prime(H_2)}$ given in Table 6. However, off-diagonal σ-spin density elements are often avoided by neglect of overlap (17) and, in so doing, π-spin densities compatible with [16] and obeying the relation $\sum_i \rho_{\pi\pi}^{(i)} = 1$ can be obtained. For the allyl radical, Snyder and Amos find $\rho_{\pi\pi}^{(1)} = \rho_{\pi\pi}^{(3)} = 0.547$, $\rho_{\pi\pi}^{(2)} = -0.094$ as the unrestricted Hartree–Fock values (ρ_{aa}) after annihilation of the quartet spin component (37). With the off-diagonal contributions thus neglected, these $\rho_{\pi\pi}^{(i)}$, in conjunction with B, yield $A_{33}^{\prime(H_1,H_3)} = -3.46$ and $A_{33}^{\prime(H_2)} = -4.35$ MHz. It is nevertheless evident that the term arising from $\rho_{\sigma\sigma}$ is significant compared with the total perpendicular component A'_{33} and, to anticipate results to follow, perinaphthenyl is similar in this regard.

Perinaphthenyl

In general, the motion of a paramagnetic molecule dissolved in a nematic mesophase is constrained by the partial alignment of the solvent molecules in the presence of an external magnetic field (38). Hence, the anisotropic magnetic interactions within a π-radical are not completely lost through motional averaging and the hyperfine splittings and g-factor are found to differ from those values observed in isotropic solvent media. For a particular nucleus, the average hyperfine coupling $\bar{a}$ in the aligned nematic environment is related to the anisotropic hyperfine tensor A'_{ij} by the expression (4)

$$[29] \qquad \bar{a} = a + \tfrac{2}{3} \sum_{ij} \vartheta_{ij} A'_{ij}$$

The quantity a is normally identified with the isotropic hyperfine coupling observed above the transition from the nematic to the isotropic solvent phase.

The alignment of the solute molecule, which is governed primarily by its physical shape, is described in terms of the traceless ordering matrix $\mathbf{\vartheta}$. Because of the D_{3h} symmetry of the planar radical perinaphthenyl, no preferential ordering occurs with respect to the in-plane molecular axes *1* and *2* shown in Fig. 3. The ordering matrix therefore has axial symmetry with diagonal elements $\vartheta_{11} = \vartheta_{22} = -\vartheta_{33}/2$ (39), so that [29] reduces to

$$[30] \qquad \delta a = (\bar{a} - a) = \vartheta_{33} A'_{33}$$

That is, the degree of alignment ϑ_{33} can be derived from the experimental shift δa and the calculated anisotropic hyperfine tensor. Subsequent correlation of other shifts and anisotropic tensors using this ϑ_{33} should then reveal any inconsistencies in the theoretical results under consideration.

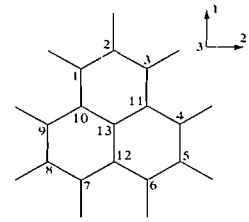

FIG. 3. Molecular axis system *1*, *2*, *3* for the π-electron free radical perinaphthenyl.

The proton hyperfine e.p.r. spectra of perinaphthenyl dissolved in 4,4′-dimethoxyazoxybenzene consist of a large septet splitting and a smaller quartet splitting (1–3). The quartet splitting arises from the symmetrically equivalent protons labelled 2, 5, and 8 in Fig. 3. The isotropic hyperfine couplings and shifts for the two sets of protons in MHz (2) are

$$[31] \qquad a^{(H_1)} = -17.6, \qquad \delta a^{(H_1)} = 0.0$$

and

$$a^{(H_2)} = 5.10, \qquad \delta a^{(H_2)} = 0.65$$

The magnitude of the larger proton coupling requires that the π-spin density $\rho_{\pi\pi}^{(1)}$ be positive. Now irrespective of whether the sign of $\rho_{\pi\pi}^{(2)}$ is positive or negative, the calculated tensor component A'_{33} for proton 2 is negative, ϑ_{33} is also negative, so that the predicted shift $\delta a^{(H_2)}$ is positive (2, 38). From experiment, $|\bar{a}| > |a|$ for proton 2, which means that $a^{(H_2)}$ must therefore be positive and $\rho_{\pi\pi}^{(2)}$ negative. This outcome is supported by the signs of the ^{13}C couplings obtained from the experimental shifts (2)

$$[32] \quad \delta a^{(C_1)} = -11.13 \text{ and } \delta a^{(C_2,C_{10})} = 3.22 \text{ MHz}$$

In using the foregoing STO functions to calculate the proton tensor components required by [30], we have employed the π-spin densities (ρ_{aa}) for perinaphthenyl given by Snyder and Amos; annihilation of the undesired spin multiplicities resulting from the self-consistent unrestricted treatment yielded (37)

$$[33] \qquad \rho_{\pi\pi}^{(1)} = 0.219, \qquad \rho_{\pi\pi}^{(2)} = -0.064,$$
$$\rho_{\pi\pi}^{(10)} = -0.054, \quad \rho_{\pi\pi}^{(13)} = 0.044.$$

The bond lengths used were again $r_{C-H} = 2.05$ and $r_{C-C} = 2.65$ a.u., and all bond angles were 120°. The sum of the thirteen π-contributions we have denoted by $K\sum\pi_{33}$, and so for a given proton

$$[34] \qquad A'_{33} = K(\sum\pi_{33} + \sigma_{33})$$

Only the σ-spin densities in the C—H portion under consideration were included in the derivation of σ_{33} and, in obtaining the results in Table 7, we have assumed [18] to be valid; that is $\rho_{\sigma'\sigma'} = \rho_{\sigma\sigma}$. The isotropic proton couplings [31] were used to find the $\rho_{\sigma\sigma}$ from [17]. The shift $\delta a^{(H_2)} = 0.65$ MHz was then used in conjunction with the various $A'^{(H_2)}_{33}$ to determine the degree of alignment from [30]. Now the product of ϑ_{33} and $A'^{(H_1)}_{33}$ should yield a shift near zero for the protons at the positive $\rho_{\pi\pi}$ sites. As can be seen from Table 7, cases *B* and *C* provide comparable agreement with experiment, and thus represent a substantial improvement over *A*, as well as previous calculations which used $\zeta_\pi \sim 1.6$ (1–4). The perinaphthenyl results under *B* were derived using [2] for sites with $\rho_{\pi\pi} > 0$; contributions from positions of negative $\rho_{\pi\pi}$ and from the σ-spin densities were obtained with the closed-shell functions *C*. The similarity between the results of *B* and *C* is not unexpected, since the magnitude of $\rho^{(1)}_{\pi\pi}$ is relatively small.

Essentially the same trends are evident from Table 7 as those already noted for the C—H fragment, and it is clear that inclusion of the σ-contributions to the anisotropic proton tensor makes a considerable difference. For *A* better, though certainly not good, agreement between theory and experiment is obtained when the σ_{33} are omitted. Under *B* and *C*, however, the sign of $K\sum\pi_{33}$ for proton 1 is opposite to that for the total component $A'^{(H_1)}_{33}$. Clearly, the outcome in these cases would be further improved by applying the approximation $\rho_{\sigma'\sigma'} = 0$ in determining the σ_{33}. Thus we find for *B* that $A'^{(H_1)}_{33} = -0.603$ and $A'^{(H_2)}_{33} = -2.147$ MHz, whence $\vartheta_{33} = -0.302$ which predicts $\delta^{(H_1)}_a = 0.19$ MHz. Setting $\rho_{\sigma'\sigma'} = 0$ in case *D* also improves agreement with experiment. In Table 8, we show separately some of the more important diagonal contributions to the anisotropic proton tensors for perinaphthenyl. It should be noted that a significant contribution to $A'^{(H_1)}_{33}$ comes from the π-spin density on carbon atom 9; under *B*, the magnitude of this term is −0.635 MHz.

To extend the present discussion, an independent estimate of ϑ_{33} was obtained from the experimental ^{13}C shifts. Neglecting the effect of σ-spin density, the necessary anisotropic tensor component for carbon atom *i* is given by

$$[35] \quad A'^{i(C_1)}_{33} = \rho^{(i)}_{\pi\pi} K(\tfrac{4}{5})\langle r^{-3}\rangle - \sum_{j\neq i} \rho^{(j)}_{\pi\pi} K r_{ij}^{-3}(P - Q)$$

in which *K* takes the value 134.15 MHz a.u.[3] The π-spin density on carbon *i*, in the first term, yields the axially symmetric part (21), whereas the second term of [35] comprises the

sum of the π-terms from neighboring carbon atoms; the first term represents the dominant contribution to the $A''^{(C_1)}_{33}$ for perinaphthenyl. However, the $2p_\pi$ STO under B, as $\rho_{\pi\pi}$ tends to zero, yields an average value of $\langle r^{-3}\rangle$ which becomes considerably smaller than the s.c.f. value of 1.692 a.u.$^{-3}$ (21). In fact, the anisotropic ^{13}C tensor components calculated entirely with B lead to invalid estimates of $|\vartheta_{33}| > 0.5$. Alternatively, if the s.c.f. $\langle r^{-3}\rangle$ is taken for the first term, along with the results from B for the remainder of [35], we obtain $A''^{(C_1)}_{33} = 39.4$, $A''^{(C_2)}_{33} = -12.13$ and $A''^{(C_{10})}_{33} = -10.46$ MHz. The average of the anisotropic tensors for carbon atoms 2 and 10 was taken, since the experimental isotropic couplings and shifts for these positions were not distinguishable (1–3). The ^{13}C shifts [32] thus yield ϑ_{33} values of −0.283 and −0.285, respectively, the average of which subsequently predicts the proton shifts 0.18 and 0.61 MHz in Table 9. Also from Table 9, the use of experimental π-spin densities (4) does not markedly alter the theoretical proton shifts. Similar overall agreement is obtained with the experimental data for perinaphthenyl in refs. 1 and 3. If the trigonal orbitals in the C—H fragment are assumed equivalent, then the spin densities in the 2s and the two $2p_\sigma$ orbitals are essentially the same and equal to $\rho_{\sigma\sigma}$ (5). The first term of [35] thus becomes

$$[36] \qquad (\rho^{(i)}_{\pi\pi} - \rho^{(i)}_{\sigma\sigma})K(\tfrac{4}{5})\langle r^{-3}\rangle$$

and when this modification is included, the $A''^{(C)}_{33}$ decrease in magnitude and consequently the $\delta a^{(H)}$ increase by about 6% over the values given in Table 9.

Discussion

Apart from differences between trapping sites in the host crystal (33), an obvious problem in the correlation of single-crystal data for species RCHR′ with theoretical results is the difficulty in gauging anisotropic contributions from neighboring groups of atoms such as $-CO_2H$. The difficulty in evaluating the effect of unpaired spin density in the C—H portion alone is emphasized by comparing the data for $\dot{C}H(CO_2H)_2$ and $\dot{C}H(SO_3^-)_2$, in Tables 3 and 10. These two radicals have similar proton tensor principal values and so the anisotropic hyperfine interactions and the $\rho_{\pi\pi}$ are essentially the same, insofar as the proton is concerned. But the ^{13}C hyperfine tensors are quite different. The deviation from axial symmetry in $\mathbf{A}''^{(C)}$, $A'_{33}/2 + A'_{11}$, for $\dot{C}H(CO_2H)_2$ is −9.7 MHz compared with only −3.5 MHz for $\dot{C}H(SO_3^-)_2$, whereas the isotropic coupling $a^{(C)}$ is substantially larger in the latter radical. The approximation $\rho_{\sigma'\sigma'} = 0$ can account for only part of the observed deviation from axial symmetry in these two ^{13}C tensors, and consequently any choice between $\rho_{\sigma'\sigma'}$ equal to $\rho_{\sigma\sigma}$ or to zero remains unresolved. The isotropic ^{13}C coupling generally reflects differences in Q^{C}_{CX} for different C—X bonds (33).

In the foregoing calculations, the σ-spin density contributions to the $A'^{(H)}_{ii}$ have been satisfactorily accommodated, but even so are not strictly necessary for experimental agreement, by reducing ζ_π from ~1.6 to 1.3. But in addition to the decrease in the absolute magnitudes of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$A'^{(H)}_{ii}$, the magnitude of $\langle r^{-3}\rangle$, which governs $\mathbf{A}'^{(C)}$, also decreases. That is, decreasing ζ_π in order to incorporate the σ-terms results in too small a value for $\langle r^{-3}\rangle$. The ζ_π under C yields 0.720 a.u.$^{-3}$ for $\langle r^{-3}\rangle$, compared with 1.214 a.u.$^{-3}$ from B ($\rho_{\pi\pi} = 1$). The $A'^{(C)}_{33}$ for CH_3 in Table 10, when substituted into [35], leads to $\langle r^{-3}\rangle \cong 1.24$ a.u.$^{-3}$. The s.c.f. value of $\langle r^{-3}\rangle$ (21), which gives $A'^{(C)}_{33} = 181$ MHz for unit $\rho_{\pi\pi}$, thus seems too large. Using the optimized basis set D and including all contributions, Vincow *et al.* (6) have calculated $A'^{(C)}_{33}$ for CH_3 to be 106 MHz. If the axially symmetric parts of the $A'^{(C)}_{33}$ for perinaphthenyl are scaled in accord with the experimental value for CH_3 rather than s.c.f. value, an alignment factor of $\vartheta_{33} \cong 0.40$ is obtained. But with this larger ϑ_{33}, the calculated proton shifts would no longer be in reasonable agreement with the experimental shifts. From these observations, the difficulty in obtaining adequate results for both proton and carbon-13 anisotropic hyperfine tensors by means of the same ζ_π is of course clear.

Further improvement could perhaps be provided by a change in the form of the $2p_\pi$ orbital, since this orbital is certainly the most important consideration in these calculations. The π-terms, which are governed by ζ_π, represent the dominant contributions to the $A'^{(H)}_{ii}$, and so the σ-terms must be judged in relation to the π_{ii}. The important factor in determining the σ-contributions is the hydrogen orbital exponent. The term $|h(\mathbf{r}_H)|^2$ in [17] is equal to ζ_h^3/π, so that an increase in ζ_h leads to a decrease in the magnitudes of the σ_{ii}. However, Pople *et al.* (40) have compared minimal basis semi-empirical INDO-UHF calculations of unpaired σ-spin densities with experimental a^H for a large variety of π-electron radicals; the best value found for $|h(\mathbf{r}_H)|^2$, equal to 0.338 a.u.$^{-3}$, corresponds to $\zeta_h = 1.02$. This outcome supports the use of unit ζ_h in the foregoing approximations. Chang *et al.* (15) have found that the magnitudes of $a^{(H)}$ and $a^{(C)}$, calculated by s.c.f.-c.i. methods which included all appropriate singly and doubly excited configurations, were improved considerably when the expanded STO basis developed by Clementi (41) was employed for the carbon atom. But these double ζ STO functions unfortunately present some major complications and become rather cumbersome when applied to the calculation of anisotropic hyperfine tensors.

The calculation of anisotropic β-proton hyperfine tensors, in the fragment $\rangle\dot{C}—CH_3$ for example, is in some respects analogous to the foregoing procedure for C—H (42, 43). Extension of the McConnell and Strathdee theory for a proton lying not necessarily in the nodal plane of the 2p orbital bearing the unpaired electron has been demonstrated by Derbyshire (42), and we have again incorporated the σ-term correction of Pitzer *et al.* (20). The isotropic hyperfine coupling for the protons of the freely rotating methyl group in $C—CH_3$ is related to the π-spin density by (30)

$$[37] \qquad a^{(Me)} = \rho_{\pi\pi}(Q' + Q'' \langle \cos^2 \beta\rangle)$$

where β is the angle between the proton and the plane defined by the C—C bond and the axis of the $2p_\pi$ orbital. From ENDOR studies of $(CH_3)_2\dot{C}CO_2H$ (44), $\rho_{\pi\pi}Q' = 3.2$ MHz and $\rho_{\pi\pi}Q'' = 123.2$ MHz, and the anisotropic tensor components for the methyl group undergoing free rotation at room temperature appear in Table 11. The principal axis *1* lies along the bond between the sp^2 and sp^3 hybridized carbon atoms and the axis *3*, which corresponds to the direction of minimum hyperfine coupling (44), lies parallel to the symmetry axis of the $2p_\pi$ orbital. The isotropic hyperfine coupling for the α-proton in $CH_3\dot{C}HCO_2H$ is −54.7 MHz (45) which yields $\rho_{\pi\pi} = 0.68$, and we have taken $\rho_{\pi\pi}$ in $(CH_3)_2\dot{C}CO_2H$ to be the same. The bond lengths used in obtaining the results in Table 11 were $r_{C-H} = 2.05$ and $r_{C-C} = 2.75$ a.u., along with the usual tetrahedral angle of 109.5°. The σ-spin density required in determining the anisotropic contribution from the C—H tetrahedral orbital was obtained using an equation analogous to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[17]. These tetrahedral orbital terms are included in parentheses in Table 11; all other σ-spin densities in the radical were neglected. The direction of the minimum hyperfine coupling is correctly predicted in all cases, and case *B*, in which the C—H tetrahedral orbital portion was obtained using the s.c.f. minimal STO exponents for methane (46), provides the closest agreement with experiment.

To summarize: the calculations on C—H show that the σ-contributions to the $A_{ii}^{\prime(H)}$ are quite substantial; the σ-terms based on the approximations herein are roughly two-thirds those derived with the complete σ-spin density matrix (6). In relation to the π-contributions, the inclusion of the σ-terms is not required for agreement with experiment when $\zeta_\pi \sim 1.6$ is employed. When the theory is extended to delocalized π-electron radicals, for example perinaphthenyl-3-carboxylic acid dissolved in 4-(*n*-pentyloxy)-benzoic acid (4), it becomes necessary to include π-contributions from neighboring atoms. However, when all the contributions arising from the $\rho_{\pi\pi}$ in perinaphthenyl are included using $\zeta_\pi \sim 1.6$, the results are clearly unsatisfactory: more so when it is noted that the σ-terms are comparable in magnitude to most of the π-contributions to the $A_{33}^{\prime(H)}$. These difficulties, insofar as the proton tensors are concerned, can be alleviated by reducing ζ_π to 1.3, when at least the $\rho_{\sigma\sigma}$ portion can be accommodated along with the terms from the $\rho_{\pi\pi}$. Although optimization of the STO exponents for C—H led to a decrease from the Slater values for carbon (6), the reduction in ζ_π to 1.3, or perhaps further to 1.25, is difficult to support. Such a decrease in ζ_π does lead to more reasonable anisotropic components for the proton tensor, but at the same time $\langle r^{-3} \rangle$ becomes smaller. Presumably the divergent dependence of $\mathbf{A}^{\prime(H)}$ and $\mathbf{A}^{\prime(C)}$ on ζ_π is a limitation of STO functions which extends to other π-electron fragments, particularly N—H.

Calculation of the anisotropic hyperfine tensors in C—F and C—Cl fragments (47) is a more complex problem than in C—H because of the non-vanishing anisotropic interaction due to spin density in the p-orbitals of the halogen atom. Spin polarization in the C—F bond of $FC(CONH_2)_2$ plays a significant part in the deviation of $\mathbf{A}^{\prime(F)}$ from axial symmetry (48). The question remains as to whether a similar reduction in ζ_π for nitrogen and oxygen is necessary in π-radicals such as carbazole-*N*-oxyl (4). Analyses of other liquid crystal data are complicated by the fact that the majority of radicals studied thus far have two-fold, or lower, symmetry. Würster's blue cation, for example, requires two parameters with which to describe its alignment in the nematic mesophase (4). Uncertain π-spin density distributions, and flexible radical geometry as in triphenylmethyl, are additional complicating features.

Infrared Studies on Rotational Isomerism. VI. Normal-Coordinate Analysis of 2-Chloro-, 2-Bromo-, and 2-Cyanoethanol

PAUL A. GIGUÈRE AND MICHEL SCHNEIDER[1]

Département de chimie, Université Laval, Québec, Québec

Received August 9, 1971

A normal-coordinate analysis of three substituted ethanol molecules X—CH_2—CH_2—OH (where X = Cl, Br, or CN) was carried out using the simple valence force field model, and a computer program of Schachtschneider translated into Fortran language by Brooks. The effect of internal hydrogen bonding was studied by adding one extra symmetry coordinate, H . . . X (two, H . . . C and H . . . N, in the case of 2-cyanoethanol). The corresponding force constants show a good correlation with the hydrogen bond strengths. Most of the other force constants maintain the same value in the *gauche* and the *trans* rotamers. In general the calculated fundamental frequencies agree closely with the observed ones. The potential energy distribution confirms the extensive coupling between certain vibrations; particularly the skeleton stretching and the CH_2 twisting and rocking. Only the C—X stretching and the skeleton bending vibrations are strongly affected by rotational isomerism.

Dans l'hypothèse du champ de force de valence et à l'aide d'un programme de Schachtschneider transcrit en langage Fortran IV par Brooks nous avons analysé en coordonnées normales trois molécules d'éthanol substitué: X—CH_2—CH_2—OH, où X = Cl, Br ou CN. Pour mieux étudier l'effet de la liaison hydrogène intramoléculaire nous avons ajouté une coordonnée de symétrie supplémentaire H . . . X (et deux, H . . . C et H . . . N, pour le cyano-2 éthanol). Les constantes de force correspondantes montrent nettement une corrélation avec l'énergie des liaisons hydrogène. La transférabilité des constantes de force entre rotamères *gauche* et *trans* est excellente dans la plupart des cas. Les fréquences de vibration ainsi calculées s'accordent très bien avec les valeurs expérimentales en général. Les calculs de distribution de l'énergie potentielle confirment que certaines vibrations sont fortement couplées: en particulier les modes de valence du squelette et celles de torsion et de rotation des groupes CH_2. Seules les vibrations de valence C—X et de déformation du squelette sont fortement affectées par l'angle azimutal.

Canadian Journal of Chemistry, **50**, 152 (1972)

Introduction

Normal-coordinate analysis of the fundamental vibrations of small molecules of known structure is usually carried out to test the assignment of the various bands in their spectra. Since the force constants thus calculated depend to some extent on the model chosen they do not always lead to definite answer in dubious cases. Nevertheless, they provide much useful information. For instance, the extent of coupling or mixing of neighboring vibrations may be derived from the potential energy distribution. Furthermore, in molecules showing rotational isomerism the force constants may be expected to remain roughly the same in the different rotamers. Therefore, it becomes possible to evaluate the dependance of certain vibrational frequencies on the azimuthal angle.

As a complement to this series of spectroscopic studies on 2-substituted ethanols (1) we have applied this theoretical method in order to learn more about the nature of the intramolecular hydrogen bond in the *gauche* conformers. The structural (2) and spectroscopic data (3, 4) available on the three alcohols 2-chloro-, 2-bromo-, and 2-cyanoethanol are adequate to determine their potential energy functions.

Method of Calculation

The **F** and **G** matrix method of Wilson (5) was followed, using a program developed by Schachtschneider (6) and transcribed in FORTRAN IV language by Brooks and Haas (7). The initial force constants were taken from the study by the latter authors of carboxylic and percarboxylic acids as well as from other similar studies on methanol (8), acetone (9), and 2,3-dibromobutane (10). Thus, 18 of the 32 force constants were left independent in the case of 2-chloroethanol. Taking into account the data for the OD deuterated molecule (3) increased that number to 26. The Cartesian coordinates for setting up the **G** matrix were taken from the microwave data for the *gauche* rotamers of 2-chloro-, and 2-bromoethanol (2). The remain-

ing undetermined parameters were given the following probable values: $r_{C-H} = 1.09$ Å, $\angle_{CCH} = 111.4°$, and $\angle_{HCH} = 108.7°$. The same parameters were used for the *trans* rotamers except, of course, for the azimuthal angle, and the O—H bond length, 0.95 Å and bond angle, 108.5°. In the case of 2-cyanoethanol the probable values (11) of 1.17 Å and 1.48 Å were chosen, respectively, for the C—CN and C ≡ N bonds.

A valence force field model was adopted in preference to a Urey–Bradley force field in view of a better transferability of force constants between related molecules. In the former model the force field is described in terms of bond stretching and deformation, plus bond–bond, bond–angle, and angle–angle interactions.

There are 23 internal coordinates in the 2-halogen substituted ethanol molecules but only 21 vibrations (26 and 24, respectively, in 2-cyanoethanol.) The two redundant coordinates were eliminated by means of the symmetry coordinates S listed in Tables 1 and 2. On the other hand an extra coordinate corresponding to the X . . . H stretching vibration was added to study the effect of the intramolecular hydrogen bond in the *gauche* isomers (Fig. 1). For 2-cyanoethanol two extra coordinates, C . . . H and N . . . H, were introduced to give still better insight into this phenomenon.

On the assumption of a C_s symmetry the *trans* molecules have 14 vibrations of class A' and 8 of class A'', (17 and 9, respectively, in cyano-

ethanol). The *gauche* molecules having no symmetry, all their vibrations are of class *A*.

Discussion

2-Chloro- and 2-Bromoethanol

The force constants given in Table 3 were obtained independently for the *trans* and *gauche* rotamers. The transferability between the two sets for a given compound, as well as between the chloro and bromo compounds is seen to be good in most cases. For vibrations which show little or no coupling the equations could be determined with high accuracy. However, for constants which always occur simultaneously, the dispersion was of the order of 10%.

Examination of the calculated frequencies and the p.e.d. listed in Tables 4 and 5 reveals some interesting features. (*1*) Vibrations in the middle range of the spectra are quite complex in nature. For instance, that at 1394 cm^{-1}

*Units for bond stretching, mdyn/Å; bond bending, mdyn Å/(radian)^2; bond–bond interaction, mdyn/Å; bond–angle interaction, mdyn/radian; angle–angle interaction, mdyn Å/(radian)^2. f = fixed force constants.

in *gauche* 2-chloroethanol is made up of five components, none of which contributes more than one-third of the whole. (Minor contributions of only a few % were left out.) (*2*) The CH_2 wagging and twisting modes have been described so far as in-phase and out-of-phase. Now the p.e.d. shows this to be inexact, particularly in the *trans* rotamers. Indeed, the high-frequency components of these two modes belong mostly to the CH_2 group adjacent to the OH group, whereas those of low frequency are due to the other CH_2 group. This explains why these modes are not appreciably affected by rotational isomerism. In contrast, the rocking modes involve both CH_2 groups; accordingly their frequencies are widely separated in the two conformers. (*3*) The OH bending mode is more strongly coupled to the CH_2 wagging in the *gauche* than in the *trans* isomers as could be expected on mechanical grounds. (*4*) The tightly coupled C—C and C—O stretching vibrations are quite insensitive to the azimuthal angle.

fusion we have represented by H_{HCX} the HCC deformation in which the last carbon is that of the cyano group. Likewise, the C—CN stretching constant was denoted by F_{CCN}. As far as the coupling of vibrations is concerned (Table 7), the situation resembles that in 2-chloro or 2-bromoethanol; except for the OH bending which is less strongly coupled to the CH_2 wagging. The C—CN stretching mode exhibits little coupling in the *trans* isomer, but rather strong coupling

with a CH_2 bending and the C—C stretching in the *gauche*.

It is noteworthy that the torsion modes are appreciably coupled to other modes. According to some authors (5, 8), these motions do not affect noticeably the other vibrations of the molecule. Nevertheless, we think they should be taken into account since at least the order of magnitude of the results is significant. For instance, in the case of dichloroethane (12) the CCCl bending frequency could only be adjusted after the C—C torsion had been included. To be sure the harmonic-oscillator approximation does not fit these modes too well; especially when the potential barriers are low, and the amplitudes of motion wide. However, the anharmonicity of their potential function apparently introduces no complication (13).

At the beginning we have alluded to the hazard of using force constants to decide between different assignments of bands. Nonetheless the present study provides examples where such data were useful in that connection. (*1*) The H_{CCO} constant has a remarkably constant value in a great variety of molecules. From that we could decide that the 392 and 305 cm^{-1} bands correspond to the *gauche* and *trans* bending

modes, respectively. (2) The C—CN stretching constant is quite different from the stretching constant of the central C—C bond (14). The value of 5.2 mdyn/Å for the former leads to frequencies of 990 and 930 cm^{-1} in the *gauche* and *trans* rotamers. (3) From the close transferability of the force constants between the two rotamers a value of 490 cm^{-1} may be predicted for the CCC deformation in the *trans* 2-cyanoethanol molecule. That vibration could not be observed in the spectrum of the vapor. (4) *A priori* one might expect nearly equal force constants for the in-plane and the out-of-plane CCN deformations. This was confirmed in the *trans* conformer. The fact that the H'_{CCN} constant of the *gauche* molecule is much larger than the other three must be due to the intramolecular hydrogen bond and/or some other sort of coupling. At any rate the calculations show that for the pair of bands at 215/380 cm^{-1} in the *gauche* and at 180/280 cm^{-1} in the *trans* isomer, the low-frequency components belong to the in-plane deformations.

The Intramolecular Hydrogen Bonds

The force constants for the various displacements of the hydroxyl proton characterize the intramolecular hydrogen bond in the *gauche* conformers. Three different methods were used to derive these constants. In the first, $F_{H...X}$ was made equal to zero. Adjustment of the other constants led to excellent agreement of the calculated frequencies. The following values of the constants were obtained:

	F_{OH}	H_{COH}	t_{OH}
Chloro-	7.359	0.947	0.0488
Bromo-	7.307	0.930	0.055
Cyano-	7.378	0.835	0.03

In a second method the three constants were given their value in the *trans* isomer and the extra constants $F_{H...X}$ were adjusted. They turned out to be of the order of 0.25 mdyn/Å but the convergence was poor. For instance the OH bending frequency was too low by some 20 cm^{-1} and the OH stretching and torsion frequencies were too high by 30 and 10 cm^{-1}, respectively. Similar results have been reported for the percarboxylic acids (7). Lastly, by allowing all the constants to "float" the values considered most reliable (in Tables 3 and 6) were arrived at. As may be seen, the $F_{H...X}$ constants for the three alcohols are not only in the same order as, but also proportional to the strength of the intramolecular hydrogen bonds. (For 2-cyanoethanol it is logical to take the sum of the two constants $F_{H...C}$ and $F_{H...N}$.) This relationship even holds for the case of the percarboxylic acids (7, 15). In fact the correlation is a fairly close one; but this must be fortuitous as the other OH force constants also are involved here.

The trend in the latter is equally instructive. For instance, the decrease of F_{OH} in the *gauche* isomers follows from the weakening of that bond as revealed by microwave spectrometry (2). Such decrease, however, remains quite small compared to the corresponding increase in H_{COH} (of the order of 20 to 30%). On structural grounds this is understandable since the force acting on the proton is presumably oriented towards a lone pair orbital on the acceptor atom. The larger upward shifts of the OH bending frequencies in the *gauche* rotamers are, therefore, seen not to arise from mixing with other vibrations. Contrary to linear hydrogen bonds, the geometry plays a considerable rôle in intramolecular hydrogen bonds. As we explained before (1) the various semi-empirical correlations based on ν_{O-H} cannot be expected to hold in strongly bent hydrogen bonds. For instance, in the series of the haloethanols (16), the shifts of that frequency in the *gauche* isomers increase in the inverse order of the electronegativity of the halogen.

In the case of 2-cyanoethanol the two extra force constants $F_{H...C}$ and $F_{H...N}$ are found to be of the same magnitude. This agrees with the conclusion, based on structural considerations, that the π electrons of the C≡N bond act as proton acceptor. The relative weakness of that hydrogen bond is due largely to the non-directional character of that electron cloud. Finally it is interesting to note that the t_{CC} force constants show considerable increase from the *trans* to the *gauche*, as expected.

The authors are very grateful to Dr. W. V. F. Brooks, from the University of New Brunswick, for the gift of the FORTRAN IV program with the complete set of punched cards, as well as for much valuable advice on its use. The computations were carried out at the *Centre de Traitement de l'Information de l'Université Laval* (on an IBM 360/50 Model OS computer with a fast memory of 500 000 digits). The cooperation of the Director and the staff is gratefully acknowledged. This research was made possible thanks to an

operating grant of the National Research Council of Canada.

An Electron Spin Resonance Study of High Energy Radiation Damage in Tetrapotassium Hexacyanoruthenate Trihydrate, $K_4Ru(II)(CN)_6.3H_2O$

R. S. EACHUS[1] AND F. G. HERRING

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received March 8, 1971[2]

Gamma-ray irradiation at 77 °K and X-ray irradiation at room temperature of single crystals of the diamagnetic tetrapotassium hexacyanoruthenate trihydrate have been shown to produce a number of interesting paramagnetic species. At room temperature the e.s.r. spectra can be interpreted in terms of the species $[Ru(CN)_5(NC)]^{5-}$. At liquid nitrogen temperature the species $[Ru(CN)_4(NC)_2]^{5-}$ is observed and the HCN^- radical is produced in an environment which does not permit it to rapidly reorientate at 77 °K. The HCN^- radical is believed to be in close association with a ruthenium(II) ion.

On a montré que l'irradiation par rayons-gamma à 77 °K et par rayons-X à la température de la pièce, de cristaux uniques de la molécule diamagnétique d'hexacyanoruthénate de tétrapotassium trihydraté produit un certain nombre d'espèces paramagnétiques intéressantes. A la température de la pièce, le spectre rpe peut être interprété en termes des espèces $[Ru(CN)_5(NC)]^{5-}$. A la température de l'azote liquide, on observe les espèces $[Ru(CN)_4(NC)_2]^{4-}$ et le radical HCN^- est produit dans un environnement qui ne lui permet pas de se réorienter rapidement à 77 °K. On croit que le radical HCN^- est associé de près avec un ion ruthénium(II).

Canadian Journal of Chemistry, **50**, 162 (1972)

Recently there has been considerable interest in the effects of high energy radiation on transition metal cyanides (1–4). There are two reports of radiation damage in $K_3Co(CN)_6$; the first (1) reports that the effect of 2 MeV electrons at liquid nitrogen temperature is to produce the stabilized complex $[Co(II)(CN)_4(NC)_2]^{4-}$. These conclusions being supported by the observation of superhyperfine interactions due to two nitrogen nuclei for the center at 77 °K and no such superhyperfine interaction for the second species. The second report (2) refers to the X-irradiation of $K_3Co(CN)_6$ at room temperature, the spin Hamiltonian parameters of the paramagnetic center produced being identical to those characterising the second radical reported by Danon *et al.* (1). Lin *et al.* (2) interpret the spin Hamiltonian parameters of this second center in terms of a d^7 octahedral system with a weak tetragonal elongation. In such situations the odd electron will occupy the d_{z^2} orbital of the Co(II) atom.

Subsequently Root and Symons (3) reported radiation damage studies on $K_4Fe(CN)_6$ doped in Group IA halides, the paramagnetic center produced in this case being the mon-isocyanide $[Fe(CN)_5NC]^{5-}$. Danon and co-workers (4) have suggested that the formation of Fe(I) and Co(II) isocyanides on irradiation of alkali metal halides doped with the corresponding transition metal cyanides is due to the influence of cation vacancies produced in the lattice by the substitution of the cyanide complex. In all of the cases referred to above the spin Hamiltonian parameters correspond to a ground state in which the odd electron is accommodated in the d_{z^2} orbital. The stabilization of the d_{z^2} orbital relative to the $d_{x^2-y^2}$ orbital is brought about by the fact that the nitrogen end of the CN^- ligand leads to a lower ligand-field strength (5) than the carbon end. The possibility of a CN^- flip had already been suggested by Shriver *et al.* (5).

We wish to report an e.s.r. study of X- and γ-ray irradiated $K_4Ru(II)(CN)_6 3H_2O$ both at liquid nitrogen temperature and room temperature.

Experimental

Single crystals of $K_4Ru(CN)_6.3H_2O$ were grown by slow evaporation of aqueous solutions containing approximately 4% KOH as described by Tsang and O'Reilly (6). Suitable crystals were irradiated with either 65 kV X-rays at 300 °K or ^{60}Co γ-rays at 77 °K. The e.s.r. spectra were observed both at room temperature and at liquid nitrogen temperature.

The room temperature crystal structure of $K_4Ru(CN)_6$-$3H_2O$ is monoclinic with a pseudotetragonal unit cell containing four molecules (7). The crystals grew as flat platelets with the $\langle 010 \rangle (b-)$ axis perpendicular to the plate. Rotations were performed about the crystallographic *a*, *b*-, and *c*-axes for our e.s.r. studies.

$[Ru(CN)_5(NC)]^{5-}$	298 °K	^{99}Ru	5.0	38.4	5.0	2.0884	1.9984	2.0884±0.0005
		^{101}Ru	5.0	35.1	5.0			
		^{14}N	$a_{iso} = 4.5$					

*The units are gauss and *a*, *b*, *c* refer to the crystal axes.

Results

At room temperature the e.s.r. spectrum consisted of a single intense line which was accompanied by six weaker symmetrically disposed features; a typical spectrum is shown in Fig. 1. These satellite lines can be attributed to the naturally occurring isotopes of ruthenium (^{100}Ru, I = 0, 70.21%; ^{99}Ru, I = 5/2, 12.81%, $\mu_N = -0.63$ N.M.; ^{101}Ru, I = 5/2, 16.98%, $\mu_N = -0.69$ N.M.). The line width of the resonances precluded the resolution of the individual ^{99}Ru and ^{101}Ru isotope lines and two of the six lines are obscured by the resonance due to ^{100}Ru. The line to the left, in Fig. 1, is due to an unknown species. The experimental data was interpreted using the spin Hamiltonian

$$\mathcal{H} = \boldsymbol{H}\cdot\mathbf{g}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\mathbf{A}\cdot\boldsymbol{I}$$

Both the hyperfine and **g**-tensors of this centre were found to be axial within experimental error and the unique components of these tensors proved to be parallel to the *b*-axis of the crystal. The results are given in Table. 1.

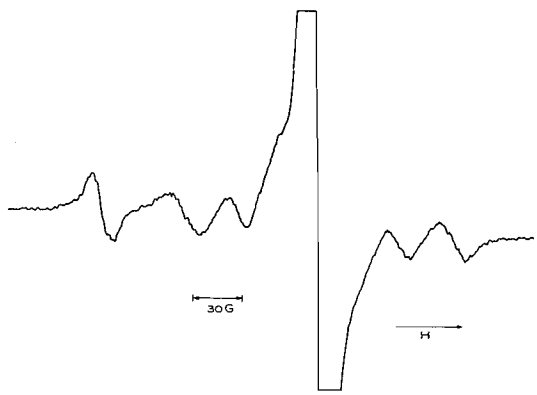

FIG. 1. The electron spin resonance spectrum at room temperature of X-irradiated $K_4Ru(CN)_6.3H_2O$. The magnetic field is parallel to the *b*-axis.

On cooling a sample of the $K_3Ru(CN)_6.3H_2O$, which had been X-irradiated at room temperature, and observing the e.s.r. spectrum it was found that the intense line due to the ^{100}Ru isotope exhibited nitrogen superhyperfine structure corresponding to one nitrogen atom. The splitting was found to be a maximum (5.1 ± 0.25 G) along the *a*-axis of the crystal and less than 4.0 G along the *b*- and *c*-directions (this last value being estimated from the line width).

The results described above suggest that the center produced at room temperature is either of the electron excess centers $[Ru(CN)_5NC]^{5-}$ or $[Ru(CN)_4NC]^{4-}$. The assignment of the presence of an isocyanide linkage at room temperature assumes that no intramolecular rearrangement occurred on cooling the crystal to liquid nitrogen temperature.

The results of γ-irradiation at liquid nitrogen temperatures are substantially more complex than those at room temperature. Three radicals are formed, two of which have been identified. The radical which was not identified had a completely isotropic spectrum consisting of three lines of approximate heights 1:4:1 with approximate line widths 2:1:2. The splitting between the lines is 21.2 ± 0.1 G and the *g*-value of the radical is 2.002 ± 0.001. This radical could be tentatively assigned as the H_2O^- radical rapidly reorientating in the crystal lattice. The extra electron would be accommodated in the antibonding b_1 orbital of H_2O; this orbital contains a contribution from the hydrogen 1s orbitals and a splitting of 20 G is not unreasonable. The H_2O^- radical could be formed in a number of ways, for example, H atoms, produced by the radiation damage of water could

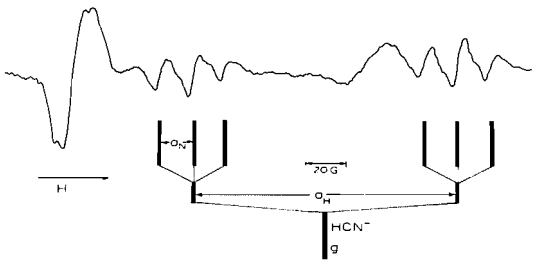

FIG. 2. The electron spin resonance spectrum at 77 °K of γ-irradiated $K_4Ru(CN)_6.3H_2O$. The magnetic field is parallel to the *c*-axis.

react with OH^- impurities in the lattice. Fortunately this radical could be annealed out on warming very slightly without significant reduction in the intensity of the other two centers produced, Fig. 2 shows a spectrum of a crystal treated in such a way.

The stronger resonance at low field, see Fig. 2, proved to be $[Ru(I)(CN)_4(NC)_2]^{5-}$. This identification is based upon the observed *g*-values of $g_{||} = 1.9982 \pm 0.0005$ and $g_{\perp} = 2.0855 \pm 0.0005$, where $g_{||}$ is parallel to the *b*-axis of the crystal and hyperfine splitting due to two nitrogen atoms. The *g*-values of this center are identical to those of the major species observed at room temperature; unfortunately the ^{99}Ru and ^{101}Ru splitting could not be observed.

The second feature shown in Fig. 2 is a doublet of triplets, the hyperfine parameters are given in Table 1. We attribute this center as being due to a HCN^- radical associated with a $Ru(II)(CN)_5^{3-}$ complex in which most of the spin density is on the HCN^-. The hyperfine coupling parameters for this species are also given in Table 1. There are two previous reports of the HCN^- radical, the first is by Root *et al.* (8) who observed it in alkali halide matrices at 77 °K. Under their experimental conditions the radical is rapidly rotating. On cooling to 4.2 °K, however, Adrian *et al.* (9) succeeded in obtaining the oriented HCN^- radical and measured the anisotropy of the spin Hamiltonian parameters. The differences between the parameters measured in this work and the work of Adrian *et al.* together with the fact that the HCN^- radical is not rotating at 77 °K in $K_4Ru(CN)_6.3H_2O$ may be satisfactorily interpreted by postulating that the HCN^- is associated with the Ru atom; this is discussed later. In addition to these three major centers very weak signals were observed for two species with **g**-tensors identical to that of $[Ru(I)(CN)_4(NC)_2]^{5-}$ except that in one case *g* is along a direction 65° from the *a*-axis and in the other along a direction 65° from the *c*-axis. The two signals are therefore expected to be due to a small concentration of $[Ru(I)(CN)_4(NC)_2]^{5-}$ formed in the *ac* plane. The direction of the unique axes for these species corresponded very closely to the RuCN directions in the *ac* plane.

When a crystal which has been γ-irradiated at 77 °K is annealed to room temperature only a ruthenium(I) species is left. The e.s.r. data show that this center is the same as that produced by X-irradiation at room temperature.

Discussion

At liquid nitrogen temperatures the irradiation of iron group transition metal cyanides produces an electron excess center at the transition metal ion. If the original complex is octahedral then the additional electron must be accommodated in the degenerate e_g level and consequently the e.s.r. spectrum of such a system would be difficult to observe. The results of Danon and co-workers (1, 4) and Root and Symons (3) show that a distortion occurs which causes the e_g level to split; this distortion takes the form of a rearrangement to form isocyanide linkages as is evidenced by the observation of nitrogen superhyperfine structure. In the pure cobalt(III) cyanide this center is unstable to warming and decays to a pentacoordinate species (1 4); however, when the cyanide is doped in the alkali halide the isocyanide center is stable indefinitely. The stability being ascribed to the interaction of the complex with cation vacancies. The results of the present study show that at liquid nitrogen temperatures the $[Ru(CN)_4(NC)_2]^{5-}$ center is the species formed. The hyperfine splitting for two equivalent nitrogens is about 3.0 G, with a small anisotropy, indicating that the majority of the spin density resides on the Ru atom. On warming to room temperature this radical decays to the $[Ru(CN)_5(NC)]^{5-}$ or $[Ru(CN)_4(NC)]^{4-}$, observed at room temperature after X-irradiation. On the basis of our results it is not possible to decide unequivocally between 5 or 6 ligands but the reversal of one isocyanide linkage may be rationalized on the basis of the crystal structure of $K_4Ru(CN)_6.3H_2O$.

The results of the structure determination by Kiriyama *et al.* (7) show that there are double

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

layers of cyanide octahedra with water molecules in between. The work of Tsang and O'Reilly (6) suggests that only one cyanide ligand from each octahedron in the double layer can hydrogen bond with this water molecule along the *b*-axis of the crystal. We would like to propose that when the $Ru(CN)_6^{4-}$ traps a thermalized electron the resultant $Ru(CN)_6^{5-}$ stabilizes itself by destroying the hydrogen bonding and forms two isocyanide linkages along the *b*-axis; this is supported by the fact that the unique axis of the **g**-tensor is along the *b*-axis. On warming we believe the isocyanide ligand which arose from that cyanide which participated in hydrogen bonding in the undamaged crystal returns to a normal form of linkage and is stabilized by the hydrogen bonding. The remaining isocyanide ligand remains to cause sufficient distortion to the octrahedron to afford a splitting of the e_g level. The existence of only one isocyanide ligand is confirmed by our e.s.r. results. The observation that the **g**-tensors of $[Ru(I)(CN)_4(NC)_2]^{5-}$ seen at 77 °K and the species observed at room temperature, which exhibits superhyperfine features due to one nitrogen only, are the same, leads us to believe that the room temperature center is the six coordinate moiety $[Ru(I)(CN)_5(NC)]^{5-}$. There is however a slight inconsistency in this analysis in as much as the maximum nitrogen hyperfine splitting for the postulated species $[Ru(I)(CN)_5(NC)]^{5-}$ is along the *a*-axis and not along the *b*-axis as may be expected if the nitrogen $2p_\sigma$ orbital (along the *b*-axis) contains the bulk of the density located on the nitrogen. This discrepancy is not readily explained but may indicate that the "flipped" CN^- ligand does not rotate fully through 180°.

The HCN^- radical, as mentioned before, has been observed in KCl at 4.2 °K (9). The anisotropy of the nitrogen hyperfine splitting constant arises from spin density in the nitrogen 2p orbital in the HCN plane and perpendicular to the CN bond. The total tensor has the form (A,0,0) (9) so that the Fermi-contact term is positive and just cancels the anisotropy perpendicular to the axis of the 2p orbital. In the present case, however, we have suggested that the HCN^- radical is associated with a Ru(II) ion in the form of a $[Ru(II)(CN)_5(HCN)]^{4-}$ complex, consequently, we may expect the nitrogen hyperfine tensor to be quite different.

The form of the nitrogen hyperfine tensor can shed some light on both the structure and the orientation of this radical. Within experimental error the diagonal nitrogen hyperfine coupling tensor elements are $|a_{bb}| = 22$, $|a_{aa}| = 5.0$, and $|a_{cc}| = 17.0$ G, where the subscripts refer to the crystal axes. The HCN^- ligand will most likely be bent so that the $[Ru(CN)_5(HCN)]^{4-}$ species will have very little symmetry and the odd electron orbital could in practice contain all the atomic orbitals on nitrogen. However, it is very likely that a reflexion plane could be preserved so that the 2p orbital perpendicular to the plane of the HCN^- radical can be ignored. Unlike the HCN^- radical observed in KCl (and HCO as discussed by Adrian *et al.* (10)) the fact that the largest hyperfine component is along the *b*-axis suggests that the 2p orbital in this direction dominates the odd electron orbital and the in-plane 2p orbital perpendicular to the CN bond contributes to a smaller degree. Les us denote the molecular orbital coefficient of these atomic orbitals by C_σ and C_δ, respectively, then we may write

$$a_1 = a_{iso} + (2C_\sigma^2 - C_\delta^2)B$$

$$a_2 = a_{iso} + (-C_\sigma^2 + 2C_\delta^2)B$$

$$a_3 = a_{iso} + (-C_\sigma^2 - C_\delta^2)B$$

where $B = g_e g_N \beta_e \beta_N \langle r^{-3} \rangle_{2p}$ and a_{iso} is the isotropic part of the coupling tensor and if the odd electron is in a σ orbital, as we believe, then it will likely be positive. Thus if $C_\sigma > C\delta$ then $a_1 > 0$, $a_1 > a_2$, and a_3 will be small and possibly negative. Since two of the hyperfine components are almost equal (a_{bb} and a_{cc}) we assign these to be a_1 and a_2, *i.e.* the plane of the HCN^- radical is in the *bc* plane. The third component $a_{aa} = a_3$ will almost certainly be negative. This assignment ($a_{bb} = +22$, $a_{cc} = +17$, and $a_{aa} = -5$ G) leads to a Fermi contact term of +11 G. These values of the anisotropy indicate that the odd electron spends about 50% of its time in the nitrogen 2p orbitals. The large isotropic coupling observed for the hydrogen nucleus is in accord with the above description of the HCN^- center and corresponds to about a 20% occupancy of the hydrogen 1s orbital. The slightly reduced **g**-tensor no doubt reflects the spin–orbit interaction from the ruthenium atom which has a large spin–orbit coupling constant.

It is of some interest to compare the bonding parameters in $[Ru(CN)_5(NC)]^{5-}$ and those in $[Fe(CN)_5(NC)]^-$ which may be inferred from the data given by Danon *et al.* (4).

The formation of the isocyanide linkage brings the nitrogen end of CN^- toward the metal atom; this, because the nitrogen end has a weaker ligand field splitting than the carbon end, causes the d_{z^2} orbital to be stabilized relative to the $d_{x^2-y^2}$ orbital. The ground state for this C_{4v} symmetry can be represented by $|E^4B_2^2A_1|$ and the corresponding g-values are (2) $g_{||} = 2.00$; $g_\perp = 2.0 - 6\lambda K_\perp/\Delta E$; where ΔE is the energy difference between the $|E^3B_2^2A_1^2|$ excited state and the ground state, λ is the spin orbit coupling parameter which has a value of approximately $-1000\ cm^{-1}$ (11) and $k_\perp$ is an orbital reduction parameter. The observed g-values are in accord with this assignment of the ground state. The form of the hyperfine tensor will be determined, to a large extent, by the spin density in the d_{z^2} which constitutes part of the A_1 orbital. If the coefficient of the d_{z^2} orbital is α then we have

$$a_{||} = -k + \tfrac{4}{7}\alpha^2 P - \tfrac{1}{7}\Delta g_\perp P$$

$$a_\perp = -k - \tfrac{2}{7}\alpha^2 P + \tfrac{15}{14}\Delta g_\perp P$$

where $P = g_e g_N \beta_e \beta_N \langle r^{-3} \rangle_{4d}$ and has a value of about $-42 \times 10^{-4}\ cm^{-1}$. This value was obtained by extrapolation of the values for Ru^{2+} and Ru^{3+} given by Abragam and Bleaney (11). Since P is negative it is almost certain that $a_{||} < 0$ and $a_\perp < 0$.

The expression for the hyperfine tensor can be used to deduce k and α^2 for a given choice of sign for $a_{||}$ and $a_\perp$. If the relative sign $a_{||} < 0$ and $a_\perp > 0$ are chosen a value of $\alpha^2 > 1$ is obtained which is not consistent with the usual chemical ideas of a high degree of covalency in a cyanide complex. The combination $a_{||} = -38.4$ and $a_\perp = 5.0$ for ^{101}Ru gives $k = +0.00126\ cm^{-1}$ and $\alpha^2 = 0.91$. The value of α^2 is somewhat higher than the values computed by Danon *et al.* (4), reflecting a slightly more ionic σ-bonding for Ru(I) relative to Co(II). Similarly the reduced nitrogen superhyperfine in $[Ru(CN)_5(NC)]^{5-}$ relative to that for $[Fe(CN)_5(NC)]^{5-}$ reinforces the above notion. Second row transition metals are generally thought to exist in more ionic bonding situations in their complexes relative to first row transition elements.

The value of k can now be used to compute the quantity χ (12), i.e. the spin density, defined by

$$\chi = \frac{4\pi}{S}\left\langle \psi \left| \sum_i \delta(r_i) S_{zi} \right| \psi \right\rangle = \frac{-3}{2} \frac{hca_0^3}{g_e g_N \beta_e \beta_N} k\,(\text{a.u.})$$

the value is $+2.15$. The nuclear magnetic moment of the ruthenium isotopes is negative so that if k is positive $\chi > 0$, and a positive value of χ indicates a direct s orbital contribution to the Ru molecular orbital in which the odd electron resides, which is in accord with the assignment of a $^2A_1$ ground state. Core polarization of the inner s orbitals will create negative spin density which will tend to reduce the overall value of χ.

The magnitude of $\Delta g_\perp$ suggests that there is a fairly substantial orbital reduction in the xz and yz orbitals of ruthenium; a reasonable estimate for ΔE ($20\,000\ cm^{-1}$) gave $k_\perp \simeq 0.4$. This low value is presumably due to substantial ligand–metal π back bonding which is needed to stabilize the low oxidation state.

The authors wish to thank Professor C. A. McDowell for his interest in this work and the National Research Council of Canada for financial support.

An Examination of the Heat Capacity of Activation for the Hydrolysis of *t*-Butyl Chloride in Water

J. M. W. SCOTT[1] AND R. E. ROBERTSON

Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received June 22, 1970[2]

The influence of ion-pair intermediates on solvolytic displacement reactions is considered for cases where the observed rate constant is complex.

Such complex and composite rate constants under certain conditions may show deviations from the Arrhenius temperature dependence law. The deviations will manifest themselves as "spurious" positive and/or negative heat capacities of activation, superimposed on the real heat capacity terms.

The hypothesis of Albery and Robinson (1) which proposes that the heat capacity of activation for *t*-butyl chloride is entirely "spurious" in the sense outlined above, is critically evaluated and rejected. An alternative hypothesis that considers the heat capacity to be a manifestation of solvation effects is retained.

The mechanism of the hydrolysis of both the methyl and *t*-butyl halides in water is discussed and the kinetic laws appropriate to each are shown to be consistent with real heat capacities of activation. The mechanism proposed differs from the classical S_N1–S_N2 description. Both series of substrates are considered to give rise to intimate-ion-pairs but in the case of the methyl halides these react further by a path which involves the nucleophilicity of the solvent in a kinetically significant way. In the cases of the tertiary compounds, solvent separation of ion-pairs becomes kinetically significant. The nucleophilic component which characterizes the destruction of the solvent-separated ion-pairs for the tertiary compounds is kinetically insignificant.

On étudie l'influence des paires d'ions intermédiaires sur les réactions de déplacement solvolytique dans le cas où la constante de vitesse observée est complexe.

Des constantes de vitesses complexes ou composées peuvent, sous certaines conditions, montrer des déviations à la loi d'Arrhénius sur la dépendance de la température. Les déviations se manifestent comme des "pseudo" capacités de chaleur d'activation, positives et/ou négatives qui se superposent aux termes réels de capacité calorifique.

L'hypothèse de Albery et Robinson (1) qui propose que la capacité calorifique d'activation pour le chlorure de tertio-butyl est entièrement "pseudo", dans le sens exprimé plus haut, est examinée et rejetée. Une hypothèse différente, qui considère la capacité de chaleur comme étant une manifestation des effets de solvatation est plutôt émise.

On discute du mécanisme d'hydrolyse des halogénures de méthyle et de tertio-butyle dans l'eau et on montre que les lois de cinétique appropriées à chacun sont consistantes avec les capacités calorifiques d'activation réelles. Le mécanisme proposé diffère de la description classique S_N1–S_N2. On considère que les deux séries de substrats donnent lieu à des paires d'ions liés, mais dans le cas des halogénures de méthyle, ceux-ci réagissent plus loin par un mécanisme impliquant la nucléophilicité du solvant et ceci de façon cinétiquement importante. Le composé nucléophile caractérisant la destruction des paires d'ions séparées du solvant pour les composés tertiaires est cinétiquement négligeable.

Canadian Journal of Chemistry, **50**, 167 (1972)

Recently Albery and Robinson (1) have chosen to interpret the large negative temperature dependence of the enthalpy of activation ($\Delta H^{\ddagger}$) characteristic of the hydrolysis of *t*-butyl chloride in water in a manner which casts serious doubts on that hypothesis based on solvent-structure reorganization which has been found useful (2). Instead of using the classical kinetic formulation for the S_N1 reaction proposed by Hughes and Ingold (3)

$$[1] \qquad RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^+ + X^- \xrightarrow{k_3} \text{Products}$$

which involves the substrate RX and the kinetically free ions R^+ and X^- together with k_1 rate determining, Robinson and Albery examine the temperature dependence of an S_N1-like reaction where the intermediate is possibly an ion-pair

rather than the kinetically free ions

$$[2] \qquad RX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R^+ + X^- \xrightarrow{k_2} \text{Product or further intermediates}^3$$

with the condition that $k_{-1} \simeq k_2$.

Reaction 2 is similar to Sneen's truncated version of the detailed mechanism proposed by Winstein and co-workers (4) where the truncated

$$[3] \qquad \begin{array}{ccccccc} RX & \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & R^+X^- & \underset{k_4}{\overset{k_3}{\rightleftharpoons}} & R^+\|X^- & \underset{k_6}{\overset{k_5}{\rightleftharpoons}} & R^+ + X^- \\ \downarrow k_{1n} & & \downarrow k_{2n} & & \downarrow k_{3n} & & \downarrow k_{4n} \\ P & & P & & P & & P \end{array}$$

version confines attention to k_1, k_2, and k_{2n} and the remaining rate constants in reaction 3 contribute nothing to the observed rate. The species R^+X^- and $R^+\|X^-$ are respectively intimate and solvent-separated ion-pairs. The solvent separated ion pair is required to accommodate, among other things, some of the stereochemical consequences of substitution. For instance, according to Sneen (5) the intimate-ion-pair leads exclusively to inversion in nucleophilic (aqueous) media, even for reactive (S_N1 tending) substrates.

Although the kinetic complexity of these reactions has been recognized, k_1 in reactions 1, 2, and 3 has invariably been assumed to be rate determining (however, see ref. 6). The ubiquity of this assumption does not guarantee its validity and the gist of the proposals put forward by Albery and Robinson (1) is to question this sort of assumption particularly with respect to their own scheme.[4] If their proposals are accepted and applied to reaction 3*a* (footnote 4) the observed rate (k^0) for a process proceeding by this reaction will be given by

$$[4] \qquad k^0 = k_1k_{2n}/(k_2 + k_{2n}) = k_1/(1 + \alpha)$$

where

$$k_2/k_{2n} = \alpha$$

The relative values of α will clearly have a strong effect on k^0. If α is small then $k^0 = k_1$ and subsequent steps are not kinetically significant. If the rate of return (k_2) is much greater than the k_{2n} step, then $k^0 = k_1k_{2n}/k_2 = K_{el}k_{2n}$, *i.e.*, that rate becomes dependent on an equilibrium constant K_{el} and the rate constant k_{2n} which leads to product formation. There is also the situation where k_2 and k_{2n} are comparable. In their scheme (reaction 2) Albery and Robinson place the hydrolysis of *t*-butyl chloride in a similar category; more specifically they consider k_{-1} and k_2 to be comparable. Granted certain premises, which seem unlikely (see below), they then go on to show that if k_{-1} and k_2 are comparable in their scheme, the temperature dependence of $\Delta H^{\ddagger}$ will logically result from an apparent or "spurious" heat capacity of activation which is unrelated to solvent reorganization.

The recognition of the importance of ion-pair intermediates in solvolytic displacements is not new (see refs. 4–6). Neither is the rationalization of non-Arrhenius behavior of rate constants in terms of a non-unitary process (7). The studies of Winstein and co-workers (4, 6), Goering and co-workers (8–10), and the more recent studies of Shiner (11) and of Sneen (5, 12, 13) provide ample evidence for the existence of ion-pair intermediates. However, whether the observed heat capacity for the hydrolysis of *t*-butyl chloride is a manifestation of the existence of ion-pair intermediates and thereby spurious or real as a consequence of solvent reorganization, or alternatively a combination of both these possibilities, is not easily established. The existence of a spurious heat capacity depends on the ratio k_2/k_{2n} (or on k_{-1}/k_2 for reaction 2 and k_2/k_3 for reaction 1). A feature common to all these mechanisms is the difficulty of establishing the magnitude of the appropriate ratios. Ritchie (6) in a detailed discussion of the Winstein mechanism (reaction 3) concludes that k_2 is the fastest rate of the ten rate constants which define the mechanism. This conclusion can reasonably be extrapolated to the Sneen truncated version

[3] Albery and Robinson do not specify the nature of the k_2 reaction in their scheme which is algebraically equivalent to reaction 1 and Sneen's truncated version of reaction 3 (see below).

[4] We draw attention to the fact that reactions 1, 2 and Sneen's truncated version of reaction 3 are all algebraically equivalent. The last, which is

$$[3a] \qquad RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^+X^- \xrightarrow{k_{2n}} \text{Product}$$

will be used subsequently to establish the consequences of this kind of rate law on the thermodynamic parameters which characterize such a process.

of reaction 3. However, the question of how k_2 might alter with the structure of RX remains open.

In their discussion Albery and Robinson maintain k_{-1}/k_2 is unity for *t*-butyl chloride reacting in water at $T = 33.4$ °C. To arrive at this value from their experimental data they assume that there are no real heat capacity terms associated with the activation of *t*-butyl chloride in water. Sneen and Larsen find values of α (see eq. 4) which are close to unity but their interpretation of their own data is open to criticism (14).

Alternative interpretations of non-Arrhenius behavior which assume the apparent heat capacities to be real and to be a manifestation of solvation phenomena have been reviewed by Kohnstam (15) and by Robertson (2). A more general review of non-Arrhenius behavior has been presented by Hullett (16).

While we are inclined to accept the hypothesis that all substitutions at the saturated carbon atom involve ion-pair intermediates (and this includes those examples which have been described traditionally as reacting by an S_N2 mechanism),[5] we are less inclined to accept the kinetic analysis provided by Sneen and Larsen (13), or alternatively the temperature dependence of *t*-butyl chloride hydrolysis presented by Albery and Robinson (1). Neither of the interpretations offered by the above authors is unique.

Granted their assumptions, the treatment of the temperature dependence of the hydrolysis of *t*-butyl chloride in water proposed by Albery and Robinson is correct in principle. However, there is good reason to believe that $\Delta C^{\ddagger}_{p0}$ (*i.e.* non-Arrhenius behavior) is a manifestation of solvent reorganization with little or no contribution from kinetic complexity.

Aside from this study by Albery and Robinson, the consequences of the Winstein or Winstein-like mechanisms with respect to temperature dependence for solvolytic displacements has been neglected. In view of the current interest, an analysis of temperature effects on this mechanism is highly desirable.

[5]Such a hypothesis provides a natural explanation for the similarity of the kinetic solvent isotope effect for the hydrolysis of primary and tertiary halides. The absence of any significant primary isotope effect associated with the solvolysis of the primary halides is regarded as particularly significant in this connection (17).

Some Thermodynamic Consequences of the Winstein Mechanism

In deriving pseudo-thermodynamic parameters it is normally assumed that the reaction involves a single energy barrier and that the temperature dependence of the rate provides a means for investigating the energetics of the reaction. However, if the Winstein mechanism is accepted for solvolytic displacement reactions, the identification of the observed rate constant with a single energy barrier is likely to be an oversimplification. While the steady state treatment of the complete Winstein mechanism is possible the resulting expression will be unwieldy, and provide little insight to the problem. Fortunately, the kinetic behavior of certain systems of interest permits a simplified treatment.

(a) S_N1-like Processes

These are cases where $k_{1n} \rightarrow k_{4n} \gg k_1, k_3, k_5$ giving rise to the following rate laws

$$[5] \qquad k^0 = k_1$$

where k_1 is rate determining

$$[6] \qquad k^0 = k_1k_3/k_2 = K_{e1}k_3$$

where k_3 is rate determining and finally where k_5 is rate determining[6]

$$[7] \qquad k^0 = k_1k_3k_5/k_2k_4 = K_{e1}K_{e2}k_5$$

Each of these rate laws is consistent with the S_N1 mechanism within the framework of the Hughes–Ingold scheme. In each of the reactions represented by the kinetic eqs. 5→7, one molecule is altering its bonding via heterolytic fission to give a more ionic species. The difference between these mechanisms and the classical S_N1 scheme is the recognition that complete heterolysis, *i.e.* the formation of kinetically free ions, does not necessarily occur in a single step.

(b) S_N2-like Processes

For these examples, $k_{2n} \rightarrow k_{4n}$ are kinetically significant. In cases where the rate of nucleophilic attack becomes either rate determining or

[6]There will also be transitional situations where k_2 is comparable to k_3 and where k_4 is comparable to k_5. The form of the rate laws in these regions can be established by an appropriate steady state treatment which we ignore here for the sake of economy. The behavior of the thermodynamic parameters in these regions can be inferred from considerations elaborated below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

comparable with the return rates (k_2, k_4, k_6) or further heterolytic rates (k_3, k_5), the observed rates will contain both nucleophilic and heterolytic components and correspond to what has usually been described as "borderline" kinetic situations (18). The designation S_N2-like is justified in the sense that nucleophilic components form part of the observed rate constant. But if, following Sneen (13), k_{1n} is deemed kinetically insignificant (see also ref. 14) then the resemblance of the remaining kinetic possibilities to the classical S_N2 description is superficial. A more complete kinetic analysis will require due consideration be given to the nine remaining rate constants in reaction 3.

When both the nucleophilic components (k_n) and the heterolytic components contribute to the observed rate a much wider selection of rate laws is possible and some examples of these, particularly with respect to the temperature dependence problem, can be examined via the truncated scheme

[8] $$RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^+X^- \underset{k_4}{\overset{k_3}{\rightleftharpoons}} R^+\|X^-$$
$$\downarrow k_{2n} \qquad \downarrow k_{3n}$$
$$P \qquad P$$

We retain the assumption originally made by Sneen and Larsen (13) that k_{1n} is kinetically insignificant in all cases, *i.e.* direct attack on the unactivated initial state of RX is unlikely.

The Sneen mechanism is evidently a truncated version of reaction 8 which confines attention to k_1, k_2, and k_{2n}. For this particular simplification we may define three kinetic regions:[7] Region I ($\alpha < 0.01$), Region II ($0.01 < \alpha < 100$), and Region III ($\alpha > 100$), with rate laws $k^0 = k_1$ (Region I), $k^0 = k_1k_{2n}/(k_2 + k_{2n})$ (Region II), and $k^0 = k_1k_{2n}/k_2 = K_{1e}k_{2n}$ (Region III). The corresponding pseudo-thermodynamic parameters for Regions I and III are:

	Region I	*Region III*
[9]	$\Delta G^{\ddagger}_0 = \Delta G^{\ddagger}_1 = \Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_2 + \Delta G^{\ddagger}_{2n} =$	$\Delta G^{\ddagger}_{1e} + \Delta G^{\ddagger}_{2n}$
[10]	$\Delta S^{\ddagger}_0 = \Delta S^{\ddagger}_1 = \Delta S^{\ddagger}_1 - \Delta S^{\ddagger}_2 + \Delta S^{\ddagger}_{2n} =$	$\Delta S^{\ddagger}_{1e} + \Delta S^{\ddagger}_{2n}$
[11]	$\Delta H^{\ddagger}_0 = \Delta H^{\ddagger}_1 = \Delta H^{\ddagger}_1 - \Delta H^{\ddagger}_2 + \Delta H^{\ddagger}_{2n} =$	$\Delta H^{\ddagger}_{1e} + \Delta H^{\ddagger}_{2n}$
[12]	$\Delta C^{\ddagger}_{p0} = \Delta C^{\ddagger}_{p1} = \Delta C^{\ddagger}_{p1} - \Delta C^{\ddagger}_{p2} + \Delta C^{\ddagger}_{p2n} =$	$\Delta C^{\ddagger}_{p1e} + \Delta C^{\ddagger}_{p2n}$

In Region II the expressions are more complex:

[13] $$\Delta G^{\ddagger}_0 = \Delta G^{\ddagger}_1 + RT \ln (1 + \alpha)$$

[14] $$\Delta S^{\ddagger}_0 = \Delta S^{\ddagger}_1 + \frac{\alpha}{1+\alpha}\frac{(\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_2)}{T} - R \ln (1 + \alpha)$$

or $$= \Delta S^{\ddagger}_1 + \frac{\alpha}{1+\alpha}(\Delta S^{\ddagger}_{2n} - \Delta S^{\ddagger}_2) + \frac{\alpha}{1+\alpha} R \ln \alpha - R \ln (1 + \alpha)$$

[15] $$\Delta H^{\ddagger}_0 = \Delta H^{\ddagger}_1 + \frac{\alpha}{1+\alpha}(\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_2)$$

[16] $$\Delta C^{\ddagger}_{p0} = \Delta C^{\ddagger}_{p1} + \frac{\alpha}{1+\alpha}(\Delta C^{\ddagger}_{p2n} - \Delta C^{\ddagger}_{p2}) - \frac{\alpha}{(1+\alpha)^2}\frac{(\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_2)^2}{RT^2}$$

Equations 9–16 show that solvolytic displacements proceeding via the Sneen or Albery mechanism will give rise to values of $\Delta H^{\ddagger}_0$, $\Delta S^{\ddagger}_0$, and $\Delta C^{\ddagger}_{p0}$ which are complex functions of the thermodynamic quantities which characterize the individual steps k_1, k_2, and k_{2n}, (or k_1, k_{-1}, and k_2 for reaction 2). Particular attention is directed to eq. 16 which contains three real heat capacity terms $\Delta C^{\ddagger}_{p1}$, $\Delta C^{\ddagger}_{p2}$, and $\Delta C^{\ddagger}_{p2n}$ and a third "spurious" term which must always be negative irrespective of the sign of $\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_2$ since the "spurious" term depends on the square of this quantity. The other

[7] Operationally Sneen and Larsen define these regions more narrowly: Region I, $\alpha < 0.10$; Region II, $0.10 < \alpha < 10$; and Region III, $\alpha > 10$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

quantities in the "spurious" term R, T, and α are all necessarily positive.

The pith of the Albery-Robinson treatment is to assume that in similar equations related to reaction 2, real heat capacity terms are zero. Alternatively, and more specifically, they assume, without any real justification, that quantities such as $\Delta H^{\ddagger}_1$, $\Delta H^{\ddagger}_2$, and $\Delta H^{\ddagger}_{2n}$, or those related to their own scheme, are all true constants and that the experimentally observed heat capacity derives entirely from the existence of the ion-pair, *i.e.*, the "spurious" heat capacity is the only sizeable term in eq. 16. We shall evaluate this assumption more critically below. In the meantime a further examination of the mechanism (eq. 8) with respect to the temperature dependence of solvolytic displacements is of interest.

Consider a system reacting according to eq. 8 where the ratio k_4/k_{3n} is small and k_2/k_{2n} large. The appropriate steady state expression with these constants is

$$[17]\quad k^0 = K_e\{k_{2n} + k_3\} = K_e k_3\{1 + k_{2n}/k_3\} = K_e k_3\{1 + \beta\}$$

where $\beta = k_{2n}/k_3$

This constitutes a "mixed kinetics" situation with a nucleophilic component k_{2n} and a further heterolytic component k_3: both contributing to the observed rate. Such a kinetic scheme will also have a profound effect on the temperature dependence which differs from the situation represented by reaction 2. A brief analysis of an analogous situation has been presented by Kohnstam (15) within the framework of a mixed classical S_N1/S_N2 case, *i.e.*, he considers $k^0 = k_1 + k_{1n}$ using the Arrhenius rather than the absolute rate theory formalism.[8]

Equation 17 also gives rise to three kinetic regions which depend on the magnitude of β. These regions are Region I*a* ($\beta < 0.01$), Region II*a* ($0.01 < \beta < 100$) and Region III*a* ($\beta > 100$).

Region III*a* corresponds to Region III in the treatment given above and Region I*a* corresponds to an S_N1 type reaction given in eq. 6. The expressions for the thermodynamic parameters have already been given for Region III and those for Region I*a* are straightforward and require no elaborate discussion. It will suffice to note that in both these regions, the heat capacity of activation will contain no "spurious" terms. On the other hand, in Region II*a* the thermodynamic parameters are given by

$$[18]\quad \Delta G^{\ddagger}_0 = \Delta G^{\ddagger}_e + \Delta G^{\ddagger}_3 - RT\ln(1+\beta)$$

$$[19]\quad \Delta S^{\ddagger}_0 = \Delta S^{\ddagger}_e + \Delta S^{\ddagger}_3 + \frac{\beta}{1+\beta}\frac{(\Delta H^{\ddagger}_3 - \Delta H^{\ddagger}_{2n})}{T} + R\ln(1+\beta)$$

$$[20]\quad \Delta H^{\ddagger}_0 = \Delta H^{\ddagger}_e + \frac{1}{1+\beta}\Delta H^{\ddagger}_3 + \frac{\beta}{1+\beta}\Delta H^{\ddagger}_{2n}$$

$$[21]\quad \Delta C^{\ddagger}_{p0} = \Delta C^{\ddagger}_{pe} + \frac{1}{1+\beta}\Delta C^{\ddagger}_{p3} + \frac{\beta}{1+\beta}\Delta C^{\ddagger}_{p2n} + \frac{\beta}{(1+\beta)^2}\frac{(\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_3)^2}{RT^2}$$

We specifically draw attention to the "spurious" heat capacity term in eq. 21 (the final expression on the r.h.s.) which, contrasting with eq. 16, must always be positive. The kinetic schemes represented by eq. 17 and eq. 14 are the simplest forms of the "bifurcated" and "intermediate" mechanisms. It follows that a complete steady state treatment of the Winstein mechanism would by inference and analogy contain both positive and negative "spurious" heat capacity terms as well as the real terms associated with the individual steps. In such a case the apparent heat capacity of activation becomes a dull tool for mechanistic diagnosis. In practice it is sharpened by noting that for every solvolytic displacement reaction in water and mixed aqueous solvents examined with sufficient care (2, 15), the apparent $\Delta C^{\ddagger}_{p0}$'s have negative values. This would suggest that the negative components (real or "spurious") dominate the situation in every case.

In a recent paper, one of us firmly placed the mechanism for substitution at the primary carbon atom in water in Region III. This

[8] k_1 here refers to reaction 1, not reaction 2.

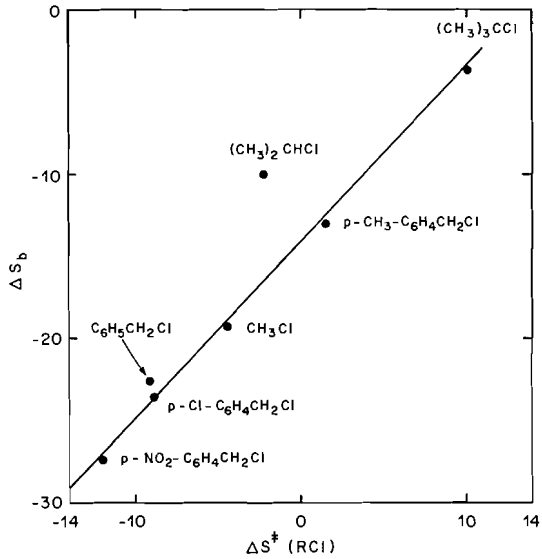

FIG. 1. A correlation between the entropy of activation for a series of alkyl and arylmethyl chlorides and the entropy of ionization of a series of structurally related amines.

hypothesis requires that the observed heat capacities of activation for the hydrolysis of the methyl halides in water are real. We therefore see no reason for abandoning the previous interpretation of $\Delta C^{\ddagger}_{p0}$ for the methyl halides (2) except to recognize that these quantities now derive from an equilibrium constant together with a term from a rate-determining nucleophilic component (eq. 12, Region III). The division of the overall heat capacity ($\Delta C^{\ddagger}_{p0}$) for the methyl halides into $\Delta C^{\ddagger}_{p1e}$ and $\Delta C^{\ddagger}_{p2n}$ is an important problem to which we can offer no solution at the present time. However, the problem represented by $\Delta C^{\ddagger}_{p0}$ for the hydrolysis of *t*-butyl chloride merits examination in terms of eqs. 9 and 21.

The Heat Capacity of Activation for the Hydrolysis of *t*-Butyl Chloride and the Mechanism for the Hydrolysis of Tertiary Halides in Water

Irrespective of the mechanistic region postulated for the hydrolysis of *t*-butyl chloride and similar substrates, we feel safe in assuming that these substances are required to pass from a weakly polar initial state, characterized by a solvation shell in which water–water interactions dominate, to a transition state in which these interactions are broken down. The likely consequences of such a change with respect to the heat capacity of activation are most clearly seen if it is recalled that the heat capacities for the ionogenic processes

[22] $R_1R_2R_3N + H_2O \rightarrow R_1R_2R_3NH^+ + OH^-$

where $R_1 = R_2 = H$, $R_3 = Me$; $R_1 = R_2 = Me$, $R_3 = H$; and $R_1 = R_2 = R_3 = Me$ are, respectively, -60, -68, and -90 cal deg^{-1} mol^{-1} (19, 20). The heat capacity terms for these equilibria are necessarily real and free of kinetic ambiguity and provide a useful model for solvolytic displacements. As models, they are also in keeping with that approach of analyzing the thermodynamics of ionic transition states using thermodynamically stable ions as analogues. The linear correlation between the Grunwald–Winstein *Y* parameter for methanol–water mixtures and the free-energy of solvation of potassium and chloride ions in the same solvent mixtures represents an early instance of this tactic (21). More recently, Arnett and coworkers (22, 23) have used the parallelism between changes in the heat content of the transition state for *t*-butyl chloride in ethanol–water mixtures with changes in the heat content of potassium and chloride ions in the same solvent mixtures as evidence for the ionic character of the transition state. The appropriate differentiation with respect to temperature of these relationships implies a corresponding relationship between the heat capacities of activation and the thermodynamic heat capacities.

The relationship between the entropy of activation and the entropy of ionization for structurally related amines, first noted by Evans and Hamman (24), also demands a corresponding relationship between the heat capacity of ionization of the amines and the corresponding solvolytic quantities. A good correlation for a series of chlorides is given in Fig. 1 (see also Table 1), although it may be of limited significance because of the variable nature of the rate determining step along the reaction series (see below). However, in spite of possible variations in the nature of the rate determining step, entropy changes ($\delta_R \Delta S^{\ddagger}$) will still be influenced by solvation changes between the initial and the transition states because all displacement processes have considerable ionogenic character[9] irrespec-

[9]Intimate-ion-pairs are considered to be common to all the displacements included in the entropy correlation.

tive of whether the nucleophilic component is kinetically significant. Hence the correlation between the thermodynamic amine entropies and the pseudo-thermodynamic entropies ($\Delta S^{\ddagger}$) demands a similar relationship between the heat capacities for the ionization and the corresponding kinetic quantities. The various correlations mentioned above provide scant justification for the cavalier dismissal of the real heat capacity terms in eq. 16.

The above qualitative considerations with respect to the entropy, free energy, and enthalpy correlations and their implications with respect to the reality of $\Delta C^{\ddagger}_{p0}$ are supported by a closer scrutiny of the quantitative methods employed by Albery and Robinson to extract the temperature dependence of $\Delta C^{\ddagger}_{p0}$ demanded by their model (see also ref. 28).

To establish the ion-pair mechanism quantitatively these authors add a further linear term in T to the empirical equation used extensively to represent the temperature dependence of solvolytic rates (2), *i.e.*

$$[23] \qquad \log k = \frac{A}{T} + B \log T + C$$

becomes

$$[24] \qquad \log k = \frac{A}{T} + B \log T + C + DT$$

The latter equation leads to a heat capacity of activation which is a linear function of temperature or alternatively to a quadratic temperature dependence of $\Delta H^{\ddagger}$. If the heat capacity of activation is calculated by the equation

$$[25] \quad \Delta C^{\ddagger}_{p0} = \frac{\alpha}{(1+\alpha)^2} \frac{(\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_{2})^2}{RT^2}$$

with $\alpha = 1$ ($T = 33.4$ °C) and $\Delta H^{\ddagger}_{2n} - \Delta H^{\ddagger}_{2} = \pm 8943$ cal (see ref. 1), the resulting temperature dependence of $\Delta C^{\ddagger}_{p0}$ is a bell-shaped curve (Fig. 2) and is only *very* approximately linear over the temperature interval (0→35 °C) used to establish the temperature dependence of $\Delta H^{\ddagger}$ by an innovative differential method. Thus, whilst the temperature dependence of $\Delta C^{\ddagger}_{p0}$ established by Albery and Robinson is not inconsistent with their mechanism, it does not establish definitely the spurious spike in $\Delta C^{\ddagger}_{p0}$ required by eq. 25 (see Fig. 2) since the range of temperature investigated was *much too small.*

In searching for an alternative to the mechanistic description proposed by Albery and Robinson for the hydrolysis of *t*-butyl chloride in water, we recognize that the order of reactivity (k^0) for the hydrolysis of the *t*-butyl halides is F < Cl < Br < I (see Table 2) while the order

for the methyl, allyl, and isopropyl halides is F < Cl < I < Br. In a previous paper (14) one of us postulated that the anomalous order found in the latter series was dependent on the nucleophilic component of the activation process, *i.e.* a consequence of the fact that log K_{e1} and log k_{2n} show differing dependencies on the nature of the leaving group and add so that the bromide reaction rate (k^0) is the fastest. The observation that $\Delta G^{\ddagger}_0$ for the hydrolysis of t-butyl X (X = F, Cl, Br, I) gives an excellent correlation with ΔG_e(MeX) (see Fig. 3 and Table 2) supports the long standing assumption that the mechanism for the hydrolysis of tertiary halides differs from that for primary halides. We retain Ritchie's proposal that k_2 is the fastest step in reaction 3, hence the intimate-ion-pair remains an important intermediate in both mechanisms. Whereas the rate controlling step for the primaries and secondaries involves k_{2n}, the corresponding step for the tertiaries involves displacement of the X^- to give a solvent separated ion-pair which shows no important tendency to return to the intimate-ion-pair stage. Further, the destruction of the solvent-separated-ion-pair, whether by front-side or back-side attack, is kinetically insignificant.

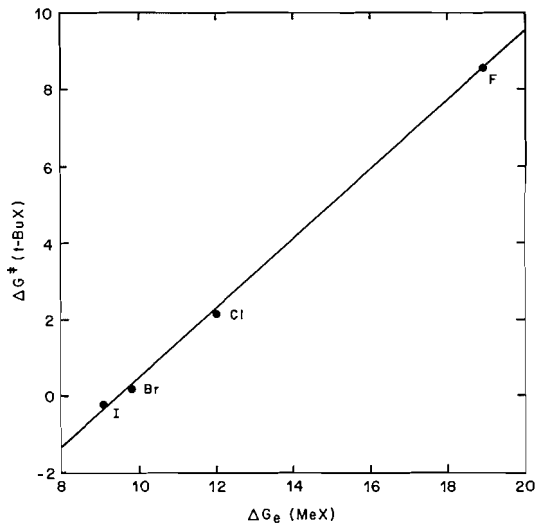

FIG. 3. A correlation between $\Delta G^{\ddagger}$ for the hydrolysis of the t-butyl halides and the free energies calculated from the ion-pair equilibrium constants for the methyl halides.

We believe that the correlation (Fig. 3) establishes three other points. Firstly, the heat capacity of activation characteristic of the hydrolysis of t-butyl chloride in water must be real if the observed rate is given by $k^0 = K_{e1}k_3$ since the latter expression cannot give rise to "spurious" terms. Hence we retain the hypothesis based on solvent reorganization for the hydrolysis of t-butyl chloride in water, and we reject the alternative interpretation proposed by Albery and Robinson. Secondly, the log K_{e1} (MeX) values appropriate to the correlation shown in Fig. 3 were calculated on the assumption of the generality of the selectivities of OH^- and H_2O acting as nucleophiles on free carbonium ions. The consistency which emerges from acceptance of this hypothesis in our view vindicates our earlier description of the mechanism for the hydrolysis of the methyl halides. Thirdly, and finally, it would seem that the anomalous order of the rate of hydrolysis of the bromide with respect to the iodide (32, 33) for displacement reactions in water is typical of processes where the nucleophilic component of the displacement rate is partly or wholly rate determining. This places the isopropyl and allyl halides securely in such a category. Thus, in water, the bromide/iodide ratios become useful tools for mechanistic diagnosis.

Spin–Orbit Relaxation of $Hg(6^3P_1)$ by Various Gases

A. C. VIKIS, G. TORRIE, AND D. J. LE ROY

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received August 16, 1971

The spin–orbit relaxation of $Hg(6^3P_1)$ to yield $Hg(6^3P_0)$ was investigated in the presence of various gases. The quantum yields of $Hg(6^3P_0)$ formation (defined as relaxation to $Hg(6^3P_0)$/total relaxation) in the presence of CO, CO_2, NH_3, ND_3, H_2O, D_2O, C_2H_6, *c*-C_3H_6, $C(CH_3)_4$, C_3H_8, 2,2-$C_3H_6D_2$, C_3D_8, *n*-C_4H_{10} and *i*-C_4H_{10} were: 0.88 ± 0.07, <0.01, 1.05 ± 0.05, 1.00 ± 0.08, 0.76 ± 0.18, 1.06 ± 0.26, 0.64 ± 0.16, 0.56 ± 0.10, 0.58 ± 0.02, 0.14 ± 0.01, 0.51 ± 0.07, 0.47 ± 0.10, 0.11 ± 0.01, and 0.05 ± 0.01, respectively. The extent of the spin–orbit relaxation process appears to be related in an inverse manner to the availability and accessibility of channels leading to the formation of $Hg(6^1S_0)$, rather than to the fulfillment of electronic–vibrational resonance conditions. This in turn suggests the existence of $Hg(6^3P_1)$—quencher intermediates having lifetimes long enough to permit several vibrations.

La relaxation spin–orbitale de $Hg(6^3P_1)$ pour donner $Hg(6^3P_0)$ a été étudiée en présence de nombreux gaz. Les rendements quantiques de la formation de $Hg(6^3P_0)$ (définis par relaxation de $Hg(6^3P_0)$ sur relaxation totale) en présence de CO, CO_2, NH_3, ND_3, H_2O, D_2O, C_2H_6, *c*-C_3H_6, $C(CH_3)_4$, C_3H_8, 2,2-$C_3H_6D_2$, C_3D_8, *n*-C_4H_{10} et *i*-C_4H_{10} sont: 0.88 ± 0.07, <0.01, 1.05 ± 0.05, 1.00 ± 0.08, 0.76 ± 0.18, 1.06 ± 0.26, 0.64 ± 0.16, 0.56 ± 0.10, 0.58 ± 0.02, 0.14 ± 0.01, 0.51 ± 0.07, 0.47 ± 0.10, 0.11 ± 0.01 et 0.05 ± 0.01. Le domaine du procédé de relaxation spin orbitale apparaît comme étant en sens inverse de la disponibilité et de l'accessibilité des canaux menant à la formation de $Hg(6^1S_0)$ plutôt que du remplissage des conditions de résonance électronique-vibrationnelle. Ceci suggère l'existence d'intermédiaires de piégeage $Hg(6^3P_1)$ qui ont des temps de vie assez longs pour permettre plusieurs vibrations.

In a recent communication from this laboratory (1) we have presented preliminary data on the spin–orbit relaxation of $Hg(6^3P_1)$ atoms to yield $Hg(6^3P_0)$ in the presence of various gases. Because of the importance of these measurements in the elucidation of the energy transfer process in mercury photosensitization (2–9) and the controversial nature of the problem (10–14), we have investigated the spin–orbit relaxation process in greater detail and extended our measurements to more molecules.

Particular attention was focused on molecules such as CO, CO_2, H_2O, D_2O, NH_3 and ND_3, that have been previously considered (2–4, 10, 15) from the point of view of the resonance theory of spin–orbit relaxation,

[1] $Hg(6^3P_1) + Q(v = 0) \rightarrow Hg(6^3P_0) + Q(v = 1) + \Delta E$

The relative increase of the total $Hg(6^3P_1)$ quenching cross section with the relative decrease of the energy discrepancy, ΔE, of the electronic and the vibrational transition, were cited as basis for the resonance theory. However, there were only few direct measurements such as rate constants for the occurrence of reaction 1. The result of Scheer and Fine (10) for CO has recently been questioned (14, 12*b*).

Also, of particular interest were the alkanes which have been thoroughly studied in the past and were shown to exhibit a number of interesting trends (8, 9), as far as their reactions with $Hg(6^3P_1)$ are concerned. Qualitative studies of $Hg(6^3P_0)$ formation in these systems were reported by Penzes *et al.* (16) using 4047 Å light absorption to monitor $Hg(6^3P_0)$ steady state populations. They had concluded that deuteration of the alkanes enhanced the rate of $Hg(6^3P_0)$ formation and that the discrepancies between $Hg(6^3P_1)$ physical and chemical quenching cross sections were due to $Hg(6^3P_0)$ formation. Yang (6*b*) arrived at a similar conclusion based on conservation of total electronic angular momentum, symmetry considerations and the phase space theory of chemical reactions. The effect of $Hg(6^3P_0)$ quenching by the molecules that form it was not taken into consideration, however. The result of this effect would be to show a greater rate of $Hg(6^3P_0)$ formation in the deuterated alkanes in comparison with the undeuterated alkanes. Also, it would tend to

For personal use only.

make physical and chemical quenching cross sections similar.

Experimental

The method of studying $Hg(6^3P_0)$ formation and decay in the presence of various molecules has been outlined in previous publications (1, 14, 17). It is based on the enhancement of the mercury photosensitized decomposition of C_2H_4 under incomplete quenching of $Hg(6^3P_1)$. The enhancement effect is due to the formation of $Hg(6^3P_0)$ atoms and their long lifetime.

A diagram of the apparatus used is shown in Fig. 1. The experiments were carried out in a flow system employing argon as the carrier gas at a flow rate of 27 cc/min and a total pressure of 20 Torr. Small partial pressures (10^{-3} to 2 Torr) of the reagent gases were introduced to the main flow through calibrated capillaries, except for H_2O and D_2O for which the carrier gas was saturated at various pressures by passage through a saturator containing H_2O and D_2O and maintained at the desired temperature with a cooled ethyl alcohol bath. The carrier gas was saturated with mercury at the desired temperature (−5 to +0.5 °C) by passage through a presaturator containing a pool of mercury maintained at 25 °C, followed by a multistage desaturator maintained at the desired saturation temperature to within ±0.2 °C. The $Hg(6^3P_1)$ lifetimes with respect to emission, τ^*, for the reaction cell used, were 1.54×10^{-7} s and 2.06×10^{-7} s, for the mercury saturation temperatures of -5.0 ± 0.2 °C and $+0.5 \pm 0.2$ °C, respectively. These were determined according to eq. 2 by observing the 2537 Å fluorescence intensity, with a Westinghouse type WL-775 photodiode, as a function of the partial pressure of C_2H_4,

$$[2] \qquad I_0/I = 1 + \tau^* k_E^1 [C_2H_4]$$

where I_0 is the fluorescence intensity in the absence of C_2H_4 and k_E^1 is the total quenching rate constant of $Hg(6^3P_1)$ by C_2H_4 which was taken to be $36 \times 10^{10}\ M^{-1}\ s^{-1}$ (8).

The reaction cell was a cylindrical quartz tube 20 cm long and 3.1 cm i.d., surrounded by an outer quartz tube, 28 cm long and 5.5 cm i.d. A nickel sulfate filter solution thermostated at 25 °C was circulated in the outer tube to attenuate radiation in the 4000 Å region which depopulates $Hg(6^3P_1)$ and $Hg(6^3P_0)$ atoms to higher states. The middle region of the reaction cell, 18 cm long, was irradiated at low light intensities with two U-shaped, cold cathode low pressure mercury lamps, which were placed parallel to and on opposite sides of the reaction cell. The lamps were operated from a Kepco regulated d.c. power supply.

The progress of the reaction was monitored by the rate of hydrogen production, from the photosensitized decomposition of C_2H_4. The H_2 detection system was similar to the one described in ref. 14 with the sensitivity improved by a factor of approximately ten. For C_3H_8, n-C_4H_{10}, and i-C_4H_{10} the rate of C_2H_2 formation was used, because of significant extraneous hydrogen formation resulting from hydrogen atom abstraction reactions. The acetylene was sampled from the flow system by condensing in a cold trap maintained at 65–67 °K with pumped liquid nitrogen. Acetylene separation and detection was accomplished with

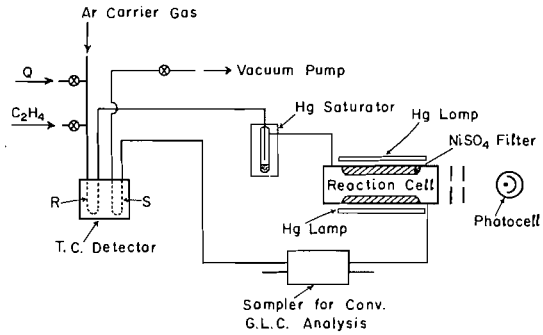

FIG. 1. Reaction and analysis system.

conventional gas chromatographic methods using helium as the carrier gas and a thermal conductivity detector.

The reagents and the manufacturer's stated minimum purity were as follows: Matheson; Ar (99.999), CO (99.9), CO_2 (99.995), NH_3 (anhydrous, 99.99), c-C_3H_6 (99.0). Phillips; C_2H_4 (99.98), C_2H_6 (99.99), $C(CH_3)_4$ (99.88), C_3H_8 (99.99), n-C_4H_{10} (99.8), i-C_4H_{10} (99.9). Merck, Sharp & Dohme; ND_3 (99% atom D), D_2O (99.7% atom D), 2,2-$C_3H_6D_2$ (98% atom D), C_3D_8 (99% atom D). Distilled water (degassed). Gases which are condensible at Dry Ice–acetone or liquid nitrogen temperatures were additionally degassed by freezing and pumping. With the exception of H_2O and D_2O all gases were passed through a spiral trap cooled at Dry Ice–acetone temperatures before entering the reaction cell.

Results

Typical enhancement curves of the decomposition of ethylene as a function of the partial pressure of quencher, Q, are shown in Fig. 2. These enhancement effects cannot be realized in terms of simple competitive quenching between C_2H_4 and Q since this would cause the S/S_0 curves to lie below the dotted line as in the case of CO_2. The effect is attributed to $Hg(6^3P_0)$ formation and we propose the following mechanism (1, 14):

$$[3] \qquad Hg + h\nu^* \longrightarrow Hg^*$$

$$[4] \qquad Hg^* \xrightarrow{1/\tau^*} Hg + h\nu^*$$

$$[5] \qquad Hg^* + Q \xrightarrow{k_Q^{*g}} Hg + Q'$$

$$[6] \qquad Hg^* + Q \xrightarrow{k_Q^{*0}} Hg^0 + Q''$$

$$[7] \qquad Hg^* + C_2H_4 \xrightarrow{k_E^{*g}} Hg + C_2H_2 + H_2$$

$$[8] \qquad Hg^0 + C_2H_4 \xrightarrow{k_E^{0g}} Hg + C_2H_2 + H_2$$

$$[9] \qquad Hg^0 + Q \xrightarrow{k_Q^{0g}} Hg + Q'''$$

$$[10] \qquad Hg^0 \xrightarrow{1/\tau^0} Hg$$

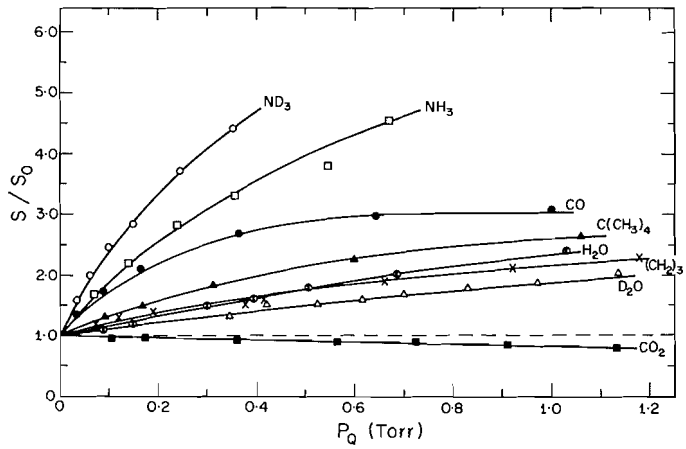

FIG. 2. Enhancement of the photosensitized decomposition of C_2H_4 by various molecules. (S/S_0 is the ratio of the rates of H_2 formation in the presence to the absence of quencher, Q. The C_2H_4 pressure in Torr $\times 10^3$ for NH_3, $(CH_2)_3$, ND_3, H_2O, D_2O, $C(CH_3)_4$, CO, and CO_2 were 11.7 ± 0.9, 10.5 ± 0.7, 10.6 ± 0.7, 11.6, 16.3, 4.3 ± 0.6, 18.4 ± 1.0, and 6.3 ± 0.7, respectively.

in which Hg*, Hg^0, and Hg represent $Hg(6^3P_1)$, $Hg(6^3P_0)$, and $Hg(6^1S_0)$, respectively. Reactions 4 and 10 include all processes, besides radiative decay, which are first or pseudo-first order under our experimental conditions (constant mercury pressure and constant total pressure). Quenching to $Hg(6^3P_0)$ by ethylene or argon is negligible and the relevant reactions are omitted from the mechanism (*cf.* Appendix 1). The reverse of reaction 6 can also be shown unimportant under our experimental conditions (12*b*, 17).

On the basis of the above mechanism the ratio of the rates of H_2 or C_2H_2 formation in the presence to that in the absence of Q is

$$[11] \qquad \frac{S}{S_0} = \frac{1 + \{\phi_E^{0g} k_E^{0g} k_Q^{*0}[Q]\}/[\phi_E^{*g} k_E^{*g}\{k_E^{0g}[C_2H_4] + k_Q^{0g}[Q] + (1/\tau^0)\}]}{1 + \{k_Q^{l}[Q]\}/\{(1/\tau^*) + k_E^{*g}[C_2H_4]\}}$$

where, k_Q^l is $k_Q^{*g} + k_Q^{*0}$ and ϕ_E^{*g}, ϕ_E^{0g} are the efficiencies of H_2 formation from reactions 7 and 8, respectively. The denominator of eq. 11 can either be calculated using the published rate constants k_Q^l and k_E^{*g} or be obtained experimentally by simultaneous observation of the ratio of $Hg(6^3P_1)$ fluorescence in the absence to that in the presence of Q, I_0/I,

$$[12] \qquad I_0/I = 1 + k_Q^l[Q]/\{(1/\tau^*) + k_E^{*g}[C_2H_4]\}$$

Experimentally determined I_0/I values were used in all cases except for $C(CH_3)_4$. The observation of the fluorescence intensity as a function of Q, either in the presence of ethylene or in its absence, was also used to obtain total quenching rate constants for the various gases used in the present experiments. This was done using eq. 12 or the analogous expression in the absence of C_2H_4. Substitution of eq. 12 in eq. 11 and rearrangement yields eq. 13,

$$[13] \qquad \left[\frac{S}{S_0}\frac{I_0}{I} - 1\right]^{-1} = \frac{\phi_E^{*g} k_E^{*g} k_Q^{0g}}{\phi_E^{0g} k_E^{0g} k_Q^{*0}} + \{(1/\tau^0) + k_E^{0g}[C_2H_4]\}\frac{\phi_E^{*g} k_E^{*g}}{\phi_E^{0g} k_E^{0g} k_Q^{*0}}\frac{1}{[Q]}$$

The values of $[C_2H_4]$ were in the range of 5×10^{-3} to 25×10^{-3} Torr and those of [Q] in the range of 10^{-2} to 2 Torr. The total pressure was kept constant at 20 Torr using argon; the latter had a threefold purpose: (*a*) it eliminated any pressure broadening of the $Hg(6^1S_0) \rightarrow Hg(6^3P_1)$ absorption, (*b*) it kept the rate constant of reaction 10 and possibly reaction 4

[a]Quantum yields of $Hg(6^3P_0)$ formation, ϕ^{*0}, are defined as k^{*0}/k^1. Values in parentheses for k^1 and ϕ^{*0} are from refs. 8 and 12*b*, respectively, except those marked by † which are from ref. 16*a*. Plus and minus values are standard deviations of the mean.

constant from any third order effects, and (*c*) it kept ϕ_E^{*g} and ϕ_E^{0g} constant and the ratio $(\phi_E^{*g}/\phi_E^{0g})$ close to unity (17).

The rate constant ratios k_E^{*g}/k_Q^{*0} were determined from plots of the left hand side of eq. 13 *vs.* $[Q]^{-1}$ at fixed $[C_2H_4]$; the slopes of these plots were then plotted again *vs.* $[C_2H_4]$ to obtain $\phi_E^{*g}k_E^{*g}/\phi_E^{0g}k_Q^{*0}$. The absolute values of k_Q^{*0} were calculated using the value of $36\times10^{10}\ M^{-1}\ s^{-1}$ for k_E^{*g} (8) and assuming $(\phi_E^{*g}/\phi_E^{0g})\sim1$ (17). Values of k_Q^{0g}/k_E^{0g} can also be determined by this method; however, the present experiments were done under conditions where quenching of $Hg(6^3P_0)$ by Q was minimal in relation to that by ethylene and the determined values are not as meaningful.

The results are shown in Table 1. Literature values are cited for comparison wherever they are available. The agreement of the present total rate constants with the literature ones is very good in all cases with the exception of ND_3. Unless rapid exchange of ND_3 to form NH_3 occurred in the Pyrex surfaces leading from the gas cylinder to the reaction vessel, this discrepancy could be accounted for by the $Hg(6^3P_1)$–ND_3 and $Hg(6^3P_0)$–ND_3 excimer emission (18). We found that even though the WL-775 photodiode we used had a wavelength cut-off of 3000 Å, the excimer emission was significant enough in this region to reduce the quenching rate constant by a factor of two in the range of 0.5 to 2.0 Torr. The present value was obtained at ND_3 pressures less than 0.5 Torr and in the presence of small amounts of C_2H_4 which suppresses the excimer emission but leaves the $Hg(6^3P_1)$ emission unaffected. The literature value (15) was obtained under conditions where excimer emission would be significant. The new quantum yields of $Hg(6^3P_0)$ formation obtained by Callear and McGurk (12*b*) are in close agreement with the present results wherever data overlap. The results on C_2H_6 were obtained by the method described in Appendix 1.

Conclusions

These results allow us to come to the following conclusions:

(*1*) Spin–orbit relaxation is important to a predominant route for all cases studied with the exception of CO_2, C_2H_4, and i-C_4H_{10}.[1] Thus, in a large number of cases studied in the past it was not $Hg(6^3P_1)$ but $Hg(6^3P_1)$ and $Hg(6^3P_0)$ reactions that were being studied, with the relative importance of each depending on the $Hg(6^3P_0)$ quantum yield and the partial pressure of the quencher Q. For this reason chemical cross sections which are reported in the literature are in many cases of questionable validity and a correct analysis of those data should be applied (21). Such an analysis is discussed in Appendix 2.

[1]A possible explanation for the CO_2 behavior may be fast electronic–electronic energy transfer from $^3P_1$ to an adjacent CO_2 triplet state. A $CO_2(^3\Pi)$ state of 4.86 eV (19) was previously proposed (20) to account for the $Hg(6^3P_1)$ reactions of CO_2.

(*2*) Does the resonance hypothesis have anything to do with the spin–orbit relaxation? The present result with CO in combination with the result on N_2 (22) seem to be in line with such a proposition. However, such statement would have to be qualified, because we are dealing with two different electronic structures. The rest of the molecules studied do not seem to be in line with resonance, because neither their spin–orbit relaxation rate constants nor their quantum yields indicate such a simple trend. Most of all, molecules such as NH_3 and H_2O have been shown (18, 23) to give significant excimer emission in quenching $Hg(6^3P_0)$. It is most likely that complex formation occurs with $Hg(6^3P_1)$ as well, whence the presence of resonance or not will not be as important in determining the magnitude of the spin–orbit relaxation process, because the system could pass several times over the configuration leading to $Hg(6^3P_0)$.

(*3*) Deuteration of the C—H bonds in the alkanes does not enhance the spin–orbit relaxation since undeuterated alkanes show comparable spin–orbit relaxation. We attribute the previous conclusions (*6b*, *16a*) which were based on chemical *vs.* physical quenching cross section discrepancies or on spectroscopic investigations of the $Hg(6^3P_0)$ steady state populations,

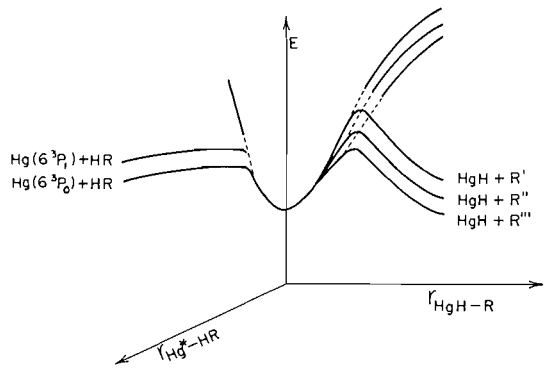

FIG. 3. Hypothetical potential energy surfaces for the quenching of excited mercury atoms by the alkanes (7).

to failure to take into account removal of $Hg(6^3P_0)$ by the molecules that form it. In comparison to the undeuterated molecules, deuterated molecules are known to be weaker quenchers of $Hg(6^3P_1)$; and particularly weaker quenchers of $Hg(6^3P_0)$ (17).

(*4*) A better approach towards an explanation of these results seems to be formation of a complex between $Hg(6^3P_1)$ and the quencher, Q. Such a process is illustrated in Fig. 3 for the alkanes (7), but it could also have wider applicability. A $Hg(6^3P_1)$ atom and an alkane, RH, form a complex, which could decompose

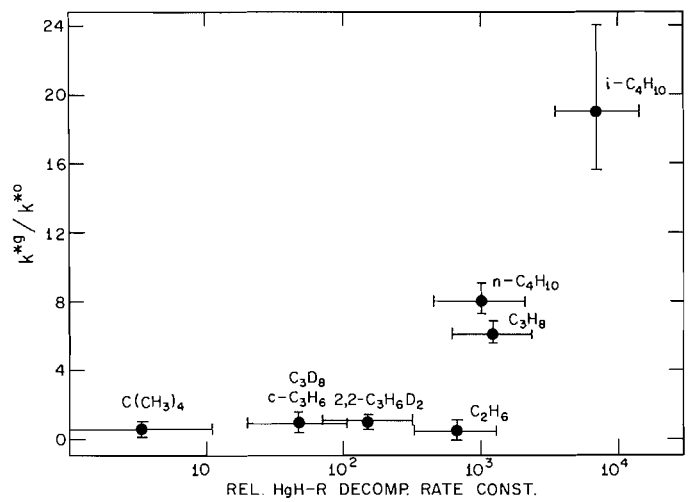

FIG. 4. (Quenching to the ground state/quenching to the $Hg(6^3P_0)$ state) *vs.* calculated relative HgH—R decomposition rate constants. (The calculated relative HgH—R decomposition rate constants are from ref. 7. The quenching rate constant ratios are from this work. They are related to each other by $k^{*g}/k^{*0} = f(k_d/k^0_{-1})$, where k_d is the HgH—R decomposition rate constant and k^0_{-1} is the rate constant for decomposition to $Hg(6^3P_0) + RH$. Vertical bars are error limits for the experimental results. Horizontal bars are relative variations of the calculated rate constants assuming relative changes of ± 1 kcal/mol in the R—HHg decomposition barrier (7)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by several channels. For the alkanes these channels are: (*a*) decomposition to the original reactants; (*b*) decomposition to $Hg(6^3P_0)$ and RH; (*c*) R—HHg bond decomposition; (*d*) excimer emission.

A model of this form was previously proposed by Yang (6*a*) to account for the C—H *vs.* C—D isotope effects in $Hg(6^3P_1)$ photosensitization. Vikis and Moser (7) investigated this model and found that the relative trends and isotope effects shown by the alkanes towards $Hg(6^1P_1)$, $Hg(6^3P_1)$, and $Hg(6^3P_0)$ are sufficiently explained, by assuming that the major variations among the alkanes are due to fractional differences in the C—HHg bond decomposition rate constants. The present results are in accord with this model because molecules with stronger bonds exhibit higher $Hg(6^3P_0)$ quantum yields. The correlation is shown in Fig. 4, which was constructed from the relative decomposition rate constants calculated in ref. 7 and the present results. The correlation separates the alkanes into three rough categories according to their bond strength (primary, secondary, tertiary).

One can infer from the above that in the absence of an accessible channel for bond rupture the excimer is bound to decompose via the $Hg(6^3P_0)$ channel even though resonance is not well obeyed. It could also be deactivated by emission but this is apparently a less important process for $Hg(6^3P_1)$ quenching.

Appendix 1

In the present work ethylene was used as the standard to detect $Hg(6^3P_1)$ and $Hg(6^3P_0)$ atoms by reacting to give C_2H_2 and H_2. Also, argon was used as the carrier gas at a pressure of 20 Torr. Both gases would influence the present results if they quench $Hg(6^3P_1)$ to $Hg(6^3P_0)$, or if Ar quenches $Hg(6^3P_0)$, significantly. These effects, when included, modify eq. 13 to eq. 14,

$$[14]\quad \frac{S}{S_0}\cdot\frac{I_0}{I}=\left[1+\frac{\phi_E^{0g}k_E^{0g}}{\phi_E^{*g}k_E^{*g}}\frac{(k_{Ar}^{*0}[Ar]+k_E^{*0}[C_2H_4]+k_Q^{*0}[Q])}{((1/\tau^0)+k_{Ar}^{0g}[Ar]+k_E^{0g}[C_2H_4]+k_Q^{0g}[Q])}\right]\times\left[1+\frac{\phi_E^{0g}k_E^{0g}}{\phi_E^{*g}k_E^{*g}}\frac{(k_{Ar}^{*0}[Ar]+k_E^{*0}[C_2H_4])}{((1/\tau^0)+k_{Ar}^{0g}[Ar]+k_E^{0g}[C_2H_4])}\right]^{-1}$$

where the symbolism is the one adopted in this paper. This effect was investigated by the study of the rate of H_2 production in the absence of Q, according to eq. 15,

$$[15]\quad S_0\left(1-\frac{I_0}{I_{00}}\right)=I_a\phi_E^{*g}\frac{k_E^{*g}}{k_E^{t}}\left[1+\frac{\phi_E^{0g}k_E^{0g}}{\phi_E^{*g}k_E^{*g}}\frac{k_{Ar}^{*0}[Ar]+k_E^{*0}[C_2H_4]}{\{(1/\tau^0)+k_{Ar}^{0g}[Ar]+k_E^{0g}[C_2H_4]\}}\right]$$

where, I_{00} is the fluorescence intensity in the absence of ethylene and I_a is the rate of reaction 3. The left hand side of eq. 15 was found to be independent of ethylene in the range of 4.6×10^{-3} to 0.26 Torr of ethylene. This means that either $k_{Ar}^{*0}[Ar]\gg k_E^{*0}[C_2H_4]$ and $(1/\tau^0)+k_{Ar}^{0g}[Ar]\gg k_E^{0g}[C_2H_4]$, or $k_E^{*0}[C_2H_4]\gg k_{Ar}^{*0}[Ar]$ and $k_E^{0g}[C_2H_4]\gg(1/\tau^0)+k_{Ar}^{0g}[Ar]$. The former possibility is excluded on the basis of the dependence of the function $(S/S_0)(I_0/I)$ on $[C_2H_4]$, *e.g.*, for 0.9 Torr of CO $(S/S_0)(I_0/I)$ increases from 3.5 at 34×10^{-3} Torr of C_2H_4 to 6.0 at 6.8×10^{-3} Torr of C_2H_4. Also, according to ref. 12*b* $(k_E^{*0}/k_E^{t})<0.1$. Thus, eq. 14 can be reduced to eq. 13, with a good approximation.

Ethane, because of its low quenching rate constant, could not be studied under the same conditions that the other gases were studied, without the addition of large partial pressures of it to the carrier gas. Therefore, we modified the method using ethane itself as the carrier gas. Equation 16 which is analogous to eq. 15 can be derived for the modified method.

$$[16]\quad S\left(1-\frac{I}{I_0}\right)=I_a\phi_E^{*g}\left[1+\frac{\phi_E^{0g}k_E^{0g}}{\phi_E^{*g}k_E^{*g}}\frac{k_{Et}^{*0}[C_2H_6]}{\{(1/\tau^0)+k_{Et}^{0g}[C_2H_6]+k_E^{0g}[C_2H_4]\}}\right]$$

By observing S and I/I_0 *vs.* $[C_2H_4]$ at fixed $[C_2H_6]$ we obtained an average value for k_{Et}^{*0} of $(0.85\pm0.08)\times10^9\ M^{-1}\ s^{-1}$. Three total pressures of C_2H_6 were investigated 2.5, 3.3, and 4.5 Torr. At these pressures quenching of $Hg(6^3P_0)$ by C_2H_6 is negligible by comparison to that by C_2H_4 (17).

Appendix 2

The discrepancy between quenching cross sections determined by the physical method and those determined by the chemical method has been considered in the past (6*b*, 8, 16*a*, 21) as an indication of $Hg(6^3P_0)$ formation by the quencher. In this Appendix the N_2O chemical method is examined in terms of a mechanism that takes into consideration $Hg(6^3P_0)$ atom formation. The results of this approach are compared to those of the present work.

The mechanism postulated for conditions of complete quenching is as follows,

[17] $Hg + h\nu \longrightarrow Hg^*$

[18] $Hg^* + N_2O \xrightarrow{k_N^{*g}} Hg + N_2 + O$

[19] $Hg^* + N_2O \xrightarrow{k_N^{*0}} Hg^0 + N_2O$

[20] $Hg^* + Q \xrightarrow{k_Q^{*g}} Hg + Q'$

[21] $Hg^* + Q \xrightarrow{k_Q^{*0}} Hg^0 + Q''$

[22] $Hg^0 + N_2O \xrightarrow{k_N^{0g}} Hg + N_2 + O$

[23] $Hg^0 + Q \xrightarrow{k_Q^{0g}} Hg + Q'''$

The symbolism is the one adopted throughout this paper.

This mechanism yields eq. 24 for the quantum yield of N_2 formation, ϕ_N,

[24] $$\phi_N^{-1} = \frac{(k_N^t/k_N^{*g}) + \{k_Q^t[Q]/k_N^{*g}[N_2O]\}}{1 + \dfrac{(k_N^{*0}/k_N^{*g}) + \{k_Q^{*0}[Q]/k_N^{*g}[N_2O]\}}{1 + k_Q^{0g}[Q]/k_N^{0g}[N_2O]}}$$

Under conditions where $k_Q^{0g}[Q] \ll k_{N_2O}^{0g}[N_2O]$, which are easily obtainable for some alkanes, RH, (17, 12*b*), eq. 24 reduces to eq. 25,

[25] $$\phi_N^{-1} = 1 + \{k_{RH}^{*g}[RH]/[N_2O]\}/\{k_N^t + k_{RH}^{*0}[RH]/[N_2O]\}$$

The slope of eq. 25 at low $[RH]/[N_2O]$ ratios, where ϕ_N^{-1} is linear with $[RH]/[N_2O]$, is k_{RH}^{*g}/k_N^t. Thus, data obtained in this manner (24) give low quenching rate constants k_{RH}^{*g} by comparison to the ones determined by the physical method which determines $k_{RH}^{*g} + k_{RH}^{*0}$. At higher $[RH]/[N_2O]$ ratios a deviation from linearity should be observed for those molecules that quench significantly to the $Hg(6^3P_0)$ state. This situation is illustrated by the results of Yang (6*b*). Employing eq. 25 for the $Hg(6^3P_1)$–$C(CH_3)_4$ and $Hg(6^3P_1)$–C_3H_8 systems studied by Yang (6*b*), we determine, using his data, k_{RH}^{*g} and k_{RH}^{*0}/k_{RH}^{*g} for $C(CH_3)_4$ and C_3H_8. These values are $1.36 \times 10^{10}\ M^{-1}\ s^{-1}$ and 0.16 for C_3H_8; $0.47 \times 10^{10}\ M^{-1}\ s^{-1}$ and 1.4 for $C(CH_3)_4$. They correspond to 14% and 58% quenching to the $Hg(6^3P_0)$ state by C_3H_8 and $C(CH_3)_4$, respectively, and are comparable to the values of 14% and 58% determined in this work. Cvetanovic (21) has examined Yang's (6*b*) data from the same point of view and arrived at similar conclusions. Also, additional data obtained in his laboratory (25) using the N_2O chemical method are in line with the results of the present work.

Etude des oxynitrates de plomb (II). Synthèse des oxynitrates de plomb hydratés et de l'oxyde de plomb anhydre ou hydraté

H. BRUSSET, J. J. P. MARTIN, C. MARTIN-LEFEVRE, Y. REPELIN, E. HUSSON ET B. DESPAGNE

Laboratoire de Recherche de Chimie Systématique, Ecole Normale Supérieure, 24, rue Lhomond et Université Paris VI, Bât, F. 8, rue Cuvier, Paris 5ème

Reçu le 5 fevrier 1971[1]

Les dosages potentiométriques et conductimétriques effectués à 27 ± 0.2 °C à partir de solutions de soude et de nitrate de plomb ont prouvé l'existence des monoxynitrate, dioxynitrate, heptoxytrinitrate et pentoxynitrate de plomb hydratés. Il a été montré que la présence de traces de silice inhibe la formation de l'oxyde de plomb anhydre et favorise celle de l'oxyde de plomb hydraté. La synthèse des oxynitrates de plomb et de l'oxyde de plomb hydraté a été effectué dans un large domaine de température avec diverses concentrations des réactifs.

Potentiometric and conductimetric measurements of solutions of sodium hydroxide and lead nitrate at 27 ± 0.2 °C have established the existence of hydrated lead monoxynitrate, dioxynitrate, heptoxytrinitrate and pentoxynitrate. It was shown that the presence of silica inhibits the formation of anhydrous lead oxide but favors that of hydrated lead oxide. The preparation of lead oxynitrates and hydrated lead oxide was carried out over a wide range of temperatures at various concentrations of reactants.

Canadian Journal of Chemistry, **50**, 184 (1972)

Introduction

Les oxynitrates de plomb hydratés présentent un intérêt particulier en tant que catalyseurs d'oxydation des aldehydes α-halogénés (1). La connaissance de l'effet catalytique d'un ou plusieurs de ces oxynitrates dans de telles réactions d'oxydation nécessite la maitrise de leur synthèse avec un bon degré de pureté.

Il s'est avéré que les résultats obtenus au cours d'un travail préliminaire (2) devaient être précisés. Nous avons donc entrepris l'étude systématique de l'évolution de la réaction de solutions aqueuses de soude sur des solutions aqueuses de nitrate de plomb, à la température de 27 ± 0.2 °C, soit par dosages conductimétriques, soit par dosages potentiométriques. Ceci nous a amené à préciser les conditions d'obtention des différents composés mis en évidence, lorsqu'on opère à 3 ± 0.5 °C, 20 ± 0.3 °C, 27 ± 0.3 °C, 50 ± 0.3 °C.

Techniques expérimentales

La conductivité du milieu réactionnel a été mesurée avec un conductimètre "Philips GM 4249". Pour tenir compte des volumes de réactifs ajoutés, on a effectué les corrections de dilution. La précision des mesures est de 2%.

Les mesures de p*H* des solutions ont été réalisées avec un p*H*-mètre "Heito PS 18". L'électrode employée est une électrode de verre combinée avec une électrode de référence au calomel. L'incertitude sur la mesure est de 0.02 unité de p*H*.

La caractérisation structurale des composés est basée sur la diffractométrie aux rayons X d'échantillons de poudres, suivant la méthode de Debye et Scherrer. Nous avons utilisé un diffractomètre à compteur de la "Compagnie Générale de Radiologie, Theta 60". Le rayonnement X est le rayonnement K_α du cuivre. Le diffractomètre est utilisé avec un montage par transmission et le domaine exploré est celui des petits angles de Bragg entre 4 et 35°.

Les solutions aqueuses de nitrate de plomb sont préparées à partir de sel cristallisé pur ("Carlo Erba" Italie).

Les solutions aqueuses de soude sont préparées à partir de pastilles de soude ("Prolabo", France).

Les oxynitrates de plomb ont été dosés selon une méthode connue (2). Elle permet de connaitre le nombre N_1 d'atomes-g de plomb engagés sous forme PbO et le nombre N_2 d'atomes-g de plomb engagés sous forme $Pb(NO_3)_2$. La formule d'un oxynitrate de plomb s'écrira alors sous la forme dualistique: $Pb(NO_3)_2.N_1/N_2PbO.xH_2O$.

L'incertitude sur la valeur du rapport N_1/N_2 est égale à 0.2.

Les expériences ont toutes été effectuées avec des solutions décarbonatées conservées une quinzaine de jours en récipients de verre "Pyrex". Pour éviter tout risque de carbonatation, elles ont été réalisées en boite à gants, sous courant d'azote.

Les dosages conductimétriques ont été effectués en versant cm^3 par cm^3 la solution de soude dans 50 cm^3 de solution de nitrate de plomb. Le mélange obtenu est agité dix minutes, à l'aide d'un agitateur magnétique, après chaque addition de soude. Avant chaque mesure de conductivité de la solution, on attend la décantation totale du solide formé.

Le p*H* du milieu réactionnel a été mesuré lorsque celui-ci devenait invariant. Ceci nécessite une attente de un à vingt jours. Nous avons donc opéré de la façon suivante: dans des flacons contenant 75 cm^3 de solution de nitrate de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

plomb, on introduit des volumes déterminés de solution de soude. Les flacons sont bouchés hermétiquement entre chaque mesure de pH.

La synthèse des oxynitrates de plomb hydratés a été effectuée en agitant pendant dix minutes, à une température fixe, dans un bain thermostaté, le mélange de 50 cm^3 de solution de nitrate de plomb et de V cm^3 de solution de soude préalablement portées à la température choisie. Les précautions élémentaires sont prises pour éviter toute évaporation pendant la préparation. Les solides obtenus sont séparés par décantation et identifiés par diffractométrie X.

Résultats expérimentaux et discussions

Dosages réalisés avec une solution de soude 0.4 mol l^{-1} et une solution de nitrate de plomb 0.4 mol l^{-1}

En appelant: M_s, la molarité de la solution de soude; M_n, la molarité de la solution de nitrate de plomb; a, le volume utilisé de la solution de soude; b, le volume utilisé de la solution de nitrate de plomb; on a les relations:

$$[1] \qquad (s) = M_s.a/(a+b)$$

$$[2] \qquad (n) = M_n.b/(a+b)$$

et on définit un rapport R par

$$[3] \qquad R = (s)/(n) = M_s.a/M_n.b$$

D'autre part, l'équation de réaction correspondant à la formation stoechiométrique des oxynitrates de plomb peut s'écrire d'une façon générale:

$$[4] \quad (m+1)\,Pb(NO_3)_2 + 2m\,NaOH \rightarrow Pb(NO_3)_2.m\,PbO.\text{hydraté} + 2m\,NaNO_3 + m\,H_2O$$

Par conséquent, le rapport R est défini par la relation

$$[5] \qquad R = M_s.a/M_n.b = 2m/(m+1)$$

On observe, sur la courbe conductimétrique (Fig. 1), des ruptures de pente pour les valeurs: $R = 0.16$, $R = 0.63$, $R = 1.00$, $R = 1.40$ et $R = 1.66$. Les valeurs $R = 1.00$, $R = 1.40$ et $R = 1.66$ correspondent respectivement à la précipitation stoechiométrique du monoxynitrate, de l'heptoxytrinitrate et du pentoxynitrate de plomb hydratés suivant les équations

$$[6] \quad 2Pb(NO_3)_2 + 2NaOH \rightarrow Pb(NO_3)_2.PbO.\text{hydraté} + 2NaNO_3 + H_2O \quad (R = 2/2 = 1)$$

$$[7] \quad 10Pb(NO_3)_2 + 14NaOH \rightarrow 3Pb(NO_3)_2.7PbO.\text{hydraté} + 14NaNO_3 + 7H_2O \quad (R = 14/10 = 1.40)$$

$$[8] \quad 6Pb(NO_3)_2 + 10NaOH \rightarrow Pb(NO_3)_2.5PbO.\text{hydraté} + 10NaNO_3 + 5H_2O \quad (R = 10/6 = 1.66)$$

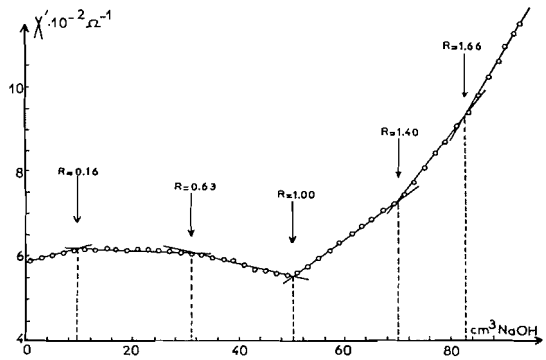

FIG. 1. Dosage conductimétrique de 50 cm^3 d'une solution de nitrate de plomb 0.4 mol l^{-1} par une solution de soude 0.4 mol l^{-1}. χ' = conductivité de la solution rapportée au volume initial, $\chi' = (1/r)(V_0 + V)/V_0$; où V_0 = volume initial de la solution, V = volume du réactif ajouté, r = résistance de la solution.

Par contre, les deux ruptures de pente observées pour $R = 0.16$ et $R = 0.63$ ne correspondent pas à la formation d'autres oxynitrates. En effet, l'analyse aux rayons X des solides obtenus pour $R < 1$ révèle la seule présence du monoxynitrate hydraté. Ces ruptures de pente mettent en évidence des propriétés particulières à la solution mais non des phénomènes de transition entre phases solides.

La courbe potentiométrique (Fig. 2, *a*) laisse tout d'abord apparaitre une brusque élévation du pH de la solution de p$H = 3.9$ (solution de $Pb(NO_3)_2$ pur) à p$H = 4.5$ après addition de 0.5 cm^3 de soude.

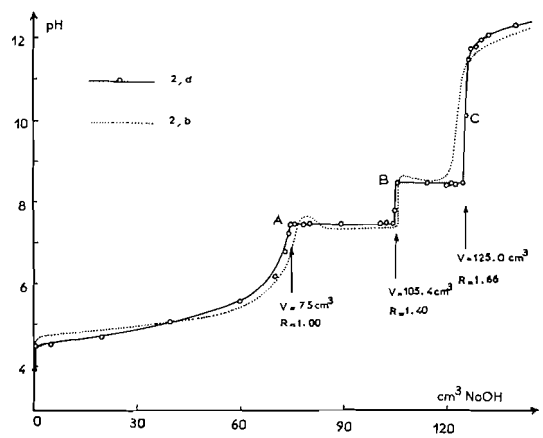

FIG. 2. Dosages potentiométriques de 75 cm^3 d'une solution de nitrate de plomb 0.4 mol l^{-1} par une solution de soude 0.4 mol l^{-1} (commentaires dans le texte).

On observe alors le début de précipitation du monoxynitrate de plomb $Pb(NO_3)_2.PbO$.hydraté. Le pH de la solution croit ensuite jusqu'à la valeur 7.5 après addition de 75 cm^3 de soude. Le point (A) correspond au rapport $R = 1.00$, en excellent accord avec le rapport R théorique de fin de précipitation du monoxynitrate de plomb. On constate ensuite que le pH reste constant (p$H = 7.5$) lorsque le volume de soude ajouté à la solution de nitrate de plomb est compris entre 75 et 104 cm^3. Le pH de la solution croit alors brusquement puis se fixe à la valeur p$H = 8.5$ après addition de 105.4 cm^3 de soude. Le point (B) correspond au rapport $R = 1.40$, en excellent accord avec le rapport R théorique de fin de formation de l'heptoxytrinitrate de plomb $3Pb(NO_3)_2.7PbO$.hydraté. Le pH de la solution reste alors constant (p$H =$ 8.50) lorsque le volume de soude ajouté est compris entre 105.4 et 124.5 cm^3. Le pH de la solution s'accroit alors brusquement. Le point C (p$H = 10.1$) correspond au rapport $R = 1.66$ en excellent accord avec le rapport R théorique de fin de formation du pentoxynitrate $Pb(NO_3)_2.$-$5PbO$.hydraté.

La solubilité du monoxynitrate étant faible (environ 14 g par l), la concentration des ions provenant de cette solubilisation reste constante et le pH du milieu réactionnel ne peut évoluer tant que la transformation en heptoxytrinitrate n'est pas achevée.

De même, l'heptoxytrinitrate étant peu soluble (environ 7 g par l), la concentration en ions provenant de sa solubilisation reste constante et impose le pH du milieu réactionnel tant que la transformation en pentoxynitrate n'est pas achevée.

Action des solutions de soude sur le pentoxynitrate de plomb hydraté

Si on poursuit les dosages précédents en continuant l'addition de soude, on constate la disparition progressive du solide précipité et la solution devient limpide.

Cependant, l'analyse aux rayons X des solides formés, montre que le pentoxynitrate n'est pas pur après addition d'un volume de soude supérieur à 250 cm^3. Elle révèle l'existence d'un autre composé qui a pu être isolé pur en laissant pendant trois jours le solide formé au contact de la solution, quelles que soient les concentration des solutions de soude ou de nitrate de plomb. C'est ainsi que nous avons préparé ce solide à partir de solutions de soude et de nitrate de plomb 0.1 mol l^{-1} lorsque le rapport R est supérieur ou égal à 7 ou lorsque le rapport R est supérieur à 5 en utilisant des solutions de soude 0.4 mol l^{-1} ou 1 mol l^{-1} réagissant sur des solutions de nitrate de plomb 0.4; 0.6; 0.8 ou 1 mol l^{-1}.

L'analyse chimique et l'analyse thermogravimétrique ont permis d'identifier ce solide à l'oxyde de plomb hydraté $PbO.\frac{1}{3}H_2O$. Cet oxyde, de couleur blanche, chauffé dans l'air à la vitesse de 150 °C par heure perd son eau d'hydratation entre 145 et 175 °C et conduit à la formation de l'oxyde de plomb jaune $PbO\beta$. L'analyse chimique a montré l'absence d'ions nitrate et sodium dans le solide. La teneur en plomb a été trouvée égale à $90.2 \pm 0.5\%$ (pourcentage en masse) alors que la teneur théorique est de 90.4%. La teneur en eau, calculée d'après les thermogrammes, est de $2.5 \pm 0.2\%$ (pourcentage en masse), en bon accord avec la teneur théorique égale à 2.62%. De plus, le diagramme de diffraction des rayons X présente toutes les raies caractéristiques de $PbO.\frac{1}{3}H_2O$ dont on connait la préparation par action d'une solution d'ammoniaque sur une solution d'acétate de plomb (3). Pour notre part, nous avons tenté la synthèse de cet oxyde de plomb hydraté en faisant réagir à la température ambiante ($21 \pm$ 2 °C), des solutions d'ammoniaque diluées ou concentrées sur une solution de nitrate de plomb de concentration 0.4 mol l^{-1}. Nous avons pu préparer ainsi tous les oxynitrates de plomb obtenus, par ailleurs, en faisant réagir des solutions de soude et de nitrate de plomb mais nous n'avons jamais observé la formation de l'oxyde de plomb hydraté.

La formation de l'oxyde de plomb hydraté a pu être observée par dosages conductimétriques ou potentiométriques. Nous avons utilisé une solution de nitrate de plomb de concentration 0.4 mol l^{-1} et des solutions de soude de concentration 1 mol l^{-1} ou 4 mol l^{-1}. Nous avons préparé une série de flacons contenant 50 cm^3 de solution de nitrate de plomb 0.4 mol l^{-1} auxquels nous avons ajouté des volumes de soude 1 mol l^{-1} compris entre 35 et 57.5 cm^3 ou des volumes de soude 4 mol l^{-1} compris entre 8.5 et 15 cm^3. La conductivité et le pH des solutions sont mesurés à intervalles réguliers entre 3 et 21 jours. Au bout de 5 à 7 jours, les

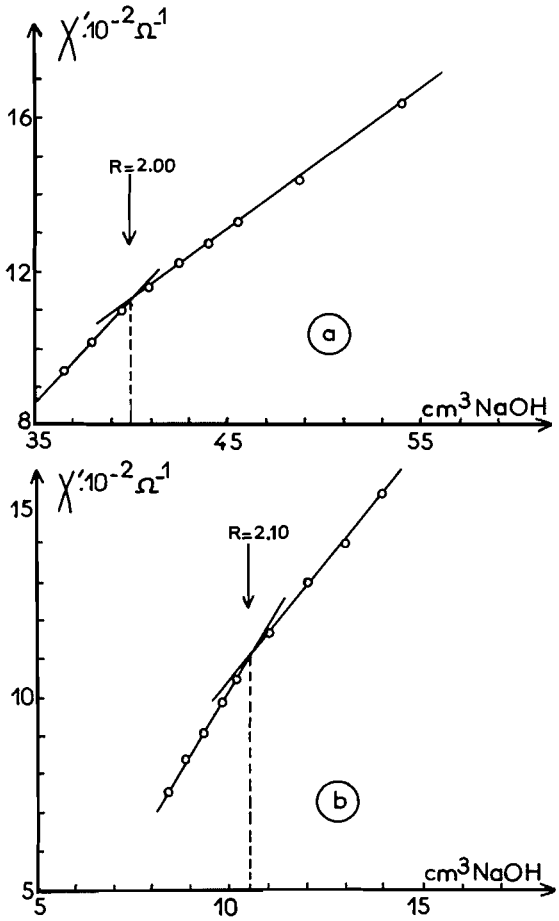

FIG. 3. Dosages conductimétriques de 50 cm³ d'une solution de nitrate de plomb 0.4 mol l^{-1} par (*a*) une solution de soude 1 mol l^{-1}, (*b*) une solution de soude 4 mol l^{-1} (commentaires dans le texte).

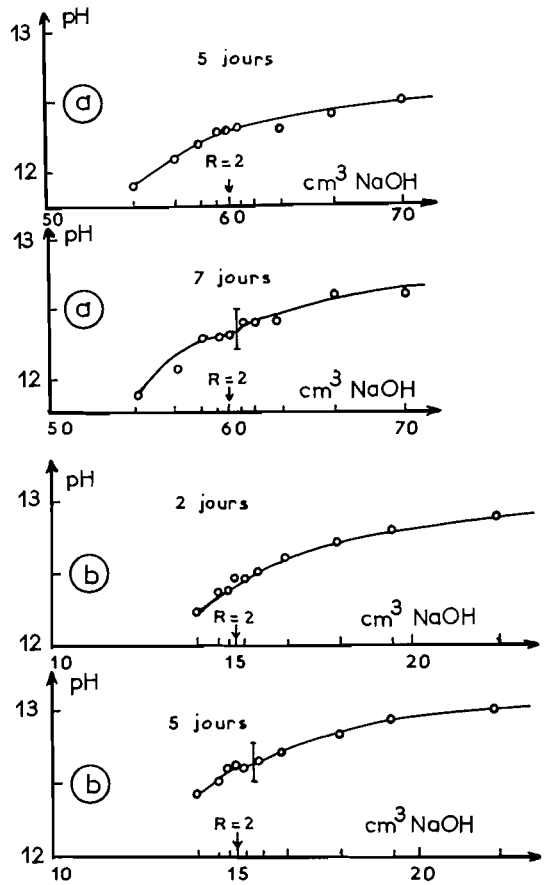

FIG. 4. Dosages potentiométriques de 75 cm³ d'une solution de nitrate de plomb 0.4 mol l^{-1} par (*a*) une solution de soude 1 mol l^{-1}, (*b*) une solution de soude 4 mol l^{-1} (commentaires dans le texte).

courbes conductimétriques (Fig. 3) font apparaitre une rupture de pente pour une valeur de R compris entre 2.0 et 2.1 et les courbes potentiométriques (Fig. 4) présentent un point d'inflexion pour cette même valeur du rapport R, le pH de la solution étant égal à 12.6. Cette valeur du rapport $R = 2$ correspond à la formation de l'oxyde de plomb hydraté selon l'équation:

[9] $Pb(NO_3)_2 + 2NaOH \rightarrow PbO.\text{hydraté} + 2NaNO_3 + H_2O \quad (R = 2/1 = 2)$

L'analyse aux rayons X des solides formés montre que pour $R < 2$, on a affaire au pentoxynitrate pur. L'oxyde de plomb hydraté peut être détecté pour $R > 3$ lorsque les dosages sont effectués à partir d'une solution de soude de concentration 1 mol l^{-1} et pour $R > 2$ si la concentration de la soude est 4 mol l^{-1}.

Dosages réalisés avec des solutions de soude 1 mol l^{-1} ou 4 mol l^{-1} et une solution de nitrate de plomb 0.4 mol l^{-1}

Les oxynitrates mis en évidence au cours des dosages conductimétriques sont ceux déjà cités mais les courbes conductimétriques ne présentent plus de rupture de pente pour des valeurs de $R < 1$. Cependant, en modifiant les conditions opératoires, nous avons pu montrer l'existence d'un autre oxynitrate de plomb. C'est ainsi que nous avons effectué le dosage de 50 cm³ d'une solution de nitrate de plomb

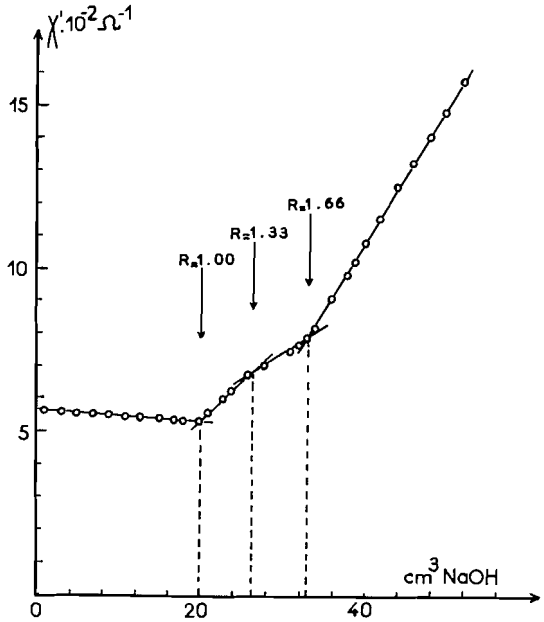

FIG. 5. Dosage conductimétrique de 50 cm^3 d'une solution de nitrate de plomb 0.4 mol l^{-1} par une solution de soude 1 mol l^{-1}.

0.4 mol l^{-1} avec de la soude de concentration 1 mol l^{-1} en versant, tout d'abord, en une seule fois, le volume de soude nécessaire à la précipitation totale du monoxynitrate (20 cm^3) avant de poursuivre l'addition de la base cm^3 par cm^3. La courbe conductimétrique (Fig. 5), tracée à partir des mesures de conductivité effectuées après agitation pendant cinq minutes et décantation des solides formés, met en évidence trois ruptures de pente pour les valeurs: $R = 1.00$, $R = 1.33$ et $R = 1.66$.

Les valeurs $R = 1.00$ et $R = 1.66$ correspondent respectivement à la précipitation stoechiométrique du monoxynitrate et du pentoxynitrate de plomb hydratés. La valeur $R = 1.33$ correspond à la formation du dioxynitrate de plomb hydraté selon l'équation:

[10] $3Pb(NO_3)_2 + 4NaOH \rightarrow Pb(NO_3)_2.2PbO.\text{hydraté} + 4NaNO_3 + 2H_2O \quad (R = 4/3 = 1.33)$

Par contre, si on effectue le dosage comme précédemment jusqu'à la précipitation totale du monoxynitrate et qu'on attende au moins une heure avant de poursuivre l'addition de la soude, on n'observe plus, sur la courbe conductimétrique, une rupture de pente pour la valeur $R = 1.33$ mais pour $R = 1.40$. Il y a donc, dans ces conditions, formation de l'heptoxytrinitrate et non du dioxynitrate de plomb hydraté.

Par conséquent, suivant le mode opératoire, la soude peut réagir sur le monoxynitrate de plomb selon deux processus différents. Il peut se former soit l'heptoxytrinitrate soit le dioxynitrate de plomb hydraté.

Les courbes potentiométriques sont analogues à celle obtenue en effectuant le dosage de la solution de nitrate de plomb 0.4 mol l^{-1} avec une solution de soude 0.4 mol l^{-1}. Les seuls oxynitrates formés sont le monoxynitrate, l'heptoxytrinitrate et le pentoxynitrate de plomb. On observe une invariance de pH de la solution au cours de la transformation du monoxynitrate en heptoxytrinitrate (pH compris entre 7.50 et 7.60) et au cours de la transformation de l'heptoxytrinitrate en pentoxynitrate (pH compris entre 8.60 et 8.80). Le pH des solutions ne se stabilise que très lentement. Il est souvent nécessaire d'attendre une vingtaine de jours avant d'observer que le pH n'évolue plus au voisinage des points correspondant à la formation des oxynitrates purs. Par exemple, la courbe potentiométrique (Fig. 2, *b*) traduit les résultats obtenus lorsque la variation de pH ne dépasse pas 0.02 unité pendant 5 min. Par conséquent, les mesures de pH effectuées au cours de dosages rapides n'ont aucune signification. Les dosages potentiométriques ne permettent donc pas de mettre en évidence la formation de dioxynitrate de plomb hydraté.

Dosages inverses réalisés avec une solution de nitrate de plomb 0.4 mol l^{-1} et une solution de soude 0.4 mol l^{-1}

Le mode opératoire est le même que lors des dosages précédents, mais ceux-ci sont effectués en versant la solution de nitrate de plomb dans un volume de soude égal à 50 cm^3 pour les dosages conductimétriques et 75 cm^3 pour les dosages potentiométriques.

La courbe conductimétrique (Fig. 6) présente quatre ruptures de pente pour les valeurs $R = 8.9$, $R = 1.80$, $R = 1.39$ et $R = 1.06$.

La première rupture de pente ($R = 8.9$) correspond à l'apparition du précipité de pentoxynitrate de plomb. Les autres ruptures de pente correspondent respectivement à la fin de formation du pentoxynitrate, de l'heptoxytrinitrate et du monoxynitrate de plomb. Cependant, les

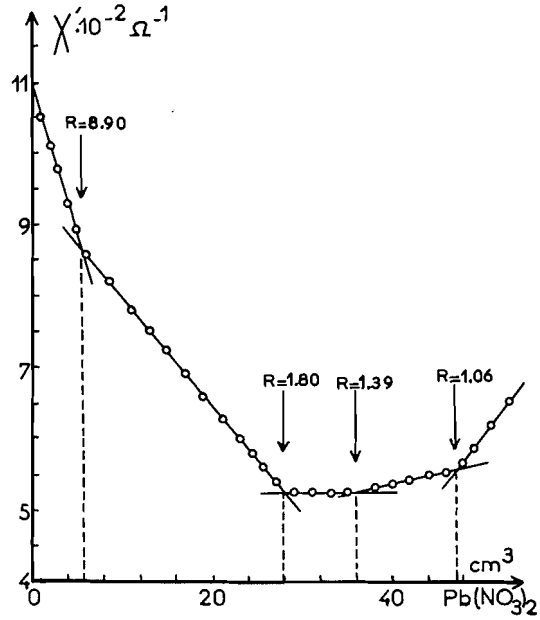

FIG. 6. Dosage conductimétrique de 50 cm^3 d'une solution de soude 0.4 mol l^{-1} par une solution de nitrate de plomb 0.4 mol l^{-1}.

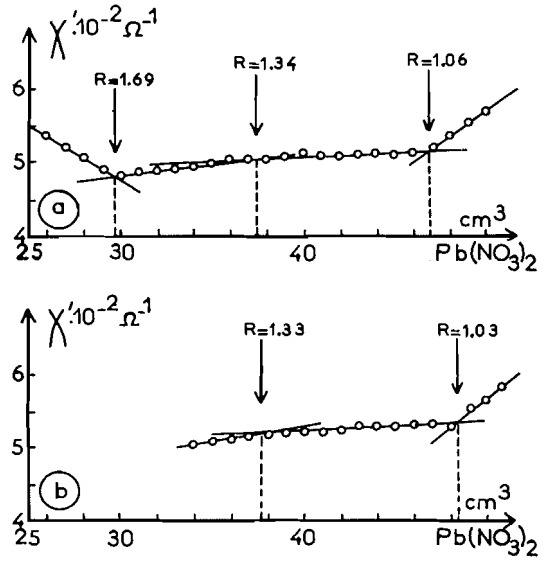

FIG. 7. Dosages conductimétriques de 50 cm^3 d'une solution de soude 0.4 mol l^{-1} par une solution de nitrate de plomb 0.4 mol l^{-1} (commentaires dans le texte).

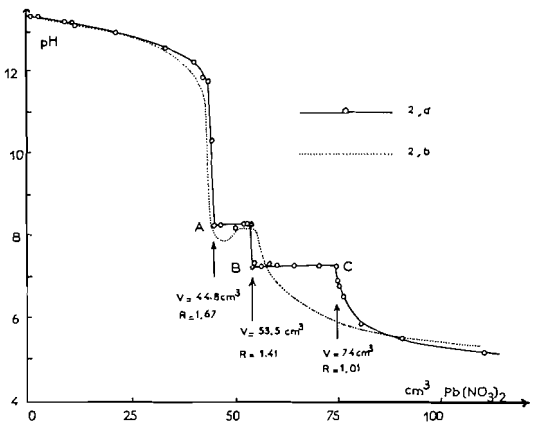

FIG. 8. Dosages potentiométriques de 75 cm^3 d'une solution de soude 0.4 mol l^{-1} par une solution de nitrate de plomb 0.4 mol l^{-1} (commentaires dans le texte).

valeurs expérimentales de R sont légèrement supérieures aux valeurs théoriques de R correspondant à la fin de formation du pentoxynitrate ($R = 1.66$) et du monoxynitrate ($R = 1.00$). Si on verse tout d'abord en une seule fois 25 cm^3 de la solution de nitrate de plomb 0.4 mol l^{-1} avant de poursuivre le dosage, la courbe conductimétrique (Fig. 7, *a*) présente trois ruptures de pente pour les valeurs $R = 1.69$, $R = 1.34$ et $R = 1.06$. La valeur $R = 1.69$ est en bon accord avec la valeur théorique du rapport R correspondant à la précipitation totale du pentoxynitrate de plomb. La rupture de pente observée pour $R = 1.34$ atteste la formation du dioxynitrate de plomb. De même, si on verse tout d'abord en une seule fois 35 cm^3 de la solution de nitrate de plomb avant de poursuivre le dosage, la courbe conductimétrique (Fig. 7, *b*) présente deux ruptures de pente pour $R = 1.33$ et $R = 1.03$. Le rapport $R = 1.33$ correspond exactement à la valeur R théorique de formation du dioxynitrate de plomb.

Ainsi en versant la solution de nitrate de plomb dans la soude, on obtient les mêmes oxynitrates de plomb hydratés que ceux déjà mentionnés lors de l'étude des dosages effectués en versant la soude dans la solution de nitrate de plomb.

La courbe potentiométrique (Fig. 8, *a*) montre que le pH de la solution décroit jusqu'à la valeur 8.30 après addition de 44.8 cm^3 de solution de nitrate de plomb. Le point (A) correspond au rapport $R = 1.67$ en accord avec le rapport R théorique de fin de précipitation du pentoxynitrate de plomb. On constate ensuite que le pH reste constant (p$H = 8.30$) jusqu'à ce

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

que le volume de nitrate de plomb ajouté soit égal à 53.5 cm^3. Le pH de la solution décroit alors brusquement et se fixe à la valeur p$H = 7.30$ après addition de 53.6 cm^3 de solution de nitrate de plomb. Le point (B) correspond au rapport $R = 1.41$, en accord avec le rapport R théorique de fin de formation de l'heptoxytrinitrate de plomb. Le pH de la solution reste alors constant (p$H = 7.30$) lorsque le volume de solution de nitrate de plomb est compris entre 53.5 et 74 cm^3. Le pH de la solution décroit ensuite brusquement et le point (C) correspond au rapport $R = 1.01$ en accord avec le rapport R théorique de fin de formation du monoxynitrate de plomb hydraté.

Le pH des solutions ne se stabilise que très lentement. Ainsi, la courbe potentiométrique (Fig. 8, *b*) est obtenue lorsque la variation de pH ne dépasse pas 0.02 unité pendant cinq minutes. Il apparait, en ce cas, que les points correspondant à la formation des oxynitrates de plomb purs ne sont pas définis d'une façon précise. En particulier, on remarque qu'aucun accident ne se manifeste sur la courbe potentiométrique pour la valeur $R = 1.00$ devant indiquer la fin de formation du monoxynitrate. La nécessité d'attendre une vingtaine de jours l'invariance du pH des solutions ne permet pas de mettre en évidence la formation du dioxynitrate de plomb pour les mêmes raisons que celles évoquées à propos des dosages effectués en versant la solution de soude dans celle de nitrate de plomb.

Synthèse des oxynitrates de plomb

Les dosages que nous avons effectués ont révélé que la soude réagit sur une solution de nitrate de plomb pour former les monoxynitrate, dioxynitrate, heptoxytrinitrate et pentoxynitrate de plomb hydratés.

Nous avons également montré qu'il est possible de préparer l'oxyde de plomb hydraté. Nous avons donc étudié les conditions de synthèse des oxynitrates de plomb hydratés et de l'oxyde de plomb hydraté dans un large domaine de température en utilisant plusieurs concentrations de solution aqueuses de soude et de nitrate de plomb. Afin de simplifier leur écriture, nous avons affecté aux différents composés les symboles suivants: $Pb(NO_3)_2.PbO$.hydraté, N1h; $Pb(NO_3)_2.2PbO$.hydraté, N2h; $3Pb(NO_3)_2.7PbO$.hydraté, N7/3h; $Pb(NO_3)_2.5PbO$.hydraté, N5h; $PbO.\frac{1}{3}H_2O$, PbO h.

Pour chacune des températures d'expérimentation, il est possible de tracer un graphique qui montre clairement les conditions optimales de

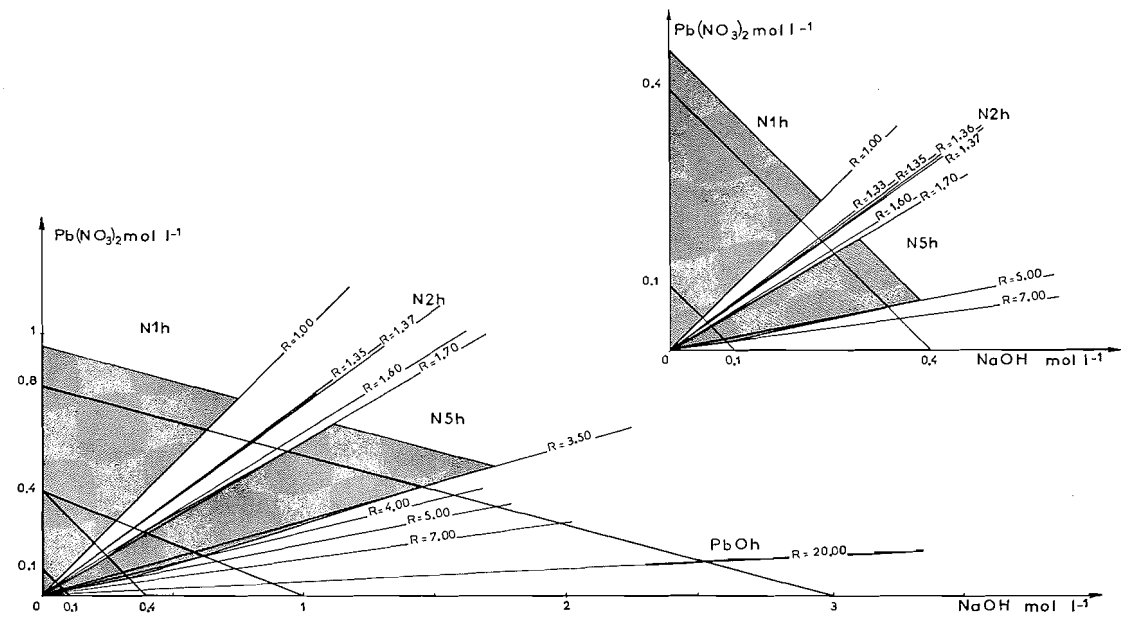

FIG. 9. Diagramme d'obtention à 3 ± 0.5 °C des oxynitrates de plomb hydratés et de l'oxyde de plomb hydraté.

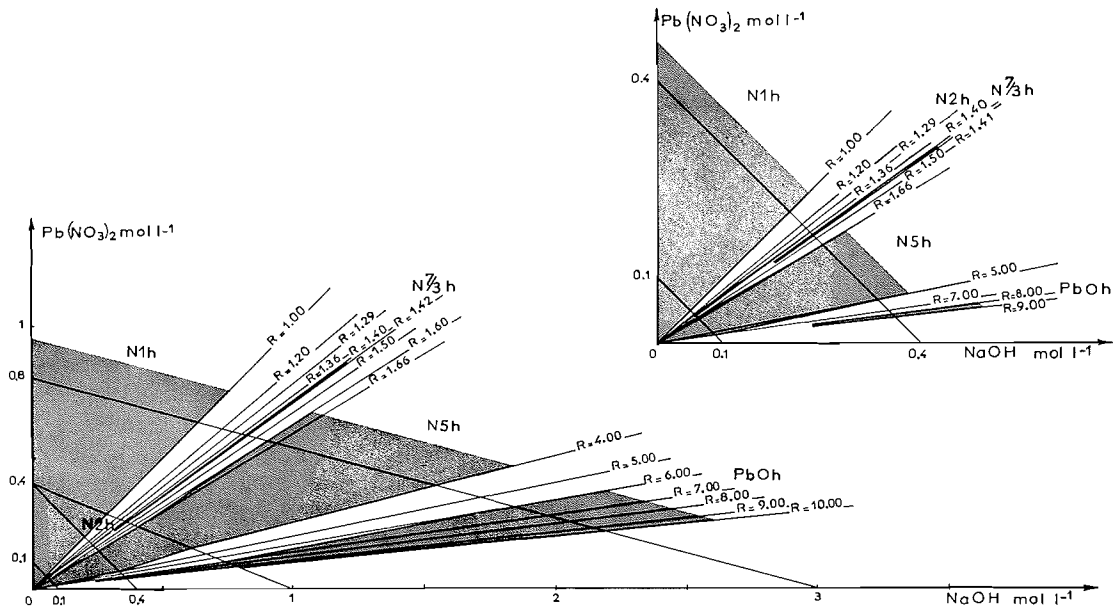

FIG. 10. Diagramme d'obtention à 27 ± 0.3 °C des oxynitrates de plomb hydratés et de l'oxyde de plomb hydraté.

synthèse de l'oxyde et des oxynitrates de plomb hydratés. Les zones colorées en gris dans les Figs. 9, 10 et 11 représentent les domaines d'obtention de ces solides purs aux températures suivantes: 3 ± 0.5, 27 ± 0.3 et 50 ± 0.3 °C.

La combinaison des relations [1] et [2] conduit à une relation linéaire entre (n) et (s):

$$[11] \qquad (n) = -(M_n.(s)/M_s) + M_n$$

La droite correspondant à cette équation est

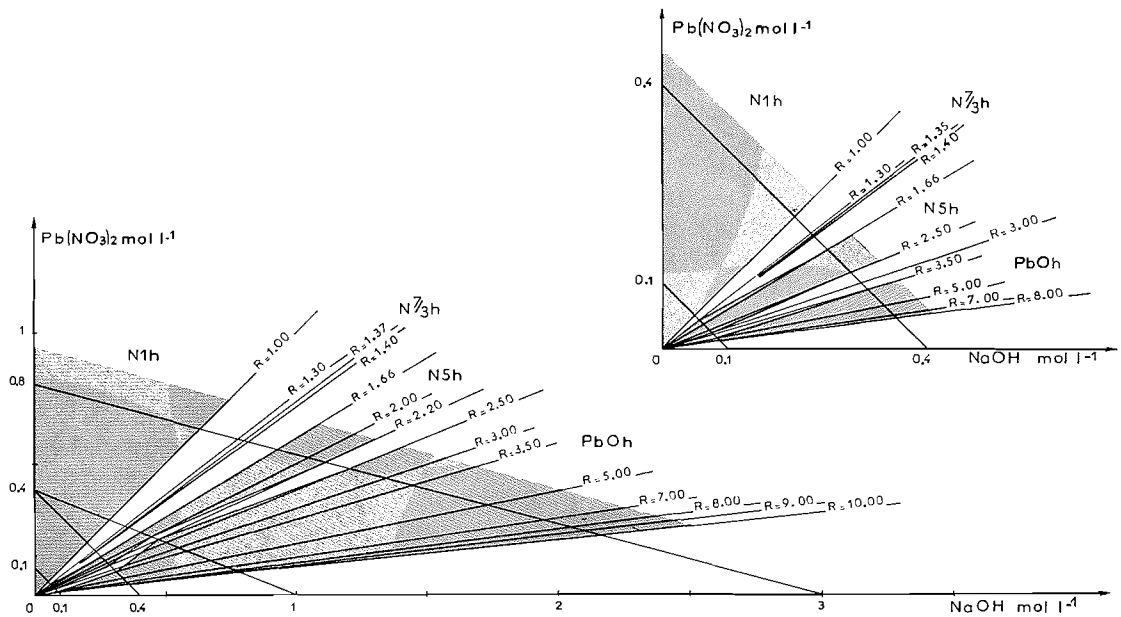

FIG. 11. Diagramme d'obtention à 50 ± 0.3 °C des oxynitrates de plomb hydratés et de l'oxyde de plomb hydraté.

le lieu des points représentatifs des mélanges d'une solution de soude de molarité M_s et d'une solution de nitrate de plomb de molarité M_n.

D'autre part, les points représentatifs des mélanges ayant même rapport R sont situés sur la droite correspondant à l'équation

$$[12] \qquad (n) = (s)/R$$

Ces expériences montrent qu'en choisissant convenablement la température et les concentrations des solutions de soude et de nitrate de plomb, on peut préparer facilement monoxynitrate, pentoxynitrate et oxyde de plomb hydratés. Par contre, la synthèse du dioxynitrate et de l'heptoxytrinitrate de plomb est plus délicate. Le dioxynitrate hydraté est obtenu à 3 °C, quelles que soient les concentrations des réactifs, pour des valeurs de R comprises entre 1.33 et 1.37. Cet oxynitrate ne se forme pas à 50 °C. Au contraire, l'heptoxytrinitrate hydraté ne se forme pas à 3 °C. A 50 °C, il peut être préparé, quelles que soient les concentrations des solutions de soude et de nitrate de plomb pour les valeurs de R comprises entre 1.37 et 1.40. Aux températures intermédiaires, l'un et l'autre de ces oxynitrates peuvent être obtenus.

Des expériences complémentaires ont montré que le lavage à l'eau distillée n'altère pas les préparations de ces solides purs. Le séchage nécessite certaines précautions pour éliminer toute trace d'humidité. Les précisions seront apportées dans une publication ultérieure.

Les dosages chimiques du monoxynitrate et du pentoxynitrate de plomb confirment ceux qui ont été signalés dans une autre étude (2). Cependant, l'incertitude sur la détermination de la valeur du rapport N_1/N_2 dans la formule générale des oxynitrates de plomb $Pb(NO_3)_2 \cdot N_1/N_2 PbO.x H_2O$ étant de l'ordre de 0.2, il est difficile de distinguer, par dosage chimique, $Pb(NO_3)_2.2PbO.y H_2O$ où $N_1/N_2 = 2$ et $Pb(NO_3)_2.\frac{7}{3}PbO.zH_2O$ où $N_1/N_2 = 2.33$. Cela, ajouté au fait qu'il est délicat de préparer l'un ou l'autre de ces oxynitrates à 20 °C, permet d'expliquer que dans une étude préliminaire (2), le dioxynitrate de plomb ait pu être confondu avec un trioxydinitrate et l'heptoxytrinitrate de plomb avec un dioxynitrate.

Préparation, à froid, de l'oxyde de plomb anhydre PbOβ

Il est connu que l'oxyde de plomb peut être préparé par voie humide, en faisant réagir une solution de soude ou de potasse sur la solution d'un sel de plomb tel que l'acétate, le perchlorate ou le nitrate mais il est spécifié que cette préparation doit être effectuée à l'ébullition (4). Or, en faisant réagir 140 cm^3 d'une solution de soude de concentration 1 mol l^{-1} et 50 cm^3 d'une solution de nitrate de plomb de concentration 0.4 mol l^{-1} (soit un rapport $R = 7$), à la température ambiante (21 ± 2 °C), nous avons abouti à des résultats différents selon que la solution de soude était préparée à partir de solutions concentrées livrées commercialement dans des récipients en verre ou préparée à partir de pastilles de soude. Dans le premier cas, nous obtenons toujours la formation de l'oxyde de plomb hydraté $PbO.\frac{1}{3}H_2O$. Dans le second cas, nous n'obtenons cet oxyde hydraté qu'après vieillissement pendant trois jours de la solution conservée en récipients de verre, sinon c'est un solide brun-jaune qui précipite. Son diffractogramme X est identique à celui de l'oxyde de plomb jaune PbOβ tel qu'il est consigné dans les fiches de l'A.S.T.M.

Il est connu que les solutions de soude attaquent faiblement et très lentement le verre, même à la température ambiante, cependant que d'autres matériaux tels que le polystyrène, le téflon offrent une bonne résistance aux solutions de soude concentrées même chaudes.

Nous avons donc comparé l'influence du vieillissement de solutions préparées à partir de pastilles de soude et conservées soit en récipients de polystyrène soit en récipients de verre. Dans le premier cas, les manipulations sont toutes effectuées en récipients de polystyrène; dans le second cas, elles sont effectuées en récipients de verre. Les expériences sont réalisées en faisant réagir 140 cm^3 de soude de concentration 1 mol l^{-1} et 50 cm^3 de solution de nitrate 0.4 mol l^{-1}. Nous avons observé que, lorsque les solutions sont préparées et conservées en récipients de polystyrène, on obtient toujours la formation de PbOβ quel que soit le temps de vieillissement (de un jour à quinze mois). Par contre, si les solutions sont préparées et conservées en récipients de verre, nous n'obtenons plus l'oxyde de plomb PbOβ après un vieillissement de trois jours; c'est l'oxyde hydraté $PbO.\frac{1}{3}H_2O$ qui se forme.

Nous avons recherché quel est, parmi les composants essentiels du verre, celui qui favorise la formation de $PbO.\frac{1}{3}H_2O$. A quatre solutions de soude de concentration 1 mol l^{-1} conservées

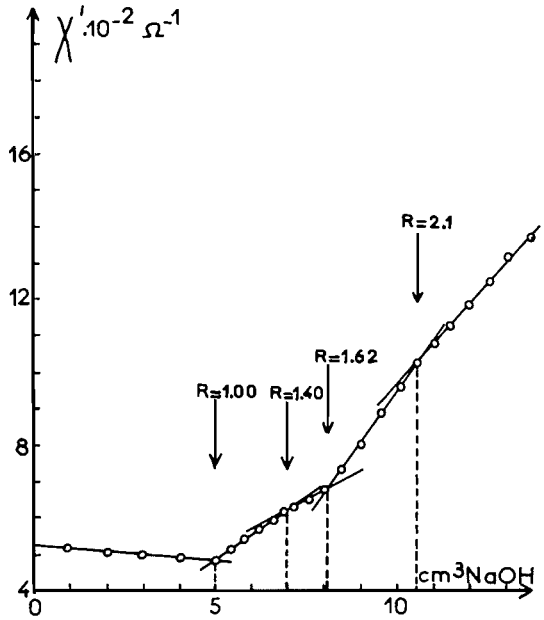

FIG. 12. Dosage conductimétrique de 50 cm^3 d'une solution de nitrate de plomb 0.4 mol l^{-1} par une solution de soude 4 mol l^{-1} (commentaires dans le texte).

en récipients de polystyrène, nous avons ajouté, dans la première, un gramme de silice en poudre; dans la seconde, des morceaux de silice vitreuse; dans la troisième, un gramme de borax; la quatrième est conservée comme témoin. Nous avons constaté qu'après un vieillissement de deux mois, la solution de soude pure et la solution de soude à laquelle on a ajouté du borax permettent encore d'obtenir l'oxyde de plomb PbOβ alors qu'après un mois de vieillissement seulement, les solutions de soude contenant de la silice conduisent à la formation de l'oxyde hydraté $PbO.\frac{1}{3}H_2O$.

En conclusion, la présence de silice, même à l'état de traces dans la solution de soude, inhibe la formation de l'oxyde PbOβ et favorise celle de l'oxyde hydraté $PbO.\frac{1}{3}H_2O$. Des expériences complémentaires, effectuées à partir de réactifs conservés en récipients de polystyrène, ont montré que la présence ou l'absence de traces de silice est sans influence sur les préparations des oxynitrates de plomb. Ainsi la courbe conductimétrique (Fig. 12) rend compte des résultats expérimentaux des dosages effectués en versant une solution de soude 4 mol l^{-1}, préparée et conservée en récipients de polystyrène, dans 50 cm^3 d'une solution de nitrate de plomb 0.4 mol l^{-1}. Les ruptures de pente correspondant aux valeurs $R = 1.00$, $R = 1.40$, $R = 1.62$ et $R = 2.1$ attestent la formation successive des monoxynitrate, heptoxytrinitrate, pentoxynitrate de plomb hydratés et de l'oxyde de plomb anhydre.

Carboxylate Complexing of Iron(III). I. The Formation of Monoacetatoiron(III) in Aqueous Solution: Equilibria and Kinetics

R. N. PANDEY AND W. MACF. SMITH

Department of Chemistry, Queen's University, Kingston, Ontario

Received August 13, 1971

The kinetics and equilibria involved in the formation of monoacetatoiron(III) from iron(III) in aqueous solution has been investigated at ionic strength 0.50 *M* and temperatures ranging from 5.2 to 25 °C for kinetic studies and 5.2 to 41 °C for equilibria. The results support the view that the mechanism of the acid independent reaction involves the reactants $FeOH^{2+}$ and CH_3COOH in an interchange dissociative (I_d) mechanism with $\Delta H^{\ddagger} = 11.1 \pm 2.2$ kcal mol^{-1}. The nature of the acid dependent reactions remains unresolved.

Les cinétiques et les équilibres impliqués dans la formation du monoacétate de fer(III) à partir du fer(III) en solution aqueuse, ont été étudiés à force ionique de 0.50 *M* et sur une échelle de température allant de 5.2 à 25 °C pour les études cinétiques et de 5.2 à 41 °C pour les équilibres. Les résultats montrent que le mécanisme de la réaction, indépendant en acide, implique les réactifs $FeOH^{2+}$ et CH_3COOH dans un mécanisme d'échange et de dissociation (I_d) avec $\Delta H^{\ddagger} = 11.1 \pm 2.2$ kcal mol^{-1}. La nature des réactions qui dépendent de l'acide demeure non élucidée.

Canadian Journal of Chemistry, **50**, 194 (1972)

The acid independent term in the expression for the rate constant for the anation reactions of iron(III) has been interpreted as associated with reactions 1 and 2

[1] $$Fe(H_2O)_6^{3+} + L^- \rightarrow Fe(H_2O)_5L^{2+} + H_2O$$

[2] $$Fe(OH)(H_2O)_5^{2+} + HL \rightarrow Fe(H_2O)_5L^{2+} + H_2O$$

occurring with an interchange (I) mechanism. In such a mechanism an outer ion pair involving the two reactants with formation constant K_0 collapses to form the complex with a first-order rate constant k; and if this constant is much smaller than that for dissociation of the ion pair and if the concentration of ion pairs is substantially less than those of the reactants, the overall reaction is first order in each reactant (second order overall) and equal to kK_0 (2, 3). In the mechanism labelled I_d (dissociative interchange) k should be closely related to the rate constant for water exchange on the unassociated metal ion and this should be substantially greater for $Fe(OH)(H_2O)_5^{2+}$ than for $Fe(H_2O)_6^{3+}$ (4).

For ligands of low basicity such as Cl^- or Br^- the dominant contribution to the rate constant appears to be that associated with reaction 1 (5) with only a modest dependence of its magnitude on ligand type, but for reactions involving ligands of higher basicity it appears that reaction 2 proceeding by an essentially I_d mechanism is consistent with experimental data (6, 7). Assuming that reaction 1 is the dominant reaction results in a dependence of k on ligand basicity which was rationalized by Eigen by the hypothesis of inner hydrolysis (8). Assuming that reaction 2 is dominant yields values for k which are approximately constant and consistent with some estimates of the rate constant for water exchange on $Fe(OH)(H_2O)_5^{2+}$ (9). Recent work by Cavasino and Di Dio (7) on the reaction of the substituted phenols definitely rules out the possibility of reaction 1 being a dominant reaction for ligands of high basicity but some uncertainty remains about the nature of reactions involving ligands of modest basicity.

When we undertook the work reported in part in this paper there was a paucity of data on reactions involving iron(III) and ligands of similar structure but with basicities covering a range. We chose to study the characteristics of the reaction of the four monocarboxylato reactants: acetate, monochloroacetate, dichloroacetate, and trichloroacetate with basic ionization constants in water at 25 °C and ionic strength 0.5 ranging from 3.7×10^{-10} to 1.2×10^{-14}. Since then the work of Accascina, Cavasino, and Di Dio (6) on the reactions of iron(III) with various aliphatic acids including acetic and monochloroacetic and of Cavasino and Di Dio (7) on the substituted phenols has been published and has provided data for reactions involving ligands with a wide range

of basicities which support the assumption that the dominant process in the reactions studied is indeed reaction 2. However, their data are restricted to a single temperature. Their measurements were made with T jump relaxation techniques and for the aliphatic acids the data were interpreted using values obtained by Perrin for the association constants of the complexes.

Our kinetic investigation involved stopped flow techniques, covered the temperature range 5.2 to 25 °C, and also involved measurement of the association constants of the mono complex. This paper is restricted to the equilibria and kinetics of the acetate complex.

Experimental

Materials

Baker reagent grade acetic acid was purified by the method of Ritter and Simons (10). Sodium perchlorate was prepared by neutralization of reagent grade perchloric acid with Baker's analyzed reagent sodium hydroxide. Reagent grade iron(III) perchlorate from G. Frederick Smith was washed repeatedly with small amounts of 70% perchloric acid to remove traces of chloride prior to preparation of solutions. Sulfate estimated by the method of Fritz, Yamamura, and Richard (11) was found to be in negligible amount. The iron(III) and acid contents of the solutions were estimated by methods previously outlined (12).

Equilibrium Measurements

The acid ionization constant was assessed via electrometric measurement of the hydrogen ion concentration in buffer mixtures of sodium acetate and acetic acid with the ionic strength adjusted to 0.50 with sodium perchlorate. The electrometric cell involved calomel and hydrogen electrodes. The hydrogen was ultra pure quality from Matheson and was passed over platinized asbestos and platinum at ~200 °C and through a presaturator. The correlation between e.m.f. readings and hydrogen ion concentration was obtained with solutions of known concentrations of perchloric acid adjusted to ionic strength 0.50 with sodium perchlorate. The correction associated with variation in the partial pressure of the hydrogen between standardization and measurement was negligible compared with the reproducibility (±0.5 mV) and was ignored.

The data, from which the association constants of the complexes were estimated, were obtained spectrophotometrically with a Beckman DK1 spectrophotometer with a thermostatted cell holder with temperature control of ±0.15 °C and cells of 1, 10, and 50 mm path length. The total iron(III) concentration varied from 2.02×10^{-4} to 2.02×10^{-3}, the total concentration of acetic acid from 0.25 to 1.50 M, the hydrogen ion concentration was in the range 0.032 to 0.32 M. The difference in absorbances (ΔA) at λ320, 310, and 295 mμ and at temperatures 5.2, 15.2, 25.0, 35.2, 41.0 °C were determined for pairs of solutions identical in ionic strength, hydrogen ion concentration, and total iron(III) concentration but differing in that one contained acetic acid and the other did not.

Kinetic measurements involving the acetate complex were made with a Model D-150 Durrum stopped-flow spectrophotometer using λ310 mμ and an optical path length of 20 mm. The pertinent data involved the optical density as a function of time. As indicated below, the reactions were pseudo first order under the conditions used and it was not essential to determine the optical densities near zero time.

Interpretation of Experimental Data

Equilibria

The data upon which estimates of the association constant, K_{ass}, are based along with the parameters in the relations used in reducing the data are as follows:

T_m = the total molar concentration of iron(III) perchlorate added;

T_L = the total concentration of acetate added (as acetic acid);

h = the concentration of hydrogen ions;

K_h = the hydrolysis constant for iron(III);

Q_a = the acid ionization constant for acetic acid;

ΔA = the difference in absorbance of two solutions differing only in that $T_L = 0$ in one of them;

q = the concentration of perchloric acid;

c = the concentration of the mono complex FeL^{2+};

$V = Q_a/(K_h + h)$;

$[L^-]$ = the concentration of acetate ion;

ε_{FeL} = the molar absorptivity of the mono-acetato complex FeL^{2+};

ε_{Fe} = the molar absorptivity of ferric ion, Fe^{3+};

ε_{FeOH} = the molar absorptivity of $FeOH^{2+}$;

$\Delta\varepsilon = \varepsilon_{FeL} - \{\varepsilon_{FeOH} K_h/(K_h + h) + \varepsilon_{Fe} h/(K_h + h)\}$;

l = length of the optical path in the spectrophotometric measurements.

The values used for K_h were those determined by Connick and co-workers (13), those used for Q_a were determined as indicated above on the basis of knowledge of the concentrations of acetic acid and sodium acetate from make-up composition and the concentration of hydrogen ion from the electrometric measurement. Values so determined are shown on Table 1 and indicate a maximum in the range between 5.2 and 25.0 °C. Harned and Ehlers (14) measured the acid ionization constant conductometrically and found a maximum near 25 °C for the thermodynamic constant (zero ionic strength). Esti-

25.0	2.70±0.31
35.2	2.50±0.12
41.0	2.50±0.15

mates of ε_{FeOH} and ε_{Fe} were made on the basis of our measurements of the absorbance of solution of ferric perchlorate at ionic strength 0.50 and various acidities and Connick *et al.*'s values for K_h using the relationship

$$A_i = T_m l\left(\varepsilon_{FeOH}\frac{K_h}{K_h+h} + \varepsilon_{Fe}\frac{h}{K_h+h}\right)$$

where A_i is the contribution of iron(III) to the absorbance. Values obtained at 25 °C are shown in Table 2.

The method of Bent and French (15) was used to check the composition of the complexes formed. If only the mono complex is formed in significant amount, a plot of log ΔA against log $[L^-]$($[L^-] \sim Q_a T_L/h$) at constant T_m should have a slope of unity. The data covering the range of conditions of the equilibrium and kinetic studies yielded a line with slope 1.03 ± 0.03.

Association constants were obtained by interpreting the data by a Benesi–Hildebrand equation (16) of the form

$$[3] \quad \frac{T_m}{\Delta A} = \frac{1}{\Delta\varepsilon l} + \frac{1}{\Delta\varepsilon l}\frac{1}{K_{ass}[L^-]}\frac{K_h+h}{h}$$

The moderately low value of K_{ass} along with the smallness of the values of $[L^-]$ experimentally accessible, because of the weakness of acetic acid and the necessity of maintaining the value of h moderately high to minimize hydrolysis, led to groups of data which yielded very small intercepts with large relative dispersion in their values for the plot of $1/\Delta A$ *vs.* $1/[L^-]$ although the values for the slopes of the plots had much less dispersion. An iterative machine calculation was used to interpret the data starting with eq. 4 which derives directly from eq. 3

$$[4] \quad \frac{T_m}{\Delta A} = \frac{1}{\Delta\varepsilon l} + \frac{1}{\Delta\varepsilon l}\frac{1}{K_{ass}}\frac{1}{V(T_L - c - [L^-])}$$

and then using eq. 5 which relates the contribution A of the complex FeL^{2+} with molar extinction coefficient ε_{FeL} to the absorbance of the solution.

$$[5] \quad \frac{T_m}{A} = \frac{1}{\varepsilon_{FeL} l} + \frac{1}{\varepsilon_{FeL} l}\frac{1}{K_{ass}}\frac{1}{V(T_L - c - [L^-])}$$

$\Delta\varepsilon$ is dependent on the value of h if hydrolysis is significant particularly at lower values for λ and this implies that eq. 4 is not strictly linear, unless the data in a group are for one value of h or unless the optical densities are corrected to apply to a common reference acidity. To attain a useful range of concentrations for $[L^-]$ which would yield significant complexing of iron(III) without appreciably reducing the activity of the solvent water, h was varied in obtaining groups of data and allowance was made for the effect of hydrolysis.

First approximations for $\Delta\varepsilon$ and K_{ass} were obtained from data using a linear least mean squares treatment with eq. 4 assuming that $\Delta\varepsilon$ was independent of h, that $(T_L - c - [L^-]) = T_L$. Further cycles were carried out with values of c from $\Delta A/l\Delta\varepsilon$ and $[L^-]$ from $Q_a(T_L - c)/(h + Q_a)$. To allow for the effect of variation in the degree of hydrolysis on absorption, eq. 5 was used iteratively with values of A for each datum point estimated from $c.l\varepsilon_{FeL}$ where $\varepsilon_{FeL} = \Delta\varepsilon + \varepsilon_{Fe}\, h/(K_h + h) + \varepsilon_{FeOH}\, K_h/(K_h + h)$.

Allowance for the effect of hydrolysis of iron(III) and of complex formation as well as ionization of HL on h was written into the program using the relation

$$[6] \quad h = q + [L^-] + c\left(1 + \frac{K_h}{Q_a K_{ass}(T_L - c - [L^-])}\right)$$

TABLE 2. Values for the molar absorptivity of Fe^{3+} and $FeOH^{2+}$; temperature = 25 °C; ionic strength = 0.50 *M*

but values yielded for h are insignificantly greater than those for q for the acetate systems of this investigation and the allowance is not necessary.

The groups of data each characterized by a given value for T_L yielded slopes (eq. 5) with relative range of about ±8% but the range of the intercepts was ±50%. The difficulty of obtaining reliable intercepts under conditions similar to those in this work has been emphasized by several writers (17, 18). Rather than taking an average based on all data we have chosen the value for ε_{FeL} from a selected group of measurements where the precision in the measurements of ΔA was optimal and the relative error in the intercepts less than 15%. The values for ε_{FeL} so obtained were 2191 M^{-1} cm^{-1} at λ310 mμ, 1839 M^{-1} cm^{-1} at λ320 mμ and 3000 M^{-1} cm^{-1} at λ295 mμ. These values of ε_{FeL}, assumed to apply at all temperatures, were used with all data where the dispersion of slopes was within ±7.5% to yield the average values for K_{ass} summarized in Table 3.

A plot of log K_{ass} *vs.* $1/T$ indicated a close approximation to linearity for all data except those for 15.2 °C. If the value for 15.2 °C be omitted the data may be summarized by the relationship log $K_{ass} = A + B/T$ with $A = 6.68 \pm 0.04$ and $B = -1.13 \pm 0.01$. We have used this relationship to obtain a value for K_{ass} at 20 °C and an alternative value for K_{ass} at 15.2 °C. The values, 641 M^{-1} at 20 °C and 604 M^{-1} at 15.2 °C, were used in reducing the kinetic data.

Kinetics

Accascina, Cavasino, and Di Dio (6) have successfully interpreted the kinetic data relating to the monoacetato complex of iron(III) obtained by T jump relaxation methods by the following reaction scheme which also successfully accommodated our results.

$$Fe(H_2O)_6^{3+} + L^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} Fe(H_2O)_5L^{2+} + H_2O$$

$$Fe(H_2O)_5OH^{2+} + HL \underset{k_{46}}{\overset{k_{64}}{\rightleftharpoons}} Fe(H_2O)_5(OH)L^+ + H_2O + H^+$$

$$Fe(H_2O)_6^{3+} + HL \underset{k_{25}}{\overset{k_{52}}{\rightleftharpoons}} Fe(H_2O)_5L^{2+} + H_2O + H^+$$

$$Fe(H_2O)_5OH^{2+} + L^- \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} Fe(H_2O)_4(OH)L^+ + H_2O$$

The following reactions are relatively fast and the products and reactants are maintained close to equilibrium concentrations.

$$HL \rightleftharpoons H^+ + L^- \qquad Q_a$$

$$Fe(H_2O)_6^{3+} \rightleftharpoons Fe(H_2O)_5(OH)^{2+} + H^+ \qquad K_h$$

$$Fe(H_2O)_4(OH)L^+ + H^+ \rightleftharpoons Fe(H_2O)_5L^{2+}$$

On the basis of this scheme it follows that

$$\frac{dc}{dt} = k_f[Fe^{3+}][L^-] - k_b[FeL^{2+}]$$

where

$$[7] \quad k_f = k_{12} + k_{64}\frac{K_h}{Q_a} + k_{52}\frac{h}{Q_a} + k_{34}\frac{K_h}{h}$$

Noting that $k_f/k_b = K_{ass}$ and assuming that the concentrations of outer ion pairs

$$(Fe(H_2O)_6^{3+}.L)$$

is negligible relative to the concentration of reactants

$$\frac{dc}{dt} = k_f\frac{h}{K_h + h}T_m[L^-] - k_f\left(\frac{h}{K_h + h}[L^-] + \frac{1}{K_{ass}}\right)c$$

which on integration yields

$$-2.303 \log\frac{c_e - c}{c_e} = k_f\left(\frac{h}{K_h + h}[L^-] + \frac{1}{K_{ass}}\right)t$$

where c_e is the concentration of the complex at equilibrium. In terms of observables this becomes

$$[8] \quad -2.303 \log\frac{A_e - A_t}{A_e - A_0} = k_f\left(\frac{h}{K_h + h}[L^-] + \frac{1}{K_{ass}}\right)t$$

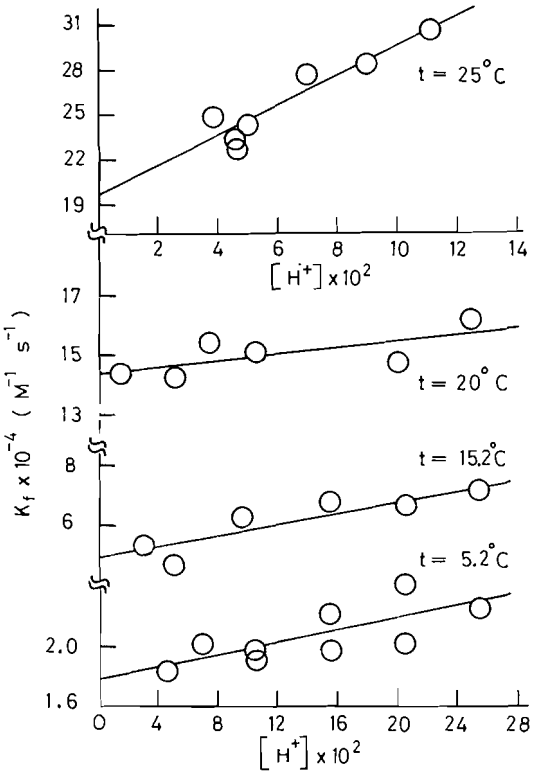

FIG. 1. Plot of forward rate constant k_f against hydrogen ion concentration.

where A_0 and A_e represent absorbances of the reacting solution initially and at equilibrium.

$$[L^-] = \frac{Q_a}{Q_a + h}(T_L - c) \sim \frac{Q_a}{Q_a + h} T_L$$

Consequently values for k_f may be estimated from the slope of the plot of $\log(A_e - A_t)$ against time.

From the exponential form of eq. 8, eq. 9 may be derived

$$[9] \quad A_t = A_e + (A_{t'} - A_e) \times \exp -k_f\left(\frac{h}{k_h + h} \cdot \frac{Q_a}{h} \cdot T_L + \frac{1}{K_{ass}}\right)(t - t')$$

where $A_{t'}$ and A_t are absorbances at times t' and t.

As has been pointed out by Guggenheim and Wiseman (19) it is statistically better to apply a least mean squares fit using the exponential relation rather than the logarithmic equation. Equation 9 is of the form $D = X + Ye^{-Zt}$ and we have used the procedure of Southworth and De Leeuw (20) to assess the values of Z and hence of k_f corresponding to a least mean squares fit of eq. 9 to the experimental data. The values of $h/(K_h + h)$ deviate from unity by at most 0.03 and were assigned a value of unity in all calculations.

A summary of the values of k_f is displayed in Fig. 1. The widest range of conditions were covered in the runs at 15.2 °C where T_m ranged from 0.505×10^{-3} to 6.88×10^{-3} M and T_L from 0.150 to 1.00 M. The data appear to show a linear dependence of k_f on h at each temperature, in consistency with the findings of Accascina, Cavasino, and Di Dio (which apply only to 20 °C) and we have therefore assumed that the term k_{34} in relation 7 is negligible, *i.e.* that

$$k_f = k_{12} + k_{64}\frac{K_h}{Q_a} + \frac{k_{52}}{Q_a} h = k_{intercept} + \frac{k_{52}}{Q_a} h$$

Table 4 contains values for $k_{intercept}$ ($= k_{12} + k_{64}K_h/Q_a$), values of k_{64} assuming that k_{12} is negligible and k_{52} estimated on the basis of the values of Q_a given in Table 1 with the value for 20 °C taken as 3.04×10^{-5} M and values for K_h of 0.67×10^{-3}, 1.18×10^{-3}, 1.51×10^{-3}, and 1.90×10^{-3} M at temperatures 5.2, 15.2, 20.0, and 25 °C, respectively. The values for K_h are based on the work of Connick and co-workers (13) with the values at 5.2 and 20 °C obtained by extrapolation and interpolation. Plots of $\log(k_{12}/T) - 1$ *vs.* $1/T$ (assuming $k_{12} = k_{intercept}$) and $\log(k_{64}/T)$ *vs.* $1/T$ (assuming k_{12} is negligible) are shown in Fig. 2. If the data for 20 °C be included, the deviation from linearity is considerable and the values for k_{64} for 20 and 25 °C show an anomalous temperature dependence. Values for the kinetic parameters obtained from lines of regression through the datum points for all four temperatures are: $\Delta H^{\ddagger}_{12} = 20.3 \pm 2.0$ kcal mol^{-1}, $\Delta S^{\ddagger}_{12} = 33.7 \pm 6.6$ cal deg^{-1} mol^{-1}, $\Delta H^{\ddagger}_{64} = 11.1 \pm 2.2$ kcal mol^{-1}, and $\Delta S^{\ddagger}_{64} = 5.4 \pm 7.0$ cal deg^{-1} mol^{-1}. The values of k_{52} also show considerable dispersion with the value applying to 20 °C deviating markedly from a moderately linear set for the other three datum points as if the intercept were too high and the slope too low. The line of regression through all four points yields a value for $\Delta H^{\ddagger}_{52}$ of 26 ± 12 kcal mol^{-1}.

TABLE 4. Formation rate constants for the complex $Fe(CH_3.COO)^{2+}$ (M^{-1} s^{-1}); ionic strength = 0.50 M

Discussion

Our data for acetic acid were obtained under conditions (ionic strength 0.50) different from those used by Accascina, Cavasino, and Di Dio (ionic strength 1.0) (6) but are consistent with those data and support the hypothesis that the dominant reaction for the acid independent path involves FeOH and HL reacting by an I_d mechanism. The magnitudes of $k_{intercept}$ at 20 and 25 °C (14×10^4 and 19×10^4 M^{-1} s^{-1}) are much greater than the values attributed to the reactions where the dominant path is assumed to involve Fe^{3+} and L^- (5) *e.g.* 9.4 M^{-1} s^{-1} for $Fe^{3+} + Cl^-$ at 25 °C and ionic strength 1.0 (21) and 20 M^{-1} s^{-1} for $Fe^{3+} + Br^-$ at 25 °C and ionic strength 1.7 (22). If the assumptions are made that $k_{intercept} = k_{12} + k_{64}K_h/Q_a$ and that k_{12} is of the same order of magnitude as k_{12} ($=k_{intercept}$) for the reactions of iron(III) with chloride and bromide, it is apparent that the term involving k_{64} is the dominant one.

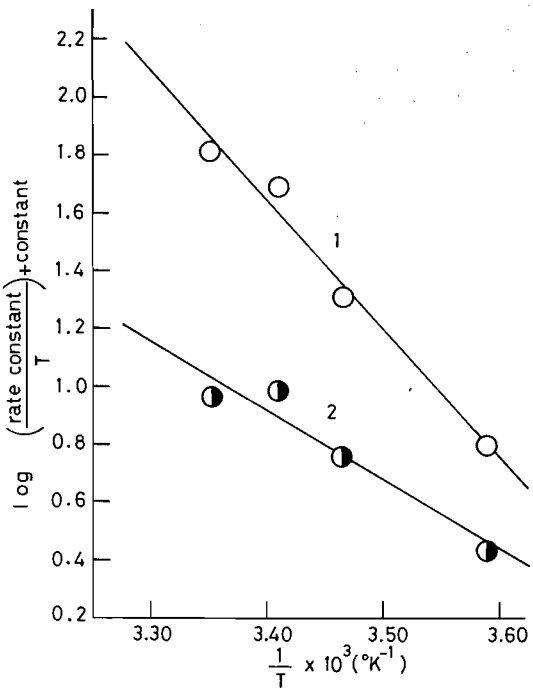

FIG. 2. Modified Arrhenius plots: (*1*) ○ plot of $\log (k_{12}/T) - 1$ against $1/T$ (values of ordinate displaced by 1 for clarity); (*2*) ◑ plot of $\log (k_{64}/T)$ against $1/T$.

The values of the first-order rate constants for collapse of the outer ion pairs (k_{012} and k_{064}) may be roughly estimated using the relations $k_{012} = k_{12}/K_{12}$ and $k_{064} = k_{64}/K_{64}$ and values $K_{12} \sim 2.3$ M^{-1} and $K_{64} \sim 0.3$ M^{-1} estimated from the Fuoss–Eigen relationships (23, 2). The value for k_{012} is substantially in excess of a recent value of 150 s^{-1} for the first-order rate constant for water exchange on $Fe(H_2O)_6^{3+}$ (9). The value for k_{064} (about 9×10^3 s^{-1}) is fairly close to the value to be anticipated for the rate constant for water exchange on $Fe(H_2O)_5OH^{2+}$ if one assumes as does Connick and Genser (4) that the rate constant for water exchange on $Fe(H_2O)_5(OH)^{2+}$ should be higher than that for water exchange on $Fe(H_2O)_6^{3+}$ by a factor of about 10^2.

Although the dispersion from linearity in the plot of $\log k_{52}$ *vs.* $1/T$ is large with the value for 20 °C anomalously low, the values of k_{52} are in the range of values for k_{12} associated with reactions of $Fe(H_2O)_6^{3+}$ with charged and uncharged ligands. The temperature coefficient for k_{52} and the associated value of $\Delta H^{\ddagger}_{52}$ (26 ± 12 kcal mol^{-1}) is, however, higher than would be anticipated for a reaction of such a nature (*i.e.* ~ 16 kcal mol^{-1}). A temperature coefficient for the slope of the plot of k_f *vs.* h, which is higher than that to be anticipated from any of the previously mentioned single mechanisms, could occur if with decrease in temperatures over the lower range of acidities there was increasing contribution to k_f from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

term involving k_{34}. Such a contribution should yield a curvature as well as a reduction in the slopes (24, 6) which if more marked at lower temperatures would yield abnormally high estimates for $\Delta H^{\ddagger}_{52}$. Such curvature is not clearly indicated by our data. However, the dispersion of the data along with the restricted range of hydrogen ion concentrations covered are such as to prevent adequate assessment of such a hypothesis or to attain acceptable precision in the estimates of the slopes.

In summary, our data support the assumption of Cavasino and co-workers (6) that the dominant component of the acid independent reaction yielding the mono acetato complex of iron(III) involves $FeOH^{2+}$ and CH_3COOH reacting by an I_d mechanism. However, data covering wider ranges of acidity and of higher precision are required to adequately assess the character of the acid dependent components.

Mössbauer and Infrared Spectra of Octahedral Complexes of Iron(II) Halides with Amides and Related Ligands

T. BIRCHALL AND M. F. MORRIS

Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 26, 1971

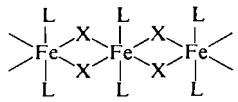
A number of complexes of $FeCl_2$ and $FeBr_2$ with amides, ureas, aniline, and benzothiazole have been prepared and characterized by means of Mössbauer and i.r. spectroscopy, and magnetic measurements. The stoichiometries FeX_2L, FeX_2L_2, FeX_2L_3, FeX_2L_4, and FeX_2L_6 have been found in which the iron is six coordinate. With the exception of an isobutyramide complex which is formulated as $[Fe(BUA)_6][FeCl_4]$, complexes of the first three types are polymeric with bridging halogens, while FeX_2L_4 is monomeric and FeX_2L_6 is formulated as $[FeL_6]Cl_2$.

Certains complexes de $FeCl_2$ et $FeBr_2$ avec les amides, l'urée, l'aniline et le benzothiazole ont été préparés et caractérisés au moyen de la spectroscopie Mössbauer et infrarouge et par des mesures magnétiques. Les stoechiométries de FeX_2L, FeX_2L_2, FeX_2L_3, FeX_2L_4 et FeX_2L_6 ont été déterminées et il apparaît que le fer y est six fois coordonné. A l'exception d'un complexe avec l'isobutyramide qui est formulé comme $[Fe(BUA)_6][FeCl_4]$, les complexes des trois premiers types sont polymériques avec des ponts halogène, alors que FeX_2L_4 est monomérique et que FeX_2L_6 est formulé comme $[FeL_6]Cl_2$.

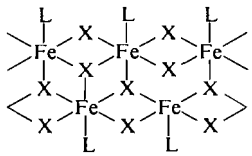
Canadian Journal of Chemistry, **50**, 201 (1972)

Introduction

Recent studies of iron(II) complexes FeX_2L_n show increasing evidence for polymeric halogen bridged structures, at least among 6-coordinate species. It has been shown (1) by X-ray diffraction methods that $FeCl_2 \cdot 2H_2O$ has the 6-coordinate polymeric chain structure **1**. $FeCl_2 \cdot 2NH_3$ and $FeBr_2 \cdot 2NH_3$ are also thought to have this structure (2), as are the $FeCl_2L_2$ complexes where L = methylcyanide (3), pyridine (4), and benzothiazole (5). It was suggested in a recent Mössbauer study (6) that the complexes $FeCl_2L_2$ (L = formamide, acetamide) also occur as the linear polymer **1**. A 1:1 pyridine complex $FeCl_2(py)$ is thought to be octahedral (7) with an extensively chlorine bridged structure such as **2**.



1



2

Polymers **1** and **2** may be thought of as derivatives of the anhydrous ferrous chloride structure in which iron is 6-coordinate and all chlorines are shared (8).

In this study a number of ferrous halide complexes with amide and urea ligands are investigated by means of Mössbauer, i.r. spectroscopy, and magnetic measurements. Complexes with aniline and benzothiazole are also investigated. Among these complexes a pronounced tendency to form halogen bridged polymers is found.

Experimental

Preparations

With the exception of $FeCl_2(BTH)_2$, $FeCl_2(UREA)_2$, $FeBr_2(DMU)_3$, and $FeCl_2(AN)_3$ all the complexes were prepared by the method of Singh and Rivest (9), alternate procedures for $FeCl_2(FA)_2$, $[Fe(MU)_6]Cl_2$, and $FeCl_2(DMU)_3$ were also used and are described below. $FeCl_2(BTH)_2$ was prepared by the method described by Chan *et al.* (5). Preparation of these samples, filtering, and washing of products, was carried out under nitrogen in a dry box. Products were white or colorless crystals except for the benzamide complex which was a white spongy material. Analytical data are presented in Table 1, where BTH = benzothiazole; FA = formamide; MFA = *N*-methylformamide; DMFA = *N,N'*-dimethylformamide; AM = acetamide; BM = benzamide; BUA = isobutyramide; MU = *N*-methylurea; DMU = *N,N'*-dimethylurea; AN = aniline.

Dichlorobisurea Iron(II)

A solution of 1.5 g ferrous chloride in 10 ml absolute ethanol was shaken with powdered iron until green. It was centrifuged, and the supernatant liquid poured into a solution of 2 g urea in ethanol. A precipitate formed in about 2 h, was filtered, washed with ether, and dried *in vacuo*.

$FeBr_2(AN)_3$	11.29	11.66		

Dichlorotetrakisformamide Iron(II)

A solution of 1.5 g anhydrous ferrous chloride in 10 ml absolute ethanol was prepared as above and poured into 2 g formamide. White crystals gradually formed and were filtered, washed with chloroform, and dried *in vacuo*.

Dichlorotris-N,N'-dimethylurea Iron(II)

A solution of 1.5 g anhydrous ferrous chloride in 10 ml acetone was prepared as above and poured into a solution of 3 g *N,N'*-dimethylurea in acetone. The mixture was then poured into 100 ml absolute ether. A white powder precipitated which was filtered, washed with chloroform and dried *in vacuo*.

Hexakis-N-methylurea Iron(II) Chloride

A solution of 1.24 g ferrous chlorine in 10 ml acetone was prepared as above and poured into a solution of 2 g *N,N'*-dimethylurea in acetone. A buff colored precipitate separated gradually, which was filtered, washed with acetone, and dried *in vacuo*.

Dibromotrisaniline Iron(II)

A solution of 1.25 g ferrous bromide in 20 ml absolute ethanol was shaken with powdered iron until green. It was filtered into 2.4 g aniline. A pale green precipitate formed which was filtered, washed with cold ethanol, and dried *in vacuo*.

Materials

All solvents were reagent grade which were dried and deoxygenated before use. Iron pentacarbonyl and tri-iron dodecacarbonyl were obtained from Alfa Inorganics and were used without further purification. All ligands were reagent grade and were used without further purification.

Mössbauer Spectra

Mössbauer spectra were recorded with an Austin Science Associates model S3 drive System used in conjunction with a Victoreen PIP400A multichannel analyzer operating in multiscalar mode. The source was ^{57}Co in a palladium matrix, obtained from the New England Nuclear Corporation. The strength of the source was approximately 5 mC. The 14.4 keV γ-ray was detected in the initial stages of the work by a thin 1/32 in. NaL(TL) activated crystal with matching photomultiplier tube manufactured by the Harshaw Chemical Company. In the later stages of the work a gas filled proportional counter was used: the filler gas was $Xe–CO_2$ at 1 atm pressure. Spectra with baselines of approximately 50 000 counts accumulated in about 6 h using the proportional counter. Samples generally contained 10 to 15 mg/cm^2 of iron. Complexes containing bromine showed very low count rates and small peak intensities. These were diluted to as little as 6 mg/cm^2 of iron in order to improve the spectra. Spectra were recorded at 295 and 77 °K.

The absorption envelopes were fitted to Lorentzian line shapes using an iterative least squares method. The velocity scale was calibrated with a sodium nitroprusside absorber and all isomer shifts are quoted with respect to the centroid of the sodium nitroprusside spectrum. The data are thought to be accurate to ± 0.02 mm/s.

Infrared Spectra

Infrared spectra in the 400–4000 cm^{-1} region were recorded on a Perkin–Elmer 521 Grating Infrared Spectrophotometer. Solid samples of ligands and complexes were recorded as Nujol or fluorolube mulls between KBr windows. Liquid samples of ligands, and solutions of ligands in dioxane, were also recorded between KBr windows in a normal i.r. cell.

Far i.r. spectra in the region 200–400 cm^{-1} were recorded as Nujol mulls between polyethylene windows on a Beckman IR 12 instrument.

Magnetic Measurements

Magnetic susceptibilities were measured by the Gouy balance method on equipment already described (10).

Results and Discussion

Mössbauer Spectra

Isomer Shift

The Mössbauer data are given in Table 2. The isomer shifts are, with one exception, greater than 1.35 mm/s, clearly in the range

expected for complexes of iron(II) (6, 11). In addition to providing information about oxidation state, this parameter can also yield useful information about coordination number. For example a decrease in isomer shift on lowering the coordination number has been observed by several workers for iron(II) (12, 13). The effect is also evident in comparing isomer shifts of a number of tetrahedral (14–16) and octahedral iron(II) complexes (6, 17–20). These data show that shifts of 1.3 mm/s, or less, are usually characteristic of tetrahedral iron(II), while shifts greater than 1.3 mm/s are characteristic of octahedral iron(II). The benzothiazole complex (Table 2) is exemplary of this effect. It has been assigned a 6-coordinate polymeric structure on the basis of its electronic spectrum (5) and its isomer shift is 1.36 mm/s. The bromo analogue $FeBr_2(BTH)_2$ is tetrahedral (5) and has an isomer shift of 1.05 mm/s. Since the isomer shifts (Table 2) for the FeX_2L_n complexes are all greater than 1.35 mm/s, it seems reasonable to conclude that in these complexes the iron is 6-coordinate.

The isobutyramide complex differs somewhat from the rest in that it has two different iron environments. The three line Mössbauer spectrum (Fig. 1) is interpreted in terms of two

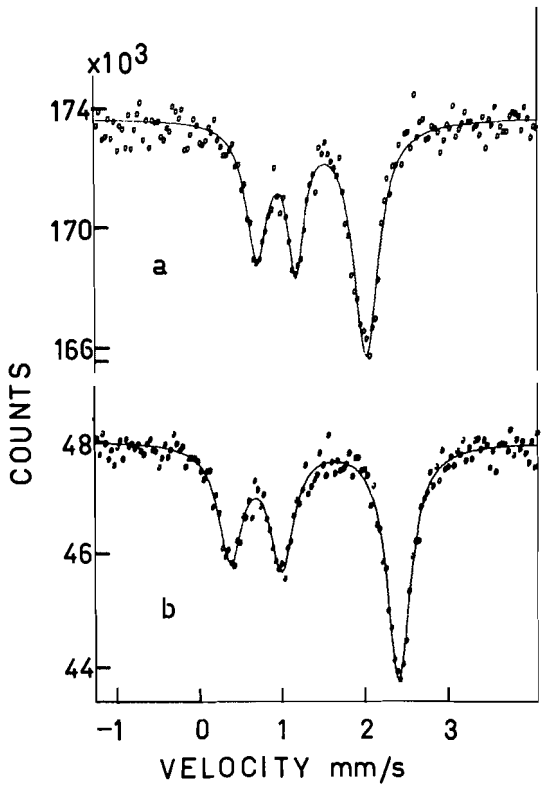

FIG. 1. Mössbauer spectrum of $[Fe(BUA)_6][FeCl_4]$ at (*a*) 195 °K (*b*) 77 °K.

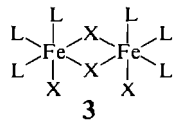
iron sites each one giving rise to a quadrupole split doublet, with the high velocity lines of each doublet coincident. The relative peak intensities at 77 °K indicates that the two sites are of equal abundance. This complex has been formulated as $[Fe(BUA)_6^{2+}][FeCl_4^{2-}]$. The doublet with larger isomer shift (1.62 mm/s at 77 °K) is assigned to the 6-coordinate cation, while the doublet of lower isomer shift is assigned to the tetrachloroferrate(II) anion. This latter value agrees well with literature values for other tetrachloroferrate(II) complexes (11, 21). Absorption by the tetrahedral species is negligible at room temperature and explains why the spectrum apparently collapses to a doublet. The methylurea complex, like the 6-coordinate cation in the isobutyramide complex, has an isomer shift significantly larger than the other complexes. We have formulated this complex as $[Fe(MU)_6]Cl_2$. While the Mössbauer, and the i.r. evidence presented below, indicate an ionic formulation for these complexes, conductivity measurements could have provided the necessary confirmation. Unfortunately these, and the other complexes investigated, do not appear to be stable in solvents in which they are soluble and conductivity data are therefore not available.

With the two exceptions discussed above, the complexes investigated are believed to be non-ionic. Since the Mössbauer isomer shift data indicate that the iron atoms are 6-coordinate, it is necessary to postulate polymeric structures for the remainder, with the exception of $FeCl_2(FA)_4$. Such polymers can be visualised as having the $FeCl_2$ structure (8), in which halogens are successively replaced by ligand to achieve the required stoichiometry. The simplest of these would be the $FeCl_2L_2$ complexes in which two bridging chlorines are replaced by two ligands, *trans* to one another as in **1** (1–6). Addition of two more ligands would break the remaining halogen bridge bonds and give a $FeCl_2L_4$ monomeric complex in which the halogens are presumably *trans*. $FeCl_2(FA)_4$ would have this structure.

The 1 : 1 complexes $FeCl_2 \cdot BM$ and $FeCl_2 \cdot AN$ are believed to be cross-linked polymers such as **2** in which only one bridging chlorine in the $FeCl_2$ structure has been replaced. It has been suggested (6) that these complexes might be chlorine bridged dimers, containing 4-coordinate iron, but this now seems to be most unlikely because of the magnitude of the isomer shifts and the supporting evidence presented below.

The complexes $FeCl_2(DMU)_3$, $FeBr_2(DMU)_3$, and $FeBr_2(AN)_3$ have been assigned dimeric chlorine bridged structures such as **3**,



3

which is one of several possible isomers. The Mössbauer spectra show peaks attributable to only one kind of iron. However, the presence of more than one geometrical isomer in these compounds cannot be ruled out since the various possible arrangements may not have very different Mössbauer parameters. The ionic formulation $[FeL_6][FeX_4]$, analogous to the isobutyramide complex, can however be eliminated.

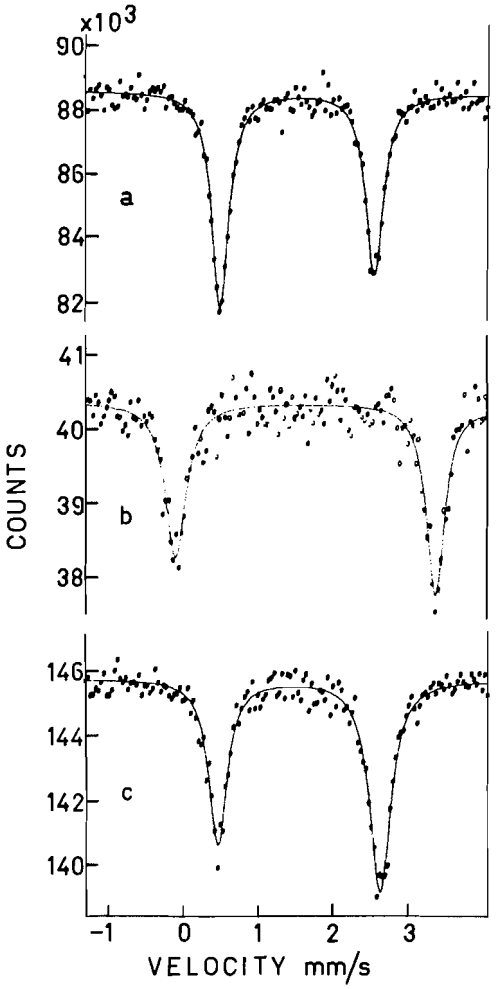

FIG. 2. Mössbauer spectrum at 77 °K of (*a*) $FeBr_2(AN)_3$ (*b*) $FeCl_2(DMU)_3$ (*c*) $FeBr_2(DMU)_3$.

No peaks attributable to the $[FeX_4]^{2-}$ anions could be detected in the spectra of these complexes (Fig. 2, Table 2) even at 77 °K at which temperature $[FeX_4]^{2-}$ peaks were clearly visible in the isobutyramide compound.

Edwards *et al.* (11) have noted an increase in isomer shift in the series $FeCl_2$, $FeCl_2 \cdot 2H_20$, $FeCl_2 \cdot 4H_2O$ in which H_2O replaces the bridging chlorine. They attributed this to the greater polarizability of the chlorine compared to the extra ligand. Allowing for the large variation in isomer shift for the $FeCl_2L_2$ complexes, we note a similar trend to more positive isomer shift as the six chlorines about the iron in $FeCl_2$ are successively replaced by amide ligands.

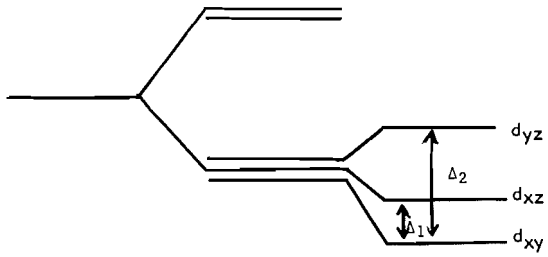

FIG. 3. Representation of the energy levels of the d orbitals in a distorted octahedral field.

Quadrupole Splitting

With the exception of the benzothiazole complex, the polymeric complexes $FeCl_2L_2$ all have room temperature quadrupole splittings in the range 2.5–3.0 mm/s and show small increases (Table 2) upon cooling to 77 °K. The fact that the splittings are all greater than 2 mm/s suggests that, in these complexes, if the *z*-axis is the O—Fe—O axis, then the d_{xy} orbital lies lowest (17). This is known to be so for $FeCl_2 \cdot 2H_2O$. Johnson (22) has studied the Mössbauer spectrum of a single crystal of this compound at 4.2 °K and 1.4 °K and concludes that the direction of maximum electric field gradient is the O—Fe—O axis. This is confirmed by the crystallographic data (1) which shows Fe—O bond lengths of 2.07 Å and Fe—Cl bond lengths of 2.49 and 2.54 Å. The observation of only a small temperature dependence in the quadrupole splittings of the $FeCl_2L_2$ complexes indicates that distortional splittings in the t_{2g} levels are of considerable size. The quadrupole splitting of $FeCl_2 \cdot 2H_2O$ shows similar behavior. Johnson (22) estimates $\Delta_1 = 520\ cm^{-1}$ and Δ_2 large with respect to the spin–orbit coupling constant of about 100 cm^{-1} (Fig. 3). The much smaller quadrupole splittings (1.46 and 1.76 mm/s at 295 °K and 77 °K, respectively) in the benzothiazole complex may be evidence for a d_{xz} or d_{yz} ground state in this compound.

The quadrupole splittings of the 1:4 formamide complex is unusually small. This, together with the large temperature dependence (Fig. 4) Table 2) points to a nearly regular octahedral structure with only small distortional splittings in the t_{2g} levels. The small value could also be due to a structure in which d_{xz} and d_{yz} lie lowest. This data suggests that the structure of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

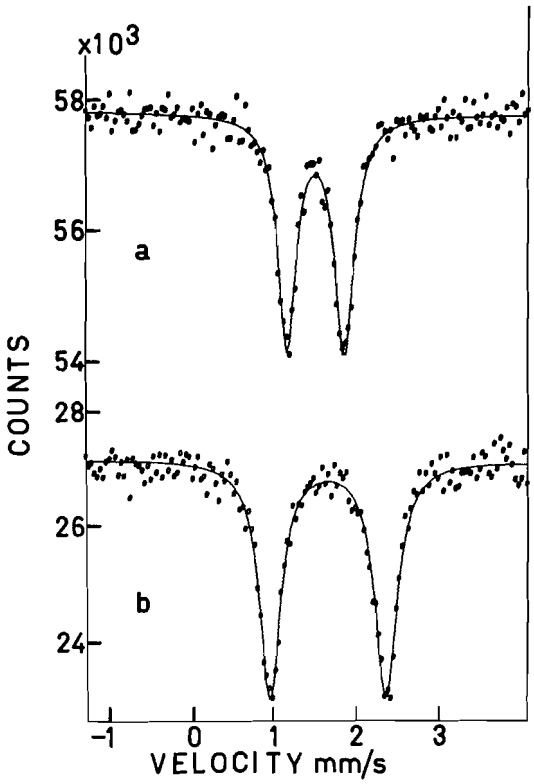

FIG. 4. Mössbauer spectrum of $FeCl_2(FA)_4$ at (*a*) 295 °K, (*b*) 77 °K.

the 1:4 formamide complex is indeed significantly different from that of $FeCl_2 \cdot 4H_2O$, for which Grant *et al.* (23) report a room temperature quadrupole splitting of 2.98 mm/s and almost negligible temperature dependence. The crystal structure (24) of $FeCl_2 \cdot 4H_2O$ shows it to have a distorted 6-coordinate *trans* structure in which Fe—Cl = 2.38, Fe—O = 2.09, and 2.59 Å, and the angle Cl—Fe—O = 81°.

The tetrachloroferrate(II) anion in the isobutyramide complex shows quadrupole splittings of 1.28 and 2.0 mm/s at 195 °K and 77 °K, respectively. The distortional splitting in the e_g levels, as calculated by the method of Edwards *et al.* (11) is 185 cm^{-1} for this complex. Presumably the bulky $Fe(BUA)_6^{2+}$ cation produces a greater distortion than do NMe_4^+ and NEt_4^+ (11, 21).

The octahedral cation $Fe(BUA)_6^{2+}$ shows quadrupole splittings of 0.82 and 1.40 mm/s at 195 °K and 77 °K, respectively. These values indicate a near cubic environment about iron and the possibility of a doublet ground state in the d-levels. The methylurea complex, suggested as containing the octahedral cation $Fe(MU)_6^{2+}$ has somewhat larger quadrupole splittings but is still within the region expected for a d_{xz} or d_{yz} ground state.

The 1:3 bromides show very similar quadrupole splittings which are smaller and less temperature dependent than those for the 1:3 chloride $FeCl_2(DMU)_3$. This may be due to a difference in d-orbital ground state or to increased covalency in Fe—Br bonds. In addition the quadrupole splitting in these complexes will depend upon η, the asymmetry parameter, which will now be none zero since these complexes are no longer axially symmetric.

One further point of interest from the data in Table 2 is that a number of the quadrupole split doublets have unequal intensities. This asymmetry could arise for one or more of the following reasons: (*i*) sample impurities, (*ii*) preferred crystal orientation, (*iii*) spin–lattice or spin–spin relaxation processes, and (*iv*) a Goldanskii–Karyagin effect. The first can be discounted on the basis of the analytical data and on the fact that the iron impurity would have to have quite unrealistic Mössbauer parameters in order to overlap only one of the doublet peaks. Asymmetry due to preferred crystal orientation is most unlikely since the compounds were extremely finely divided and the spectra are temperature dependent. Relaxation effects are discounted because of the sharpness of the lines < 0.3 mm/s. The most likely cause of the asymmetry would appear to be the Goldanskii–Karyagin effect (25) which is due to anisotropy of the recoil free fraction arising from a stiffening of the bonding in one direction compared to that in another. This is not unreasonable for compounds of this nature which are chain polymers. It is interesting to note that the most marked asymmetry occurs with the *N*-substituted ligands and is in the opposite sense (Fig. 2) to that for the $FeCl_2(BTH)_2$ and $FeBr_2(AN)_3$ complexes, in which the organic ligand is *N*-coordinating: the amides and ureas are O-coordinating (see i.r. data).

Infrared Spectra

The i.r. spectra in the region 1000–4000 cm^{-1} of the amide and urea ligands and their complexes have been set out in Tables 3–11 which

TABLE 12. Far infrared bands of the amide and urea complexes*

*Parentheses denote unassigned frequencies.

have been placed in the Depository of Unpublished Data.[1] Since the region from 400 to 1000 cm^{-1} provided little in the way of useful structural information the bands in this region have not been included. Significant shifts to lower frequency are seen, particularly in the N—H and C=O stretching bands, on going from a dilute solution of the ligand to the neat or mulled form, due to hydrogen bonding effects and comparisons have therefore been made between the complex and its ligand in dilute solution.

Bands arising from N—H, C=O, and C—N stretching, and NH_2 bending vibrations, which occur in the 1000–4000 cm^{-1} region, can all provide information about the mode of coordination of the ligand to the metal. If coordination were through the nitrogen one would expect a significant shift of the N—H band to lower frequency and this is not observed. In addition coordination through N would result, for the urea complexes, in two different kind of nitrogens and hence different N—H stretching bands. No change in overall peak pattern is observed and only one strong N—H stretching band is noted in this region. A further general observation regarding these N—H bands is that they often occur at lower frequency in the complex than when the ligand is in a dilute solution, but at higher frequency when in the pure or mulled form. This suggests that some hydrogen bonding is still effective in the coordinated ligand. Singh and Rivest (9) suggested that hydrogen bonding may occur between the amide hydrogens and the halogen.

That the carbonyl bands are in all cases shifted 30–60 cm^{-1} to lower frequency, provides firm evidence for coordination through oxygen in these complexes. Negative shifts in NH_2 bending frequencies are observable in all except the *N*-methylformamide case, and this gives additional support to coordination through oxygen.

Bands of C—N stretching character are expected to shift to higher frequency if coordination takes place through oxygen. This is the case for all but the *NN'*-dimethylformamide complex, where the peak at 1500 cm^{-1}, assigned as ν(C—N) in the ligand, appears at 1490 cm^{-1} in the complex. In view of the difficulties involved in unequivocally assigning bands in these complex systems the evidence presented above seems fairly conclusive of coordination through oxygen in all of these complexes.

An i.r. study of the aniline and benzothiazole complexes in the 400–4000 cm^{-1} region was not carried out. Aniline is a nitrogen coordinating ligand and it has been suggested by Chan *et al.* (5) that benzothiazole also coordinates through nitrogen.

The far i.r. bands of the amide and urea complexes are listed in Table 12. The similarity of

the spectra of the 1:2 complexes is evident. It is proposed that all of these are 6-coordinate chlorine bridged complexes. Four bands, generally poorly resolved, appear in most cases between 180 and 260 cm^{-1}. Gill *et al.* (4) have observed a similar far i.r. spectrum for the polymeric octahedral complex $FeCl_2(py)_2$ and report three poorly resolved peaks at 238, 227, and 219 cm^{-1}.

The spectra of these 1:2 complexes are strikingly different from tetrahedral 1:2 complexes which show strong, well resolved Fe—Cl stretching bands close to 300 cm^{-1} (16, 26). The shift of the ν(Fe—Cl) absorption region to lower frequency in the polymeric complexes is attributed to the weaker bridged chlorine bonds. Assignment of separate Fe—Cl of Fe—O stretching character to the peaks has not been attempted since it is expected that these vibrations will be strongly coupled.

It is noteworthy at this point to mention the ν(Fe—Cl) and ν(Fe—O) band assignments made by Singh and Rivest (9) for $FeCl_2(FA)_2$, $FeCl_2(MFA)_2$, and $FeCl_2(AM)_2$. These workers assign Fe—Cl stretches to bands between 350 and 380 cm^{-1}. Based on assignments made here and elsewhere (26–28), it is thought that this region is too high for Fe—Cl stretching in iron(II) complexes, even if these complexes were tetrahedral as claimed by Singh and Rivest (9). Rather Fe—Cl stretching in this region is indicative of iron(III), and it is possible that their complexes (9) may have been at least partially oxidized. Assignment of Fe—O stretching to bands between 400 and 475 cm^{-1} by these workers (9) is also questioned. Little information is available on iron(II) complexes with oxygen coordinating ligands. However, Kermarrec (29) reports Fe—O stretching at 357 cm^{-1} for $[Fe(H_2O)_6][SiF_6]$. Coordinated bonds with amides would be expected to be weaker than with water as a result of lower Lewis basicity, and (Fe—O) absorption should accordingly be at lower frequency (see below).

The 1:1 benzamide complex gives a spectrum very similar to those observed for the 1:2 complexes with an additional band at 291 cm^{-1}. The bands between 180 cm^{-1} are assigned as ν(Fe—O), bridged ν(Fe—O), and bridged ν(Fe—Cl) vibrations, as for the 1:2 complexes, in keeping with the polymeric structure **2** proposed for this complex. The band at 291 cm^{-1}, however, suggests that at least one of the Fe—Cl bonds is short and has essentially non-bridged character.

The complex $FeCl_2(DMU)_3$ shows a peak at 280 cm^{-1} which is attributable to free Fe—Cl stretching as well as peaks at 255 cm^{-1} and 203 cm^{-1} attributable to bridged Fe—Cl stretching and Fe—O stretching. This is consistent with the proposed structure **3** of this complex. The analogous bromide complex shows a single band at 220 cm^{-1} which is probably a strongly coupled Fe—Br and Fe—O stretching mode. Absorption due to bridged bromine bonds is expected to occur below 200 cm^{-1} (26).

The 1:4 formamide complex shows only broad, unresolved absorption between 200 and 275 cm^{-1} in the far i.r. Although Fe—Cl stretching is expected to occur in this region for monomeric octahedral complexes (26), no further interpretation was possible. $FeCl_2(MU)_6$ shows two peaks at 234 and 196 cm^{-1}. If this complex is $[Fe(MU)_6]Cl_2$, as proposed, then these must be Fe—O vibrations. The isobutyramide complex, formulated as $[Fe(BUA)_6][FeCl_4]$, shows a strong peak at 285 cm^{-1} assigned as ν(Fe—Cl) and a weak peak at 220 cm^{-1} assigned as ν(Fe—O). Clark and Dunn (29) observe ν(Fe—Cl) at 282 cm^{-1} in $[NEt_4]_2[FeCl_4]$.

Magnetic Moments

The magnetic moments of some of the amide and urea complexes are shown in Table 13. The room temperature moments are for the most part much larger than the spin only magnetic moment of 4.90 β. This indicates considerable orbital contribution, as is expected to occur in high spin octahedral iron(II) compounds in which the splitting in the t_{2g} levels is not large.

In all the complexes except $FeCl_2(AM)_2$ the magnetic moments show an abnormally large temperature dependence, dropping to values which are near the spin only values at 77 °K. Golding *et al.* (37) have calculated the temperature dependence of the magnetic moment of high spin iron(II) for various values of Δ, the distortional splitting in the t_{2g} levels, and λ, the spin–orbit coupling constant. Their calculation is based on the assumption that Δ and λ themselves do not vary with temperature. From

TABLE 13. Magnetic moments of amide and urea complexes

Complex	Temperature (°K)	$\mu_{eff}(\beta)$
$FeCl_2(AM)_2$	295	5.50
	77	5.32
$FeCl_2(UREA)_2$	295	5.45
	77	5.01
$FeCl_2(MFA)_2$	295	5.63
$FeCl_2(FA)_4$	295	5.46
	77	4.84
$FeCl_2(BM)$	295	5.34
	77	4.95
$FeCl_2(DMU)_3$	295	5.47
	77	5.04
$[Fe(MU)_6]Cl_2$	295	5.45
	77	4.93

their calculated curves it would appear that for moderate Δ values considerable orbital contribution to the magnetic moment should remain at 77 °K. It is therefore suggested that there may be some temperature dependence of Δ and/or λ in the present case.

Golding *et al.* (37) have also calculated a relationship between magnetic moment and quadrupole splitting for high spin iron(II) compounds in which d_{xy} lies lowest. Some of the data from this study have been compared with their calculated curve for the room temperature case in which λ is given its free ion value. Agreement with the curve, even when errors in the quadrupole splittings and magnetic moments are allowed, is not especially good, possibly indicating that the assumption of free ion spin–orbit coupling is a poor one. The 1:4 formamide and 1:6 *N*-methylurea complexes, in particular, show deviations from this curve, but as suggested earlier these complexes may have a d_{xz}, d_{yz} rather than a d_{xy} ground state.

The temperature variation of the magnetic moments could also be the result of some antiferromagnetic interaction between the iron atoms in these polymeric species, but a more comprehensive study would be needed to confirm this.

We thank the National Research Council of Canada for financial support.

Mössbauer and Infrared Spectra of Tetrahedral Complexes of Iron(II) Halides with Thioamides and Related Ligands

T. BIRCHALL AND M. F. MORRIS

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 27, 1971

A number of complexes of iron(II) halides with thioamides and ureas have been prepared and characterized by means of Mössbauer, infrared spectroscopy, and magnetic measurements. These complexes are shown to have distorted tetrahedral structures.

Un certain nombre de complexes d'halogénure de fer(II) avec les thioamides et les urées ont été préparés et caractérisés par spectroscopie Mössbauer, infrarouge et par des mesures magnétiques. Il est montré que ces complexes possèdent une structure tétrahédrique distordue.

Introduction

Tetrahedral complexes of iron(II) $[FeX_4]^{2-}$ where X = Cl, Br, NCS etc. have been characterized by means of their electronic spectra (1–6) and more recently by Mössbauer spectroscopy (7, 8). This latter technique has been invaluable in detecting Jahn Teller distortion Δ (Fig. 1) in these symmetrically substituted anions. The first estimate of the extent of distortion on $[FeCl_4]^{2-}$ was made by Gibb and Greenwood (7) and was obtained from an analysis of the temperature dependence of the quadrupole splitting parameter. Edwards *et al.* (8) have carried out similar studies on other tetrahedral Fe(II) salts and have shown that the ground state orbital in $[Me_4N]_2FeCl_4$ is the d_{z^2} orbital.

Complexes of the type FeX_2L_2 are also known where X = halogen and L = pyridine and substituted pyridines (1), triphenylphosphine (9, 10), triphenyl arsine (2), quinoline and 3-methylisoquinoline (11), benzothiazole (3), thioacetamide (12–14), and thiourea (15). With this stoichiometry (FeX_2L_2) it is, however, not necessary that the environment about the iron be tetrahedral. Polymerization can occur, via bridging halogen, to give an iron environment which is octahedral rather than tetrahedral. This has recently been demonstrated for a number of amide complexes of Fe(II) by means of Mössbauer spectroscopy (16, 17).

We wish to report here the preparation of some tetrahedral complexes of iron(II) with some thio-ligands and their characterization by means of Mössbauer, infrared, and magnetic measurements.

Experimental

Preparation of Complexes

A solution of 1.5 g ferrous chloride in 10 ml of either acetone, or ethanol, was shaken with powdered iron until green, centrifuged, and the supernatant liquid poured into a solution of ~3 g of the ligand in either acetone or ethanol. The complexes precipitated immediately, or on cooling in an ice bath, and were filtered, washed with solvent, and dried *in vacuo*.

All solvents were reagent grade and were dried and deoxygenated before use. All ligands were reagent grade and used without further purification. Thioacetamide (THA) and thiourea (THU) were obtained from Fisher Scientific Co., benzothiazole (BTH) from Eastman Organic Chemicals, *N,N*-dimethylthiourea (DMTHU) from Aldrich Chemical Co., and *N*-methylthiourea (MTHU) from K & K Laboratories. The preparation, filtering, washing of products and spectroscopic sample preparation were all carried out under nitrogen in a dry box.

Analysis

Chlorine was determined by the Volhard method, iron as

ferric oxide and sulfur by the barium sulfate method. Analytical data are presented in Table 1.

Mössbauer spectra were recorded as previously described (16, 17). The drive system was calibrated by a standard sodium nitroprusside absorber and all shifts are relative to the center of the sodium nitroprusside doublet as zero velocity. Spectra were computer fitted to Lorentzian line shapes.

Infrared spectra were recorded on Perkin–Elmer 521 and Beckman IR 12 instruments. Magnetic susceptibilities were measured by the Gouy method.

Results and Discussion

Iron(II) halides form 1:2 complexes with many ligands in which the coordination number about the central iron may be either six or four. When the ligand is benzothiazole an octahedral complex is formed with $FeCl_2$, while $FeBr_2$ gives a tetrahedral complex (3). The structures of these complexes are based on an analysis of their electronic spectra. Dichlorbisbenzothiazoleiron-(II) has two low intensity bands at 9050 and 6600 cm^{-1} (3) similar to those found for $FeCl_2$-(pyridine)$_2$ which has an octahedral chlorine bridged polymeric structure (18). The analogous bromide, $FeBr_2(BTH)_2$, was found to have a quite different spectrum, with an intense absorption at 6330 cm^{-1} and a series of weak bands at higher energy (3). This is typical of iron(II) complexes in a tetrahedral environment, the intense absorption being due to the $^5E \rightarrow {}^5T_2$ transition. Similar electronic spectra have been observed for the tetrahedral species FeX_2L_2-(X = Cl, Br; L = quinoline, 3-methylisoquinoline) (11). Iron(II) halide complexes with thioacetamide, *i.e.* $FeX_2(TA)_2$ have been reported and concluded to have tetrahedral structures (12).

The structures assigned to the complexes reported here are based upon a comparison of the spectral data for $FeCl_2(BTH)_2$ and $FeBr_2$-$(BTH)_2$ which have octahedral and tetrahedral geometries about the iron, respectively. Mössbauer data for these complexes are presented in Table 2. It is immediately apparent that the $FeCl_2(BTH)_2$ has a significantly higher isomer shift, and hence a lower s electron density, than the bromo analogue. Some of this difference could be the result of a difference in covalent character of the Fe–Br and Fe–Cl bonds, but this effect is thought to be minor (19). A more satisfactory explanation is that the chloro complex being six coordinate (d^2sp^3 hybridized) has more d electrons which shield the s electrons from the nucleus and results in a lower s electron density at the nucleus than in the four coordinate (sp^3 hybridized) bromo complex.

One notes also the strong absorption at room temperature for the chloro complex but a weak absorption for the bromo. Furthermore there is a relatively greater temperature dependence of this absorption for the bromo than the chloro complex. Both of these observations suggest a lower Debye temperature for $FeBr_2(BTH)_2$ compared to $FeCl_2(BTH)_2$. Again this is expected behavior from tetrahedral and polymeric six coordinate structures, respectively. Other workers (7, 8, 16) have noted that tetrahedral compounds of iron exhibit weak or undetectable absorption at room temperature.

Far infrared data are given in Table 3 and spectra for $FeCl_2(BTH)_2$ and $FeBr_2(BTH)_2$ are shown in Fig. 2. The $FeBr_2(BTH)_2$ complex gives a relatively well resolved spectrum with two strong bands at 266 and 244 cm^{-1} assigned to Fe—Br stretches and a band at 205 cm^{-1} assigned to an iron–nitrogen vibration. Coordination of the benzothiazole is assumed to be through N rather than S, by analogy with

$Co(BTH)_2(ClO_4)_2$ and $Ni(BTH)_2I_2$, where the evidence of Chan *et al.* (3) suggests coordination via nitrogen. This spectral pattern is typical of tetrahedral coordination (2, 20, 21). The spectrum of $FeCl_2(BTH)_2$ is less well resolved with only two prominent bands and a number of weak absorptions between 175 and 250 cm^{-1}. The absence of any Fe—Cl stretching vibrations at ~ 300 cm^{-1} is strong evidence in favor of the polymeric chlorine bridged structure (3, 17).

Mössbauer Data

Mössbauer data for all of the complexes are summarized in Table 2. With the exception of $FeCl_2(THU)_4$ the complexes with thio-ligands all have isomer shifts similar to the tetrahedral $FeBr_2(BTH)_2$ complex and less positive than the octahedral $FeCl_2(BTH)_2$ complex. This, together with the relatively weaker room temperature absorption than the $FeCl_2(BTH)_2$ complex, indicates that these thio-complexes have four coordinate tetrahedral geometries. Substitution of bromide for chloride, or variation of ligand L in these complexes, appears to have no detectable effect on the isomer shift. This is perhaps not too surprising since the σ character of the bonds is not likely to vary much with the ligand used and π bonding changes, which would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

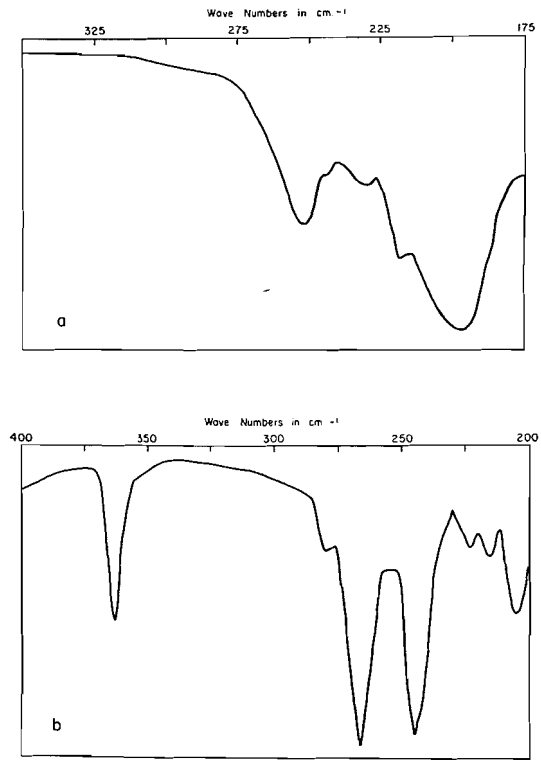

FIG. 2. Far infrared spectra of (*a*) $FeCl_2(BTH)_2$, (*b*) $FeBr_2(BTH)_2$.

remove d electrons and hence decrease δ, are likely to be small. There are variations in the magnitude of quadrupole splitting parameter but no obvious trends are apparent. These splittings are greater than ~ 3 mm/s and have only small temperature dependencies, indicating that the complexes are considerably distorted from a tetrahedral geometry. From the quadrupole splitting data one can estimate the degree of distortion Δ in the e levels (Fig. 1) in an analogous manner to that for the $FeCl_4^{2-}$ ion (7, 8). We estimate distortional splitting Δ of $\sim 800\ cm^{-1}$ in all of these tetrahedral complexes. Such highly distorted structures arise from the bulky nature of L and differences in covalent character of the Fe—X and Fe—L bonds.

The 1:4 thiourea complex $FeCl_2(THU)_4$ has a significantly more positive isomer shift than the tetrahedral complexes discussed above and is more consistent with six coordination about the iron. An alternate formulation would be $FeCl_2(THU)_2.2THU$, *i.e.*, with two lattice thiourea's. However, infrared evidence presented below favors the octahedral arrangement. Allowing a six coordinate iron(II) then the magnitude of the quadrupole splitting requires the complex to have the d_{xy} orbital lowest in energy (16). Complexes with the d_{xz}, d_{yz} orbitals lowest generally have splittings which are about one half those having the d_{xy} orbital lowest, and it has been suggested that this is the situation for $FeCl_2(BTH)_2$ (17) which has $\Delta E_Q = 1.76$ mm/s at 77 °K. The small temperature dependence of the quadrupole splitting for $FeCl_2(THU)_4$ indicates that the distortion in the t_{2g} levels is $\sim 1000\ cm^{-1}$. Spin–orbit coupling effects in such highly distorted structures are likely to be very small.

Infrared Spectra

Infrared spectral data of the complexes in the 400–4000 cm^{-1} range are summarized in Tables 4–7 which have been placed in the Depository of Unpublished Data.[1] No spectra were recorded for the benzothiazole complexes in this region. Flint and Goodgame (12) suggest that thioacetamide is coordinated through sulfur in the complex $CoCl_2(THA)_2$. The spectra of the iron–thioacetamide complexes are very similar to that of the cobalt complex, again supporting coordination through sulfur. In the N—H stretching region the iron complexes absorb at higher frequency than the ligand, in mull form, but at somewhat lower frequency than the ligand in dioxane solution, suggesting that the NH_2 group is still not as free as in dilute solutions of the ligand. Singh and Rivest (23) have suggested that some hydrogen bonding may occur between the NH_2 hydrogens and the halide in amide complexes. In neither of the iron complexes are there low lying N—H stretching bands which might result from coordination through nitrogen. The C—N stretching band at 1386 cm^{-1} is shifted to higher frequencies, as expected for coordination through sulfur. The bands at 973 and 719 cm^{-1}, which are of C=S stretching character, are shifted significantly to lower frequencies due to formation of S—Fe bonds.

The diagnostic vibrations for the thiourea complexes are the N—H stretching bands and the bands of C—N and C=S stretching charac-

ter. Bands in the ν(N—H) region are at significantly higher frequencies in the complexes than in the pure ligand. The absence of low lying absorption in this region again precludes the presence of N→Fe bonds. The N—C—N stretching band at 1472 cm^{-1} is found at higher frequencies in the complexes. The 1409 cm^{-1} band is split, presumably into a band of predominantly C—S stretching character, appearing at lower frequency, and one of predominantly N—C—N stretching character at higher frequency. The band at 730 cm^{-1}, which is largely of ν(C—S) character, is both split and lower in frequency. These effects have been noted by Swaminathan and Irving (25) in other thiourea complexes and are associated with coordination through sulfur.

The spectra of *N*-methylthiourea, *N,N'*-dimethylthiourea and their complexes with FeCl show no significant shifts to lower frequency of the bands in the ν(N—H) region. The dimethylthiourea complex shows only one strong N—H stretching band, supporting the presence of only one kind of nitrogen. The bands of mixed N—H bending and C—N stretching character at about 1550 cm^{-1} are shifted 20–25 cm^{-1} to higher frequencies, as are the bands of mixed C—N and C=S stretching character near 1500 cm^{-1}. It is thought that both these effects are due to an increase in C—N double bond character in the sulfur bonded ligand. *N,N'*-dimethylthiourea shows another band at 1355 cm^{-1} which has been tentatively assigned as mixed C—N and C=S stretching. This peak is also shifted to higher wave number on complex formation. The bands at 774 cm^{-1} in *N*-methylthiourea and 727 cm^{-1} in *N,N'*-dimethylthiourea are predominantly of C=S stretching character, and are shifted to lower frequency on coordination. The observation that none of the N—CH_3 stretching or deformation bands are significantly shifted also indirectly supports coordination through sulfur.

A comparison of the far infrared spectra of the thioacetamide and thiourea complexes with that of $FeBr_2(BTH)_2$ indicates clearly that all have the tetrahedral structure. Table 3 summarizes the data and a comparison of Fig. 2*b* and Fig. 3*a* shows the similarity, though the bands in the bromide complex are shifted to lower frequency as expected. The two bands in the 300 cm^{-1} region are assigned to the two expected Fe—Cl stretches. The analogous bromide complexes $FeBr_2(THA)_2$ and $FeBr_2(THU)_2$ show a similar, though less well resolved, pattern and individual assignments have not been made. It has been suggested in the case of $FeBr_2(THA)_2$ that ν(Fe—Br) and ν(Fe—S) vibrations are strongly coupled (12) and this may be the reason for the lack of resolution. The far infrared spectra of the methylthiourea and dimethylthiourea complexes are somewhat different from those of the thioacetamide and thiourea complexes. This difference is illustrated in Fig. 3*b* and one notes that while there are still two strong bands and a less intense absorption at lower frequency, the shapes and relative intensities have changed. The very strong band at 305 cm^{-1} in $FeCl_2(DMTHU)_2$ is broad, suggesting the presence of another band at ~315 cm^{-1}; in the MTHU complex this is somewhat better resolved with band at 300 cm^{-1} and a shoulder at 325 cm^{-1}. These have been assigned as Fe—Cl stretching vibrations while the bands to lower frequency are assigned to Fe—S vibrations. These assignments are again consistent with a tetrahedral geometry

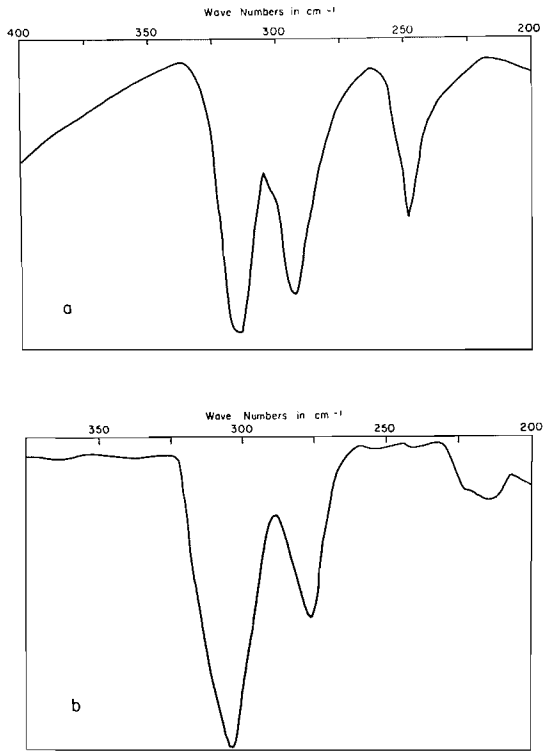

FIG. 3. Far infrared spectra of (*a*) $FeCl_2(THU)_2$, (*b*) $FeCl_2(DMTHU)_2$.

TABLE 8. Magnetic moments of thioacetamide and thiourea complexes

Complex	Temperature (°K)	μ_{eff} (β)
$FeCl_2(THA)_2$	295	5.27
$FeCl_2(THU)_2$	295	4.89
$FeCl_2(THU)_4$	295	5.25
$FeCl_2(MTHU)_2$	295	5.17
	77	4.83
$FeCl_2(DMTHU)_2$	295	5.09
	77	4.79

and the difference in spectral patterns is possibly the consequence of the bulkier ligand.

The 1:4 thiourea complex shows two bands at low frequency and by comparison with the far i.r. spectra of $FeCl_2(BTH)_2$ and related compounds (Table 3 and ref. 17) a *trans* octahedral structure is proposed. Both the ν(FeCl) and ν(Fe—S) vibrations are expected to be shifted to lower frequency as a result of longer, weaker bonds in the octahedral complex. The difference in Fe—Cl stretching frequency for the 1:2 and 1:4 thiourea complexes may be compared with that noted by Clark (27) for Co—Cl stretching in 1:2 and 1:4 pyridine complexes, where the tetrahedral complex has two ν(Co—Cl) bands at 344 and 304 cm^{-1}, but the octahedral species has only one ν(Co—Cl) band at 230 cm^{-1}.

Magnetic Moments

Magnetic data for some of the thioacetamide and thiourea complexes are summarized in Table 8. All of the data are consistent with magnetic moments expected for either tetrahedral or octahedral iron(II) in highly distorted environments.

Etude des mouvements de molécules linéaires en phase liquide par analyse du profil des bandes d'absorption infrarouge. II. Bande ν_3 du sulfure de carbonyle

A. M. BIZE, J. SOUSSEN-JACOB ET J. VINCENT-GEISSE
Laboratoire de Recherches Physiques, associé au C.N.R.S., Groupe infrarouge, 11 quai Saint Bernard, Paris (5°)

D. LEGAY ET J. P. PERCHARD
Laboratoire de Spectrochimie Moléculaire, 11 quai Saint Bernard, Paris (5°)

Reçu le 10 juin 1971

On a examiné la largeur et le profil de la bande ν_3 du sulfure de carbonyle (OCS) en solution dans une trentaine de solvants. L'étude de la variation de la largeur en fonction de la température permet de séparer les effets vibrationnel et rotationnel et de déterminer la barrière de potentiel s'opposant à la rotation. On a d'autre part tiré les fonctions de corrélation des résultats expérimentaux et calculé, à partir des deuxième et quatrième moments, la valeur du couple de rappel agissant sur le sulfure de carbonyle dans différents solvants. Les résultats obtenus mettent en évidence un effet rotationnel prépondérant dans les hydrocarbures saturés, tandis que, dans les autres solvants, l'élargissement vibrationnel se montre important.

The band width and profile of ν_3 mode of carbonyl sulfide (OCS) dissolved in about 30 solvents have been examined. The study of temperature broadening permits the separation of the vibrational and rotational effects and the determination of the potential barrier to rotation. Correlation functions have been plotted from the experimental results; the mean squared torques acting on carbonyl sulfide in various solvents have been calculated from the second and the fourth moments. The obtained results bear evidence of a dominant rotational effect for solutions in saturated hydrocarbons while, for the other solvents, vibrational broadening proves important.

Canadian Journal of Chemistry, **50**, 217 (1972)

Introduction

Une étude précédente, effectuée sur la molécule N_2O (1) a montré l'intérêt que présentait la détermination du profil des bandes d'absorption et des grandeurs que l'on peut en tirer, dans le cas des molécules triatomiques linéaires. Nous nous sommes proposé ici d'examiner la molécule OCS, elle aussi linéaire et dissymétrique, mais qui se distingue de N_2O, d'une part par l'existence d'un moment dipolaire non négligeable, égal à 0.71 D, et, d'autre part, par un moment d'inertie, sensiblement double de celui de N_2O, et égal à 141.2×10^{-40} g cm^2.

La molécule OCS possède, comme N_2O, trois modes fondamentaux de vibration dont deux, ν_1 et ν_3, parallèles à l'axe et un, ν_2, perpendiculaire à l'axe et dégénéré. L'étude des bandes parallèles conduisant à des résultats plus directement interprétables, nous nous limiterons dans le présent article à l'examen de la bande ν_3, la plus intense, et dont la fréquence se situe dans un domaine où de très nombreux solvants se montrent transparents.

Nous examinerons en premier lieu la largeur de bande à température ordinaire, puis sa variation en fonction de la température, dans tout le domaine de l'état liquide. Nous nous intéresserons en second lieu à la fonction de corrélation et aux moments des bandes.

Etude expérimentale

Le sulfure de carbonyle utilisé, de pureté 97%, provenait de la firme Matheson; les impuretés, principalement CO_2, CS_2 et CO, ne sont pas gênantes car elles n'absorbent pas dans le domaine spectral considéré.

Le spectre de OCS à l'état gazeux, dans la région de ν_3, est bien connu (2); la bande de vibration–rotation ν_3 a son centre à 2062.2 cm^{-1} et elle est accompagnée, du côté des basses fréquences, par une bande chaude parasite, $\nu_3 + \nu_2 - \nu_2$ située à 2054.9 cm^{-1}; en effet, le niveau ν_2, relativement bas (524 cm^{-1}), est peuplé à la température ordinaire par 18% des molécules. D'autre part un effet isotopique non négligeable peut se présenter, à cause, essentiellement, de l'isotope 34 du soufre, d'abondance naturelle 3%; le spectre de cette molécule isotopique n'a pas été examiné à notre connaissance, mais un calcul approché des fréquences de vibration nous a donné une différence de 1 cm^{-1} entre les nombres d'ondes des vibrations ν_3 correspondant aux deux espèces; compte tenu de l'ordre de grandeur de la largeur de ν_3, il est légitime de supposer que l'existence de cet isotope ne perturbe pas sensiblement le profil de la bande. Il en va tout autrement de la bande chaude, bien visible sur nos

spectres (Fig. 2) et dont nous devrons tenir compte dans la suite.

Les solvants utilisés, au nombre d'une trentaine, sont des produits pour spectroscopie de Prolabo et Fluka dont la pureté a été considérée comme suffisante. Les solutions ont été préparées par barbotage à température ordinaire ou piégeage à 77 °K du sulfure de carbonyle dans les divers solvants; leur titre reste toujours inférieur à 0.1 mol/l.

Les spectres ont été enregistrés au moyen d'un spectromètre Perkin–Elmer 225; la largeur de fente spectrale est voisine de $0.7\ cm^{-1}$; un étalonnage en fréquences, obtenu à partir des raies d'absorption de l'oxyde de carbone, permet de fixer à $0.15\ cm^{-1}$ la précision des pointés. Les largeurs sont déterminées à $\pm 0.3\ cm^{-1}$ près. A la température ordinaire le rapport entre la largeur de fente spectrale et la largeur à mi-hauteur de la bande reste inférieur à 0.07 de sorte que la distorsion du profil par l'appareil peut être considérée comme négligeable. A très basse température il n'en va plus de même car le rapport précédent peut atteindre 0.25; les largeurs se montrent peu affectées mais le profil au centre de la bande davantage; nous n'en avons pas tenu compte dans ce qui suit.

Les spectres à température variable ont été obtenus, suivant le cas, de deux manières différentes. Dans un premier montage, la solution est placée dans une cellule thermostatée située dans une enceinte remplie en général d'un gaz sec (azote ou argon) et la température, mesurée au moyen d'un thermocouple fixé sur une face de la cellule, est stabilisée par circulation d'un fluide cryogénique de débit règlable; les mesures sont alors effectuées l'une à la suite de l'autre sur la solution et le solvant à même température, d'où la nécessité de ramener entre chaque mesure l'ensemble à la température ordinaire pour éviter les condensations d'eau et les chocs thermiques sur les fenêtres au moment du remplissage. Dans un deuxième montage, nous avons utilisé un cryostat de modèle RIIC, la cuve étant sous vide et le refroidissement effectué avec de l'azote liquide. Nous avons alors, dans une série de mesures, enregistré les spectres de la solution successivement à différentes températures et dans une autre série, ceux du solvant, ce qui nous a permis d'obtenir un plus grand nombre de points que dans le premier procédé.

Largeur de bande

(a) Température ordinaire

Nous avons rassemblé dans le Tableau 1 les résultats de nos mesures de largeur à la tempéra-

ture ordinaire, soit 313 °K. La première colonne indique le nombre d'ondes du maximum d'absorption de la solution, la deuxième la largeur à mi-hauteur $\Delta\nu_{1/2}$ et la troisième la largeur symétrisée $\Delta\nu^s_{1/2}$, c'est-à-dire le double de la demi-largeur correspondant aux hautes fréquences; ces deux derniers chiffres se montrent assez nettement différents, dans le cas des faibles largeurs, à cause de l'existence, signalée plus haut, de la bande chaude. Dans ce qui suit nous discuterons les résultats relatifs à $\Delta\nu^s_{1/2}$, c'est-à-dire en supposant la bande symétrique. Cette hypothèse se justifie par le fait qu'à basse température la bande observée est effectivement symétrique en raison de la disparition de la bande chaude. Par ce procédé l'influence de cette dernière, qui varie selon la température, se trouve éliminée.

Nous avons porté, dans la Fig. 1, la largeur $\Delta\nu^s_{1/2}$ en fonction du déplacement $\nu_{gaz} - \nu_{sol}$, ce dernier facteur représentant, en quelque sorte, le degré d'activité du solvant. Les points représentatifs se classent nettement en deux groupes: Dans le premier, celui des solvants non polaires, ils se placent, excepté CS_2, au voisinage d'une droite de pente négative, assez forte, la largeur étant en première approximation d'autant plus grande que le solvant est plus inerte. Si nous émettons l'hypothèse, assez vraisemblable, que, dans ces solvants, la largeur est due principalement à la diffusion rotationnelle, nous voyons que celle-ci est la plus rapide pour le pentane, résultat en accord avec ce que nous avions observé pour N_2O (1). Les points correspondant aux solvants polaires, auxquels il faut ajouter le benzène, se situent tous nettement au-dessus des précédents et, si certains d'entre eux se placent au voisinage d'une droite horizontale, il ne semble plus y avoir de relation aussi nette entre largeur et déplacement. On peut en conclure que l'origine de l'élargissement n'est plus ici la diffusion rotationnelle, mais plutôt un effet vibrationnel dû à des actions intermoléculaires entre dipôles.

Nous avons porté, dans le Tableau 2, la valeur de la constante D de diffusion rotationnelle, calculée à partir de $\Delta\nu^s_{1/2}$ pour les solvants dans lesquels ce processus semble important.

$$[1] \qquad D = \tfrac{1}{2}\pi c \Delta\nu^s_{1/2}$$

Dans cette expression les effets vibrationnels sont négligés de sorte que la largeur entière de la bande est supposée provenir de la contribution rotationnelle. Par suite la valeur de D ainsi

obtenue doit être considérée comme une limite supérieure. Si nous comparons les chiffres obtenus à ceux de N_2O dans les mêmes solvants (1), nous voyons qu'ils leur sont inférieurs, ce qui s'explique aisément par l'inertie plus grande de OCS.

(b) Variation en fonction de la température

Il est intéressant d'essayer de vérifier les conclusions précédentes par l'étude de la variation de largeur en fonction de la température. En effet, si celle-ci est due essentiellement à la diffusion rotationnelle, la largeur est donnée, d'après Rakov (3), par une formule de la forme:

$$[2] \qquad \Delta\nu_{1/2} = A\, e^{-U/RT} + \delta$$

dans laquelle le premier terme représente l'effet rotationnel et le second, δ, l'effet vibrationnel, petit par rapport au premier, et supposé, en première approximation, indépendant de T; U est la barrière de potentiel opposée à la rotation de la molécule. La Fig. 2 montre, à titre d'exemple, les spectres obtenus dans le cas de l'heptane; on voit que la variation du profil est très importante; la bande chaude, visible comme un épaulement à 300 °K, se montre nettement séparée à 200 °K alors que son intensité a considérablement diminué. Nous avons porté, dans la Fig. 3, la variation de la largeur $\Delta\nu_{1/2}$ en fonction de T ($\Delta\nu^s_{1/2}$ n'étant pas mesurable sur tous les spectres), dans le cas des solutions étudiées de manière continue; nous y avons ajouté les trois points relatifs à l'hexane et qui se placent sur la courbe du 2-méthylbutane (courbe 7), et ceux de l'acétone (courbe 27), bien qu'il n'y en ait que quatre; nous examinerons un peu plus loin, en prenant l'exemple de l'heptane, l'incidence du choix de $\Delta\nu_{1/2}$ ou $\Delta\nu^s_{1/2}$ sur la détermination des constantes. L'examen de la Fig. 3 suggère les commentaires suivants: les courbes 3, 5, 7 montrant la plus forte variation, correspondent à des points situés, sur la Fig. 1, dans le groupe auquel nous avons attribué un effet rotationnel prépondérant; les courbes 13 et 11, nettement différentes des autres sont celles, d'une part de CS_2, très distinct des autres solvants sur la Fig. 1, et, d'autre part de C_2Cl_4; enfin, et comme on pouvait s'y attendre, les courbes 17 et 27, correspondant à des solvants polaires, montrent une

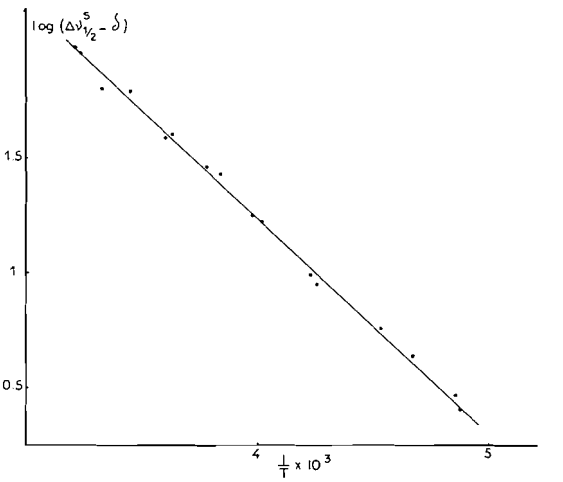

FIG. 5. ln ($\Delta\nu^s_{1/2} - \delta$) fonction de $1/T$. Solution dans le cyclopentane.

variation relative beaucoup plus faible que les précédentes.

A partir des courbes de la Fig. 3, nous avons calculé les constantes U, A et δ de la formule [2]. Tout d'abord, nous voyons que la solution dans le 2-méthylbutane (courbe 7) peut être étudiée jusqu'à une température suffisamment basse pour que $\Delta\nu_{1/2}$ tende vers une valeur constante qui nous fournit δ. Nous pouvons alors tracer le graphique donnant ln ($\Delta\nu_{1/2} - \delta$) en fonction de $1/T$ (Fig. 4); les points se placent bien sur une droite dont la pente nous permet de calculer la barrière de potentiel U et l'ordonnée à l'origine la constante A. Dans les autres cas nous déterminons les constantes en dérivant la formule [2] par rapport à $1/T$. En posant $y = \Delta\nu_{1/2}$ et $x = 1/T$ on obtient

$$[3] \qquad \frac{dy}{dx} = \frac{U}{R}(y - \delta)$$

L'incertitude entachant les résultats s'obtient en faisant varier systématiquement δ autour de la valeur approchée obtenue, de façon à connaître les valeurs extrêmes pour lesquelles la courbe semblable à celles des Figs. 4 et 5 est encore une droite. La Fig. 5 montre les résultats relatifs au cyclopentane; avec ce solvant, comme avec l'heptane, l'accord entre les résultats expérimentaux et la formule [2] est très bon.

Nous avons porté, dans le Tableau 3, les constantes U, A et δ de la formule [2], calculées dans tous les cas, sauf celui du 2-méthylbutane,

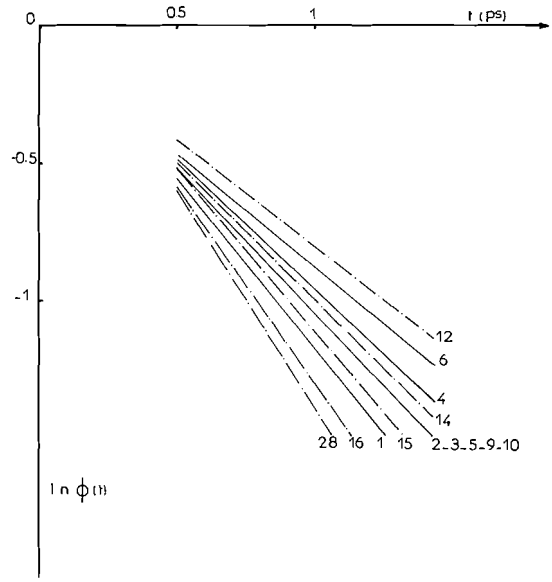

FIG. 6. Partie rectiligne de $\ln \Phi(t)$ dans différents solvants. Pour les numéros des courbes se rapporter au Tableau 1. — hydrocarbures saturés, -·-·- autres solvants.

avec la largeur symétrisée $\Delta\nu^s_{1/2}$. Afin de connaître l'incertitude due à l'emploi de $\Delta\nu_{1/2}$ au lieu de $\Delta\nu^s_{1/2}$, nous avons effectué les deux calculs pour l'heptane; nous voyons que l'utilisation de $\Delta\nu_{1/2}$ fournit une valeur plus grande pour U et pour A; la valeur de U pour le 2-méthylbutane est donc probablement surestimée et voisine en réalité de celle de l'heptane. Il est intéressant de comparer les valeurs obtenues pour δ aux largeurs totales de bandes (Tableau 1). Nous voyons que, dans le cas du cyclopentane, de l'heptane et du 2-méthylbutane, l'effet rotationnel fournit les deux tiers ou les trois quarts de la largeur totale à la température ambiante et nous estimons que la formule de Rakov nous donne une bonne approximation. Ailleurs il faut se montrer plus réservé: pour les trois derniers solvants du tableau, les points des graphiques semblables aux Figs. 4 et 5 s'alignent moins bien, et l'incertitude se montre beaucoup plus grande; ceci correspond au fait que l'élargissement rotationnel ne représente plus qu'une faible part de l'élargissement total. Il ne faut donc pas attacher trop d'importance aux chiffres des trois dernières lignes, particulièrement à ceux du dichlorométhane. Il existe dans ce cas un effet vibrationnel important et supposé indépendant de la température, ce qui n'est sans doute qu'une grossière approximation.

Fonctions de corrélation

Les fonctions de corrélation ont été calculées comme précédemment (1) pour la plus grande partie des spectres à température ordinaire et pour certains d'entre eux à température variable, mais, dans ce dernier cas, la précision avec laquelle elles sont connues, est moins bonne et nous n'en parlerons pas ici. Le calcul a été effectué dans un domaine d'intégration égal à environ 17 fois la largeur de la bande. Dans le cas des solutions en solvants inertes, on a pris les courbes symétrisées. On a cependant vérifié que l'utilisation de la bande entière ne modifiait que d'une façon négligeable la fonction de corrélation aux temps courts; par contre la pente de la partie linéaire varie approximativement dans le rapport des demi-largeurs $\Delta\nu_{1/2}/\Delta\nu^s_{1/2}$. Si nous traçons les courbes donnant $\ln \Phi$ en fonction du temps, celles-ci se classent en deux catégories: dans l'une d'elles correspondant à la plupart des solvants polaires, on n'obtient pas de partie rectiligne et ce fait se montre en accord avec l'hypothèse, faite plus haut, que, dans ces solvants, l'effet rotationnel est secondaire; il faut remarquer que ces courbes ne sont pas non plus des paraboles comme on s'y attendrait si l'élargissement était purement vibrationnel (4), mais se situent entre les deux. Dans le deuxième groupe, comprenant la plupart des solvants non polaires et l'acétonitrile, on observe une partie parabolique au voisinage de l'origine et ensuite une droite (Fig. 7); la Fig. 6 montre un certain nombre de ces droites. On voit que la corrélation diminue d'autant plus vite que la rotation est plus rapide ou les interactions moléculaires plus importantes.

Sur la Fig. 7 sont rassemblées quelques unes des fonctions de corrélation. La partie des courbes proche de l'origine, peut présenter deux allures différentes: ou bien elle suit d'abord la courbe du rotateur libre (R dans 7*a*, 7*b*, 7*c*) puis s'en écarte, passe par un point d'inflexion et devient rectiligne, la transition s'effectuant très rapidement, ou bien (7*d*, courbes 16 et 28) elle se place dès le départ au-dessous de R et ne présente plus de point d'inflexion. Les deux extrêmes sont la courbe du pentane (7*a*, courbe 1) qui se confond avec R jusqu'à $t = 0.3$ ps, l'angle de rotation correspondant étant 40°, et

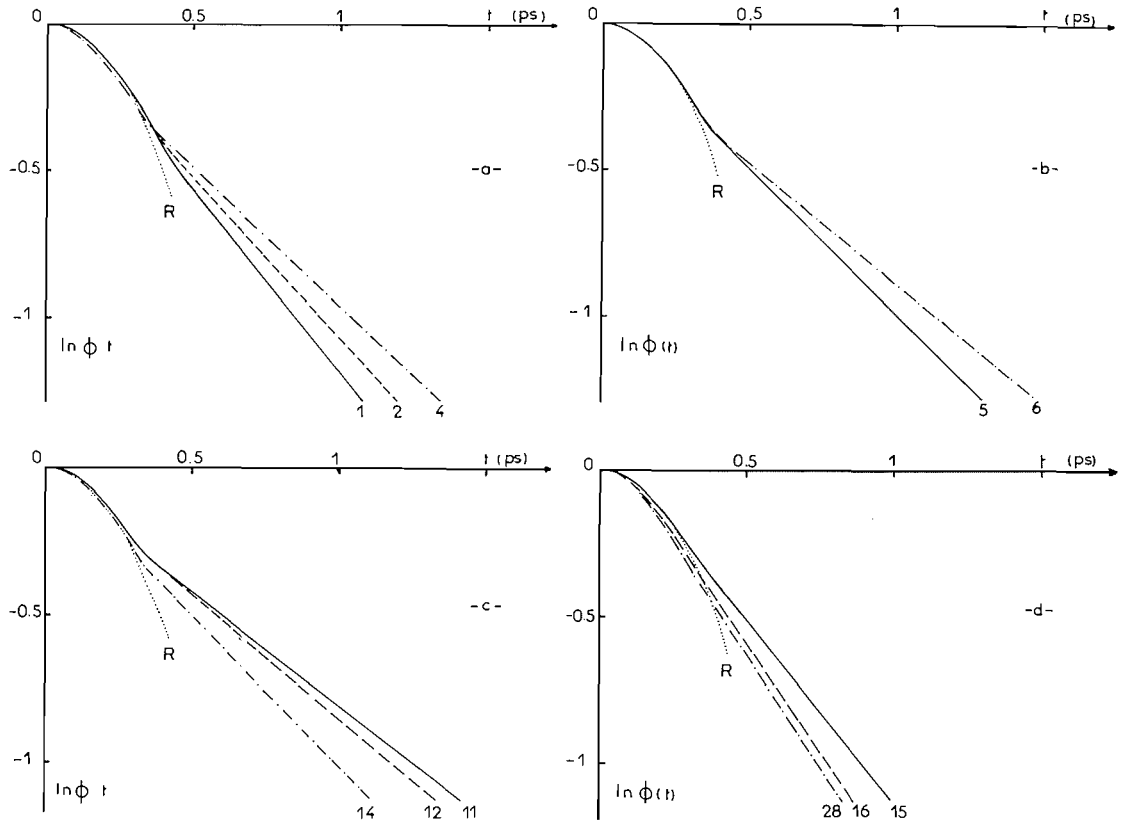

FIG. 7. ln $\Phi(t)$ dans différents solvants. R: courbe du rotateur libre. Pour les numéros des courbes, se rapporter au Tableau 1.

celle de l'acétonitrile (7*d*, courbe 28) pour laquelle la corrélation diminue plus rapidement, en accord avec le fait qu'il existe alors un effet vibrationnel supplémentaire important.

Nous avons porté dans le Tableau 4 diverses constantes tirées des graphiques précédents: τ_d est le temps correspondant au début de la diffusion rotationnelle; on remarque qu'il est le même, aux erreurs expérimentales près, pour tous les solvants de 1 à 15 et le même que pour N_2O (1). τ est le temps de corrélation calculé à partir de la pente des droites et D le coefficient de diffusion correspondant [4] $D = 1/2\,\tau$; nous pouvons comparer les chiffres de cette dernière colonne à ceux donnés dans le Tableau 2; l'accord se montre assez bon, bien que dans certains solvants (11 à 15) l'élargissement d'origine vibrationnelle ne soit pas négligeable.

TABLEAU 4. Constantes tirées des fonctions de corrélation présentant une partie linéaire

Solvant*	τ (ps)	D (ps)$^{-1}$	τ_d (ps)	φ_d
1	0.77	0.65	0.35	45°
2	0.91	0.55	0.40	47°

TABLEAU 5. Deuxième et quatrième moments

Solvant*	$M(2)$ 10^{24} (s^{-2})	$M(4)$ 10^{50} (s^{-4})	$\langle C^2\rangle^{1/2}$ (cm^{-1}/rad)
1	7.3	3.3	870
2	6.6	2.6	870
3	7.0	3.1	870
4	7.6	3.9	940
5	6.5	2.5	850
6	8.0	4.8	
8	7.2	3.4	
9	6.4	2.5	860
10	6.6	2.7	870
11	6.9	3.8	1050
12	6.8	3.7	1060
14	7.0	3.3	910
15	6.6	2.7	900
16	8.0	4.0	870
17	9.6	7.5	
18	9.3	6.6	
20	8.3	4.8	
24	8.4	4.6	
25	6.9	2.6	1060
27	9.5	7.9	
28	8.9	4.9	

*Pour l'identification des solvants, se rapporter au Tableau 1.

Enfin la dernière colonne du Tableau 4 donne un ordre de grandeur de l'angle moyen dont a tourné la molécule avant le début de la diffusion rotationnelle. Cet angle varie de 40 à 50°, alors qu'il était de 50 à 60° pour N_2O pour un temps sensiblement égal; la molécule OCS tourne moins vite en moyenne que N_2O, à cause de son plus grand moment d'inertie.

Deuxième et quatrième moments

Nous avons calculé, comme précédemment (1), dans tous les cas où le solvant ne présentait pas de bande d'absorption proche de ν_3, le deuxième et le quatrième moment. Les résultats obtenus sont loin de se montrer satisfaisants. En particulier nous avons observé quelquefois une croissance du deuxième moment en fonction de l'absorption maximale $\ln (I_0/I)_{max}$. On peut se demander s'il ne s'agit pas d'un effet dû à la concentration, bien que celle-ci reste toujours très faible. Une étude systématique entreprise sur OCS, en même temps que sur d'autres molécules linéaires non polaires, est en cours, et nous permettra peut-être d'expliquer les phénomènes observés. D'une manière générale les chiffres obtenus se montrent supérieurs à la valeur théorique: $6.2 \times 10^{24}\ s^{-2}$ (Tableau 5). Ce résultat pourrait peut-être s'interpréter par l'existence de l'élargissement vibrationnel qui devrait ajouter une contribution au second moment (6).

Dans ces conditions la détermination du couple de rappel, à partir de la valeur du quatrième moment, se montrait délicate; nous l'avons tout de même effectuée en nous limitant aux spectres donnant des valeurs de $M(2)$ assez proches de la valeur théorique et en appliquant la formule de Gordon (5),

$$[5] \qquad \frac{\langle C^2\rangle}{I^2} = M(4) - 2[M(2)]^2$$

espérant ainsi compenser, en prenant pour $M(2)$ la valeur expérimentale, les chiffres trop grands obtenus pour $M(2)$ et $M(4)$. Le Tableau 5 résume les résultats obtenus; les chiffres donnés pour le couple quadratique moyen, $\langle C^2\rangle^{1/2}$, fournissent au mieux un ordre de grandeur; celui-ci est de 870 cm^{-1}/rad (2.5 kcal/mol rad) pour un certain nombre de solvants et peut être comparé à la barrière de potentiel trouvée à partir de la variation de largeur en fonction de la température (Tableau 3); les valeurs sont voisines. Il est intéressant également de comparer ce chiffre à celui trouvé pour N_2O, $3kT$/rad, c'est-à-dire 1.9 kcal/mol rad. Le couple de rappel sur OCS serait plus important que celui agissant sur N_2O.

For personal use only.

Conclusion

L'étude simultanée de la largeur et de la fonction de corrélation de la bande ν_3 de OCS en solution, à température ordinaire et à basse température, nous a permis de mettre en évidence un effet rotationnel prépondérant dans le cas des hydrocarbures saturés, et de calculer la constante de diffusion et la barrière de potentiel s'opposant à la rotation. Pour les autres solvants et, en particulier, les solvants polaires, on ne peut plus négliger l'élargissement vibrationnel et celui-ci, mal connu, masque en grande partie l'effet rotationnel.

Carbanions in Carbohydrate Chemistry: Novel Methods for Chain Extension and Branching[1]

S. HANESSIAN AND P. DEXTRAZE[2]

Department of Chemistry, University of Montreal, Montreal, Quebec

Received June 24, 1971

Methods are described for the introduction of two and three carbon units in carbohydrates by the reaction of suitable epoxides with sodio diethyl malonate. The reactions represent a means of branching and chain extension in the carbohydrate series and lead to the incorporation of highly functionalized carbon units at predetermined sites in the sugar molecule.

Des méthodes sont décrites pour l'introduction de fragments à deux ou trois atomes de carbone par l'action du sel de sodium du malonate de diéthyle sur l'époxyde approprié. Ces réactions représentent un moyen d'introduction d'une ramification et d'allongement d'une chaîne dans la série des hydrates de carbone et conduisent à l'incorporation en des sites prédéterminés sur la molécule de sucre de chaînes carbonées comportant de très nombreux groupes fonctionnels.

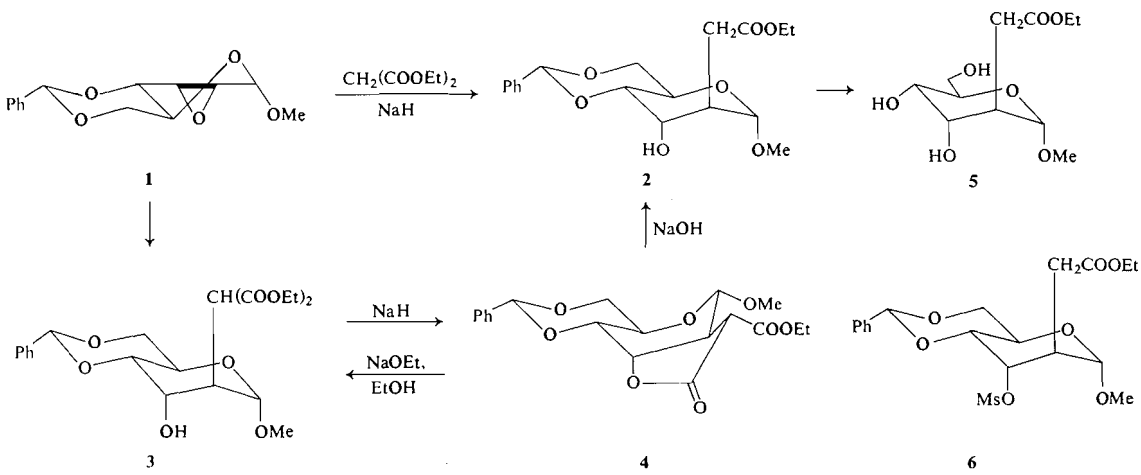
Branched-chain sugars (3) occupy a unique position among the various classes of carbohydrates, in that they are of considerable biological significance due to their occurrence as components of medicinally important antibiotics (4), and whose structural features still represent a challenge to the synthetic chemist. Unlike deoxy (5) and amino sugars (6) which occupy the uppermost ranks as biologically significant sugars, the methods of introduction of *C*-branching in carbohydrates are somewhat limited. The problem is further complicated when stereochemical considerations are taken into account. Quite fortuitously, those branched-chain sugars which occur as components of antibiotics are with few exceptions *C*-methyl hexoses containing a tertiary hydroxyl group at the branch site. Their syntheses by the reaction of appropriately substituted hexosuloses with organometallic or other reagents as the one-carbon source of the methyl group, has become relatively easy (4). Two preparatively significant routes to deoxy branched-chain sugars involve the opening of appropriate epoxides with organometallic reagents, which leads generally to a preponderance of one of two possible isomers, and the reaction of appropriately substituted hexosuloses with Wittig reagents (7, 8) followed by catalytic reduction which affords epimeric *C*-alkyl sugars. From a consideration of synthetic value and versatility, it would be desirable to introduce a *C*-chain that is functional, and not chemically inert as an alkyl group. Access to such functionalized substituents is somewhat scarce and it is this aspect of chain-branching reactions that is the subject matter of this paper. The application of the hydroformylation reactions of substituted glycals affords 2-*C*-hydroxymethyl sugars (9). In isolated examples, dimethylvinyl (10) and aldehyde (11, 12) chains have been introduced in the carbon skeleton by epoxide opening ring contraction and oxidation reactions respectively. Such groups as ($Me_2C{=}CH{-}$, $-CHO$, $-CH_2OH$, etc.), when attached to the carbohydrate skeleton represent functionally useful ramifications and they are amenable to further transformations.

Carbanions derived from malonic esters represent potentially interesting reactants as a means of introduction of highly functionalized substituents in carbohydrates. Despite the multitude of applications in other classes of organic compounds (13) carbanions of this type have been sparsely used in carbohydrate chemistry (14–17). We report in this paper our studies involving the stereoselective ring opening of carbohydrate epoxides with sodio diethyl malonate, as a means of branching and chain-extension.

To the best of our knowledge, the reaction of sodio diethyl malonate with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (**1**) represents the only recorded example of its kind in the carbohydrate series (Scheme 1). As reported by

[1]Part of a series on "Preparative and exploratory carbohydrate chemistry", see also refs. 1, 2.

[2]NRCC Predoctorate Fellow, 1969–1971.



SCHEME 1

Kochetkov and coworkers (18), the reaction leads to a 25–30% yield of compound **2**. We reinvestigated this reaction with the objective of obtaining optimum and improved yields, searching for the possible formation of other products related to **2**, securing unambiguous proof of their structures and stereochemistry and shedding some light on the mechanism of the reaction.

At the outset, it was of interest to establish unambiguously the position of branching in the product **2** prepared according to the published procedure (18). Hydrolysis of the benzylidene group with dilute hydrochloric acid gave the crystalline product **5** in high yield. This compound was totally oxidized by periodate, as would be expected of its structure and the presence of the branching at C-2 was thus firmly established. Our efforts were then directed to the preparative and mechanistic aspects of the reaction of **1** with the carbanion.

After a detailed study of the effect of different solvents on the nature of the products, it appeared that benzene as used by the Russian workers (18), was the solvent of choice. It was more convenient however, to use sodium hydride instead of dispersed sodium to prepare the carbanion. The nature of the products between sodio diethyl malonate and **1** appeared to depend very strongly on the moisture content as well as on the temperature of the reaction. After prolonged periods at 40°, the reaction product was found to be the crystalline diester **3**, which was formed in 52% yield. Attempts to shorten the reaction time by raising the temperature led to mixtures of **2** and **3**. When the reaction was carried out in a strictly anhydrous medium, in refluxing benzene, a 74% yield of a new crystalline product was formed. Spectroscopic and chemical evidence permitted the assignment of the highly strained lactone structure **4** to this product. Treatment of **4** with sodium ethoxide in ethanol at room temperature afforded an almost quantitative yield of the diester **3**. On the other hand treatment of **3** with sodium hydride in benzene converted it into **4**, thus establishing the structural relationship between these products. Careful treatment of **4** with aqueous sodium hydroxide opened the lactone ring selectively to give an intermediate sodium salt (not isolated) which was decarboxylated upon heating, to give the monoester derivative **2** in quantitative yield. It is thus apparent that the initial reaction product in the reaction of sodio diethyl malonate with **1** is the diester **3** which cyclizes to the lactone **4** under the conditions of the reaction. In the presence of trace amounts of water, the lactone is hydrolyzed to the monoester **2**. These results explain the variable yields of **2** and its admixture with the diester **3**, when strict moisture control was not exercized. In fact, investigation of the mother liquors from such reactions invariably revealed the presence of lactone bands in the i.r. As a result of the present study, the

10 R = CCH_2COEt (O, O)
11 R = Me

SCHEME 2

recommended procedure for the preparation of compound **2** appears to be through the lactone **4**.

Chain extension reactions through the terminal carbon atom of various carbohydrate derivatives have been done long before most of the *C*-methyl branched-chain sugars were found. The main reason for this was the availability of *aldehydo*-derivatives, which were suitable substrates for condensation reactions. Grignard reagents (19) organometallic reagents (20), nitromethane (21), and cyanohydrin condensation (22) have been used for this purpose. More recently, side chains of varying degrees of oxidation state have been introduced into carbohydrate structures (23), and these are amenable to a variety of transformations. The discovery of the antibiotic lincomycin (24–26) consisting of a C_8 amino dideoxy sugar (lincosamine) and more recently of the antibiotic polyoxin (27), a nucleoside of 5-amino-5-deoxy-D-alluronic acid has provided an added interest for the elaboration of newer methods of chain extension in the carbohydrate series.

We report herein the synthesis of sugar derivatives containing a highly functionalized C_3 unit, by the reaction of a terminal epoxide such as 5,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose (**7**) (28) with the carbanion derived from diethyl malonate (Scheme 2). Treatment of the epoxide **7** with 3 equiv of the carbanion in refluxing benzene gave a crystalline product (53%), to which we assign structure **10**. This assignment is substantiated by spectroscopic (n.m.r.) and mass spectral data as well as by an unambiguous independent synthesis. Thus, treatment of the epoxide with ethylmalonyl chloride in the presence of dimethylaniline in ether afforded the ester **9** as a syrup. Treatment of **9** with sodio diethyl malonate in refluxing benzene gave the product **10** in 44% yield. It should be noted that the opening of the epoxide in **9** was considerably faster than in **7**, which suggests that the transesterification step is slow. To obtain some measure of the reactivity of the C-3 hydroxyl group, sodio diethyl malonate was allowed to react with 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**12**) (29) (Scheme 3). Even in the presence of a large excess of carbanion, the esterification was very slow compared to the reaction with **7**. Mild acid hydrolysis of the ester **13** afforded a product **14**, which on attempted purification on a column containing silica gel, was converted into the isomeric 6-*O*-(ethyl malonyl)-1,2-*O*-isopropylidene-α-D-glucofuranose (**15**). Such ester migrations from C-3 to C-6 in glucofuranose derivatives are not unprecedented but rare. The internal transesterification **14** → **15** presumably proceeds through a double migration, involving six- and five-membered orthoacid intermediates respectively (30).[3] The structure of compound **15** was proved by an independent route that involved the esterification of 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose (32) with ethyl malonyl chloride followed by mild hydrolysis.

The reaction of 5,6-anhydro-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (**8**) (33)

[3]The possibility of a bicyclic orthoester involving C-3, -5, and -6 oxygen atoms as reported in some related cases cannot be eliminated (31).

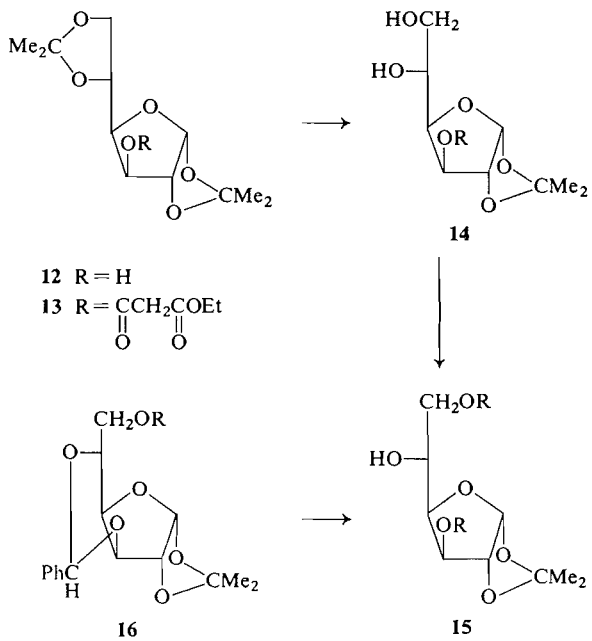

SCHEME 3

with sodio diethyl malonate was attempted in order to assess the role of a free hydroxyl group at C-3 in determining the type of product in such condensations. As in the case of **7**, the product of condensation was a cyclic lactone ester **11**, resulting from opening of the epoxide ring at C-6 and subsequent lactonization, with ejection of an ethoxide moiety.

Finally, it is of interest to note that in the products **4**, **10**, and **11**, a potential asymmetric center is created at the carbon bearing the carbethoxy group. Should the lactonization occur with some degree of chiral control, then these transformations would represent efficient procedures for asymmetric syntheses at a predetermined center in the molecule. These concepts are being actively studied in our laboratory.

Experimental

Melting points are uncorrected. The n.m.r. spectra were obtained in chloroform-*d* at 60 or 100 MHz, with tetramethylsilane as internal standard. The i.r. spectra (from Nujol) were recorded on a Beckman IR-8 instrument. Mass spectra were obtained on a Hitachi–Perkin–Elmer model RMU-6D instrument. The t.l.c. was performed on silica gel GF_{254} (Merck) and the spots were detected with a solution containing sulfuric acid in ethanol after heating the plates. Column chromatography on small scale (1–2 g) was done on short columns containing silica gel GF_{254} with moderate suction. Conventional processing signifies drying organic solutions over anhydrous sodium sulfate, filtration, and evaporation under diminished pressure.

Methyl 4,6-O-Benzylidene-2-(carboxymethyl)-2-deoxy α-D-altropyranoside Ethyl Ester (2)[4]

A solution containing 6 ml (39.1 mmol) of diethyl malonate and 0.72 g (30.0 mmol) of sodium hydride[5] in 75 ml of benzene (distilled from sodium hydride) was refluxed during 30 min. The solution was cooled and treated with 3.9 g (13.6 mmol) of **1** in 75 ml of benzene. After stirring at reflux temperature for 10–12 h, the mixture was cooled, excess base was neutralized with glacial acetic acid, and the insoluble salts were filtered. The filtrate was evaporated to a syrup and the residual diethyl malonate was removed by distillation under vacuum at 27°. The resulting syrup (5.5 g) was dissolved in absolute ethanol and a crystalline product (2.1 g, 44%) which proved to be a mixture of **2** and the diester **3**, was recovered. The mother liquors were chromatographed on a column containing silica gel GF_{254} and a further 1.37 g (27%) of mixed product was recovered. Recrystallization of the product from ethyl acetate afforded **2** as a chromatographically homogeneous product, in 50% yield (based on the mixture), m.p. 109–110°; recorded 109–110° (18); n.m.r. data ($CDCl_3$): τ 8.81 (CH_3CH_2—, t,

[4]The nomenclature adopted in this work is that suggested by Dr. K. Loening, Chemical Abstracts Service, Columbus, Ohio. We thank Dr. Loening for his assistance in naming these compounds.

[5]No precautions were taken to ensure the exclusion of moisture during the transfer and weighing of sodium hydride in this experiment.

$J = 7.2$ Hz), 7.50 (CH_2COO—, H_2, m), 6.64 (CH_3O—, s), 5.46 (H_1, s), 4.49 (C*H*Ph, s) etc.

Methyl 2-(Carboxymethyl)-2-deoxy-α-D-altropyranoside Ethyl Ester (5)

A solution containing **2** (0.15 g) in a mixture of ethanol (23 ml) and concentrated hydrochloric acid (0.06 ml) was stirred at room temperature for 2 h. The acid was neutralized with lead carbonate and the filtered suspension was processed as usual to give a syrup which was purified by preparative t.l.c. A syrup (0.11 g, 96%) was thus obtained that crystallized from cyclohexane to give the title compound, m.p. 78–79°, recorded, 80–82° (18).

Treatment of an aqueous solution of **5** with sodium periodate resulted in complete oxidation as evidenced by t.l.c.

Methyl 4,6-O-Benzylidene-2-deoxy-2-(dicarboxymethyl)-α-D-altropyranoside Diethyl Ester (3)

A solution containing 3.1 ml (20.2 mmol) of diethyl malonate and 0.37 g (15.3 mmol) of sodium hydride in 90 ml of benzene was refluxed in an atmosphere of nitrogen for 30 min. After cooling, 2 g (7.57 mmol) of **1** was added and the stirring was continued at 40° for 2 weeks, under nitrogen. Glacial acetic acid was cautiously added to the cooled solution, the salts were filtered, and the filtrate was evaporated to a syrup which crystallized upon trituration with ether. The crystals (0.39 g, 20%) were filtered and proved to be starting material. The filtrate was evaporated to a semi-crystalline syrup and traces of diethyl malonate were removed by distillation. The resulting residue was a mixture of the desired diester **3** and the lactone **4** which could be separated from each other by fractional crystallization from ethanol since the lactone is much less soluble. In this manner 1.1 g (35%) of the diester **3** was obtained. The mother liquors were chromatographed on a column containing silica gel to give additional product: total yield 1.24 g (52%, based on the reacted epoxide **1**) of **3**, m.p. 115–115.5°; $[\alpha]_D^{25}$ 69.1° (*c* 3.05, $CHCl_3$); n.m.r. data: τ 8.72 (CH_3CH_2—, t, $J = 7$ Hz), 7.00 (C*H*COO—, d, $J = 11.2$ Hz), 6.56 (CH_3O—, s), 5.35 (H_1, s), 4.37 (C*H*Ph, s), etc.

Anal. Calcd. for $C_{21}H_{28}O_9$: C, 59.43; H, 6.65. Found: C, 59.76; H, 6.78.

Methyl 4,6-O-Benzylidene-2-deoxy-2-(dicarboxymethyl)-α-D-altropyranoside γ-Lactone Ethyl Ester (4)

A solution containing 1.6 ml (10.54 mmol) of diethyl malonate and 0.24 g (10.0 mmol) of sodium hydride[6] in 70 ml of benzene was refluxed for 30 min. After cooling, 1 g (3.93 mmol of **1** was added and the solution was stirred under reflux, in an atmosphere of nitrogen for 13 h. Glacial acetic acid was added and the salts were filtered through a bed of Celite. The filtrate was evaporated to a syrup that crystallized slowly. The crystals were triturated with ether, filtered, and the filtrate was evaporated and the crystalline residue was treated again by the same process; yield 0.82 g (55%) of **4**. The mother liquors were freed from traces of diethyl malonate by distillation of the latter and an additional 0.29 (17%) of product was recovered from the residue; total yield 1.11 g (74%). Recrystallization from carbon tetrachloride afforded an analytical sample, m.p. 174–175°; $[\alpha]_D^{25}$ 92.0° (*c* 2.14, $CHCl_3$); λ_{max}: 1799 (lactone), 1738 cm^{-1} (ester); n.m.r. data: τ 8.71 (CH_3CH_2—, t, $J = 7.2$ Hz), 6.54 (CH_3O—, H_2, C*H*COO), 4.75 (H_1, d, $J_{12} = 7.9$ Hz), 4.38 (C*H*Ph, s), etc.

Methyl 4,6-O-Benzylidene-2-(carboxymethyl)-2-deoxy-3-O-methylsulfonyl-α-D-altropyranoside Ethyl Ester (6)

Mesylation of **2** (0.15 g) was done in the usual manner using mesyl chloride (0.3 ml) in pyridine (9 ml). After storing at 0° for 20 h and at room temperature for 3 h, the solution was poured into ice-water and the crystalline product was filtered and washed with cold water; yield 0.11 g (60%). Recrystallization was effected from toluene, m.p. 138.5–139.5° (dec.); $[\alpha]_D^{25}$ 61.5° (*c* 3.36, $CHCl_3$); n.m.r. data: τ 8.69 (CH_3CH_2—, t, $J = 7.1$ Hz), 7.36 (CH_2COO—, H_2, m), 7.16 (CH_3SO_3—, s), 6.56 (CH_3O—, s), 5.41 (H_1, s), 5.03 ($CHOSO_2$—, t), 4.36 (C*H*Ph), etc.

Anal. Calcd. for $C_{19}H_{26}O_9S$: C, 53.01; H, 6.09; S, 7.47. Found: C, 53.16; H, 6.09; S, 7.53.

Methyl 4,6-O-Benzylidene-2-deoxy-2-C-(hydroxyethyl)-α-D-altropyranoside

A solution of **2** (0.3 g) in 10 ml of tetrahydrofuran was added dropwise to a suspension of lithium aluminum hydride (0.1 g) in 15 ml of the same solvent. The suspension was stirred at room temperature for 15 min and excess reagent was destroyed with the cautious addition of water. The product was obtained as a chromatographically homogeneous syrup (0.25 g, 96%), after conventional processing. A sample of the syrup was further purified by preparative t.l.c. ($CHCl_3$: hexane: MeOH, 20:30:0.5) but the product did not crystallize.

Acetylation afforded a syrupy acetate that had the expected spectroscopic (i.r., n.m.r.) properties.

Alcoholysis of the Lactone 4

A solution containing 70 mg of **4** in 4 ml of ethanol was treated with 1 ml of a 0.182 *N* solution of sodium ethoxide. After stirring for 1 h at room temperature the solution was neutralized with Rexyn 102 (H^+), previously washed with ethanol, and the solution was filtered. Evaporation gave a syrup (72 mg, 96%) that crystallized from ethyl acetate to give a product identical with **3**, m.p. 113–114°.

Partial Hydrolysis and Decarboxylation of the Lactone 4

A solution containing 70 mg (0.183 mmol) of **4** in 6 ml of tetrahydrofuran was treated with 3 ml of water containing 15 mg (0.375 mmol) of sodium hydroxide. After 1 h at room temperature, the solution was acidified to p*H* 2 with 2 *N* hydrochloric acid and it was extracted with ether. The organic layer was dried and evaporated to a crystalline residue which was dissolved in 25 ml of dioxane and 3 ml of an aqueous solution saturated with sodium bicarbonate was added. The solution was refluxed for 1 h, the solvent removed under reduced pressure and the solution was diluted with dichloromethane. The latter was washed with water and processed in the usual way to give 62 mg (97%) of **2**, m.p. 109–110°.

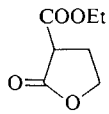
7,7-Di-C-carboxy-6,7-dideoxy-1,2-O-isopropylidene-α-D-glucoheptofuranose γ-Lactone Ethyl Ester 3-(Ethyl Malonate) (10)

A solution containing 1.15 ml (7.57 mmol) of diethyl malonate and 0.18 g (7.3 mmol) of sodium hydride in 40 ml

[6]The weighing of sodium hydride and transfer to the reaction flask was done in a dry box in an atmosphere of nitrogen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of benzene was refluxed for 30 min. The solution was cooled, 0.5 g (2.47 mmol) of **7** was added and the solution was refluxed for 6 h. After cooling, glacial acetic acid was added to neutralize excess reagent and the insoluble salts were filtered. The filtrate was evaporated to a syrup and the residual diethyl malonate was co-distilled with water. The residue was dissolved in chloroform, the solution was dried and processed in the usual manner to give a syrup. Purification on a column containing silica gel GF_{254} (CH_2Cl_2 developer) gave 0.56 g (53%) of a syrup which crystallized from ethanol. Recrystallization from ethanol gave pure material, m.p. 97.5–99°; $[\alpha]_D^{22}$ −47.3 (*c* 5.0, $CHCl_3$); λ_{max} 1783 (lactone), 1766, 1735, 1725 cm^{-1} (esters); n.m.r. data: τ 8.71, 8.58 (CH_3CH_2—, centers of triplets, $J = 7.2$ Hz); 8.67, 8.47 (CH_3—C); 6.56 (CH_2COOEt, s); 5.38 (H_2, d, $J_{21} = 3.6$ Hz); 5.16 (H_3, m); 4.05 (H_1, d, $J_{12} = 3.6$ Hz), etc.; *m/e* 415 (M^+-15); 273 (M^+-157,



Anal. Calcd. for $C_{19}H_{26}O_{11}$: C, 53.02; H, 6.09. Found: C, 52.74; H, 6.11.

*7,7-Di-C-carboxy-6,7-dideoxy-1,2-O-isopropylidene-3-O-methyl-α-D-gluco-heptofuranose γ-Lactone Ethyl Ester (**11**)*

A solution containing 0.29 ml (1.89 mmol) of diethyl malonate and 44 mg (1.82 mmol) of sodium hydride in 10 ml of benzene was refluxed for 30 min then it was treated with 0.18 g (0.833 mmol) of **8** in 40 ml of benzene. The solution was refluxed for 9 h and processed as described for **10**. After removal of diethyl malonate by co-distillation with water, the product **11** was obtained as a chromatographically homogeneous syrup (0.2 g, 74%) (t.l.c., $CHCl_3$: hexane: MeOH, 4:6:0.1). Attempted purification of a portion by preparative t.l.c. failed to give a crystalline product; λ_{max} 1790 (lactone), 1737 cm^{-1} (ester); n.m.r. data were consistent with the expected structure; *m/e* 315 (M^+-15).

*3-O-(Ethyl Malonyl)-1,2:5,6-di-O-isopropylidene-α-D-glucofuranose (**13**)*

A solution containing 13.8 ml of diethyl malonate (90 mmol) and 2.1 g (88 mmol) of sodium hydride in 600 ml of benzene was refluxed for 30 min, it was then treated with 7.7 g (29.6 mmol) of **12**. The solution was refluxed for 30 h, the reagent was neutralized with glacial acetic acid, and the solution was processed as described before to give a syrup. Residual diethyl malonate was removed by distillation during which some **12** sublimed (1.5 g, 20%). The residual syrup was chromatographed on a column containing silica gel (CH_2Cl_2 developer) to give the title compound as a syrup which could not be crystallized; 4.4 g (57%); λ_{max} 1754, 1733 cm^{-1} (ester); n.m.r. data were consistent with the structure.

*6-O-(Ethyl Malonyl)-1,2-O-isopropylidene-α-D-glucofuranose (**15**)*

An amount of **13** (0.44 g) in 20 ml of 0.5 *N* hydrochloric acid was stirred at room temperature until the solution became clear and homogeneous (1.5–2 h). The acid was neutralized with lead carbonate, the solution was extracted with dichloromethane, and the organic phase was processed in the usual manner, to give a syrup (0.3 g, 79%). Spectroscopic (n.m.r.) and chromatographic analysis indicated that the product was the desired 3-*O*-(ethyl malonyl) derivative **14**. When the syrup was chromatographed on a column containing silica gel (CH_2Cl_2—MeOH, 97:3), a crystalline product **15** was obtained which had the same chromatographic properties as **14**. Recrystallization was effected from benzene to give **15**, m.p. 100–100.5°; $[\alpha]_D$ 0 ± 1° (*c* 2.70, $CHCl_3$); n.m.r. data indicated beyond doubt that the ester function was situated on C-6.

Anal. Calcd. for $C_{14}H_{22}O_9$: C, 50.30; H, 6.63. Found: C, 50.69; H, 6.68.

The same product was obtained from 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose by sequential esterification (sodio diethyl malonate, benzene) to give a syrup **16** (75%), and partial hydrolysis (0.5 *N* HCl, 70°, 3h); m.p. 100–100.5° (undepressed upon admixture with **15**).

*Reaction of Sodio Diethyl Malonate with 5,6-Anhydro 3-O-(Ethyl Malonyl)-1,2-O-isopropylidene-α-D-glucofuranose (**9**)*

A solution containing 0.1 g (0.49 mmol) of **7** and 1 ml of dimethylaniline in 25 ml of ether was treated with 0.12 g (0.78 mmol) of ethyl malonyl chloride (34) at 0°. After stirring at room temperature for 15 min the solution was washed successively with dilute hydrochloric acid, aqueous sodium bicarbonate, and water. Processing the ethereal solution gave a syrup consisting of **9** (34%). The n.m.r. spectrum of a sample that was further purified by preparative t.l.c. was consistent with the structure.

Treatment of the product **9** (50 mg) with sodio diethyl malonate as described for the preparation of **10**, (reflux 2.5 h) gave the desired product **10** in 78% yield (chromatographically homogeneous syrup). Crystallization from ethanol afforded a product with m.p. 97–100° (44%), identical with a sample prepared from **9** and the carbanion.

The generous financial assistance from the National Research Council of Canada and an NRCC fellowship for P.D. are gratefully acknowledged.

Chemistry and Synthetic Utility of α-(Dimethylamino)benzylidene and 1-(Dimethylamino)ethylidene Acetals[1,2]

S. HANESSIAN AND E. MORALIOGLU[3]

Department of Chemistry, University of Montreal, Montreal, Quebec

Received June 24, 1971

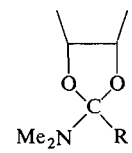
N,N-Dimethylbenzamide and *N,N*-dimethylacetamide dimethyl acetals react with vicinal *cis*-diols to give cyclic α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals respectively. In aqueous methanol, the acetals are hydrolyzed to the original diol. At p*H* 4–5, cleavage occurs to give benzoate and acetate esters, presumably by the sequential formation of acyloxonium and orthoacid intermediates. The acetals are thus useful as temporary protecting groups for vicinal diols and can be used for indirect, selective benzoylation and acetylation. They are compatible with the reaction conditions of acylation (acetylation, benzoylation, tosylation) and nucleophilic displacement (N_3^-).

Les acétals diméthyliques de la *N,N*-diméthylbenzamide et la *N,N*-diméthylacétamide réagissent avec les diols vicinaux *cis* pour donner les acétals cycliques α-(diméthylamino)benzylidénique et 1-(diméthylamino)-éthylidénique respectivement. Ces acétals sont hydrolysés dans le méthanol aqueux pour redonner le diol initial. A p*H* 4–5, le clivage conduit aux benzoates et acétates correspondants probablement par la formation successive d'un ion acyloxonium et d'un orthoacide comme intermédiaires. Ces acétals cycliques sont donc particulièrement utiles comme groupe protecteur momentané pour des diols vicinaux et peuvent être utilisés indirectement pour des benzoylations et acétylations sélectives. Ces acétals cycliques sont compatibles avec les réactions d'acylation (acétylation, benzoylation, tosylation) et de déplacements nucléophiles N_3^-).

Canadian Journal of Chemistry, **50**, 233 (1972)

The problem of temporary blocking of reactive functions, such as hydroxyl and amino groups, is one of primordial importance in synthetic organic chemistry. The utility of blocking groups is largely dependent on their compatibility with various reaction conditions and it is not surprising that an "all purpose" blocking group is still non-existent. There is at present a wide enough choice of protecting groups for isolated hydroxyl and amino functions and the design of a particular synthetic sequence using molecules containing such functions is relatively facile. The problem is somewhat different in the case of vicinal diols, as the number of possible modes of simultaneous blocking is limited. Acetals are among the most frequently utilized derivatives in the case of diols and they represent a distinct advantage in their ease of formation. A wide variety of syntheses in the area of carbohydrates (2), utilize acetals as intermediates, mainly because of their ease of formation and eventual hydrolysis.

Our interest in the reactions of amide halides and amide acetals with carbohydrates in general (3) and with nucleosides (4) in particular, prompted us to investigate the chemistry of (dimethylamino)benzylidene and ethylidene acetals of the 1,3-dioxolane type, as shown below, particularly with regard to their modes of preparation and cleavage, their stability and their utility as potential temporary blocking groups for 1,2- and 1,3-diols systems. In this paper, we report on our findings with α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals, utilizing selected carbohydrate derivatives as model substrates (1).



R = Me, Ph

Since their discovery by Meerwein and coworkers (5), amide acetals of the type

$$Me_2N{-}\overset{\overset{R}{|}}{C}(OMe)_2 \quad (R = H, \text{methyl})$$

have been known to be powerful electrophilic reagents. Their reactivity is due largely to the existence in solution of the corresponding imino

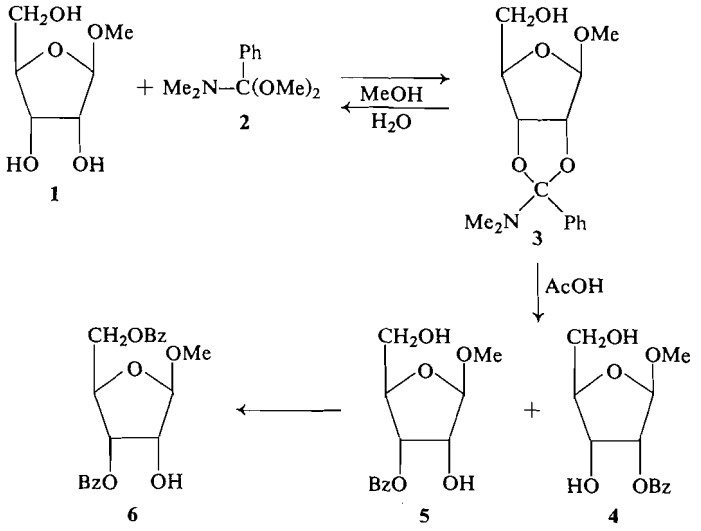
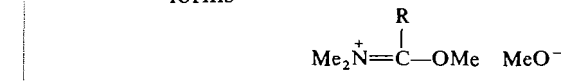


SCHEME 1

forms



which are susceptible to attack by nucleophiles at the central carbon atom. For example, such amide acetals are excellent esterifying agents, even for hindered acids (6–8). With higher alcohols, the dimethyl acetal of *N*,*N*-dimethylformamide undergoes acetal exchange (5, 6) to give the corresponding dialkyl acetal. In the original work of Meerwein and coworkers (5), DMF and DMAC dimethyl acetals were reacted with ethylene glycol and the corresponding cyclic acetals were isolated, indicating the possibility of acetal exchange reactions with vicinal diols. Žemlička and Holý (9) have used DMF dimethyl acetal as a blocking group for amino groups in the heterocyclic moiety in various ribonucleosides, with simultaneous formation of 2′,3′-*O*-(dimethylamino)methylene acetals. The authors have pointed out, however, the extreme instability of this acetal. Employing methyl β-D-ribofuranoside **1** (10) as a model, we have also noted in our preliminary studies the particular lability of the corresponding 2,3-*O*-(dimethylamino)methylene acetal, obtained with DMF dimethyl acetal. While our work was in progress, a report appeared on the reactions of DMF dimethyl acetal with *cis* and *trans* cyclohexane 1,2-diols (11). We show in this paper that, in marked contrast to cyclic DMF acetals, those derived from *N*,*N*-dimethylbenzamide dimethyl acetal and *N*,*N*-dimethylacetamide dimethyl acetal, are of practical and preparative utility. In addition to their ease of formation and usefulness for the temporary protection of vicinal diols, they lend themselves to a variety of novel transformations, such as their cleavage to benzoate and acetate esters respectively. To the best of our knowledge, cyclic acetals of *N*,*N*-dimethylbenzamide have not been previously studied and the above-mentioned aspects may prove useful in synthetic organic chemistry.

Methyl β-D-ribofuranoside **1** was chosen as one of the model substrates, because it contains a vicinal diol system required for transacetalization, and a primary hydroxyl group which could serve to test the compatibility of the acetal with various transformations. The presence of the D-ribofuranose moiety in various biologically important molecules, such as nucleosides, was an added incentive for its choice as model substrate.

Reaction of **1** with a slight excess of *N*,*N*-dimethylbenzamide dimethyl acetal **2** (12) in 1,1,1-trichloroethane[4] was essentially complete at room temperature within 10–12 h. The product was isolated by rapid washing of the organic phase with water and processing to give methyl 2,3-*O*-[α-(dimethylamino)benzylidene]-β-D-ribofuranoside (**3**) as a syrup in high yield (Scheme 1). The n.m.r. spectral characteristics of **3** were those expected of its structure.

[4]This solvent was inadvertently termed 1,1,2-trichloroethane in ref. 1.

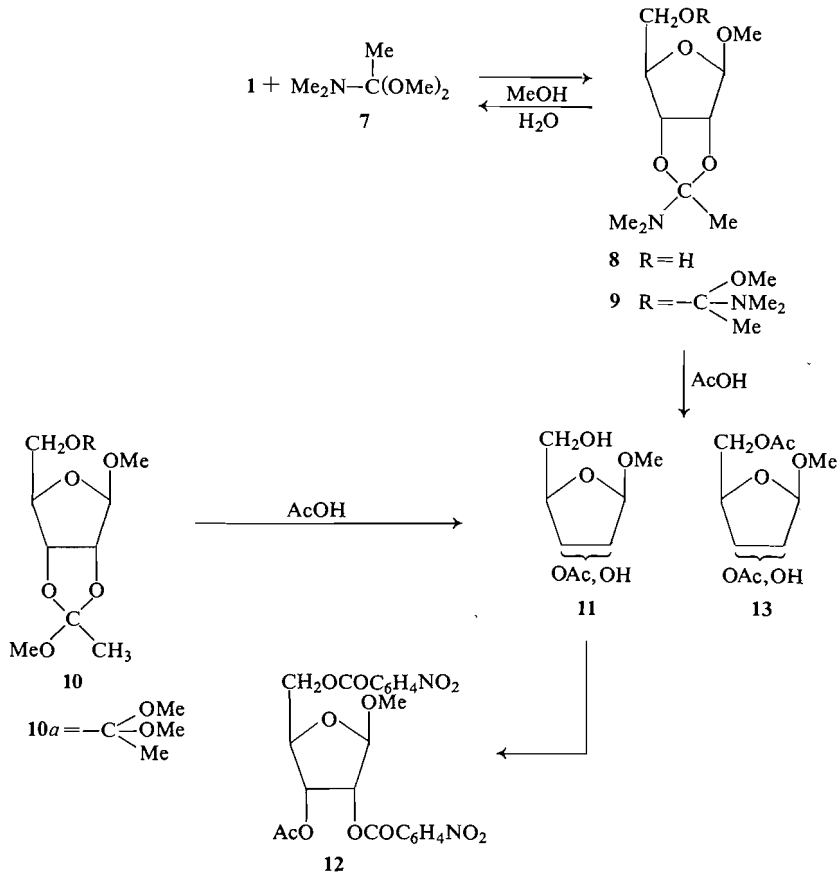

SCHEME 2

Reaction of **1** with *N*,*N*-dimethylacetamide dimethyl acetal **7** (5) in 1,1,1-trichloroethane for 1 h led to an almost quantitative conversion into the corresponding methyl 2,3-*O*-[1-(dimethylamino)ethylidene]-β-D-ribofuranoside (**8**) (Scheme 2). Processing the reaction mixture by direct evaporation, instead of a preliminary rapid washing with water to remove residual reagent, afforded, in addition to **8**, a second product of higher chromatographic mobility, which was proved to be the mixed acetal **9**.[5] The formation of this byproduct took place during the evaporation process, when the effective concentration of reagent (present in slight excess) became relatively high. The formation of such mixed acetals could be avoided by using equimolar amounts of reagent, or better yet, using a slight excess of reagent and rapid washing of the reaction mixture with water. This procedure afforded the acetal **8** as a relatively pure liquid in over 80% yield that was suitable for further transformations. Distillation at 103–108°/0.4 Torr afforded **8** as a 1:1 mixture of two diastereoisomers (see Fig. 1). This ratio was not always the same and varied with the time of reaction, the conditions of isolation and temperature. Attempts to separate the diastereoisomers by careful fractional distillation were unsuccessful although different cuts within a narrow temperature range showed different ratios as evidenced by n.m.r. In one instance, a fraction consisting predominantly of a single diastereoisomer was isolated (see Fig. 1). The acetal derivatives **3** and **8** were stable for prolonged periods, when kept under anhydrous conditions. When refluxed in 3% aqueous methanol, hydrolysis ensued, with the quantita-

[5]An alternative structure is one in which two molecules of **1** have condensed with **7** through the 5-hydroxyl group.

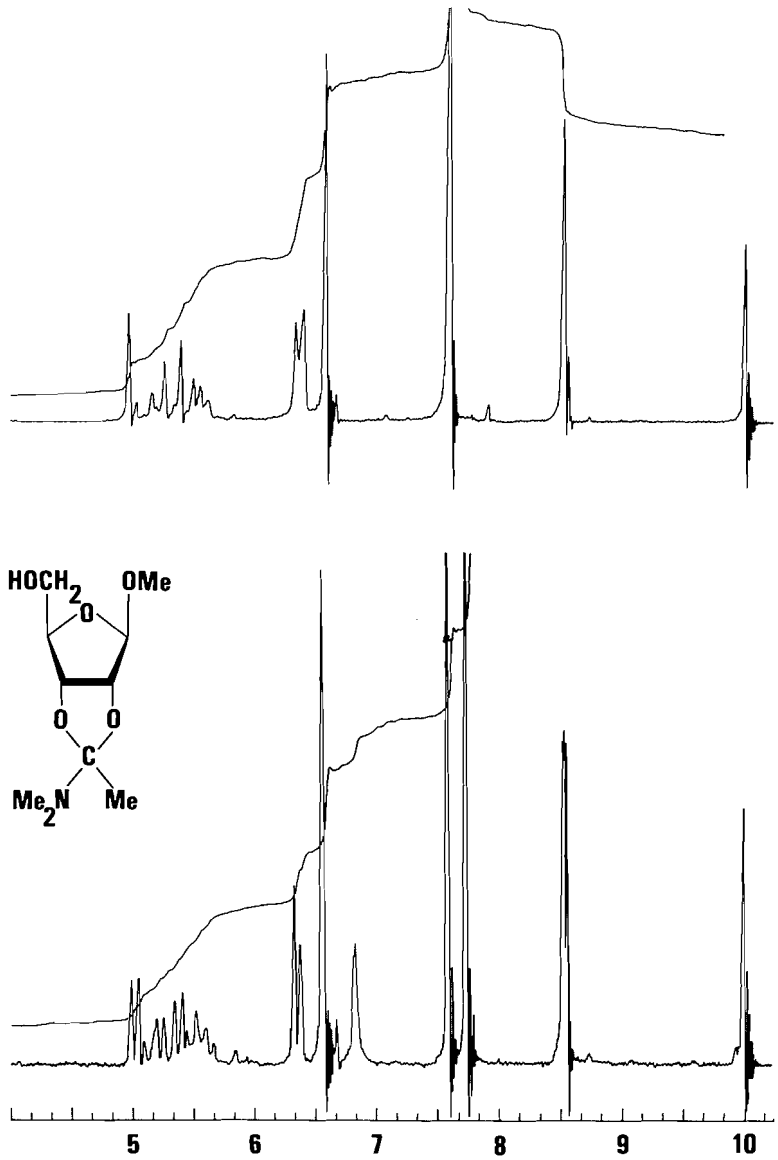

FIG. 1. The 60 MHz n.m.r. spectra of methyl 1-(dimethylamino)ethylidene-β-D-ribofuranoside: pure diastereoisomer (upper spectrum); mixture (lower spectrum).

tive recovery of the starting material **1**. Thus, both the formation and removal of cyclic α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals take place under very mild conditions. The facile regeneration procedure, which could be carried out at room temperature also, accentuates the role of acetals such as **2** and **7** as reagents for the temporary protection of vicinal diols, particularly when other substituents in the molecule are relatively base-stable.[6] The hydrolytic instability of these acetals in aqueous media is not unexpected in view of their orthoester structure. It should be pointed out however, that the instability is less

[6]Solutions of the reagents and the cyclic acetals are basic ($pH \simeq 10$).

pronounced than that of an alkoxy analog such as methyl 2,3-*O*-methoxyethylidene-β-D-ribofuranoside (**10**) (Scheme 2). The latter was prepared from trimethylorthoacetate in DMF containing *p*-toluenesulfonic acid as catalyst, and was isolated as a liquid that was slightly contaminated with the corresponding mixed acetal **10***a* arising from condensation of the primary hydroxyl group.

The possibility of controlled cleavage of the α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene groups was investigated with the objective of preparing selectively acylated products. At p*H* 4–5 in aqueous acetic acid, cleavage of the acetal **3** took place within 1–2 h to give a syrup which consisted of methyl 2-*O*-benzoyl-β-D-ribofuranoside (**4**) and methyl 3-*O*-benzoyl-β-D-ribofuranoside (**5**) (predominant product) (Scheme 1). Catalytic debenzoylation of the mixture gave crystalline **1**, thus confirming the preservation of the D-*ribo* configuration in the acetal cleavage process. Selective benzoylation of the mixture containing **4** and **5** afforded a crystalline material from which a single product could be obtained by fractional crystallization. This product is designated as methyl 3,5-di-*O*-benzoyl-β-D-ribofuranoside (**6**), based on its n.m.r. spectral data and comparison with data for closely related compounds (13). The sequence leading to the dibenzoate **6** could also be effected without the isolation of the intermediate product **3**.

At p*H* 3–4 in 95% aqueous acetic acid, the acetal **8** was quantitatively cleaved to give a mixture of 2- and 3-monoacetates **11** and trimethylamine acetate (Scheme 2). A mixture of monoacetates was also formed in the presence of a variety of other aqueous acids at p*H* 3–4. Although the isomeric acetate derivatives could not be separated, their presence in approximately equal amounts in the product was ascertained by n.m.r. spectral studies. A crystalline di-*O*-*p*-nitrobenzoate was obtained from this syrupy mixture, which upon fractional crystallization from absolute ethanol afforded a single product, presumably methyl 3-*O*-acetyl-2,5-di-*O*-*p*-nitrobenzoyl-β-D-ribofuranoside(**12**). The mixture of monoacetates **11** could also be obtained by hydrolysis of the orthoester **10** in 10% aqueous acetic acid (p$H \simeq 5$) during 30 min. When samples containing both **8** and **9** were subjected to hydrolysis, the product consisted of the mixture of monoacetates **11** derived from **8** and a mixture of diacetates, corresponding to a 3,5- or a 2,5-diacetate **13**, resulting from hydrolysis of the minor component **9**. The isolation of these diacetates provides supporting evidence for the structure of **9**, which upon hydrolysis should give a diacetate, or a diacetate and a monoacetate if a dimeric structure for **9** is assumed. In order to assess the reactivity of the primary hydroxyl group in **8**, methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (14) was allowed to react with a large excess of **7**. After prolonged times, only a small amount of a new product was formed (t.l.c.). The reaction mixture was processed with aqueous acid and the less polar product was separated from unreacted starting material and proved to be methyl 5-*O*-acetyl-2,3-*O*-isopropylidene-β-D-ribofuranoside, thus providing conclusive proof that a transacetalization had taken place with the primary hydroxyl group. The much slower rate of the reaction compared to **8** may indicate a catalyzing effect of the 2,3-*O*-(dimethylamino)ethylidene group on the reactivity of the 5-hydroxyl group. The acetylated products **11**, **12**, and **13** were also converted into methyl β-D-ribofuranoside, upon treatment with sodium methoxide in methanol, indicating the absence of configurational inversions in the hydrolytic process.

Our exploratory experiments on acetal formation with model substances were continued with 1,2-*O*-isopropylidene-α-D-glucofuranose **14** as substrate. In this case, two aspects were to be considered, namely the type of acetal formed in view of the existence of two possibilities, and the direction of ring opening in weakly acidic media. Reaction of **14** with **2** revealed a selective acetal formation with the vicinal diol system and gave 5,6-*O*-[α-(dimethylamino)benzylidene]-1,2-*O*-isopropylidene-α-D-glucofuranose (**15**) (Scheme 3). Controlled cleavage of the 5,6-acetal function at p*H* 4–5 gave a good yield of crystalline 6-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**16**). The latter was prepared in low yield by the controlled benzoylation of **14** according to a reported procedure (15).

The reaction of **14** with **7** was monitored by t.l.c. which indicated the formation of a product after stirring at room temperature for 20 h. Processing afforded a syrup which consisted of some starting material and 5,6-*O*-[1-(dimethylamino)ethylidene]-1,2-*O*-isopropylidene-

SCHEME 3

α-D-glucofuranose (**15***a*) as a mixture of diastereoisomers (Scheme 3). Unlike the acetal **8**, compound **15***a*, in which the acetal spans a primary and a secondary hydroxyl group, was much more sensitive to water and hydrolyzed to starting material. Treatment of the mixture with aqueous acetic acid gave an 88% yield of 6-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**16***a*) (16). Although optimum or forcing conditions were not explored, the yield of the acetal derivative **16***a* could be considerably improved by working under strictly anhydrous conditions.

From these results, it is evident that when polyhydroxy compounds containing vicinal diols, such as **14**, are treated with the acetals **2** or **7**, formation of a 1,3-dioxolane ring is clearly preferred under the conditions of the reaction. The directive influence in the acetal cleavage leads to a preparative method for the selective esterification of the primary hydroxyl group in such compounds.

The aforementioned reactions demonstrate some of the uses of α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals in preparative organic chemistry. The acid-catalyzed cleavage of these acetals to give monobenzoylated and monoacetylated diols is of synthetic and mechanistic significance. It is reasonable to assume the formation of benzoxonium, acetoxonium and/or iminium type intermediates such as **17**, **17***a*, **18**, **18***a* respectively, depending on the site of protonation (Scheme 4).

It is difficult at this stage to determine the underlying factors in the cleavage of the acetals **3** and **8**, which sometimes leads to a predominance of one isomer, since the initial products could conceivably equilibrate in the mildly acidic medium. The intermediacy of benzoxonium and acetoxonium ions of type **17** and **17***a* and orthoacids derived from them, rather than iminium ions of type **18** and **18***a* is suggested by the highly selective opening of acetals involving a primary alcohol group, such as **15** and **15***a*. The formation of a primary benzoate (and

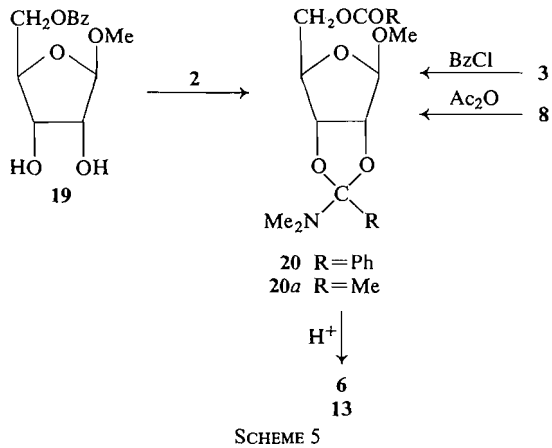
acetate) is in agreement with similar cleavage reactions involving benzoxonium ions spanning primary and secondary carbon atoms (17–22). In this respect, the presence of a (dialkylamino) group in these benzylidene and ethylidene acetals may offer some advantage over the analogous alkoxybenzylidene and alkoxyethylidene acetals. These aspects will be elaborated upon in future papers in this series. It has been reported (23–25) that equilibration of isomeric 2′- and 3′-acetates in certain ribonucleosides favors acetyl migration away from the glycosyl carbon atom, *i.e.* a predominance of the 3′-acetate isomer at equilibrium. Attempts to increase the proportion of one of the two isomers in **11** by equilibration have so far been unsuccessful in our hands. This aspect may be dependent on the nature of the aglycone. In contrast to **8**, the direction of ring opening of orthoesters spanning vicinal diols in conformationally rigid six-membered rings is such that a preponderance of one ester derivative is usually observed (26–28). In conformationally flexible systems, the selectivity is much less pronounced (29). Although the cleavage of acetals of type **8**, spanning two secondary hydroxyl groups in a pentofuranose system, proceeds in a non-selective manner, the reaction retains both preparative and interpretive significance. Except for the orthoester approach, there are no practical methods for effecting monoacetylation or monobenzoylation of the 2- and 3-positions in the ribofuranose series. The problem of selective acylation (25) is an important one, in connection with approaches to oligonucleotide syntheses as well as in understanding the mechanisms of aminoacylation and acyl migration in *t*-RNA.

In the interest of assessing the utility of α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals as temporary blocking groups, we investigated the possibilities of effecting various transformations at the primary hydroxyl groups in the presence of the acetal function as well as testing the compatibility of certain groups with the conditions of acetal formation.

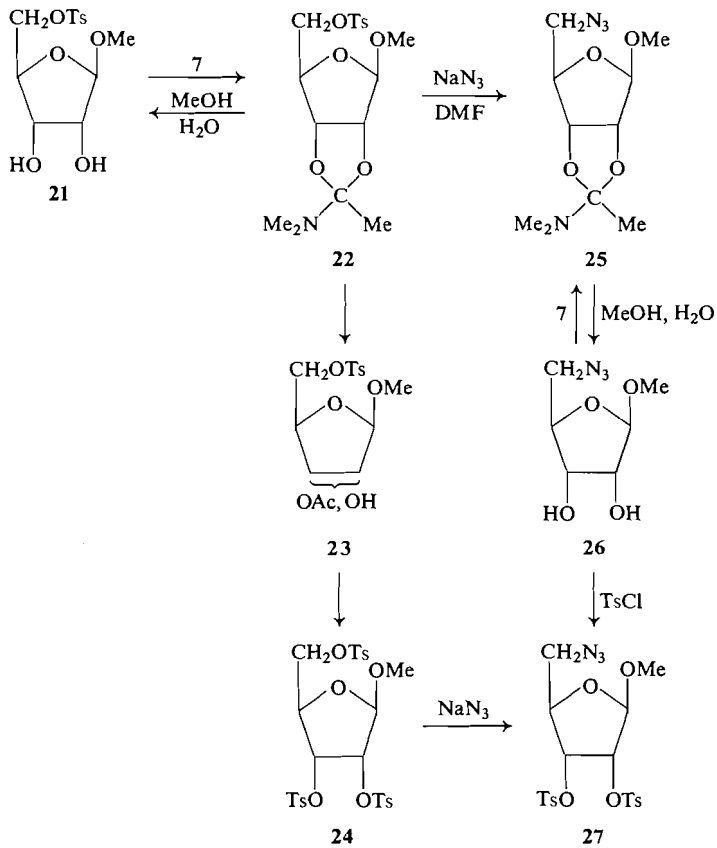
Thus in an alternative approach to the dibenzoate **6**, the suitability of benzoate esters as *O*-protecting groups during cyclic acetal formation was explored. The reaction of methyl 5-*O*-benzoyl-β-D-ribofuranoside (**19**) (30) with **2** was carried out in 1,1,1-trichloroethane at 0° during



SCHEME 5

2 h and at room temperature for 5 h, to give methyl 5-*O*-benzoyl-2,3-*O*-[α-(dimethylamino)-benzylidene]-β-D-ribofuranoside (**20**) as a syrup in good yield (Scheme 5). The acetal **20**, probably a mixture of diastereoisomers, was sufficiently pure for further transformations. It is thus evident that benzoate esters are compatible with the conditions of acetal formation. Alternatively, compound **20** could be prepared from **3** by benzoylation with benzoyl chloride in pyridine. In order to avoid hydrolysis of the acetal group during the work-up process, a convenient procedure was to dilute the solution with 1,1,1-trichloroethane and to process by extraction with cold water. In this manner, the water-sensitive acetal remained in the organic phase during the work-up operation. Treatment of **20** prepared by the above methods with 95% aqueous acetic acid at p*H* 4–5 resulted in rapid cleavage of the acetal group to give a mixture of methyl β-D-ribofuranoside dibenzoates from which the pure 3,5-dibenzoate isomer **6** could be easily obtained by fractional crystallization (Scheme 5).

Methods of selective benzoylation of secondary hydroxyl groups in D-ribofuranose derivatives are scarce and somewhat tedious (31, 32). An indirect method of benzoylation of vicinal diols involves the acid-catalyzed cleavage of methoxybenzylidene derivatives, which are structurally related to the α-(dimethylamino)-benzylidene acetals. Selective benzoylations of uridine (33) and *N*,*N*-dimethyladenosine (34) have been effected by this method. Selective benzoylation with concomitant introduction of a bromine atom in the molecule can be effected



SCHEME 6

by the cleavage of *O*-benzylidene acetals with *N*-bromosuccinimide (17–20). Application of this reaction to *O*-benzylidene nucleosides has been demonstrated also (21). Furthermore, it has been shown that the presence of water in these reaction mixtures leads to the cleavage of the *O*-benzylidene acetals and the formation of benzoate esters (17, 22). Treatment of the acetal **8** with acetic anhydride in pyridine at room temperature overnight, followed by dilution with 1,1,1-trichloroethane and extraction with water, gave the corresponding 5-*O*-acetyl derivative **20***a* (92%) as a mixture of diastereoisomers (Scheme 5). The n.m.r. spectrum of **20***a* clearly showed the acetyl group to be in the primary position. Hydrolysis at p*H* 3–4 with 95% acetic acid gave a syrup in good yield which consisted of a mixture of 2,5- and 3,5-diacetates, **13**. Attempts to obtain a crystalline mono-*p*-nitrobenzoate were not unsuccessful. Treatment of **20***a* with 3% aqueous methanol afforded crystalline **1** in over 90% yield. The successful acylations of **3** and **8** point out the distinct advantages of α-(dimethylamino)benzylidene and 1-(dimethylamino)ethylidene acetals over the corresponding dimethylaminomethylene acetals derived from vicinal diols and DMF acetals. It has been reported that all attempts to acylate alcohol groups in such acetals have been unsuccessful, and led to acetal cleavage (9).

It was of interest to attempt nucleophilic displacement reactions in the presence of one of the acetal functions. The desired substrate, methyl 2,3-*O*-[1-(dimethylamino)ethylidene]-5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**22**) was prepared by acetalation of the corresponding methyl 5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**21**). The latter was obtained as a colorless syrup by controlled monotosylation of **1** and purification by column chromatography. Alternatively, the acetal **22** could also be prepared by tosylation of **8**, demonstrating another example of

acylation in the presence of the 1-(dimethylamino)ethylidene function (Scheme 6). Acid hydrolysis of **22** at p*H* 4–5 afforded methyl 5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside as a mixture of 2- and 3-monoacetates **23**. Deacetylation and tosylation afforded the known crystalline methyl 2,3,5-tri-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**24**) (35). Treatment of **22** with aqueous methanol regenerated the tosylate **21** in good yield. As an example of displacement reaction we selected the system consisting of sodium azide in anhydrous DMF, which has become the classical and practical approach to amino sugar derivatives. Treatment of **22** at 90° during 6 h in the above system, followed by dilution with 1,1,1-trichloroethane and extraction with small portions of water afforded the desired methyl 5-azido-5-deoxy-2,3-*O*-[1-(dimethylamino)ethylidene]-β-D-ribofuranoside (**25**) as the major product. Traces of ring cleavage products could not be avoided in this case because of the difficulties with the complete removal of DMF and the necessity for repeated evaporation by codistillation with other solvents. Alternatively, the solvents could be lyophilyzed and work-up effected as usual. The syrupy **25** possessed the expected n.m.r. spectral characteristics and proved suitable for subsequent reactions. Hydrolysis with aqueous methanol afforded the known (35) methyl 5-azido-5-deoxy-β-D-ribofuranoside (**26**), that was also prepared from the corresponding 5-tosylate **21** for purposes of comparison. Reaction of **26** with **7** in the usual manner gave the corresponding acetal **25** in excellent yield. Both chromatographic and n.m.r. spectral properties of **25** were the same as those recorded in the alternate route described above. Cleavage of the acetal ring in **25** with aqueous acetic acid gave the expected mixture of 2- and 3-acetates as the sole products. Deacetylation and tosylation afforded the known crystalline methyl 5-azido-5-deoxy-2,3-di-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**27**), prepared also from the corresponding tritosylate by selective displacement with azide ion (35).

Experimental

Melting points are uncorrected. The n.m.r. spectra were obtained in chloroform-*d* at 60 or 100 MHz, with tetramethylsilane as internal standard. The i.r. spectra were recorded on a Beckman IR-8 instrument. The t.l.c. was performed on silica gel GF_{250} (Merck) and the spots were detected with a solution containing sulfuric acid in ethanol after heating the plates. Column chromatography was done using Davidson silica gel.

Conventional processing signifies drying organic solutions over anhydrous sodium sulfate, filtration, and evaporation under diminished pressure. Optical rotations were measured with a Perkin–Elmer model 141 photoelectric spectropolarimeter.

N,N-Dimethylbenzamide Dimethyl Acetal (2)

A mixture of *N,N*-dimethylbenzamide (14.9 g, 0.1 mmol) and dimethylsulfate (12.6 g, 0.1 mmol) was heated at 90° for 4 h. The yellowish viscous solution was cooled and added dropwise and with stirring to a solution of sodium methoxide in methanol (prepared from 2.3 g of sodium in 35 ml of methanol). The desired product **2** was recovered by distillation, 8.6 g, 44%; b.p. 30–33°/0.1 Torr (12). The n.m.r. data: τ 1.48, 2.32 (aromatic protons); 6.64 (OCH_3); 7.80 ($—N(CH_3)_2$). The sample was contaminated with a small amount of *N,N*-dimethylbenzamide.

N,N-Dimethylacetamide Dimethyl Acetal (7)

A mixture of *N,N*-dimethylacetamide (43.6 g, 0.5 mmol) and dimethylsulfate (63.1 g, 0.5 mmol) was heated at 60–80° during 2 h. The viscous solution was then added dropwise to a solution of sodium methoxide (from 11.5 g sodium in 160 ml of methanol) with stirring at 0°. The resulting solution was heated gradually to 190° and the desired product 7 was obtained from a fraction with b.p. 103–112°/740 Torr (5). Redistillation gave 15 g, 23% of **7** as a colorless liquid which was stored in the dark at 0°. The n.m.r. data: τ 8.73 ($—CH_3$, singlet); 7.69 ($—N(CH_3)_2$, singlet); 6.76 ($—(OCH_3)_2$, singlet).

Methyl 2,3-O-[α-(Dimethylamino)benzylidene]-β-D-ribofuranoside (3)

A mixture of **1** (1 g, 6.1 mmol) and *N,N*-dimethylbenzamide dimethyl acetal **2** (2.2 g, 11 mmol) in 25 ml of chloroform was stirred in the dark at room temperature for 18 h. The solution was cooled, diluted with 1,1,1-trichloroethane (75 ml) and water (50 ml). The organic layer was separated, rapidly extracted with cold water, and processed to give the product as a syrupy mixture of diastereoisomers (82:18, by n.m.r.); yield 1.8 g, quant. The product exhibited a single spot by t.l.c. ($CHCl_3$–MeOH, 10:1) although a minor quantity of *N,N*-dimethylbenzamide was present. The n.m.r. data: 2.16, 2.80 (aromatic protons); 5.00, 5.03 (H_1, singlets); 5.38 (H_2–H_4, multiplet); 6.32 (OH, $H_{5,5'}$, multiplet); 6.48 (OCH_3); 7.42, 7.48 ($—N(CH_3)_2$, singlets).

Methyl 2,3-O-[1-(Dimethylamino)ethylidene]-β-D-ribofuranoside (8)

Method a

A solution containing 4 g (24 mmol) of **1** and 3.25 (24 mmol) of *N,N*-dimethylacetamide dimethyl acetal **7** in 100 ml of 1,1,1-trichloroethane was stirred at room temperature in the dark for 6 h. The solution was extracted with two 50 ml portions of cold water and the organic phase was dried and evaporated to a syrup (4.1 g, 80%) consisting essentially of the desired product as a mixture of diastereoisomers, b.p. 103–108°/0.4 Torr (t.l.c., $CHCl_3$–MeOH, 10:1). A portion was redistilled at 103–108°/0.4 Torr to give a small quantity of a pure diastereoisomer; n.m.r. data: τ 4.97 (H, singlet); 5.22 (H_2, doublet, $J_{2,3} = 6$ Hz); 5.41 (H_3, doublet, $J_{3,2} = 6$ Hz); 5.54 (H_4, triplet, $J_{4,5} = 4$ Hz);

For personal use only.

6.35 ($H_{5,5'}$ and OH, multiplet); 6.57 (OMe, singlet); 7.54 (Me_2N—, singlet); 8.51 (CH_3—C, singlet).

Method b

The reaction was repeated as above in the presence of **2** equivalents of *N,N*-dimethylacetamide dimethyl acetal. Processing in the usual manner after a reaction period of 1 h afforded a syrup in quantitative yield, consisting predominantly of **8**. A minor product was the mixed acetal **9** which could be readily detected by t.l.c., ($CHCl_3$–MeOH, 10:1) as a component of higher chromatographic mobility.

Regeneration of Methyl β-D-Ribofuranoside from 3 and 8

Amounts of **3** (0.2 g) and **8** (0.5 g) were dissolved each in 10 ml of 3% aqueous methanol and the solutions were heated at reflux for 2 h. Evaporation of the respective solutions gave syrups which crystallized from ethyl acetate to give **1** (0.1 g, 90% and 0.26 g, 74% respectively), m.p. 78°, reported m.p. 79–80° (10). The mother liquors contained additional product in each case.

Acid Hydrolysis of Methyl 2,3-O-[α-(Dimethylamino)-benzylidene]-β-D-ribofuranoside (3)

A solution of **3** (0.6 g, 2 mmol) in 10 ml of 95% aqueous acetic acid (p*H* 3–4) was stirred at room temperature for 2 h. The solution was neutralized with sodium hydrogen carbonate and extracted with chloroform. Processing the organic phase afforded a syrup (0.25 g, 46%) consisting entirely of methyl 2-*O*-benzoyl-β-D-ribofuranoside **4** and the corresponding 3-benzoate **5** in an approximate ratio of 2:3; λ_{max} (film) 1740 cm^{-1} (benzoate); n.m.r. data; τ 2.09, 2.64 (aromatic protons); 4.64 (H_2, H_3, doublet, $J = 4$ Hz); 5.03, 5.12 (H_1, singlets); 5.64 (H_2, H_3, and H_4, multiplet); 6.32 ($H_{5,5'}$, multiplet); 6.64 (—OCH_3); 7.06 (OH).

Methyl 3,5-Di-O-benzoyl-β-D-ribofuranoside (6)

The mixture of esters **4** and **5** (0.13 g) was dissolved in 5 ml of dry pyridine and the solution was treated with 1 equiv of benzoyl chloride in pyridine at 0°. After standing at 4° overnight, and 1 h at room temperature, the solution was poured into ice-water and the mixture was extracted with chloroform. Processing of the organic layer gave a semi-crystalline syrup which was chromatographically homogeneous; yield 0.18 g (95%). Fractional crystallization from absolute ethanol gave the desired product (50 mg), m.p. 132–133°; $[\alpha]_D^{25}$ −8.77° (*c* 0.49, $CHCl_3$); λ_{max} 1740 cm^{-1} (benzoate); n.m.r. data: τ 2.06, 2.67 (aromatic protons); 4.70 (H_3, $J_{3,2} = 4$ Hz); 5.06 (H_1, singlet); 5.51 (H_2–$H_{5,5'}$, multiplet); 6.70 (—OCH_3); 7.32 (OH).

Anal. Calcd. for $C_{20}H_{20}O_7$: C, 64.69; H, 5.38. Found: C, 64.42; H, 5.44.

Methyl 5-O-Benzoyl-2,3-O-[α-(Dimethylamino)-benzylidene]-β-D-ribofuranoside (20)

(a) From Methyl 5-O-Benzoyl-β-D-ribofuranoside (19)

A solution containing **19** (0.5 g, 1.8 mmol) and *N,N*-dimethylbenzamide dimethyl acetal **2** (0.73 g, 3.7 mmol) in 12 ml of chloroform was stirred in the dark at 0° for 2 h and at room temperature for 4 h. The solution was processed as described for the preparation of **3** to give the product **20** as a syrup (0.74 g, quant.); λ_{max} (film) 1740 cm^{-1}. The n.m.r. data indicated a mixture of diastereoisomers in the ratio 3:1; τ 2.06, 2.64 (aromatic protons); 4.80, 4.83 (H_1, singlets); 5.06–5.80 (H_2–$H_{5,5'}$, multiplet); 6.48, 6.54 (—OCH_3, singlets); 7.64, 7.77 (—$N(CH_3)_3$, singlets).

(b) From 3 by Controlled Benzoylation

A solution of **3** (0.9 g, 2.5 mmol) in 20 ml of dry pyridine was cooled to 0° and treated dropwise with a solution of benzoyl chloride (0.43 g, 3 mmol). After standing overnight at 4° and at room temperature for 2 h, the solution was diluted with 1,1,1-trichloroethane, cooled, and extracted with cold water. The organic phase was separated and processed as usual to give the product **20** as a mixture of diastereoisomers; yield, 1.2 g, 98%; λ_{max} (film) 1740 cm^{-1}. The product was chromatographically homogeneous ($CHCl_3$–MeOH, 10:1) and was identical (i.r., n.m.r.) to that obtained by method *a*.

Acid Hydrolysis of Methyl 5-O-Benzoyl-2,3-O-[α-(Dimethylamino)benzylidene]-β-D-ribofuranoside (20)

A solution of **20** (0.735 g) in 10 ml of 95% acetic acid (p*H* 3–4) was stirred at room temperature for 1.5 h. The solution was neutralized with sodium hydrogen carbonate; it was extracted with chloroform and the extracts were processed in the usual manner to give a chromatographically homogeneous semi-crystalline residue (0.56 g, 81%). The n.m.r. data indicated the presence of a 1:1 mixture of the dibenzoate **6** and the isomeric 2,5-dibenzoate. Fractional crystallization from ethanol gave the pure dibenzoate **6** (0.27 g, 47%); m.p. 132–133°; identical in all respects with material prepared from **5**.

Acid Hydrolysis of Methyl 2,3-O-[1-(Dimethylamino)-ethylidene]-β-D-ribofuranoside (8)

An amount of **8** (0.5 g) was dissolved in 95% aqueous acetic acid (10 ml, p*H* 3–3.5), the solution was stirred at room temperature for 2 h and then it was lyophilyzed. The syrupy residue (0.36 g, 90%) was homogeneous by t.l.c. ($CHCl_3$–MeOH, 10:1) and consisted of a mixture (**11**) of methyl 2-*O*-acetyl-β-D-ribofuranoside and the corresponding 3-acetate in an approximate ratio of 1:1. The n.m.r. data: τ 4.74, 4.86 (pair of doublets, H_2, H_3, $J = 3.2$ Hz); 5.06 (H_1, singlet); 5.70 (H_4, H_2, or H_3, multiplet); 6.22 ($H_{5,5'}$, multiplet); 6.51, 6.52 (OCH_3, singlets); 7.22 (OH, broad); 7.80, 7.83 (—$COCH_3$, singlets).

A portion of the above mixture of acetates (0.3 g) was *p*-nitrobenzoylated in pyridine (room temperature, overnight) and processed by adding the solution to ice-water. The precipitated product was filtered, washed with aqueous sodium hydrogen carbonate, then with water to give 0.5 g (75%) of a chromatographically homogeneous product, m.p. 102–104°. Recrystallization from absolute ethanol afforded 0.1 g of pure *methyl 3-O-acetyl-2,5-di-O-p-nitrobenzoyl-β-D-ribofuranoside* (**12**) m.p. 147.5–148°; $[\alpha]_D^{25}$ 29.8° (*c* 0.5, $CHCl_3$);[7] λ_{max} 1600 cm^{-1} (carbonyl); n.m.r. data: τ 1.83 (aromatic protons, multiplet); 4.57 (H_2, H_3, multiplet); 4.89 (H_1, singlet); 5.41 (H_4, $H_{5,5'}$, multiplet); 6.64 (OCH_3, singlet); 8.06 (—$COCH_3$, singlet).

Anal. Calcd. for $C_{22}H_{20}N_2O_{12}$: C, 52.30; H, 4.00; N, 5.55. Found: C, 52.27; H, 4.02; N, 5.38.

Reaction of Methyl β-D-Ribofuranoside with Trimethylorthoacetate

A solution containing **1** (0.5 g), trimethylorthoacetate (2.1 ml), and 0.11 g of *p*-toluenesulfonic acid in 0.7 ml of DMF was stirred at room temperature for 3 h. The solution was neutralized with sodium methoxide in methanol and it was evaporated to dryness. Traces of DMF were removed

[7]The rotation value was previously reported as 37.5° (1).

For personal use only.

by repeated evaporation from *n*-butanol to give *methyl 2,3-O-methoxyethylidene-β-D-ribofuranoside* (**10**), as a syrupy mixture of diastereoisomers (0.66 g, quant.) contaminated with a small quantity of the mixed acetal **10***a*, as evidenced by t.l.c. ($CHCl_3$–MeOH, 10:1). The product was particularly sensitive to moisture and was hydrolyzed to a mixture of monoacetates. Treatment of the acetal **10** (0.46 g) with 10% aqueous acetic acid (room temperature, 30 min), followed by lyophilization afforded a 76% yield of the mixture of acetates **11**. The crystalline di-*p*-nitrobenzoate derivative **12** could be obtained as in the previous case.

Acetylation of Methyl 2,3-O-[1-(Dimethylamino)-ethylidene]-β-D-ribofuranoside

An amount of **8** (0.7 g, 0.3 mmol) in 10 ml of dry pyridine was cooled and treated with acetic anhydride (0.46 g, 0.4 mmol). After standing overnight at room temperature, the solution was cooled, diluted with 1,1,1-trichloroethane and water. Extraction and processing of the organic phase afforded a syrup which was codistilled with toluene to remove residual pyridine. The resulting syrup (0.76 g, 92%) was homogeneous by t.l.c. ($CHCl_3$–MeOH, 10:1) and consisted approximately of a 3:2 mixture of diastereoisomers of *methyl 5-O-acetyl-2,3-O-[1-(dimethylamino)ethylidene]-β-D-ribofuranoside* (**20***a*); λ_{max} (film) 1740 cm^{-1} (acetate); n.m.r. data: 4.94, 5.00 (H_1, singlets); 5.32–6.00 (H_2–$H_{5,5'}$, multiplet); 6.64 (OCH_3, singlet); 7.64, 7.76 (—$N(CH_3)_2$, singlets); 7.89 (—$COCH_3$, singlet); 8.54, 8.57 (—CH_3, singlets).

Heating a solution of **20***a* in 3% aqueous methanol regenerated **1** in 90% yield.

Acid Hydrolysis of Methyl 5-O-Acetyl-2,3-O-[1-(Dimethylamino)ethylidene]-β-D-ribofuranoside (20a)

A solution containing **20***a* (0.76 g) in 10 ml of 95% aqueous acetic acid was kept at room temperature for 2 h and lyophilyzed. The residue was a homogeneous syrup (0.65 g, 94%), corresponding to 1:1 mixture (**13**) of methyl 2,5-di-*O*-acetyl-β-D-ribofuranoside and the corresponding 3,5-diacetate; n.m.r. data: 4.90, 5.00 (H_2, H_3, doublets, $J = 4$ Hz); 5.15 (H_1, singlet); 5.70 (H_4, $H_{5,5'}$, H_2, or H_3, multiplet); 6.50 (OH); 6.65 (OCH_3, singlet); 7.85, 7.92 (—$COCH_3$, singlets).

Treatment of the mixture with sodium methoxide in methanol gave a quantitative yield of **1**. The same mixture of **13** could be obtained by acid hydrolysis of fractions containing the mixed acetals corresponding to **9** and **10***a* respectively. The mixture of monoacetates **11** could then be separated from the diacetates **13** from such hydrolyses by extraction of the latter from an aqueous solution with chloroform.

5,6-O-[α-(Dimethylamino)benzylidene]-1,2-O-isopropylidene-α-D-glucofuranose (15)

A solution containing 1,2-*O*-isopropylidene-α-D-glucofuranose (**14**) (36) (0.5 g, 2.2 mmol) and **2** (0.88 g, 4.5 mmol) in 15 ml of chloroform was stirred in the dark at room temperature for 18 h. The solution was processed as described for the preparation of **3**, to give a syrup (0.8 g, quant.) which consisted of a major component (t.l.c., $CHCl_3$–MeOH, 10:1) and a minor component of lower mobility, in addition to traces of *N,N*-dimethylbenzamide; n.m.r. data indicated a 3:2 diastereoisomeric mixture: τ 2.22, 2.80 (aromatic protons); 4.32 (H_1, doublet $J_{1,2} = 4$ Hz); 5.80 (H_2–H_4, multiplet); 6.48 ($H_{6,6'}$, multiplet); 7.06 (OH); 7.70, 7.80 (—$(CH_3)_2$, singlets); 8.51, 8.67 (CH_3, singlets).

Heating a solution of **15** in 3% aqueous methanol regenerated **14** in high yield.

6-O-Benzoyl-1,2-O-isopropylidene-α-D-glucofuranose (16)

A solution of **15** (0.2 g) in 5 ml of 95% acetic acid was left at room temperature for 2 h. Neutralization with sodium hydrogen carbonate followed by extraction with chloroform and processing afforded a crystalline residue (0.1 g, 55%) which was chromatographically homogeneous ($CHCl_3$–MeOH, 10:1). Recrystallization from ethanol gave the product **16**, m.p. 193–194°, reported m.p. 196° (15); λ_{max} 1740 cm^{-1} (benzoate).

Compound **16** was also prepared by selective benzoylation of **14** with benzoyl chloride in pyridine (15); the yield was 7–10%.

5,6-O-[1-(Dimethylamino)ethylidene]-1,2-O-isopropylidene-α-D-glucofuranose (15a)

To a suspension of 1,2-*O*-isopropylidene-α-D-glucofuranose (**14**) (3 g, 13 mmol) in 30 ml of chloroform, was added 4.5 g (33 mol) of **7** and the resulting solution was stirred in the dark at room temperature for 4 h. Successive evaporation from toluene, petroleum ether (b.p. 30–60°) and diethyl ether gave a syrup (3.6 g, 90%) consisting predominantly of the desired product **15***a* (t.l.c., $CHCl_3$–MeOH, 10:1) and contaminated slightly with **16***a*. The n.m.r. data indicated the presence of diastereoisomers (3:2): τ 4.00 (H_1, doublet, $J_{1,2} = 4$ Hz); 5.43 (H_2, doublet, $J_{2,1} = 4$ Hz); 5.73 (H_3–H_5, multiplet); 7.00 ($H_{6,6'}$, multiplet); 7.56 (OH); 7.61, 7.63 (—$N(CH_3)_3$, singlets); 8.42, 8.51 (—$C(CH_3)_2$); 8.64 (—CH_3).

Heating **15***a* in 3% aqueous methanol regenerated **14** in 72% yield, m.p. 160°. The mother liquors contained additional product which was not recovered.

6-O-Acetyl-1,2-O-isopropylidene-α-D-glucofuranose (16a)

A solution containing **15***a* (0.125 g) in 6 ml of 95% aqueous acetic acid was stirred at room temperature for 1 h. The solution was neutralized with sodium hydrogen carbonate, it was extracted with chloroform, the extracts were processed as usual and evaporated to dryness. The crystalline residue was triturated with ether–pentane and the crystals were filtered to give **16***a* (0.1 g, 88%). Recrystallization was effected from ethanol, m.p. 145–147°, reported, 145–146° (16); n.m.r. data ($CDCl_3$ – pyridine-d_5): τ 3.64 (OH); 4.06 (H_1, doublet, $J_{1,2} = 4$ Hz); 5.48 (H_2, doublet, $J_{2,1} = 4$ Hz); 5.64 (H_3–$H_{6,6'}$, multiplet); 8.03 (—$COCH_3$); 8.48, 8.70 (—$C(CH_3)_2$).

Methyl 2,3-O-[1-(Dimethylamino)ethylidene]-5-O-p-toluenesulfonyl-β-D-ribofuranoside (22)

(a) From 8

To a solution containing 2 g (8 mmol) of **8** in 25 ml of dry pyridine was added *p*-toluenesulfonyl chloride (2.45 g, 1.2 mmol). After stirring at room temperature for 24 h, the solution was cooled and diluted with 1,1,1-trichloroethane and with water. The organic phase was processed as usual to give a syrup which was dissolved in toluene and evaporated several times. The final syrup (2.64 g, 80%), consisted of a 3:2 diastereoisomeric mixture of methyl 2,3-*O*-[1-(dimethylamino)ethylidene]-5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**22**); n.m.r. data: τ 2.32, 2.64 (aromatic protons); 5.06, 5.09 (H_1, singlets); 5.32–6.16 (H_2–$H_{5,5'}$, multiplet);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

6.32 (OCH_3, singlet); 7.32 ($—C_6H_4CH_3$); 7.64, 7.73 ($—N(CH_3)_2$, singlets); 8.51, 8.54 ($—CH_3$, singlets).

(b) From Methyl 5-O-p-Tolylsulfonyl-β-D-ribofuranoside (21)

A solution containing 5 g (3 mmol) of **1** in 30 ml of pyridine was cooled and treated with 5.8 g (3 mmol) of *p*-toluenesulfonyl chloride in 15 ml of pyridine. After standing at 4° overnight, the solution was poured into ice-water and the resulting solution was extracted with chloroform. Processing the organic phase in the usual way afforded a syrup which consisted of a major product by t.l.c. ($CHCl_3$–MeOH, 10:1). Purification over a column containing silica gel afforded methyl 5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**21**) (3.85 g, 40%) as a syrup which had the expected spectral (i.r., n.m.r.) properties. A portion of **21** (0.37 g, 1 mmol) was treated with 0.38 g (2.8 mmol) of **7** in 13 ml of chloroform. After 26 h at room temperature in the dark, the solution was diluted with 1,1,1-trichloroethane, cold water, and chilled. Separation of the organic phase, drying and evaporation afforded a syrupy mixture of diastereoisomers of methyl 2,3-*O*-[1-(dimethylamino)ethylidene]-5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**22**) (0.45, quant.).

Acid hydrolysis of **22** in 95% aqueous acetic acid (p*H* 3–4, 1.5 h) followed by neutralization ($NaHCO_3$) and extraction with chloroform afforded a 66:44 mixture (**23**), of methyl 2-*O*-acetyl-5-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside and its 3-*O*-acetyl analog, as a syrup (0.63 g, 84%); n.m.r. data: τ 2.48, 2.70 (aromatic protons); 5.16, 5.22 (H_2, H_3, two doublets, $J = 4$ Hz); 5.33 (H_1, singlet); 6.00 (H_4, $H_{5,5'}$, H_2, H_3, multiplet); 6.86 (OCH_3, singlet); 7.16 (OH); 7.64 ($—C_6H_4CH_3$); 7.74, 8.00 ($—\overset{O}{\overset{\|}{C}}CH_3$, singlets).

Heating a solution of **22** in 3% aqueous methanol at reflux for 1–2 h or treatment of **23** with sodium methoxide afforded the starting 5-tosylate as the sole product in both cases. Tosylation of the product so obtained afforded in each case the known methyl 2,3,5-tri-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**24**) m.p. 124–125°; reported 126° (35).

Preparation of Methyl 5-Azido-5-deoxy-2,3-O-[1-(dimethylamino)ethylidene]-β-D-ribofuranoside (25)

(a) From Methyl 5-Azido-5-deoxy-β-D-ribofuranoside (16)

A solution containing **21** (0.6 g) and 0.6 g of sodium azide in 25 ml of *N*,*N*-dimethylformamide was heated with stirring at 90°. The solution was cooled, treated with 75 ml of diethyl ether, the solids were filtered, and the filtrate was evaporated to dryness (*n*-butanol azeotrope). The resulting chromatographically homogeneous syrup (0.35 g, 98%) consisted predominantly of the desired product **26**; λ_{max} (film) 2100 cm^{-1} (N_3). The syrup (0.35 g, 1.8 mmol) was dissolved in 15 ml of chloroform, 0.48 g (3.6 mmol) of **7** was added and the solution was stored in the dark at room temperature overnight. The solution was processed as described for the corresponding tosylate **22**, to give the desired product **25** as a syrupy mixture of diastereoisomers (0.2 g, 48%). Traces of ester were present (i.r.) due to some hydrolysis.

(b) From 22 by Displacement with Azide Ion

A solution containing **22** (0.8 g, 2 mmol), sodium azide (0.835 g, 18 mmol) in 40 ml of dry *N*,*N*-dimethylformamide was heated with stirring at 90° for 6 h. The solution was cooled to 0°, it was diluted with 100 ml of diethyl ether and the salts were filtered with minimum exposure to moisture. The filtrate was evaporated to dryness (*n*-butanol azeotrope) to give the desired **15** as a syrupy mixture of diastereoisomers (0.4 g, 75%) in a ratio of 64:36; n.m.r. data: τ 5.00, 5.16 (H_1, singlets); 5.19–6.00 (H_2–H_4, multiplet); 6.64–6.70 ($—OCH_3$, two singlets; $H_{5,5'}$, multiplet); 7.64, 7.80 ($—N(CH_3)_2$, singlets); 8.16, 8.32 ($—CH_3$, singlets).

Treatment of **25** with aqueous acetic acid as previously described afforded a mixture of methyl 5-azido-5-deoxy-β-D-ribofuranoside monoacetates in 52% yield. The n.m.r. data indicated a 4:1 mixture of 3- and 2-acetates.

Heating a solution of **25** in 3% aqueous methanol regenerated the starting 5-azido derivative **26** in quantitative yield. Tosylation of **26** afforded in good yield the known crystalline methyl 5-azido-5-deoxy-2,3-di-*O*-*p*-tolylsulfonyl-β-D-ribofuranoside (**27**), m.p. 116–117°; reported 122–123° (35); n.m.r. data: τ 2.35, 2.83 (aromatic protons); 5.19 (H_1, singlet); 5.32 (H_2, doublet, $J_{2,3} = 2$ Hz); 5.38 (H_3, doublet, $J_{3,2} = 2$ Hz); 5.70 (H_4, multiplet); 6.80 (OCH_3, $H_{5,5'}$); 7.54 ($—C_6H_4CH_3$, singlet).

Treatment of Methyl 2,3-O-Isopropylidene-β-D-ribofuranoside with 7

A solution of methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (14) (0.5 g) in 5 ml of dichloromethane containing 1 ml of **7** was stirred in the dark for 3 days. The solution was diluted with aqueous acetic acid and evaporated to dryness. Chromatographic examination revealed the presence of methyl 5-*O*-acetyl-2,3-*O*-isopropylidene-β-D-ribofuranoside, in addition to starting material. The acetate was separated by preparative t.l.c. and isolated as a syrup (80 mg). Its physical properties (i.r., n.m.r.) were identical with those of an authentic specimen, prepared by the acetylation of the starting material. Deacetylation (NaOMe, MeOH) of the acetate regenerated the initial substrate.

The Reaction of *O*-Benzylidene Sugars with *N*-Bromosuccinimide. VI. A New Synthesis of 2′-Deoxyuridine and some of its Selectively Substituted Derivatives[1]

M. M. PONPIPOM[2] AND S. HANESSIAN

Department of Chemistry, University of Montreal, Montreal, Quebec

Received June 24, 1971

A new synthesis of 2′-deoxyuridine and its selectively substituted derivatives has been developed, based on the reaction of appropriately substituted 2′,3′-*O*-benzylideneuridines with *N*-bromosuccinimide (NBS). The preponderant products are uridines containing bromine and benzoate groups in the 2′- and 3′-positions respectively.

Une nouvelle synthèse de la 2′-déoxyuridine et de ses dérivés sélectivement substitués a été développée. Elle est basée sur la réaction des 2′,3′-*O*-benzylideneuridines substitués appropriées avec la *N*-bromosuccinimide (NBS). Les produits prépondérants sont les uridines contenant les substituants brome et benzoate respectivement en position 2′ et 3′.

For personal use only.

In previous reports from this laboratory, the preparative and mechanistic aspects of the reaction of *O*-benzylidene acetals with *N*-bromosuccinimide (NBS), were adequately discussed (2, 3). The reaction provides easy access to selectively brominated and benzoylated derivatives which have been utilized in a number of synthetic sequences leading to deoxy, aminodeoxy, and other sugar derivatives. We now report on the successful application of the reaction to 2′,3′-*O*-benzylidene acetals of uridine and some of its derivatives, leading to the stereoselective bromination of these nucleosides in the sugar as well as in the heterocyclic ring (1). The incorporation of a halogen atom in the sugar ring, particularly in the 2′- and 3′-positions, provides compounds that are useful intermediates in the chemical modification of nucleosides. Halogenated pyrimidine nucleosides are compounds of considerable biochemical, medicinal, and chemical interest. The introduction of a halogen atom in the 5-position of the uracil ring, imparts biologically and therapeutically significant properties to the parent nucleoside, as in the case of 2′-deoxy-5-halouridines (4). Of the procedures available for the synthesis of 2′-deoxyuridine, those based on nucleoside interconversion, resulting in the ultimate placement at C-2′ of a reducible function such as halogen (5–10) or thioether (11) groups, are among the more practical. Under certain conditions, quasi-phosphonium halides (12–14), may lead to selective halogenation of pyrimidine nucleosides. Bromination and chlorination of uridine and some of its substituted derivatives with appropriate halomethylene (dimethylammonium) halides leads to selective substitution at the C-5′ position (15, 16). The direct substitution of a hydroxyl group by chlorine with the aforementioned reagents had been previously described from our laboratory (17). Catalytic reduction of these halogenonucleosides leads to the respective deoxynucleosides, including the biologically important 2′-deoxyuridine.

Uridine was allowed to react with benzaldehyde in the presence of zinc chloride, to give 2′,3′-*O*-benzylideneuridine (**1**) (18), which, based on its n.m.r. spectrum, appeared to consist of a pair of diastereoisomers. Treatment of **1** with 2.2 equiv of NBS in a mixture of 1,1,2,2-tetrachloroethane and carbon tetrachloride, in the presence of barium carbonate at 85–90°, afforded a crystalline product in 56% yield. Experiments described in this and the following paper (19), led to the unambiguous assignment of the structure as 3′-*O*-benzoyl-2′,5-dibromo-2′-deoxyuridine, (**2**) (1) (Scheme 1). The incorporation of two bromine atoms in the product was ascertained from its mass spectrum and the location of one of the bromine atoms at the 5-position of the uracil moiety was clearly evident from the n.m.r. spectrum. The sites and relative dispositions of

1 2 3

4, R = Bz
5, R = H

SCHEME 1

the second bromine atom and the benzoate group could not be conclusively derived from n.m.r. studies and independent chemical proof was sought. By a proper choice of catalyst (6% Pd–C), it was possible to effect a selective hydrogenolysis of the bromine atom attached at C-5, to give crystalline 3′-*O*-benzoyl-2′-bromo-2′-deoxyuridine (**3**) in 94% yield. Catalytic reduction of **2** or **3** in the presence of 20% Pd–C (20) afforded crystalline 3′-*O*-benzoyl-2′-deoxyuridine (**4**), in 80–85% yield. Debenzoylation in methanolic ammonia gave crystalline 2′-deoxyuridine (6, 9, 21) **5** in 80% yield. The synthesis of **5** can also be effected starting from **1**, without the isolation of intermediates. Another route (7, 22) to **5** consists in the reaction of 2,2′-anhydro-[1-(β-D-arabinofuranosyl)uracil] (**9**) (23, 24) with hydrogen bromide and subsequent reduction. Although the overall yields of **5** by this method are higher, the sequence **1**–**5** described in this paper is more versatile, since it incorporates in it, the feature of selective benzoylation at C-3′ and provides derivatives that could be useful in nucleoside interconversions and transformations.

Treatment of the 5′-*O*-acetyl derivative (**6**) (25) with NBS under essentially the same conditions as for **1**, afforded a crystalline product in 50% yield (Scheme 2). Based on mass spectral, n.m.r., and chemical data, the structure of this product was proved to be 2,2′-anhydro-[1-(5′-*O*-acetyl-3′-*O*-benzoyl-β-D-arabinofuranosyl) 5-bromouracil] (**7**) (1). Catalytic hydrogenation afforded the crystalline product (**8**) which upon de-esterification with methanolic ammonia at 0° gave, among other products, the known (23, 24) crystalline 2,2′-anhydro-[1-(β-D-arabinofuranosyl)uracil] (**9**). Alternatively, catalytic de-esterification of **7** under controlled conditions gave crystalline 2,2′-anhydro-[1-(β-D-arabinofuranosyl)-5-bromouracil] (**10**). Treatment of **9** with NBS led to a complex mixture of products, that contained minor amounts of **10**. Investigation of the mother liquors from the reaction product of **6** with NBS, revealed the presence of further quantities of **7** and at least three other products. The identities of some of these are discussed in the subsequent paper (19).

The somewhat unexpected behavior of **6**, compared to **1**, indicated a strong influence of substituents on the nature of products. Based on our previous experiences (26) with the effect of

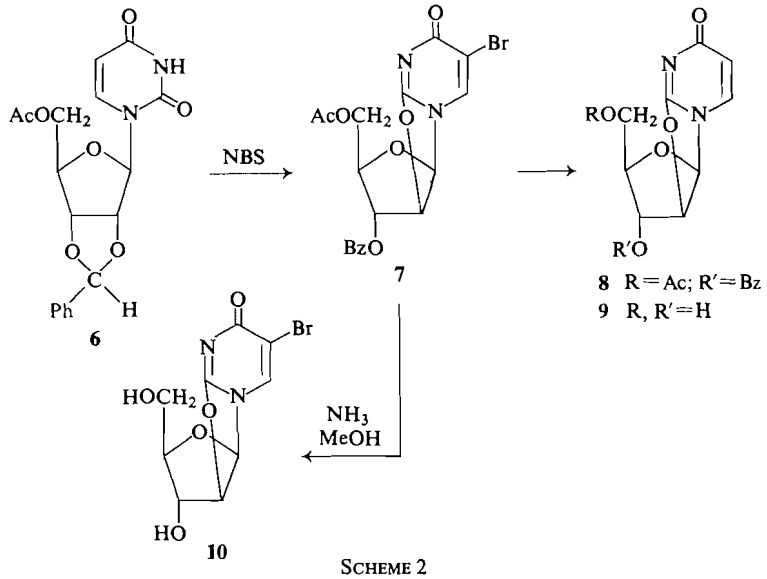

SCHEME 2

substituents, it was of interest to study the effect of a non-participating function at C-5′. Methylation of **1** with methyl iodide in *N*,*N*-dimethylformamide, in the presence of sodium hydride gave the corresponding *N*,*O*-dimethyl analog **11** as a chromatographically homogeneous syrup, having the expected n.m.r. spectral characteristics (Scheme 3).

Treatment of **11** with NBS in a mixture of carbon tetrachloride and 1,1,2,2-tetrachloroethane at 85–90° for 2.5 h afforded a crystalline product in 65% yield. Based on mass spectral

For personal use only.

and n.m.r. data, the product was formulated as 3′-*O*-benzoyl-2′, 5-dibromo-2′-deoxy-3-*N*-methyl-5′-*O*-methyluridine (**12**) (1). This structure was also confirmed unambiguously by chemical means as shown here and in the following paper (19). Compound **12** could be obtained in two inconvertible crystalline forms, melting at 164–166° and 183–185°. Each form could be transformed into the other by recrystallization and nucleation. When equal amounts of each crystalline modification were co-crystallized, only the higher-melting form was obtained.

When the reaction of **11** with NBS was performed in the absence of 1,1,2,2-tetrachloroethane, or in concentrated solution, a second crystalline product, isomeric with **12**, was formed in low yield, in addition to **12**. Based on its mass spectrum and n.m.r. spectral data, its structure is assigned as 3′-*O*-benzoyl-2′,6-dibromo-2′-deoxy-3-*N*-methyl-5′-*O*-methyluridine (**13**). Halogenation of pyrimidines with *N*-halogenosuccinimides leads, in general, to the 5-halogeno derivatives and we are not aware of similar brominations in the 6-position of uridine derivatives. It appears that bromination in this position is a function of the effective concentration of bromine in the medium, since the formation of the 6-bromo derivative is observed principally in concentrated solutions or when the reaction is performed in carbon tetrachloride. In the latter solvent, the starting **11** is not very soluble and homogeneity is attained during the reaction. Attempts to increase the amount of **13** in the reaction of **11** with NBS were unsuccessful.

As in the other series, selective hydrogenolysis of the 5-bromo function was possible in the presence of 6% palladium-on-charcoal to give crystalline 3′-*O*-benzoyl-2′-bromo-2′-deoxy-3-*N*-methyl-5′-*O*-methyluridine (**14**) in 96% yield. Further hydrogenolysis in the presence of 20% palladium-on-charcoal afforded 3′-*O*-benzoyl-2′-deoxy-3-*N*-methyl-5′-*O*-methyluridine (**15**) as a chromatographically homogeneous syrup. Debenzoylation of **12** could be effected with methanolic ammonia or with sodium methoxide in methanol at 0° or higher temperature. A crystalline product **16** was obtained which upon benzoylation regenerated the starting benzoate **12**. Acetylation of **16** on the other hand, gave the crystalline acetate **17**. These experiments confirm the *cis*-relationship between the bromine and benzoate groups. A *trans*-relationship would have led to the formation of a 2′,3′-epoxide (or products derived from its opening). The formation of 2′-deoxy-3-*N*-methyl-5′-*O*-methyluridine derivatives, as shown by n.m.r. studies, combined with the indirect evidence for the disposition of the bromine atom in **12** and its transformation products, are in strong support of a D-*ribo* configuration. Conclusive proof and configurational interrelationships with other members of this series are discussed in the following paper (19).

Experimental

Melting points are uncorrected. The i.r. spectra were recorded with a Beckman IR-8 instrument. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. The t.l.c. was performed on plates (20 cm length) coated with silica gel GF_{254} (Merck) and the spots were detected with a sulfuric acid spray and by u.v. visualization. Column chromatography was done on short columns containing silica gel GF_{254}, by application of a moderate suction. The n.m.r. spectra were measured on JEOL-4H-100 and 60 MHz instruments (s, singlet; d, doublet; t, triplet; m, multiplet; b, broad). Mass spectra were obtained on a Hitachi–Perkin–Elmer medium resolution mass spectrometer.

2′,3′-O-Benzylideneuridine (1)

A mixture of uridine (5.0 g) and anhydrous zinc chloride (7.5 g) in freshly distilled benzaldehyde (25 ml) was stirred at room temperature for 2 days. The clear mixture was diluted with ether. The precipitate was collected by decantation, it was dissolved in ethyl acetate, and washed with water. The organic layer was dried over anhydrous sodium sulfate and evaporated to a syrup which crystallized upon addition of ether. Recrystallization from ethyl acetate afforded pure material, 4.75 g (70%), m.p. 195–196°; reported m.p. 193–194°.

3′-O-Benzoyl-2′,5-dibromo-2′-deoxyuridine (2)

To a suspension of 2′,3′-*O*-benzylideneuridine (1.0 g) and barium carbonate (0.4 g) in 1,1,2,2-tetrachloroethane (50 ml) and carbon tetrachloride (10 ml) was added NBS (1.18 g). The mixture was stirred, while being heated at 85–90° (bath temperature), for 3 h. The hot solution was filtered and the filtrate was evaporated to dryness by co-distilling with toluene. The syrup (2.25 g) was dissolved in methylene chloride (70 ml) and washed with water (2 × 80 ml). The aqueous layer was re-extracted with ethyl acetate (70 ml). The methylene chloride layer was dried and evaporated to a small volume and allowed to crystallize in the refrigerator. The crystals were collected and the filtrate was evaporated to dryness. A minimum amount of chilled methylene chloride was added and, upon scratching, further crops of material were obtained. The combined crystals weighed 0.51 g and showed one spot on t.l.c. which moved slightly faster than the starting material (chloroform–methanol, 10:2, 20 cm plate). The mother liquor was evaporated to a syrup and triturated with ether and petroleum ether (b.p. 30–60°) to give a solid mass (0.88 g). The latter was passed through a column of silica gel and eluted with a mixture of methanol and chloroform (1:9). Fractions containing the desired compound were pooled together and evaporated to dryness. Crystallization from methylene chloride gave addi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tional product (0.32 g). The total yield of **2** was 0.83 g (56%), m.p. 209–212°. Alternatively, the original methylene chloride extracts were evaporated to dryness and the resulting crystalline residue was suspended in 20 ml of chilled methylene chloride. The suspension was stirred with external cooling until the crystals were well dispersed. Filtration and washing gave an essentially chromatographically homogeneous product (0.56 g). Recrystallization from acetone afforded an analytical sample, m.p. 212–214°; $[\alpha]_D$ −85° (*c* 1.56, DMF); n.m.r. data (DMSO-d_6): τ −2.11 (NH, s); 1.43 (H-6, s); 3.65 (H-1′, d, $J_{1',2'} = 6.8$ Hz); 4.40 (H-3′, OH); 4.96 (H-2′, t, $J = 6.8$ Hz), etc.

Anal. Calcd. for $C_{16}H_{14}O_6N_2Br_2$: C, 39.30; H, 2.86; N, 5.71; Br, 32.65. Found: C, 39.31; H, 2.89; N, 5.86; Br, 32.83.

The ethyl acetate extract was evaporated to a syrup (0.16 g) which showed at least three spots on t.l.c. in addition to that corresponding to **2**. The major spot moved slower than the starting material. Owing to the low yields of these side products, their identities were not pursued.

*3′-O-Benzoyl-2′-bromo-2′-deoxyuridine (**3**)*

An amount of **2** (500 mg) was dissolved in warm methanol (90 ml) and the solution was allowed to cool before adding 6% palladium-on-charcoal (120 mg) and barium carbonate (300 mg). The stirred mixture was hydrogenated during 2 h at room temperature, it was then filtered and the filtrate was evaporated to a solid mass which was dissolved in methylene chloride. The solution was evaporated to a syrup (451 mg) which had a slightly slower chromatographic mobility than the starting material. Ethanol and ether were added and a trace of insoluble material was filtered. The filtrate was concentrated to dryness and triturated with ether to give crystals of **3** (395 mg, 94%), m.p. 175–178°. Recrystallization from absolute ethanol gave pure material, m.p. 179–181°; $[\alpha]_D$ −46.3° (*c* 1.43, DMF).

Anal. Calcd. for $C_{16}H_{15}O_6N_2Br$: C, 46.70; H, 3.65; N, 6.81; Br, 19.45. Found: C, 46.71; H, 3.70; N, 6.74; Br, 19.30.

*3′-O-Benzoyl-2′-deoxyuridine (**4**)*

The hydrogenation was carried out in the same manner as above using 20% palladium-on-charcoal. Conventional processing gave crystalline **4** (276 mg, 81.5%), m.p. 215–221°. Recrystallization from methanol–ethanol gave pure material, m.p. 225–226.5°; $[\alpha]_D$ −27.7° (*c* 0.75, DMF). The n.m.r. data (DMSO-d_6): τ −1.40 (N-H, b); 3.70 (H-1′, τ, $J \simeq 6.8$ Hz), etc.

Anal. Calcd. for $C_{16}H_{16}O_6N_2$: C, 57.80; H, 4.82; N, 8.43. Found: C, 57.39; H, 4.86; N, 8.26.

*2′-Deoxyuridine (**5**)*

3′-*O*-Benzoyl-2′-deoxyuridine (100 mg) was dissolved in anhydrous methanolic ammonia (7 ml) and the solution was allowed to stand in the cold overnight. Evaporation to dryness below 20° (bath temperature) followed by addition of methanol and repeated evaporation afforded a syrup. Crystallization and recrystallization from absolute ethanol gave the title compound (55 mg, 80%), m.p. 158–161°. The m.p. was not depressed upon admixture with authentic 2′-deoxyuridine.[3]

*5′-O-Acetyl-2′,3′-O-benzylideneuridine (**6**)*

A mixture of acetic anhydride (8 ml) and 2′,3′-*O*-benzylideneuridine (1.0 g) in dry pyridine (10 ml) was allowed to stand at room temperature for 5 h. The mixture was processed in the usual manner to give a syrup (1.1 g) which was relatively homogeneous on t.l.c. (chloroform–methanol, 10:1) and gave a satisfactory n.m.r. spectrum. It was used for subsequent steps without purification.

*2,2′-Anhydro-[1-(5′-O-acetyl-3′-O-benzoyl-β-D-arabinofuranosyl)-5-bromouracil] (**7**)*

To a suspension of 5′-*O*-acetyl-2′,3′-*O*-benzylideneuridine (1.1 g) and barium carbonate (0.4 g) in carbon tetrachloride (40 ml) and 1,1,2,2-tetrachloroethane (10 ml) was added NBS (1.2 g). The mixture was heated at reflux, with vigorous stirring, for 2.5 h. It was worked-up in the usual manner to give a syrup. Anhydrous ether was added and solids were collected (1.38 g). Crystallization from acetone–ether gave the title compound (0.42 g). Examination of the mother liquor on t.l.c. ($CHCl_3$—MeOH, 9:1) revealed two components, the anhydro derivative (**7**) and a faster-moving spot. Chromatographic separation (silica gel) gave additional material (0.25 g). The total isolated yield of the title product was 0.67 g (50%), m.p. 212–218°. Recrystallization from acetone afforded pure material, m.p. 220–220.5°; $[\alpha]_D$ −116° (*c* 2.27, DMF). The n.m.r. data (DMSO-d_6): τ 1.41 (H-6, s); 3.45 (H-1′, d, $J = 6$ Hz); (H-2′, d, $J_{2',1'} = 6.0$ Hz); 4.36 (H-3′, bs), etc; M^+ 450, 452 (bromine isotopes).

Anal. Calcd. for $C_{18}H_{15}O_7N_2Br$: C, 47.80; H, 3.32; N, 6.20; Br, 17.70. Found: C, 47.83; H, 3.35; N, 6.17; Br, 17.88. The faster-moving spot contained at least two compounds. One of the products was identified as 5′-*O*-acetyl-3′-*O*-benzoyl-2′,5-dibromo-2′-deoxyuridine, m.p. 198–203° by comparison with an authentic sample.

*2,2′-Anhydro-[1-(5′-O-acetyl-3′-O-benzoyl-β-D-arabinofuranosyl)uracil] (**8**)*

Compound **7** (0.5 g) was heated in methanol (90 ml) until solution was attained. The solution was allowed to cool before adding 20% palladium-on-charcoal (0.12 g) and barium carbonate (0.3 g) and the mixture was hydrogenated during 2.5 h at room temperature and processed in the usual way to give a syrup. Trituration with absolute ethanol gave crystalline **8** (0.39 g, 94.5%), m.p. 239–243°. Recrystallization from 50% ethanol afforded pure material, m.p. 240–243° (dec.); $[\alpha]_D$ −104.5° (*c* 1.34, DMF). The n.m.r. data (DMSO-d_6): τ 3.49 (H-1′, d, $J_{1',2'} = 6.0$ Hz); 4.10 (H-5, d, $J_{5,6} = 6.8$ Hz); 4.25 (H-2′, d, $J_{2',1'} = 6.0$ Hz); 4.4 (H-3′, bs), etc.

*2,2′-Anhydro-[1-(β-D-arabinofuranosyl)uracil] (**9**)*

Compound **8** (280 mg) was dissolved in anhydrous methanolic ammonia (25 ml) and the solution was allowed to stand at 3° overnight. The solution was processed as usual to give a syrup (272 mg). Addition of absolute ethanol and scratching gave colorless crystals which were recrystallized from the same solvent; yield 105 mg (62%), m.p. 235–238° (dec.). An authentic sample[4] melted at 238–241° (dec.), mixed m.p. 235–241° (dec.).

*2,2′-Anhydro-[1-(β-D-arabinofuranosyl)-5-bromouracil] (**10**)*

The anhydronucleoside derivative **7** (200 mg) was deacetylated with anhydrous methanolic ammonia (10 ml) in the usual manner to give a syrup. Crystallization from absolute ethanol yielded the title compound (80 mg, 59%), m.p. 166–175°. Recrystallization from absolute ethanol

[3]Purchased from Raylo Chemical Company, Edmonton, Alberta.

[4]We thank Dr. J. J. Fox for a sample of this compound.

afforded pure material, m.p. 195° (dec.); $[\alpha]_D$ 20.7° (*c* 1.17, DMF); M^+ 304, 306 (bromine isotopes).

*2',3'-O-Benzylidene-3-N-methyl-5'-O-methyluridine (**11**)*

Sodium hydride (1.0 g) was added to a cooled solution of 2',3'-*O*-benzylideneuridine (2.0 g) in DMF (30 ml) and the suspension was stirred for 10 min before the addition of methyl iodide (4 ml) at 0°. The reaction mixture was stirred at room temperature overnight and methanol was added gradually to destroy the excess sodium hydride. When the effervescence had ceased, the solution was concentrated to dryness, the residue was partitioned between methylene chloride (200 ml) and water (200 ml), the organic layer was separated and was washed with water (2 × 100 ml). The solution was dried, then it was evaporated to a syrup (2.12 g) which was homogeneous on t.l.c. and showed a satisfactory n.m.r. spectrum (in $CDCl_3$). This product was used for subsequent steps without purification.

*3'-O-Benzoyl-2'-deoxy-2',5-dibromo-3-N-methyl-5'-O-methyluridine (**12**)*

(a) Using 1,1,2,2-Tetrachloroethane and Carbon Tetrachloride as Solvents

To a solution of 2',3'-*O*-benzylidene-5'-*O*-methyl-N^3-methyluridine (2.12 g) in carbon tetrachloride (80 ml) and 1,1,2,2-tetrachloroethane (20 ml) was added barium carbonate (0.8 g) and NBS (2.36 g). The mixture was heated to reflux, while being vigorously stirred for 2.5 h. It was worked-up as usual to give a solid which was crystallized from anhydrous ether to give the title compound (1.87 g). The mother liquor (0.78 g) was chromatographed on a column containing silica gel. Fractions containing the desired product **12** were pooled together and evaporated to a syrup (0.25 g) which crystallized from anhydrous ether to give additional material (0.15 g). The total yield of **12** was 2.02 g (65%), m.p. 160–162°. Recrystallization from methanol with minimum heating afforded pure material, m.p. 164–166°; $[\alpha]_D$ −78° (*c* 2.02, $CHCl_3$). Recrystallization of this product from hot methanol gave the title product in another crystalline form, m.p. 183–185°; $[\alpha]_D$ −81° (*c* 1.86, $CHCl_3$). The lower melting form could be transformed into higher melting form and vice versa by recrystallization and seeding. When equal amounts of the two forms were mixed and crystallized, only the higher melting form was obtained. The n.m.r. data (in $CDCl_3$), τ 1.64 (H-6, s), 3.47 (H-1', d, $J_{1',2'} = 6.0$ Hz); 4.52 (H-3', $J_{3',4'} = 3.0$, $J_{3',2'} = 5.3$ Hz); 5.35 (H-2', $J_{2',3'} = 5.3$, $J_{2',1'} = 6.0$ Hz); 6.45, 6.56 (*O*,N^3-dimethyl protons); M^+ 518.

Anal. Calcd. for $C_{18}H_{18}O_6N_2Br_2$: C, 41.70; H, 3.48; N, 5.41; Br, 30.85. Found: C, 42.10; H, 3.55; N, 5.43; Br, 30.68.

(b) In the Absence of 1,1,2,2-Tetrachloroethane

This experiment was similar to that described in (*a*), except only 25 ml of carbon tetrachloride was used. The reaction was processed as usual to give a syrup which showed two major components on t.l.c. The n.m.r. spectrum of the crude mixture indicated the presence of the title compound and another isomeric compound. After crystallization and chromatographic separation of the mother liquors, the 5-bromo derivative **12** was obtained in 45% yield, m.p. 160–162°. Fractions containing the slower-moving component crystallized and the crystals were collected, washed with cold ether and dried. The n.m.r. spectrum was in accord with the structure of 3'-*O*-benzoyl-2'-bromo-2'-deoxy-2',-6-dibromo-3-*N*-methyl-5'-*O*-methyluridine (**13**), m.p. 159–162°; n.m.r. data: τ 3.62 (H-5, s); 3.79 (H-1', d, $J_{1',2'} = 7.2$ Hz); 4.52 (H-3', q, $J_{3',2'} = 7.0$, $J_{3',4'} = 4.5$ Hz); 5.23 (H-2', t, $J_{2',1'} = 7.2$, $J_{2',3'} = 7.0$ Hz); M^+ 518.

*3'-O-Benzoyl-2'-bromo-2'-deoxy-3-N-methyl-5'-O-methyluridine (**14**)*

The nucleoside derivative **12** (500 mg) was warmed in methanol (90 ml) until solution was attained. The solution was allowed to cool before adding 6% palladium-on-charcoal (120 mg) and barium carbonate (300 mg) and the mixture was hydrogenated during 2 h at room temperature, then it was processed as usual to give a syrup (478 mg) which crystallized upon standing. Trituration with cold absolute ethanol gave the title compound (401 mg, 96%), m.p. 117–122°. Recrystallization from the same solvent afforded pure material, m.p. 123–126°; $[\alpha]_D$ −59.2° (*c* 1.55, $CHCl_3$); n.m.r. ($CDCl_3$): τ 2.60 (H-6, d, $J_{6,5} = 8.0$ Hz); 3.73 (H-1', d, $J_{1',2'} = 7.0$ Hz); 4.40 (H-5, d, $J_{5,6} = 8.0$ Hz); 4.73 (H-3', t); 5.60 (H-2', d, $J_{2',1'} = 7.0$ Hz), etc.

Anal. Calcd. for $C_{18}H_{19}O_6N_2Br$: C, 49.25; H, 4.33; N, 6.38; Br, 18.22. Found: C, 48.84; H, 4.31; N, 6.21; Br, 18.11.

*3'-O-Benzoyl-2'-deoxy-3-N-methyl-5'-O-methyluridine (**15**)*

The hydrogenation was carried out in the same manner as above except using 20% palladium-on-charcoal. The solution was processed as usual to give a syrup which was relatively homogeneous on t.l.c. (chloroform–ethyl acetate, 4:1). Ethanol–ether was added, a trace of insoluble material was filtered, and the filtrate was evaporated to give a syrup (300 mg, 86%). A small sample was purified by preparative t.l.c., $[\alpha]_D$ −31.1° (*c* 3.39, $CHCl_3$); n.m.r. ($CDCl_3$): τ 2.23 (H-6, d, $J_{6,5} = 8.0$ Hz); 3.50 (H-1', $J = 6.0, 8.0$ Hz); 4.20 (H-5, d, $J_{5,6} = 8.0$ Hz); 7.60 (H-2', m), etc.

*Debenzoylation of 3'-O-benzoyl-2'-deoxy-2',-5-dibromo-3-N-methyl-5'-O-methyluridine (**12**)*

Compound **12** was stirred in anhydrous methanolic ammonia (10 ml) until a homogeneous solution was obtained. The resulting solution was allowed to stand at room temperature for 4 h, then it was worked-up in the usual manner to give a syrup (500 mg). A sample of the product was purified by preparative t.l.c. to give a syrup that crystallized upon standing. Cold absolute ethanol was added, the crystals were collected and recrystallized from the same solvent to afford 2'-bromo-2'-deoxy-5'-*O*-methyl-5-bromo-N^3-methyluridine (**16**), 135–136°; $[\alpha]_D$ −33° (*c* 1.44, $CHCl_3$). The same product was obtained when the debenzoylation was carried out with sodium methoxide in methanol.

*3'-O-Acetyl-2'-deoxy-2',5-dibromo-3-N-methyl-5'-O-methyluridine (**17**)*

A mixture of acetic anhydride (2 ml) and crude **16** (212 mg) in pyridine (2 ml) and methylene chloride (5 ml) was kept at 3° overnight. The solution was processed as usual to give a syrup which crystallized upon standing. Cold ethanol was added and crystals were collected (150 mg), m.p. 162–166°. Recrystallization from the same solvent afforded pure material, m.p. 167–168°; $[\alpha]_D$ −26.4° (*c* 1.65, $CHCl_3$).

Anal. Calcd. for $C_{13}H_{16}O_6N_2Br_2$: C, 34.20; H, 3.51; N, 6.14; Br, 35.10. Found: C, 34.42; H, 3.57; N, 6.25; Br, 34.54.

The Reaction of *O*-Benzylidene Sugars with *N*-Bromosuccinimide. VII. Stereochemical and Mechanistic Aspects in the Pyrimidine Nucleoside Series[1]

M. M. PONPIPOM[2] AND S. HANESSIAN

Department of Chemistry, University of Montreal, Montreal, Quebec

Received June 24, 1971

The reaction of 2′,3′-*O*-benzylideneuridine with *N*-bromosuccinimide (NBS) leads to 3′-*O*-benzoyl-2′,5-dibromouridine. The stereoselectivity of bromination in the sugar ring can be explained by invoking the sequential formation of benzoxonium ion and 2,2′-anhydronucleoside intermediates. Protonation of the appropriate 2,2′-anhydronucleoside, followed by treatment with NBS, recreates the conditions which prevail in the original reaction of the benzylidene acetal with NBS.

La réaction de la 2′,3′-*O*-benzylideneuridine avec la *N*-bromosuccinimide (NBS) conduit à la 3-*O*-benzoyl-2′,5-dibromouridine. La stéréosélectivité de la bromuration sur le reste hydrate de carbone peut être expliquée en invoquant la formation successive de l'ion benzoxonium et du 2,2′-anhydronucléoside comme intermédiaires. La protonation du 2,2′-anhydronucléoside approprié suivi du traitement par la NBS reconstituent les conditions existantes dans la réaction initiale de l'acétal benzylidénique sous la NBS.

In the preceding paper (1), it was shown that the reaction of 2′,3′-*O*-benzylideneuridine (**1**) (2) and the corresponding 3-*N*-5′-*O*-dimethyl analog (**2**) underwent bromination with *N*-bromosuccinimide (NBS), to give crystalline nucleoside derivatives, in which bromine atoms were incorporated in the 5- and 2′-positions stereoselectively (Scheme 1). Under essentially the same reaction conditions, the 5′-acetate derivative **5** afforded the 2,2′-anhydro analog **6**, with a bromine atom in the C-5 position only. Having established (1) that the bromine atom in the sugar portion of the nucleoside derivatives **3** and **4** was situated in the 2′-position, by catalytic reduction to the corresponding 2′-deoxyuridine derivatives, there remained to ascertain the stereochemical orientation of the bromine atom at this position in these products. The aim of this paper is to elucidate the stereochemistry of these halogenated nucleosides, to demonstrate their interrelations, and to discuss the mechanistic aspects involved in the stereoselective ring opening of the benzylidene acetal with concomitant bromination.

As part of their extensive researches on the chemical modification of pyrimidine nucleosides, Fox and coworkers (3, 4) have prepared several 2′-deoxy-2′-halogenouridines, by the opening of 2,2′-anhydro-[1-(β-D-arabinofuranosyl)uracil] (**7**) with the appropriate hydrogen halide (Scheme 2). Debenzoylation of the partially reduced derivative **8** (1) with methanolic ammonia, under controlled conditions, afforded

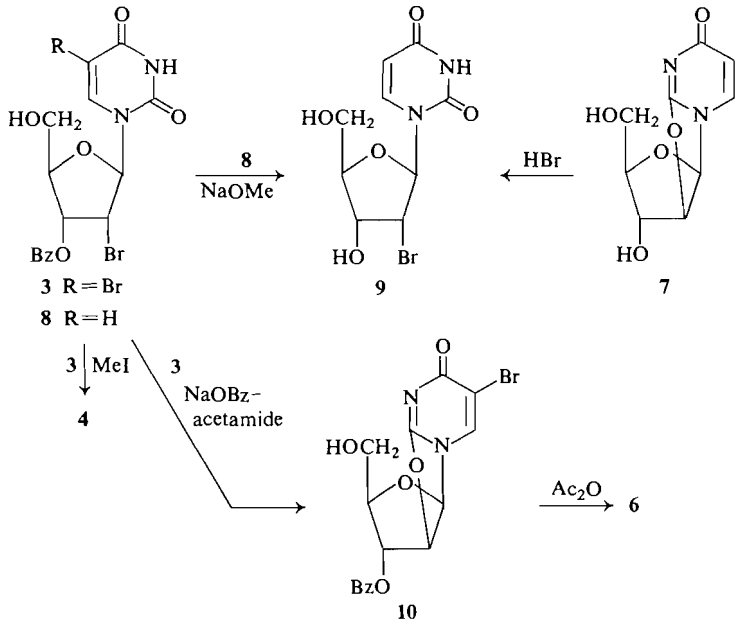

SCHEME 2

the known 2′-bromo-2′-deoxyuridine **9** (3). Since the conditions for the formation of **9** from **8** preclude any secondary transformations, it can be unambiguously established that the preponderant crystalline product isolated from the reaction of **1** with NBS (1) has the D-*ribo* configuration (structure **3**). The stereochemical assignment of the product resulting from the reaction of **2** with NBS was accomplished by controlled *N*,*O*-methylation of **3** (now of established configuration) with methyl iodide and sodium hydride in *N*,*N*-dimethylformamide. The reaction led to a mixture of products, from which the desired product was separated by preparative t.l.c., to give crystalline material identical with **4**, as obtained from the reaction of **2** with NBS. The stereochemical identity of compound **3**, hence that of **4**, was also confirmed by another route. It was shown in the preceding paper (1) that the 2,2′-anhydro derivative **6** could be transformed into **7**, thereby confirming its structure. Treatment of **3** with sodium benzoate in molten acetamide (5) gave a 67% yield of a crystalline product, that corresponded to the expected 2,2′-anhydro [1-(3′-*O*-benzoyl-β-D-arabinofuranosyl)-5-bromouracil] (**10**). Acetylation of this product afforded a crystalline product, identical with **6**. The transformation illustrated in Scheme 2 shows beyond doubt the stereochemical identities and interrelationships of compounds **3**, **4**, and **6**.

In previous papers in this series, the mechanism of the ring-opening reaction of *O*-benzylidene acetals with NBS was discussed in detail (6–8). The available data support the transformation of the benzylidene acetal, presumably via an α-bromo intermediate, into a benzoxonium ion and bromide ion. The latter attacks the oxonium ion at the two possible sites, depending on the nature of the positions involved, which leads to the attachment of a bromine atom and a benzoate group on the ring carbon atoms bearing the acetal function.

In the methyl 2,3-*O*-benzylidene-β-D-ribofuranoside series, which in our initial studies represented the simplest model for eventual applications to nucleoside analogs, the nature of the products resulting from the reaction with NBS was influenced by the type of substituent at C-5 (8). In the absence of a participating group, as in the case of the 5-*O*-methyl derivative, the products were a mixture of 2-bromo and 3-bromo derivatives, resulting from an attack of bromide ion on the intermediate 2,3-benzoxonium ion. In the presence of a participating group, as in the 5-*O*-benzoyl deriva-

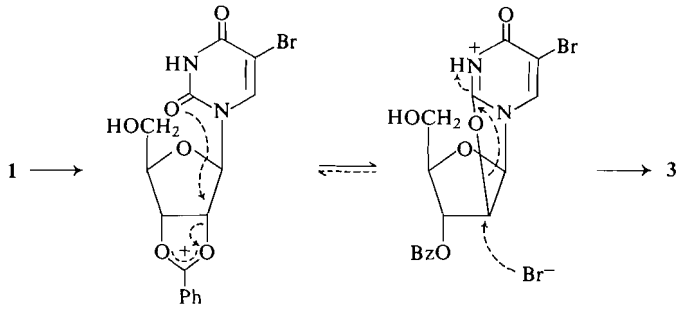

SCHEME 3

tive, the major product was a 5-bromo derivative, resulting from a participation by the C-5 benzoate group, to give a rearranged benzoxonium ion, spanning C-5 and -3, that was subsequently attacked by bromide ion.

The intermediacy of 2′,3′-benzoxonium ions in the reaction of 2′,3′-*O*-benzylidene nucleosides such as **1**, with NBS, presents some intriguing mechanistic implications (9) and important synthetic possibilities. In the intermediate benzoxonium ion **11** (Scheme 3), attack at C-2′ and/or C-3′ can occur by the external nucleophile in the medium, namely bromide ion, to give the corresponding products (D-*arabino*, D-*xylo* configurations). Since it was previously established (1) that the bromine atom was situated at the 2′-position, the mechanistic relevance of the reaction will be focused on the mode of formation of the 2′-bromonucleosides, and more explicitly compound **3**. Another mechanistic consideration is the internal attack on the benzoxonium ion **11** by the C-2 oxygen function, as has been shown in numerous cases involving solvolyses of C-2′ sulfonate esters and related nucleoside derivatives (9–11), which leads to the 2,2′-anhydro intermediate **12**. The preponderant formation of compound **3** can be satisfactorily explained by invoking a 2,2′-anhydro intermediate, that undergoes nucleophilic attack by bromide ion at C-2′. It is also possible that small amounts of the other products (D-*xylo*, D-*arabino* configurations) might be present in the crude reaction product. It is of interest that previously recorded examples, in which the transitory formation of benzoxonium ions was postulated, dealt with fully substituted nucleoside derivatives (9). The successful application of the acetal ring-opening reaction in the pyrimidine nucleoside series is perhaps reflective of the reactivity of the benzoxonium ion and the enhanced participating ability of the C-2 oxygen function, leading to conformationally rigid anhydro intermediates.

The researches of Fox and coworkers (5, 9) have shown that nucleophilic displacements of 2,2′-anhydronucleosides and 2-sulfonates of pyrimidine ribonucleosides are facilitated by adding to the reaction mixture 1 equiv of benzoic acid, which effects protonation of the 3-*N* atom, thus rendering the 2,2′-anhydro ring more labile. Displacement of such "primed" intermediates by nucleophiles in anhydrous media, occurs with overall retention of configuration at C-2′. From a consideration of the mechanistic pathways shown in Scheme 3, it can be seen that the 2,2′-anhydro intermediate **12** generated during the reaction is in fact protonated and the formation of a product having the D-*ribo* configuration as a result of an attack by bromide ion would be fully expected. Conclusive evidence for these mechanistic considerations was obtained in the following manner. Treatment of **3** with sodium benzoate in molten acetamide (9) gave crystalline 2,2′-anhydro-[1-(3′-*O*-benzoyl-β-D-arabinofuranosyl-5-bromouracil] (**10**). The latter was treated with 1 equiv of methane-

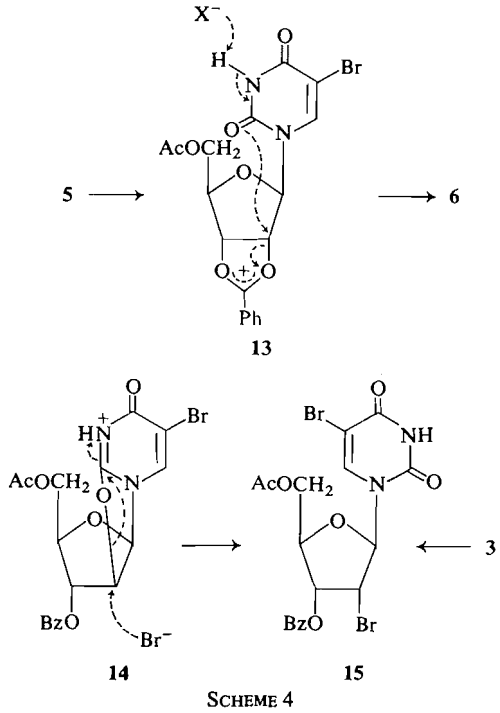

SCHEME 4

sulfonic acid (12) in a mixture of carbon tetrachloride and tetrachloroethane, followed by NBS and the mixture was heated at 80° as in the previous case. A 95% yield of compound **3** was obtained, with no trace of side-products. In the absence of added acid, negligible reaction took place (Scheme 3).

The formation of 2,2′-anhydro-[1-(5′-*O*-acetyl-3′-*O*-benzoyl-β-D-arabinofuranosyl)-5-bromouracil] (**6**), as a preponderant product in the reaction of **5** with NBS, accentuates the influence of subtle structural modifications, on the mechanistic pathway of the reaction (Scheme 4). It is evident that intramolecular attack of the carbonyl oxygen atom in the benzoxonium ion intermediate **13** is favored, but in this case, the protonated 2,2′-anhydro intermediate **14** is deprotonated to give the observed product. The operation of this process, in preference to an attack by bromide ion is particular to this derivative only, although the presence of a small amount of the expected D-*ribo* nucleoside **15** among the reaction products was ascertained from an investigation of the mother liquors of crystallization. The mechanistic aspects of its formation were verified by "priming" the 3-*N* position with methanesulfonic acid, then subjecting the protonated intermediate **14** to the conditions of the bromination reaction. This led to the formation of **15** in 90% yield. Although the "priming" experiment recreates the activated protonated intermediate that is presumably present in the original reaction, it can be seen that the product distribution is different in both cases (compare **6** and **15**). A plausible explanation can be offered at this time, although a detailed study involving appropriate substrates would be eventually desirable. It is conceivable that compound **13** is deprotonated by an anionic species X^- (X = Br, succinimidyl anion) *prior* to intramolecular participation by the carbonyl group, and that such a participation is done in a concerted fashion (Scheme 4). The results of the "priming" experiments clearly show that once the protonated 2,2′-anhydro intermediate **14** is formed, it will be attacked by bromide ion to give **15**, rather than being deprotonated to give **6**. Another aspect worthy of consideration is the relative concentrations of the intermediate **14** in solution, with respect to bromide ion when comparing the results of the transformation **5** → **6** (via NBS) and **6** → **15** (via $MeSO_3H$, NBS). In the latter case the substrate is available entirely in its activated form, while in the former case, the relative concentration of **14** in solution at any interval is low. To what extent the C-5 substituent influences the course of the reaction cannot be answered at the present time. The identity of compound **15** was also substantiated by an independent synthesis from **3** by simple acetylation.

The stereoselectivity of the bromination reaction in the series discussed in this paper is most pronounced in the case of the 3-*N*-5′-*O*-dimethyl analog **2**, as reflected in the isolation of the corresponding C-2′ bromo derivative **4** in 65% yield. The intermediate benzoxonium ion is presumably transformed into the 2,2′-anhydro intermediate which undergoes attack by bromide ion to give the observed product. The presence of the 3-*N*-methyl group thus provides only one possible pathway for termination. Any hindering effect by the C-5′ substituent, in preventing intramolecular participation in this case, is overcome by the highly activated nature of the benzoxonium ion intermediate and the enhanced participating ability of the C-2 oxygen function.

Experimental

Melting points are uncorrected. The i.r. spectra were recorded with a Beckman IR-8 instrument. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. The t.l.c. was performed on plates (20 cm length) coated with silica gel GF_{254} (Merck) and the spots were detected with a sulfuric acid spray and by u.v. visualization. Column chromatography was done on short columns containing silica gel GF_{254}, by application of a moderate suction. The n.m.r. spectra were measured on a JEOL-4H-100 and 60 MHz instruments (s, singlet; d, doublet; t, triplet; m, multiplet; b, broad).

*2′-Bromo-2′-deoxyuridine (**3**)*

3′-*O*-Benzoyl-2′-bromo-2′-deoxyuridine (250 mg) (1) was dissolved in cold anhydrous methanolic ammonia (7 ml) and the solution was allowed to stand at 3° for 4 h. Examination of the reaction mixture on t.l.c. (chloroform–methanol, 10:3) revealed two major components in addition to two minor slow-moving components. The solution was concentrated *in vacuo* below 20° (bath temperature). Methanol was added and distilled off several times to remove all ammonia and the mixture was separated by preparative t.l.c. The spot having highest R_f was shown to be the starting material, m.p. 177–181°; mixed m.p. 175–181°. The second spot crystallized upon standing. Recrystallization from water gave pure material, m.p. 182–186°. The m.p. was not depressed on a mixture with authentic 2′-bromo-2′-deoxyuridine[3] (m.p. 186–190°) and the two products had identical n.m.r. spectra and chromatographic mobility.

3′,5′-Di-O-benzoyl-2′-bromo-2′-deoxy-3-N-benzoyluridine

*(a) From 2′-Bromo-2′-deoxyuridine (**9**)*

To a solution of 2′-bromo-2′-deoxyuridine (**9**, 0.5 g) in dry pyridine (8 ml) and dry methylene chloride (8 ml) was added benzoyl chloride (2.5 ml) dropwise at 0°. The mixture was allowed to stand at 3° overnight, and then poured into ice-water. The product was extracted with methylene chloride and washed successively with cold 5% sulfuric acid, aqueous sodium bicarbonate, and then water. The organic layer was dried and evaporated to dryness by co-distilling with toluene. The residue was washed several times with petroleum ether (b.p. 30–60°), cold ether, and then a small amount of cold methanol. The final residue was triturated with petroleum ether to give a solid (0.75 g) which was purified by chromatography on a column containing silica gel using ethyl acetate – chloroform (1:5) as irrigating solvent. The title compound was obtained as a colorless syrup, $[\alpha]_D$ −15° (*c* 1.45, $CHCl_3$); n.m.r. data: τ 3.54 (H-1′, $J_{1',2'} = 5.2$ Hz); 4.21 (H-5, $J_{5,6} = 8.2$ Hz); 4.35 (H-3′, multiplet), etc.

*(b) From 3′-O-Benzoyl-2′-bromo-2′-deoxyuridine (**8**)*

To a solution of 3′-*O*-benzoyl-2′-bromo-2′-deoxyuridine (0.19 g) (1) in pyridine (2 ml) and methylene chloride (2 ml) was added benzoyl chloride (1 ml) at 0°. The reaction mixture was allowed to stand at 3° overnight, and then poured into ice-water. It was worked-up in the usual manner to yield a solid (150 mg) after chromatography. The product was identical to that obtained by the above described method *a*.

[3]A sample was provided by Dr. J. J. Fox, see ref. 3.

*2,2′-Anhydro-[1-(3′-O-benzoyl-β-D-arabinofuranosyl) 5-bromouracil] (**10**)*

A mixture of 3′-*O*-benzoyl-2′,5-dibromo-2′-deoxyuridine (**3**, 0.5 g), sodium benzoate (0.5 g), and acetamide (9.0 g) was heated to a melt. The solution was vigorously stirred, while heating at 100–105° (bath temperature) for 20 min. The hot solution was poured into cold water (250 ml) with stirring and the solution was extracted with ethyl acetate. The extracts were concentrated to a syrup which crystallized upon standing (1 g). A minimum amount of cold ethanol was added and the crystals were collected. Recrystallization from aqueous methanol gave pure material (0.28 g, 67%), m.p. 208–211°; $[\alpha]_D$ −124° (*c* 0.90, $CHCl_3$). The mother liquor contained an appreciable amount of the starting material (t.l.c.).

Anal. Calcd. for $C_{16}H_{13}O_6N_2Br$: C, 47.0; H, 3.18; N, 6.85; Br, 19.55. Found: C, 47.04; H, 3.26; N, 6.81; Br, 19.36.

*Ring Opening of 2,2′-Anhydro-[1-(3′-O-benzoyl-β-D-arabinofuranosyl) 5-Bromouracil] (**10**) with NBS*

(a) In the Absence of an Acid

To a suspension of the title compound **10** (0.1 g) and barium carbonate (0.04 g) in 1,1,2,2-tetrachloroethane (5 ml) and carbon tetrachloride (1 ml) was added NBS (0.118 g). The mixture was stirred, while heating at 85–90° (bath temperature), for 3 h. It was worked-up in the normal way to give a syrup which showed the presence of the starting material, and a fast moving component which had the same chromatographic mobility (chloroform–methanol, 15:1, multiple developments) as 3′-*O*-benzoyl-2′,5-dibromo-2′-deoxyuridine (1).

(b) In the Presence of Methanesulfonic Acid

To a suspension of the title compound **10** (0.1 g) in 1,1,2,2-tetrachloroethane (5 ml) and carbon tetrachloride (1 ml) was added methanesulfonic acid (0.0159 ml, made up in anhydrous ether) followed by NBS (0.118 g). The reaction mixture was stirred, while heating at 85–90° (bath temperature), for 3 h. The cooled solution was neutralized by stirring with anhydrous sodium carbonate. The solids were filtered and the filtrate was evaporated to dryness by co-distilling with toluene. The resulting syrup (196 mg) which showed traces of starting material was dissolved in chloroform and washed with water. The chloroform layer was dried and concentrated to dryness. Chilled methylene chloride was added and crystals were collected (0.11 g, 92%), m.p. 204–207°. Recrystallization from acetone afforded pure material, m.p. 209–212°; mixed m.p. 210–213° (with a sample obtained from **1**).

*5′-O-Acetyl-3′-O-benzoyl-2′,5-dibromo-2′-deoxyuridine (**15**)*

A mixture of acetic anhydride (5 ml) and 3′-*O*-benzoyl-2′,5-dibromo-2′-deoxyuridine (**3**, 500 mg) in pyridine (5 ml) and methylene chloride (10 ml) was kept overnight at 5°. The reaction mixture was poured into ice-water and the solution was extracted with methylene chloride and washed successively with water, aqueous sodium bicarbonate, and then water. The organic layer was dried and evaporated to give a crystalline mass which was triturated with anhydrous ether and filtered to give the title compound (486 mg). Recrystallization from acetone–methanol afforded pure material, m.p. 199–202°; $[\alpha]_D$ −84° (*c* 2.49, $CHCl_3$).

Anal. Calcd. for $C_{18}H_{16}O_7N_2Br_2$: C, 40.6; H, 3.0; N, 5.27; Br, 30.0. Found: C, 40.38; H, 3.04; N, 5.18; Br, 29.69.

Ring Opening of 2,2'-Anhydro-[1-(5'-O-acetyl-3'-O-benzoyl-β-D-arabinofuranosyl) 5-Bromouracil] (6) with NBS

(a) In the Absence of an Acid

To a suspension of the title compound (100 mg) and barium carbonate (40 mg) in carbon tetrachloride (4 ml) and 1,1,2,2-tetrachloroethane (1 ml) was added NBS (47.3 mg). The mixture was heated to reflux, while stirring, for 4.5 h. It was processed as usual to give a syrup which showed the presence of starting material and traces of a faster moving component that had the same chromatographic mobility (chloroform–methanol, 10:3) as 5'-*O*-acetyl-3'-*O*-benzoyl-2',5-dibromo-2'-deoxyuridine (**15**).

(b) In the Presence of Methanesulfonic Acid

To a suspension of the title compound (100 mg) in carbon tetrachloride (4 ml) and 1,1,2,2-tetrachloroethane (1 ml) was added methanesulfonic acid (0.0144 ml, made up in anhydrous ether) followed by NBS (120 mg). The solution was heated to reflux, while stirring, for 2.5 h. The cooled solution was neutralized by stirring with anhydrous sodium carbonate and the mixture was worked-up in the normal way to give a syrup which showed traces of starting material. Addition of absolute ethanol gave a crystalline product (105 mg, 89%), m.p. 196–199°. Recrystallization from acetone–methanol afforded pure material, m.p. 198–201°, identical with the desired product **15**.

N,O-Methylation of 3-O-Benzoyl-2',5-dibromo-2'-deoxyuridine (3)

Sodium hydride (10 mg) was added to a cooled solution containing 100 mg of the title compound **3** in DMF (5 ml). The suspension was stirred at 0° for 10 min and methyl iodide (0.25 ml) was added slowly. After the mixture was stirred at room temperature for 5 h, methylene chloride was added and the solution was washed with water. The organic layer was processed as usual to give a syrup that showed at least five discernible spots on t.l.c. The desired component was separated by preparative t.l.c. and it was crystallized from ether to give pure material (5 mg) identical with authentic **4**, m.p. 157–160° (1).

Molecular Rearrangements. Part I. The Thermal Rearrangement of the Benzyl Naphthyl Ethers

M. ZARIF A. BADR[1] AND H. A. H. EL-SHERIEF

Department of Chemistry, Faculty of Science, University of Assiut, Assiut, Egypt, U.A.R.

Received July 27, 1971

Heating benzyl-β-naphthyl ether at 260° for some days causes benzylic migration to the α-position, together with the formation of β-naphthol, toluene, dibenzyl, and 9-phenyl-1,2,7,8-dibenzoxanthene.

Benzyl-α-naphthyl ether rearranges under similar conditions to give 2- and 4-benzyl-1-naphthol, toluene, dibenzyl, and 9-phenyl-3,4,5,6-dibenzoxanthene.

Rearrangement of the benzyl-α-naphthyl ether in quinoline gives the normal products of the rearrangement together with 2- and 4-benzylquinolines and 2-quinolyl-1-hydroxynaphthalene. In phenol and in anisole, the rearrangement is accompanied by benzylation of the solvent.

It is concluded that the thermal rearrangement of the benzyl naphthyl ethers depends on a homolytic fission of the ether to benzyl and naphthyloxy radicals.

En chauffant l'éther de benzyl-β-naphtyl à 260° pendant plusieurs jours, il se produit une migration benzylique vers la position α, en même temps que la formation de β-naphtol, toluène, dibenzyle et de 9-phényl-1,2,7,8-dibenzoxanthène.

L'éther de benzyl-α-naphtyl se transpose sous des conditions similaires pour donner le 2- et 4-benzyl-1-naphtol, le toluène, le dibenzyle et le 9-phényl-3,4,5,6-dibenzoxanthène.

La transposition de l'éther de benzyl-α-naphtyl dans la quinoléine donne les produits normaux de transposition avec en plus le 2- et 4-benzylquinoléines et le 2-quinolyl-1-hydroxynaphtalène. Dans le phénol et dans l'anisole, la transposition est accompagnée par une benzylation du solvant.

Il en a été conclu que la transposition thermique des éthers de benzyl-naphtyl est fonction de la rupture homolytique de l'éther en radicaux benzyl et naphtyloxy.

Canadian Journal of Chemistry, **50**, 259 (1972)

It was reported by Behagel and Friensehner (1), that benzyl-α-naphthyl ether gave 22% 4-benzyl-1-naphthol with 16% α-naphthol and unidentified higher boiling materials, when it was heated at 240° for 20 h. Benzyl-β-naphthyl ether and other aryl benzyl ethers also rearrange under similar conditions. However, the heating of ether in a sealed tube with 38% HCl, gave rearrangement products from which α-naphthol was identified as observed by Braun and Reich (2). It is not impossible that these results might be due to hydrolysis of benzyl chloride retained in the ether. The hydrochloric acid thus formed would catalyze the rearrangement. This explanation is not so improbable since it is found that benzyl chloride is persistently retained by benzyl ethers prepared from benzyl chloride and is not easily removed. Furthermore the observation that zinc accelerates such type of change (3) in other aryl ethers, can be explained as due to the formation of zinc chloride from the hydrochloric acid produced in the reaction.

[1]Present address; Department of Chemistry, University of Libya, Tripoli, P.O. Box 2558, Libya.

The object of the work described in this paper was to examine more closely the behavior of carefully purified benzyl naphthyl ethers on heating and if the thermal rearrangement did take place, to determine what products are formed and what bearing on the course of the change.

Benzyl-β-naphthyl ether, rigorously freed from all traces of benzyl chloride, changes on heating for some days in sealed tubes at about 260°. 1-Benzyl-2-naphthol is formed together with 9-phenyl-1,2,7,8-dibenzoxanthene, some toluene, dibenzyl, and β-naphthol. The ether, when heated at its boiling point under reflux gives the same products with the difference that some β-dinaphthol was isolated.

From benzyl-α-naphthyl ether, under similar conditions, 2- and 4-benzyl-1-naphthols are formed together with 9-phenyl-3,4,5,6-dibenzoxanthene, α-naphthol, and some toluene and water.

The products of these thermal rearrangements differ markedly, from those of the proton catalyzed rearrangements, from which neither

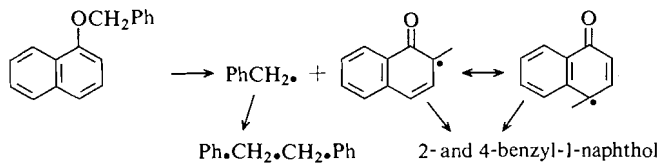
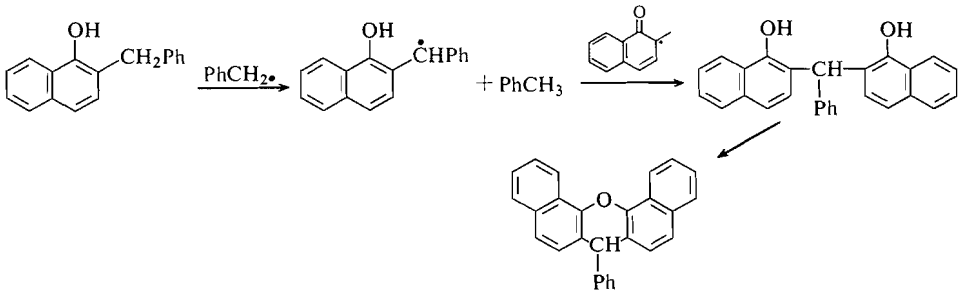


SCHEME 1



SCHEME 2

benzoxanthene, nor toluene nor dibenzyl have yet been reported (1, 2).

The formation of toluene and dibenzyl in the products of the thermal rearrangements is significant and suggests that the benzyl group takes part in the change as a free radical. If this is so, it should be possible to trap the benzyl group if the thermal rearrangement is carried out in a suitable solvent.

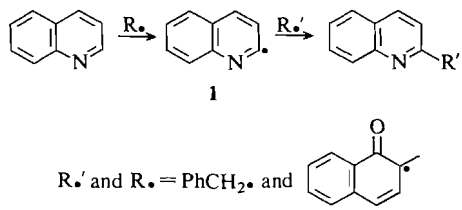
This has been realized, by heating benzyl-α-naphthyl ether in phenol. The normal products of rearrangement are accompanied by 2- and 4-benzylphenols. Similarly, in anisole, 2- and 4-benzylanisoles are formed.

Rearrangement of benzyl-α-naphthyl ether in quinoline gives the normal products of rearrangement together with those derived by substitution of quinoline; 2- and 4-benzylquinolines and an aminophenol provisionally identified as 2-quinolyl-1-naphthol. 2,2′-Biquinolyl is also isolated. A product is separated in all solvents and provisionally assigned as 4-benzyldi-α-naphthylene oxide from its elemental, i.r. and mass spectral analysis.

The simplest explanation of the rearrangement of the benzyl-α-naphthyl ether is to assume an initial homolytic fission to benzyl and naphthyloxy free radicals (see Scheme 1) and their substitution on the aromatic nuclei of the solvents used, through a mechanism analogous to that proposed by Williams and coworkers (4). However, subsequent recombination of both radicals is not excluded to give dibenzyl and some 2- and 4-benzyl-1-naphthols. Benzyl-β-naphthyl ether rearrangement is assumed to follow the same rule giving the corresponding products of its rearrangement.

The dibenzoxanthenes can be supposed to arise according to Scheme 2.

In quinoline, the formation of 2,2′-biquinolyl strongly suggests that (**1**) is also formed by reaction with a free radical (see Scheme 3). Combination of two such free radicals gives 2,2′-biquinolyl; with a benzyl radical, 2-benzylquinoline is formed; and a naphthyloxy radical gives 2-quinolyl-1-naphthol.



SCHEME 3

Experimental

Analysis

The lower boiling products of the rearrangement were analyzed by high-temperature g.l.c. of F. and M. scientific corporation Model 500, with flame ionization attachment and copper columns, 6 ft × 4 mm. The column used was 20% SE 30 on Chromosorb W (35–80 mesh) at 200° for the phenolic products and 215° for the neutral products. Infrared spectroscopic analysis was carried out on a Pye–Unicam I.R., Model SP200G.

Benzyl-α- and β-Naphthyl Ethers

These ethers were prepared by two methods: (*a*) By refluxing benzyl chloride for 5 h with a slight excess of the appropriate naphthol in acetone having finely powdered anhydrous potassium carbonate in suspension. (*b*) From the sodium naphthoxide and benzyl chloride in alcohol.

The crude ethers from these preparations persistently retained benzyl chloride, which was removed by refluxing with excess of pyridine for some time. The ether was recovered from this solution by dilution with water, adding ether and then washing the ethereal solution with dilute hydrochloric acid till freed from pyridine. Evaporation of this ether solution, after washing with alkali and drying, left the benzyl naphthyl ether. It was subjected to further treatment with pyridine until no trace of chloride could be detected in the redistilled ether. Only then were the benzyl naphthyl ethers considered pure enough for study of their rearrangement.

Benzyl-α-naphthyl ether was obtained, m.p. 74° from petroleum ether (60–80°).

Benzyl-β-naphthyl ether, m.p. 101–102° from ethyl alcohol.

Thermal Rearrangement of Benzyl Naphthyl Ethers

(a) Benzyl-β-naphthyl Ether

Benzyl-β-naphthyl ether (38 g) was boiled under reflux for 22 h. The first 2 h boiling caused the liquid temperature to drop from 257 to 235°, accompanied by a darkening from yellow to red–brown. The products of the change were the same as those detailed later with the exception that some β-dinaphthol (0.6 g) was isolated, m.p. and mixed m.p. 212–213°, dibenzoate, white needles m.p. and mixed m.p. 160°. Its i.r. spectrum was identical with that of an authentic specimen.

Better yields were achieved by heating the ether (38 g) in sealed tubes at 265° for 6 days. The ether was converted to a brown viscous mass with a green fluorescence. Distillation up to 200° removed toluene (1.8 g), (2,4-dinitro derivative m.p. and mixed m.p. 72°) and water (0.3 g).

The higher boiling material was separated into phenolic (*A*) and neutral products (*B*) by extraction with methyl alcoholic potassium hydroxide (Claisen's solution) after dilution with ether and benzene.

The neutral products (*B*) were separated by distillation into benzyl-β-naphthyl ether (6 g) b.p. 160–161°/1 mm, m.p. and mixed m.p. 101°, and 9-phenyl-1,2,7,8-dibenzoxanthene, as yellowish crystals from acetic acid, m.p. and mixed m.p. 189° (1 g).

From the neutral liquid fraction, b.p. 200–240°/13 mm, by its fractional crystallization from dilute ethanol, dibenzyl was separated (0.4 g), m.p. and mixed m.p. 52° (4,4′-dinitro derivative, m.p. and mixed m.p. 180°). It was further recognized by its i.r. spectrum and by its g.l.c. retention time.

The phenolic fraction (*A*) gave β-naphthol (5 g) and 1-benzyl-2-naphthol, m.p. and mixed m.p. 108–109°, benzoate, m.p. and mixed m.p. 96°. The yield estimated from g.l.c. was 8.4 g of 10.2 g of distillate.

(b) Benzyl-α-naphthyl Ether

The conditions were the same as those for the β-ether. The products were, toluene, water, dibenzyl, α-naphthol, 2-benzyl-1-naphthol, m.p. and mixed m.p. 74°, 4-benzyl-1-naphthol, m.p. and mixed m.p. 124°, and 9-phenyl-3,4,5,6-dibenzoxanthene, m.p. and mixed m.p. 248°. The i.r. spectra of these compounds were identical with those of authentic specimens.

Rearrangement of Benzyl-α-naphthyl Ether in Solvents

(a) Phenol

The ether (39 g) and phenol (11 g) were heated together in a sealed tube at 255° for 6 days. The product was worked up as described before where water (0.6 g) and toluene (2 g) were separated and identified. From the phenolic products, phenol and α-naphthol were isolated together with 2-benzyl-1-naphthol m.p. and mixed m.p. 73°, and 4-benzyl-1-naphthol m.p. and mixed m.p. 124°. From the liquid phenolic fractions, 2- and 4-benzylphenols were separated by fractional crystallization from benzene–petroleum ether (60–80°), where 4-benzylphenol separated, m.p. and mixed m.p. 84°, benzoate m.p. and mixed m.p. 87°. They were also recognized by their i.r. spectra and by g.l.c. analysis where they comprise 77% ortho-isomer and 23% para-benzylphenol.

A solid, m.p. 179–180° was isolated from the neutral fractions, b.p. 225–280°/11 mm provisionally identified as 4-benzyl-di-α-naphthylene oxide.

Anal. Calcd. for $C_{27}H_{18}O$ (mol. wt. 358): C, 90.1; H, 5.0. Found (358): C, 89.7; H, 5.3.

The i.r. spectrum had bands at 3010 and 3025 cm^{-1}, and showed the absence of OH. The m.p. was not changed by admixture with a sample of the same product separated in the following rearrangement.

From the neutral fraction, b.p. 310–320°/11 mm, 9-phenyl-3,4,5,6-dibenzoxanthene was isolated, m.p. and mixed m.p. 248–249°.

(b) Anisole

The ether (45 g) and anisole (11 g) heated together at about 260° for 10 days, gave water and toluene together with the same phenolic products as from the ether in absence of any solvent. The neutral fractions gave unchanged anisole, dibenzyl and 4-benzyl-di-α-naphthylene oxide. The remaining oil was recognized by g.l.c. as *o*-benzylanisole 40%, and *p*-benzylanisole 60%. They were further recognized by comparison of their i.r. spectra with those of the authentic specimens.

(c) Quinoline

The ether (70 g) and redistilled quinoline (40 g) were heated together at 260° for 14 days in sealed tube. Toluene (12 g) and water (1 g) were removed from the products by distilling up to 200°.

The higher boiling material was diluted with ether and extracted with Claisen's solution to remove phenols and aminophenols (*A*). Amines (*B*) were extracted from the ether solution by dilute hydrochloric acid. The remaining ether solution of neutral material (*C*) was distilled to give, 4-benzyl-di-α-naphthylene oxide, m.p. and mixed m.p. with the previously separated samples, 180–181°, and 9-phenyl-3,4,5,6-dibenzoxanthene, m.p. and mixed m.p. 248°. From the liquid fraction, b.p. 120–135°/10 mm, dibenzyl was separated, m.p. and mixed m.p. 52° (4,4′-dinitro derivative, m.p. and mixed m.p. 180°). It was further recognized by its i.r. spectrum and its retention time in g.l.c. analysis.

The amines liberated from the acid extract (*B*) were quinoline and a mixture of 2- and 4-benzylquinolines, b.p. 178–185°/8 mm which were separated by fractional crystallization of their picrates, into 4-benzylquinoline picrate m.p. and mixed m.p. 179°, and also 2-benzylquinoline picrate,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

m.p. and mixed m.p. 158°. From the fraction b.p. 210–230°/8 mm, 2,2′-biquinolyl was separated (0.8 g), m.p. and mixed m.p. 194–195°, picrate, m.p. and mixed m.p. 210°. Its i.r. spectrum was identical to that of an authentic specimen.

The phenol and aminophenol extract was concentrated to remove the methyl alcohol and acidified with hydrochloric acid to liberate the phenolic products; α-naphthol and 2- and 4-benzyl-1-naphthols which were identified by their m.p. and mixed m.p. and the similarity of their i.r. spectra with that of authentic specimens.

The aminophenols in the acid extract of (*A*) were liberated by neutralizing with sodium carbonate. A quinolyl-1-naphthol, m.p. 262°, was isolated.

Anal. Calcd. for $C_{19}H_{14}NO$: C, 83.8; H, 5.2: N, 5.2. Found: C, 83.9; H, 5.0; N, 5.0.

(d) Heating Authentic Benzyl Naphthols in Sealed Tubes

Samples of 1-benzyl-2-naphthol (6 g) and 2-benzyl-1-naphthol (6 g) were heated separately in sealed tubes at 260° for 6 days. Identification of the reaction products by g.l.c., i.r. spectra and mixed m.p. method confirmed that the starting isomers were recovered unchanged in both cases, without formation of toluene or dibenzoxanthenes by-products.

Preparation of Reference Compounds

1-Benzyl-2-naphthol: prepared by the action of benzyl chloride, on a suspension of sodium-β-naphthoxide in toluene. On crystallization from benzene–petroleum ether (60–80°), white crystals separated, m.p. 109–110°, benzoate m.p. 96° (lit. 5*a*, m.p. 111–112°, benzoate m.p. 97°).

2-Benzyl-1-naphthol: prepared with a similar procedure as above. On crystallization from petroleum ether (60–80°), yellowish white crystals separated, m.p. 74° (lit. 5*b*, m.p. 74°).

4-Benzyl-1-naphthol: prepared by refluxing benzyl alcohol, α-naphthol in CS_2 and anhydrous $AlCl_3$. After extraction and crystallization from petroleum ether (60–80°), gave m.p. 125–126° (lit. 6, m.p. 125–126°).

2-Benzylanisole: prepared by methylation of 2-benzyl phenol. Its crystallization from ethanol gave white crystals, m.p. 27–28° (lit. 7, b.p. 123–124°/3 mm, m.p. 29–30°).

4-Benzylanisole (8): prepared from anisole, benzyl alcohol, and $AlCl_3$ by refluxing in petroleum ether (60–80°). It was collected by fractional distillation at 150–155°/7 mm, n_D^{20} 1.5781.

4-Benzylphenol: prepared from benzyl alcohol and phenol in CS_2, by the action of $AlCl_3$. From the oily fraction collected, on crystallization of the precipitated crystals from petroleum ether (60–80°) gave hairy needles, m.p. 84°, benzoate m.p. 87° (lit. 9, m.p. 84°).

4-Benzylquinoline: prepared by heating quinoline-1-oxide, and benzyl magnesium chloride in dry dioxane. On fractional distillation, it was collected at 228–235°/14 mm.

Anal. Calcd. for $C_{16}H_{13}N$: C, 87.6; H, 6.0; N, 6.4. Found: C, 87.5; H, 6.2; N, 6.3.

The picrate, m.p. 178–179° (lit. 10, b.p. 230°/17 mm, picrate, m.p. 178–179°).

2-Benzylquinoline picrate: separated from a mixture of 2- and 4-benzyl-quinolines obtained by treatment of quinoline with benzyl magnesium chloride in dry dioxane. Fractional crystallization of their picrates, separated 2-benzylquinoline picrate, m.p. 156–157° (lit. 10, b.p. 230°/14 mm, picrate m.p. 158–159°).

9-Phenyl-1,2,7,8-dibenzoxanthene: separated when boiling β-naphthol and benzaldehyde in glacial acetic acid saturated with HCl gas. On its crystallization from acetic acid gave rosy rhombic crystals, m.p. 189° (lit. 11, m.p. 189–190°).

9-Phenyl-3,4,5,6-dibenzoxanthene: prepared by reduction of 9-phenyl-3,4,5,6-dibenzoxanthenol with zinc dust and few crystals of platinum chloride in boiling acetic acid. On crystallization from acetic acid–acetic anhydride mixture, white crystals separated, m.p. 250° (lit. 12, m.p. 253°).

Anal. Calcd. for $C_{27}H_{18}O$: C, 90.5; H, 5.0. Found: C, 90.3; H, 5.3.

9-Phenyl-3,4,5,6-dibenzoxanthenol: prepared by reaction of phenyl magnesium bromide with dibenzoxanthenone. On crystallization from petroleum ether (60–80°), white crystals separated, m.p. 215°.

Anal. Calcd. for $C_{27}H_{18}O_2$: C, 86.6; H, 4.8. Found: C, 86.4; H, 5.0.

2,2′-Dihydroxy-1,1′-binaphthyl (β-dinaphthol): prepared by heating β-naphthol and copper sulfate in ammonium hydroxide solution. On extraction with chloroform and crystallization from toluene, it was separated as pale yellow crystals, m.p. 217–218°, dibenzoate, m.p. 160° (lit. 13, m.p. 218–219°).

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.9; H, 4.9. Found: C, 83.7; H, 5.0.

2,2′-Biquinolyl: prepared by heating quinoline and 5% (w/w) iodine, in a sealed tube at 320° for 1 h. On crystallization from ethanol, white crystals separated, m.p. 195–196°, picrate, m.p. 210° (lit. 14, m.p. 196°, picrate m.p. 210°).

Dibenzyl: prepared by refluxing, for 15 h, a mixture of benzoin, zinc amalgam, and concentrated HCl. It was crystallized from ethanol as white crystals, m.p. 52°, 4,4′-dinitro derivative, m.p. 180°.

Anal. Calcd. for $C_{14}H_{14}$: C, 92.3; H, 7.7. Found: C, 92.1; H, 7.9.

The Electroreduction of Substituted Benzofurazans

W. R. FAWCETT,[1] P. A. FORTE, R. O. LOUTFY, AND J. M. PROKIPCAK[1]

Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 16, 1971

The electroreduction of 4- and 5-substituted benzofurazans was investigated at a platinum electrode in acetonitrile. Standard potentials for the reactions were linearly related to the energy of the lowest vacant molecular orbital as estimated by Hückel theory. Standard rate constants for electron transfer decreased as standard potentials in the series became more cathodic. This decrease is attributed to a double layer effect. No correlation was obtained between standard rate constants and observed hyperfine splitting constants for the anion radicals.

L'électroréduction des benzofurannes substitués en -4 et -5 a été étudiée dans l'acétonitrile au moyen d'une électrode en platine. Les potentiels standard pour les réactions ont été reliés d'une façon linéaire aux orbitales moléculaires vacantes les plus basses telles qu'estimées par la théorie d'Hückel. Les constantes de vitesse standard pour le transfert d'électrons décroissent au fur et à mesure que les potentiels standard dans les séries deviennent plus cathodiques. Cette diminution est attribuée à un effet de double couche. Aucune corrélation n'a été obtenue entre les constantes de vitesse standard et les constantes hyperfines de dédoublement observées pour les radicaux anioniques.

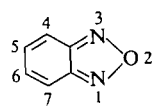
Introduction

It has been pointed out recently that, although substituent effects on the free energy of formation of radical ions are well documented (1), very few studies of substituent effects on the kinetics of electron transfer have been reported (2, 3). When organic electrode reactions are studied in aprotic solvents, one often observes a simple one electron transfer process with formation of a stable radical ion uncomplicated by adsorption on the electrode or accompanying proton transfer reactions. Atherton *et al.* (4) and Zhdanov *et al.* (5) have shown that benzofurazan (**1**) undergoes a one electron reduction to form



1

a stable anion radical at a dropping mercury electrode in dimethyl formamide and acetonitrile. The former authors, Strom and Russell (6), and Solodovnikov and Todres (7) investigated the e.s.r. spectrum of the anion radical, and demonstrated the applicability of the Hückel molecular orbital (HMO) model to interpreting the experimental results. In the present paper, the results of a study of the kinetics of electroreduction of 4- and 5-substituted benzofurazans, and of the e.s.r. spectra of their anion radicals are presented and discussed with respect to the corresponding HMO calculations.

Experimental

All experiments were carried out in acetonitrile (AN) solution containing 0.05 *M* tetraethylammonium perchlorate (TEAP). The solvent purification procedure was based on two previously described techniques (8, 9). Anhydrous Na_2CO_3 (20 g) and $KMnO_4$ (30 g) were added to 2 l of practical grade acetonitrile in a 3 l flask. Solvent was distilled from the mixture at a rate of 5 to 10 ml min^{-1} under atmospheric pressure with exclusion of water vapor. After adding 5 g P_2O_5 to each liter of product, it was fractionally distilled at a moderate rate. This product was stirred with CaH_2 (10 g l^{-1}) for 12 h and then fractionally distilled from fresh CaH_2 (5 g l^{-1}). The resulting distillate contained no detectable water (Karl Fischer titration and g.l.c.). In addition, the solvent's u.v. absorbance was similar to that prepared by the method of O'Donnell *et al.* (9), indicating that it was quite suitable for u.v. spectroscopy. TEAP was recrystallized twice from doubly distilled water and dried at 60 °C in a vacuum oven for 2 days. The accessible range on Pt in 0.05 *M* TEAP (+2.7 to −2.1 V *vs.* Ag/AgCl/0.1 *M* TEAP in AN//) was better than that obtained by either of the previous techniques (8, 9), indicating little or no water contamination from either the solvent or the salt.

Benzofurazan, 4- and 5-methoxy-, 4- and 5-methyl-, 5-chloro-, and 5,6-dimethylbenzofurazan were prepared as described previously (10). 4-Chloro- and 4- and 5-nitrobenzofurazan were supplied by Professor D. DalMonte, Universita di Bologna, Italy. All benzofurazans were purified by sublimation at 30 °C and 1 mm Hg.

The electrochemical cell, designed for use with a rotating disc electrode (RDE), was 6 cm in diameter and 9 cm high. The platinum working electrode (Pine Instrument Co.) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

embedded in a teflon cylinder (1.9 cm diameter) and had a circular area (0.76 cm diameter) exposed to the test solution. The counter electrode was a square of platinum (1.5 cm^2) opposite the working electrode on the bottom of the cell. The reference electrode (Ag/AgCl/0.1 *M* TEAP in AN//), placed close to and above the working electrode, was enclosed in a glass sleeve and joined to the system under investigation by a sintered glass disc.

The working electrode was cleaned before each run by immersing it in hot nitric acid for a few minutes, and rinsing several times with distilled water; it was then immersed in acidic ferrous ammonium sulfate and again rinsed repeatedly with distilled water. It was electrochemically pretreated in the base electrolyte solution by applying -1.5 V until the observed current decayed to a small constant value; the potential was then shifted anodically to $+0.05$ V in order to oxidize any adsorbed hydrogen. This cycle was repeated until the current at the potential limits was constant. The base electrolyte current–potential curves did not vary markedly from run to run, indicating that the above pretreatment technique resulted in reproducible surface conditions at the working electrode.

The thermodynamic and kinetic parameters of the reduction reactions were obtained by rotating disc voltammetry, cyclic voltammetry, and phase selective a.c. admittance measurements. Current–voltage curves were obtained with the above three electrode systems using a PAR Model 170 Electrochemistry System. In the case of RDE voltammetry, rotational speeds in the range 400–2500 r.p.m. were achieved using a Pine Instrument Rotator. For cyclic voltammetry, symmetrical triangular potential sweeps with slopes in the range 10–500 mV s^{-1} were applied to the stationary working electrode. In phase and out-of-phase a.c. admittances were measured in the frequency range 15–200 cycles s^{-1} with a 5 mV peak to peak a.c. signal superimposed on the d.c. potential of the working electrode. Depolarizer concentrations were in the range 1×10^{-4} to 1×10^{-3} *M*. All experiments were conducted in a dry box under a nitrogen atmosphere at 25.0 ± 0.5 °C.

The e.s.r. spectra were obtained using a Varian E3 spectrophotometer. The radical anions were generated electrochemically in a cell designed for use in the e.s.r. cavity. A quartz tube with 2 mm i.d. containing a concentric platinum cathode was sealed to the bottom of a simple Pyrex cell in which the anolyte and catholyte compartments were separated by sintered glass. The electrolyte solution was 0.05 *M* TEAP in AN with a depolarizer concentration in the catholyte of $\sim 1 \times 10^{-3}$ *M*.

Results and Discussion

Current–voltage curves for all the compounds except the nitro-substituted benzofurazans exhibited one reduction wave within the polarizable range of platinum in acetonitrile. For cyclic potential scan with rates up to 10 mV s^{-1}, reduction and oxidation peaks of equal height separated by 59 mV were observed on the cathodic and anodic sweeps respectively, indicating that a stable anion radical was formed in a one electron reduction process. As expected, the separation between the peaks increased at higher scan rates where the electrode process was no longer reversible (Fig. 1.). Two admittance peaks were obtained in the case of the nitro compounds. For cyclic potential scan at 20 mV s^{-1} in the region of the first peak, it was observed that the anodic peak current was considerably less than the cathodic, the peak potentials being separated by 59 mV. These results were interpreted as evidence that the first step involved formation of an ion radical in a one electron reduction. This radical then underwent a chemical reaction producing a species which was electroreducible at potentials cathodic of the first step (ECE mechanism).

Standard potentials for the one electron reduction reaction, determined in the usual manner from the a.c. admittance data and the peak potentials of cyclic voltagrams obtained at low scan rates, are recorded in Table 1. It is obvious that the standard potential continuously shifts in the cathodic direction as the substituent becomes more electron donating in character. The rate of electron transfer at this potential and the transfer coefficient were also determined from the current–potential data. The relationship derived by Gokhshtein and Gokhshtein (11) between peak currents and potentials was used in the case of cyclic voltagrams (Fig. 2). The standard rate constants were also determined from the frequency dependence of the in-phase and out-of-phase components of the faradaic admittance at low frequencies according to the procedure of Sluyters-Rehbach and Sluyters (12). Finally, the two kinetic parameters were obtained by analyzing current–voltage curves from RDE voltammetry at rotational speeds where the electrode process was both mass transfer and electron transfer controlled (13). Rate constants determined by the three methods agreed well with one another (Table 1), indicating that the assumption that the reactant is not adsorbed on the electrode is valid. This assumption was also confirmed by examining the frequency dependence of $\omega^{1/2}/Y'_{cl}$ at constant potential where ω is the angular velocity and Y'_{cl}, the in-phase component of the admittance. The fact that this function increased with frequency in all cases is an indication that reactant adsorption was non-existent or very weak (12). Furthermore, it should be noted that the range of the

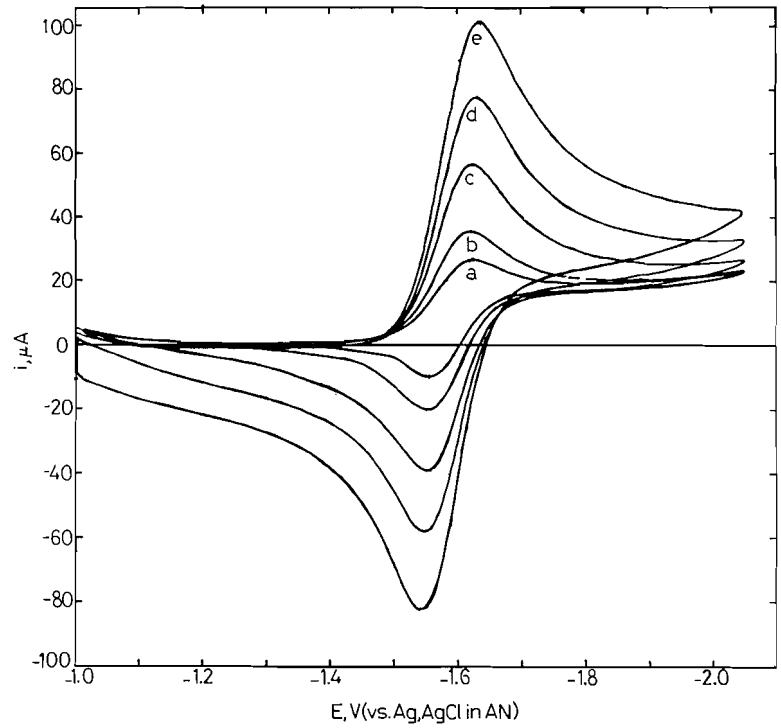

FIG. 1. Cyclic voltagrams for the electroreduction of 5-methyl benzofurazan at platinum in 0.05 *M* TEAP in AN at various scan rates: (*a*) 10, (*b*) 20, (*c*) 50, (*d*) 100, and (*e*) 200 mV s^{-1}.

observed faradaic current varied with the kinetic method, the largest current being obtained in RDE voltammetry. This fact considered together with the good agreement between rate constants determined by the three methods suggests that errors due to possible *IR* drop between the working and reference electrodes or non-uniform current distribution on the working electrode were negligible. Finally, it is apparent from the kinetic results that the rate of electron transfer decreased as the standard reduction potential became more cathodic.

The e.s.r. spectra were obtained for the anion radicals of all compounds except those with nitro substituents. In the case of benzofurazan, the hyperfine splitting constants (h.f.s.c.) were 5.40 G for the nitrogen atoms, and 3.37 and 2.00 G for the two pairs of equivalent hydrogen atoms. These results agree well with those reported earlier (4, 6, 7), the small differences being probably due to the fact that the spectra were obtained in different solvents and at several temperatures. The corresponding constants for the nitrogen atoms in substituted benzofurazans are recorded in Table 2. The HMO parameters for benzofurazan have been considered in detail by Atherton *et al.* (4). These authors concluded that the best parameters for the heteroatoms were $h_N = 0.75$, $h_O = 2.30$, $k_{CN} = 1.22$, and $k_{NO} = 0.80$ where h_x and k_{xy} are defined by eqs. 1 and 2,

$$[1] \qquad \alpha_x = \alpha_c + h_x\beta_{cc}$$

and

$$[2] \qquad \beta_{xy} = k_{xy}\beta_{cc}$$

α_c and β_{cc} being the coulomb and resonance integrals respectively, for the conjugated carbon atoms. Furthermore, they assumed that the proton and nitrogen h.f.s.c. were directly proportional to the spin densities at the contiguous ring carbon atoms and at the nitrogen atoms, respectively. They then pointed out that the energy of the lowest vacant molecular orbital (LVMO) in the Hückel approximation considering the symmetry properties of benzofurazan is given by $m = (a_4/a_5)^{1/2} - 1$ where m is the energy of the LVMO in units of β_{cc} above

*From spin densities for LVMO assuming $Q_N = 24.5$.

TABLE 3. Parameters for HMO calculations

>C—NO_2	$h_C = 0.20$ $h_N = 2.20$ $h_O = 1.40$	$k_{CN} = 1.20$ $k_{NO} = 1.45$
>C—Cl	$h_C = 0.50$ $h_{Cl} = 2.00$	$k_{C-Cl} = 0.40$
>C—CH_3	$h_{CH_3} = 2.00$	$k_{C-CH_3} = 0.70$
>C—OCH_3	$h_{OCH_3} = 2.00$	$k_{C-OCH_3} = 0.90$
	$h_N = 0.70$ $h_O = 2.00$	$k_{C-N} = 1.22$ $k_{N-O} = 0.80$

the reference energy level, α_c, and a_4 and a_5 are the h.f.s.c. at C-4,7 and C-5,6, respectively. A better fit to the present data was obtained assuming $h_N = 0.70$ and $h_O = 2.00$. The resulting spin densities were 0.219 at N-1,3, 0.125 at C-4,7, and 0.074 at C-5,6, and the calculated value of m, 0.296. The latter result is in excellent agreement with the value calculated from h.f.s.c. (0.298). Assuming McConnell constants, $Q_N = 24.5$ and $Q_H = 27$, the calculated h.f.s.c. are 5.37, 3.38, and 2.00.

The HMO calculations for the substituted molecules were carried out using the parameters listed in Table 3, the parameters for —Cl, —CH_3, and —CH_3O being taken from the tabulation of Purcell and Singer (14). The —NO_2 parameters were based on those used by Brodskii *et al.* (15) but were modified in order to obtain a better fit with the experimental data. A plot of the energy of the LVMO obtained in units of β_{cc} (Table 1) *vs.* the observed shift in half-wave potential for substituted benzofurazans is shown in Fig. 3. A good correlation was obtained by least squares (regression coefficient = 0.993), the equation of the straight line being

$$[3] \qquad \Delta E_{1/2} = 1.26 - 4.20\, m$$

If it is assumed that the half-wave potential is equal to the standard potential on the given potential scale, and that the difference in real solvation energies between an anion radical and the corresponding molecule does not depend on the nature of the substituent, then the slope

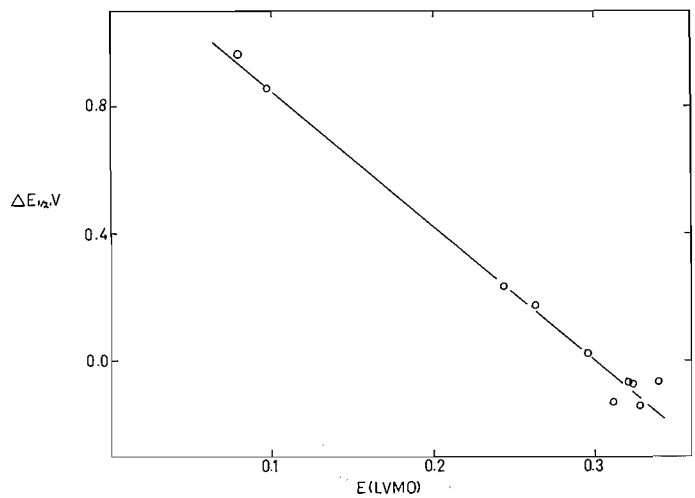

FIG. 3. Plot of the shift in the half-wave potential for substituted benzofurazans from that for benzofurazan, $\Delta E_{1/2}$ *vs.* the energy of LVMO in units of β_{cc} as calculated from HMO theory.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the line gives β_{cc} in eV. The present result is higher than that observed for conjugated hydrocarbons and aromatic nitro-compounds but falls within the expected range (16). However, the assumption of a constant difference in real solvation energies is undoubtedly invalid for the present series since the charge distribution in both the neutral molecule and anion radical depends on the substituent (17, 18). The h.f.s.c. calculated from spin densities at the nitrogen atoms for the LVMO are recorded in Table 2. Agreement with observed h.f.s.c. is as good as can be expected considering the approximate nature of the calculation.

The variation in the rate of electron transfer with substituent can be partially attributed to a double layer effect (19). If it is assumed that the charge center of the activated complex is located at the outer Helmholtz plane in the transition state, then the true rate constant for transfer of one electron to a neutral species, k_t is given by eq. 4, where k_0 is the observed rate constant at the standard potential, ϕ_2, the

$$[4] \qquad k_t = k_0 \exp(-\alpha f \phi_2)$$

potential drop across the diffuse layer, and $f = F/RT$. Since ϕ_2 is negative at potentials cathodic of the point of zero charge in the absence of ionic adsorption, the double layer correction results in true rate constants which are larger than those calculated ignoring it. Unfortunately double layer data are not available for the Pt/AN interface; however, the magnitude in the change in the effect with potential may be estimated from diffuse layer theory from which it can be shown that, at cathodic potentials,

$$[5] \qquad d\phi_2/dE = -2C/fq$$

where C is the differential capacity of the interface per unit area, and q, the surface charge density. Assuming that $C \sim 20\ \mu F\ cm^{-2}$ and $q \leqslant -10\ \mu C\ cm^{-2}$, then $d\phi_2/dE \leqslant 0.1$. Thus the total change in $\alpha\phi_2$ in a 400 mV potential range is less than 16 mV. The assumption that the molecule is at the outer Helmholtz plane in the transition state is subject to some doubt (20), the double layer effect being greater if it is in fact closer to the electrode. The corresponding change in observed rate constants expressed as $(1nk_0)/f$ is 25 mV. Thus, it would appear that the majority of the observed decrease in rate constants can be attributed to a double layer effect if ionic specific adsorption is absent.

If the corrected or true rate constants vary with potential, then, according to current theories (21, 22), the change is mainly due to a corresponding change in the contributions to the free energy of activation from solvent reorientation (2). Assuming that free energies of solvation can be estimated by the Born model, and that the distance of the activated complex from the electrode in the transition state is constant, the change in free energy of solvation reorientation with substituent can be calculated from the spin densities at the component atoms in the molecule. Peover and Powell (2) applied the above model to kinetic data for the electroreduction of nitro-compounds and were able to correlate a decrease in rate of electron transfer to an increase in spin density at the nitrogen atom in the nitro-group. According to both the e.s.r. data and HMO calculations the nitrogen atoms in the anion radicals have the highest spin densities, so that a correlation might be expected between these spin densities and the observed rate constants. However, such a correlation is not apparent from the data in Tables 1 and 2. This is probably due to the fact that the total change in observed rate constants and spin densities is small so that any existing relationship is obscured by experimental error and by the fact that a correction could not be applied for the double layer effect.

Finally, it is interesting to note that the rate constants observed here are at the low end of the range of values reported for nitro compounds (2). In the latter case, the rate constant varied markedly with reactant structure, being lowest when the charge on the resultant anion radical was localized on the nitro group, that is, when a species of higher dipole moment was formed. Benzofurazan is similar to the nitro compounds in that it has a high dipole moment. The fact that the dipole moment of the benzofurazan anion radical is higher than that of the neutral molecule is probably the chief reason for the low rate constant for electron transfer. However, it should be noted that the kinetics for the two series were measured at different electrodes (Pt and Hg) and in different solvents (AN and dimethyl formamide). The correspond-

ing differences in double layer structure and solvation energies for reactants and products will affect the observed rate constants but these effects are not expected to be large (23, 24).

The authors wish to thank Dr. T. E. Gough for making available e.s.r. facilities at the University of Waterloo, Waterloo, Ontario, and for valuable assistance in analysis of the spectral data, and Professor D. DalMonte for supplying some of the compounds used. Financial assistance was received from the National Research Council of Canada and Defence Research Board of Canada, and from the Department of Chemistry, University of Guelph through an equipment grant.

Flash Thermolysis: Quinones[1]

P. DE CHAMPLAIN[2] AND P. DE MAYO

Department of Chemistry, University of Western Ontario, London, Ontario

Received August 9, 1971

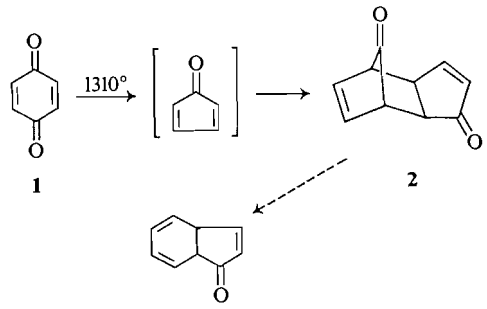
The flash thermolysis of a number of quinones is reported. *p*-Benzoquinone gives cyclopentadienone, isolated as the dimer. 2,5-Diphenylbenzoquinone gives 1- and 2-phenylnaphthalene together with benzo-[1,2-*b*:4,5-*b*']bisbenzofuran. Yields are very poor. Anthraquinone and phenanthraquinone give fluorenone, and the latter quinone gives small amounts of biphenylene.

La thermolyse-éclair d'un certain nombre de quinones est décrite. La *p*-benzoquinone donne la cyclopentadiénone qui est isolée sous la forme de son dimère. La diphényl-2,5 benzoquinone donne le phényl-1- et le phényl-2-naphthalène ainsi que le benzo-[1,2-*b*:4,5-*b*']bisbenzofuranne. Les rendements sont très faibles. L'anthraquinone et la phénanthraquinone donnent la fluorénone et cette dernière quinone donne de petites quantités de biphénylène.

Canadian Journal of Chemistry, **50**, 270 (1972)

The loss of carbon monoxide by the thermolysis of a variety of carbonyl compounds is a well-known process (for a review see ref. 1). Until recently, however, such a loss from quinones had only been observed in the mass spectrum (2). In 1967, DeJongh and his coworkers (3) showed that *o*-benzoquinone and some of its possible thermal progenitors (catechol sulfite and carbonate) lost one molecule of carbon monoxide to give, at 800°, cyclopentadienone which was isolated in good yield as its dimer (**2**). We considered that such decarbonylation might be a route to substituted cyclopentadienones, or, with more extravagant hopes, to cyclobutadiene derivatives.

For our initial experiments, we chose the readily available *p*-benzoquinone. The technique used has already been described and the apparatus was that represented in Fig. 1*b* of ref. 4. A platinum–rhodium resistor heater coil was used to reach the higher temperatures (above 1200°), but the coils had comparatively short life-times and could not be used at temperatures higher than 1350 °C. At 1310°, the maximum temperature at which the oven could be maintained for time enough to carry out 4–5 thermolyses before burning out the coil, *p*-benzoquinone gave the dimer of cyclopentadienone in 2.5% yield. At lower temperatures, down to 1150°, the yield of dimer progressively decreased.[3]



SCHEME 1

Since the completion of these experiments Suhr and Kruppa (5) have reported the obtention of **3** from **1** in the plasma glow discharge tube (see Scheme 1). DePuy and Lyons (6) have shown that **3** is easily derived from **2**.[3] In these experiments, we were unable to isolate any substance which could be derived from cyclobutadiene (*i.e.* the dimer, for instance). The high temperature required for the initial cleavage of the *p*-quinone was presumably responsible.

Substitution of the quinone should, in principle, lead to lowering of the bond strength of the vinyl–carbonyl linkage, and should, in addition, render the derived cyclopentadienone or other transformation product more easily isolable and identifiable (7). Thermolysis of **4**, indeed, proceeded at 1180° although in this case it was necessary to have a 100μ pressure flow

[1]Flash Thermolysis, Part 8.

[2]Holder of NRCC Scholarships 1969–1971.

[3]Professor O. L. Chapman and Dr. C. L. McIntosh have informed us that they have obtained cyclopentadienone from *o*-quinone, and measured its i.r. spectrum. We have also (with Dr. R. A. Marty) observed bands in the i.r. at 77 °K to be attributed to this substance.

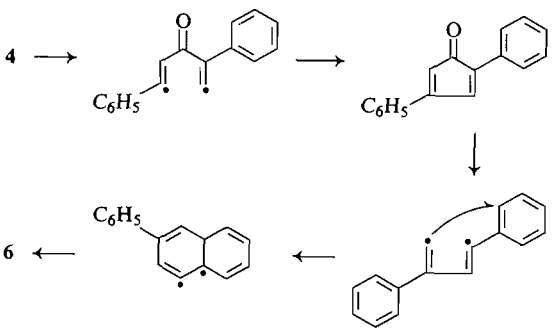
4 5 6 7

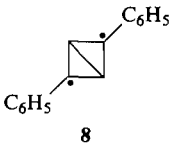
SCHEME 2

of nitrogen to ensure passage of the substance through the furnace. The products isolated were 1-phenylnaphthalene (**5**) (8%), 2-phenylnaphthalene (**6**) (8%), and benzo-[1,2-*b*:4,5-*b*']-bisbenzofuran (**7**) (6%) (see Scheme 2).

One possible product from such a reaction could be phenylacetylene, and the naphthalene could, in principle, have derived from the dimerization of this. Such a possibility was excluded by a control run using phenylacetylene: no naphthalenes were obtained. A second possibility which existed was that one isomer of the phenylnaphthalene was formed, by rearrangement, from the other (see Scheme 3). Since the formation of **6** may be more simply envisaged, the more likely rearrangement would be **6**→**5**. However, control runs with either isomer failed to show any isomerization. Only two general types of process appear to exist to allow for the formation of both isomers: either a phenyl migration occurs in an intermediate before formation of the naphthalenes, or the reaction pathway passes through a symmetrical

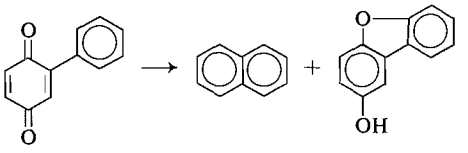


SCHEME 3



8

species having at least the symmetry of **8**. We have no data which could enable us to distinguish between these pathways. It is interesting that an equivalent transformation appears to have been recorded in the thermolysis of tetracyclone (8). Very recently Hageman and Wiersum (9) have reported the thermolysis of phenyl-*p*-benzoquinone (**9**) (see Scheme 4).



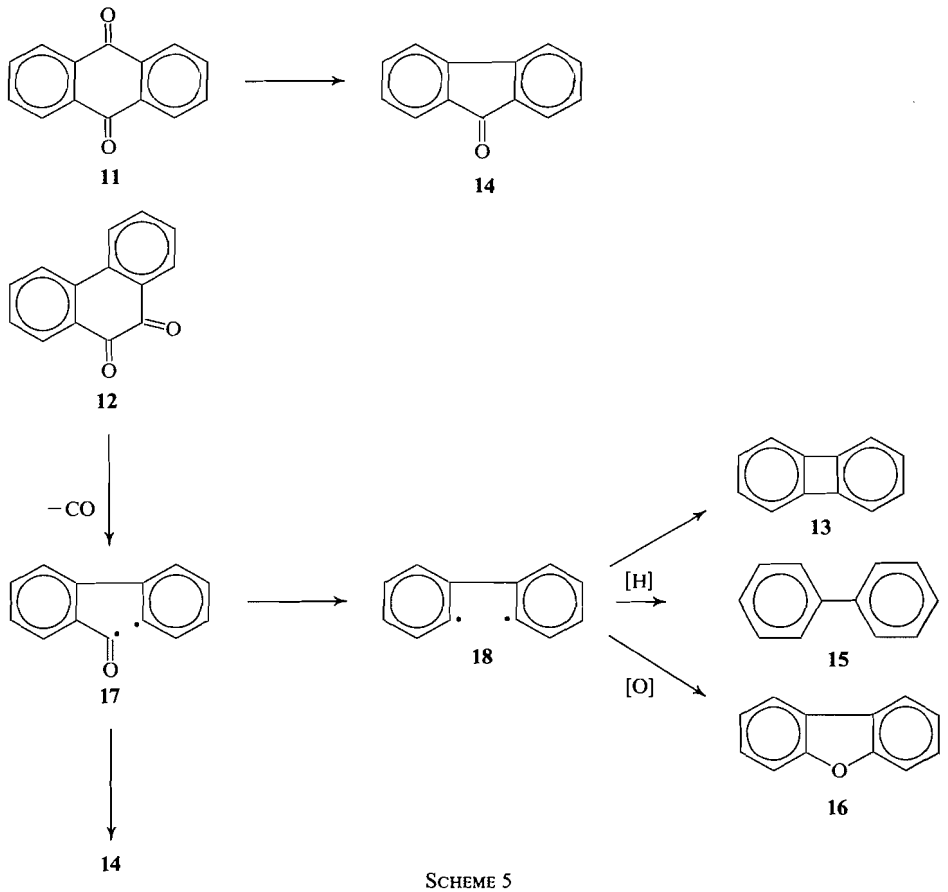
9 10

SCHEME 4

They obtained as products naphthalene and 4-hydroxydibenzofuran (**10**). It will be noted that the formation of **7** is essentially a cyclodehydrogenation very similar in nature to that obtained by Hay (10) in the thermolysis of 3,3',5,5'-tetraphenyldiphenoquinone.

Finally, we attempted the chemical verification of the best known mass spectrometric decarbonylations (2*c* and *d*); namely those of anthraquinone (**11**) and phenanthraquinone (**12**) to fluorenone (**14**) (see Scheme 5). Brown and Solly (11) had already succeeded in obtaining **14** from **12** in 76% yield at 800° in a packed silica tube and also identified traces of biphenylene (**13**) and biphenyl (**15**) as arising from fluorenone (**14**). Furthermore, they mention unsuccessful attempts (12) at obtaining fluorenone from anthraquinone (**11**). In our system, at 1180° and under 100 μ nitrogen carrier gas pressure, **11** and **12** yielded 40 and 53% fluorenone respectively. Furthermore, **12** yielded 2% biphenylene (**13**) and 1% each of biphenyl (**15**) and dibenzofuran (**16**). Under the same conditions, fluorenone gave only a trace of biphenylene. The presence of **13**, **15**, and **16** can be explained as occurring from the further decarbonylation of some intermediate species, presumably **17**, which is more readily generated from **12** than from **14**, the diradical **18** resulting from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 5

decarbonylation of **17** could close to form **13**, abstract hydrogen to give **15**, or react with a trace of oxygen contained in the carrier gas to yield **16**.

Experimental

Melting points were taken on a Kofler hot stage and are uncorrected. The i.r. spectra were determined on a Beckmann IR-10 spectrophotometer using sodium chloride cells. The n.m.r. spectra were taken on a Varian A-60. The t.l.c. was carried out on Merck GF-254 silica gel and the chromatographic columns were run on Merck PF-254 silica gel (with no binder). The u.v. spectra were run on a Carey 14 ultraviolet spectrophotometer. All yields expressed are based on the recovered starting material.

The thermolysis apparatus has been described previously (4).

Thermolysis of p-Benzoquinone (1)

p-Benzoquinone (220 mg; Matheson, resublimed) was sublimed through the oven under a pressure of 3 μ and thermolyzed at a temperature of 1310° (contact time: 1 ms.). After removal of the liquid nitrogen from the cold finger, the residual solid deposited was extracted with chloroform and transferred to a sublimation apparatus where the unreacted quinone (4%) was sublimed out. Preparative t.l.c. of the remaining solid ($CHCl_3$) yielded 2.5% of the cyclopentadienone dimer (**2**): ν_{max} 1705 and 1775–1785 cm^{-1} (lit. (13) 1705 and 1780 cm^{-1}), m.p. (hexane) 103–104.5° (lit. (13) 103–104°), the mass spectrum was identical to that of 1-indanone (see ref. 6).

Thermolysis of 2,5-Diphenyl-p-benzoquinone (4)

2,5-Diphenyl-*p*-benzoquinone (550 mg; Eastman Organic) was passed through the oven at 1180°, with 100 μ of nitrogen gas as carrier, over a period of 6 h. The solid left on the cold finger after pressurization and removal of liquid nitrogen was separated by preparative t.l.c. to yield 1-phenylnaphthalene (**5**) (8%), 2-phenylnaphthalene (**6**) (8%), benzo[1,2-*b*:4,5-*b*']bisbenzofuran (**7**) (6%), and 6% starting material.

1- and 2-phenylnaphthalenes were identified by comparison of i.r., n.m.r., and u.v. spectra with authentic specimens (Aldrich). The latter was also identified by mass spectrum and mixed m.p.

Benzo[1,2-*b*:4,5-*b*']bisbenzofuran (**7**) gave an m.p. (EtOAc) 269–270° (lit. (14) 265–266°) and had a u.v. spectrum identical to that recorded in the literature (15), λ_{max} (log ε):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

328(4.52), 308(4.52), 260(4.18), and 247(3.94). The mass spectrum gave a parent peak at *m/e* 258.[4]

Thermolysis of Anthraquinone (11)

Anthraquinone (440 mg; Eastman Organic, resublimed) was thermolyzed in the same way as the diphenyl-*p*-benzoquinone (100 μ N_2, 1180 °C). The mixture of solids was chromatographed on a silica gel column to yield fluorenone (**14**; 40%)[5] identical with an authentic specimen.

Thermolysis of Phenanthrenequinone (12)

Phenanthrenequinone (350 mg; Eastman) was thermolyzed at 1180 °C with 100 μ pressure of N_2 carrier gas. The solid mixture was chromatographed on a silica gel column to give 53% of fluorenone, identical with an authentic sample, and a hydrocarbon fraction that was shown to contain biphenylene in 2% yield (from the u.v. spectrum of the crude mixture). Sublimation of the hydrocarbon fraction at 50°/0.1 mm afforded a yellow solid that was recrystallized from methanol to give biphenylene (**13**) m.p. 109–110.5°, mixed m.p. (Pflatz and Bauer) 110–111.5° (lit. (16) 110–111°).

Another run, performed under the same conditions and followed by sublimation of the solid residue at 100°/12 mm, afforded a mixture that was analyzed by v.p.c. (3% Poly A 103 on Gaschrom Q, $2\frac{1}{2}$ ft. × $\frac{1}{4}$ in., 60 cc He/min. 130 °C) and was shown to give yields of 2% biphenylene (**13**) and 1% each of biphenyl (**15**) and dibenzofuran (**16**) by integration of the peaks with an internal reference of 1-methylnaphthalene. The latter two reaction products were isolated by preparative v.p.c. (same column, 90 °C) and identified by mass and u.v. spectroscopy. No starting material was recovered.

[4]The authors would like to thank Prof. D. B. Maclean of McMaster University for kindly supplying them with the mass spectrum of this compound.

[5]Forty-five percent of the original anthraquinone was recovered.

This work was supported by the Petroleum Research Fund, administered by the American Chemical Society, and by the National Research Council of Canada.

Proton Magnetic Resonance Spectra, Conformational Preferences, and Approximate Molecular Orbital Calculations for the *syn* and *anti* 2-Furanaldoximes

R. WASYLISHEN[1] AND T. SCHAEFER

Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received August 5, 1971

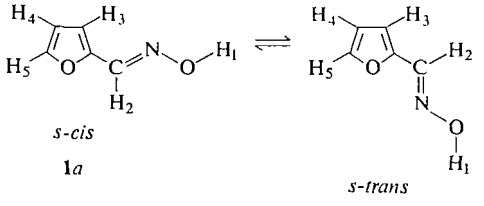
Evidence is adduced, mainly from proton chemical shift and long-range coupling constant data, that the *anti* isomer of 2-furanaldoxime exists almost exclusively in the *s-cis* form in solution, independently of the type of intermolecular association that occurs. Intramolecular hydrogen bonding apparently is absent in this isomer. Similarly, the *syn* isomer exists in roughly equal mixtures of *s-cis* and *s-trans* forms in solvents of widely different polarities. A variety of nuclear spin–spin coupling constants are calculated via the INDO and CNDO molecular orbital approximations, as are the dipole moments and conformational energies, for 2-furanaldehyde and its oximes. On the whole the experimental trends are well reproduced by the computations.

Les données relatives aux déplacements chimiques des protons et des constantes de couplage à longue distance constituent les preuves principales d'après lesquelles l'isomère *anti* du furanaldoxime-2 existe presque exclusivement en solution sous la forme *s-cis*; ceci indépendamment du type d'association intermoléculaire est apparemment absente dans cet isomère. D'une façon similaire, l'isomère *syn* est en gros constitué d'un égal mélange des formes *s-cis* et *s-trans* dans des solvants de polarités très différentes. De nombreuses constantes de couplage nucléaire spin–spin sont calculées au moyen des approximations d'orbitales moléculaires INDO et CNDO, et il en est de même pour les moments dipolaires et les énergies conformationnelles du furanaldéhyde-2 et de ses oximes. Dans l'ensemble, les données expérimentales sont bien reproduites par les calculs.

Canadian Journal of Chemistry, **50**, 274 (1972)

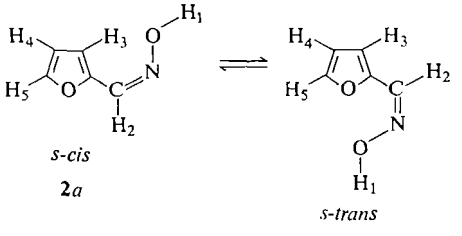
Introduction

The purpose of this paper is the investigation of the conformational preferences in solution of the *syn*, **1**, and *anti*, **2**, isomers of 2-furanaldoxime by means of solvent effects on the proton chemical shifts, stereospecific long-range proton–proton spin–spin coupling constants and by molecular orbital calculations in the INDO and CNDO approximations.



s-cis **1***a* ⇌ *s-trans* **1***b*

syn, m.p. 75 °C

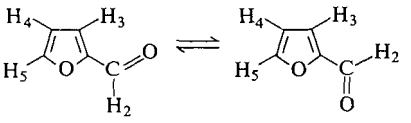


s-cis **2***a* ⇌ *s-trans* **2***b*

anti, m.p. 91 °C

[1]Holder of an NRCC Scholarship 1971-1972.

Some supplementary i.r. and shift reagent experiments are performed. 2-Furanaldehyde, **3**, is also discussed because it serves as a guide in the MO calculations and in the application of long-range coupling data in deducing conformational preferences for the oximes.



s-cis **3***a* ⇌ *s-trans* **3***b*

Experimental

The isomer of 2-furanaldoxime which melts at 75–76 °C was prepared by the method of Brady and Goldstein (1) and the isomer melting at 91–92 °C was obtained from Aldrich Chemical Co. The p.m.r. spectra of degassed solutions of these isomers in dry DMSO-d_6, 10 mol %, and in C_6D_6 and $CDCl_3$, both 3 mol %, were calibrated in the frequency sweep mode on an HA100-D spectrometer at a sweep rate of 0.02 Hz/s. A 7.7 mol % solution in acetone-d_6 of the isomer melting at 91–92 °C was studied at 60 MHz on a DA-60-I spectrometer in a similar way. The i. r. spectra of dilute solutions of both isomers in CCl_4 were recorded. Induced low-field shifts of H_2 to H_5 in each isomer were observed in $CDCl_3$ solution on the addition of 0.2 molar equivalents of 2,2,6,6-tetramethyl heptane dionate, europium (III), the latter obtained from Pierce Chemical Co. (Euro-shift). Rather severe broadening of peaks occurred on addition of the shift reagent.

$^3J(4,5)$	1.825	1.825	1.819	1.793	1.790	1.789

*Chemical shifts in DMSO-d_6 are given in Hz to low field of the methyl signal of the undeuterated DMSO.

†Chemical shifts in $CDCl_3$ and C_6D_6 are given in Hz to low field of internal tetramethylsilane.

The coupling constants are probably accurate to 0.02 Hz; a first-order analysis of the 60 MHz spectrum of the *anti* isomer in acetone-d_6 yielding values within 0.01 to 0.03 Hz of those given above.

In the *anti* isomer in DMSO-d_6 the hydroxyl proton couples over four bonds to H_2 with magnitude of 0.35 Hz and also couples to H_3 on the ring by about 0.05 Hz. Similarly the hydroxyl proton of the *syn* isomer couples to H_2 with a magnitude of 0.35 Hz in DMSO-d_6.

Results and Discussion

(1) Spectral Analysis

All spectra were analyzed using the computer program LAME (2) and the results are given in Table 1. The spectra are not far from first order in appearance and are not reproduced here, their quality being similar to those recently published from this laboratory (3). The r.m.s. deviations between observed and calculated transition frequencies lie between 0.006 and 0.014 Hz for the various samples. The standard errors in the spectral parameters vary from 0.002 to 0.012 Hz, the average standard error being 0.006 Hz.

In addition to the tabulated data there exists a coupling over four bonds of ± 0.35 Hz between the hydroxyl proton and H_2 in both **1** and **2** in the DMSO-d_6 solutions. In **2** the hydroxyl proton also couples to H_3 on the ring by $\pm 0.05 \pm 0.01$ Hz, as determined by decoupling experiments.

(2) Assignment of Isomers

2-Furanaldoxime was the first aldoxime to be obtained in two forms (4). The assignment shown above is in agreement with dipole moment measurements (5), electronic absorption spectra (6), conductivity measurements (5), and chemical considerations (1, 7). In Table 1 there is a difference of 3.21 ppm between the OH and C—H_2 resonance positions in DMSO for the *syn* isomer, **1**, in excellent accord with the criterion established by Kleinspehn *et al.* (8). The analogous shift difference of 4.26 p.p.m. for the *anti* isomer also agrees with the criterion of these authors.

(3) Conformation about the Ring Carbon–Imino Carbon Bond

(a) Stereospecific Coupling over Five Bonds

The use of the zig–zag rule for coupling over five bonds between the aldehyde and ring protons in benzaldehyde derivatives is well-established (9–11). For a time it was thought (12) that the rule did not apply in 2-furanaldehyde. Correct assignments (13) have now shown that the rule holds in this compound as well: $^5J(2,5)$ is large in **3***b* and small in **3***a*. This fact encourages us to apply the zig–zag rule to the 2-furanaldoximes in an attempt to establish whether the *s-cis* or *s-trans* forms (see **1** and **2**) are more stable.

$^5J(2,5)$ is zero in the *anti* isomer, **2**, in all three solvents, which range in dielectric constant from 49 to 2. On the other hand, $^5J(2,4) = 0.70 \pm 0.01$ Hz in each of the solvents, suggesting that **2** exists in the *s-cis* form, **2***a*.

In the *syn* isomer, **1**, the sum of $^5J(2,4)$ and $^5J(2,5)$ is 0.61 ± 0.01 Hz in all three solvents. On the assumption that 0.61 Hz is the value of $^5J(2,4)$ in **1***a* and of $^5J(2,5)$ in **1***b* it follows that **1** exists 41% in the *s-cis* form. A 5% change in this number follows if a 0.1 Hz variation is assumed in the 0.61 Hz base value. The value of

TABLE 2. The aromatic solvent induced shift* $\Delta^{C_6D_6}_{CDCl_3}$ for four protons in the *anti* and *syn* isomers of 2-furanaldoxime

Proton†	$\Delta^{C_6D_6}_{CDCl_3}$ *syn*	*anti*
H_2	18.0	17.1
H_3	45.8	−4.1
H_4	53.1	45.9
H_5	54.8	56.2

*The solvent shift is found in Hz at 100 MHz by subtracting the shift in $CDCl_3$ to low field of internal TMS from the shift in C_6D_6 to low field of internal TMS.

†See structural formulae **1** and **2** for the numbering system used here.

41% is valid only if $^5J(2,5)$ in **1***a* and $^5J(2,4)$ in **1***b* are both zero.

(b) Aromatic Solvent Induced Shifts (ASIS)

It is known that benzene solvent molecules tend to avoid electron rich regions of solute molecules (14–16). In these oximes these regions are in the vicinity of the hydroxyl oxygen (see calculations below). Consequently the protons situated near the hydroxyl group are expected to display the smallest ASIS. In Table 2 the ASIS values are given for H_2, H_3, H_4, and H_5 of the two isomers.

In the *anti* form the ASIS value of H_3 is actually negative, strongly supporting the assignment of the *s-cis* form as the stable one in these solutions. H_3 lies very near the hydroxyl group in the *s-cis* form of the *anti* isomer. In both forms of the *syn* isomer H_3 does not approach the hydroxyl group as closely as it does in the *s-cis* form of the *anti* isomer (see **1** and **2**) and hence its ASIS value is now much larger and comparable to the ASIS values of the ring protons.

The ASIS numbers in Table 2 support the assignment of the *s-cis* form to the *anti* isomer and are qualitatively consistent with the proportions of *s-cis* and *s-trans* forms of the *syn* isomer deduced from the five-bond proton–proton couplings.

(c) Chemical Shifts of H_2 and H_3 in $CDCl_3$

The deshielding of nearby protons by the hydroxylimino group is thought to arise from the NOH anisotropy (15, 17). Thus in $CDCl_3$ proton 2 of the *syn* isomer lies to low field of H_2 in the *anti* isomer by 0.5 p.p.m. Again, in the same solvent H_3 in the *anti* isomer is deshielded by 0.7 p.p.m. compared to the *syn* isomer; constituting further support for the stability of the *s-cis* form of the *anti* isomer.

(d) Stretching Frequencies of the OH Group

Oximes can act as either proton donors or acceptors with various solvents (18–20). Perusal of the spectral data in Table 1 suggests that hydrogen bonding to the solvent does not alter the proportions of the *s-cis* and *s-trans* forms of the two isomers of 2-furanaldoxime. In CCl_4 the free OH stretching frequencies are found at 3600 cm^{-1} with equal intensities for both isomers. The hydrogen-bonded OH frequencies occur at 3250 cm^{-1} in the *anti* isomer and at 3300 cm^{-1} in the *syn* isomer, again with equal intensity. These results apparently rule out any *intra*molecular hydrogen-bonding in the *anti* isomer (18) while competition between self-association and hydrogen-bonding to the solvent does not affect the conformation about the ring carbon–imino carbon bond if the J data in Table 1 is to be believed. The i.r. data is therefore consistent with a stable *s-cis* form of the *anti* isomer.

(e) Use of the Shift Reagent, 2,2,6,6-Tetramethylheptane-dionate, Europium(III)

Wolkowski (21*a*) used tris(dipivalomethanato)europium as a shift reagent to distinguish between *syn* and *anti* isomers of some oximes. The magnitude of the induced proton shift varied as $r^{-2.3}$ where r was the proton to hydroxyl oxygen distance. Of course, for a pseudo contact shift a dependence on angle as well as on distance from the complexation site (actually the europium atom) is expected and the induced shift can be upfield or downfield from the shift positions in the uncomplexed molecule (21*b*).

For the experiments on the isomers of 2-furanaldoxime the observed downfield shifts at 100 MHz are as follows: $\Delta H_2 = 417$ (93), $\Delta H_3 = 265$ (96), $\Delta H_4 = 111$ (53), $\Delta H_5 = 60$ (39) Hz, where the shifts of the *syn* isomer are given in brackets.

The important point for our purposes is that in the *anti* isomer the *s-cis* form has H_3 relatively near the hydroxyl oxygen, assumed to be the site of complexation (21). Therefore a much larger shift is expected and observed for H_3 than for H_4 and H_5. If the *s-trans* form, **2***b*, were the

For personal use only.

stable one the shifts of these three protons might well be much closer in magnitude. Hence the induced shifts are consistent with an *s-cis* form for the *anti* isomer.

The interpretation of the much smaller shifts observed for the *syn* isomer is ambiguous and examination of the geometry of the *s-cis* and *s-trans* forms, **1***a* and *b*, suggests that an angle dependence as well as a distance dependence is important (21*b*). At any rate, the induced shifts do not disprove the conformational deductions in previous sections.[2]

(4) INDO and CNDO Computations (22, 23)

(a) Dipole Moments and Relative Energies

These were calculated in an attempt at confirming the conformational deductions arrived at above. For the furan ring the atomic coordinates found by microwave work (24) were used. For furan itself we calculate $\mu = 0.72$ D, in exact agreement with experiment (25) while CNDO computes $\mu = 0.86$ D (26). For furanaldehyde standard geometries (22) were employed for the CHO fragment following the assumptions of Maciel *et al.* (27) in their calculations of the vicinal coupling constants on the ring.

The planar *s-cis* form of the aldehyde, **3***a*, was calculated to have $\mu = 2.79$ D by INDO and 2.64 D by CNDO while the planar *s-trans* form was calculated to have $\mu = 3.58$ D by INDO and 3.51 D by CNDO. The observed dipole moment is 3.6 D (5) suggesting the *s-trans* form as the predominant form at room temperature. From published $\Delta H°$ data (12) we calculate $P_t = 0.64$ and $P_c = 0.36$ at 30 °C. The calculated dipole moments of the two forms then predict a dipole moment of 3.3 D at 30 °C, in good agreement with experiment. Contrary to experiment (12) INDO calculates the *s-cis* form to be more stable than the *s-trans* by 1.2 kcal/mol.

For the planar *s-cis* form of the *anti* oxime, **2***a*, one finds $\mu = 0.67$ D by INDO while $\mu = 0.61$ D if the CHNOH group is twisted to lie 19° above the plane of the furan ring (this angle of twist occurring in the solid state for *anti p*-Cl-benzaldoxime (28, 29)). The observed dipole moment of the *monomeric* form of the *anti* isomer is 1.9 D in benzene (5). However, the calculated dipole moment of the oximes is very sensitive to the conformation of the O—H fragment. For example, if the OH bond in **2***a* is twisted 30° out of the plane of the CHNO group but pointing towards the ring the calculated dipole moment becomes 3.73 D. For this reason (the O—H bond being very polar, in agreement with the chemical properties), the calculated moment of 1.22 D of the *s-trans* form of the *anti* oxime, **2***b*, cannot be taken as evidence for the relative stability of this form. When, in **2***b*, the OH bond is turned through 180°, *i.e.* simulating an intramolecular hydrogen bond to the ring oxygen, the INDO dipole moment becomes 4.76 D and because this is so much larger than the observed value of 1.9 D, we tend to regard it as confirmatory evidence against such hydrogen bonding.

The *s-cis* form, **2***a*, is calculated by INDO to be 1.7 kcal/mol more stable than the *s-trans* form, **2***b*, of the *anti* isomer, in almost quantitative agreement with the available experimental evidence. However, INDO also finds the intramolecularly hydrogen bonded form of **2***b* (180° flip of the OH bond) to be 5.5 kcal/mol more stable than the *s-cis* form, **2***a*. Of course, intermolecular hydrogen bonding to solvent molecules in DMSO or to other solute molecules (cyclic dimers or trimers (18)) in $CDCl_3$ and C_6D_6 is not considered in the MO computations. The i.r. evidence (18) leaves little doubt about the occurrence of intermolecular hydrogen bonding but note that the coupling constant data in Table 1 almost certainly proves that the conformation about the C—C bond is independent of the type of intermolecular association.

The calculated dipole moments of the *syn* isomer are 1.28 D for the *s-cis* form, **1***a*, and 1.44 D for the *s-trans*, **1***b*. The monomer has a dipole moment of 1.2 D in C_6D_6 (5). The *s-trans* form is predicted to be 0.17 kcal/mol more stable than the *s-cis* form at room temperature; in close agreement with the deductions based on the long-range coupling constants in section 3. Again, the proportion of conformers is apparently independent of solvent and of the type of intermolecular association.

Intramolecular hydrogen bonding is most unlikely in the *syn* isomer for geometrical reasons. According to INDO the hydroxyl oxygen carries a negative charge of 0.24 electrons and the hydrogen a positive charge of 0.16

[2]One cannot rule out the possibility that complexation of the oximes to the shift reagent may affect the equilibrium between the *s-cis* and *s-trans* forms to some extent.

electrons, in both isomers, values quite compatible with hydrogen bonding tendencies.

(b) Spin–Spin Coupling Constants

(i) Long-range to the Ring Protons

These were calculated using the finite perturbation technique (30). In Table 3 the calculated long-range couplings from the aldehydic to the ring protons in 2-furanaldehyde display stereospecificity for both methods, but CNDO is clearly in better overall agreement with experiment. Inasmuch as INDO considers one-center exchange integrals it includes the π electron contribution to the couplings but it apparently overestimates its magnitude somewhat. We have found a similar situation in benzaldehyde and its derivatives (3). Nevertheless, both INDO and CNDO are in semiquantitative agreement with the empirical zig–zag rule (10) of maximum coupling between protons over the "straightest" five-bond path and if the exact geometry of the sidechain were known the computational methods might even be exact (there is no evidence that solvents affect the long-range couplings).

In Table 4 (bottom) the CNDO results for $^5J(2,4)$, $^5J(2,5)$, and $^4J(2,3)$ are in best agreement with observations (Table 1) and agree with an *s-cis* form for the *anti* oxime isomer.

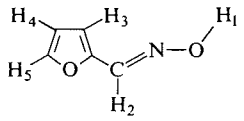
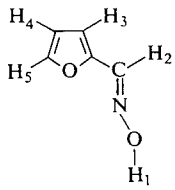
For personal use only.

TABLE 5. Computed coupling constants in Hz involving H_1 and H_2 of the *s-cis* and *s-trans* forms of the *syn* isomer of 2-furanaldoxime



syn, s-cis



syn, s-trans

	INDO	CNDO	INDO	CNDO
$^4J(H_1, H_2)$	−2.95	−0.30	−2.85	−0.30
$^2J(H_2, ^{14}N)$	−1.87	2.07	−2.00	2.09
$^1J(H_2, ^{13}C)$	148.91	117.94	154.44	122.25
$^4J(H_2, H_3)$	−2.28	−0.11	−2.41	−0.24
$^5J(H_2, H_4)$	1.59	0.57	0.67	0.03
$^5J(H_2, H_5)$	−1.16	0.07	−0.11	0.63

Again, the CNDO results in Table 5 support our method of calculating the proportion of *s-cis* and *s-trans* forms of the *syn* isomer in solution.

(ii) Other Coupling Constants

A variety of coupling constants was calculated for the two oxime isomers (Tables 4 and 5).[3] The couplings over two bonds, $^2J(2,^{14}N)$, are not known for these oximes but are of interest because they are predicted to have a much larger magnitude in the *anti* than in the *syn* isomer, in agreement with the data available for some other oximes (31). The magnitudes of the calculated one-bond ^{13}C—H couplings in the sidechain are dependent on isomer type as is observed in the two isomers of acetaldoxime (32).

Sterically Hindered Aromatic Compounds. III.[1] Acid-catalyzed Reactions of 2,4,6-Tri-*t*-butyl- and 2-Methyl-4,6-di-*t*-butylbenzyl Alcohols and Chlorides

L. R. C. BARCLAY, H. R. SONAWANE,[2] AND M. C. MACDONALD
Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received August 30, 1971

Treatment of 2,4,6-tri-*t*-butylbenzyl alcohol (**2**), the corresponding benzyl chloride (**3**) and methyl ether (**5**) with strong acids gave high yields of 1,1-dimethyl-4,6-di-*t*-butylindane (**10**). On the other hand, acid-catalyzed reactions on 2-methyl-4,6-di-*t*-butylbenzyl alcohol (**13**), chloride (**16**), and methyl ether (**12**) yielded nucleophilic substitution products. According to comparative hydride transfer reactions between triethylsilane and carbonium ions generated from **2**, **3**, **13**, and **16** in trifluoroacetic acid, the 2,4,6-tri-*t*-butylbenzyl cation is very readily formed. A mechanism suggested for the formation of **10** involves this cation as an intermediate.

L'action des acides forts sur l'alcool tri-*t*-butyl-2,4,6 benzylique (**2**), sur le chlorure de benzyle (**3**) correspondant et sur l'éther méthylique (**5**) conduit au diméthyl-1,1 di-*t*-butyl-4,6 indane (**10**). D'un autre côté, les réactions acido-catalysées sur l'alcool méthyl-2 di-*t*-butyl-4,6 benzylique (**13**), sur le chlorure (**16**) correspondant, et sur l'éther méthylique (**12**) conduisent à des produits de substitution nucléophile. D'après des réactions comparables par transfert d'hydrure entre le triéthylsilane et les ions carboniums engendrés à partir de **2**, **3**, **13** et **16** et l'acide trifluoroacétique, le cation tri-*t*-butyl-2,4,6 benzyle se forme très rapidement. Un mécanisme est proposé pour la formation de **10** et celui-ci implique ce cation en tant qu'intermédiaire.

Canadian Journal of Chemistry, **50**, 281 (1972)

Introduction

Previous investigations in this laboratory established that two ortho *t*-butyl groups exert extreme steric hindrance on a carboxyl function. This was evident in the properties of 2,4,6-tri-*t*-butylbenzoic acid (1) and the unusual alkaline hydrolysis ($B_{AL}2$) of its methyl ester (2). The present investigation was undertaken to determine the effect of alkyl substituents, especially *o*-*t*-butyl, on reactions at an adjacent tetrahedral carbon function. Polyalkylated benzyl alcohols and chlorides were therefore required for solvolyses and related studies. A preliminary communication (3) reported unexpected high reactivity of 2,4,6-tri-*t*-butylbenzyl alcohol and -methyl ether. Under acid conditions, these compounds underwent a novel cyclization between the benzylic position and an ortho-*t*-butyl group. The purpose of the present paper is to report the details of these and related results. The nature of the side chain insertion reaction has been explored by the use of deuterium tracer in the benzylic group and by some carbonium ion–hydride transfer reactions.

[1]References 1 and 2 are considered as part I and II in this series.

[2]On leave of absence from the National Chemical Laboratory, Poona, India.

Results and Discussion

(a) Synthesis of Tri-t-butylbenzyl Compounds and the Cyclization Product 1,1-Dimethyl-4,6-di-t-butylindane

2,4,6-Tri-*t*-butylphenyllithium (**1**) prepared by bromine–lithium exchange on 2,4,6-tri-*t*-butylbromobenzene (1), was the starting point for synthesizing various 2,4,6-tri-*t*-butylbenzyl compounds (Scheme 1).

As reported earlier (4), reaction of **1** with formaldehyde yielded 2,4,6-tri-*t*-butylbenzyl alcohol (**2**) and reaction of the latter with thionyl chloride yielded the benzylchloride **3**. The reaction sequence **1**→**2**→**3** using dideutero formaldehyde proved very convenient for the synthesis of α,α-dideutero-2,4,6-tri-*t*-butylbenzyl chloride for tracer studies. The formation of **2** was accompanied by varying amounts of the ester 2,4,6-tri-*t*-butylbenzyl formate (**4**). This side reaction was not studied in detail. It is presumably a consequence of reaction of the intermediate 2,4,6-tri-*t*-butylbenzyloxy anion with formaldehyde followed by a hydride ion transfer analogous to the Cannizzaro reaction. Reaction of **1** with chloromethylmethyl ether yielded 2,4,6-tri-*t*-butylbenzylmethyl ether (**5**) and cleavage of **5** with boron chloride yielded **3** in high yield. The reaction sequence **1**→**5**→**3** was the preferred method for larger scale

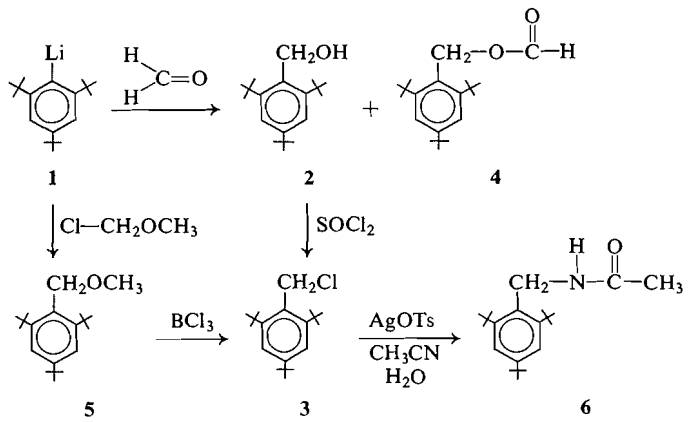


SCHEME 1

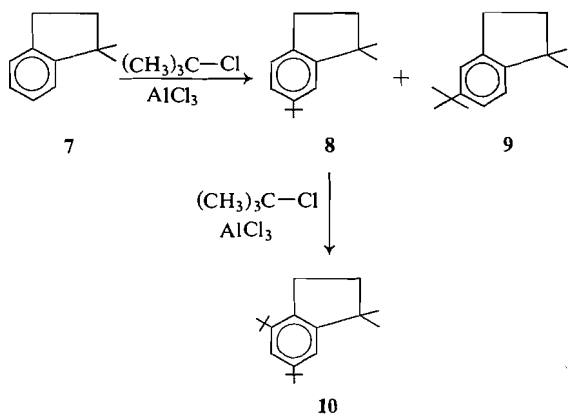
preparations of **3**. The intermediate ether (**5**) is readily purified and the side reaction involved in the conversion of **1** → **2** → **4** is avoided.

The alcohol **2** failed to react with toluenesulfonyl chloride. Steric hindrance afforded by the two *o*-*t*-butyl groups is evidently sufficient to prevent the alcohol **2** from attacking the sulfonyl chloride group. An attempt to prepare the tosylate from the chloride **3** by the action of silver tosylate in acetonitrile (5) resulted in the formation of the *N*-acetate (**6**) as the only identifiable product. The formation of **6** apparently results from attack of the carbonium ion derived from **3** on the solvent acetonitrile in a manner analogous to the Ritter reaction (6). This result was a preliminary indication of the reactivity of **3** under ionizing conditions.

Treatment of the alcohol **3** or the ether **5** was reported earlier (3) to yield a new hydrocarbon which was assigned the structure 1,1-dimethyl-4,6-di-*t*-butylindane (**10**) from spectroscopic evidence. It was desirable to have an independent synthesis of **10**. This was accomplished by Friedel–Crafts *t*-butylation of 1,1-dimethylindane (**7**) and of 1,1-dimethyl-6-*t*-butylindane (**8**) (see Scheme 2). It was necessary to carry out the *t*-butylations under mild conditions (below 0°, using pentane solvent which does not dissolve aluminum chloride) to avoid complex hydride transfers and dealkylation which may take place on compounds such as **7** (7). These mild conditions effected partial *t*-butylation of **7** to yield initially a mixture of approximately equal amounts of **8** and a new hydrocarbon. Comparison of its n.m.r. spectrum with that of **8** indicated that the structure is most probably 1,1-dimethyl-5-*t*-butylindane (**9**). On longer reaction time, **8** was converted into **10** (7%) while the relative amount of **9** increased. A separate partial *t*-butylation of **8** yielded **10** (25%) directly.

(b) Acid-catalyzed Reactions of the Trialkylbenzyl Compounds

The results from various acid-catalyzed reactions on 2,4,6-tri-*t*-butylbenzyl compounds are given in Table 3 (see Experimental) and outlined in Scheme 3. Reaction of methyl 2,4,6-tri-*t*-butylbenzyl ether (**5**) with hydriodic acid–acetic acid (Table 3, no. 1) yielded 1,1-dimethyl-4,6-di-*t*-butylindane (**10**). Reaction of 2,4,6-tri-*t*-butylbenzyl alcohol (**2**) with a variety of acids also yielded **10** as a major reaction product



SCHEME 2

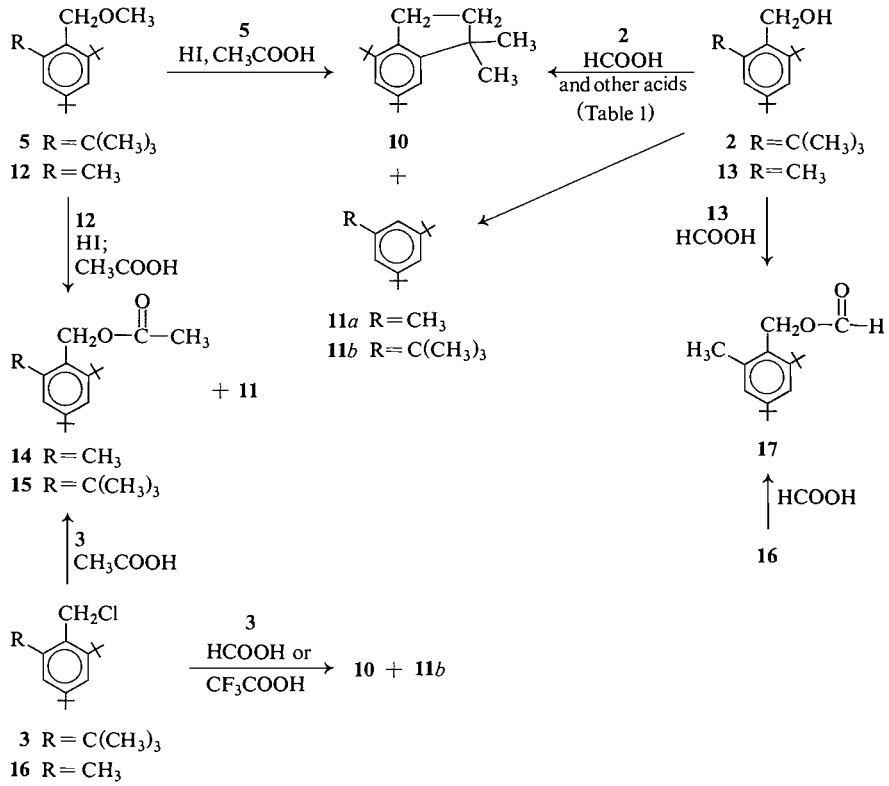

SCHEME 3

(nos. 2–6). Treatment of the chloride (**3**) with formic acid also gave a high yield of **10** (run 7*a*). The latter reaction apparently takes place by initial formation of 2,4,6-tri-*t*-butylbenzyl formate (**4**) (run 7*b*, *c*). On the other hand reaction of **2** with acetic acid stopped at formation of the corresponding acetate (run 8); there being no evidence for cyclization in this case.[3]

2-Methyl-4,6-di-*t*-butylbenzyl compounds were selected for a comparative study with the results on the tri-*t*-butylbenzyl series outlined above. The results are summarized in Table 4. (For structural formulas see Scheme 3.) Acid-catalyzed reactions on 2-methyl-4,6-di-*t*-butylbenzyl methyl ether (**12**) (Table 4, no. 1), corresponding alcohol (**13**) (nos. 2–5), and chloride (**16**) all led to the formation of expected nucleophilic substitution products (**14**, **16**, **17**) as the main reaction.

There was no evidence for the formation of cyclization products into the ortho-*t*-butyl group analogous to that found for the tri-*t*-butylbenzyl series.

(c) Carbonium Ion–Hydride Transfer Reactions of Alkyl Benzyl Chlorides and Alcohols

One mechanism considered (3) for the formation of the substituted indane **10** from the 2,4,6-tri-*t*-butylbenzyl compounds involved insertion of a hindered benzylic cation into a C—H bond of an ortho-*t*-butyl group. It was desirable therefore, to obtain some independent indication of the tendency of our trialkylbenzyl systems to form carbonium ions. Carey and Tremper (8) found that organosilanes such as triethylsilane will efficiently transfer hydride to free carbonium ions generated in acid medium from corresponding alcohols. Their studies in-

[3]A referee has suggested two explanations for the failure of acetic acid to produce the indane **10**: (*1*) acetic acid is a better nucleophile than the other acids used and (*2*) a more intimate ion pair is formed with the weaker acetic acid than the others acids. A shorter cation lifetime would be the result in either case with a resultant lower probability of indane formation.

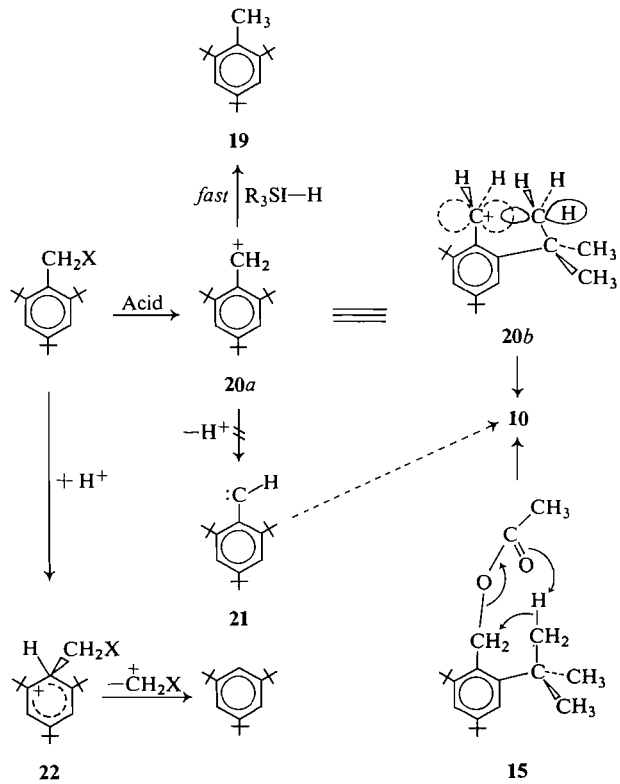


SCHEME 4

cluded hydride transfer to the 2,4,6-trimethyl cation to yield isodurene. We employed this technique as a probe for the behavior of the carbonium ions generated from trialkylbenzyl chlorides as well as alcohols. The results of our preliminary study are shown in Table 5. Benzyl chloride failed to undergo the hydride transfer in the presence of trifluoroacetic acid and triethylsilane even on prolonged treatment. This is in agreement with the behavior reported for benzyl alcohol (8). 2,4,6-Trimethylbenzyl chloride, like the corresponding alcohol (8), efficiently underwent the hydride transfer to yield isodurene (no. 2) and this shows that the method can be used to trap carbonium ions generated from chlorides as well as from alcohols. Both 2-methyl-4,6-di-*t*-butylbenzyl alcohol (**13**) and 2,4,6-tri-*t*-butylbenzyl alcohol (**2**) were readily converted (nos. 3 and 4) into the respective hydrocarbons, 2-methyl-4,6-di-*t*-butyltoluene (**18**) and 2,4,6-tri-*t*-butyltoluene (**19**) presumably via formation of intermediate substituted benzylic cations. An effort was made to determine the relative tendencies for carbonium ion formation from the corresponding trialkyl chlorides **16** and **3** (nos. 5 and 6) with some success. Direct n.m.r. observations showed that **16** was one half converted into the respective hydrocarbon (**18**) in 40 min. On the other hand the conversion of 2,4,6-tri-*t*-butylbenzyl chloride (**3**) was almost too fast to measure; being more than 80% converted into 2,4,6-tri-*t*-butyltoluene in 5 min. The results definitely establish the strong tendency for **3** (and **2**) to ionize to form the cation and indicate that the relative tendency for carbonium ion formation is -2,4,6-tri-*t*-butylbenzyl > 2-methyl-4,6-di-*t*-butylbenzyl > 2,4,6-trimethylbenzyl.

(d) A Mechanism for the Cyclization Reaction of 2,4,6-Tri-t-butylbenzyl Compounds

The very facile hydride transfer reactions observed for 2,4,6-tri-*t*-butylbenzyl chloride and alcohol in acid medium indicate ready formation of the carbonium ion (**20***a*, Scheme 4). Furthermore the cyclization reaction was observed under conditions (Table 3, no. 5) similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to those used for the direct observation of the carbonium **20***a* by n.m.r. methods (4). These results indicate that the carbonium ion **20***a* is an intermediate in the cyclization leading to **10**. The detailed mechanism of this unique cyclization remains to be determined. Certain carbonium ions are known to form carbenes (9) by α-proton elimination and we considered that the cyclization might have taken place by insertion of the carbene **21** into a C—H bond of an *o*-*t*-butyl group. However, this possible mechanism must be excluded by the fact that there is no loss or rearrangement of deuterium during the cyclization of α,α-dideutero-2,4,6-tri-*t*-butyl chloride (Table 3, no. 9). This result also makes untenable complex mechanisms for cyclization which involve rearrangements, hydride shifts, and alkylations. We favor a mechanism involving insertion of the benzylic cation into an ortho-*t*-butyl group. Examination of space filling molecular models for the cation **20***a* shows strong steric congestion between the $\overset{+}{C}$—H bonds and the ortho-*t*-butyl groups when the —$\overset{+}{C}H_2$ group is coplanar with the aromatic ring. This congestion is relieved by rotation of the —$\overset{+}{C}H_2$ group out-of-plane. In the resulting conformer (**20***b*), the tail of an sp^3 orbital of a C—H in an ortho-*t*-butyl can line up in very close proximity to the —$\overset{+}{C}H_2$ group so as to overlap with the vacant p orbital. Steric congestion is not nearly so evident in the 2-methyl-4,6-di-*t*-butylbenzyl cation. This could explain why the latter undergoes intermolecular nucleophilic reactions rather than insertion into the ortho-*t*-butyl group.

There does not appear to be a very close analogy to this kind of carbonium ion insertion. On the other hand cyclizations into an ortho-*t*-butyl group are known. A comparison has been made (3) between our reaction forming the substituted indane (**10**) and the bond insertion by cationic nitrogen into an ortho-*t*-butyl group observed by Lansbury and co-workers (10). The formation of 1,1-dimethyl-4-carboxyl-6-nitrobenzocyclobutene from the diazonium salt of 3-amino-4-*t*-butyl-5-nitrobenzoic acid could be explained by an intramolecular electrophilic substitution of an aromatic cation into an ortho-*t*-butyl group (11) but a free radical mechanism was also considered. A mechanistic analogy was made by Baker and Davis (12) between our reaction and their reported cyclization into an aromatic methyl group by cationic oxygen during decomposition of the hypobromite of 1,5,8-trimethyl-1,2,3,4-tetrahydronaphth-1-ol. However, this analogy is probably not valid because Boido and Edwards have recently shown (13) that reactions of this kind are homolytic rather than ionic.

Trialkyl benzenes were formed in varying yields during various acid-catalyzed reactions of the trialkylbenzyl compounds. These hydrocarbons are most probably formed by protonation of the aromatic ring (*e.g.* **22**, Scheme 4) and elimination of the —CH_2—X group via a reverse Freidel–Crafts type reaction.

Examination of the fragmentation pattern in the mass spectrum of 2,4,6-tri-*t*-butylbenzyl acetate (**15**) indicated possible formation of the cyclic hydrocarbon **10** especially in the appearance of a peak at *m/e* 243, which is the most intense peak observed for the hydrocarbon **10**. This could result from a cyclic elimination on the acetate (**15**) (Scheme 4) similar to reactions observed in the pyrolysis of acetates and analogous to reactions recently observed in the mass spectrometer by Field (14). Vapor phase pyrolysis of the substituted benzyl acetates is now under investigation.

Experimental

The n.m.r. spectra were recorded on a Varian A-60 NMR Spectrometer using carbon tetrachloride solvent containing tetramethylsilane as internal standard. The i.r. spectra were recorded on a Perkin–Elmer model 337 Grating Spectrophotometer using potassium bromide pellets for solids and films for liquids. The u.v. spectra were recorded on a Beckmann DK-2 Spectrophotometer using cyclohexane solvent. The g.l.c. analyses were determined by means of F & M model 500 and model 700 programmed temperature gas chromatographs with dual columns. The columns were 1/4 in. by approximately 10 ft and packed with Apiezon grease (20%), unless noted otherwise, on Chromosorb W. Melting points were determined on a hot stage equipped with a microscope and are uncorrected. Elemental analyses were determined by C. Daesslé, Montreal and by A. Bernhardt, West Germany.

Preparations of Tri-t-butylbenzyl Compounds

(1) 2,4,6-Tri-t-butylbenzyl Alcohol (2)

2,4,6-Tri-*t*-butylbromobenzene was prepared as described previously (1). The crude product was always contaminated with a small amount of a yellow compound. The latter was separated readily due to its insolubility in cold carbon disulfide. Recrystallization from carbon disulfide yielded brilliant yellow needles, m.p. 165–166°.

Anal. Calcd. for $C_{14}H_{18}NO_4Br$ (mol. wt. 344): C, 48.85; H, 5.26; Br, 23.22. Found (344 (mass spectrum)): C, 48.82, 48.71; H, 5.47, 5.50; Br, 23.34, 22.92.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This yellow compound showed i.r. bands at 1675 and 1690 (s) (conjugated carbonyls), 1540 cm^{-1} (s) (NO_2 group); u.v. bands at λ_{max} 269 (ε 8800), 334 (ε 634), 415.5 (ε 103), and 555 mμ (ε 50.5); and n.m.r. bands at 8.66 and 8.51 τ (singlets) of equal intensity, assigned to two *t*-butyl groups.[4]

2,4,6-Tri-*t*-butylbromobenzene was converted into 2,4,6-tri-*t*-butylphenyllithium (1) and the latter reacted with formaldehyde as described (4) to prepare 2,4,6-tri-*t*-butylbenzyl alcohol (**2**). A mixture of the alcohol and a carbonyl compound (i.r.) was obtained. The latter compound was separated by chromatography on basic alumina and elution with petroleum ether. After sublimation the crystalline compound melted at 109–110°.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59. Found: C, 78.60; H, 10.57.

It showed an i.r. band at 1710 cm^{-1} (s) (carbonyl), n.m.r. bands at 8.66–8.56, 4.41, 2.61, and 0.02 τ (all singlets) with intensity ratios of 27:2:2:1 and assigned to the three *t*-butyls, benzylic methylene, aromatic hydrogens, and aldehydic hydrogen respectively.

(2) Methyl 2,4,6-Tri-t-butylbenzyl Ether (5)

2,4,6-Tri-*t*-butylbromobenzene (5.48 g, 0.016 mol) in 300 ml anhydrous ethyl ether was exchanged with *n*-butyllithium (13.2 ml hexane solution, 0.020 mol) under a dry nitrogen atmosphere for 1 h. Freshly distilled chloromethyl methyl ether (1.5 ml, 0.02 mol) in anhydrous ethyl ether was slowly added to the reaction at room temperature. The reaction was continued until g.l.c. analyses on aliquots indicated that the amount of desired ether (**5**) was optimized (12 h, 67% **5**). The reaction mixture was then shaken with diluted hydrochloric acid, water, dried over calcium chloride, and the solvent distilled. The residue was recrystallized from ethanol to yield colorless crystals, m.p. 79–80°.

Anal. Calcd. for $C_{20}H_{34}O$: C, 82.76; H, 11.72; OCH_3, 10.69. Found: C, 83.04; H, 11.82; OCH_3, 10.47.

It showed an i.r. band at 1050 cm^{-1} (s) (ether group) and n.m.r. bands at 8.72, 8.56, 6.76, 5.38, 2.72 τ (all singlets) in intensity ratios of 9:18:3:2:2 and assigned to *p*-*t*-butyl, *o*-*t*-butyls, -O-CH_3, benzylic methyl and aromatic hydrogens respectively.

(3) 2,4,6-Tri-t-butylbenzyl Chloride (3) and the α,α-Dideutero Chloride

Methyl 2,4,6-tri-*t*-butylbenzyl ether (1.53 g, 0.053 mol) was placed in a test tube cooled in an acetone–liquid nitrogen trap and 12 ml of boron trichloride was condensed in the test tube. After 30 min, the boron trichloride was allowed to evaporate, the crystalline residue dissolved in ethyl ether, the solution extracted with 1% sodium hydroxide, and the extract washed with water. Distillation of the ether left colorless crystals, m.p. 141–144° (lit. (4) 141.5–143.5°). The n.m.r. spectrum showed bands at 8.70, 8.47, 4.72, and 2.60 τ (singlets) in the intensity ratios of 9:18:2:2 and assigned to the *p*-*t*-butyl, *o*-*t*-butyls, methylene group, and aromatic hydrogens, respectively. This chloride proved identical by mixed m.p. and n.m.r. spectra to the chloride prepared from 2,4,6-tri-*t*-butylbenzyl alcohol (**2**) by the reaction of **2** with thionyl chloride (4).

α,α-Dideutero-2,4,6-tri-*t*-butylbenzyl alcohol was prepared by the reaction of 2,4,6-tri-*t*-butylphenyllithium with formaldehyde-d_2 (Merck, Sharp & Dohme) according to the procedure used for **2** above. The dideutero alcohol was converted into α,α-dideutero-2,4,6-tri-*t*-butylbenzyl chloride by the thionyl chloride method as before. The deuterium substitution at the methylene position of this chloride was found by comparative mass spectroscopic analysis to be essentially complete. The results for the major peaks are summarized in Table 1.

TABLE 1. Major mass spectral peaks 2,4,6-tri-*t*-butylbenzyl chloride and dideutero chloride

	Peak	Relative intensity	Assignment
Chloride **3**	294	58	M^+ (parent mass)
	279	46	M—CH_3
	259	100	M—Cl
	243	75	M—(CH_3, HCl)
α,α-Dideutero chloride	296	65	M^+ (parent mass)
	281	53	M—CH_3
	261	100	M—Cl
	245	75	M—(CH_3, HCl)

(4) Reaction of 2,4,6-Tri-t-butylbenzyl Chloride (3) with Silver Tosylate in Acetonitrile

The chloride (**3**) (0.294 g, 1.0 mmol) was added to a solution of silver tosylate (0.279 g, 1.0 mmol) in 2 ml of acetonitrile cooled to 0°. The precipitated silver chloride was removed by filtration and the solvent distilled to leave an amorphous residue which crystallized on adding water (yield 0.200 g, 63%). Recrystallization from petroleum ether yielded colorless crystals, m.p. 264–265°.

Anal. Calcd. for $C_{21}H_{35}ON$: C, 79.44; H, 11.11. Found: C, 79.96, 79.79; H, 11.20, 11.13.

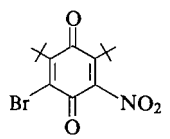
This compound showed i.r. bands at 3280 cm^{-1} (m) (>N—H) and 1670 cm^{-1} (s) (carbonyl) and n.m.r. bands at 8.68, 8.55, 8.12, 5.17, and 2.55 τ (singlets) in intensity ratios of 9:18:3:2:2 assigned to *p*-*t*-butyl, *o*-*t*-butyls, —$COCH_3$, benzylic methylene, and aromatic hydrogens respectively.

(5) 2,4,6-Tri-t-butyltoluene (19)

(a) From 2,4,6-Tri-t-butylphenyllithium

2,4,6-Tri-*t*-butylphenyllithium was prepared from 2,4,6-tri-*t*-butylbromobenzene (2.5 g, 7.7 mol) and *n*-butyllithium (16 mmol) in ethyl ether. The solvent and butyl bromide formed were removed by distillation to dryness under reduced pressure at room temperature. Methyl iodide (2.8 g, 20 mmol) in ethyl ether was added to the residue and the mixture heated under reflux for 18 h. The reaction mixture was extracted with dilute hydrochloric acid, the solvent distilled and the residue sublimed at 70° and 0.7 mm. The colorless crystals obtained melted at 161–162° (0.95 g, 48%). This compound showed a broad u.v. band at λ_{max} 270 mμ (ε 204) and n.m.r. bands at 8.66, 8.51, 7.37 and 2.62 τ in intensity ratios of 9:18:3:2 and assigned to the *p*-*t*-butyl, *o*-*t*-butyls, arylmethyl, and aromatic hydrogens respectively.

[4]The structural formula



is assigned to this compound. Its mode or formation is not yet understood. It presumably involves nitration, bromination, and oxidation as well as di-*t*-butylation. The latter reaction is quite common under similar conditions (15).

TABLE 2. *t*-Butylation of 1,1-dimethylindane

Reaction time (h)		Products (%) in order of elution by g.l.c.
2	A	1,1-Dimethylindane (**7**) (88)
	B	6-*t*-Butyl-1,1-dimethylindane (**8**) (5.8)
	C	5-*t*-Butyl-1,1-dimethylindane (**9**) (6.1)
5.5	D	Trace of 1,1-dimethyl-4,6-di-*t*-butylindane (**10**) as well as A, B, and C
24*	A	**7** (18)
	B	**8** (29)
	C	**9** (45)
	D	**10** (7)

*More *t*-butyl chloride (3.80 g, 0.041 mol) and aluminum chloride (0.65 g) were added during this period

Mass spectroscopic analysis showed the expected parent mass of 260 with the base peak at 245 (M—CH_3). The above n.m.r. spectrum agrees with that reported in the literature (16) for **19** but there is a disparity between the melting points (lit. (16) m.p. for **19** is 149°). Therefore, we confirmed the identity of our **19** by an alternate synthesis below.

(b) From 2,4,6-Tri-t-butylbenzyl Chloride (3)

The chloride (3) (0.15 g, 0.51 mmol) was reduced by treatment with lithium aluminum hydride (0.5 g) in tetrahydrofuran at reflux temperature for 4 h followed by standing overnight. The excess hydride was destroyed with ethyl acetate, the product poured over ice, and extracted with ethyl ether. Distillation of the solvent yielded 0.12 g (92%) of crystalline product, m.p. 157°. Recrystallization from methanol raised the m.p. to 159°. It proved identical to the hydrocarbon from procedure *a* by mixed m.p. and n.m.r. spectra.

Synthesis of 1,1-Dimethyl-4,6-di-t-butylindane (10)

(1) t-Butylation of 1,1-Dimethylindane (7)

1,1-Dimethylindane (American Petroleum Institute) (17) (1.00 g, 6.8 mmol) was dissolved in 10 ml freshly distilled pentane and the mixture cooled to −5°. *t*-Butyl chloride (1.30 g, 13.6 mmol) in 10 ml of pentane and anhydrous aluminum chloride (0.266 g, 2.0 mmol) were slowly added to the reaction mixture over a period of 2 h, while the reaction course was monitored by g.l.c. analyses on aliquots. The results of the alkylation after 2 h, and after an extended period are summarized in Table 2.

The three products (g.l.c. components B, C, and D) were collected from the gas chromatograph. Components B and D were identified as 6-*t*-butyl-1,1-dimethylindane and 1,1-dimethyl-4,6-di-*t*-butylindane by comparison of their n.m.r. spectra and g.l.c. retention times with authentic samples. The main product (C) was a new liquid hydrocarbon.

Anal. Calcd. for $C_{15}H_{22}$: C, 89.04; H, 10.96. Found: C, 89.16, 89.07; H, 10.68, 10.67.

It showed n.m.r. bands at 8.79 (singlet), 8.74 (singlet), 8.14 (triplet $\Delta = 7$ Hz), 7.17 (triplet $\Delta = 7$ Hz), and 2.94 τ (multiplet) with intensity ratios of 6:9:2:2:3, assigned to the *gem*-dimethyls, *t*-butyl, β-methylene, α-methylene and aromatic hydrogens respectively. This spectrum was very similar to that of 6-*t*-butyl-1,1-dimethylindane (**8**) but they could be distinguished by slight differences in the aromatic hydrogen region.

(2) t-Butylation of 6-t-Butyl-1,1-dimethylindane (8)

6-*t*-Butyl-1,1-dimethylindane (American Petroleum Institute) (17) (1.00 g, 5.0 mmol) was alkylated with *t*-butyl chloride (1.38 g, 14.9 mmol) and anhydrous aluminum chloride (0.27 g, 2.0 mmol) using the above procedure. After a reaction time of 24 h, g.l.c. analysis and n.m.r. spectra on collected fractions showed 75% starting hydrocarbon (**8**) and 25% 1,1-dimethyl-4,6-di-*t*-butylindane (**10**).

Preparation of 2-Methyl-4,6-di-t-butyl Compounds

2-Methyl-4,6-di-*t*-butylbenzyl chloride (**16**), 2-methyl-4,6-di-*t*-butylbenzyl alcohol (**13**), and methyl 2-methyl-4,6-di-*t*-butylbenzyl ether (**12**) were prepared by procedures of Beets and co-workers (18).

(1) 2-Methyl-4,6-di-t-butylbenzyl Formate (17)

2-Methyl-4,6-di-*t*-butylbenzyl chloride (**16**) (0.253 g, 1 mmol) was added to a solution containing 0.7 ml of dioxane, 0.5 ml of formic acid, and 0.07 g of sodium formate. The mixture was heated on the steam cone until the n.m.r. spectrum showed that the benzylic methylene absorption of **16** (5.0 τ) had disappeared and was replaced by a new band at 4.5 τ (approximately 3/4 h). Solid sodium carbonate was added to neutralize excess acid and the solvent was distilled under reduced pressure. The crystalline residue was sublimed at 40°, 0.05 mm to give colorless crystals, m.p. 50–51.5°.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.81; H, 9.99. Found: C, 77.88, 78.00; H, 10.02, 10.18.

This compound had an i.r. band at 1725 cm^{-1} (carbonyl) and n.m.r. bands at 8.69 (singlet), 8.58 (singlet), 7.67 (singlet), 4.57 (singlet), 2.93 (doublet), 2.60 (doublet), and 1.92 (singlet) in intensity ratios of 9:9:3:2:1:1:1 and assigned to the *p*-*t*-butyl, *o*-*t*-butyl, aryl methyl, benzylic methylene, aromatic hydrogens, and aldehydic hydrogen respectively.

(2) 2-Methyl-4,6-di-t-butyltoluene (18)

2-Methyl-4,6-di-*t*-butyltoluene was prepared by hydride reduction of 2-methyl-4,6-di-*t*-butylbenzyl chloride according to the procedure under 5*b* (above). An analytical sample of the liquid hydrocarbon **18** was obtained by collection from g.l.c.

Anal. Calcd. for $C_{16}H_{26}$ (mol. wt. 218): C, 88.06; H, 11.94. Found (218 (mass spectrum)): C, 88.06, 87.92; H, 12.12, 12.11. The n.m.r. spectrum showed bands at 8.73, 8.59, 7.78, 7.68 (singlets), 3.04 (doublet), and 2.77 (doublet) in intensity ratios of 9:9:3:3:1:1, assigned to the *p*-*t*-butyl, *o*-*t*-butyl, two aryl methyls, and aromatic hydrogens respectively.

Acid-catalyzed Reactions of 2,4,6-Tri-t-butylbenzyl Compounds

Details on the conditions and yields of products from acid-catalyzed reactions of methyl 2,4,6-tri-*t*-butylbenzyl ether (**5**), alcohol (**2**), and chloride (**3**) are outlined in Table 3. Products from the reactions with thionyl chloride were obtained by distillation of the excess reagent under reduced pressure followed by g.l.c. analysis of the product (no. 2*a*) or crystallization (no. 2*b*). The other reactions were worked-up by pouring the reaction mixtures into crushed ice, followed by ether extraction, washing with dilute sodium carbonate and with water. The ether extracts were concentrated to a small volume for g.l.c. analyses. Compounds were identified by the use of known synthetic samples as internal standards on g.l.c. analyses and by collection of samples from the g.l.c. for spectral analyses.

For personal use only.

1,1-Dimethyl-4,6-di-*t*-butylindane (**10**) was first obtained from reaction no. 1 (Table 3) as colorless crystals, m.p. 129–130°.

Anal. Calcd. for $C_{19}H_{30}$: C, 88.37; H, 11.63. Found: C, 88.56, 88.61; H, 11.63, 11.69.

Its n.m.r. spectrum had singlets at 8.78, 8.72, and 8.65 τ of relative intensity ratios 6:9:9 assigned to the *gem*-dimethyls, 6-*t*-butyl, and 4-*t*-butyl. Two triplets centered at 8.15 ($\Delta = 7$ Hz) and 7.00 ($\Delta = 7$ Hz) τ were assigned to the β-methylene and α-methylene hydrogens respectively. Two doublets, at 3.12 and 2.92 τ ($\Delta = 1.8$ Hz) (intensity 1 H each) were assigned to the aromatic hydrogens. The mass spectrum showed the expected parent mass of 258 with the base peak at 243 (M—CH_3). The main product from treatment of α,α-dideutero-2,4,6-tri-*t*-butylbenzyl chloride with formic acid (no. 9) was identified as 3,3-dideutero-1,1-dimethyl-4,6-di-*t*-butylindane from comparison of its n.m.r. and mass spectra with those of **10**. The labelled hydrocarbon showed no absorption in the α-methylene region of the n.m.r. spectrum and as expected the β-methylene gave a broadened singlet. The mass spectrum of the labelled hydrocarbon showed the expected parent mass of 260 with the base peak at 245 (M—CH_3). There was no evidence of compounds that would result from loss or rearrangement of deuterium.

The acetate (**15**) from reaction no. 8 was purified by sublimation, m.p. 130–131.5°.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76. Found: C, 78.54; H, 10.60.

The mass spectrum showed the expected parent mass of 318 and an accurate mass determination agreed with the formula $C_{21}H_{34}O_2$. It showed an i.r. band at 1725 cm^{-1} (s) (carbonyl) and n.m.r. bands at 8.66, 8.56, 8.05, 4.55, and 2.60 τ (singlets) with intensity ratios of 9:18:3:2:2, assigned to the *p*-*t*-butyl, *o*-*t*-butyls, methyl, benzylic methylene, and aromatic hydrogens respectively.

Acid-catalyzed Reactions of 2-Methyl-4,6-di-t-butylbenzyl Compounds

Table 4 outlines the experimental details on the acid-catalyzed reactions of methyl 2-methyl-4,6-di-*t*-butylbenzyl ether (**12**), alcohol (**13**), and chloride (**16**). The products from the reactions were worked-up and identified by the same procedures used for the tri-*t*-butylbenzyl compounds previously. The main product from reaction no. 5 was separated by chromatography on alumina and elution with petroleum ether followed by ethyl ether. The latter eluted this compound (81% yield) as colorless crystals, m.p. 122–124°.

Anal. Calcd. for $C_{32}H_{50}O$: C, 85.33; H, 11.11. Found: C, 85.23, 85.54; H, 11.23, 11.36.

It showed a strong i.r. band at 1050 cm^{-1} (ether) and n.m.r. bands at 8.72, 8.53, 7.64 and 5.24 (singlets), and 3.07, 2.83 τ (doublets) of intensities ratios 18:18:6:4:2:2. These bands were assigned to the 4,4′-*t*-butyls, 6,6′-*t*-butyls, 2,2′-methyls, two benzylic methylenes and aromatic hydrogens of 2,2′-dimethyl-4,4′,6,6′-tetra-*t*-butyldibenzyl ether.

Carbonium Ion – Hydride Transfer Reactions of Alkyl Benzyl Compounds

Experimental details and product analyses for the reduction of various alkyl benzyl alcohols and chlorides with triethylsilane in the presence of trifluoroacetic acid (TFA) are summarized in Table 5. Each experiment was set up to monitor it directly by n.m.r. measurement of the loss of the benzylic methylene absorption and conversion into an aryl methyl group. The benzyl alcohol or chloride was dissolved in 0.5 ml of methylene chloride (in the case of alcohol **2** and chloride **3** CD_2Cl_2 was required for the n.m.r. measurements), triethylsilane was added and the n.m.r. spectrum was run. Then the trifluoroacetic acid was added and the spectrum was scanned repeatedly. In no case did reductions occur in the absence of trifluoroacetic acid. For example 2,4,6-tri-*t*-butylbenzyl chloride (**3**), the most reactive compound, was stable to triethylsilane alone even after prolonged treatment. Reactions were terminated by adding solid sodium carbonate. This was removed by filtration, the solvent distilled, and the residue dissolved in benzene for g.l.c. analyses using columns (10 ft × 1/4 in.) packed with 8% carbowax on Chromosorb W. The hydrocarbons were identified by the use of known synthetic samples as internal standards on the g.l.c. as well as by the n.m.r. spectra.

The financial support of this research provided by the National Research Council of Canada is gratefully acknowledged. We thank Dr. W. D. Jamieson of the Atlantic Regional Laboratory (NRCC), Halifax, for providing the mass spectroscopic analyses.

Addition of ICl to Norbornene. The Preparation and Photochemical Isomerization of *syn*-7-Iodonorbornene

N. H. WERSTIUK, I. VANCAS, J. WARKENTIN, AND F. R. S. CLARK
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 16, 1971

The addition of ICl to norbornene in the presence of pyridine yields nortricyclyl iodide (**1***c*), *endo*-2-chloro-*exo*-3-iodonorbornane (**2***c*), and *syn*-7-iodo-*exo*-2-chloronorbornane (**3***b*) as the major products. Base-catalyzed elimination of HCl from **3***b* yields *syn*-7-iodonorbornene (**6***a*) which is isomerized photochemically to *anti*-7-iodonorbornene (**6***b*).

L'addition de ICl au norbornène en présence de pyridine conduit à l'iodure nortricyclyl (**1***c*), à l'*endo*-chloro-2 *exo*-iodo-3 norbornane (**2***c*), et au *syn*-iodo-7 *exo*-chloro-2 norbornane (**3***b*) en tant que produits majoritaires. L'élimination baso-catalysée de HCl à partir de **3***b* conduit au *syn*-iodo-7 norbornène (**6***a*) qui subit une isomérisation photochimique en *anti*-iodo-7 norbornène (**6***b*).

Canadian Journal of Chemistry, **50**, 291 (1972)

Introduction

The electrophilic addition of polar reagents to olefins and cycloolefins is of mechanistic (1–4) and theoretical interest (5). Studies have shown that product distribution, resulting from capture of the intermediate onium-3 ion, rearrangement and 1,3 elimination of a proton, as for example in the bicyclo[2.2.1]heptyl system, depends on the electrophile (1–4). Molecular orbital calculations on the system E^+ and ethylene by Bach and Henneike (5) indicate that the degree of double bond pertubation and therefore the extent of charge development on carbon also depends on the electrophile. That this would be important in directing the reactions of the intermediate onium ion is certain.

In this study ICl was added to norbornene to establish the behavior of I^+ and thereby provide data for a comparison of the results obtained with Cl^+ (2, 4) and Br^+ (2, 3). The synthesis of the previously unknown *syn*-7-iodonorbornene, via base-catalyzed elimination of HCl from *syn*-7-iodo-*exo*-2-chloronorbornane could be accomplished if the *syn-exo*-dihalide was a major product as in the bromination of norbornene (2, 3). The 7-iodonorbornene would then be a useful precursor for the 7-norbornenyl radical (6–8) and anion (9, 10) species in which there has been considerable interest.

Results

The addition of ICl in CH_2Cl_2 to norbornene in CH_2Cl_2 containing an equimolar quantity of pyridine gave nortricyclyl iodide (**1***c*), *endo*-2-chloro-*exo*-3-iodonorbornane (**2***c*), and *syn*-7-iodo-*exo*-2-chloronorbornane (**3***b*) as 85–90% of the reaction mixture (Fig. 1). Compound **1***c* was identified by its mass spectrum (M^+, *m/e* 220) and n.m.r. spectrum, the latter corresponding exactly to that reported for **1***c* by Diner and Lown (11). That **2***c* is *endo*-2-chloro-*exo*-3-iodonorbornane was established chemically and by n.m.r. spectroscopy. Treatment of **2***c* with KO*t*Bu–*t*BuOH gave the norbornenyl chloride **8** and established the 2,3 substitution. That the *endo*-2-*exo*-3-orientation was correct was established by several facts. The n.m.r. spectrum of **2***c* showed triplets at δ 4.75 and 3.85 for the C-3-*exo*- and C-2-*endo*-protons, respectively, exactly the pattern reported for the dibromide **2***b* by Marshall *et al.* (3). Treatment of **2***c* with *n*-$(Bu)_3SnH$ gave *endo*-norbornyl chloride **9***b*, the result of preferential reduction of iodine (12). The facile elimination of HI from **2***c* (reaction time less than 3 h) is further evidence that orientation of hydrogen and iodine is *cis-exo* at C-2, C-3 (13). That dihalide **3***b* is *syn-exo* was established by consideration of its n.m.r. spectrum and the results of several reactions. The

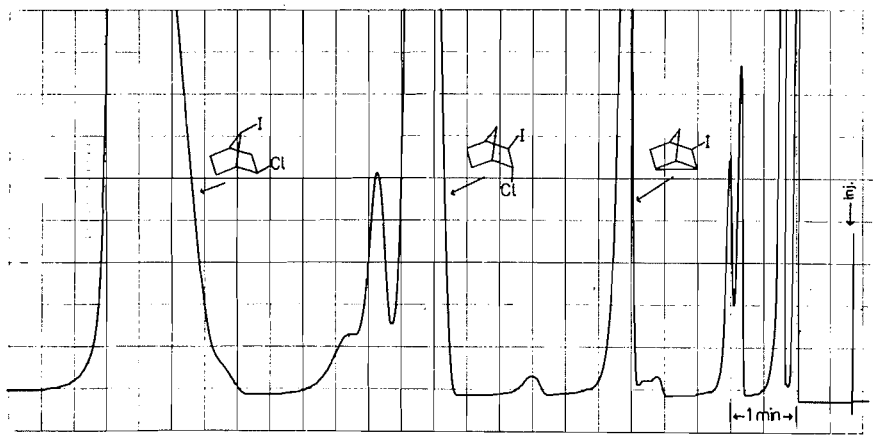

FIG. 1. The g.l.c. of products of ICl addition to norbornene.

n.m.r. of **3***b* which showed a multiplet at δ 4.08 (C-2-*endo*-H) which overlapped with a sharp multiplet at 3.90 (*anti*-7-H) was pattern-wise very similar to the corresponding absorptions for *syn*-7-bromo-*exo*-2-bromonorbornane reported by Marshall *et al.* (3). The assignment was corroborated by formation of **6***a*, **6***c*, and **7***a* when **3***b* was reacted with KO*t*Bu–*t*BuOH. That **6***a* was the *syn*-7-iodide was established by decoupling experiments and by photochemical isomerization to the *anti*-iodide **6***b*. Decoupling experiments on **6***b* as described in the experimental further supported the assignments. Reduction of **3***b* with *n*-$(Bu)_3SnH$ gave *exo*-norbornyl chloride by preferential reduction of iodine.

*See refs. 13 and 14.
†EX (0.02 *M*) in CH_2Cl_2 was added dropwise to norbornene (0.02 *M*) and pyridine (0.02 *M*) in CH_2Cl_2.

The minor components of r_t 3.20, 7.35, and 7.70 min obtained in the addition are likely norbornenyl iodides and the *anti*-7-iodo-*exo*-2-chloro- and *exo*-3-iodo-*exo*-6-chloronorbornanes **4***b* and **5***b*, respectively, analogous to the dibromides **4***a* and **5***a* obtained in the bromination of norbornene (3, 4).

Discussion and Conclusions

The product distributions for the addition of Cl_2, Br_2, and ICl to norbornene in CH_2Cl_2 are listed in Table 1. Interestingly, the quantity of tricyclic component decreases from 65% in chlorination to 12% in the ICl addition, while the reverse trend is established for the *syn-exo*- and 2,3-*trans*-dihalides. Possibly, the 2,3-*trans*-trend reflects the degree of double bond pertubation ($Cl^+ > Br^+ > I^+$) and therefore the degree of bending of the olefinic C—H bonds, as suggested by Bach and Henneike (5), into an "*endo*-like" position. The greater the pertubation and thus distortion of the C—H bonds, the less favorable is nucleophilic attack by X^- on the onium ion. The minor amount of 2,3-*trans*-product in the bromination is accounted for by an increased pertubation by Br^+ over I^+, as well as the likely decreased nucleophilicity of Br^- over Cl^- in the aprotic solvent CH_2Cl_2 (15, 16). Certainly greater steric requirements of Br^- over Cl^- would also contribute to the effect. That the amount of 1,3 elimination and the stereochemistry of the process (2) leading to tricyclic product must be governed by the charge development at C-2, C-3 which occurs as E^+ attacks or as the onium ion opens or rearranges (2), is indicated by the decrease of relative percent yields of the nortricyclenes in the addition of Cl_2, Br_2, and ICl, respectively. It is attractive to postulate that E(Br or I) assists 1,2 Wagner–Meerwein rearrangement via partial Br-4 or I-4 participation by stabilizing the charge developed at C-1. This would account for the larger amounts of 2,7-dihalide formed when Br^+ and I^+ add and for the apparent *endo* and *exo* stereoselectivity observed for the 1,3 process in chlorination and bromination, respectively (2).

This work provides the first synthesis of the *syn*- and *anti*-7-iodonorbornenes, the latter via a previously unknown photochemical *syn–anti* isomerization. The formation of **6***c* and **7***a* during KO*t*Bu–*t*BuOH treatment of **3***b* has precedent since **6***d*, **7***b*, and **6***e*, **6***c* have been obtained previously by Brookhart *et al.* (17) and Tufariello *et al.* (18), respectively, from solvolysis of 7-substituted norbornenes. However, the preparation of *anti*-7-X-norbornenes and *endo*-6-X-tricyclo[3,2,0,0]^{2,7} heptanes is now possible directly in two steps from norbornene via ICl addition followed by elimination of HCl in a highly concentrated solution of the base M^+X^-.

The *syn–anti* isomerization of the 7-iodonorbornenes is the expected result of irradiating them at about 254 nm. Homolytic dissociation of the n–σ^* excited state of alkyl iodides is well known (19) and recombination of the 7-norbornenyl radical with iodine atoms in both stereochemical senses is in keeping with the non-stereospecific H-abstraction reactions of the 7-norbornenyl radical (7, 8). The photostationary state appears to favor the *anti*-iodide, the *syn*:*anti* ratio from photolysis at high dilution being about 1:1.5. However, one cannot conclude that the *anti*-iodide is thermodynami-

cally the more stable isomer in the absence of further information such as quantum yields.

The *syn*- and *anti*-7-iodonorbornenes will be useful precursors for preparation of the 7-norbornenyl radical (6–8) and perhaps the 7-norbornenyl anion (9) in that, for example, attempts to prepare the organolithium derivatives of 7-norbornenyl bromides and chlorides (20) and 7-benzonorbornenyl bromide (10) have failed.

Experimental

General

The n.m.r. spectra were recorded on Varian T-60 and HA-100 spectrometers in CCl_4 or $CDCl_3$ with tetramethylsilane as the internal standard. Ultraviolet spectra were obtained on a Carey Model 14 spectrophotometer. Preparative gas chromatographic isolations were done on a Varian-Aerograph 90-P-3 instrument with 5–10 ft × 1/4 in. 10–15% SE-30 on Chromosorb W glass and stainless steel columns with He as the carrier. Analytical chromatograms were obtained on a Varian-Areograph Model 204 chromatograph on a 10 ft × 1/8 in. 10% SE-30 on Chromosorb W column with He as the carrier. Pentane was stirred over fuming H_2SO_4, washed with bicarbonate solution, and distilled. All solutions were dried over anhydrous Na_2SO_4 and $MgSO_4$.

Addition of ICl to Norbornene in CH_2Cl_2–Pyridine

In a three-necked 1 l flask was added norbornene (44.5 g, 0.47 mol), pyridine (38.5 ml, 0.47 mol), and CH_2Cl_2 (290 ml). The mixture was cooled to 0° in an ice-bath and stirred magnetically as dry N_2 was bubbled through. ICl (75.8 g, 0.47 mol) in CH_2Cl_2 (140 ml) was added dropwise to the norbornene solution. After the mixture had stood for 20 min, the CH_2Cl_2 layer was washed three times with dilute thiosulfate solution, twice with dilute HCl, twice with distilled water, then dried. Most of the methylene dichloride was removed by distillation through a 1 ft Vigreux column. The g.l.c. on a 10 ft × 1/3 in. 5% SE-30 on Chromosorb W column at 150° (Fig. 1) showed products at r_t (flow rate ca. 25 ml/min) 1.8 min (6.8%) unknowns, 3.20 (<1%) norbornenyl iodides, 3.60 (15%) nortricyclyl iodide (**1***c*), 4.95 (<1%) unknown, 6.60 (35%) *endo*-2-chloro-*exo*-3-iodonorbornane (**2***c*), 7.35 (5%) and 7.80 (2%) chloroiodonorbornanes, 9.80 (<1%) unknown, 11.0 (40%) *syn*-7-iodo-*exo*-2-chloronorbornane (**3***b*). Vacuum distillation through a 1.5 ft vacuum jacketed Vigreux column gave fraction 1, b.p. 46–52° (3.8 mm), containing the first components including nortricyclyl iodide; fraction 2 (15 g), b.p. 56–58° (3.6 mm) nortricyclyl iodide, 90% pure by g.l.c.; fractions 3 and 4, b.p. 48–50° (2.5 mm) **2***c* and **3***b*; fraction 5 (20 g), b.p. 50–55° (4 mm) **2***c* (95% pure by g.l.c.); fraction 6 (30 g), b.p. 50–60° (2.5 mm) **3***b* (90% pure by g.l.c.).

The n.m.r., 60 MHz (CCl_4) **1***c*; δ 3.78 (1H, singlet, —C(H)—I), 2.10 (2H, singlet overlapping with doublet which was the low field portion of an AB quartet, C-4-H and C-7-H *syn* to the iodide) 1.7–0.9 (6H, multiplet, nortricyclyl envelope). The mass spectrum of **1***c* taken after preparative g.l.c. showed M^+ at *m/e* 220 corresponding to C_7H_9I. The n.m.r., 60 MHz (neat) **2***c*; δ 4.75 (1H, triplet; J = 2.5, 2.0 Hz, C-3-*exo*-H) 3.85 (1H, triplet; J = 1.5, 1.5 Hz, C-2-*endo*-H) 2.5 and 2.7 (2H, broad singlets, bridgehead-H's) 2.3–1.1 (norbornyl envelope). The n.m.r., 60 MHz (CCl_4) of **3***b*; δ 4.08 (1H, broad multiplet, C-2-*endo*-H), 3.90 (1H, sharp multiplet, *anti*-7-H), 2.7–1.1 (norbornyl envelope). After the first distillation the reddish-brown fractions 5 and 6 were dissolved in ether and washed with dilute thiosulfate. The ether was distilled off after drying and the remaining oil was distilled. In this way **2***c* and **3***b* were obtained as pale yellow-brown liquids.

*Reaction of **2***c* with Potassium t-Butoxide in t-Butyl Alcohol*

Compound **2***c* (2.1 g, 90% **2***c*, 5% **4***b*, 5% **3***b*) was dissolved in saturated KO*t*Bu–*t*BuOH solution (55 ml) in a 100 ml flask fitted with a condenser and a calcium chloride drying tube. The mixture was refluxed and stirred and after 3.5 h was 98% complete as determined by analytical g.l.c. The mixture was poured into water (100 ml) and extracted with pentane (3 × 50 ml). The pentane layer was washed with water (4 × 100 ml), dried, and the solvent was distilled off. The major peak (90%) was collected by preparative g.l.c. Mass spectrum, M^+ at *m/e* 128, 130 corresponded to C_7H_9Cl. The n.m.r., 60 MHz (CCl_4); δ 5.75 (1H, doublet, J = 3.5 Hz, olefinic-H), 2.85 (2H, broad multiplet, bridgehead-H's), 1.4–1.0 (6H, norbornenyl envelope).

*Reaction of **3***b* with KO*t*Bu in t*BuOH. Preparation of **6***a*

Run 1

Compound **3***b* (2.1 g, 95% **3***b*, 5% **2***c*) was refluxed in saturated KO*t*Bu–*t*BuOH solution (55 ml). Five aliquots were removed at 3.7, 14.3, 19.5, 25.0, and 35.0 h and analyzed by analytical g.l.c. Three products of r_t 2.0, 2.6, and 3.0 min were present as well as minor components (2%) of r_t 1–1.5 and 2.4 min relative to **3***b* of r_t 10.2. There was a gradual decrease in intensity of peaks r_t 10.2 and 3.0 min and an increase in the intensity of the peaks of r_t 2.0 and 2.6 min. After 35 h 10% of starting material remained and the ratio of the products of r_t 2.0, 2.6, and 3.0 was 2:1:1. The three components were isolated by preparative g.l.c. on a 10 ft × 3/8 in. 30% SE-30 Chromosorb W column maintained at 130°. The n.m.r., 60 MHz (CCl_4) of peak r_t 2.0 (**6***c*); δ 5.88 (2H, triplet, J = 1.5, 1.5 Hz, olefinic-H's), 3.25 (1H, broad singlet, —C(H)—O*t*Bu), 2.35 (2H, multiplet, bridgehead-H's), 1.80 (2H, multiplet, C-5, C-6-*exo*-C-H's), 1.10 (9H, singlet, —$C(CH_3)_3$), and 0.85 (2H, multiplet, C-5, C-6-*endo*-C-H's).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.52; H, 10.84. Found: C, 79.59; H, 10.97.

The n.m.r., 60 MHz (CS_2) of peak r_t 2.6 (**7***a*); δ 3.98 (1H, quartet, J = 8, 4 Hz, —C(H)—O—*t*Bu), 2.50 (1H, multiplet, bridgehead-H), 2.1–1.2 (7H, multiplet, norbornyl envelope including cyclopropyl-H's), 1.1 (9H, singlet, —$C(CH_3)_3$).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.52; H, 10.84. Found: C, 79.66; H, 10.72.

The n.m.r., 60 MHz (CS_2) of peak r_t 3.6; δ 6.15 (2H, multiplet, olefinic-H's), 3.82 (1H, multiplet, *anti*-C-7-H), 3.13 (2H, multiplet, bridgehead-H's), 1.83 (2H, multiplet, C-5,C-6-*exo*-H's), 1.13 (2H, multiplet, C-5,C-6-*endo*-H's). The n.m.r., 100 MHz (CCl_4); showed the band at δ 6.0 to be a triplet of doublets with J = 2.2, 1.8, 0.7 Hz. Irradiation of the *anti*-7-H collapsed the triplet of doublets to a triplet with J = 2.2 and 1.8 Hz. The u.v.; λ_{max} (hexane), 254 nm (ε 600).

Anal. Calcd. for C_7H_9I: C, 38.19; H, 4.09. Found: C, 38.50; H, 3.92.

Run 2

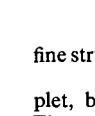
Compound **3***b* (5.8 g, 95% **3***b*, 5% **2***c*) was refluxed in saturated KO*t*Bu–*t*BuOH solution (150 ml) for 41.5 h. Work-up as described previously and analysis by analytical g.l.c. on 10 ft × 1/8 in. 5% SE-30 on Chromosorb W column showed the reaction to be 95% complete. The products **6***a*, **7***a*, and **6***c* were present in a ratio of 2:1:1.

Reaction of 2c with n-(Bu)$_3$SnH

To **2***c* (1.0 g, 90% **2***c*, 10% **4***b*) in pentane (25 ml) was added *n*-$(Bu)_3SnH$ (1.1 g, 3.8×10^{-3} mol) in pentane (30 ml) dropwise at 25°. After the addition was complete the pentane layer was washed with water (3 × 50 ml) and dried. The g.l.c. showed that the reaction was 95% complete. The pentane was distilled through a 6 in. Vigreux column and the major product (95%) was isolated by preparative g.l.c. The n.m.r. (CCl_4) showed the product to be a mixture of 90% of *endo*-norbornyl chloride and 10% *exo*-norbornyl chloride by comparison of the absorptions at δ 4.15 (C-2-*exo*-H) and 3.82 (C-2-*endo*-H), respectively, in accord with the percentage of **2***c* and **4***b* originally present in the starting material.

Reaction of 3b with n-(Bu)$_3$SnH

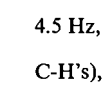
Compound **3***b* (1.3 g, 95% **3***b*, 5% **2***c*) in pentane (32 ml) was added dropwise to *n*-$(Bu)_3SnH$ (1.3 g, 4.6×10^{-3} mol) in pentane (37 ml) at 25°. The solution was washed with water (3 × 50 ml) and dried. The g.l.c. analysis showed one major product **9***a* (85%) and 10% of **3***b* and 5% of **2***c*. The major product was isolated by preparative g.l.c. after the pentane was removed by distillation through a 6 in. Vigreux column. The n.m.r., 60 MHz (neat); δ 3.9 (1H, triplet with



fine structure, $J = 6, 4.5$ Hz, —C—Cl), 2.3 (2H, broad multiplet, bridgehead-H's), 2.0–0.9 (8H, norbornyl envelope). There was less than 3% of absorption at δ 4.15 due to *endo*-norbornyl chloride.

Preparation of exo-Norbornyl chloride (9a)

exo-Norbornyl chloride (**9***a*) was prepared by treating norbornene with anhydrous HCl in pentane (21). The n.m.r., 60 MHz (neat); δ 3.92 (1H, triplet with fine structure, $J = 6$,



4.5 Hz, —C—Cl), 2.3 (2H, broad multiplet, bridgehead C-H's), 2.0–0.9 (8H, norbornyl envelope).

Irradiation of syn-7-Iodonorbornene (6a)

Run 1

Compound **6***a* (0.19 g, 8.7×10^{-5} mol, 99% pure) and iodine (0.0055 g, 2.0×10^{-5} mol, sublimed) were dissolved in *n*-hexane (0.7 ml, spectral grade) which contained a trace of methylene chloride as an internal standard. Irradiation (254 nm) of the solution in a quartz n.m.r. tube at 30° was carried out in a Rayonet reactor. After 30 min the C-7-H region of the n.m.r. showed two peaks of approximately equal intensity. A small amount of insoluble material accumulated in the tube and the vinyl absorption had decreased in intensity relative to CH_2Cl_2. After 6.8 h there was no change in the relative intensities of the peaks in the C-7-H region. The g.l.c. analysis on a 5 ft × 1/4 in. 20% SE-30 Chromosorb W column showed two products r_t 6.3 (55.6%) and 7.3 min (44.4%) amounting to 99% of the g.l.c. peak area. The peak of r_t 7.3 corresponded exactly to starting material **6***a*. The other product **6***b* was isolated by g.l.c. The n.m.r., 100 MHz (CCl_4); δ 6.0 (2H, triplet, $J = 2.0, 2.0$ Hz, olefinic-H's), 3.81 (1H, multiplet, *syn*-7-H), 2.86 (2H, multiplet, bridgehead-H's), 2.15 (2H, multiplet, C-5,C-6-*exo*-H's), and 1.12 (2H, multiplet, C-5, C-6-*endo*-H's). Irradiation of the *syn*-7-H did not change the olefinic absorption. The u.v.; λ_{max} (hexane) 251 nm (ε 892).

Run 2

Compound **6***a* (0.012 g) was dissolved in purified pentane (50 ml) and irradiated in a 1 in. diameter quartz tube for 3 h as described previously. The solution turned deep purple and some polymeric material accumulated. The mixture was shaken with aqueous KI to remove the free iodine, dried over anhydrous K_2CO_3, and the solvent was distilled off. The g.l.c. of the recovered oil (0.10 g, 83%) showed a *syn*:*anti*-iodide ratio of 1:1.7.

Run 3

Irradiation of **6***a* (0.0071 g) in purified pentane (50 ml) (degassed) for 15 min as described previously gave a *syn*:*anti* ratio of 1:1.4 as was determined by g.l.c.

Hydrogen Bonding in the case of Self-associated Fluoroalcohols

A. PLANCKAERT AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec
Received July 19, 1971

The OH stretching band of polymeric fluoroalcohols exhibits a much higher rate of shifting with temperature but it is less anharmonic than the corresponding band of ordinary alcohols. The degree of self-association in their solutions is discussed.

Les vibrations de valence des groupements OH des fluoroalcools polymères se déplacent avec la température beaucoup plus rapidement que les vibrations analogues des alcools correspondants mais elles sont moins anharmoniques. On examine le degré d'autoassociation dans leurs solutions.

Introduction

The changes with temperature of the frequency and width of the fundamental and first overtone of the OH stretching vibration of self-associated, polymeric alcohols were recently studied in solution down to liquid nitrogen temperature (1, 2). It has been found that both the fundamental and first overtone shift linearly and at about the same rate to lower frequencies with decreasing temperature. At the same time the anharmonicity constant

$$X_{12} = \nu_{01} - \frac{\nu_{02}}{2}$$

also decreases, by about half of the shift of the frequencies themselves. It seemed interesting to us to study the anharmonicity and temperature dependance of the OH stretching vibration of fluoroalcohols and compare these with the corresponding data for alcohols.

Results

n-Pentafluoropropanol and *n*-heptafluorobutanol were chosen because of their relatively good solubility in solvents which can be used for low temperature measurements. These were a 1:1 mixture of CCl_3F (freon-11) and $C_2F_4Br_2$ (freon 114-B-2) and a 1:1 mixture of decafluorocyclohexene and perfluoromethylcyclohexane (the abbreviated notation FR and DP will be used for these). Experimental details were given previously (1, 3). Poor solubility prevented us from going down to liquid nitrogen temperature. The results summarized in Table 1 relate to 173 °K. The data on unsubstituted alcohols are taken from Asselin and Sandorfy (1) and are given for comparison.

The following observations can be made:

(*1*) As in the case of alcohols the fundamental and first overtone of the fluoroalcohols shift at about the same rate with decreasing temperature (to lower frequencies).

(*2*) The rate of shift is much greater, by about a factor of two, for the fluoroalcohols.

(*3*) The OD deuterated fluoroalcohols have a lesser rate of temperature shift, just as OD deuterated alcohols (about half).

(*4*) The anharmonicity constants, X_{12}, are smaller for the fluoroalcohols than for the alcohols (82 and 91 cm^{-1} compared to 135 and 147 cm^{-1}).

(*5*) The free OH bands have a much greater relative intensity at the level of the first overtone than at the level of the fundamental at similar concentrations (Figs. 1 and 2).

(*6*) As in the case of alcohols, X_{12} varies by about half the shift of the frequencies when temperature decreases.

(*7*) The harmonic frequencies computed with the X_{12} given in Table 1 are significantly lower for the fluoroalcohols.

(*8*) The isotopic ratios show that the OH vibrations are of the same high degree of localizability for alcohols and fluoroalcohols.

(*9*) The half-width of the fundamental of dissolved fluoroalcohols is larger than that of dissolved alcohols.

Discussion

Fluoroalcohols are much more acidic than the related alcohols (4) and, with the same bases, form much stronger hydrogen bonds (HB) than do the corresponding alcohols. Purcell *et al.* (5–7 and earlier papers) measured the ΔH values

TABLE 1. The frequencies (in cm^{-1}) of the fundamental (ν_{01}) and first overtone (ν_{02}) of some dissolved alcohols and fluoroalcohols followed by the half width $(\nu_{1/2})_{01}$ of the fundamental, the rate of shift of ν_{01} and ν_{02} with temperature, the first anharmonicity constant X_{12}, the harmonic frequency, and isotopic ratios. The concentrations of the solutions was approximately 0.2 *M*.

for a number of these calorimetrically and found good linear relationships between ΔH and $\Delta\nu$ for HB between fluoroalcohols and a series of bases. Drago *et al.* (8) found linear relationships for series including alcohols and fluoroalcohols and a given base. Although the anharmonicities are not given in these papers it is clear that $\Delta\nu$ is a valid measure of HB energy for these acid–base pairs.

Conditions are less clear in the case of self-associated fluoroalcohols. Kivinen and Murto (9) investigated solutions of 2,2,2-trifluoroethanol and 1,1,1,3,3,3-hexafluoro-2-propanol. Fluoroalcohols are better proton-donors than ordinary alcohols but, for the same reasons, they are weaker proton-acceptors. The net result seems to be a lesser degree of self-association in fluoroalcohols than in alcohols (9, 10 and references 22–28 in ref. 9). The i.r. evidence for this is based on smaller values of association constants, the fact that polymer bands appear at higher concentrations for the fluoroalcohols than for alcohols and the greater intensity and persistence at higher concentrations of the free OH band in fluoroalcohols. The free OH band is well distinguished even in undiluted fluoroalcohols when it is completely absent from the spectra of the corresponding ordinary alcohols. Kivinen and Murto remark, however, that the intrinsic intensity of the free band is greater in the fluoroalcohols than in alcohols.

Now, the much higher temperature sensitivity

of the OH frequency of the fluoroalcohols would seem to indicate stronger bonds. Since HB in solutions become shorter at lower temperatures (11, 1, 2) it is natural to think that a given decrease of temperature has more effect on the potential surface and the $\Delta\nu$ of a stronger bond which already has a shorter 0 --- 0 distance. The lower frequency of the fluoroalcohol polymers is in line with this (if there is at least a smooth relationship between ΔH and $\Delta\nu$).

The low mechanical anharmonicity of the OH vibration in the case of fluoroalcohols (meaning a steeper potential) together with the shorter HB length could contribute to explaining the high rate of temperature shift.

Normally, for hydrogen bonds formed by alcohols the OH stretching vibrations of stronger HB have higher anharmonicities. Anharmonicity diminishes, however, with decreasing temperature due probably to a shortening of the HB which becomes more symmetrical (*cf.* the $[FHF]^-$ ion). These observations show that when the 0 --- 0 distance is varied from infinite to near-zero the value of the mechanical anharmonicity must pass through a maximum. It is thus possible that a stronger HB has lower anharmonicity. The lower anharmonicity could also be a factor in making the relative intensities of the polymer bands lower (a lesser anharmonicity means lesser polarizability and weaker interactions with the surrounding medium) explaining that in the case of fluoroalcohols they start appearing at higher concentrations than in the case of ordinary alcohols. The low electrical anharmonicity of the polymers (12, 13) could be the cause of the much greater relative intensity of the free band at the level of the first overtone than at the level of the fundamental. A similar phenomenon is observed for alcohols except that there the mechanical anharmonicity of the polymer is higher than that of the monomer (13–15) and the electrical anharmonicity alone must be responsible for the decreased intensity of the polymer overtone (13). In the case of the fluoroalcohols mechanical anharmonicity would not oppose electrical anharmonicity and this could lead to very much weaker overtones, for the polymers, and this is observed.

It is also interesting to point out that the frequencies of the OH stretching fundamentals of fluoroalcohols are only about 40 cm^{-1} lower than those of ordinary alcohols but the differences between the harmonic frequencies (ω_{12}) are of the order of 100 cm^{-1}. Thus if the vibrations were entirely harmonic in both cases the fluoroalcohols would appear to form much stronger HB. Anharmonicity acts to diminish the difference in frequency between alcohol and fluoroalcohol polymers. This might perturb the $\Delta\nu - \Delta H$ relationship when alcohols and fluoroalcohols are considered together.

In conclusion we should like to make two points. First, we cannot give a definite answer to the important question: what are the factors determining the rate of temperature shift of bands affected by HB? Second, it is not yet known in our opinion if fluoroalcohols are more, or less associated than the corresponding ordinary alcohols.

Use of *N*-Carboxyanhydrides in the Synthesis of Dipeptides. The Improvement of Isolated Yields by the Facile Removal of Buffer Components[1]

R. J. GAIT,[2] J. R. LANGLOIS, AND R. E. WILLIAMS[3]
Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received July 21, 1971

A modification of the *N*-carboxyanhydride synthesis of dipeptides is described. An improvement in the yield during dipeptide preparation is made possible by use of only organic acids and bases during the reaction to facilitate their removal before product isolation.

Une modification de la synthèse des dipeptides par l'emploi des *N*-carboxyanhydrides y est décrite. On obtient un meilleur rendement des produits isolés en employant les acides et bases organiques pendant la réaction; facilitant, ainsi, leur séparation du produit désiré.

Canadian Journal of Chemistry, **50**, 299 (1972)

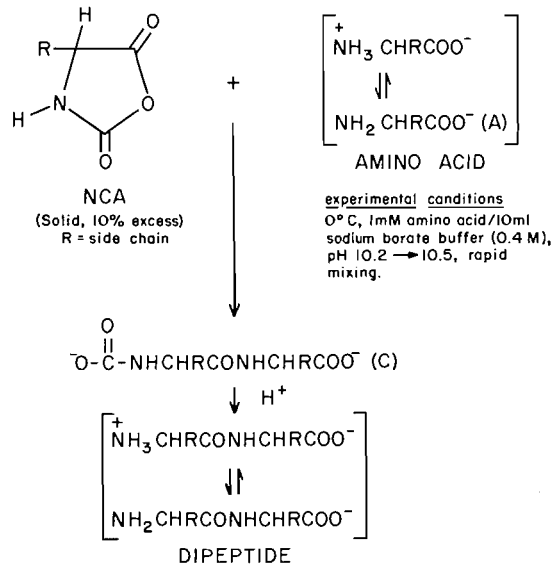
Introduction

The preparative synthesis of peptides using *N*-carboxyanhydrides (NCA's) (Leuch's anhydrides) has had a long and varied history (1). In most cases, low yields were found and the method did not receive serious attention until a report that NCA's could be used to synthesize peptides under controlled conditions of temperature, concentration, and p*H*, appeared in 1967 (2). These experimental conditions and the reaction sequence are summarized in Scheme 1.

In general, to ensure adequate reaction, the method requires low temperatures, controlled p*H*, and rapid mixing. Even in the presence of an external buffer (borate) base addition was found necessary to achieve the p*H* control.

The general usefulness of the borate procedure and the fact that it is racemization free (3) has been illustrated by its use in the preparation of diasteriomeric dipeptides as a tool for the investigation of amino acid racemization (4) and in the preparation of fragments for the ultimate synthesis of a polypeptide having RNAase activity (5).

Several modifications of the original procedure have been made. The use of an external organic buffer whose basic component had a p*K* closer to the p*H* 10.2 normally used in the reaction was tried (6). Addition of a base (sodium hydroxide) was still found to be necessary to control the p*H* within the prescribed limits. Recently, another modification was made in which the reaction was run in 0.2 *M* sodium carbonate solution containing acetonitrile (7). No p*H* control was used in this case.



SCHEME 1. NCA dipeptide formation.

Each of these modifications has been used with success as evident in the high yields found in the preparation of di- and tripeptides. The resulting products have not, however, been easily isolated from the reaction mixture except in the cases where the product was insoluble and could be filtered off.

In view of the general usefulness of the NCA reaction we wish to report an additional modification of the original procedure which, for preparative purposes, will greatly aid in the isolation of the resulting products.

Experimental

Rotations were taken in a 1 dm tube on a Perkin–Elmer polarimeter, model 141. Melting points were taken either on a Fisher–Johns melting point apparatus or, where indicated, in a sealed capillary tube. They are uncorrected. Combustion analyses were performed by H. Seguin, Biochemistry Laboratories, NRCC, Ottawa. All chemicals were of reagent quality. Water was doubly distilled from glass. Phosgene C.P. was purchased from Matheson, Whitby, Ontario. The amino acids were obtained from Bion Biochemicals, Toronto, Ontario.

Thin-layer chromatography was performed on layers of silica gel (Camag Kieselgel, DF5) with a single solvent system (*n*-butanol, acetic acid, water, 4:1:1, v/v/v) being used. All R_f's reported are for this system. After development, the plates were developed with a ninhydrin spray (ninhydrin, *n*-butanol, acetic acid, 0.3:100:3 w/v/v).

Amino acid analyses were performed by A. E. Castagne on a Beckman amino acid analyzer, model 120C, using a standard amino acid elution programme on the 69 × 0.9 cm column (resin UR 30, sodium citrate buffers, 0.2 *N* in sodium ion, p*H* 3.25 and 4.30 (buffer change appearing at 130 min), temperature 55.5 °C, flow rate 68 ml/min). Amino acid and dipeptide elution times (in min) were as follows: asn, 54; gln, 57; gly, 86; met, 140; metasn, 161; metgln, 160; alagly, 141.5.

To ensure rapid mixing in all the NCA coupling experiments a Waring blendor was used. Analytical scale experiments were run on 40.0 ml of solution in a jacketed blendor of 125 ml capacity. After acidification at the end of the run, the contents of the blendor were diluted to 100.0 ml and 0.1 ml applied to the amino acid analyzer column. Preparative scale experiments were run on approximately 300 ml of solution in a jacketed blendor of 1000 ml capacity. The measurement of p*H* was made with a Radiometer Titrator, Model TTTlc, equipped with a Thomas combination electrode, Model 4858-L60 (1/4 in. × 6 in.), standardized to p*H* 7.0 at 20 °C.

The N-Carboxyanhydrides

These compounds were prepared in a *Hood* according to established procedures (1, 8, 10), L-methionine NCA, m.p. 34–35 °C dec. (lit. m.p. 42–44 °C dec. (8); 36–37° dec. (9)); L-alanine NCA, m.p. 89–90 °C dec. (lit. m.p. 90° dec. (10)).

Preparation of Methionylasparagine (metasn)

Methionylasparagine (m.p. 227–228 °C (sealed capillary); $[\alpha]_D$ + 12.7° (*c* 1.74, 10% NH_4OH); R_f 0.31) was prepared by each of the methods below.

Anal. Calcd. for $C_9H_{17}N_3O_4S$: C, 39.56; H, 6.23; N, 15.88: Found: C, 39.39; H, 6.29; N, 15.61.

(a) Borate Buffer.

Asparagine was dissolved in sodium borate buffer, p*H* 10.0, 0.4 *M* in borate, to give a solution containing 1 m*M* asparagine in 10 ml. The solution was cooled to 2 °C in the blendor and the p*H* adjusted to 10.2 with 4 *N* NaOH. Solid methionine NCA (10% excess) was added in one portion to the rapidly stirred solution while the p*H* was maintained at 10.2 with 4 *N* NaOH. At cessation of base uptake (approximately 3 min) the solution was rapidly acidified to p*H* 3–4 with concentrated HCl.

Isolation of the product was accomplished by evaporation of the filtered and acidified solution to dryness and extraction of the residue with hot methanol. Evaporation of the methanol gave a residue which was crystallized from ethanol–water to yield the pure dipeptide. A preparative experiment gave 4.4 gm dipeptide from 5.9 gm asparagine (37% yield).

(b) Triethylamine

Asparagine was dissolved in water to make a solution containing 1 m*M* asparagine in 10 ml. The solution was cooled to 2 °C in the blendor and the p*H* adjusted to 10.2 with neat triethylamine (approximately 0.2 ml per m*M* of amino acid). Solid methionine NCA (10% excess) was added in one portion to the rapidly stirring mixture while the p*H* was maintained at 10.2 by the syringe addition of triethylamine. At cessation of base uptake (approximately 3 min) the solution was rapidly acidified to p*H* 3–4 with concentrated formic acid.

Product isolation was accomplished as follows: the filtered and acidified solution was evaporated to remove the water. The oily residue was triturated several times with chloroform to yield a solid residue. This residue was crystallized from ethanol–water to give pure dipeptide. A preparative experiment gave 6.2 gm dipeptide from 5.9 gm asparagine (53% yield).

Methionylglutamine

Methionylglutamine (m.p. 215–216 °C (sealed capillary); $[\alpha]_D$ +13.80° (*c* 1.5, 10% NH_4OH); lit. m.p. 220–221 °C (12*a*), 232–233 °C (12*b*); $[\alpha]_D$ +14.1° (10% NH_4OH) (11*a*), $[\alpha]_D$ +17.3° (*c* 1.4 10% NH_4OH) (11*b*); R_f 0.33) was prepared by both the procedures above.

Anal. Calcd. for $C_{10}H_{19}N_3O_4S$: C, 43.32; H, 6.86; N, 15.16. Found: C, 43.57; H, 6.99; N, 15.29.

Work-up for the borate procedure (*a*) consisted of concentration of the filtered reaction mixture to about one half the original volume, cooling overnight, and filtering to remove the resulting crystals. Additional crystals could be obtained from the filtrate by addition of a small amount of ethanol and cooling. An analytical scale experiment gave 200 mg of dipeptide from 730 mg of glutamine (14.5% yield). Work-up for the triethylamine procedure (*b*) consisted of evaporation of the filtered reaction mixture to an oily residue, trituration with chloroform, and crystallization of the resulting solid from ethanol–water. A preparative scale experiment gave 7.8 gm dipeptide from 6.3 gm of glutamine (65% yield).

Alanylglycine

Alanylglycine ($[\alpha]_D$ +22.4° (*c* 1.9, 0.5 *N* HCl); (lit. $[\alpha]_D$ +22.6° (*c* 2.0, 0.5 *N* HCl) (12); R_f 0.21) was prepared by the triethylamine procedure (*b*) only.

Anal. Calcd. for $C_5H_{10}N_2O_3$: N, 19.15. Found: N, 18.98.

Work-up was essentially the same as for the methionyl dipeptides. Crystallization was from ethanol–water. A preparative experiment gave 5.7 gm of dipeptide from 3.8 gm of glycine (80% yield).

Results and Discussion

In general, product isolation from the reaction mixture after peptide formation by the NCA procedure implies the use of one or more of four general methods. For water insoluble products their isolation is achieved simply by filtering the mixture. For those compounds that are soluble

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in water and insoluble in organic solvents addition of a water-miscible organic solvent, *e.g.* alcohol, usually results in the crystallization of the product from solution. For products that are soluble in organic solvents, evaporation of the water and extraction of the residue by the organic solvent usually suffices. Finally, for compounds not readily isolated by the above methods, chromatography of the reaction mixture has to be used. Carbon, silica gel, and ion exchange columns have been so far used (3).

In all cases the product must be isolated from the side products of the reaction including the starting amino acids and the buffer components. Since the reaction is run at a concentration of reactants of 0.01 *M* and a buffer concentration of 0.4 *M* the buffer components thus constitute a major portion of the residues and present a major separation problem.

In conjunction with other work going on in these laboratories (13) the preparation of two dipeptides, methionylasparagine (metasn) and methionylglutamine (metgln), became necessary. These two compounds served to illustrate to us the problems that are faced when product isolation after use of the NCA reaction is attempted. This led us to try to further simplify the procedure for product isolation.

The preparation of metasn from methionine NCA and asparagine by the borate procedure led to the production of a product which was soluble in both water and an organic solvent (methanol). It could be isolated by the complete evaporation of the reaction mixture and extraction of the residue with hot methanol. Subsequent crystallization of the extracted material from ethanol–water led to the isolation of pure product (37% yield).

The preparation of metgln led to a product that was slightly insoluble in water and almost completely insoluble in organic solvents. The isolation of adequate quantities of this compound proved very difficult. A small amount (15% yield) could be isolated either by concentration of the reaction mixture or by addition of a small amount of alcohol to the cooled solution. In both cases, as indicated by t.l.c., the major portion of the product remained in solution and could only be isolated along with large quantities of the buffer components.

The problems faced in the isolation of adequate quantities of the latter compound led us to consider the complete removal of the buffer components from the reaction mixture to aid in the product isolation.

Closer consideration of the reaction sequence (see Scheme 1) indicates that the reaction is simply the attack of an amino acid in the unprotonated form (A) on the NCA. The presence of an added buffer might not be absolutely necessary for the reaction to take place in adequate fashion. As long as the p*H* of the solution could be maintained above that corresponding to the pK_a of the α-amino group of the attacking amino acid the reaction should occur. It would be only necessary to use a base to establish and maintain the p*H* of the solution so that sufficient unprotonated α-amine would be present to react with the NCA. The base used could be either an inorganic one or a nonnucleophilic organic one. The amino acid being used as the nucleophile would be now serving as its own "buffer".

Use of an inorganic base, however, leads back to the same problem of removing it from the solution after the reaction. The use of an organic base would not necessarily suffer from this problem since it could be more easily removed from the evaporated mixture by trituration of the residue with an organic solvent in which the products were not soluble.

A series of analytical experiments were then run in order to see if the removal of the external buffer made any difference to the reaction yields. The preparation of metasn was attempted with no external buffer being used. The organic base selected was triethylamine. This liquid tertiary amine base is easily handled and is sufficiently strong as a base (pK_a 10.6) to allow the p*H* of the solution to be maintained above that of the pK_a of the α-amino group of most amino acids.

To allow a comparison with the borate procedure, metasn was prepared both ways under identical experimental conditions. The results are tabulated in Table 1. Under experimental conditions identical with those recommended for use with the borate buffer the per cent of asparagine consumed from solution was identical within experimental error for each procedure. The use of triethylamine did give a slightly better overall yield of dipeptide. This is attributable to the fact that conversion of the initial NCA/asparagine reaction product (Scheme 1, C) to metasn was beset by fewer side reactions.

TABLE 1. NCA preparation of methionylasparagine (metasn). Comparison of borate and triethylamine procedures*

Reaction medium	p*H*†	Temperature (°C)	% asparagine consumed‡, ‖	Overall yield§, ‖
Sodium borate	10.3	2	75	47
Triethylamine	10.3	2	80	63

*Analytical scale experiments (4 m*M*), 1 m*M* asn/10 ml of solution, rapid mixing, methionine NCA added as a solid (10% excess), RJG 1/79,83.
†Electrode standardized to p*H* 7.0, 20 °C.
‡Calculated as m*M* asn consumed from the solution/m*M* asn in solution at start × 100.
§Calculated as m*M* metasn formed/m*M* asn in solution at the start × 100.
‖Experimental errors, determined for at least three runs, amounted to approximately ±8% in each one of these calculated percentages. This variability can be attributed in part to the purity of the NCA used, the rate at which it was added, the variation of the p*H* from that desired during the reaction, as well as the time elapsed before the reaction was acidified in order to terminate it.

TABLE 2. NCA preparation of dipeptides. Comparison of borate and triethylamine procedures; isolated yields

Dipeptide	Dipeptide isolated yield (%)*	
	Borate	Triethylamine
Methionylasparagine	37	53
Methionylglutamine	15	65
Alanylglycine	—	80

*All yields are those isolated after purification by crystallization from a suitable solvent.

To be synthetically useful, any new modification should improve isolated yields. A few analytical scale runs might be necessary to ensure optimum conditions for most preparative scale experiments (approximately 30 m*M*, 5–10 g scale). For metasn and metgln, however, conditions approximating those recommended for the borate procedure, p*H* 10.2 and 2 °C, were chosen for the preparative runs since close p*H* control was possible and the overall reaction yields as determined by the analytical scale experiments were still synthetically acceptable. Methionylasparagine, methionylglutamine and, as an additional check on the procedure, alanylglycine were prepared using these conditions and the yields of pure product isolated are given in Table 2. These yields can be compared with those found for the preparative runs where borate was used as an added buffer. The advantage of using triethylamine to establish and maintain the p*H* is obvious. The higher yields resulted mainly from the simplification of the isolation procedure. After reaction, the p*H* of the solution was lowered to approximately 3.5 with an organic acid (*e.g.* formic acid) to form a completely organic acid/base salt (triethylamine formate). Trituration of the evaporated reaction mixture with chloroform to remove this acid/base salt gave a solid residue. The solid residue containing starting amino acids and product was finally crystallized from a suitable solvent to give the analytically pure dipeptides.

In summary, the use of an organic base to establish and maintain the p*H* during the reaction of an amino acid NCA with another amino acid is sufficient for the preparation of dipeptides in yields which are synthetically useful. The isolation of the resulting products is, in addition, aided since the added base (in this case, triethylamine), as an organic acid/base salt, can be easily removed by trituration of the evaporated reaction mixture with an organic solvent and the dipeptide can then be crystallized from a suitable solvent. Chromatography would have to be applied only where starting materials and side products were inseparable from the products by crystallization. Even here, prior removal of the large quantities of acid/base salt would be of benefit to the chromatographic separation.

ET

F. BISSONNETTE

Département de Chimie, Collège Militaire Royal de St-Jean, St-Jean, Québec

Reçu le 14 juin 1971

Le coefficient de frottement d'une chaîne de polymère en solution peut être relié soit au coefficient de sédimentation soit à la viscosité de la solution. Plusieurs auteurs ont essayé de trouver des constantes universelles pour relier les mêmes valeurs déterminées par ultracentrifugation et par viscosimétrie. Il existe présentement certaines divergences dans l'interprétation des résultats, ces divergences venant surtout des points de vue différents sur le comportement des polymères en solvant thêta. Le présent travail étudie l'effet de concentration sur le coefficient de sédimentation au voisinage du point thêta pour des solutions de polystyrène dans le cyclohexane et de polyisobutylène dans le *n*-heptanoate d'éthyle. Pour fin d'interprétation, ce travail nécessite aussi des mesures de viscosité et de diffusion de la lumière dans les mêmes conditions. Les résultats sont interprétés à la lumière des théories de Wales et Van Holde, de Yamakawa, de Pyun et Fixman et d'Imai. Seule la théorie de Pyun et Fixman admet un effet de la concentration sur le coefficient de sédimentation au point thêta et les résultats expérimentaux rapportés dans ce travail appuient cette théorie.

Sedimentation coefficients (ultracentrifuge), second virial coefficients (light scattering) and intrinsic viscosities have been measured at various concentrations near the θ-point for solutions of polystyrene in cyclohexane and of polyisobutylene in ethyl heptanoate. The results have been analyzed in the light of several current theories, but are correlated satisfactorily only by the theory of Pyun and Fixman.

Canadian Journal of Chemistry, **50**, 305 (1972)

Introduction

Il est bien connu que le coefficient de sédimentation d'une macromolécule en solution varie avec la concentration. Cette variation peut être mathématiquement représentée par la relation

$$[1] \qquad \frac{1}{S_0} = \frac{1}{S_0^0}(1 + k_s c)$$

où S_0 et S_0^0 sont les coefficients de sédimentation sous une pression d'une atmosphère à la concentration c, exprimée en g/100 cc, et à dilution infinie respectivement. La constante k_s, en relation avec les propriétés thermodynamiques et hydrodynamiques des macromolécules en solution, a fait l'objet de plusieurs travaux théoriques. Ainsi, Wales et Van Holde (1), en admettant la définition du coefficient de frottement à dilution infinie donnée par

$$[2] \qquad f_0 = \eta_0 P \langle R_0^2 \rangle^{\frac{1}{2}}$$

où η_0 est la viscosité du solvant, P, une constante et $\langle R_0^2 \rangle$, la distance quadratique moyenne entre les bouts d'une chaîne non perturbée, en admettant également la théorie de Fox–Flory sur la viscosité des solutions de polymères et la relation de Burgers relative à la constante de sédimentation de particules sphériques en suspension, arrivent à la relation

$$[3] \qquad k_s/[\eta] = \Lambda N_A (\Phi^{\frac{1}{3}} P^{-1})^{-3}/16200\,\pi^2$$

où Λ est une constante venant de la théorie de Burgers, N_A, le nombre d'Avogadro, Φ, la

For personal use only.

constante universelle de Fox–Flory et $[\eta]$, la viscosité intrinsèque. L'équation [3] montre que k_s est proportionnel à $[\eta]$ et que la constante de proportionalité (1.66) est indépendante de la nature du solvant, de la température et de la masse moléculaire du polymère. Par ailleurs, le traitement théorique de Yamakawa (2) veut que la valeur de k_s soit nulle à la température thêta, *i.e.* que S_0 soit indépendant de la concentration dans ces conditions. D'après sa théorie, $k_s/[\eta]$ est défini par

$$[4] \qquad k_s/[\eta] = \lambda(x)(A_2M/[\eta])$$

où $x = z/\alpha_0^3$, z étant le paramètre du volume exclu, α_0, le coefficient d'expansion linéaire à dilution infinie, A_2, le deuxième coefficient du viriel et M, la masse moléculaire du polymère. En bon solvant, $\lambda(x) \simeq 1.1$ et $(A_2M/[\eta]) \simeq 1.5$ et ainsi on se rapproche de la valeur constante de la relation [3]. Cependant, au point thêta, $A_2 = 0$ et $k_s/[\eta]$ s'annule. Un certain nombre de résultats expérimentaux (3–5) semblent confirmer les prédictions de la théorie de Yamakawa tandis que d'autres résultats la mettent en doute (6–13). Pyun et Fixman (14) ont relevé des faiblesses dans le développement théorique de Yamakawa; ce dernier a fait certaines approximations mathématiques discutables et il n'a pas tenu compte de l'effet de perturbation hydrodynamique sur la fonction de distribution intra et intermoléculaire dans les équations de base. Pyun et Fixman on traité le cas des sphères rigides et celui des sphères interpénétrables et ils ont trouvé pour k_s l'expression suivante

$$[5] \quad k_s = (4/300)(M/N_A\pi)^2 \times [(1 - \bar{v}\rho_0)/6\eta_0 S_0^0]^3[7.16 - \kappa(A)]$$

où $\bar{v}$ est le volume spécifique partiel du polymère, ρ_0, la densité du solvant et $\kappa(A)$ est une fonction où $A = 3n^2\ X/8\pi a^3$, n étant le nombre de segments par chaîne, a, le rayon de la sphère et X, le deuxième coefficient du viriel pour les intéractions segment–segment. Pour des petites valeurs de A, $\kappa(A)$ peut s'écrire (15)

$$[6] \qquad \kappa(A) = \kappa_0 - A\kappa_1 + A^2\kappa_2 + \ldots$$

Pour le cas de sphères interpénétrables, la valeur de $\kappa_0 = 4.2$ à 4.93 selon le modèle choisi pour décrire les intéractions hydrodynamiques entre les sphères. De plus, étant donné que $X \propto A_2$, $n^2 \propto M^2$ et que $a = (1 - \bar{v}\rho_0)M/6\pi\eta_0 N_A S_0^0$, l'équation [5] peut être réécrite sous la forme (14)

$$[7] \qquad k_s/[\eta] = C(7.16 - \kappa_0 + C'A_2M/[\eta])$$

où C et C' sont deux constantes. Au point thêta, $A = 0$, mais $\kappa(0) \neq 0$; il s'ensuit que $k_s \neq 0$ au point thêta contrairement à la théorie de Yamakawa. La constante k_s s'annule pour $A \simeq -1$, *i.e.* à une température inférieure à thêta pour le modèle des sphères interpénétrables. Plus récemment, Imai (16) a élaboré un long traitement mathématique à partir des relations de Fixman sur l'effet de la concentration sur la fonction de distribution des segments d'une chaîne de polymère et il a trouvé que k_s est relié au coefficient d'expansion linéaire viscosimétrique α_η de la façon suivante

$$[8] \qquad k_s = C_0M^{\frac{1}{2}}(\alpha_\eta - \alpha_\eta^{-1})$$

ou

$$[8a] \qquad k_s/[\eta] \simeq b(\alpha_\eta^{-2} - \alpha_\eta^{-4})$$

où C_0 et b sont des constantes dépendant des dimensions de la chaîne non-perturbée.

Ce présent travail rapporte les résultats obtenus sur l'étude de la variation de k_s avec la concentration au voisinage de la température thêta pour deux systèmes polymère-solvant différents et ses relations avec $[\eta]$ et A_2.

Partie expérimentale

Les échantillons de polystyrène (PS) utilisés dans ce travail proviennent de diverses sources; quatre fractions soient celle de $\bar{M}_p = 411\,000$ (Pressure Chemical Company), celle de 125 000 (Dr. McCormick, Dow Chemical of Canada) et celles de 2 380 000 et 1 590 000 (17) sont de très faible polydispersité ($\bar{M}_p/\bar{M}_n \leqslant 1.07$); les échantillons dont $\bar{M}_p = 7\,900\,000$ et 1 790 000 (17) et finalement, 243 000 (Lustrex, Monsanto) ne sont pas fractionnés. Les deux échantillons de polyisobutylène (PIB) proviennent d'un double fractionnement d'un polymère commercial Vistanex L-100 (Enjay Co. Inc.) et $\bar{M}_p = 920\,000$ et 1 750 000, respectivement (18). Les solvants utilisés sont de qualité réactif analytique.

Les mesures de sédimentation sont effectuées à l'aide d'une ultracentrifugeuse analytique Spinco modèle E-HT; les détails techniques et la façon de traiter les données expérimentales ont déjà été décrits ailleurs (19). Les viscosités intrinsèques sont obtenues à partir de mesures effectuées à l'aide d'un viscosimètre automatique Hewlett–Packard; la température du bain est maintenue à $\pm$ 0.05 °C. Les valeurs du second coefficient du viriel sont tirées de données expérimentales de diffusion de la lumière obtenues à l'aide d'un photo-gonio-diffusomètre Sofica; la technique expérimentale est décrite ailleurs (20). Les concentrations des solutions ne dépassent pas 0.5% (P/V) pour les différentes techniques utilisées.

Résultats et discussion

Les résultats pour quatre systèmes polymère–solvant sont donnés dans le Tableau 1. Les valeurs de α_η ont été calculées à partir de la relation

$$[9] \qquad [\eta] = [\eta]_\theta \alpha_\eta^3$$

où $[\eta]_\theta$ est la viscosité intrinsèque à la température thêta. Les valeurs de A_2 ont été calculées par la méthode graphique de Zimm. Dans tous les calculs où apparait la masse moléculaire du polymère, c'est la valeur moyenne en poids ($\bar{M}_p$) qui a été utilisée. La courbe de la Fig. 1 montre que $k_s/[\eta]$ est une fonction monotone de la température contrairement aux prédictions de la relation [3], et qu'elle ne s'annule pas au point thêta contrairement aux prédictions de la relation [4]. Cependant, il semble que $k_s/[\eta]$ tende lentement vers la valeur limite de 1.66 lorsqu'on s'éloigne au-dessus de la température thêta, en accord avec les théories de Wales et Van Holde et de Yamakawa.

La Fig. 2 montre que $k_s[\eta]$ est bien une fonction linéaire de $A_2M/[\eta]$ tel que prévu par les relations [4] et [7] sauf qu'elle ne passe pas par l'origine des coordonnées au point thêta comme prédit par la relation [4].

En ce qui concerne la variation de $k_s/[\eta]$ en fonction du coefficient d'expansion linéaire, la Fig. 3 montre que son allure correspond bien à celle prédite par l'équation [8*a*] sauf que les droites ne passent pas par l'origine des coordonnées à la température thêta. L'équation empirique est plutôt de la forme

$$[10] \qquad k_s/[\eta] \simeq (k_s/[\eta])_\theta + b(\alpha_\eta^{-2} - \alpha_\eta^{-4})$$

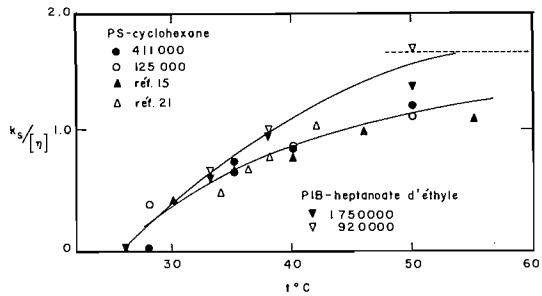

FIG. 1. Variation de $k_s/[\eta]$ en fonction de la température; la droite brisée représente la valeur limite 1.66.

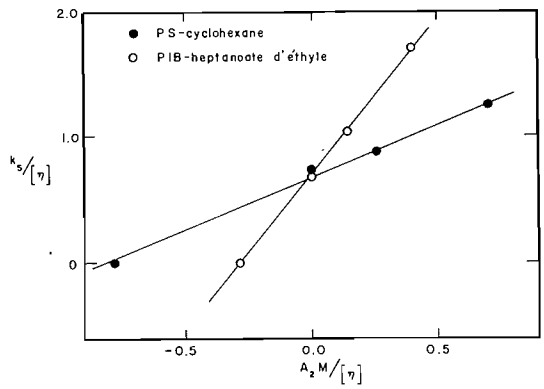

FIG. 2. Variation de $k_s/[\eta]$ en fonction de $A_2M/[\eta]$.

For personal use only.

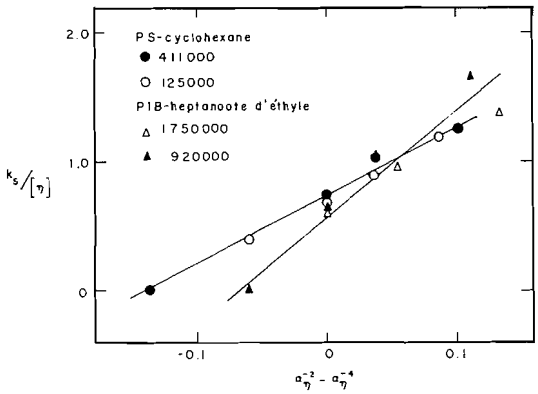

FIG. 3. Variation de $k_s/[\eta]$ en fonction de $(\alpha_\eta^{-2} - \alpha_\eta^{-4})$.

Dans le cas du système PS–cyclohexane, $b = 5.0$ tandis que Petrus et coll. rapportent une valeur de 4.5 pour le même système. Selon l'équation [10], la fonction $k_s/[\eta]$ dépend d'une part de la fonction de distribution des segments, contribution représentée par le deuxième terme tel que défini par Imai et d'autre part, de sa valeur propre au point thêta qui est due principalement à l'effet hydrodynamique décrit par Pyun et Fixman et à l'effet d'environnement décrit par Orofino (23), *i.e.* que $(k_s/[\eta])_0$ serait fonction de la nature du solvant thêta utilisé. En définitive, il semble bien que la théorie de Pyun et Fixman dans le cas de sphères interpénétrables soit celle qui se rapproche le plus des résultats expérimentaux présentés dans ce travail. Une petite remarque d'ordre pratique découle de ceci; il serait préférable de travailler à une température inférieure, à la température thêta lorsqu'on veut utiliser la méthode de la sédimentation à l'analyse de la polydispersité d'un échantillon de polymère afin d'éliminer toute correction due à l'effet de concentration. Cette température reste à déterminer empiriquement pour chaque cas car elle varie avec la masse moléculaire (15, 21).

Il existe, bien sûr, une relation entre k_s et $\bar{M}_p$ à une température donnée pour un système donné. A partir des relations [3] ou [7], il est possible de montrer que cette relation à la température thêta est de la forme (14)

$$[11] \qquad k_s = cte\ \bar{M}_p^{\frac{1}{2}}$$

Une telle relation est illustrée dans la Fig. 4 où sont groupés les résultats de ce travail et ceux de la littérature pour le système PS–cyclohexane à 34.5 °C. Dans le cas d'échantillons polydispersés, les résultats donnent une droite qui semble parallèle à celle obtenue pour les échantillons de faible polydispersité et la valeur moyenne des deux pentes est de 0.52×10^{-3} comparativement à 0.48×10^{-3} calculée par Pyun et Fixman.

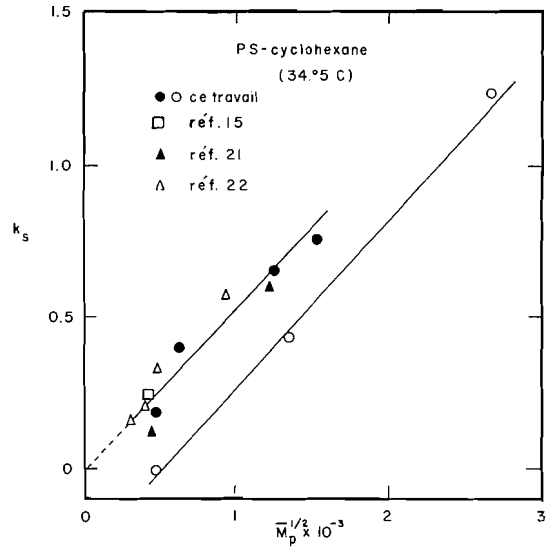

FIG. 4. Variation de k_s en fonction de $\bar{M}_p$ pour le polystyrène dans le cyclohexane à 34.5 °C. La droite supérieure est en relation avec les échantillons monodispersés et la droite inférieure, avec les échantillons polydispersés.

The Dipole Moment Derivative of the Hydrogen Bond in Ice[1]

E. WHALLEY

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 28, 1971

The dipole moment derivative of the hydrogen bond in ice has been calculated assuming that the molecules can be represented as non-overlapping polarizable charge distributions characterized by dipole and quadrupole moments. The value is 0.1 electron charges which is about one third of the experimental value obtained from the far-infrared spectrum. The model predicts therefore only about one tenth of the experimental integrated intensity from which the effective charge was derived. Most of the intensity must therefore be due to specific hydrogen-bond interactions.

On a calculé la dérivée du moment dipolaire de la liaison hydrogène dans la glace en supposant qu'on peut représenter les molécules par des distributions de charges polarisables et sans recouvrement, caractérisées par des moments dipolaires et quadrupolaires. La valeur est de 0.1 charge d'électron, ce qui représente environ le tiers de la valeur expérimentale obtenue du spectre d'infra-rouge lointain. Donc, le modèle prédit seulement environ le dixième de l'intensité expérimentale intégrée, à partir de laquelle on avait dérivé la charge effective. La plupart de l'intensité doit donc être due à des interactions spécifiques de liaison hydrogène.

Canadian Journal of Chemistry, **50**, 310 (1972)

Introduction

It is quite generally accepted on quantum theoretical grounds[2] that hydrogen bonds cannot be explained by the classical interaction of non-overlapping polarizable charge distributions, and that there is probably an intermolecular transfer of charge when a hydrogen bond is formed. One of the strongest experimental evidences for this conclusion is the large increase in the intensity of the X—H stretching vibration when a hydrogen bond is formed.

Nevertheless, the effects of hydrogen bonding in ice are frequently described in terms of the interaction of classically polarizable molecules with permanent electrostatic moments (2, 3). Indeed, for many purposes only this kind of model is reasonably tractable, and it is often used to describe the polarization of a molecule by its neighbors. The dielectric constant of ice, for example, indicates (see ref. 4 for a brief recent discussion) that the dipole moment of a water molecule is enhanced appreciably by intermolecular interaction. If Kirkwood's correlation parameter g is taken as 3.0, which is the value calculated from the geometry of ice (5, 6), the dielectric constant indicates that the dipole moment is enhanced by a factor 1.3, which can easily be accounted for by the polarization of a molecule by the electrostatic field of the multipole moments of its neighbors.

A quantitative measure of the polarization of water molecules by hydrogen bonding (strictly speaking the variation of the polarization with hydrogen bonding) has recently been obtained (7) from another source. The far-infrared spectrum of ice below 320 cm^{-1} is caused by the translational vibrations of the molecules. The intensity of absorption of this band can be interpreted in terms of the dipole moment derivative $\boldsymbol{M}$ with respect to the change of intermolecular distance r

$$\boldsymbol{M}_i = d\boldsymbol{\mu}/dr_i$$

where subscript i refers to the ith bond and $\boldsymbol{\mu}$ is the dipole moment of the crystal. $\boldsymbol{M}$ has the dimensions of charge and is also known as the effective charge. Because ice I is orientationally disordered, $\boldsymbol{M}$ can have several different values and directions, and the quantity obtained from experiment is the root-mean-square value, denoted e^*, and has the value

$$e^* = 0.3e$$

where e is the electronic charge. The question to be discussed in this paper is the origin of this effective charge.

Its value has been calculated for the model in which the water molecules are treated as non-overlapping polarizable charge distributions. The calculations indicate that the model is quite inadequate.

Calculation of Multipole-induced Dipole Moments

In ice I the distribution of molecules is, at least on the average, tetrahedral. The tetrahedron is not perfect because the ratio of the c and a axes of the hexagonal unit cell is 1.6280 ± 0.0002 (8), instead of the 1.633 it would be if the tetrahedron were perfect. Nevertheless, the assumption of a perfect tetrahedron is adequate for our purposes. The intermolecular distance is taken as 2.76 Å, the intermolecular distance in ice. The effects of both the dipole and quadrupole moment are taken account of.

The vapor dipole moment of 1.85 D is assumed although the actual moment of a molecule in the solid is undoubtedly enhanced by intermolecular interaction. There is no simple way of taking account of this enhancement. It can be done, as shown in the Appendix, for an isolated pair of molecules, and the dipole moment derivative can be written as a power series in α/r^3 where α is the polarizability of the molecule. Since α/r^3 has the value 0.0687 (see below), it is a reasonable approximation to take only the first term, which is of the first power.

The quadrupole moments were those calculated from the "c.i.7" wave function of McWeeny and Ohno (9) by Glaeser and Coulson (10). The moments used were defined as

$$\Theta_{\alpha\beta} = \tfrac{1}{2}\int \rho(3r_\alpha r_\beta - r^2\delta_{\alpha\beta})\,d\mathbf{r}$$

where ρ is the charge density at position $\mathbf{r}$, r_α are components of $\mathbf{r}$, $d\mathbf{r}$ is the element of volume at position $\mathbf{r}$, and $\delta_{\alpha\beta}$ is the Kronecker delta function, and were centered on the oxygen nucleus. The values were $\Theta_{xx} = -1.211$, $\Theta_{yy} = 0.853$, and $\Theta_{zz} = 0.358$, all $\times 10^{-26}$ e.s.u. cm^2, where the z axis coincides with the molecular axis, the y axis is in the plane of the molecule, and the system is right-handed. Intermolecular interaction will undoubtedly change the quadrupole moment of a molecule in ice, but nothing is known about the change, and it is ignored. The polarizability of a water molecule is assumed to be isotropic and equal to 1.444 Å^3 per molecule as calculated from the visible refractive index extrapolated to infinite wavelength and the Lorentz–Lorenz equation (11, 12).

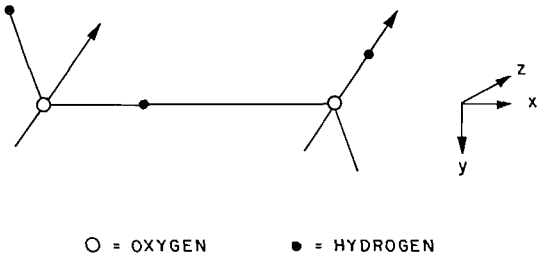

FIG. 1. The hydrogen-bonded water molecules. The left-hand molecule is in the plane of the paper. The plane of the right-hand molecule is perpendicular to the plane of the paper and in configuration S1 of Fig. 2.

For the calculations, the left-hand molecule was fixed in the position shown in Fig. 1, and the right-hand molecule rotated to the positions S1, S2, S2′, E1, E2, and E2′, shown in Fig. 2 in which Fig. 1 is viewed from the right. The dipole moment derivatives for settings S2 and S2′ and for E2 and E2′ differ of course only in direction but not in magnitude.

The effective charges of the pair of water molecules in the various settings, for a displacement along the lines of centers, is given in Table 1 where the coordinate system is that shown in Fig. 1.

The effective charge e^*/e does not differ more than 2% from the mean for any of the relative orientations of the molecules that occur in ice. It follows that its value for our model is 0.10 for both hexagonal and cubic ice.

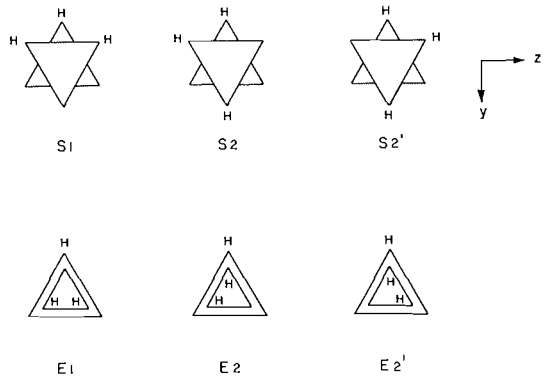

FIG. 2. Relative orientations of two water molecules in ice, viewed along the O---O bond from direction of the right-hand molecule in Fig. 1.

Discussion

The effective charge calculated for the model of non-overlapping polarizable charge distributions is only about one third of the experimental value. The model therefore predicts only about one tenth of the experimental infrared integrated intensity from which the effective charge was derived.

The calculations have neglected the moments induced by the induced moments. The induced moment can be obtained in several ways. Coulson and Eisenberg (2) calculated the average field at a molecule due to its neighbors and calculated the induced moment from this field and the low-field polarizability. The total moment obtained in this way is 1.41 times the moment of the isolated molecule. The contribution of the orientation polarization to the dielectric constant yields the moment that reorients when a molecule reorients. According to Onsager's theory (13), the reorienting moment is greater than the moment μ_0 of the isolated molecule because of the effect of the reaction field. For substances of high dielectric constant like ice the enhancement factor is $(n^2 + 2)/3$, where n is well approximated by the visible refractive index. For ice it is 1.15. According to Kirkwood's theory (14), the difference between the limiting dielectric constants ε_0 and ε_∞ at low and high frequency of the orientation polarization region is, for substances of high dielectric constant,

$$\varepsilon_0 - \varepsilon_\infty = 2\pi N g \mu^2 / kT$$

where g is an orientation correlation parameter. The value of g calculated for ice from the known structure is 3.0 (5, 6) and this with the measured values (ref. 15 and many later workers) of ε_0 and ε_∞ leads to the value of μ of 1.3 times the vapor value. None of these moments is high enough to significantly reduce the discrepancy between theory and experiment. The relationship between them and the "effective moment" of a molecule for the translational vibrations is not at all clear. Nevertheless, it would seem impossible that the "effective moment" could be three times the moment of the isolated molecule which is what would be required to bring experiment and theory into agreement. It is concluded therefore that the model of non-overlapping polarizable dipolar and quadrupolar molecules fails by about an order of magnitude to explain the integrated far-infrared intensity of ice.

It follows therefore that there is a strong polarization caused by varying the O---O distance that is not accounted for on our model. Either the moment induced in each molecule by a small variation of the O---O distance is much greater than the simple model would imply, or there is a transfer of charge from one molecule to the other. Experiment can, at present, tell us no more.

Most quantum mechanical theories of hydrogen bonding discuss it in terms of charge transfer between molecules, but none has calculated the effective charge in the sense used in this paper. Kollman and Allen (16) on the other hand, using what are described as essentially Hartree–Fock-quality atomic orbitals as a basis, conclude that the enhancement of the O—H stretching intensity of water on hydrogen bonding is due more to charge redistribution within a molecule than to charge transfer. It appears that at present only theory can decide the relative importance of intermolecular charge transfer and intramolecular charge redistribution.

Appendix

We consider two molecules 1 and 2 carrying permanent dipoles $\boldsymbol{\mu}_{10}$ and $\boldsymbol{\mu}_{20}$ and dipoles $\boldsymbol{m}_{10}$ and $\boldsymbol{m}_{20}$ induced by their mutual interaction. The total moments of the molecules are therefore

$$\boldsymbol{\mu}_1 = \boldsymbol{\mu}_{10} + \boldsymbol{m}_{10} \quad [1]$$

$$\boldsymbol{\mu}_2 = \boldsymbol{\mu}_{20} + \boldsymbol{m}_{20} \quad [2]$$

The vector $\boldsymbol{r}$ joins the molecular centers. The moment induced in one molecule by the dipole of the other is the polarizability multiplied by the field. If the polarizability is isotropic, then

$$\boldsymbol{m}_{10} = \beta\left\{\frac{(3\boldsymbol{\mu}_2 \cdot \boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{\mu}_2\right\} \quad [3]$$

$$\boldsymbol{m}_{20} = \beta\left\{\frac{3(\boldsymbol{\mu}_1 \cdot \boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{\mu}_1\right\} \quad [4]$$

where

$$\beta = \alpha/r^3$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

By inserting eqs. 1 and 2 into eqs. 3 and 4

$$[5]\quad \boldsymbol{m}_{10} = \beta\left\{\frac{3(\boldsymbol{\mu}_{20}\cdot\boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{\mu}_{20} + \frac{3(\boldsymbol{m}_{20}\cdot\boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{m}_{20}\right\}$$

$$[6]\quad \boldsymbol{m}_{20} = \beta\left\{\frac{3(\boldsymbol{\mu}_{10}\cdot\boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{\mu}_{10} + \frac{3(\boldsymbol{m}_{10}\cdot\boldsymbol{r})\boldsymbol{r}}{r^2} - \boldsymbol{m}_{10}\right\}$$

Then we find

$$[7]\quad \boldsymbol{m}_{10}\cdot\boldsymbol{r} = \beta(2\boldsymbol{\mu}_{20}\cdot\boldsymbol{r} + 2\boldsymbol{m}_{20}\cdot\boldsymbol{r})$$

$$[8]\quad \boldsymbol{m}_{20}\cdot\boldsymbol{r} = \beta(2\boldsymbol{\mu}_{10}\cdot\boldsymbol{r} + 2\boldsymbol{m}_{10}\cdot\boldsymbol{r})$$

$$[9]\quad \boldsymbol{m}_{10}\times\boldsymbol{r} = -\beta(\boldsymbol{\mu}_{20}\times\boldsymbol{r} - \boldsymbol{m}_{20}\times\boldsymbol{r})$$

$$[10]\quad \boldsymbol{m}_{20}\times\boldsymbol{r} = -\beta(\boldsymbol{\mu}_{10}\times\boldsymbol{r} - \boldsymbol{m}_{10}\times\boldsymbol{r})$$

By appropriate combinations from eqs. (7)–(10)

$$[11]\quad \boldsymbol{m}_{10}\cdot\boldsymbol{r} = \frac{2\beta}{1-4\beta^2}(\boldsymbol{\mu}_{20}\cdot\boldsymbol{r} - 2\beta\boldsymbol{\mu}_{10}\cdot\boldsymbol{r})$$

$$[12]\quad \boldsymbol{m}_{10}\times\boldsymbol{r} = -\frac{\beta}{1-\beta^2}(\boldsymbol{\mu}_{20}\times\boldsymbol{r} - \beta\boldsymbol{\mu}_{10}\times\boldsymbol{r})$$

and there are similar equations for the components of $\boldsymbol{m}_{20}$.

The terms in the first power of β in eqs. 11 and 12 describe the polarizations induced directly by the permanent moments of each molecule, and the terms of higher order in β describe the moments induced by the mutual induction. The value of β for ice is 0.069, and so no significant error is made if second and higher order terms are ignored.

The derivatives of the components of the moment with respect to the intermolecular distance is given by

$$r\frac{\partial}{\partial r}\left(\frac{\boldsymbol{m}_{10}\cdot\boldsymbol{r}}{r}\right) = -\frac{6\beta(1+4\beta^2)}{(1-4\beta^2)^2}\frac{\boldsymbol{\mu}_{20}\cdot\boldsymbol{r}}{r} - \frac{24\beta^2}{(1-4\beta^2)^2}\frac{\boldsymbol{\mu}_{10}\cdot\boldsymbol{r}}{r}$$

$$r\frac{\partial}{\partial r}\frac{\boldsymbol{m}_{10}\times\boldsymbol{r}}{r} = \frac{3\beta(1+\beta^2)}{(1-\beta^2)^2}\frac{\boldsymbol{\mu}_{20}\times\boldsymbol{r}}{r} + \frac{6\beta^2}{(1-\beta^2)^2}\frac{\boldsymbol{\mu}_{10}\times\boldsymbol{r}}{r}$$

I am indebted to Miss M. B. Howes for help with the calculations.

An X-Ray Structure Determination of the Twinned Crystals of Dinitrato-2,2′-dipyridylsilver(II)

G. W. BUSHNELL AND M. A. KHAN
Department of Chemistry, University of Victoria, Victoria, British Columbia

Received July 27, 1971

The crystal structure of dinitrato-2,2′-dipyridylsilver(II) has been solved and refined to an *R*-value of 0.070. Four circle diffractometer measurements were obtained from the twinned triclinic crystals. The unit cell dimensions at 22 °C are: $a = 697.5 \pm 0.2$ pm, $b = 999.4 \pm 0.2$ pm, $c = 1032.2 \pm 0.2$ pm, $\alpha = 113.46 \pm 0.02°$, $\beta = 100.71 \pm 0.02°$, $\gamma = 95.28 \pm 0.02°$. The space group is $P\bar{1}$ (No. 2) with two molecules per unit cell. The density is 2.06 ± 0.04 g cm^{-3} (measured), 2.02 g cm^{-3} (calculated). The four shortest bond lengths to silver are: Ag—O(1), 214.8 ± 1.5 pm; Ag—O(4), 213.6 ± 1.5 pm; Ag—N(1), 212.4 ± 1.6 pm; Ag—N(2), 220.7 ± 1.6 pm. These four bonds are distorted from square planar geometry with the silver atom lying 19.90 ± 0.17 pm out of the mean plane of the other four atoms. There are also long bonds to the nitrato groups of neighboring molecules: Ag—O(1′), 275.3 ± 1.3 pm; Ag—O(2″), 276.3 ± 1.6 pm. Inclusion of these bonds gives a distorted octahedral silver coordination. Though predominantly unidentate, there is a slight tendency toward bidentate bonding in both nitrato ligands: Ag—O(2), 305.8 ± 1.4 pm; Ag—O(5), 295.0 ± 1.7 pm. O(2) and O(5) approach the convex side of the distorted square planar coordination. The deviation from planarity of the closely bonded square, and angular distortions in the above mentioned octahedral coordination can be rationalized by considering the silver as eight coordinate. The bonds to silver may be grouped 4:2:2 by length or 4:3:1 by angular disposition.

Nous avons a déterminé la structure cristalline du dinitrato-2,2′-dipyridylargent(II) et l'avons raffinée pour obtenir une valeur de *R* de 0.070. Nous avons obtenu des mesures avec un diffractomètre à quatre cercles pour les cristaux tricliniques jumelés. Les dimensions de la maille à 22 °C sont $a = 697.5 \pm 0.2$ pm, $b = 999.4 \pm 0.2$ pm, $c = 1032.2 \pm 0.2$ pm, $\alpha = 113.46 \pm 0.02°$, $\beta = 100.71 \pm 0.02°$, $\gamma = 95.28 \pm 0.02°$. Le groupe spatial est $P\bar{1}$ (No. 2) avec deux molécules par maille. La densité est 2.06 ± 0.04 g cm^{-3} (mesuré), 2.02 g cm^{-3} (calculé). Les quatre liens les plus courts de l'argent sont: Ag—O(1), 214.8 ± 1.5 pm; Ag—O(4), 213.6 ± 1.5 pm; Ag—N(1), 212.4 ± 1.6 pm; Ag—N(2), 220.7 ± 1.6 pm. Ces quatre liens sont déformés à la géométrie du plan carré, l'atome d'argent se situant à 19.90 ± 0.17 pm en dehors du plan formé par les quatre autres atomes. Il y a aussi des liens longs entre l'argent et les groupes nitrato des molécules avoisinantes: Ag—O(1′), 275.3 ± 1.3 pm; Ag—O(2″), 276.3 ± 1.6 pm. L'inclusion de ces liens donne à l'argent une coordination octaédrique déformée. Même si les liens ont une prédominance à être monodentés, on remarque une légère tendance vers des liens bidentés pour les deux ligands nitrato: Ag—O(2), 305.8 ± 1.4 pm; Ag—O(5), 295.0 ± 1.7 pm. O(2) et O(5) approchent le côté convexe de la coordination du plan carré déformé. La deviation des quatre atomes liés de près à une structure planaire, ainsi que les déformations angulaires dans la coordination octaédrique ci-dessus mentionnée, peut-être rationnalisée en considerant l'argent comme ayant une coordination de huit. On peut grouper les liens à l'argent dans le rapport 4:2:2 pour la longueur ou 4:3:1 pour la disposition angulaire.

Canadian Journal of Chemistry, **50**, 315 (1972)

Introduction

There are many known crystal structures of copper(II) complexes and relatively few for silver(II) compounds. The difference in reduction potential between $e + Ag^{2+} \rightarrow Ag^{+}$ ($E^0 = +1.987$ *V* in 4 *M* $HClO_4$) and $e + Cu^{2+} \rightarrow Cu^{+}$ ($E^0 = +0.158$ *V*) greatly affects the chemical reactivity. Silver (II) species are strong oxidizing agents which react with water, decomposing quite rapidly with oxygen evolution. Copper(II) is a generally important oxidation state, but silver(II) is not. However, silver(II) compounds are theoretically and spectroscopically interesting, and it is fitting that a comparison of the structural aspects of Cu(II) and Ag(II) compounds should be attempted in the solid state where the silver(II) compounds may be long lived. In this way fresh information on the stereochemistry of d^9 species is obtainable, and the scarcity of suitable silver(II) compounds is compensated by the detail of the crystallographic results. The choice of a ligand or anion for the preparation of a silver(II) complex is limited to those species able to co-exist with a strong oxidizing agent. Pyridine and several related ligands meet this requirement and may also stabilize the silver(II) state. A number of pyridine, 2,2′-dipyridyl, and 1,10-phenanthroline complexes of silver(II) have been prepared (1). Nitrate, perchlorate, chlorate, hydrogen sulfate,

and persulfate have been successfully employed as anions (2). Synthetic methods have involved prior formation of $Ag(I)Ag(III)O_2$ (3), electrolytic oxidation (4), and the use of strong oxidizing agents such as ozone (5) or potassium persulfate (2).

Dinitratodipyridylsilver(II) was chosen for study after exploratory preparative work had shown that suitable crystals were obtainable. In addition to its intrinsic interest as a silver(II) complex, the bonding of the nitrato ligands was worth investigating and there was strong likelihood of meaningful comparison to copper(II) structures of a similar nature.

Experimental

Bisdipyridylsilver(I) nitrate was prepared according to the method of Morgan and Burstall (2). Dinitratodipyridylsilver(II) was prepared by ozone oxidation of bisdipyridylsilver(I) nitrate in 5 *M* nitric acid. Ozone was bubbled through a solution of 0.5 g of bisdipyridylsilver(I) nitrate in 10 mls of 5 *M* HNO_3 for 4 h. The dark brown crystals were filtered immediately, washed with small quantities of water and acetone, and dried *in vacuo*. Recrystallization was not practicable.

Anal. Calcd. for $C_{10}H_8AgN_4O_6$: C, 30.95; H, 2.08; Ag, 27.80; N, 14.44. Found: C, 31.25; H, 2.21; Ag, 27.94; N, 14.14.

Crystallographic Measurements

All the crystals were multiply twinned with no obvious reentrant angles visible under the microscope. Most of the crystals were too small for mounting convenience with a short columnar habit and an approximately hexagonal cross section difficult to observe on the microscope stage. The specimen used for intensity measurements had dimensions 0.10 × 0.08 × 0.24 mm. The column axis coincided with the axis *a*, the most convenient mounting direction. Most rotation photographs about *a* showed almost mirror symmetry across the zero layer in spot position, but not necessarily in spot intensity. On this axis the zero layer Weissenberg appeared like that of a single crystal, but each upper layer showed two triclinic patterns superimposed. The crystals were rotationally twinned with a two-fold twin axis along *a*. The angles β^* and γ^* were first obtained by indexing and then using the method of double offsets (6). The double offset was measured in the first layer between spots $1,k,l$ for twin 1 and $1,k,l$ for twin 2, with k and l selected so that both reflections have the same value of 2θ. All such pairs were found approximately on a line in the first layer passing through *a* and at 46° from the plane through *a* and b^*. The initial values of β^* and γ^* thus obtained made it possible to mount crystals for confirmatory precession photographs of the $h0l$ and $hk0$ planes of one of the twins. The crystal was set on a Picker 4-circle diffractometer mounted about *a*. The $0,k,l$ reflections of the two twins were superimposed. Further superimpositions, seen from the photographic results to be unlikely, were not observed. A set of 72 2θ measurements was obtained and the cell parameters were refined by the method of least squares. The crystal data are listed in Table 1. No piezoelectric effect was found using the Wooster Mark III piezoelectric test apparatus. Confirmation of space group $P\bar{1}$ was done solely by structure refinement. The density was measured by flotation in a solution of ethyl iodide and methyl iodide. Intensity measurements were obtained manually on a Picker 4-circle diffractometer using MoKα radiation ($\lambda = 71.069$ pm) and $\theta/2\theta$ scans for 1 min at a rate of 2°/min in 2θ. The diffractometer was operated in the bisecting position with $\omega = 0$. Background counts were measured for 30 s at each end of the scan. A set of three reflections was measured twice a day for orientation checking, and a standard reflection was examined after every batch of 50 scans. A total of 1275 reflections were measured up to a 2θ angle of 41°, 1019 of these were above background using the criterion that the net count must be $>3\sigma$, where σ is the standard deviation of the background count. Corresponding intensity measurements from the two twins were equal, the $0,k,l$ intensities were therefore halved. Apart from the $0,k,l$ set, all measurements were done on one of the twins. Lorentz and polarization factors were applied, but no absorption correction [$\mu t(\text{max}) = 0.38$, $\mu t(\text{min}) = 0.13$].

Structure Determination

The atomic scattering factor curve for silver was obtained from the work of Cromer and Waber (7). Atomic scattering factor curves for C, N, and O were obtained from the International Tables (8). All atoms were assumed to be uncharged, and a correction was made for the anomalous dispersion of silver (9). The calculations were done using a set of programs supplied by Penfold (10). The silver atom and the four most closely coordinated light atoms were positioned by interpretation of a three dimensional Patterson function. A Fourier synthesis phased with these five atoms treated as Ag + 4N, revealed the complete structure. The refinement was by minimization of $w(|F_o| - |F_c|)^2$ using full matrix least squares. The weights were derived from counting statistics and an experimentally determined instrument instability factor using the formulae given by Stout and Jensen (11). No systematic variations of $w(|F_o| - |F_c|)^2$ were found during refinement. The unobserved reflections were included in the structure factor calculations but excluded from the least squares sums. Conventional R values are given excluding the unobserved reflections. After one cycle of refinement the (Ag + 4N) model with isotropic temperature factors gave $R = 0.286$. The first structure factor calculation with all C, N, and O atoms included gave $R = 0.180$. The refinement was then continued with anisotropic temperature factors

and the R-value sequence was 0.084, 0.071, 0.070, 0.070. Defining the weighted R value as $(\Sigma w\Delta^2/wF_o^2)^{1/2}$, the corresponding weighted R-value sequence was 0.359, 0.211, 0.101, 0.092, 0.088, 0.088. Including the un-observed reflections the final conventional $R = 0.103$, the final weighted $R = 0.104$. On the final cycle the maximum shift/error ratio was 0.02. A final difference synthesis gave no indication of any misplaced atoms. The maximum electron density was 1.35×10^{-6} e pm^{-3} attributable to a hydrogen atom on C(7). Similar but slightly lower peaks were found for the hydrogens on C(1), C(4), and C(9). Negative minima were found of the same order of magnitude. The estimated standard deviations of the parameters were calculated using the full variance-covariance matrix. The structure factor table is in the Depository for Unpublished Data.[1]

Results

The fractional atomic coordinates of dinitratodipyridylsilver(II) are listed in Table 2. The crystal structure is given in Fig. 1. The weaker coordinate bonds to silver are represented by single lines. If the single line bonding is ignored the structure is molecular. Fig. 1 shows one complete molecule and two other molecules in which the carbon atoms have been omitted for simplicity. The origin of the cell is at the lower right front and the axes are labelled. The central molecule with no primes on the atom labels has the fractional coordinates x, y, z given in Table 2. The right hand molecule with the single primes has coordinates $-x, -y, -z$, and the left hand molecule with double primes has coordinates $(1-x), -y, -z$. Table 3 gives the intramolecular bond lengths and also two intermolecular distances involving the silver atom. In Table 3(*a*) we list eight coordinate bonds to silver. Row 1 shows that the bonds from silver to the closest oxygens of the two nitrato groups are equal. The bond length indicates covalently bound nitrato ligands rather than nitrate ions. Row 2 contains distances of approximately 300 pm from the silver atom to the next nearest oxygen atom of each nitrato group. At this distance any bonding would be weak. Row 3 contains the silver to dipyridyl nitrogen distances and indicates that Ag—N(1) is not equal to Ag—N(2). This might be caused by the limited dipyridyl span. Row 4 contains two intermolecular coordinate bonds to silver which are equal in length at approximately 276 pm. Classified according to length there are four bonds at approximately 215 pm, two bonds at 276 pm, and two very long bonds at approximately 300 pm.

Table 3(*b*) contains the bond lengths for the two nitrato ligands. Differences between the two groups are hardly significant. A free nitrate ion has all three N—O bond lengths equal and close to 124.5 pm (12). We observe a marked lengthening of the N—O bonds to those oxygens which are strongly coordinated to the silver atom. The other N—O distances are shorter than 124.5 pm. Similar effects have been observed in other monodentate nitrato complexes (13, 14).

Table 3(*c*) gives the bond lengths of the dipyridyl ligand. There are no significant differences between the two pyridine rings as can be seen by comparing columns 1 and 2. The bond lengths are similar to those of the parent dipyridyl even though the free dipyridyl molecule is in the *trans* planar conformation (15).

Table 4 gives various least squares planes for the molecule. The orthogonal axis system used has x along a, y in the (a, b) plane, and z along c^*. The quantity minimized was $R = \sum_i W_i P_i^2$, where the weight W_i for atom i is given by $3/[\sigma^2(x_i) + \sigma^2(y_i) + \sigma^2(z_i)]$ and P_i is the perpendicular distance of atom i from the plane.

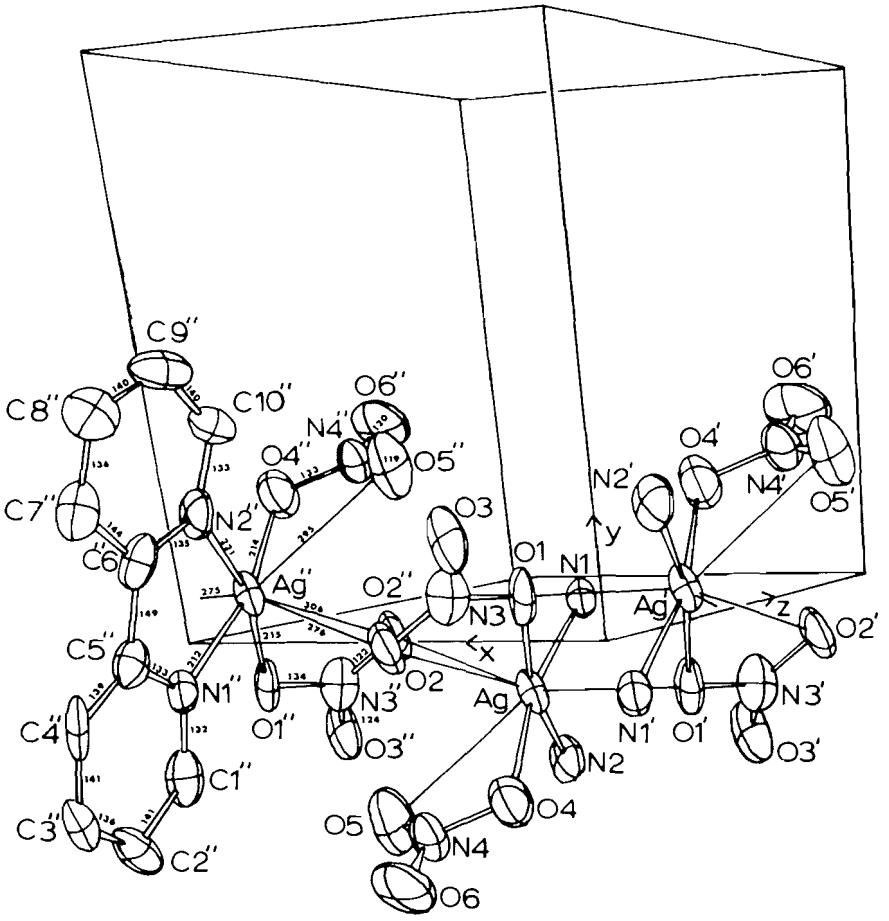

FIG. 1. The crystal structure of dinitratodipyridylsilver(II).

The quantity $\chi^2 = \sum_i [P_i^2/\sigma^2(P_i)]$, is calculated as an index of the planarity of the group. The perpendicular distance of the silver atom from the planes is denoted P_{Ag}, and the estimated standard deviations for this column are all 0.2 pm. Planes *1* and *2* are calculated in an attempt to find a central plane for the molecule. The set N(1)—N(4) is more planar than the set N(1), N(2), O(1), O(4) through the four most closely coordinated atoms. Plane *1* is only 1.12° from the crystallographic 1,0,0 plane. The nitrato ligands are definitely planar as shown by the results for planes *3* and *4*. The silver atom does not lie exactly in the plane of either nitrato ligand. The χ^2 values for planes *5* and *6* show that each pyridyl group is planar. The silver atom is much closer to plane *5* than to plane *6*, indicating that the first pyridyl group with the shorter Ag—N(1) bond maintains a more regular coordination position than the second pyridyl group with the longer Ag—N(2) distance. The results for plane *7* show that the dipyridyl ligand as a whole is significantly non-planar. The angle between planes *5* and *6* is 7.9°. This angle can be expressed in two components on an axis system natural to the ligand. To bring the second pyridyl group into the plane of the first pyridyl group requires a rotation of 6.7° about the C(5)—C(6) bond, and a bend of 4.2° about the midpoint of the same bond, perpendicular to the plane of the first group.

Table 5(*a*) is a list of the bond angles for the distorted silver octahedron obtained by consideration of bonds up to 276 pm. Row 1 gives the angles between ligands *trans* to each other, thereafter columns 1, 2, and 3 give angles ap-

*Estimated standard deviations are given in parentheses in tenths of a pm.

proximately in the three mutually perpendicular planes of the octahedron. The deviations from 90° or 180° are considerable. One element of the distortion is the angle N(1)—Ag—N(2) = 75.9 ± 0.7° caused by the limited span of the dipyridyl ligand. The shorter Ag—N(1) bond maintains a regular position relative to the nitrate ligands whereas the longer Ag—N(2) bond does not (O(1)—Ag—N(1) = 90.9° whereas N(2)—Ag—O(4) = 99.4°).

Table 5(*b*) gives the angles necessary to locate a second oxygen atom from each nitrato ligand in the coordination. Row 1 places O(2) in an octahedral quadrant, and row 2 similarly places O(5) in an adjacent quadrant. The single entry in row 3 is the angle between the two very long bonds. As may be seen in Fig. 1, the atoms surrounding the silver atom can be classified into groups of 4, 3, and 1 according to their angular distribution.

Table 5(*c*) gives the angles of the nitrato ligands. Comparison of row 1 with row 2 shows that both ligands are behaving identically. The angle facing the silver atom is close to 120°, but the remaining 240° is not bisected equally by Ag—O(3) or Ag—O(6). The reason for this probably lies in the similar way in which the nitrato ligands are bound to the silver atom. Both O(3) and O(6) are involved in intermolecular contacts but the involvement of the two atoms will be shown to be different. Intermolecular contacts therefore do not provide an explanation for the similarity of the angles in the two nitrato ligands. Rows 3 and 4 of Table 5(*c*) are comparable, and the difference between columns 1 and 2 for these rows emphasizes that the nitrato ligands are predominantly unidentate, and very far from being symmetrically bidentate.

Table 5(*d*) gives the angles of the dipyridyl ligand. Columns 1 and 2 are associated with pyridyl rings 1 and 2, respectively. Most of the angles in this table are close to 120°. The exceptions are C(6)—N(2)—Ag and N(1)—C(5)—C(6) at 112.4 ± 1.4° and 114.3 ± 1.9°. These values are reasonable considering the bonding and geometry of the pentagon Ag, N(1), C(5), C(6), N(2).

Table 6 is a compilation of intermolecular contacts. The molecules of dinitratodipyridylsilver(II) are shaped like disks which lie parallel

to the (1,0,0) planes of the crystal. The disks are stacked in the x direction so that the arrangement of each pile in the triclinic crystal resembles a slipping stack of coins. The molecules are assymmetric, as is a coin if the engraving is considered. In the space group $P\bar{1}$ there are centres of inversion between successive disks in each pile and also an equal number of such centres between the piles. Using the coin analogy still further, contacts in each stack must be head-to-head and tail-to-tail alternately. One side of the dinitratodipyridyl molecule is distinguished by the protrusion of the nitrato groups, particularly atoms O(2) and O(5). The other side is relatively flat. Figure 2 shows diagrammatically how the first nitrate group is involved in the face-to-face contacts, and may be compared with Fig. 1. The shorter and more relevant face-to-face contacts are listed in Table 6(*a*). Those involving the silver atom are particularly important. Column 1 contains the flat back-to-back intermolecular contacts and column 2 is concerned with contacts involving O(2) and O(5). Note that O(5) approaches the face of the nitrato group N(3″), O(1″), O(2″), O(3″). The shorter edge-to-edge contacts between different molecular stacks are given in Table 6(*b*). The peripheral atoms of the molecule are involved. These are O(3), O(6), and some of the carbon atoms.

The anisotropic temperature parameters are

given in Table 7. The corresponding thermal ellipsoids scaled to include 50% probability are shown in Fig. 1.

Discussion

In Table 8 we present the known coordinate bond lengths for Ag(II) in pyridine complexes. The values for dinitratodipyridylsilver(II) lie within the previously recorded ranges. Both bis(pyridine-2,3-dicarboxylate)silver(II) dihydrate (16), and dinitratodipyridylsilver(II) structures contain tetragonally lengthened and distorted octahedra. Bis(pyridine-2,6-dicarboxylate)silver(II) monohydrate has a very distorted octahedral coordination about the silver atom

TABLE 8. Bond lengths in Ag(II) complexes

Compound	Bond length (pm)			
	Ag—N (Square planar)	Ag—O		Reference
		Square planar	Extended	
Silver(II)-bis(pyridine-2,3-dicarboxylate) dihydrate	212	213	297	16
Silver(II)-bis(pyridine-2,6-dicarboxylate) monohydrate (anionic ligand)	209	220		17
Silver(II)-bis(pyridine-2,6-dicarboxylate) monohydrate (neutral ligand)	221		253	17
Dinitratodipyridylsilver(II)	212, 221	214, 215	275, 276	This work

(17), presumably due to ligand restraints. The electronic absorption spectrum is unlike those of other silver(II) species in tetragonally distorted octahedral environments, but as far as bond lengths are concerned we see a similarity. One ligand becomes ketonic and the other anionic and in this way the silver atom attains four short bonds in the range 209–221 pm and two longer bonds at 253 pm. The available evidence indicates that silver(II) complexes are structurally similar to those of copper(II). Since the structural chemistry of copper(II) is much better developed than that of silver(II), comparison of our results with some copper(II) structures is profitable.

Stephens determined the structure of bisnitrito-2,2′-dipyridylcopper(II) and found an approximately square planar complex (18). The 2,2′-dipyridyl ligand is twisted by only 3.2° about the 2,2′-bond and the two Cu—N lengths are the same. The mean Cu—O length in the square plane is 198.7 pm, but a second oxygen in each ligand approaches to give a mean Cu—O distance of 249.3 pm. This is interpreted as a compromise between purely monodentate or bidentate behavior. The more distant oxygen atoms of each nitrito ligand are on opposite sides of the square plane, tending to complete a very distorted octahedron. Comparing bis-nitrito-2,2′-dipyridylcopper(II) and dinitratodipyridylsilver(II) we find that the nitrito groups have more bidentate character, whereas one of the nitrato groups is heavily involved in intermolecular bridging. Thus six coordination is approached in different ways.

Procter and Stephens have determined the structure of nitritobis-2,2′-dipyridylcopper(II) nitrate (19). The copper atom is *cis*-distorted octahedral and the compound has unequally bound dipyridyl ligands (Cu—N = 199 and 208 pm). The 2,2′-dipyridyl ligands are nonplanar having planar pyridyl rings twisted by 10.8 and 11.6° about the 2,2′-bonds. Since the Cu—O bond distances are 224 and 233 pm, the nitrito group is considered to be bidentate. From our point of view it is interesting that this compound contains ionic nitrate and a bidentate nitrito ligand. Comparing the nitritobisdipyridylcopper(II) ion with the dinitratodipyridylsilver(II) molecule we find some similarity in the behavior of the dipyridyl ligands.

The crystal structure of nitrato-bis(2,2′-dipyridyl)copper(II) nitrate monohydrate has been determined by Nakai, Ooi, and Kuroya (20). The coordination about the copper atom is distorted trigonal bipyramidal and the monodentate nitrato ligand is in the equatorial plane. The Cu—O bond length is 230 pm, which is appreciably longer than the Ag—O bonds in dinitratodipyridylsilver(II).

Recently a small set of crystallographic results has accumulated for unidentate nitrato ligands. The compounds involved are nitratotris(methyldiphenylphosphine)copper(I) (21), nitratobisdipyridylcopper(II) nitrate monohydrate (20), *trans*-dinitratobis(methyl cyanide)copper(II) (22), potassium tetranitratoaurate(III) (13), nickel nitrate tetrahydrate (14), *cis*-dinitratobis(dimethylsulfoxide)palladium(II) (23). Our results on dinitratodipyridylsilver(II) make a significant addition since they fit into the series Cu(I), Cu(II), Ag(II), Au(III). It has been observed by Garner and Wallwork (13) that all unidentate nitrato ligands will probably have some weak interaction between the metal atom and a second oxygen atom more distant than the definitely bonded one. This seems to be inevitable considering the size, shape, and bonding of

a unidentate nitrato group. The results for dinitratodipyridylsilver(II) are in accord with this view, and also show some stereochemical consequences of the presence of the second oxygen atom.

The way in which the nitrato group N(3), O(1), O(2), O(3) in dinitratodipyridylsilver(II) is connected to form bridges is illustrated in Fig. 2. The assymmetric bridging through O(1), N(3), and O(2), for which the Ag—Ag″ distance is 466.4 ± 0.3 pm, is the same as that in *trans*-dinitratobis(methyl cyanide)copper(II) (22), and similar to the more symmetric bridging in solid $Cu(NO_3)_2$ and $Cu(NO_3)_2MeNO_2$ (24, 25). It is rather unusual and interesting that the same nitrato group is also involved in an assymmetric one atom bridge through O(1). This gives a Ag—Ag′ distance of 403.4 ± 0.3 pm and an O(1)—O(1′) distance of 284.7 ± 2.7 pm. The bridges involve bonds which are 276 pm in length.

Conclusion

Dinitratodipyridylsilver(II) may be regarded as a distorted square planar complex by considering coordinate bonds less than 221 pm only. If we consider bonds with lengths up to 277 pm, one nitrate group is monodentate and the other bridging, dinitratodipyridylsilver(II) becomes polymeric in the *x*-direction, and the geometry about the Ag(II) atom becomes that of an elongated octahedron with distortions. Finally we consider the distances Ag—O(2) at 305.8 pm and Ag—O(5) at 295.0 pm in order to provide some explanation for the angular distortions in the octahedral coordination. Figure 1 shows the even angular distribution of three oxygen atoms on the convex side of the primary square. Either over-crowding or weak bonding on this side of the molecule causes the silver atom to be 19.90 pm from the mean plane of O(1), O(4), N(1), and N(2).

Operating funds were obtained from the National Research Council of Canada and the Committee for Research, Leave and Travel of the University of Victoria. A major equipment grant and computing facilities were provided by the University of Victoria. Dr. A. Tweedale of the University of Victoria Computing Centre has generously given assistance. The Crystal and Molecular Structure of Two Thiathiophthen Nitrogen Isosteres

F. LEUNG[1] AND S. C. NYBURG

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received May 27, 1971

Three dimensional crystal structure analyses have been carried out on two nitrogen isosteres (*a*) **5** and (*b*) **6** using diffractometer data. The crystal data are: (*a*) system: monoclinic, $P2_1/c$; $a = 7.350(3)$, $b = 12.309(5)$, $c = 23.268(8)$ Å, $\beta = 118.35(8)°$; (*b*) system: monoclinic, $P2_1/c$; $a = 9.34(1)$, $b = 9.58(1)$, $c = 25.65(3)$ Å, $\beta = 108.08(8)°$.

The S...S distances are 2.396(12) and 2.814(8) Å, respectively. This difference is an indication of the cleavage of the S—S "bond" in **5** when the terminal sulfur atom is methylated. The nature of the bonding of the outer sulfur atom in **6** is discussed.

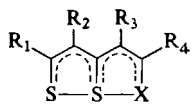
Les analyses de structure d'un cristal tridimensionnel ont été menées à bien pour deux isostères de l'azote (*a*) **5** et (*b*) **6** en utilisant des données du diffractomètre. Les données du cristal sont: (*a*) système: monoclinique, $P2_1/c$; $a = 7.350(3)$, $b = 12.309(5)$, $c = 23.268(8)$ Å, $\beta = 118.35(8)°$; (*b*) système: monoclinique, $P2_1/c$; $a = 9.34(1)$, $b = 9.58(1)$ $c = 25.65(3)$ Å, $\beta = 108.08(8)°$.

Les distances S...S sont respectivement 2.396(12) et 2.814(8) Å. Cette différence est une indication du clivage de la liaison S—S dans **5** quand l'atome terminal de soufre est méthylé. On discute la nature de la liaison de l'atome de soufre extérieur dans **6**.

Canadian Journal of Chemistry, **50**, 324 (1972)

Introduction

Crystal structure analyses of thiathiophthen **1***a* (1), many of its derivatives **1***b* (2) and its isosteres **1***c* (3–6) have been reported. These



1*a* R1 = R2 = R3 = R4 = H; X = S
1*b* X = S
1*c* X = Se, O, N-3-quinolyl

investigations have revealed a wide variation in the S...S distance. As pointed out by Hordvik (7) and by Leung and Nyburg (6), the S...S distance seems to be dependent on the electronegativities of the terminal atom in the usually almost linear arrangements S...S...S and S...S...X. The "S—S bonding" in this type of compound is evidently very weak, and therefore one may expect a substantial difference in the S—S distance for different substituent groups attached to the thiathiophthen ring. This was in fact found to be the case when the S...S distances in 2,4-diphenylthiathiophthen **2** and in 2-*p*-dimethylanilino-4-phenyl-thiathiophthen **3** (7) were compared. The crystal structure of a

thiathiophthen nitrogen isostere, 3,5-epidithio-2,5-diphenyl-2,4-pentadienylidene-3-aminoquinoline **4**, has been published (6). The purpose of the present work is to compare this structure with two other thiathiophthen nitrogen isosteres, 3,5-epidithio-2,5-diphenyl-2,4-pentadienylidene-aniline **5**, and its *S*-methylated derivative, 2,4-diphenyl-5-(3′-phenyl-2′-thiabutene-4′-yl)-isothiazolium iodide **6**. The relative importance of the resonance forms **6** and **6***a* is discussed below.

Experimental

(a) 3,5-Epidithio-2,5-diphenyl-2,4-pentadienylideneaniline **5**

This compound was crystallized from nitromethane giving orange plate-like crystals. The cell parameters were determined from diffractometer measurements and refined by a least squares procedure. The data were collected by 2θ scan at room temperature on a Picker four-circle automatic diffractometer using Cu$K\alpha$ radiation. A total of 2991 independent reflections were collected within $\sin\theta \leqslant 0.8918$, of which 614 were classified as unobserved. The crystal data are:

$C_{23}H_{17}NS_2$ f.w. = 371.5

Monoclinic, $a = 7.350(3)$, $b = 12.309(5)$, $c = 23.268(8)$ Å, $\beta = 118.35(8)°$, $V = 1852.6$ Å^3, $D_m = 1.32(2)$ g/cc, $D_c = 1.33$ g/cc, $Z = 4$, space group $P2_1/c$, $\mu = 25.4$ cm^{-1} (CuKα, $\lambda = 1.5418$ Å).

Structure Determination

The structure of **5** was determined by the symbolic addition procedure (8). After the normalized structure factor magnitudes had been generated, they were sorted into eight groups according to the parity of the indices *hkl*. The number of reflections with $|E| \geqslant 1.5$ in each of the parity groups is listed in Table 1 (g = even, u = odd). From Table 1 it is obvious that all reflections with large $|E|$'s are those with l = even. The reason for this is due to the fact that most atoms of the molecule lie near $y = 1/4$ and 3/4 thus making all reflections strong with l even and weak with l odd. From Table 4 it is clear that many of the nonhydrogen atoms lie near $y = \pm 1/4$.

From a total of 342 reflections with $|E| \geqslant 1.5$, the signs of 285 E's were determined using the Σ_2 equation. The starting set of reflections used in the application of the Σ_2 equation is shown in Table 2. There were numerous Σ_2 relationships indicating that the product *abc* is negative. Four different allocations of signs to the symbols are shown in Table 3. The sign combinations given in Table 3 were used successively to compute E-maps. (Computation of E-map 4 was not required.)

The peaks on both E-map 1 and E-map 2 could be interpreted as atomic sites for S(1), S(2), N, C(1), C(2), C(3), C(4), C(5), C(6), C(9), C(12), C(15), C(18), and C(21). All these peaks lay very close to $y = 1/4$, those lying elsewhere did not make chemical sense.

Structure factors were calculated based on the partial structures implied by E-maps 1 and 2 using the XFLS program (9). The R factors were 0.52 and 0.53, respectively. Fourier maps computed after the structure factors calculations contained no more information than the original E-maps. No further attempts were made to interpret E-maps 1 and 2.

3	−	−	−
4	+	+	−

E-map 3 was then calculated, which showed the "thiathiophthen moiety" S(1), S(2), N, C(1), C(2), C(3), C(4), and C(5), the whole benzene ring attached to the nitrogen atom, C(9), and C(12), a total of 16 atoms. Refinement varying the atomic coordinates and the scale factor gave an R factor of 0.42, the Fourier synthesis computed subsequently revealed the whole structure.

Refinement

The atomic coordinates estimated from the final Fourier map were refined by full-matrix least squares using the XFLS program with the weighting scheme suggested by Abrahams and Bernstein (10). The atomic scattering factors used were calculated from the parameters given by Cromer and Mann (11). After anisotropic thermal refinement, an R factor of 0.09 was obtained and a difference Fourier computed at this stage revealed all the hydrogen-atom positions. Further refinement was carried out varying only positional parameters. The hydrogen atoms were assigned the same thermal parameters as the carbon atoms to which they were bonded and R finally converged to 0.07. The maximum shift calculated in the final cycle was 0.4σ of the parameter. The final positional and thermal parameters are listed in Table 4 and Table 5, respectively. The β_{ij} in Table 4 are the coefficients in the expression: $\exp(-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{13}hl + 2\beta_{12}hk + 2\beta_{23}kl))$. Final F_o and F_c values have been placed in the Depository for Unpublished Data.[2] Bond lengths and standard deviations from the ORFFE program (12) are given in Table 6; the lengths and angles are illustrated in Fig. 1. The largest standard deviation for the bond angles is 0.75°, and the average is 0.6°. Figure 2 shows the orientation and packing of the molecules in the

unit cell as projected along the b-axis. The labelled molecule corresponds to the atomic coordinates listed in Table 4.

(b) 2,4-Diphenyl-5-(3'-phenyl-2'-thiabutene-4'-yl)-isothiazolium iodide **6**

The compound was crystallized from a mixture of ethanol and methanol giving crystals suitable for x-ray work as orange-red prisms. The cell parameters were determined as for (*a*) but using MoKα radiation. A total of 3930 independent reflections were collected in the same manner as for compound **5** within $\sin\theta \leqslant 0.4226$, of which 857 reflections were unobservably weak. The crystal data are:

$C_{24}H_{20}NS_2I$ f.w. = 513.5

Monoclinic, $a = 9.34(1)$, $b = 9.58(1)$, $c = 25.65(3)$ Å, $\beta = 108.08(8)°$, $V = 2182.7$ Å^3, $D_m = 1.57(2)$ g/cc, $D_c = 1.57$ g/cc, $Z = 4$, space group $P2_1/c$, $\mu = 17.0$ cm^{-1} (MoKα, $\lambda = 0.7071$ Å).

Structure Determination

The structure determination of **6** was straightforward. After the atomic coordinates of the iodine atom were deduced from the Patterson function, the structure was revealed by two successive Fourier syntheses.

The atomic coordinates estimated from the final electron density map were refined by full-matrix least squares in the same manner as in (*a*). All atoms except the I^- ion were assumed to be neutral, but the corresponding positive charge on the isothiazolium ion was not assigned. Isotropic temperature factors of 3.0 Å^2 were allocated to all the atoms as the initial thermal parameters. The refinement was continued with anisotropic thermal parameters, varying positional and thermal parameters in alternate cycles. An R factor of 0.071 was reached in the final cycle, the largest shift (in one of the carbon parameters) being 0.6 σ.

The sp^2 hydrogen positions were calculated from carbon atom positions obtained in the final cycle of refinement, assuming a C—H bond length of 1.00 Å. The difference Fourier map showed positive electron density in all the regions expected for sp^2 hydrogen atoms. Of the remaining three hydrogen atoms of the methyl group only one showed

clearly on the difference map; the positions of the other two hydrogen atoms were calculated from this. The hydrogen atoms were assigned the same thermal parameters as those of the carbon atoms to which they were bonded. Structure factor calculations, including the hydrogen atoms, showed a drop of 0.005 in R. The final F_o and F_c values have been placed in the Depository for Unpublished Data.[2] Further refinements varying all positional parameters, resulted in abnormal C—H bond lengths with negligible change in R value, hence no significance was attached to these shifts. The positional and thermal parameters are listed in Tables 7 and 8, respectively. The β_{ij}'s have the same meaning as in Part (*a*). Bond lengths and their standard deviations are given in Table 9, and the lengths and angles illustrated in Fig. 3. The maximum standard deviations for the bond angles is 0.7°. Figure 4 shows the orientations and packing of the molecules in the unit cell as viewed along the a^*-axis. The atomic coordinates listed in Table 7 correspond to the asymmetric molecule closest to (1/2, 0, 1/2).

Discussion

The bond lengths obtained for the system (S(1), S(2), N, C(1), C(2), C(3), C(4), and C(5)) in **5** are in good agreement with those obtained for the "thiathiophthen moiety" 3,5-epidithio-2,5-diphenyl-2,4-pentadienylidene-3-aminoquinoline **4**. The differences are about 1.0σ with the exception of the S...S distances, which differ by 2.7σ (σ is the standard deviation of the S...S distance listed in Table 6). The standard deviation, σ', in the S...S length estimated for **4** is 0.007 Å (6), and thus the

*Coordinates were estimated from the difference map.

standard deviation of the difference ($\sigma_{diff} = \sigma^2 + \sigma'^2)^{1/2}$) in S...S lengths is 0.0139 Å. The actual difference in the S...S distances is thus 2.30 σ_{diff}. The probability that the difference occurs by chance is between 1 to 5%. According to Cruickshank (13), this difference is classified as of possible significance. The variation of the S...S distance from **4** to **5** is far less than that from **2** to **3**.

Of the three substituent phenyl groups in **5**, that attached at C(4) is most twisted out of coplanarity with the central ring (46.3°), a situation analogous to that found in compound **4**.

Since the S...S and the S...N distances lie between the sum of the corresponding van der Waals' radii and the normal single bond length, it is of interest to estimate the bond dissociation energies of these "bonds" using the Huggins' equation (14)

$$R_{AB} = r_A^* + r_B^* - \tfrac{1}{2} \log D_{A-B}$$

where R_{AB} is the bond distance of the bond A—B, D_{A-B} is the bond dissociation energy, r_A^* and r_B^* are constant energy radii for atoms A and B, respectively. Values of constant energy radii for various elements have been published by Huggins. The results of such calculations together with those calculated for some other thiathiophthen isosteres are shown in Table 11. The estimated dissociation energies for the S—S bond, the S—N bond, and the S—Se bond correspond approximately to 0.2, 0.5, and 0.5 of the respective single-bond energy. This suggests that any covalent bonding present is very weak. Similarly one may conclude that there is virtually no covalent bond ($D_{S-O} = 0.76$ kcal/mol) between the sulfur and oxygen atoms in **7** (15), in which the S...O distance (2.64 Å) is greater than the sum of the constant energy radii (2.58 Å), in spite of the fact that this

S...O distance is much shorter than the sum of the van der Waals' radii (3.25 Å). These results agree with the EHMO calculations performed by Kapecki and Baldwin (16), who concluded that the covalent bonding between S and O in these molecules is very weak or nonexistent.

The S...S distance observed in **6** (2.81 Å) is shorter than the "non-bonded" S...S distances in **8** (17), **9** (18), and **10** (19). The average "non-bonded" S...S distances for structures **6**, **8**, **9**, and **10** is 2.96 Å, which is longer than the sum of the constant energy radii of 2.92 Å (*i.e.*, D_{S-S}

TABLE 11. Dissociation energies estimated using the Huggins' equation

*The energy values for single bonds of like atoms, D(A—A), were taken from Pauling (20). The values for bonds of unlike atoms, D(A—B), were calculated using equation (20), $D(A—B) = \{D(A—A) \cdot D(B—B)\}^{1/2} + 30(x_A - x_B)^2$, where x_A and x_B are electronegativities for atoms A and B, respectively.

< 1 kcal/mol). In view of this, it appears more appropriate to consider the question of covalent bonding by comparing the interatomic distance with the sum of the constant energy radii rather than the sum of the van der Waals' radii.

The geometry of the molecule can be used as a guide as to which of the two resonance forms, **6** or **6***a*, predominates (20). First, a least squares plane analysis, Table 12, shows that whereas S(2), C(3), C(4), C(5), and N are strictly coplanar the atoms in the other five-membered ring S(1), C(1), C(2), C(3), and S(2) are not. (The angle between the two mean planes is 5.8°.) Moreover the methyl carbon atom is substantially out of the mean plane of this second ring. This geometry militates strongly against **6***a*. Secondly the C(Me)—S—C(1) angle is 104.1° (Fig. 3) whereas for **6***a* an angle closer to 120° would be expected. Lastly there is decidedly double bond character in the S(2)—C(3) and C(5)—N bonds. Thus this S—C bond is significantly shorter than S(1)—C(1), an unusual situation for a thiathiophthen isostere, and the C—N bond resembles the presumably partially double bond in formamide, length 1.322 Å (21).[3] All this geometric evidence implies that resonance hybrid **6** predominates. The phenyl group attached to nitrogen is virtually coplanar with the central molecular plane (4.2°) unlike the situation in compound **5** (31.8°, see Table 10).

In summary, therefore, we see that whereas changing one substituent in going from nitrogen isostere **4** to **5** seems to have had little effect on the geometry of the central part of the molecule, in **6**, methylation of the sulfur atom has had a profound effect. Rather than compare the distances between atoms doubtfully bonded together with the sum of their van der Waals radii, it is possibly more instructive to compare the distance with that calculated from Huggins' constant energy radii.

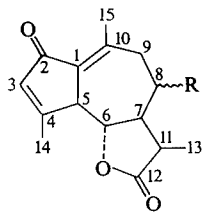
The Structure and Stereochemistry of Hydroxyachillin

F. W. BACHELOR AND A. B. PARALIKAR[1]
Department of Chemistry, University of Calgary, Calgary 44, Alberta
AND
SHÔ ITÔ
Department of Chemistry, Tohoku University, Sendai, Japan
Received July 13, 1971

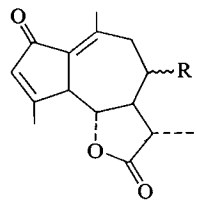
The sesquiterpene lactone hydroxyachillin has been isolated from *Artemisia frigida* Wild. The position and stereochemistry of the free hydroxyl group has been established by n.m.r. examination as well as the conformation of the molecule using nuclear Overhauser effects.

L'hydroxyachilline lactone sesquiterpénique a été isolée à partir de *l'Artemisia frigida* Wild. La position et la stéréochimie des groupes hydroxyles libres ont été déterminés par r.m.n.; il en a été de même pour la conformation de la molécule en se servant de l'effet nucléaire Overhauser.
Canadian Journal of Chemistry, **50**, 333 (1972)

Although hydroxyachillin (**1***a*) has been previously isolated from *Achillea lanulosa* by White and Winter (1), its structure is based on its conversion to achillin (**1***d*) by removal of the free hydroxyl group. This was accomplished by preparing the nitrosylate (**1***b*), converting this to the



1



2

a R = OH
b R = *p*-$NO_2C_6H_4SO_2O$—
c R = I
d R = H

b R = H

iodide (**1***c*), and removing the iodine by reduction. This sequence still leaves the position of the hydroxyl group in doubt and although there are a sufficient number of analogies to suggest that the hydroxyl group is at C-8, including matricarin (**2***a*) (2), which is found in the same plant, this is not sufficient to prove its location.[2]

In our investigation of local *Artemisia* species we have found hydroxyachillin to be the principal sesquiterpene lactone present in *Artemisia frigida* Wild. Comparison of the i.r. spectrum of our compound with an authentic specimen showed them to be identical.[3] The recent stereospecific total syntheses of leukodin (**2***b*) and achillin (**1***d*) from α-santonin firmly establish the structures and stereochemistry of these molecules (4–6). There remains only the position and stereochemistry of the hydroxyl group of hydroxyachillin to be determined.

We have been able to complete the structure of hydroxyachillin by examination of the n.m.r. spectra of the free alcohol and its acetate. The n.m.r. data for these compounds are given in Table 1. Examination of these data shows that the hydroxyl group can only be located at C-8 or -9. As the new signal from the hydrogen on the alcohol carbon atom is found at 6.26 τ this places the hydroxyl group at C-8. If it were at C-9 it would be allylic and its position would be expected at lower field. For example the corresponding allylic hydrogen atom in geraniol is found at 5.85 τ (7). This hydrogen atom in hydroxyachillin is shifted to 5.24 τ in the acetate and is clearly seen as a triplet of doublets with

[1]Abstracted in part from the thesis of Mr. A. B. Paralikar submitted to the University of Calgary for the Ph.D. degree, 1970.

[2]A private communication from Prof. E. H. White informed us that the stability of the nitrosylate **1***b* and the formation of an impure cyclopropane derivative obtained on reduction of the iodide **1***c*, similar to that obtained from the corresponding compound in the matricarin series suggested to them that the hydroxyl was at C-8 (3).

[3]We wish to thank Dr. R. E. K. Winter for running the i.r. comparison of the two compounds.

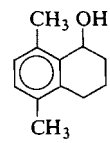
§See ref. 5.

coupling constants of 10 and 3 Hz. This splitting is also only compatible with the location of the hydroxyl group at C-8 having three hydrogen atoms on the adjacent carbon atoms.

Spin–spin decoupling on the acetate **1***e* firmly established the relationship of a number of the proton signals. Irradiation of the vinyl hydrogen at 3.83 τ caused the allylic splitting to disappear in the methyl signal at 7.70 τ thus establishing it as the C-14 methyl group. Decoupling of the methyl doublet at 8.89 τ caused the quintet at 7.18 τ to collapse to a doublet ($J = 7$ Hz) for the hydrogen at C-11. A quintet of this type with similar stereochemistry has been observed in β-santonin (8). Although the complexity of the region did not allow us to locate exactly the position of the hydrogen at C-7, irradiation at 7.3 τ caused the signal at 5.24 τ to collapse to a broad unresolved peak and the triplet at 6.10 τ became a doublet. Finally, decoupling of the allylic hydrogen at 6.59 τ reduced the hydrogen signal at 6.10 τ to a doublet and the vinyl hydrogen signal which showed complex allylic coupling became a simple quartet ($J = 1.5$ Hz). This evidence firmly establishes the relationship of the hydrogen atoms at C-3, -5, -6, -7, -8, -11, -13, -14, and -15.

Guaianolide lactones with a *trans* lactone at C_6—C_7 and *trans* hydrogens at C-5 and -6 are capable of ring inversion. This leaves the possibility for the stereochemistry of the C-8 hydroxyl of being either α or β, each of which could exist in one of two conformations, unless the conformations are freely interconvertible. Examination of models of the four different possibilities showed that they could easily be distinguished from each other by determining the nuclear Overhauser effect (n.O.e.) of selected protons. Initially it must be remarked that there is a decided upfield shift of the C-13 methyl signal in the n.m.r. spectrum of hydroxyachillin acetate (**1***e*) from that of hydroxyachillin (**1***a*). This spatial interaction effect has been noted in the case of substituted tetralins (9). For example, in 1,4-dimethyl-5-hydroxydecalin (**3**), it was



3

found that acetylation caused an upfield shift of the peri methyl group of 0.17 p.p.m. We observe an upfield shift of 0.18 p.p.m. in hydroxyachillin acetate. This shift is not observed if the two groups are *trans* diaxial or pseudo *trans* diaxial as they would be in one conformation of hydroxyachillin where the hydroxyl group is α. All of the other three conformations would allow for this spatial interaction.

Of the remaining conformations, one α and one β conformation could account for the observed coupling constants. In the case of the conformer with the oxygen substituent α, the hydrogen atom at C-8 approaches very closely to that at C-6.[4] Irradiation of either the hydrogen signal at C-6 or -8 of hydroxyachillin acetate (**1***e*) pro-

[4]From Dreiding models the internuclear distance is estimated to be 2.13 Å. For comparison of this n.O.e. with compounds showing similar signal enhancements and similar proton relationships see refs. 10 and 11.

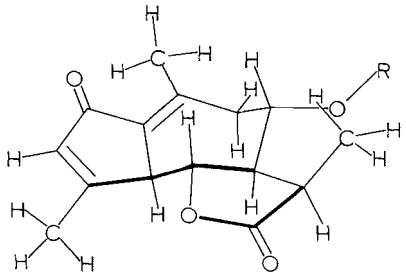

FIG. 1. The conformation of hydroxyachillin acetate ($R = COCH_3$).

duced a definite signal enhancement of approximately 10% in the other signal. This definitely establishes the hydrogen atom at C-8 as β and the conformation of the seven-membered ring such that the hydroxyl or acetate group is pseudo equatorial. This is in contrast to the oxygen functions at C-8 of the matricarin series which have been shown to have the α configuration (4). The complete conformational picture of hydroxyachillin acetate is given in Fig. 1. In addition to the n.O.e. at C-8 when radiating the C-6 proton signal, there was no observable enhancement of the signal due to the hydrogen atom at C-5. This verifies the *trans* relationship of these atoms.

The strong spatial interaction between the C-11 β-methyl group and the 8α-hydroxyl group is probably also responsible for the lack of reactivity of this hydroxyl group. Although it can be acetylated and the nitrosylate prepared, we have been unable to prepare the tosylate, brosylate, or iodoacetate. It is not oxidized to a ketone with the chromium trioxide – pyridine complex, but under more drastic conditions extensive oxidation takes place.

Experimental

The n.m.r. spectra were measured with a Varian HA-100 spectrometer with a frequency swept and tetramethylsilane-locked mode. Double and triple resonance experiments were performed by using the spectrometer in conjunction with two Hewlett–Packard HP-200ABR audio oscillators. The n.O.e. experiments were carried out by measuring the integrated intensities of a signal four times with and without irradiation at the resonance frequency of another signal at a sweep rate of 0.4 Hz/s. Samples were not degassed before carrying out n.O.e. measurements.

Extraction and Isolation of Hydroxyachillin

The aerial parts of *Artemisia frigida* Wild collected in the vicinity of Calgary, Alberta were dried and ground. The ground material (6 kg) was extracted successively with hexane and chloroform. The chloroform extract was concentrated to dryness and the residual gum dissolved in 3 l of ethanol. The ethanolic solution was mixed with a solution of 75 g of lead acetate in 3 l of water and 20 ml of acetic acid. After 4 days the clear supernatant was decanted through glass wool and the residue washed twice with ethanol. The ethanol–water mixture was concentrated to a small volume and extracted thoroughly with chloroform. The chloroform extract was dried (Na_2SO_4), filtered, and concentrated at reduced pressure. The residual gum (56 g) was taken up in benzene and chromatographed over 1500 g of alumina. The column was eluted with benzene, benzene–chloroform (1:1), chloroform, chloroform–methanol (1:1) and methanol. The benzene–chloroform fractions showed characteristic bands in the i.r. at 1775 cm^{-1} for a γ-lactone and these were combined and concentrated yielding a residue of 8.7 g. This material was again chromatographed on alumina (320 g). Elution with benzene–chloroform gave 6.5 g of a brown gum. This gum was crystallized first from benzene and the crystalline material then recrystallized from ethyl acetate to give 1.4 g of hydroxyachillin, m.p. 159.5–160 °C, $[\alpha]_D^{23}$ +112° (*c* 1.0 in CH_3OH); (lit. (4) m.p. 161–162°, $[\alpha]_D^{22}$ +110°).

Hydroxyachillin Acetate

A solution of 0.1 g of hydroxyachillin in 1 ml of pyridine was mixed with 2 ml of acetic anhydride. The solution was warmed for 3 h on a steam bath, then left overnight at room temperature. The reaction mixture was then poured over ice and the resulting crystalline solid collected by filtration. Crystallization and recrystallization gave 0.06 g of hydroxyachillin acetate, m.p. 194–195 °C, $[\alpha]_D^{25}$ + 110° (*c* 0.20 in $CHCl_3$) λ_{max} (MeOH) 255 mμ (ε 15 000); lit. (1) m.p. 193–194°, $[\alpha]_D^{22}$ + 116°).

We wish to thank the National Research Council of Canada for support of this work.

Total Synthesis of (+)-Occidentalol[1]

M. SERGENT,[2] M. MONGRAIN,[3] AND P. DESLONGCHAMPS[4]

Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received June 10, 1971

A synthesis of (+)-occidentalol (**1**) has been realized in six steps, starting from the readily available enone alcohol **3**.

La synthèse du sesquiterpène (+)-occidentalol (**1**) a été réalisée en six étapes en utilisant un produit de départ très facilement accessible, l'énone alcool **3**.

Canadian Journal of Chemistry, **50**, 336 (1972)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The structure of (+)-occidentalol, a sesquiterpene isolated (1) from the wood of Eastern white cedar (*Thuja occidentalis L.*) was first formulated as **2** (2) and later corrected to structure **1** (3).

We wish now to report a total synthesis of (+)-occidentalol which confirmed the proposed structure **1** for this sesquiterpene. A synthesis of (−)-occidentalol has recently appeared in the literature (4) and a synthesis of the naturally occuring (+)-occidentalol together with a chemical correlation have been completed by Heathcock and Amano (5).

The enone alcohol **3** is very readily available in large scale from (+)-dihydrocarvone in three steps (6). This compound (**3**) has served as key intermediate in a synthesis of α-agarofuran (6).

Structurally, compound **3** and (+)-occidentalol (**1**) have the same skeleton and both of which possess the same absolute stereochemistry at C-7 and -10. Thus, a specific reduction of the double bond of **3** to obtain a *cis*-decalone system (**4**), and the use of the remaining carbonyl group for the introduction of the diene chromophore in ring A, seemed to be a very logical approach. Consequently, the enone alcohol **3** appears to be an excellent precursor for (+)-occidentalol and it was therefore selected as starting material.

Catalytic hydrogenation of compound **3** in methanol in the presence of 10% palladium-on-charcoal gave directly the crystalline *cis*-ketol **4** in 65% yield. Treatment of the resulting mother liquor[5] with methanolic sodium hydroxide furnished a further crop of **4**, bringing up the total yield to 83%.

In order to confirm the *cis* juncture of **4**, a reduction of **3** with lithium in liquid ammonia was carried out and a mixture of two compounds was obtained. The minor product was found identical with **4**. Since, it is known that this reduction (7) generally affords the *trans* product, the major product must have the *trans* structure.[6]

The introduction of a double bond between C-1 and -2 was next considered and to realize such a transformation in a specific manner, ketol **4** was first converted into the corresponding hydroxy methylene derivative **5** in essentially quantitative yield. From this intermediate (**5**), we have developed two different routes to obtain the enone **6**.

Treatment of the sodium salt of **5** with bromine gave an unstable mixture of the two epimeric bromo-aldehydes **7** which was therefore directly subjected to dehydrobromination condition ($LiCl–Li_2CO_3$/DMF (8)) and the crystalline enone aldehyde **8** was readily isolated in 65% yield after column chromatography.

Deformylation of **8** to give the crystalline enone **6** was achieved in 80% yield with tris-triphenylphosphinerhodium chloride in boiling dichloromethane (9).

Alternatively, the transformation of bromo-aldehydes **7** to enone **6** can be accomplished by first performing a retro Claisen reaction (**7** → **9**)

[1]This paper has been presented at the "Congrès de l'Association Canadienne-Française pour l'Avancement des Sciences (ACFAS)", October 16–17, 1970 Québec.

followed by dehydrobromination (**9** → **6**). This procedure (10) has the advantage of avoiding the use of the expensive rhodium complex.

In fact, we have carried out the bromination and the deformylation reaction in a single operation without the isolation of the unstable isomer **7**. Treatment of the hydroxymethylene **5** with bromine in the presence of an excess barium

hydroxide in ethanol gave directly the bromoketone **9**. Barium hydroxide served to generate the enolate salt of **5** necessary for bromination (→**7**) and to mediate *in situ* the retro Claisen reaction (**7** → **9**) (11).

Dehydrobromination of **9** proceeded smoothly to give the desired enone **6**. This sequence of reaction afforded **6** in 74% overall yield from **5**.

The enone **6** was then reduced in high yield with lithium aluminum hydride in ether to give the allylic alcohol **10**. The crude allylic alcohol dissolved in benzene containing *p*-toluenesulfonic acid at room temperature gave the alcohol **1** which was found to be completely identical with authentic (+)-occidentalol.

Experimental

Melting points are not corrected. The U.V. spectra (λ_{max}) were measured on a Cary model 14 spectrophotometer and i.r. spectra (ν_{max}) were recorded on a Perkin–Elmer spectrophotometer, model 257. The n.m.r. spectra (τ values) were taken on a Varian A60 spectrometer with tetramethylsilane as an internal standard. Anhydrous magnesium sulfate was used as the drying agent in working up reaction. Fisher Florisil 100–200 mesh was used for preparing all column chromatograms. Low boiling petroleum ether (b.p. 30–60 °C) was used.

(+)-Dihydrocarvone was prepared by the method of Malhotra *et al.* (12). The method of Hortmann *et al.* (13) was found superior to the one of Howe and McQuillin (14) to prepare (+)-5-α-hydroxy-4,7α*H*-eudesm-11-en-3-one which is the precursor of **3** (6).

cis-Ketol **4**

Enone alcohol **3** (9.45 g, 40 mmol) was hydrogenated in freshly distilled methanol (500 ml) with 10% palladium-on-charcoal (1 g) for 24 h. The catalyst was removed by filtration on Celite and the filtrate was evaporated to dryness to give a white solid (9.54 g). Crystallization from hexane afforded pure *cis*-ketol **4** (6.19 g, 65% yield).

The mother liquor (3.35 g) was dissolved in methanol (100 ml) and treated with 50% aqueous sodium hydroxide (10 ml) for 3 h at room temperature. After removal of the methanol and addition of water, the reaction mixture was extracted twice with ether. The combined extract was washed with brine, dried, and evaporated. Column chromatography yielded an additional quantity of the ketol **4** (1.72 g). Total yield 83%. The analytical sample was prepared by crystallization with petroleum ether, m.p. 87–88 °C; i.r. ν_{max} 3600, 3460, and 1710 cm^{-1}; n.m.r.: τ ($CDCl_3$) 8.69 (3H, s, CH_3), 8.83 (6H, s, *i*-propylol CH_3), and 9.02 (3H, d, $J = 6.5$ Hz, CH_3).

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.26; H, 10.96.

Hydroxy Methylene Derivative **5**

To sodium hydride (4 g, 50% suspension), which was previously washed with dry benzene to remove the oil, was added ketol **4** (2 g, 8.4 mmol), ethyl formate (50 ml), and anhydrous ether (400 ml). The mixture was refluxed for 5 h. After cooling, water was cautiously added and the aqueous phase was washed with ether, acidified to p*H* 5 with dilute hydrochloric acid and extracted with ether. The organic phase was washed with brine, dried, and evaporated to dryness to give crude **5** (2.24 g); i.r.: ν_{max} ($CHCl_3$) 3600, 3450, 1710, 1650, and 1580 cm^{-1}; n.m.r.: τ ($CDCl_3$) 1.52 and 2.08 (1H, s, hydroxymethylene hydrogen), 8.85 (6H, s, *i*-propylol CH_3) 8.85 (3H, d, $J = 7$ Hz, CH_3), and 9.00 (3H, s, CH_3).

Bromo-aldehydes **7**

Compound **5** (2.24 g, 8.4 mmol) dissolved in chloroform (100 ml) was mixed with an aqueous solution of sodium hydroxide (0.25 *N*, 33.6 ml). To the above mixture was added dropwise a solution of bromine in chloroform (1%, 44.8 ml) with stirring. After 45 min at room temperature, water was added and the phases were separated. The organic layer was washed with water, dried, and evaporated *in vacuo* at room temperature to give the crude bromo-aldehydes **7** (2.7 g) as an oil; i.r.: ν_{max} ($CHCl_3$) 3600, 3460, 1730, and 1710 cm^{-1}; n.m.r.: ($CDCl_3$) 0.33 and 0.67 (1H, 2s, (intensity ratio 4:1), aldehydic H). This unstable material was used immediately for the next step.

Enone Aldehyde **8**

The crude bromo-aldehydes **7** (2.7 g, 7.08 mmol) dissolved in dimethyl formamide (300 ml) containing lithium chloride (2.42 g, 55 mmol) and lithium carbonate (484 mg, 6.5 mmol) was heated at 125 °C (oil bath temperature) under nitrogen for 2.5 h. After cooling, water was added and the mixture was extracted with ether. The organic phase was washed with brine, dried, and evaporated to dryness. The resulting product was purified by column chromatography. Elution with ether–benzene (4:1) gave crystalline **8** (1.44 g, 65% yield from ketol **4**). The analytical sample was prepared by crystallization with ether–petroleum ether, m.p. 101.5 °C; $\alpha_{578}^{CHCl_3}$ −247°; i.r.: ν_{max}($CHCl_3$) 3600, 3500, 1730, 1705 and 1685 cm^{-1}; n.m.r.: τ ($CDCl_3$) 0.07 (1H, s, aldehydic H), 2.64 (1H, d, $J = 2$ Hz, olefinic H), 8.67 (3H, s, CH_3), 8.88 (3H, d, $J = 6$ Hz, CH_3), and 8.95 (6H, s, *i*-propylol CH_3); u.v.: λ_{max} (EtOH) 237 nm (ε 8100).

Anal. Calcd. for $C_{15}H_{24}O_3$: C, 72.69; H, 9.15. Found: C, 72.54, H, 8.91.

Bromo-ketone **9**

To a stirred mixture of the hydroxymethylene derivative **5** (266 mg, 1 mmol) and barium hydroxide (946 mg, 3 mmol) in ethanol (95%, 8 ml) was slowly added a solution of bromine (160 mg) in ethanol (5 ml). After 45 min at room temperature, water was added and the resulting mixture was extracted with ether. The organic phase was washed with dilute hydrochloric acid, brine, dried, and evaporated to dryness. The crude product (315 mg, 100% yield) was suitable for the next step. The analytical sample was purified by column chromatography (eluant: benzene–ether (7:3)) and crystallized from etherpetroleum ether, m.p. 88.5 °C (dec.), $\alpha_{578}^{CHCl_3}$ +206°; i.r.: ν_{max} ($CHCl_3$) 3590, 3440, and 1727 cm^{-1}; n.m.r.: τ ($CDCl_3$) 5.05 (1H, oct, $J = 1$, 6.5 and 12 Hz, H_2), 8.36 (3H, s, CH_3), 8.86 (6H, s, *i*-propylol CH_3), and 8.93 (3H, d, $J = 6.5$ Hz, CH_3).

Anal. Calcd. for $C_{15}H_{25}BrO_2$: C, 56.78; H, 7.94; Br, 25.19. Found: C, 56.92; H; 7.91; Br, 25.15.

Enone 6

(a) From Enone Aldehyde 8

The enone aldehyde **8** (83 mg, 0.3 mmol) and tris-triphenylphosphinerhodium chloride (335 mg, 0.36 mmol) in dichloromethane (12 ml) were kept at reflux for 16 h under nitrogen and 14 h at room temperature. The solvent was removed *in vacuo* and the residue was triturated with ethanol. After evaporation of the ethanolic extract the crude product was purified by chromatography. Elution with benzene–ether (7:3) gave crystalline **8** (66 mg, 83% yield). The analytical sample was prepared by crystallization from hexane, m.p. 84 °C, i.r.: ν_{max} ($CHCl_3$) 3600, 3450, 1675, and 1640 cm^{-1}; n.m.r.: τ (CCl_4) 3.65 (1H, quad, $J = 2$ and 10 Hz, H_1), 4.23 (1H, d, $J = 10$ Hz, H_2), 8.79 (3H, s, CH_3), 8.99 (6H, s, *i*-propylol CH_3), and 9.01 (3H, d, $J = 6.5$ Hz, CH_3); u.v.: λ_{max} (EtOH) 230 nm (ε 7950).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.23. Found: C, 76.22; H, 10.08.

(b) From Bromo-ketone 9

The bromo-ketone **9** (3.1 g, 10 mmol) dissolved in dimethylformamide (150 ml) containing lithium bromide (3.1 g, 35 mmol) and lithium carbonate (2.6 g, 35 mmol) was heated at 130 °C (bath temperature) for 24 h. Water was added to the cooled reaction mixture which was then extracted with ether. The organic phase was washed with brine, dried, and evaporated to dryness (2.2 g). A portion of this crude material (812 mg) was purified by column chromatography with silica gel. Elution with benzene–ether (4:1) gave a pure sample (639 mg) which was identical to enone **6** obtained by the above procedure. The overall yield from the hydroxymethylene derivative **5** was 75%.

(+)-Occidentalol (1)

The enone **6** (371 mg, 1.7 mmol) dissolved in ether (25 ml) was slowly added to a suspension of lithium aluminum hydride (123 mg) in ether (25 ml) cooled in an ice bath. After 1 h at room temperature, the excess hydride was destroyed by addition of brine. The organic phase was separated, dried, and evaporated to dryness to give the crude allylic alcohol **10** (374 mg, 100% yield); i.r.: ν_{max} ($CHCl_3$) 3600, 3470, and 3450 cm^{-1}; n.m.r.: τ ($CDCl_3$) 4.17 (1H, quad, $J = 4$ and 10 Hz, H_2), 4.52 (1H, d with additional splitting, $J = 10$ Hz, H_1), 6.05 (H, t, $J = 4$ Hz), 8.86 (6H, s, *i*-propylol CH_3), 8.88 (3H, d, $J = 6$ Hz, CH_3), and 9.02 (3H, s, CH_3).

The above crude product dissolved in benzene (60 ml) was treated with *p*-toluenesulfonic acid (58 mg) for 3 h at room temperature. Water was added and the benzene layer was separated. The aqueous phase was extracted with ether and the combined organic solution was dried and evaporated to dryness. The crude product (345 mg) was purified by column chromatography. Elution with benzene gave (+)-occidentalol (214 mg, 62% yield from **6**). The allylic alcohol **10** (98 mg, 26%) was recovered from further elution with benzene–ether (1:1).

The (+)-occidentalol was further purified by sublimation and crystallization (petroleum ether), m.p. 95 °C; $\alpha_{578}^{CHCl_3}$ +369° (lit. (*2b*) m.p. 94–96.5 and 97.5–98 °C; $\alpha_{D}^{CHCl_3}$ +363.2°). The i.r. and n.m.r. spectra were identical with those of an authentic sample of (+)-occidentalol. Also, a mixed m.p. showed no depression.

Support for this work by the National Research Council of Canada and by the "Ministère de l'Education" (Québec) is gratefully acknowledged. We also thank Dr. E. von Rudloff for a generous gift of (+)-occidentalol.

(+)-Occidentalol: Absolute Stereostructure and Total Synthesis[1]

YOUNG AMANO AND CLAYTON H. HEATHCOCK
Department of Chemistry, University of California, Berkeley, California 94720

Received June 10, 1971

Hydroxy ketone **7** has been prepared from both (+)-dihydrocarvone (**3**) and (+)-occidentalol (**2**), thus establishing the absolute stereostructure of the latter. The three-stage conversion of compound **7** into (+)-occidentalol constitutes a total synthesis of the sesquiterpene.

L'hydroxycétone **7** a été préparée à partir des deux produits (+)-dihydrocarvone (**3**) et (+)-occidentalol (**2**) établissant par le fait même la stéréostructure absolue de ce dernier. La conversion en trois étapes du composé **7** en (+)-occidentalol constitue une synthèse totale du sesquiterpène.

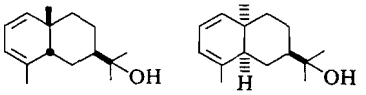
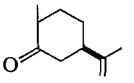
Introduction

The sesquiterpene alcohol (+)-occidentalol was first isolated from the wood of Eastern white cedar (*Thuja occidentalis* L.) by Nakatsuka and Hirose (1). Subsequent reports from various laboratories lead to the acceptance of structure **1** for this interesting sesquiterpene (2–5). In 1969, Hortmann and De Roos reported a careful analysis of the 100 MHz p.m.r. spectrum of (+)-occidentalol and suggested structure **2** (6).



1 **2**

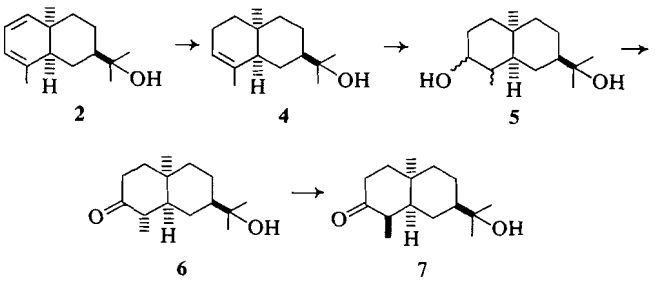
We have carried out a straightforward chemical correlation of (+)-occidentalol and (+)-dihydrocarvone (**3**) as well as a total synthesis of the sesquiterpene. Our results confirm Hortmann's structure, as well as the absolute configuration previously assigned to (+)-occidentalol on the basis of o.r.d. studies (3, 4). Since this work was completed, another synthesis of (+)-occidentalol (**7**) and one of its enantiomorph (8) have been reported.



3

Natural (+)-occidentalol, generously provided by Professor H. Erdtmann, was selectively hydrogenated to obtain dihydrooccidentalol (**4**) (3) (see Scheme 1). Hydroboration of **4** yielded a mixture of diols, **5**, which was oxidized with bispyridinechromium(VI) oxide in methylene chloride (9). The initial product, which was mostly hydroxy ketone **6**, was converted to the more stable epimer **7** upon filtration through alumina. Compound **7**, m.p. 89–90°, had $[\alpha]_D^{CHCl_3}$ −18°.

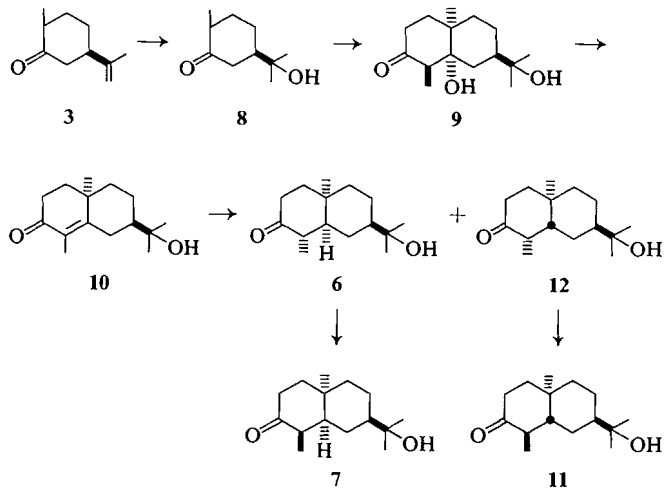
Oxymercuration–demercuration (10) of (+)-



2 **4** **5** **6** **7**

SCHEME 1

[1]Presented at the Joint Meeting of the Chemical Institute of Canada and the American Chemical Society, Toronto, Ontario, May 26, 1970.



SCHEME 2

dihydrocarvone (**3**) yielded hydroxy ketone **8** (see Scheme 2). Base-catalyzed condensation of **8** with ethyl vinyl ketone gave the crystalline diol **9**, which was dehydrated to hydroxy-enone **10** by treatment with hydrogen chloride in refluxing tetrahydrofuran. The relative stereochemistry of this material, *epi*-carrisone, has been rigorously established as *trans* (11). Compound **10** was hydrogenated in methanol over palladized charcoal, yielding an oily mixture of dihydro derivatives. This crude product gave a poorly-resolved p.m.r. spectrum which was not identical to that of crystalline **7**. When a solution of the dihydro products was passed through a column of alumina, or simply stirred in contact with basic alumina, hydroxy ketone **7**, m.p. 88–89°, $[\alpha]_D^{CHCl_3}$ −16° was isolated in 32% yield.

The crude mother liquors remaining after the above treatment contained mainly *trans*-dihydro-*epi*-carrisone (**11**), an oil having $[\alpha]_D^{CHCl_3}$ +40°. Compound **11** was also obtained by reduction of *epi*-carrisone (**10**) with lithium in ammonia.

The dramatic transformation brought about by exposure to basic alumina of the oily mixture initially isolated after hydrogenation of *epi*-carrisone can be attributed to equilibration of the new axial, secondary methyl groups to their more stable epimeric positions.

The formation of the less stable *trans*-fused epimer **12** is expected, since this results from *cis*-delivery of hydrogen. However, the initial production of the less stable epimer **6** in the *cis*-series is at first sight surprising, since this stereochemistry implies *trans*-addition of hydrogen. Overall *trans*-addition can be achieved by initial 1,4-addition, followed by kinetic protonation of the resultant enol (see Scheme 3).

A more complicated mechanism for formation of **6**, involving prior double-bond isomerization, followed by hydrogenation, was ruled out by the following experiment. Catalytic *deuteration* of **10** yielded a mixture of hydroxy ketones which was stirred with methanolic sodium methoxide to epimerize the first formed products and also to assure exchange of the α-positions. Mass spectral analysis of the recrystallized, deuterated **7** showed the presence of only a single deuterium atom, presumably at the angular position.

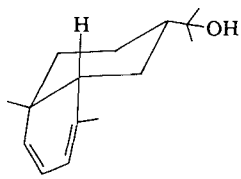
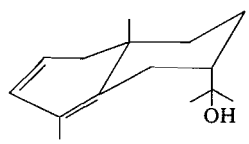
With the absolute stereostructure of (±)-occidentalol secured to our satisfaction, we set about to prepare the sesquiterpene by total synthesis. Our initial approach to the synthesis was based on a consideration of the stereochemistry of occidentalol (**2**) and its double-bond isomer **13**. Since occidentalol is a *cis*-fused decalin, it may exist in a conformation, **2***a*, in which the bulky isopropylol group occupies an equatorial position. Isomer **13**, on the other hand, is constrained to a single conformation, in which the isopropylol group is axial. From this consideration, it is clear that occidentalol

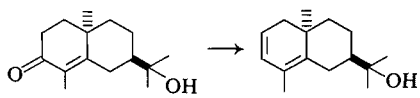


2*a*[2]



13[2]

should be more stable than isomer **13** (or the *trans*-fused isomer corresponding to **2**). It appeared attractive, therefore, to examine the isomerization of compound **13**, which was prepared in quantitative yield from *epi*-carrisone (**10**) by Shapiro's modification of the Bamford–Stevens reaction (12).



10 **13**

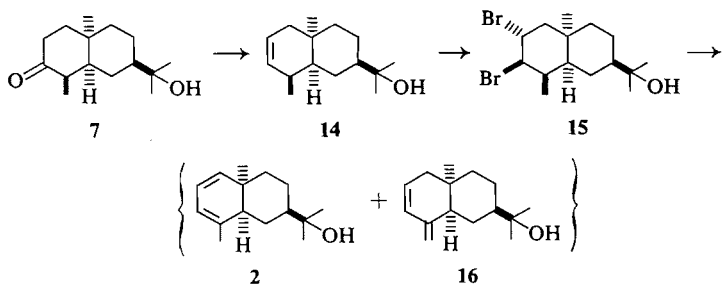
When diene **13** was treated under acidic conditions, only extensive degradation was observed. When **13** was treated with potassium *t*-butoxide in dimethylsulfoxide at 80°, there was no reaction. At 115°, some change occurred, but no occidentalol was formed (monitored by watching the δ 5.0–6.5 region in the p.m.r. spectrum, where occidentalol has a highly characteristic vinyl absorption pattern).

In order to test the stability of occidentalol itself under these conditions, it was heated with potassium *t*-butoxide in hexadeuteriodimethylsulfoxide at 80° for 50 h. After this period, the occidentalol was recovered in good yield, and extensive deuteration had occurred (20% d_3, 46% d_4, 30% d_5, and 4% d_6).

Having been thwarted in this attempt to prepare occidentalol from *epi*-carrisone, we turned to a less direct route. *cis*-Dihydro-*epi*-carrisone (**7**), prepared as outlined above, was subjected to the modified Bamford–Stevens reaction (12), to obtain the crystalline unsaturated alcohol **14** in 75% yield (see Scheme 4). This olefin reacted with bromine in CCl_4 to yield a dibromide (**15**, quantitative yield), which was dehydrobrominated by heating in 2,6-lutidine at 135° for 1 h. The product, obtained in 83% yield, was a mixture of (+)-occidentalol (**2**) and its isomer **16**, in a ratio of 55:45. The synthetic (+)-occidentalol, $[\alpha]_D^{CHCl_3}$ +313°, was indistinguishable from natural (+)-occidentalol by p.m.r., i.r., and v.p.c. mobility. The structure of isomer **16** was assigned on the basis of its spectra and empirical formula ($C_{15}H_{24}O$), determined by high resolution mass spectrometry.

The dehydrobromination of dibromide **15** was also accomplished with ethanolic KOH and with pyridine; similar ratios of **2** and **16** were obtained. Lithium dimethylpiperidide in hexane converted dibromide **15** back into olefin **14**.

Although the ratio of **2** to **16** was not changed



7 **14** **15**

2 **16**

SCHEME 4

[2]Enantiomeric projections have been used to more clearly illustrate the stereochemical point being made.

upon heating the mixture with potassium *t*-butoxide in dimethylsulfoxide, the percentage of occidentalol in the mixture did increase when it was treated in refluxing tetrahydrofuran with a trace of HCl. However, quantitative v.p.c. showed that this enhancement resulted from preferential destruction of **16**, rather than from conversion of **16** to **2**.

Experimental

All melting points are uncorrected. All p.m.r. spectra were measured on a Varian T-60 spectrophotometer.[3] Chemical shifts are given in p.p.m. downfield from internal tetramethylsilane. The i.r. spectra were measured on Perkin–Elmer 137 and 237 Infrared Spectrophotometers. Mass spectra were determined on a Consolidated 110 High Resolution Mass Spectrometer. Microanalyses were performed by the University of California Microanalytical Laboratory, Berkeley, California.

7β-(2-Hydroxy-2-propyl)-1,4aα-dimethyl-8aα-decahydronaphth-2-ol (5)

Dihydrooccidentalol (**4**) prepared by the method of von Rudloff and Erdtmann (3), was hydroborated by the method of Zweifel and Brown (13). From 1.9 g of unsaturated alcohol **4** was obtained 1.74 g of diol **5** (90% yield). The non-crystalline mixture was used directly in subsequent transformations.

7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-3,4,4a,5,6,7,8aα-octahydronaphthalen-2(1H)-one (7)

To a magnetically-stirred solution of 200 mg diol mixture **5** in 8.5 ml dry methylene chloride was added in one portion 430 mg red bispyridinechromium(VI) oxide (9). After stirring for 5 min, the supernatant liquid was decanted and the dark, tarry residue remaining was washed twice with 10 ml portions of ether. The combined organic fractions were washed successively with dilute, aqueous NaOH, dilute hydrochloric acid, and saturated brine. After drying over anhydrous $MgSO_4$, the solvent was removed to obtain 104 mg yellow oil, which gave a poorly resolved p.m.r. spectrum. Several rapid filtrations of a CCl_4 solution of this material through neutral alumina afforded 65 mg of a colorless oil which crystallized upon standing. The p.m.r. spectrum of this crystalline material was well resolved and completely different from that of the crude product. Recrystallization from hexane yielded material of analytical purity, m.p. 89–90°, $[\alpha]_D^{CHCl_3}$ −18°. The p.m.r. in CCl_4: δ 0.19 (C-1 Me, d, $J = 7$ Hz), 1.11 (*i*-propyl Me, s), 1.31 (angular Me, s); i.r. in CCl_4: 3400, 1700 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.40; H, 11.11.

(+)-5β-(2-Hydroxy-2-propyl)-2α-methylcyclohexanone (8)

A 50 g sample of (+)-dihydrocarvone (**3**) was added in one portion to a stirred solution of 104 g mercuric acetate in 360 ml water and 360 ml THF (10). Characteristic decolorization occurred after 20 s. After 7 min, 360 ml of 3 *M* aqueous NaOH was added, followed by 360 ml 0.3 *M* $NaBH_4$ in 3 *M* aqueous NaOH.[4] The product was isolated in the normal way by extraction into ether. After stirring over 20 g basic alumina (to remove the residual, finely dispersed mercury), the solvent was removed to obtain 52 g (93%) of keto alcohol **8** as a colorless oil, which was used without further purification. The p.m.r. in CCl_4: δ 0.97 (Me, d, $J = 6$ Hz), 1.18 (*i*-propyl Me, s).

8aα-Hydroxy-7β-(2-hydroxy-2-propyl)-1β,4aα-dimethyl-octahydronaphthalen-2(1H)-one (9)

To a well-stirring solution of 52 g ketone **8** in 110 ml ether at 0°, under nitrogen, was added a solution of 3.8 g KOH in 12 ml 95% ethanol. After 10 min, 13 g ethyl vinyl ketone in 75 ether was added dropwise over a period of 1 h. Stirring was continued at 0° for an additional 1 h, then at 25° for 1.5 h, during which time considerable quantities of product **9** precipitated. The reaction mixture was concentrated to approximately one-half volume (vacuum) and the resulting precipitate isolated by filtration.[5] The solid was taken up in ethyl acetate, washed twice with water and once with brine. The aqueous washes were extracted once with ether and the organic portions were combined. The solvent was evaporated from the crude solution on a steam bath at atmospheric pressure until crystals began to appear. Compound **9** was obtained as colorless needles, m.p. 189–190°. The yield was 13.0 g (31%). The p.m.r. in CH_3OH: δ 0.99 (Me, s), 1.02 (Me, d, $J = 7$ Hz), 1.10 (Me, s); i.r. in KBr: 3500, 1690 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30. Found: C, 70.55; H, 10.15.

7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3H)-one (epi-Carrisone (10))

A solution of 27 g keto-diol **9** in 600 ml THF was treated with 10 ml concentrated hydrochloric acid. After refluxing for 2 h, the solution was cooled and concentrated to 100 ml under reduced pressure. The concentrated solution was diluted with 400 ml ether and washed with 30% aqueous NaOH until the aqueous phase remained basic. After back-extraction of the aqueous washes with ether, the combined organic phases were washed with brine, dried, and evaporated under reduced pressure. The resultant oil was seeded with crystalline *epi*-carrisone, which had been previously obtained by chromatography of 6.5 g of the crude product (11). The solid obtained in this way was recrystallized from hexane – ethyl acetate to give 18.5 g (74% yield) of crystalline ketone **10**, m.p. 54–56° (lit. (13) m.p. 56°). The n.m.r. in CCl_4: δ 1.12 (angular Me, s), 1.22 (Me, s), 1.23 (Me, s), 1.74 (vinyl Me, s); i.r. in CCl_4: 3400, 1660 cm^{-1}.

[3]We thank the Dupont Company and the Research Committee, Berkeley Division, University of California, for the purchase of this instrument.

[4]Brown and Geohagen's procedure (10) calls for 0.5 *M* $NaBH_4$ in 3 *M* aqueous NaOH. However, some carbonyl reduction was observed when such a concentration was utilized in the present experiment.

[5]When these original mother liquors were washed several times with water and the volatile material evaporated under reduced pressure, a residue containing mostly ketone **8** was obtained. This oil could be resubmitted to the annelation reaction with ethyl vinyl ketone to give better yields of keto-diol **9** (greater than 50%) than were obtained using pure **8**.

TABLE 1. Catalytic hydrogenation of *epi*-carrisone

Run	Catalyst/solvent	Product ratio (7/11)	Method of analysis
(1)	10% Pd–C/95% ethanol	3:2	p.m.r.*
(2)	10% Pd–C/95% ethanol with a trace of KOH	1:1	p.m.r.*
(3)	10% Pd–C/ethyl acetate	2:1‡	p.m.r.;* v.p.c.†
(4)	10% Pd–C/acetic acid	4:1§	v.p.c.
(5)	10% Pd–C/95% ethanol with a trace of HCl	2:1	p.m.r.*
(6)	10% Pd–C/methanol	3:2	p.m.r.*
(7)	10% Pd–C/methanol with 5% (by weight) acidic Al_2O_3	3:1§	p.m.r.*
(8)	Rh–Al_2O_3/hexane	1:4§	p.m.r.*
(9)	Pt–C/95% ethanol	Complex mixture‖	p.m.r.*

*Estimates of *cis* to *trans* ratios were made by comparison of the relative areas of the isopropyl methyl peaks at δ 1.11 and 1.19, respectively.

†The v.p.c. analyses were made on the previously trimethylsilylated compounds.

‡This run gave 40% reduction of the carbonyl, which was not included in the *cis*/*trans* ratio.

§Although hydrogenation in acetic acid (run 4) gave the maximum *cis*/*trans* ratio, experience has shown that for ease of work-up and for optimum recovery of pure, crystalline *cis* isomer **7**, reduction in methanol with acidic alumina (run 7) is the method of preference.

‖This mixture probably includes products resulting from reduction of the carbonyl and hydrogenolysis.

7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-3,4,4a,5,6,7,-8,8aα-octahydronaphthalen-2(1H)-one (cis-Dihydro-epi-carrisone (7)) and 7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-3,4,4a,5,6,7,8,8aβ-octahydronaphthalen-2(1H)-one (trans-Dihydro-epi-carrisone (11))

A 4.79 g sample of *epi*-carrisone (**10**) in 100 ml absolute methanol was hydrogenated at atmospheric pressure over a mixture of 1.2 g acidic alumina and 0.2 g 10% palladium-on-carbon. Consumption of hydrogen ceased abruptly after the uptake of 1 *M* equiv. (500 ml hydrogen in 50 min). The reaction mixture was filtered and 2 ml water added to hydrolyze a small amount of methyl ketal (comprising about 5% of the product, as estimated by p.m.r.), which was observed to have formed in previous runs. After 2.5 h at room temperature, the reaction mixture was concentrated to 10 ml and partitioned between water and ether. The organic layer was washed with brine, dried, and evaporated. The crude crystalline product was obtained in quantitative yield. The crude material was shown by v.p.c. analysis to consist of a 3:1 mixture of *cis* and *trans*-dihydro-*epi*-carrisones (**7** and **11**, respectively). This conclusion was corroborated by comparison of the relative peak heights of the respective isopropylol methyl groups of **7** and **11** in the p.m.r. spectrum of the mixture (δ 1.11 for **7**, 1.19 for **11**).

By a combination of column chromatography (silica gel) and fractional crystallization, crystalline **7** was obtained; 2.09 g (43% yield), m.p. 88.5–89.5°, $[\alpha]_D^{CHCl_3}$ −18°. This material was identical by p.m.r., i.r., v.p.c. retention time, mixture m.p. and optical rotation with ketol prepared from (+)-occidentalol.

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 57.83; H, 10.98.

The structure assignment for the other product of this hydrogenation, **11**, was made on the basis of its p.m.r. spectrum, which was superimposable upon the p.m.r. spectrum of an authentic sample of **11** (see below), and its indistinguishability from authentic **11** by v.p.c.

Various other hydrogenation conditions were explored and are summarized in Table 1.

7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-3,4,4a,5,6,7,-8,8aβ-octahydronaphthalen-2(1H)-one (trans-Dihydro-epi-carrisone (11))

A solution of 0.4 g *epi*-carrisone (**10**) in 3 ml dry THF was added in one portion to 0.025 g lithium metal dissolved in 20 ml ammonia (freshly distilled from sodium). After 50 min, enough ammonium chloride was added to discharge the blue color, followed by enough dilute aqueous hydrochloric acid to acidify the solution to litmus. The mixture was extracted several times with ether and the combined ether extracts were washed with brine, dried, and evaporated under reduced pressure. *trans*-Dihydro-*epi*-carrisone was obtained as an oil; 0.353 g (88%). The analytical sample was obtained by preparative v.p.c. on a Carbowax column. The analytically pure material could not be crystallized from various proportions of ethyl acetate and hexane; $[\alpha]_D^{CHCl_3}$ +40°; p.m.r. in CCl_4: δ 0.95 (Me, d, J = 6 Hz), 1.08 (Me, s), 1.19 (*i*-propyl Me, s); i.r. in CCl_4: 3400, 1680 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.85; H, 10.75.

7β-(2-Hydroxy-2-propyl)-1,4aα-dimethyl-4,4a,5,6,7,8-hexahydronaphthalene (13)

A 0.20 g sample of *epi*-carrisone (**10**) (11) 0.16 g *p*-toluenesulfonylhydrazide, and 1 drop concentrated hydrochloric acid was added to 10 ml tetrahydrofuran and the mixture was refluxed for 30 h. The mixture was then diluted with 10 ml benzene and distilled until all the tetrahydrofuran and benzene–water azcotrope had been collected and the b.p. had reached 80°. The remaining solution was cooled to 0°, under nitrogen, and diluted with 5 ml dry tetrahydrofuran. Ethereal methyllithium was added (1.8 ml of a 1.6 *M* solution), and the red reaction mixture was stirred for 2 h at room temperature. Excess methyllithium was de-

stroyed by the addition of 10 ml water, and the layers were separated. The aqueous layer was extracted several times with pentane. After drying, the combined organic solutions were evaporated to yield 0.19 g (99% yield) of diene **13**, as a slightly yellow oil, which was used directly without further purification. The p.m.r. in CCl_4: δ 0.91 (angular Me, s), 1.07 (Me, s), 1.13 (Me, s), 1.71 (vinyl Me, s); i.r. in CCl_4: 3400 cm^{-1}.

7β-(2-Hydroxy-2-propyl)-1β,4aα-dimethyl-1,4,4a,5,6,7,8,-8aα-octahydronaphthalene (14)

A 0.200 g sample of *cis*-dihydro-*epi*-carrisone (**7**) (1) in 20 ml tetrahydrofuran together with 0.147 g *p*-toluenesulfonylthydrazide and 2 drops concentrated hydrochloric acid was refluxed for 7 h on a steam bath. The nearly colorless reaction mixture was cooled and washed twice with 2 ml portions of saturated brine. The organic layer was diluted with 10 ml ether and 20 ml benzene and distilled until the b.p. reached 80°. The reaction flask was sealed with serum stoppers, cooled to 0°, and 5 ml of tetrahydrofuran was introduced. Ethereal methyllithium (3 ml of a 1.6 *M* solution) was added by syringe and the mixture was kept for 10 min at 0°. The cooling bath was then removed and the mixture was stirred at room temperature for 2.5 h, at which time gas evolution had ceased. The resultant brown mixture was treated cautiously with 5 ml water and then 3 ml pentane. The phases were then separated and the aqueous portion extracted twice with pentane. The combined organic phases were dried and evaporated to obtain 0.190 g of a lightly colored glass. Chromatography on 7 g silica gel yielded 0.138 g unsaturated alcohol **14** (75% yield) as a white solid, m.p. 75.5–76.5°, $[\alpha]_D^{CHCl_3}$ +54°; p.m.r. in CCl_4: δ 0.90 (Me, s), 0.95 (Me, d, J = 7 Hz), 1.08 (*i*-propyl Me, s), 5.25 (H-2 and -3, unresolved m); i.r. in CCl_4: 3400 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.77; H, 11.84.

2β,3α-Dibromo-7β-(2-hydroxy-2-propyl)-1β,4aα-dimethyl-8aα-decahydronaphthalene (15)

To a 0.42 g sample of unsaturated alcohol **14** in 20 ml carbon tetrachloride at 0° was added a solution of 0.35 g bromine in 1 ml carbon tetrachloride. The reaction mixture was stirred for 2.5 h at 0°. The cooling bath was then removed and 0.5 ml water and sufficient sodium hydrogen sulfite to quench the excess bromine were added. The mixture was diluted with 50 ml pentane and washed with 5 ml portions of water, saturated aqueous sodium bicarbonate and brine. After drying and evaporation at reduced pressure, dibromide **15** was obtained in quantitative yield (0.75 g). The p.m.r. in CCl_4: δ 1.11 (*i*-propyl Me, s), 1.13 (Me, d, J = 7 Hz), 1.33 (Me, s), 4.58 (CBr—*H*, m, $w_{1/2}$ = 10 Hz), 4.97 (CBr—*H*, m, $w_{1/2}$ = 10 Hz); i.r. in CCl_4: 3300 cm^{-1}. This crude product was used in the succeeding transformation with further purification.

(+)-7β-(2-Hydroxy-2-propyl)-1,4aα-dimethyl-4a,5,6,7,8,-8aα-hexahydronaphthalene ((+)-occidentalol (2)) and 7β-(2-Hydroxy-2-propyl)-4aα-methyl-1-methylene-1,4,4a,5,6,7,8,8aα-octahydronaphthalene (16)

A solution of 0.626 g dibromide **15** in 9 ml freshly distilled 2,6-lutidine was heated in an oil bath at 133–135° for 1 h. During the heating period, the mixture darkened and lutidine hydrobromide precipitated. The reaction mixture was cooled to room temperature and decanted. After washing the solid residue with 40 ml of pentane, the combined organic solutions were diluted with more pentane to a total volume of 70 ml. The solution was washed with 15% aqueous hydrochloric acid until the wash remained acidic (five 10 ml portions), and the combined aqueous washes were extracted with pentane. The organic fractions were combined, washed with 5 ml 0.1 *M* aqueous NaOH, dried, and evaporated. The product was 0.298 g (82.5%) of pale yellow semi-solid, shown by v.p.c. analysis (3 ft × 1/4 in. Carbowax, 190°) to be a 55:45 mixture of (+)-occidentalol (**2**) and its isomer **16**. Analytical samples were obtained by preparative v.p.c. on the aforementioned column.

The synthetic (+)-occidentalol so obtained was identical to natural (+)-occidentalol by p.m.r. and i.r. spectroscopy and by v.p.c. and t.l.c. mobility. The synthetic material, collected by preparative v.p.c., melted over the range 86.5–92° (lit. (3) 97.5–98°, 95.2–95.6°). The m.p. of an authentic sample of (+)-occidentalol, generously supplied to us by Professor Erdtmann, m.p. 92–93°, was not depressed in admixture with the synthetic material. Our synthetic (+)-occidentalol had $[\alpha]_D^{CHCl_3}$ +313° (lit. (3) $[\alpha]_D^{CHCl_3}$ +361°). The authentic sample supplied us by Professor Erdtmann had $[\alpha]_D^{CHCl_3}$ +327°.

Anal. *m/e* for $C_{15}H_{24}O$: 220.1830.

The structural assignment for the isomeric product was made on the basis of its empirical formula, p.m.r. spectrum and i.r. spectrum; $[\alpha]_D^{CHCl_3}$ −67.7°; p.m.r. in CCl_4: δ 0.83 (Me, s), 1.14 (*i*-propyl Me, s), 4.71 (=CH_2, m); i.r. in CCl_4: 3400 cm^{-1}.

Anal. *m/e* for $C_{15}H_{24}O$: 220.1843.

We acknowledge financial support by the National Science Foundation, the Public Health Service, and the Alfred P. Sloan Foundation. We also thank Professor H. Erdtmann for a generous gift of (+)-occidentalol.

The Relative Rates of the Reaction of Active Nitrogen with Perfluoro-olefins and Perfluorobutyne-2[1]

M. RUJIMETHABHAS[2] AND W. E. JONES
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received March 12, 1971[3]

A formulation of the diffusion-kinetic model based on the spherical diffusion flame method is presented and discussed. The application of this technique has been made to obtain the relative rates of the reaction of active nitrogen with perfluoroethylene, perfluoropropene, perfluorobutadiene-1,3, and perfluorobutyne-2.

Une mise en formule du modèle de diffusion cinétique, fondé sur la méthode de la flamme à diffusion sphérique, est présentée et discutée. L'application de cette technique a servi à déterminer les vitesses relatives de la réaction entre l'azote actif et le perfluoroéthylène, le perfluoropropène, le perfluorobutadiène-1,3, et le perfluorobutyne-2.

Canadian Journal of Chemistry, **50**, 346 (1972)

Introduction

The reaction of active nitrogen with unsaturated perfluorocarbons has been found to produce a large number of products (1). Three of these, N_2O, probably produced by the action of N_2F_2 on the glass walls, FCN, and a polymer are the only products found to contain nitrogen. FCN and N_2O appear in negligibly small amounts. It is difficult in such a complicated system to study the kinetics by the usual methods. Since these reactions give very bright spherical flames with active nitrogen it was felt that the diffusion flame method could be applied to these reactions.

The spherical diffusion flame technique was first developed by Hartel and Polanyi (2). It has since been investigated by a number of workers and several reviews have been published (3–5) on the method. It has been applied to study the kinetics of the reaction of active nitrogen with ethylene by Greenblatt and Winkler (6) and later by Milton and Dunford (7). Both reports were based on the assumption that the rate constant obtained was due only to the primary reaction. Heller (8) has made a significant contribution by investigating the errors involved in the diffusion flame method and discussed many aspects of experimental conditions. The theory of the experimental method has also been studied by Reed and Rabinovitch (9, 10). The application has been extended by Garvin, Guinn, and Kistiakowsky (11, 12) to study the kinetics by mapping the steady state temperature pattern of the reaction zone, thereby providing a method for studying the kinetics of reactions which are not accompanied by a flame or other means of visual detection.

In applying the diffusion flame method, in which the visual boundaries of the flame are used to calculate the reaction rate, it is necessary that the chemical reaction follows the light emission. This is very likely true for the reactions of alkanes and alkenes with active nitrogen where the reactions proceed to complete consumption of the reactive species (13, 14). However, in certain reactions, for example active nitrogen $+C_2N_2$, reactive species have been found to be present after the light emitting reactions are complete (15). In the present study we have assumed that the flame produced in the reaction of active nitrogen with fluorocarbons is representative of the reaction.

Experimentally, one reactant (referred to here as the nozzle reactant) is carried by an inert gas and allowed to escape through a nozzle into the center of the reaction vessel containing a constant flow of the second reactant, normally known as the atmosphere reactant. The conditions of the experiment are adjusted so that the nozzle reactant reacts as it diffuses into the atmosphere reactant giving a reaction zone which has spherical symmetry.

In the treatment of Hartel and Polanyi the following simplifying assumptions were introduced: (*1*) There is a spherical symmetric dis-

For personal use only.

tribution of the nozzle reactant in the reaction zone. (*2*) The effect of convective flow is negligible. (*3*) The concentration of the atmosphere reactant is constant throughout the reaction zone.

Reed and Rabinovitch observed that the flame was distorted from spherical to slightly oval in shape when seen from the direction perpendicular to the flow axis. They attributed this effect to convective flow. This effect has been estimated to be small and generally is considered negligible (10, 12).

The case involving only two reactive species where the concentration of one is assumed to be constant as in the third assumption above, has been studied by previous workers. This treatment leads to a single differential equation as obtained by Hartel and Polanyi. An attempt to eliminate the third assumption, *i.e.* taking into consideration the depletion of atmosphere reactant, has been made by Cvetanovic and Le Roy (16, 17). Two simultaneous second order nonlinear partial differential equations have been derived, which unfortunately cannot be solved analytically. An approximate solution was obtained by a trial and error numerical computation. Later, Smith (18) succeeded in solving a similar set of differential equations as derived by Cvetanovic and Le Roy, in terms of tabulated functions by successive approximations.

The reaction of atomic sodium with fluorinated methyl chlorides, where more than two reactive species are present has been discussed by Reed and Rabinovitch (9, 10). In this case they were able to obtain the overall rate constants for the reaction. The extent of the secondary reactions could be estimated by the ratio of NaCl:NaF formed as products. From this information corrections to the overall rate constants could be made, yielding the primary rate constants.

So far no attempt has been made to formulate a diffusion-kinetic model for the spherical diffusion flame for the case of more than two reactive species. In order to discuss the application of the diffusion flame method to the active nitrogen–fluorocarbon reactions, such formulation is necessary.

The derivation follows from the general equation of continuity for a chemical reaction in an isothermal system and an isotropic medium (19, 20, *cf.* 9–10):

$$[1]\quad \partial C/\partial t = D \text{ div grad } C - (\mathbf{v} \text{ grad } C) + q$$

where D = diffusion coefficient; $\mathbf{v}$, the convection velocity; C, the concentration of the diffusing substance as a function of time and space; q, the chemical source term (the amount of material changed through chemical reactions per unit volume per unit time). If the effect of convective flow is neglected, the equation takes the following form, *cf.* Crank (21) and Frank-Kamenetskii (20):

$$[2]\quad \partial C/\partial t = D\nabla^2 C + q$$

writing div grad $\equiv \nabla^2$ = Laplacian operator.

The reaction of active nitrogen with perfluoroethylene has been investigated and the following *principal* reaction steps have been proposed by Madhavan and Jones (1):

$$[3]\quad C_2F_4 + N \xrightarrow{k_3} CF_2N + CF_2$$

$$[4]\quad C_2F_4 + N \xrightarrow{k_4} FCN + CF_3$$

$$[5]\quad CF_2N \xrightarrow{k_5} FCN + F$$

$$[6]\quad CF_2 + N \xrightarrow{k_6} FCN + F$$

$$[7]\quad CF_3 + N \xrightarrow{k_7} FCN + 2F$$

$$[8]\quad C_2F_4 + FCN \xrightarrow{k_8} (C_3F_5N)\text{ polymer}$$

By application of [2], the diffusion-kinetic equations describing reactions 3 through 8 are given by [9], *cf.* (22) and its previous references,

$$[9]\quad \begin{cases} \partial P_{C_2F_4}/\partial t = D_{C_2F_4}\nabla^2 P_{C_2F_4} - k_3 P_{C_2F_4}P_N \\ \qquad - k_4 P_{C_2F_4}P_N - k_8 P_{C_2F_4}P_{FCN} \\ \partial P_N/\partial t = D_N\nabla^2 P_N - k_3 P_{C_2F_4}P_N \\ \qquad - k_4 P_{C_2F_4}P_N - k_6 P_N P_{CF_2} - k_7 P_N P_{CF_3} \\ \partial P_{CF_2N}/\partial t = D_{CF_2N}\nabla^2 P_{CF_2N} \\ \qquad + k_3 P_{C_2F_4}P_N - k_5 P_{CF_2N} \\ \partial P_{CF_2}/\partial t = D_{CF_2}\nabla^2 P_{CF_2} \\ \qquad + k_3 P_{C_2F_4}P_N - k_6 P_N P_{CF_2} \\ \partial P_{CF_3}/\partial t = D_{CF_3}\nabla^2 P_{CF_3} \\ \qquad + k_4 P_{C_2F_4}P_N - k_7 P_N P_{CF_3} \\ \partial P_{FCN}/\partial t = D_{FCN}\nabla^2 P_{FCN} + k_4 P_{C_2F_4}P_N \\ \qquad + k_5 P_{CF_2N} + k_6 P_N P_{CF_2} \\ \qquad + k_7 P_N P_{CF_3} - k_8 P_{C_2F_4}P_{FCN} \end{cases}$$

where P_i is the partial pressure of the i^{th} species.

$$\nabla^2 \equiv \frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r}$$

for spherical symmetry. This set of simultaneous second order non-linear partial differential eqs. 9 are representative of the species predicted in the overall mechanism. While [9] cannot be solved analytically, in principle, the numerical integration should be possible. However, the limitation has been set in the present study by inadequate knowledge of many of the parameters *e.g.* many unknown D's and k's. Without such information the model is too flexible and any number of sets of values might be substituted to reproduce the experimental data. This includes the variation of the k's which are normally constants. In addition, since a truly comprehensive mechanistic study has not been made for the active nitrogen–fluorocarbon reactions, other mechanistic interpretations might be possible and these would affect the flexibility of the model in the same manner as the unknown D's and k's. Because of these difficulties we have attempted to assume without loss of (mechanistic) generality, a simplified mechanism as follows:

[10] $$C_2F_4 + N \xrightarrow{k_{10}} FCN + CF_3$$

[11] $$CF_3 + N \xrightarrow{k_{11}} FCN + 2F$$

[12] $$C_2F_4 + FCN \xrightarrow{k_{12}} (C_3F_5N)\text{polymer}$$

The diffusion-kinetic equations corresponding to eqs. 10–12 are:

[13] $$\partial P_{C_2F_4}/\partial t = D_{C_2F_4}\nabla^2 P_{C_2F_4} - k_{10}P_{C_2F_4}P_N - k_{12}P_{C_2F_4}P_{FCN}$$

[14] $$\partial P_N/\partial t = D_N\nabla^2 P_N - k_{10}P_{C_2F_4}P_N - k_{11}P_{CF_3}P_N$$

[15] $$\partial P_{CF_3}/\partial t = D_{CF_3}\nabla^2 P_{CF_3} + k_{10}P_{C_2F_4}P_N - k_{11}P_{CF_3}P_N$$

[16] $$\partial P_{FCN}/\partial t = D_{FCN}\nabla^2 P_{FCN} + k_{10}P_{C_2F_4}P_N + k_{11}P_{CF_3}P_N - k_{12}P_{C_2F_4}P_{FCN}$$

Even with the simplified mechanism, these partial differential equations cannot be integrated analytically. Again there are many parameters which are not known. Since we know only the boundary conditions of the original reactants, *i.e.* $P_{C_2F_4}$ and P_N, it is only possible for us to further develop eqs. 13 and 14. For the steady reaction at any spatial position in the reaction volume, $\partial P_i/\partial t = 0$, so that at any instant it is possible to write:

$$k_{12}P_{C_2F_4}P_{FCN} = ak_{10}P_{C_2F_4}P_N$$

$$k_{11}P_{CF_3}P_N = bk_{10}P_{C_2F_4}P_N$$

where a and b are constants, and eqs. 13 and 14 take the following form:

$$D_{C_2F_4}\nabla^2 P_{C_2F_4} - (1+a)k_{10}P_{C_2F_4}P_N = 0$$

$$D_N\nabla^2 P_N - (1+b)k_{10}P_{C_2F_4}P_N = 0$$

Replacing $(1+a)\,k_{10}$ by k_a and $(1+b)\,k_{10}$ by k_b, where k_a and k_b are apparent rate constants, the above equations can be expressed as:

[17] $$D_{C_2F_4}\nabla^2 P_{C_2F_4} - k_aP_{C_2F_4}P_N = 0$$

[18] $$D_N\nabla^2 P_N - k_bP_{C_2F_4}P_N = 0$$

If it is assumed that the partial pressure of nitrogen atoms is constant throughout the reaction zone (*cf.* the third assumption of Hartel and Polanyi) which is a reasonable assumption in view of the experimental conditions that, in all cases, the spherical flame is photographed against the yellow background of active nitrogen, *i.e.* atomic nitrogen is always present in excess. To this approximation [18] will disappear and [17] could be written, in the case of spherical symmetry as:

[19] $$D_{C_2F_4}\left(\frac{d^2P_{C_2F_4}}{dr^2} + \frac{2}{r}\frac{dP_{C_2F_4}}{dr}\right) - k_aP_{C_2F_4}P_N = 0$$

the approximate solution to [19] similar to that obtained by Hartel and Polanyi is

[20] $$k_a = \frac{(\ln P_f/P_0)^2}{d^2/4}\cdot\frac{D}{P_N}$$

where k_a = the apparent rate constant; P_f, the partial pressure of fluorocarbon at the jet; P_0, the partial pressure of fluorocarbon at the edge of the flame; P_N, the partial pressure of nitrogen atoms; d, the diameter of the flame; D, the diffusion coefficient. Equation 20 has been used to obtain the apparent rate constants for the present work. In the derivation of this equation, which is strictly true for a point source nozzle, the finite nozzle size has been neglected. However, this approximation should not intro-

duce significant errors in the calculated rate constants.

The physical meaning of k_a may need further clarification, k_a as it is derived from [13] is equivalent to $(1 + a)k_{10}$, and thus not only represents k_{10}, the desired rate constant, but an added quantity ak_{10}. The value ak_{10} is related to k_{12} as follows

$$ak_{10}P_{C_2F_4}P_N = k_{12}P_{C_2F_4}P_{FCN}$$

It is impossible to know the size of a, but it is probable that it is small, since depletion of C_2F_4 by [12] is the second step of a consecutive reaction scheme. Provided, therefore, that a is small $(1 + a)k_{10}$ reduces to k_{10} the desired rate constant.

Experimental and Instrumental Method

Perfluoroethylene was obtained by the decomposition of Teflon at 450 °C, the product was purified by passing through a gas chromatographic column of silica gel coated with 3% squalane, only that fraction identified as perfluoroethylene by i.r. (23) was collected. Perfluoropropene and perfluorobutyne-2 were obtained from Peninsular Chemresearch Inc., and Pierce Chemical Company, respectively. These were purified by bulb-to-bulb distillation. Perfluorobutadiene-1,3 was obtained from Pierce Chemical Company and was used without further purification. Gas chromatographic analysis of these gases indicated no impurity. Nitric oxide was obtained from Matheson of Canada Ltd., purified by condensation in and evaporation from ascarite (8–20 mesh). Purified nitrogen from Canadian Liquid Air Corp. was further purified by passing through a column of heated copper at 425 °C and through a liquid nitrogen trap. It was activated either by a glow discharge excited by a 125 W microwave unit operating at 2450 MHz and at a power output of 85% or by a condensed electric discharge.

The reaction was studied in a fast flow system similar to that described by Madhavan and Jones (24).

The concentration of nitrogen atoms was measured by the NO gas titration technique (25, 26). Molecular diameters of the various gases necessary for the calculation of D (27), were taken as 3.75, 5.6, 6.6, 6.4, and 6.2 Å for nitrogen (28), perfluoroethylene, perfluoropropene, perfluorobutyne-2, and perfluorobutadiene-1,3, respectively. The diameter of molecular rather than atomic nitrogen was used, since the amount dissociated was only a small percentage of the total concentration. The diameters of perfluoropropene, perfluorobutyne-2, and perfluorobutadiene-1,3 were obtained from viscosity measurements (29), while the diameter of perfluoroethylene was calculated from the known viscosity (30).

Results and Discussion

Table 1 presents the data necessary for the calculation of the apparent rate constants for the reaction of active nitrogen with the perfluorocarbons. Columns P_f and P_0 denote the partial pressures of perfluorocarbon at the jet and at the edge of the flame respectively. P_N is the partial pressure of nitrogen atoms; d is the diameter of the flame, and D is the diffusion coefficient of fluorocarbon into the gas mixture. The data obtained by both the condensed and microwave discharges for each reaction are tabulated, except for the reaction of perfluorobutyne-2 with active nitrogen produced by microwave discharge in which case it was impossible to measure the extremely low flow rate of perfluorobutyne-2 necessary to produce a spherical flame.

The average apparent rate constants for the reactions of active nitrogen with, perfluoroethylene (C_2F_4), perfluoropropene (C_3F_6), *trans*-perfluorobutene-2 (t-C_4F_8-2), perfluorobutadiene-1,3 (C_4F_6-1,3), and perfluorobutyne-2 (C_4F_6-2) are collected in Table 2.

The use of the diffusion flame technique to obtain the absolute rate constant is rather difficult as has been pointed out by Benson (31). The normal sources of errors are the effect of the convective flow, the exact mathematical treatment of which is rather remote. The effect of pressure of the nozzle reactant and the problem associated with the boundary conditions at the flame edge. These effects have been investigated and discussed at length by Reed and Rabinovitch. They have applied different formula for the evaluation of k, the overall rate constants; from their results the major difference among k's are about a factor of 2. The photographs of the flame, see *e.g.* (24), taken in the direction perpendicular to the flow axis for the reaction of active nitrogen with perfluoro-olefins are seen to have a reasonably sharp flame edge. The flame is spherical rather than oval in shape as is usually observed for the reaction of atomic sodium with alkyl halides.

Cvetanovic and Le Roy (16) have estimated that the error created by neglecting the effect of atmosphere depletion is about 20% for the reaction of sodium atoms with CH_3CH_2Cl.

The difficulty in estimating the absolute rate constant for the primary reaction when the process is accompanied by the secondary reactions could be even more pronounced as evidenced by the previous workers (9, 10). The present work also encounters a somewhat similar difficulty; apart from the fact that there are many parameters which are presently unknown,

the accuracy in estimating the rate constant for the primary process will depend upon how well the evaluation of the rates for many secondary reactions steps are carried out.

Although the simplified mechanism used as a model to derive the diffusion-kinetic equations leaves out some of the steps in the principal mechanism, it is considered that such a model

*The rate of *trans*-perfluorobutene-2 has been taken as unity.
†See ref. 24.
‡Unobtainable due to the difficulty in measuring the extremely small flow rates necessary to produce a spherical flame.

should be sensitive to the secondary reactions. Evidence which may be used to support such a position comes from the work of Herron and Huie (32) who estimate by mass spectrometry the absolute rate constant for the reaction of active nitrogen with *trans*-C_4F_8-2 at 500 °K to be $\leqslant 4 \times 10^9$ cc mol^{-1} s^{-1} which is less than the value estimated by the diffusion flame method (24) of 2.5×10^{10} cc mol^{-1} s^{-1} at 313 °K.

It has not been possible for us to obtain the absolute rate constant for the reaction of active nitrogen with perfluorocarbons for the reason given earlier, however, since they produce very similar products (1), it is probable that the reaction of various fluorocarbons have very similar mechanisms, and the relative rates should yield useful information about the reactivities of these compounds. We, therefore, calculate the relative rate constants using the value of *trans*-perfluorobutene-2 as reference. These values are also presented in Table 2.

From Table 2 it is evident that the reactions of active nitrogen with perfluorocarbons could be arranged in order of increasing reactivity as follows: $t\text{-}C_4F_8\text{-}2 < C_3F_6 < C_4F_6\text{-}1,3 < C_4F_6\text{-}2 < C_2F_4$.

It has been suggested by Chesick (33) that the fluorine atoms in C_2F_4 exert a π-electron destabilization effect and that C_2F_4 is 16–18 kcal/mol less stable than ethylene. From the data obtained by his study, together with that of Schlag and Kaiser (34), Chesick has proposed as a working rule that it is the first substitution of a CF_3 group for a fluorine at the double bond which causes the principal stabilization of the π-electron system (to the extent of about 10 kcal/mol) and the effect of the second substitution of a CF_3 group is small relative to the first substitution. It is interesting to note that the relative rate constants for the reactions of active nitrogen with C_2F_4, C_3F_6 and $t\text{-}C_4F_8\text{-}2$ seem to indicate such a trend.

A Study of the Barriers to Rotation in Some Highly Substituted Diphenyl Ethers[1]

J. J. BERGMAN[2] AND W. D. CHANDLER[3]

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

Received July 27, 1971

Energy barriers to rotation about Ar–O bonds have been obtained from an analysis of the variable temperature n.m.r. spectra of a number of highly substituted diphenyl ethers. These barriers are explained on the basis of structural and conformational effects and their implication for the resolution of optical isomers is discussed.

Les barrières d'énergie de rotation autour des liaisons Ar—O ont été obtenues à partir des spectres r.m.n. à température variable d'un certain nombre de diphényl éthers fortement substitués. Ces barrières sont expliquées en fonction des effets structuraux et conformationnels; leur conséquence en vue de la résolution d'isomères optiques est discutée.

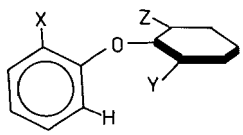
Introduction

It has been established that many triply ortho-substituted diphenyl ethers exist in solution preferentially in an H-inside conformation as shown in Fig. 1 (1, 2). Appropriately substituted ethers (*e.g.* 1) are dissymmetric (without reflection symmetry) in this conformation and could, in principle, be resolved into optical isomers. Several attempts to carry out resolution have, however, failed (3–7). Since rotation of either or both rings about the ether linkage would convert **1** to either an enantiomer or a diastereomer (see Discussion), it is of interest to determine the magnitude of the energy barriers for these rotational processes. This is especially important as these systems provide fundamental models to aid in the study of rotational barriers of ethers related to thyroxine and other medicinally important ethers which have been shown to exist in the same preferred conformation (8).



1

FIG. 1. H-Inside conformation of a triply ortho-substituted diphenyl ether.

[1]Abstracted from the Ph.D. Thesis of J. J. Bergman, University of Saskatchewan, Regina, June 1971.

[2]Present Address: Department of Chemistry, Saint Francis Xavier University, Antigonish, Nova Scotia.

[3]Author to whom correspondence should be addressed.

Nuclear magnetic resonance spectroscopy offers an excellent method for determining energy barriers if signal shapes or patterns are temperature dependent. Free energy barriers to rotation in diphenyl ethers may be calculated from coalescing signals by means of the Eyring equation, the logarithmic form of which is [1]

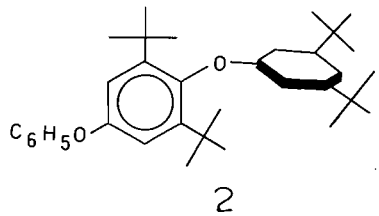
$$[1] \quad \Delta G^{\ddagger} = 4.57 T_c \,(10.32 + \log\,(T_c/k_c))$$

where T_c is the coalescence temperature and k_c is the rate constant for rotation at the coalescence temperature (9). Equation 1 will be applicable to rotation about Ar—O bonds if the protons whose signals are coalescing are exchanged by this rotation. The value of k_c may be calculated for the collapse of two singlets to one singlet from eq. 2, where $\Delta\nu$ is the chemical shift difference in Hz between the two singlets obtained from

$$[2] \quad k_c = \pi\Delta\nu/\sqrt{2}$$

the n.m.r. spectrum taken well below T_c (9). Equation 2 assumes equal concentrations of the equilibrating species and no coupling between the protons whose signals are coalescing. If $\Delta\nu$ is large compared with the natural line widths and coupling constants, coupling may be neglected but such coupling, when this is not the case, will result in an apparent k_c larger than the true one and too low a value for $\Delta G^{\ddagger}$ (10). There are other equations used to estimate k_c; the validity of these and [2] for different situations has been investigated recently by Kost *et al.* (11).

Since the spectra of ethers we studied pre-



2

FIG. 2. H-Inside conformation suggested by Bolon (12).

viously (1, 2) indicated no temperature dependence, it seemed advisable to investigate ethers with larger ortho substituents. Bolan (12) has noted that the two *t*-butyl groups meta to the ether linkage in **2** appear to be non-equivalent from the n.m.r. spectrum, and this observation led him to suggest the H-inside conformation shown in Fig. 2. Kessler *et al.* (13) have calculated a free energy barrier to rotation of 17.8 kcal/mol for **3** based on the coalescence of the n.m.r. signals for the methyl groups within a given isopropyl group (henceforth referred to as the isopropyl methyl groups) at temperatures above 57°. This would appear to be the first direct measurement of the barrier in highly substituted diphenyl ethers although Lehmann (14) has argued that the coalescence phenomenon may be explained by hindered rotation about the Ar—isopropyl bond rather than about an Ar—O bond.

In this paper we report a study of rotation in other highly substituted diphenyl ethers using variable temperature spectroscopy. In some cases $\Delta G^{\ddagger}$ appears to be of suitable magnitude that optical resolution of the enantiomeric

conformers of similar ethers containing the necessary dissymmetry may be possible.

Results

Variable temperature n.m.r. spectra of **3**, **4**, **5**, **6**, and **8** are reproduced in Figs. 3–7. Table 1 contains coalescence data (T_c and k_c) and $\Delta G^{\ddagger}$ determined at T_c for **3**, **4**, **5**, and **8**. The parameters k_c and $\Delta G^{\ddagger}$ were calculated from eqs. 1 and 2;[4] the estimated error in values of the latter is

TABLE 1. Coalescence data and $\Delta G^{\ddagger}$ values

Compound	Absorption measured	T_c (°C)	$\Delta\nu$ (Hz)[a]	$k_c(s^{-1})$[b]	$\Delta G^{\ddagger}$ (kcal/mol)[c]
3	Isopropyl methyls	57			17.8[d]
4	Isopropyl methyls	−70	7.0	15.6	10.6
	Ring protons	−60	107.0	238.0	10.1
5	Isopropyl methyls	−70	6.0	13.3	10.7
8	Ring protons	67	66.7	150.0	16.5

[a]The $\Delta\nu$ values for compounds **4** and **5** were obtained at 100 MHz. That for **8** was obtained at 60 MHz.
[b]From eq. 2.
[c]From eq. 1 at T_c.
[d]Reported by Kessler *et al.* (9, 13).

[4]Although the exchanging ring protons couple in these compounds, $\Delta\nu \gg J$ so that eq. 2 was used without correction for the coupling (9–11). It has been pointed out that the use of [2] for the isopropyl methyl absorptions is suspect. However, even if k_c were wrong by an order of magnitude, which is unlikely, $\Delta G^{\ddagger}$ would be wrong by less than 1 kcal/mol.

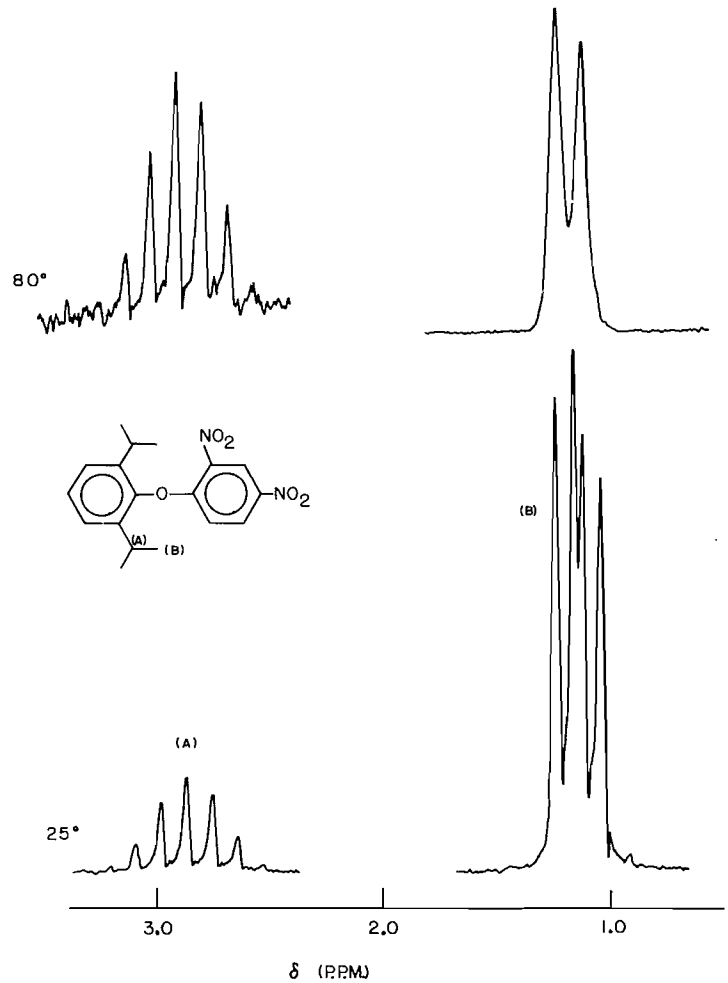

FIG. 3. Variable temperature n.m.r. spectra of **3**.

± 0.4 kcal/mol, based almost exclusively on uncertainties in T_c.

Compound **7** was found to undergo coalescence around ambient temperature at 60 MHz, having what appeared to be an AA′BB′C pattern for the protons of the non-alkylated ring above this temperature and an ABCDE pattern below it. No indication of n.m.r. changes were noted for **9** or **10** over a temperature range of -70 to 150° at 60 MHz.

Discussion

The basis for the observation of non-equivalence of the isopropyl methyl groups of an ether such as **3** (Fig. 3) is that in one H-inside conformer[5] the methyl groups within each isopropyl are anisochronous (15) although the two isopropyls are themselves enantiotopic[6] and are therefore normally equivalent in the n.m.r. spectrum. This non-equivalence of the methyl groups holds for all conditions of rotation about the Ar—isopropyl bond and is an example of a

[5]In this case there are two identical H-inside conformers, differing only by rotation of the di-isopropyl-substituted ring through 180°. If the alkyl-substituted ring had no plane of symmetry these two conformers would be enantiomers (see later discussion and Fig. 10). There is no spectral indication of any NO_2-inside conformers.

[6]Groups are enantiotopic if they can be interchanged by a rotation–reflection operation (S_n) to give a structure indistinguishable from the original (15).

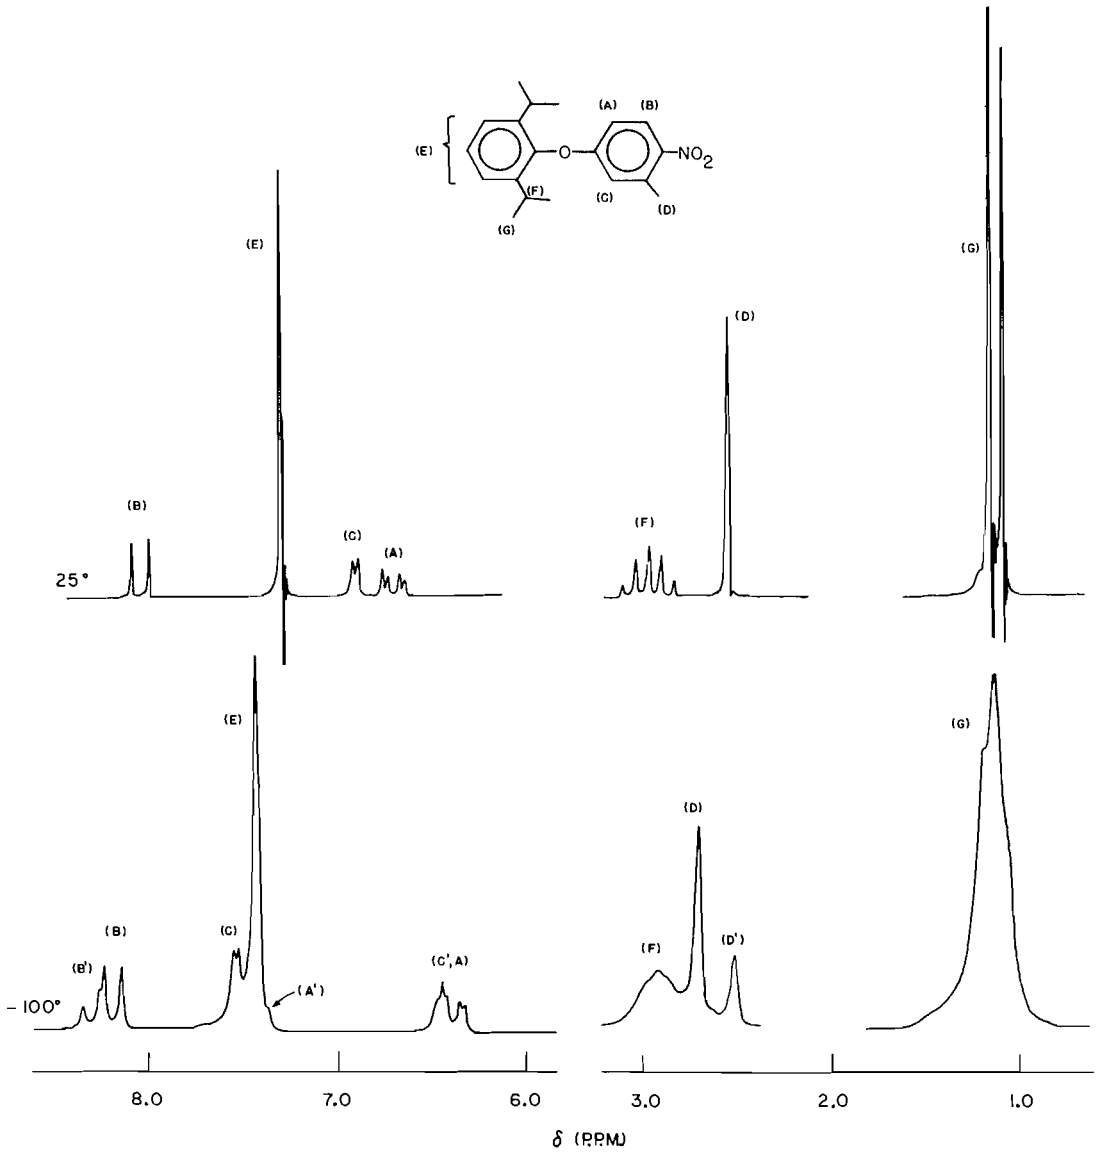

FIG. 5. Variable temperature n.m.r. spectra of **5**.

fairly well documented phenomenon (16–18) which produces non-equivalence of the X groups in any A-CX_2-B system where either A or B is asymmetric. Since the rate of rotation about the Ar—O bond increases with temperature, the n.m.r. spectrometer sees only a time average of the conformers above T_c (Fig. 8). The methyls in an isopropyl group exchange identity when the conformers are interconverted and are therefore seen as equivalent. At temperatures below T_c, interconversion of the conformers is slow enough for the spectrometer to be able to distinguish two different methyls. Thus, a study of the variable temperature behavior of isopropyl methyl signals is a study of rotation of the isopropyl-substituted ring about the Ar—O bond.

The spectrum of **6** (Fig. 6) shows one set of absorptions for the two sec-butyl groups at temperatures above 50° and two sets at lower

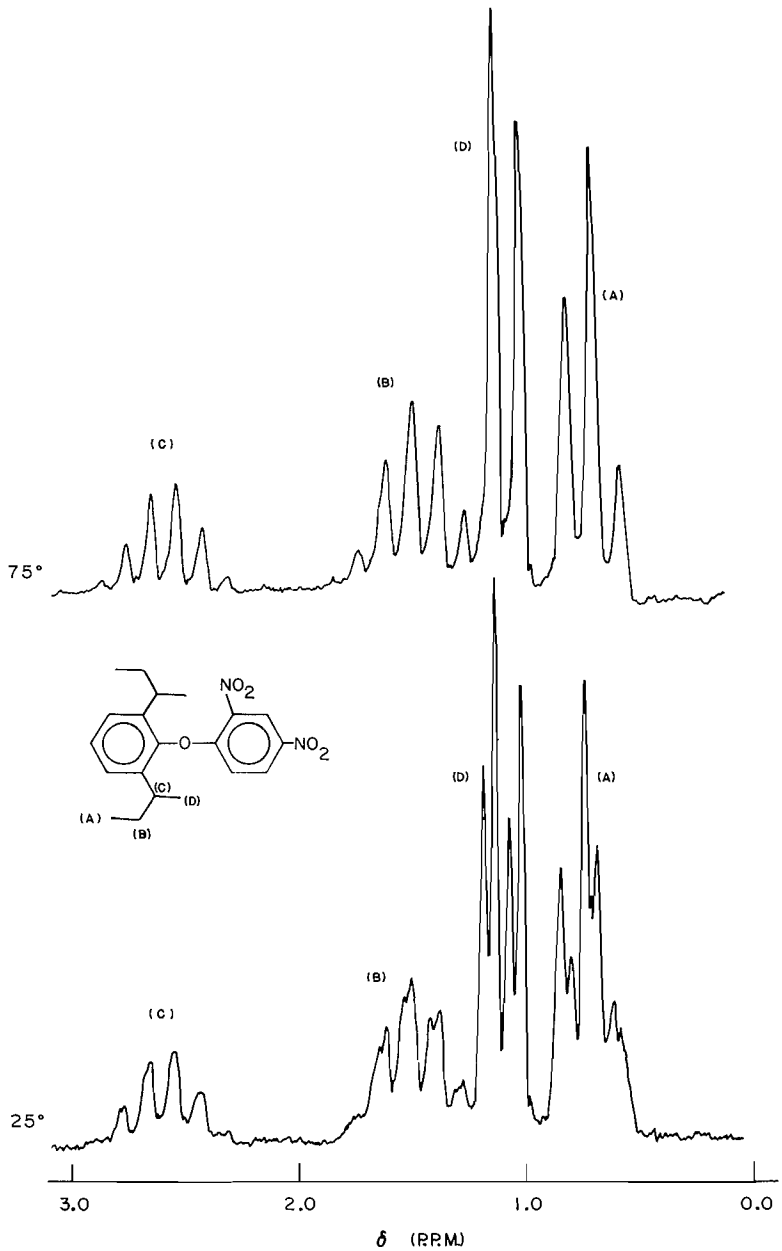

FIG. 6. Variable temperature n.m.r. spectra of **6**.

temperatures. Compound **6** possesses two asymmetric carbons in the sec-butyl substituents so the possibility of RR, SS, and RS combinations exists. Since in the meso RS form the sec-butyls are enantiotopic under all conditions of rotation about AR—O, it would be expected to show a temperature independent sec-butyl absorption provided that only the two identical H-inside conformers are equilibrating. If either the RR or SS form is *frozen into* one of the identical H-inside conformations, the two sec-butyl groups are diastereotopic (15) and are therefore magnetically non-equivalent. Rotation of the alkylated ring through 180° (see Fig. 8 for **3**)

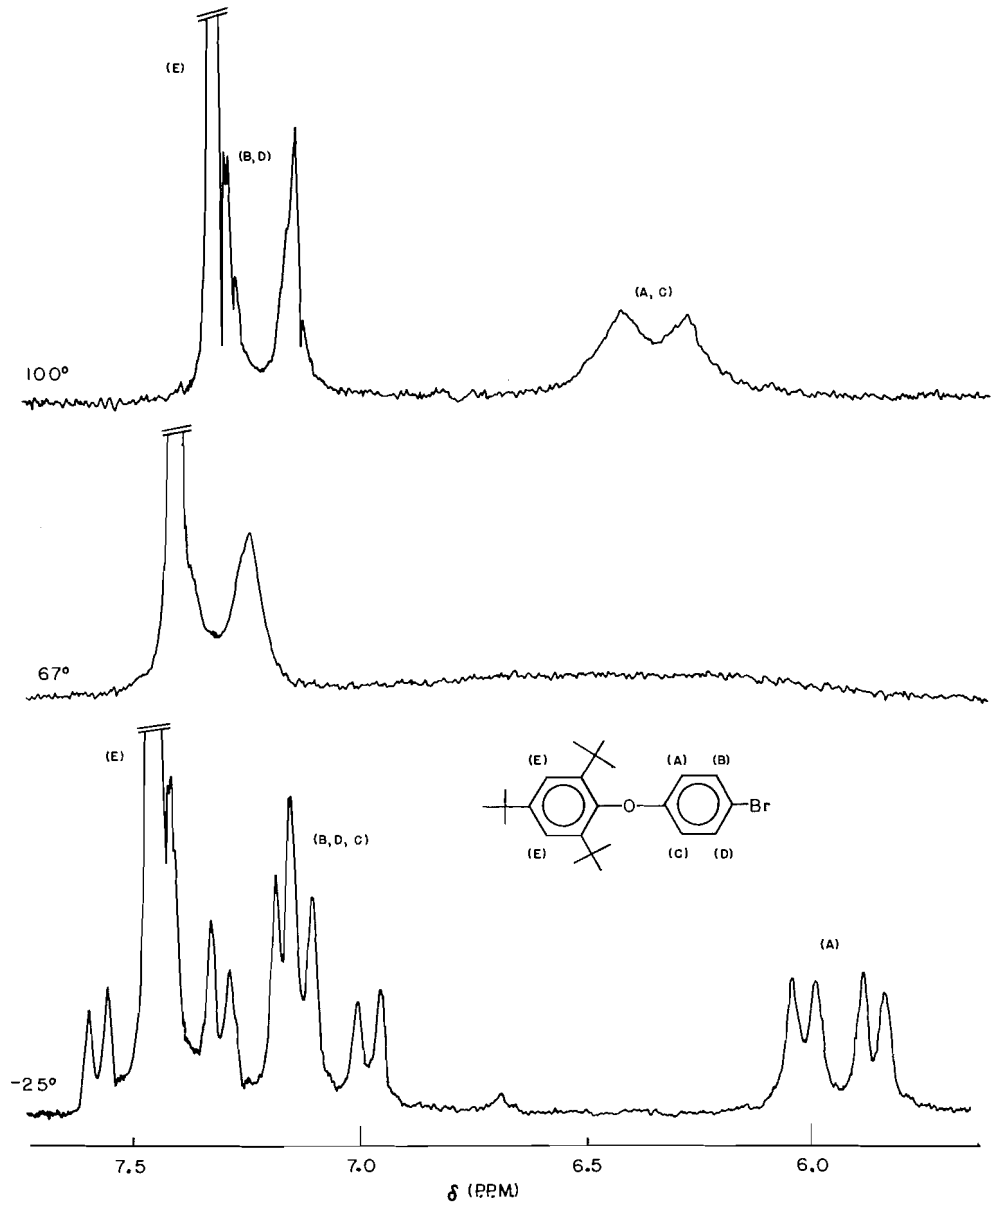

FIG. 7. Variable temperature n.m.r. spectra of **8**.

exchanges the identity of the two groups and they are seen as being equivalent in the high temperature spectrum.

The variable temperature n.m.r. spectra of **5** (Fig. 5) are quite revealing; in the high temperature extreme the meta-methyl appears as a slightly broadened singlet, the nitrated ring protons as an AMX pattern and the isopropyl methyl groups as a single doublet. All of this is consistent with fast exchange between two different H-inside conformations which, for convenience, we will refer to as the methyl-inside and the methyl-outside conformations[7]

[7]Each H-inside conformer is really two identical conformers differing by rotation of the alkylated ring (*cf.* footnote 5).

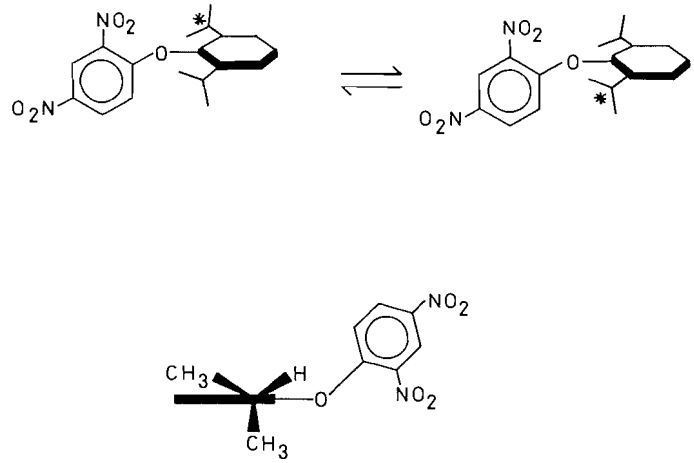

FIG. 8. Equilibration of conformers in **3**.

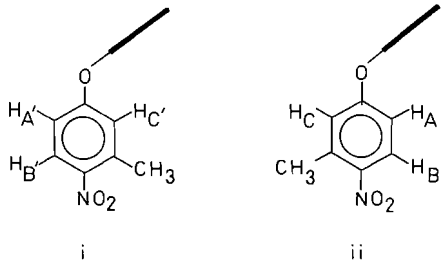

FIG. 9. (*i*) -ethyl-inside and (*ii*) Methyl-outside conformations of **5**.

(Fig. 9). At $-100°$ there are two sets of absorptions for all the protons including the isopropyls. This observation and the observed chemical shifts are consistent only with the *freezing out* of both conformations as well as the rotation of the di-isopropyl-substituted ring. The sets of signals for the two conformers are of unequal intensity since the methyl-outside conformer, in which there is less steric interaction between the methyl and the other ring is present in higher concentration.[8] The low intensity signals for the meta-methyl (D′) and for $H_{C'}$ (methyl-inside) appear at higher field than the corresponding high intensity signals (methyl-outside). This is due to the long-range shielding experienced in an H-inside conformation arising from the induced ring current of the other ring.[9] Similarly, the high intensity signals for H_A and H_B appear at higher field than the corresponding low intensity signals for $H_{A'}$ and $H_{B'}$.

The n.m.r. spectra of **4**, **7**, and **8** are also consistent with frequent interconversion between equivalent H-inside conformers at temperatures above T_c. Below T_c one observes ABCD or ABCDE patterns for the non-alkylated ring protons. Above T_c only the average resultant AA′BB′ or AA′BB′C patterns are observed.

That **9** showed no indication of hindered rotation is not surprising since there are only the two identical H-inside conformers resulting from rotation of the alkylated ring. Because the *t*-butyl groups, unlike isopropyls, are symmetric and are unable to be used as probes in the same way, one cannot observe the *freezing out* of the alkylated ring–O rotation even though it must occur.

In view of the results obtained by Kessler *et al.* (13) for **3**, the more hindered **10** might be expected to show similar results with an even higher coalescence temperature and $\Delta G^{\ddagger}$. That it does not may be explained in one of two ways: (*i*) free rotation occurs over the entire temperature range studied (-70 to $150°$) or, (*ii*) the compound is locked into some symmetrical conformation (or exchange occurs between two or more symmetrical conformations). In support of the former explanation is the fact that for **10**

[8]Although the two methyl signals overlap the isopropyl methine H signal at $-100°$, from their relative intensities the equilibrium constant was calculated to be about 3.5 leading to a value of 0.4 kcal/mol for ΔG. This appears to be the first experimental estimate of a conformational energy difference in diphenyl ethers.

[9]For a discussion of this effect in diphenyl ethers see ref. 2.

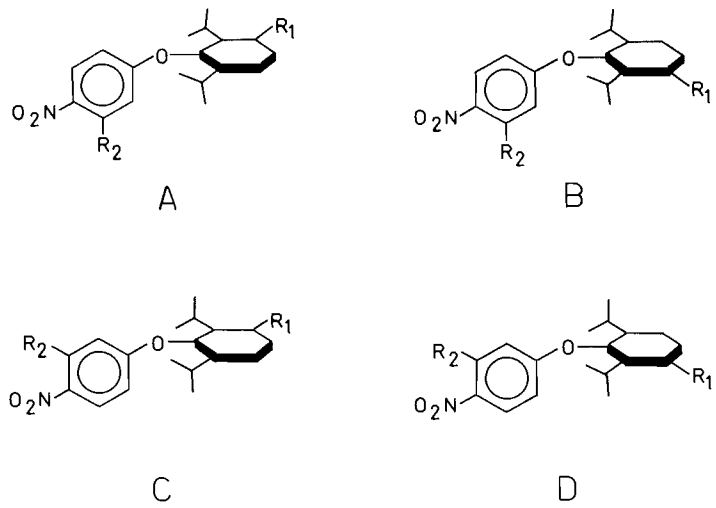

FIG. 10. The four stereoisomers of a dissymmetric, di-*ortho*-substituted diphenyl ether adopting H-inside conformations.

there can be no relatively low energy, H-inside conformation which the molecule can adopt. As a result, the conformer energies are high and the $\Delta G^{\ddagger}$ to rotation about the Ar—O bonds is low when compared with that of other molecules considered in this study.

It is worth mentioning again that calculation of an energy barrier using the data from ring proton coalescence is inherently more reliable than using data from the isopropyl methyl groups. In the former case $\Delta\nu$ is very large. Because of this it is possible to neglect coupling of the protons undergoing coalescence without introducing serious error into the calculated $\Delta G^{\ddagger}$ (see footnote 4). The major factor influencing the calculation of $\Delta G^{\ddagger}$ in either case is T_c.

The problem remains of assigning $\Delta G^{\ddagger}$ values to particular rotational processes. For a dissymmetric diphenyl ether with two vacant ortho positions on the same ring there may be four possible stereoisomeric H-inside conformers (Fig. 10, see also footnote 7 for the case when one ring has a plane of symmetry). This particular example was chosen because of its maximum lack of symmetry and the possibility of two enantiomeric pairs of H-inside conformers (the pair A and B and the pair C and D). Rotation about the alkylated ring—O bond alone interconverts enantiomers while rotation about the other Ar—O bond alone produces a diastereomer (A and C are interconverted as are B and D). A third rotational process that has been suggested (3) is the cogwheel rotation in which both rings rotate synchronously interconverting the pair A and D, and the pair B and C. Although a cogwheel mechanism will not by itself produce racemization of an optically active ether, the cogwheel rotation in concert with either or both of the other two processes can cause racemization. In order to isolate pure optical isomers, all of these rotational processes would have to be inhibited.

The variable temperature n.m.r. spectra of **4** could be accounted for by either the one-step, cogwheel rotation or by a two-step process in which rotation occurs first about one Ar—O bond and then the other. Inspection of molecular models suggests that rotation of the alkylated ring should be more hindered (should have a larger $\Delta G^{\ddagger}$) than rotation of the nitrated ring. The fact that, within experimental error, the values of $\Delta G^{\ddagger}$ determined from T_c and k_c for isopropyl and ring proton exchange are the same (Table 1) would seem to indicate that a one-step process occurs in ethers of this type (that would include **7** and **8** as well as **4**).

For triply ortho-substituted ethers (**3**, **6**, **9**) the cogwheel process would force the molecule into a high energy NO_2-inside conformation which is not observed by the n.m.r. spectrometer. It would seem unlikely that rotation of the alkyl-substituted ring occurs alone as that rotation would be highly hindered in the ethers studied. It would be possible for the two rings

For personal use only.

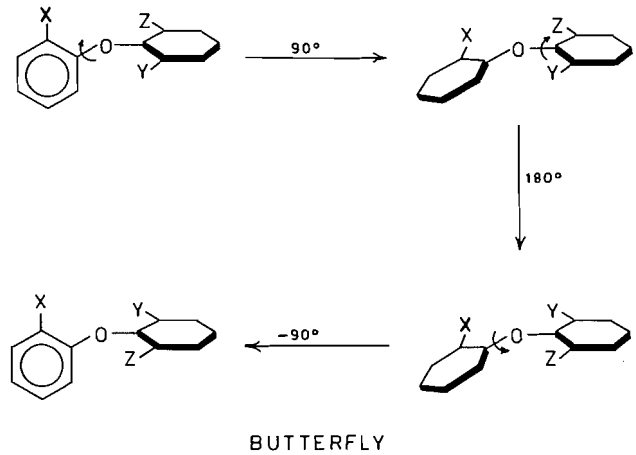

FIG. 11. Butterfly mechanism for rotation about an Ar—O bond in triply *ortho*-substituted diphenyl ethers.

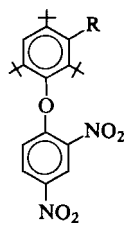
to slip by one another through a *butterfly* intermediate (Fig. 11). This process could be envisaged as a three-step one involving both rings although not simultaneously as for the cogwheel mechanism. The butterfly mechanism could also account for the observations noted with the doubly ortho-substituted ethers as a single $\Delta G^{\ddagger}$ would be expected for both ring rotations; the final step could be rotation of the non-alkyl-substituted ring by 90° in either sense.

It appears likely, in the light of the experimental evidence, that a diphenyl ether such as **11** could be resolved into enantiomers. Comparing **3** and **4**, one sees that the introduction of an ortho-nitro group in **3** raises the T_c for rotation of the alkylated ring by about 130°.[10] A similar structural change in **8** would raise $\Delta G^{\ddagger}$ to around 23 kcal/mol, a barrier sufficient to allow separation of individual, enantiomeric H-inside conformers (9). Compound **11**, then should have a barrier to rotation sufficiently high and both rings are dissymmetric so that the two enantiomers could, in theory, be resolved at room temperature. It may be that the use of an ortho substituent such as CHO, CN or CO_2R which is less easily distorted from coplanarity with the ring than NO_2 might effect an even larger increment in the rotational barrier. The failure to observe hindered rotation in **10** indicates that one vacant ortho position should be maintained if diphenyl ethers for optical resolution studies are being synthesized.



11

[10]It is interesting to note that a meta-methyl does not increase T_c or $\Delta G^{\ddagger}$ for this rotation (*cf.* values for **4** and **5**).

Experimental

The n.m.r. spectra were recorded on Varian A-60A and HA-100 spectrometers. For studies at low temperatures the samples were dissolved in acetone-d_6; otherwise chloroform-*d* was used as solvent. The chemical shifts of the aromatic protons on the brominated ring of **8**, in the low temperature spectrum, were reproduced to within ±0.1 Hz by means of an iterative computer calculation in order to estimate k_c.

Compounds **4** and **5** were prepared by the method of Wright and Jorgensen (19). Compounds **3** and **9** have been reported previously (20) while **6** and **10** were synthesized by the method of that reference. The properties of **6** and **10** are recorded in Table 2.

The n.m.r. and i.r. spectra of all compounds were consistent with the assigned structures.

2-Phenoxy-1,3,5-tri-t-butylbenzene (7)

2-(2′,4′-Dinitrophenoxy)-1,3,5,-tri-*t*-butylbenzene (**9**, 1.0 g) was dissolved in 95% ethanol (200 ml) and about 2 g of W-2 Raney Nickel added. Hydrogenation was performed in a Parr shaker apparatus for 12 h at a pressure of 40 lb/in.^{2} and the catalyst was removed by filtration. The resulting colorless solution was evaporated to give off-white crystals (0.8 g, 95%) of what, from n.m.r. and i.r. spectra, appeared to be 2-(2′,4′-diaminophenoxy)-1,3,5-tri-*t*-butylbenzene.

Without further purification, the crude diamine was dis-

solved in a mixture of concentrated sulfuric acid and glacial acetic acid (40 ml, 1:1). A solution of sodium nitrite (0.5 g) in concentrated sulfuric acid (20 ml) was prepared and both solutions were cooled to 5°. The nitrous acid solution was added to the amine over a period of 45 min and the deep red product was allowed to stand at 5° for a further 30 min. It was then added slowly to a mixture of hypophosphorus acid (75 ml, 50%) and crushed ice (300 g) and left for 24 h. At the end of this time, the contents were extracted with chloroform (100 ml) and the chloroform was evaporated to yield a red oil (0.66 g, 90%). A portion of this product was used without purification in the n.m.r. experiments then was recovered and combined with the remainder for use in the next synthetic step.

2-(4'-Bromophenoxy)-1,3,5-tri-t-butylbenzene (8)

Crude 2-phenoxy-1,3,5-tri-*t*-butylbenzene (0.6 g) was dissolved in glacial acetic acid (10 ml) and a solution of bromine (0.28 g) in acetic acid (10 ml) was added dropwise as described by Hamilton and Blanchard (21) for the bromination of other highly substituted diphenyl ethers. Even after standing for 15 h, the mixture did not appear to have reacted so that ferric chloride (0.01 g) was added and stirring was continued for another 24 h. During this time there was a slow evolution of HCl and/or HBr. The solution was poured into water (200 ml) and the precipitate collected by filtration. This solid could not be purified by recrystallization from common solvents but was obtained as white crystals after being eluted through an alumina column (neutral, Brockman activity 1, 80–200 mesh) with petroleum ether (b.p. 30–60). The pure product was obtained in 61% (0.42 g), m.p. 146–148°.

The Deamination of the 3α- and 3β-Aminocholestanes and their Amide Derivatives

F. W. BACHELOR
Department of Chemistry, The University of Calgary, Calgary 44, Alberta
AND
E. H. WHITE
Department of Chemistry, The Johns Hopkins University, Baltimore, Maryland 21218

Received July 30, 1971

The nitroso acetamides, naphthamides, and benzylcarbamates of 3α- and 3β-aminocholestanes were decomposed in various solvents and the nitrous acid deaminations of the free amines in acetic acid and aqueous acetic acid mixtures were studied. In these reactions the intramolecular process leads to products with high degrees of retention of configuration, whereas the intermolecular process leads to products which are predominantly equatorial. Diazoalkanes were shown not to be intermediates in these deaminations.

Les nitroso acétamides, les naphthamides, et les benzylcarbamates des amino-3α et 3β-cholestanes ont été décomposés dans plusieurs solvants. La désamination nitreuse des amines libres a été étudiée dans l'acide acétique et dans des mélanges acide-acétique – eau. Dans ces réactions, le processus intramoléculaire conduit à des produits où la rétention de configuration est très importante, alors que le processus intermoléculaire donne des produits surtout équatoriaux. Il est montré que les diazoalcanes ne sont pas des intermédiaires dans ces désaminations.

In recent years an increasing number of workers have reported on the deamination of cyclohexyl, decalyl, and steroidal amines (1–11) and have discussed the reaction paths and stereochemistry of these systems. Of these, however, only one (4) dealt with the deamination of nitrosoamides and this study was not concerned with the epimer ratios of the derived esters. It is apparent from these studies that in conformationally rigid systems few rearrangements take place with equatorial amines but are fairly common with the axial epimers. We wish to report the details of our work on the deaminations via the nitrosoacetamides, naphthamides, and benzylcarbamates of 3α- and 3β-aminocholestanes, as well as our studies of the deaminations of the free amines in acetic acid and acetic acid water mixtures. The latter studies were undertaken to reexamine the report of Shoppee *et al.* that deaminations of both isomers yielded essentially alcohols with complete retention of configuration (12).

On the basis of subsequent work (13, 14) where it has been shown that deaminations of substituted cyclohexylamines yield alcohols with retained and inverted configuration, Shoppee's results appear to be anomalous. Our results show that with both equatorial and axial amines, both alcohols are produced. This has been reported in a previous communication (15). Subsequently, Shoppee repeated his earlier work and has reported similar results (6).

The aminocholestanes were prepared by previously published procedures (16, 17) and purified by crystallization of their acetamides. The free amines were regenerated by prolonged hydrolysis in concentrated hydrochloric acid – acetic acid. The 3β-nitrosoamides (**1***a*, *b*, *c*) and the 3α-nitrosoamides (**1***a*, *c*) were prepared by the reaction of the parent amides with N_2O_4 in methylene chloride at −20 °C while the 3α-nitrosonaphthamide (**1***b*) was prepared by a low temperature modification (18). All the axial

‖In addition, there was obtained 10% acetates, % composition: 25% 3α, 75% 3β.

α-nitrosoamides were unstable and decomposed at temperatures much lower than their corresponding β-epimers. The decomposition reaction mixtures were chromatographed on alumina and separated into alkene, ester, and alcohol fractions. The esters and alcohols were then analyzed by i.r. analysis, chromatographic analysis (19), gas chromatography, or by a combination of these methods. The naphthoates were converted to the alcohols via lithium aluminum hydride and analyzed as such. The reaction scheme is presented in eq. 1.

[1] $$RNHCR' \xrightarrow{N_2O_4} RN(NO)-C(=O)-R' \longrightarrow \begin{cases} ROCR' + N_2 \\ \text{Alkenes} + R'CO_2H + N_2 \end{cases}$$

The results shown in Table 1 indicate that retention of configuration predominates in all cases. The source of the inverted products is of some interest. Since these solvents are non-solvolytic, inversion must occur via an intramolecular reaction or by the reaction of some intermediate with the acid produced in the elimination reaction. The latter pathway can be checked in two ways: (*1*) by adding a scavenger for the freed carboxylic acid (in the present case diazomethane) or (*2*) by adding a large excess of a competing acid. Both of these methods were used. The addition of a large excess of diazomethane did not eliminate the inversion product. In the case of the decomposition of *N*-nitroso-3β-(2)-naphthoylamidocholestane (**1***b*) in the presence of a large excess of deuterioacetic acid, virtually no deuterium was incorporated in either the naphthoates or the acetates produced. Of these esters, only 10% was acetate and 18% of the naphthoates still had the inverted configuration. These results indicate clearly that an intramolecular inversion reaction is taking place. The mechanism of this reaction has been discussed in detail elsewhere (20). The absence of any significant deuterium incorporation in the acetates from the excess deuterioacetic acid experiment also precludes the possibility of a diazoalkane intermediate. Such intermediates are formed in non-polar solvents when the nitroso-amido group is attached to a primary carbon atom (21).

The relative unimportance of solvolysis as a source of product under these reaction conditions is shown by the low yield of acetates in the decomposition of *N*-nitroso-3β-(2)-naphthamidocholestane in the presence of a large excess of deuterioacetic acid. The ratio of acetates to naphthoates is approximately 1:6 although the ratio of acetic acid to starting nitrosonaphthamide is 165:1. Solvolysis becomes even less important when one considers that some of the

*Yields corrected for recovered amine.

acetate stems from frontside exchange (22), although the composition of the acetates approaches that of an equilibrium mixture with some net retention of configuration.[1]

We have found evidence for solvent bonding in runs performed in ether. A small amount (approximately 1%) of 3-ethoxycholestane of undetermined stereochemistry was found by gas chromatographic analysis of the cholestene fractions. This is in agreement with the results found by White and Billig (24) where the elements of tetrahydrofuran have been found in a nitrosoamide decomposition in this solvent. In addition to this, two other examples of solvent incorporation have been found resulting from the deamination of bridgehead amines. White *et al.* (25) have found the incorporation of the elements of benzene or chloroform during the deamination of *N*-nitroamides of norbornylamine, and Wilhelm and Curtin (26) found an 8% yield of 9-ethoxy-9,10-dihydro-9,10-ethanoanthracene from a nitrosyl chloride deamination of the corresponding amine.

We have also examined the nitrous acid deaminations of the 3α- and 3β-cholestanylamines in acetic acid and aqueous acetic acid solutions. The results are listed in Table 2. In all runs appreciable inversion is observed. The composition of the acetates does not change significantly regardless of which isomer one uses, nor over the solvent range used in our work. This data is in agreement with the revised results of Shoppee *et al.* (4, 6, 12) and with similar examples in the steroid field (5, 8, 10).

[1]An equilibrium mixture of the epimeric 4-*t*-butylcyclohexanols has been shown to consist of approximately 66% of the equatorial isomer (23). If we assume that the steric interactions involved at the 3-position of the cholestane nucleus are approximately the same, then the same equilibrium ratio should also apply here.

The source of the alcohols in anhydrous acetic acid is of some interest. Since water is produced in the reaction they could be the result of a bimolecular reaction. However, since there is such a high degree of retention of configuration in the deamination of both the 3α- and the 3β-amines it is more than likely that most of the alcohols result from an intramolecular process involving the hydroxyl group immediately associated with diazo hydroxide. In addition, deaminations in aqueous acetic acid do not significantly increase the amount of alcohols produced. These results are in agreement with those found by White and Stuber (18) and Cohen and Jankowski (3).

Products of solvolysis appear to favor the more stable 3β configuration. In all cases the acetates formed were predominantly equatorial. Also, as the concentration of water increased, the axial amine gave more of the equatorial alcohol. This is also seen in the work of Cohen and Jankowski (3) with their studies of the deamination of the axial 2-amino-*trans*-decalin in aqueous acetic acid at various concentrations. It is noteworthy in their studies as well as our own that the ratio of equatorial to axial acetate is fairly constant over a wide range of acetic acid – water mixtures. This is not true, however, in the case of the equatorial amines (27). In this case, as the water concentration increased, the ratio of equatorial to axial acetate increased, as did also the alcohol ratio to a smaller extent. From these results it is obvious that there are at least two mechanisms leading to solvolysis products. It has been suggested (3, 15) that specifically solvated ion pairs can lead to solvation products with a high degree of retention of configuration in acetic acid or in acetic acid rich aqueous reactions. In the case of the axial 2-amino-*trans*-decalin (3) and our work

For personal use only.

this cannot apply completely since in all cases a predominance of inverted solvolysis product occurs.

Although we have examined our reactions for rearranged products, *i.e.* cholestanes substituted at the 2 and 4 positions, we have not been able to detect any significant amounts of these products. However, these rearrangements rarely exceed 5% and would not detract meaningfully from the results of this work.

Experimental

All melting points are corrected and were obtained with total immersion Anschutz thermometers. The i.r. spectra were recorded with a Perkin–Elmer model 21 spectrophotometer with scale expander. Deuterium was analyzed by combustion and i.r. comparisons. The g.l.c. measurements were performed on a Hewlett–Packard Biomedical Model 402 Gas Chromatograph.

3-Cholestanone Oxime

To a solution of 20 g of 3-cholestanone in 500 ml of refluxing ethanol was added 9.0 g of sodium acetate and 7.0 g of hydroxylamine hydrochloride. Refluxing was continued for 2 h. The solvent was then removed *in vacuo* and the residue taken up in ether, washed with water, and concentrated to dryness *in vacuo*. The residue was recrystallized from ethyl acetate. Yield 19.5 g (94%), m.p. 201–202 °C.

3α-Cholestanylamine

3α-Cholestanylamine was prepared by reduction of 3-cholestanone oxime in acetic acid over platinum according to the method of Shoppee *et al.* (16).

3β-Cholestanylamine

3β-Cholestanylamine was prepared by reduction of the oxime with sodium in refluxing amyl alcohol according to the method of Dodgson and Haworth (17).

3β-Acetamidocholestane

3β-Cholestanylamine (5.0 g) was dissolved in 150 ml of anhydrous ether and 2 ml of acetic anhydride added to the stirred solution. A precipitate formed almost immediately. The reaction was stirred for 1 h, ether then removed *in vacuo*, and the residue taken up in chloroform. The chloroform solution was washed with aqueous sodium bicarbonate and water, dried over sodium sulfate, and concentrated to dryness *in vacuo*. The amide was recrystallized from acetone to constant m.p.; m.p. 249–250°.

3α-Acetamidocholestane

This was prepared in the same manner as 3β-acetamidocholestane. Repeated recrystallization from acetone gave pure 3α-acetamidocholestane, m.p. 217–218° (lit. (28) 217–218°).

Hydrolysis of the α-Acetamidocholestane

The 3α-acetamidocholestane (1.0 g) was suspended in a mixture of 75 ml of glacial acetic acid and 30 ml of 6 *N* hydrochloric acid and refluxed for 8 days. On cooling the amine, hydrochloride precipitated as flakes. This was collected by filtration and dried *in vacuo* over P_2O_5 and KOH pellets; yield, 768 mg. Hydrolysis of 3β-acetamidocholestane was carried out in the same manner.

Benzyl-N-3α-cholestanyl Carbamate

3α-Cholestanylamine hydrochloride (1.0 g) was suspended between 40 ml of ether and 30 ml of 30% potassium hydroxide solution. The mixture was stirred until all the solid material had dissolved. Carbobenzyloxy chloride (0.41 ml) was added and stirring was continued for 2 h. The layers were then separated, the ether layer washed with water, 2*N* hydrochloric acid, water, and then dried over sodium sulfate. The ether was removed by concentration and the residue recrystallized from methanol; yield, 782 mg, m.p. 143.2–144.0 °C.

Anal. Calcd. for $C_{35}H_{55}O_2N$: C, 80.56; H, 10.62; N, 2.69. Found: C, 80.60; H, 10.39; N, 2.88.

Benzyl-N-3β-cholestanyl Carbamate

This was prepared in the same manner as the 3α-isomer. Recrystallized from ethanol; m.p. 145.0–145.5 °C.

Anal. Calcd. for $C_{35}H_{55}O_2N$: C, 80.56; H, 10.62; N, 2.69. Found: C, 80.38; H, 10.65; N, 2.85.

Benzyl-3α-cholestanyl Carbonate

3α-Cholestanol (201 mg) was dissolved in dry methylene dichloride (20 ml) and 1.0 ml of carbobenzyloxy chloride added. While stirring, a solution of 0.5 ml of dry pyridine in 12 ml of dry methylene chloride was added dropwise over a period of 2 h. The solution then stood overnight. The solution was poured into water and the organic layer washed twice with water, dried over sodium sulfate, and concentrated to dryness *in vacuo*. The residue was dissolved in a minimum amount of benzene–hexane and chromatographed on alumina (10.0 g Woelm, neutral, activity III). The carbonate (265 mg) was eluted with 5% benzene in hexane. Recrystallization from methanol–chloroform gave pure benzyl-3α-cholestanyl carbonate, m.p. 67.2–68.0 °C.

Anal. Calcd. for $C_{35}H_{54}O_3$: C, 80.41; H, 10.41. Found: C, 80.40; H, 10.56.

Benzyl-3β-cholestanyl Carbonate

This compound was prepared in the same manner as the 3α-isomer. Recrystallized from methanol, m.p. 95.2–96.2 °C.

Anal. Calcd. for $C_{35}H_{54}O_3$: C, 80.41; H, 10.41. Found: C, 80.61; H, 10.50.

3α-(2-Naphthamido)-cholestane

To 25 ml of dry pyridine was added 1.0 g of 3α-aminocholestane hydrochloride and 1.0 g of 2-naphthoyl chloride and the reaction stirred for 24 h. The reaction was then diluted with 100 ml of water and extracted with chloroform. The chloroform extract was washed with dilute sodium carbonate, water, 2 *N* hydrochloric acid, and water, then dried over sodium sulfate. Evaporation of the solvent left a residue which was recrystallized from acetone to yield the pure naphthamide; yield, 540 mg, m.p. 219.6–219.8 °C.

Anal. Calcd. for $C_{38}H_{55}ON$: C, 84.23; H, 10.23; N, 2.58. Found: C, 84.22; H, 9.97; N, 2.62.

3β-(2-Naphthamido)-cholestane

This compound was prepared in the same manner as the 3α-isomer. Recrystallized from acetone; m.p. 238.2–238.8 °C.

Anal. Calcd. for $C_{38}H_{55}ON$: C, 84.23; H, 10.23; N, 2.58. Found: C, 84.22; H, 10.12; N, 2.61.

For personal use only.

Benzyl-N-nitroso-N-3β-cholestanyl Carbamate

Benzyl-*N*-3β-cholestanyl carbamate (398 mg) was dissolved in dry methylene chloride (10 ml) in a flask equipped with a drying tube. Anhydrous sodium acetate (300 mg) and anhydrous sodium sulfate (300 mg) were added to the solution and the mixture cooled to −20 °C in an ice-salt bath. To this was added, all at once, 10 ml of 0.325 *M* N_2O_4 in dry methylene chloride (1 ml liquid N_2O_4/50 ml CH_2Cl_2) with stirring, and the stirring continued for ½ h at −10 °C. The excess N_2O_4 was then removed *in vacuo* at 0 °C. The reaction was poured into 50 ml of ice cold concentrated sodium carbonate solution and the reaction flask washed with 50 ml of cold ether which was then added to the reaction mixture. The mixture was vigorously shaken and the layers separated. The organic layer was washed with ice cold concentrated sodium chloride solution and dried over sodium sulfate at 0 °C. After decantation the solvent was removed *in vacuo* at 0 °C. The solid yellow residue was dissolved in a minimum amount of pentane and cooled in a Dry Ice – acetone bath for several hours. The crystalline nitroso carbamate was collected by filtration–decantation and dried in hi-vac over P_2O_5; yield 372 mg, m.p. 113–114 °C (dec.).

Anal. Calcd. for $C_{35}H_{54}O_3N_2$: C, 76.32; H, 9.88; N, 5.09. Found: C, 76.45; H, 10.08; N, 5.24.

Benzyl-N-nitroso-N-3α-cholestanyl Carbamate

This compound was prepared in the same manner as the 3β-isomer. This compound could not be separated from unreacted amide and the crude nitroso-derivative was used in subsequent reactions.

N-Nitroso-3β-acetamidocholestane

This nitroso derivative was prepared in the same manner as benzyl-*N*-nitroso-3β-cholestanyl carbamate. It was recrystallized by dissolving in pentane, removing the unreacted amide by filtration, and cooling in a Dry Ice – acetone bath; yield (from 399 mg amide) 253 mg, m.p. 117.0° (dec.).

Anal. Calcd. for $C_{29}H_{50}O_2N_2$: C, 75.93; H, 10.99; N, 6.11. Found: C, 75.75; H, 10.92; N, 6.32.

N-nitroso-3β-(2-naphthamido)-cholestane

This nitroso derivative was prepared in the same manner as the nitroso carbamates. It was not possible to obtain this nitroso compound free from amide and the crude compound was used directly in decomposition reactions.

Preparation and Decomposition of N-Nitroso-3α-(2-naphthamido)-cholestane

A three-necked flask was fitted with two stopcock adapters, a rubber syringe cap, and a magnetic stirrer. One of the stopcock adapters was attached to a source of dry nitrogen. The other was alternately attached to a vacuum pump or opened when nitrogen was flowing through the system. A portion of 3α-(2-naphthamido)-cholestane (1.0 g) was dried in the flask under hy-vac for 2 h. The flask was then filled with dry nitrogen and 25 ml of ether freshly distilled from $LiAlH_4$ was added to the flask. A solution of *n*-butyllithium (1.4 ml, 1.64 *N* in hexane) was added with stirring via a syringe, after which time the solution was clear. The reaction was cooled to −60 °C in a Dry Ice – acetone bath and 50 ml of N_2O_4 gas (dried in the liquid state over P_2O_5) was added with a syringe. The solution rapidly turned yellow.

While continuing stirring, the temperature of the solution was allowed to slowly rise. At approximately −30 °C a small evolution of bubbles could be seen. At −20 °C the evolution of gas was quite evident, and a precipitate began to form. At 0 °C the evolution of gas was finished.

When the reaction had reached room temperature water was added and the layers separated. The non-aqueous layer was washed with concentrated sodium carbonate and water, dried over sodium sulfate, and concentrated to dryness *in vacuo*.

The naphthoates were isolated by chromatography on alumina and analyzed in the same manner as in the case of the decomposition of the 3β-isomer.

Preparation and Decomposition of N-Nitroso-3α-acetamidocholestane

N-Nitroso-3α-acetamidocholestane was prepared in the same manner as benzyl-*N*-nitroso-*N*-3β-cholestanyl carbamate. On the addition of ether during the work-up at 0 °C, the yellow color characteristic of the nitrosoamides disappeared completely and the reaction was then worked-up for the decomposition products. The organic layer was dried over sodium sulfate and concentrated to dryness *in vacuo*. The residue was then analyzed.

Decomposition of Nitrosoamides

The following are given as typical of the methods for decomposition of the nitrosoamides and nitrosocarbamates. All decompositions were performed at room temperature except as otherwise noted in Table 1.

Decomposition of N-Nitroso-3β-acetamidocholestane in Ether

N-Nitroso-3β-acetamidocholestane (175 mg) was dissolved in anhydrous ether (50 ml), 1 g of anhydrous sodium sulfate added, and the mixture was heated under reflux for 18 h. After this time the solution was completely colorless. The solvent was removed *in vacuo*, the residue dissolved in benzene and chromatographed on alumina (8.5 g, Woelm, neutral, activity I). Elution with benzene (45 ml) yielded 62 mg (44.0%) of mixed Δ^2- and Δ^3-cholestanes. Further elution with 2% ether in benzene (6 × 15 ml fractions) yielded 22 mg of pure 3β-cholestanyl acetate and 12 mg of mixed 3α- and 3β-cholestanyl acetates. Further elution with 20% ether in benzene eluted 18 mg of pure 3α-cholestanyl acetate; total acetates, 32.3%. Final stripping of the column with ether and 5% methanol in ether yielded 33 mg (20.2%) of material which was mostly denitrosated amide. The fractions were analyzed first by t.l.c. The composition of the mixed acetate fraction was estimated to be about 70% 3α-cholestanyl acetate by comparison with standard i.r. curves. Total recovery of material was 96.5%.

As a check the acetates were combined and analyzed by i.r. Comparison against standards showed the mixture to be 52% 3β-cholestanyl acetate and 48% 3α-cholestanyl acetate. Values from chromatography were 50% of each isomer.

Decomposition of Benzyl-N-nitroso-N-3α-cholestanyl Carbamate in Ether Containing Excess Diazomethane

Benzyl-*N*-nitroso-*N*-3α-cholestanyl carbamate (152 mg) was dissolved in a freshly prepared solution of diazomethane (approximately 1 g) in 50 ml of ether, which had been dried over KOH pellets. This stood for 48 h in the dark. The excess diazomethane and ether were then removed *in vacuo* and the residue dissolved in a minimum amount of hexane–benzene and chromatographed on alumina (15 g, Woelm,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

neutral, activity III). Elution with hexane (75 ml) yielded 61 mg of mixed Δ^2- and Δ^3-cholestenes. Further elution with 2% benzene in hexane (150 ml) gave 6 mg of mixed benzyl-3α- and 3β-cholestanyl carbonates. Elution with 50% benzene–hexane yielded 54 mg of recovered carbamate. The carbonate mixture was analyzed by comparison with i.r. standards and was found to consist of 74% of benzyl-cholestan-3α-yl carbonate and 26% benzyl-cholestan-3β-yl carbonate.

Decomposition of N-Nitroso-3α-(2-naphthamido)-cholestane in O-Deuterioacetic Acid

N-Nitroso-3α-(2-naphthamido)-cholestane was prepared in the usual manner from 0.99 g of the amide. It was not isolated but was used directly. The nitroso amide was dissolved in a mixture of 40 ml of dry methylene chloride and 10 ml of 99+% *O*-deuterioacetic acid. The reaction was protected from moisture and stood for 3 days at room temperature. The solvents were then removed *in vacuo*. The residue was chromatographed on alumina (30 g, Woelm, neutral, activity II). Hexane (200 ml) eluted 131 mg of cholestenes. Further elution with 200 ml of 50% hexane–benzene gave 544 mg of mixed esters. Finally, elution with benzene yielded 203 mg of naphthamide. This amounts to a recovery of 96.5% based on starting amide.

The esters were separated by fractional sublimation at 0.06–0.03 mm Hg and 108 °C. After 3 days, all of the acetates had sublimed. The sublimation was followed by t.l.c. Analysis of the acetates (71.3 mg) was made by comparison with standards in the i.r. The mixture of acetates contained 25% 3α-cholestanyl acetate and 75% 3β-cholestanyl acetate.

The naphthoates (465 mg) were dissolved in 100 ml of dry ether and excess $LiAlH_4$ added. The reaction was heated at reflux overnight. The excess $LiAlH_4$ was decomposed with ethyl acetate, and then 6 *N* HCl added slowly until the solution was clear. The layers were separated and the ether layer washed twice with water. After drying over anhydrous sodium sulfate, the ether was removed *in vacuo*. The residue (456 mg) was then chromatographed on alumina (150 g, Alcoa F-20). Benzene eluted 59 mg of 3α-cholestanol and benzene–ether (8:1) eluted 355 mg of a mixture of 3β-cholestanol and 2-naphthyl carbinol. The naphthyl carbinol was removed by sublimation at 60° and 0.05 mm Hg. There remained 274 mg of 3β-cholestanol. Samples of the alcohols were crystallized for deuterium analysis. The acetates were used directly.

Thin-layer Chromatography Analyses

Analyses were made using silica gel G specially prepared for t.l.c. according to Stahl. Benzene was used for the moving phase and sulfuryl chloride vapors followed by steam and heating in an oven at 110° was found most satisfactory as a developing agent. Naphthoates could readily be seen with a u.v. lamp prior to sulfuryl chloride treatment. All isomeric pairs were clearly separated when sufficiently small spots of dilute solutions were applied. Only the two cholestenes did not separate. The amides did not move from the origin under these conditions but were readily analyzed by using ethyl acetate as the moving phase.

Analysis of Acetate Mixtures

(a) By Chromatography

The acetate mixture was dissolved in a small amount of benzene and placed on an alumina column (50 times the weight of acetate, Woelm, activity I, neutral). Careful elution with 5% ether in benzene separated the two acetates, the 3β-isomer being the first to come off the column. When no more 3β-isomer was present in the eluants, the remainder was eluted with ether. The composition of the fractions could be followed by t.l.c. The fractions containing each isomer were then combined and weighed.

(b) By Infrared Spectroscopy

A series of standard solutions of mixtures of 3α- and 3β-cholestanyl acetates was prepared varying in steps of 5%. The standards were dissolved in carbon tetrachloride to a final concentration of 30.0 mg/ml. The total acetate mixture from a reaction was also made up to the same concentration. Using a pair of matched 0.5 mm i.r. cells, a base line was recorded and then the reaction mixture recorded against this base line without changing any settings on the instrument. Immediately following this, standard solutions were recorded until the reaction spectrum was bracketed. The peaks used for analysis occur at 1160 and 1131 cm^{-1}. The former is characteristic of 3α-cholestanyl acetate whereas the latter is due to 3β-cholestanyl acetate. It was assumed that the absorption was linear in these small concentration variations and the value of the intermediate peaks of the reaction obtained by extrapolation.

(c) By Gas–Liquid Chromatography

Using a 4 ft × 3/8 in. pretested steroid column containing 3.8% SE-30 on AW-DMCS chromosorb W the acetates were clearly separated at 236 °C. Using an attached integrator the areas under the curves were readily calculated.

The three methods agreed very well.

Analysis of Carbonate Mixtures

A series of standards of mixed 3α- and 3β-benzylcholestanyl carbonates was prepared with a final concentration of 40 mg/ml in carbon disulfide. The spectra of these mixtures were recorded against a base line in matched 0.5 mm cells with the scale expander attachment to a Perkin–Elmer IR-21 set at 5X. Transmission *vs.* % composition was then plotted for five selected absorption peaks, 1389, 1163, 1001, 973, and 951 cm^{-1}. With the exception of the absorption at 1389 cm^{-1} the plots were essentially linear. The carbonate mixtures from the reactions were made up to the same concentration and the spectra recorded. The concentration was then estimated and the value of the 1389 cm^{-1} peak read from the graph for this concentration. The recorded 1389 cm^{-1} peak was then normalized and this factor used for the other peaks. The absorption bands at 1163 and 973 cm^{-1} were used for 3α-isomer rich solutions and those at 1001 and 951 cm^{-1} used for 3β-isomer rich solutions.

Analysis of Naphthoate Mixtures

Naphthoate mixtures were analyzed by reduction to the alcohols with $LiAlH_4$, removal of the 2-naphthyl alcohol by sublimation, and analyzing the residual cholestanols.

Analysis of 3-Cholestanol Mixtures

The cholestanol mixtures were analyzed by the chromatographic method of Vail and Wheeler (19).

Deamination of 3β-Aminocholestane in Glacial Acetic Acid

3β-Aminocholestane (prepared from 523 mg of amine hydrochloride) was dissolved in 50 ml of glacial acetic acid and 2.05 g of sodium nitrite added portionwise over a period of 2 h with stirring. The reaction was stirred overnight. Solvent was removed *in vacuo* and the residue treated

with water and ether. The layers were separated and the aqueous layer extracted twice more with ether. The combined ether layers were dried over sodium sulfate and concentrated to dryness. The residue was analyzed in the same manner as with the nitrosoacetamidocholestanes.

Deamination of 3α-Aminocholestane in Glacial Acetic Acid

The deamination of 3α-aminocholestane and the analysis of its products were similar to the method used for the 3β-isomer.

Deamination of 3β-Aminocholestane in Aqueous Acetic Acid

3β-Aminocholestane (from 433 mg of amine hydrochloride) was dissolved in a mixture of 30 ml H_2O, 40 ml acetic acid, and 20 ml of dioxane. A solution of 1.0 g of sodium nitrite in 10 ml of water was added portionwise over a period of ½ h with stirring, and stirring continued overnight. The insoluble amine nitrate (140 mg) was collected by filtration and the residue concentrated to dryness *in vacuo*. The residue was worked up as with the products from the acetic acid deamination.

Deamination of 3α-Aminocholestane in Aqueous Acetic Acid

The 3α-aminocholestane was deaminated in the same manner as the 3β-isomer except that it was dissolved in a mixture of 40 ml of water and 50 ml of acetic acid. The sodium nitrite was added in a solution of 1.0 g in 10 ml of water.

We wish to thank the National Research Council of Canada and the National Science Foundation (G 12311) for their support of this work.

Synthesis and Isomerization of Adducts of Azodicarbonyl Compounds and Cyclopentadiene

J. A. CAMPBELL, DONALD MACKAY, AND T. D. SAUER
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received August 20, 1971

The synthesis of a range of bicyclic Diels–Alder adducts (structures *b*) of cyclopentadiene with symmetrical and unsymmetrical azodicarbonyl compounds is described. Thermal isomerization of these adducts to the bicyclic 1,3,4-oxadiazines (structures *c* and *d*) is especially rapid with bulky acyl groups. In unsymmetrical adducts with acyl groups of markedly different size, the larger group dictates completely the direction of isomerization. Adducts with two different aroyl groups give both isomers.

Spectroscopic properties of the adducts, the oxadiazines and the dihydro derivatives of the oxadiazines are described.

La synthèse d'une gamme de composés d'addition bicycliques du type Diels–Alder (structures *b*) du cyclopentadiène avec des composés azo-dicarbonyles symétriques et non symétriques est décrite. L'isomérisation thermique de ces composés d'addition en oxa-1,3,4 diazines bicycliques (structures *c* et *d*) est rapide spécialement avec des groupes acylés volumineux. Dans les composés d'addition non symétriques avec des groupes acyles de taille nettement différente, le groupe le plus gros impose complètement la direction d'isomérisation. Les composés d'addition avec deux groupes aroyles différents donnent à la fois des isomères.

Les propriétés spectroscopiques des composés d'addition, les oxadiazines et les dérivés dihydro des oxadiazines sont décrits.

We have recently shown (1) that the thermal isomerization of the cyclopentadiene adduct **1***b* (2) gives, as suspected (3), the racemic 1,3,4-oxadiazine derivative **1***c,d*. The isomerization was cleanly first order, was relatively insensitive to solvent character, had a negative entropy of activation, and thus possessed all the features of a [3,3] sigmatropic process (4).

We now wish to describe the synthesis and properties of a range of adducts from cyclopentadiene and azodicarbonyl compounds and of their thermal isomers. These include the achiral[1] adducts **2***b*–**7***b* from symmetrically substituted azo compounds which give the racemates **2***c,d*–**7***c,d*[2] and the chiral ones (one enantiomer shown) **8***b*–**12***b* from unsymmetrically substituted azo compounds, and from each of which potentially two structural isomers, **8***c*–**12***c* and **8***d*–**12***d*, can be expected.

All of the azo compounds **2***a*–**12***a* required for the present study were obtained by oxidation of the appropriate dicarbonylhydrazine with *N*-bromosuccinimide (NBS) in the presence of pyridine (5) or by oxidation of the mercury(II) salt of the hydrazine with bromine (2). Only **3***a*, **7***a*, **9***a*, and **12***a* (6–9) have been previously prepared as pure substances.

The diaroyl azo compounds **2***a*, m.p. 155.5–157.5°, **4***a*, m.p. 157°, and **8***a*, m.p. 96–97° were all stable crystalline substances. None of the others could be isolated in crystalline form.

There have been several attempts (9–13) to synthesize azodiacetyl, the simplest aliphatic azodiacyl, but in no case has the product been adequately characterized. Stollé (10) described it as an unstable red oil, obtained by treating the mercury(II) salt of diacetylhydrazine with iodine, and Inhoffen *et al.* (11) prepared a solution of it by a similar method, and converted it into diacetyl by heating with cupric oxide. Curtin and Miller (13) measured its C=O stretching frequency in carbon tetrachloride but did not attempt to isolate it. We failed to obtain a satisfactory product using the mercury salt method but realized consistent, if modest, yields (30–35%) by stirring equimolar amounts of the hydrazine, NBS, and quinoline[3] in a suitable solvent (tetrachloroethylene, carbon tetrachloride, or benzene) and co-distilling the azo compound with the solvent. Azodiacetyl is a volatile red oil with a penetrating odor. Its solutions were in fact stable indefinitely at room tempera-

[1]On the basis of time-averaged conformational processes.
[2]Hereafter these will be designated simply as *e.g.* **2***c*.
[3]Preferred over pyridine (the more usual base in NBS oxidations) which also co-distilled with the solvent.

ture and it had a half-life of 2 days in refluxing benzene.

Azodipivaloyl (**5***a*) has not been described It was obtained as a red oil by NBS oxidation of dipivaloylhydrazine (14) and was purified by vacuum distillation; it was stable only if stored below $-10°$. It was a rather unreactive dienophile, its condensation with cyclopentadiene taking 2 days at 10°.

NBS oxidation in carbon tetrachloride of 1-acetyl-2-benzoylhydrazine and of 1-benzoyl-2-pivaloylhydrazine (from benzoylhydrazine and pivaloyl chloride) gave the unsymmetrical azo compounds acetylazobenzoyl (**11***a*) and benzoylazopivaloyl (**10***a*), respectively. Both were unstable and were used directly in dilute solution; evaporation of the solvent caused rapid decomposition.

The azo compounds, except **5***a* and **10***a*, reacted rapidly at room temperature with cyclopentadiene, directly, or in solution in benzene or carbon tetrachloride, to give the adducts **2***b*–**12***b*, all of which were crystalline except **8***b*. Their melting points, spectroscopic data, and elementary analyses are shown in Table 1.

The i.r. spectra in the carbonyl region in general showed a doublet, even for the symmetrically substituted adducts. The appearance of the n.m.r. spectra of the latter closely resembled that of the related *N,N'*-dialkoxycarbonyl derivatives (*e.g.* **7***b*) (15), the vinyl and tertiary protons being an isochronous pair at room temperature and the methylene protons a very tight AB system, rarely (an example is **2***b*) discernible as a quartet. The unsymmetrical adducts **9***b*, **10***b*, and **11***b* showed non-equivalence in their tertiary protons.

The methyl group of the dianisoyl compound **3***b* absorbed sharply, but those of the dipivaloyl compound **5***b* and the diacetyl compound **6***b* showed slight broadening, which in the case of the latter sharpened by 55° (**5***b* was too labile to be examined at higher temperatures). These broadening effects are doubtless due to slow interconversion of planar rotamers involving the amide C—N bonds, and are strictly analogous to those found in their *N,N'*-dialkyoxycarbonyl counterparts (15) and in amides and urethanes in general (16).

As observed for **1***b* (1) the isomerization of the adducts **2***b*–**12***b* (except **7***b*, which was stable) could be achieved by heating neat or in solution and was quantitative in either case. Routinely they were refluxed in aqueous alcohol, isooctane, or (for the rather stable **6***b* and **12***b*) tetrachloroethylene, the residue from the solution after reflux being the pure oxadiazines. The adduct **5***b* was exceptionally labile, isomerizing slowly at room temperature and rapidly above its m.p. of 68°. (The m.p. had to be taken by insertion of the capillary tube into the apparatus just below this temperature. After melting the sample solidified and remelted at 74.5–75.5°, that of the pure oxadiazine **5***c*.) Table 2 lists properties of these oxadiazines.

The quantitative nature of the reaction with respect to oxadiazine formation was also revealed by u.v. analysis which was especially

suitable for a kinetic study by following the development of the R—C(=N)— chromophore in the oxadiazine. This ranged between 280 and 350 nm for aromatic R groups and occurred around 240 nm for aliphatic ones. In all instances one or more isobestic points were observed. Detailed kinetic studies on the isomerization of these and related adducts have been carried out over a range of temperatures, and a discussion of the effect of structure and solvent on rates and thermodynamic activation parameters will be presented in a later publication. Relative rate constants for the isomerization of the symmetrical adducts at 77° in 71% aqueous ethanol are shown in Table 3, the value for **1***b* being taken as unity. Similar trends were found in iso-octane.

The remarkable rate enhancement for the dipivaloyl adduct **5***b* and retardation for the diacetyl adduct **6***b* suggest that the rearrangement is strongly subject to steric assistance. In line with this the adduct **10***b* from benzoylazopivaloyl isomerized rapidly to give only the oxadiazine **10***c* arising by participation of the pivaloyl group, while the adduct **11***b* gave only the oxadiazine **11***c* arising by participation of the benzoyl group. An inhibiting effect in carbonyloxy substituents is inferred by the fact that the adduct **7***b* from diethyl azodicarboxylate was stable indefinitely at 77°,[4] and the adduct **12***b* from ethyl benzoylazocarboxylate isomerized slowly, but by participation of the benzoyl group only, to the oxadiazine **12***c*.

In the isomerization of each of these three unsymmetrical adducts no trace of the isomeric oxadiazine, **10***d*, **11***d*, or **12***d* could be detected. All spectra of the total reaction product were superimposable on those of purified oxadiazine and samples of the adducts heated in sealed capillary tubes at 100° eventually (minutes for **10***b*, up to 2 days for **11***b* and **12***b*) gave the melting points of analytically pure products.

In the ensuing structure proofs of oxadiazines from unsymmetrical adducts great advantage was taken of the ease of removal by sulfuric acid of the *N*-acyl substituent on the dihydro derivative of an oxadiazine, first observed for the dihydro derivative **1***e* (1). The resulting base could then be converted into a range of *N*-acyl derivatives. Some properties of the dihydro oxadiazines obtained by this technique and by direct hydrogenation are shown in Table 4.

The structure of **10***c* follows from the absence of a u.v. band around 290 nm, required by the Ph—C(=N)— chromophore in the isomer **10***d*, and by its conversion into the dihydro derivative **5***e* as shown in Scheme 1. Hydrogenation (di-imide) of **10***c* to **10***e* and de-benzoylation gave a base (not isolated) which was converted by pivaloyl

*Crystallization from aqueous MeOH; (*s*), purified by sublimation.

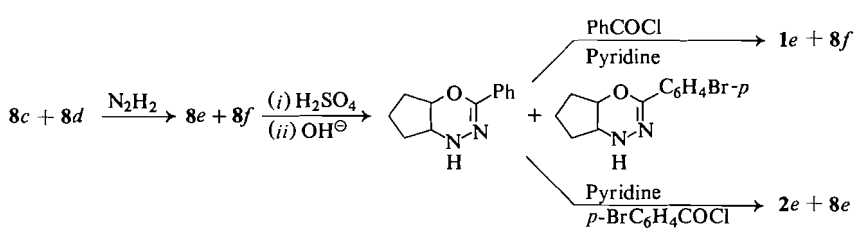
chloride in pyridine into **5***e*, an authentic sample of which was obtained from **5***c* by catalytic hydrogenation with PtO_2.

The structure proof for the products **11***c* and **12***c* was obtained in a related manner as shown in Scheme 1, involving a rational synthesis of their dihydro derivatives.

As Table 3 shows, the rearrangement is evidently less sensitive to electronic than to steric effects. All para substituents appear to be rate enhancing, even when these have electronic effects as different as nitro and methoxy. The small spread in the rate values for the adducts **1***b*–**4***b* was reflected in the behavior of the two unsymmetrical adducts **8***a* and **9***a* from which both isomeric oxadiazines were produced in each case.

The adduct **8***b*, a glassy solid, was isomerized in 71% aqueous ethanol to give a crystalline product which showed only a single peak under a wide range of gas chromatographic conditions. The i.r., u.v., and n.m.r. spectra likewise failed to show whether one or both isomers had been produced; no major distinctions would indeed be expected in the spectra of these isomers. The proof of the formation and identities of both isomers, **8***c* and *d*, is outlined in Scheme 2.

Hydrogenation of the product with di-imide gave the dihydro derivatives **8***e* and *f*, again inseparable by g.l.c., which were de-aroylated with sulfuric acid to the mixture of non-isomeric bases. These were readily distinguished by analytical g.l.c. and had exactly equal peak areas. Assuming that the hydrogenation and de-aroylation steps were equally efficient (the yields were close to quantitative in each), and that the peak areas reflect molar ratios, the yields of the oxadiazines **8***c* and *d* were equal. A portion of the mixture of bases was treated with benzoyl chloride in pyridine to give the



SCHEME 2

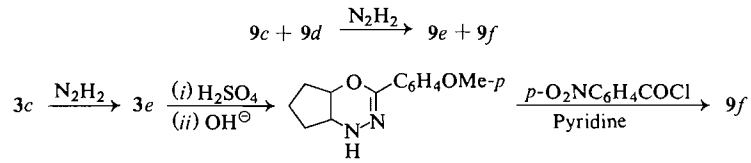

SCHEME 3

benzoyl derivatives separable by g.l.c. The more volatile had the same retention time as authentic **1***e* (by comparative g.l.c.) and the other the same retention time as the mixture of **8***e* and *f*, and was therefore **8***f*. *p*-Bromobenzoylation of the remainder of the basic mixture likewise gave two oxadiazines, the more volatile (**8***e*) in the g.l.c. having the retention time of the mixture of **8***e* and *f* and the other that of authentic **2***e*, obtained by hydrogenating **2***c*.

The analysis of the isomer mixture obtained from **9***b* in refluxing ethanol was more straightforward. The n.m.r. spectroscopy showed two methoxy singlets which were sufficiently shifted at 100 MHz to permit accurate integration, and were found to be in the ratio 60:40 (the ratio was identical when the isomerization was carried out in refluxing benzene). Separation of the isomers was partially achieved by chromatography on silica gel and completed by crystallization from aqueous methanol, giving an oxadiazine of m.p. 134–135°, λ_{max} 281 nm and one of m.p. 201–202°, λ_{max} 345 nm, the methoxy peak of the latter being coincident with the major peak in the spectrum of the mixture. The identities of these were inferred as **9***d* (40%) and **9***c* (60%), respectively, by the position of their ArC(=N)— chromophores (see later), and were proven more directly (Scheme 3) by reaction sequences analogous to those used for the brominated oxadiazines. Hydrogenation of the mixture gave dihydro derivatives **9***e* and *f* in which the ratio of the methoxy peak areas in the n.m.r. spectrum was unaltered: the minor peak was coincident with the methoxy peak of synthetic **9***f*, obtained by de-anisoylation of the dihydro-derivative of **3***b* and *p*-nitrobenzoylation of the resulting base.

The possibility has been recognized of a variety of structural types isomeric with the adducts *b*, all of which may be considered as formally arising by various cycloaddition modes of the azo compound to one double bond of the diene. These include [2 + 2] addition (to 1,2-diazetidines) and [2 + 4] addition (to dihydro-1,3,4-oxadiazines), as well as [2 + 3] and [2 + 6] addition (17).

The thermal isomers generated in the present series of reactions are indeed the bicyclic dihydro-oxadiazines; they are formed directly by the sigmatropic rearrangement of the parent adduct and not by a retro Diels–Alder reaction of the latter with recombination of the resulting diene and azo compound by reverse roles (heterodiene reaction). These conclusions follow from the similarity of spectra and properties of the isomers and their dihydro derivatives with those of **1***b* and *e*, respectively, (1), and by the quantitative nature of the isomerization reaction and its thermodynamic activation parameters.

The i.r. and n.m.r. spectra of the oxadiazines present a particularly uniform picture. Data from these are listed in Table 2.

The C=O and C=N stretching frequencies occurred between 1675 and 1625 cm^{-1} either as a broad band or as a doublet with the lower frequency peak being the less intense and presumably assignable to the C=N. The peak separation was more distinct in the solid phase (Nujol) than in carbon tetrachloride or chloroform solutions. A strong peak around 1090 cm^{-1} was also present; this has been attributed to the C—O—C stretching mode (18).

The key features of the n.m.r. absorptions of the cyclopentadiene derived protons in the oxadiazines were a well spaced strongly split methylene AB quartet (J_{AB} in the range 9–18 Hz), a complex overlapping pattern for the tertiary hydrogens, peaked towards the high field end, and a closely spaced vinyl AB quartet; both AB quartets showed additional fine structure.

The u.v. absorption data for the pyridazines, their isomeric oxadiazines, and the dihydro derivatives of the latter are listed in Table 5. As expected neither the position nor the intensity of the C=O and C=N bands in the oxadiazine was affected by hydrogenation of the olefinic

bond. Examination of these spectra show them to be of unmistakeable diagnostic value.

The di-*p*-bromobenzoyl derivative **2***b* and the dianisoyl derivative **3***b* both absorb at longer wavelengths than the unsubstituted **1***b*, in keeping with the expected re-inforcing effect of two benzenoid substituents of opposite electronic character para to one another (19). The *p*-bromobenzoyl group and the anisoyl group in the unsymmetrical adducts **8***b* and **9***b*, respectively, likewise show this shift. By contrast the di-*p*-nitrobenzoyl derivative **4***b* shows little band shift.[5]

An electron releasing effect from the C=N group to the benzene ring is evident in the 3-aryloxadiazines since the band in the parent phenyl derivative **1***c* at 292 nm shifts to longer wavelengths (333 nm) in the dinitro compound **4***c*. There is also an interaction with the amide aroyl group since the *p*-nitrobenzimidoyl chromophores are even further shifted (to 345 nm) when the electron releasing, and hence stabilizing, *N*-anisoyl group is present (**9***c*). The isomer of **9***c* in which the substituent positions are exchanged, **9***d*, shows a dramatic reversal of these electronic effects: the *p*-methoxybenzimidoyl and *p*-nitrobenzoyl chromophores form a composite band at 281 nm.

The aliphatic imidoyl chromophores are evidently at longer wavelengths than the *N*-acyl chromophores. The *N*-acetyl and *N*-pivaloyl bands cannot be resolved from the end absorption (see the adducts **6***b* and **5***b*, or the oxadiazine **11***c* in which only the PhC=N band is detectable) and so the bands in the oxadiazines **6***c* and **5***c* at 239 and 238 nm are due to the acetimidoyl and pivalimidoyl chromophores, respectively.

The synthetic potential implicit in the sequence of isomerization, hydrogenation, dearoylation, and re-aroylation (see *e.g.* Schemes 1–3) points to the feasibility of a detailed study of these electronic effects with an almost unrestricted choice of substituents.

[5]The short wavelength bands in many of these adducts appeared as shoulders on the end absorption, and the absorption maximum was in some cases hard to estimate. The trends described, however, were clear.

Experimental

The i.r. spectra were taken on a Beckman IR 10 spectrophotometer. A Coleman EPS-3T Hitachi spectrophotometer or a Bausch and Lomb Spectronic 505 were used for measuring u.v. and visible spectra. The n.m.r. analyses were done on a Varian T-60 or HA-100 spectrometer and absorptions are quoted in τ values against tetramethylsilane as internal standard. For g.l.c. a Beckman GC4 instrument fitted with a dual flame ionization detector was used; the columns were 6 ft. × 1/8 in. 3% SE30 on Chromosorb W.

Solvents were purified by conventional means. Anhydrous magnesium sulfate was used as drying agent for solutions in organic solvents. Melting points are uncorrected.

Azo Compounds (2a–12a)

Compounds 3a, 7a, 9a, and 12a

Compounds **3***a* (m.p. 131–132° (6)), **9***a* (m.p. 131–132° (8)), and **12***a* (an oil (9)) were prepared by published procedures. Compound **7***a* was purchased from Aldrich Chemical Co.

Azo-di-p-bromobenzoyl (2a)

Compound **2***a* was obtained by oxidation of the mercury(II) salt of 1,2-di-*p*-bromobenzoylhydrazine (20) with bromine in carbon tetrachloride (2). It formed yellow crystals, m.p. 155.5–157.5° (dec.), from cyclohexane.

Anal. Calcd. for $C_{14}H_8Br_2N_2O_2$: Br, 40.5. Found: Br, 40.9.

p-Bromoazodibenzoyl (8a)

Compound **8***a* was prepared similarly from 1-benzoyl-2-*p*-bromobenzoylhydrazine (21). It was a pale orange solid, m.p. 96–97°, after crystallization from carbon tetrachloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Anal. Calcd. for $C_{14}H_9BrN_2O_2$: Br, 25.2. Found: Br, 25.5.

Azodi-p-nitrobenzoyl

Oxidation of the mercury salt of 1,2-di-*p*-nitrobenzoylhydrazine (22) with bromine in methylene chloride gave the sparingly soluble *azodi-p-nitrobenzoyl* which was precipitated from its solution by addition of pentane as a yellow solid, m.p. 157° (dec.).

Azodipivaloyl (5a)

A slurry of 1,2-dipivaloylhydrazine (4.0 g, 20 mmol) (14), *N*-bromosuccinimide (3.56 g, 20 mmol), and pyridine (1.61 ml, 20 mmol) in carbon tetrachloride (75 ml) was stirred for 45 min with exclusion of moisture. The whole was filtered and evaporated under reduced pressure and the residue taken up in pentane (20 ml) which caused the precipitation of some hydrazine. Filtration, evaporation, and distillation gave pure *azodipivaloyl* (2.0 g, 50%) as a red oil, b.p. 54°/1.3 mm; $\nu(CCl_4)$ 1752 cm^{-1} (C=O); $\tau(CCl_4)$ 8.73 p.p.m. (sharp singlet).

The azo compound decomposed slowly at room temperature but was stable at −10°.

Azodiacetyl (6a)

1,2-Diacetylhydrazine (Aldrich Chemical Co., recrystallized from benzene–methanol to m.p. 138.5–139.5°) (12.0 g, 105 mmol), *N*-bromosuccinimide (17.8 g, 100 mmol), and quinoline (12.9 g, 100 mmol) were stirred at room temperature for 3 h in tetrachloroethylene (120 ml). The mixture was filtered and the precipitate washed with further solvent (50 ml, in portions). The filtrate and washings were distilled through a 10 in. fractionating column under reduced pressure so that the temperature at the top of the column was in the range 30–35°. Towards the end of the distillation fresh solvent was added to the flask and the whole process continued till the distillate was almost colorless. The total red distillate (*ca.* 170 ml) contained 33 mmol (33%) of azodiacetyl, determined by n.m.r. analysis against the methyl peak in methyl benzoate added as an internal standard (analysis before distillation showed the yield to be 51%). The distillate was free of bromine (negative iodide test) and of quinoline (n.m.r.).

Benzene and carbon tetrachloride could also be used as solvents for the oxidation, but the final distillation then required the addition of fresh solvent several times to complete the co-distillation of the azo compound. Concentration of the solution at room pressure then gave a solution of any desired concentration.

Evaporation of a solution gave a red oily residue of azo compound which volatilized on standing and had a sharp penetrating odor. Solutions were stable indefinitely at room temperature, and in refluxing benzene (7×10^{-2} *M*) it had a half-life of 2 days.

The azo compound had $\nu(CCl_4)$ 1767 cm^{-1} (C=O) (lit. (13) 1765 cm^{-1}); λ_{max} (C_2Cl_4) 455 nm (ε 32); $\tau(CCl_4)$ 7.61, (C_2Cl_4) 7.75 p.p.m.

Benzoylazopivaloyl (10a)

Benzoylhydrazine (38.7 g, 282 mmol) and pivaloyl chloride (34.0 g, 282 mmol) were allowed to react in pyridine (200 ml) for 3 h at room temperature. The resulting slurry was added to water and the product recrystallized from aqueous ethanol (58%) or, more efficiently, sublimed at 200°/0.5 mm (85%) to give colorless 1-benzoyl-2-pivaloylhydrazine, m.p. 189–190°; $\nu(CCl_4)$ 3415, 3250 (NH), 1640 cm^{-1} (C=O); $\tau(CDCl_3)$ 0.13 (1 NH, doublet), 1.0 (1 NH, doublet, J = 5 Hz), 2.0–2.8 (5 phenyl H), 8.77 p.p.m. (9 *t*-Bu H, sharp singlet).

Anal. Calcd. for $C_{12}H_{16}N_2O_2$: C, 65.4; H, 7.3; N, 12.7. Found: C, 65.2; H, 7.2; N, 12.9.

The hydrazine was oxidized by the same method and on the same scale as in the preparation of azodipivaloyl. The carbon tetrachloride filtrate was concentrated and pentane added to precipitate out impurities. The red solution was used directly in synthesis since concentration to a small volume led to rapid evolution of nitrogen. The azo compound had $\nu(CCl_4)$ 1749, 1726 cm^{-1} (C=O); $\tau(CCl_4)$ 1.9–2.7 (5 phenyl H), 8.7 p.p.m. (9 *t*-Bu H, sharp).

Acetylazobenzoyl (11a)

Similar oxidation of 1-acetyl-2-benzoylhydrazine (from benzoylhydrazine and acetic anhydride with a trace of sulfuric acid) gave the azo compound which was also unstable (10) and was used in solution. The n.m.r. spectrum showed solutions so prepared to be slightly contaminated (pyridine and some aliphatic absorptions); the mercury salt method, though more troublesome, gave a cleaner product. The deep red carbon tetrachloride solution had ν 1767, 1727 cm^{-1} (MeC=O, PhC=O); τ 1.7–2.8 (5 phenyl H), 7.69 p.p.m. (3 methyl H, sharp).

2,3-Diaroyl-(or diacyl)-2,3-diazabicyclo[2.2.1]hept-5-enes (2b–12b)

The azo compounds were allowed to react with cyclopentadiene at room temperature, directly or in solution in benzene or carbon tetrachloride. Reaction was complete within minutes for azodiaroyls but was retarded by aliphatic acyl groups, azodiacetyl taking 1 h under the same conditions and azodipivaloyl 2 days at 10°. The n.m.r. analysis in all cases indicated the residue on evaporation to be essentially pure adduct. Solvents for crystallization, m.p.'s, i.r., and n.m.r. data and elementary analyses are shown in Table 1 and u.v. data in Table 5.

Sharp m.p.'s could not be obtained for **4***b*, **5***b*, or **10***b* by heating capillary tubes from room temperature in the conventional manner. The tube had to be inserted just below the m.p., found by trial and error; after melting the samples solidified and remelted at the m.p. of the pure oxadiazine.

cis-4-Aroyl-(or acyl)-4,4a,5,7a-tetrahydro-2-aryl-(or alkyl)-cyclopenta-1,3,4-oxadiazines (Structures c, d).

The isomerization of the adducts (**2***b*–**12***b*) was effected by heating neat or in solution as shown in Table 6.

The product in each case had spectra superimposable on those of purified oxadiazines or mixtures of isomeric oxadiazines. Most of the isomerizations were also followed in

TABLE 6. Reaction conditions for the isomerization of adducts **2***b*–**12***b*

Adduct	Reaction conditions	Time
2*b* and **8***b*	Refluxing EtOH:H_2O (4:1)	4 h
3*b* and **9***b*	Refluxing EtOH	8 h
4*b*	Refluxing EtOH	5 h
11*b*	Refluxing iso-octane	6 h
12*b*	Refluxing tetrachloroethylene	6 h
6*b*	Refluxing tetrachloroethylene	2 days
5*b*	Room temperature (or 70°)	1 day (or 5 min)
10*b*	Room temperature (or 70°)	3 days
(**7***b*	Stable indefinitely up to 150°)

solution by repeated scanning u.v. spectrophotometry as part of a detailed kinetic study: one or more isobestic points were observed throughout.

Table 3 lists properties of these oxadiazines, analogous to those in Table 1; u.v. data are in Table 5.

cis-4-Aroyl-(or acyl)-4,4a,5,6,7,7a-hexahydro-2-aryl-(or alkyl)-cyclopenta-1,3,4-oxadiazines (Structures e, f)

(a) Direct Hydrogenation of Oxadiazines c, d

Di-imide was used in these reductions, generated from hydrazine and hydrogen peroxide for compounds **2***e*, **3***e*, **9***e* and *f*, and **12***e*, or from *p*-toluenesulfonylhydrazine in refluxing dioxane for **8***e* and *f* and for **11***e*; full details of reaction conditions and work-up have been described earlier (1). Compound **5***e* was obtained catalytically, with PtO_2 in ethanol.

(b) Acylation of cis-4,4a,5,6,7,7a-hexahydro-2-aryl-(or alkyl)-cyclopenta-1,3,4-oxadiazines

Brief treatment of the hydrogenated derivatives *e* and *f* with hot concentrated sulfuric acid, followed by neutralization with aq. sodium hydroxide and extraction with carbon tetrachloride (1) gave the title compounds which were not further purified. Acylation was performed in pyridine at room temperature over 18 h with the acid chloride (ethyl chloroformate for the synthesis of **12***e* and acetic anhydride for the synthesis of **11***e*). Work-up entailed neutralization with ice and dil. hydrochloric acid and extraction with ether and crystallization.

Compounds made by this method were **5***e* (debenzoylation of **10***e*, followed by pivaloylation), **9***f* (de-anisoylation of **3***e*, *p*-nitrobenzoylation), **11***e* (debenzoylation of **1***e*, acetylation) and **12***e* (debenzoylation of **1***e*, carbethoxylation). Taken in conjunction with the previous steps, *viz.* isomerization and hydrogenation, the above syntheses constitute unambiguous structure proofs of **10***e*, **9***f*, **11***e* and **12***e*, respectively.

Melting points, i.r. bands, and elementary analyses of the pure dihydro oxadiazine derivatives made by both of the above methods are listed in Table 4 and u.v. data for some of them in Table 5. The n.m.r. assignments are not included. They were of little interest, those for protons on the cyclopentane ring being very similar to those described for **1***e* (1).

Analysis of Isomer Mixture 8c and d from Isomerization of 8b

The mixture was crystalline and had ν(Nujol) 1650, 1630 cm^{-1} (C=O, C=N); $\tau(CDCl_3)$ 1.3–2.7 (9 aryl H) 3.55 (2 vinyl H, broad quartet), 4.95 (2 *t*-H, broad), 6.95, 7.55 p.p.m. (methylene AB quartet). The g.l.c. failed to separate the isomers under a wide range of conditions.

The dihydro derivatives **8***e* and *f*, obtained by refluxing with *p*-toluenesulfonylhydrazine in dioxane, were also inseparable by g.l.c. They were de-aroylated with sulfuric acid to the mixture of bases 2-phenyl- and 2-*p*-bromophenyl-*cis*-4,4*a*,5,6,7,7*a*-hexahydrocyclopenta-1,3,4-oxadiazine which were clearly separated and had equal peak areas in their gas–liquid chromatogram.

A portion of the bases was benzoylated as described above to give a mixture of oxadiazines. These were identified by g.l.c., in order of elution, as **2***e* and **8***f* by co-injection of authentic **2***e* (1) which increased the size of the first peak, and co-injection of the mixture **8***e* and *f* which increased the size of the second. Similarly the rest of the basic mixture was converted into the *p*-bromobenzoyl derivatives identified by g.l.c. as (in order) **8***e* and **4***e* by co-injection, respectively, of the mixture **8***e* and *f* and of authentic **4***e*.

Analysis of Isomer Mixture 9c and d from Isomerization of 9b

The composition of the crystalline mixture was determined by comparing the areas of the methoxy peaks in the 100 MHz spectrum of a solution of it in $CDCl_3$. The mean of a large number of determinations showed the ratio of **9***c*:**9***d* to be 60:40.

A portion of the mixture was chromatographed on silica gel with 1:1 ether:petroleum ether (b.p. 40–60°). Compound **9***d* was eluted first, followed by **9***c* which was contaminated with the end fractions of **9***d*; the latter could be removed by crystallization from aqueous methanol. Both oxadiazines formed yellow prisms from aqueous acetone, **9***d* having m.p. 134–135° and **9***c*, m.p. 201–202°.

Anal. Calcd. for $C_{20}H_{17}N_3O_5$: C, 63.3; H, 4.5; N, 11.1. Found for original mixture: C, 63.5; H, 4.5; N, 11.4.

Photolysis of Aqueous Solutions of 9,10-Anthraquinone-2-sulfonate. Part I. Dependence of Product Yields on Reaction Conditions

A. D. BROADBENT AND R. P. NEWTON

Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received June 30, 1971

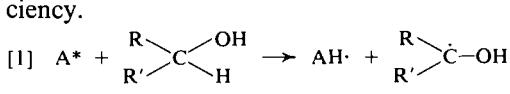
The products of the photolysis of neutral aqueous solutions of 9,10-anthraquinone-2-sulfonate or of the action of Fenton's reagent on this quinone have been identified as 1- and 2-hydroxy- and dihydroxy-9,10-anthraquinone sulfonates. High quinone and low oxygen concentrations favor production of monohydroxy-anthraquinone sulfonates, while low quinone and high oxygen concentrations result in preferential formation of dihydroxylated derivatives of the quinone. Photolysis in aqueous NaOH solution gives essentially only 2-hydroxy-9,10-anthraquinone sulfonates.

Les produits de la photolyse de solutions aqueuses neutres de sulfonate-2 anthraquinone-9,10 ou de l'action du réactif de Fenton sur ce quinone ont été identifiés comme étant des sulfonates d'hydroxy-1 et -2 et de dihydroxy-anthraquinone-9,10. De fortes concentrations en quinone et faibles en oxygène favorisent la production de sulfonates d'anthraquinone monohydroxylée tandis que de faibles concentrations en quinone et fortes en oxygène conduisent préférentiellement à la formation de dérivés dihydroxylés de la quinone. La photolyse en solution aqueuse de soude ne donne essentiellement que des sulfonates d'hydroxy-2 anthraquinone-9,10.

Canadian Journal of Chemistry, **50**, 381 (1972)

Introduction

The crucial primary photochemical process in the photo-oxidation of alcohols sensitized by 9,10-anthraquinones is considered (1–5) to be hydrogen atom abstraction from the alcohol by the electronically excited quinone, according to eq. 1. The available evidence (4–6) indicates that the electronically excited 9,10-anthraquinone in reaction 1, A*, is a n,π^* triplet state molecule generated with high quantum efficiency.



[1] $A^* + \begin{matrix} R \\ R' \end{matrix}\!\!>\!C\!<\!\begin{matrix} OH \\ H \end{matrix} \rightarrow AH\cdot + \begin{matrix} R \\ R' \end{matrix}\!\!>\!\dot{C}\!-\!OH$

Few studies have been conducted on the photolysis of 9,10-anthraquinones in purely aqueous solution, despite the fact that photo-oxidation of chloride and bromide ion sensitized by such quinones have been established (7), and that photoreduction of anthraquinones proceeds readily in aqueous solution in the absence of alcohols (8–11). Pfeilsticker (12) originally demonstrated that photolysis of sodium 9,10-anthraquinone-2-sulfonate (2-AS) in water caused reduction of the quinone and formation of what he incorrectly believed to be 2-hydroxy-9,10-anthraquinone. Subsequently, Mooney and Stonehill (13) indicated that at least four different hydroxyanthraquinone sulfonates are produced in this photolysis, by reaction of 2-AS with photochemically generated hydroxyl radicals. The formation of such colored hydroxy-anthraquinones had been observed in the 2-AS sensitized photo-oxidation of alcohols in aqueous solution (1, 3, 14, 15), particularly at low alcohol concentrations. A preliminary investigation (16) confirmed that the major products of the photolysis of 2-AS in aqueous solution were, in fact, 1- and 2-hydroxy-9,10-anthraquinone sulfonates and that the products of the primary photochemical reaction were hydroxyl radical and reduced 2-AS. Recent studies by Phillips *et al.* (17) have produced evidence, which suggests that the primary photochemical products are formed by reactions 2 and 3. However, Blyumenfel'd and coworkers

[2] $$A^* + A \rightarrow A^{\cdot -} + A^{\cdot +}$$

[3] $$A^{\cdot +} + HO^- \rightarrow A + HO\cdot$$

have also investigated this photolysis in alkaline solution (18–21). They conclude that reduction of 2-AS by hydroxide ion (reaction 4) occurs in the dark but is accelerated by light absorption resulting in electronic excitation of 2-AS.

[4] $$A + HO^- \rightarrow A^{\cdot -} + HO\cdot$$

This paper is concerned with the nature of the hydroxylated products from photolysis of 2-AS in aqueous solution and the dependence of the product distribution on the p*H* of the solution, its oxygen concentration and the initial 2-AS concentration. Such product distribution studies are a necessary prerequisite to elucidation of the

primary photochemical process from rates of product formation on photolysis.

Results

Product Identification

Chromatography after photolysis of 2-AS in air-saturated water (p*H* 6) gave six fractions (Table 1). Fractions 4 and 6 obtained from photolyses at p*H* 13 appeared identical to the corresponding fractions from neutral photolysis. Although photolysis of 2-AS in water and NaOH solution yielded essentially the same products, the distribution of products was markedly p*H* dependent.

The u.v. and i.r. spectra of fraction 1 were superimposable on those of the original 2-AS (Tables 2 and 3).

Fraction 2 was readily soluble in water, being yellow in acidic and red in alkaline solution. Addition of $Na_2S_2O_4$ to the alkaline solution produced color changes characteristic of 2-hydroxy-9,10-anthraquinone sulfonates and confirmation of this was obtained by polarography (22). The i.r. and u.v. spectra of fraction 2 (Tables 2 and 3) were found to be composites of the essentially identical spectra of 2-hydroxy-9,10-anthraquinone-6-and-7-sulfonates. There was no indication of additional components in this fraction. Fraction 2 was converted into a mixture of 2,6- and 2,7-dihydroxy-9,10-anthraquinone (23), which were separated by fractional crystallisation of their calcium salts. However, the reaction gave poor yields, considerable amounts of polyhydroxyanthraquinones, and efficient separation was impractical. No further attempts to prepare derivatives were undertaken. Fraction 2, therefore, arises from hydroxylation of 2-AS at the 6- and 7-positions.

Fraction 3 was also water-soluble and gave similar color changes to those observed for fraction 2. However, reduction in alkaline solution with $Na_2S_2O_4$ gave an easily oxidized deep red product but no green anthrasemiquinone reduction intermediate was observed, indicating

that fraction 3 was composed of 1-hydroxy-9,10-anthraquinone sulfonates (22). This conclusion was supported by the i.r. spectrum (Table 2) (24, 25). Both the u.v. and i.r. spectra of fraction 3 were almost identical with those of 1-hydroxy-9,10-anthraquinone-6-sulfonate and very similar to those of 1-hydroxy-9,10-anthraquinone-2-sulfonate but the i.r. spectra indicated that the latter compound is not a major component. Fraction 3 was, therefore, considered to be a mixture of 1-hydroxy-9,10-anthraquinone sulfonates, probably the 1,6- and 1,7-isomers, being formed by hydroxylation of 2-AS at the 5- and 8-positions.

The identity of fraction 4 was not established as only very small amounts of this minor component could be isolated. Treatment with $Na_2S_2O_4$ caused reduction, which was easily reversed on shaking the solution with air. Its u.v. spectrum was very similar to that of a 2-hydroxy-9,10-anthraquinone sulfonate but fraction 4 did not appear to be 2-hydroxy-9,10-anthraquinone-3-sulfonate.

Fraction 5 (blue on Al_2O_3) could be eluted with weakly alkaline ethanol containing 30% H_2O by volume but fraction 6 (violet on Al_2O_3) could not be eluted. The eluent containing fraction 5 contained considerable amounts of material dissolved from the Al_2O_3 column which prevented isolation of a pure product. Its visible absorption spectrum in strongly alkaline solution was very similar to that of alizarin and related dihydroxyanthraquinones. Fraction 5 gave yellow aqueous solutions, which became violet and then blue on addition of NaOH. The blue alkaline solutions turned orange on treatment with $Na_2S_2O_4$, the blue color being easily regenerated by shaking the solution with air.

Photolysis of 2-AS at low concentrations (1×10^{-4} *M*) in neutral, O_2-saturated solution gave almost exclusively fractions 5 and 6 alone (see later). This provided a convenient means of studying these products. Color changes and visible absorption spectra (Table 3) indicated that fractions 5 and 6 are apparently 1,2-, 2,3-, or 1,4-dihydroxy-9,10-anthraquinone derivatives (26, 27). The blue alkaline solutions slowly faded in the presence of air, supporting this

assignment (26, 27). Chromatography of the photolysis products under various conditions, and also the absence of fraction 5 in photolyses of 2-AS at p*H* 13, indicated that fractions 5 and 6 were not different forms of the same substance.

Both the reaction products and the synthesized anthraquinone derivatives were difficult to purify so that molar absorptivities could not be determined. The recovery of substance on recrystallization was often low and removal of residual inorganic salts such as sodium chloride and sulfate is difficult. The hydroxyanthraquinone sulfonates are also hygroscopic. In addition to these problems, the identification of the photolysis products is further complicated because more conveniently handled derivatives, in which the sulfonate group has been replaced, cannot be prepared in high yield and also because each fraction from chromatography of the photolyzed solutions is probably a mixture of closely related isomers. Unambiguous identification of the reaction products was therefore not possible. Nevertheless, in many instances, the almost exact superimposition of the u.v. and i.r. spectra of the chromatographic fraction and of the appropriate model compounds strongly suggests that the reaction products are 1- and 2-hydroxy- and dihydroxy-9,10-anthraquinone sulfonates, the sulfonate group being at its original site but mainly in the non-hydroxylated ring.

Dependence of Product Yields on pH

On increasing the p*H* of the solution from 6 to 13, the striking change in product distribution (see Table 1) was accompanied by a fourfold increase in the rate of formation of hydroxylated derivatives of 2-AS. The pronounced change in product distribution and the increase in hydroxylation rate both occurred as the HO^- concentration was increased above 1×10^{-3} *M*.

Fractions 2 and 3 were separated by column chromatography and their relative yields measured by absorption spectrophotometry assuming identical molar absorptivities for the two species at the wavelengths of their absorption maxima.

Photolysis of neutral 3×10^{-3} *M* aqueous 2-AS solutions for 1 h gave yield (3)/yield (2) $= 3.5 \pm 0.8$ for both air- and O_2-saturated solutions. Similar photolyses in 0.4 *M* aqueous NaOH gave a ratio <0.01. The molar absorptivity ratio probably differs from unity, *e.g.* in aqueous NaOH for 2,7-$HOAQSO_3Na$, $\varepsilon_{472} = 5400$ and for 1,4-$HOAQSO_3H$, $\varepsilon_{492} = 7140$ (28). In addition, some tailing of fraction 2 may have resulted in contamination of fraction 3 during chromatography. Therefore, the above values of the ratio of yields should be considered as upper limits.

The change in the pattern of monohydroxylation on changing the p*H* of the photolyzed solution appeared related to the changes in the yields of dihydroxyanthraquinones (fractions 5 and 6). The striking decrease in the value of the ratio of yields above p*H* 11 was accompanied by the total disappearance of fraction 5 and a reduced yield of fraction 6.

Dependence of Product Yields on the Initial Concentrations of Oxygen and 2-AS

Photolyses of 2-AS at various initial concentrations in neutral and alkaline aqueous solutions saturated with air or oxygen showed that the formation of monohydroxyanthraquinones is favored at high quinone and low oxygen concentrations, whereas dihydroxyanthraquinones are the major products at low quinone and high oxygen concentrations. Some typical spectra of photolyzed 2-AS solutions are shown in Fig. 1, and data on the effects of O_2 and 2-AS concentrations on the relative yields of mono- and dihydroxylated derivatives are given in Table 4.

Reactions with Fenton's Reagent

In previous investigations (13, 16) it was established that reaction of 2-AS with Fenton's reagent (aqueous $FeSO_4 + H_2O_2$) gave deeply colored solutions, which after precipitation of $Fe(OH)_3$ and column chromatography on Al_2O_3, gave fractions whose u.v. spectra were identical with those of the photolysis products. This supports the proposal that hydroxyl radicals, generated by photolysis of 2-AS in water, are responsible for the observed hydroxylation of this quinone.

Because of the dependence of product yields on the conditions of photolysis, reactions of 2-AS with equimolar quantities of $FeSO_4$ and H_2O_2 were conducted in aqueous solution in the dark at various O_2 and 2-AS concentrations. In solutions containing O_2, decreasing its concentration reduced only the yield of dihydroxyanthraquinones but even under N_2 substantial

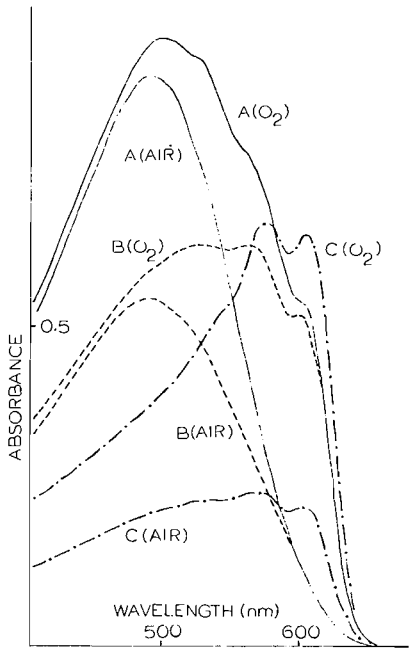

FIG. 1. Absorption spectra of photolyzed aqueous 2-AS solutions. Neutral O_2- or air-saturated aqueous solutions of 2-AS, at various initial concentrations, were photolyzed for 6 min at 366 nm, NaOH added to give a concentration of 1.0 *M*, and absorption spectra recorded in 1.0 cm (A and B) or 5.0 cm (C) optical cells. Initial 2-AS concentrations were: (A) 1.0×10^{-3} *M*, (B) 5.0×10^{-4} *M*, and (C) 5.0×10^{-5} *M*.

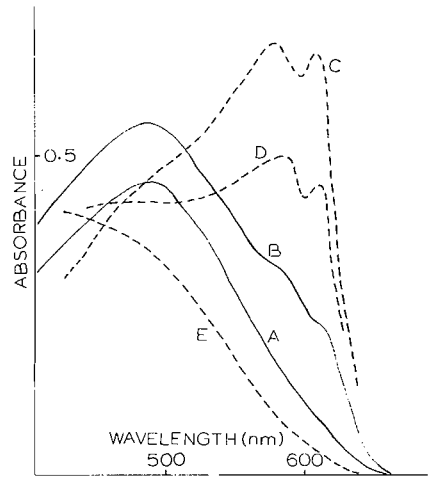

FIG. 2. Absorption spectra of 2-AS solutions. Solutions of 2-AS, $FeSO_4$, and H_2O_2 (all 2×10^{-3} *M*) reacted 10 min and then made alkaline with NaOH and oxygenated (A) or oxygenated and made alkaline (B). Neutral, oxygen-saturated solutions of 2-AS (5×10^{-5} *M*) photolyzed in the presence of zero (C), 5×10^{-5} *M* (D), and 1×10^{-4} *M* $K_3Fe(CN)_6$ (E) and subsequently made alkaline.

quantities of these products still resulted. However, the distribution of products from reactions in O_2-free solution was dependent on the treatment of the solution after reaction. Even after 15 min reaction under N_2, it was possible to influence the product distribution by treatment of samples of the reaction mixture with NaOH or O_2 (see Fig. 2). The formation of dihydroxylated products ($\lambda_{max} = 610$ nm) on introducing O_2 in such reactions was also suppressed by addition of excess 2-AS (as saturated aqueous solution) and completely prevented by addition of an equimolar amount of $K_3Fe(CN)_6$ shortly after the initial mixing. Therefore, in reactions with Fenton's reagent, the product distribution could be influenced by the concentrations of

O_2, HO^-, and 2-AS in solution, as well as by addition of $K_3Fe(CN)_6$, just as in photolysis (see later).

Photolysis in the Presence of Ferricyanide Ion

Photolysis of neutral, O_2-saturated solutions of 2-AS at a concentration of 5×10^{-5} *M* gave products which are violet or blue in alkaline solution, exhibiting absorption maxima at about 570 and 610 nm characteristic of dihydroxyanthraquinones. Potassium ferricyanide has no absorption above 475 nm and did not interfere with product analysis. Although $K_3Fe(CN)_6$ absorbed some of the incident light at 366 nm, its addition to the solution being photolyzed efficiently suppressed the formation of dihydroxylated products and significantly increased the relative yields of monohydroxyanthraquinones (see Fig. 2).

Discussion

The variations in product distribution in the reactions of 2-AS with $HO^{\cdot}$, generated either by photolysis of 2-AS or from Fenton's reagent, can be explained in terms of the reactions of the intermediate radical produced by addition of $HO^{\cdot}$ to 2-AS. Hydroxyl radical is known to be electrophilic (29) and the available evidence suggests that it reacts with benzene derivatives by addition, generating hydroxycyclohexadienyl radicals, rather than by abstraction of a hydrogen atom from the benzene ring. The addition of $HO^{\cdot}$ to 2-AS can produce several adducts. Product analysis indicated that hydroxylation of 2-AS occurred mainly in the non-sulfonated ring, in agreement with the known electrophilic character of $HO^{\cdot}$ and the electronic and steric effects of sulfonate groups.

Land and coworkers (30) have observed a transient intermediate in pulse radiolysis of oxygen-free aqueous solutions of 2-AS, which is believed to be the product of the addition of hydroxyl radical to the quinone. They have measured the rate constant for the addition and also established that the adduct disappears by a second order process in dilute 2-AS solutions. Clark and Stonehill (31) find that this transient disappears very rapidly in the presence of oxygen. Phillips *et al.* (17) postulated that monohydroxyanthraquinone sulfonates result from the coupling of the quinone–hydroxyl radical adduct with O_2, followed by elimination of $HO_2^{\cdot}$. Our results have shown that this is not so, since monohydroxylation occurs exclusively on photolysis in the absence of oxygen.

In the reactions of 2-AS with Fenton's reagent, the product distribution could be varied by addition of O_2, HO^-, $K_3Fe(CN)_6$, or excess 2-AS. This can be explained by postulating reactions of these species with the quinone–hydroxyl radical adduct. Reaction with O_2 would generate dihydroxyanthraquinones while reaction with HO^- would result in monohydroxylation. In the presence of $K_3Fe(CN)_6$, or excess 2-AS, oxidation of the adduct to monohydroxyanthraquinones is proposed.

Detailed kinetic studies are now in progress to confirm these proposals, particularly since the effects of quinone concentration on rate of hydroxylation reported by Phillips *et al.* (17) as confirming reactions 2 and 3 may well arise from the effects of 2-AS concentration on the relative rates of the secondary reactions producing hydroxylated derivatives rather than from the proposed reaction 2.

Experimental

Anthraquinone Derivatives

Sodium 9,10-anthraquinone-2-sulfonate monohydrate was purified by repeated recrystallization from hot water in the dark. Prolonged heating of the solutions was avoided to prevent hydrolysis to 2-hydroxy-9,10-anthraquinone.

Sodium 2-hydroxy-9,10-anthraquinone-6- and 7-sulfonates, and 1-hydroxy-9,10-anthraquinone-4-sulfonic acid were available from previous studies (22). 1-Hydroxy-, 2-hydroxy-, and 1,2-dihydroxy-9,10-anthraquinone and sodium 1,2-dihydroxy-9,10-anthraquinone-3-sulfonate were purified by recrystallization of commercial samples.

Sodium 1-hydroxy-9,10-anthraquinone-2-sulfonate was prepared by sulfonation of 1-hydroxy-9,10-anthraquinone with 20% oleum at 80 °C for 1.5 h. Higher temperatures give the 2,4-disulfonate. 2-Hydroxy-9,10-anthraquinone was sulfonated with 65% oleum for 8 h on the steam bath to yield after neutralization, sodium 2-hydroxy-9,10-anthraquinone-3-sulfonate. Sodium 1,2-dihydroxy-9,10-anthraquinone-6-sulfonate was prepared by refluxing the 2,6-disulfonate with NaOH solution (26). It was separated from 2-hydroxy-9,10-anthraquinone-6-sulfonate by chromatography on Al_2O_3, but required 5% aqueous HCl for elution.

The literature method of preparing 1-hydroxy-9,10-anthraquinone-6-sulfonate (26) based on reaction of the 1,6-nitro sulfonate with CH_3OH/NaOH and subsequent hydrolysis of the methyl ether gave several products. Sodium 1-nitro-9,10-anthraquinone-6-sulfonate (32) (ν (Nujol) 1673, 1543, 1375 cm^{-1}) was reduced with $Na_2S_2O_4$ in 2 *M* aqueous NaOH at room temperature. Subsequent air oxidation gave sodium 1-amino-9,10-anthraquinone-6-sulfonate, (ν (Nujol) 3280, 3170, 1670, 1640, 1620 cm^{-1}) which was diazotized at 0 °C with $NaNO_2$/HCl and gave N_2 and the sodium 1-hydroxy-9,10-anthraquinone-6-sulfonate on warming.

All the anthraquinone sulfonates were recrystallized from water.

Photolysis

All photolyses were conducted in a Rayonet Photochemical Reactor, using lamps with strong emission at 365 nm.

For product identification studies sodium 9,10-anthraquinone-2-sulfonate ($1–5 \times 10^{-3}$ *M*) was photolyzed in water or 0.1–0.5 *M* aqueous NaOH saturated with air and contained in a Pyrex vessel. The neutralized solution was evaporated under vacuum below 50 °C and 95% ethanol and a small amount of dilute aqueous NaOH were added to give a solution containing 80% ethanol by volume. Any unreacted 2-sulfonate and NaCl which crystallized out were removed and the resulting solution run through a column of basic activated Al_2O_3, using 80% ethanol as eluent and subsequently diluting this with water containing a little NaOH. The collected fractions were neutralized and evaporated to dryness under vacuum and the solid products recrystallized from water. During all photolyses, the solutions were stirred by bubbling with O_2, air, or N_2. Rates of formation of hydroxyanthraquinones were sufficiently low, that depletion of oxygen was assumed negligible.

Estimation of product yields

In addition to chromatographic examination, the following procedure was used to obtain information about the relative yields of mono- and dihydroxyanthraquinone sulfonates. After reaction, NaOH was added to the solution to give a solution of 1.0 *M* hydroxide ion. In the case of reactions with Fenton's reagent, precipitated iron hydroxides were removed by centrifugation. The yield of dihydroxyanthraquinone sulfonates was determined from measurements of the absorbance of the alkaline solution at 610 nm; that of monohydroxy derivatives being related to absorbance at the wavelength of maximum absorbance in the region 470–500 nm. Examination of the spectra of the model compounds showed that eq. 5 gave a suitable measure of the relative yields of products.

$$[5] \quad \frac{\text{Yield AQOH}}{\text{Yield AQ(OH)}_2} = \frac{A_{470-500} - 0.45\,A_{610}}{A_{610} - 0.03\,A_{470-500}}$$

The yield ratio was partially corrected to account for the absorbance of the other products at the particular wavelength. Equation 5 should actually contain three absorbance values in the numerator and in the denominator. The equation was derived assuming that 45% of the contribution to the total absorbance at 610 nm by AQOH and 3% of the contribution to the total absorbance at 470–500 nm by $AQ(OH)_2$ were negligible. Because these terms could not be experimentally determined and were also minor corrections, they were not considered. In addition, the unknown ratio of the molar absorptivities of the mono- and dihydroxylated products was taken as unity, although it is probably somewhat higher.

Despite the qualitative nature of the procedure, it proved exceedingly useful in providing new information about product distributions under different conditions.

Deuterium Isotope Effects in the Reduction of Cyclohexanones. The Concepts of Steric Approach Control and Product Development Control[1]

DONALD C. WIGFIELD AND DAVID J. PHELPS
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 30, 1971

Definitions for the terms *steric approach control* and *product development control* in relation to the degree of bonding in the transition state are put forward. Kinetic deuterium isotope effects in the reduction of a graded series of ketones by $NaBH_4$ and $NaBD_4$ have been measured. These effects are inverse, and show no systematic dependence on the degree of steric hindrance of the ketone. This evidence appears to invalidate the steric approach control–product development control explanation of the axial to equatorial product ratios (1). The primary isotope effect is very small, which is consistent with an early transition state in these reductions, as demanded by other explanations of product ratios, but since several other factors causing small isotope effects may be applicable, the evidence does not constitute proof of an early transition state.

The main conclusions of this work have already been published in preliminary form (2).

Les notions de *"steric approach control"* et *"product development control"* en relation avec le degré de liaison dans l'état de transition, sont précisées. Les effets isotopiques du deutérium sur la cinétique de réduction d'une série de cétones par $NaBH_4$ et $NaBD_4$, ont été mesurés. Ces effets sont inverses et ne montrent aucune dépendance systématique avec le degré d'empêchement stérique de la cétone. Cette mise en évidence montre que l'explication des rapports du produit axial et équatorial par le "steric approach control" et "product development control", n'est pas valable (1). L'effet isotopique primaire, très faible, est compatible avec un début d'état de transition dans ces réductions. Ce résultat, déjà mentionné dans d'autres études, ne constitue pas une preuve puisque de nombreux autres facteurs peuvent être la cause de ces faibles effets isotopiques. Les conclusions principales de ce travail ont déjà été publiées dans une note préliminaire (2).

Canadian Journal of Chemistry, **50**, 388 (1972)

Introduction

It has been well known for many years that the stereochemical outcome of reducing cyclic ketones with complex metal hydrides depends crucially on the degree of steric hindrance around the carbonyl group. In the case of simple cyclohexanones a predominance of equatorial alcohol arises from non-hindered ketones, whereas more axial alcohol is formed from more hindered ketones (1) (see Fig. 1). Various suggestions as to the basis of this striking stereochemical dependence have been offered (1, 3–5). Fifteen years ago, in a paper which has now become a classic in this area of hydride reductions, Dauben *et al.* (1) put forward the first explanation and introduced the terms steric approach control and product development control. Since that time, confusion has reigned over precisely what these terms mean, and it is clear that today, although the terms are used widely, there is no uniformity of meaning. We regard this situation as very unfortunate, since the terms are extremely useful when used uniformly, but of no value if they have no definite signification. It is this confusion that has prompted our work in this area and this paper will be concerned primarily with clarifying these terms and evaluating the correctness of the Dauben explanation.

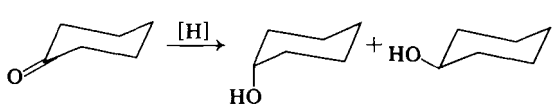

FIG. 1. Reduction of cyclic ketones.

[1]Transition State Analysis III.

Discussion and Results

The Terms Steric Approach Control and Product Development Control

The definition of steric approach control given by Dauben *et al.* is "a steric postulate involving competitive attacks from a favoured (unhindered) or an unfavoured (hindered) side"; that of product development control "an energy consideration involving the relative stability of the possible products" (1). In attempting to produce a more uniform and precise definition of these terms it must be remembered that these reductions of ketones are purely kinetically controlled. The axial to equatorial product ratio must therefore depend on, and only on, the

relative free energies of the two transition states leading to the two diastereomeric products. Thus, in a reaction where the product ratio is being controlled by (steric) ease of approach of the attacking reagent (steric approach control), the transition states in question must be at an early stage of bond breakage and bond formation. Similarly, in reactions where factors controlling the relative energies of the transition states are similar to those controlling the relative energies of the products (product development control), the structures and geometries of transition state and product must be similar and thus a "late" transition state is involved. Therefore a convenient redefinition[2] of the terms steric approach control and product development control may be made purely in terms of the degree of bonding in the transition state. The need for this type of thinking has been pointed out by Brown and Deck (6), and probably the most general interpretation of these terms has been in relation to transition states, many workers in the field having concerned themselves with "early" or "late" transition states (6–16). Using this type of definition, the Dauben explanation of product ratios simplifies to the hypothesis (*a*) that a late transition state is involved in reduction of unhindered ketones and thus the lower energy alcohol (equatorial hydroxyl) is produced since the transition state leading to formation of the equatorial alcohol is of lower energy than the transition state leading to formation of the axial alcohol; and (*b*) that an early transition state pertains to reduction of hindered ketones, the transition state energy being controlled by such factors as ease of approach of the hydride, which thus attacks from the equatorial side to yield the axial alcohol. In contrast to this type of definition, Eliel and Senda (7) have defined the expressions in terms of individual steric interactions. In this particular reaction we feel that the transition state definitions and the steric interaction definitions are equivalent, the steric interaction definition being precise and restricted to this reaction, and the transition state definition being more general. We prefer the transition state definition because of its ready applicability to reactions besides reductions of ketones.

In order to try to clarify this situation, we put forward for consideration the following definitions, which we believe will be of general utility to reactions besides the one under present consideration. We suggest that *the terms approach control and product development control refer in a relative sense to the position of the transition state along the reaction coordinate, approach control inferring a reactant-like or early transition state, and product development control a product-like or late transition state.* The term *steric approach control* then becomes a special case of approach control where the factors involved are steric.[3]

The Validity of the Steric Approach Control–Product Development Control Concept

Having defined the above terms, it becomes clear that the explanation of product ratios rests on the concept of different transition states for reduction of hindered and unhindered ketones, with the transition state being later with less steric hindrance. It is precisely this point which sets this explanation apart from others, which postulates an early transition state for all cases (3–5). The test of the Dauben hypothesis thus becomes one of evaluating the extent of bond breaking and bond making in the transition states of reduction of ketones with varying steric hindrance and determining whether or not there is a transition state shift. In the past few years, the majority of workers engaged in rationalizing axial:equatorial product ratios have lent their support to explanations involving early transition states (3–5, 7, 8, 10, 16), and in particular have regarded product development control as "an unnecessary concept" (10). However, these conclusions have rarely rested on any experimental evidence other than the product ratios they are supposed to explain. It is interesting that workers using other approaches to the nature of the transition state have often arrived at an opposing conclusion: Lamaty and coworkers (12), on the basis of Hammett relationships (18, 19) have concluded that the borohydride reductions of ketones pass through product-like transition states, and Karabatsos and Althuis have argued

[2]It should be stressed that this redefinition is considered to be a logical extension of the original definition. It does not necessarily imply that the original authors (1) had this type of definition in mind.

[3]See ref. 17 for a case of regiospecificity where the factors involved in approach control are electronic.

on the basis of the breakdown of a model for carbonyl additions that the transition state for borohydride and aluminohydride reduction of aldehydes is also product-like (11). From the point of view of the Dauben explanation it is particularly fascinating, although not very relevant to the reaction under consideration, that a Hammett plot of borohydride reductions of aromatic acid chlorides was non-linear, indicating a change in mechanism or transition state (20).

Finally, one recent publication deserves comment. Lamaty and his coworkers have published evidence which "prove beyond any reasonable doubt that the transition state is product-like" in borohydride reduction of ketones (13). This evidence is a comparison of rates of attack on 4-*t*-butylcyclohexanone and adamantanone by borohydride and by the sulfite anion. It is found that $k_{\text{adamantanone}} \simeq 2k_a$ for sulfite attack and $k_{\text{adamantanone}} \simeq 2k_e$ for borohydride attack, where k_a and k_e are axial and equatorial rate constants of attack by the appropriate species on 4-*t*-butylcyclohexanone, respectively. This is interpreted in terms of a reactant-like transition state for sulfite addition, and a product-like transition state for borohydride reduction. We feel that there is an alternative explanation of these data. As the authors point out, attack from either side of the carbonyl group in adamantanone is equivalent, being equatorial to one ring and axial to another. Attack at this center on either side, therefore, is equivalent to attack at the least favored side of 4-*t*-butylcyclohexanone, regardless of whether this happens to be axial or equatorial. Since there are two equivalent sides to attack, one would then immediately predict that $k_{\text{adamantanone}} \simeq 2k_u$, where k_u is the rate constant for attack at the least favored side of 4-*t*-butylcyclohexanone by the appropriate nucleophile. This is the result observed in both cases, and thus it would seem that the evidence put forward by these authors does not constitute unambiguous evidence for a late transition state in the borohydride reduction of ketones.

In view of these conflicting data, and the lack of a systematic study involving *both* product ratios and an independent indication of transition state structure, we have investigated the borohydride reduction of a graded series of cyclohexanones with various degrees of steric hindrance. The experimental parameter selected to indicate transition state structure was the magnitude of the kinetic deuterium isotope effect, which, despite recent controversy (21), has long been accepted to be sensitive to the degree of bond breaking in the transition state (22). Axial-equatorial alcohol product ratios were determined independently by gas chromatography and n.m.r. spectroscopy, giving results in close accord. The rate constants for reduction by sodium borohydride and sodium borodeuteride were determined spectrophotometrically by following the disappearance of the n–π^* ketone band at around 285 nm. The data were treated by standard second-order kinetics and gave satisfactorily reproducible plots. Two such typical plots are shown in Figs. 2 and 3. It was found that an $x\%$ error in the ketone extinction coefficient caused an approximately $x\%$ error in the rate constant and the extinction coefficients were therefore determined with sufficient accuracy ($<2\%$) to make this contribution to the error of the rate constant insignificant. The overall reproducibility of the rate constants was generally found to be around 5%. Product ratios and kinetic data obtained are summarized in Table 1.

A number of features of the values of the isotope effects deserve comment. The most obvious feature is that they are all inverse. This feature is not surprising since hydrolysis of sodium borohydride (27), hydrolysis of pyridine alkylboranes (28), and the methanolysis of lithium borohydride (29) all have inverse isotope effects. In the reduction of ketones by borohydride, it has been shown (30, 46) that the rate determining step is transfer of the first hydrogen (Fig. 4).

Thus the observed isotope effect is the composite of the primary isotope effects of the hydrogen being transferred superimposed on the secondary isotope effects of the three hydrogens not being transferred. It is probable that the inverse effect arises from the three secondary effects outweighing the primary effect (27, 31, 32) and this view is substantiated by the observation that reduction of methyl alkyl ketones with morpholine-borane (33) shows a small normal isotope effect.

The second, and most important feature of the values of the isotope effects is that, regardless of whether the isotope effects are normal or inverse, there is no systematic relationship

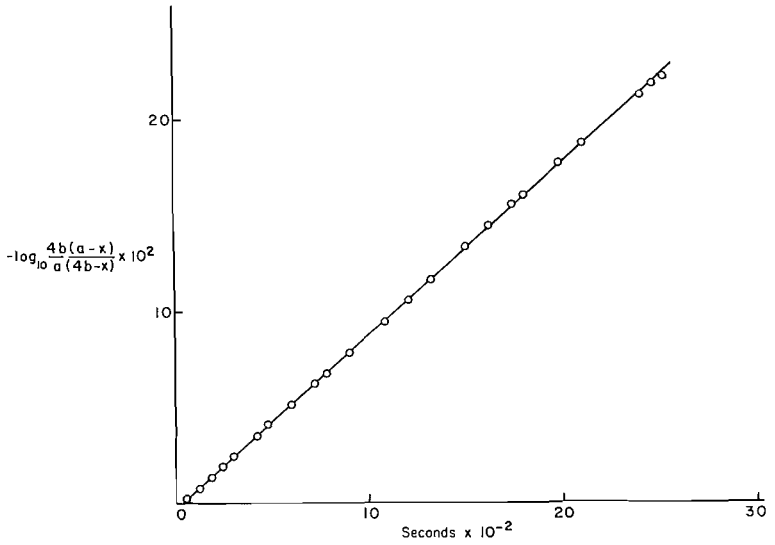

FIG. 2. Typical kinetic plot of the reduction of 2-methylcyclohexanone by sodium borohydride.

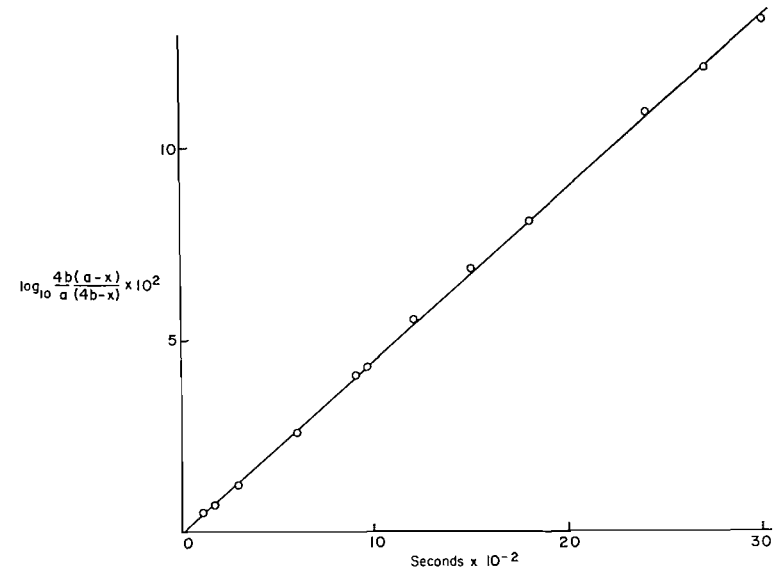

FIG. 3. Typical kinetic plot of the reduction of 2-methylcyclohexanone by sodium borodeuteride.

between product ratio and magnitude of the isotope effect. The product ratios vary from essentially 100% equatorial alcohol through 3,3,5-trimethylcyclohexanone with an excess of axial alcohol and to 3,3,5,5-tetramethylcyclohexanone with presumably an even greater amount of initial equatorial hydride attack but for which no "product ratio" is obtainable. Although the question of whether transfer of the first hydrogen gives the same product ratio as transfer of subsequent hydrogens has been ignored, the results of Rickborn and Wuesthoff (47) indicate that this change in product ratio, although significant, would be far overshadowed by the differences due to the varying steric hindrances of the ketones themselves. Clearly there is no trend towards lower isotope effect with formation of a greater proportion of axial isomer as would be anticipated if the steric approach control–product development control

were operative. *This evidence appears to invalidate the steric approach control–product development control* (as redefined) *explanation of stereo-chemical product ratios*, for the reduction of ketones by sodium borohydride. It does not, however, detract from the value of the concepts (1) themselves which may well be operative in other reactions.

A third feature is concerned with the absolute magnitude of the *primary* isotope effect. Although masked by the secondary isotope effects, it is clear that if the secondary effects are able to overshadow the primary effect, then the primary effect itself must be very small, probably less than 2. This small value is certainly consistent with an early transition state as required by other explanations of product ratios (3–5); it is also equally consistent with a very late transition state, where the hydrogen has been substantially transferred. Other possible reasons for a very small isotope effect concern the nature of the reaction and the geometry of the transition state itself. Isotope effects in hydride transfers as opposed to proton transfers have been the subject of some discussion (34, 35) and in general, on both theoretical and experimental grounds, the magnitude of isotope effects in hydride transfers appears to be considerably smaller than in proton transfers, rarely exceeding 2.5 (34). Additionally, the transition state for hydride reductions has frequently been considered to be four-centered (15, 24) as shown in Fig. 5, which suggests a B.....H.....C angle in the neighborhood of 90°.

Recently More O'Ferrall (36) has calculated that isotope effects where such an angle deviates significantly from 180° can drastically diminish from 6–8 down to 1–2. As mentioned above, the weight of current opinion of those workers concerned with explaining product ratios favors an early transition state, and thus *the magnitudes of the isotope effects, while not constituting unambiguous evidence for this opinion, do not contradict it*. We have experiments currently in progress which we hope will shed further light on the primary isotope effect and on the geometry of the transition state in hydride reduction of ketones.

Experimental

General

Melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. The i.r. spectra

were measured on a Perkin–Elmer 237B Grating Infrared Spectrophotometer, and u.v. spectra on a Perkin–Elmer 202 Ultraviolet–Visible Spectrophotometer. The n.m.r. spectra were obtained on a Varian T60 NMR spectrometer using deuteriochloroform as solvent and tetramethylsilane as internal standard. A Hewlett–Packard F and M Scientific 402 High Efficiency Gas Chromatograph was employed for all g.l.p.c. measurements.

Reagents

Sodium borohydride (98%, Fisher Scientific) and sodium borodeuteride (Merck, Sharpe and Dohme) were used without further purification, care being taken to keep them dry. 2-Propanol (Fisher, spectral grade) was passed through a neutral alumina column, dried over anhydrous calcium sulfate, and distilled before use. All ketones except 3,3,5-trimethylcyclohexanone and cholestan-3-one were commercial samples purified by distillation. 3,3,5-trimethylcyclohexanone was prepared from 3,3,5-trimethylcyclohexanol by dichromate oxidation (37) and was purified by distillation. Cholestan-3-one (K and K Laboratories) was used without further purification. Gas chromatography showed all ketones to have a purity greater than 99%. The appropriate physical data are summarized in Table 2.

Product Ratios

The following procedure is typical. To a solution of sodium borohydride (0.47 g; 12.4 mmol) in 2-propanol (50 ml) was added the ketone solution (12.4 mmol) in 2-propanol (10 ml). The mixture was stirred overnight. Concentrated hydrochloric acid (5 ml) was added to destroy excess borohydride and hydrolyze the borate esters, 2-propanol was removed by rotary evaporation, and the alcohol products extracted into ether (2 × 10 ml). The combined ether extracts were dried (Na_2SO_4) and injected into g.l.p.c. For the cyclohexanols the following conditions were used: 6 ft QF-1 column; flash heater 120°; column oven 50–75°; carrier gas flow 3.1 ml/min: for cholestanols: 6 ft OV-210 column; flash heater 290°; column oven 250°; carrier gas flow 3.1 ml/min. Peak areas were determined either by mechanical integration or by the peak height–half-width product.

For n.m.r. determination of product ratios, the dried ether extract was evaporated and the n.m.r. spectrum measured. The chemical shift (38, 39) and the splitting (40) of the methine proton on the hydroxyl-bearing carbon depends on the axial–equatorial nature of the proton, the axial protons appearing in the range δ 3.2-3.7 p.p.m. and the equatorial protons in the range 3.6–4.2 p.p.m. Integration of the signals due to these protons gave the product ratio.

Kinetic Method[4]

A spectrophotometric method employing a Gilford 240 spectrophotometer, equipped with a Haake constant temperature device to maintain the temperature at 25.0 ± 0.02°, was used. The wavelength used was the appropriate absorption maximum for each ketone (see Table 2). The reference cell consisted of 2.0 ml of 2-propanol and 1.0 ml of standardized sodium borohydride solution in 2-propanol (45) in a 3.0 ml, 1.0 cm quartz cuvette. The sample cell contained 1.0 ml of the standardized sodium borohydride solution to which 2.0 ml of a 2-propanol solution of the ketone was added. Zero time was taken as the half-time of addition. Mixing was achieved by inversion of the cuvette three times. Beer's law plots were used to calculate ketone concentration from absorptions at appropriate time intervals. The data were treated by plotting $\log_{10} 4b(a-x)/a(4b-x)$ against t where a is the initial ketone concentration, b, initial borohydride concentration, and x, concentration of reacted ketone at time t. The slope, equal to $k(a-4b)/2.303$, where k[5] is the second-order rate constant, was computed with a least-squares programme[6] on an Olivetti–Underwood Programma 101 desk computer. Figures 2 and 3 show typical plots for reduction of 2-methylcyclohexanone by sodium borohydride and sodium borodeuteride, respectively. Initial concentrations of ketone ranged from 1.36×10^{-2} to 6.84×10^{-2} M, and those of sodium borohydride from 0.44×10^{-2} to 1.71×10^{-2} M, giving a [ketone]/[hydride] ratio ranging from 1.05 to 6.48. In the case of 3-cholestanone, owing to solubility problems, the ketone concentration was kept in the range 0.17×10^{-2} to 0.28×10^{-2} M, giving a [ketone]/[hydride] ratio of 0.24 to 0.59. Satisfactorily

[4]The titration method (46) was found to be less consistent than the spectrophotometric method.

[5] The rates of disappearance of ketone and borohydride obviously differ by a factor of 4. Previous rate constants (46) refer to borohydride and, in order that direct comparisons may be made, our values also refer to this rate, despite the fact that our measurements are based on ketone concentrations.

[6]We are very grateful to Dr. M. Parris for this programme.

reproducible rate constants were obtained, the values being found to be independent of the initial concentrations chosen, in agreement with the findings of Brown *et al.* (46) and in confirmation of the assumption of second-order kinetics. The values of k_H and k_D are summarized in Table 1 and represent the results of at least three independent kinetic runs for each determination.

The Photochemistry of 1-Methoxy-1,4-dihydro-1,4-enthenoanthracene

C. O. BENDER, J. L. M. ELDER,[1] A. J. HERBST,[1] AND L. E. MILLER[1]

Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received August 5, 1971

The primary photoproducts of direct and benzophenone sensitized irradiation of the barrelene 1-methoxy-1,4-dihydro-1,4-ethenoanthracene are the semibullvalenes 2- and 5-methoxynaphtho[2,3-*c*]tricyclo[3.3.0.0^{2,8}]-octa-3,6-diene (**6** and **7**), formed with quantum efficiencies of $\Phi_6 \simeq 0.23$ and $\Phi_7 \simeq 0.31$ in each case. Whereas **6** is inert to further direct irradiation, **7** photoisomerizes to 6-methoxycycloocta[*b*]naphthalene (**4**) ($\Phi = 0.40$); **4** photoisomerizes to 10*b*-methoxy-2*a*, 10*a*-dihydrocyclobut[*a*]anthracene upon direct ($\Phi = 0.11$) or benzophenone-sensitized irradiation ($\Phi = 0.05$).

Les produits primaires issus de l'irradiation directe et de l'irradiation photosensibilisée par la benzophénone, du barrelène méthoxy-1 dihydro-1,4 étheno-1,4 anthracène sont les semi-bullvalènes méthoxy-2 et -5 naphto[2,3-*c*] tricyclo[3.3.0.0.^{2,8}] octadiène-3,6 (**6** et **7**) obtenus avec des rendements quantiques de $\Phi_6 \simeq 0.31$ respectivement. Tandis que **6** est inerte à une irradiation ultérieure directe, **7** s'isomérise en méthoxy-6 cycloocta[*b*] naphtalène (**4**) ($\Phi = 0.40$); **4** s'isomérise en méthoxy-10*b* dihydro-2*a*,10*a* cyclobuta[*a*] anthracène par irradiation directe ($\Phi = 0.11$) ou photosensibilisée par la benzophénone ($\Phi = 0.05$).

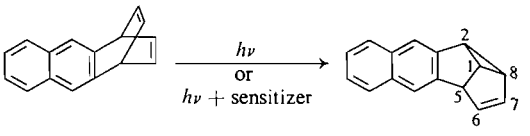
Introduction

In a recent study, the photochemistry of 2,3-naphthobarrelene (**1**) was shown to be strikingly different from that of barrelene (1), benzobarrelene (2), 1,2-naphthobarrelene (3), and other barrelenes (4), in that cyclooctatetraene product was not observed to result from direct irradiation (3). Instead, 2,3-naphthosemibullvalene (**2**), from di-π-methane rearrangement, was found to be the exclusive product (see Scheme 1), and was formed with the same efficiency ($\Phi = 0.46$) as when derived from triplet sensitization. In order to examine the further generality of this behavior, the photochemistry of the bridgehead methoxyl derivative **3** was investigated.



1 2

SCHEME 1

Results

1-Methoxy-1,4-dihydro-1,4-ethenoanthracene (**3**) was obtained in 12% yield from the addition of 2,3-naphthyne to anisole. The structural assignment follows from the n.m.r. spectrum: the aromatic protons appear as a multiplet centered at τ 2.54, the vinyl protons as a multiplet at 3.25, the bridgehead proton as a multiplet at 5.36, and the methoxyl protons as a singlet at 6.34.

During exploratory runs, the direct irradiations of **3** at 313 nm were monitored by n.m.r. spectroscopy, which indicated the formation of four products (see Scheme 2): 6-methoxycycloocta[*b*]naphthalene (**4**), 10*b*-methoxy-2*a*,10*a*-dihydrocyclobut[*a*]anthracene (**5**), and 2- and 5-methoxynaphtho[2,3-*c*]tricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**6** and **7**), in time-dependent proportions as shown in Fig. 1.

The methoxycyclooctatetraene structure for **4** was suggested by its 60 MHz n.m.r. spectrum which besides a 6H aromatic multiplet centered at τ 2.57 and a methoxyl singlet at 6.33, showed only complex absorption for five protons in the vinylic region between τ 3.20 and 4.88. Treatment of **4** with acid led to the formation of a ketonic product **8** (see Scheme 3) ($\nu_{C=O}$ (KBr) 1670 cm^{-1}), the u.v. spectrum of which showed extensive conjugation: λ_{max} (MeOH) 261 (44 000), 323 inf (5300), and 367 nm (2400) [*cf.* the long-wavelength band of 2-naphthaldehyde (MeOH) at 344 nm (2000) (5)]. Since the 60 MHz n.m.r. spectrum of **8** contains, besides a 5H aromatic multiplet centered at

[1]Undergraduate Research Assistants, 1970.

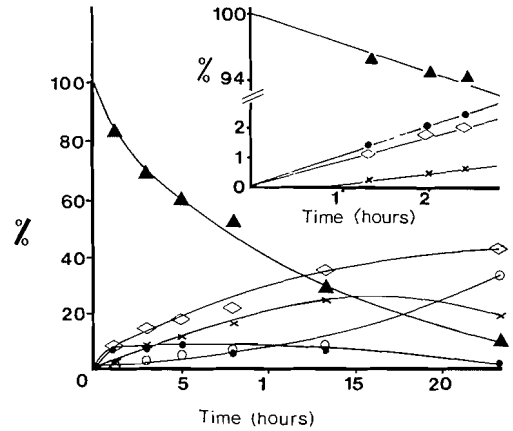


FIG. 1. Plot of extended conversions of barrelene **3** (▲) and the appearance of cyclooctatetraene **4** (×), cyclobutene **5** (○), and semibullvalenes **6** and **7** (◇ and ●) *vs.* time of irradiation. The insert is a plot of low conversion runs *vs.* time of irradiation.

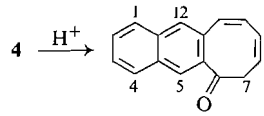
τ 2.28 and complex absorption for four vinylic protons between 2.88 and 4.32, a methylene doublet at 6.46 ($J = 8$ Hz), and a strongly deshielded 1H aromatic singlet (H-5) at 1.09, the position of the carbonyl in **8** and hence the position of the methoxyl group in **4** is tentatively established as being alpha to the aromatic ring.

The structure of cyclobutene **5** was also deduced mainly from n.m.r. spectral data. The aromatic protons appear as a multiplet centered at τ 2.46 and the methoxyl as a singlet at 6.97; the methine proton, H-2*a*, is coupled to three of the four vinylic protons, forming the X part of two ABX spin systems, one comprising H-4 (τ 3.50, d, $J_{AB} = 10$, $J_{AX} = 0$ Hz), H-3 (τ 4.04,

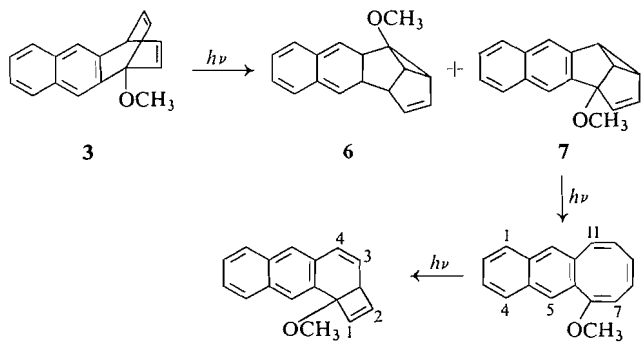


8

SCHEME 3

d of d, $J_{BA} = 10$, $J_{BX} = 4.8$ Hz), and H-2*a* (τ 6.60, br d, $J_{XB} = 4.8$ Hz), and the other H-2 (τ 3.88, d of d, $J_{AB} = 2.8$, $J_{AX} = 1.3$ Hz), H-1 (τ 4.12, d of d, $J_{BA} = 2.8$, $J_{BX} = 0.8$ Hz), and H-2*a*. These designations were confirmed by spin decoupling techniques: irradiation of the methine proton simplified the vinylic region to two AB quartets. Thus, whereas H-4 was unchanged, H-3 was collapsed to a doublet ($J = 10$ Hz), H-2 to a doublet ($J = 2.8$ Hz), and H-1 to a doublet ($J = 2.8$ Hz). The 2.8 Hz coupling constant between H-1 and -2 is characteristic of cyclobutene vinylic protons (6).

The semibullvalene structures assigned to the photoproducts **6** and **7** follow straightforwardly from comparison of their n.m.r. spectral parameters with those of 2,3-naphthosemibullvalene (**2**) (Table 1). Chemical evidence for structure **6** derives from its protolysis, typical of methoxycyclopropanes, to the ketonic compound **9** during chromatography on silicic acid[2] (7) (see Scheme 4). 3,3*a*,4,10*b*-Tetrahydro-4-oxonaphtho[2,3-*a*]pentalene (**9**) shows a u.v. (cyclohexane) long-wavelength band at 352 nm (1600) and an i.r. carbonyl band at 1700 cm^{-1}. The n.m.r. spectrum contains no methoxyl protons, a singlet at τ 1.75 (H-5), a multiplet at 2.35 (remaining aromatics), a doublet of doublets at



SCHEME 2

[2]In order to limit this reaction when isolation of **6** was desired, chromatography columns were eluted rapidly under reduced pressure (see Experimental).

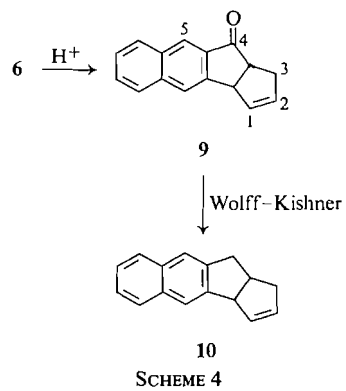
§Center limb obscured by methoxyl signal.



SCHEME 4

4.18 (H-1, $J = 2$ and 5.5 Hz), another doublet of doublets at 4.42 (H-2, $J = 2$ and 5.5 Hz), a broad doublet at 5.46 (H-10*b*, $J = 5.5$ Hz), a multiplet at 6.63 (H-3*a*), and another multiplet at 7.28 (methylene). The structure of ketone **9** is supported by its reduction under Wolff–Kishner conditions to give the alkene **10**. The i.r. spectrum of 3,3*a*,4,10*b*-tetrahydronaphtho-[2,3-*a*]pentalene (**10**) shows no carbonyl band and the u.v. spectrum shows no absorption maxima above 323 nm. In the n.m.r. spectrum, the aromatic protons appear as a multiplet at τ 2.58, the vinylic protons as a multiplet at 4.34, the allylic methine (H-10*b*) as a broad singlet at 5.73 (H-10*b*), the C-4-methylene as a multiplet at 6.77, the C-3 methylene as a multiplet at 7.27, and the remaining methine (H-3*a*) as a multiplet at 7.80.

The photoproducts **4**–**7** were irradiated separately at 313 nm in order to examine for the occurrence of secondary photochemical processes. It was revealed that cyclooctatetraene **4** yields cyclobutene **5** with a quantum yield of $\Phi = 0.11$ [ferrioxalate actinometry], a photocyclization reaction also observed with cyclooctatetraene (8), while semibullvalene **7** affords **4** ($\Phi = 0.40$), a transformation unknown with 2,3-naphthosemibullvalene (**2**) (3). Cyclobutene **5** was photochemically inactive as was, surprisingly, semibullvalene **6**.

It was of interest to determine the multiplicities of the excited state species involved in the above reactions, thus sensitization runs with benzophenone at 343 nm, with the sensitizer capturing more than 95% of the light, were investigated. Whereas cyclooctatetraene **4** readily gave cyclobutene **5** ($\Phi = 0.05$), semibullvalene **7** was found to be unreactive. Since the photoreduction of benzophenone was efficiently quenched in the presence of **7**, it seems certain that triplet energy transfer to the semibullvalene had been successful. In the case of barrelene **3**, triplet sensitization led cleanly to the formation of **6** and **7** with appearance quantum yields of $\Phi = 0.24$ and 0.30, respectively.

Thus far, two processes can account for the formation of cyclooctatetraene **4** during direct irradiations of barrelene **3**. Either it arises from a $(2 + 2)\pi$-cycloaddition, or it derives from photoisomerization of initially formed semibullvalene **7**. In order to distinguish between these two pathways, runs to low conversion were carried out. Extrapolation of the cyclooctatetraene (**4**) product concentration to zero time did not pass through the origin (insert to Fig. 1): thus **4** is not a primary photoproduct and must arise exclusively from semibullvalene **7**. The fact that the extinction coefficient of **7**

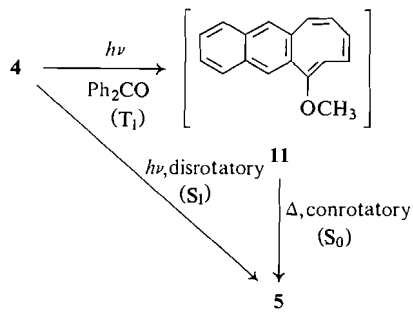
is approximately six times that of barrelene **3** at 313 nm and that the quantum yield for its conversion to **4** is $\Phi = 0.40$, readily explains how the cyclooctatetraene appears so early on during the direct irradiation of **3**.

The low conversion runs also enabled values of $\Phi = 0.22$ and 0.32 to be calculated for the unsensitized appearance quantum yields of **6** and **7**, after correcting for light utilized to form small amounts of cyclooctatetraene **4**. Summarized in Table 2 are the quantitative data for the observed photochemistry.



SCHEME 5

Discussion

The primary photoproducts of both direct and sensitized irradiations of methoxybarrelene **3** are the semibullvalenes **6** and **7**. Their dual formation is consistent with their arising from a di-π-methane rearrangement which proceeds with almost equal facility from both modes of initial vinyl–vinyl bridging. Because the quantum yields for the direct and sensitized formations of the semibullvalenes are the same, within experimental error, it is feasible that they derive from the same excited state, providing we assume an intersystem crossing efficiency of almost unity. Such an assumption seems to be reasonable in view of the small fluorescence quantum yield ($\Phi_f = 0.08$) noted for 2,3-naphthobarrelene (3). The introduction of a methoxy group into the bridgehead position is seen therefore, not to alter the course of the excited state reaction of the 2,3-naphthobarrelene system.

With regard to the cyclooctatetraene transformation, the quantum yield data indicate cyclobutene **5** to be attainable both from an excited singlet and, less efficiently, from an excited triplet pathway (see Scheme 5). By analogy with Lui's work on 1,3-cyclooctadiene (9) it is possible that the singlet pathway involves a concerted disrotatory closure (10), while the triplet pathway involves a two step mechanism, with initial isomerization of the all *cis* isomer **4** to a highly strained mono *trans* isomer[3] such as **11**, which then undergoes symmetry allowed thermal conrotatory closure to **5**. We have not obtained evidence for the formation of an intermediate such as **11** during sensitized runs, but this may simply be due to the rate of closure to **5** being much greater than the rate of formation of **11** at the photolysis temperature employed ($\sim 20°$). Whichever pathway is utilized, the cyclization of the methoxyl

[3]White *et al.* have recently shown that the all *cis* isomer of 1,2,4,7-tetraphenylcyclooctatetraene can be converted to the mono *trans* isomer during photolysis (11).

substituted diene moiety appears to be totally selective, and we attribute this to the ability of the methoxy group to localize excitation into the attached vinyl (12, 13). Chapman and coworkers have noted a similar exclusive selectivity to operate in the photoisomerization of 1-methoxycycloheptatriene to 1-methoxybicyclo[3.2.0]hepta-3,6-diene (12).

Examination of the photochemistry of semibullvalenes **6** and **7** has revealed the formation of **4** to be subject to a dramatic positional substituent effect. We are presently investigating the photolysis of other semibullvalenes to determine whether this effect is uniquely associated with the methoxy group and its attachment at C-5, and hence if its origin is steric or electronic in nature. Finally, the singlet excited state seems to be responsible for the highly efficient formation of **4** since the reaction occurs only during direct irradiations.

Experimental

The n.m.r. spectra were run on Varian A-60 and HA-100 instruments with TMS as internal standard. The i.r. spectra were recorded on a Perkin–Elmer Model 337 spectrophotometer and the u.v. spectra on a Cary 15 spectrophotometer. All m.p. are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, Tennessee. Cyclohexane solvent for photolyses was stirred with 30% fuming sulfuric acid for 6 h, washed with 10% aq sodium hydroxide, dried ($MgSO_4$), and distilled from calcium hydride. Benzophenone sensitizer was recrystallized twice from ethanol, m.p. 47–49°.

1-Methoxy-1,4-dihydro-1,4-ethenoanthracene (3)

A mixture of 6.0 g of 3-diazonium-naphthalene-2-carboxylate (3) and 300 ml of anisole was heated with stirring at 90° for 4 h in a nitrogen atmosphere. The mixture was concentrated *in vacuo* and the oily residue column chromatographed on silicic acid. Elution with 0.5% ether/hexane gave 833.5 mg (12%) of colorless **3**, m.p. 84–86°, from early fractions. Crystallization from hexane raised the m.p. to 95–97°: u.v. max (cyclohexane) 233 (68 000), 237 (65 000), 255 (9500), 263 (10 000), 273 (9000), 283 (5 000), 296 (330), 299 inf (260), 305 (260), 309 (400), 318 (200), and 323 nm (310); n.m.r. (100 MHz, CCl_4) τ 2.54 (m, 6H, arom) 3.25 (m, 4H, vinyl), 5.36 (m, 1H, bridgehead), and 6.34 (s, 3H, methoxyl).

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02. Found: C, 87.08; H, 5.89.

Direct Irradiation of 3: Preparation of 4, 5, 6, and 9

A nitrogen-flushed solution of 250.5 mg (1.07 mmol) of **3** in 250 ml of cyclohexane was irradiated for 250 min with a quartz-jacketed Hanovia 450 W water-cooled, medium pressure immersion lamp fitted with a Pyrex filter sleeve. The solvent was evaporated *in vacuo* and the residue chromatographed on a 2 × 18 cm silicic acid column with 3 l of hexane and then 500 ml of 5% ether/hexane as eluting agent. The flow-rate was maintained at 50 ml/min with the aid of an aspirator; 100 ml fractions were collected. Fractions 8–13 gave 9.4 mg (4%) of **4**. Crystallization from ethanol gave colorless crystals, m.p. 85–87°: u.v. max (cyclohexane) 225 (55 000), 246 inf (24 500), 280 (12 000), 291 inf (10 500), and 304 nm inf (6300); n.m.r. (60 MHz, $CDCl_3$) τ 2.57 (m, 6H, arom), 3.23 (br d, 1H, H-11, $J = 12$ Hz), 3.78–4.30 (m, 3H, H-8, -9, -10), 4.88 (m, 1H, H-7), and 6.33 (s, 3H, methoxyl).

Anal. Found: C, 87.10; H, 6.24.

Fractions 18–28, after crystallization from hexane and sublimation (80°/0.1 mm), gave 45.2 mg (18%) of colorless **6**, m.p. 94–96°: u.v. max (cyclohexane) 237 (65 000), 264 (5200), 273 (6000), 283 (5700), 294 inf (3400), 313 (840), 319 (420), and 327 nm (1000); n.m.r., see Table 1.

Anal. Found: C, 86.85; H, 6.31.

Fractions 29–34 contained a mixture of **5**, **6**, and **9**. The mixture was applied to a 2 × 35 cm silicic acid column slurry-packed with hexane and left for 24 h without elution, to ensure complete protolysis of **6** to **9**. After this time the column was eluted with 1% ether/hexane; 100 ml fractions were collected. Fractions 8–14 contained 87.8 mg (35%) of **5** as an oil. Crystallization from hexane and sublimation (85°/0.1 mm) gave colorless crystals, m.p. 92–94°: u.v. max (cyclohexane) 252 (57 000), 266 (24 000), 285 (11 000), 295 (14 000), and 306 nm (10 800); n.m.r. (100 MHz, CCl_4) τ 2.46 (m, 6H, arom), 3.50 (d, 1H, H-4, $J = 10$ Hz), 3.88 (d of d, 1H, H-2, $J = 2.8$, 1.3 Hz), 4.04 (d of d, 1H, H-3, $J = 10$, 4.8 Hz), 4.12 (d of d, 1H, H-1, $J = 2.8$, 0.8 Hz), 6.60 (br d, 1H, H-2*a*, $J = 4.8$ Hz), and 6.97 (s, 3H, methoxyl). Double resonance was performed on the HA-100 MHz n.m.r. Irradiation of H-2*a* collapsed H-1 to a d ($J = 2.8$ Hz), H-2 to a d ($J = 2.8$ Hz), and H-3 to a d ($J = 10$ Hz).

Anal. Found: C, 87.37; 6.08.

Fractions 18–27 yielded 11.8 mg (5%) of colorless **9**, m.p. 145–147°, after crystallization from hexane: i.r. (KBr) 1700 cm^{-1}, C=O; u.v. max (cyclohexane) 245 inf (45 000), 248 (50 000), 272 inf (2500), 281 (4500), 293 (8000), 306 (10 000), 321 (1000), 336 (1500), and 352 nm (1600); n.m.r. (100 MHz, $CDCl_3$) τ 1.75 (s, 1H, H-5), 2.35 (m, 5H, remaining aromatics), 4.18 (d of d, 1H, H-1, $J = 5.5$, 2.0 Hz), 4.42 (d of d, 1H, H-2, $J = 5.5$, 2.0 Hz), 5.46 (br d, 1H, H-10*b*, $J = 5.5$ Hz), 6.63 (m, 1H, H-3*a*), and 7.28 (m, 2H, methylene).

Anal. Calcd. for $C_{16}H_{12}O$: C, 87.24; H, 5.49. Found: C, 86.96; H, 5.60.

Acetophenone Sensitized Irradiation of 3: Preparation of 7

A solution of 233.2 mg (1.0 mmol) of **3** and 10 ml of acetophenone in 250 ml of cyclohexane was photolyzed under nitrogen for 14 min with a quartz-jacketed Hanovia 450 W water-cooled, medium pressure immersion lamp fitted with a Pyrex filter sleeve. The solvent and acetophenone were removed *in vacuo* and the residue, diluted with 10 ml of hexane, was loaded onto a 2 × 40 cm silicic acid chromatography column, slurry-packed in hexane, and left to stand for 24 h. The column was then eluted with 3 l of 1% ether/hexane followed by 1 l of 3% ether/hexane; 100 ml fractions were collected. Fractions 11–13 contained 32.6

For personal use only.

mg (14%) of **3**; 16–23, 119.1 mg (51%) of **7**; and 30–39, 48.9 mg (22%) of the ketone **9**.

Fractions 16–23, after crystallization from hexane, gave colorless **7**, m.p. 63–65°: u.v. max (cyclohexane) 240 (80 000), 281 inf (6000), 286 (6300), 297 inf (4600), 313 (1100), 320 (600), and 328 nm (1200); n.m.r., see Table 1.

Anal. Found: C, 87.46; H, 6.09.

6,7-Dihydro-6-oxocycloocta[b]naphthalene (8)

A solution of 150.1 mg (0.64 mmol) of cyclooctatetraene **4** in 5 ml of glacial acetic acid was heated at 90° for 4 h. After cooling, the solution was basified (aqueous NaOH) and extracted with benzene (2 × 50 ml). The extracts were dried ($MgSO_4$), concentrated *in vacuo*, and the residue chromatographed on a silicic acid column. Elution with 1% ether/hexane gave, after crystallization from benzene/hexane and sublimation (120°/0.1 mm), 119.0 mg (84%) of pale-yellow **8**, m.p. 120–122°: i.r. (KBr) 1670 cm^{-1}, C=O; u.v. max (methanol) 261 (44 000), 323 inf (5300), and 367 nm (2400); n.m.r. (60 MHz, $CDCl_3$) τ 1.09 (s, 1H, H-5), 2.28 (m, 5H, remaining aromatics), 2.95 (br d, 1H, H-11, $J = 13$ Hz), 3.55–4.32 (m, 3H, H-8, 9, 10), and 6.46 (d, 2H, methylene, $J = 8$ Hz).

Anal. Found: C, 87.27; H, 5.39.

*Protolysis of Semibullvalene **6** to Ketone **9***

A solution of 29.9 mg (0.13 mmol) of **6** in 20 ml of hexane was loaded onto a silicic acid chromatography column slurry-packed in hexane, and allowed to stand for 24 h. Elution with 3% ether/hexane gave 28.2 mg (100%) of ketone **9**, m.p. 142–144°; sublimation (130°/0.1 mm) gave 27.9 mg (99%), m.p. 145–147°.

3,3a,4,10b-Tetrahydronaphtho[2,3-a]pentalene (10)

A solution of 113.3 mg (0.51 mmol) of ketone **9**, 2 g (0.36 mol) of potassium hydroxide, 2 ml (2.1 g, 0.04 mol) of hydrazine hydrate, and 10 ml of triethylene glycol was refluxed for 46 h, cooled, diluted with 100 ml of 20% aqueous HCl, and extracted with ether. The extracts were washed with water, dried ($MgSO_4$), concentrated *in vacuo*, and the residue chromatographed on a 2 × 120 cm silicic acid column. Elution was with hexane; 50 ml fractions were collected. Fractions 11–12 contained 8.4 mg of an unidentified colorless solid; 13–17 gave, after crystallization from hexane, 75.4 mg (71%) of colorless **10**, m.p. 61–63°, which was raised to 64–66° after sublimation (75°/0.1 mm): u.v. max (cyclohexane) 219 (84 000), 254 (3600), 264 (4600), 273 (5600), 283 (6200), 294 (4300), 302 (1300), 309 (1500), 313 (700), 315 (800), 318 (600), and 323 nm (2100); n.m.r. (100 MHz, CCl_4) τ 2.58 (m, 6H, arom), 4.34 (m, 2H, H-1 and -2), 5.73 (br s, 1H, H-10*b*), 6.77 (m, 2H, C-4 methylene), 7.27 (m, 2H, C-3 methylene), and 7.80 (m, 1H, H-3*a*).

Anal. Calcd. for $C_{16}H_{14}$: C, 93.16; H, 6.84. Found: C, 93.02; H, 6.95.

Quantum Yield Apparatus

This consisted of a "merry-go-round" apparatus fitted with a 450 W Hanovia medium-pressure mercury arc and surrounded by a water-cooled quartz immersion well and filter solutions. For direct irradiations, 313 nm light was isolated by a two compartment filter consisting of a 1.5 cm path length of a solution of 28 g of cobaltous sulfate heptahydrate per 100 ml of water, and a 0.6 cm path length of a solution of 0.252 g of potassium carbonate; transmittance was 300–332 nm with a maximum at 313 nm (13%). For benzophenone sensitized irradiations, 343 nm light was isolated by a one compartment filter consisting of a 2.0 cm path length of a solution of 450 g of cobaltous chloride hexahydrate, 60 g of stannous chloride dihydrate, and 150 g of nickel chloride hexahydrate per 1.2 l of 20% aqueous HCl; transmittance was 319–382 nm with a maximum at 343 nm (5%).

Quantum Yield Irradiations

Prior to irradiations, solutions of the sample ($3–41 \times 10^{-4}$ *M*) and benzophenone ($2.3–2.7 \times 10^{-3}$ *M*, if any) in 35 ml of cyclohexane, contained in 25 × 150 mm constricted Pyrex test-tubes, were degassed by two freeze–pump–thaw cycles (1.5×10^{-3} mm minimum pressure) and sealed under vacuum. During sample runs, the lamp output was measured by potassium ferrioxalate actinometry (14). After irradiation, the solvent was removed *in vacuo*, a known amount of para-xylene was added to serve as internal standard, and the mixture analyzed by n.m.r. spectroscopy. The peak areas in the spectra were calibrated against authentic reactant and product mixtures of closely similar constitution. Quantum yields for the observed processes are given in Table 2 and were obtained from runs to $\leqslant 17\%$ conversion; the estimated probable errors are $\pm 10\%$.

*Monitored Direct Irradiations of Barrelene **3***

Extended Conversions

Six sample solutions of **3** (~ 0.43 m*M*) in 35 ml of cyclohexane, and prepared as for quantum yield runs, were irradiated in the "merry-go-round" apparatus at 313 nm. Samples were removed periodically and component concentrations were determined by n.m.r. spectroscopy as before. The results are plotted in Fig. 1.

Low Conversions

Three sample solutions of **3** in 35 ml of cyclohexane, prepared as for quantum yield runs, were irradiated in the "merry-go-round" apparatus at 313 nm to $<6\%$ conversions. Component concentrations of the photolysates were obtained from column chromatography; samples were removed periodically, loaded onto a silicic acid column slurry-packed in hexane, left to stand for 24 h, and then eluted as before to give **3**, **4**, **7**, and **9**. The conversion of **6** to **9** was assumed to be quantitative in each case. The results of the low conversion runs are plotted in the insert to Fig. 1.

The authors thank Mr. David Gifford of the Spectroscopic Services Laboratory, University of Alberta, for the 100 MHz n.m.r. spectra and interpretative discussions, and gratefully acknowledge the financial support of the National Research Council of Canada, and the University of Lethbridge Research Committee.

Rates of Reaction of Nickel(II) with Terpyridine in Dimethyl Sulfoxide

PATRICIA A. COCK, C. E. COTTRELL, AND R. K. BOYD
Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 4, 1971

The rates at which 2,2′,2″-terpyridine reacts with nickel(II) ion to form the monoligand–nickel(II) and the bisligand–nickel(II) complexes were determined in DMSO solution. $Ni(terpy)Cl_2$ was isolated, and used to study the rate of formation of bis complex. The second-order rate constants were found to parallel the rates of DMSO exchange, determined using n.m.r. techniques, from the respective paramagnetic nickel species. Attempts were made to relate the results to the generally accepted "dissociative" pathways for this class of substitution reactions.

On a déterminé les vitesses auxquelles réagit la terpyridine-2,2′,2″ avec l'ion nickel(II) pour former les complexes monoligand–nickel(II) et biligand–nickel(II) dans une solution de DMSO. On a isolé le complexe $Ni(terpy)Cl_2$ et on l'a utilisé pour étudier la vitesse de formation du complexe bis. Les constantes de vitesse de second ordre vont de pair avec les vitesses d'échange de DMSO, ce qu'on a déterminé en utilisant les techniques de r.m.n., à partir des espèces paramagnétiques respectives de nickel. On a tenté de relier les résultats aux mécanismes "dissociatifs" qui sont généralement acceptés pour cette classe de réactions de substitution.

Canadian Journal of Chemistry, **50**, 402 (1972)

I. Introduction

The kinetics of replacement reactions of complexes of certain aquated transition metal ions with 2,2′,2″-terpyridine were studied by Holyer *et al.* (1). The rates of formation of the $M(terpy)(H_2O)_n^{2+}$ species (mono complex) were found (1) to fall into the general pattern of such ligand substitution reactions, usually described (2) in terms of the dissociative interchange model [1]:

$$[1] \qquad NiS_6^{2+} + L \overset{K_E}{\rightleftharpoons} NiS_6^{2+} \cdot L$$

$$NiS_6^{2+} \cdot L \overset{k_s}{\rightarrow} NiS_5L^{2+} + S$$

Reaction 1 has been written for the special case of an electrically neutral, monodentate ligand L; the solvent molecules are represented by S. For the present case of the tridentate ligand terpyridine, it is believed (1) that the first attachment to the metal ion is rate-determining, the subsequent completion of the chelate being extremely rapid. The encounter complex $NiS_6^{2+} \cdot L$ is assumed to be in equilibrium with NiS_6^{2+} and L; the rate constant k_s is then the rate constant for solvent exchange k_{ex}, modified by a statistical factor accounting for the probability of L occupying an outer sphere site close to the inner sphere solvent molecule in the process of exchange (3). The second-order rate constant k_f is thus interpreted as k_sK_E.

For the cases M = Fe, Co, and Ni, the solid mono complexes may be isolated in the pure state, as the bromide, chloride, or thiocyanate (4, 5). The kinetics of the reaction of mono complex with terpyridine to form the bis complex, $M(terpy)_2^{2-}$, could thus be studied unambiguously (1). The observed rate constants in aqueous solution were reported to be some 200 times greater than the corresponding values for the formation of mono complex although, from stereochemical and statistical considerations, it might be expected that the rate constants for bis formation should be significantly smaller (1).

The present work was undertaken with the hope that some light might be thrown on this problem by studying the reaction using dimethylsulfoxide (DMSO) as solvent, instead of water; it was hoped that comparison of the two systems might offer some clue to the correct explanation of the discrepancy. In addition, puzzling features exist in results obtained for ligand replacement reactions of $Ni(DMSO)_6^{2+}$ in DMSO as solvent (6, 7). The present work was also undertaken to provide further documentation of these features.

II. Experimental

Materials

$Ni(DMSO)_6^{2+}(ClO_4^-)_2$ was prepared by keeping a saturated DMSO solution of the corresponding hexahydrate over concentrated sulfuric acid, under vacuum, until crystallization occurred. Stock solutions of $Ni(DMSO)_6^{2+}$ in DMSO were analyzed by EDTA titration using murexide indicator; 1 ml of the stock solution was added to 50 ml of

water, and titrated with EDTA according to standard procedures. $Ni(terpy)_2^{2+}(ClO_4^-)_2$ was prepared according to the method of Harris and Lockyer (4); both of these perchlorate salts were found to be extremely explosive when dry.

$Ni(terpy)Cl_2$ (the mono complex chloride) was prepared by the method of Harris and Lockyer (4); attempts to use the method of Hogg and Wilkins (5), starting from the bis complex dichloride, were unsuccessful.

Anal. Calcd. for $Ni(terpy)Cl_2$: C, 49.5; H, 3.05; N, 11.55. Found: C, 49.04; H, 3.17; N, 11.45.

The DMSO used was spectroanalytical grade, obtained from Fisher Scientific Co.; other chemicals were reagent grade.

Spectroscopic and Conductance Measurements

All u.v.–visible spectra (room temperature) were recorded on a Unicam SP-800 spectrophotometer; the wavelength calibration was checked, before each spectrum, using the calibration standards supplied with the instrument. Nuclear magnetic resonance spectra were obtained using a Varian A-60-A spectrometer. Conductances were measured on a Beckman RC-18A conductivity bridge, at room temperature.

Kinetic Experiments

Slower reactions were followed spectrophotometrically using the Unicam SP-800 instrument, either at fixed wavelength or by repetitive scans over a small wavelength range. Faster reactions were studied using an all-glass stopped-flow apparatus designed to permit the use of non-aqueous solvents (8). The basic design of this apparatus followed that used by Holyer *et al.* (1), with certain modifications (9). The light source used was a Bausch and Lomb xenon lamp and monochromator, with a specially designed stabilized power supply. The mixing and observation chambers, plus the long glass capillary coils used to connect the chambers to the syringes, were all contained in a thermostatted tank (± 0.1 °C). This arrangement permitted full thermal equilibration of the solutions before mixing, and also minimized mechanical disturbance of the quartz observation chamber while operating the syringes (9).

Treatment of Data

Treatment of kinetic data was straightforward in all cases except those in which the rate of formation of the bis complex, from $Ni(terpy)Cl_2$ plus terpyridine, was studied. The two complexes have such similar u.v. absorption spectra that it was not possible to follow the reaction at a wavelength such that only one species absorbed. However, it may be readily shown that the standard kinetic equations, in terms of absorbances, also apply to pseudo-first order cases like the present one, in which

$$[\text{product}] + [\text{reactant}] = [\text{reactant}]_{t=0}$$

the effective extinction coefficient is the difference of the extinction coefficients of the two absorbing species (reactant and product) (8).

III. Results

(a) Characterization of Species in Solution

Formation of complexes from terpyridine plus $Ni(DMSO)_6^{2+}(ClO_4^-)_2$ in DMSO solution may be inferred from the appearance of a double peak in the region 320 to 350 mμ, where neither component alone absorbs. If the Ni(II) concentration is at least 40 times greater than that of terpyridine, the peaks are observed at 323 and 337 mμ, with $\varepsilon_{323} = 1.9 \times 10^4$ and $\varepsilon_{337} = 1.8 \times 10^4$ mol^{-1} cm^2. For Ni(II): terpy ratios much less than 40, the two peaks shifted to 327 and 341 mμ, with $\varepsilon_{327} = 3.5 \times 10^4$ and $\varepsilon_{341} = 3.4 \times 10^4$ mol^{-1} cm^2. It seems reasonable to identify the first spectrum as that of the mono complex, and the latter as that of the bis complex. The bis complex in water was reported (1) as having very similar extinction coefficients, though the reported peak wavelengths (1) are about 5 mμ less than those reported here for DMSO solution.

As a check on our present techniques, spectra were run on an aqueous solution of $Ni(H_2O)_6^{2+}$ perchlorate, in 50-fold excess over terpyridine. It was found that the spectrum changed with time, reaching its final form over approximately 24 h. The results obtained were as follows:

(*i*) Immediately after mixing, peaks at 333 and 321 mμ. $\varepsilon_{333} = 2.3 \times 10^4$ and $\varepsilon_{321} = 2.4 \times 10^4$ mol^{-1} cm^2.

(*ii*) After 24 h, peaks at 331 and 319 mμ. $\varepsilon_{331} = 2.4 \times 10^4$ and $\varepsilon_{319} = 1.9 \times 10^4$ mol^{-1} cm^2. The final spectrum (*ii*) appears entirely consistent with that reported by Holyer *et al.* (1) for the mono complex in aqueous solution.

The u.v. spectra of $Ni(terpy)Cl_2$ were also obtained, in both DMSO and water as solvents. In DMSO, peaks were observed at 334 and 321 mμ, with $\varepsilon_{334} = 0.9 \times 10^4$ and $\varepsilon_{321} = 1.1 \times 10^4$ mol^{-1} cm^2; these peak wavelengths are about 2 mμ lower than those quoted above for excess $Ni(DMSO)_6^{2+}(ClO_4^-)_2$ plus terpyridine in DMSO, and the extinction coefficients are about a factor of two lower. In water, $Ni(terpy)Cl_2$ gave peaks at 332 and 320 mμ, with $\varepsilon_{332} = 1.6 \times 10^4$ and $\varepsilon_{320} = 1.7 \times 10^4$ mol^{-1} cm^2. No change occurred in this spectrum over a period of days; the same was true of all the DMSO solutions.

The nickel(II) perchlorate–terpyridine system thus does not appear to be at all well defined in aqueous solution. In particular, the species formed in the initial fast reaction, the kinetics of which were studied previously (1), is different from both the fully equilibrated species, and from the species formed by $Ni(terpy)Cl_2$ in aqueous solution.

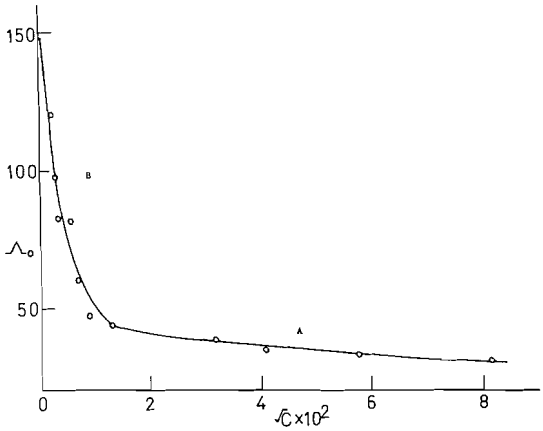

FIG. 1. Molar conductance of solutions of $Ni(terpy)Cl_2$ in DMSO, at 25 °C. Region A, species mainly $[Ni(terpy)Cl(DMSO)_2]^+$; Region B, dissociation of second chloride.

In view of the latter discrepancy, also observed in DMSO solution, conductivity data were obtained for the $Ni(terpy)Cl_2$ species in both solvents, in an attempt to further characterize the solutions. The results obtained in DMSO solution are shown in Fig. 1, and are typical of the behavior of a weak electrolyte, which approaches complete dissociation at infinite dilution. The limiting value at high concentration appears typical of that for a 1:1 electrolyte in DMSO at 25 °C, (*e.g.* for LiCl, Λ_0 in DMSO is 35.5 ohm^{-1} $mmol^{-1}$ cm^{-1} (10)), while the extrapolated value at zero concentration seems consistent with that of a 2:1 electrolyte. Since no extra chloride was present in the system, the most probable interpretation would appear to be the simplest one, whereby the predominant species in solution, at higher concentrations, are $[Ni(terpy)Cl(DMSO)_2]^+$ and Cl^-; at concentrations below about 10^{-4} *M*, the dissociation of the second chloride becomes increasingly important. This explanation in terms of coordinated chloride offers a reasonable explanation of the discrepancies in the u.v. spectra obtained for mono complexes in DMSO, and is also consistent with n.m.r. results described below. The data of Fig. 1 were treated by a non-linear least squares procedure, on the above assumption. A value of K_{diss}, for the dissociation of the second chloride, of $(2.1 \pm 0.4) \times 10^{-5}$ *M* was obtained, using the additional erroneous assumption that activity coefficients and ionic mobilities are independent of ionic strength; the quoted uncertainty in K_{diss} thus refers only to the random error in the measurements, and takes no account of such systematic errors in the interpretation.

In aqueous solution, $Ni(terpy)Cl_2$ gave a molar conductivity typical of a 2:1 electrolyte over the entire concentration range. The chloride thus appears to be completely dissociated in aqueous solution, and the discrepancies observed in the u.v. spectra thus remain unexplained in this case.

(b) Kinetics of Complex Formation

The rate at which terpyridine reacts with $Ni(DMSO)_6^{2+}$ perchlorate to form the mono complex $[Ni(terpy)(DMSO)_3]^{2+}$ in DMSO solution was investigated on the stopped-flow apparatus, at the peak absorption wavelength of the mono complex. The initial terpyridine concentration was always 2.5×10^{-5} mol l^{-1}, and the Ni(II) was in at least 40-fold excess; excellent pseudo-first order behavior was obtained, and the plot (Fig. 2) of the pseudo-first order rate constant k_{obs} *vs.* [Ni(II)] extrapolated through the origin, to within experimental uncertainty. Thus, under the conditions used, formation of mono complex perchlorate is essentially irreversible. The slope of such a plot gives the second-order rate constant for complex formation, k_f. The variation of k_f with temperature was studied over the range 25 to

50 °C, and the results are summarized in Table 1, which also lists the derived activation parameters.

Attempts were made to study the kinetics of the reaction between $[Ni(DMSO)_6]^{2+}$ and terpyridine, under conditions such that both mono and bis complexes were expected to be formed (*i.e.* Ni(II):terpy < 40:1). The reaction was followed using the peak wavelength of both the reactant ligand and the complex product. Unfortunately, we were unable to interpret these data in any self-consistent fashion, and they will not be presented here. The negative conclusion is in marked contrast to the findings of Holyer *et al.* (1) who, from the analogous data obtained in aqueous solution, extracted a rate constant identified as that controlling the rate of formation of mono complex.

Since pure $[Ni(terpy)(DMSO)_3]^{2+}(ClO_4^-)_2$ could not be isolated, the rate of formation of the bis complex from terpyridine plus mono complex in DMSO solution was studied using the mono complex chloride, which in the solid state exists as $Ni(terpy)Cl_2$. In this case, pseudo-first-order behavior was obtained when either terpyridine or $Ni(terpy)Cl_2$ was in excess; again, the back (dissociation) reaction was immeasurably slow. The results obtained are summarized in Table 2, and are plotted in Arrhenius form in Fig. 3.

It is clear from these results that, even though good pseudo-first-order behavior was obtained in each case, the second-order rate constants differ in the two cases, both in absolute magnitude and in temperature dependence. A more complete discussion of these findings is given below; however, it seems clear that this effect must be connected with the partial dissociation of coordinated chloride on the nickel, discussed in section III(*a*) above.

Finally, it seemed useful to study the kinetics of formation of the mono complex perchlorate in mixed DMSO–water solvent; this reaction is free of the complicating effects associated with the chloride ion. The results obtained are shown

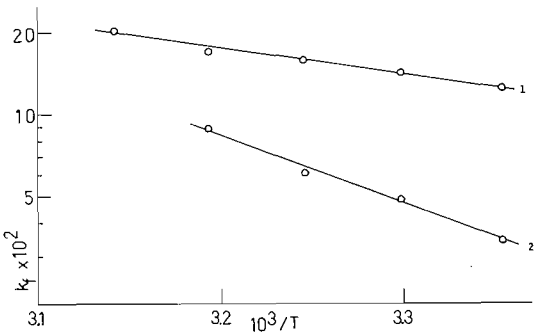

FIG. 3. Arrhenius plots of second-order rate constants for reaction of DMSO solutions of $Ni(terpy)Cl_2$, plus terpyridine to give bis complex. (*1*) Excess $Ni(terpy)Cl_2$; (*2*) excess terpyridine.

in Fig. 4; the dramatically slower rate observed in pure DMSO, compared with that in H_2O, is apparent (6, 7). In addition, the effect on the rate of adding water to DMSO is not significant until the mole fraction of water is about 0.4. This undoubtedly reflects the greater basicity of DMSO.

(c) Solvent Exchange Rates from Nuclear Magnetic Resonance Line Broadening

The solvent exchange rate constant k_{ex} for $[Ni(DMSO)_6]^{2+}(ClO_4^-)_2$ in DMSO solution has been studied previously (11–14). Present experiments confirmed the findings that the exchange rate is rapid on the n.m.r. timescale (15). At 25 °C, the value obtained for k_{ex}, calculated from the relevant solution of the Bloch equations for the system (16), is $7.4 \pm 0.7 \times 10^3$ s^{-1}, with an activation enthalpy of 6.2 ± 0.7 kcal mol^{-1} and an entropy of activation of -20 ± 2 cal deg^{-1} mol^{-1}, measured over the range 20 to 100 °C.

Over the same temperature range, a solution of $Ni(terpy)Cl_2$ in DMSO yielded no significant broadening of the DMSO line. The characteristic terpyridine pattern, between 4.31 and 7.38 p.p.m. downfield from DMSO, was not present, so that it seems clear that the species in solution was paramagnetic. It seemed likely that the exchange at room temperature was sufficiently fast, on the n.m.r. timescale, to be unobservable. Since DMSO freezes at 18 °C, it was not possible to lower the temperature sufficiently to slow the exchange rate to match the n.m.r. timescale. However, a 1:1 mixture of DMSO and nitromethane could be cooled at −40 °C without freezing; over the range −40 to +40 °C, neither broadening nor contact shift of the nitromethane peak was observed, within the precision of our measurements, when $Ni(terpy)Cl_2$ was dissolved. Only slight broadening was observed previously (3) using the nitrate salt of $[Ni(DMSO)_6]^{2+}$.

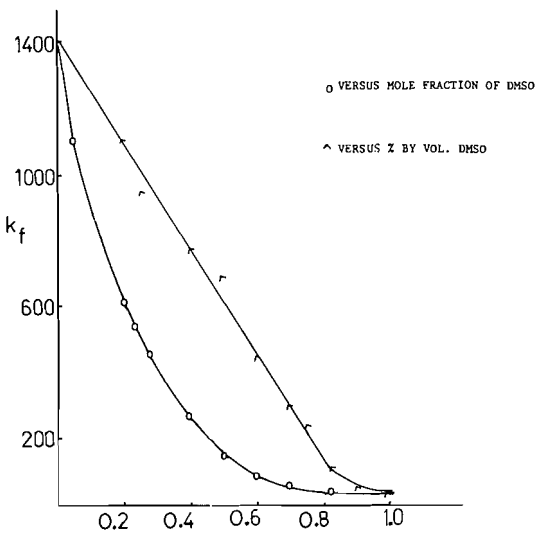

FIG. 4. Variation of second-order rate constant for mono complex formation with solvent composition, in DMSO–water mixtures, at 25 °C.

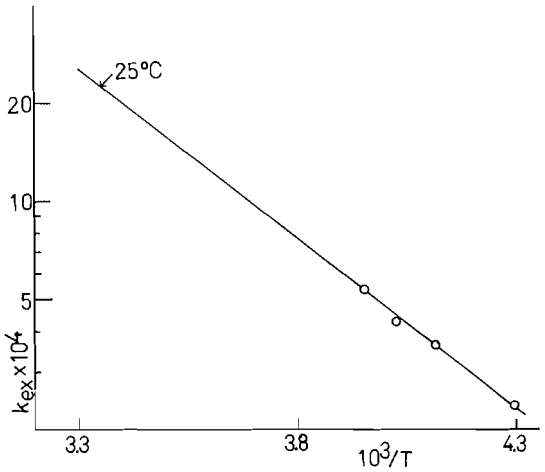

FIG. 5. Arrhenius plot of rate constant for DMSO exchange in concentrated solutions of $Ni(terpy)Cl_2$ in mixed DMSO–nitromethane solvent.

When $Ni(terpy)Cl_2$ was dissolved in this mixed solvent, the DMSO exchange rate fell in the fast-exchange region, over the range −40 to −20 °C. The Arrhenius plot of the derived values for k_{ex} is shown in Fig. 5, which also makes clear the extent of the extrapolation necessary to estimate k_{ex} at 25 °C as $3 \pm 2 \times 10^5$ s^{-1}; the activation enthalpy is 4 ± 2 kcal mol^{-1}, and $\Delta S^{\ddagger} = 20 \pm 9$ cal deg^{-1} mol^{-1}. The solvent exchange rate is thus about 40 times faster if the solute used is $Ni(terpy)Cl_2$, instead of $[Ni(DMSO)_6]^{2+}$.

IV. Discussion

The differences observed, between the u.v. spectra of various preparations of the mono complex in DMSO solution, may be satisfactorily explained in terms of coordinated chloride

ion. Thus, at concentrations of $Ni(terpy)Cl_2$ in DMSO greater than 10^{-4} mol l^{-1}, the predominant species present is probably $[Ni(terpy)Cl(DMSO)_2]^+$; addition of terpyridine to excess Ni(II) perchlorate, on the other hand, is expected to give $[Ni(terpy)(DMSO)_3]^{2+}$ in solution. No such explanation is available for the corresponding discrepancies observed in aqueous solution, in view of the conductance data. In addition, the time-dependence of the spectra observed on mixing excess Ni(II) perchlorate with terpyridine, in aqueous solution, is not readily explained. A slow partial disproportionation to the bis complex is one possibility (5); another related possibility involves the initial formation, in a large excess of Ni(II), of bridged species such as $^{2+}Ni(H_2O)_5$—(terpy)—$^{2+}Ni(H_2O)_5$, which slowly disproportionate to give the more stable mono species $[Ni(terpy)(H_2O)_3]^{2+}$. Either possibility is consistent with the fact that the absorbance peak due to $Ni(H_2O)_6^{2+}$ was invariably observed to *increase* slightly, concurrently with the more extreme changes in the complex spectrum.

Kinetic parameters of interest for the present discussion have, for convenience, been collected in Table 3. The activation parameters were obtained by fitting the rate constants, as functions of temperature, to the usual Eyring equation (17) using a non-linear least squares procedure (18). The value and standard deviation quoted for k_{ex} at 25 °C, for DMSO on $[Ni(terpy)Cl(DMSO)_2]^+$, were obtained from the values quoted for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ and from the covariance matrix, including the cross-correlation coefficients (18).

The solvent exchange data, for DMSO on $[Ni(DMSO)_6]^{2+}$ perchlorate, show a wide spread; the present results agree well with those of two of the previous investigations (11, 12); the other two measurements (13, 14) differ, while agreeing with each other. The activation parameters for DMSO exchange, listed in Table 3, are those quoted in the original work (11–14), since insufficient information was available to use the present fitting procedure (18).

Although the enthalpies and entropies of activation for DMSO exchange on $[Ni(DMSO)_6]^{2+}$ vary markedly (Table 3), the $\Delta G^{\ddagger}$ values (*i.e.* the actual rate constants) are in reasonable agreement, with respect to the usual uncertainties in work of this type. It seems likely that the spreads in $\Delta H^{\ddagger}$ (7 kcal) and $\Delta S^{\ddagger}$ (23 cal deg^{-1}) may be attributed (20) to systematic errors; these arise, in some cases, from the use of approximate formulae, as well as from the fact that dynamic n.m.r. parameters are susceptible to spurious effects such as field in-

homogeneities (20). In principle, the spin-echo method, used by Blackstaffe and Dwek (12) is more accurate than line-shape analysis, since T_2 is measured directly, and a wider temperature range can be studied. However, in practice, this method does not appear to have proven superior (21).

We are indebted to a referee for drawing to our attention the work of Bennetto and Caldin (19), on the (terpy + Ni^{2+}) reaction, which appeared while the present work was in the process of being refereed; the activation parameters from this work (19), quoted in Table 3, were for comparison purposes computed from the original data (19) using the present procedure (18). The rate constants obtained in the present work are some 30% higher than the comparable data of Bennetto and Caldin (19), the activation enthalpies being in good agreement.

The second-order rate constant for the reaction of terpyridine with $[Ni(terpy)Cl(DMSO)_2]^+$ (*i.e.* with excess $[Ni(terpy)Cl_2] > 10^{-4}$ *M*, in DMSO), is about 40 times greater than that for the reaction with excess $[Ni(DMSO)_6]^{2+}$, at 25 °C; this is also the ratio of the corresponding solvent-exchange rate constants. In spite of this excellent agreement, it should be borne in mind that the long extrapolation necessary to obtain k_{ex} at 25 °C for $[Ni(terpy)Cl(DMSO)_2]^+$ necessarily involves a large uncertainty (Table 3). In addition, although these latter data were obtained in DMSO–nitromethane mixtures, it has been shown (14) that the DMSO exchange rates of $[Ni(DMSO)_6]^{2+}$, in mixed DMSO–nitromethane solvents, are independent of solvent composition. Unfortunately, it was not possible to make a similar test for $[Ni(terpy)Cl(DMSO)_2]^+$, in the present work, due to the problem of keeping the temperature sufficiently low. However, if arguments by analogy have any validity here, the present results indicate that variations in the overall rate constant k_f parallel those in the solvent exchange rate constant, associated with the coordinated chloride; this conclusion lends support to a dissociative mechanism for the reaction (7). Labilization of coordinated solvent by coordinated chloride has been previously observed (23) for the Co(II) ion in methanol.

The rate constant obtained for the reaction of excess terpyridine with an initial concentration of 10^{-5} mol l^{-1} of $Ni(terpy)Cl_2$ in DMSO, may be interpreted in terms of reaction scheme [2]

[2]
$$[Ni(terpy)Cl(DMSO)_2]^+ + Cl^- \underset{}{\overset{K_{diss}}{\rightleftharpoons}} [Ni(terpy)(DMSO)_3]^{2+} + 2Cl^-$$
$$+ terpy \ (k_{2x}) \qquad + terpy \ (k_{2y})$$
$$[Ni(terpy)_2]^{2+}$$

In scheme [2], k_{2x} corresponds to k_f measured using excess $Ni(terpy)Cl_2$, at concentrations such that $[Ni(terpy)Cl(DMSO)_2]^+$ is the predominant species. However, when the concentration is only 10^{-5} mol l^{-1}, the degree of dissociation, α, of the second chloride, is only about 50%, as calculated from K_{diss} obtained from the conductance data. The simple mechanistic scheme [2] then leads to the following rate expression

[3] $$dC_B/dt = k_{2x}[terpy](C_x + C_y) \times [1 - \alpha(1 - k_{2y}/k_{2x})]$$

where C_B, C_x, and C_y are the concentrations of $[Ni(terpy)_2]^{2+}$, $[Ni(terpy)Cl(DMSO)_2]^+$, and $[Ni(terpy)(DMSO)_3]^{2+}$, respectively. Equation 3 predicts pseudo-first-order behavior, in excess terpyridine, only if α is constant. In fact, for the initial $(C_x + C_y) = 10^{-5}$ mol l^{-1}, the value of K_{diss} derived from the conductance data predicts that α varies only over the range 0.54 to 0.60, over three half-lives; the derivation of eq. 3, and the computations of α, are outlined in the Appendix.

The ratio of the two second-order rate constants, for formation of bis complex from $Ni(terpy)Cl_2$ in DMSO, should thus be $[1 - \alpha(1 - k_{2y}/k_{2x})]$, where α and k_{2x} are known. The resulting value of k_{2y} turns out to be negative. If, however, k_{2y}/k_{2x} is set to its minimum possible value of zero, and an effective value of α is then calculated, the resulting value of K_{diss}

TABLE 4. Substitution rates on nickel ion in DMSO at 25 °C

§Present work.

at 25 °C is 4×10^5, a factor of two greater than that obtained from the conductance data. In view of the approximations used in the interpretations of both sets of data, it seems likely that this agreement is acceptable, and that mechanism [2] accounts satisfactorily for the differences observed; k_{2y} is unlikely to be *exactly* zero, but appears to be much smaller than k_{2x}. The reaction system in DMSO solution thus appears to be susceptible to a self-consistent interpretation.

The present work offers no such rationale for the same reaction system in aqueous solution. The solvent exchange rates are practically identical (22) for $[Ni(H_2O)_6]^{2+}$ and for $[Ni(terpy)(H_2O)_3]^{2+}$, formed by dissociation of $Ni(terpy)Br_2$ in solution (5); on the other hand, the rates of reaction of these species with terpyridine differ by a factor of 155 (1). The only clue, offered by the present work, to the resolution of this dilemma, arises from the rather indeterminate characterization of the actual species present in solution, as shown by the u.v. spectra.

The present kinetic results fall into the pattern observed previously (6, 7, 19) for substitution reactions of Ni(II) ion in DMSO solution; these results are, for convenience, collected together in Table 4. Activation parameters are available only for the present systems (Table 3), plus a value of 12.6 kcal mol^{-1} for the activation enthalpy, and -7.7 cal deg^{-1} mol^{-1} for the activation entropy, for the bipyridine reaction. As pointed out previously (7), these data are not readily correlated in terms of the I_d (dissociative interchange) mechanism [1]; either K_E or k_{ex}, (or both) would be required to be much smaller than theoretically acceptable values. In addition, K_E would require to have a temperature coefficient corresponding to an enthalpy change of 4–5 kcal mol^{-1}, which seems very large (6). The mechanism is, however, believed to be of a dissociative nature (7); this conclusion is supported by the present observation that the solvent exchange rates parallel the rates of complex formation, although this evidence is not entirely unequivocal.

It has been suggested (7) that these reactions in DMSO solution might proceed via a pathway involving a five-coordinate intermediate $[Ni(DMSO)_5]^{2+}$, of lifetime sufficient to discriminate between different ligands in reaction. This proposed scheme is shown below

$$[4] \quad [Ni(DMSO)_6]^{2+} \underset{k_{-ex}}{\overset{k_{ex}}{\rightleftharpoons}} [Ni(DMSO)_5]^{2+} + DMSO$$
$$+ L \Big\downarrow k_2$$
$$[Ni(DMSO)_5L]^{2+}$$

As in scheme [1] the mechanism has been written for the special case of a monodentate neutral ligand L. Assuming the initial step to be essentially at equilibrium, the overall second-order rate constant is now identified as $k_f = k_{ex}k_2/k_{-ex}$. As pointed out by Langford and Tsiang (7), if the competition ratio $k_2[L]/k_{-ex}[S]$ is very small, relative to K_E of mechanism [1] the values of k_f will indeed be smaller than expected on the basis of the latter. In addition, mechanism [4] readily accounts for results obtained on the broadening of the n.m.r. line of nitromethane in mixed

CH_3NO_2–DMSO solvents (7) containing Ni(II) ion.

However, it does not appear that this suggestion can be the complete explanation. In particular, it is not at all clear why mechanism [4] should predominate over mechanism [1] in the present case; in view of the correlation between solvent exchange rate and overall reaction rate in DMSO solution found in the present work it seems unlikely that k_s is vastly different from k_{ex}, the rate constant for solvent exchange. If this conclusion is valid, the effective value of K_E must be much smaller than that predicted by the Fuoss equation (24); for neutral ligands, this equation gives:

$$[5] \qquad K_E = (N_0(4/3)\pi a^3)/(1000)$$

where a is the distance of closest approach of the two species. The numerator of this expression is the volume surrounding one mole of one of the species (say the metal ion), available to an added ligand molecule for formation of an encounter complex; the denominator (1 liter) is the volume available to the added ligand if it is to remain in solution as "free" ligand. These considerations apply, as they must, to the standard state of 1 mol l^{-1}. Since K_E is taken as the ratio of these volumes, with no account taken of any solvent–solute interactions or solvent structuring etc., it is clear that the Fuoss equation (24) is based upon the assumption of an ideal solution, for which the probability of finding a neutral molecule, at *any* location in the solution, is a constant. The only solvent property taken into account in the Fuoss equation (24) is the bulk dielectric constant. Thus, deviations from the *absolute* values predicted by the Fuoss equation (24) are to be expected, though the relative effects of charges on the species, and of dielectric constant of solvent, are taken into account. Indeed, it is a matter of surprise that the Fuoss equation, in conjunction with the I_d mechanism (1), accounts so well for the data obtained in such a highly structured solvent as water.

It seems entirely possible that the effect of solvent structure is reflected in the activation parameters listed in Table 3. The slower rates observed in DMSO, relative to those in water, are entirely due to the entropy term; indeed, the activation energies are higher in water than in DMSO. The release of structured solvent in the bulk liquid during the activation process will increase both the entropy and energy of activation, due to the break-up of the solvation shells. These effects will be largest in solvents like water, which are known to form rigid solvation structures. Thus, the mere fact that the absolute value of K_E, required for the reaction to be interpreted in terms of the I_d mechanism [1], is lower than that calculated from the Fuoss equation (24), seems to be no reason for discarding the I_d mechanism.

An even more problematical aspect concerns the effect of the charge of the entering ligand L, on the reaction rate. As may be seen from Table 4, this parameter has absolutely no effect on the rate of reaction in DMSO solution, in marked contrast to the situation in aqueous solution. This is not easily reconciled with the I_d mechanism [1], but this is also true of mechanism [4], since regardless of the precise nature of the second slower step, it is not obvious how k_2 might fail to be affected by the charge on L. Thus, if the five-coordinate intermediate $[Ni(DMSO_5]^{2+}$ can, indeed, react discriminately with incoming ligands (7), it is difficult to imagine how such discrimination might stop short at the nature of the charge on L.

It appears, then, that no completely self-consistent explanation of the results listed in Tables 3 and 4 has yet been given. The present authors believe (8) that the almost complete disavowal of specific solvent effects, in previous interpretations, is at least partly to blame for this situation; somewhat similar views have been expressed previously (6). Speculative interpretations of the present observations, in terms of solvent structuring, have been presented elsewhere (8). More data, for a wider variety of ligands in DMSO and other solvents, seem necessary.

Appendix

Rate Equation Derived from Mechanism [2]

Let the concentrations of $[Ni(terpy)Cl(DMSO)_2]^+$, $[Ni(terpy)(DMSO)_3]^{2+}$, $[Ni(terpy)_2]^{2+}$, and Cl^-, be denoted by C_x, C_y, C_B, and C_{Cl}, respectively. If $C^0 = (C_x + C_y)$ at time $t = 0$, then in excess terpyridine, $C^0 = C_B^\infty$ (the infinite time concentration of bis complex), since the reaction is essentially irreversible.

Then

[A1] $$C_B^\infty = C_x + C_y + C_B$$

[A2] $$C_y C_{Cl^-} / C_x = K_{diss}$$

[A3] $$C_{Cl^-} = C_B^\infty + C_B + C_y$$

Equation [A3] takes account of the fact that one chloride is always completely dissociated (C_B^∞ term), while one additional chloride ion is in solution for every molecule of bis complex formed (C_B term) and for every molecule of the x species which dissociates to give a y molecule (C_y term).

According to mechanism [2]

[A4] $$dC_B/dt = k_{2x} C_L C_x + k_{2y} C_L C_y$$

Combining eqs. [A1] and [A4] gives

[A5] $$dC_B/dt = k_{2x} C_L (C_B^\infty - C_B) \times [1 + C_y/(C_B^\infty - C_B)(k_{2y}/k_{2x} - 1)]$$

Since $C_B^\infty - C_B = C_x + C_y$ (eq. [A1]), and since the degree of dissociation α is given by:

[A6] $$\alpha = C_y/(C_x + C_y)$$

the final equation is:

[A7] $$dC_B/dt = k_{2x}[1 + \alpha(k_{2y}/k_{2x} - 1)] \times C_L(C_x + C_y)$$

To evaluate α, eliminate (C_y/C_x) from eqs. [A2] and [A6], to give:

[A8] $$\alpha = K_{diss}/(K_{diss} + C_{Cl})$$

Now rewrite eq. [A3] as

[A9] $$C_{Cl} = C_B^\infty + C_B + \alpha(C_B^\infty - C_B)$$

so that equation [A8] becomes

[A10] $$\alpha^2(C_B^\infty - C_B) + \alpha(C_B^\infty + C_B + K_{diss}) - K_{diss} = 0$$

Thus, α may be calculated for any C_B^∞ and C_B. Qualitatively, the reason why α varies so slowly as reaction proceeds is that, although $(C_x + C_y) = (C_B^\infty - C_B)$ decreases as reaction proceeds, thus tending to increase α (Ostwald dilution law), the remaining $(C_x + C_y)$ is present in an ever-increasing excess of free Cl^-, which tends to suppress the dissociative equilibrium.

Note added in proof

While the present work was being refereed, the extensive work of Bennetto and Caldin (19), together with their interesting discussion (25) of the effects of solvent structure on these reactions, was published.

It is a pleasure to acknowledge the assistance and advice offered by Dr. R. H. Holyer in the earlier stages of this work. Financial support by the National Research Council of Canada and the Ontario Department of University Affairs is also gratefully acknowledged.

Nuclear Magnetic Resonance Experiments on Acetals. 35. Proton Magnetic Resonance Spectra and Quantitative Conformational Analysis of 4-Fluoromethylated-6-Me-1,3-dioxanes[1]

P. DIRINCK AND M. ANTEUNIS

State University of Gent, Department of Organic Chemistry, Laboratory for NMR Spectroscopy, Krijgslaan, 271, S.4, B-9000 Gent, Belgium

Received July 12, 1971

4-Substituted (CF_3-, CHF_2-, and CH_2F)-6-Me-1,3-dioxanes together with model derivatives (*cis*- and *trans*-4-CH_nF_{3-n}-6-*t*.Bu-1,3-dioxane, and 2-Me-4,6-disubstituted 1,3-dioxanes) were prepared and their p.m.r. spectra analyzed, using i.a. INDOR techniques. Special features which correlate configuration and p.m.r. data are discussed and especially the fluorine–hydrogen (long-range) couplings have been studied. From vicinal (ring) coupling data (using appropriate models), from the vicinal *exo*-couplings $^3J(H4,CF_{3-n}H_n)$ and from absolute shift values, the equilibria were obtained in the conformational heterogenous *trans*-4-CH_nF_{3-n}-6-Me-1,3-dioxanes ($n = 0 \rightarrow 2$). The results, according to the different methods, are mutually in excellent agreement, as is also the case for $\Delta G^0(CF_3)$, obtained approximately from dipole moment measurements. The anomeric effect is pronounced, and the conformer with the axial fluoromethylated substituent is the preferred one (CF_3: 76%; CF_2H: 62%) at room temperature in CS_2. For CH_2F the contrary seems to be the case (presumably for entropy reasons also). Finally ΔH^0(chair–twist) was evaluated at 3.7 kcal/mol (ΔS^0(ch$\rightleftarrows$ tw) = 6.1 e.u.) using ^2J(H2) criteria in *trans*-4-CF_3-6-*t*.Bu-1,3-dioxane.

On a préparé les 4-(CF_3-, CHF_2-, et CH_2F)-6-Me-1,3-dioxannes de même que des dérivés modèles (*cis*- et *trans*-4-CH_nF_{3-n}-6-*t*.Bu-1,3-dioxanne, et 2-Me-1,3-dioxannes 4,6-disubstitués) et analysé leurs spectres r.p.m., utilisant les techniques INDOR. On discute des aspects spéciaux qui établissent la correlation entre la configuration et les données de r.p.m. et spécialement des couplages fluor–hydrogène (à longue portée). A partir des données de couplage vicinal (anneau) (utilisant les modèles appropriés), des couplages vicinaux "*exo*" $^3J(H4,CF_{3-n}H_n)$ et des valeurs de déplacement absolues, on a obtenu les équilibres dans le cas des molécules *trans*-4-CH_nF_{3-n}-6-Me-1,3 dioxannes ($n = 0 \rightarrow 2$) de conformation hétérogène. Les résultats, selon les différentes méthodes, sont mutuellement en excellent accord, comme c'est le cas pour $\Delta G^0(CF_3)$, obtenu approximativement des mesures de moment dipolaire. L'effet anomérique est prononcé, et le conformère avec le substituant fluorométhylé en position axiale est le plus abondant (CF_3: 76%; CF_2H: 62%) dans du CS_2 à température ambiante. Le cas contraire semble se produire pour le CH_2F (vraisemblablement du pour des raisons d'entropie). On a évalué finalement ΔH^0 (chaise–bateau croisé) comme étant de 3.7 kcal/mol (ΔS^0(ch.$\rightleftarrows$ bat.cr.) = 6.1 e.u.) utilisant le critère ^2J(H2) dans le cas du *trans*-4-CF_3-6-*t*.Bu-1,3-dioxanne.

Canadian Journal of Chemistry, **50**, 412 (1972)

As part of a wider project of conformational studies on 1,3-dioxanes possessing polar groups, we report in this paper some results of fluoromethylated derivatives of the 1,3-dioxane system. Our choice for F is inspired by several considerations *e.g.* (*a*) the increasing importance (in n.m.r.) of fluorinated compounds enabling ^{19}F-n.m.r. investigations where necessary, and/or allowing studies of ^{19}F-H interactions; (*b*) its relative and acceptable bulkiness with respect to H or other halogens, and (*c*) its expected pronounced electrical influence on conformation, as the result of the large C—F dipole.

1,3-Dioxanes with fluorinated methyl groups in different positions (C-4 and -5) were prepared, the substituents ranging from CH_2F, CHF_2, to CF_3. In order to obtain eventually non-anancomeric (biased) systems, additional methyl groups were introduced as a counterbalance in adequate positions. For comparative purposes, and in order to obtain suitable reference p.m.r. parameters, a *t*.Bu-group (*e.g.* in C-6 position) or a methyl group in C-2 position was also introduced (Chart 1). The C-2 substituted fluoromethyl derivatives will be investigated in the future.

(1) Nuclear Magnetic Resonance Spectroscopic Features

Because the *trans*-4-fluoromethyl-6-Me-1,3-dioxane (**2***a* $\rightleftarrows$ **3***a*; **2***b* $\rightleftarrows$ **3***b*) could not be frozen out, conformational data could not be obtained

from parameters extracted from low temperature studies. One must rely instead upon model compounds to obtain suitable reference parameters. These model compounds can be divided into two series: (*a*) the *cis*-4-fluoromethyl-6-Me-1,3-dioxanes, as well as *cis*- and *trans*-4-CF_nH_{3-n}-6-*t*.Bu-1,3-dioxanes; (*b*) the 2-Me-substituted derivatives. In the latter series theoretically four configurations are possible, but through g.c. separation only three could be isolated (*e.g.*, 2-Me-4-CF_3-6-Me-1,3-dioxanes: **1***i*, **2***i*; **3***i*).

The assignation of configurations can easily be done on basis of n.m.r. criteria.

(i) Shift Criteria (Table 1)

(*a*) The shift difference between H-2a and H-2e (δ(2a → 2e) for the AB spin system of H-2) is >30 Hz in all *cis*-derivatives, but it is only 0–10 Hz in the corresponding *trans* derivatives.

(*b*) A deshielding of H-2a in the 2-Me-substituted series is observed when a *syn-axial* substituent is present.

(*c*) In the *cis* derivatives H-2a resonates at higher field, while in the *trans*-series this situation is reversed (1). This is easily ascertained by inspection of proton–proton long-range phenomena (n.m.d.r.) (*e.g.*, *J*(2e,5e), *J*(2e,4e) (2)).

(*d*) The shifts of the H-atoms of the CF_nH_{3-n}-substituents are characteristic of the substituent in axial or equatorial position (*vide infra*).

(ii) Fluorine–Proton and CF_nH_{3-n}-Coupling (Table 2)

These data afforded several possibilities for the determination of the axial or equatorial character of the fluoromethyl substituents, distinguishing the two possible *cis–trans* configurations in the 2-Me-substituted compounds.

(*a*) The $^3J^{exo}$(4aCF_3,H4e) is larger than $^3J^{exo}$(4eCF_3,H4a). This is useful for the determination of the equilibrium constant in *trans*-4-CF_3-6-Me-1,3-dioxane.

(*b*) ^{19}F–^{1}H long-range coupling: in the derivatives with axial 4-fluoromethyl groups, pronounced fluorine–proton long-range couplings were found with H-5a, H-2a, and H-2e. ^5J(F,H-2) is larger with Ha than with He. A non-classical long-range ^5J(4aCF_3,H6a) was also observed. Figures 1 and 2 are typical for *trans*-4-CF_3-6-*t*.Bu-1,3-dioxane.

(*c*) Coupling non-equivalency: in the (CF_2H-a) derivatives, there is a coupling non-equivalency for CHF_2 in ^2J(H,F) and ^5J(2a,F), only visible by extended sweeps, which is not observed in the derivatives with an equatorial CF_2H group. This is the result of the diastereotopicity of these fluoratoms and this is clearly enhanced for axial substitution by unequivalent rotamer distribution. Also the *exo*-couplings ^3J(H4,CHF_2) are different in axial and equatorial difluoromethyl. Figures 3 and 4 represent typical examples.

Due to the diastereotopicity of the CFH_2 protons in these compounds, the pattern is also quite different for the axial and equatorial position. In both cases there is no coupling non-equivalency in ^2J(H,F). From Fig. 5 one can conclude that the two diastereotopic atoms are isochronous, resulting in a doublet of doublets for the monofluormethyl H-atoms in axial position. For the CFH_2 in equatorial position the situation is more complicated (Fig. 6). Neglecting the ^2J(H,F) the CFH_2 protons form the AB part of an ABX system (X = H4), almost an ABC. We can, however, evaluate the necessary parameters quite accurately by the subspectral procedure (3), showing a different ^3J(CH_2F,H_4) with both hydrogens.

(2) Quantitative Conformational Data for trans-4-Fluoromethyl-6-Me-1,3-dioxanes

As stated, the 4,6-disubstituted compounds could not be frozen out down to −110 °C, a situation which parallels the 4,6-dialkyl series

(4). This is understandable if one takes into account *syn-axial* no-bond strain in the ground state, which lowers the barrier for inversion (5). Thus, conformational data cannot be obtained from line-shape analysis and one must rely upon criteria, such as coupling and shift values. Although in most instances (as for example in phenyl-substituted derivatives (5–7)) these criteria are untrustworthy, in the actual compounds and in other 4,6-dialkyl-substituted derivatives (3), the results obtained are consistent and independent methods such as dipole moment measurements indicate that they are reliable.

Data from Vicinal (Ring) Coupling Values

Vicinal (ring) coupling values are obtained from subspectral procedures (3) for the ABXY spin system, formed by H5, H4, and H6. The AB (H5) consists of four subspectral ab systems, defining eight subspectral shifts from which the vicinal coupling values are obtained.

The "axial" and "equatorial" parts in the AB part may be identified (n.m.d.r.) from long-range considerations (see section *1*, parts *ic* and *iib*). Subspectral parts could easily be relayed by appropriate INDOR experiments. The X- and Y-part, is well separated in the spectrum for the *t*.Bu derivatives (see Fig. 1) but not in the Me-substituted derivatives. Here ^{19}F-decoupled spectra obtained with a Heteronuclear Spindecoupler (NMR-Specialities) were very useful. It is relatively easy to obtain directly $\Sigma^3 J(X) = {}^3J(AX) + {}^3J(BX)$ of the X-part, $\Sigma^3 J(Y) = {}^3J(AY) + {}^3J(BY)$ for the Y-part. Furthermore semi-quantitative considerations of the Karplus relation allow unambiguous assignation in the anancomeric derivatives. The results are gathered in Table 3.

Once the vicinal couplings are extracted from the spectra one can interpolate values for the conformational mobile systems using the equations shown in Chart 2.

for ^3J are known from the anancomeric 4-CF_3-1,3-dioxane (CF_3 100% equatorial (8, 9)).

The results obtained in Table 4 in general are mutually consistent. Fluctuations are easily explained by considerations of (*a*) difficulties encountered in analyses of overlapping resonance lines, as the result of the small differences in shifts of H-5a and H-5e (see $\delta(5a \rightarrow 5e)$, Table 1); especially for the *cis* derivatives, where often the subspectral ab systems are greatly degenerated; (*b*) the possibility of the occurrence of a certain amount of flexible forms. This is suggested by the low (absolute) values of ^2J(H2) in *trans*-4-CF_3-6-*t*.Bu- and *trans*-4-CF_2H-6-*t*.Bu-1,3-dioxane (-5.73 and -5.60 Hz, respectively, where it is normally -6.30 Hz (in solution)). It was shown that ^2J(H2) is a sensible criterium for the presence of flexible forms (10, 11). We will show later, however, that the amount of flexible forms at room

temperature cannot greatly influence the reference values for vicinal coupling, as it is only 4% for the CF_3 derivative; and (*c*) possible ring shape deformation caused by typical substitution in these model compounds.

(ii) r-2-Me-trans-4-Fluoromethyl-cis-6-Me-1,3- and r-2-Me-cis-4-Fluoromethyl-trans-6-Me-1,3-dioxanes as Model Compounds

In spite of several attempts, we did not succeed in preparing the 4-CFH_2-6-*t*.Bu-1,3-dioxanes. Therefore we considered the use of the 2-Me-substituted derivatives in order to obtain the necessary reference ring coupling values. In some of these cases the AB parts of the ABXY spin systems were partly hidden under the Me protons, and could only be analyzed by INDOR experiments (12). The 2-Me-4-CF_2H-6-Me-1,3-dioxanes could not be used because g.c. separations of the configurations failed. In Table 5 results are collected.

The accuracy of the coupling constant method is determined by the wisdom of the model-choice. Ring deformations have an important influence on ^3J(ring). We think that the 2-Me-substituted derivatives are, in that respect, superior, and therefore the data of Table 6 somewhat more trustworthy than those of Table 5. This is confirmed by inspecting Table 6 where the summarized values $\sum^3J$ of the vicinal (ring) coupling constants are collected, as they can be extracted directly from the H-4 pattern after ^{19}F-decoupling (separation of outer peaks).

The introduction of a *t*.Bu group or the taking of a *cis* configuration as model compound for the conformer with equatorial fluoromethyl group (as is the case in the first series of model compounds) is clearly illustrated.

We may conclude therefore, that the coupling constant method supplies with good approximation the energy differences for the equilibrium in *trans*-4-CF_2H-6-Me-1,3- and *trans*-4-CFH_2-6-Me-1,3-dioxanes. We estimate even more accurately the mean value for the equilibrium in *trans*-4-CF_3-6-Me-1,3-dioxane, as obtained from the second series of model compounds. These mean values are summarized in Table 7.

Data from Vicinal exo-Coupling Values

In agreement with earlier published data, there is a general trend that *exo*-coupling values are larger where axial, rather than equatorial, substituents are involved (13). This is also found here. The *exo*-coupling value can be obtained from inspection of the H-4 pattern, which, however, is also coupled with H-5a (and in the *trans* derivative additionally with H-2e). It was found that $^3J^{exo}$ does not depend on additional alkyl substitution. As the result of the diastereotopicity the situation for CF_2H is too complicated, and the *exo* values are not obtainable with enough accuracy. The method was therefore checked only for the CF_3-substituted derivative (**2***c*). From $^3J^{exo}$(4aCF$_3$,H4e) = 9.62 Hz (**2***f* and *i*) and $^3J^{exo}$(4eCF$_3$,H4a) = 6.27 Hz (**1***f*, *i*, and *c*) it follows from the value of 8.71 Hz in (**2***c*) that $a = 72.8\%$ at equilibrium and at room temperature ($\Delta\Delta G^0 = 588$ cal/mol), in satisfactory agreement with the mean value obtained from ring coupling constants (Table 7).

Data from Absolute Shift Values

Precise absolute shift values (TMS internal) were obtained for the 4-CF_2H-6-R-1,3-dioxanes (Hewlett Packard 5512A Electronic Counter), and it was found that $\delta(CF_2H)$ is characteristic for the position of the substituent: $\delta(CF_2H$-ax) = 5.906 (from **2***e*) and $\delta(CF_2H$-eq) = 5.511 from (**1***b* and *e*). For the conformational mixture (**2***b*) a value of 5.757 is found, and from this it follows $a = 62.28\%$ ($\Delta\Delta G^0 = 299$ cal/mol), again in excellent agreement with the data obtained from ring coupling values.

Data from Dipole Moments

Calculations of dipole moments for both conformers of the *trans*-4-fluoromethyl-6-Me-1,3-dioxanes show that the difference between the dipole moment of the conformer with an axial fluoromethyl and equatorial fluoromethyl group, respectively, is largest for the CF_3 derivative. In continuation of the n.m.r. method, the conformational equilibrium in *trans*-4-CF_3-6-Me-1,3-dioxane (**2***c*) may be calculated using the expression for the mean square moment of the equilibrium mixture:

$$\mu^2 = a\mu_a^2 + e\mu_e^2$$

in which a and e denote the molar fractions of both conformers. Here *cis*-4-CF_3-6-Me-1,3-dioxane (**1***c*) and *trans*-4-CF_3-6-*t*.Bu-1,3-dioxane (**2***f*) may serve as model compounds for the evaluation (17, 18) of μ_e and μ_a which were found to be 3.07 and 1.26 D, respectively. *trans*-4-CF_3-6-Me-1,3-Dioxane has $\mu = 1.80$ D, therefore $\%a = 78.9\%$ ($\Delta\Delta G^0_{298} = 782$ cal/mol), a value which is somewhat higher than obtained in previous methods.

Due to the electric nature of the system, especially accentuated in the equatorial conformer, we may expect that in cyclohexane the less polar conformation (axial CF_3) will tend to be more highly represented. Therefore, the method based upon dipole moment interpolation (in cyclohexane) entirely confirms the n.m.r. findings obtained in carbon disulfide, the latter method being by far superior.

*(3) Chair–Twist Interconversion in trans-4-CF_3-6-t.Bu-1,3-Dioxane (**2***f*)*

As mentioned above, the too positive values for $^2J(2)$ in **2***f* and *e* (see Table 3), led us to suppose (10) that some flexible forms may occur here. If that is the case, one should find a temperature dependency for $^2J(2)$, from which, with the aid of appropriate limit values for the chair and the twist forms respectively, the thermodynamic properties for chair–twist interconversion may be calculated (10). As for other 4,6-disubstituted dioxanes we have supposed that the limiting forms are the classical chair ($^2J2 = -6.19$ Hz for the pure liquid compounds as follows from spectra at −25 °C) and the twist–boat with alternating two-fold axes through C2–C5 for which the 4-(1′-adamantyl)-6-*t*.Bu-1,3-dioxane serves as a model having $^2J2 = 2.8$ Hz (10).

From the variation of $^2J2$ with temperature (Table 8) for the pure *trans*-4-CF_3-6-*t*.Bu-1,3-dioxane we can calculate ΔH^0(twist ⇄ chair **2***f*) = 3.72 kcal/mol and ΔS^0(twist ⇄ chair **2***f*) = 6.1 e.u. ($r = 0.895$).

We have previously found (10) that ΔH^0(tw ⇄

446	5.45	21.8	1131
458	5.43	22.4	1128

ch) for 1,3-dioxane amounts to 6.2 ± 0.3 kcal/mol (see also ref. 14; $\Delta H^0 = 6.8 \pm 0.7$ kcal/mol). Therefore with the actual value in *trans*-4-CF_3-6-*t*.Bu-1,3-dioxane we come to the conclusion that $\Delta H^0(CF_3\text{-}4) \simeq 2.5$ kcal/mol. Accepting that the additivity principle can be applied, a value of $\Delta G^0(CF_3\text{-}4) = 2.3$ kcal/mol was deduced from the previously described equilibria data (see Table 7). In view of the totally different approach, and the fact that ΔS^0 has been neglected, this is an unexpected conformity.

(4) Conclusion

Although a CF_3 group is a "larger" group for a carbocyclic ring ($\Delta G^0(CF_3) = 2.1$ kcal/mol; $\Delta G^0(Me) = 1.7$ kcal/mol (16)), this is not the case in heterocyclic compounds, at least when substituted next to oxygen. The influence of the mutual dipole interaction (*cf.* anomeric effect) is well illustrated, when one knows that $\Delta G^0(Me4) = 3.1$ kcal/mol for Me4 in dioxane (15) and that we, therefore, expect a still higher value *e.g. ca.* 3.8 kcal/mol, merely on the basis of pure steric interactions.

Instead the axial CF_3 group is preferred. The "anomeric" effect (19) is thus evaluated at 3.8–2.3 = 1.5 kcal/mol. Similar behavior is found for less fluorinated methyl groups. Unfortunately no thermodynamic data such as ΔH^0 and ΔS^0 could be obtained, due to the lack of accurate temperature dependent criteria. It would be interesting to obtain such data and also the dependency on polarity of the medium, in order to obtain more insight into the nature and operation of the different effects which determine the conformational behavior of polar substituents (on polar substrates).

Nuclear Magnetic Resonance Experiments on Acetals. 36. Proton Magnetic Resonance Spectra and Quantitative Conformational Data in 5-Fluoromethylated-5′-Me-1,3-Dioxanes[1]

M. ANTEUNIS AND P. DIRINCK

State University of Gent, Department of Organic Chemistry, Laboratory for NMR Spectroscopy, Krijgslaan 271 (S4) Gent; Belgium B-9000

Received July 12, 1971

A proton magnetic resonance study of 5-CHF_2- and 5-CH_2F-5′-Me-1,3-dioxanes and the corresponding 2-Me-substituted derivatives enables approximate conformational insights. The system prefers an equatorial polar substitutent at C-5. This is very pronounced for CHF_2, and to a lesser but still important extent for CH_2F ($\Delta\Delta H^0 = 488$ cal/mol; $\Delta\Delta S^0 = -3.0$ e.u.).

L'étude r.m.n. des CHF_2-5 et CH_2F-5 CH_3-5′ dioxannes-1,3 et des dérivés correspondants méthyl-2 substitués, donne un aperçu approximatif de leurs conformations. Le système adopte préférentiellement la conformation où le substituant polaire en C-5 est équatorial. Cet effet, très prononcé pour CHF_2, l'est moins dans le cas de CH_2F ($\Delta\Delta H^0 = 488$ cal/mol; $\Delta\Delta S^0 = -3.0$ e.u.).

Canadian Journal of Chemistry, **50**, 423 (1972)

Introduction

We have discussed in the preceding paper (1) the spectra and conformational features of the parent 4,6-disubstituted-1,3-dioxanes. We wish to report in this paper, the data obtained in 5-CF_nH_{3-n}-5′-Me-1,3-dioxanes ($n = 1, 2$) (Chart 1).

In contrast with the 4,6-disubstituted compounds in this series (1), conformational data can usually be obtained by a variable temperature study because at *ca.* −65 °C mixed spectra of both conformations (CF_nH_{3-n} axial and equatorial) are observed. However, due to the anancomeric (biased) nature of the equilibrium in 5-CF_2H-5′-Me-1,3-dioxane, suitable reference parameters could not be obtained by low temperature measurements and for this derivative, one must again rely upon anancomeric model compounds. They can easily be obtained by introducing a supplementary methyl group on C-2, which is a "blocking" group (2).

Proton Magnetic Resonance Spectroscopic Data

Shift and coupling values for (2-Me)-5-fluoromethyl-5′-Me-1,3-dioxanes are collected in Table 1. In contrast with a fluoromethyl group on C-4 (1), inspection of Table 1 reveals ^{19}F–H long-range coupling occurring when the fluoromethyl on C-5 is in equatorial position. This ^4J(H4,F) is more important with H-4a than with H-4e. Furthermore, pronounced down- and upfield shifts are observed for the CF_2H and Me-5 protons, respectively, in the conformer with equatorial fluoromethyl group, in contrast with the conformer with CF_2H in axial position (Figs. 1 and 2).

Conformational Data for 5-CF_2H-5′-Me-1,3-Dioxane (1b)

This derivative is not soluble enough in CS_2 to allow low temperature measurements (it crystallizes out at $\leqslant -50$ °C). In Freon-12 ($CFHCl_2$) however, spectra can be obtained down to −100 °C. Although a certain broaden-

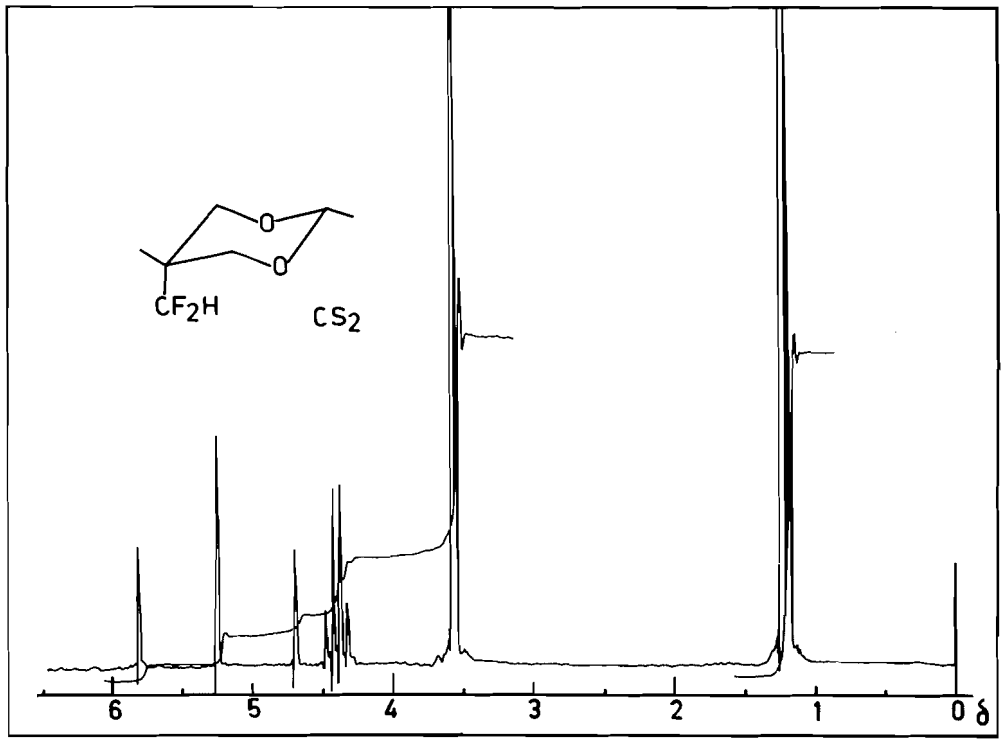

FIG. 1. The 100 MHz spectrum (CS_2, TMS int.) for *r*-2-Me-*cis*-5-CF_2H-*trans*-5′-Me-1,3-dioxane (2*h*).

ing at *ca* −65 °C is observed, the conformational equilibrium is too one-sided to compute any reasonable equilibrium value (with the aid of line-shape analysis or interpolation of shift values). Therefore we tried to estimate the equilibrium at room temperature from shift data. Shifts (in CS_2 and $CFHCl_2$) were measured in (1*b*) for CHF_2 and *Me*-5, and they were compared with the respective values in anancomeric model compounds such as *r*-2-Me-*trans*-5-CF_2H-*cis*-5′-Me-1,3-dioxane (1*h*) and *r*-2-Me-*cis*-5-CF_2H-*trans*-5′-Me-1,3-dioxane (2h). To keep the results uniform fluorodichloromethane, which is an excellent low temperature solvent, was also so used for 5-CFH_2-5′-Me-1,3-dioxane. It also enables us in that case to observe the influence of dielectric constant on the conformational equilibrium. In Table 2 results are gathered.

Table 2 shows that $\Delta\Delta G^0$ values differ a lot, whether the equilibrium determination is assessed from absolute shift measurement of CF_2H or of Me-5. However, we estimate the free energy difference as found from shift interpolation of CF_2H proton to be more trustworthy because: (*a*) in the 4-fluoromethyl-6-alkyl-1,3-dioxane series it is proved that characteristic absolute shifts of protons geminal to fluor (whether we deal with equatorial or axial fluoromethyl groups) are independent of other ring substituents; (*b*) for the equilibrium under investigation the conformer with CF_2H equatorial is the less polar one.[2] On changing from carbon disulfide to fluorodichloromethane we expect an equilibrium shift to the side of the more polar conformer, *e.g.* the one with axial difluoromethyl group. This is confirmed by the calculations from CF_2H which show the more polar conformer to become stabilized with an additional $\simeq$200 cal/mol, on changing from carbon disulfide to fluorodichloromethane.

From this we estimate $\Delta\Delta G^0$ (Me5, CF_2H5) $\simeq$ 1.87 kcal/mol, suggesting from additivity calcultation and with ΔG^0 (Me-5) = 0.9 kcal/mol (2, 3), that ΔG^0 (CF_2H5; CS_2) $\simeq$ 2.77 kcal/mol. No data concerning ΔH^0 and ΔS^0 however, could be obtained.

[2]This contrasts with the 4-substituted series, as is easily understood from considerations of dipole–dipole interactions between C-CF_nH_{3-n} and the dioxanic ring.

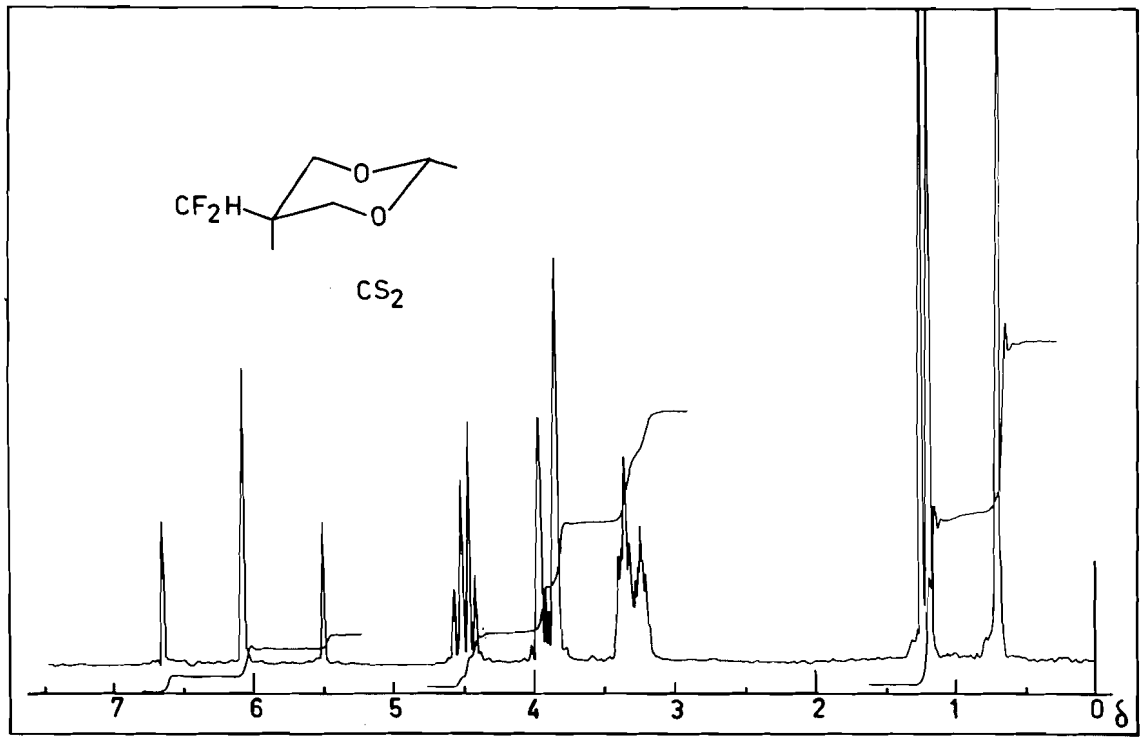

FIG. 2. The 100 MHz spectrum (CS_2, TMS int.) for *r*-2-Me-*trans*-5-CF_2H-*cis*-5′-Me-1,3-dioxane (1*h*).

Conformational Data for
5-CFH_2-5′-Me-1,3-Dioxane (1a)

This compound could be "frozen out" (T_c = 207.3 °K) and the appearance of a second Me peak shows the conformational system not to be biased. The AB spin system for H-2 however, remains unique (in $CHFCl_2$), showing accidental shift equivalency (isochronism) for both conformers. Table 3 gives us the variation of $\delta(2a \rightarrow 2e)$ in function of the temperature (173–300 °K). With the aid of a PDP-8/1 computer program (4), and following the procedure discussed in earlier papers (5), we obtain the data for $\Delta\Delta G^0$ gathered in Table 4.

It follows that $\Delta\Delta G^0{}_{300}$ (**1***a*) = 1.4 kcal/mol in favor of the axial Me conformer with $\Delta\Delta H^0$ (**1***a*) = 488 cal/mol and $\Delta\Delta S^0$ (**1***a*) = −3.0 e.u. It is interesting to note that we do not expect a large difference in $\Delta\Delta G^0$ on steric grounds (ΔG^0 (Me-5) = 0.9 kcal/mol and ΔG^0 (*t*.Bu-5) = 1.7 kcal/mol (2, 3). The observed difference is thus mainly due to electric contributions, disfavoring by mutual dipole–dipole orientation, the conformer with the axial CF_2H-substituent. Furthermore, again for electric (and presumably also steric) reasons the latter conformer is restricted in rotamers with respect to population as is depicted in Chart 2. This is the more plausible because it is in general difficult to locate the exact origin of the dipole vector (6).

Conclusion

Unfortunately we were unable to synthesize the 5-CF_3-5′-Me-1,3-dioxane. In view of the biased situation for the (less polar) CHF_2 derivative however, we may predict the compound to be anancomeric. It would be interesting

therefore to study the parent 5′-*t*.Bu derivative, but even the introduction of a 5-CF_2H together with a 5′-*t*.Bu group has failed until now. The conformational results for 5-CFH_2-5′-Me-1,3-dioxane show a pronounced preference for equatorial population of the polar substituent, both for ethalpy and entropy reasons. Undoubtedly entropy participation comes from the exclusions of rotamers, where the F atom is orientated over the ring, *e.g.* in close approach with the axial p-orbitals of the ring-oxygen atoms. Even some deformation (flattening) of the ring is suggested by the somewhat lowered (absolute) value observed for $^2J2$ (7).

The Racemization and Geometrical Isomerization of Oxiranes

HELEN H. J. MACDONALD AND ROBERT J. CRAWFORD
Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received August 4, 1971

Optically active *trans*-2-phenyl-3-*p*-tolyloxirane and *cis*-2-phenyl-3-*p*-tolyloxirane were synthesized and the kinetics of their racemization and geometrical isomerization were studied.

The slower rate of racemization of the *cis*-isomer compared with that of the *trans* is attributed to the con-rotatory opening of the oxirane ring.

Le *trans*-2-phényl-3-*p*-tolyloxiranne et le *cis*-2-phényl-3-*p*-tolyloxiranne optiquement actifs ont été synthétisés et les cinétiques de leur racémisation et isomérisation géométrique ont été étudiées.

La vitesse de racémisation plus lente de l'isomère *cis*, par rapport à celle de l'isomère *trans*, est attribuée à une ouverture con-rotatoire du cycle oxirannique.

Introduction

Convincing evidence for the cleavage of the carbon–carbon bond in an oxirane ring has been demonstrated by the addition of tetracyanoethylene oxide (TCNEO) to olefins (1). It has been shown that the reaction takes place in two steps, the first being the cleavage of the carbon–carbon bond with the formation of an intermediate. The intermediate was found to have little ionic character as ascertained by a study of solvent polarity and olefin substituent changes. Additional evidence of a reversible ring opening and closing at the carbon–carbon bond was provided by the observation that the racemization of *trans*-stilbene oxide proceeds 172 times faster at 220° than does the *trans* to *cis* isomerization (2).

The ring open form of oxiranes is a 4π electron system since the lone pair electrons on the oxygen mix with the p-orbitals on the terminal carbons. This system, with its highest occupied molecular orbital antisymmetric, resembles the allyl anion (3). Orbital symmetry considerations (4) suggest that a conrotatory mode of ring close is preferred, see Fig. 1.

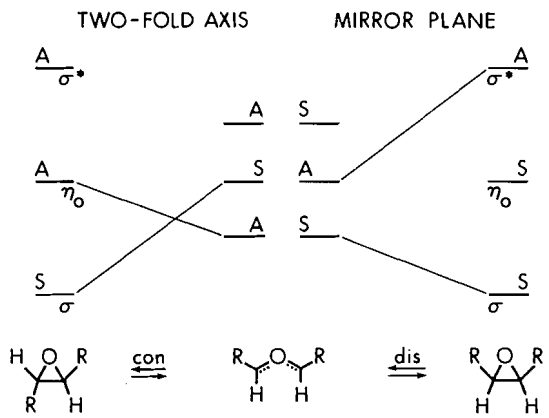

FIG. 1. Correlation diagram for the oxatrimethylene ring closure.

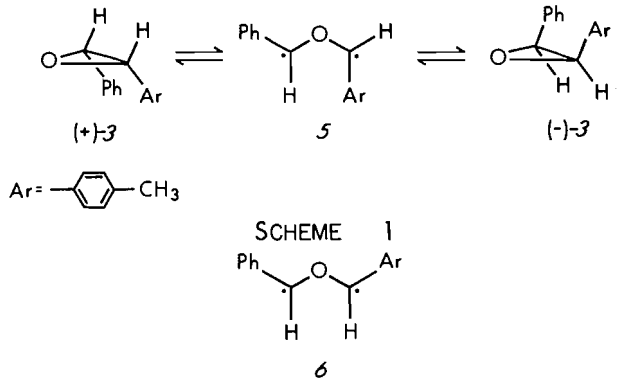
Recently a nonempirical self-consistent-field and configuration-interaction study of ethylene oxide, and other three-membered ring systems, has shown the open form to be essentially a linear combination of the resonance system, $C{=}\overset{+}{O}{-}\overline{C}\leftrightarrow\overline{C}{-}\overset{+}{O}{=}C$ and a diradical $\dot{C}{-}O{-}\dot{C}$ (5).

That the conrotatory mode is preferred in the ring opening of aziridines has been convincingly demonstrated by Huisgen *et al.* with the stereospecific conversion and trapping of the azomethine ylides (6). In the absence of a trapping agent some geometrical isomerization has been observed (7).

Arnold and coworkers (8) have elegantly demonstrated the existence of the open form of the oxirane ring in both the thermal and photochemical reactions of the 5-oxabicyclo[2.1.0]-pentane system. They were able to trap the intermediate by a 1,3-dipolar addition with benzonitrile. Such a ring opening is constrained to occur in a disrotatory mode. The driving force for Arnold and Karnischky's reaction is provided by the two phenyl groups and the ring strain of the 1,2-diphenyl-3,3,4,4-tetramethyl-5-oxabicyclo[2.1.0]pentane. The oxatrimethylene, or carbonyl ylide, intermediate has also been postulated in photochemical processes by Do-Minh *et al.* (9).

The preference of a conrotatory or dis-



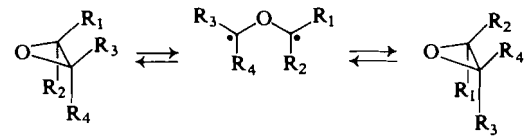
rotatory mode of ring opening and closing has not been demonstrated experimentally for oxiranes. Trapping agents are not as successful in competing with the ring closure in the oxirane–oxatrimethylene system as is the case in the aziridine system (2).[1] An alternative way to approach the problem is to note that in the oxatrimethylene species (**2**) the four ring substituents of the oxirane (**1**) have been rotated into the C—O—C plane and thus starting from a chiral oxirane we can detect the rate at which this isomerization proceeds by measuring the rate of loss of chirality by the oxirane. We have undertaken such a study choosing as our model compounds, *cis*-2-phenyl-3-*p*-tolyloxirane (**3**) and *trans*-2-phenyl-3-*p*-tolyloxirane (**4**).

If the conrotatory mode of ring opening is the reaction path then (+)-**3** will open to **5** and reclose to (±)-**3**, see Scheme 1. If however the disrotatory mode prevails then (+)-**3** would open to the more stable intermediate **6** and would reclose to (±)-**3**. The converse is true for (+)-**4**. Thus orbital symmetry considerations predict that the rate constant for the racemization of the *trans*-oxirane (**4**), k_t^a, will be larger than the rate constant for the racemization of the *cis*-oxirane (**3**), k_c^a.

Results

(a) Synthesis

The *trans*-oxirane ((−)-**4**) was obtained by treating the quaternary ammonium salt of (*1S*:*2R*)-(+)-2-amino-2-phenyl-1-*p*-tolylethanol (**7**) with silver oxide. The alcohol (+)-**7** was obtained using (+)-glutamic acid in 50% ethanol and the configurations assigned by comparison



with the assignments of configuration to 2-amino-1,2-diphenylethanol (**10**). The *cis*-oxirane (**3**) was obtained by inversion of the hydroxyl group of (+)-**7** to give (−)-**8** by the oxazoline method (11). The synthesis of (+)-**3** is outlined in Scheme 2.

(b) Kinetic Studies

Of the several solvent systems investigated chlorobenzene was found to be the most suitable over the temperature range required. One factor in its choice was its lack of absorption in the region of the n.m.r. spectrum of the oxiranes ring hydrogen. Initially some erratic rates were observed with the intervention of other products in the higher temperature runs. These products were also produced if a small amount of hydrogen chloride was added. This side reaction was prevented by carefully distilling the solvent immediately before it was used, and by adding a small amount of anhydrous sodium carbonate to each tube. The rate of disappearance of the n.m.r. absorption attributed to the ring protons of **3**, and the appearance and increase in the absorption of the signal attributed to the ring protons of **4** were carefully measured. The reaction was found to follow first order kinetics and the slope of $\ln (P_t - P_\infty)/P_0 - P_\infty)$ *vs.* time gave k_{obs}, where P_t is the percentage of **3** present at time t, P_0 is the percentage of **3** at $t = 0$, and P_∞ is the percentage of **3** at equilibrium.

The kinetic data for the *cis–trans* equilibration are presented in Table 1. The value of K_{eq}

[1]NOTE ADDED IN PROOF: Huisgen *et al.* (16) have now provided evidence for the conrotatory ring opening of oxiranes.

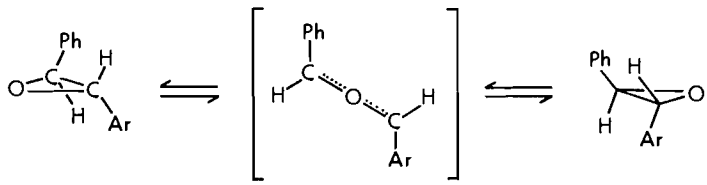

SCHEME 3

was found to be essentially constant over the temperature range examined ($K_{eq} = [trans]/[cis] = 9.52$).

The racemization of **3** was conveniently measurable in the temperature range 225–250°. At these temperatures the conversion of **3** to **4** is also occurring and so the observed rate must be corrected to account for the formation of **4**. Several samples from the racemization studies were checked using n.m.r. to see that the geometrical isomerization was proceeding in the normal fashion. In each instance excellent agreement between the calculated percentage of **3** and the observed percentage of **3** was obtained. The rate constants, k_c^a, and activation parameters for the racemization of **3** are given in Table 2.

The racemization of **4** was found to be considerably more facile than the other processes studied and was found to be conveniently measurable in the temperature range of 180–210°. The rate constants for the racemization of the *trans*-isomer **4**, k_t^a, are listed in Table 3 along with the activation parameters.

Discussion

At 207.2° the *trans*-oxirane (**4**) racemizes sixty times faster than the *cis*-oxirane (**3**). This may be rationalized by the conrotatory ring opening of **3** producing the oxatrimethylene intermediate (**5**) wherein one of the bulky aryl groups is in a sterically crowded configuration, whereas **4** racemizes via **6**. Although the ground state for the racemization of the *cis*-isomer is 2.2 kcal mol^{-1} higher than that of the *trans*-isomer, the bulky aryl group on the inside of the C—O—C angle in **5** causes sufficient destablization to increase the barrier to its formation by 6 kcal mol^{-1}. This is consistent with, and best explained by, the conrotatory mode of oxirane ring opening. There are few other methods by which simultaneous inversion of two asymmetric centers can occur. One alternative route would be to force the oxygen of the oxirane through a point between the two carbons to the opposite side as per Scheme 3. It is difficult to see how the *cis*-oxirane (**3**) would be at such a disadvantage relative to the *trans*-isomer in the racemization process in such a scheme.

Huisgen *et al.* (7) have recently presented a reaction scheme to explain both the geometrical and optical isomerization of aziridines. The analogous route for the oxiranes is presented in Scheme 4 with the corresponding reaction coordinate as Fig. 2. This implies that *cis* to *trans* isomerization proceeds by going through both intermediates. The possibility also exists that a non-allowed disrotatory ring closure converts **5** to **4** and **6** to **3**. Such a process would be controlled by the splitting between the highest occupied molecular orbital and the lowest unoccupied molecular orbital. There also exists the possibility that the *cis–trans* isomerization

is independent of the racemization processes as indicated in the reaction coordinate in Fig. 3. While the oxatrimethylene species are useful in rationalizing the TCNEO cycloaddition and other reactions (7) as well as the racemization process, a more subtle probe may be required to define the mode of geometrical isomerization.

Experimental

Microanalyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of Alberta. Mass spectra were measured using an A.E.I. MS-2 spectrometer at an ionization potential of 70 eV. The n.m.r. spectra were recorded on a Varian Associates A-60, A-56-60-A, and A-60D using TMS as internal standard and $CDCl_3$ as solvent unless otherwise stated.

4-Methylbenzoin

The procedure used was similar to that of Fuson *et al.* (12) except toluene was used as the solvent. Yield of white needle-like crystals was 59%, m.p. 119–129°; i.r. (KBr discs) ν_{max} 3400 (O—H) and 1670 cm^{-1} (C=O); n.m.r. τ 7.7 (s, 3, methyl), 5.55 (S, 1H, OH), 4.1 (S, 1H, methine), 2.5 (m, 9H, aromatics).

Anal. calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24. Found: C, 79.52; H, 6.31.

4-Methylbenzoin Oxime

The method used was essentially that of Goldschmidt and Polonowska (13). The yield of white crystals was 87.6%, m.p. 139–139.5°; i.r. (Nujol) ν_{max} 1675 cm^{-1} (C=N); n.m.r. τ 7.92 (s, 3H, methyl), 4.42 (q, 2H methine and OH), 2.98 (d, 9H, aromatics), 0.5 (s, 1H, NOH) with D_2O exchange of NOH and OH hydrogens was observed.

Anal. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81. Found: C, 74.41; H, 6.06; N, 5.83.

erythro-2-Amino-2-phenyl-1-p-tolylethanol (7)

The hydrogenation of 4-methylbenzoin oxime using Pd-on-charcoal in ethanol was analogous to the procedure of Huffman and Elliot (14). Needle-like crystals were obtained in a 96% yield, m.p. 142–143°; i.r. (KBr discs) ν_{max} 3410 (O—H), 3360, and 3295 cm^{-1} (NH_2); n.m.r. τ 7.99 (s, 3H, NH_2 and OH), 7.68 (s, 3H, methyl), 5.62 (2d, chemical shift difference 35 cps, 2H methines), 2.89 (s, 4H, aromatics), 2.72 (s, 5H, aromatics) with D_2O the NH_2 and OH protons exchanged; M (mass spectrometry), 227.

Anal. Calcd. for $C_{15}H_{17}ON$: C, 79.26; H, 7.54; N, 6.16. Found: C, 79.26; H, 7.44; N, 6.16.

The hydrochloride was prepared by adding **7** to a 1:1 ether–ethanol solution containing excess hydrochloric acid.

The method of resolution of **7** was essentially that of Tishler *et al.* (10*d*) using L-(+)-glutamic acid in 50% ethanol. $[\alpha]_D^{20}$ + 5° (*c*, 1.0, ethanol).

(2S:3S)-(−)-2-Phenyl-3-p-tolyloxirane (4)

The quaternary ammonium salt of (+)-**7** (3.6 g, 9 mmol) was treated with silver oxide (about 3 g, 9.6 mmol) in water and the solution was steam distilled, as described by Read and Campbell (15), yielding 1.47 g of **4** (7 mmol, 7690), m.p. 76–76.5°, $[\alpha]_D^{20}$ −380° (*c*, 0.16, ethanol); n.m.r. τ 7.65 (s, 3H, methyl), 6.18 (s, 2H, methines), 2.78 (s, 4H, aromatics), and 2.65 (s, 5H, aromatics); M (mass spectrometry), 210.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.67; H, 6.71. Found: C, 85.56; H, 6.62.

(1R:2R)-(−)-2-Amino-2-phenyl-1-p-tolylethanol (8)

The hydrochloride of (+)-**7** was treated with formamide to give the *N*-formyl derivative and this in turn was treated with thionyl chloride as described by Attenburrow *et al.* (11). Care was taken to purify **10** by several recrystallizations from 60% ethanol; $[\alpha]_D^{20}$ −141° (*c*, 1.7, ethanol), m.p. 116–118°; n.m.r. τ 7.72 (s, 6H, methyl, NH_2 and OH), 5.72 (2d, chemical shift difference 40 Hz, 2H, methines), 2.98 (s, 4H, aromatics), 2.82 (s, 5H, aromatics) with D_2O the NH_2 and OH protons exchanged.

Anal. Calcd. for $C_{15}H_{17}NO$: C, 79.26; H, 7.54; N, 6.16. Found: C, 78.98; H, 7.46; N, 6.24.

(2S:3R)-(+)-2-Phenyl-3-p-tolyloxirane (3)

The quaternary ammonium salt of (−)-**8** was prepared by heating (−)-**8** to reflux in the presence of iodomethane, anhydrous sodium carbonate and anhydrous methanol for 3–4 days. The oxirane (**3**) was prepared in a similar manner to **4**. The yield of pale yellow oil was 70%; $[\alpha]_D^{20}$ +12.8° (*c*,

For personal use only.

1.7, ethanol); n.m.r. τ 7.8 (s, 3H, methyl), 5.72 (s, 2H, methines), 3.02 (s, 4H, aromatics), and 2.88 (s, 5H, aromatics); M (mass spectrometry), 210.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.67; H, 6.71. Found: C, 85.46; H, 6.74.

Kinetic Studies

The racemization studies were carried out using 1.00 ml aliquots of the respective solutions which were placed in ampoules of 2 mm walled glass tubing with an inner diameter of 0.5 cm and about 1.5 cm long. Each sample was degassed on a vacuum rack with liquid nitrogen cooling during evacuation. Three freeze–degas–thaw cycles were performed on each ampoule. After the appropriate times in the constant temperature bath the samples were immediately quenched in an ice-water bath. Each ampoule contained about 15 mg anhydrous potassium carbonate to prevent any acid-catalyzed reactions. Infinity tubes were checked by n.m.r. and the only products observed were **3** and **4**.

The authors wish to acknowledge the support of the National Research Council of Canada. They also wish to thank Prof. T. R. Lynch for some early exploratory work and Mr. Utz Liebe for some technical assistance.

The Mechanism for Hydrolysis of Primary Alkyl Chlorosulfates in Water. The Kinetic Solvent Isotope Effect and the Secondary Deuterium Isotope Effect

E. C. F. Ko[1] AND R. E. ROBERTSON

Department of Chemistry, University of Calgary, Calgary 44, Alberta

Received September 17, 1971

The temperature coefficients of the enthalpy of activation ($\Delta C_p^{\ddagger}$) for the hydrolysis of the three chlorosulfates, methyl, ethyl, and β-chloro, are shown to have values of -50, -55, and -60 cal deg^{-1} mol^{-1}; values in the same range as previously reported for the hydrolysis of the sulfonyl chlorides. The corresponding value for the β-methoxy isomer was -40 cal deg^{-1} mol^{-1}, about the same as found for the *p*-methoxybenzenesulfonyl chloride. The kinetic solvent isotope effect, however, was significantly lower than reported for the sulfonyl chloride series, being about the same as found for the hydrolysis of the alkyl halides. While some degree of nucleophilic overlap is probably required in the activation process, the requirement here is reduced to about the same level as that for the primary halides, and there is no need to postulate a different mechanism on passing from the methyl to the ethyl member of the series, confirming the earlier conclusion of Buncel and Millington.

On montre que les coefficients de température de l'enthalpie d'activation ($\Delta C_p^{\ddagger}$) pour l'hydrolyse des trois chlorosulfates, méthyle, éthyle, et β-chloro, ont les valeurs de -50, -55, et -60 cal deg^{-1} mol^{-1}; valeurs se situant dans le même domaine que celle rapportées précédemment pour l'hydrolyse des chlorures de sulfonyl. La valeur correspondante pour l'isomère β-méthoxy était de -40 cal deg^{-1} mol^{-}, environ la même que celle trouvée pour le chlorure de *p*-méthoxybenzènesulfonyl. L'effet cinétique de solvant isotopique était toutefois largement plus faible que celui rapporté pour la série des chlorures de sulfonyl et ressemblait à celui qu'on avait trouvé pour l'hydrolyse des halogénures d'alkyles. Alors que le procédé d'activation demande un certain degré de recouvrement nucléophilique, le recouvrement dans le cas qui nous concerne est réduit environ au même niveau que dans le cas des halogénures primaires, sans besoin de postuler un mécanisme de passage différent du méthyle à l'éthyle dans la série, confirmant une conclusion précédente de Buncel et Millington.

Canadian Journal of Chemistry, **50**, 434 (1972)

Introduction

Three possible mechanistic pathways have been proposed (1–6) for nucleophilic displacement reactions involving alkyl chlorosulfates. These proposals are summarized in eqs. 1–3.

Pathway 2 would lead to an alkylhydrogen sulfate which is stable under our reaction conditions and is not found among the reaction products. The final products for paths 1 and 3 are the same and can be represented by the overall equation:

[4] $ROSO_2Cl + 2H_2O \rightarrow ROH + 3H^+ + SO_4^{2-} + Cl^-$

Current opinions (3, 4) favor the mechanism

(1) Nucleophilic displacement at carbon

$$\overset{\delta+}{R}\ \ldots\overset{\delta-}{O}SO_2Cl \xrightarrow[H_2O]{S_N2} \text{Products} \qquad [a]$$

[1] $ROSO_2Cl \rightleftarrows$

$$\overset{\delta+}{ROSO_2}\ \ldots\ \overset{\delta-}{Cl} \xrightarrow{S_N1} R^+ \,\|\, OSO_2Cl$$

$$\text{or} \longrightarrow \text{Products} \qquad [b]$$

$$\overset{\delta+}{ROSO_2} \,\|\, \overset{\delta-}{Cl}$$

(2) Nucleophilic displacement at sulfur

[2] $ROSO_2Cl + H_2O \rightarrow \langle ROSO_2 \ldots Cl\rangle \rightarrow ROSO_2OH + Cl^- + H^+$

(3) Fragmentation

[3] $ROSO_2Cl \rightarrow \langle R^+ \ldots OSO_2 \ldots Cl^-\rangle \rightarrow R^+ + SO_3 + Cl^- \rightarrow \text{Products}$

*n is number of rate constants with a temperature range from T_1 to T_2.

represented by eq. 1. However, if the R group is neopentyl, Buncel and Millington suggest (4, 5) that mechanism 3 is probable.

While direct attack of water on the methyl carbon of methyl chlorosulfate is acceptable, a rate determining ionization of the sulfur–chlorine bond was suggested for the ethyl chlorosulfate followed by a rapid reaction of the nucleophile with the ethoxysulfonylium ion at carbon.[2] If the ethyl compound reacts by a rate controlling ionization [1*b*], this fact should be evident by the contrast between the value of $\Delta C_p^{\ddagger}$ for the hydrolysis of this compound in water and that for the hydrolysis of the methyl isomer (6).

There is always the possibility that no one mechanism is dominant resulting in "mixed kinetics". If such a complexity is present, this too will be apparent in the value of $\Delta C_p^{\ddagger}$. Accordingly, to determine whether significant differences exist in charge development at the transition state for the hydrolysis of methyl and ethyl chlorosulfates and two related compounds, we have determined the temperature dependency of the rate for hydrolysis in water over a sufficient range of temperature to permit an estimate of the temperature coefficient of $\Delta H^{\ddagger}$.

Results and Discussion

Rate constants[3] for the hydrolysis of methyl, ethyl, β-methoxyethyl, and β-chloroethyl chlorosulfates were measured over a temperature range of at least 20°. These rate data were fitted to the usual empirical three constant equation

[5] $$\log_{10} k = A_1 + A_2/T + A_3 \log_{10} T$$

The corresponding values of the empirical constants, A_1, A_2, and A_3 are given in Table 1 and provide a convenient means for calculating the rate of hydrolysis at temperatures within the experimental range and for short extrapolations outside that range. Pseudo-thermodynamic parameters for the activation processes have been calculated from eq. 5 according to the method of Clarke and Glew (7) and making the usual assumptions regarding the attenuation of the rate–temperature relation (6). The values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ are given in Table 2. Rate constants calculated for 25 °C and corresponding relative rates are given in Table 3.

Rossal and Robertson have shown from a consideration of kinetic solvent isotope effects (k.s.i.e.) that there is good evidence for nucleophilic interaction at the transition state in the hydrolysis of a series of benzenesulfonyl chlorides (8) in contrast to the rather small to negligible effect in the hydrolysis of the alkyl halides (6) and the even smaller effect for the hydrolysis of alkylbenzenesulfonic esters (9). This rate ratio thus provides an indication of the presence or absence of nucleophilic interaction in excess of interactions present in bulk solvent. According to this criteria, it is apparent (Table 3) that nucleophilic interaction up to the transition state is small or absent in the hydrolysis of the four chlorosulfates studied here.

Initial State Interaction

Interpretation of $\Delta C_p^{\ddagger}$ and k.s.i.e. values for ionogenic reactions in water depend largely on changes in water structure in the activation process either as a consequence of change of temperature, or of isotopic substitution. The conclusions are suggestive rather than final. These effects depend to an important degree on the nature of solvation of the reactants in the initial state (6), the dominant feature of the solution of many non-electrolytes in water being the fact that water–water interaction > water solute interaction. The alkyl chlorosulfates are relatively insoluble, the tendency of the sulfonyl oxygens to hydrogen bond with water being

[2]For a review of other possibilities under varying conditions see Buncel (5).

*Calculated from eq. 5.

somewhat less than that of the oxygens in the sulfonyl chlorides according to the test used by Kartha and co-workers (10), Table 5. This tendency is significantly less than the interaction found for the alkyl sulfonic esters according to the same test (10). The greater value of $\Delta\nu$ for the 2-methoxyethylchlorosulfate is attributed to interaction of water with the ether oxygen rather than with the sulfonyl oxygens, rate comparison (Table 4) showing the electronic effect of MeO and Cl are similar. Hence, the effect of the methoxy group on the hydrogen bonding of the sulfonyl oxygens is in the direction of reduced interaction in the initial state solvation shell. This is the opposite effect to that required to account for the change in $\Delta C_p^{\ddagger}$.

The k.s.i.e. for the four chlorosulfates are in the narrow range 1.2–1.25 (Table 3) about the same as found for the hydrolysis of the alkyl halides (6); significantly higher than recorded for the hydrolysis of the alkyl benzenesulfonates and significantly less than the corresponding values found for the substituted benzenesulfonyl chlorides (1.3–1.9). That the ratio k_{H_2O}/k_{D_2O} is higher than that for the sulfonic esters may be attributed to the greater degree of interaction of the latter with water in the initial state and the more diffused charge in the leaving group. That the value of k.s.i.e. for the chlorosulfates is significantly less than found for the sulfonyl chlorides and about the same as found for the halides, does not necessarily imply the absence of nucleophilic interaction at the transition state but rather that if such interaction is required, it is similar to that required in the hydrolysis of a primary halide. The inverse secondary deuterium isotope effect ($k_H/k_D = 0.95$), Table 3, is similar to that found in the hydrolysis of the methyl halides (11) and is at least consistent with the above hypothesis. The same conclusion is supported by the values of $\Delta C_p^{\ddagger}$.

Heat Capacity of Activation

The values of the temperature coefficient of the enthalpy of activation for three of the chlorosulfates (Table 5) are about the same as reported for the sulfonyl chlorides (8). It is probable that the initial state interaction of the chlorosulfates is, if anything, less than that of the sulfonyl

chlorides (Table 5), hence the charge distribution on the chloride at the transition state is similar. Were the product forming step to occur subsequent to the transition state, we would have expected a much more negative value of $\Delta C_p^{\ddagger}$. Thus the value of this coefficient for the hydrolysis of dimethylsulfamoyl chloride is -76 cal deg^{-1} mol^{-1} (12) an example of a sulfonyl chloride where structural considerations predicate an S_N1 mechanism. Such steric hindrance to nucleophilic interaction is absent in the chlorosulfate series.

The value of $\Delta C_p^{\ddagger}$ is somewhat lower for the β-methoxyethyl isomer, an effect which was also observed for the hydrolysis of p-methoxybenzenesulfonyl chloride (13) and was attributed in the latter case to the effect of temperature on the interaction of the methoxy group with adjacent water molecules. We have advanced arguments why similar effect will account for the abnormal values of ΔC_p found for the ionization of benzoic acids substituted with the methoxy group (13). We do not regard the more positive value of $\Delta C_p^{\ddagger}$ found for this member of the series reflects a breakdown of water structure about the sulfonyl group in the initial state since the effect of the methoxy group on the rate is similar to that of the β-chloro substituent.

From the above evidence we conclude that there is no substantial difference in mechanism between the four members of the chlorosulfate series reported here. This conclusion confirms the earlier conclusion reached by Buncel and Millington on other evidence (3, 4). From a consideration of isotope effects and a comparison of $\Delta C_p^{\ddagger}$ values with the corresponding values found for the sulfonyl chloride series, some small degree of bonding between water and carbon is required in the activation process for the examples studied.

Experimental

Alkyl chlorosulfates were made by the reaction of sulfuryl chloride and the appropriate alcohol at low temperature as outlined by several workers (14–16). Two to three vacuum distillations on a spinning band column furnished the pure product on basis of the homogeneous absorption on a 5% silicone–gum–rubber column on an analytical v.p.c. and on n.m.r., b.p. methyl, 24–25/~2.5 (lit. 48/29, (14)); methyl-d_3, 22–23/~2.5; ethyl, 23/~2 (lit. 42/10, (14)); β-methoxy, 72/~15; and β-chloroethyl, 58/~3.

The purification of solvents and the procedures of kinetic measurements were as reported in the previous paper (17).

The hydrolyses gave cleanly reaction products analyzed by titration and v.p.c. as summarized in eq. 4.

Sur la réduction par les hydrures complexes de quelques benzylidène-3 camphres

JEAN-CLAUDE RICHER ET ARMAND ROSSI[1]

Département de chimie, Université de Montréal, B.P. 6128, Montréal, Québec

Reçu le 10 mai 1971

L'action de $LiAlH_4$, $LiAlH(OtBu)_3$, le tétrakis-(*N*-déhydropyridil) aluminate de lithium (LDPA), et $NaBH_4$ sur quelques benzylidène-3 camphres a été examinée. Les quantités relatives d'addition 1:2 *vs.* 1:4 sur ces dérivés sont déterminées; les résultats obtenus sont discutés en fonction de la nature de l'agent réducteur, du solvant et du caractère électroaffinitaire ou électrorépulsif des substituants portés par le noyau benzénique.

Reduction by $LiAlH_4$, $LiAlH(OtBu)_3$, lithium tetrakis-(*N*-dehydropyridil)aluminate (LDPA), and $NaBH_4$ of several 3-benzylidene camphors have been studied. The relative amounts of the 1:2 *vs.* 1:4 addition are determined. The results obtained are discussed with respect to the nature of reductive species, solvents, and withdrawing and repulsive effects of the aromatic ring substituents.

Canadian Journal of Chemistry, **50**, 438 (1972)

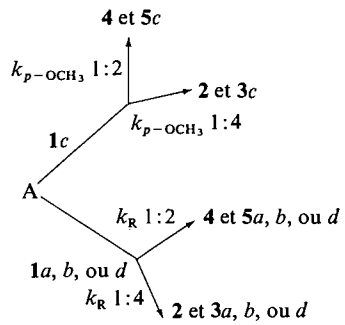
Introduction

Il a été établi antérieurement (1–3) que la réduction par les hydrures complexes de méthylène-3 camphres substitués **1** peut conduire à des quantités variables d'addition 1:2 et 1:4 des hydrures sur le groupement carbonyle conjugué. Afin d'évaluer avec plus de précision la nature des facteurs pouvant influencer le cours de ces réactions, le benzylidène-3 camphre (**1***a*), ses homologues *p*-méthylé (**1***b*), *p*-méthoxylé (**1***c*), et *m*-fluoré (**1***d*) sur le noyau benzénique, et pour lesquels le noyau aromatique occupe une position figée dans le plan du système conjugué (4), ont été réduits par $LiAlH_4$ et $NaBH_4$ dans différents solvants, $LiAlH(OtBu)_3$ dans la pyridine. Les résultats de cette étude font l'objet de la présente communication.

Résultats et discussion

Pour fins de comparaison tous les produits de réduction des benzylidène-3 camphres (**1**) ont déjà été préparés, leurs constantes physiques et leurs caractéristiques spectrales rapportées (5).

Les pourcentages d'addition 1:4 des hydrures sur le système conjugué des benzylidène-3 camphres (**1**) peuvent être résumés dans le tableau 1. Il ressort de ces résultats que le caractère électroaffinitaire ou électrorépulsif influence peu sur les quantités relatives d'addition 1:2 *vs.* 1:4 pour les réductions effectuées dans cette série en milieu aprotique. Parallèlement afin d'évaluer la réactivité relative des composés **1**, la réduction compétitive par $LiAlH(OtBu)_3$ dans le THF à 70 °C et le LDPA dans la pyridine à 35° du *p*-méthoxy benzylidène-3 camphre (**1***c*) et de chacun de ses homologues différemment substitués **1***a*, *b*, ou *d*, de mélanges prélevés, à différents intervalles de temps, sur les milieux réactionnels, permet de constater que les quantités relatives d'addition 1:2 *vs.* 1:4 sont constantes à tous les stades de la réduction (schéma 1). Les lois de vitesse sont donc du même ordre en cétone et en hydrure pour les deux modes d'addition, 1:2 et 1:4. Il a été rapporté



INDICES: p-OCH_3 = *p*-méthoxy benzylidène-3 camphre
R = benzylidène-3 camphres autrement substitués (R = H, p-CH_3, *m*-F)
1:2 = addition 1:2
1:4 = addition 1:4

a X = C_6H_5—
b X = *p*-$CH_3C_6H_4$—
c X = *p*-$OCH_3C_6H_4$—
d X = *m*-FC_6H_4—

d'autre part, que la réduction de cétones saturées par $LiAlH(OtBu)_3$ dans le THF (6) et le LDPA dans la pyridine (7) est du premier ordre en cétone et en hydrure. Dans le cadre de ce travail, il paraît logique d'admettre que l'ordre en cétone est le même pour la réduction du groupe carbonyle d'une cétone α,β insaturée et d'une cétone saturée.[2]

A partir de ces données et en accord avec le schéma réactionnel 1, l'éq. 1 donnant $\log b_0/b$ *vs.* $\log b_0/b'$ a été établie pour l'addition 1:2; b_0 représente la concentration initiale des deux cétones dans les mélanges de réduction, b et b' les concentrations respectives en *p*-méthoxy benzylidène-3 camphre (**1***c*) et ses homologues différemment substitués (**1***a*, *b*, ou *d*) à un instant donné.

$$[1]\quad \log\frac{b_0}{b} = \frac{k_{p\text{-}OCH_3}\,1:2}{k_R\,1:2} \times \left[\frac{1+\dfrac{k_{p\text{-}OCH_3}\,1:4}{k_{p\text{-}OCH_3}\,1:2}}{1+\dfrac{k_R\,1:4}{k_R\,1:2}}\right] \times \log\frac{b_0}{b'}$$

$$\frac{k_{p\text{-}OCH_3}\,1:2}{k_R\,1:2}$$

Les résultats obtenus pour les deux réactions étudiées sont résumés par les courbes (fig. 1).

Les rapports des constantes de vitesse donnés par la pente des droites, sont déterminés par la méthode des moindres carrés. Les valeurs calculées et les coefficients de corrélations *r* sont rapportés dans le tableau 2. Ces résultats nous ont permis d'établir une corrélation de Ham-

[2]Des mesures cinétiques directes sur la réduction du benzylidène-3 camphre ont été effectuées et elles ont permis de mettre en évidence que ces réactions étaient du premier ordre en cétone. Toutefois les valeurs obtenues pour les constantes de vitesse n'ont pu être retenues à cause du manque de précision sur les mesures des concentrations initiales en hydrure.

TABLEAU 2. Mode de réduction

	LiAlH (O*t*Bu)$_3$/THF		LDPA/pyridine	
R	$k_{p\text{-}OCH_3}$ 1:2 / k_R 1:2	r	$k_{p\text{-}OCH_3}$ 1:2 / k_R 1:2	r
H	0.536	0.996	0.382	0.996
p-CH_3	0.662	0.998	0.582	0.994
m-F	0.302	0.998	0.166	0.990

mett, $\log k_H = \log k_{R'} + \rho\sigma$ ($R' = OCH_3$, *p*-CH_3, *m*-F) pour les deux modes d'addition de l'hydrure (1:2 et 1:4) intervenant dans les réactions étudiées. Les courbes (fig. 2) résument les résultats obtenus.

Les valeurs de ρ positives, obtenues pour les additions 1:2 et 1:4 d'hydrure sur les composés **1**, confirment que ces réactions sont favorisées par des substituants à constantes σ positives, c'est à dire attracteurs d'électrons. De plus la différence des valeurs ρ 1:2 − ρ 1:4, faible, est en accord avec le fait que la différence d'énergie libre d'activation pour les deux modes d'addition concurentiels (1:2 et 1:4) reste sensiblement constante et est indépendante du substituant porté par le noyau aromatique. Il semble donc qu'en milieu aprotique la densité de charge répartie sur le système conjugué (groupe carbonyle–double liaison éthylénique) est différente pour chacun des composés **1**; cependant les résultats des réductions semblent indiquer que le rapport des densités de charge des deux sites réagissant est constant et indépendant de la nature des substituants.

Une solvatation spécifique du groupe carbonyle avec formation de liaison hydrogène (8) entre le solvant et l'oxygène du groupe carbonyle peut expliquer les résultats des réductions des benzylidène-3 camphres (**1**) par $NaBH_4$ dans le propanol-2 et le diglyme contenant 2% d'eau. Dans ce cas la conjugaison du groupe aryle avec le groupe carbonyle sera plus importante que dans la cétone libre. La contribution à la résonance allant en décroissant dans le sens: *p*-OCH_3, *p*-CH_3, H, *m*-F et une addition 1:4 détruisant entièrement la conjugaison du système, l'énergie nécessaire pour atteindre l'état de transition diminuera dans le même sens.

Les valeurs rapportées dans le tableau 3 expriment les pourcentages normalisés des benzylidène-3 isobornéols (**4**) par rapport aux isomères *endo* **1** obtenus en cours de l'addition

TABLEAU 3. Quantité d'isomère *exo* obtenu au cours de l'addition 1:2 d'hydrure sur le groupe carbonyle des benzylidène-3 camphres (**1**) et du camphre

Mode de réaction	**1**	Camphre (5)
$LiAlH_4$/éther	84.0	92.0
$LiAlH_4$/THF	96.0–88.0	—
$LiAlH_4$/diglyme	96.0–87.0	—
LiAlH (O*t*Bu)$_3$/THF	94.0	93.0
LDPA/pyridine	67.0	62.5
$NaBH_4$/iso-PrOH	84.0	86.0
$NaBH_4$/diglyme/2% H_2O	82.0	—

1:2 d'hydrure sur le groupe carbonyle des benzylidène-3 camphres (**1**); pour fins de comparaisons les résultats obtenus pour la réduction du camphre (**5**) sont inclus. De ces données, il ressort que l'introduction des groupes benzylidènes en position 3 des cétones **1** influence peu sur la stéréochimie de la réduction du groupe carbonyle comparée aux résultats obtenus pour la réduction du camphre. Au cours de ce travail il a été vérifié également que les alcools **4** et **5** ne réagissent pas dans les conditions utilisées pour la réduction des benzylidène-3 camphres (**1**).

Un autre aspect des résultats obtenus mérite des commentaires. Alors que l'action de LiAlH (O*t*Bu)$_3$ et le LDPA sur les cétones **1** conduit principalement aux cétones saturées **2** et **3** et aux alcools allyliques **4** et **5** (dans tous les cas moins de 3% d'alcools saturés sont formés); en général des quantités plus importantes d'alcools saturés **6**–**9** sont obtenus lors des réductions par $LiAlH_4$ et sont dûes à des traces d'humidité ou à l'addition d'eau utilisée pour décomposer l'hydrure en excès, en accord avec les résultats déjà mentionnés dans la littérature (3). Les pourcentages relatifs des alcools saturés présents dans les mélanges de réduction des cétones **1** par $NaBH_4$ dans le propanol-2 et le diglyme renfermant 2% d'eau sont comparables à ceux qui seraient obtenus en réduisant dans les mêmes conditions, un mélange des cétones saturées (**2** et **3**) dans les proportions *exo*:*endo* de l'ordre de 7:93 [proportions obtenues pour la mise à l'équilibre des deux cétones **2** et **3** (5)] (voir tableau 4).

Les alcools saturés (**6**, **8**, et **9**) présents en fin de réaction proviennent donc, pour les deux derniers cas cités, de la réduction des cétones saturées **2** et **3** correspondantes, obtenus après hydrolyse du borate intermédiaire, produit

TABLEAU 4. Pourcentages relatifs pour la réduction des cétones **1**

	-2 *exo* -3 *endo* **6**	-2 *endo* -3 *exo* **7**	-2 *exo* -3 *exo* **8**	-2 *endo* -3 *endo* **9**
$NaBH_4$/iso-PrOH	41.0	—	18.8	40.2
$NaBH_4$/diglyme/2% eau	42.5	—	12.8	44.7

d'addition 1:4, en accord avec le mécanisme classique proposé déjà par plusieurs auteurs (9, 10), cette réduction se faisant probablement avec une épimérisation du groupe benzyle en position 3 (5).

Partie expérimentale

Pour fins de comparaison tous les produits de réduction des benzylidène-3 camphres (**1**) ont déjà été préparés, leurs constantes physiques et leurs caractéristiques spectrales rapportés (**5**). Les conditions de réduction des benzylidène-3 camphres **1** sont celles décrites pour la réduction des benzyl-3 camphres **2** et **3** (5).

Les temps de rétention de chacun des produits et les conditions expérimentales permettant de faire une analyse complète, en c.p.g. de tous les produits de chaque série sont résumés dans une publication précédente (5).

*(1) Réduction compétitive des benzylidènes-3 camphres **1** par $LiAlH(OtBu)_3$ dans le THF*

On ajoute 20 ml de THF anhydre fraîchement distillé sur $LiAlH_4$, à 0.5 mmol de chaque cétone pesée dans un Erlenmeyer de 50 ml. Le récipient est bouché soigneusement et placé dans un bain à 70 °C pendant 1 h. Cette solution est ajoutée à 20 ml de THF contenant 2 à 4 mmol de $LiAlH(OtBu)_3$, maintenue sous azote et à la même température. Des prélèvements de 10 ml sont effectués à des intervalles de temps différents et hydrolysés dans 30 ml d'une solution de soude à 5%. Après extraction à la manière habituelle, les produits de la réaction sont analysés par c.p.g.

*(2) Réduction compétitive des benzylidène-3 camphres **1** par le LDPA dans la pyridine*

On ajoute 20 ml de pyridine anhydre à 0.5 mmol de chaque cétone pesée dans un Erlenmeyer de 100 ml. Le récipient est fermé hermétiquement à l'aide d'un septum en caoutchouc et placé dans un bain à 35 °C. Un récipient identique contenant une solution de LDPA préparée d'après la méthode décrite par Lansbury et Peterson (11) (1 g de $LiAlH_4$ pour 100 ml de pyridine), est maintenu à la même température. Après 1 h, 20 ml (environ 3 mmol) de la solution de LDPA sont ajoutés à la solution cétonique à l'aide d'une seringue. Le mélange est agité vigoureusement et replacé dans le bain. Des prélèvements sont effectués à différents intervalles de temps à l'aide d'une seringue. Après hydrolyse dans 50 ml d'une solution d'HCl très diluée (2%) et extraction des produits à la manière habituelle, les mélanges réactionnels sont analysés par c.p.g.

Paniculatin, a New Coumarin from *Murraya paniculata* (L.) Jack[1]

WARREN STECK

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received August 16, 1971

The coumarin derivatives osthol and coumurrayin were isolated from foliage of *Murraya paniculata* (Rutaceae). In addition, a new coumarin, *paniculatin*, was obtained. By means of chemical degradation and u.v., n.m.r., and mass spectroscopy, the new compound was identified as 7-methoxy-8-(isovaleryloxy-2-keto-3-methylbutyl)coumarin.

L'osthol et la coumurrayine des dérivés de la coumarine, ont été isolés à partir du *Murraya paniculata* (Rutaceae). En plus, une nouvelle coumarine, la *paniculatine*, a été obtenue. En utilisant la dégradation chimique et la spectroscopie u.v., r.m.n., et de masse, le nouveau composé a été identifié comme étant le méthoxy-7 (isovaléryloxycéto-2 méthyl-3 butyl)-8 coumarine.

Canadian Journal of Chemistry, **50**, 443 (1972)

The plant *Murraya paniculata* (L.) Jack (*M. exotica* L.), family Rutaceae, is known to contain coumarin derivatives. Bose and Mookerjee (1) isolated scopoletin glucoside from the petals, while from other organs Ramstad *et al.* (2) and Dreyer (3) obtained 5,7-dimethoxy-8-(3-methyl-2-butenyl)coumarin (coumurrayin), and Chakraborty *et al.* (4) 5,7-dimethyoxy-8-(2,3-dihydroxy-3-methylbutyl)coumarin (mexoticin).

Gas chromatographic examination of foliage extracts of this plant have now revealed the presence of coumurrayin and several other coumarins. Osthol (7-methoxy-8-(3-methyl-2-butenyl)coumarin) was identified by u.v. and n.m.r. spectroscopy (5) and by co-chromatography with an authentic standard, and two other 8-isopentenyl-type derivatives present only in trace amounts were partly characterized. These, isolated by gas chromatography, had the same fluorescence and u.v. absorption characteristics as osthol. In their n.m.r. spectra doublets could be discerned at δ 6.2, 7.7, 6.9, and 7.4, indicating they were 8-alkyl coumarins (5). Both showed 7-methoxyl at δ 3.9 but the aliphatic end of the spectrum was obscured by instrument noise: in one derivative signals (3H?) could be seen at δ 1.23, 1.31 and 1.70, in the other at δ 1.78 and 2.42. In addition, a new coumarin for which the name *paniculatin* is suggested, was isolated in reasonable quantities and identified as 7-methoxy-8-(1-isovaleryloxy-2-keto-3-methylbutyl)coumarin (**1**) on the basis of the following evidence. The compound had a molecular formula $C_{20}H_{24}O_6$, determined by mass spectroscopy (calcd. and found *m/e* 360.1573), and fluoresced violet under u.v. excitation in the same way as osthol. The u.v. spectrum, λ_{max} (EtOH) 247, 256, and 320 nm, unchanged by the addition of NaOH or $AlCl_3$, was typical of 7-alkoxycoumarins. This was confirmed by the [^{1}H]n.m.r. spectrum in $DCCl_3$ (Fig. 1), in which the characteristic coumarin H-3/H-4 and H-5/H-6 doublet pairs appeared. The position of the H-4 doublet at δ 7.66 showed clearly that no oxygen function was present at C-5, a possibility not excluded by the u.v. spectrum. An oxygen function at C-5 would require the H-4 doublet to be located at $\delta > 7.9$ (6). The H-6 doublet was not meta-coupled, so C-8 must bear a carbon chain. At δ 6.94 was a sharp one-proton singlet with an extremely low field which was reminiscent of the benzylic protons of the coumarins athamantin and archangelicin (7), which resonated at δ 6.97 and 7.12, respectively, under the same conditions. The septet at δ 2.88 was shown by spin decoupling to be coupled ($J = 6.7$ Hz) to the methyl doublets at 1.03 and 1.17, forming an isopropyl group which must be adjacent to a carbon lacking protons entirely. The multiplet at 2.0–2.3 and the coupled doublet at 0.95 indicated the presence of an isovalerate residue.

Mild alkaline hydrolysis of paniculatin gave

[1]NRCC No. 12275.

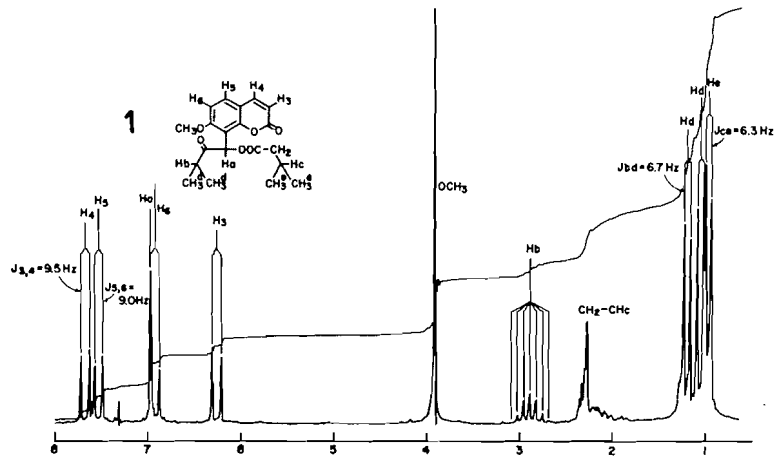

FIG. 1. The 100 MHz[^{1}H]n.m.r. spectrum of paniculatin; solvent, $DCCl_3$; TMS internal standard.

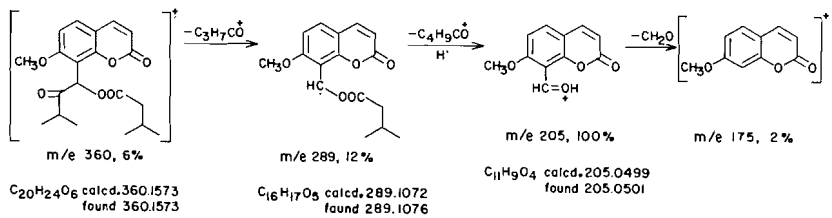

FIG. 2. Fragmentation of paniculatin, from the mass spectrum.

isovaleric acid, a coumarin identified as 7-methoxy-8-(1-hydroxy-2-keto-3-methylbutyl)-coumarin (**2**) and a trace of a compound with the same fluorescence, u.v. absorption, and chromatographic characteristics as authentic 7-methoxy-8-(2-keto-3-methylbutyl)coumarin synthesized from osthol (8). Acid hydrolysis gave a somewhat larger proportion of this last compound along with the same two major products. Isovaleric acid was identified by gas co-chromatography with authentic material on UC-W98 and FFAP columns, and on UC-W98 and 1.5% SE-52 after methylation with diazomethane. A strong odor of isovaleric acid was also apparent in the acidified hydrolyzate. Compound **2** was isolated by g.l.c. and identified by its u.v. and n.m.r. spectra; the absorption spectrum was identical with that of the parent ester. The n.m.r. spectrum was similar except for the absence of isovalerate signals, the appearance of a hydroxyl proton at δ 4.2 and the shift from δ 6.94 to 5.89 of the benzylic proton signal, thus confirming the position of the ester group.

The only structure for paniculatin in harmony with the above spectral, chromatographic, and hydrolytic data is **1**, optical configuration unknown. The mass spectrum of the coumarin supported this assignment, showing major peaks at *m/e* 360 (M) and 289 (M-71, loss of C_3H_7CO), further fragmenting with rearrangement to a very strong base peak at 205 (loss of C_4H_9CO and hydrogen transfer), then to 7-methoxycoumarin ion at *m/e* 175 (loss of CH_2O). Fragment *m/e* peaks at 43 ($C_3H_7^+$), 57 ($C_4H_9^+$), 71 ($C_3H_7CO^+$) and 85 ($C_4H_9CO^+$) corroborated this scheme; the expected metastable peaks were present at *m/e* 232.0 (360 → 289), 145.3 (289 → 205), and 149.3 (205 → 175). High resolution measurements showed the fragment formulas were $C_{16}H_{17}O_5$ at *m/e* 289 and $C_{11}H_9O_4$ at 205, consistent with the scheme shown in Fig. 2.

Paniculatin represents a novel type of coumarin in having an α-keto ester moiety, and is of some biosynthetic interest. It is doubtless derived from 7-hydroxycoumarin, probably via osthol; the subsequent stages in its formation may involve benzylic hydroxylation and esterification of meranzin (osthol epoxide) or meran-

The Basicity of Aliphatic Ethers

Donald G. Lee and Ronald Cameron

Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received October 1, 1971

The pK_{BH^+} values of aliphatic ethers have been calculated from n.m.r. chemical shift data to be approximately -6.4.

Les valeurs des pK_{BH^+} d'éthers aliphatiques ont été calculées à partir des données r.m.n. des déplacements chimiques. Ces valeurs sont voisines de -6.4.

Canadian Journal of Chemistry, **50**, 445 (1972)

Introduction

The basicities of aliphatic ethers is a topic of current interest and debate (1). The results of distribution studies which indicate that the pK_{BH^+}[1] values for these compounds are approximately -3 to -4 were at one time widely accepted (2, 3). However, more recent work has shown that aliphatic ethers may be less basic than the distribution studies suggested. Edward and coworkers (4, 5), on the basis of indicator measurements and n.m.r. studies, found the pK_{BH^+} of diethyl ether to be about -6, while Arnett *et al.* (6), using heats of protonation data, calculated it to be -5.1. Estimated basicity constants obtained by other methods have been tabulated elsewhere (2, 6).

We recently reported an n.m.r. method which gave reliable pK_{BH^+} values for aliphatic ketones (7) and we wish now to report results obtained when the protonation of aliphatic ethers was studied in a similar manner. Although the earlier literature (2, 4) seemed to indicate that n.m.r. chemical shifts were not suitable physical properties to use for protonation studies, later reports have shown that this procedure can be successfully employed with a wide variety of functional groups (7–13).

Edward's most recent results indicate that the chemical shifts of cations are influenced by the solvent through hydrogen bonding; hence the use of ammonium ions as internal standards introduces a potential error into the analysis (14). To overcome this we have used the difference (Δ) between the chemical shifts of α- and β-hydrogens as a measure of the extent of protonation (7). Since the α-hydrogens are closer to the site of protonation they are subject to greater shifts and consequently Δ increases with the extent of protonation. Thus when weak organic bases are dissolved in H_2SO_4 solutions

[1]In this context, pK_{BH^+} is taken to be the H_0 (15) of the solution in which the ether is one-half protonated.

Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received October 1, 1971

The pK_{BH^+} values of aliphatic ethers have been calculated from n.m.r. chemical shift data to be approximately −6.4.

Les valeurs des pK_{BH^+} d'éthers aliphatiques ont été calculées à partir des données r.m.n. des déplacements chimiques. Ces valeurs sont voisines de −6.4.

Canadian Journal of Chemistry, **50**, 445 (1972)

Introduction

The basicities of aliphatic ethers is a topic of current interest and debate (1). The results of distribution studies which indicate that the pK_{BH^+}[1] values for these compounds are approximately −3 to −4 were at one time widely accepted (2, 3). However, more recent work has shown that aliphatic ethers may be less basic than the distribution studies suggested. Edward and coworkers (4, 5), on the basis of indicator measurements and n.m.r. studies, found the pK_{BH^+} of diethyl ether to be about −6, while Arnett *et al.* (6), using heats of protonation data, calculated it to be −5.1. Estimated basicity constants obtained by other methods have been tabulated elsewhere (2, 6).

We recently reported an n.m.r. method which gave reliable pK_{BH^+} values for aliphatic ketones (7) and we wish now to report results obtained when the protonation of aliphatic ethers was studied in a similar manner. Although the earlier literature (2, 4) seemed to indicate that n.m.r. chemical shifts were not suitable physical properties to use for protonation studies, later reports have shown that this procedure can be successfully employed with a wide variety of functional groups (7–13).

Edward's most recent results indicate that the chemical shifts of cations are influenced by the solvent through hydrogen bonding; hence the use of ammonium ions as internal standards introduces a potential error into the analysis (14). To overcome this we have used the difference (Δ) between the chemical shifts of α- and β-hydrogens as a measure of the extent of protonation (7). Since the α-hydrogens are closer to the site of protonation they are subject to greater shifts and consequently Δ increases with the extent of protonation. Thus when weak organic bases are dissolved in H_2SO_4 solutions

[1]In this context, pK_{BH^+} is taken to be the H_0 (15) of the solution in which the ether is one-half protonated.

of various concentrations and the difference in chemical shift between the α- and β-hydrogens is plotted against H_0 (15) sigmoidal curves are obtained, with the inflection points occurring at the position of one-half protonation. Since the α- and β-hydrogens are both in approximately the same chemical environment medium effects are minimized by this procedure.

Experimental

The experimental procedures used were identical to those previously reported (7). The spectra of the unprotonated ethers were all consistent with an approximately first order analysis and with published spectra (16). Diethyl ether exhibited a well defined quartet and triplet under all conditions, while diisopropyl ether gave a doublet and a septet. With the latter compound an additional signal, probably due to cleavage products, was observed in concentrations of H_2SO_4 greater than 80%. However, the presence of this signal did not interfere seriously with the measurement of Δ. The spectrum of tetrahydrofuran consisted of two multiplets both with prominent spikes near their centers. The values of Δ for this compound were consequently measured using the points of these spikes as an estimation of the chemical shifts for α- and β-hydrogens.

Results and Discussion

When the Δ values (Table 1) were plotted against H_0, well defined titration curves were obtained as indicated in Fig. 1. The inflection points of these curves then correspond to the acidity at which the ethers are one-half protonated; *i.e.* the apparent pK_{BH^+} values. A more accurate estimation of the pK_{BH^+} can, however, be obtained from the relationship, $\log [BH^+]/[B] = -mH_0 + pK_{BH^+}$, where [B] is the concentration of unprotonated ether and $[BH^+]$ is the concentration of the protonated species (7). Plots of $\log [BH^+]/[B]$ against H_0 should thus be linear with the intercept equal to the pK_{BH^+} of the compound. Least-squares statistical methods can then be applied to these plots and the apparent pK_{BH^+} values can consequently be defined more precisely. The ratio $[BH^+]/[B]$, which we have designated as I, is equal to $(\Delta - \Delta_B)/(\Delta_{BH^+} - \Delta)$ where Δ_B is the difference between the chemical shifts of the α- and β-hydrogens of the unprotonated ether, Δ_{BH^+} is

†Correlation coefficient.

the same parameter for the protonated ether, and Δ is the chemical shift when the ether is partly protonated.

The calculated values of log I are given in Table 1 and the statistical data obtained from plots of log I against H_0 are summarized in Table 2. These results clearly indicate that the apparent pK_{BH^+} values for these compounds are approximately -6.4, in reasonably good agreement with the most recent results reported by Arnett *et al.* (6) and Edward (5). Hence it can be concluded that aliphatic ethers are one-half protonated in about 80% H_2SO_4.

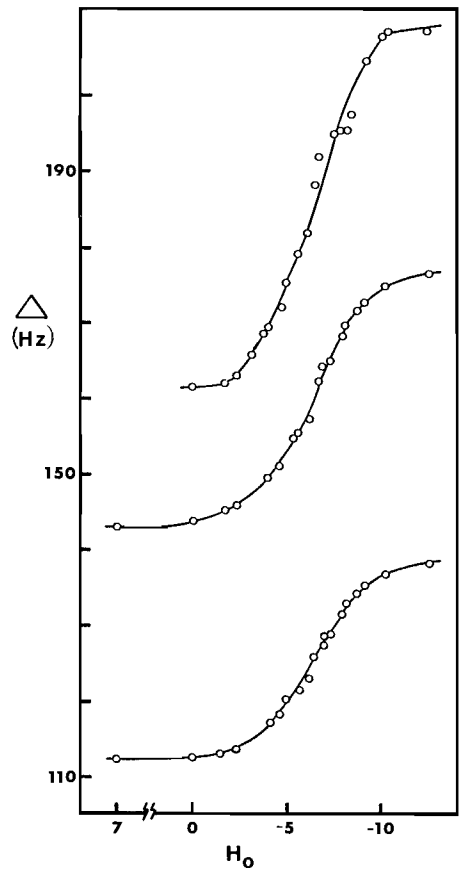

FIG. 1. Titration curves for the protonation of diisopropyl ether, diethyl ether, and tetrahydrofuran (top to bottom).

However, the fact that none of the slopes reported in Table 2 are close to unity indicates that the H_0 acidity function does not correctly define the protonation equilibria for aliphatic ethers. This is not too surprising since it is likely that aromatic amine indicators (on which the H_0 function is based) have different solvation requirements than the aliphatic ethers. Similar observations have previously been made when comparing the protonation of other oxygen bases with this function (9, 11, 13, 17–21).

It should be noted that Edward *et al.* (4) and Arnett (2) have both reported previous attempts to study the protonation of aliphatic ethers in this way. It would appear that their failure to obtain good sigmoidal curves was probably associated with the limited range over which they studied the reaction. Since the slopes of the log I vs. H_0 plots are much less than unity it is necessary to study the behavior of the ethers over a very wide range of acidities.

The authors are grateful to the National Research Council of Canada for financial support.

Application of Factor Analysis to Gas–Liquid Chromatography

PAUL H. WEINER[1] AND DARRYL G. HOWERY[2]

Department of Chemistry, Brooklyn College of the City University of New York, Brooklyn, N.Y. 11210

Received August 12, 1971

The mathematical method of factor analysis is applied to a data matrix of retention indices for 30 solutes on 23 stationary liquid phases. Eight abstract eigenvectors are required to reproduce the data within experimental error. A gas phase imperfection term based on the van der Waals equation of state tests successfully as a fundamental factor of the space. A test vector termed the uniqueness test is used to determine the extent to which molecules possess a particular property. The uniqueness test is applied to rank solutes in terms of (*1*) alcohol-like character and (*2*) electron-donor ability.

La méthode mathématique d'analyse des facteurs est appliquée à une matrice de données d'indices de rétention pour 30 solutés sur 23 phases liquides stationnaires. Huit eigenvecteurs abstraits sont nécessaires pour reproduire les données dans le domaine de l'erreur expérimentale. Un terme d'imperfection de la phase gazeuse fondé sur l'équation d'état de van der Waals se comporte avec succès comme un facteur fondamental de l'espace. Un vecteur test exprime comme par un test d'unicité est utilisé pour déterminer le domaine dans lequel les molécules possèdent une propriété particulière. Le test d'unicité est appliqué pour ranger les solutés en termes du (*1*) caractère d'alcool et (*2*) de possibilité de donneur d'électrons.

Canadian Journal of Chemistry, **50**, 448 (1972)

Recently the mathematical technique of factor analysis has been applied to studies of the determination of activity coefficients in gas–liquid chromatography (1) and of the effect of solvent on proton magnetic resonance spectra (2–5). We report here the use of factor analysis to determine the number and the nature of some of the fundamental factors which govern retention indices in gas–liquid chromatography (g.l.c.).

The mathematical development of factor analysis is presented elsewhere (2, 5). Here it is sufficient to point out that we must be able to express the quantity being factor analyzed as a linear sum of factors each of which is a product function. For retention indices measured in g.l.c., we look for a solution of the form

$$[1] \qquad I_{i,\alpha} = \sum_j U_{ij} V_{j\alpha}$$

where $I_{i,\alpha}$ is the retention index of solute i on stationary liquid solvent α; U_{ij} is the jth solute factor of the ith solute; and $V_{j\alpha}$ is the jth solvent factor of the αth solvent. The sum is taken over the number of controlling factors or eigenvectors, j, necessary to span the factor space. Factor analysis allows us to determine the number of controlling factors, and, by using a least squares mathematical rotational scheme, to test physically significant parameters for possible identification with the abstract eigenvectors of the space.

In g.l.c. the free energy of evaporation of a solute from a stationary liquid solvent in principle can be expressed as a sum of terms representing the free energies of the different types of interactions between the solute and the environment. Rohrschneider (6) states that the retention index also can be given as a sum of terms associated with the different types of solute-stationary phase interactions. He further assumes that each term in the sum can be expressed as a product of solute and solvent parameters. Thus we anticipate that a solution to the retention index problem in the form of eq. 1 does exist and therefore that factor analysis should yield useful information when applied to a matrix of retention index data.

The matrix of experimental data used in the present study was taken from the careful work of Rohrschneider (6) who measured the retention indices of 30 nonpolar and polar solutes on 23 stationary liquid solvents. With the data matrix having rows corresponding to solutes and columns corresponding to solvents, we find by applying the factor analysis technique (2) that a minimum of eight eigenvectors ($j = 8$) are sufficient to span the retention index factor space such that all data are reproduced to better than 1%, *i.e.*, within experimental error. All calculations were performed on a PDP 10 or an IBM 360-40 digital computer, using a Fortran IV program (2).

Now let us see the results of attempts to rotate physically significant parameters of the solutes into the abstract eigenvectors. A major advantage of the factor analysis technique is that each suspected factor can be tested individually by a purely mathematical route without any knowledge of the other factors.

Gas Imperfection Test

One interaction which might lead to variations in retention indices is gas non-ideality. As pointed out by Littlewood (7), several authors have treated this effect using second virial coefficients to estimate gas imperfections. However, reliable values of the second virial coefficients for most of the polar solutes contained in our scheme are not available. We therefore proceeded to evaluate the gas imperfection term using the van der Waals equation of state which holds for both nonpolar and polar solutes.

We can consider the evaporation of a solute to occur in two steps: (*1*) evaporation of the solute from the sorbed state to form an ideal gas and (*2*) transformation of the ideal gas to the real gas at the same pressure. If we assume that the van der Waals equation of state holds for a gaseous solute and that the fugacity of a solute–carrier gas mixture can be evaluated by treating the mixture as ideal even though the components are non-ideal, then the change in free energy per mole for the gas-phase transformation is

$$[2]\quad \Delta G = RT\left\{\left(\ln\frac{RT}{\bar{V}-b}+\frac{b}{\bar{V}-b}-\frac{2a}{RT\bar{V}}\right)-\ln P\right\}$$

$$\approx \frac{RTb}{\bar{V}}-\frac{2a}{\bar{V}}$$

where $\bar{V}$ is the gaseous molar volume, and a and b are the van der Waals constants of the solute. A solute test vector having the form of eq. 2 can be checked for possible rotation into one of the abstract eigenvectors. Fortunately, all the a's and b's need not be available in order to test a given factor; factor analysis predicts values for the missing data if a successful rotation is made (2).

The test for eq. 2 at 373 °K using critical constant data to calculate the a's and b's is shown in Table 1. If each of the test points on the test vector is rotated to a nearly equivalent value on the abstract eigenvector, we have indeed identified a physically significant parameter with an abstract factor. The reasonable agreement between the theoretical free energy test term calculated from eq. 2 and the complete rotated vector clearly indicates that gas imperfection is a factor of the retention index space and does have a measurable effect on retention index. Unfortunately, the magnitude of the effect cannot be predicted by factor analysis unless all eight factors (2) are identified. The form of eq. 2 is consistent with the form required for the product-type terms in eq. 1, with the solute term being evaluated by eq. 2 and the solvent part being unity. Predicted values of the non-ideality term for those gases for which van der Waal constants were missing are also included in Table 1.

Uniqueness Test

The rotation part of the factor analysis scheme has considerable potential for determining on a qualitative scale the extent to which a molecule

or group of molecules possesses a property which would lead to a unique type of interaction. For this "uniqueness" test, a crude test factor is created in which those solutes felt to possess this unique factor are assigned a value of unity and those solutes which are felt not to have the attribute are assigned a value of zero. If one is in doubt about the value to assign a particular solute in the test vector, that solute can be allowed to free float, *i.e.*, left blank, to avoid biasing the test vector. We recall that factor analysis yields values for the missing points if the test vector is rotated into an eigenvector of the factor space.

A uniqueness test of this kind was tried for the alcohols, which should be unique among the 30 solutes in their potential for hydrogen bonding. Since Rohrschneider speculated that chloroform also exhibits hydrogen-bonding characteristics (6), the value for chloroform in particular was allowed to free float. The uniqueness test for alcohols given in Table 1 indicates that alcohols definitely have a unique property since the predicted value for each of the alcohols is quite near one whereas nearly all the other solute terms are near zero. The value predicted for chloroform shows that chloroform does exhibit some alcohol-like character. The quite high value predicted for pyridine suggests that pyridine (which cannot be a hydrogen-bond donor) might be a unique solute. A pyridine uniqueness test (Table 1) shows that pyridine is truly unique, as suggested by Rohrschneider (6).

Rohrschneider also postulated that the nitro group and the nitrile group each shows distinctive properties (6). A uniqueness test for acetonitrile in which all the other solutes are assigned values of zero predicted a low value for acetonitrile, implying that the nitrile group is not unique. If the nitro-containing solutes and other solutes which might have properties similar to those of the nitrile group are allowed to free float during the nitrile uniqueness test, we find that the nitro- and nitrile-containing solutes have rotated values quite near one while several of the free floated solutes have relatively large values. Essentially the same results were obtained from a uniqueness test for nitro compounds in which acetonitrile and several other solutes were free floated and from a combined test for nitro-nitrile solutes. The results of three illustrative rotations are presented in Table 1. We conclude that individually the nitro and nitrile groups do not have unique behavior, but that the nitro-nitrile combined test defines an upper limit to a test vector. This uniqueness test may furnish an estimate of the combined ability of a solute to function as an electron donor and as a hydrogen-bond acceptor (6).

We express our appreciation to Edmund R. Malinowski for helpful discussions and to the Computer Centers at Stevens Institute of Technology and Brooklyn College. This work was supported by a grant from the City University of New York Faculty Research Award Program.

Gallium(III)-trisfluorosulfate

A. STORR, P. A. YEATS, AND F. AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 19, 1971

Gallium(III)-trisfluorosulfate is prepared by the reaction of gallium(III)-trichloride with either $S_2O_6F_2$ or $BrOSO_2F$. The i.r. spectrum is interpreted in terms of a polymeric compound containing bridging bidentate fluorosulfate groups only, thus resulting in hexacoordination around gallium. Gallium(III)–trisfluorosulfate is found to react with trimethylamine, however adducts of variable composition are formed.

Le trifluorosulfate de gallium(III) a été préparé par action du trichlorure de gallium sur $S_2O_6F_2$ ou sur $BrOSO_2F$. Le spectre infrarouge est interprété en fonction d'un composé polymérique contenant uniquement des groupes fluorosulfates bidentates servant de ponts; il en résulte ainsi une hexacoordination autour du gallium. Le trifluorosulfate de gallium(III) réagit avec la triméthylamine en donnant des produits de composition variable.

Canadian Journal of Chemistry, **50**, 452 (1972)

Introduction

We became interested in the synthesis and the structural characterisation of anhydrous gallium(III)-trisfluorosulfate $Ga(SO_3F)_3$ for a number of reasons. Only very few stable binary metal trisfluorosulfates are reported (1). Aluminum(III)-trisfluorosulfate appears to be obtainable only as a 1:3 complex with acetonitrile (2) and only for the recently reported $Fe(SO_3F)_3$ (3), an i.r. spectrum and magnetic susceptibility measurements are reported.

On the other hand, of the gallium(III) salts with oxyanions only $Ga_2(SO_4)_3$ (4) is said to exist in its anhydrous form, whereas $Ga(ClO_4)_3$ (5) and $Ga(NO_3)_3$ (6) are known as hydrates with all dehydration attempts resulting in the formation of basic salts (7).

Gallium(III)-fluorosulfate could feasibly act in the HSO_3F solvent system as an acid, that is as an SO_3F^- ion acceptor, and could play a similar role as $B(SO_4H)_3$ in the sulfuric acid system (8). Not many solutes are known to act as acids in the HSO_3F system (9).

Suitable fluorosulfonating agents can be seen in peroxydisulfuryl difluoride (10) ($S_2O_6F_2$) and in bromine(I)-fluorosulfate (11) ($BrOSO_2F$). Both have been found to replace chlorine quite readily (12, 13), so that $GaCl_3$ could be used as the substrate resulting hopefully in the formation of anhydrous $Ga(SO_3F)_3$.

The compound should also be a suitable Lewis acid and is expected to form addition compounds with trimethylamine.

[1]To whom all correspondence should be addressed.

Experimental

Chemicals

Gallium(III)-chloride was prepared and purified as previously described (14). Peroxydisulfuryl difluoride was obtained in a flow reaction of F_2 (Allied Chem. Corp.) with SO_3 (Baker and Adamson) over AgF_2 according to Cady and Shreeve (15). Bromine(I)-fluorosulfate was synthesized from Br_2 (British Drug House Corp. Ltd.) and $S_2O_6F_2$ as reported before (16). Trimethylamine was obtained from Matheson of Canada and HSO_3F was purified by double distillation according to Barr *et al.* (17).

Instrumentation

The i.r. spectra were obtained on a Perkin–Elmer 457 spectrophotometer. Silver chloride and bromide as well as KRS-5 (all from Harshaw Chemicals) were used. All manipulations were carried out either in a standard high vacuum line, fitted with greaseless Teflon stem stopcocks for the transfer of $S_2O_6F_2$ or $BrOSO_2F$, or in a glove box, filled with dry nitrogen.

Preparation

(a) $Ga(SO_3F)_3$

The reaction between $S_2O_6F_2$ (present in an approximately 10-fold excess) and $GaCl_3$ is performed in a 100 ml Pyrex reactor with a flat bottom. Gallium trichloride is introduced in the drybox through an attached side arm fitted with B14 ground-glass joint from a small storage ampule via sublimation. The side arm is sealed off after addition, the amount of $GaCl_3$ added can be determined by weighing the ampule before and after addition. $S_2O_6F_2$ is introduced through a Teflon stem stopcock via distillation. The reaction mixture is allowed to warm up to room temperature where immediate exothermic reaction and the release of Cl_2 is noted. A fine white powder is formed. The reaction mixture is stirred externally, in order to complete the reaction, for about 1 h. The volatile reaction product and the excess $S_2O_6F_2$ are removed under vacuum, $Ga(SO_3F)_3$ is left behind as a hygroscopic white powder. In a typical reaction 1.318 g $GaCl_3$ are converted into 2.733 g $Ga(SO_3F)_3$, indicating complete conversion.

The reaction of $GaCl_3$ with $BrOSO_2F$ is carried out in the

same way. The reaction proceeds less vigorously and a slightly yellowish powder is left behind.

(b) $Ga(SO_3F)_3.xN(CH_3)_3$

When an excess of trimethylamine is condensed onto samples of $Ga(SO_3F)_3$, ranging in amounts from 150 to about 400 mg, solid white products are formed which exhibit $Ga(SO_3F)_3:N(CH_3)_3$ ratios of 1:1.2 to 1:1.7. A typical analysis is given below. All products were found to be thermally stable up to 230 °C. Analysis: Gallium was determined gravimetrically as the 8-hydroxyquinolate. Microanalysis for carbon was done by Mr. P. Borda of this department and analysis for S and F was carried out by A. Bernhardt, microanalytical laboratory in Elbach, West Germany.

Anal. Calcd. for $Ga(SO_3F)_3.N(CH_3)_3$: Ga, 16.38; C, 8.46. Found: Ga, 15.80; C, 9.95.

Discussion

Gallium(III)-trisfluorosulfate is formed in a fast and clean reaction from $GaCl_3$ and $S_2O_6F_2$ or $BrOSO_2F$, according to

$$2GaCl_3 + 3S_2O_6F_2 \xrightarrow{25\ °C} 2Ga(SO_3F)_3 + 3Cl_2$$

or

$$2GaCl_3 + 6BrOSO_2F \xrightarrow{25\ °C} 2Ga(SO_3F)_3 + 3Cl_2 + 3Br_2$$

Since $BrOSO_2F$ is obtained from $S_2O_6F_2$ the first route is less circuitous and therefore preferable. The obtained product is thermally stable without melting up to 320 °C at atmospheric pressure. The thermal decomposition under vacuum starts at 240 °C and proceeds rather slowly under the release of sulfur trioxide only. Disulfuryl difluoride ($S_2O_5F_2$) and sulfuryl fluoride, the two other likely products in a pyrolysis of metal fluorosulfates (3) are not observed. Attempts to study the solution behavior of $Ga(SO_3F)_3$ in HSO_3F failed. Addition of the solute to the acid did not result in any change of the specific conductance, it must therefore be concluded that the compound is completely insoluble in this medium as is visually apparent. Addition of KSO_3F did not increase the solubility of $Ga(SO_3F)_3$. This observation may possibly be interpreted in terms of a polymeric structure for gallium(III)-trisfluorosulfate.

All attempts to synthesize other group III fluorosulfates with either $S_2O_6F_2$ or $BrOSO_2F$ as fluorosulfonating agents were unsuccessful. Neither $AlCl_3$, $InCl_3$, nor indium metal were found to react even at temperatures up to +100 °C.

The i.r. spectrum of $Ga(SO_3F)_3$ is rather uncomplicated, indicating the presence of only one type of SO_3F group in the molecule. The vibrational frequencies are listed in Table 1 together with the corresponding modes for some related compounds and a proposed assignment.

It has been pointed out before (3, 18, 19) that the symmetry of the free SO_3F^- ion will be reduced from C_{3v} to C_s where the SO_3F group acts as a covalently bonded mono- or bidentate group. As a consequence the number of fundamentals will increase from 6 to 9, all i.r. and Raman active.

A decision, whether a monodentate or a bidentate fluorosulfate group is present can be made when considering the position of the three SO stretching modes. These three modes are produced from the 2 SO_3 modes in ionic SO_3F^-, an A_1 mode found at 1080 cm^{-1} and an E mode

at 1285 cm^{-1} (20), when the degeneracy of the latter is lifted and the band splits up.

For $(CH_3)_2Sn(SO_3F)_2$ (21), where the existence of bidentate bridging SO_3F group is demonstrated by X-ray diffraction (22), and for $SnCl_2(SO_3F)_2$ (18), where a similar configuration is postulated based on the ^{119}Sn Mössbauer spectrum, the two higher SO stretching modes are found at 1355–1385 and 1130–1180 with the position of the last SO mode virtually unchanged in respect to its position for KSO_3F.

For monodentate SO_3F groups, as found in solids of the type $K[Hal(OSO_2F)_4]$ (19) with Hal = Br and I, the three SO modes are found at ~1410, ~1240, and ~985 cm^{-1}, respectively.

As seen in the table, not only the stretching but also the deformation modes of the SO_3F group in $Ga(SO_3F)_3$ compare well to the identical modes in the two tin(IV) derivatives. It is on this evidence that we prefer to interpret the i.r. spectrum in terms of a bidentate bridging SO_3F group in $Ga(SO_3F)_3$, with bridging occurring over two oxygen atoms. This will result in hexacoordination for gallium, GaF_3 and most modifications of Ga_2O_3 (23, 7) are precedents for this coordination among simple binary gallium(III) compounds, and in a polymeric structure, consistent with our previous observations.

The relatively close resemblance of the i.r. spectra of $Ga(SO_3F)_3$ and $Fe(SO_3F)_3$ (3) suggests a similar conformation of the SO_3F group in both compounds.

In addition to the discussed absorption bands, attributed to the SO_3F group, a broad and rather weak band is found at 445 cm^{-1}. We interpret this absorption as being due to gallium–oxygen stretching. Attempts to obtain a Raman spectrum on the solid were unsuccessful.

The interaction of $Ga(SO_3F)_3$ with trimethylamine proceeds spontaneously at room temperature under formation of white, thermally stable solids. However, in contrast to observations in the $GaCl_3$–$N(CH_3)_3$ system (24), where 1:1 adducts are obtained under these conditions, the uptake of amine was higher resulting in composition between 1:1 and 1:2 stoichiometry. The amine uptake was found to be highest where finely powdered samples of $Ga(SO_3F)_3$ were used. Similar observations were made by us (25) in reaction of a large range of N-donor ligands with a number of methyltin(IV)-fluorosulfate compounds where also bridging bidentate SO_3F groups are present (12, 21, 22). The observations reported here again suggest a polymeric structure for $Ga(SO_3F)_3$.

This study was financially supported by the National Research Council of Canada.

A Novel Phosphate Protecting Group for Oligonucleotide Synthesis

R. H. WIGHTMAN

Biochemistry Laboratory,[3] National Research Council of Canada, Ottawa, Canada K1A 0R6

Received November 10, 1971

2-Phenylmercaptoethanol is found to be a very stable phosphate protecting group during oligonucleotide synthesis. However, when necessary it can be easily removed, after activation.

Le phényl-2 mercaptoéthanol apparaît comme étant un groupe phosphate protecteur très stable pendant la synthèse d'oligonucléotides. Il est cependant facile à enlever, après activation, lorsque c'est nécessaire.

Canadian Journal of Chemistry, **50**, 456 (1972)

Protection of the terminal phosphomonoester group is a necessary step in any chemical synthesis of oligonucleotides. We wish to report 2-phenylmercaptoethanol (**1**) (1) as a new phosphate protecting group which is easily introduced and stable to conditions normally encountered in oligonucleotide manipulations, such as (*i*) 1 *N* aqueous sodium hydroxide at room temperature for 8 h, (*ii*) concentrated ammonium hydroxide at 50° for 2 h, (*iii*) aqueous pyridine at room temperature for 1 week, (*iv*) mesitylene sulfonyl chloride in anhydrous pyridine at room temperature for 3 h, (*v*) aqueous hydrochloric acid (p*H* 2) at room temperature for 3 days. However, when "activated" this group is readily removed. Additionally, it incorporates one benzene ring to take advantage of the absorptive property of benzoylated DEAE Sephadex for purification of products (2).

Protection of the deoxymononucleotide 5′-phosphate **2** was completed in 24 h by treating its pyridinium salt with 2-phenylmercaptoethanol and dicyclohexylcarbodiimide (both in 10 *M* excess). Unused DCC was then decomposed with aqueous pyridine, the urea filtered off, and excess reagent removed by extraction with ethyl acetate. The aqueous phase was concentrated and a final purification was achieved by gel-filtration on a Sephadex G-25 (superfine) column, using 0.1 *M* triethylammoniumbicarbonate buffer, (p*H* 7.5) as eluant.

Each of the protected mononucleotides **3** was condensed with 3′-*O*-acetyl thymidine 5′-phosphate **4**. Work-up with aqueous pyridine and 2 *N* aqueous sodium hydroxide followed by sequential chromatography on benzoylated DEAE Sephadex and Sephadex G-25 superfine (2) gave the desired protected dinucleotides **5** (see Scheme 1). The 2-phenylmercaptoethyl group was removed by treating the protected nucleotide in aqueous solution (or in 0.1 *M* triethylammoniumbicarbonate) with sodium metaperiodate (approximately 5 *M* excess, as a freshly prepared 0.1 *M* aqueous solution) at room temperature for 1 h. It was apparently oxidized to the corresponding sulfoxide derivative **6** (3). After decomposition of the excess periodate with ethylene glycol and precipitation of inorganic residues with 90% aqueous pyridine, the free dinucleotide **7** was liberated by treatment with 2 *N* aqueous sodium hydroxide at room temperature for 30 min. A similar approach has been reported (4) for peptide synthesis.

Since some *N*-acetyl groups were labile to alkali, we found it more convenient for this initial investigation to deblock any amino func-

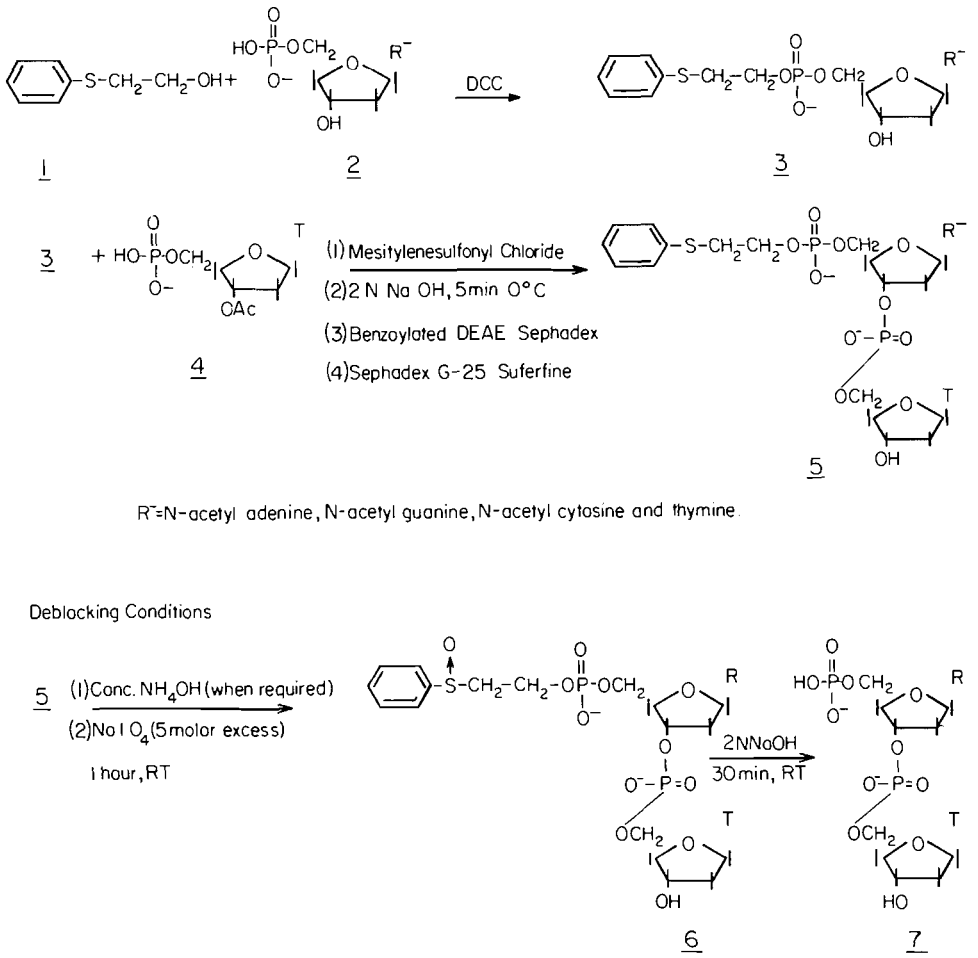

SCHEME 1

tions before activating the 2-phenylmercaptoethyl group for removal. Consequently each of the four 5′-mononucleotides (*i.e.* d-pA, d-pC, d-pG, and pT) obtained from **3** via a complete deblocking sequence were fully characterized by t.l.c. in three solvent systems (5) and u.v. spectroscopy to ensure that the periodate treatment in no way affected the heterocyclic bases. Indeed all the dinucleotides **7** were characterized by t.l.c. as well as u.v. spectra of the components obtained by enzymic degradations. We feel the properties of this protecting group, make it more generally applicable than 2-cyanoethanol (6) for many aspects of oligonucleotide synthesis.

We wish to acknowledge helpful suggestions by Dr. T. Durst, Department of Chemistry, University of Ottawa.

The reaction of acetylene with silicon difluoride at low temperatures has been studied. Three products have been identified as volatile species after the reaction: tetrafluorodisilacyclobutene, 3,4-tetrafluorodisilahex-1-yne-5-ene, and 5,6,7-hexafluorotrisilanorborn-2-ene. Spectroscopic data for the compounds are presented, together with a possible mechanism to account for the formation of the observed products.

La réaction de l'acétylène avec le difluorure de silicium a été étudiée à basse température. Trois produits ont été identifiés comme des espèces volatiles après la réaction: le tétrafluorodisilacyclobutène, le 3,4-tétrafluorodisilahex-1-yne-5-ène et le 5,6,7-hexafluorotrisilanorborn-2-ène. Les données spectroscopiques des composés sont présentées en même temps qu'un mécanisme possible pour rendre compte de la formation des produits observés.

Canadian Journal of Chemistry, **50**, 459 (1972)

Introduction

The low-temperature reaction chemistry of silicon difluoride (SiF_2) has been the subject of a number of recent studies, and has resulted in the formation of a variety of new silicon–fluorine derivatives (1). Of considerable interest has been the reactivity of SiF_2 with unsaturated organic compounds such as ethylene (2), benzene (3), and trifluoropropyne (4). We have studied the reactions of SiF_2 with a range of alkyne and alkene derivatives, and shall report the products from these reactions in this and subsequent papers.[3]

Experimental

A greaseless vacuum system was used for the reactions and for the manipulation of volatile compounds which were studied by mass spectrometry, n.m.r. spectroscopy, and i.r. spectroscopy.

SiF_2 (gas) was prepared, as has been described previously (5), by reduction of silicon tetrafluoride with silicon metal at 1150 °C. The gaseous mixture of SiF_2 and SiF_4 was co-condensed at −196 °C with an approximately 2:1 excess of

acetylene. Such conditions led to the largest quantities of volatile products, which, however, were only formed in up to 5% yield based on acetylene consumed in the reaction.

Results

(i) Reaction between SiF_2 and $HC{\equiv}CH$

Co-condensation of the reagents at −196 °C produced a reddish-brown condensate, which, on warming slowly to room temperature, evolved volatile material and left a brown residue.

(ii) Involatile Residue

The residue was spontaneously inflammable in moist air, the heat evolved during combustion being sufficient to melt Pyrex glass, and also dissolved violently in dilute HF or KOH solutions. Heating in vacuo at 250–300 °C led to the formation of only small quantities of volatile material, insufficient for further investigation, while a small quantity of the residue exploded in the vacuum line at about 350 °C. The solid was insoluble in all solvents with which it did not react, and hence little is known of its composition or structure.

(iii) Volatile Material

SiF_4 and $HC{\equiv}CH$ were removed by distillation at −120 °C, after which the remaining volatile species were further separated by trap-to-trap distillation into two main fractions.

(a) Fraction Held at −80 °C, Volatile at −55 °C

At room temperature this was a colorless liquid and was shown mass spectrometrically to contain two species of *m/e* 158 and 184, corresponding to molecular formulae $C_2H_2Si_2F_4$ (**1**) and $C_4H_4Si_2F_4$ (**2**). Due to their similar volatilities and to the ready decomposition of (**1**), the two compounds could not be separated by distillation and **1** was never obtained in a pure state. However, by allowing the mixture to stand at room temperature for 3 h, it was found that no **1** remained as a volatile species, but that a spontaneously inflammable solid residue remained. Thus **2** could be obtained in a relatively pure form, but attempts to remove all traces of impurities (such as Si_3F_8, detected by n.m.r. and mass spectrometry) by gas chromatography failed due to its ready decomposition on the columns used. The gas phase molecular weight of **2** was 187 ± 5, which is further support for the molecular formula suggested from the mass spectrum. Nuclear magnetic resonance spectra were obtained from mixtures of **1** and **2** and from **2** alone, thus allowing some of the details of the spectra of **1** to be deduced. The results are shown in Fig. 1 and Table 1. Gas phase i.r. spectra of the mixture and of **2** showed only minor differences, which did not permit assignment of specific absorptions to **1**. However, **2** showed characteristic bands at (cm^{-1}) 3315(m) (νH—C≡), 3016(m) (νH—C=), 2165(w) (νC≡C), 1599(w) (νC=C), and 920(vs) (νSiF). Hydrolysis of **2** with dilute HF yielded approximately equal amounts of acetylene and ethylene.

On the basis of all these results the structures shown in Fig. 1 are assigned to **1** and **2**.

A planar four-membered ring for **1** would in

theory show n.m.r. patterns corresponding to the $A_2A_2'XX'$ spin-system. No full analysis of our spectra has yet been attempted, but it is noted that the observed patterns are quite similar in appearance, for both the A and X parts, to those observed and analyzed for the analogous spin-system in perfluorocyclobutene (6). The highly strained ring, with a comparatively weak silicon–silicon bond, might be expected to result in an unstable compound as we

observed. No information has yet been obtained as to the mode of decomposition or the nature of the eventual pyrophoric products.

The asymmetric open-chain structure of **2** is assigned from the n.m.r. and i.r. spectra. As has been found in other vinyl-substituted silicon fluorides (7), the three protons in the vinyl group have similar chemical shifts and are highly coupled amongst themselves and to two pairs of fluorine atoms resulting in the very complex multiplet observed in the proton spectrum.

(b) Fraction Held at −35 °C, Volatile at −10 °C

This contained colorless needle-like crystals (m.p. 34°) which sublimed in the vacuum system. The mass spectrum showed the heaviest ion at *m/e* 250, which corresponds to a formula $C_4H_4Si_3F_6$ **3**, with an important fragment at *m/e* 52 ($C_4H_4^+$). Elemental analysis (Crobaugh Laboratories) confirmed the molecular formula.

Anal. Calcd. for $C_4H_4Si_3F_8$: H, 1.6; C, 19.2; Si, 33.6; F, 45.6. Found: H, 1.68; C, 19.31; Si, 32.88; F, 46.14.

3 was not very soluble in common organic solvents, but satisfactory n.m.r. spectra were eventually obtained from dilute solutions in $CDCl_3$. The spectra (Table 1 and Fig. 2) showed several important differences from those obtained from **2** and indicated that **3** was not a simple homologue of **2** with the additional SiF_2 unit in the chain. The fluorine spectrum indicates single non-equivalent fluorine atoms coupled in pairs, while the equal relative intensities of the two resonances in the proton spectrum show equal numbers of hydrogen atoms. On the basis of this n.m.r. data the structure shown in Fig. 2 is indicated. The rigid skeleton of this trisilanorbornene derivative leads to four types of chemically non-equivalent fluorine atoms (5 or 6, 5′ or 6′, 7 and 7′) and the spin-coupling of, for example 5 with 5′ and 6′, accounts for the observed n.m.r. spectra. The chemical shift differences between the geminal fluorine atoms of 17.4 (5′ and 6′) and 19.2 (7′) p.p.m. are similar to those found in some norbornene derivatives with CF_2 in the 7-position, where typical chemical shift differences ranged between 16 and 20 p.p.m. (8). However the *gem F*—Si—*F* coupling of 56.0 Hz in the 7-position is considerably lower than J_{F-C-F} of around 175 Hz found previously (8, 9). Since **3** represents the first silicon fluorine compound for which $J_{FF(gem)}$ can be determined, it is not yet possible to say whether the smaller value may be characteristic of SiF_2 compounds or whether it is associated with the structure of this particular compound.

Preliminary results from a single crystal X-ray structure determination have confirmed the structure of **3** as shown in Fig. 2. Full details of the structure will be reported when refinement of the data is completed (11).

Discussion

With the exception of **3**, which has in addition a single bridging SiF_2 unit, each of these compounds is apparently formed by attack of Si_2F_4 radicals on the acetylenic triple bond. Such disilicon-compounds are apparently the general type of product formed in SiF_2 reactions with unsaturated carbon compounds, except when there is a fluorine atom directly bound to unsaturated carbon (2, 3). It thus seems likely that the initial stages of the reaction proceed via

$$HC{\equiv}CH + \cdot Si_2F_4 \cdot \rightarrow \underset{a}{H\dot{C}{=}CH{-}SiF_2{-}\dot{S}iF_2}$$

The intermediate species *a* may then undergo either ring closure to form **1**, or reaction with further SiF_2 units probably forming polymers, or reaction with acetylene to form a second possible intermediate

$$\underset{b}{H\dot{C}{=}CH{-}SiF_2{-}SiF_2{-}CH{=}\dot{C}H}$$

We do not isolate the ring closure product of (*b*), which would be a 5,6-disilacyclohexa-1,3-diene, however **3** might be regarded as being formed from reaction of SiF_2 with the cyclic diene. The reason for the formation of the single silicon bridge is not at all clear, since no other monosilicon units have been found in this type of reaction, and it is known that this disilacyclohexadiene system is not inherently unstable (ref. 4, and part 2 of this series). **2** may be formed from (*b*) through a 1,5-hydrogen migration to form the unsymmetrical chain compound. Such migrations involving vinyl-type radicals have been previously postulated to explain the range of products found in other free radical addition reactions to substituted acetylenes (10).

A proposed reaction scheme for SiF_2–acetylene reaction is shown in Scheme 1.

Received September 16, 1971

The reactions between silicon difluoride and propyne, propyne-d_1, 1-butyne, 2-butyne, and 3,3-dimethyl-1-butyne were studied. In each case products resulting from combining ratios (SiF_2:alkyne) of 2:1 and 2:2 were isolated and identified. The 2:1 compounds were shown to be derivatives of disilacyclobutene, while three types of 2:2 compounds were identified. These either had an open chain structure, resulting from migration of either α (to C≡C)—CH or acetylenic H, or were derivatives of disilacyclohexadiene. Rationalizations of the types of products found and of the conditions which affect the reaction mechanism are discussed.

On a étudié les réactions entre le difluorure de silicium et le propyne, le propyne-d_1, le butyne-1, le butyne-2 et le diméthyl-3,3 butyne-1. Dans chaque cas, on a isolé et identifié les produits résultant des rapports de combinaison (SiF_2:alcyne) de 2:1 et 2:2. On constate que les composés 2:1 sont des dérivés du disilacyclobutène, alors que trois types de composés 2:2 ont été identifiés. Ceux-ci avaient, soit une structure à chaîne ouverte, résultant de la migration du H acétylénique ou celui en α du CH (en C≡C), ou étaient des dérivés du disilacyclohexadiène. On discute des rationalisations des types de produits isolés et des conditions qui affectent le mécanisme de réaction.

Canadian Journal of Chemistry, **50**, 465 (1972)

Introduction

We have recently reported the reactions of silicon difluoride (SiF_2) with acetylene (1) and with 3,3,3-trifluoropropyne (2). In both of these systems we identified derivatives of disilacyclobutene formed by combination of two SiF_2 units with one molecule of the alkyne. In addition we also found products resulting from 2:2 combination of the reagent molecules. In the case of acetylene this product was a straight chain compound resulting from migration of an acetylenic hydrogen atom during the reaction. However, from trifluoropropyne this was not observed and we identified the 2:2 product as a derivative of disilacyclohexadiene. We now report our results from studies of the reactions of SiF_2 with a number of alkyl-substituted alkynes, which give products similar to those mentioned above, but also show that a further hydrogen migration may occur in specific cases.

[1]To whom correspondence should be addressed (Toronto).

Experimental

All volatile products were manipulated in a greaseless vacuum system. SiF_2 was prepared as previously described (3) and co-condensed with approximately equimolar quantities of the alkyne reagants. The latter were either commercially available or were prepared ($CH_3C{\equiv}CD$ (4) and $(CH_3)_3CC{\equiv}CH$ (5)) by standard methods. Reaction products were separated by trap-to-trap distillation and examined by n.m.r., i.r., and mass spectroscopy.

Results

Each alkyne formed a brownish-yellow deposit on co-condensation with the SiF_2/SiF_4 mixture at −196 °C. On gently warming to room temperature, volatile material was evolved and a yellow involatile residue remained. Except in the reaction of $(CH_3)_3CC{\equiv}CH$ (see below), no further products were obtained from heating the solid residues. Each was spontaneously inflammable in air and dissolved vigorously in dilute HF or KOH solutions.

In addition to SiF_4 and excess unreacted alkyne, the volatile products also contained

compounds formed from combination of SiF_2 and alkyne in the ratios 2:1 and 2:2. Distillation temperatures are given in Table 1.

*(i) 2:1 Compounds (**1–5**)*

The molecular formulae were established by mass spectrometry (Table 2) and structural evidence obtained from the i.r. (Table 3) and n.m.r. (Table 4) spectra. All the evidence supports the assignment of the structure of each of these compounds as a derivative of disilacyclobutene. Such was also the case in the reactions of acetylene and trifluoropropyne, whose n.m.r. data are also given in Table 4 for comparison.

None of these compounds is very stable at room temperature, turning yellow within a few minutes and subsequently forming involatile residues. This process is thought to be polymerization. In the product from propyne (**1**) it was observed that the n.m.r. signal due to the vinylic proton decreased in intensity while a new broad peak at τ 7.90 increased in intensity. Thus the polymerization probably involves reaction at the C=C bond perhaps being preceded by cleavage of Si—C or Si—Si bonds.

The i.r. and Raman data for the product from butyne-2 (**4**) are consistent with a molecule of C_{2v} symmetry and agree with the supposition of a planar ring indicated by the n.m.r. data.

(ii) 2:2 Compounds

*(a) From Propyne (**6**), Propyne-d_1 (**7**), 1-Butyne (**8**), 2-Butyne (**9**)*

The mass spectrometric, i.r., and n.m.r. data are given in Tables 2, 3, and 5, respectively, and the proton n.m.r. spectra shown schematically in Fig. 1. All the evidence points to open chain compounds of the type shown in Table 5. The assignment of specific groups *trans* to each other at R_4 and R_6 is based on the magnitude of the H–H coupling constants of about 19 Hz when $R_4 = R_6 = H$.

Each of these products results from H-migration when there is the CH—C≡C grouping in the starting alkyne, and when this condition is met, this particular mode of reaction appears to be the favored one since we have no evidence in these reactions for the types of compounds (to be discussed below) found in reactions with the remaining alkynes.

Alcoholysis of **6** with methanolic KOH in a vacuum sealed tube yielded allene as the most volatile product, a small amount of oily liquid tentatively identified from its n.m.r. and mass spectra as $H_2C{=}C{=}CH{-}Si(OCH_3)_2{-}Si(OCH_3)_2{-}CH{=}CHCH_3$, a series of compounds, probably $(CH_3O)_nSi_2F(5-n)CH{=}CHCH_3$, mixed with excess methanol and an

unidentified white solid. The liberation of allene is further evidence for the proposed structure. Similar results and the formation of methylallene were obtained from **8** and **9**.

*(b) From 3,3-Dimethyl-1-butyne (**10** and **11**)*

Two isomers of a 2:2 compound were obtained: one liquid which was volatile at room temperature in the vacuum system, and a second compound which was sublimed as colorless crystals from the reaction residue at 60 °C. Mass spectrometric, i.r., and n.m.r. data are given in Tables 2, 3, 6. On the basis of this evidence we assign the structures also shown in Table 6.

The open chain compound (**10**) is similar to that obtained from the reaction of SiF_2 with acetylene, and results from the migration of acetylenic-H during the reaction, while the derivative of disilacyclohexadiene (**11**) is analogous to the compound formed in the trifluoropropyne reaction. The positions of the two *t*-butyl groups in the latter compound are assigned on the basis of the number of areas of resonance in the proton spectrum and on the coupling constants between magnetic nuclei. No volatile organic products were obtained from HF, KOH, or CH_3OH/KOH hydrolysis of this material.

The two complex sets of peaks observed in the fluorine n.m.r. spectra of (**11**) are not immediately consistent with the structural assignment. However, if there are two adjacent *t*-butyl groups on the ring, one might anticipate a rigid "half-chair" conformation which would give one "axial" and one "equatorial" fluorine atom on each silicon atom, with a significant chemical shift difference. No change was observed in the ^{19}F n.m.r. spectrum up to 75 °C

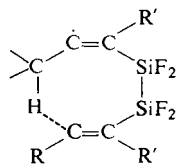
when decomposition of the compound occurred. With a rigid ring structure the compound should exhibit optical isomerism. No separation of the two forms has yet been achieved, but work is continuing on this aspect and on an X-ray crystal structure determination.

Discussion

Since we do not observe silacyclopropene derivatives, analogous to the cyclopropenes produced in carbene chemistry, in any of these reactions, it seems clear that the dimeric radical $\cdot SiF_2—SiF_2\cdot$ is the most reactive species towards alkyne reagents, as all the products found here are based on the Si_2F_4-unit. Also, since the type of compound formed appears to be fairly specifically related to the structure of the starting alkyne one can make some observations as to a possible mechanism for these reactions.

Diradical $\cdot SiF_2—SiF_2\cdot$ initially adds to an alkyne $RC{\equiv}CR'$ to form an intermediate $R\dot{C}{=}CR'SiF_2SiF_2\cdot$ which may either undergo ring closure to form a 2:1 compound, or react with further SiF_2 units (probably leading to polymers) or react with another molecule of alkyne to give $R\dot{C}{=}CR'SiF_2SiF_2R'C{=}\dot{C}R$. The latter intermediate then has at least three possibilities in addition to further reactions with either SiF_2 or alkyne units: ring closure to give a disilacyclohexadiene, H-migration from R or from R′. Sterically, because of the length of Si—Si and Si—C bonds it appears that the 8-membered transition state required for a migration of H from R is likely to be the most favored, and this is indeed what we found in the alkynes with the CH—C≡C grouping.



For migration of R′ (when R′ = H) or for ring closure a six-membered ring interaction is required and this is less favored on steric grounds, but the expected types of products are found when there is no CHC≡C group in the alkyne. Electronic and steric factors may explain why both processes occur in the $(CH_3)_3CC{\equiv}CH$ and $HC{\equiv}CH$ (1) reactions, while only ring closure is observed when $CF_3C{\equiv}CH$ is the starting alkyne (1, 6).

The ring compound **11** formed from $(CH_3)_3$-$CC{\equiv}CH$ is unusual in that 2,3-di(*t*-Bu)-cyclohexa-1,3-dienes are apparently unknown. Some of the strain between the two *t*-butyl groups is probably relieved by the greater puckering of the ring allowed by the longer (than C—C)Si—C and Si—Si bonds. Estimates of the strain energy in *o*-di(*t*-bu)benzenes are of the order of 22 kcal/mol (7), which would correspond very roughly to an n.m.r. coalescence temperature for the ^{19}F resonances 210 °C (8). Thus the limited stability of the compound did not permit study of the n.m.r. spectra at temperatures high enough to cause any significant changes.

The non-appearance of more complex (than 2:2) species in any of these reactions is probably due to their being less volatile and also less stable than the identified compounds. Heating of some of the polymeric residues directly into the mass spectrometer leads to very extensive ranges of mass peaks $(acetylene)_m(SiF_2)_n$, but apart from those discussed here none have been isolated in sufficient quantities for identification.

This work was initiated at Rice University under a grant from the U.S. Army Research Office (Durham). It has been continued at the University of Toronto with support from the National Research Council of Canada and the Ontario Department of University Affairs. One of us (C.S.L.) thanks the Ontario Department of University Affairs for a Postgraduate fellowship.

The Dissociation of Anilinium Ions in Aqueous Dimethylsulfoxide

KEITH YATES AND GRAEME WELCH[1]

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received September 15, 1971

The pK_a values of ten substituted primary anilines and six substituted tertiary anilines have been determined in 70% DMSO–water. The ΔpK_a values relative to those in aqueous solution indicate that DMSO is about 2 log units stronger as a base than H_2O. The normal order of basicity (tertiary > primary) is inverted in this solvent system and the Hammett ρ values for the two series provide evidence for a different ionization mechanism than that in water.

Les valeurs des pK_a de dix anilines primaires substituées et de six anilines tertiaires substituées ont été déterminées dans une solution aqueuse de DMSO à 70%. Les valeurs de ΔpK_a, correspondant à celles en solution aqueuse, indiquent que le DMSO est une base plus forte que H_2O par environ 2 log unités. L'ordre normal de basicité (tertiaire > primaire) se trouve inversé dans ce système de solvant et les valeurs ρ de Hammett pour les deux séries constituent une preuve d'un mécanisme d'ionisation différent que dans l'eau.

Canadian Journal of Chemistry, **50**, 474 (1972)

Introduction

The changes in pK_a of organic acids and bases on transfer from water to DMSO solutions is often very large (1). This variation is thought to arise from DMSO's inability to solvate anions effectively, whereas the opposite is true for cations (2). The consequent high activity of anions has excited considerable interest in the behavior of basic DMSO solutions (3) but little attention has been given to the behavior of its acidic solutions. The behavior of cation acids is nonetheless of considerable interest and Kolthoff and Chantooni (4) have commented on the "puzzling" nature of the pK_a changes of primary and tertiary alkylammonium ions between water and DMSO solution.

In connection with a study of the acidity of aqueous-DMSO solutions we have found it necessary to measure the pK_a values of a number of anilinium and dimethylanilinium ions in 70% DMSO–water. We now wish to report these data since the observed ΔpK_a values offer evidence that the mechanism of proton transfer of anilinium ions in DMSO is quite different from that reported by Grunwald and Yu (5) for purely aqueous solutions.

Results and Discussion

The pK_a values of a series of primary and tertiary aromatic amines, determined in 70% (w/w) DMSO–H_2O[2] are listed in Table 1 and compared with the values reported for aqueous solution (8). These were measured by standard potentiometric methods, except for *N*,*N*-dimethyl-4-nitroaniline, *N*,*N*-dimethyl-3-nitroaniline, 4-nitroaniline, and 3-nitroaniline which were too weakly basic in DMSO–H_2O. The values for these four compounds were obtained spectrophotometrically by the standard acidity function approach, as described by Rochester (9).

The pK_a values of the primary anilinium ions are about 1–2 units smaller in DMSO–H_2O than in aqueous solution, whereas those for the tertiary anilinium ions are the order of 2–3 units smaller. Both these differences qualitatively reflect the greater basicity of DMSO relative to water. The relationship between the pK_a's of a species BH^+ in two different solvents is given by the equation

$$(pK_a)_s - (pK_a)_w = \log {}^mf_{H^+} + \log \frac{{}^mf_B}{{}^mf_{BH^+}}$$

where the ${}^mf$ terms are the medium activity coefficients (10), representing the differences in standard chemical potential of each solute in the two solvents. For solvents of similar dielectric

[1]Present address: Department of Chemistry, McGill University, Montreal, Quebec.

[2]This particular composition, which corresponds to a mole ratio DMSO:H_2O of 1:2, was selected because its physical properties (6) suggest minimal structural resemblance to either pure H_2O or pure DMSO. However, both pK_a values and acidity function behavior in this system resemble those in pure DMSO (7) much more closely than those in pure H_2O.

constant, as is the case with 70% DMSO–H_2O (61) and water (78.4) (11), the difference in the electrostatic contribution to the standard chemical potential of the proton should be small and ${}^mf_{H^+}$ should mainly reflect the difference in solvent basicity.[3] However, unless ${}^mf_B \approx {}^mf_{BH^+}$ it is not possible to obtain an exact value of the difference in solvent basicity from such ΔpK_a values. For DMSO solutions this can be a serious problem because of the large differentiation between DMSO's ability to solvate cationic, anionic, and neutral species. As a result $(pK_a)_{H_2O} - (pK_a)_{DMSO}$ is of the order of −7 for carboxylic acids (1) but is about +2 for alkylammonium ions. However, solubility measurements on tertiary anilines and their pentacyanopropenide salts (13) show very similar degrees of "salting in" to DMSO–water, which suggests ${}^mf_B \approx {}^mf_{BH^+}$ in this system, lending support to a basicity difference between water and DMSO of about 2 log units, based on the values in Table 1. Various attempts to measure the pK_{BH^+} of both DMSO (14) and H_2O (15) have yielded little unanimity; however, an average value of $\Delta pK = pK_{H_3O^+} - pK_{DMSOH^+} = 2$ does not seem unreasonable. Kolthoff *et al.* (4) have estimated a difference of 1.5 ± 0.5 on the basis of comparison of their basicities in acetonitrile.

The problem of estimating solvent basicities from indicator measurements is clearly illustrated by the ΔpK_a values in Table 1. These ΔpK_a values are not only dependent on the basicity of individual indicators, but the relative basicity of the primary and tertiary aniline series has been inverted with respect to that in aqueous solution (in which the tertiary anilines are the stronger bases). These points are illustrated by means of linear free energy relationships of the $\rho\sigma$ type in Fig. 1.

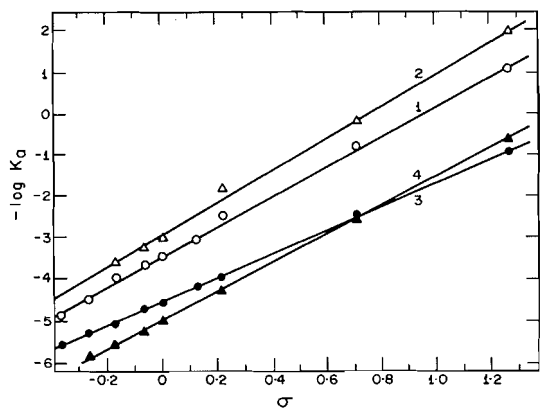

FIG. 1. Plots of pK_a *vs.* σ for (*1*) primary anilines in DMSO–H_2O, (*2*) tertiary anilines in DMSO–H_2O, (*3*) primary anilines in H_2O, (*4*) tertiary anilines in H_2O.

[3]Schaal and co-workers (12) have estimated a value of ${}^mf_{H^+}$ in 70% DMSO–H_2O of 0.85 p*H* units based on potentiometric measurements in dilute solutions. The same value was obtained in the present work. However, such estimates are made uncertain by unknown junction potentials.

[1] 
[2] 
Although solvate complexes between primary and tertiary anilines and DMSO have been reported not to involve hydrogen-bonding (16), it seems more reasonable in the present case to conclude that the above reversal in basicity must arise from the ability of DMSO to act as a strong hydrogen bond acceptor. At least one stable complex of ammonia and DMSO has been reported (17) and the strong interaction of aniline protons with DMSO has been demonstrated by n.m.r. measurements (18). Interaction of DMSO with the anilinium cation would be expected to be even stronger.

One way of assessing such interactions is through the medium dependence of the ρ values, which for the present type of dissociation reaction should represent a measure of the balance between external charge dispersal (through solvation interactions) and internal charge delocalization (via the aromatic ring substituents).[4] This must be considered in terms of the detailed mechanisms for proton transfer in the two media. In purely aqueous solution, Grunwald and Yu (5) have demonstrated that for the dissociation equilibria of amines the mechanism is as shown in reaction 1. The proton is not lost directly from the nitrogen atom but is removed by the basic solvent from the periphery of a hydrated anilinium ion. Since the proton is transferred from the periphery of a hydrated cation, the sensitivity of its dissociation to ring substituents should be reduced. When the equilibrium is shifted to an aprotic (or predominantly aprotic[5]) medium such as DMSO the corresponding solvated anilinium ion would be as shown if the cation were solvated only by DMSO molecules, reaction 2. In this case the solvate would present an essentially lyophobic face to the solvent, and no peripheral proton transfer mechanism such as that described for purely aqueous solutions would seem possible. Thus dissociation would be more likely to take place by a completely different mechanism, that is, by loss of a protonated DMSO molecule. Since the proton is lost directly from nitrogen, and the charge on the cation is more shielded from the solvent, the internal charge dispersal should be relatively more important than in aqueous solution. Therefore the sensitivity of the dissociation to ring substituents should be increased.[6] The medium dependence of ρ for each series is fully consistent with the above description.

[4]Ritchie and Uschold (1) have suggested that the ρ value for ionization of carboxylic acids reflects the ability of the solvent to form hydrogen bonds to the carboxylate ion; hence the very high value (2.8) obtained in DMSO (poor anion solvation) compared with ρ in water (1.0).

[5]Although the present medium is not strictly aprotic, both the pK_a values and their substituent dependence closely resemble the values reported for anilinium ions in pure DMSO acid solutions ($\rho = 3.3$) (7).

[6]In this discussion the pK_a variations and hence the ρ values are considered to be predominantly controlled by the effect of substituents on the "uphill" dissociation step, in the sense described in the extensive investigations of Eigen (19).

For the primary anilines ρ changes from 2.77 (20) in water to 3.64 in DMSO–water, and for the tertiary anilines from 3.43 (21) in water to 3.87 in DMSO–water. The effect of stabilizing the anilinium ion with an aprotic solvent molecule such as DMSO would be very similar to the effect of introducing alkyl substituents on nitrogen. Thus the ρ value for *N*,*N*-dimethylanilinium ion dissociation in water is higher than that for the anilinium series. In addition the medium effect on this ρ in changing from water to DMSO solution would be expected to be less pronounced, as observed.

Experimental

The compounds used for potentiometric pK_a measurements are shown in Table 1. They were all commercial samples, purified either by recrystallization or by distillation at reduced pressure where appropriate.

DMSO was carefully purified by fractional distillation in a specially designed still similar to that described by Schlafer and Schaffernicht (22), under a dry nitrogen atmosphere at reduced pressure (b.p. 35–40 °C/1–2 mm Hg). Standard HCl solutions were prepared by diluting constant boiling (aqueous) HCl with the appropriate quantities of DMSO and doubly distilled water to give 0.1 *M* HCl in 70% (w/w) DMSO–H_2O. The concentration was checked by potentiometric titration and the less concentrated acids prepared by dilution with 70% DMSO–H_2O.

The pK_a's of the aniline indicators were determined by standard techniques. However, it was first necessary to define a "pH" scale in 70% DMSO–H_2O, as follows. A Leeds and Northrup 7405 p*H* meter was standardized with aqueous buffers (KH phthalate, 0.05 *m*, p*H* = 4.01; KH_2PO_4, 0.025 *m*/Na_2HPO_4 0.025 *m*, p*H* = 6.86) and shown to give good linear response in the range p*H* 3–7. The electrodes were an L and N STD.1190-30 glass electrode with calomel internal and an L and N 117208 calomel reference (saturated KCl) incorporating a diffusion junction. The meter p*H* readings for a series of standard HCl solutions of known concentration in 70% w/w DMSO–H_2O were determined with respect to the aqueous buffer standards. Each p*H* value was determined by the following procedure. The electrodes were placed in the aqueous buffer and the meter corrected to the buffer p*H*. The buffer solution was removed and the electrodes were rinsed with distilled water, wiped with tissue, and placed in the DMSO–H_2O solution. The meter response was immediate and there was no evidence of drift in the p*H* value. The p*H* value was recorded and the electrodes again rinsed and dried, and replaced in the aqueous buffer. In all cases, the original aqueous buffer value was reproduced, without evidence of slow response or drift. Successive measurements on identical solutions were reproducible within the readability error of the meter.

The concentrations of the HCl solutions were converted to activities by use of the empirical (Debye-Hückel) expression:

$$-\log a_{H^+} = -\log c_{H^+} - \frac{0.5\sqrt{I}}{1 - 1.5\sqrt{I}}$$

where *I* is the ionic strength. The constant terms were those used for aqueous solution; the small correction for the difference in dielectric constant (70% w/w DMSO–H_2O, 60.5; H_2O, 78.30) was not considered warranted.

When the calculated $pa^S_{H^+}$ ($-\log a_{H^+}$) and measured p*H* values for the solutions were plotted against each other (Fig. 2) a straight line of unit slope (error of fit ±0.025) could be drawn demonstrating that the term = $(-\bar{E}_j - \log {}^m f_{SH^+})$[7]

TABLE 2. Calculation of pK_a of acetic acid in 70% (w/w) DMSO–H_2O

$V_{titrant}$	V_{total}	p*H*	pa_{H^+}	log *I*	p*K*′
0	50.0	10.42

$$pK_a = pa_{H^+} - \log \frac{c_{HOAc}}{c_{OAc}} - \log f_{OAc^-}$$

Temperature = 25.00 ± 0.05 °C
Titrant = 0.102 *m* HCl
Volume at half-ionization = 52.5 ml
Concentration of NaOAc = 0.0187 *m*
Mean* value of p*K*′ = 6.89 ± 0.04
At half-ionization, $-\log f_{OAc^-} = 0.12$
$pK_a = pK'_a + 0.12$
$= 7.01 \pm 0.04$

*Calculated as arithmetic mean of antilog ($-pK'_a$).

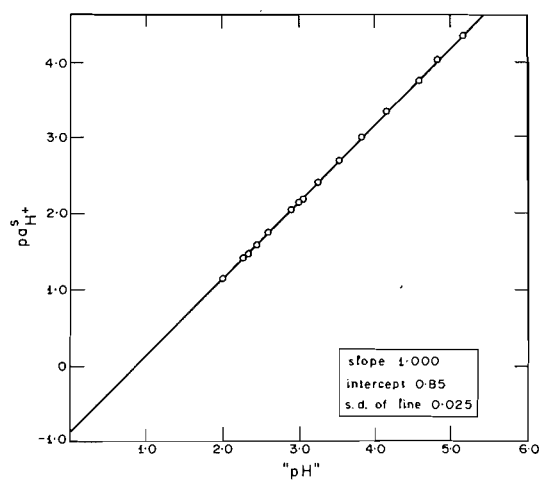

FIG. 2. Plot of $pa^S_{H^+}$ *vs.* "p*H*" determined potentiometrically in the DMSO–H_2O system.

[7] $\bar{E}_j$ is the junction potential and ${}^m f_{SH^+}$ is the medium activity coefficient for the proton.

is essentially constant over the range of activity studied. The value of $pa^{S}_{SH^+}$, referred to a standard state of 70% w/w DMSO–H_2O, could therefore be obtained from the pH meter (standardized against aqueous buffers) simply by subtracting 0.85 pH units from the meter reading. In order to verify the validity of the calibration, the pK_a of acetic acid was measured by the standard titrimetric method (see Table 2). The value of 7.01 $\pm$ 0.04 obtained for its pK_a is in excellent agreement with the value of 6.99 obtained from an exact potentiometric determination in this solvent system by Morel (23).

The $pa^{S}_{H^+}$ scale defined above was used to determine the pK's of the anilines from the data given in Table 3.[8] The pH values of the indicator buffer solutions were determined by the same technique described for the calibration of the meter. No corrections were made for the activity coefficient of the protonated aniline.

Phase Equilibria in the Systems Acetone–Methanol, Acetone–Cyclohexane, Methanol–Cyclohexane, and Acetone–Methanol–Cyclohexane

A. N. CAMPBELL AND S. C. ANAND

Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received July 27, 1971

The vapor pressure and vapor composition of the methanol–cyclohexane system were investigated at temperatures ranging from 25 to 50°. The same properties of the binary systems: acetone–methanol and acetone–cyclohexane, as well as those of the ternary system: methanol–cyclohexane–acetone, were determined experimentally at 25°. The total pressures and compositions of the vapor for solutions lying close to the critical solution temperature of the binary system or close to the plait point of the ternary system are constant within the range of experimental accuracy. All these systems show azeotropic behavior. The methanol–cyclohexane system has an equimolar excess Gibbs free energy, G^E, at 25° of 384.7 cal/mol, while the corresponding equimolar value of G^E for the acetone–methanol system at 25° is 102.6 and for the acetone–cyclohexane system, at 25°, it is 274.5 cal/mol.

La pression de vapeur et la composition de vapeur du système méthanol–cyclohexane ont été étudiées sur une échelle de température allant de 25 à 50°. Les mêmes propriétés des systèmes binaires: acétone–méthanol et acétone–cyclohexane, ainsi que celles des systèmes ternaires: méthanol–cyclohexane–acétone, ont été déterminées expérimentalement à 25°. Les pressions totales et les compositions de la vapeur pour des solutions proches de la température critique de la solution du système binaire ou proches du point de plissement du système ternaire, sont constantes dans l'intervalle d'exactitude expérimental. Tous ces systèmes montrent un comportement azéotropique. Le système méthanol–cyclohexane a un excès d'énergie libre équimolaire de Gibbs, G^E, de 384.7 cal/mol à 25°, alors que les valeurs équimolaires correspondantes de G^E pour le système acétone–méthanol est de 102.6 à 25° et pour le système acétone–cyclohexane de 274.5 cal/mol à 25°.

Canadian Journal of Chemistry, **50**, 479 (1972)

Introduction

Because of our interest in the critical phenomena, liquid ⇄ gas (1–3), and in the analogous critical phenomena, liquid$_1$ ⇄ liquid$_2$ (4–7), which has continued for several years, it was decided to extend our study to still another partially miscible system, *viz.* methanol–cyclohexane. By the addition of a third component, acetone, this system becomes homogeneous and it is then possible to study critical phenomena isothermally, in the ternary system methanol–cyclohexane–acetone. The complete study of the ternary system also involves that of the binary systems acetone–methanol and acetone–cyclohexane.

The methanol–cyclohexane system was chosen for the following reasons: (*a*) This system has a low critical solution temperature, *viz.* 45.87°. It was easily possible to work at temperatures above the critical solution temperature. (*b*) Both components, methanol and cyclohexane, have high vapor pressures, and it is therefore possible to investigate the partial pressures of both. (*c*) The difference in density of cyclohexane and methanol is slight and hence the effect of gravity in altering the shape of the coexistence curve in the neighborhood of the critical solution temperature, is almost negligible (8, 9). Previous work on the binary systems is summarized in Table 1. The equilibrium diagram of the ternary system methanol–cyclohexane–acetone has not been investigated previously.

Experimental Procedures

Purification of Materials

All three reagents were purified with great care; the details are to be found in ref. 22. Some physical properties of the products are given in Table 2.

Determination of Vapor Pressures and Equilibrium Vapor Compositions

The vapor pressures were measured directly with a manometer in the static manner, and the vapor compositions by means of isothermal distillation, using the air displacement method. Theoretically, at least, the latter method should give partial pressures directly, but this requires an exact knowledge of the volume of dry air passed through the apparatus and this is not easy to obtain. The combination of the two methods obviates the necessity for any knowledge of the volume of air passed through.

The Static Method: The method is well known and needs no specific mention here (23).

The Differential Method: The differential manometric method was employed to measure the difference in vapor pressure of solutions lying in the critical region and for measuring the difference in vapor pressure between pure solvent and solutions low in the other component. The

System	Investigators	Property measured	Numerical Value of Result
Methanol–cyclohexane	Mondain-Monval (10)	CST	49.1°
	Jones and Amstall (11)	CST	45.60° (72 wt.% cyclohexane)
	Eckfeldt and Lucasse (12)	CST	45.14°
	Debye, Chu, and Kaufman (13)	CST	45.14°
	Campbell and Kartzmark (4)	CST	45.87°
	Marinichev and Susarev (14)	$l \rightleftarrows v$ equilibrium at 35°, 45°, and 55°	Azeotrope at 35° contains 58.4 mol% methanol: at 55°, 61.2 mol% methanol
	Storonkin, Morachevskii, and Belousov (15)	$l \rightleftarrows v$ equilibrium	Azeotrope at 35° contains 55.7 mol% methanol
	Morachevskii and Komarova (16)	$l \rightleftarrows v$ equilibrium	Azeotrope at 55° contains 60.6 mol% methanol Azeotrope under 760 mm Hg pressure contains 60.4 mol% methanol
	Madhavan and Murti (17)	$l \rightleftarrows v$ equilibrium	Azeotrope under 760 mm pressure contains 60.4 mol% methanol
	Wood (18)	Excess thermodynamic functions (calculated)	G^E and H^E positive throughout TS^E positive except in solutions very rich in methanol
Acetone–methanol	Marinichev and Susarev (14)	$l \rightleftarrows v$ equilibrium, at 35°, 45°, and 55°, and under constant pressure (760 mm)	Exhibits azeotropic behavior
	Bushmakin, Molodenko, and Lyzlova (19)	$l \rightleftarrows v$ equilibrium	Confirm result of ref. 14
	Lang (20)	$l \rightleftarrows v$ equilibrium	Confirm result of ref. 14
Acetone–cyclohexane	Marinichev and Susarev (14)	$l \rightleftarrows v$ equilibrium	Exhibits azeotropic behavior
	Kurmanadharao and Vendata-Rao (21)	$l \rightleftarrows v$ equilibrium	Confirm results of ref. 14 but differ as to numerical results.

TABLE 2. Physical properties of pure reagents

Reagent	Density ($d_4^{25°}$) (g/ml)	Refractive index (n_{25}^{D})	Viscosity (cp)	Freezing point (°C)
Acetone	0.78425	1.35615	0.302	—
Methanol	0.78655	1.32693	0.545	—
Cyclohexane	0.77384	1.42355	—	6.55

apparatus used was that of Campbell, Kartzmark, and Oliver (24) who modified that of Gibson and Adams (25). Since vacuum pump oil, diethylphthalate, *n*-butyl phthalate, and other manometric liquids are soluble in one or other of the organic liquids of this research, it was necessary to use mercury as the manometric fluid. The diameter of the manometer tube was 22 mm, so that no meniscus correction was necessary.

Degassing was accomplished by freezing the liquid either in liquid nitrogen or in a mixture of Dry Ice and acetone, then evacuating until the residual pressure was less than 0.001 mm Hg. The liquid was then melted and the freezing and evacuating procedure repeated four or five times. The manometer was evacuated to about 1 μ and placed in a bath at the required temperature.

Determination of Vapor Composition

The composition of mixed vapor in equilibrium with mixed liquid of known composition was determined by isothermal distillation in a current of air. The apparatus of Bichowsky and Storch (26) was used. Nitrogen from a cylinder was passed into a pre-saturator whose temperature was kept 5° above that of the saturator. The nitrogen then passed through a heated tube to the saturator, whose temperature was controlled to $\pm 0.005°$. After leaving the last unit of the saturator, the nitrogen was led to a trap through a heated tube. After the vapor had condensed, the nitrogen was passed out of the system through a drying tube, to prevent condensation of water vapor from the air.

Methods of Analysis

The binary and ternary systems were analyzed as follows:

Methanol–Cyclohexane System. The refractive index method was used here, as the refractive indices of methanol and cyclohexane are 1.32693 and 1.42355 at 25°, respectively. The refractive index was measured with an old Zeiss–Pulfrich refractometer (it must be at least sixty years old) which is extremely accurate and has one great advantage, from our point of view, *viz.* the refractomer cell holds 2 ml of solution. This meant that evaporation from so large a quantity of solution during the short time required for a determination produced no appreciable change in composition, as was shown by the constancy of the reading. A volatile mixture in an Abbé refractomer changes continuously, as shown by the drift in the reading. Our thermostated Pulfrich instrument gave an accuracy of ± 0.0001 in the refractive index which corresponds to an analytical accuracy of about 1 in 1000 or somewhat less if the dilution effect consequent on the addition of excess pure liquid is taken into account. It was sometimes necessary to do this, because at temperatures above room temperature, mixtures of certain compositions became heterogeneous on cooling to room temperature. Therefore, a weighed excess of the appropriate pure component (methanol) was added to a known weight of solution. The composition of the homogeneous solution produced was determined from a calibration curve of refractive index *vs.* wt. % methanol.

Acetone–Cyclohexane System. This system was also analyzed by the refractive index method, since the refractive indices of acetone and cyclohexane are 1.35615 and 1.42355, respectively, at 25°.

Acetone–Methanol System. The compositions of the solutions were determined by viscosity, using a viscometer of the Cannon and Fenske type. Compositions were further checked by dielectric constant. The two methods gave an overall accuracy of $\pm 0.5\%$.

Methanol–Cyclohexane–Acetone System. Theoretically, the composition of a ternary mixture may be obtained from a knowledge of any two physical properties. It is necessary first to prepare calibration curves of the physical properties for all compositions and to express the results on a triangular diagram in the form of curves of equal values. The choice of physical properties is determined by the following considerations: they must (*a*) be easily and accurately determinable; (*b*) vary largely for small changes in composition; and (*c*) exhibit a graphical behavior such that curves of the different properties intersect at a steep angle. Viscosity and dielectric constant were found to satisfy these conditions for this system. The overal accuracy of determination was about $\pm 0.75\%$.

Results

We record here only such numerical results as are necessary for the understanding of the paper by the general reader. The numerical results "in toto" are to be found in the Depository of Unpublished Data.[1]

Vapor Pressure

We have used the Antoine equation (27)

$$\log P = A - \frac{B}{C + t}$$

to express our results for the vapor pressures of pure cyclohexane and of pure methanol. The constants A, B, and C were calculated by the

method of weighted least squares (28), using the non-linear formulae (29). The values of the constants are listed in Table 3.

Liquid–Vapor Equilibria

(a) Cyclohexane–Methanol. These equilibria were investigated, for liquid mixtures of different original compositions, at the temperatures 25, 40, 46, 48, and 50°. From these data[1] the relative volatility of methanol (y_1x_2/y_2x_1) and the ratio of the activity coefficients ($\log \gamma_1/\gamma_2$) were calculated, using the equation

$$[1] \qquad \log \frac{\gamma_1}{\gamma_2} = \log \frac{y_1 x_2}{y_2 x_1} - \log \frac{p_1^0}{p_2^0}$$

where p_1^0 and p_2^0 are the vapor pressures of pure methanol and of pure cyclohexane, respectively, x_1 is the mole fraction of methanol in the liquid ($x_2 = 1 - x_1$), y_1 the mole fraction of methanol in the vapor ($y_2 = 1 - y_1$). Similar calculations were done for the following systems:

(b) Acetone–Methanol. Investigated at 25° only, for 11 different liquid mixtures, covering the entire composition range.

(c) Acetone–Cyclohexane. Investigated at 25° only, for 10 different liquid mixtures.

(d) Methanol–Cyclohexane–Acetone. Investigated at 25° only, for 10 different liquid mixtures.

Total Vapor Pressures

(a) Methanol–Cyclohexane. These were determined for 15 different liquid mixtures, covering the whole composition range, at the temperatures of 25.0, 40.0, 45.0, 45.8, 45.9, 46.0, 46.1, 46.2, 46.3, 46.4, 47.0, 48.0, and 50.0°.

(b) Acetone–Methanol. These were determined for 12 different liquid mixtures at 25° only.

(c) Acetone–Cyclohexane. These were determined for 11 different mixtures at 25° only.

(d) Methanol–Cyclohexane–Acetone. Determined for 10 different mixtures at 25° only.

Difference in Pressure between Solutions lying close to the Heterogeneous Region of the Methanol–Cyclohexane System

Three sets of solutions, whose compositions lay on opposite sides of the critical composition but not far from it, were prepared and the difference in vapor pressure of the solutions determined with the differential manometer at temperatures just above the critical solution temperature, *viz.* 45.8, 45.9, 46.0, 46.1, 46.2, 47.0, 48.0, and 50.0°. Only at 50.0° was a difference in vapor pressure amounting to 0.01 mm Hg observed. This indicates that the equality of vapor pressure, which is thermodynamically necessary for congruent solutions, also persists

for several degrees above the critical solution temperature, for solutions whose compositions are not far from the critical. The same effect was observed (isothermally) for the ternary system methanol–cyclohexane–acetone, at 25°, for solutions of compositions lying near the critical.

Congruent Compositions for the System: Methanol–Cyclohexane–Acetone at 25°

See Table 4.

Partial Pressures

(a) Methanol–Cyclohexane. From the total pressures of this system, and the equilibrium vapor compositions, the partial pressures of both components were calculated, using Dalton's law; that is, assuming that the vapors behaved ideally. This no doubt produces some error in the values of the partial pressures but, when calculating the excess free energy of mixing, G^E, the error in G^E due to our error in determining the exact composition of the solution (liquid phase) is greater than that due to errors in partial pressure. The calculation was made for mixtures of various composition, at 25.0, 40.0, 46.0, 48.0, 50.0°.

(b) Acetone–Methanol. Similar calculations were made for 25° only.

(c) Acetone–Cyclohexane. Similar calculations for 25° only.

(d) Methanol–Cyclohexane–Acetone. Similar calculations for 25° only.

Discussion

Vapor Pressure of Pure Components

The agreement between our values for the vapor pressure of cyclohexane and those of Cruikshank and Cutler (30) is excellent, while the agreement with the results of Brown and Ewald (31) and of Willingham (32) is satisfactory. Our values for the vapor pressure of methanol at different temperatures are in excellent agreement with those of Scatchard and Ticknor (33) and Harper and Moore (34) but differ slightly from those of Singh and Benson (35). Our value for the vapor pressure of acetone at 25.0° (230.40 mm Hg) agrees well with the literature values (36, 37).

Thermodynamic Analysis

Consistency Tests

Numerous forms of consistency tests exist (38–43), most of which are based directly on the Gibbs–Duhem equation. When the thermodynamic data satisfy the Gibbs–Duhem equation, it is likely, but by no means certain, that they are correct but, if they do not satisfy this equation, it is certain that they are incorrect.

The vapor–liquid equilibrium data for the methanol–cyclohexane system could not be fitted to the van Laar (44), Margules (45), Wilson (46), or Scatchard and Hamer equations (47). This, however, does not necessarily mean that the vapor–liquid equilibrium data for this system are thermodynamically inconsistent, because the above equations may not apply to partially miscible liquid mixtures (48). The liquid–vapor equilibrium data of the acetone–methanol and acetone–cyclohexane systems can be fitted to the van Laar equation of the third order.

The consistency of the vapor–liquid equilibrium data was tested by the equal area test proposed independently by Coulson and Herington (38) and by Redlich and Kister (39). Figure 1 shows a plot of $\log \gamma_1/\gamma_2$ *vs.* mole fraction methanol for the system methanol–cyclohexane at 46°. Similar plots for the systems acetone–methanol and acetone–cyclohexane, respectively, were made. By graphical integration, the two areas, one above and the other below the zero axis, were found to be equal within 1.25 to 1.75% for these systems. The smallness of the deviations indicates that the vapor–liquid equilibrium data of all these systems are thermodynamically

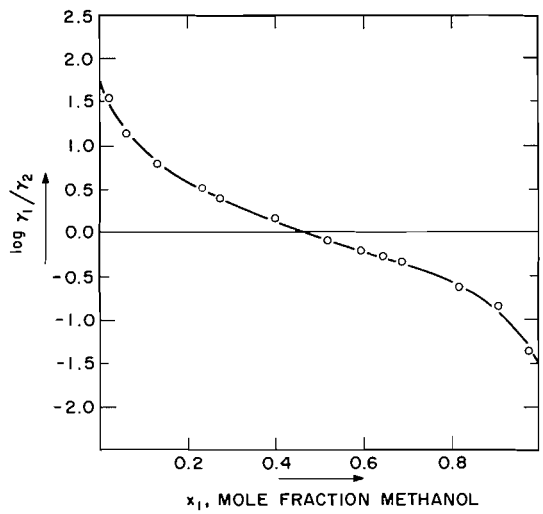

FIG. 1. $\log \gamma_1/\gamma_2$ for the methanol–cyclohexane system at 46°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

consistent. The equal area test could not be applied to the methanol–cyclohexane system, at 25 and 40°, because the two components are not miscible in all proportions at these temperatures.

The consistency of the vapor–liquid equilibrium data was also tested by a unified method described by Tao (43). This method requires a knowledge of the total vapor pressures of solutions, in order to calculate activity coefficients. As we measured total vapor pressures at solution concentrations different from those used in the vapor–liquid experiments, we were obliged to obtain the total vapor pressures by graphical interpolation. The method of Tao showed our data to be thermodynamically consistent within the limits of experimental error (maximum error in vapor pressure = 0.2 mm, in temperature control = 0.01°, and in composition = 0.3%).

Vapor–Liquid Equilibria

(a) Methanol–Cyclohexane System. The experimental results for this system are to be found in Depository.[1] Representation of the experimental data in the form of relative volatility as a function of solution composition reveals the main features of the interaction between the components of the system. This system is characterized by positive deviations from ideal solution behavior as shown by the decrease in the magnitude of the relative volatility of methanol with increase in mole fraction of methanol in the solution (Fig. 2). The relative volatility of methanol increases with increase in temperature. The influence of temperature on relative volatility can be described by Vrevskii's first law (49), which can be written in the form

$$[2] \qquad \frac{d}{dT}\ln \alpha_{12} = \frac{\bar{L}_1 - \bar{L}_2}{RT}$$

where α_{12} is the relative volatility of methanol in the methanol–cyclohexane system and $\bar{L}_1$, $\bar{L}_2$ are the partial molar heats of volatilization of methanol and of cyclohexane, respectively. From the fact that the isotherms of relative volatility of methanol have no points of intersection, it follows that the difference in $\bar{L}_1$ and $\bar{L}_2$ has the same sign throughout the whole concentration.

(b) Acetone–Methanol System. This system is also characterized by positive deviations from Raoult's law, the magnitude of the relative volatility of acetone decreasing with increase in mole fraction of acetone. The vapor–liquid equilibrium data of this system can be fitted to van Laar's equation of the third order (50). A straight line is obtained when $\sqrt{\log \gamma_2}$ is plotted *vs.* $\sqrt{\log \gamma_1}$, as shown in Fig. 3. The constants A and B of the van Laar equations

$$[3] \qquad \log \gamma_1 = \frac{A}{(1 + Ax_1/Bx_2)^2} \qquad \log \gamma_2 = \frac{B}{(1 + Bx_2/Ax_1)^2}$$

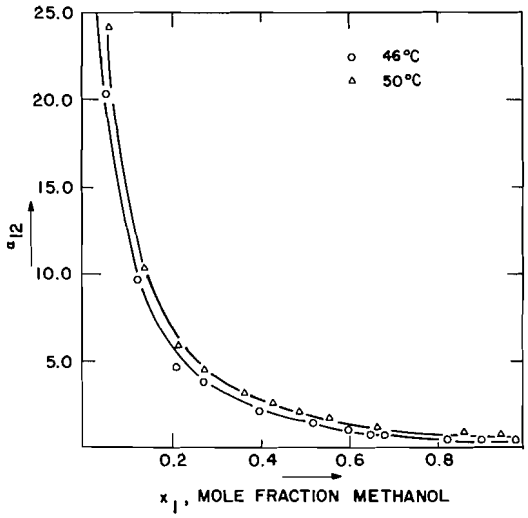

FIG. 2. Relative volatility of methanol in the methanol–cyclohexane system at different temperatures.

were obtained from the intercepts which this line makes with the axis. A close look at the data[1] and Fig. 3 reveals that there are some points in the region of 0.7 to 1.0 mole fraction acetone which do not lie on a straight line. This is because the van Laar equation does not give constant values of A and B throughout the whole range of concentration, when the solutions show azeotropic behavior (51).

The methods of Carlson and Colburn (52) and of Prigogine (53) could not be used to calculate the azeotropic composition of this system at different temperatures because the vapor pressures of the components differ appreciably.

From Fig. 3, the values of A and B were found to be 0.306 and 0.314, respectively, *i.e.*, the value of A is almost equal to the value of B; in other words the vapor–liquid equilibrium data for this system can also be represented by the equation

$$[4] \qquad G^E = 2.303\ RTAx_1x_2$$

Thus G^E for the acetone–methanol system can be represented by eq. 4 with $A = B = 0.310$. Both the Margules and van Laar equations reduce to eq. 4 when $A = B$. Table 5 gives the results of these calculations. The agreement between the calculated and the experimental values of the excess Gibbs free energy is not good for concentrations lying close to the azeotrope.

The variation in the values of A and B with composition is especially large in this system, as the azeotrope occurs near an extreme range of concentration (51) at 25° (greater than 0.918 mole fraction acetone).

(c) Acetone–Cyclohexane System. This system is again characterized by positive deviation from Raoult's law; the magnitude of the relative volatility of acetone decreases with increase in the mole fraction of acetone. Of various equations tried for this system, the van Laar equation (44) was found to be the best. Again, the scattering of points from the straight line can be explained in a similar manner as due to the occurrence of an azeotrope. The values of the constants A and B of the van Laar equation were found to be 1.156 and 0.656. As seen from Table 6, the van Laar equation reproduces only qualitatively the behavior of the excess Gibbs free energy for this system, because it fails to give satisfactory values for azeotropic solutions (51).

Activity Coefficients and Excess Gibbs Free Energy

All systems of this study, both binary and ternary, show large positive deviations from Raoult's law, since the activity coefficients in all these systems are greater than unity. It is to be expected that the activity coefficients will be largest in the methanol–cyclohexane system, as this is a partially miscible mixture. Actually, as our data show, the activity coefficients for the methanol–cyclohexane system are greater than those of the acetone–cyclohexane system and these again greater than those of the acetone–methanol system. The plots of the logarithms of the activity coefficients of the various constituents of the systems and their form (48, 51) suggest that the data, as a whole, are thermodynamically consistent.

*Subscript 1 for methanol, 2 for cyclohexane.

(a) Methanol–Cyclohexane System. The magnitude of the activity coefficients in this system decreases with increase of temperature. The temperature dependence of the activity coefficients can be represented by the following equation (51)

$$[5] \qquad \left(\frac{\partial \ln \gamma_i}{\partial T}\right)_{P,x} = -\frac{(\bar{H}_i - H_i^0)}{RT^2}$$

where the term $(\bar{H}_i - H_i^0)$ gives the difference between the partial molar enthalpy of the ith constituent in the solution and the molar enthalpy of the pure constituent. As the values of the activity coefficients of this system fall with rising temperature, $(\bar{H}_i - H_i^0)$ must be positive, that is, heat is absorbed on mixing and this agrees with the data of Campbell and Kartzmark, who found the partial molar heat of mixing of both constituents to be positive in this system.

An important question arises as to the magnitude of the activity coefficients for solutions showing a miscibility gap. A thermodynamic argument, which need not be gone into here, applied to eq. 4, yields the results:

$$[6] \qquad \log \gamma_1 \geqslant 0.868 x_2^2$$
$$\log \gamma_2 \geqslant 0.868 x_1^2$$

Thus, for a partially miscible liquid mixture whose excess Gibbs free energy varies in a symmetrical manner, the values of the activity coefficients γ_1 and γ_2 should be greater than 5.047 and 1.221, respectively, for $x_1 = 0.1$, and so on for other proportions. This argument may be taken to mean that if a system shows partial miscibility, it will exhibit very large positive activity coefficients for both constituents or conversely, if a system exhibits very large positive activity coefficients, it will be partially miscible.

In Tables 7 and 8, the excess Gibbs free energy calculated from the liquid–liquid equilibrium data of Campbell and Kartzmark is compared

*Subscript 1 for methanol, 2 for cyclohexane.

with the experimental value. The lack of agreement is due to the failure of the van Laar and Scatchard and Hamer equations to apply to this partially miscible system. Wood (18) calculated the excess Gibbs free energy, for this system at 31 and 40° from the solubility data of Eckfeldt and Lucasse (12), using certain empirical equations. Again, the agreement is not good. There are several reasons for this, the most important being that he used an incorrect equation, on the basis of his own reasoning, unless this is a printer's error.

(b) Acetone–Methanol System. As already stated, the excess Gibbs free energy of this system was expressed by eq. 4. Table 5 shows that the agreement between the calculated and experimental G^E is good, despite the fact that an azeotrope exists in this system. The activity coefficients of this system are greater than unity and hence there is a possibility that this system may exhibit partial miscibility at some lower temperature. Campbell and Kartzmark (unpublished data) have recently measured the heats of mixing for this system at 25° and find the heat of mixing to be positive at all concentrations. It therefore follows that the activity coefficients increase with falling temperature. In other words, the region of partial miscibility will be approached by lowering the temperature.

Other Excess Thermodynamic Functions

(a) Methanol–Cyclohexane System. The excess thermodynamic functions of this system at 50°, are given in Table 9 and shown graphically in Fig. 4. The general shape of all the curves is the same at temperatures ranging from 46 to 50°. The methanol–benzene system (54) and other systems containing a polar and a non-polar component (55) show a similar type of behavior.

TABLE 9. Excess thermodynamic functions for the methanol–cyclohexane system at 50 °C

0.80	74.2	118.5	110.4	−0.20	44.3
0.90	39.1	61.4	62.3	−0.11	22.3

*A. N. Campbell and E. M. Kartzmark, unpublished data.

The excess entropy is negative for all mixtures containing more than 0.23 mole fraction methanol but the values differ greatly from those calculated by Wood (18). A possible source of error lies in the value of the heat of mixing which Wood calculates to be 800 cal/mol at the maximum. Wood admits, however, that due to uncertainties in the heat of mixing, too great emphasis should not be placed on his numerical value of the excess entropy.

(b) Acetone–Methanol System. The excess free energy of this system can be represented by eq. 4. From this equation, the other excess thermodynamic functions can be derived as follows:

$$[7] \quad S^E = \left(\frac{-\partial G^E}{\partial T}\right)_p = -2.303 x_1 x_2 R \left[A + T\left(\frac{\partial A}{\partial T}\right)_p\right]$$

$$[8] \quad H^E = G^E + TS^E = -2.303 x_1 x_2 R T^2 \left(\frac{\partial A}{\partial T}\right)_p$$

The excess heats of mixing, H^E, calculated from eq. 8, using $(\partial A/\partial T)_p = -0.00169$, are compared with the experimental values of H^E of Campbell and Kartzmark in Table 10. The agreement between the calculated and experimental values of H^E is good for solutions having less than 0.50 mole fraction acetone. Again, the difference between the calculated and experimental values of H^E is to be explained as due to the failure of the van Laar equation, when applied to azeotropic solutions.

TABLE 11. Excess thermodynamic functions for the acetone–cyclohexane system at 25 °C

*A. N. Campbell and E. M. Kartzmark, unpublished data.

(c) Acetone–Cyclohexane System. The excess thermodynamic functions for this system are given in Table 11 for 25°. All the excess thermodynamic functions are positive in this system. Again, the positive excess heat is small in mixtures rich in acetone, since the addition of a small amount of an inert solvent like cyclohexane to a large amount of acetone breaks few bonds in acetone. This heat is large in mixtures weak in acetone, as the addition of a small amount of it to a large amount of cyclohexane must break most of the bonds in acetone. The excess entropy is positive, owing to the loss of orientation order consequent on the breaking of the bonds.

The Hydrogen–Oxygen Reaction on Lanthanide Oxides. I. Hydrogen and Oxygen Adsorption on Some Lanthanide Oxides

JOHN F. READ

Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received June 28, 1971

Hydrogen and oxygen adsorption have been measured on neodymium oxide and dysprosium oxide from 77 to 771 °K up to equilibrium pressures of approximately 6 Torr. In addition, hydrogen adsorption measurements have been made on samarium oxide and gadolinium oxide from 77 °K to approximately 100 °K. The adsorption is effectively instantaneous in all cases except for oxygen adsorption on neodymium oxide at 491 and 541 °K. Adsorption appears to be dissociative for all cases studied except for hydrogen adsorption on neodymium oxide at all temperatures and for hydrogen adsorption on dysprosium oxide at high temperatures. For neodymium oxide and dysprosium oxide three types of adsorption are observed in different temperature ranges. At low temperatures, the adsorption is probably physical; at intermediate temperatures, it is either physical, or chemical on isolated double sites; and at high temperatures it is chemical. In general, the Freundlich isotherm gives the highest correlation between calculated and experimental data. The isosteric heat of adsorption and the equilibrium uptake of hydrogen increase as the ionic radius of the metal ion decreases.

L'adsorption d'hydrogène et d'oxygène sur l'oxyde de néodyme et l'oxyde de dysprosium ont été mesurées de 77 °K jusqu'à 771 °K avec une pression à l'équilibre d'approximativement 6 Torr. En supplément, les mesures d'adsorption de l'hydrogène sur l'oxyde de samarium et l'oxyde de gadolinium ont été faites de 77 °K jusqu'à environ 100 °K. L'adsorption est effectivement instantanée dans tous les cas excepté pour l'adsorption d'oxygène sur l'oxyde de néodyme à 491 °K et 541 °K. L'adsorption paraît être dissociative pour tous les cas étudiés excepté pour l'adsorption d'hydrogène sur l'oxyde de néodyme à toutes températures et pour l'adsorption d'hydrogène sur l'oxyde de dysprosium à hautes températures. Pour l'oxyde de néodyme et l'oxyde de dysprosium, trois types d'adsorption sont observés dans différents intervalles de températures. A basses températures, l'adsorption est probablement physique; à températures intermédiaires, elle est soit physique, soit chimique sur les sites doubles isolés; et à hautes températures elle est chimique. En général, l'isotherme de Freundlich donne une corrélation maximum entre les données calculées et expérimentales. La chaleur isostérique d'adsorption et la fixation à l'équilibre de l'hydrogène augmentent comme le rayon ionique de l'ion métallique diminue.

Canadian Journal of Chemistry, **50**, 490 (1972)

Introduction

There is evidence in the literature that the lanthanide oxides can act as either Lewis acids or Lewis bases, making them effective catalysts for reactions which involve the adsorption of either hydrogen or oxygen. The elementary reactions that have been studied include para-hydrogen conversion (1–4), hydrogen–deuterium equilibration (2, 3), hydrogen–oxygen reaction (5–8), isotopic oxygen exchange, *e.g.* (9–12). Preliminary studies have also been made of the adsorptive properties of the lanthanide oxides (13, 14).

The purpose of this contribution is to present data on the adsorption of hydrogen and oxygen on some of the lanthanide oxides, as a basis for further detailed studies of the hydrogen–oxygen reaction.

Experimental

The apparatus comprised a conventional high-vacuum system. Spectroscopically pure oxygen was supplied by the British Oxygen Company and the hydrogen was purified by passage through a palladium thimble. The adsorption was carried out by admitting a known amount of gas onto the sample. The pressure was then measured every few minutes for at least 30 min using a McLeod gauge, the stopcock between the sample and the gauge always being closed before a reading was taken. Further doses of the gas were added until a final equilibrium pressure of approximately 6 Torr was obtained. A trap, surrounded by liquid nitrogen, protected the sample from contamination by grease or mercury vapors.

The adsorption was studied over the temperature range 77 to 771 °K. Low temperatures were obtained by using coolant baths of liquid nitrogen (77 °K), liquid oxygen (90 °K), or solid carbon dioxide in acetone (195 °K). A specially constructed cryostat (15) was used to obtain temperatures in the range 90 to 193 °K. The volume of the system was measured at each temperature.

The four oxides used in the adsorption studies were neodymium oxide, samarium oxide, gadolinium oxide, and dysprosium oxide. They were of "Specpure" grade supplied by Johnson Matthey. X-Ray and i.r. analysis confirmed that all four oxides possessed the C-type structure (16) and that there was no change in structure during the experiments. The C-type structure is derived by the ordered absence of the oxygen ions from a quarter of the lattice positions of the

TABLE 1. Summary of results

Oxide	Specific surface area ($m^2\ g^{-1}$)	Total surface area (m^2)	Temperature range studied (°K)	
			Hydrogen adsorption	Oxygen adsorption
Nd_2O_3	6.38	20.3	77–689	273–677
Sm_2O_3	4.04	20.8	77–99	—
Gd_2O_3	7.55	36.5	77–97	—
Dy_2O_3	2.73	9.0	77–689	333–771

face-centered cubic fluorite structure, space group *Ia*3. There was no change in the powder diffraction patterns or the i.r. spectra for any of the oxides after heating in vacuum at various temperatures in the range 650 to 800 °K. Structural changes occurred at much higher temperatures, for example neodymium oxide changed from C-type to A-type after prolonged heating at 1300 °K. It is possible that neodymium oxide is hydrated. Infrared analysis showed that water was present and the cubic lattice dimension of 11.16 Å, calculated from the powder diffraction pattern, compared favorably with the value of 11.518 Å found by Glushkova *et al.* (17) for cubic $3Nd_2O_3.2H_2O$. The powder pattern changed slightly after the neodymium oxide had been stored in a desiccator for nine months.

The oxides were specifically chosen because of their relative structural and stoichiometric stability at the pressures and temperatures used in this investigation (18). Surface areas were measured by the B.E.T. method using krypton.

The oxides were conditioned by heating for seven days at 700 °K and $<10^{-6}$ Torr pressure. The system was evacuated overnight for experiments at different temperatures. The hydrogen adsorption measurements were performed first and then the oxide was left in contact with 15 Torr of oxygen for 10 h. The oxide was then baked out for two days at 700 °K and $<10^{-6}$ Torr pressure before proceeding with the oxygen adsorption experiments.

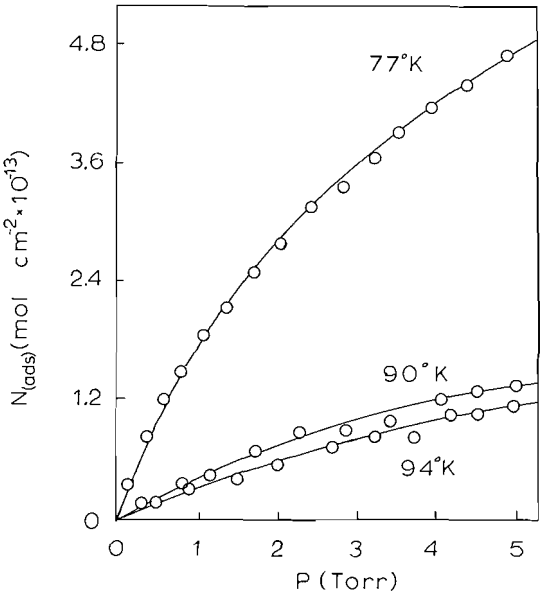

FIG. 1. Hydrogen isotherms on neodymium oxide.

Results

Hydrogen and oxygen adsorption were studied over neodymium oxide, samarium oxide, gadolinium oxide, and dysprosium oxide in the temperature ranges indicated in Table 1 at about twelve different equilibrium pressures up to 6 Torr. The adsorption was effectively instantaneous in all cases except for oxygen adsorption on neodymium oxide at 491 and 541 °K.[1]

The isotherms for the three lowest temperatures on each oxide are shown in Figs. 1–4,

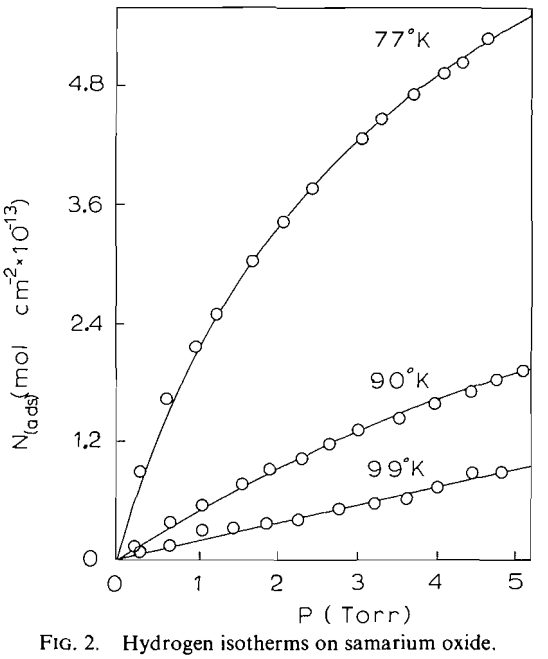

FIG. 2. Hydrogen isotherms on samarium oxide.

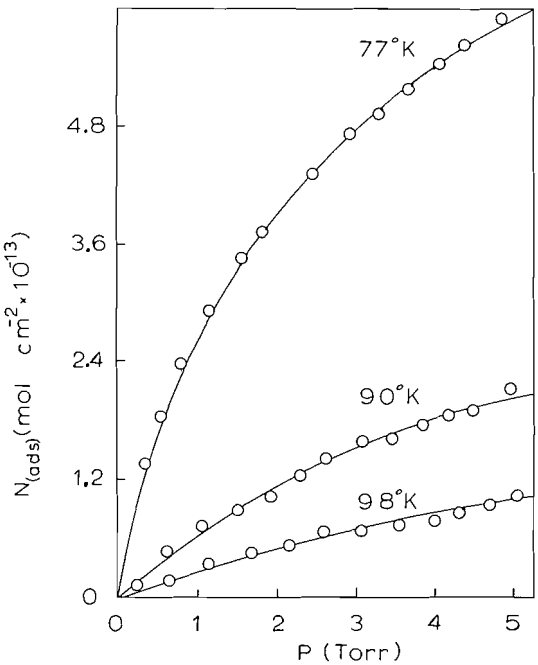

FIG. 3. Hydrogen isotherms on gadolinium oxide.

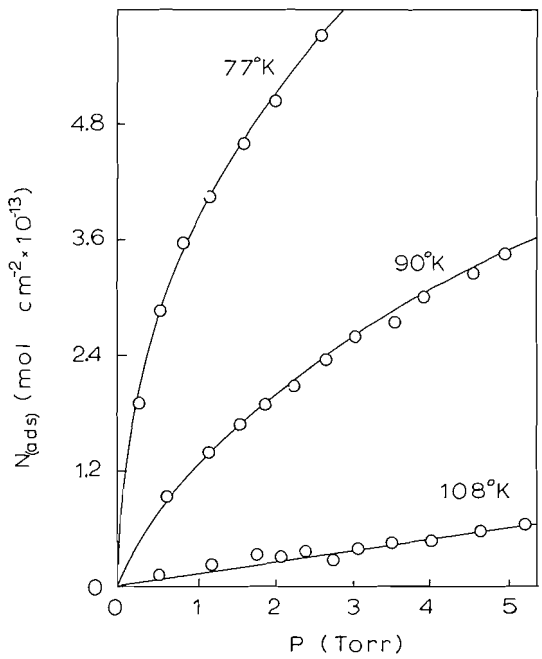

FIG. 4. Hydrogen isotherms on dysprosium oxide.

where P is the equilibrium pressure in Torr and $N_{(ads)}$ is the total number of molecules adsorbed per unit surface area standardized to the value at S.T.P. Isobars for hydrogen and oxygen adsorption on neodymium oxide and dysprosium oxide are shown in Figs. 5 and 6. These are shown for an equilibrium pressure of 4 Torr except for oxygen adsorption on neodymium oxide which is for an equilibrium pressure of 0.2 Torr.

Discussion

(A) Hydrogen Adsorption

Isobars

(a) Neodymium Oxide

The isobar at an equilibrium pressure of 4 Torr is shown in Fig. 5. Maximum adsorption occurs at the three lowest temperatures with a decrease in the amount of adsorption as the temperature increases from 77 to 94 °K. The amount of adsorption in the range 195 to 491 °K is negligible or very small, with an indication of a slight increase at 359 °K. The amount of adsorption then increases as the temperature increases from 548 to 689 °K.

In Fig. 5, the isobar is compared with the graphs obtained by Ashmead, Eley, and Rudham (2, 3) of log (rate of parahydrogen conversion), at a pressure of 4 Torr, against the reciprocal of the absolute temperature (log k_m *vs* $1/T$), and of log (rate of hydrogen–deuterium equilibration), at a pressure of 4 Torr, against the reciprocal of the absolute temperature (log k_m *vs.* $1/T$). All three plots have a similar shape at high temperatures and the isobar and the parahydrogen conversion plots are similar at all temperatures.

By comparing the parahydrogen conversion and the hydrogen–deuterium equilibration reaction, Ashmead *et al.* considered that the parahydrogen conversion proceeded by a paramagnetic physical mechanism at low temperatures, and by a chemical mechanism at high temperatures. It follows that the adsorption is probably physical at low temperatures and chemical at high temperatures.

At intermediate temperatures, a peak occurs in both the isobar, and the rate of conversion against temperature graph, whereas the equilibration reaction is immeasurably slow. Ashmead *et al.* considered that the conversion proceeded by a physical mechanism in this temperature range, on sites associated with an energy of accessibility. The rate of conversion increases

For personal use only.

with temperature up to a maximum, after which the desorption of hydrogen is favored, and the rate decreases. An alternative mechanism in this intermediate temperature range is a chemical mechanism on isolated double sites with no surface migration. Either mechanism can be adopted to explain the adsorption results. Within this temperature range (290 °K), the system was partially evacuated and a Tesla discharge was passed through the remaining hydrogen. Negligible hydrogen adsorption occurred. The discharge would not be expected to affect the amount of physical adsorption, or the amount of chemisorption, unless dissociative hydrogen adsorption was a slow, rate determining step.

(b) Dysprosium Oxide

In Fig. 6 the isobar at an equilibrium pressure of 4 Torr is shown together with the parahydrogen conversion and hydrogen–deuterium equilibration graphs obtained by Ashmead *et al.* (2, 3). A comparison of these plots indicates that adsorption is probably physical at low temperatures and chemical at high temperatures.

Form of the Isotherms

The data obtained at the three lowest temperatures on each of the oxides were used to determine the form of the isotherms. The results for the Freundlich isotherm,

$$N_{(ads)} = kP^n$$

where k and n are temperature dependent constants, are shown in Table 2 (C is the correlation coefficient).

TABLE 2. Values for k and n with the correlation coefficient using the Freundlich isotherm

Oxide	Temperature (°K)	k	n	C
Nd_2O_3	77	1.6	0.70	0.998
	90	0.37	0.81	0.996
	94	0.30	0.79	0.996
Sm_2O_3	77	2.1	0.61	0.997
	90	0.52	0.79	0.999
	99	0.23	0.77	0.991
Gd_2O_3	77	2.6	0.53	0.998
	90	0.66	0.72	0.999
	98	0.28	0.75	0.995
Dy_2O_3	77	3.7	0.42	0.998
	90	1.3	0.61	0.999
	108	0.20	0.60	0.947

For all the oxides, the results fit the Freundlich isotherm although the correlation is lowest at

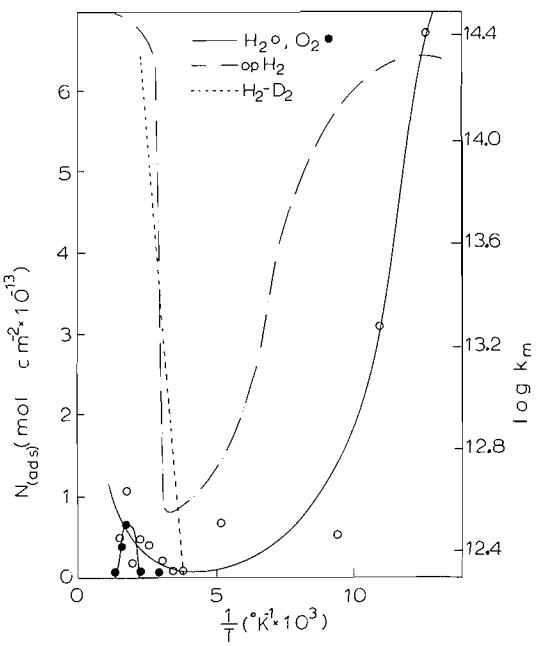

FIG. 6. Comparison of the oxygen isobar, the hydrogen isobar, the rate of the parahydrogen conversion and the rate of the hydrogen–deuterium equilibration on dysprosium oxide.

TABLE 3. Heat of adsorption and equilibrium uptake for hydrogen

Oxide	Ionic radius of metal ion, Me^{3+} (Å)	Hydrogen uptake at an equilibrium pressure of 4 Torr (molecules $cm^{-2} \times 10^{-13}$)		Isosteric heat of adsorption (kcal mol^{-1})
		77 °K	90 °K	
Nd_2O_3	1.15	4.15	1.14	1.85
Sm_2O_3	1.13	4.87	1.56	2.06
Gd_2O_3	1.11	5.37	1.81	2.13
Dy_2O_3	1.07	6.55	3.03	2.26

the highest temperature. This may be due to the fact that the cryostat was used to obtain the highest temperature resulting in a lower temperature stability. The expected trend of increasing n and decreasing k with increasing temperature is seen for all the oxides. In addition, n decreases and k increases as the ionic radius of the metal decreases. Using the model for the Freundlich isotherm that the heat of adsorption decreases exponentially with coverage, values for the heat of adsorption can be calculated from the constants given in Table 2. The heats are 0.9, 1.0, 1.1, and 1.3 kcal mol^{-1} for neodymium oxide, samarium oxide, gadolinium oxide, and dysprosium oxide, respectively. These values agree to within 1 kcal mol^{-1} with the isosteric heats of adsorption calculated from the Clausius–Clapeyron equation (see Table 3).

As expected for the low coverages studied, the data also fitted the Langmuir isotherm, although the correlation was usually slightly lower than for the Freundlich isotherm. For samarium oxide, gadolinium oxide, and dysprosium oxide the results indicated dissociative adsorption whereas non-dissociative adsorption was indicated for neodymium oxide. This is in accord with the results of Bakumenko and co-worker (5, 7) for the hydrogen–oxygen reaction where the order with respect to hydrogen was higher for neodymium oxide than for the other oxides studied.

The results from the adsorption on neodymium oxide at 548, 618, and 689 °K, and on dysprosium oxide at 594 and 689 °K were also analyzed. Again, the highest correlations were obtained using the Freundlich isotherm. The results from the Langmuir isotherm indicated that non-dissociative adsorption was occurring on both oxides, though the correlation was very low in all cases. The similarity between the rates of parahydrogen conversion and hydrogen–deuterium equilibration at high temperatures (2, 3) suggest that dissociative adsorption is occurring. Therefore, it is not possible to state conclusively which type of adsorption is occurring at high temperatures though it appears to be non-dissociative.

Heat of Adsorption and Surface Coverage

The isosteric heat of adsorption was determined from the results at the three lowest temperatures on each of the oxides studied by plotting log (equilibrium pressure) at a particular coverage *vs.* the reciprocal of the absolute temperature. This plot is shown in Fig. 7 for

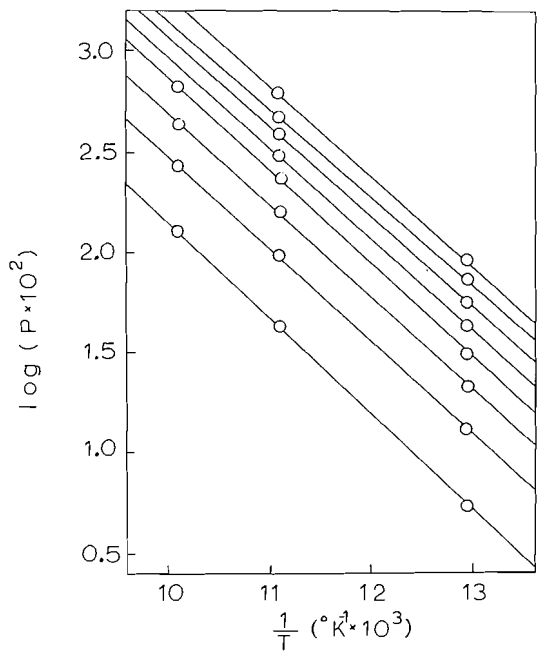

FIG. 7. Clausius–Clapeyron plot for hydrogen adsorption on samarium oxide.

samarium oxide at coverages from 0.25×10^{13} molecules cm^{-2} to 2.50×10^{13} molecules cm^{-2} at intervals of 0.25×10^{13} molecules cm^{-2}. The resulting plot of heat of adsorption *vs.* coverage is shown for all four oxides in Fig. 8. The average heats of adsorption are shown in Table 3. No systematic change in heat of adsorption with coverage could be detected. The magnitude of the heat is suggestive of a physical process.

The surface coverage of hydrogen at an equilibrium pressure of 4 Torr at 77 and 90 °K is shown for the four oxides in Table 3. The calculated value for a monolayer coverage of physically adsorbed hydrogen is 2.6×10^{15} molecules cm^{-2} (assuming a totally accessible surface and a value for the molecular diameter of hydrogen of 2.2×10^{-8} cm). The coverage at an equilibrium pressure of 4 Torr on neodymium oxide, at 77 and 90 °K is, therefore, 0.016 and 0.004 of a monolayer, respectively. For physical adsorption, the low coverage would be expected because of the very high value for the vapor pressure of hydrogen at these temperatures. For chemisorption, it must be assumed that only a small fraction of the surface is active. It is possible that most of the surface is poisoned by irreversibly adsorbed gases, the most likely contaminant being water. Anderson and Gallagher (13) have found that praseodymium oxide adsorbs carbon dioxide very strongly but it must be noted that praseodymium oxide has a much stronger tendency to become non-stoichiometric than do the oxides presently being studied. An alternate explanation for the low coverages is that adsorption only occurs on specially active sites. The C-type oxides contain anion vacancies. Assuming a surface containing equal areas of the (100), (110), and (111) planes, the number of anion vacancies for neodymium oxide is 2.49×10^{14} cm^{-2}. The amount of gas adsorbed is less than the number of anion vacancies but it is possible that clusters of these vacancies form the active sites. These same active sites may be responsible for the high temperature adsorption and the coverage agrees well with the value of 0.001 calculated by Ashmead *et al.* (2, 3). The low coverages are also in line with experimental results indicating that the lanthanide oxides are insulators (8).

In Table 3, the equilibrium uptake of hydrogen at 77 and 90 °K is shown with the isosteric heat of adsorption and the ionic radius of the

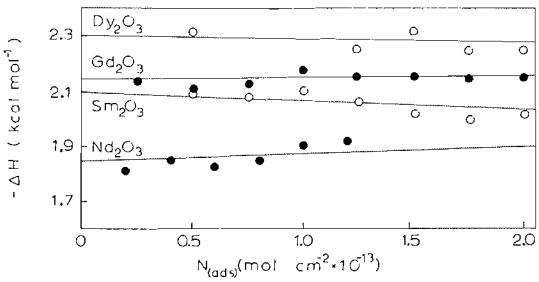

FIG. 8. Heat of adsorption for hydrogen *vs.* coverage.

metal ion for each of the four oxides studied. It can be seen that both the equilibrium uptake and the heat of adsorption increase as the ionic radius of the metal ion decreases. The increase in uptake can be explained by an increase in the number of anion vacancies per cm^2. The increase in heat of adsorption parallels the increase in the bond energy between hydrogen and the surface calculated by Balandin and Tolstopiatova (19).

(B) Oxygen Adsorption

Isobars

For both neodymium oxide and dysprosium oxide, adsorption was measurable over only a small temperature range. At an equilibrium pressure of 0.2 Torr, there is a maximum adsorption of 1.31 molecules cm^{-2} at 500 °K for neodymium oxide and 0.15 molecules cm^{-2} at 600 °K for dysprosium oxide. Barrett and Barry (14) observed a similar maximum in the isobar on A-type neodymium oxide and explained this by noting that below about 600 °K, adsorption is dominant over incorporation, whereas above this temperature incorporation becomes dominant. The relatively large uptake of oxygen for neodymium oxide is in line with the anomalously high activity reported for this oxide towards hydrogen oxidation (5, 7). The insulator character of these oxides is illustrated by the similarity between the amounts of hydrogen and oxygen adsorbed at high temperatures.

Form of the Isotherms

The data obtained from the isotherms at 677 °K on neodymium oxide and 591 °K on dysprosium oxide was used to determine the form of the isotherms. For both oxides, the results fitted the Freundlich isotherm and the Langmuir dissociative adsorption isotherm. The correlation was much higher for neodymium

oxide than for dysprosium oxide. The dissociative adsorption is to be expected in view of the activity of these oxides towards oxygen exchange reactions and the fact that adsorption increased considerably when a discharge was passed through the oxygen gas.

Kinetics of Adsorption

The adsorption was effectively instantaneous for all measurements except at 491 and 541 °K on neodymium oxide. The change in the kinetics of adsorption above 600 °K may result from the change in mechanism suggested by Barrett and Barry (14). The results at 491 °K were analyzed according to the integrated form of the Elovich equation:

$$N_{ads} = \frac{1}{\alpha}[\log_e (t + t_0) - \log_e t_0]$$

where α and t_0 are constants during any one run. A linear plot was obtained with a value of $t_0 = 15$ min.

In general, the data presented in this paper confirm the conclusions reached by Ashmead, Eley, and Rudham (2, 3) on the type of hydrogen adsorption occurring on neodymium oxide and dysprosium oxide. The results also show that, at high temperatures, hydrogen and oxygen adsorption occurs to similar extents, indicating that these oxides should be effective catalysts for the hydrogen–oxygen reaction. Comparison of the results over the four oxides show that there is a steady increase in both the equilibrium uptake and the heat of adsorption of hydrogen as the ionic radius of the metal ion decreases.

Appreciation is expressed for considerable help given by Dr. R. Rudham of Chemistry Department, Nottingham University, England.

A Selective Determination of the Proton Nuclear Relaxation Times of the Alkaloid Vindoline[1]

R. BURTON, C. W. M. GRANT,[2] AND L. D. HALL[3]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received August 9, 1971

An audiofrequency-pulse n.m.r. spectrometer has been used to measure the nuclear relaxation times of individual protons of the alkaloid, vindoline. For this substance in deuterochloroform solution the spin–lattice relaxation times (T_1) vary between 1.15 and 1.50 s and the spin–spin relaxation times (T_2) are between 0.90 and 1.40 s. The *N*-methyl group has the shortest relaxation time of those resonances which were measured. A discussion of the apparatus and methodology is given.

On a utilisé un spectromètre à pulsations audiofréquences r.m.n. pour mesurer les temps de relaxation nucléaire des protons individuels de l'alcaloïde vindoline. Si on met cette substance en solution dans le deutérochloroforme, les temps de relaxation spin–réseau (T_1) se situent entre 1.15 et 1.50 s. Les temps de relaxation spin–spin (T_2) varient entre 0.90 et 1.40 s. Le groupe *N*-méthyle possède le temps de relaxation le plus court parmi les résonances qui ont été mesurées. On donne une discussion sur l'appareillage et la méthode utilisés.

Canadian Journal of Chemistry, **50**, 497 (1972)

Introduction

The high resolution proton n.m.r. spectrum of a chemical substance may be characterized by four sets of parameters, namely: (*i*) the relative areas of the individual resonance bands or multiplets; (*ii*) the chemical shifts of the individual resonances; (*iii*) the coupling constants of each spin-multiplet; and (*iv*) the characteristic nuclear relaxation times T_1 and T_2 of each resonance or of each individual transition of a resonance multiplet.

The many, varied ways in which the first three sets of data can be used as the basis of structural, configurational, and conformational assignments are too well known to require discussion here. However, the diagnostic potential of the fourth set of parameters remains to be established and although experiments with simple chemical substances have been described (1), applications to more complex systems have remained unexplored.

The principal reason why measurements of proton relaxation times have, in the past, been confined to comparatively simple substances is that suitable instrumentation for selective measurements with complex molecules *on a routine basis* has not been available until very recently. The major instrumental breakthrough in this area is the audiofrequency pulse technique described by Freeman and Wittekoek in 1969 (2). Prior to that development the methods available, which included the so-called saturation recovery (3), multiple resonance (4), progressive saturation (5), and $(T_1)_\rho$ (6) techniques all suffered from a variety of limitations as far as larger molecules were concerned. Furthermore, the conventional types of radiofrequency-pulse experiments lacked the selectivity necessary for studies of complex systems.

In the present paper we shall show that the audiofrequency-pulse technique is suitable for relaxation-time measurements with substances having the molecular complexity commonly associated with "natural products". Specifically, we shall discuss measurements made with vindoline, a substance which is of interest because of its relation with the anti-tumour principles obtained from *Vinca rosea lin* (7). The important point which we wished to establish was whether the individual protons of a substance of this complexity would still have differing nuclear relaxation times: as will be seen a differential does exist, although all of the relaxation times are rather short.

It is inappropriate to give a detailed discussion here of the principles and of the limitations of the audiofrequency pulse technique since Freeman and Wittekoek (2) have already given an excellent account. Suffice for the present discussion to comment that since all of the radiofrequency fields of a Varian HA-100 n.m.r.

spectrometer are produced by audio-modulation techniques, the pulsed radiofrequency field required for nuclear-relaxation studies may be conveniently obtained by "gating" (switching) of the audio-modulation signal. In like fashion, the required radiofrequency phase-shifts are also conveniently obtained by introducing a phase change in the audio-modulation circuitry. It is important to note that these audio-frequency-pulse experiments have extremely stringent requirements as regards frequency stability; following Freeman and Wittekoek (2), we find it convenient to use a frequency synthesiser as the source of the audio-frequencies used for both the "lock" and the "observing" channels of the spectrometer.

Experimental

The basic format of the spectrometer used for nuclear relaxation experiments follows that of Freeman and Wittekoek (2). Because we were uncertain as to which pulse-durations would be most suitable for studies of complex organic substances we chose to use a small digital computer to control all pulse durations and intervals. It should be emphasized that the components which we used as the basis for the gate and other circuits were selected solely because they were already available in our laboratory at the time we started these experiments; more versatile, and cheaper, components are now available from a variety of manufacturers.

A block diagram of the instrument, together with the intersystem connections required for interface with a Varian HA-100 spectrometer, is given in Fig. 1. The two major components of the system are a JEOLCO computer (model JRA-5) and a Hewlett–Packard Frequency Synthesiser (model 5110B), which is driven by a "master oscillator" (Hewlett–Packard, model 5105B). For the convenience of these initial experiments a commercially available lock-in amplifier (Princeton Applied Research, model 121) was used for the detection of resonances in the observation channel in preference to the unit which is included in the Varian lock-box (V-4354).

The principal components of the pulse-unit are summarized in Fig. 2. Briefly, the circuitry used here serves the following functions:

(*a*) In the lock-channel, it takes a 1 MHz signal from the master oscillator and reduces it by digital division to a 2.5 KHz square wave. This signal (at 1 V p.p) is then used in the Varian lock-box (V-4354) instead of the signal normally provided by the manual oscillator (card 910868). We have made this interchange switchable so that it does not require physical removal of the manual oscillator card. All subsequent operations of the lock-circuitry are unaltered

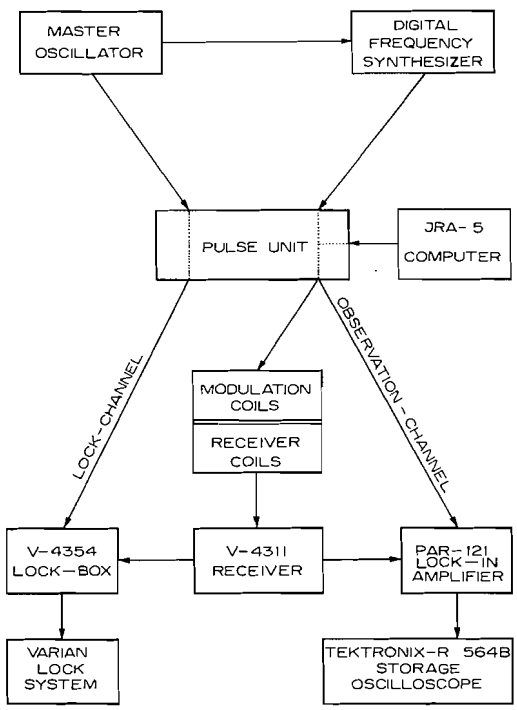

FIG. 1. Block diagram of the components used in the audiofrequency-pulse spectrometer.

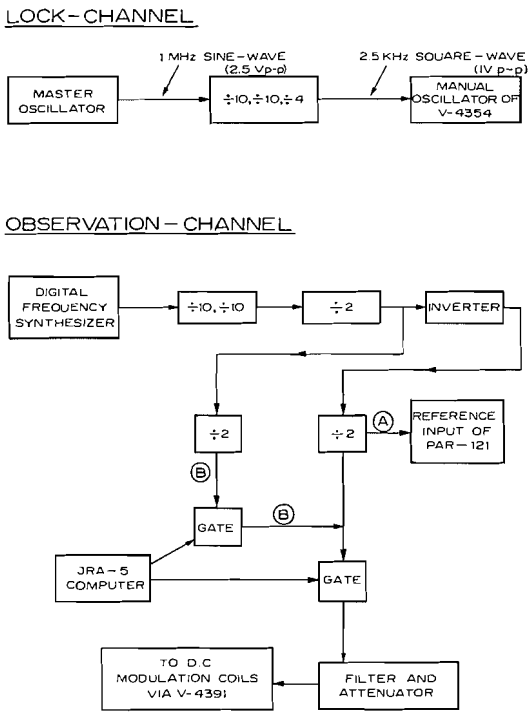

FIG. 2. Block diagram of the components used in the pulse-unit.

by this interchange except that lock-offsets are not possible.

(*b*) In the observation channel the circuitry provides the audio-modulation frequency required for the detection of resonances. At the same time this channel requires provision for switching, phase shifting, and filtering. In order to obtain a sufficiently fine (± 0.01 Hz) control of the frequency of the observation side-band, the digital frequency synthesizer is generally run at *ca.* 1 MHz and the required audiofrequency (*ca.* 2.5 KHz) is obtained by digital division as for the lock-channel. Since the phase-shifts required in pulse experiments are integral units of 90° these are conveniently obtained during the above division. Sequential division $\div 10$, $\div 10$, $\div 2$, invert, $\div 2$ gives the required audiofrequency square-wave which is used in line A (Fig. 2) as the reference signal to the PAR lock-in amplifier and to the gate. Using the first three stages of the above sequence ($\div 10$, $\div 10$, $\div 2$) followed by a separate $\div 2$ stage gives a second audiofrequency square-wave in line B. This square wave has precisely the *same frequency* as that of line A but differs from it and the signal in the lock-in amplifier by a *precisely 90° phase-shift*. Either of these two audiofrequencies can then be connected to the modulation coils via a filter and an attenuator. The latter is 10-turn, 200 ohm helipot.

The switching of both line A and line B is controlled by the JEOLCO JRA-5 computer which is programmed to perform the following:

(*a*) To accept positive integers ($<32\,000$) from the teletype; nine of these integers may be used. Each of these controls a specific switching operation.

(*b*) To turn on, or off, either line A or line B of the observation channel. When line A of Fig. 2 is "on" pulse, the phase-shift of the irradiating field is zero and when line B is "on" the phase-shift[4] is 90°.

(*c*) To pause for a time-interval which is numerically equal to the integer selected in (*a*) above, multiplied by 10 ms.

It is of course a trivial matter to vary the pulse-lengths, pulse-intervals, and phase sequences in any of a wide variety of ways.

The spectra obtained from the pulse spectrometer are conveniently recorded on a storage oscilloscope (Tektronix, model R564 B) and a permanent record obtained with a homemade scope camera[5] using Polaroid film. For very long relaxation-times it should be possible to use a highly responsive chart recorder; that of our Varian HA-100 is too slow.

Each individual relaxation measurement requires the sequential adjustment of the correct observing frequency, of the amount of power contained in a single pulse, and of the phase of the irradiating field. In general it is convenient to set up these parameters in the order: (*1*) pulse phasing, (*2*) exact frequency determination, (*3*) pulse power.

With the apparatus available to us at this juncture we have found it convenient to correctly adjust the phase of the observing field in the fashion generally used in high resolution n.m.r. experiments: by using the sweep-oscillator of the frequency synthesizer it is convenient to sweep repeatedly in both directions through the resonance of interest and to make adjustments of the phasing control of the PAR lock-in amplifier. Freeman and Wittekoek (2) have described previously how $(T_1)_\rho$ experiments can be used for optimizing the phasing controls. We have used their method and find it to be quite convenient providing that a $(T_1)_\rho$ experiment can be meaningfully performed on the particular sample: however, we have found such experiments to be difficult to perform in the presence of near-neighbor transitions (*vide infra*) and this seriously limits their generality.

The precise frequency required for a particular experiment can be obtained either of two ways. Either by direct measurement and calibration of the high resolution spectrum or by observation of the decay occuring after a pulse of 90° or less. In the latter case the line position is quickly measured to within 0.5 Hz and the frequency is adjusted in small increments to achieve a smooth exponential decay to baseline after each pulse. The off-resonance condition is marked by the trace of the magnetization vector either continuing through the baseline before returning to its equilibrium position or by a hump in the otherwise smooth decay curve. This method is very fast and quite general, and can give the frequency to within ± 0.02 Hz (depending on the linewidth).

The amount of power required to produce a particular pulse is conveniently ascertained by setting up the condition for a π-pulse; it is then a simple matter to halve the power for a $\pi/2$ pulse.

The set of spectra shown in Fig. 3 were obtained during the initial "debugging" of the instrument and serve to show the type of spectra which are readily obtained. In this regard they may be regarded as being truly "typical" results. These experiments are unexceptional. It is of interest to note in Fig. 3*e* the close superimposition of the T_2 and $(T_1)_\rho$ curves, which accords well with prediction (3*a*, 8).

It is convenient to obtain the numerical values of T_1 and T_2 from the scope photograph by graphical methods as follows.

Evaluation of T_1

The outline of the overall exponential decay curve, which is exemplified in Fig. 4*f* is given by

$$M_t = M_0(1 - 2\,e^{-t/T_1})$$

$$\therefore \qquad \ln (M_0 - M_t) = \ln (2M_0) - \left(\frac{1}{T_1}\right)t$$

where M_0 is the initial magnetization, M_t is the magnetization at some time t. Thus a plot of $\ln (M_0 - M_t)$ *vs.* t has slope $-(1/T_1)$ and intercept $\ln (2M_0)$.

Evaluation of T_2

The exponential decay of either a $(T_1)_\rho$ or a modified Carr–Purcell experiment is represented by the relationship

$$M_t = M_0 . e^{-t/T_2}$$

$$\therefore \qquad \ln M_t = \ln M_0 - \left(\frac{1}{T_2}\right)t$$

It follows from this that a plot of $\ln M_t$ against t has a slope of $-1/T_2$ and an intercept of $\ln M_0$.

[4]More accurately, the phase-shift between the reference signal going to the PAR-121 lock-in amplifier and the signal going to the modulation coil.

[5]Derived from a Polaroid camera (model 210). It is necessary to divide the original camera into two parts, the back-film holder and the lens-shutter mechanism. The two parts are then remounted approximately twice as far apart as in the original camera. The total cost of our camera was less than $50.

Discussion

The normal ^1H n.m.r. spectra of vindoline in deuterochloroform solution is shown in Fig. 4. Initially, the relaxation times of the acetate-methyl and N-methyl singlets were determined.

The measurement of the spin–spin relaxation times (T_2) for these two resonances followed the usual Meiboom–Gill modification (9) of

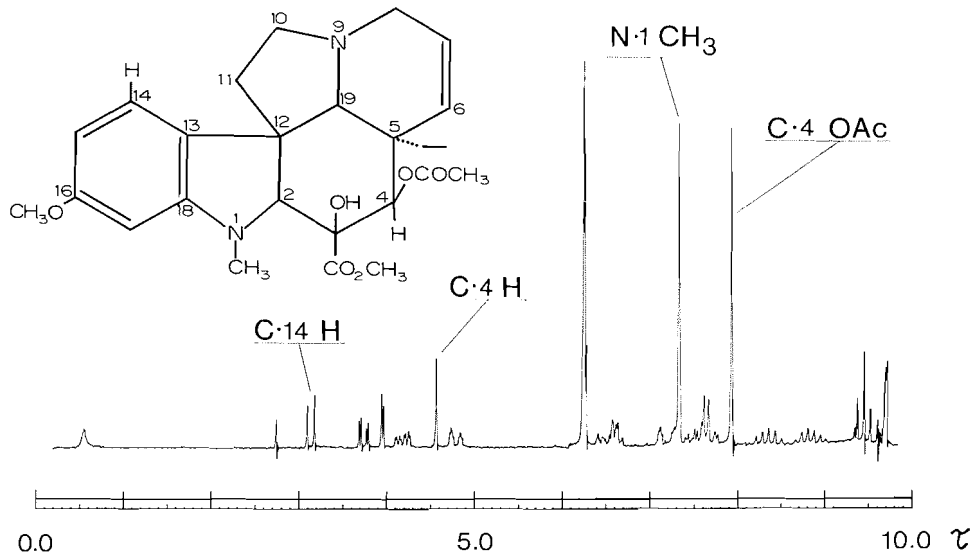

FIG. 4. The ^{1}H n.m.r. spectrum (100 MHz) of vindoline (0.100 g) in deuterochloroform (1.00 ml).

the Carr–Purcell experiment (10). A typical experiment is shown in Fig. 5. Because of the rather short relaxation time of these protons, the spin-echo trace falls to zero rather rapidly and only the first few echoes can be used for measurement purposes. The plot required for the estimation of the T_2 of this transition is shown in Fig. 6. It can be seen that even though the oscilloscope trace is not "elegant" the data it contains are internally consistent.

The determination of the spin–lattice relaxation time (T_1) is, in principle, possible via a single pulse sequence consisting of an initial π-pulse followed by a series of 2π-pulses at regular intervals. However, this technique can have a number of drawbacks: (*a*) errors in setting the length of the 2π-pulse are cumulative; (*b*) for transitions having short relaxation times the total time required by even the first few pulses may be prohibitive; indeed in the case of very short T_1 values the time required for application of a single 2π-pulse may be an appreciable fraction of the total T_1; (*c*) in the same context, the selectivity required for a particular experiment may be incompatible with the power needed to apply a series of 2π-pulses.

An alternative approach which is more time consuming but which is less influenced by the presence of near-neighbor lines, involves a

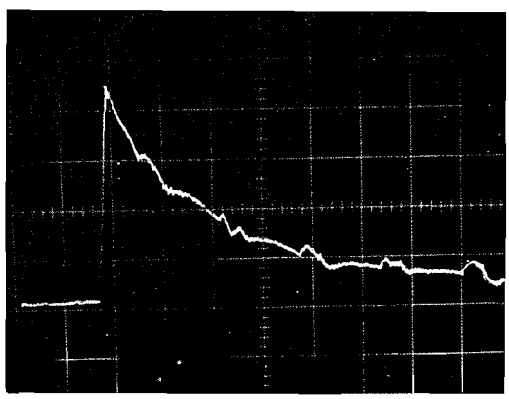

FIG. 5. Measurements of T_2 of the C-4 acetate resonance of vindoline, using a modified Carr–Purcell sequence. $\pi/2$-Pulse duration 0.1 s, scale 0.5 s/cm.

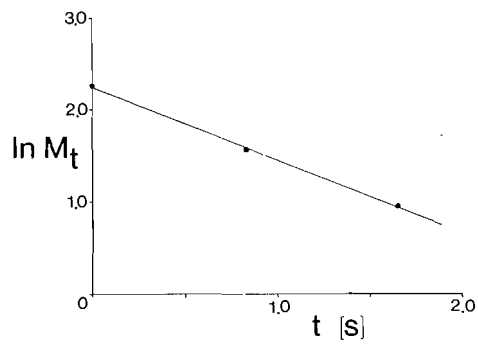

FIG. 6. Plot for measurement of T_2 of the C-4 acetate resonance of vindoline based on data derived from Fig. 5. For each measurement several runs were recorded at different pulse intervals and were averaged.

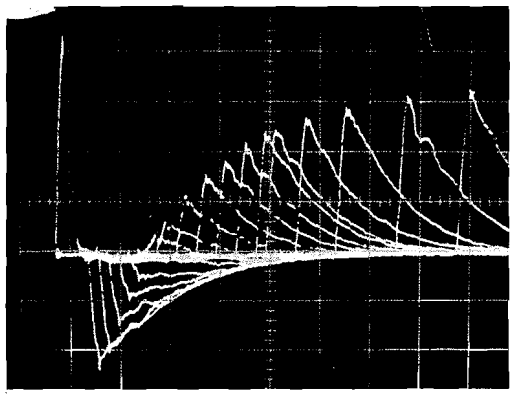

FIG. 7. The T_1 measurement on the C-4 acetate resonance of vindoline. $\pi/2$-Pulse duration, 0.10 s, scale 0.5 s/cm.

repeated series of two-pulse experiments. Initially a π-pulse is applied to tip the magnetization vector along the $-z$-axis and then after a specified delay-time, during which the magnetization vector undergoes some decay, the remaining magnetization is assayed by application of a $\pi/2$-pulse which then tips the vector along the observation axis. After a suitable resting period the whole process is repeated using a different delay-time. A sequence of such experiments gives the entire T_1-decay envelope including the zero-point, as is illustrated in Fig. 7.

Instrumentally, the measurement of $(T_1)_\rho$ values is particularly straightforward by the audiofrequency-pulse method. Thus, the initial $\pi/2$-pulse is readily phase-shifted by precisely 90° and the $(T_1)_\rho$ decay detected. Unfortunately, these particular measurements appear to be sufficiently prone to interference from neighboring lines that their general application to complex organic substances would appear to be somewhat limited. For example, the $(T_1)_\rho$ measurement shown in Fig. 8 clearly fails to return to the baseline as it should.

Following these comparatively simple experiments on the intense singlet resonances, attention was next directed to the other resonances. The two methoxyl groups gave two resonances which were only separated by *ca.* 1 Hz and it proved impossible to effect any recognizable experiments with them. On the other hand, the singlet due to the single C-4 proton was readily amenable to measurements of both T_1 and T_2. Of the many spin-multiplets only the sharp doublet due to the C-14 proton proved suitable for relaxation measurements. This doublet has a splitting of 8.0 Hz and it was possible to perform measurements on both of the transitions. We were disappointed that it was impossible to make measurements on the other well-resolved multiplets: unfortunately the small peak-separations and the rather short relaxation times effectively precluded meaningful experiments. Indeed we were so concerned by the lack of success that extensive efforts were made to degass a solution of vindoline: no appreciable lengthening of relaxation times was observed.

It does not seem appropriate to make any lengthy discussion of the values of the relaxation times obtained, beyond a brief comment that even though they are all quite short, some differential still remains. As can be seen from the data summarized below the *N*-methyl group has the shortest relaxation time as might have been expected. The experiments on vindoline give values which are probably accurate to $\pm 10\%$ in terms of reproducibility.

In conclusion then, it seems that selective

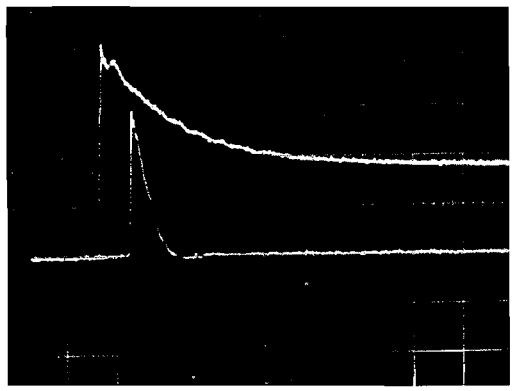

FIG. 8. Traces arising from application of a $\pi/2$-pulse (lower trace) and a $(T_1)_\rho$-pulse (upper trace) to the resonance of the C-4 proton. $\pi/2$-Pulse duration 0.10 s, scale 1.0 s/cm. Note the extra height of the $(T_1)_\rho$-pulse and the fact that its trace does not return to the baseline.

measurements of the individual relaxation times of the protons of reasonably complex organic substances are feasible. The audiofrequency-pulse technique is compatible with measurements for transitions separated by 5 Hz or more from a neighboring resonance, providing that the monitored transition is sharp, *i.e.* $T_2 > 3$ s: for broader transitions a separation of 8–10 Hz is a more realistic one. Providing these limitations are satisfied these measurements can be performed by rather modest modifications to many commercially available high resolution n.m.r. spectrometers.[6] Although relaxation times may in principle be used as the basis for a variety of structural assignments, it is clearly necessary for a systematic catalogue of data to be accumulated before this potential can be realized. If more complete relaxation determinations are to be made for complex organic molecules then techniques having a greater degree of selectivity than those discussed in this paper will be required.

It is also noteworthy that Fourier Transform (F.T.) techniques are being developed (12–14) which should shorten considerably the amount of time required for the routine measurement of selective relaxation times. In this context it is interesting to note that the measurement of T_1 by the F.T. method may involve the repeated application of two-pulse sequences and is thus somewhat analogous to the two-pulse experiments described in this paper. The principal limitations of the F.T. method at this time are associated with measurements of T_2.

[6]Two other laboratories have recently reported the development of audiofrequency-pulse accessories; see ref. 11.

It is a pleasure to thank Dr. Ray Freeman of Varian Associates for his advice and encouragement in the early stages of this project. This work was supported by equipment grants (E-1338 and E-I854) and by an operating grant (A-1905) from the National Research Council of Canada. The sample of vindoline was provided by Dr. J. P. Kutney of this Department.

Measurements of Deuterium Chemical Shifts by $^1H-\{^2H\}$ INDOR Spectroscopy[1]

J. R. CAMPBELL,[2] L. D. HALL, AND P. R. STEINER[3]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 13, 1971

Heteronuclear $^1H-\{^2H\}$ INDOR spectroscopy has been used to measure the deuterium chemical shifts of acetone-d_5, dimethylsulfoxide-d_5, and of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose-3-*d*.

La spectroscopie hétéronucléaire $^1H-\{^2H\}$ INDOR a été utilisée pour mesurer les déplacements chimiques du deutérium dans l'acétone-d_5, le diméthylsulfoxyde-d_5, et dans le 1,2:5,6-di-*O*-isopropylidène-α-D-allofuranose-3-*d*.

Canadian Journal of Chemistry, **50**, 504 (1972)

Introduction

With the ever increasing availability of reagents for introducing deuterium substituents into organic systems the need for information concerning deuterium chemical shifts has become more pressing. Direct detection of a deuterium (^2H) resonance is possible, but is complicated somewhat by the comparatively low relative intrinsic sensitivity of deuterium compared (1) with that of protons (9.65×10^{-3}:1). The present paper demonstrates that the measurement of deuterium chemical shifts by the INDOR[4] technique is facile. Since there appears to be a general paucity of absolute deuterium chemical shift data we have included measurements with several simple substances which are commonly used as solvents for n.m.r. studies; these latter data are of particular importance because of the development of n.m.r. instruments[5] which rely on a deuterium resonance as the basis for a heteronuclear lock. Surprisingly, we could find no previous record of this application of INDOR spectroscopy.

Experimental

All n.m.r. measurements were made with an extensively modified Varian HA-100 spectrometer operating in the frequency-swept mode, and using tetramethylsilane as internal reference for the field-frequency lock. The transmitter coil of the V-4332 probe was double-tuned to accept the 100 and the 15 MHz frequencies, as described elsewhere (3). The components used for the heteronuclear INDOR accessory have been described previously (4).

The samples of deuteroacetone, deuterobenzene, and deuterodimethylsulfoxide were commercially available[6] solvents. 1,2:5,6-Di-*O*-isopropylidene-α-D-allofuranose-3-d was kindly provided by Mr. Bruce Donaldson of this laboratory.

The experimental values of the deuterium resonance frequencies, measured in Hz, were converted to a scale on which the ^1H resonance of tetramethylsilane occurs at precisely 100 MHz, using the formula (5),

$$X_{TMS} = \frac{10^8 . X_{obs}}{10^8 + \text{lock sideband frequency}}$$

where X_{TMS} is the chemical shift relative to the protons of tetramethylsilane resonating at exactly 100 000 000 Hz and X_{obs} is the resonance frequency actually recorded (TMS is the the lock signal).

Results and Discussion

In order to ascertain the feasibility of this project, and also the power levels at which the deuterium resonance might be best detected, a detailed study was made of a sample of commercially available acetone-d_6. This material contained a small amount of acetone-d_5 as an isotopic impurity. The ^1H resonance of this "impurity" is shown in Fig. 1A; it is a 1:2:3:2:1 quintet due to the coupling of the lone proton with two equivalent deuterium nuclei, each having spin of unity. The geminal hydrogen–deuterium coupling is 2.2 Hz. INDOR measurements were made in which these five transitions were sequentially monitored while the frequency synthesizer was digitally swept through the appropriate frequency range.

The traces shown in Figs. 1B, C, D, E, and F indicate the observed INDOR responses; the

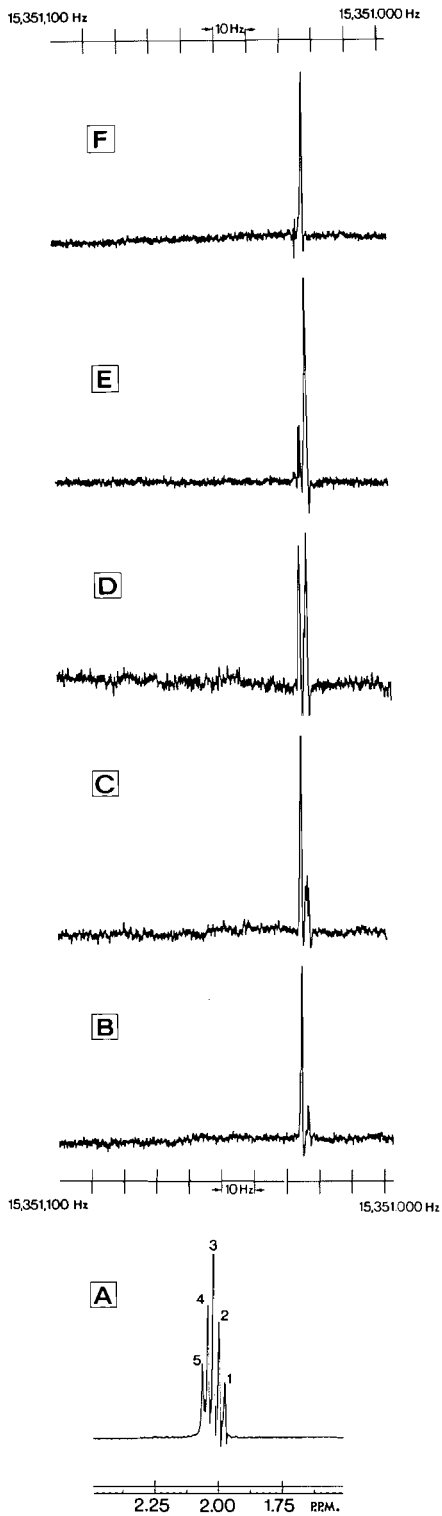

FIG. 1. A, The ^1H n.m.r. spectrum (100 MHz) of the acetone-d_5 "impurity" present in deuteroacetone. The traces shown in B, C, D, E, and F are the INDOR responses obtained by monitoring sequentially transitions 1 through 5 while scanning a radio frequency through the deuterium resonance region.

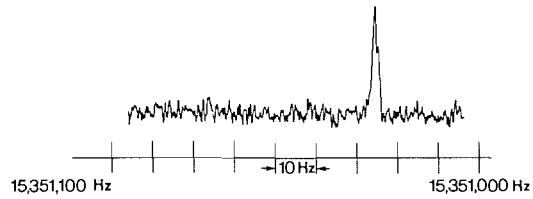

FIG. 2. The response observed during a $^1H-\{^2H\}$ INDOR experiment in which the central transition of the resonance of the acetone-d_5 "impurity" of a solution of deuteroacetone–tetrachloromethane (10% v/v) was monitored. The power level of the deuterium radio frequency field was chosen to give the optimal signal-to-noise ratio.

power level of the radio frequency used to irradiate the deuterium spectrum was chosen such that the doublet shown in Fig. 1D had the optimal resolution (the line width at half-height is 0.5 Hz). The splitting of the observed doublet (2.2 Hz) is, as expected, identical with that of the proton resonance shown in Fig. 1A. A singlet response is observed in the other four traces because the monitored lines correspond to a single deuterium spin state: only transition 3 is degenerate in this regard.

Subsequent experiments with the same sample of deuteroacetone showed that an increase in the radio frequency power caused an enormous improvement in the effective signal-to-noise ratio of the measurement, albeit with some increase in half-height width (to 2.0 Hz). The spectrum shown in Fig. 2 of a solution of deuteroacetone in tetrachloromethane (10% v/v), gives some indication of the sensitivity available.

With these experiments completed it was a simple matter to measure the chemical shifts of the isotopic impurities of deuterobenzene (benzene-d_5) and of deuterodimethylsulfoxide (dimethylsulfoxide-d_5). The chemical shift data, corrected as described in the experimental section are given in Table 1. It must be emphasized that these values are slightly different from those of the related perdeutero derivatives

TABLE 1. Deuterium chemical shifts

Compound	Deuterium chemical shifts	
	Observed frequency (Hz)	Calculated value* (Hz)
$CD_3C(O)CD_2H$	15 351 026	15 350 641
C_6D_5H	15 351 103	15 350 718
$CD_3S(O)CD_2H$	15 351 031	15 350 646
	15 351 056	15 350 671

*Using the formula given in the Experimental section.

because of a small isotope shift.[7] Strictly, the value for benzene is that of the deuterium substituents which are ortho to the proton substituent.

In order to demonstrate the feasibility of measuring the deuterium shifts of a specifically deuterated substance having somewhat higher molecular weight, measurements were made with a sample of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose-3-d. The spectrum obtained by monitoring an H-2 transition is shown in Fig. 3

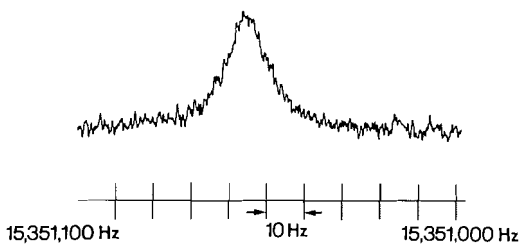

FIG. 3. Response obtained from a $^1H-\{^2H\}$ INDOR experiment on 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose-3-*d* in deuterochloroform solution (20% w/v). The high field transition of the H-2 resonance was monitored.

[7]We do not wish to discuss such isotope effects here although two referees requested that we should. For a paper on the isotope effects of deuterium substituents on ^1H *shifts* see ref. 6.

and the chemical shift is listed in Table 1. Although the resolution of this resonance is poorer than that observed for the traces shown in Fig. 1 the accuracy of the chemical shift is entirely adequate for most chemical purposes.

In summary then, it is possible to measure deuterium chemical shifts *via* the $^1H-\{^2H\}$ INDOR method for compounds having a deuterium substituent which is coupled with a proton; however, the shifts obtained will not be the same as those of the perdeutero-derivative.

It is a pleasure to thank the National Research Council of Canada for their generous financial support, via both equipment and operating grants.

Addition of Pseudohalogens to Unsaturated Carbohydrates. V. Addition of Iodine Trifluoroacetate[1]

R. G. S. RITCHIE AND W. A. SZAREK
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 20, 1971

Treatment of 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (**1**) with silver trifluoroacetate and iodine in acetonitrile gave 3,6-anhydro-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-gluco(and β-L-ido)-furanose (**2**) and 5-deoxy-5-iodo-1,2-*O*-isopropylidene-6-*O*-trifluoroacetyl-α-D-gluco(and/or β-L-ido)furanose (**3**). Component **2** was converted into 3,6-anhydro-5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**5**) by hydrogenation over Raney nickel, and component **3** was converted into 5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**6**) by treatment with methanol, followed by hydrogenation. Treatment of 5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-trifluoroacetyl-α-D-*xylo*-hex-5-enofuranose (**7**) with silver trifluoroacetate and iodine in acetonitrile gave the addition product **8**, but no 3,6-anhydro derivative; **8** was converted into the iodohydrin **4** by treatment with methanol. The preparation of the 5-deoxy derivative **6** by way of the iodohydrin **4** represents an overall anti-Markovnikov hydration of the olefin **1**; the reactions described are a convenient alternative to the hydroboration–oxidation procedure for the preparation of **6**.

Le traitement du 5,6-didéoxy-1,2-*O*-isopropylidène-α-D-*xylo*-hex-5-énofuranose (**1**) par le trifluoracétate d'argent et l'iode dans l'acétonitrile conduit aux 3,6-anhydro-5-déoxy-5-iodo-1,2-*O*-isopropylidène-α-D-gluco(et β-L-ido)furanose (**2**) et 5-déoxy-5-iodo-1,2-*O*-isopropylidène-6-*O*-trifluoroacétyl-α-D-gluco(et/ou β-L-ido)furanose (**3**). Le composé **2** a été transformé en 3,6-anhydro-5-déoxy-1,2-*O*-isopropylidène-α-D-*xylo*-hexafuranose (**5**) par hydrogénation sur nickel de Raney et le composé **3** a été transformé en 5-déoxy-1,2-*O*-isopropylidène-α-D-*xylo*-hexofuranose (**6**) par traitement avec le méthanol puis par hydrogénation. Le traitement du 5,6-didéoxy-1,2-*O*-isopropylidène-3-*O*-trifluoroacétyl-α-D-*xylo*-hex-5-énofuranose (**7**) par le trifluoroacétate d'argent et l'iode dans l'acétonitrile conduit au produit d'addition **8**, mais pas au dérivé 3,6-anhydro; le composé **8** a été transformé en iodohydrine **4** par traitement dans le méthanol. La préparation du dérivé 5-déoxy **6** au moyen de l'iodohydrine **4** représente une hydratation anti-Markovnikov de l'oléfine **1**; les réactions décrites représentent un autre moyen possible d'hydroboration-oxydation pour la préparation de **6**.

Canadian Journal of Chemistry, **50**, 507 (1972)

Introduction

The addition of pseudohalogens to unsaturated carbohydrates, as a method of introducing nitrogen-containing functional groups, has been the subject of several recent publications (1–6). In connection with a study (7) of the addition of iodine nitrate, it was necessary to prepare some carbohydrate iodohydrins. Such compounds have been obtained mainly from sugar epoxides (8). Recently, the preparation of iodohydrins directly from olefins, by reaction with iodine in the presence of water and a suitable oxidizing agent, was described by Cornforth and Green (9). Here we report some results of an investigation of the synthesis of carbohydrate iodohydrins by way of the addition of iodine trifluoroacetate to unsaturated carbohydrates. The trifluoroacetyl group has been used in carbohydrate chemistry as a blocking group, particularly, because of its ease of hydrolysis; removal of the group has been achieved under extremely mild conditions at room temperature with anhydrous methanol, aqueous acetone, or aqueous pyridine (10).

Iodine trifluoroacetate is produced by the reaction of iodine and silver trifluoroacetate; the positive iodine generated in this way has been shown (11) to be very reactive in electrophilic aromatic substitution. Henbest (12) first reported the addition of iodine trifluoroacetate to ethylenic compounds, although in that work, the adducts were not isolated. In 1966 Hey *et al.* (13) showed that iodine trifluoroacetate adds stereospecifically to 5α-cholest-2-ene to give 3α-iodo-5α-cholestan-2β-yl trifluoroacetate in high yield. In the present work the reaction of iodine trifluoroacetate with 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (**1**) (14) and a 3-*O*-substituted derivative (**7**) has been studied.

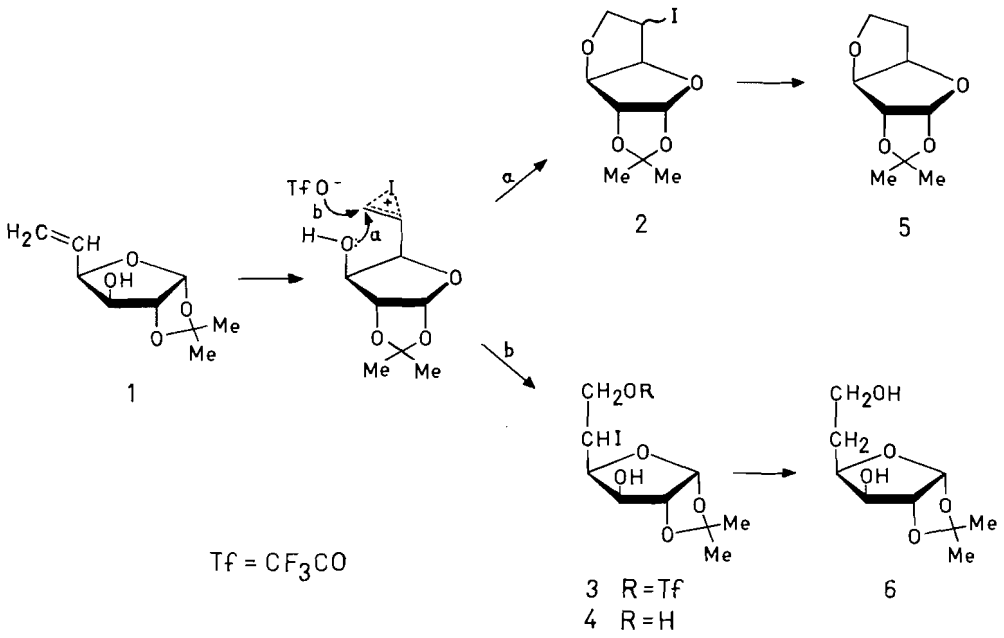

SCHEME 1

Results and Discussion

Addition of silver trifluoroacetate and olefin **1** to a solution of iodine in acetonitrile[2] at room temperature gave in 5 min a syrupy mixture of two components; the i.r. spectrum showed absorptions at 3460 and 1790 cm^{-1} attributable to the presence of hydroxyl and trifluoroacetate groups, respectively. The isolation of a compound containing a trifluoroacetate group could not, however, be achieved by column chromatography on silica gel, because of the lability of this group. Instead, the mixture was briefly treated with methanol, and the resultant syrupy material was fractionated on silica gel. Two components were obtained, which were assigned the structures **2** and **4** (Scheme 1). The first component was a crystalline solid with a 5° m.p. range; its i.r. spectrum and elemental analysis were consistent with the assigned structure (**2**). However, the presence in the n.m.r. spectrum of two doublets with equal spacings (3.7 Hz) at τ 3.76 and 4.06, attributable to H-1, indicated that this component was a mixture of two compounds; the ratio of peak areas was 2:15, respectively. Hydrogenation over a Raney nickel catalyst gave only one compound, which was assigned the structure of 3,6-anhydro-5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**5**) on the basis of its n.m.r. spectrum. The first component was, therefore, a 2:15 mixture of epimers: 3,6-anhydro-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-glucofuranose and the β-L-*ido* isomer. The isomer distribution was assigned on the basis of the chemical shifts of the H-1 signals in the n.m.r. spectrum. In the L-*ido* compound, the iodine is *exo* in the bicyclic system formed by the furanose and 3,6-anhydro rings, whereas, in the D-*gluco* compound, it is *endo*, and relatively close to H-1. The H-1 signal in the former compound should, therefore, be less affected by the iodine at C-5, and it is reasonable to expect that its chemical shift would be very close to that of the H-1 signal in the 5-deoxy compound **5** (τ 4.08). Thus, the preponderant isomer, whose H-1 signal is at τ 4.06, has been assigned the L-*ido* structure.

The second component (**4**) was isolated as a syrup in 37% yield. Its i.r. spectrum showed a very strong hydroxyl absorption at 3460 cm^{-1}, but no absorption attributable to a trifluoroacetate group. The assignation of the iodine to

[2]The use of acetonitrile for the *in situ* generation of iodine trifluoroacetate gave satisfactory results with equimolar amounts of silver trifluoroacetate and iodine; other workers used an excess of the silver salt with nitrobenzene (11) or methylene chloride (13).

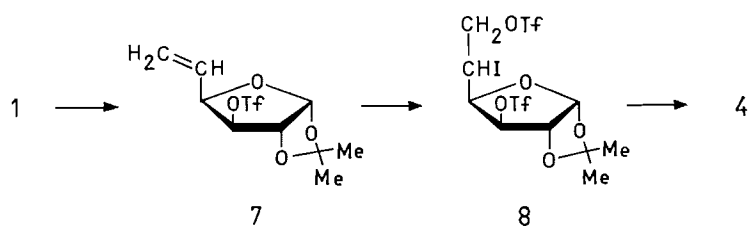
C-5 was established by the conversion of **4** into 5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**6**) by hydrogenation over a Raney nickel catalyst. The preparation, in the present work, of the 5-deoxy derivative **6** by way of the iodohydrin **4** represents an overall anti-Markovnikov hydration of the unsaturated sugar **1**. An improved protocol for the conversion of **1** into **6** is described later in this paper. A synthesis of **6** from **1** has been reported previously (15), namely, by hydroboration. A number of other syntheses of compound **6** have also been achieved (16).

Component **4** was unstable on standing, and an iodine-colored syrup was formed even in the dark at 5°. The structure proposed for **4** was supported by its mass spectrum, which shows many of the features of the spectra of monosaccharide isopropylidene derivatives (17). A weak molecular ion was observed at *m/e* 330 ($C_9H_{15}O_5I$), and a more intense peak at *m/e* 315 (M-15) owing to the ion formed from the molecular ion by elimination of one of the methyl groups; the most intense peak was at *m/e* 59, attributable to protonated acetone.

The reaction of 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (**1**) with silver trifluoroacetate and iodine in acetonitrile is considered to proceed by way of an intermediate cationic species such as that shown in Scheme 1. Attack by the C-3 hydroxyl group at the less-hindered C-6 position (route *a*) would then yield a 3,6-anhydro derivative (**2**), whereas attack by trifluoroacetate ion (route *b*) would give a 5-deoxy-5-iodo-6-*O*-trifluoroacetyl derivative (**3**). Treatment of **3** with methanol afforded the iodohydrin **4**. The possibility of the formation of **2** from the adduct **3** in the reaction mixture was excluded by the observation that the proportion of the products remained unchanged when the time of the reaction was extended from 5 to 40 min. Moreover, the formation of **2** was not observed, within 40 min, when olefin **1** was treated with only iodine in acetonitrile; a decomposition of **1**, involving elimination of acetone, was observed with longer reaction times. Since the two faces of the double bond in **1** are diastereotopic, the addition of iodine trifluoroacetate by the mechanism suggested above would be expected to yield two diastereoisomers. Although the presence of two isomers of **2** was clearly discernible in its n.m.r. spectrum by the observation of two anomeric signals, such was not the case for **4**. The spectrum of **4** showed what appeared to be only one anomeric signal. It is interesting that, in the reaction of the pseudohalogen iodine azide (IN_3) with olefin **1**, the formation of a 3,6-anhydro derivative was not reported (4); the product isolated was the adduct 6-azido-5,6-dideoxy-5-iodo-1,2-*O*-isopropylidene-β-L-idofuranose. The addition of iodine azide presumably also occurs by way of the cyclic iodonium ion intermediate shown in Scheme 1. In the present work, the formation of the 3,6-anhydro component **2** as the preponderant product is probably attributable to the trifluoroacetate anion's low nucleophilicity.

In order to obviate the formation of a 3,6-anhydro derivative, it was clearly necessary to block the hydroxyl group at C-3 in the olefin **1** with a non-participating group. For this purpose, the highly electronegative trifluoroacetyl group was selected. Thus, treatment of olefin **1** with trifluoroacetic anhydride – sodium trifluoroacetate gave an almost quantitative yield of the 3-*O*-trifluoroacetyl derivative **7** (Scheme 2). The reaction of **7** with silver trifluoroacetate and iodine in acetonitrile then gave the adduct **8** in high yield without the formation of a 3,6-anhydro derivative. A brief treatment of **8** with methanol afforded the iodohydrin **4**. The preceding reactions constitute a convenient procedure for the preparation of **4**, and hence of



SCHEME 2

For personal use only.

the 5-deoxy sugar derivative **6** with subsequent hydrogenation.

Hey *et al.* (13) have reported that heating 3α-iodo-5α-cholestan-2β-yl trifluoroacetate, the adduct from the reaction of 5α-cholest-2-ene and iodine trifluoroacetate, with silver trifluoroacetate and hydrolyzing the intermediate (presumably the 2β,3β-diester) gave the 2β,3β-diol. In the present work, an attempted displacement of an iodo group by trifluoroacetate in **8**, using silver trifluoroacetate in acetonitrile, gave only an intractable material. With dichloromethane–toluene as the solvent, even after refluxing for 24 h, no change in the starting material was observed.

Experimental

Melting points were determined with a Fisher–Johns apparatus and are uncorrected. Microdistillations were performed with a Gallenkamp heating block. Optical rotations were measured using a Perkin–Elmer Model 141 automatic polarimeter at 23 ± 2°. The i.r. spectra were recorded on a Unicam SP 1000 or a Perkin–Elmer 180 spectrophotometer. The n.m.r. spectra were obtained on a Varian A-60 spectrometer in chloroform-*d* with tetramethylsilane (τ 10.00) as internal standard; coupling constants were measured at a 250 Hz sweep width. High resolution mass spectra were determined with a JEOLCO double focusing spectrometer, Model JMS-01SC, equipped with a heated, direct sample-injection system operated at 83°, and fitted to record data by a photoplate; ionizing potential 75 eV. The t.l.c. was performed with silica gel G as the adsorbent in the following solvent systems (v/v): (A) petroleum ether (b.p. 60–80°) – ethyl acetate, 3:2; (B) 3:1; (C) 2:3. The developed plates were air-dried, sprayed with 5% ethanolic sulfuric acid, and heated at about 150°. Column chromatography was performed on Brinkmann silica gel (70–325 mesh) with the following eluants (v/v): (D) carbon tetrachloride – ethyl acetate, 3:1; (E) 1:1; the glass columns were covered with aluminum foil to exclude light. Carbon tetrachloride was freshly distilled, and acetonitrile was kept over Type 3A molecular sieves for at least 1 week prior to its use. Solvents were evaporated under reduced pressure below 35°. Silver trifluoroacetate was prepared as described by Janssen and Wilson (18).

Reaction of 5,6-Dideoxy-1,2-O-isopropylidene-α-D-xylo-hex-5-enofuranose (1) with Silver Trifluoroacetate and Iodine

Olefin **1** (395 mg, 2.1 mmol) and silver trifluoroacetate (563 mg, 1.2 equiv) in dry acetonitrile (15 ml) were added, in one portion, to a stirred solution of iodine (647 mg, 1.2 equiv) in dry acetonitrile (25 ml) in a flask covered with aluminum foil. After 5 min, the reaction mixture was filtered, and the filtrate was concentrated to a dark red syrup. The syrupy residue was extracted with carbon tetrachloride (50 ml), and the extract was washed with aqueous sodium thiosulfate solution, dried over anhydrous sodium sulfate in the presence of decolorizing charcoal, and filtered through Celite. The clear, colorless filtrate was concentrated to a syrup (761 mg). The t.l.c. (solvent A) showed that all of the starting olefin (R_F 0.5) had been consumed and revealed the presence of two new components, one as a well defined spot (R_F 0.8) and the other as a tailing spot (R_F 0.6). The i.r. spectrum (film) showed absorptions at 3460 (OH) and 1790 cm^{-1} ($CF_3C{=}O$). The syrup was dissolved in methanol; after 1 min, t.l.c. (solvent A) showed the presence of two components having R_F values of 0.8 and 0.2. The solvent was evaporated to leave a pale yellow syrup (633 mg), which was fractionated on silica gel, with solvent D as eluant, to yield the two components **2** and **4**.

Component **2** was obtained from ethanol as a crystalline solid (295 mg, 45%), m.p. 105–110°, $[\alpha]_D$ +4° (*c*, 1.0 in chloroform); ν_{max} ($CHCl_3$) 1380, 1390 cm^{-1} (CMe_2), no absorption attributable to OH or $CF_3C{=}O$; n.m.r. data: τ 3.76, 4.06 (1-proton, two doublets with a ratio of peak areas of 2:15, respectively, $J_{1,2} = 3.7$ Hz, H-1 of two isomers), 5.15 (1-proton quartet, $J_{3,4} = 3.4$ Hz, $J_{4,5} = 2.4$ Hz, H-4), 5.25 (1-proton doublet, $J_{2,3} < 0.5$ Hz, H-2), 5.45 (1-proton doublet, H-3), 5.7–6.3 (3-proton multiplets, H-5, 2H-6's), 8.50, 8.67 (3-proton singlets, CMe_2).

Anal. Calcd. for $C_9H_{13}O_4I$: C, 34.6; H, 4.2; I, 40.7. Found: C, 34.8; H, 4.2; I, 40.4.

Component **4** was obtained as a syrup (260 mg, 37%), $[\alpha]_D$ −2°, $[\alpha]_{365}$ +10° (*c*, 0.9 in chloroform), ν_{max} (film) 1380, 1390 (CMe_2), 3440 cm^{-1} (very strong, OH), no absorption attributable to $CF_3C{=}O$; n.m.r. data: τ 4.04 (1-proton doublet, $J_{1,2} = 3.6$ Hz, H-1), 5.32 (1-proton doublet, $J_{2,3} <$ 0.5 Hz, H-2), 5.68 (3-proton broad singlet), 5.88 (2-proton singlet, disappeared on deuteration, 2OH's), 6.03 (2-proton multiplet), 8.48, 8.64 (3-proton singlets, CMe_2).

Anal. Calcd. for $C_9H_{15}O_5I$: C, 32.7; H, 4.6. Found: C, 32.4; H, 4.7.

Syrupy **4** was unstable on standing, and a satisfactory analysis for iodine could not be obtained. The molecular formula was confirmed by mass spectrometry: M^+ 329.994, M^+-Me 314.970 (Calcd. for $C_9H_{15}O_5I$: 329.996; M^+-Me: 314.973).

3,6-Anhydro-5-deoxy-1,2-O-isopropylidene-α-D-xylo-hexofuranose (5)

A solution of component **2** (168 mg, 0.54 mmol) in ethanol containing W-4 Raney nickel catalyst and triethylamine (1 ml) was subjected to a hydrogen pressure of 40 p.s.i.g. The t.l.c. (solvent B) showed that the reaction was complete in 80 min. The catalyst was removed by filtration and extracted with boiling ethanol. The combined filtrate and extract were concentrated, and the residue was partitioned between ether and water. The dried (sodium sulfate) ether solution was decolorized with charcoal and then concentrated to give **5** as an oil (79 mg, 79%), b.p. 56–60°/0.06 Torr, $[\alpha]_D$ +15.5° (*c*, 2.0 in chloroform); n.m.r. data: τ 4.08 (1-proton doublet, $J_{1,2} = 3.9$ Hz, H-1), 5.02 (1-proton multiplet, H-4), 5.39 (1-proton doublet, $J_{2,3} <$ 0.5 Hz, H-2), 5.58 (1-proton doublet, $J_{3,4} = 3.4$ Hz, H-3), 5.86–6.34 (2-proton multiplet, 2H-6's), 7.75–8.18 (2-proton multiplet, 2H-5's), 8.49, 8.67 (3-proton singlets, CMe_2). The i.r. spectrum did not show any absorptions attributable to OH or $CF_3C{=}O$.

Anal. Calcd. for $C_9H_{14}O_4$: C, 58.0; H, 7.6. Found: C, 57.9; H, 7.7.

For personal use only.

5-Deoxy-1,2-O-isopropylidene-α-D-xylo-hexofuranose (6)

A solution of freshly prepared component **4** (264 mg, 0.8 mmol) in ethanol containing W-4 Raney nickel catalyst and triethylamine (1 ml) was subjected to a hydrogen pressure of 40 p.s.i.g. for 3 h; the progress of the reaction was followed by t.l.c. (solvent C). The catalyst was removed by filtration and extracted with boiling ethanol. The combined filtrate and extract were concentrated to a crystalline residue, which was extracted with ether. The ether was evaporated, and the residue was chromatographed on silica gel (60–120 mesh), with, initially, 1:2 carbon tetrachloride–ethyl acetate and, finally, ethyl acetate as eluants, to yield compound **6** (104 mg, 64%). After recrystallization from ether–petroleum ether (b.p. 60–80°), the compound had m.p. 93–94.5° and $[\alpha]_D$ −10.5° (*c*, 1.7 in chloroform). These physical constants are in agreement with those reported for compound **6** by other workers (15, 16); its n.m.r. spectrum was identical with that published by Wolfrom *et al.* (15).

5,6-Dideoxy-1,2-O-isopropylidene-3-O-trifluoroacetyl-α-D-xylo-hex-5-enofuranose (7)

5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (**1**) (312 mg, 1.68 mmol) and sodium trifluoroacetate (77 mg) were treated with ice-cold trifluoroacetic anhydride (1 ml). The vigorous, exothermic reaction subsided in 5 min, and the mixture was then concentrated to dryness, under reduced pressure and a bath temperature of less than 35°, three times with 50 ml portions of carbon tetrachloride. The residue was extracted with hot carbon tetrachloride, and the solvent was evaporated to give **7** as a colorless oil (450 mg, 95%), b.p. 40–43°/0.008 Torr, $[\alpha]_D$ +24.4° (*c*, 3.0 in carbon tetrachloride); ν_{max} (film) 1385, 1390 (CMe_2), 1790 cm^{-1} (strong, $CF_3C{=}O$), no absorption attributable to OH; n.m.r. data: τ 3.95 (1-proton doublet, $J_{1,2}$ = 3.8 Hz, H-1), 3.9–4.8 (4-protons, H-3, H-5, 2H-6's), 5.13 (1-proton multiplet, H-4), 5.34 (1-proton doublet, $J_{2,3}$ < 0.5 Hz, H-2), 8.45, 8.65 (3-proton singlets, CMe_2). As would be expected, the n.m.r. spectrum of **7** showed an "acylation shift" compared with the spectrum of olefin **1**; the magnitudes of the shifts were even greater than those observed with the 3-*O*-acetate of **1** (19).

Anal. Calcd. for $C_{11}H_{13}O_5F_3$: C, 46.8; H, 4.6; F, 20.2. Found: C, 46.3; H, 4.6; F, 20.4.

Reaction of 5,6-Dideoxy-1,2-O-isopropylidene-3-O-trifluoroacetyl-α-D-xylo-hex-5-enofuranose (7) with Silver Trifluoroacetate and Iodine

Olefin **7** (300 mg, 1.06 mmol) and silver trifluoroacetate (277 mg, 1.2 equiv) in dry acetonitrile (8 ml) were added to a stirred solution of iodine (319 mg, 1.2 equiv) in dry acetonitrile (10 ml) in a flask covered with aluminum foil. After 10 min, the reaction mixture was filtered through Celite, and the filtrate was concentrated to dryness. The residue was extracted with hot carbon tetrachloride, and the extract was washed with aqueous sodium thiosulfate solution and dried over anhydrous sodium sulfate. The solvent was evaporated to leave an oil (498 mg) from which **8** was obtained by distillation, b.p. 88–92°/0.008 Torr, $[\alpha]_D$ −5°, $[\alpha]_{365}$ −9° (*c*, 1.2 in carbon tetrachloride); ν_{max} (film) 1378, 1385 (CMe_2), 1790 cm^{-1} (very strong, $CF_3C{=}O$), no absorption attributable to OH; n.m.r. data: τ 3.98 (1-proton doublet, $J_{1,2}$ = 3.7 Hz, H-1), 4.55 (1-proton doublet, $J_{3,4}$ = 1.5 Hz, H-3), 5.1–5.7 (5-protons, H-2, H-4, H-5, 2H-6's), 8.45, 8.66 (3-proton singlets, CMe_2).

Anal. Calcd. for $C_{13}H_{13}O_7IF_6$: C, 29.9; H, 2.5. Found: C, 30.4; H, 2.6.

A portion (470 mg) of the crude oil obtained above was dissolved in methanol (15 ml), and the solvent was subsequently evaporated to leave a syrup (274 mg). Chromatography of this material on silica gel, with solvent E as eluant, gave the expected **4** (190 mg) and some 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose (**1**) (21 mg). The presence of **1** was probably the result of incomplete addition of iodine trifluoroacetate to olefin 7.

Studies on Fluorinated Vinylic and Aromatic Alcohols and Esters[1]

I. S. CHANG, J. T. PRICE, A. J. TOMLINSON, AND C. J. WILLIS[2]

Department of Chemistry, University of Western Ontario, London 72, Ontario

Received September 2, 1971

Synthetic studies and pK_a measurements are reported on a number of highly fluorinated tertiary alcohols and diols, namely $(CF_2CF)C(CF_3)_2OH$, $(CF_2CF)_2C(CF_3)OH$, $(C_6F_5)C(CF_3)_2OH$, $(C_6F_5)_2C(CF_3)OH$, $(C_6F_5)_3COH$, $(C_6H_5)C(CF_3)_2OH$, $[(CF_3)_2COH]_2$, and $[(C_6F_5)C(CF_3)OH]_2$. General agreement is found with earlier work reporting a correlation between pK_a values and differences between free and H-bonded O—H stretching frequencies.

The reaction of C_6F_5Li with the acyl halides CF_3COCl and C_6F_5COCl in appropriate molar ratio gives the esters $(C_6F_5)_2C(CF_3)OCOC_6F_5$ and $(C_6F_5)_3COCOC_6F_5$, respectively; this constitutes a useful preparative route to fully fluorinated esters.

On rapporte des études synthétiques et des mesures de pK_a sur certains alcools et diols tertiaires fortement fluorés, notamment $(CF_2CF)C(CF_3)_2OH$, $(CF_2CF)_2C(CF_3)OH$, $(C_6F_5)C(CF_3)_2OH$, $(C_6F_5)_2C(CF_3)OH$, $(C_6F_5)_3COH$, $(C_6H_5)C(CF_3)_2OH$, $[(CF_3)_2COH]_2$, et $[(C_6F_5)C(CF_3)OH]_2$. On est généralement d'accord avec les travaux précédents rapportant une correlation entre les valeurs de pK_a et les différences entre les fréquences d'élongation du groupement O—H libre et relié à un proton.

La réaction de C_6F_5Li avec les halogénures d'acyle CF_3COCl et C_6F_5COCl dans les rapports molaires appropriés donne les esters $(C_6F_5)_2C(CF_3)OCOC_6F_5$ et $(C_6F_5)_3COCOC_6F_5$ respectivement; cela constitue une voie de préparation utile vers les esters totalement fluorés.

Canadian Journal of Chemistry, **50**, 512 (1972)

Introduction

Reported studies on fully fluorinated alcohols have been largely confined to tertiary species, because of the limited stability of primary and secondary fluorinated alcohols with respect to elimination of hydrogen fluoride. Knunyants and coworkers (1) reported the first authentic fluorinated tertiary alcohol, nitroperfluoro-*t*-butanol (**1**), and subsequently (2) prepared perfluoro-*t*-butanol (**2**) itself via *t*-nitroso-perfluoroisobutane. Other workers have since reported alternative routes to perfluoro-*t*-butanol (3–5).

The pronounced acidic character of perfluoro tertiary alcohols has been investigated by several workers. Knunyants and Dyatkin found a pK_a of 3.9 for **1** and 5.4 for **2**, while pK_a's for the alcohols CF_3CH_2OH and $(CF_3)_2CHOH$ were 12.8 and 9.3, respectively (2). Using these data, pK_a values were related to the sum of the Taft polar substituent constants, σ^*, by the equation

$$[1] \qquad pK_a = -1.44 \sum \sigma^* + 16.67$$

and $\sigma^*(CF_3)$ was found to be 2.6, on a scale where $\sigma^*(H) = 0$.

The general validity of this equation was confirmed by Filler and Schure (3), who also discovered that the acidity of the alcohol could be related linearly to the difference, $\Delta\lambda$, between the free O—H stretching frequency (in carbon tetrachloride solution) and the hydrogen-bonded O—H frequency (in tetrahydrofuran). Middleton and Lindsey (6) had previously observed that this difference correlated roughly with the relative order of hydrogen-bond strength between the alcohol and tetrahydrofuran. They also noted that tenacious hydrogen-bonded complexes, stable to distillation, are formed between the alcohols and various donor solvents.

Perfluoropinacol (PFP) and the hydrates of several perfluoroketones (*i.e. gem*-diols) are also strongly acidic, and can be regarded as monobasic acids obeying eq. 1 [PFP, p$K_a = 5.95$; $(CF_3)_2C(OH)_2$, p$K_a = 6.58$ (6)].

Hydrogen-bonding and acidity studies on perfluorotertiary alcohols have so far been confined to those containing only perfluoroalkyl groups, and it was the object of the present study to extend this to include those containing trifluorovinyl and pentafluorophenyl groups.

Trifluorovinyl Alcohols

Considerable work in this area has been re-

[1]Presented in part at the Sixth International Symposium on Fluorine Chemistry, Durham, England, 1971.

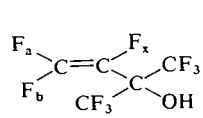
TABLE 1. The ^{19}F n.m.r. spectra of trifluorovinyl alcohols

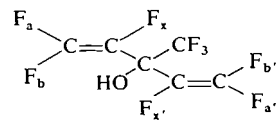
Chemical shift*	**3** $(CF_2CF)C(CF_3)_2OH$	**4** $(CF_2CF)_2C(CF_3)OH$
CF_3	76.9	78.2
F_a	90.9	93.5
F_b	107.3	108.5
F_x	184.9	183.4
Coupling constant (*J*, Hz)		
a–b	62.0	63.5
a–x	40.1	38.8
b–x	114.6	115.6
a–CF_3	0.9	—
b–CF_3	4.6	6.2
x–CF_3	8.2	9.4
a–b′	—	—
a–x′	—	—
b–x′	—	4.4

*All chemical shifts are in p.p.m. from $CFCl_3$.

ported by Tarrant *et al.* They have prepared trifluorovinyl-lithium from bromotrifluoroethylene (7) or trifluoroethylene (8) or the Grignard reagent from C_2F_3Br (8) and obtained alcohols by reaction with various carbonyl-containing compounds. When the carbonyl compound contained no perfluoroalkyl substituents, the alcohols produced were generally unstable, rearranging with elimination of HF to give α-fluoroalkenyl carboxylic acids. With partially fluorinated compounds, such as trifluoroacetone, both alcohol and acid were obtained (8), while hexafluoroacetone gave only perfluoro(2-methyl-3-buten-2-ol), $CF_2{:}CFC(CF_3)_2OH$ (**3**). Recently, reaction of trifluorovinyl-lithium with trifluoroacetyl chloride has been reported (9) to give perfluoro(3-methyl-1,4-pentadien-3-ol), $(CF_2{:}CF)_2C(CF_3)OH$ (**4**), with b.p. 91°, in close agreement with that found in our work (92–94°). With alcohol **3**, however, we find b.p. 65–66°, the reported b.p. of 86° being that of the ether complex. The pure alcohol, which we isolated from the ether adduct by distillation from sulfuric acid, had C=C absorption at 1780 cm^{-1} in its i.r. spectrum and was further characterized by preparation of its trimethylsilyl ether derivative.

We have unsuccessfully attempted to prepare the third member of this series, tris(trifluorovinyl)carbinol, by the reaction of trifluorovinyl-lithium or -Grignard with dimethyl carbonate, but in each case a black oil was obtained, which eliminated HF on attempted distillation. This is in accord with the reported failure to prepare the unfluorinated analogue, $(CH_2{:}CH)_3COH$, when only polymeric material was obtained (10).





The ^{19}F n.m.r. spectrum of alcohol **3** (Table 1) showed the expected four peaks, ratio 6:1:1:1 (field increasing). The chemical shifts are very similar to those reported for $CF_2CFC(CF_3)$-$(CH_3)OH$ (11). The three vinylic fluorine peaks each appear as doublets of doublets of septuplets ($J_{a\text{-}CF_3} = 0.9$, $J_{b\text{-}CF_3} = 4.6$, $J_{x\text{-}CF_3} = 8.2$ Hz), while the CF_3 peak is a doublet of doublets of doublets. These long-range couplings have been observed previously, though of lower magnitude, in several trifluorovinyl compounds (11).

Alcohol **4** also has four peaks, ratio 3:2:2:2, the chemical shifts being very similar to the equivalent ones in **3**. The CF_3 group in this case is coupled only to b ($J = 6.2$ Hz) and x ($J = 9.4$ Hz), but an extra inter-vinyl coupling ($J_{x\text{-}b'} = 4.4$ Hz) is present. Couplings between two vinyl groups have been previously observed in several trifluorovinyl derivatives of metals and metalloids (12).

CF_3-ortho	14.6	15.0	—

Attempts were made to prepare metal complexes of alcohols **3** and **4**. Alcohol **3** could possibly act as a bidentate ligand, coordinating via both the double bond and the oxygen atom. Reactions in basic aqueous solution with the metal ions Ag(I), Pd(II), Fe(III), Ni(II), Zn(II), VO(II), Hg(II), Co(II), Cu(II), and Cr(III) were carried out, but in no case was any evidence of complex formation observed. Likewise, alcohol **4** could complex via a double bond and the oxygen atom, or via both double bonds. No complexes were obtained with the above metals nor with low valent carbonyls of Fe, Mn, or Ni.

The reported (13) addition of perfluoroketones to tetrafluoroethylene in the presence of cesium fluoride to give saturated perfluoro alcohols offered a possible means of converting alcohol **3** to perfluoro tertiary diols, which would be potentially useful ligands, but reactions of this type carried out in either diglyme or acetonitrile gave, on hydrolysis, none of the desired diols, the only identifiable products being unchanged alcohol **3** and hexafluoroacetone hydrate.

Pentafluorophenyl Alcohols

Several primary, secondary, and tertiary alcohols containing the C_6F_5-group are known. Pentafluorobenzyl alcohol and bis(pentafluorophenyl)methanol were both prepared from pentafluorobenzaldehyde by Tatlow and coworkers (14), and tris(pentafluorophenyl)carbinol (**7**) has been made through the reaction of pentafluorophenyl-lithium with decafluorobenzophenone by two groups of workers (15, 16). Tamborski *et al.* (17) prepared several tertiary arylalkyl perfluoroalcohols, including perfluoro-α,α-dimethylbenzyl alcohol (**5**), from reactions of fluoroaryl lithium reagents with hexafluoroacetone. None of these alcohols showed any tendency to form stable isolable complexes with tetrahydrofuran or other solvents, although i.r. studies suggested that hydrogen bonding between the alcohols and tetrahydrofuran was present in solution.

In the present work, alcohols **5** and **7** were prepared by the above methods. Perfluoro(1,1-diphenylethanol) (**6**), which was not previously reported, was made by reaction between pentafluorophenyl-lithium and trifluoroacetyl chloride. It was obtained as a viscous oily liquid, b.p. 108–112°/0.01 mm, which did not solidify neat but formed white crystals, m.p. 34–36°, from cold pentane solution. The ^{19}F n.m.r. spectra of the aromatic alcohols were, as expected, considerably more complex. Principal data for these spectra are given in Table 2.

Alcohol **5** showed the expected four peaks, ratio 6:2:1:2. The aliphatic fluorine peak, at 76.2 p.p.m. from $CFCl_3$, appeared as a triplet ($J = 14.6$ Hz) by coupling with the two aromatic ortho-fluorines. The para- and meta-fluorine peaks, at 149.5 and 160.6 p.p.m., had typical chemical shifts and general shapes, while the ortho-fluorine peak appeared as a broad, unresolved multiplet centered on 135.3 p.p.m.

The ^{19}F n.m.r. spectrum of alcohol **6** also contained four peaks, ratio 3:4:2:4. The CF_3 peak appeared as a pentuplet ($J = 15.0$ Hz) by coupling with four ortho-fluorines. The para- and meta-fluorines gave multiplets slightly broadened as compared to those in alcohol **5**; this may be ascribed to inter-ring coupling between the two pentafluorophenyl groups. The peak due to the ortho-fluorine atoms appeared as a broad triplet (or pentuplet), width 85 Hz. Prediction of this multiplet from the other data in the spectrum gave an 80-line multiplet in good agreement with the observed peak.

Alcohol **7** had three peaks in its spectrum, 2:1:2, all of which were considerably broadened,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

presumably by inter-ring coupling. However, an alternative explanation, based on steric hindrance, had been advanced (18) to account for similar broadenings in the spectra of the compounds $(C_6F_5)_nMX_{(4-n)}$ (X = Me, Ph).

Tertiary Perfluoro-1,2-diols

The only previously known compound of this type, perfluoropinacol (**8**), may be synthesized by several methods. Knunyants and coworkers (19) used the reaction between hexafluoroacetone and triethyl phosphite, giving a cyclic phosphorane which can be hydrolyzed to perfluoropinacol. The diol has also been prepared by Middleton and Lindsey (6) by reductive dimerization of hexafluoroacetone, either with magnesium amalgam or photolytically with isopropanol. We have previously reported (20) preparation of the dilithium and disodium salts in solution by reaction of hexafluoroacetone with the metal in tetrahydrofuran or diglyme, the pinacol being given on hydrolysis. Perfluoropinacol is a fairly strong monobasic acid, but attempts to form the dianion in aqueous solution lead to hydrolysis and decomposition. Stable derivatives of complexes with main-group elements and transition metals can readily be made. (20–22).

The mixed C_6F_5-, CF_3-substituted diol **9** was prepared by the photolytic route from octafluoroacetophenone.

$$2CF_3COC_6F_5 \xrightarrow[h\nu]{\text{2-PrOH}} C_6F_5{-}\underset{\text{HO}}{\overset{\text{CF}_3}{\text{C}}}{-}\underset{\text{OH}}{\overset{\text{CF}_3}{\text{C}}}{-}C_6F_5$$

Attempted synthesis via the triethyl phosphorane intermediate failed to give any product, possibly because of unfavorable (eclipsed) steric requirements in the cyclic phosphorane. It was, however, possible to prepare metal complexes of the diol (23). Like perfluoropinacol (19) and 2,3-diphenylhexafluorobutane-2,3-diol (which was also prepared photolytically) (24), diol **9** did not undergo a pinacol–pinacolone rearrangement in conditions much more acidic than those normally required (concentrated H_2SO_4/100°). The presence of the electrophilic CF_3 and C_6F_5 groups apparently precludes the development of the carbonium ion character necessary for the rearrangement to take place (24).

The diol **9**, containing two asymmetric carbon atoms, can exist in three isomeric forms; a *meso*-isomer and two optically active enantiomers. It was purified by sublimation and recrystallization to give a white solid (m.p. 123–125°) which had a satisfactory analysis. However, the complex appearance of the n.m.r. spectra and other properties of the compound suggested that more than one isomer was present, and work is continuing in an attempt to separate and characterize these completely, when a fuller account of this interesting alcohol will be published.

Acidity Studies

Ballinger and Long (25) have related the acidities of a series of primary alcohols, RCH_2OH, to the polar substituent constants, σ^*, for the groups R by the equation

$$[2] \qquad pK_a = -1.42\,\sigma^* + 15.9$$

This is very similar to eq. 1, given above, which Knunyants and co-workers developed for fluorinated alcohols. It was hoped that the numerical values of the polar substituent constants for the pentafluorophenyl and trifluorovinyl groups, which have not been reported, could be obtained by measuring the acidities of various alcohols containing these groups.

Only two of the five alcohols studied were freely soluble in water, so in all cases the pK_a was measured in a range of ethanol/water mixtures using the half end-point method. Values obtained are shown in Table 3.

Both the trifluorovinyl-containing alcohols were soluble in water. Alcohol **3** had a pK_a of 6.82, measured in water, while a plot of pK_a values against mole fraction (*mf*) of ethanol gave a curve corresponding to the quadratic relationship

$$[3] \qquad pK_a = 19.6(mf)^2 + 1.7mf + 6.80$$

For alcohol **4**, the pK_a value found in water was 7.71, while measurements in ethanol/water mixtures gave the linear relationship

$$[4] \qquad pK_a = 5.95mf + 7.70$$

Application of these values to Knunyant's equation (eq. 1), using $\sigma^*(CF_3) = 2.6$, gives values of $\sigma^*(CF_2{=}CF)$ as 1.65 (alcohol **3**) and 1.82 (alcohol **4**) for an average σ^* value of 1.7_3.

For the pentafluorophenyl-containing alcohols and the diol, the limited solubility in water necessitated extrapolation from ethanol/water mixtures to obtain aqueous pK_a values. The

TABLE 3. The pK_a values for fluorinated alcohols and diols

70	0.419			9.82	10.97	9.69	

*i.s. = insufficiently soluble for readings to be obtained.

accuracy of the values obtained was further reduced by the very weakly acidic nature of the alcohols.

Alcohol **5**, $C_6F_5C(CF_3)_2OH$, was soluble only in mixtures containing at least 30% ethanol. The plot of pK_a against mole fraction of ethanol gave a quadratic dependence

$$[5] \qquad pK_a = -6.4(mf)^2 + 7.25mf + 7.90$$

from which the extrapolated pK_a value is 7.90.

Alcohol **6**, $CF_3C(C_6F_5)_2OH$, required at least 40% ethanol for adequate solubility and gave the relationship

$$[6] \qquad pK_a = -3.65(mf)^2 + 5.7mf + 9.2$$

giving an extrapolated pK_a value of 9.2.

The completely aromatic alcohol **7**, $(C_6F_5)_3COH$, was only soluble in 60% ethanol, and no end-point could be detected in titration. From data obtained from the other alcohols, a pK_a of at least 11 would be expected.

The diol **9** dissolved in a minimum of 40% ethanol, and the linear equation found was

$$[7] \qquad pK_a = 2.0mf + 8.85$$

giving an extrapolated pK_a of 8.85.

The pK_a values for alcohols **5** and **6** were then used to calculate the substituent constant σ^* for the pentafluorophenyl group, again using $\sigma^*(CF_3) = 2.6$. Values found were 0.9 and 1.3 from the pK_a's of **5** and **6**, respectively, giving an average of 1.1.

In the case of the diols perfluoropinacol (**8**, $pK_a = 5.95$) and $[CF_3C(C_6F_5)OH]_2$ (**9**), the σ^* values for the R_2COH groups can be estimated from the pK_a values for the first ionization, leading to $\sigma^*[(CF_3)_2COH] = 2.3$ and $\sigma^*[CF_3C(C_6F_5)OH] = 1.8$.

Filler and Schure (3) related the pK_a of several fluorinated alcohols to the difference, $\Delta\lambda$, in O—H stretching frequencies between solutions in CCl_4 (free O—H) and THF (H-bonded O—H), obtaining a linear relationship. In the present work, we have extended this to include all new alcohols and diols prepared (except alcohol **7**), together with the known compound $C_6H_5C(CF_3)_2OH$ (**12**) (Fig. 1). For the majority of the alcohols, pK_a and $\Delta\lambda$ values fitted well to the straight line obtained by Filler and Schure, which has the equation

$$[8] \qquad pK_a = -25.7\Delta\lambda + 18.15$$

However, the alcohols containing pentafluorophenyl groups (*i.e.* alcohols **5** and **6** and diol **9**) each showed slightly higher pK_a values than would be consistent with this relationship, indicating a limitation to its general applicability.

Esters of Perfluoro Tertiary Alcohols

The published method (14) for the preparation of octafluoroacetophenone, which was required for the synthesis of diol **9**, makes use of the reaction between pentafluorophenyl Grignard reagents and lithium trifluoroacetate. This method gives only moderate yields (20–50%) and reactions between lithium reagents and acid chlorides were therefore investigated as possible routes to octafluoroacetophenone and other perfluoroarylketones.

Using trifluoroacetyl chloride, an oily liquid was obtained which had a C=O stretch in its i.r. spectrum. It boiled at 160°, whereas octafluoroacetophenone has b.p. 130°. Elemental

SCHEME 1

analysis showed it had the same empirical formulation as octafluoroacetophenone, but its mass spectrum showed a molecular weight twice that of the ketone. The ^{19}F n.m.r. spectrum (Table 4) confirmed that it was ester **10**, produced in the sequence shown by Scheme 1.

This spectrum contained five peaks, three aromatic and two aliphatic, ratio 3:3:4:2:4

TABLE 4. The ^{19}F n.m.r. spectra of esters

field increasing. The aliphatic peaks consisted of a high field peak (acidic CF_3, triplet or pentuplet, $J = 1.0$ Hz) and a low field pentuplet (alcoholic CF_3, $J_{CF_3\text{-ortho}} = 15.3$ Hz). The aromatic peaks consisted of a broad low field pentuplet (ortho-F), a triplet of triplets (para-F, $J_{p-m} = 19.9$; $J_{p-o} = 5.8$ Hz), and a complex multiplet at high field (meta-F). The latter four peaks were almost identical to those found in the spectrum of alcohol **6**, $CF_3C(C_6F_5)_2OH$. The aliphatic-ortho coupling of 15.3 Hz is very similar to those observed in alcohols **5** and **6**, and the splitting observed in the acidic CF_3 part of the spectrum indicates that even these fluorines may be slightly coupled to the aromatic ortho-fluorines.

Formation of the ester in this reaction, but not in the published preparation using C_6F_5MgBr, presumably arises from the much greater reactivity of C_6F_5Li.

In the attempted preparation of decafluorobenzophenone by this method, reaction followed a similar route, yielding a white solid (96% yield) formulated as the ester $(C_6F_5)_3COCOC_6F_5$ (**11**) by elemental analysis and ^{19}F n.m.r. and mass spectroscopy. The ^{19}F n.m.r. spectrum contained six peaks, two in each region; ortho-, para-, and meta- as deduced from chemical shifts. In each case the higher field peak (alcoholic C_6F_5) was three times as intense as, and also considerably broader than, the lower field peaks, indicating considerable inter-ring couplings. The broadness precluded any attempt to measure these inter-ring couplings. The alcoholic C_6F_5 peaks were very similar in chemical shift and shape to those observed in the alcohol $(C_6F_5)_3COH$ (**7**).

The i.r. spectra of the esters showed carbonyl stretching vibrations at 1805 and 1740 cm^{-1} for **10** and **11**, respectively.

This reaction scheme forms a possibly useful method for formation of appropriate fully fluorinated esters, in view of the known difficulties (3, 4) in preparation and purification of esters when both acid and alcohol contain polyfluoro groups.

Experimental

General Techniques

Volatile compounds were manipulated in the absence of air in a conventional vacuum manifold. Hexafluoroacetone, bromotrifluoroethylene, and trifluoroacetyl chloride were commercial samples purified by fractional condensation *in vacuo*. The i.r. spectra were recorded on a Beckman IR-10 instrument and fluorine n.m.r. spectra on a Varian HA-100 (94.1 MHz). Titrations were followed with a Corning model 12 p*H* meter. Microanalyses were performed by Alfred Bernhardt Laboratories.

Mass spectra (Varian M-66 instrument) were used in characterization, a molecular ion peak being observed in all cases except for alcohol **4**, $(CF_2CF)_2C(CF_3)OH$, this presumably reflecting the lesser stability of poly(trifluorovinyl) compounds.

Perfluoro(2-methyl-3-buten-2-ol) (Alcohol 3) (8)

A solution of trifluorovinyl-lithium was prepared by passing bromotrifluoroethylene (20.5 g, 0.127 mol) into a solution of methyl-lithium (0.679 g, 0.127 mol) in ether (150 ml) at −78°. After 0.5 h, when the solution had become dark-colored, hexafluoroacetone (21.1 g, 0.127 mol) was bubbled in and the solution allowed to warm to 20°. The light-brown solution remaining was hydrolyzed (dilute HCl), ether-extracted, the organic layer dried ($MgSO_4$), and fractionated to give alcohol **3** as its ether complex, b.p. 80–86° (lit. b.p. (8), given for pure alcohol, 85°). Distillation from sulfuric acid gave the pure alcohol, b.p. 65–66° (lit. b.p. (26), 67°) (16.9 g, 54%).

Anal. Calcd. for C_5HF_9O: C, 24.2; H, 0.4; F, 68.9. Found: C, 24.1; H, 0.5; F, 69.2.

The trimethylsilyl ether derived from **3** was prepared by refluxing the alcohol with hexamethyldisilazane, followed by distillation (b.p. 106–110°).

Anal. Calcd. for $C_8H_9F_9OSi$: C, 30.0; H, 2.8; F, 53.4. Found: C, 30.0; H, 3.2; F, 53.0.

Attempted Reaction of Alcohol 3 with Cesium Fluoride and Hexafluoroacetone

Alcohol **3** (6.75 g, 27.2 mmol) and dry cesium fluoride (4.14 g, 27.4 mmol) were added to acetonitrile (20 ml, dried over P_2O_5) in a Carius tube. Hexafluoroacetone (4.52 g, 27.2 mmol) was condensed into the tube, which was sealed and heated to 70° for 3 days, by which time most of the cesium fluoride had dissolved. The mixture was then hydrolyzed, ether-extracted, and distilled to give only two fractions. The first, b.p. 90–105° (5 g) was mainly the trihydrate of hexafluoroacetone (lit. b.p. (27), 105°) as shown by i.r., n.m.r., and mass spectrum. A further reaction, using diglyme as solvent, likewise gave none of the desired product.

Perfluoro(3-methyl-1,4-butadien-3-ol) (Alcohol 4)

This alcohol was prepared by the same procedure as alcohol **3** by the reaction of trifluorovinyl-lithium with trifluoroacetyl chloride in a 2:1 mol ratio. The ether complex, b.p. 102–104° was converted to the pure alcohol, b.p. 92–94° (lit. b.p. (9), 91°) by sulfuric acid distillation.

Anal. Calcd. for C_6HF_9O: C, 27.7; H, 0.4; F, 65.7. Found: C, 27.9; H, 0.5; F, 65.2.

Attempted Preparation of Tris(trifluorovinyl)carbinol

(*a*) Trifluorovinyl-lithium (0.164 mol), prepared as described above, was kept in ether (150 ml) at −78° and dimethyl carbonate (4.92 g, 0.055 mol) in ether was added dropwise. The solution was allowed to warm to 20°, hydrolyzed, and worked-up as before, when the product was a black oil which evolved hydrogen fluoride on attempted distillation.

(*b*) The above procedure was repeated using trifluorovinyl magnesium bromide, with the same result.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Perfluoro(2-phenylpropan-2-ol) (Alcohol 5) (17)

Pentafluorophenyl-lithium was prepared from *n*-butyllithium (31.5 ml, 23.1% in hexane, 0.075 mol) and bromopentafluorobenzene (18.53 g, 0.075 mol) in ether (100 ml) at −30°. After 10 min, hexafluoroacetone (12.5 g, 0.075 mol) was bubbled in and the mixture allowed to warm to 20°. The solution was hydrolyzed (dilute HCl), ether-extracted, dried ($MgSO_4$), and fractionated to give alcohol **5**, b.p. 156–162° (lit. b.p. (17), 158–160°; 22.9 g, 91%). Further purification was effected by distillation from sulfuric acid (b.p. 101–102°/150 mm).

Perfluoro(1,1-diphenylethanol) (Alcohol 6)

Pentafluorophenyl-lithium (0.0875 mol) was prepared as described above and trifluoroacetyl chloride (5.8 g, 0.044 mol) bubbled in. Work-up as before gave 13.5 g (71%) of a viscous oil, b.p. 108–112°/0.01 mm, which formed white crystals from cold pentane, m.p. 34–36°.

Anal. Calcd. for $C_{14}HF_{13}O$: C, 38.9; H, 0.2; F, 57.1. Found: C, 39.0; H, 0.3; F, 57.4.

Perfluoro(triphenylcarbinol) (Alcohol 7) (15, 16)

The compound was prepared as previously reported from pentafluorophenyl-lithium and decafluorobenzophenone. Residual ketone could not be separated by recrystallization, but sublimed out slowly at 45°/0.01 mm. Further sublimation gave alcohol **7**, m.p. 113–115° (lit. m.p. (15), 117°).

Perfluoro(2,3-diphenyl-butane-2,3-diol) (Alcohol 9)

Octafluoroacetophenone (12 g), prepared from lithium trifluoroacetate and pentafluorophenylmagnesium bromide (14), in 2-propanol (75 ml) with a few drops of hydrochloric acid, was irradiated (Hg lamp) for 5 days. Removal of volatile materials gave a yellow solid which was sublimed at 100°/0.01 mm and recrystallized from ethanol/hexane to give the diol **9**, m.p. 123–125°.

Anal. Calcd. for $C_{16}H_2F_{16}O_2$: C, 36.2; H, 0.4; F, 57.3. Found: C, 36.0; H, 0.3; F, 57.1.

Perfluoro(1,1-biphenylethyl Acetate) (Ester 10)

Pentafluorophenyl-lithium (0.104 mol) in ether (150 ml) was held at −78° and trifluoroacetyl chloride (13.7 g, 0.103 mol) bubbled in. A white solid formed as the solution was allowed to warm to 20°. Filtration and solvent removal gave a pale-yellow oil, fractionally distilled to give ester **10** (b.p. 160–163°/60 mm, 19.0 g, 70%).

Anal. Calcd. for $C_{16}F_{16}O_2$: C, 36.4; H, 0.0; F, 57.5. Found: C, 36.4; H, 0.1; F, 57.6.

The ester was also produced in a similar experiment in which the lithium reagent was added to the acid chloride. Hydrolysis (KOH in ethanol/water for 2 h) followed by ether extraction and work-up gave alcohol **6**, identified by i.r. spectroscopy.

Perfluoro(triphenylmethyl Benzoate) (Ester 11)

Pentafluorophenyl-lithium (0.2 mol) was held at −78° and carbon dioxide (1.7 mol) bubbled through. Lithium pentafluorobenzoate, which precipitated immediately, was hydrolyzed (dilute H_2SO_4) and the acidified solution extracted with ether to give pentafluorobenzoic acid (31 g, 0.142 mol, 73%) m.p. 99–101° (lit. m.p. 103°). Thionyl chloride (17.4 g, 0.146 mol) was added to this acid and the mixture gently refluxed until evolution of acid vapors ceased (4 h). Distillation gave 21.0 g (62%) of pentafluorobenzoyl chloride, b.p. 157–160° (lit. b.p. 158–159°). Pentafluorophenyl-lithium (0.061 mol) in ether (100 ml) was held at −78° and pentafluorobenzoyl chloride (14.1 g, 0.061 mol) in ether (15 ml) added dropwise, when an immediate precipitate formed. The mixture was allowed to warm to 20°, filtered, and volatile materials removed to give a white solid (21.3 g, 96%) recrystallized from cyclohexane/ether to give the pure ester **11**, m.p. 132-134°.

Anal. Calcd. for $C_{26}F_{20}O_2$: C, 43.1; H, 0.0; F, 52.5. Found: C, 43.2; H, 0.15; F, 52.6.

Hydrolysis as before gave a yellow solid, shown by i.r. spectroscopy to be a mixture of perfluoro(triphenylcarbinol) (7) and pentafluorobenzoic acid.

α,α-Bis(trifluoromethyl)benzyl Alcohol (Alcohol 12)

This compound was prepared by the reaction of hexafluoroacetone with phenylmagnesium bromide according to Knunyants *et al.* (28) and had b.p. 152–155°. Its identity was confirmed by i.r. and mass spectrum. For pK_a measurements, it was found to be sufficiently soluble only in solutions containing at least 10% ethanol in water: the extrapolated pK_a value in aqueous solution was 8.80.

Financial support from the National Research Council of Canada is gratefully acknowledged. We thank Dr. M. C. Woods for helpful discussions concerning the ^{19}F n.m.r. spectra.

Conformational Studies of Substituted Trimethylene Sulfites by Proton Magnetic Resonance[1]

GORDON WOOD, G. W. BUCHANAN,[2] AND M. H. MISKOW[3]
Department of Chemistry, University of Windsor, Windsor, Ontario
Received June 15, 1971

Proton n.m.r. chemical shifts and coupling constants are reported for trimethylene sulfite and 10 alkyl derivatives in CCl_4. Data are discussed in terms of possible chair and non-chair conformations and results are compared with those from dipole moment studies. The shift reagent $Eu(dpm)_3$ is used to aid configurational assignments. Conclusions from n.m.r. and dipole moments are consistent and indicate that several of the sulfites exist to a considerable degree in non-chair conformations.

Les déplacements chimiques des protons en r.m.n. et les constantes de couplage sont données dans CCl_4 pour le triméthylène sulfite et pour dix dérivés alkylés. Les données sont discutées en fonction des conformations possibles chaise et non-chaise et les résultats comparés à ceux des études de moment dipolaire. Le réactif de déplacement $Eu(dpm)_3$ est utilisé pour faciliter les assignations de configuration. Les conclusions tirées de la r.m.n. et des moments dipolaires sont importantes et indiquent que plusieurs des sulfites existent pour une part importante sous des conformations non-chaise.
Canadian Journal of Chemistry, **50**, 521 (1972)

Introduction

Although much effort has been directed toward elucidating the conformations of trimethylene sulfites, a clear picture of the shapes of these molecules has been slow to develop. The bulk of the published data comes from dipole moment measurements, i.r. spectroscopy, and ultrasonic relaxation studies (1–7). Recently (5) we reported dipole moments for a series of alkyl-substituted sulfites and emphasized the importance of vicinal electron pairs in determining their conformations (8). It was concluded that chair⇌chair interconversion barriers must be high[4] in these molecules and the existence of non-chair forms for several sulfites was suggested.

Herein, we present proton n.m.r. results for the above sulfites. Some of the parameters are particularly sensitive to conformational change, permitting a somewhat more confident appraisal of the observed trends than do the dipole moments. Chemical shifts of methine, methylene, and methyl protons are discussed in detail and shielding trends can be explained on the basis of various contributions from chair and non-chair forms. Coupling constants are compared with values for chair and twist forms of the related trimethylene phosphites to gain information regarding sulfite geometry. The proton shift reagent, tris(dipivaloylmethanato)-europium, $Eu(dpm)_3$ has been used to aid the configurational assignments since the magnitudes of the shifts are primarily dependent on the individual proton–Eu distances.

Results and Discussion

To facilitate comparison with the n.m.r. data, the previously determined dipole moments (5) are listed in Table 1.

Proton Chemical Shifts

Table 2 contains the proton shieldings for trimethylene sulfite and 10 alkyl derivatives. In general, the spectra are first order and assignments are straightforward. An exception is that of compound **3** where the only precise shift obtained is for the methyl group. It should be noted that in compounds **4** and **5**, the overlap of resonances for the C-5 protons in CCl_4 can

[4]The barrier in 5,5-dimethyltrimethylene sulfate is 8.3 kcal/mol (9). Recently, the barrier for the molecule with no exocyclic oxygens, 5,5-dimethyl-1,3,2-dioxathiane was found to be 12.5 kcal/mol (10). Accordingly, the chair⇌chair barrier for the sulfites is likely in the accessible n.m.r. range. The lack of observed coalescence phenomena for compounds thought to be chairs with axial S=O functions can be attributed to the low population of the higher energy form with equatorial S=O ($-\Delta G^{\circ}_{S=O} = 2.1 \pm 0.5$ kcal/mol) (5, 13).

be removed in DMSO. Bracketed values in Table 2 denote tentative assignments.

Data for **1**, **4**, **5**, and **6** agree well with those recently reported by Wucherpfennig (11). From double resonance experiments we have verified in compound **5** that the CH_3 group at $\delta = 1.27$ p.p.m. is coupled to the proton at $\delta = 4.97$ p.p.m.

On examination of the data and comparison with the dipole moments, several trends are apparent. (*a*) For compounds whose moments correspond to a chair conformation with axial S=O (**1**, **2**, **4**, and **10**), the shifts for protons in the "*syn*-diaxial" orientation relative to the S=O group are nearly identical (4.91 ± 0.03 p.p.m.). The deshielding influence of the axial S=O group in trimethylene sulfite on the 1,3-diaxial protons is now well documented (11, 12). A close similarity in the equatorial proton shifts at C-4 and -6 of **1**, **2**, and **10** is also apparent. (*b*) Compounds **2** and **4** have nearly identical shifts for their equatorial CH_3 groups. The 0.1 p.p.m. downfield shift in compound **3** sug-

gests a small contribution from the diaxial form. This is consistent with the high dipole moment for **3**, which indicates that it exists predominantly (but not exclusively) in some form with an equatorial S=O (be it a chair or a non-chair with a similar geometry at the sulfite end of the molecule). Compound **8**, with a moment near that of **3** shows a like behavior in the shifts of its R^1 and R^5 methyl groups. (*c*) For compound **6**, the observed moment is interpreted in terms of a chair form with equatorial S=O (5). Calculations[5] of van Woerden are in accord with this (13). The C-4 and -6 methine protons of **6** are now shifted upfield by *ca.* 0.35 p.p.m. relative to **4**, as expected for an equatorial S=O orientation. (*d*) Moments for **5** and **7** are thought to imply either a distortion of the S=O axial chair or a non-chair form (5, 11). The downfield shifts of the R^5 and R^1 CH_3 groups in **5** and **7**, respectively, are indicative of a quasi 1,3-diaxial $CH_3 \cdots S{=}O$ interaction. It is interesting that the R^5 methine proton in **7** and its R^1 counterpart in **5** are at even lower field than when the S=O is pure axial (*i.e.* in **1**, **2**, **4**, and **10**). This can be attributed to an extra Van der Waals deshielding of the methine protons by the *syn*-axial CH_3 functions (14). (*e*) The tetramethyl derivative **9** has a moment of intermediate value (independent of solvent polarity) and accordingly was postulated to be almost exclusively in a non-chair form. In agreement with this, the ^1H methyl group shifts of **9** are at lower field than those observed for "pure" equatorial methyls and at higher field than for axial or quasi-axial (R^1 in **7**) substituents. (*f*) For compound **11**, dipole moment behavior indicates a mixture of interconverting conformations with that of higher moment being favored in the more polar solvent. In CCl_4, the deshielding of the *t*-butyl methyl protons of **11** relative to **10** coincides with the trends observed for 1.3 dioxanes (15) and cyclic phosphites (16) with axial *t*-butyl functions. However, the 0.1 p.p.m. upfield shift of the R^1 and R^5 methine protons of **11** relative to **10** does suggest some contribution from an equatorial or pseudo-equatorial S=O moiety. In more polar solvents (*i.e.* acetone) this shift difference does not increase noticeably. Association factors are known to be operative in these systems (17, 18) and thus preclude any meaningful discussion of solvent shifts in terms of conformational changes. (*g*) In most of the sulfites, axial protons at C-5 appear at lower field than their equatorial counterparts, as is true for 1,3 dioxanes and phosphites. The positive end of the dipole in the sulfites is at C-5 and accordingly this position is the most susceptible to association phenomena. The overlap of some C-5 proton resonances in CCl_4 and their resolution in DMSO reflect this property. Previously reported results from this laboratory (18) show that in benzene solution, the equatorial proton at C-5 of **1** is shifted to the greatest extent. Recently, a model for benzene–sulfite association at the C-5 end of the molecule has been proposed (11).

[5]van Woerden has recently measured moments for the two isomers of *trans*-1,3,2-dioxathiadecalin-2-oxide (13). Values are 3.85 and 5.15 D. These structures are assigned as chairs having axial and equatorial S=O groups, respectively.

Proton Nuclear Magnetic Resonance Coupling Constants

Table 3 lists the couplings measured for trimethylene sulfite and its alkyl derivatives. In all cases the numbers represent absolute values, although the geminal couplings can be assumed to be negative. Generally, the geminal couplings between methylene protons at C-5 are *ca.* 2 Hz larger than for protons on C-4 and -6.

Most of the discussion to follow will deal with vicinal couplings and their relation to molecular conformation. It is of interest to note, however, that in compound **10** both the equatorial and axial C-4 and -6 protons are split into triplets by a ^4J coupling of *ca.* 1 Hz. The existence of an equatorial–equatorial coupling is not surprising since the geometry is close to the most suitable planar "W" arrangement (19). Anderson (20) has reported a ^4J axial–axial coupling of 0.8 Hz between protons at C-4 and -6 of 1,3 dioxanes. Apparently, the axial–axial coupling in sulfite **10** is of similar magnitude.

^3J couplings between methine and methyl protons are the same in all the sulfites, *ca.* 6.5 Hz.

It is useful to compare the vicinal methine–methylene couplings for **10**, believed from dipole moments to be a chair having an equatorial *t*-butyl group and an axial S=O, with the recently studied *cis*-5-*t*-butyl-2-methoxyl-1,3,2-dioxaphosphorinane (16). Bentrude and Hargis

have pointed out the striking similarity in the equilibration behavior of these compounds and assign a chair conformation with equatorial *t*-butyl and an axial methoxyl on phosphorus to the above phosphite. From a computer analysis, $J_{4a,5e} = 3.8$ and $J_{4a,5a} = 11.9$ Hz for this *cis*-phosphite. Corresponding values for the sulfite **10** are in reasonable agreement with these and accordingly the assignment of a "rigid" chair for **10** is supported. From Table 3, it can be seen that couplings for the other compounds expected to be chairs with axial S=O functions (*i.e.* **1**, **2**, and **4**) closely coincide with those for **10**.

For compound **6**, the couplings indicate a chair conformation in accord with the dipole moment studies. The 11.8 Hz coupling in **8** is characteristic of an axial–axial interaction and thus a large contribution from a chair form is suggested in this molecule.

Intermediate values for the vicinal methine–methylene coupling are noted for compounds **5**, **7**, and **11**. These data can be interpreted in terms of chair⇌chair equilibria (21) or by the existence of non-chair or twist forms (11). Cazaux and Maroni (22) have postulated twist conformations for a series of racemic 4,6-diisopropyl-5,5-dimethyl trimethylene sulfites as has Wucherpfennig (11) for compound **5**. Both **5** and **7** have axial methyl–axial S=O interactions in their chair forms and it is highly likely that twist forms or distorted chairs predominate in these molecules. The constancy of the dipole moments for **5** and **7** in various solvents support this, as a chair⇌chair equilibrium should produce a large dipole moment change with solvent polarity. Recently, Bentrude and Hargis (16) have estimated couplings for a twist form of *trans*-5-*t*-butyl-2-methoxy-1,3,2-dioxaphosphorine. With the assumption that the twist conformation of the sulfites has a similar geometry to that of the above phosphite, a comparison of results is valid. For the twist phosphite, estimated values of $J_{4e,5e}$ and $J_{4a,5e}$ are 5.12 and 7.0 Hz, respectively. The couplings of 5.7 for R^3R^6 in **5**, 6.8 for R^1R^3 in **5**, and 6.6 for R^3R^5 in **7**, are consistent with twist geometries in these sulfites. Although compound **11** has been assumed to be a mixture of chair conformers (23, 24) because of its dipole moment variation with solvent, alternative explanations involving non-chair forms seem more attractive. The single small coupling (5.3 Hz) points either to a mixture of non-chair forms (12, 22, 25) with near equal couplings but different dipole moments or to a mixture of chair and non-chair forms (which should have different dipole moments) (11), including the chair with an axial *t*-butyl group. We tend to favor the latter possibility as does Bentrude for the corresponding *trans*-5-*t*-butyl phosphite. Using the predicted values of 4.0 and 2.0 for $J_{4a,5e}$ and $J_{4e,5e}$ of the *trans*-diaxial chair phosphite (16) along with the above values for the twist form,

one can approximate the 5.3 Hz coupling in the sulfite **11** by a 25% contribution from the *trans*-diaxial chair and 75% from the twist conformation.

Eu(dpm)$_3$ Shift Studies

In recent months many reports of the application of lanthanide complexes to spread out and simplify proton spectra have appeared in the literature (26, 27). The origin of the induced effects is thought to involve a pseudocontact interaction (28). Accordingly the magnitudes of the observed shifts in fixed systems are found to be proportional to $1/r_i^3$ where r_i is the lanthanide–proton distance.

Fraser and Wigfield (29) have used $Eu(dpm)_3$ induced shifts for the configurational assignment of several sulfoxides, however, no studies on sulfites have been published to date.

The effects of addition of 0.48 equiv of $Eu(dpm)_3$ on the spectra of the 11 sulfites are listed in Table 4. All shifts were essentially linear with complex concentration up to *ca.* 0.5 equiv where solubility problems prevented further study. To ensure correct assignments, the shift changes for individual protons were monitored at four concentrations of $Eu(dpm)_3$ up to the maximum. Included in Table 4 in parentheses are the relative distance factors for each proton as measured from models, assuming 3.5 Å as the europium–oxygen distance (29).

Shift values for compounds **1**, **2**, **4**, and **10** in Table 4 are remarkably similar. Assuming that the europium atom complexes on the exocyclic oxygen of the chair conformation with axial S=O, the expected distance–shift relationship is obtained. Compound **10** having an equatorial *t*-butyl function, and compound **4**, with two equatorial methyls, can be considered to be essentially locked into chair forms with axial S=O. Apparently, complexing with $Eu(dpm)_3$ does not appreciably alter the geometries of **1** and **2** relative to **4** and **10**, although **1** and **2** lack definite "locking" substituents. Clearly, the protons closest to the axial S=O group, namely the axial protons at C-4 and -6 are most affected by the shift reagent (5.8 ± 0.1 p.p.m.) in all compounds thought to exist in chair confirmations on the basis of dipole moments.

Compound **6**, deemed a chair with equatorial S=O shows a similar distance–shift relationship. Axial C-4 and -6 protons are again affected the most by the complex, but to a much smaller extent (2.8 p.p.m.) than when the S=O is axial. Equatorial methyl groups, be they in chairs with axial S=O (**2**, **4**) or equatorial S=O (**6**) are shifted downfield to nearly the same extent (1.35 p.p.m.).

For all other sulfites the existence of chair $\rightleftharpoons$ non-chair equilibria are postulated (with the exception of **9**, which may be exclusively a twist form). The question of preferential conformational biasing due to the $Eu(dpm)_3$ now arises, precluding estimation of meaningful distance factors since weighted averages must now be considered.

Nevertheless, several qualitative trends are clear. Compounds **5** and **7** again exhibit behavior consistent with their dipole moments. The *ca.* 5.3 p.p.m. shifts of the axial protons at

C-4 and -6 (R^1 in **5** and R^5 in **7**) denote a high contribution from a form with a pseudo-axial S=O. Also, the much larger downfield shift for the R^5 and R^1 methyls of **5** and **7** (*ca.* 3.2 p.p.m.) *vs.* 1.3 p.p.m. for equatorial methyls denote at least a quasi-axial orientation for these groups.

For **11**, the 4.95 p.p.m. shift for the axial C-4 and -6 protons (R^1 and R^5) indicates a mixture of forms including that with an axial S=O chair.

In compound **3**, the only reliable shift is 3.05 p.p.m. for the methyl group, again indicative of a quasi-axial substituent. This is not entirely consistent with the dipole moment results and probably reflects the difficulty in predicting conformer populations for $Eu(dpm)_3$ complexes of conformationally mobile molecules.

The axial C-6 proton in **8** (R^6) shows the expected behavior for a molecule having a large contribution from a chair form with equatorial S=O. In contrast, the 7.75 p.p.m. shift for R^3 clearly does not correlate with the expected distance from the metal.

In compound **9**, deemed to be a twist form, the CH_3 group shifts of 2.70 and 1.80 p.p.m. are intermediate between those for axial and equatorial methyls as expected on the basis of a twist configuration. The 5.50 p.p.m. shift for R^4, however, again shows that $Eu(dpm)_3$ induced shifts at C-5 are unreliable for assigning conformations to mobile sulfites.

A parallel thus is evident between the proton n.m.r. shieldings in CCl_4 and the $Eu(dpm)_3$ induced values. Using shifts of substituents at the C-4 and -6 ring positions one can seemingly obtain valuable information regarding sulfite conformation. It is abundantly clear that association phenomena in any form most strongly perturbs the C-5 ring carbon. Consequently, parameters for substituents at this position must be viewed with caution.

Summary and Conclusions

A comprehensive treatment of the proton n.m.r. data for an extensive series of related sulfites has been presented for the first time. The applicability of shift reagents for studying sulfite conformation has been critically tested. The data provided supporting evidence for previous conclusions based on dipole moments.

The results are consistent with a large free energy difference between the two chair conformations and lower free energy differences between chair and boat conformations. Also, the high preference for axial S=O orientation is seen from the observed $Eu(dpm)_3$ shifts.

Like trimethylene sulfite **1**, compounds **2**, **4**, and **10** can be regarded as chair forms with axial S=O functions. Increased steric interactions between the *syn*-axial methyl groups and the exocyclic oxygen atom lead to the adoption of non-chair forms for **3**, **5**, **7**, **8**, and **9**. For **6**, the presence of the alternative chair form with equatorial S=O is verified. It appears in **11**, that the 5-*t*-butyl group cannot "anchor" the ring into a diequatorial chair, but rather the molecule probably exists as a mixture of the diaxial chair and non-chair conformations.

Further studies on these and related molecules using ^{13}C n.m.r. spectroscopy are presently in progress.

Experimental

The syntheses of the sulfites have been described elsewhere (5). The proton n.m.r. spectra were obtained on a JEOL JNM-C60S or C60HL using TMS as internal standard. Chemical shifts were measured by interpolation. $Eu(dpm)_3$ was purchased from the Pierce Chemical Company.

Photocyclization Reactions of Aryl Polyenes. V.[1] Photochemical Synthesis of Substituted Chrysenes[2]

CLIFFORD C. LEZNOFF AND ROGER J. HAYWARD
Department of Chemistry, York University, Downsview, Ontario

Received September 14, 1971

The photocyclization-oxidation reaction of 1,6-di-*p*-substituted-phenyl-1,3,5-hexatrienes gave 3,9-disubstituted-chrysenes. Similarly, irradiation of 1-*p*-substituted-phenyl-6-phenyl-1,3,5-hexatrienes yielded 3-substituted-chrysenes. The 3-substituted-chrysenes were independently prepared in a high yield by the photocyclization-oxidation of 1-α-naphthyl-2-*p*-substituted-phenylethylenes.

La réaction d'oxydation-photocyclisation des di-(phényl *p*-substitué)-1,6 hexatriènes-1,3,5 conduit aux chrysènes disubstitués-3,9. D'une façon similaire, l'irradiation des (phényl *p*-substitué)-1 phényl-6 hexatriènes-1,3,5 conduit aux chrysènes substitués-3. Les chrysènes substitués-3 ont été préparés d'une façon indépendante avec un haut rendement par l'oxydation-photocyclisation des α-naphtyl-1 (phényl *p*-substitué)-2 éthylènes.

Although chrysene itself is commercially available, substituted chrysenes are little known and can be obtained only by tedious synthetic pathways (1–3). Chrysenes substituted in the 6 and 12 positions are readily obtained by electrophilic substitution reactions (4), but other substituted chrysenes are rare and many polysubstituted chrysenes are completely unknown. Chrysenes are interesting polyaromatic compounds in that the 6-methylchrysene is known to be carcinogenic (5), but 6-aminochrysene is carcinostatic (6). Although chrysenes have been obtained directly from steroids by catalytic dehydrogenation (7), the formation of steroids from substituted chrysenes has not been attempted, probably due to the lack of available substituted chrysenes.

In 1962 Fonken (8) described the formation of chrysene by the photochemical-oxidation of 1,6-diphenyl-1,3,5-hexatriene. In this paper, we present a general synthesis of 3-substituted- and 3,9-disubstituted-chrysenes using the photochemical method of Fonken (Scheme 1).

The 1,6-di-*p*-substituted-phenyl-1,3,5-hexatrienes (**1***a–e*) were prepared in moderate yield (Table 1) by reacting 2-butene-1,4-bis(tri-*n*-butylphosphonium chloride) (9) with the appropriate *p*-substituted-benzaldehyde in a Wittig reaction (10). The 1-*p*-substituted-phenyl-6-phenyl-1,3,5-hexatrienes (**2***a–e*) were prepared in moderate yield (Table 1) by reaction of *p*-substituted-benzylphosphonium chlorides with 5-phenylpenta-2,4-dien-1-al in a Wittig reaction (10).

b R = Me
c R = Cl
d R = F
e R = CN

SCHEME 1

The hexatrienes, **1***a–e* and **2***a–e*, were readily characterized by their spectral data (Table 2) and by comparison with known 1,6-diaryl-1,3,5-hexatrienes. Mass spectroscopy revealed the presence of strong parent ions for **1***a–e* and **2***a–e*. The u.v. and i.r. spectra clearly showed the presence of the hexatriene moiety.[3]

Irradiation of 8.0×10^{-4} *M* solutions of 1,6-di-*p*-substituted-phenyl-1,3,5-hexatrienes (**1***a–d*) in dry benzene, containing 3.2×10^{-3} *M* iodine, gave after 24 h 3,9-disubstituted-chrysenes (**3***a–*

[1]For Part IV, see Leznoff and Hayward (17).

[2]Taken in part from the thesis submitted by Roger J. Hayward in partial fulfilment of the requirements for the Ph.D. degree.

[3]It is assumed that the all-*trans* hexatrienes are formed from the method of preparation and the i.r. spectral data of **1***a–e* and **2***a–e*, which show absorption peaks for *trans* double bonds.

d) in 12–14% yield. The 1,6-di-*p*-cyanophenyl-1,3,5-hexatriene (**1***e*) gave 3,9-dicyanochrysene (**3***e*) in 60% yield. Compound **3***e* was very insoluble in benzene and precipitated from solution as it was formed, and this fact may account for the relatively high yield of **3***e*.

Similarly, irradiation of 1-*p*-substituted-phenyl-6-phenyl-1,3,5-hexatrienes (**2***a–e*) gave 3 substituted-chrysenes (**4***a–e*) in 12–15% yield (Scheme 2).

The stilbene-like photocyclization-oxidation of 1-α-naphthyl-2-phenylethylene yields chrysene (11) and it is highly likely that the irradiation of **2***a–e* (and **1***a–e*) goes through 1-α-naphthyl-2-*p*-substituted-phenylethylene inter-

mediates. To test this possibility, a series of 1-α-naphthyl-2-*p*-substituted-phenylethylenes (**5***a–e*) were prepared by the Wittig reaction of 1-*p*-substituted-benzylphosphonium chlorides and 1-naphthaldehyde and irradiated under conditions identical to those for **1***a–e* and **2***a–e*. The physical and spectral properties of **5***a–e* were consistent with the assigned structures (see Experimental).

Irradiation of **5***a–e* gave **4***a–e* in 30–60% yield. The 3-substituted-chrysenes (**4***a–e*), obtained from **5***a–e*, showed identical physical and spectral properties to **4***a–e* obtained by the irradiation of **2***a–e* (Tables 3 and 4). It is thus highly likely that **5***a–e* are intermediates in the photocyclization-oxidation reactions of **2***a–e* to **4***a–e*.[4]

In an experiment designed to show that all the 1,6-diaryl-1,3,5-hexatrienes underwent an identical type of photocyclization-oxidation reaction, an attempt was made to convert the photoproducts, 3,9-dichlorochrysene (**3***c*) and 3-chlorochrysene (**4***c*), obtained from **1***c* and **2***c*, respectively, into the photoproducts 3,9-dicyanochrysene (**3***e*) and 3-cyanochrysene (**4***e*), obtained from **1***e* and **2***e*, respectively. When **3***c* and **4***c* were heated under reflux in pyridine with cuprous cyanide for 24 h, **3***e* and **4***e* were obtained in 25 and 33% yield, respectively.

The structures of the previously unknown 3,9-substituted-chrysenes (**3***a–e*) and 3-substituted-chrysenes (**4***a–e*) were determined from their method of preparation and spectral data (Table 4). Mass spectroscopy revealed the presence of strong parent ions for **3***a–e* and **4***a–e*. The u.v. (12) and i.r. spectra of **3***a–e* and **4***a–e* were characteristic of chrysenes. The n.m.r. spectra of **3***a–e* and **4***a–e* were typical of chrysene itself (13). Martin *et al.* and Memory and Cobb (13) found that protons at H-4, -5, -10, and -11 in chrysene itself were abnormally deshielded and occurred downfield by approximately 0.65 p.p.m. compared to the other eight protons in the molecule. The n.m.r. spectra of **3***a–b* and **4***a–e* showed the same deshielding effect for the four protons, which emphasize that the substituents could not be at C-4, -5, -10, and -11 of chrysene and support the assigned structures. Compounds **3***a* and *b* were identical to compounds previously synthesized by a totally unambiguous route (14) and thus the structure of these compounds is confirmed. It is very unlikely that any functional group or skeletal migrations have occurred during irradiation.

It has been demonstrated that substituted chrysenes can be synthesized in reasonable yield by a simple one-step photocyclization-oxidation reaction from readily available precursors.

[4]The intermediacy of 1-styryl-7-substituted-naphthalenes is equally likely, especially in light of the fact that a substituent on a phenyl ring of the related 1,4-diphenyl-1,3-butadiene does not appreciably affect the direction of photocyclization (16).

Experimental

All m.p.s. were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer 257 spectrometer using KBr discs. The u.v. spectra were measured using a Cary 14 u.v. spectrometer and benzene as a solvent. The n.m.r. spectra were measured on a Varian A60 spectrometer using tetramethylsilane as an internal standard ($\delta = 0$ p.p.m.) and deuterochloroform as solvent. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer. Silica gel was used for thin- and thick-layer chromatography. All photochemical reactions were carried out in a Rayonet photochemical reactor using RPR 3500 °A lamps. Microanalyses were performed by A. B. Gygli of Toronto.

Synthesis of 1,6-Di-p-substituted-phenyl-1,3,5-hexatrienes

All the 1,6-di-*p*-substituted-phenyl-1,3,5-hexatrienes were synthesized in a manner identical to that of *1,6-di-p-chlorophenyl-1,3,5-hexatriene* (**1***c*). To a mixture of 5 g (0.035 mol) of *p*-chlorobenzaldehyde and 9.0 g (0.017 mol) of 2-butene-1,4-bis(tri-*n*-butylphosphonium chloride) (9) in 50 ml of methanol was added 80 ml of 0.4 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which crystals of 1,6-di-*p*-chlorophenyl-1,3,5-hexatriene were filtered off.

Synthesis of 1-p-Substituted-phenyl-6-phenyl-1,3,5-hexatrienes

A typical example is given for the preparation of *1-p-methoxy-phenyl-6-phenyl-1,3,5-hexatriene* (**2***a*). To a mixture of 2.0 g (0.0126 mol) of 5-phenylpenta-2,4-dien-1-al (15) and 5.83 g (0.012 mol) of *p*-methoxybenzyltriphenylphosphonium bromide in 30 ml of methanol was added 50 ml of 0.4 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which the product was filtered off.

*Physical and Spectral Properties of the 1,6-Di-p-substituted-phenyl-1,3,5-hexatrienes (**1***a–e*) and 1-p-Substituted-phenyl-6-phenyl-1,3,5-hexatrienes (**2***a–e*)*

The physical and spectral properties of these compounds are given in Tables 1 and 2, respectively.

Synthesis of 1-(α-Naphthyl)-2-p-substituted-phenylethylenes

A typical example is given for the preparation of *1-(-α-naphthyl)-2-p-methylphenylethylene* (**5***a–e*). To a mixture of 3 g (0.0193 mol) of 1-naphthaldehyde and 7.75 g (0.0193 mol) *p*-methylbenzyltriphenylphosphonium chloride in 20 ml of methanol was added 25 ml of 1.2 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which the product was filtered off.

*Preparation of 1-(α-Naphthyl)-2-p-fluorophenylethylene (**5***d*)*

This compound was made by a Grignard reaction. To the ice cold Grignard-reagent from 5 g (0.035 mol) *p*-fluorobenzylchloride and 0.8 g (0.035 mol) of magnesium in 50 ml of dry ether was added 5.0 g (0.032 mol) of 1-naphthaldehyde in 10 ml of ether. After the addition was completed the mixture was stirred for 2 h at room temperature, then cooled with ice. To this mixture was added 100 ml of ice-cold saturated ammonium chloride solution. The mixture was then boiled under reflux, cooled, and extracted with ether. The ether solution was dried with anhydrous magnesium sulfate and evaporated. The remaining crude product was distilled at a reduced pressure; the fraction boiling at 171–173 °C (0.1 mm) was found to be 1-(α-naphthyl)-2-*p*-fluorophenylethylene.

*Physical and Spectral Properties of the 1-(α-Naphthyl)-2-p-substituted-phenylethylenes (**5***a–e*)*

The physical and spectral properties of these compounds are given in Tables 5 and 6, respectively.

F	Cl	315–316	75	73.62	5.86	73.30	5.56

Preparation of p-Substituted-benzyltriphenylphosphonium halides

The *p*-substituted-benzylphosphonium halides were synthesized in a manner identical to that described before (16). Physical properties of phosphonium halides are given in Table 7.

Irradiation of Starting Materials

The general techniques of irradiation on a preparative scale have been described previously (16). The photocyclization-oxidation reaction products were isolated by preparative t.l.c. using hexane:benzene (3:1) as eluant. All photocyclization-oxidation monomeric products moved faster than the starting materials on t.l.c. Compounds moving slower than the starting material invariably turned out to be dimeric products.

Since the starting materials **1***a*, **1***b*, and **2***a* were so insoluble in organic solvents a different technique was used to irradiate them. An example is given for 1,6-di-*p*-methoxyphenyl-1,3,5-hexatriene (**1***a*). A slurry of 100 mg of **1***a* in 500 ml of benzene containing 3.2×10^{-3} *M* iodine was irradiated for 3 days in the usual way. The mixture was subjected to vigorous agitation by passing through it a dry stream of nitrogen. After 3 days no starting material could be detected by t.l.c. The mixture was then worked-up in the usual way (16).

The physical and spectral properties of the substituted chrysenes are given in Tables 3 and 4, respectively.

Preparation of Cyanochrysenes from Chlorochrysenes

The procedure given previously for the preparation of cyano-1-phenylnaphthalenes from chloro-1-phenylnaphthalenes was followed exactly.

Reactions of Tetrasubstituted Azomethine Ylides Generated from Tetracyanoethylene Oxide

J. W. LOWN AND K. MATSUMOTO[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received September 2, 1971

Reaction of a series of Schiff bases (bearing substituents which effect electron release in either the benzal or aniline moieties), with tetracyanoethylene oxide generates several tetra-substituted azomethine ylides which may be trapped in the presence of dipolarophiles both heteromultiple and homomultiple. The methine n.m.r. assignments in the adducts are obtained by using benzal-$[^2H]_1$-2,4,6$[^2H]_3$-aniline in the reactions which results in >98% deuterium incorporation. Diphenylcyclopropenone reacts preferentially with tetracyanoethylene oxide to give 3,4-diphenyl-5,5,6,6-tetracyano-5,6-dihydropyran-2-one while diphenylcyclopropenethione reacts with tetracyanoethylene oxide to give 1,2-diphenyl-3-dicyanomethylenecyclopropene in a 67% yield superior to that of existing preparations.

La réaction d'une série de bases de Schiff (substituants porteurs avec perte d'effet électronique dans une partie du benzylidène ou de l'aniline) avec l'oxyde de tétracyanoéthylène produit plusieurs ylides d'azométhine substitués qui peuvent être piégés en présence de dipolarophiles à la fois hétéromultiple et homomultiple. Les attributions du groupe méthinique en r.m.n. dans les composés d'addition sont obtenus par l'utilisation du benzylidène $[^2H_1]$-2,4,6$[^2H_3]$-aniline dans les réactions qui résultent d'une deutération 98%. Le diphénylcyclopropenone réagit préférentiellement avec l'oxyde de tétracyanoéthylène pour donner la diphényl-3,4-tétracyanoéthylène-5,5,6,6-dihydropyrane-5,6-one-2 tandis que la diphénylcyclopropènethione réagit avec l'oxyde de tétracyanoéthylène pour donner le diphényl-1,2-dicyano-méthylène cyclopropène-3 dans un rendement de 67%, supérieur aux préparations existantes.

Canadian Journal of Chemistry, **50**, 534 (1972)

The orbital symmetry-controlled thermal and photochemical cleavage of aziridines to azomethine ylides (1) and subsequent 1,3-dipolar cycloaddition of the latter species to a variety of homomultiple and heteromultiple bonds leads to several useful synthetic routes to many heterocyclic systems (2). In the monocyclic aziridine series the systems that have been examined from this viewpoint are limited to the examples **1***a–g*. In examples of type **1***h* substituents of the type $R_3 = R_4 = X$ where X is a strongly electron-withdrawing group *e.g.* CN, would be expected to confer increased stability and longer lifetimes on the azomethine ylides which otherwise enjoy only transient existence. Since such aziridines of the type **1***h* are inaccessible synthetically we have reexamined the generation of tetrasubstituted azomethine ylides produced from tetracyanoethylene oxide reported by Linn and Ciganek (14). Tetracyanoethylene oxide (**2**) reacts with benzalaniline in benzene to give species **3** and **4** which can react

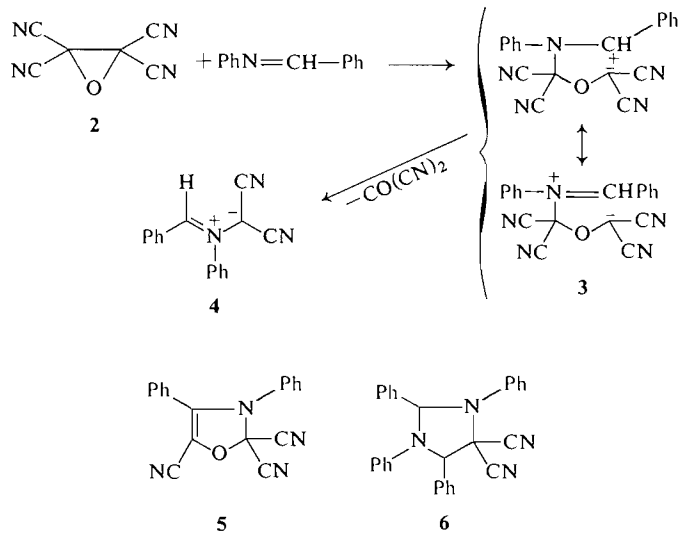

SCHEME 1

with dipolarophiles to give products of 1,3-dipolar addition (14). In the absence of other dipolarophiles the 4-oxazoline **5** is formed (by ring closure of **3** and elimination of a molecule of hydrogen cyanide) together with the imidazolidine **6** (formed by 1,3-dipolar addition of benzalaniline to the azomethine ylide **4** in a regiospecific manner), see Scheme 1.

It seemed worthwhile to extend the synthetic usefulness of the reaction by introducing more reactive dipolarophiles into the reaction to take advantage of the relatively low dipolarophilic activity of benzal aniline and other simple imines. Therefore reaction of tetracyanoethylene oxide and benzal aniline in the presence of *N*-phenylmaleimide gave the substituted pyrrolidine **7***a* in 51% yield. The pyrrolidine **7***a* exhibited an AMX spectrum for the methine protons. All the chemical shifts and corresponding coupling constants were obtained unambiguously by a parallel experiment employing benzal-*d*-2,4-6-trideuteroaniline (prepared by the condensation of formyl-*d*-benzaldehyde (99.5% *d*) with 2,4,6-*N*,*N*-pentadeuteroaniline) with tetracyanoethylene oxide and *N*-phenylmaleimide. Examination of the n.m.r. spectrum of the deuterated pyrrolidine showed >98% deuterium incorporation implying little or no proton exchange from intermediate **3** or **4** into the reaction medium. By comparison of the spectra of the protium and deuterium compounds values for the vicinal coupling constants of $J_{2,3} = 6$ and $J_{3,4} = 10$ Hz were derived, which favor the configuration shown (see Scheme 2).

Reactions of several benzal anilines (bearing different substituents in both the benzal and aniline moieties) and tetracyanoethylene oxide in the presence of an equivalent of *N*-phenylmaleimide were now examined. The effects of the substituents on production of the pyrrolidine are summarized in the legend in Scheme 2.

Substituents which effect electron release by resonance mechanisms in either the benzal or aniline moieties and increase the basicity of the nitrogen promote the reaction leading to the trapping of the azomethine ylide. These results are consistent with, on the one hand, increased nucleophilicity of the imine nitrogen promoting the ring cleavage of the oxirane, and on the other hand, with the enhanced resonance stabilization afforded intermediate **3**. Conversely, electron-withdrawing substituents in either moiety of the imine preclude the reaction.

Electron-releasing substituents in the aniline moiety, are only effective provided their influence is not countermanded by electron-withdrawing substituents in the benzal moiety (contrast **7***d* with **7***k* and *l*).

Dimethyl fumarate reacted readily with **2** and benzal aniline to form the pyrrolidine **8***a* which consisted of one stereoisomer only. The assignments of the chemical shifts and coupling con-

stants were made by comparison with the n.m.r. spectrum of the deuterated analog **8***b*, prepared using benzal-*d*-2,4,6-trideuteroaniline, which demonstrated values for the coupling constants of $J_{2,3} = 9$ and $J_{3,4} = 11.5$ Hz. The flexibility of the five-membered pyrrolidine ring precludes rigorous assignment of the relative configuration of the 2- and 3-groups, in the absence of the stereoisomer for comparison.

Dimethyl maleate proved insufficiently reactive under these conditions to form the isomeric pyrrolidine. While the lower reactivity of dimethyl maleate than dimethyl fumarate in 1,3-dipolar additions is well documented (15) the former reacts readily and retains its configuration during the addition to 3-benzoyl-1-cyclohexyl-2-(2′-thienyl)aziridine (16). The failure of dimethyl maleate to react with **4** in the present reaction may indicate the enhanced stability afforded the latter by two nitrile groups and hence the lower reactivity of **4**.

trans-Dibenzoylethylene reacted readily with tetracyanoethylene oxide in the presence of benzal aniline to give a single pyrrolidine **9**. The methine protons exhibited a strongly coupled ABC spectrum in the n.m.r. from which an $H_{2,3}$ coupling of 10 Hz could be estimated. This was confirmed when, upon standing in chloroform for 1 week at room temperature, **9** underwent spontaneous *trans*-4,5 elimination of hydrogen cyanide to give the 2-pyrroline **10** quantitatively. The latter exhibited a clean AB quartet $J_{2,3} =$ 10 Hz for the methine proton n.m.r. signals.

Reaction of *N*-phenylmaleimide and maleimide, respectively, with tetracyanoethylene oxide in the presence of benzal aniline gave pyrrolidines **7***a* and **11***a*. Each exhibited an AMX spectrum for the methine protons. All the
