After cooling to room temperature, the sample was transferred quantitatively to the 150 ml gas washing bottle, and was diluted to 60 ml with distilled water. Two ml of 10% $SnCl_2$ was added to reduce the dichromate and ionic mercury and the sparger was replaced in the gas washing bottle. A constant air flow of 1.5 standard cubic ft per h was immediately redirected through the sparger of the gas washing bottle where the finely divided metallic mercury was vaporized. The mercury vapor was carried with the air stream through the quartz cell where it was detected using a Techtron AA 120 atomic absorption spectrophotometer. The spectrophotometer signal was traced on a Varian G-2000 strip-chart recorder. The spectrophotometer parameters were mercury hollow-cathode lamp current 3 mA, slit height 10 mm, slit width 0.10 mm, and wavelength 253.6 nm.

Standard solutions containing 500 p.p.m. (by weight) Hg were prepared from mercuric chloride. Comparison of old and fresh standards showed that they were stable for at least 6 months. A 1.0 p.p.m. Hg standard was prepared daily by dilution of the 500 p.p.m. Hg standard. The spectrophotometer was calibrated with salt solutions containing 0.10 to 1.0 μg Hg, which were prepared using aliquots of the 1.0 p.p.m. Hg standard and the same weight of 6.1 *m* NaCl as in the unknown to be determined. The linear peak height – concentration calibration curve was used to determine the unknown mercury solubility in the NaCl brine.

In this work acid dichromate was used as the oxidizing agent for mercury in preference to the acid permanganate used previously (1) because it does not require the addition of hydroxylamine hydrochloride (3). Identical results were obtained by both techniques.

[1]Contribution No. 195.

[2]Method for determination of mercury in effluent and process streams from a mercury-cell chlorine plant (atomic absorption flameless method). This report is available on request from the company.

The concentration of sodium chloride in the solubility cell was determined by potentiometric titration with silver nitrate.

All equilibrium equations were derived by least-squares using the Clarke–Glew method (4) assuming that the logarithms of the solubilities were normally distributed: this was consistent with the experimental determination of *S*, which was known with a constant percentage experimental error. In contrast with our earlier study (1) all mercury solubilities reported in this work are expressed in molality units, mol Hg/1000 g H_2O.

Results

The solubility of mercury in water, S^0 (mol Hg/1000 g H_2O), between 0 and 120 °C derived from our earlier measurements (1) is best represented by the equation

$$[1] \quad \log_{10} S^0 = -126.345 + 4715.2/T + 42.0288 \log_{10} T$$

where T is the absolute temperature (273.15 K = 0 °C (11)). This equation is equivalent to eq. 2 of ref. 1. The standard thermodynamic function changes with their standard errors at 25 °C, derived from eq. 1, are $\Delta G_2^0(l_2 \rightarrow l_1) = 8912 \pm 9$ cal, $\Delta H_2^0(l_2 \rightarrow l_1) = 3326 \pm 150$ cal, $\Delta S_2^0(l_2 \rightarrow l_1) = -18.7 \pm 0.5$ cal/deg, and $\Delta C_{p2}^0(l_2 \rightarrow l_1) = 83.5 \pm 5.6$ cal/deg and correspond with the transfer of 1 mol of mercury from the liquid metallic phase l_2 into the water phase l_1 at unit mercury activity. Values of solubility S^0 given in Table 1 were calculated from eq. 1 at those temperatures used for determination of the mercury solubility in salt solutions.

Experimental values for the solubility S (mol Hg/1000 g H_2O) of mercury in brine between 5 and 70 °C are given in column 4 of Table 1; the sodium chloride molality c varied between 6.09 and 6.29 *m* NaCl and is given in column 3. Salting-out constants, $k = (\log_{10} S^0/S)/c$, were evaluated from each of the solubility determinations and were used to calculate corrected mercury solubilities S' in 6.10 *m* NaCl. Values of S' are given in column 5.

The temperature dependence of the mercury solubility in 6.10 *m* NaCl between 5 and 70 °C is represented by the equation

$$[2] \quad \log_{10} S' = -6.043 - 1639.8/T + 1.9230 \log_{10} T$$

The standard error on a single determination of S′ assessed from eq. 2 is 7.7%, which agrees well with the 7.5% error assessed from analogous measurements in water between 4 and 72 °C (1). The standard thermodynamic function changes and standard errors derived from eq. 2 at 25 °C are $\Delta G_2^0(l_2 \rightarrow l_1) = 9256 \pm 9$ cal, $\Delta H_2^0(l_2 \rightarrow l_1) = 8642 \pm 148$ cal, $\Delta S_2^0(l_2 \rightarrow l_1) = -2.1 \pm 0.5$ cal/deg, and $\Delta C_{p2}^0(l_2 \rightarrow l_1) = 3.8 \pm 11.9$ cal/deg and correspond with the transfer of 1 mol of mercury from phase l_2 into the aqueous 6.10 *m* NaCl phase l_1 at unit mercury activity.

Since the regression coefficient of $\log_{10} T$ in eq. 2 is small and indistinguishable from zero, the temperature dependence of S' between 5 and 70 °C can be represented by

$$[3] \quad \log_{10} S' = -0.424 - 1895.9/T$$

The standard error, assessed from eq. 3, on a single S' determination is 7.6%, essentially the same as assessed from eq. 2.

The mercury solubility in 6.10 *m* NaCl together with its standard error evaluated from eq. 3 is given in Table 2 and shown by the solid line in Fig. 1. The solubility in water evaluated from eq. 1 is shown by the dashed line.

The temperature dependence between 5 and 70 °C for the salting-out constant, k (m^{-1}), derived from each of the experimental solubilities S, is given by

$$[4] \quad k = -20.373 + 1072.2/T + 6.7966 \log_{10} T$$

The standard error on a single determination of k is 0.0054 m^{-1}. Salting-out constants and their standard errors from eq. 4 are given in Table 2. The salting-out constants decrease rapidly with increasing temperature and change sign at 50.8 ± 1.0 °C. At higher temperatures the mercury solubility in 6.10 *m* NaCl is greater than in water.

Discussion

The standard thermodynamic function changes for mercury transfer into 6.10 *m* NaCl and into water, evaluated from eqs. 2 and 1, are compared in Fig. 2.

In aqueous 6.10 *m* NaCl all standard thermodynamic function changes vary little between 5 and 70 °C. The large, slowly varying $\Delta G_2^0(l_2 \rightarrow l_1)$ arises predominantly from the large $\Delta H_2^0(l_2 \rightarrow$

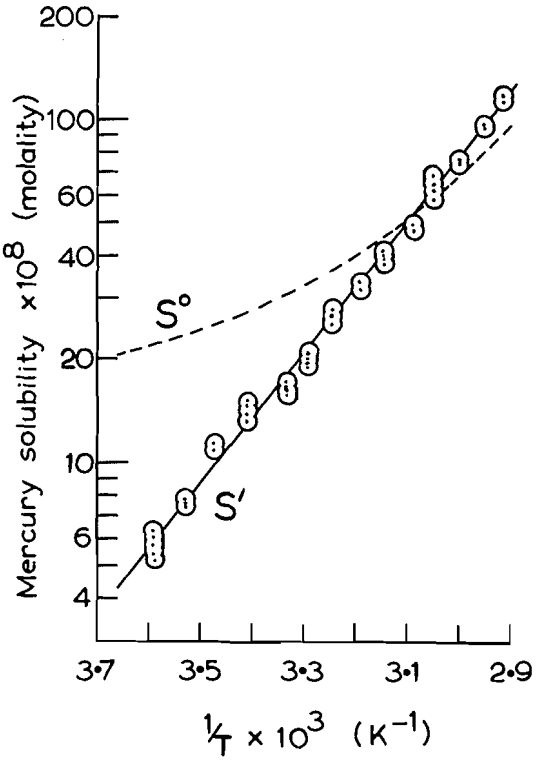

FIG. 1. The temperature dependence of mercury solubility in water, S^0, and in 6.10 *m* NaCl, S'.

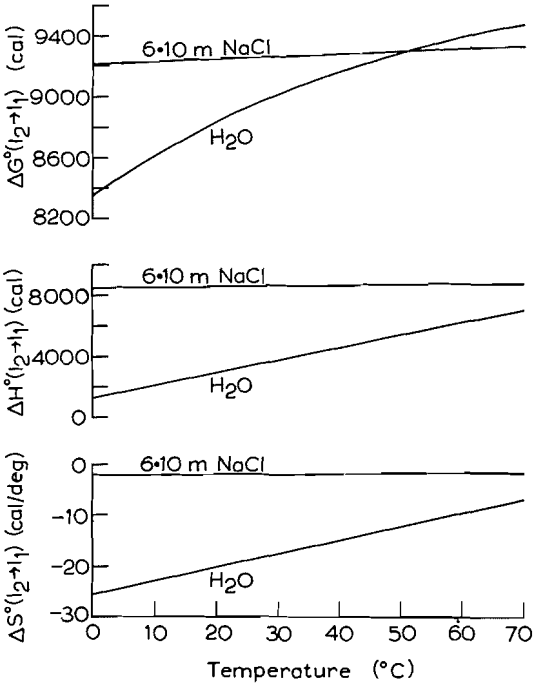

FIG. 2. Standard thermodynamic function changes for the transfer of mercury into water and into 6.10 *m* NaCl.

l_1), with only a small contribution from $\Delta S_2^0(l_2 \rightarrow l_1)$. The small temperature dependence of $\Delta H_2^0(l_2 \rightarrow l_1)$ and $\Delta S_2^0(l_2 \rightarrow l_1)$ correspond with the small positive value of $\Delta C_{p2}^0(l_2 \rightarrow l_1)$. The nearly temperature-invariant thermodynamic function changes probably occur because all of the water in the 6.10 *m* NaCl is in the primary hydration shell of the sodium and chloride ions, and the structure of this tightly bound water is relatively unaffected by the 5 to 70 °C change of temperature.

In contrast in water the free energy, enthalpy, and entropy changes are highly temperature sensitive with a large value for the heat capacity change. The large temperature dependence of the standard thermodynamic function changes probably occurs because of the rapid variation of water structure with temperature (1).

In 6.10 *m* NaCl and water the standard changes of free energy are equal at 50.8 °C, of enthalpy equal at 92 °C, and of entropy equal at 94 °C. Thus it is found that the enthalpy and entropy for mercury transfer into 6.10 *m* NaCl between 5 and 70 °C are similar to those for transfer into water at about 90 °C. The value of $\Delta C_{p2}^0(l_2 \rightarrow l_1)$ is very sensitive to sodium chloride concentration changing from 83.5 ± 5.6 in water to 3.8 ± 11.9 cal/deg in 6.10 *m* NaCl.

The sodium chloride salting-out constant for mercury in water is of the same order of magnitude, but smaller than those found for the inert gases at ambient temperatures (5–7). The high sodium chloride concentration used in this study would result in smaller salting-out constants than obtained for dilute sodium chloride solutions (8, 9). The change of the salting-out constant with temperature is 0.002 m^{-1} deg^{-1} at 25 °C for this work compared with approximately 0.001 from earlier work with nitrous oxide (9, 10) and the inert gases (6). The value of dk/dT falls as temperature is increased, as shown previously (9).

The Oxidation of Tetrahydrofuran by Ruthenium Tetroxide

DONALD G. LEE AND MATTHIJS VAN DEN ENGH[1]

Department of Chemistry, The University of Saskatchewan Regina Campus, Regina, Saskatchewan

Received March 23, 1972

The kinetics of the oxidation of tetrahydrofuran by ruthenium tetroxide in aqueous perchloric acid solutions have been investigated. The rate of reaction is found to be directly dependent on the concentrations of oxidant and reductant, but inversely dependent on the acidity of the medium. A mechanism involving hydride abstraction in the rate determining step was found to be consistent with the evidence obtained from isotopic labeling and an analysis of the activation parameters ($\Delta H^* = 14.0$ kcal/mol, $\Delta S^* = -18.4$ e.u.) of the reaction. This conclusion is further substantiated by noting the similarity between the reactions of ruthenium tetroxide with alcohols and ethers.

Les cinétiques de l'oxydation du Tétrahydrofurane par le tétroxyde de Ruthénium, dans des solutions aqueuses d'acide perchlorique, ont été étudiées. La vitesse de la réaction dépend directement des concentrations de l'oxydant et du réducteur et inversément de l'acidité du milieu. Le mécanisme faisant intervenir un arrachement d'hydrure dans l'étape déterminante de la cinétique est prouvé compatible avec le marquage isotopique et l'analyse des paramètres d'activation de la réaction ($\Delta H^* = 14.0$ kcal/mol, $\Delta S^* = -18.4$ e.u.). Cette conclusion est confirmée par la suite, en notant la similitude entre les réactions du tétroxyde de Ruthénium avec les alcools et les éthers. [Traduit par le journal]

The oxidation of aliphatic ethers to the corresponding esters (or lactones in the case of cyclic ethers) can be accomplished by the use of chromium trioxide, lead tetraacetate, or ruthenium tetroxide as oxidants (1). The most effective of these reagents, ruthenium tetroxide, has been used in the oxidation of a variety of acyclic, cyclic, and bicyclic ethers (2–4). The reaction, which can be carried out either in aqueous solutions or in non-oxidizable, non-polar solvents (*e.g.*, carbon tetrachloride or chloroform), is free of side reactions and usually gives quantitative yields of pure products.

Despite the apparent utility of this procedure little attention has been paid to the mechanism of this and other related oxidation reactions involving the use of ruthenium tetroxide. Consequently we have undertaken a detailed study of these reactions and wish to report the results obtained from an investigation into the mechanism whereby tetrahydrofuran is converted into γ-butyrolactone in aqueous perchloric acid solutions (reaction 1).

[1] 
[1]NRCC Scholarship holder 1969–1971.

Experimental

Reagents

Ruthenium tetroxide was prepared by the oxidation of hydrated ruthenium dioxide (0.5 g) obtained from Engelhard Industries Inc., with a solution of sodium periodate (2 g) in 25 ml of water. The mixture was shaken until the reaction was complete (as evidenced by the disappearance of the insoluble black ruthenium dioxide). The bright yellow product of this reaction, ruthenium tetroxide, was extracted into carbon tetrachloride and stored over sodium periodate. Just prior to a kinetic experiment an aliquot of the solution was removed and the ruthenium tetroxide extracted into an aqueous perchloric acid solution of the desired molarity.

Tetrahydrofuran and tetrahydrofuran-d_8 were obtained commercially and purified just prior to use by g.l.c. A diethylene glycol column was found to be satisfactory for this purpose.

Perchloric acid solutions were prepared by the dilution of 70% perchloric acid with doubly distilled water (5).

Kinetic Measurement

In a typical kinetic experiment 3.0 ml of a perchloric acid solution containing a specified amount of ruthenium tetroxide were pipetted into a cuvet which was placed in a thermostated cuvet holder for about 20 min. Then the desired quantity of tetrahydrofuran was added using a microsyringe. The timer was started immediately and the absorption at 310 nm was recorded periodically using a Unicam SP500 Spectrophotometer. As the reaction proceeded the color of the solution changed from bright yellow to brown. The absorption spectrum of ruthenium tetroxide can be shown to obey the Beer–Lambert law in aqueous perchloric acid solutions (Fig. 1); consequently the decrease in absorbance could be taken as a measure of the extent of reaction.

The data obtained in this way were analyzed by a differen-

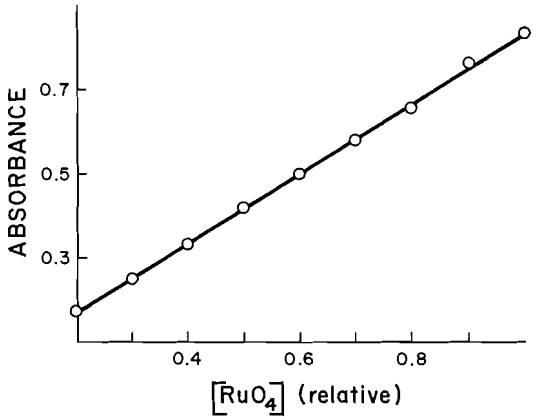

FIG. 1. Verification of Beer's law for ruthenium tetroxide.

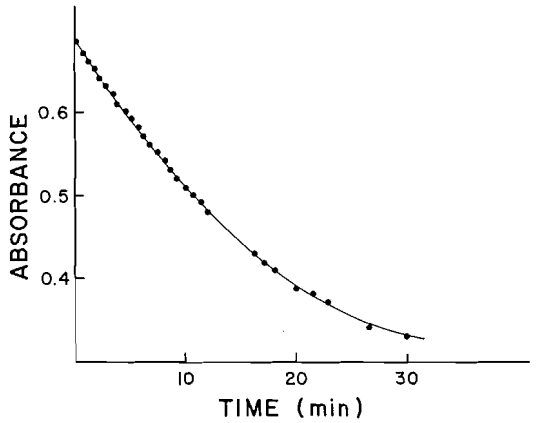

FIG. 2. Typical rate plot for the oxidation of tetrahydrofuran by ruthenium tetroxide in 1.94 M $HClO_4$.

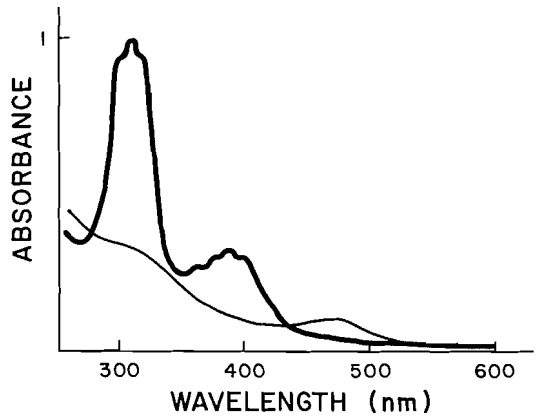

FIG. 3. Absorption spectra before (top) and 2 h after (bottom) addition of an excess of tetrahydrofuran to a solution of ruthenium tetroxide in 2.89 M $HClO_4$.

tial method, which involved the use of initial rates as determined from the initial slopes of plots of absorbance *vs.* time. (A typical plot has been reproduced in Fig. 2.) An integral method of analysis was not satisfactory under these conditions because the products of the reaction also absorb in the same region of the spectrum (Fig. 3). Under such conditions it is more reliable to use initial rates where the concentrations of products will be negligibly small, than to attempt to use an integral method which requires larger corrections (6).

All rates and rate constants reported herein are the average of at least two determinations which agreed to within $\pm 5\%$ or less.

Results

Rate Law

The order of the reaction with respect to oxidant was determined by following the rate of reaction at several different initial concentrations of ruthenium tetroxide while holding the concentration of tetrahydrofuran at a high constant excess. Under these conditions the rate of the reaction can be expressed as in eq. 2.

$$[2] \qquad \frac{d[RuO_4]}{dt} = k[RuO_4]^x$$

Since the concentration of ruthenium tetroxide is approximately proportional to absorbances in the initial stages of the reaction eq. 2 can be expressed as eq. 3.

$$[3] \qquad \frac{d(\text{initial absorbance})}{dt} = k\,(\text{initial absorbance})^x$$

By noting that the first term of eq. 3 is just the initial slope and taking logarithms eq. 4 is obtained.

$$[4] \qquad \log(\text{initial slope}) = x \log(\text{initial absorbance}) + \log k$$

Consequently the order of the reaction with respect to ruthenium tetroxide can be obtained from a plot of log (initial slope) *vs.* log (initial absorbance). Several such plots were prepared and found to be linear with slopes ranging from 0.95 to 1.10. A typical example has been reproduced in Fig. 4. Hence the order of the reaction with respect to ruthenium tetroxide is unity.

The order of the reaction with respect to ether was then determined by observing the change in initial slope when the concentration of tetrahydrofuran was varied at constant ruthenium

‡Average of at least three different experiments. The largest deviation from the mean was ±2%.

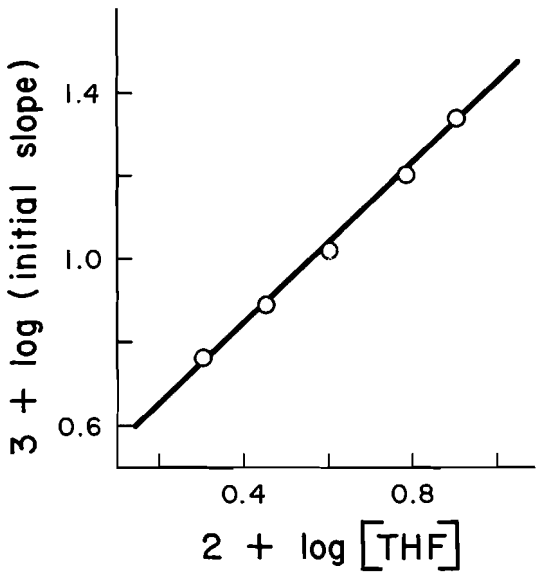

FIG. 5. Plot for determining the order with respect to tetrahydrofuran.

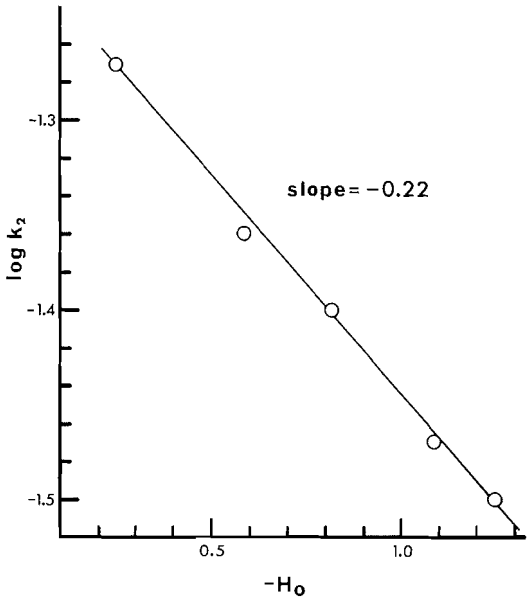

FIG. 6. Variation of rate with acidity.

tetroxide concentrations. As Fig. 5 shows, a plot of log (initial slope) *vs.* log [tetrahydrofuran] was found to be linear with a slope of 0.95. Hence the order with respect to the ether is also unity and the rate law for the reaction can be expressed as in eq. 5.

$$[5] \qquad v = k_2[RuO_4][THF]$$

However, the calculated second order rate constants, k_2, were also found to be dependent on the acidity of the solution. As indicated by the data summarized in Table 1 the rate of reaction decreases as the concentration of perchloric acid increases. A plot of the logarithms of the second order rate constants *vs.* the Hammett acidity function ($-H_0$) gives a straight line with a slope of -0.22 as indicated in Fig. 6. Consequently the complete empirical rate law for the reaction in aqueous perchloric acid could be expressed in the form of eq. 6.

$$[6] \qquad v = k_3[RuO_4][THF]h_0^{-0.22}$$

Isotope Effects

When the oxidation of tetrahydrofuran-d_8

was compared with that of unlabeled tetrahydrofuran the rate of reaction was found to decrease by a factor of about 33% (Table 2). This could be either a very large secondary isotope effect or a rather small primary isotope effect. Although it is not possible, on the basis of the available evidence, to distinguish between these two the latter is most probably the case, thus indicating that carbon–hydrogen bond cleavage is involved in the rate determining step.

Activation Parameters

The activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, were obtained by determining the rate constants at several temperatures and plotting ln k_2/T *vs.* $1/T$. The results, summarized in Table 3 and Fig. 7, give $\Delta H^{\ddagger} = 14.0 \pm 0.5$ kcal/mol and $\Delta S^{\ddagger} = -18.4 \pm 1.2$ e.u.

Discussion

The results presented in the previous section are all consistent with a mechanism that involves the transfer of a hydride ion to the oxidant in the rate limiting step. The isotope effect indicates

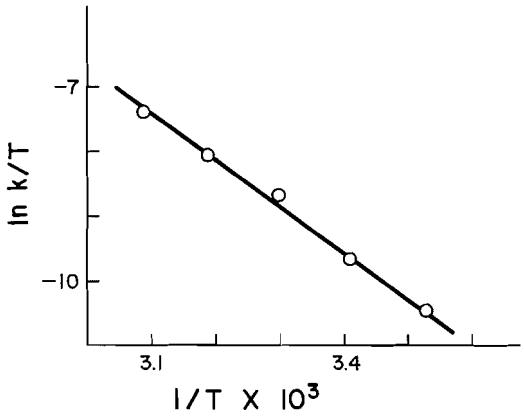

FIG. 7. Plot for determination of activation parameters. Slope = -7070 ± 252 °K^{-1}; intercept = 14.5 ± 0.1; correlation coefficient = 0.998.

that the α-carbon–hydrogen bond is cleaved in the rate determining step and the activation parameters are very similar to those obtained for other reactions which are known to proceed via similar mechanisms (7). Furthermore it has been observed that under similar conditions the oxidations of tetrahydrofuran and 2-propanol by ruthenium tetroxide proceed at comparable rates and exhibit almost identical activation parameters (8). Consequently it appears that the oxidation of ethers is very similar to that of alcohols where it has also been suggested that the rate limiting step involves a hydride ion transfer (8). The proposed mechanism has been outlined in Scheme 1.

The suggestion that the carbonium ion and ruthenium(VI) species recombine to give an ester as indicated in Scheme 1 has not been established, but it would seem to be a logical step. Other work has shown that tetrahydrofuran is not rapidly oxidized by ruthenium(VI) under basic conditions (9); however, the carbonium ion would in all probability be more susceptible to attack.

The inverse dependence of rate on acidity that is indicated by Fig. 6 could be a consequence of either the decrease in water concentration in highly acidic solutions or the protonation of tetrahydrofuran. The oxonium ions formed by protonation of tetrahydrofuran would not readily undergo a hydride transfer, since such a process would create a dipositive species. Hence extensive protonation of the ether would de-

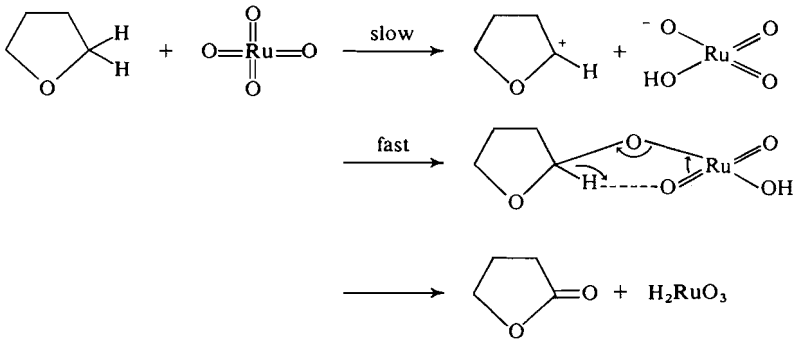

SCHEME 1

crease the rate of reaction; however, calculations show that tetrahydrofuran would *not* be extensively protonated under these conditions and that decreases in substrate concentration through formation of the corresponding oxonium ions can be neglected (10).

The decrease in water concentration (or activity) over the range of acidities studied is substantial and could account for the decrease in rate if the transition state were more highly solvated than the ground state. Such a possibility is not unlikely since it is known from spectral evidence that ruthenium tetroxide is not highly solvated (11), but that the reduced forms of ruthenium are strongly hydrated (12). Thus it is not unreasonable to expect that the transition state, which would contain a reduced ruthenium species, would have a higher demand for solvation than the ground state of the reaction.

In Figs. 8 and 9 $\log k_2$ has been plotted against $\log a_{H_2O}$ and $\log [H_2O]$. Both plots indicate that the rates of reaction are proportional to the amount of available water and the latter suggests an alternative rate law for the reaction (eq. 7) which would be equivalent to eq. 6, but more descriptive of the actual process.

$$[7] \qquad v = k_4[RuO_4][THF][H_2O]^6$$

The approximately linear plot obtained using the concentration of water is similar to that observed for the oxidation of 2-propanol by ruthenium tetroxide (8). Such linear plots have been observed for other reactions (13) and the slopes have generally been taken as an indication

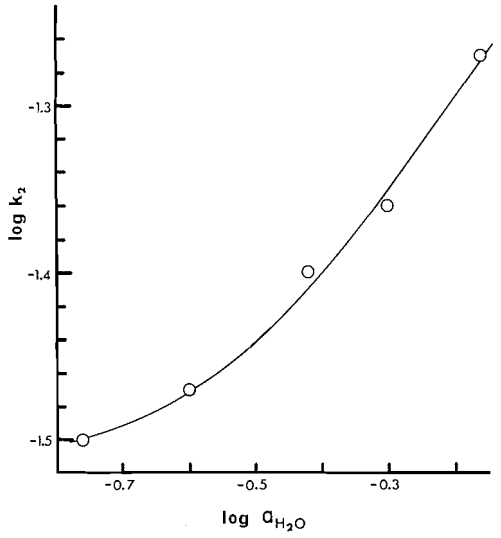

FIG. 8. Variation of rate with the activity of water.

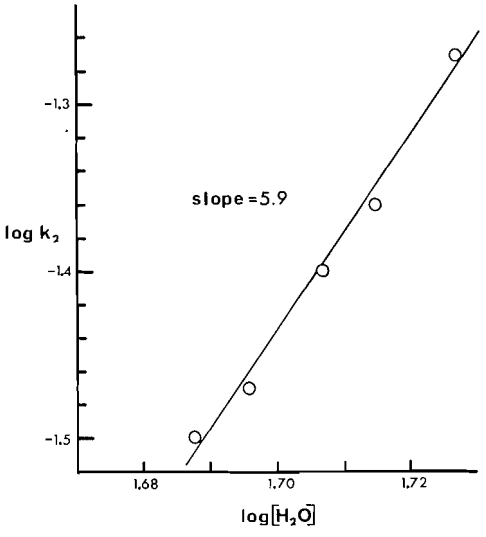

FIG. 9. Variation of rate with water concentration.

of the additional number of water molecules required to solvate the transition state. If such an interpretation is correct in this case it would mean that the transition state is highly polar, probably resembling the products of the first step in Scheme 1.

A transition state in which the carbon–hydrogen bond has been extensively cleaved is also consistent with the observed small isotope effect (14).

Analysis of a First-order Perturbation Theory for the Direct Correlation Function of Dense Fluids

S. W. BRELVI AND J. P. O'CONNELL

Department of Chemical Engineering, University of Florida, Gainesville, Florida 32601

Received April 10, 1972

An approximate expression for the direct correlation function of a real fluid in terms of its intermolecular potential and hard-sphere distribution functions is examined. Calculations for argon using the Percus–Yevick hard-sphere distribution functions are compared with molecular correlation functions from X-ray scattering data and the macroscopic integral of the correlation function related to the isothermal compressibility. The results are not satisfactory for any pair potential unless the parameters are made state dependent. However, since partial compensation occurs on integration, fairly good correlation of the isothermal compressibility can be obtained up to twice the critical density (except near the critical point itself) using Lennard–Jones (6–12) potential parameters obtained from second virial coefficient data and the Barker–Henderson hard-sphere diameter.

Nous utilisons une expression approximative dans le but de déterminer la fonction de corrélation directe d'un fluide réel en termes de potentiel intermoléculaire et de fonctions de distribution de sphère rigide. Nous comparons les calculs pour l'argon, effectués à partir des fonctions de distribution de Percus–Yevick pour des sphères rigides aux fonctions de corrélation moléculaires tirées de résultats de diffraction de rayons-X; nous établissons ensuite la relation entre l'intégrale macroscopique de la fonction de corrélation et la compressibilité isotherme. Les résultats ne sont pas satisfaisants pour toute paire de potentiel, à moins que les paramètres dépendent de l'état. Toutefois, puisqu'une compensation partielle se produit durant l'intégration, nous pouvons obtenir une assez bonne corrélation de la compressibilité isotherme, jusqu'au double de la densité critique (à l'exception des environs du point critiqué), en utilisant les paramètres de potentiel (6–12) de Lennard–Jones, obtenus à partir du second coëfficient du viriel et du diamètre de la sphère rigide de Barker–Henderson. In statistical thermodynamic studies of fluids, the structure of a real fluid state can be approximated as a perturbation about a reference state whose properties are known (1–3, 12). The relation between the properties in the two states is then found in terms of a perturbation parameter. Most work in this area has been directed towards describing the radial distribution function of the real fluid. Barker and Henderson (3, 12) have successfully used their perturbation theory to model the real fluid as a perturbation about the rigid sphere fluid. They have calculated the radial distribution function and thermodynamic properties to a high degree of accuracy. However, little attention has been given to determining a satisfactory expression for the direct correlation function which is of shorter range than the radial distribution function and could lead to more accurate thermodynamic properties. In this paper we have analyzed an analytical expression for the direct correlation function which is an approximation of a perturbation expression based on the Percus–Yevick functional (4). The real fluid direct correlation function is described only qualitatively; for quantitative agreement state dependent potential parameters are necessary. However, the isothermal compressibility of the fluid can be fairly well correlated up to twice the critical density with potential parameters obtained from second virial coefficients.

Derivation of Expressions

The central expression of the first order perturbation theory (4) is

$$[1] \quad g^{rf}(r)\, e^{\beta\phi^{rf}(r)} = g^{hs}(r)[1 + g^{rf}(r) - g^{hs}(r) - c^{rf}(r) + c^{hs}(r)]$$

where $g^{rf}(r)$, $c^{rf}(r)$, $\phi^{rf}(r)$ are the radial distribution function, the direct correlation function, and the intermolecular pair potential for the real fluid; $g^{hs}(r)$ and $c^{hs}(r)$ are the corresponding properties for the hard-sphere fluid. Equation 1 holds in the region $r \geqslant a$, where "a" is the hard-sphere diameter. For distances $r < a$, the real fluid functions are the same as those of the hard-sphere fluid. This equation

TABLE 1. Potential parameters for modeling direct correlation function of argon, $\sigma = 3.375$ Å

Temperature (°K)	Density (g/cc)	Hard-sphere diameter a (Å)	Well depth ε/k (°K)
163.15	0.536	2.942	100.6
	0.78	2.917	90.3
153.15	0.536	2.906	97.0
	0.78	2.901	86.6
	0.91	2.911	83.4
148.15	0.28	2.901	117.9
	0.78	2.909	86.8
	0.91	2.919	81.1
	0.982	2.919	80.1
143.15	0.91	2.950	79.4
	0.982	2.950	75.1

has been shown to agree more closely with the molecular dynamics calculations of $g^{rf}(r)$ for all r at state points in the liquid region of a Lennard–Jones (6–12) fluid than does the usual first order Percus–Yevick eq. 4. For the purposes of these calculations, the hard-sphere functions will be those given by a modified solution of the first-order Percus–Yevick theory (5, 6). Equation 1 is a relation between the real fluid properties and those of the hard-sphere fluid. For another independent relation between the real fluid properties, we make the assumption of the first-order Percus–Yevick equation for the real fluid (7)

$$[2] \qquad c^{rf}(r) = g^{rf}(r)[1 - e^{\beta\phi^{rf}(r)}]$$

This leads to

$$[3] \quad c^{rf}(r) = \frac{[1 + c^{hs}(r) - g^{hs}(r)][e^{-\beta\phi^{rf}(r)} - 1]g^{hs}\, e^{\beta\phi^{hs}(r)}}{[1 - g^{hs}\, e^{\beta\phi^{hs}(r)}]}$$

giving

$$[4] \quad c^{rf}(r) = \frac{g^{hs}(r)[1 + c^{hs}(r) - g^{hs}(r)][e^{-\beta\phi^{rf}} - 1]}{[1 - g^{hs}(r)]}$$

for $r \geqslant a$. For $r < a$ we have

$$[5] \qquad c^{rf}(r) = c^{hs}(r)$$

Finally, assumption of a functional form for the intermolecular potential will specify the real fluid direct correlation function in terms of hard sphere properties only. While this expression suffers the disadvantages of the normal first-order Percus–Yevick theory through use of eq. 2, use of eq. 3 allows several tests to be made of the applicability of this first-order perturbation about rigid-sphere fluids. First, there is the direct comparison with the experimental direct correlation function. Second, since a fluid with a spherically symmetric intermolecular potential has the compressibility equation of state

$$[6] \qquad \frac{1}{kT}\left(\frac{\partial P}{\partial \rho}\right) = 1 - 4\pi\rho \int_0^\infty r^2 c(r)\, dr$$

comparisons for the integrated form of eq. 3 with macroscopic data can be made.

Comparison with Direct Correlation Functions of Argon

The microscopic direct correlation function data for liquid argon (Mikolaj and Pings (8)) were used to test eq. 3. For this comparison, the hard-sphere diameter, and the intermolecular potential function with its parameters must be chosen. The hard-sphere diameter, a, was determined by fitting the experimental curve of $r^2c(r)$ to one calculated from the first-order Percus–Yevick direct correlation function for hard spheres (5):

$$[7] \quad c(x) = -\frac{1}{(1-\eta)^4} \times \left[(1+2\eta)^2 - \frac{3\eta}{2}(2+\eta)^2 x + \frac{\eta}{2} x^3 (1+2\eta)^2\right] \quad \text{for } x \leqslant 1$$

$$= 0 \quad \text{for } x > 1$$

$$x = \frac{r}{a}; \qquad \eta = \frac{\pi}{6}\rho a^3$$

The desired value of a was that giving the best possible agreement in the minima of the experimental and calculated curves. This usually occurred at values of x from 0.85 to 0.95 in eq. 7, but varied significantly with temperature and slightly with density. Table 1 shows the values obtained. Then eq. 4 was used to determine the potential energy function. The form of this function was modelled by the Dymond and Alder (9) potential with two parameters. However, although the zero potential distance

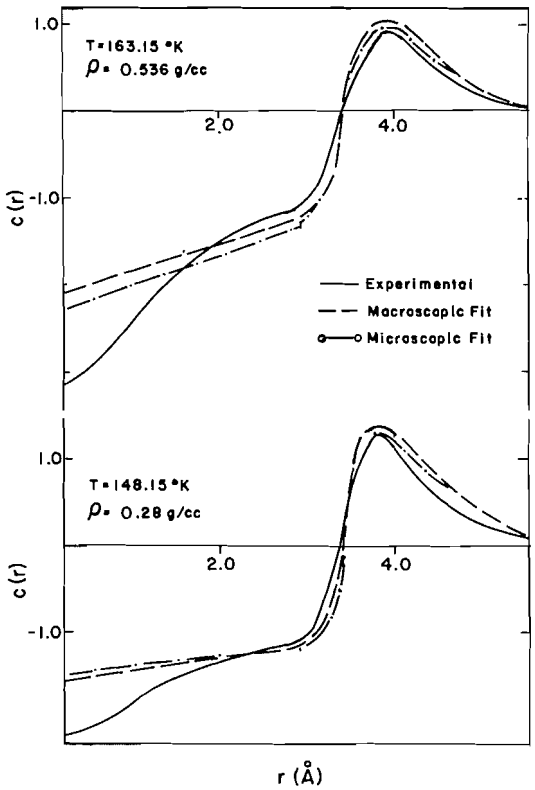

FIG. 1. Direct correlation function of argon from (*i*) experimental compressibility (macroscopic), and (*ii*) experimental direct correlation function (microscopic).

(3.375 Å) was essentially independent of temperature and density, the well depth ε/k varied significantly with density, and somewhat with temperature. (Similar observations were made by Mikolaj and Pings (10) in applying the first-order Percus–Yevick result, eq. 2, directly to the data for the radial distribution function and the direct correlation function. These have been attributed to nonadditivity of the potential.) Figure 1 shows a comparison of the experimental and calculated direct correlation functions. The major discrepancies appear at very short distances where the hard sphere direct correlation function does not vary as much with distance, and in the region between the hard-sphere diameter and the minimum in the well. Although some of this latter difference is due to the choice of the Dymond and Alder potential model, similar differences were observed with the Lennard–Jones 6–12 potential, and apparently the rapid variation of the hard sphere radial distribution function is the major reason for the erroneous steep slope in this region.

Direct Comparison of First-Order Theory with Compressibility of Argon

The Strobridge equation of state for argon (11) was used for macroscopic testing of the theory. The state points covered were in the range $\rho_c \leqslant \rho \leqslant 2\rho_c$. In these determinations, however, the hard-sphere diameter corresponding to a given macroscopic state was obtained by matching the calculated and experimental values of the integral of eq. 6, *i.e.*,

$$[8] \qquad \int_0^a r^2 c(r)\,dr = \int_0^a r^2 c_{py}^{hs}(r)\,dr$$

Again, the hard-sphere size was found to depend primarily on temperature. This variation was correlated by the equation

$$[9] \qquad a_R = 0.137 + \frac{0.657}{T_R} - \frac{0.200}{T_R^2}$$

where $a_R = N_0 a/V_c^{1/3}$; $T_R = T/T_c$. N_0 is Avogadro's number, V_c is the critical volume and T_c is the critical temperature. Although there was a slight density dependence of a, mean values were chosen at each temperature. The zero potential distance was again held constant at 3.375 Å. The best value of ε/k at each macroscopic state was determined by fitting calculated isothermal compressibilities from eq. 6 to experimental compressibilities. In the critical region, the compressibility is extremely sensitive to small errors in the integral, so a weighting factor of $1/\Delta I_c$ was used in the fitting, where ΔI_c is the change in the integral which results in a 100% change in the calculated value of the compressibility. The final equation was

$$[10] \qquad \frac{\varepsilon}{kT_c} = 0.3177 + \frac{3.2148}{\rho_R} - \frac{2.8136}{\rho_R^{1.084}}$$

where $\rho_R = \rho/\rho_c$ and ρ_c is the critical density. The results for the above calculations for reduced densities up to about 2 are summarized in Table 2. While the agreement of the calculated compressibility with the Strobridge compressibility is not within experimental error, it is at least as good as that obtained by numerical

†Numerical integration of Mikolaj and Pings scattering data up to $r = 20$ Å.

integration of the experimental scattering data. The latter result is subject to some error since the long distance tail of $c(r)$ is difficult to estimate. Apparently, however, the density dependence of the hard-sphere diameter or second order terms are of considerable consequence.

The present calculations were extended to other temperature and density regions to determine the limits on the model. Figure 2 shows the comparisons of the second virial coefficient as a function of temperature. The agreement (r.m.s. deviation 1.2 cc/g mol) indicates that the temperature dependence for the hard-sphere diameter is essentially correct for this property

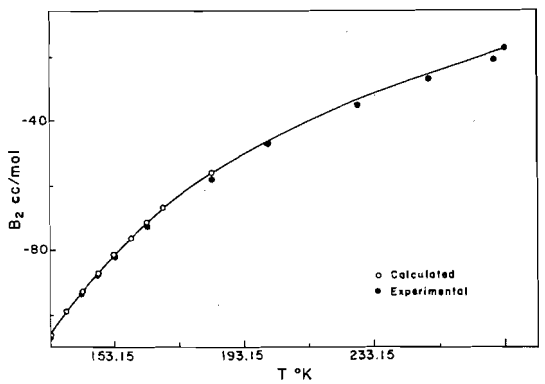

FIG. 2. Second virial coefficient of argon from temperature dependent hard-sphere diameter (eq. 9) and Dymond and Alder potential function ($\varepsilon/k = 115.2$ °K).

and that the energy parameter is not sufficiently sensitive to temperature to affect the calculation.

Comparison with Compressibilities Using Second Virial Coefficient Parameters and Temperature Dependent Hard-Sphere Diameter

The results of calculations in the preceding section fail to distinguish whether the errors of the theory are in the perturbation method or in the choice of intermolecular potential. An alternative to strict correlation of the compressibility is to use a result of the Barker and Henderson perturbation theory (12) for modifying the hard-sphere diameter with temperature and obtain the potential parameters σ and ε/k from a potential model and second virial coefficient data. An additional motivation for this test is to see how accurately the compressibility can be determined from these relatively simple parameter requirements and be applicable to other fluids through corresponding states relations. The numerical values of the potential parameters used are summarized in Table 3.

The dependence of the hard-sphere diameter on temperature is through the intermolecular potential, *i.e.*,

$$[11] \qquad a^* = \frac{a}{\sigma} = \int_0^1 [1 - e^{-\phi(x)/kT}]\, dx$$

where x is the reduced distance r/σ.

Krypton	3.6*	171.	3.476†	196.
Oxygen	3.46	118.	3.275‡	141.67‡

*Reference 16.
†Reference 17.
‡These parameters were derived from two-parameter corresponding states relations, using parameters for krypton.

For purposes of numerical computation, the compressibility integral is separated into two parts, a hard-sphere contribution and a perturbed, or soft-sphere, contribution.

$$[12] \quad I = \int_0^\infty c(r)r^2\,dr = \int_0^a c^{hs}(r)r^2\,dr + \int_0^\infty c^{ss}(r)r^2\,dr$$

The hard-sphere contribution was determined from two separate theoretical equations to test its effect on the total integral. The first was the direct analytical integration of eq. 7, which is the first-order Percus–Yevick solution for the hard-sphere direct correlation function. The second method was to use the Carnahan and Starling (13) equation of state for hard spheres to calculate the total compressibility integral for the hard-sphere fluid,

$$[13] \quad I^{hs} = \int_0^a c^{hs}(r)r^2\,dr + \int_a^\infty c^{hs}(r)r^2\,dr$$

Since the quantity of interest was the first integral in eq. 13, when I^{hs} is substituted into eq. 12, a small correction must be made to the integrand in the second term there.

The effect of varying the perturbation (or soft sphere) potential was studied by using the Lennard–Jones 6–12 and the Dymond and Alder potentials in two corresponding sets of calculations. The fluids chosen for study were argon, krypton, and oxygen. To extend the reduced density range and determine an upper limit on the applicability of this method, experimental data for Kr in the reduced density range $1.43 \leqslant \rho^* \leqslant 2.48$ were taken from Trappeniers *et al.* (14) and data for O_2 in the reduced density range $2.0 \leqslant \rho^* \leqslant 2.5$ from Weber (15). The numerically computed compressibility integrals for argon, krypton, and oxygen are shown in Tables 4, 5, and 6 and compared with experimental values. Figure 3 shows the integrals for argon and krypton plotted as functions of temperature and density. An overall appraisal of the results indicates that the isothermal compressibility may be determined to about 10% accuracy up to twice the critical density when one uses the Lennard–Jones potential as the attractive potential. The integrals incorporating the Dymond and Alder potential are too positive, *i.e.*, there is a net positive contribution due to the width of the attractive bowl. The shallower and narrower bowl of the Lennard–Jones potential is appar-

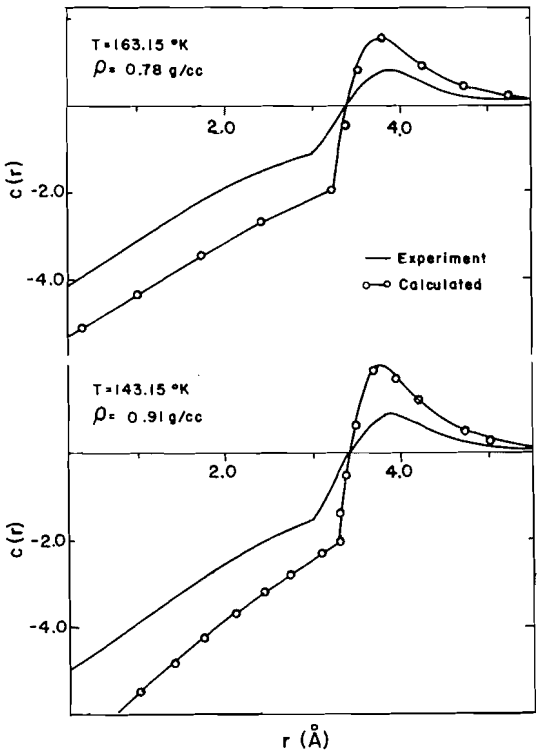

FIG. 4. Direct correlation function of argon from first-order expression for $c(r)$ (eq. 3) and Lennard–Jones 6–12 potential.

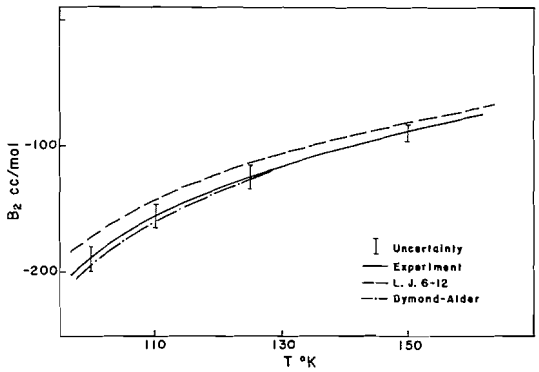

FIG. 5. Second virial coefficient of oxygen from temperature dependent hard-sphere diameter (eq. 11) and (*i*) Lennard–Jones 6–12 potential, (*ii*) Dymond and Alder potential. Experimental values from ref. 18.

ently more representative of the effective intermolecular potential. At the lower densities there is little to choose between the hard-sphere contributions of the Percus–Yevick and the Carnahan and Starling equations; at higher densities the Percus–Yevick hard-sphere contribution is significantly better.

A comparison of the calculated direct correlation function with the experimental data for argon using the Lennard–Jones potential is instructive. These are shown plotted in Fig. 4. It is apparent that the microscopic function is modeled only qualitatively; quantitative agreement would not be obtained except by a simultaneous dependence of both hard-sphere diameter and ε/k on temperature and density. On the other hand, significant cancellation of errors occurs in the integration of this correlation function since the calculations for compressibilities are in reasonable agreement with experiment. The calculated second virial coefficients for oxygen are compared with experimental values in Fig. 5. The values calculated with the Dymond–Alder potential are within experimental error (r.m.s. deviation 2.14 cc/g mol) indicating that the temperature variation of the hard-sphere diameter is accurate for this potential. The second virial coefficient from the Lennard–Jones potential is less accurate (r.m.s. deviation = 11.8 cc/g mol) but this is typical of the inadequacy of this potential for second virial coefficients at low temperatures.

Conclusions

Calculations indicate that the present first-order perturbation theory about a hard-sphere base is not adequate for microscopic modeling of a real fluid in a dense state. The difficulty is shown in attempting to separate the intermolecular potential parameters into density dependent and temperature dependent quantities. Although the temperature dependence of the hard-sphere diameter is well described (as shown by the calculations for second virial coefficients), the density dependence of the microscopic property $c(r)$ cannot be completely defined by a density dependent ε/k and the hard-sphere correlation functions. The errors are sensitive to the potential model but it is likely that second order terms are also important.

With the method of the last section, one can use low density intermolecular potential parameters to describe the temperature variation of the isothermal compressibility. Quantitative agreement with experiment (up to 15% error) appears possible up to about twice the critical density.

However, precise agreement with experimental results is not attainable at higher densities. Apparently, a first-order theory requires a density-dependent hard-sphere diameter before it can properly model the microscopic, as well as the macroscopic, state of the dense liquid.

Homogeneous Catalysis of D_2–H_2O Isotope Exchange by Pentacyanocobaltate(II)[1]

G. G. STRATHDEE AND M. J. QUINN

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba, R0E 1L0

Received April 4, 1972

The rate of exchange of deuterium between hydrogen gas and water catalyzed by pentacyanocobaltate(II) has been measured as a function of pressure and temperature at a constant total cobalt concentration, 0.05 *M*, and ionic strength, 1 *M*. The rates of evolution of hydrogen from solutions of hydridopentacyanocobaltate(III) have been determined under identical conditions. These data have been employed to test the validity of a mechanism for the $Co(CN)_5^{3-}$-catalyzed isotope exchange reaction, and to clarify the controversy over the magnitude of the specific rate for the deuterium transfer step

$$DCo(CN)_5^{3-} + H_2O \xrightarrow{k_3} HCo(CN)_5^{3-} + HDO$$

Calculations show that kinetic isotope and ion pairing effects are significant.

La vitesse d'échange du deutérium entre l'hydrogène gazeux et l'eau, catalysée par le pentacyanocobaltate(II), a été mesurée en fonction de la pression et de la température pour une concentration totale et constante en cobalt de 0.05 *M* et une force ionique de 1 *M*. Les vitesses de dégagement d'hydrogène à partir des solutions d'hydridopentacyanocobaltate(III) ont été déterminées dans des conditions identiques. Ces données ont été utilisées pour contrôler la validité d'un mécanisme d'échange isotopique catalysé par $Co(CN)_5^{3-}$ et pour clarifier la controverse sur la grandeur de la vitesse spécifique dans l'étape de transfert du deutérium:

$$DCo(CN)_5^{3-} + H_2O \xrightarrow{k_3} HCo(CN)_5^{3-} + HDO$$

Les calculs montrent l'importance des effets isotopiques sur la cinétique et appariement des ions.

Canadian Journal of Chemistry, **50**, 3144 (1972)

Introduction

Several investigations of isotope exchange between D_2 and water homogeneously catalyzed by pentacyanocobaltate(II), $Co(CN_5^{3-}$, have been reported (1–3) but the validity of the mechanism suggested by Kemball and coworkers (5) and Schindewolf (2) for deuterium exchange has not been demonstrated.

A number of studies have been focussed upon the reactions incorporated in this mechanism. For example, the rates of activation of hydrogen by $Co(CN)_5^{3-}$ (1, 5, 7–10):

$$[1] \qquad H_2 + 2Co(CN)_5^{3-} \xrightarrow{k_1} 2HCo(CN)_5^{3-}$$

and the evolution of hydrogen from solutions of $HCo(CN)_5^{3-}$ (5, 10):

$$[2] \qquad 2HCo(CN)_5^{3-} \xrightarrow{k_2} H_2 + 2Co(CN)_5^{3-}$$

have been measured. In addition, the magnitude of the equilibrium constant for reversible hydrogen absorption has been determined by both hydrogen uptake and spectroscopic techniques (5, 8, 9).

Reversible homolytic activation of D_2 is not sufficient to cause exchange of deuterium between D_2 and water, and the transfer reaction 3 must occur

$$[3] \qquad DCo(CN)_5^{3-} + H_2O \xrightarrow{k_3} HCo(CN)_5^{3-} + HDO$$

However, there is some uncertainty in the magnitude of the specific rate constant k_3. For example, Kemball has used the fact that since a ^1H resonance for $HCo(CN)_5^{3-}$ prepared by reaction of $Co(CN)_5^{3-}$ with H_2 in D_2O was not detectable, then the rate of the transfer step between $HCo(CN)_5^{3-}$ and D_2O must be fast on the n.m.r. time scale (5). The broad ^1H resonance and the lack of ^1H–^{13}C coupling in the spectrum of $HCo(CN)_5^{3-}$ in H_2O would support this claim, but these observations are more likely due to fast cyanide exchange or the presence of paramagnetic Co(II) species (4, 6). In contrast, the observation of HD in the gas phase during D_2–H_2O exchange experiments

(1) did not appear to us to be consistent with a rapid transfer step. Since the rate determining step in the overall exchange scheme is believed to be the dehydrogenation reaction 2, which is slow, HD should only be observed in the gas phase if the rate of transfer step 3 is comparable to or slower than that of [2]. If [3] is as rapid as has been suggested, predominantly H_2 should be evolved. This is not normally the case.

In this paper, a more comprehensive study is presented of the pressure and temperature dependence of the D_2–H_2O exchange catalyzed by $Co(CN)_5^{3-}$, and the H_2 evolution reaction 2, than has previously been reported (1–3). In addition, the effect of ionic strength on the overall D_2–H_2O exchange and the aging reaction

$$[4]\quad 2Co(CN)_5^{3-} + H_2O \rightarrow HCo(CN)_5^{3-} + (HO)Co(CN)_5^{3-}$$

has been re-examined under our experimental conditions. These data are employed to test the validity of the mechanism which has been proposed to explain D_2–H_2O exchange catalyzed by $Co(CN)_5^{3-}$, and to attempt to resolve the inconsistency in current estimates of the specific rate of the transfer reaction 3.

Experimental

Pentacyanocobaltate(II) solutions were prepared in the reaction flask by injecting the required amounts of degassed aqueous solutions of cobalt(II) chloride, and potassium cyanide containing potassium chloride to adjust the ionic strength. Reactions were conducted in jacketted Pyrex glass cells of typically 100 ml capacity. Solutions were magnetically stirred, usually at 3000 r.p.m., with a Teflon-covered bar in the cell. Temperature was controlled to better than 0.1 °C.

Hydrogen was purified by passing the gas through an Engelhard Deoxo unit and molecular sieve drier. Deuterium was evolved at 450 °C from uranium deuteride which had been prepared from uranium turnings and D_2 at 225 °C. Other reagents were used as received.

The evolution of H_2 from solutions of $HCo(CN)_5^{3-}$ prepared by hydrogenation of $Co(CN)_5^{3-}$ was followed by observing the increase in pressure in a calibrated cell, after pumping off the excess H_2, by means of a Viatran Corporation Model 103 pressure transducer. The output was variably biased to permit a maximum recorder sensitivity of about 25 Torr on the 1 mV scale. Experiments without $Co(CN)_5^{3-}$ demonstrated that the cell was re-saturated with water vapor within a few seconds and therefore did not affect initial rates of evolution calculated from the slopes of pressure–time data.

Rates of the decomposition of aging reaction 4 were determined spectroscopically by observation of the 980 nm band of $Co(CN)_5^{3-}$ with a Unicam SP700 spectrophotometer while the solution was rapidly circulated through a 0.1 cm pathlength optical cell by means of a peristaltic pump.

Exchange experiments were conducted with solutions 0.05 *M* in cobalt, $CN^-:Co^{2+} = 6$, and ionic strength = 1 *M* unless noted otherwise. These solutions were reacted with either excess D_2 (pre-deuteration) or excess H_2 (pre-hydrogenation) for about 30 min at the pressure of the subsequent exchange experiment. Thirty ml of those deuterated or hydrogenated solutions were transferred by syringe to a reaction vessel containing D_2 at the appropriate pressure. Samples of the resultant D_2, HD, and H_2 gas mixtures were removed from the flask with a gas-tight syringe and analyzed with a CEC-21-130 mass spectrometer. Initial exchange rates were calculated with the relation

$$[5]\quad -d(D_2)/dt = \ln[(\theta_0 - \theta_e)/(\theta_t - \theta_e)]A/t = k_x A$$

where θ_0, θ_t, and θ_e represent the mole percent D_2 at $t = 0$, $t = t$ s, and at equilibrium, and A is the effective solubility, moles per liter, = initial D_2, m mole ÷ the volume of the solution, ml. The experimental specific rate k_x was obtained from the slope of log $D_2 - t$ plots.

Results

Data from a typical D_2–H_2O exchange experiment are shown in Fig. 1. In this example, the $Co(CN)_5^{3-}$ solution was initially pre-deuterated. The slow disappearance of D_2 in the first 1000 s is characteristic of this type of experiment and reflects the relatively slow rate of the transfer reaction 3. This is discussed below. In comparison, exchange reactions preceded by hydrogenation rather than deuteration did not exhibit this curvature in the disappearance of D_2, and relative initial HD:H_2 yields were lower. If the reactions were followed for sufficient time, maximum HD concentrations were observed in the range 35 to 45 mol%. The ratio of initial rates of evolution of HD and H_2 was obtained from the slopes of plots of mol% HD and H_2 against time which were linear at less than 20% D_2 conversion.

The rates of D_2–H_2O exchange at 0, 15, and 30 °C as a function of total hydrogen pressure are shown in Fig. 2, along with curves calculated by the method discussed later in this section. All solutions of $Co(CN)_5^{3-}$ were pre-deuterated except for those experiments at 30 °C, distinguished by filled circles and a dashed calculated line in the figure, in which $Co(CN)_5^{3-}$ solutions were hydrogenated prior to exchange with D_2. Although experimental data are scattered, calculations suggest pre-hydrogenation gives higher initial rates of exchange than does pre-deuteration. Rates of exchange decrease

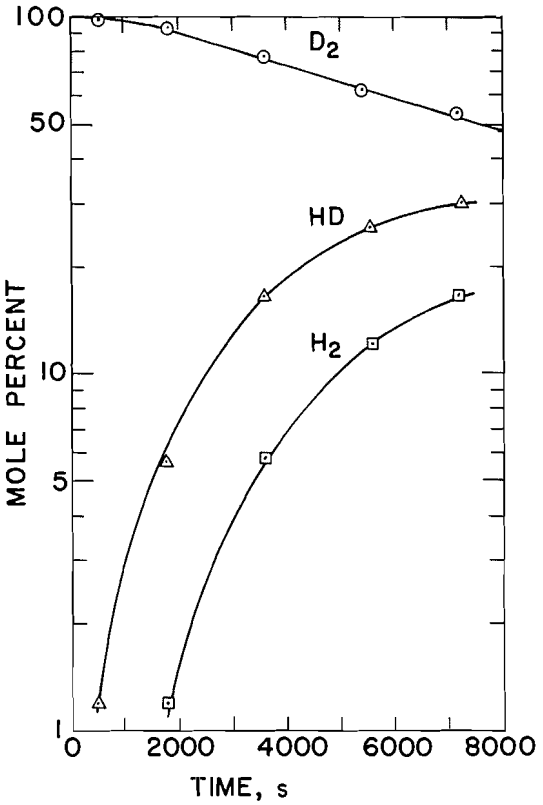

FIG. 1. Typical D_2–H_2O exchange data. Total cobalt: 0.05 *M*; initial D_2: 300 Torr; ionic strength: 1.0 *M*; T = 30 °C; V_G: 75 ml; V_L: 30 ml.

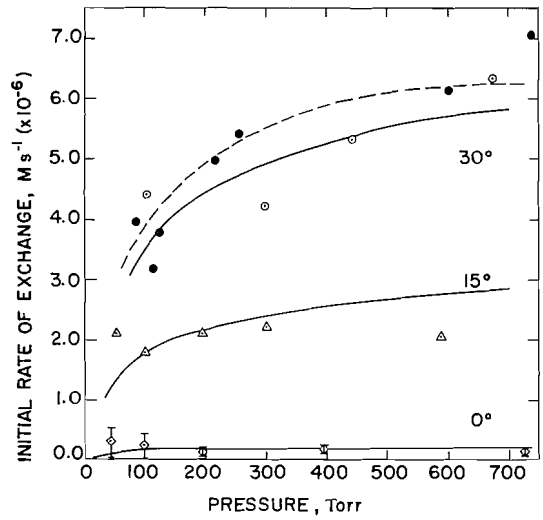

FIG. 2. Initial rates of D_2–H_2O exchange. Total cobalt 0.05 *M*; ionic strength: 1.0 *M*. Predeuteration, —; prehydrogenation ---.

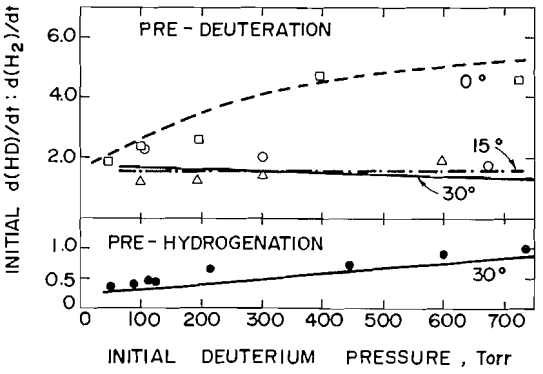

FIG. 3. Initial rate ratio HD:H_2. Total cobalt: 0.05 *M*; ionic strength: 1.0 *M*.

gradually with decreasing pressure. This is similar to the change in rate with pressure expected for the component reactions 1 and 2 in the overall hydrogen uptake equilibrium.

The ratio of initial rates of formation of HD and H_2 are plotted in Fig. 3, and these data are compared with calculated curves. It may be seen that the HD:H_2 initial rate ratios decrease significantly with increasing temperature. Prehydrogenation gives a lower ratio than does pre-deuteration, primarily due to the higher initial rate of evolution of H_2. A relatively greater concentration of $HCo(CN)_5^{3-}$ compared to $DCo(CN)_5^{3-}$ must therefore exist in solution upon pre-hydrogenation rather than pre-deuteration. These observations qualitatively suggest that the rate of the transfer reaction 3 is slower than, but of comparable magnitude to, the rate of the de-hydrogenation reaction 2.

The rates of evolution of H_2 from hydrogenated solutions of $Co(CN)_5^{3-}$ are shown in Fig. 4, together with fitted curves. These results have the same general pressure-dependence as do exchange rate data, indicating the common dependence of these observations on the dehydrogenation reaction 2. However, the rates of evolution of hydrogen are about a factor of three greater than the rates of D_2–H_2O exchange. This is another indication that the rate of reaction 3 is less than that of reaction 2.

The decomposition or aging of 0.05 *M* $Co(CN)_5^{3-}$, reaction 4, increased with ionic strength. Second order plots, $1/[Co(CN)_5^{3-}]$ *vs.* time, were linear at 1.0 *M* ionic strength, but showed curvature at higher ionic strengths. A comparison of apparent specific aging rates at 30 °C, k_4

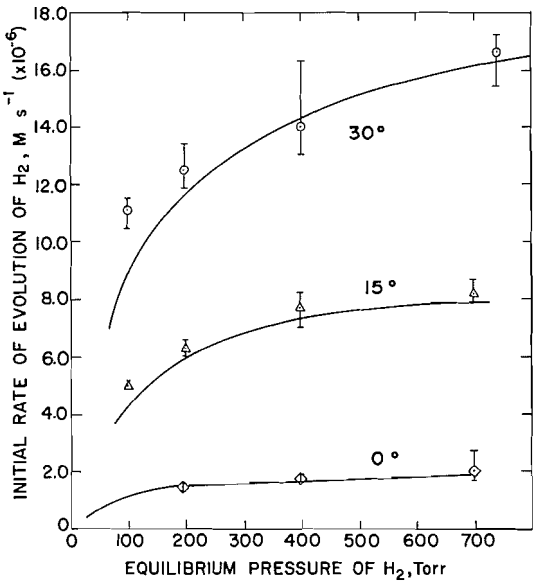

FIG. 4. Initial rates of evolution of H_2. Total cobalt: 0.05 *M*; ionic strength: 1.0 *M*.

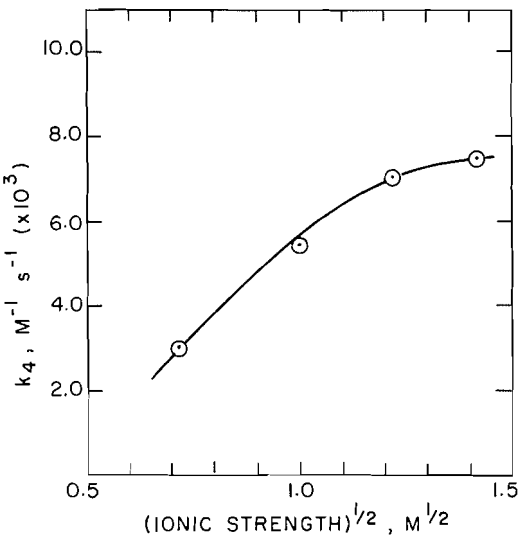

FIG. 5. Effect of ionic strength on the specific rate of aging. Decomposition of $Co(CN)_5^{3-}$.

$= d(1/[Co(CN)_5^{3-}])/dt$, evaluated at 200 s after mixing the reagents is shown in Fig. 5.

Increasing the ionic strength also accelerates the initial D_2–H_2O exchange and increases the HD:H_2 initial yield ratio, Fig. 6. For this dependence to be observed, the effect of ionic strength on the rates of reactions 2 and 3 must differ.

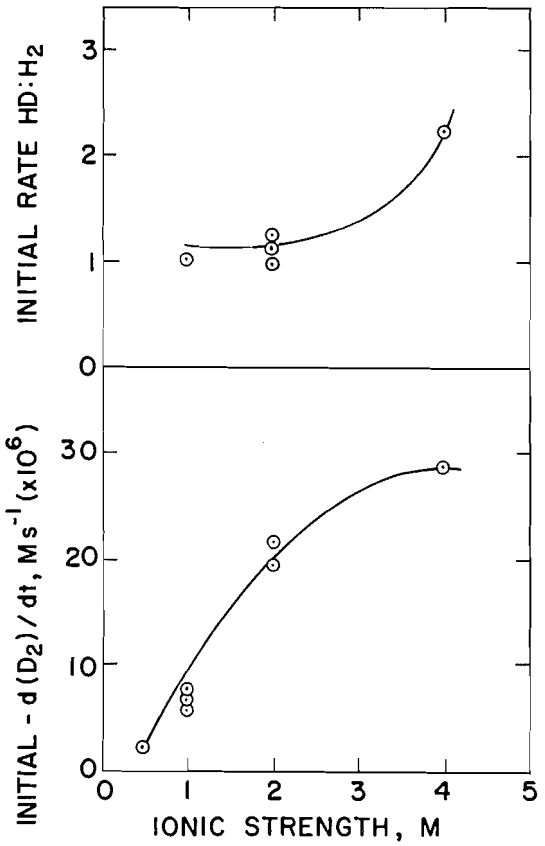

FIG. 6. Effect of ionic strength on the initial rate of isotope exchange and the initial HD:H_2 rate ratio. Initial D_2: 700 Torr. *T*: 30 °C.

Although expressions which describe the effect of ionic strength (11) on rate constants are not generally applicable at the high electrolyte concentrations used in our experiments, it is interesting to note that the rate of exchange increases more rapidly than would be predicted for the enhancement of reaction rate of two triply charged anions by ionic strength. The possible influence of ion–pair formation in this system is discussed later.

The full set of reactions included in the mechanism for D_2–H_2O exchange are shown in Table 1. Isotope exchange and hydrogen evolution experiments were simulated by numerical integration of the seven differential equations shown in Table 2 by a modified Hammings predictor–corrector method.[2] The term (1 +

$dc_7/dt = 0.5k_4c_4^2$

*$c_1 = [D_2]$, $c_2 = [HD]$, $c_3 = [H_2]$, $c_4 = [Co(CN)_5^{3-}]$, $c_5 = [DCo(CN)_5^{3-}]$, $c_6 = [HCo(CN)_5^{3-}]$, $c_7 = [(HO)Co(CN)_5^{3-}]$. H = Henry's Law constant for H_2 in water, in mol l^{-1} atm^{-1}, R = gas constant, T = absolute temperature, V_G = volume of gas phase, in l, V_L = volume of solution, in l.

$V_G/RT\,V_LH$) accounts for the transfer of D_2, HD, and H_2 between the gas and solution phases. These assumptions were made: (*i*) the gas phase and dissolved hydrogen mixtures were in continuous equilibrium, (*ii*) kinetic isotope effects could be neglected, therefore reactions in sets [1*a*–*c*] and [2*a*–*c*], shown in Table 1, have specific rates k_1 and k_2 respectively, and (*iii*) the aging reaction 4 is irreversible. Reversal of the transfer step 3 under our experimental conditions was insignificant and related differential terms were omitted from equations in Table 2. Rate constants were expressed in terms of moles of cobalt species. The solubility of hydrogen in 1 *M* KCl (12) and an enthalpy of solution for H_2 in water of 1.29 kcal mol^{-1} calculated from published data (13) gave these hydrogen solubilities in our 1 *M* electrolyte: 0°: 0.76; 15°: 0.67; 30°: 0.60 *M* ($\times 10^3$).

The characteristic shape of the D_2–H_2O exchange and hydrogen evolution rate curves included in Figs. 2 and 4, respectively, is determined by the common dependence of these rates on the overall concentration of $HCo(CN)_5^{3-}$ and its deuterated analogue. Since the hydrogenation equilibrium has been assumed to hold:

[6] $H_2 + 2Co(CN)_5^{3-} \overset{K}{\rightleftharpoons} 2\,HCo(CN)_5^{3-}$

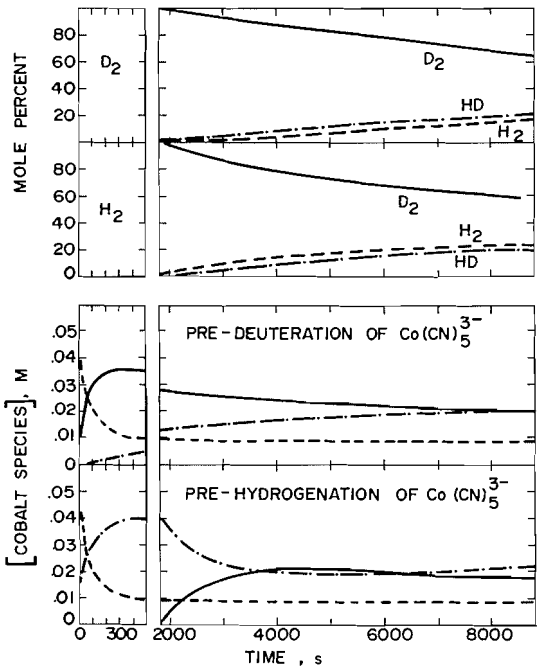

FIG. 7. Comparison of calculated change in composition of gas phase and solution components during D_2–H_2O exchange. Cobalt species: --- $Co(CN)_5^{3-}$; —$DCo(CN)_5^{3-}$; ·-·- $HCo(CN)_5^{3-}$. Total hydrogen: 700 Torr. T: 30 °C. V_G: 75 ml. V_L: 30 ml.

the concentration of $HCo(CN)_5^{3-}$ plus $DCo(CN)_5^{3-}$ is given by the expression

$$[7] \quad [HCo(CN)_5]^{3-} = [Co]_T \frac{K[H_2]_T}{1 + K[H_2]_T}$$

where $[Co]_T$ = total cobalt, $[H_2]_T$ = total hydrogen, if the aging reaction 4 is neglected. The curves through our data are therefore determined by the model we have employed and are representative within the errors discussed here.

The calculated variation with time of the three catalytically important species $Co(CN)_5^{3-}$ and $HCo(CN)_5^{3-}$ is illustrated in Fig. 7 for both pre-deuteration and pre-hydrogenation of 0.05 M $Co(CN)_5^{3-}$ at 700 Torr and 30 °C prior to isotope exchange. The corresponding change in the composition of the gas phase is also shown. The first segment of the figure shows calculated concentration changes when 30 ml of solution contacted 600 ml of either D_2 or H_2 gas. The second segment shows the effect on these concentrations when 30 ml of these solutions exchange deuterium with 75 ml of D_2 gas.

The course of exchange reactions is significantly dependent on the pre-treatment. Pre-deuteration yields mainly $DCo(CN)_5^{3-}$, the concentration of which decreases slowly as the transfer 3 and evolution reactions 2*a* and *b* occur. The initially high D:H ratio of the gas reservoir maintains the concentration of $DCo(CN)_5^{3-}$ by reactions 1*a* and *b*. In contrast, pre-hydrogenation gives a high initial concentration of $HCo(CN)_5^{3-}$ which disappears relatively rapidly due to evolution reactions 2*b* and 2*c*. Absorption of D_2 and HD, reactions 1*a* and *b*, causes an increase in the concentration of $DCo(CN)_5^{3-}$ which then decays at a rate similar to that in the case of the pre-deuteration. If the exchange reaction is examined at reduced pressure, the amount of isotopic hydrogen in the gas phase is proportionally decreased, and the changes described in Fig. 7 occur more rapidly.

Discussion

The objectives of this study were to test the validity of the simple mechanism which has been proposed to explain the manner in which D_2–H_2O exchange is catalyzed by $Co(CN)_5^{3-}$, and to obtain a reliable estimate of the specific rate for the deuterium transfer reaction 3. In view of the many reports on the reversible hydrogenation of $Co(CN)_5^{3-}$ (1, 5, 8–10, 13, 14, 16) it was evident that the kinetics of the two basic reactions had been satisfactorily established. However, rate constants reported in the literature for the component reactions 1*c* and 2*c* of the scheme shown in Table 1 could not satisfactorily be employed in a computer simulation of the D_2–H_2O exchange process. Principally, the quantitative effects of ionic strength and electrolyte on k_2 and k_3 were unknown. We therefore measured the rates of H_2 evolution and D_2–H_2O exchange, under comparable conditions of solution composition and reactor configuration, from which the magnitudes of k_2 and k_3 could be derived. These conditions have been specified in the Experimental section.

The major assumptions (*i*) that the dissolved hydrogen mixture is in continuous equilibrium with that in the gas phase, (*ii*) that kinetic isotope effects could be neglected, and (*iii*) that the decomposition reaction 4 is irreversible are conservative. In our experiments the half-life of the overall exchange reaction was con-

TABLE 3. Specific rate constants

Constant	Value at 0°	Value at 15°	Value at 30°
k_1 M^{-2} s^{-1}	614	606	600
k_2 M^{-1} s^{-1} ($\times 10^3$)	1.6	8.5	20.0
k_3 s^{-1} ($\times 10^5$)	2.5	15.0	33.0
k_4 M^{-1} s^{-1} ($\times 10^3$)	0.9	2.2	5.0

siderably greater than expected for dissolution of hydrogen in water under conditions of turbulent mixing (*e.g.* hours compared to seconds). Multiple exchange processes of the type described by Halpern and James (17) were therefore considered unlikely to occur. Kinetic hydrogen–deuterium isotope effects undoubtedly exist for reactions 1–3. Partly for simplicity, but mainly because of lack of supporting data, assumption (*ii*) is made for reactions 1 and 2. Under our conditions the reverse of reaction 3 is not significant, therefore neglect of this isotope effect is valid. Additional comment on these topics is included later in this discussion.

The rate constant parameters which yielded the fits to our data in Figs. 2–4 are shown in Table 3. The manner in which these values were determined requires some discussion: The magnitude of k_1 was based on available data; k_2 was varied until the fits to hydrogen evolution data shown in Fig. 4 were obtained; k_3 was then adjusted to provide the fits to exchange results shown in Figs. 2 and 3; k_4 was based on our measurement of the rate of aging. It should be noted that k_3 was established subsequent to and independently of the evaluation of k_2. Within the framework of the calculation the estimated error in k_2 is $\pm 10\%$ and in k_3 is $\pm 20\%$. A discussion of each rate constant follows:

Activation, k_1

A value for the specific rate of hydrogen activation at 30 °C of 600 M^{-2} s^{-1} was selected and an enthalpy of activation of -0.7 kcal mol^{-1} was used to calculate k_1 at 0 and 15 °C (8, 9). This may be compared with values found by Burnett *et al.* (5), 620 M^{-2} s^{-1} at $\mu = 0.51$ M, and DeVries (8), 830 M^{-1} s^{-1} at $\mu = 1.0$ M and 25 °C. There is evidence that k_1 may be somewhat lower under our conditions.[3] In general, data in the literature shows that k_1 increases with the ionic strength of the solution (5, 8, 9). Mills has reported that k_1 is dependent on the square root of the ionic strength, but is not a function of the electrolyte used. However, mass transport of hydrogen may have influenced these results, and the validity of this correlation has not been checked under chemical rate limiting conditions. Since our calculations showed the D_2–H_2O exchange rate was only slightly dependent on k_1, re-determination of k_1 for our conditions was considered unnecessary. For example, a 3.5-fold increase of this parameter to 2100 M^{-2} s^{-1} increased the calculated exchange rate by only 12% at 700 Torr and 30 °C.

[3]W. J. Wallace. Personal communication.

Evolution, k_2

Our value of 16×10^{-3} M^{-1} s^{-1} at 25 °C for 1 M ionic strength taken from Fig. 8, an Arrhenius plot of k_2 and k_3 data, is somewhat higher than the 4.5×10^{-3} M^{-1} s^{-1} Burnett *et al.* have reported for k_2 at 0.51 ionic strength (5). However, it may be seen in Fig. 6 that the rate of initial D_2–H_2O exchange at 30 °C and 700 Torr initial D_2 pressure increases by a factor of about four when the ionic strength is increased from 0.5 to 1.0 M. Since the HD:H_2 rate ratio does not change within this range, the dependence of the exchange rate on ionic strength must reflect the change in k_2. Therefore if our value for k_2 quoted above is lowered by this factor of four to 4×10^{-3} M^{-1} s^{-1}, it agrees with that of Burnett *et al.*

Transfer, k_3

Previous exchange studies have provided no quantitative estimate of k_3. However, our value of k_3 at 20 °C, 1.5×10^{-4} s^{-1}, for first-order decay of $DCo(CN)_5^{3-}$ may be compared with the rate of OH^- catalyzed deprotonation of $HCo(CN)_5^{3-}$ discussed by Venerable and Halpern (18). Using their value of k_{-2} (their notation) = 0.12 M^{-1} s^{-1} for the reaction

$$[8] \qquad HCo(CN)_5^{3-} + OH^- \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} Co(CN)_5^{4-} + H_2O$$

the pseudo first-order constant $k_{-2}[OH^-]$ in the solutions of pH 11.5–12.0 which we employed would be about 1×10^{-3} s^{-1}. If a relatively large H–D isotope effect exists for the OH^- catalyzed dissociation of the hydrido

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

compared to the deuterido complex (the maximum would be about 5), then the agreement between our value of k_3 and Venerable's $k_{-2}[OH^-]$ would considerably improve. In view of the relatively slow rate of this transfer step, it is surprising that the ^1H resonance of $HCo(CN)_5^{3-}$ prepared by reaction of H_2 and $Co(CN)_5^{3-}$ in D_2O solution has not been observed at the intensity expected (4, 5). If no gaseous H_2 is present, or if gas–liquid equilibration of H_2 is slow as might be the case in an n.m.r. tube, $HCo(CN)_5^{3-}$ could decay with a half-life of about 10^3 s. This could be sufficiently rapid to make direct observation of the transfer reaction difficult by n.m.r.

Decomposition, k_4

We used our measured value of the specific rate of the aging reaction 4 at 30 °C, 5×10^{-3} M^{-1} s^{-1}, and calculated the values at 0 and 15 °C shown in Table 2 with an activation energy of 9.8 kcal mol^{-1} obtained by Sokol and Brubaker (19). They measured $k_4 = 1.35 \times 10^{-3}$ M^{-1} s^{-1} for 0.17 M $Co(CN)_5^{3-}$, and DeVries obtained 1.5×10^{-3} M^{-1} s^{-1} at $\mu =$ 0.86 M and 30 °C (8). Measurements of k_4 by Burnett *et al.* were erratic (5). The aging reaction did not greatly affect the results of exchange reaction calculations, except at pressure below about 100 Torr where the effect of reaction 4 noticeably increased the concentration of $(HO)Co(CN)_5^{3-}$ which we have assumed to be catalytically inactive. In general, competition by the aging reaction was not significant.

The temperature-dependence of the rate constants k_2 and k_3, reported in Table 3, are shown in an Arrhenius plot in Fig. 8. The curvature of each parameter with T^{-1} is considered real. By bracketting hydrogen evolution and deuterium exchange data with calculated curves, the errors in k_2 and k_3 are estimated to be less than 10% and less than 20%, respectively. This is not enough to introduce the curvature shown in Fig. 8. We suggest that this deviation from linearity may be due to ion pair formation between potassium cations and cobalt complex anions. If it is assumed that the specific rate constants for the de-hydrogenation and transfer steps are higher for the ion-paired compared to the "free" $DCo(CN)_5^{3-}$ and $HCo(CN)_5^{3-}$ species, then the relative decrease in stability

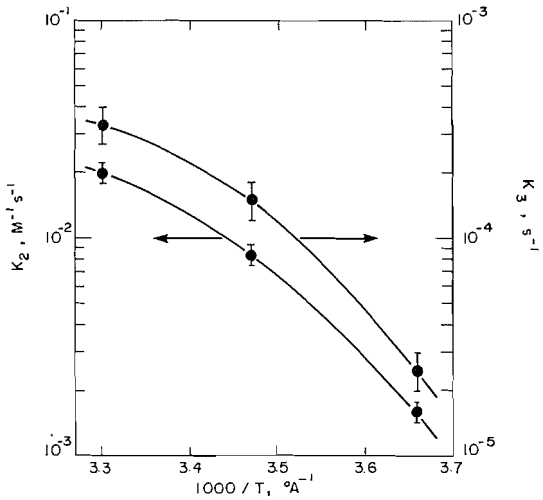

FIG. 8. Temperature dependence of constants k_2 and k_3.

of the ion-paired species with increasing temperature would result in a non-linear dependence of k_2 and k_3 on $1/T$ as observed. There is spectroscopic evidence for ion pair formation with $Co(CN)_5^{3-}$ in concentrated electrolyte solutions (15, 20), and pentacyanocobaltate(I) is believed to exist as a dimer possessing a proton bridge (21). Piringer and Farcas (10) have also implied that ion-pairing is important.

The activation enthalpies for k_2 and k_3 do not differ greatly. Tangents to the curves in Fig. 8 at 15 °C give values of about 12 kcal mol^{-1}. This agrees with the enthalpy of activation for k_2 of about 11 kcal mol^{-1} suggested by DeVries' data (8). Since the temperature dependence of the overall exchange reaction rate is governed by $\Delta H^{\neq}$ for k_2 and k_3 and must be at least as large as the lowest $\Delta H^{\neq}$, the 7 kcal mol^{-1} reported by Schindewolf (2) and by Piringer and Farcas (3, 10) appears somewhat low.

The isotope effect for the overall exchange was in the sequence $k_{D_2} > k_{HD} > k_{H_2}$. This is based on the experimental fact that the maximum in the HD yield was 5–10% higher than the maximum calculated assuming no H–D isotope effect for rate constants k_1 and k_2. The effect must originate with reactions 1 and 2 of the hydrogen absorption equilibrium. It is suggested that either an inverse sequence of specific rates for activation of D_2, HD, and H_2, $k[1a] > k[1b] > k[1c]$, or a normal sequence for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evolution of H_2, HD, and D_2, $k[2c] > k[2b] > k[2a]$, or both possibilities could account for this observation. Schindewolf (2) has argued that $k(H_2):k(D_2)$ is 1.5, based on the relative rate of para–ortho hydrogen conversion to D_2–H_2O isotope exchange catalyzed by $Co(CN)_5^{3-}$. By comparing our data in Figs. 2 and 4 it may be seen that under our conditions the rate of H_2 evolution, presumably representative of para-ortho conversion, is three times as great as the rate of D_2–H_2O exchange. The latter data are, of course, dependent on pH. In view of the complex dependence of the rate of D_2–H_2O exchange on k_1, k_2, and k_3 the applicability to our system of the isotope effect discussed by Schindewolf is doubtful.

In general, other homogeneous catalysts which activate hydrogen exhibit isotope effects, $k(H_2):k(D_2)$, in the range 1.0 ± 0.3 (17, 22–24). Because of the uncertainty in the value for the $Co(CN)_5^{3-}$ system, we chose to exclude this effect as a parameter in the calculations. Accordingly, it must be kept in mind that the rate constants quoted here have been evaluated with the basic assumption that the deuterium isotope effect may be neglected. The error limits assigned to k_2 ($\pm 10\%$) and k_3 ($\pm 20\%$) define the degree of fit to our data within this framework. Also, the different solubilities of D_2, HD, and H_2 will affect the corresponding equilibria, but information is not available on the magnitude of this effect in concentrated electrolyte solutions. Further refinement of specific rates k_1 and k_2 requires experimental evaluation of the deuterium isotope effect for reactions 1 and 2. Gross departures from the values quoted in Table 3 are not expected.

The equilibrium constant for absorption of hydrogen by $Co(CN)_5^{3-}$ obtained from the ratio of our rate constants $K = k_1/k_2$ is 0.4×10^5 M^{-1} at 25 °C and 1 M ionic strength. This is about a factor of three lower than has already been reported (5, 8, 16) at an ionic strength of 0.5 M. Since our data for the rate of the hydrogen evolution reaction have enabled the estimation of k_2 with an error of about 10%, the apparent discrepancy between these values for K must arise with k_1. It has already been noted that there is no experimental evidence for k_1 being greater than 830 M^{-1} s^{-1} at 1.0 M ionic strength. On the basis of present information we must conclude that K for the overall hydrogenation equilibrium in concentrated electrolytes decreases with increasing ionic strength.

It is clear that while the mechanism which has been proposed to explain D_2–H_2O exchange catalyzed by $Co(CN)_5^{3-}$ adequately accounts for the general features of our experimental data, discrepancies do exist. The non-linearity of k_2 and k_3 with T^{-1}, and the comparatively low value of K predicted by our results have been attributed to ion-pair equilibria not included in the simple scheme. The assumption that kinetic and thermodynamic isotope effects may be neglected does not seem justified. However, further experimental investigation of these topics is required before alternative or additional mechanisms will displace the present model.

The authors wish to thank their colleagues for helpful discussions, particularly Dr. Norman Sagert and Dr. Allan Symons. We also thank David Bell and the mass spectrometry section for completing all the isotopic analyses, and Mrs. D. Wuschke for programming and assistance.

Electrical Conductivity of Pure and Doped Ammonium Perchlorate Crystals

P. W. M. JACOBS, FRANCES E. LOVATT, and WEE LAM NG[1]

Department of Chemistry, The University of Western Ontario, London 72, Ontario

Received March 23, 1972

The conductivity of single crystals of pure ammonium perchlorate and of ammonium perchlorate doped with Ba^{2+} and with SO_4^{2-} ions has been measured at a frequency of 1591 Hz between room temperature and 260 °C. All three systems display a marked increase in conductivity at the temperature of the orthorhombic → cubic phase transition. It is suggested that this sudden increase in conductivity is more probably due to secondary effects (specifically, dislocation generation) than to the actual change in crystal structure. The general similarity between the results for pure and doped crystals tends to support a proton transfer mechanism for a.c. conductivity that does not involve vacancies. However, vacancies may be important in d.c. conductance mechanisms.

Nous avons mesuré la conductivité de cristaux uniques du perchlorate d'ammonium pur et contaminé avec des ions Ba^{2+} et SO_4^{2-}, à la fréquence de 1591 Hz, de la température de la pièce à 260 °C. Les trois systèmes montrent une augmentation sensible de la conductivité à la température de la transition orthorhombique → cubique. On suggère que cette soudaine augmentation de conductivité est probablement due à des effets secondaires (plus spécialement à la naissance de dislocation) plutôt qu'à des changements de la structure cristalline comme telle. La ressemblance générale entre les résultats pour les cristaux purs et contaminés suppose un mécanisme de transfert de proton pour la conductivité a.c., ce qui n'implique pas d'absences. Toutefois, les absences peuvent devenir un facteur important dans les mécanismes de conductance d.c.

The electrical conductivity of both compressed pellets and single crystals of ammonium perchlorate has been investigated before (1–5) but there have been no previous attempts to examine the effect on the conductivity of doping with divalent cation or anion impurities. A recent detailed study (5) of the effects of annealing, partial decomposition, and the adsorption of water and ammonia on the a.c. conductivity led to a proposed mechanism for charge transport involving proton transfer from NH_4^+ ions to proton defects (NH_3 molecules) on normal lattice sites in the cation sub-lattice. The proton defects were considered to be formed by proton transfer from NH_4^+ ions to water or ammonia molecules either on the surface or inside the crystal in voids or at dislocations. It was also suggested that in very thoroughly annealed crystals which had, however, not been heated to a temperature sufficient to induce thermal decomposition, proton defects would be formed by transfer of a proton from NH_4^+ to ClO_4^-. It was considered that these molecular defects would form primarily at the surface and at dislocations and internal boundaries. Of course, a surface NH_3 can be rapidly converted to a proton defect in the bulk by the process

$$[1] \qquad NH_4^+ (l) + NH_3 (s) \rightarrow \boxed{NH_3}_+ + NH_4^+ (s)$$

where (l) denotes a normal lattice site, $\square_+$ a cation vacancy, $\boxed{NH_3}_+$ a cation vacancy occupied by an ammonia molecule (= proton defect), and (s) the site where the ammonia molecule is first formed, adjacent to the surface or a dislocation. The migration of proton holes in the bulk we represent similarly by

$$[2] \qquad NH_4^+ (l) + \boxed{NH_3}_+ \rightleftharpoons \boxed{NH_3}_+ + NH_4^+ (l)$$

In unannealed crystals the role of NH_3 (s) as a proton acceptor in eq. 1 is assumed by water molecules present in the virgin crystal or deliberately introduced by exposure to water vapor (5). The main differences between pellets and single crystals arise from the dominance of surface effects in the former, *i.e.*, it is the water or ammonia adsorbed on the surface rather than that sorbed into the bulk that functions as a proton acceptor.

The activation energy E for proton migration, process 2, appears to be very small (5); that for the formation of proton defects depends on the acceptor and lies on the range 0.5–1.0 eV. For the formation of instrinsic molecular defects

$$[3] \qquad NH_4^+ (s) + ClO_4^- (s) \rightleftharpoons \boxed{NH_3}_+ (s) + \boxed{HClO_4}_- (s)$$

[1]Present address: Surface Physics, Cavendish Laboratory, Cambridge, England.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

followed by process 1, E appears to be close to 0.85 eV (5). When (s) is a surface site, reaction 3 is the first step in the sublimation process. Such molecular defects are believed to be responsible for the anomalous thermodynamic properties of ammonium chloride (6). The conductivity of ammonium chloride has been investigated by Herrington and Staveley (6) and by Fuller and Patten (7). Isotope effects (7) indicate that protons are the charge carriers. Herrington and Staveley (6) proposed a three-stage mechanism for proton conduction in ammonium chloride which involves the participation of either cation or anion vacancies. These stages are: (*i*) proton transfer from NH_4^+ to Cl^- adjacent to a vacancy; (*ii*) the jump of either the NH_3 molecule into a cation vacancy, or the HCl molecule into an anion vacancy, depending on which type is present; (*iii*) proton transfer from HCl to NH_3. Since step (*iii*) involves a species that has interchanged with a vacancy, the final configuration differs from the initial one in that the cation or anion vacancy has moved one lattice site on its own sub-lattice. This mechanism is supported by the appearance of a low-temperature extrinsic region in NH_4Cl crystals doped with Cd^{2+} (6).

Our mechanism (5) for conduction in ammonium perchlorate via proton defects does not rely on the presence of cation or anion vacancies. However, it is possible to envisage cation vacancies acting as proton acceptors

[4] $$NH_4^+ (l) + \square_+ \rightarrow \boxed{NH_3}_+ + H^+ (l)$$

and it would seem important, therefore, to examine the effect of doping ammonium perchlorate with divalent cations or anions. An increase in conductivity on doping with either divalent cations or anions would support the Staveley mechanism, whereas an increase in σ on doping with cations and a decrease on doping with anions would support process 4. The absence of a significant effect would, by default, tend to support the charge transport mechanism based on process 2, plus either process 1 or 3, as the case might be.

The work described in this paper comprises measurements of the conductivity of ammonium perchlorate single crystals doped with Ba^{2+} and with SO_4^{2-} together with further measurements on pure ammonium perchlorate. A subsidiary aim was to look for any effects that could be ascribed to the orthorhombic → cubic phase transformation that occurs at around 240 °C. In previous work (5) such effects had not been carefully distinguished from those connected with thermal decomposition which occurs in the same temperature range.

Experimental

Ammonium perchlorate of 99.99% purity was purchased from the Fisher Scientific Co. Large single crystals of average size 12 × 12 × 4 mm were grown by slow cooling of a saturated solution of ammonium perchlorate containing seed crystals mounted on the arms of a glass crystal "tree" which was rotated continuously in alternate directions for 3½ revolutions by a 25 r.p.m. motor via a rack and pinion gear. Doped crystals were grown in a similar manner from solutions containing 0.1 mol% $(NH_4)_2SO_4$ or 1.0 mol% $Ba(ClO_4)_2$, respectively. It was expected that the crystals would contain much smaller concentrations of the foreign ions. Crystals were analyzed amperometrically with 0.001 M Pb^{2+} for SO_4^{2-} and 0.0018 M SO_4^{2-} for Ba^{2+}. Trial analyses with standard solutions showed that SO_4^{2-} down to 10^{-5} M and Ba^{2+} down to 10^{-3} M could be analyzed by this method. However, the crystal analyses were negative showing that they contained $< 10^{-2}$ mol% SO_4^{2-} and < 1 mol% Ba^{2+}, respectively. Nevertheless, the crystals did contain sufficient of these impurities to affect significantly their rate of thermal decomposition for the overall reaction time was shortened for both Ba^{2+}- and SO_4^{2-}-doped crystals. For example, the time to reach 50% decomposition at 230 °C was 350 min for the pure crystal, 200 min for the SO_4^{2-}-doped, and only 50 min for the Ba^{2+}-doped ammonium perchlorate.

The crystals were mounted in a conductivity cell similar to that described previously (8) except that a grounded guard ring electrode was employed. Conductance measurements were made at a frequency of 1591 Hz using a Wayne Kerr B221 transformer ratio arm bridge. The temperature of the crystal was measured by two Pt/Pt + 13% Rh thermocouples in contact with each of the Pt electrodes. The vacuum line included provision for admitting pure dry nitrogen to the conductance cell.

Results

Ammonium Perchlorate Containing Ba^{2+}

The dependence on temperature (T) of the specific conductance (σ) of a crystal doped with Ba^{2+} ions is shown in Fig. 1 in the form of a plot of log σT *vs.* T^{-1}. These data were obtained after a preliminary annealing procedure. After mounting the crystal in the conductance cell, the cell was evacuated to a pressure of $\sim 10^{-6}$ Torr and the temperature of the crystal was then raised slowly to 103 °C. It was annealed at 103 °C under vacuum for 21 h and then cooled slowly to room temperature (r.t.). After a further 16 h at r.t. dry nitrogen gas was admitted at a pressure of 400 Torr and the

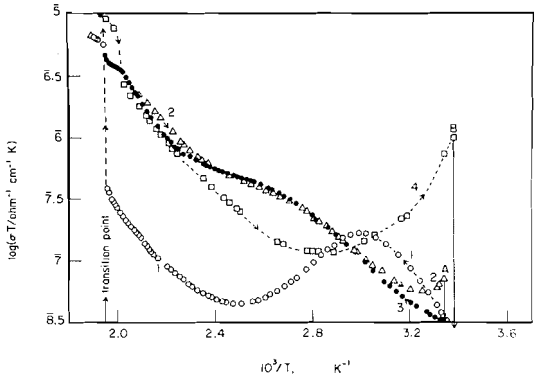

FIG. 1. Conductivity of a Ba^{2+}-doped ammonium perchlorate crystal. The numbers on the curves show the order in which the runs were performed. Arrows on the curves show whether measurements were made on heating or cooling. Vertical arrows (full lines) indicate conductivity changes on annealing in vacuum. Vertical arrows (broken lines) indicate the sudden increase in σ at the transition point.

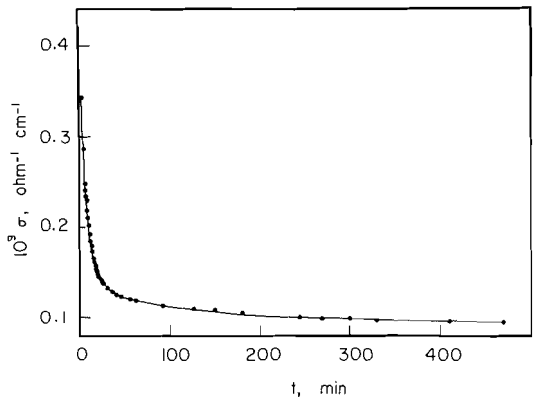

FIG. 2. Time-dependence of the specific conductance of an ammonium perchlorate crystal doped with Ba^{2+} during annealing at room temperature after partial thermal decomposition under 400 Torr nitrogen. The conductivity change corresponds to arrow B in Fig. 1.

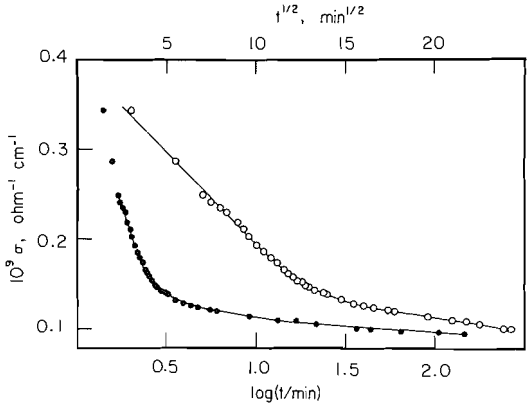

FIG. 3. Kinetics of the isothermal conductivity change shown in Fig. 2. ●, σ *vs.* $t^{1/2}$; ○, σ *vs.* log t.

measurements recorded in Fig. 1 were then made. Curve 1 shows the changes in conductivity that occurred on heating up to 255 °C. The conductivity at first increases, passes through a maximum at ~65 °C, and then decreases with further increase in temperature passing through a minimum at ~130 °C after which it increases steadily. This discontinuity in σ close to 240 °C appears to be associated with the orthorhombic → cubic phase change in ammonium perchlorate (9). However, on cooling (run 2) the conductivity remains an order of magnitude greater than, but roughly parallel to, curve 1. The low-temperature maximum has also disappeared. On reaching r.t. the nitrogen was pumped out and the apparatus evacuated continuously for 65 h during which time the conductivity fell by a factor of 2.2 (arrow A). On re-heating in 400 Torr dry nitrogen the conductivity curve (run 3) follows the cooling curve 2 rather closely from 60 to 150 °C. It then lies slightly below curve 2 and goes through a smaller increase than curve 1 around the transition point. On cooling (run 4) the conductivity follows curve 3 at first but then goes through a minimum, increasing steadily down to r.t. at which point it is a factor of 20 greater than before the heating cycle. On pumping for 26 h at r.t. the conductivity fell (arrow B) thus recovering its value before run 3. At this stage oxygen at a pressure of 400 Torr was admitted to the cell but no change in σ occurred.

The kinetics of the change in σ during the last evacuation at room temperature (arrow B in Fig. 1) were followed. The plot of σ against time t (Fig. 2) has a hyperbolic character. In Fig. 3 are shown plots of σ against log t and σ against $t^{1/2}$ to test if the rate-controlling step is desorption or a diffusion process. There are evidently two processes involved with widely different relaxation times. At short times the logarithmic function appears to give the better fit but at long times $\sigma \propto t^{1/2}$ is a better representation of the data.

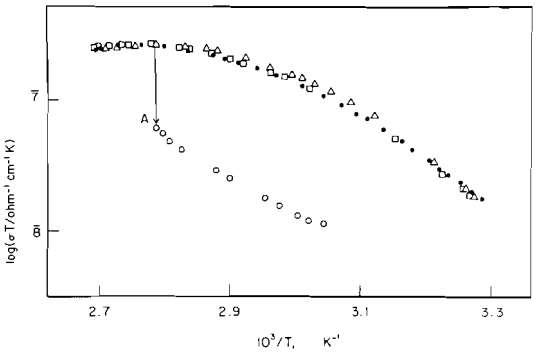

FIG. 4. Conductivity of a SO_4^{2-}-doped ammonium perchlorate crystal on thermal cycling between r.t. and 100 °C. After an initial anneal, as described in the text, the conductivity is reproducible provided the crystal is not heated to higher temperatures or suffers a prolonged anneal. If it is annealed, the conductivity decreases, arrow A; ●, run 1, heating; △, run 2, cooling; □, run 3, heating; ○, run 4, cooling.

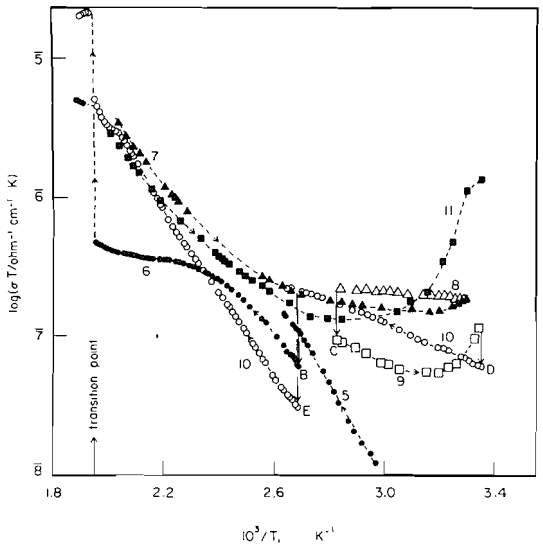

FIG. 5. Conductivity of a SO_4^{2-}-doped ammonium perchlorate crystal. The numbers indicate the order in which the runs were performed. Vertical arrows (full lines) indicate conductivity changes on annealing isothermally. Vertical lines (broken lines) indicate the increase in conductivity that occurs at the transition point.

Ammonium Perchlorate Containing SO_4^{2-}

The temperature dependence of the conductivity of a SO_4^{2-}-doped ammonium perchlorate crystal is shown in Figs. 4 and 5. Figure 4 shows the effects of thermal cycling between r.t. and ~100 °C. The crystal was first heated slowly in vacuum from r.t. to 102 °C and then annealed at this temperature in vacuum for 65 h. The crystal was then cooled slowly to r.t. and the conductivity measured during slow heating to 98 °C (run 1, Fig. 4). Below 50 °C, σT obeys the Arrhenius equation with an activation energy E of 0.70 eV. At higher temperatures the slope of the curve decreases and it passes through a very flat maximum at ~90 °C (*cf.* run 1, Fig. 1). On cooling (run 2) the curve is re-traced with fair reproducibility. At r.t., 400 Torr nitrogen was introduced into the cell and on reheating (run 3) curve 1 was again reproduced, showing that the crystal is in a reproducible state after the initial anneal and also that the conductivity is independent of whether the crystal is in vacuum or in a nitrogen atmosphere. The crystal was now annealed in nitrogen for a further 88 h at 98 °C when the conductivity fell by a factor of 4 (arrow A). The activation energy over the linear section (run 4) is 0.65 eV.

Further experiments, involving heating to higher temperatures, are shown in Fig. 5. The crystal was reheated to 106 °C (run 5, $E = 0.65$ eV) and on further annealing for 18 h at 100 °C, σ fell by 70% (arrow B). Run 6 shows the variation in σT as the crystal was heated from 100 °C (point B in Fig. 5). Between 185 and 225 °C the conductivity increases very slowly with temperature, the slope at the point of inflection corresponding to $E = 0.04$ eV. Above 225 °C σ increases somewhat and then it increases suddenly by a factor of 10 at the transition point. On cooling, run 7, the low temperature conductivity is much larger than previously (*cf.* Fig. 4). On re-heating the conductivity is substantially independent of temperature up to 79 °C but on annealing at this temperature (still under nitrogen) for 16 h, σ fell by a factor of 2.5 (arrow C). The significant feature on cooling again to r.t. (run 9) was the increase in σ that occurred at low temperatures. (This is also evident, but less marked, in run 7.) The system was then evacuated for 28 h at r.t. and the conductivity fell by 80% (arrow D). The crystal was then heated in nitrogen to 100 °C, annealed there for 64 h (run 10, arrow E), and then heated to 253 °C ($E = 0.62$ eV, over the range 110–135 °C). There was again a sudden marked increase in σ at the transition point. On cooling

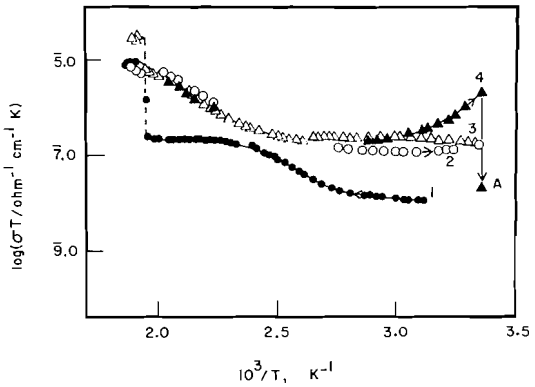

FIG. 6. Conductivity of a pure ammonium perchlorate crystal after a very thorough anneal at 116 °C. The numbers indicate the order in which the runs were performed. The vertical arrow A shows the decrease in conductivity that occurs on pumping at room temperature after partial thermal decomposition and the vertical lines (broken lines) show the increase in σ that occurs at the transition point.

(run 11) the significant feature is the big increase in σ at low temperatures.

Pure Ammonium Perchlorate

The conductivity plot for a pure ammonium perchlorate crystal is shown in Fig. 6. This crystal had been subjected to thermal cycling between r.t. and 116 °C and had also been very thoroughly annealed at 116 °C but had not been heated above this temperature prior to the first run shown (1 in Fig. 6). The conductivity is at first practically independent of temperature, increases above the anneal temperature and is again almost constant from 160 °C to the transition point. In this run it was possible to fix the sharp increase in σ quite precisely since the conductivity changed by a factor of 21 between 238.6 and 239.6 °C. The crystal was again under 400 Torr of nitrogen during this experiment. The curves 2, 3, and 4 show the conductivity changes during successive cooling, heating, and cooling cycles. As with the SO_4^{2-}-doped crystal there was a second but smaller increase in σ at the transition point on heating the crystal above 240 °C for the second time, (run 3). Again, there is a marked increase in σ on cooling to r.t. (run 4). However, the conductivity fell by two orders of magnitude on pumping at r.t. for 18 h.

The time-dependence of σ on annealing a pure (undecomposed) ammonium perchlorate crystal at 89 and 114 °C had been studied previously (5). Plots of σ against $t^{1/2}$ were linear and showed only a single relaxation time, in contrast to Fig. 3. Again in contrast to Fig. 3 plots of σ against log t showed a decided curvature.

Discussion

Ammonium perchlorate at room temperature belongs to the space group *Pnma* which also includes barium sulfate. Indeed the orthorhombic crystal structures and lattice parameters are so similar that Ba^{2+} and SO_4^{2-} were chosen as the divalent impurities to be incorporated in the ammonium perchlorate crystals. The NH_4^+ ions are freely rotating down to very low temperatures, at least 20 K (9), thus indicating the absence of significant hydrogen-bonding (10). The phase transition to the cubic form is accompanied by the onset of free rotation of the perchlorate anions. The temperature generally quoted for the phase transition is 240 °C (9).

The effect on its conductivity of doping a uni-univalent ionic salt with divalent ions is well understood when charge transport proceeds by the motion of vacancies or interstitial ions. One anticipates the low temperature will be increased by doping and that a sufficiently high temperature (depending on the impurity concentration) the conductivity of the pure and doped crystals will all follow the same (intrinsic) curve. Unfortunately, there is no such thing as truly intrinsic behavior for ammonium perchlorate single crystals although both compressed pellets and single crystals will yield reproducible results on the same sample if it is carefully annealed. (It should be stressed here that these remarks apply to a.c. conductance measurements. We have made no d.c. measurements and it is possible for these to yield different results if, for example, there should be a substantial orientational polarization.) Thus one should not expect different crystals to show even qualitatively the same behavior. This is due to the very important role played by adsorbed or occluded water in the a.c. conductance mechanism.

The experimental results for pure and doped ammonium perchlorate crystals (Figs. 1, 4, 5, and 6) can be understood in terms of the proton

defect mechanism advanced previously (5) without any need to invoke a mechanism involving vacancies. It may be, in view of the low doping levels achieved, that there are some minor effects due to vacancies but the present results are dominated by water in the crystals. If ammonium perchlorate is thoroughly annealed at about 100 °C then reproducible results are obtained on thermal cycling (Fig. 4). The broad maximum indicates that saturation of carriers has been achieved, *i.e.*, that all the available water has been utilized as a proton acceptor. On either prolonged annealing (Fig. 4, A; Fig. 5, B and E) or further increase in temperature (Fig. 1, run 1) the conductivity decreases as water is driven off, evidently from inside the crystal as the kinetics are diffusion controlled (5). The apparent differences between the annealing kinetics of Ba^{2+}-doped ammonium perchlorate (Figs. 2, 3) and pure ammonium perchlorate arise because the experiments described in ref. 5 refer to undecomposed crystals that had never been heated above 120 °C. Hence diffusion processes prevail over desorption. The experiment described here was performed on a partially decomposed crystal. Now decomposition causes the crystal to become porous (11) and the resultant increase in (internal) surface area results in detectable desorption of water. This is followed by the slower loss of water by diffusion out of the crystal and hence two processes are observed (Figs. 2, 3). On further heating (*e.g.* runs 6 and 10, Fig. 5, or run 1 in Fig. 1) the conductivity again increases. In run 10 of Fig. 5 there is reasonable Arrhenius behavior up to 185 °C with $E = 0.62$ eV, indicating proton transfer to water, not intrinsic behavior.

Why does the conductivity in run 6 saturate while that in run 10 goes on increasing? Because in the latter there is more water available, this having come from the occlusion of water formed by thermal decomposition of the crystal during run 6. Notice that in runs 7, 9, and 11 the conductivity increases at low temperature as more water is adsorbed by the crystal from the gas phase. Some of this water can be removed by pumping (D in Fig. 5). These results are not specific to the SO_4^{2-}-doped crystals and broadly similar behavior can be seen in Figs. 1, 5, and 6.

The phase transition is clearly marked by a sudden increase in σ, runs 1 and 3 in Fig. 6, runs 6 and 10 in Fig. 5, and runs 1 and 3 in Fig. 1. However, there is substantial hysteresis and the conductivity does not follow the heating curve. There are at least three possible explanations for this: (*a*) the cubic phase might be metastable and revert only slowly to the orthorhombic structure; (*b*) the lattice reorganization during the phase change might re-distribute sufficient water within the crystal or generate a sufficient number of dislocations to increase the conductivity permanently; (*c*) the water formed by concomitant thermal decomposition might be responsible for the observed increase in σ. The increase in conductivity on heating is too sharp to be accounted for entirely by thermal decomposition. Thus the phase transition undoubtedly does increase the conductivity substantially but whether this is a direct result of the change in crystal structure is unclear. It could be due to re-location of water, generation of dislocations or due to the onset of free rotation of the perchlorate anions facilitating the transfer of protons from NH_4^+ to ClO_4^-.

Conclusion

Although ammonium perchlorate crystals doped with Ba^{2+} or SO_4^{2-} show substantially different characteristics to pure crystals on thermal decomposition (12), there are no differences in their a.c. electrical conductivity that can be ascribed directly to the presence of vacancies in the doped crystals. The changes in the conductivity of these crystals on thermal cycling can be explained in terms of charge transport via proton defects. Proton defects (NH_3 molecules) are formed by transfer of a proton from an NH_4^+ lattice cation to water molecule or to a ClO_4^- anion. Defect formation occurs initially at special sites such as the surface or in the neighborhood of dislocations.

Finally, it should be emphasized that all the measurements described in this paper were made at the single frequency of 1591 Hz and it is certainly possible that at this frequency other dielectric loss mechanisms are operative in addition to conductance losses.

Model Calculations on the Influence of Mechanical and Electrical Anharmonicity on Infrared Intensities: Relation to Hydrogen Bonding

THÉRÈSE DI PAOLO,[1] C. BOURDÉRON, AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec

Received April 20, 1972

The influence of mechanical and electrical anharmonicity on the intensity of X—H stretching vibrations is investigated by means of model calculations in relation to hydrogen bonding. It is found that while both kinds of anharmonicities have a significant effect on the intensity, they cannot explain the characteristic increase in intensity of the fundamental and the equally characteristic decrease in the intensity of the first overtone. It is shown that not only the first but both these phenomena are due to the large value of the first derivative of the dipole moment in hydrogen bonded systems. This is linked to the possibility that the effect of electrical anharmonicity ($d^2\mu/dQ^2$) might be cancelled by a high value of $(d\mu/dQ)_e$ in the expression of the overtone intensity.

L'influence des anharmonicités mécanique et électrique sur l'intensité des vibrations de valence X—H est étudiée à l'aide de calculs de modèle en relation avec la liaison hydrogène. On trouve que les deux types d'anharmonicité ne peuvent pas expliquer l'augmentation caractéristique de l'intensité de la fondamentale et la diminution également caractéristique de l'intensité de la première harmonique même si elles ont un effet significatif sur l'intensité. On montre que ces deux phénomènes sont dûs à la grande valeur de la première dérivée du moment dipolaire dans les liaisons hydrogènes. L'effet de l'anharmonicité électrique ($d^2\mu/dQ^2$) peut être compensé par une grande valeur de $(d\mu/dQ)_e$ dans l'expression de l'intensité de l'harmonique.

Introduction

The formation of hydrogen bonds has a marked influence on the frequency, intensity, and width of infrared X—H stretching bands. (X is O or N in the most important cases). It has been concluded, in previous publications from this laboratory (1, 2), that the increase in mechanical anharmonicity accounts for a large part of the frequency shift which occurs when the OH groups of alcohols are engaged in hydrogen bonding, and that it is also an important factor causing the great width of the hydrogen bonded OH stretching bands. These studies concerned mainly the so called "polymer" band of alcohols.

The influence of mechanical anharmonicity on the intensities has not been studied systematically. On the other hand electrical anharmonicity has been linked (3, 4), to the surprising weakness of the first polymer overtone (5).

The purpose of the present study was to obtain an insight into the effect of mechanical and electrical anharmonicity on the intensity of the fundamental and the first overtone of X—H stretching bands. An explanation was sought for the increase in the intensity of the fundamental by about an order of magnitude (*cf.* 6), and for the decrease in the intensity of the first overtone, characteristic of many hydrogen bonded systems. This has been attempted through model calculations. A somewhat similar study of the frequencies was carried out previously by Foldes and Sandorfy (7).

The transition moment for a vibrational transition of a diatomic oscillator can be given by:

$$R^{v'v''} = \int \Psi^*_{v'} \mu \Psi_{v''} \, d\tau \qquad [1]$$

where v' and v'' are the vibrational quantum numbers for the upper and lower vibrational states. The potential will be represented to the second order by the usual expansion

$$V = \tfrac{1}{2}kQ^2 + k_3Q^3 + k_4Q^4 \qquad [2]$$

where k, k_3, and k_4 are the harmonic, cubic, and quartic potential constants, respectively, and Q is the normal coordinate. The variable dipole moment will be taken to be

$$\mu(Q) = \mu_e + \mu_1 Q + \mu_2 Q^2 \qquad [3]$$

where μ_e is the equilibrium dipole moment,

$$\mu_1 = \left(\frac{d\mu}{dQ}\right)_e, \qquad \mu_2 = \tfrac{1}{2}\left(\frac{d^2\mu}{dQ^2}\right)_e \qquad [4]$$

[1]Holder of NRCC postgraduate scholarship 1970–1972.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and we have neglected higher terms. The effect of the next term in the expansion of μ ($\mu_3 Q^3$) will be examined in a separate note (8). Then

$$[5] \qquad R^{v'v''} = \mu_1 R_1^{v'v''} + \mu_2 R_2^{v'v''}$$

where

$$R_1^{v'v''} = \int \Psi_{v'}^* Q \Psi_{v''} \, d\tau$$

and

$$R_2^{v'v''} = \int \Psi_{v'}^* Q^2 \Psi_{v''} \, d\tau$$

The Ψ_v will be harmonic oscillator wave functions perturbed to the second order. The expressions for the R_i were given by Herman and Shuler (9) and will not be reproduced here.[2] The intensities of the fundamental and the first overtone are, from Herman and Shuler's equation [10]:

$$[6] \quad A^{1,0} = \left(\frac{8\pi^3 N_{v^0}}{3hc}\right) \times \omega^{1,0} \left\{\mu_1\left(\frac{1}{\sqrt{2}} - \frac{3}{2\sqrt{2}} g + \frac{11}{4\sqrt{2}} b^2\right) + \mu_2\left(-\frac{5b}{\sqrt{2}} + \frac{88}{\sqrt{2}} bg - \frac{715}{12\sqrt{2}} b^3\right)\right\}^2$$

$$[7] \quad A^{2,0} = \left(\frac{8\pi^3 N_{v^0}}{3hc}\right) \times \omega^{2,0} \left\{\sqrt{2}\mu_1\left(\frac{b}{2} - \frac{111}{8} bg - \frac{71}{48} b^3\right) + \frac{\mu_2}{\sqrt{2}}\left(1 - \frac{15}{4} g + \frac{3}{8} b^2\right)\right\}^2$$

where ω is the wave number in cm^{-1}; $b \equiv k_3/\omega_e$, $g \equiv k_4/\omega_e$, and N_{v^0} is the number of molecules per cm^3 in the lower vibrational level. (The validity of eqs. 6 and 7 is not linked to the choice of these units, however).

Outline of the Work

(*I*) As a starting point, we needed reasonable representative values for k_3, k_4, and the first and second derivatives of the dipole moment for a band not perturbed by hydrogen bonding. We choose the *free* OH stretching mode of 2,6-ditertiary-butyl-paracresol, which, for steric reasons, does not enter into any association at room temperature. We measured the band due to the fundamental on a Perkin–Elmer model 621 spectrometer and the first overtone on a Cary 17 instrument. We computed the anharmonicity constant from the observed frequencies and, from these, the potential constants (see below). We then determined the intensities from the band areas, through the Lorentz (Cauchy) formula. Thus, having $A^{1,0}$, $A^{2,0}$, k_3, and k_4, we could compute the squares of μ_1 and μ_2 from eqs. 6 and 7. We then examined the influence of k_3, k_4, μ_1, and μ_2 on the absorption intensities of 2,6-ditertiary-butyl-paracresol. We successively put each of these parameters equal to zero while keeping the others unchanged, and computed $A^{1,0}$, $A^{2,0}$ in each case.

(*II*) In the second part of our work we varied k_3, k_4, μ_1, and μ_2 separately between *wide limits* in order to approach conditions prevailing in hydrogen bonded systems. We then attempted to explain the usually large increase in the intensity of the fundamental and the decrease in the intensity of the first overtone.

Results of the Calculations

(*I*) Second order perturbation theory is known to be valid when applied to the free OH stretching vibration (10). This implies that k_4 is very small, and we therefore neglected it, since our aim was merely to obtain starting values. k_3 can then be obtained from the expression of the first anharmonicity constant ($X = (15k_3^2/4\omega_e) - (3/2)\,k_4$ in cm^{-1}). We thus found from

$$X = \nu_{01} - \frac{\nu_{02}}{2} = \frac{\nu_{02}}{2} - \frac{\nu_{03}}{3} = \frac{\nu_{03}}{3} - \frac{\nu_{04}}{4}$$

$X = 88\ cm^{-1}$, $\omega_e = 3826\ cm^{-1}$, $k_3 = -300\ cm^{-1}$. (The measured values of ν_{03} and ν_{04} were 10 418 and 13 540 cm^{-1}. As to the value of k_3 in similar cases see, for example, ref. 11 or 12.)

Experimentally we found

$$A^{1,0} = 12\,800\ l\ mol^{-1}\ cm^{-2}$$

$$A^{2,0} = \quad 310\ l\ mol^{-1}\ cm^{-2}$$

We fed these values of the band areas and k_3 and k_4 into eqs. 6 and 7 to compute μ_1 and μ_2. In order to circumvent the difficulty due to the presence of cross terms in these equations, we first took their square roots. The values of the μ_i

[2] A more elaborate treatment was given by Toth *et al.* (15) and should be used, if quantitative results were sought for given molecules.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

obtained with the two possible different combinations of signs are given in Table 1.

Since we have no sure way of determining their signs we had to consider both these combinations ((+ +) and (+ −)) where the signs relate to eqs. 6 and 7, respectively, in each bracket. (The two other combinations in which all + are replaced by − and *vice versa* yield the same results with opposite signs.) We are going to describe the results obtained with each of these two combinations of signs in the hope of being led to the right combination by making comparisons with experiment. Table 2 contains the results.

In order to assess the contribution of mechanical anharmonicity to the intensities given in Table 2, we carried out another set of calculations in which mechanical anharmonicity was neglected (that is $k_3 = k_4 = 0$); and harmonic oscillator wave functions were used for obtaining the expressions of $A^{1,0}$ and $A^{2,0}$. (The matrix components needed for this and the previous calculations were given, for example, by Barchewitz (13)). The results are shown in Table 3.

Tables 2 and 3 show that the influence of electrical and mechanical anharmonicity on the intensity of the fundamental is small. The difference between (+ +) and (+ −) is much greater without mechanical anharmonicity than with it. Furthermore, without electrical anharmonicity the overtone is much weaker.

(*II*) We varied separately k_3, k_4, and μ_2 while keeping the values of the others unchanged and then we varied them jointly.

The fixed values were, as before,

$$k_3 = -300\ \text{cm}^{-1}, \qquad k_4 = 0$$

and the fixed values of μ_2 were as given before for the two different combinations of signs (Table 1).

We varied k_3 from -200 to $-400\ \text{cm}^{-1}$. This corresponds to anharmonicity constants (X) equal to 50 and 200 cm^{-1}. All the anharmonicity constants for associated alcohols, amines, etc. fall into this range (2, 14).

$A^{1,0}$ kept increasing from $k_3 = -200$ to $k_3 = -400\ \text{cm}^{-1}$ but in no case did the total variation exceed 10%. This is true even if $\mu_2 = 0$ and even if k_4 varies from $+k_3/10$ to $-k_3/10$ for both (+ +) and (+ −).

TABLE 1. Values of the first and second derivatives of the dipole moment for the OH stretching vibration of 2,6-di-tert-butylparacresol for the two possible selection of signs in the square roots of eqs. 6 and 7

	μ_1 (e.s.u. cm)	μ_2 (e.s.u. cm)
(+ +)	1.53×10^{-19}	3.03×10^{-20}
(+ −)	1.67×10^{-19}	-5.72×10^{-21}

TABLE 2. The influence of electrical anharmonicity on the intensities of the fundamental and first overtone of the OH stretching vibration of 2,6-di-tert-butylparacresol: $k_3 = -300\ \text{cm}^{-1}$, $k_4 = 0$

	$A^{1,0}$ (l $\text{mol}^{-1}\ \text{cm}^{-2}$)	$A^{2,0}$ (l $\text{mol}^{-1}\ \text{cm}^{-2}$)
(*a*) Case (+ +)

$\mu_1 = 1.67 \times 10^{-19}$ e.s.u. cm	13 200	150
$\mu_2 = 0$		

TABLE 3. The influence of electrical anharmonicity on the intensities of the fundamental and first overtone of the OH stretching vibration of 2,6-di-tert-butylparacresol: $k_3 = 0$, $k_4 = 0$

	$A^{1,0}$ (l $\text{mol}^{-1}\ \text{cm}^{-2}$)	$A^{2,0}$ (l $\text{mol}^{-1}\ \text{cm}^{-2}$)
(*a*) Case (+ +)		
$\mu_1 = 1.53 \times 10^{-19}$ e.s.u. cm	10 600	820
$\mu_2 = 3.03 \times 10^{-20}$ e.s.u. cm		
$\mu_1 = 1.53 \times 10^{-19}$ e.s.u. cm	10 600	0
$\mu_2 = 0$		
(*b*) Case (+ −)		
$\mu_1 = 1.67 \times 10^{-19}$ e.s.u. cm	12 800	30
$\mu_2 = -5.72 \times 10^{-21}$ e.s.u. cm		
$\mu_1 = 1.67 \times 10^{-19}$ e.s.u. cm	12 800	0
$\mu_2 = 0$		

The intensity of the first overtone decreases steadily from $k_3 = -200$ to $k_3 = -400\ \text{cm}^{-1}$, the total variation being about 40% for (+ +) and 50% for (+ −).

In the case of (+ +) if μ_2 is varied from 1.5×10^{-20} e.s.u. cm to 6.0×10^{-20} while k_3 and k_4 are kept constant, $A^{1,0}$ varies by about $\pm 20\%$ with respect to its previous value of 12 800. $A^{2,0}$ is

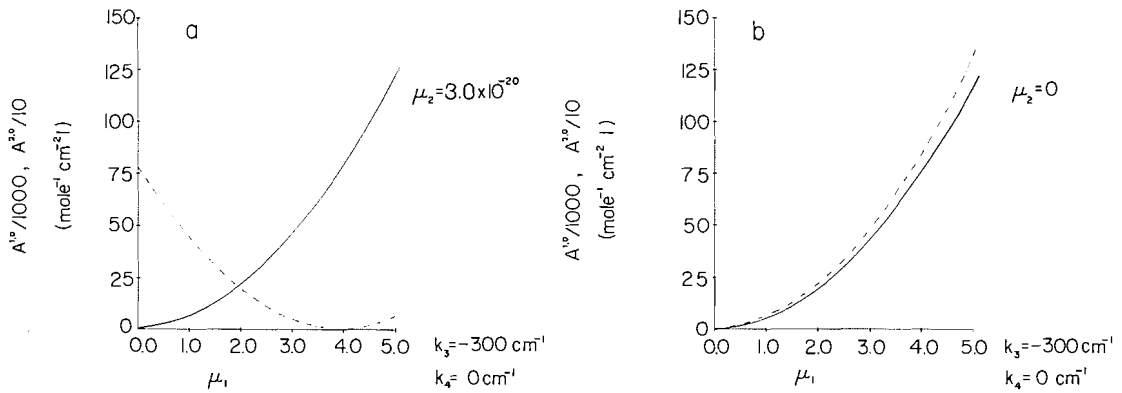

FIG. 1. Variation of the intensities of the fundamental — and the first overtone ····· as a function of $\mu_1 = d\mu/dQ$ for case (+ +); (*a*) for $\mu_2 = 3.0 \times 10^{-20}$ e.s.u. cm; (*b*) for $\mu_2 = 0$. The numbers on the abscissa should be multiplied by 10^{-19} e.s.u. cm.

practically zero for 1.5×10^{-20} and, for 6.0×10^{-20} it increases by an order of magnitude with respect to its value at 3.0×10^{-20} e.s.u. cm (30). For (+ −) the variations are very slight for both the fundamental and the overtone. This is expected in view of the small value of μ_2 which we have obtained in this case. The simultaneous variation of k_3, k_4, and μ_2 between the limits indicated above leads only to slight departures from these results.

On the whole we can say that variation of the mechanical and electrical anharmonicities between reasonable limits varies $A^{1,0}$ by about 20% at most.

(*III*) These results would have a certain interest if we were dealing with infrared intensities in general, but do not explain the intensity changes observed with hydrogen bonded systems.

So we varied μ_1 from zero to about six times its original fixed value. Figure 1*a* shows the obtained variation of the intensities $A^{1,0}$ and $A^{2,0}$ for the case (+ +) while k_3 was equal to $-300\ \text{cm}^{-1}$, k_4 to 0, and μ_2 had its fixed value. It is a striking result. Whereas the intensity of the fundamental undergoes a rapid increase when μ_1 increases, the intensity of the first overtone decreases rapidly in accord with experimental observation.

If we set $\mu_2 = 0$, that is, if we have no electrical anharmonicity, the picture changes completely and $A^{1,0}$ and $A^{2,0}$ exhibit a parallel increase with increasing μ_1 (Fig. 1*b*).

The reason for this is found if we take a closer look at the expression of $A^{2,0}$ (eq. 7). While the coefficient of μ_1 is normally small in this expression, and μ_2 is the main factor in determining the intensity of the first overtone, a very large value of μ_1 can cancel the contribution of μ_2 because of the negative value of the first term in eq. 7. For (+ −) the intensities of both the fundamental and first overtone increase with increasing μ_1 (Fig. 2*a*, *b*), whether μ_2 is different from zero or not. This is contradictory to what is observed in the case of hydrogen bonds and it leads to (+ +) as the right combination of signs in eqs. 6 and 7.

It is then clear that the decrease in intensity of the first overtone does not necessarily imply a decrease in electrical anharmonicity as might have been thought (4). It is connected with the high value of μ_1, making a compensation possible between the terms containing μ_1 and μ_2 in eq. 7.

It can be equally seen from eq. 7 that mechanical anharmonicity is needed to give μ_1 an appreciable coefficient. As we ascertained, any value of k_3 from -200 to $-400\ \text{cm}^{-1}$ would be sufficient.

Discussion and Conclusions

It follows from the above results that neither mechanical nor electrical anharmonicity can explain the most important intensity changes that occur upon hydrogen bond formation; the large increase in the intensity of the fundamental and a large decrease in the intensity in the first

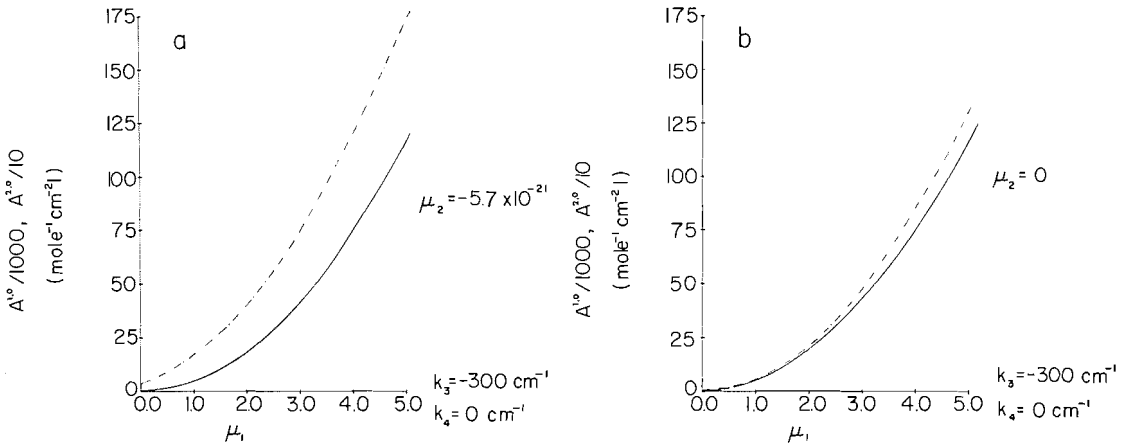

FIG. 2. Variation of the intensities of the fundamental — and the first overtone ····· as a function of $\mu_1 = d\mu/dQ$ for case (+ −); (*a*) for $\mu_2 = -5.7 \times 10^{-21}$ e.s.u. cm; (*b*) for $\mu_2 = 0$. The numbers on the abscissa should be multiplied by 10^{-19} e.s.u. cm.

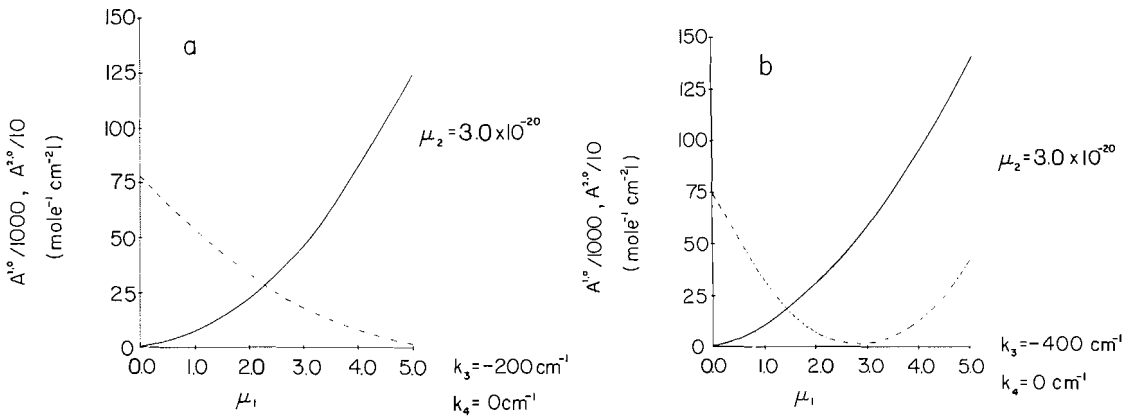

FIG. 3. Variation of the intensities of the fundamental — and the first overtone ····· as a function of $\mu_1 = d\mu/dQ$ for case (+ +) with $\mu_2 = 3.0 \times 10^{-20}$ e.s.u. cm; (*a*) $k_3 = -200\,\text{cm}^{-1}$; (*b*) $k_3 = -400\,\text{cm}^{-1}$. The numbers on the abscissa should be multiplied by 10^{-19} e.s.u. cm.

overtone. We need, of course, the large variation of the dipole moment (μ_1) to explain the high intensity of the fundamental. We have now shown that a high value of μ_1 equally explains the low intensity of the first overtone with any reasonable values of the anharmonicities. It is important to point out that agreement with the experimental facts requires that μ_1 and μ_2 have the same sign.

We might go a step further. It has been found previously (3) in the case of self-associated alcohols that only the polymer bands (OH bonds in inner positions, not in small rings) show the above mentioned two main intensity changes; dimers and oligomers (like cyclic trimers and tetramers) have weaker fundamentals and relatively strong overtones. This is actually helpful in ascertaining the presence of certain associated species in liquid or dissolved alcohols and amines (14). Now, in looking at Fig. 1*a* we see that a relatively small change in μ_1 can bring about large differences in the relative intensities of the fundamental and its first overtone, giving a qualitative explanation of the different behavior of oligomer bands and polymer bands.

A Comparative Study of Bu_4NBr, $NaBPh_4$, Ph_4PCl, and Ph_4AsCl in Water and Methanol at 25 °C: Partial Molal Volumes, Heat Capacities, and Viscosities

C. JOLICOEUR, P. R. PHILIP, G. PERRON, P. A. LEDUC, AND J. E. DESNOYERS

Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received March 29, 1972

The apparent molal volumes (ϕ_v) and heat capacities (ϕ_c) of Bu_4NBr, $NaBPh_4$, Ph_4PCl, and Ph_4AsCl have been measured in water and methanol at 25 °C in the concentration range 0.01–0.2 *M*. The viscosity of aqueous $NaBPh_4$ and Ph_4AsCl have also been measured at 25 °C and in the same concentration range. Individual ionic values have been estimated for most of these properties. A comparison of these values for the quaternary ions Bu_4N^+, BPh_4^-, Ph_4P^+, Ph_4As^+ illustrates sizable differences in the solute–solvent interactions of alkyl and aryl substituted ions. Some specificity is also suggested in the solvation of the tetraphenyl ions, as shown by a comparison of the properties which should reflect directly the size of the ions (r_{Stokes}, $\bar{V}^0$, and B_η) and also in ($H_2O \rightarrow CH_3OH$) transfer functions.

Le volume apparent molaire (ϕ_v) et la capacité calorifique apparente molaire (ϕ_c) de Bu_4NBr, $NaBPh_4$, Ph_4PCl, et Ph_4AsCl ont été mesurés dans l'eau et dans le méthanol à 25 °C, dans un domaine de concentration variant de 0.01 à 0.2 *M*. Egalement, la viscosité de solutions aqueuses de $NaBPh_4$ et Ph_4AsCl a été déterminée. Pour la majorité de ces propriétés, des valeurs ioniques individuelles ont pu être estimées. La comparaison de ces valeurs pour les différents ions quaternaires met en évidence une différence significative entre les interactions soluté–solvant des ions quaternaires, selon que les substituants sont aliphatiques ou aromatiques. Dans la série BPh_4^-, Ph_4P^+, et Ph_4As^+, une certaine spécificité dans la solvatation est également apparente, particulièrement dans les propriétés qui reflètent directement la dimension des ions (r_{Stokes}, $\bar{V}^0$, et B_η) et dans les fonctions thermodynamiques de transfert ($H_2O \rightarrow CH_3OH$).

Introduction

In the study of aqueous hydrophobic solutes, molecules or ions containing unsaturated side chains are usually avoided because of ill-defined interactions between water molecules and π-electron systems, and also because there are no convenient homologous series such as those found in the aliphatic substituents. Differences between the water–solute interactions of aliphatic and aromatic solutes have been suggested for some time[1] and recently emphasized by systematic transfer studies (2). It has been possible to illustrate these differences in solute–solvent interactions from an investigation of the near-i.r. spectra of water in solutions containing alkyl and aryl substituted quaternary ions (3). While Bu_4N^+ changed the water spectrum in a way similar to a decrease in temperature, Ph_4As^+, Ph_4P^+, and BPh_4^- all produced spectral changes which could not be correlated with simple structural modifications of water. Furthermore, it could be inferred from the spectra that BPh_4^- and Ph_4As^+ or Ph_4P^+ behave quite differently in their interactions with water. In spite of the *a priori* similarity of the latter ions, indications of specific behavior were also found in their heats of transfer between protic and aprotic solvents (4), their apparent molal expansitivities (5),[2] and also in their effects on the electron spin relaxation of stable nitroxide radicals (6). Since this work was completed, solvent chemical shifts in solutions of Ph_4AsCl, Ph_4PCl, and $NaBPh_4$ have also shown specific solvation effects for Ph_4P^+, Ph_4As^+, and BPh_4^- (7).

Knowledge of the effects of hydrophobic solutes on the structure of water, and on the interactions among hydrophobic solutes, was originally (and frequently since) inferred from thermodynamic properties (8–11) and viscosity data (9, 10). It thus seemed appropriate to use these properties to try to confirm and specify differences between alkyl and aryl substituted ions, and between various ions in the latter

[1]See for example the different apparent molal expansitivities (ϕ_E) of benzene and CH_4, C_2H_6, or C_3H_8 in water (ref. 1).

[2]For $NaBPh_4$ and Ph_4AsCl, ϕ_E^0 and $d\phi_E^0/dT$ are quite different; also, $d\phi_E^0/dT$ for these salts is of opposite sign to that of Bu_4NCl.

group. In the present comparative study of Bu_4NBr, $NaBPh_4$, Ph_4PCl, and Ph_4AsCl we have chosen to investigate apparent molal volumes (ϕ_v), apparent molal heat capacities (ϕ_c) and viscosities (η); for simple electrolytes, these properties are sometimes rather well correlated (12). Measurements in methanol were carried out in an attempt to resolve specific interactions between water and aromatic substituents from the influence of hydrophobic solutes on the water structure. Some measurements were also carried out on benzene and triphenylmethane for the purpose of comparing the behavior of the neutral molecules with that of the tetraphenyl ions.

Experimental

(a) Materials

The solvents and other materials required in this work were: water doubly distilled over alkaline $KMnO_4$ in a glass still; methanol (see discussion below); hexane and benzene Fisher spectranalyzed; $NaBPh_4$, Ph_4AsCl, Ph_4PCl, and Ph_3CH, K and K. The salts were purified following procedures described elsewhere (3, 6*b*) and triphenylmethane was recrystallized from anhydrous ether. All solutions were filtered immediately prior to their use.

(b) Measurements

Since it is very difficult to obtain anhydrous methanol, several tests were conducted in order to evaluate the effect of the water content on the partial molal volumes and heat capacities of solutes in this solvent. For different lots Karl Fisher titrations gave the following water contents: 500 p.p.m. or less for Fisher certified methanol and 500–1000 p.p.m. for Spectrograde methanol. Distillation of Fisher certified material over $MgSO_4$ under a dry nitrogen atmosphere yielded methanol containing less than 100 p.p.m. H_2O. Between 100–500 p.p.m. H_2O content it was not possible to establish a significant influence of water on the properties investigated. The tests were more convincing for partial molal volumes than for partial molal heat capacities; the latter bear larger uncertainties, because of other problems encountered as discussed below. The results given here were all obtained using Fisher certified grade methanol containing less than 300 p.p.m. H_2O.

Density measurements were carried out with a buoyancy densitometer (described in detail elsewhere, ref. 13) which is capable of an accuracy of 2×10^{-6} g cm^{-3}. With solutions in methanol, evaporation of the solvent increased the uncertainty to 10^{-5} g cm^{-3}. For these, density measurements were also carried out using a digital densitometer, DMA (Anton Parr, Austria); both methods yielded values agreeing to within 10^{-5} g cm^{-3}.

The specific heats of the solutions were obtained using a differential flow microcalorimeter reported recently by Picker *et al.* (14). The instrument measures directly the ratio of the volumetric specific heats (σ) of a solution relative to that of its solvent. For aqueous solutions, the detection limit of the instrument is typically 2×10^{-5} cal K^{-1} cm^{-3} when using a temperature increment of ~ 1.5 K. As mentioned above, additional problems were encountered with solutions in methanol due to its high vapor pressure, its high fluidity and its ability to dissolve sealing materials. The constant rate of flow required for the specific heat measurements was thus very difficult to achieve. The viscosity of the solutions was determined with a flow viscometer also described previously (15); with water at 25 °C, the flow time of the instrument was 811.05 s with a reproducibility of ± 0.05 s. For the quaternary salts (except Ph_4PCl) in water and methanol, the concentration range investigated was 0.01–0.2 *M*. In methanol, measurements at two or three concentrations only were carried out, repeating each measurement 4–6 times.

The specific heat of aqueous benzene solutions was measured at the saturation concentration only (0.0231 *m* at 25 °C (1)). Similarly the density and specific heat of Ph_3CH in hexane and methanol were obtained for a single low concentration: 0.03635 and 0.03022 *m*, respectively. In the above instances, the results are assumed to correspond to infinite dilution values.

Results

The apparent molal volumes (ϕ_v) were calculated from the density measurements using standard equations (*e.g.* ref. 15); the density of water, methanol, and hexane at 25 °C were taken respectively as 0.997044, 0.78636, and 0.66265 g cm^{-3};[3] the data were fitted to the Redlich–Meyer equation (17)

$$[1] \qquad \phi_v = \phi_v^0 + A_v c^{1/2} + B_v c$$

where $A_v = 1.868$ (17) in water and 15.77 in MeOH (18). The results obtained for aqueous solutions of $NaBPh_4$, Ph_4PCl, and Ph_4AsCl are given in Table 1 and some of the results are plotted in Fig. 1.

The densities of methanol solutions and the calculated ϕ_v of Bu_4NBr, $NaBPh_4$, Ph_4PCl, Ph_4AsCl, and Ph_3CH are reported in Table 2.

The parameters ϕ_v^0 and B_v of eq. 1 for the aqueous solutions are given in Table 3 along with ϕ_v^0 of the solutes in methanol.

Specific heats (cal K^{-1} g^{-1}) are readily obtained from the relative increment of the volumetric specific heats ($\Delta\sigma/\sigma_0$ cal K^{-1} cm^{-3}) using the densities of the solution (d) and that of the solvent (d_0):

$$[2] \qquad \frac{c_p}{c_p^0} = \left(1 + \frac{\Delta\sigma}{\sigma_0}\right)\frac{d_0}{d}$$

[3]Density of H_2O taken from ref. 16; density of methanol and hexane measured using a buoyancy densitometer.

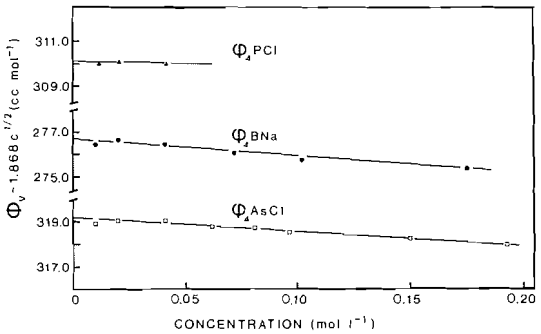

FIG. 1. Apparent molal volumes of $NaBPh_4$, Ph_4PCl, and Ph_4AsCl in water at 25 °C, corrected for the Debye–Hückel limiting slope.

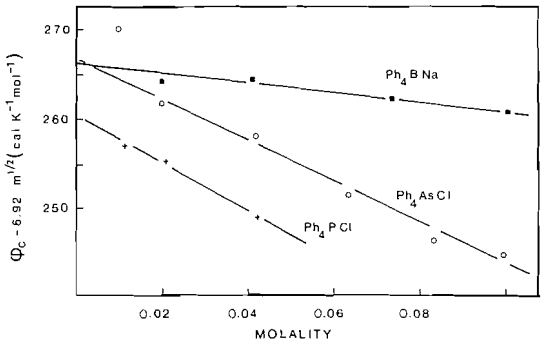

FIG. 2. Apparent molal heat capacities of aqueous $NaBPh_4$, Ph_4PCl, and Ph_4AsCl at 25 °C, corrected for the Debye–Hückel limiting slope.

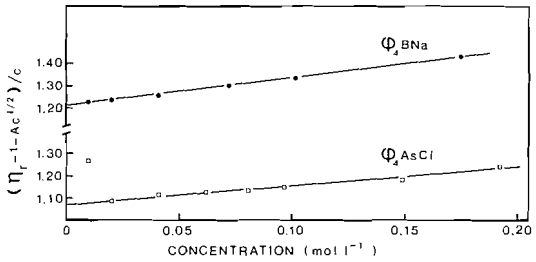

FIG. 3. Changes in the relative viscosity of aqueous solutions of $NaBPh_4$ and Ph_4AsCl corrected for long range coulombic forces.

The apparent molal heat capacities, ϕ_c, are then calculated in the usual way:

$$[3] \qquad \phi_c = Mc_p + 1000\,\frac{(c_p - c_0^0)}{m}$$

where M is the formula weight of the solute. The specific heats of the solvents used were taken as: water, 0.99888; methanol, 0.6056; hexane, 0.54220 cal K^{-1} g^{-1}.[4]

The calculated ϕ_c's of aqueous $NaBPh_4$, Ph_4PCl, and Ph_4AsCl were fitted to the equation

$$[4] \qquad \phi_c = \phi_c^0 + A_c m^{1/2} + B_c m$$

where A_c can be evaluated as 6.92 for ϕ_c given in cal K^{-1} mol^{-1} (26). For solutions in MeOH, the magnitude of A_c is not available and ϕ_c^0 was estimated from a plot of ϕ_c *vs.* m. The values of $\Delta\sigma/\sigma_0$ and ϕ_c for aqueous systems are given in Table 1, and in Table 2 for the other solvent systems; the derived ϕ_c^0's and B_c's are reported in Table 3. Figure 2 shows $(\phi_c - 6.92\,m^{1/2})$ plotted against m for the above salts in aqueous solutions.

Data for volume and heat capacity of Ph_3CH at low concentration in MeOH and hexane are included in Table 2, along with the heat capacity of aqueous benzene. For the latter, the results were obtained at saturation concentration and in both cases the concentration dependence was assumed negligible.

The apparent molal volumes of benzene was taken as 83.2 cm^3 mol^{-1} (1) and its ϕ_c was determined as 132 ± 3 cal K^{-1} mol^{-1}, in close agreement with that calculated from the $\Delta\bar{C}_p$ of solution measured by Franks *et al.* (27): 129 cal K^{-1} mol^{-1}.[5]

The viscosity of aqueous solutions of $NaBPh_4$ and Ph_4AsCl were fitted to the equation:

$$[5] \qquad \frac{\eta}{\eta_0} = 1 + A_\eta c^{1/2} + B_\eta c + D_\eta c^2$$

The data are shown on Fig. 3 where $(\eta/\eta_0 - 1 - Ac^{1/2})/c$ is plotted against c (15). The B_η and D_η coefficients are obtained from this plot though, for the present discussion, only B_η is used (Table 3).[6] The A_η coefficients required to subtract the effect of the long-range coulombic forces on the viscosity (24) were calculated from the conductance data (24, 28, 29).

Uncertainties

The uncertainties of the various ϕ_v^0 and ϕ_c^0 data were estimated as follows: ϕ_v^0 in aqueous

[4]Data for H_2O taken from ref. 25; data for methanol and hexane interpolated from values reported in ref. 45.

[5]The specific heat of liquid benzene was taken as 0.4178 cal K^{-1} g^{-1} (ref. 46).

[6]Though these coefficients are known to account for solute–solute interactions, in the R_4NX and alkali halides series they have no simple interpretation; see ref. 20.

* $\bar{V}^0 = \phi_v^0$, $\bar{C}_p^0 = \phi_c^0$; for the $\bar{C}_p^0$(ion) the first value given was obtained from an ionic scale proposed by Noyes (30); the other values follow from a scale suggested by Criss and Cobble (31) (see text).

solutions, ± 0.1 cm^3 mol^{-1}; in methanol solutions, ± 1 cm^3 mol^{-1}; ϕ_c^0 in aqueous solutions, ± 1 cal K^{-1} mol^{-1}; in methanol solutions, $\pm$ 5 cal K^{-1} mol^{-1}. Data obtained in *n*-hexane bear the same uncertainty as those obtained for solutions in methanol. The uncertainty on B_η is ± 0.01 l mol^{-1}. For the data on aqueous solutions, the error assigned to the intercepts and slopes was the calculated standard deviations. For solutions in methanol, the uncertainties reported were estimated from the extrema of the graphical intercepts, taking into account the standard deviation in a series of measurements at each concentration.

Ionic Values

The purpose of this work being to compare the properties of quaternary ions, ionic contributions to the infinite dilution properties are most appropriate. Table 4 lists various ionic properties to be used in the following discussion; the values reported are those which could be estimated with reasonable certainty. For ionic ϕ_c^0 values, two widely different scales have been proposed so the results obtained by the two methods are included in Table 4.

The individual ionic volumes are based on the scale determined by Conway *et al.* (21) which gives $\bar{V}^0$ $(H^+) = -5.5$ cm^3 mol^{-1}. Although other means of estimating $\bar{V}^0$ (ions) have been proposed (32, 33), the differences in the various scales only amount to 1 or 2 cm^3 mol^{-1}.

In methanol, $\bar{V}^0$ (Br^-) has also been obtained by Conway's method using data from Padova and Abrahamer (18), *i.e.* plotting $\bar{V}^0(R_4NBr)$ against number of carbon atoms of the cations. $\bar{V}^0(Br^-)$ was found as 19 ± 5 cm^3 mol^{-1} which compared reasonably well with 16.6 cm^3 mol^{-1} obtained by Millero (35) using a different method. For the present purpose, the former value is used throughout.

Ionic contributions to $\bar{C}_p^0$ of electrolytes have been assigned following two methods or assumptions. The ionic scale of $\bar{C}_p^0$ tabulated by Noyes (30) assumes that $\bar{C}_p^0(K^+) = \bar{C}_p^0(F^-)$, which gives $\bar{C}_p^0(H^+) = -14.5$ cal K^{-1} mol^{-1}. It is now rather well established that the structure-breaking effects of the larger alkali and halide ions contribute significantly to their $\bar{C}_p^0$ in water (19); however there is no way of ensuring that the overall structural effects around F^- and K^+ should lead to identical contributions to $\bar{C}_p^0$. From a "correspondence principle", Criss and Cobble (31) derived a scale of ionic $\bar{C}_p^0$ from which $\bar{C}_p^0(H^+) = 28$ cal K^{-1} mol^{-1}. On the latter scale, all halide ions have negative $\bar{C}_p^0$ while those of the alkali metal ions are all positive. In view of the known structure-breaking influences of both the larger anions and cations, *e.g.*, I^-, Cs^+, such different values seem unacceptable.

It should be mentioned that a plot of $\bar{C}_p^0(R_4NBr$, $R = Me \rightarrow Bu)$ *vs.* formula weight of cation (19) is nearly linear and, upon extrapolation to zero cation mass, gives $\bar{C}_p^0(Br^-) = -65 \pm 10$ cal K^{-1} mol^{-1}; on this scale, $\bar{C}_p^0(H^+) = 31$ cal K^{-1} mol^{-1}. However good the agreement with the estimate of Criss and

Cobble (31), there is reason to expect that the extrapolation procedure used for $\bar{V}^0$ (21) will not be valid for $\bar{C}_p^0$: structure-making ions such as Bu_4N^+ will increase $\bar{C}_p^0$, whereas structure-breaking ions such as Me_4N^+ will decrease $\bar{C}_p^0$ (19, 34); these combined effects will lead to an extrapolated $\bar{C}_p^0(Br^-)$ being much too negative. Since none of these scales of $\bar{C}_p^0$ can, at present, be considered reliable, we included in Table 4 the $\bar{C}_p^0$ of the quaternary ions computed from both the Noyes assumption and the correspondence principle.

The ionic contributions to the B_η coefficients, given in Table 4, are based on Kaminsky's method of separation (12) which yields $B_\eta(Br^-) = -0.04$; other estimates of ionic B_η have been shown to be in good agreement with the one used here (20). The Stokes radii were taken from the literature as calculated from limiting ionic conductances (21, 28, 29). Most of the individual ionic values in aqueous solutions are collected on Fig. 4 where we have plotted the ionic B_η, $\bar{V}^0$, and $\bar{C}_p^0$ (two sets) against the formula weight of the quaternary ions.

Nonelectrolytes

Together with the results given in previous tables, additional data for nonelectrolytes in water were also found desirable. The apparent molal volume of butane in water was extrapolated from data for methane, ethane, and propane (1) which gave $\bar{V}^0(\text{butane}) = 82\,\text{cm}^3\,\text{mol}^{-1}$. The apparent molal heat capacity of butane was calculated as $125._3$ cal K^{-1} mol^{-1} from the $\Delta\bar{C}_p$ of solution measured by Kresheck *et al.* (36).[7]

Discussion

In the following sections we will attempt to bring forward the aspects of the above results which, as in the case of previous spectral investigations (3, 7), can help to establish specific solvation behavior among the various quaternary ions studied.

(*a*) *Effective Ionic Sizes*

The interpretation of differences in the properties of the hydrophobic ions studied first requires an examination of their relative sizes

[7]The specific heat of butane was taken as 0.40261 cal $K^{-1}g^{-1}$ (ref. 47). The correction from 1 atm. to 1 mm Hg required to compare with values for benzene was found negligible.

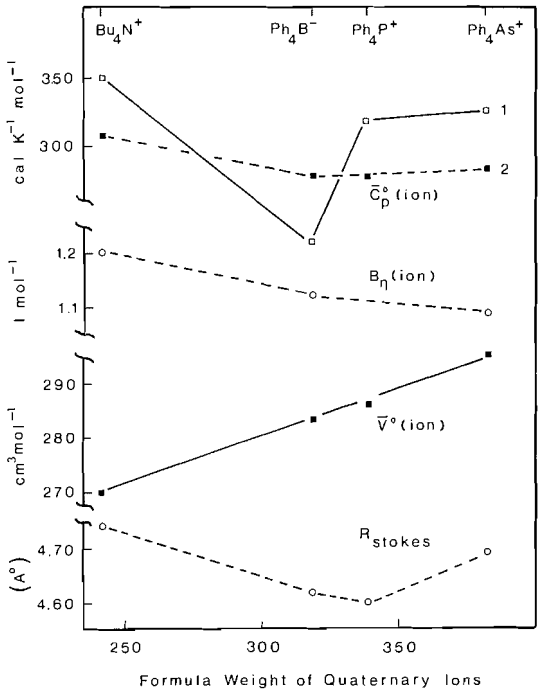

FIG. 4. Estimated ionic contributions to the viscosity B_η coefficients and partial molal volumes and heat capacities at infinite dilution ($\bar{V}^0$ and $\bar{C}_p^0$) and 25 °C. The two sets of data for $\bar{C}_p^0$ were obtained by different methods of assignment: (*1*) —, Criss and Cobble (31); (*2*) ---, Noyes (30).

in solution, and of the properties most directly related to the size. As can be seen from Fig. 4, a comparison of r_s, B_η, and $\bar{V}^0$ clearly shows irregularities in the behavior of the various ions studied. In the tetraphenyl series, the radii of the ions should increase as the size of the central atom, X, increases through X = B, P, As; as can be seen from Table 4, the Stokes radii agree reasonably with such an order and so does $\bar{V}^0$ for these ions in water (Fig. 4).

The same trend does not, however, carry on for Bu_4N^+ which has a larger r_s and a smaller $\bar{V}^0$, in spite of the similar $\bar{V}^0$(aq) of butane and benzene. To explain this observation we can adopt the proposed view (for further discussion and references, see ref. 37) that, while the alkyl groups stabilize hydrogen-bonded networks in water (increasing local viscosity and thus r_s), they occupy some of the void space in these networks (decreasing $\bar{V}^0$). The comparisons of $\bar{V}^0$ and r_s then suggests that the aryl substituted ions do not perform structure stabilization to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the same extent or in the same fashion as Bu_4N^+ does.[8]

Effective radii, such as r_s, are usually a combined measure of the particle size and of the effect of the particle on the surrounding solvent (solute–solvent interactions and structural effects). Similarly, viscosity B_η coefficients include both a size effect and a contribution arising from changes in the local viscosity around the solutes (24, 38). Therefore, r_s and B_η should follow the same pattern in the series of ions studied here. Indeed, B_η is largest for Bu_4N^+ (Fig. 4); however, for BPh_4^- and Ph_4As^+, the relative magnitude of B_η is opposite to that observed for r_s. Though the difference is small, this suggests different solute–solvent interactions for BPh_4^- and Ph_4As^+, which is consistent with previous spectral studies of these ions (3, 7).

Desnoyers and Perron (20) have used the deviation from the Einstein hydrodynamic model, *i.e.* $B_\eta = 0.0025V$ (24), as a criterion of overall structural influence of a solute, when the hydrodynamic volume is replaced by $\bar{V}^0$. For the ions examined, $(B_\eta - 0.0025\bar{V}^0)$ is found as 0.52, 0.41, and 0.35 for Bu_4N^+, BPh_4^-, and Ph_4As^+, respectively. These large positive deviations suggest that all of these ions have overall structure-making influences, decreasing in the order Bu_4N^+, BPh_4^-, Ph_4As^+.

(b) $\bar{V}^0$ and $\bar{C}_p^0$ in Water

As can be seen from Fig. 4, the relation between $\bar{V}^0$ of the quaternary ions in aqueous solution and their molecular weight is very nearly linear. As mentioned earlier, the larger volume of BPh_4^- compared to Bu_4N^+ can be the result of packing effects. On the other hand, the increase in $\bar{V}^0$ of the tetraphenyl ions with formula weight is of the same order as the increase in volume of the central atom, calculated from the covalent radii. Thus, for these salts, little can be learned on specific solute–solvent interactions from the $\bar{V}^0$ data in water only.

In comparing the $\bar{C}_p^0$ values of the quaternary ions in the series shown on Fig. 4, an additional problem arises because of the uncertainty on the intrinsic heat capacity of the organic ions. Specific heat data are not available for all the salts studied here, but the molar heat capacities of solid Bu_4NBr and $NaBPh_4$ have been estimated as 114 and 102 cal K^{-1} mol^{-1}.[9] Thus, the corresponding $\Delta\bar{C}_p^0$ (*i.e.*, $\bar{C}_p^0 - \bar{C}_p^0(s)$) would be 175 and 164 cal K^{-1} mol^{-1}. Since the water structure-breaking effects of ions contributes a negative quantity to $\bar{C}_p^0$ (19), and since Br^- consistently appears as a more effective structure breaker than Na^+, ionic values of $\Delta\bar{C}_p^0$ for Bu_4N^+ and BPh_4^- would be even more different. In terms of the current interpretation of the large positive $\Delta\bar{C}_p^0$ (34), all the quaternary ions studied here appear to promote water structure to a high degree. From either $\bar{C}_p^0$ (ionic) or $\Delta\bar{C}_p^0$ (salts), a clear distinction is seen between BPh_4^- and Bu_4N^+, the latter being a more efficient structure promoter. Unfortunately, from the $\bar{C}_p^0$ alone, nothing can be inferred on the relative hydration of the three aryl substituted ions. Following the above discussion on ionic $\bar{C}_p^0$ scales, one can anticipate that true ionic $\bar{C}_p^0$ will also reflect specific solvation effects amongst the tetraphenyl ions. On the other hand, the small degree of specificity of $\bar{C}_p^0$ towards the different ions studied here may be a coincidence, similar to that observed with the partial molal expansitivities (ϕ_E^0). Millero (5) has shown that the temperature coefficient of ϕ_E^0's has opposite sign for Bu_4NCl and Ph_4AsCl (or $NaBPh_4$), though at 25 °C, ϕ_E^0 for these salts are all of similar magnitude. If the same is true for the partial molal heat capacities, then a study of the temperature coefficient of $\bar{C}_p^0$ would help elucidate the specific solvation effects.

(c) Additivity of Side Chain Contributions to $\bar{V}^0$ and $\bar{C}_p^0$ in Water

The additivity of chain contributions to the heats of transfer $R_{4-n}NH_n^+$ has been thoroughly investigated in water and in aprotic solvents (39). There, as with other properties, (*e.g.* salting-in of benzene by the quaternary salts (40)), additivity of group contributions to the properties of aqueous solutes is not found. In the present case, a different kind of additivity can be examined if we compare the properties ($\bar{V}^0$, $\bar{C}_p^0$) of the aqueous hydrocarbons (side chains) and the quaternary ions. We can define

[8]Compared to *e.g.* Ph_4P^+, the r_s of Bu_4N^+ is expected to be smaller if folding of the butyl chains is significant.

[9]The molar heat capacity of solid $NaBPh_4$ had been estimated as 102 ± 2 cal K^{-1} mol^{-1} (22). From the data in ref. 34, we can calculate the heat capacity of solid Bu_4NBr as 114 cal K^{-1} mol^{-1}.

TABLE 5. Non-additivity of side-chain contributions to $\bar{V}^0$ and $\bar{C}_p^0$ in aqueous solutions, as defined in eq. 6

	$\delta\bar{V}^0$ ($cm^3\ mol^{-1}$)	$\delta\bar{V}^0/\bar{V}^0$	$*\delta\bar{C}_p^0$ (cal K^{-1} mol^{-1})	$\delta\bar{C}_p^0/\bar{C}_p^0$
Bu_4N^+	58	0.22	197	0.65
BPh_4^-	49	0.17	253	0.92
Ph_4P^+	47	0.16	253	0.92
Ph_4As^+	37	0.13	248	0.89

*Using the ionic scale of Noyes (30).

the non-additivity for property X as $\delta\bar{X}^0$ where

[6] $\delta\bar{X}^0 = 4\bar{X}^0$(hydrocarbon) $- \bar{X}^0$(quaternary ion)

where $\bar{X}^0$ is a thermodynamic property for which the hydrocarbon and the quaternary ions have identical reference states. $\delta\bar{V}^0$ and $\delta\bar{C}_p^0$ were calculated from $\bar{V}^0$ and $\bar{C}_p^0$ for several quaternary ions in water and the data on aqueous butane and benzene solutions. The results are shown in Table 5.

As in previous studies mentioned above the non-additivity of side chain contributions is marked, and much more important for $\bar{C}_p^0$ than for $\bar{V}^0$. In spite of the additional volume of the central atom, $\delta\bar{V}^0$ is positive and must result from interference of the substituents. $\delta\bar{V}^0$ is maximum for Bu_4N^+ and decreases with formula weight of the quaternary ions; at least for the tetraphenyl ions, this might be expected since side-chain interference should decrease as the size of the central atom increases. (Using data in the literature (1, 21) one finds that in the series R_4N^+ (R = Me → Bu), $\delta\bar{V}^0$ is independent of chain length for R > Me; this suggests that folding of the longer side chains, *e.g.* Bu, does not contribute significantly to the larger $\delta\bar{V}^0$ observed for Bu_4N^+.)

The comparison of the various $\delta\bar{C}_p^0$ is more rewarding; the data in Table 5 confirm that $\bar{C}_p^0$ is much more sensitive than $\bar{V}^0$ to changes in solute–solvent interactions and packing effects.[10] Because of the uncertainty in the assignments of ionic $\bar{C}_p^0$, no conclusion can be firmly drawn from a comparison among the tetraphenyl ions, but $\delta\bar{C}_p^0$ shows a pronounced difference between these and Bu_4N^+. In the simplest picture, one can say that Bu_4N^+ is the one that retains, to the largest extent, the hydrophobic (structure-making) character of the hydrocarbon substituents.

[10] $\delta\bar{C}_p^0$ also contains a contribution from the normal modes of the quaternary ion; however, it seems reasonable to assume that these will be similar in all the ions considered here.

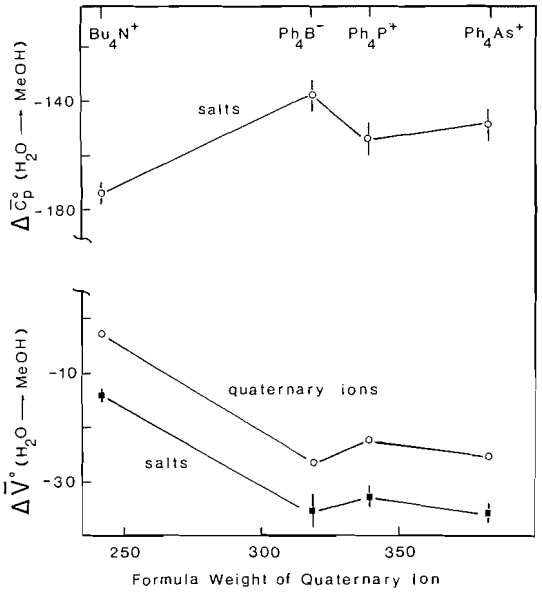

FIG. 5. Change in $\bar{V}^0$ and $\bar{C}_p^0$ of the quaternary ions (or salts) for ($H_2O \rightarrow CH_3OH$) transfer at 25 °C.

(*d*) *$H_2O \rightarrow CH_3OH$ Transfers*

The change in apparent molal volumes and heat capacities observed when the ions are transferred from water to methanol should provide some clues to the relative importance of the water structure stabilization by the organic ions and the solute–solvent interactions particularly of the type Ph · · · H—O—R. In methanol, the effect of large organic ions on the solvent structure has been shown to be much less than in water (42); on the other hand, solute–solvent interactions involving the —OH group should be possible to similar degrees in both solvents. Figure 5 shows $\Delta\bar{V}^0(H_2O \rightarrow CH_3OH)$ for quaternary ions and their salts and $\Delta\bar{C}_p^0$ ($H_2O \rightarrow CH_3OH$) for the salts only, since we have no reliable means of assigning ionic values to $\bar{C}_p^0$(MeOH). Clearly the transfer $\Delta\bar{V}^0$ and $\Delta\bar{C}_p^0$ are inversely related, and the distinction between Bu_4N^+ and the tetraphenyl salts is neatly established; also, some discrimination between BPh_4^-, Ph_4P^+, and Ph_4As^+ now seems apparent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

To estimate the importance of the Ph · · · H—O—R interactions with the tetraphenyl ions in methanol, we can examine the results obtained with Ph_3CH (Table 2); as a rough approximation to the behavior of a neutral tetraphenyl molecule, we multiply the data for Ph_3CH throughout by 4/3.[11] For this hypothetical Ph_4C molecule, the $\Delta\bar{V}^0$(*n*-hexane → MeOH) is found as $+3\ cm^3\ mol^{-1}$ and the $\Delta\bar{C}_p^0$(*n*-hexane → MeOH) as $+30\ cal\ K^{-1}\ mol^{-1}$. Thus, for such a molecule, hydrogen-bonding type interactions of —OH groups with the phenyl rings do not appear as a major contributor to $\bar{V}^0$ and $\bar{C}_p^0$ in methanol. A comparison of $\frac{4}{3}\bar{V}^0(Ph_3CH)$ and $\bar{V}^0$(tetraphenyl ions) in methanol (Table 4) would suggest that the charging process decreases $\bar{V}^0$ significantly; the same is true for $\bar{C}_p^0$ unless $\bar{C}_p^0(Na^+)$ and $\bar{C}_p^0(Cl^-)$ are both strongly negative in methanol.

The $(H_2O \rightarrow CH_3OH)$ transfers of the salts studied are readily interpreted, at least for the trends observed. $\Delta\bar{C}_p^0(H_2O \rightarrow CH_3OH)$ is largest for Bu_4NBr, as expected if Bu_4N^+ is the most hydrophobic: contributions arising from the structure-promoting phenomenon will be much weaker in MeOH (42). On the other hand, $NaBPh_4$ has the smallest $\Delta\bar{C}_p^0(H_2O \rightarrow CH_3OH)$ which is also readily understood if the hydrophobic character of BPh_4^- is less than that of the other ions. An equivalent statement would be that the solute–solvent interactions of BPh_4^- in methanol more closely resemble those in water.

The $\Delta\bar{V}^0(H_2O \rightarrow CH_3OH)$ for Bu_4N^+ (Bu_4NBr) is very small, much less than for the tetraphenyl ions. If the $\Delta\bar{V}^0(H_2O \rightarrow CH_3OH)$ was dominated by molecular packing effects, one might expect that the tetraphenyl ions would have a more positive $\bar{V}^0$ in MeOH, *i.e.*, since the aryl chains are not as flexible as the alkyl chains, the larger solvent molecules would lead to more free space around the tetraphenyl ions (see also a discussion by Coetzee and Sharpe (7)). It thus seems logical to infer that in water, there is more free space around the tetraphenyl ions than around Bu_4N^+, which is in agreement with the earlier statement of water structure promotion and void occupancy by the alkyl chains.

[11]This approach is similar to that used by Grunwald *et al.* (41) who compared tetraphenyl methane with BPh_4^- and Ph_4As^+ in dioxane–water mixtures.

Though we believe the differences in $\bar{V}^0$ among the tetraphenyl ions in MeOH to be beyond experimental error, their significance is not readily established.

(e) Concentration Dependences

In aqueous solutions of electrolytes containing large hydrophobic ions, negative deviations to the Debye–Hückel limiting law (DHLL) have often been interpreted on the basis of structural interactions between the hydrophobic ions (37, 43). The observed concentration dependence of ϕ_v in water, corrected for the DHLL, is negative for all the salts studied; the B_v parameter (Table 3) is increasingly negative in the order Ph_4PCl, Ph_4AsCl, $NaBPh_4$, Bu_4NBr. Following the above discussion, it seems unlikely that this situation reflects mainly the order of the hydrophobic character of the organic ions, as for instance, in the series R_4NX where R is changed from Me to Bu (43). Similarly, in aqueous solutions, the observed deviations from the DHLL of ϕ_c are also negative (B_c, Table 3); however, the trend among the B_c coefficients is exactly opposite to that observed with the B_v parameters. On the basis of a structural interaction model, it thus appears that anion–cation structural interactions (37, 43) contribute significantly to the excess volumes and heat capacities, and in different ways for the different salts. More extensive measurements, together with a quantitative account of the size effects (44) should lead to a better understanding of the deviations from a limiting theory of the various excess functions.

Conclusion

The comparative study of the large organic ions Bu_4N^+, BPh_4^-, Ph_4P^+, and Ph_4As^+, using different thermodynamic methods and (water → methanol) transfer properties, illustrates some of the points made in earlier work. Differences in the solvation of alkyl and aryl substituted quaternary ions are emphasized in most of the properties examined. Within the series of tetraphenyl ions, some specific solvation effects are suggested in comparing properties which depend most directly on the size of the solute particles (r_s, $\bar{V}^0$, and B_η) and in $(H_2O \rightarrow CH_3OH)$ transfers.

A comparison of the results for Bu_4N^+ with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

those for the tetraphenyl ions shows consistently that Bu_4N^+ is more hydrophobic than the $Ph_4X^{\pm}$, *i.e.*, in the sense currently employed, water structure promotion by Bu_4N^+ is more extensive than by the others. Also, the results are consistent with the view that occupancy of the void space in water hydrogen-bonded networks by the solute side chains is more effective with aliphatic substituents than aromatic groups.

Among the tetraphenyl ions, mild differences in behavior are observed, particularly in $H_2O \rightarrow CH_3OH$) transfer. However, the discrimination is not nearly as sharp as has been found in spectral studies of solvation (3, 7). It should be remarked, on the other hand, that spectral studies of solvation in which the properties of the protons are examined (*i.e.*, OH stretching frequencies or H chemical shifts) are expected to distinguish more efficiently between anions and cations, if water (or methanol) molecules are oriented differently in each case. The leading contributions to the spectral properties and the thermodynamic properties need not, therefore, result from the same effects, which indeed appears to be the case with the large organic ions studied here.

Financial support from the National Research Council of Canada through grants to C.J. and J.E.D. is gratefully acknowledged. The extensive help of Mr. P. Picker with many experimental problems is acknowledged with pleasure. We also acknowledge the help of Professor A. Hade of the Université du Québec, Montreal, who kindly lent us a Digital Densitometer.

Rearrangement Studies with ^{14}C. XXXVII. The Treatment of 1-^{14}C-1-Chlorobutane with Aluminum Chloride

C. C. Lee and I. Y. Zea Ponce

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 3, 1971[1]

After treatment of 1-^{14}C-1-chlorobutane with anhydrous $AlCl_3$ at 20° for 20, 60, or 120 min, the isomeric chlorobutanes recovered were mainly *n*-butyl and *sec*-butyl, with small amounts of *t*-butyl and *iso*-butyl chlorides. Degradations showed only 0.2–0.4% rearrangement of the ^{14}C-label from C-1 to -2 in the recovered ^{14}C-1-chlorobutane, while extensive scramblings over all four carbon positions were noted for the recovered ^{14}C-2-chlorobutane. Successive 1,2-hydride shifts interconverting the 2-butyl cations or ion-pairs were found to play a major role in accounting for the scrambling data. It was concluded that processes involving protonated methylcyclopropanes could not be the main pathway for the rearrangement of the label into C-2 and -3 of the ^{14}C-2-chlorobutane. 1,2-Ethyl followed by 1,2-hydrogen shifts giving rise to encumbered 2-butyl cations with different structural features appeared to be required to explain the ^{14}C-contents in the C-2 and -3 positions.

Le traitement du ^{14}C-chloro-1 butane par $AlCl_3$ anhydre à 20° pendant 20, 60 et 120 min, conduit aux chlorobutanes isomères dont les principaux sont les chlorures de *n*-butyle et de *sec*-butyle, avec de petites quantités de chlorures de *t*-butyle et d'*iso*-butyle. Les dégradations montrent seulement un réarrangement de 0.2–0.4% du ^{14}C de la position C-1 à -2 dans le ^{14}C-chloro-1 butane retrouvé tandis qu'un mélange important de marquage a été trouvé à travers les quatre carbones dans le ^{14}C-chloro-2 butane final. Les déplacements-1,2 successifs d'hydrure, interconvertissant les cations butyl-2 ou les paires d'ions, jouent un rôle majeur permettant de rendre compte des données de ce mélange. On a conclu que les transformations faisant intervenir les méthylcyclopropanes protonés ne pouvaient être le processus réactionnel principal dans le réarrangement en C-2 et -3 du ^{14}C-chloro-2 butane marqué. Les déplacements-1,2 d'éthyle puis d'hydrogène conduisant à des cations butyl-2 encombrés avec diverses caractéristiques structurales, apparaissent nécessaires pour expliquer les teneurs en ^{14}C sur les positions C-2 et -3. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3179 (1972)

Protonated cyclopropanes as reaction intermediates are of some current interest and much of the work in this area has dealt with unsubstituted protonated cyclopropane, $C_3H_7^+$ (1, 2). Recently, Deno and coworkers (3) have obtained evidence suggesting a role for protonated cyclopropane intermediates in the reaction of D_2SO_4 with suitably substituted cyclopropanes such as cyclopropanecarboxylic acid and its 1-methyl derivative. However, the addition of DCl to methylcyclopropane (4) and the deamination of various *d*-labeled 1-butylamines (5) failed to give any isotopic scrambling data in support of the intermediacy of protonated methylcyclopropane. On the other hand, proton scramblings in the 2-butyl cation observed by n.m.r. (6) and the $HF–SbF_5$ catalyzed isomerization of 1-^{13}C-butane to 2-^{13}C-butane (7) were interpreted as proceeding via protonated methylcyclopropane. In the present work the study on the involvement of protonated cyclopropane intermediates in the treatment of 1-^{14}C-1-chloropropane with $AlCl_3$ (8) was extended to include an investigation of the rearrangements induced by treatment of 1-^{14}C-1-chlorobutane (**1**-Cl-1-^{14}C) with $AlCl_3$ in an attempt to ascertain whether protonated methylcyclopropane intermediates would play a role in the reaction.

Results and Discussion

1-Cl-1-^{14}C (10.0 g) and anhydrous $AlCl_3$ (1.0 g) were stirred at 20° for 20, 60, or 120 min and then quenched by the addition of ice-water. The recovered material was converted to the Grignard reagent and treated with oxygen (9). Inactive *n*-, *sec*-, *t*- and *iso*-butyl alcohols (**1**-OH, **2**-OH, **3**-OH, and **4**-OH, respectively) were added as carriers and the four diluted alcohols were recovered by preparative v.p.c. Isotope dilution calculations gave the relative amounts of these isomeric alcohols derived from the original mixture of butyl chlorides in the recovered product. The results are given in Table 1.

The **1**-OH-^{14}C and **2**-OH-^{14}C, purified by preparative v.p.c., were degraded to give the

iso-BuOH	0.2	0.3	0.3	0.3	0.3	0.6	0.5	0.9	1.2

*Obtained by isotope dilution calculations; the ^{14}C-activities were determined on the v.p.c. purified *t*-BuOH and on the α-naphthylurethanes of the other alcohols. The lowest activities measured were about 1100 c.p.m./mmol for the diluted *iso*-BuOH from the experiments with 60 min contact time. Different batches of $AlCl_3$ were used for the 60 min and for the 20 and 120 min experiments.
†The **1**-Cl-1-^{14}C used as reactant was contaminated by about 5–10% diethyl ether, which apparently deactivated the catalyst.

isotopic distributions in the butyl group. **1**-OH-^{14}C was oxidized to butyric acid, converted to 1-propylamine, and then oxidized to propionic acid (10), which in turn was degraded by conversion to acetic acid and then to methylamine (11). The **2**-OH-^{14}C was treated with Br_2–NaOH to give CBr_4 and propionic acid (9), the latter again being degraded to acetic acid and methylamine. The activities of appropriate solid derivatives of the degradation products gave the ^{14}C-distributions. The results indicate that for the recovered 1-butyl product, there was only about 0.2–0.4% rearrangement of the ^{14}C-label from C-1 to -2, and essentially none to C-3 and -4. Extensive scrambling of the label was found in the **2**-OH-^{14}C, the data being summarized in Table 2.

In previous studies on the deamination of various *d*-labeled 1-butylamines (5, 12), no isotope position rearrangement was found in the 1-butanol product and this was interpreted as evidence eliminating the possibility of a 1,2-ethyl shift. The presently observed 0.2–0.4% rearrangement of the ^{14}C-label from C-1 to -2 in the 1-butyl product, though small, is believed to be real since the activities observed for C-2 were beyond experimental errors. Also in the deamination studies (5), it was noted that the only isotope position isomers observed in the 2-butanol product were attributable to successive 1,2-hydride shifts involving interconversions between 2-butyl cations. Similarly, in earlier work with ^{14}C-labeled 2-butyl systems (9, 13), only 1,2-hydride shifts interconverting the 2-butyl cations were reported. Such processes operating in the present system would only scramble the ^{14}C-label over the C-1 and -4 positions of the recovered **2**-Cl-^{14}C. The rearrangements of the ^{14}C-label into C-2 and -3 in the 2-butyl product (Table 2), which have not been observed previously, would require some explanation other than successive 1,2-hydride shifts.

A possible route involving protonated methylcyclopropane intermediates could lead to the scrambling of the ^{14}C-label into C-2 and -3 of the **2**-Cl-^{14}C. Much of the recent discussion on protonated cyclopropanes has been concerned with edge- and corner-protonations (1, 2, 8, 14). Equilibration of protonated methylcyclopropanes could proceed via edge-protonated species **5***a–c* and corner-protonated species **6***a–c*. **2**-Cl-3-^{14}C could be formed from **5***b* or **6***b*, and under the reaction conditions, **2**-Cl-3-^{14}C could give rise to **2**-Cl-2-^{14}C. Such processes would lead to the expectation that shorter contact times between the reactants should give more **2**-Cl-3-^{14}C than **2**-Cl-2-^{14}C, but this is opposite to what was observed (Table 2).

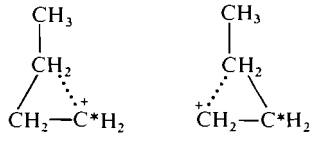
Pertinent to the above representation of protonated methylcyclopropanes as **5***a–c* or **6***a–c* are the recently reported calculations of Radom and coworkers (15) on the $C_3H_7^+$ cations. These workers concluded that besides the stable 2-propyl cation, a "methyl eclipsed 1-propyl cation" with distorted geometry, which could be regarded as a distorted corner-protonated cyclopropane (the term "partially-bridged" structure was also used in a private communication from Professor P. v. R. Schleyer), may well be the only other potential minimum in the complete $C_3H_7^+$ surface. If partially-bridged structures **7***a* and *b* were stable species, equilibrating through **6***a* as a transition state, 1,3-hydride shifts could give rise to **2**-Cl-4-^{14}C and

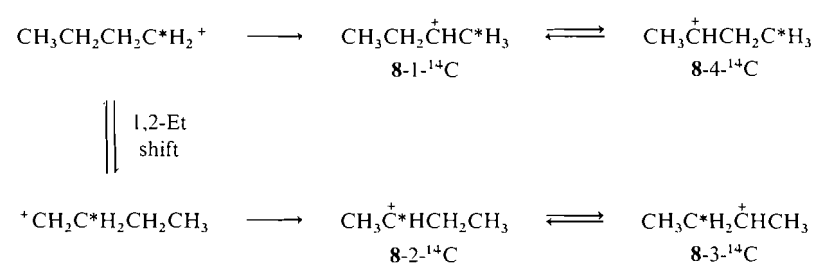


7a *7b*

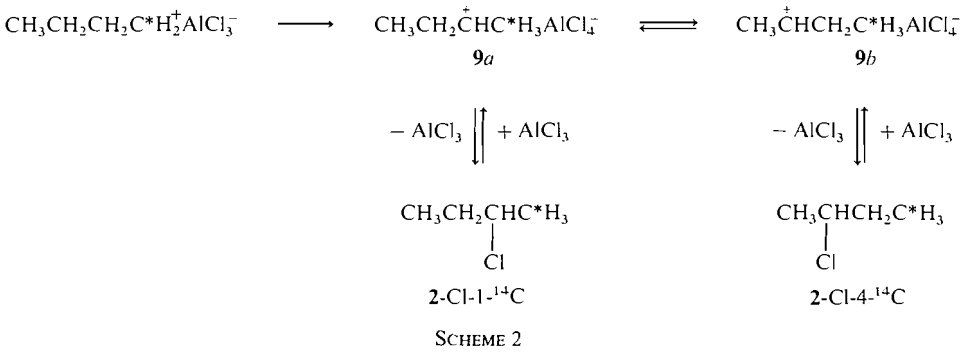
2-Cl-3-^{14}C, respectively, from **7***a* and *b* via **5***a* and *b* as transition states. As pointed out in the preceding paragraph, such a route would also be expected to give more **2**-Cl-3-^{14}C than **2**-Cl-2-^{14}C with shorter contact time between the reactants, and this does not agree with the observed results.

The above considerations thus suggest that protonated methylcyclopropane intermediates would not likely be involved in the main pathway leading to the rearrangement of the isotopic label into the C-2 and -3 positions of the recovered **2**-Cl-^{14}C. However, the possibility of minor involvements of protonated methylcyclopropanes could not be unequivocally eliminated. The formation of *i*-BuCl (**4**-Cl) (Table 1) via only classical ions is unlikely as this would require the unfavorable rearrangement of *sec*-butyl to isobutyl cations. Bimolecular reactions followed by rearrangement and fragmentation (16, 17) conceivably could give rise to *t*-BuCl (**3**-Cl) and *i*-BuCl (**4**-Cl), with **3**-Cl dominating. Alternatively, **4**-Cl could be derived from protonated methylcyclopropanes **5***c* or **6***b* and *c*, and subsequent effects of the $AlCl_3$ would convert much of the **4**-Cl to **3**-Cl. It is of interest to note that more than a decade ago, Roberts and coworkers (18, 19) had observed that at relatively high temperatures of 80 or 100°, $AlCl_3$ could induce the isomerization of *sec*-butylbenzene to isobutylbenzene, and these workers have attributed the process to the intervention of an intermediate π-complex between the benzene ring and a methyl-bridged cation (corner-protonated methylcyclopropane) analogous to **6***b* and *c*.

An alternative route for the scrambling of the ^{14}C-label into C-2 and -3 of the recovered **2**-Cl-^{14}C could involve 1,2-shifts in the classical 1-butyl and 2-butyl cations. A simple scheme might be as depicted in Scheme 1. A significant role is assigned to the 1,2-ethyl shift, and if product formation from the primary 1-butyl cation to give **1**-Cl were relatively slow compared to its rearrangement to the 2-butyl cation, only very small amounts of **1**-Cl-2-^{14}C would be formed as was observed. The processes would predict more **2**-Cl-2-^{14}C than **2**-Cl-3-^{14}C with shorter contact time as was also observed. Such a scheme, however, is not adequate as a complete explanation of the data in Table 2. If the ions were free and unencumbered as depicted, and if the ^{14}C isotope effects were relatively minor and negligible, **8**-1-^{14}C and **8**-2-^{14}C should behave in the same way as they differ only in the location of the isotopic label. Therefore, the scrambling between C-1 and -4 should be related



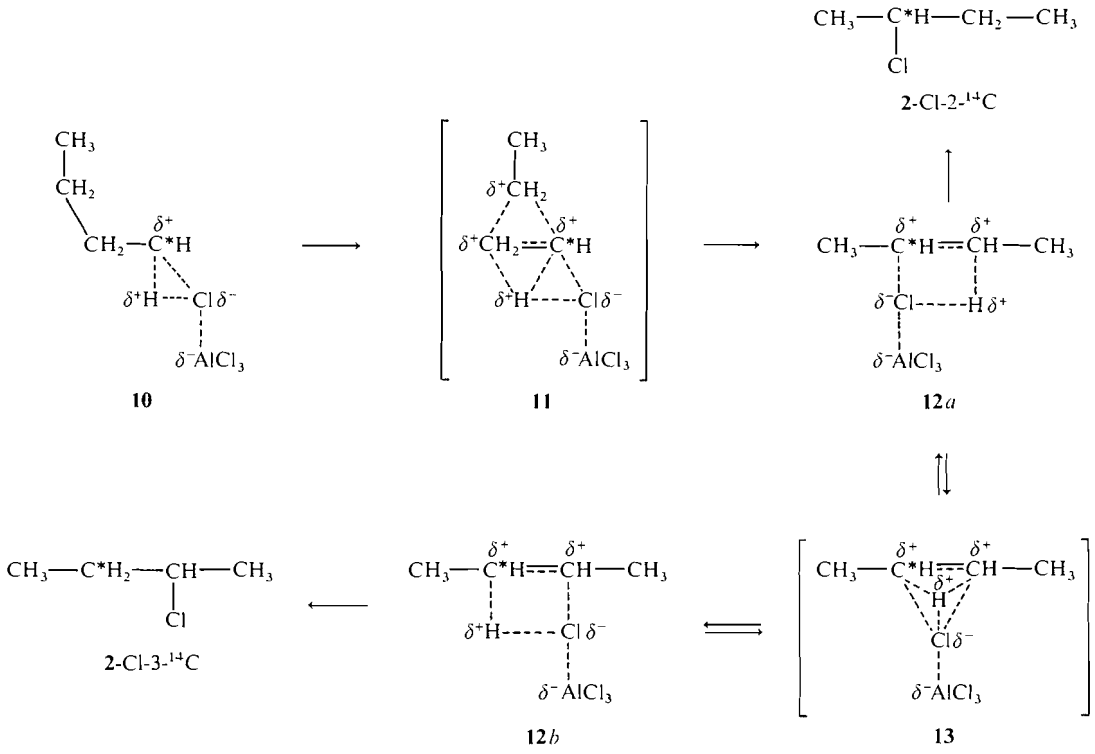
SCHEME 1



SCHEME 2

to the scrambling between C-2 and -3 so that, in a given experiment, the ratio of **2**-Cl-1-^{14}C to **2**-Cl-4-^{14}C must be equal to the ratio of **2**-Cl-2-^{14}C to **2**-Cl-3-^{14}C, and this was not observed. From Table 2, it can be seen that in the recovered **2**-Cl-^{14}C, the ratio of the ^{14}C-contents for C-2/C-3 is greater than that for C-1/C-4 in the experiments with contact times of 20 or 60 min. On the other hand, with a longer contact time of 120 min, apparently complete equilibration between C-2 and -3 has been achieved, while the ^{14}C ratio for C-1/C-4 is still greater than unity. To account for these differences, modifications of the simple classical ion scheme appear to be necessary.

Firstly, there must be a fast process leading from reactant to **2**-Cl-1-^{14}C and **2**-Cl-4-^{14}C, and which could eventually equilibrate these two isotope position isomers. Successive 1,2-hydride shifts, probably involving ion-pairs which gave the final product only upon quenching, as depicted in Scheme 2, would be adequate in



SCHEME 3

For personal use only.

accounting for this scrambling of the label between C-1 and -4.

Secondly, there must be another process, fairly fast but slower than the first one, leading from reactant to **2**-Cl-2-^{14}C and **2**-Cl-3-^{14}C. Initially, this process would give mostly **2**-Cl-2-^{14}C with little, if any, **2**-Cl-3-^{14}C, but eventually, **2**-Cl-2-^{14}C would equilibrate with **2**-Cl-3-^{14}C and this would have to take place at a rate faster than the equilibration between **2**-Cl-1-^{14}C and **2**-Cl-4-^{14}C in order to account for the results observed with a contact time of 120 min (Table 2). Thus the intermediates responsible for the formation of **2**-Cl-2-^{14}C and **2**-Cl-3-^{14}C would have to be different structurally, and hence behave differently, from ion-pairs **9***a* and *b*. A possible representation of these intermediate species with different structural features could be encumbered butyl cations, as depicted in Scheme 3, involved in the 1,2-ethyl and the subsequent 1,2-hydrogen shifts.

It might be visualized that under the influence of the $AlCl_3$, stretching of the C—Cl bond of the reactant, **1**-Cl-1-^{14}C, could impart positive characteristics to the C-1 carbon and hydrogen atoms, allowing the chlorine atom to be hydrogen-bonded to give **10**. Ethyl and hydrogen shifts could then occur as shown in Scheme 3, giving rise to **12***a* and *b* with **11** and **13** as transition states. Formation of the products, **2**-Cl-2-^{14}C and **2**-Cl-3-^{14}C, would take place only upon quenching; otherwise, if these isotope position isomers were formed during the reaction, they would behave and equilibrate similarly as **2**-Cl-1-^{14}C and **2**-Cl-4-^{14}C. The essential assumption that **9***a*, *b* and **12***a*, *b* could behave differently would also suggest that these species could undergo side reactions, such as elimination, at different rates. This would provide an explanation for the observation of a lesser percentage of rearrangement of the ^{14}C-label into C-2 and -3 in the experiments with longer contact time, as recorded in Table 2.

Experimental

*1-^{14}C-1-Chlorobutane (**1**-Cl-1-^{14}C)*

The reaction of 1-propylmagnesium chloride with $^{14}CO_2$ to give 1-^{14}C-butyric acid, followed by $LiAlH_4$ reduction to 1-^{14}C-1-butanol and conversion of the latter to 1-^{14}C-1-butyl tosylate (**1**-OTs-1-^{14}C), b.p. 134–135° at 2.5 mm (lit. (20) b.p. 135° at 2.5 mm) were carried out according to standard procedures. Conversion of the **1**-OTs-1-^{14}C to **1**-Cl-1-^{14}C was effected in 75% yield by a displacement reaction with $CaCl_2$ in ethylene glycol in the same manner as previously described for the preparation of 1-^{14}C-1-chloropropane (21). The **1**-Cl-1-^{14}C was purified by preparative v.p.c. using a Pye Automatic Preparative Chromatograph with a 15 ft × 3/8 in. copper column packed with 25% β,β'-oxydipropionitrile on 60/80 mesh chromosorb P. Degradation (see below) of the **1**-Cl-1-^{14}C so obtained gave inactive 1-propylamine, indicating that all of the ^{14}C-label was located at C-1.

*Treatment of **1**-Cl-1-^{14}C with $AlCl_3$*

In a 100-ml round-bottom flask, equipped with magnetic stirrer and reflux condenser, 10.0 g (108 mmol) of **1**-Cl-1-^{14}C and 1.0 g (7.5 mmol) of anhydrous $AlCl_3$ were stirred at 20° for 20, 60, or 120 min. Ice-water was then added. The organic layer was separated, washed successively with 10% NaOH solution and with water, and then dried over anhydrous $MgSO_4$. The recoveries of organic material from the various experiments ranged between 61–71%.

The recovered material was converted to the Grignard reagent and treated with oxygen as previously described (9) to give a mixture of isomeric butyl alcohols. A small sample of this mixture of alcohols was separated by preparative v.p.c. (Aerograph Autoprep with a 10 ft × 3/8 in. copper column packed with 20% Carbowax 20 M on 60/80 mesh chromosorb P) to give pure, undiluted **1**-OH-^{14}C whose specific activity would be equal to the specific activity of any one of the four undiluted, isomeric butyl alcohols. To another small sample of the mixture of alcohols (usually about 0.4–0.5 g), appropriate amounts of ordinary *n*-, *sec*-, *t*-, and *iso*-butyl alcohols (**1**-OH, **2**-OH, **3**-OH, and **4**-OH, respectively) were added as carriers and pure samples of the four diluted alcohols were recovered by preparative v.p.c. using the Carbowax column. Knowing the weights of the carriers and the specific activities of the undiluted and diluted alcohols, the yields of the undiluted alcohols were calculated. The following actual data from experiment 2 will serve as an illustration of the calculations.

The specific activity of the isomeric butyl alcohols before isotopic dilution, as measured by the α-naphthylurethane of the v.p.c. purified, undiluted **1**-OH-^{14}C, was 726 000 c.p.m./mmol.

The weights of inactive **1**-OH, **2**-OH, **3**-OH, and **4**-OH added as carriers were, respectively, 501.0, 690.7, 624.6, and 662.4 mg, and the specific activities of these four diluted alcohols (measured as the α-naphthylurethanes except for 3-OH) were, respectively, 231 900, 83 600, 4740, and 1140 c.p.m./mmol.

If x = the yield of **1**-OH-^{14}C in mg, then (726 000 c.p.m./mmol) (x/74.12 mmol) = (231 900 c.p.m./mmol)[(x + 501.0)/74.12 mmol]; x = 234 mg.

Similarly, the yields of **2**-OH-^{14}C, **3**-OH-^{14}C, and **4**-OH-^{14}C were calculated to be 89.8, 4.1 and 1.0 mg, respectively.

Hence for experiment 2, the relative percentage yields of **1**-OH-^{14}C, **2**-OH-^{14}C, **3**-OH-^{14}C, and **4**-OH-^{14}C, respectively, were 71.1, 27.3, 1.2, and 0.3%, as given in Table 1.

Degradation Procedures

The main products, **1**-OH-^{14}C and **2**-OH-^{14}C, derived from the above treatments, were purified by preparative v.p.c. and diluted with inactive carriers to provide sufficient quantities of material for the degradations.

The 1-OH-^{14}C was oxidized to butyric acid in alkaline $KMnO_4$. A typical run is as follows. A solution of 5.0 g (68 mmol) of 1-OH-^{14}C in 300 ml of 20% NaOH was stirred and cooled in an ice-bath. With the temperature kept below 15°, 25 g (158 mmol) of $KMnO_4$ was added in small portions over a period of 2 h. The mixture was left at room temperature overnight and then filtered to remove the MnO_2. Acidification of the filtrate with H_2SO_4, followed by steam distillation, neutralization, and evaporation gave 5.7 g (76%) of the sodium salt of butyric acid, part of which was converted, for ^{14}C-determination, to the solid derivative, *S*-benzylisothiouronium butyrate, m.p. 148–149° (lit. (22*a*) m.p. 149°).

The sodium butyrate was converted by a Schmidt reaction (11, 23) to 1-propylamine, benzamide derivative, m.p. 84° (lit. (22*b*), m.p. 84°) or α-naphthylurea derivative, m.p. 195–196° (lit. (24) m.p. 196°). The 1-propylamine was oxidized to propionic acid by alkaline $KMnO_4$ according to the method of Mosbach and coworkers (10) and the propionic acid, in turn, was degraded to acetic acid and then to methylamine as previously described (11).

The 2-OH-^{14}C was converted to CBr_4 and propionic acid by treatment with Br_2–NaOH (9) and the propionic acid was similarly degraded to acetic acid and methylamine (11).

Valuable comments and suggestions made by Professor Arthur Fry, who suggested the explanation given in Scheme 3, and the financial support given by the National Research Council of Canada are gratefully acknowledged.

Thermal Routes to Substituted Cyclopentadienes

D. M. FINDLAY, MARIE LESSARD ROY, AND STEWART MCLEAN
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received April 19, 1972

An investigation has been made with the aim of finding a route to cyclopentadienes, particularly those with a single substituent at the 5-position, in which the final step is a thermal process of low enough activation energy that the cyclopentadiene produced does not undergo rearrangement by hydrogen migration under the reaction conditions. In the routes studied the final intermediates have been suitably substituted norbornenes which can lead to the required cyclopentadiene and an aromatic fragment by a retro-Diels–Alder reaction. In one series the intermediate was a phenyl azide adduct of norbornadiene which fragmented to cyclopentadiene and phenyltriazole, but the temperature required for this was clearly too high to allow substituted cyclopentadienes to be isolated before they had rearranged. In the course of this work, in addition to the *exo*-adduct of phenyl azide, the *endo*-adduct and a number of bisadducts were obtained and studied. In another series, adducts of tetraphenylcyclopentadienone and dimethyldiphenylcyclopentadienone with norbornadiene and 7-phenylnorbornadiene were prepared and studied. Decarbonylation of the adducts was effected both thermally and photochemically; in the latter case the reaction could be carried out at low temperature and the dihydrobenzene (a dihydrobenzonorbornadiene) produced was isolable. With or without isolation, the dihydrobenzene underwent a subsequent retro-Diels–Alder reaction to provide the cyclopentadiene and a substituted benzene. Kinetic studies showed that the activation energy for this process was almost but not quite low enough to satisfy the conditions stipulated, and in no case was a 5-substituted cyclopentadiene isolated before it had rearranged.

Une voie d'accès aux cyclopentadiènes a été étudiée (particulièrement ceux possédant un seul substituant en position 5) dans laquelle l'étape finale est un processus thermique d'énergie d'activation suffisamment basse pour que le cyclopentadiène formé ne subisse pas de réarrangement par migration d'hydrogène, dans les conditions de la réaction. Dans les voies d'accès envisagées, les intermédiaires finals ont été des norbornènes convenablement substitués pouvant mener au cyclopentadiène voulu plus un fragment aromatique résultant d'une réaction du type "rétro-Diels–Alder". Dans une série, l'intermédiaire qui résulte de l'addition entre un phénylazide et le norbornadiène, se fragmente en cyclopentadiène et phényltriazole mais la température utilisée nettement trop élevée, n'a pas permis d'isoler les cyclopentadiènes substitués avant leur réarrangement. Au cours de ce travail, en plus du composé d'addition *exo* du phénylazide, le produit *endo* et un certain nombre de composés de bis-addition ont été obtenus et examinés. Dans une autre série, on a préparé et étudié les produits d'addition entre les tétraphénylcyclopentadiènone et diméthyldiphénylcyclopentadiènone et le norbornadiène et phényl-7 norbornadiène. La décarbonylation des produits résultants a été effectuée à la fois par voie thermique et photochimique, dans ce dernier cas, la réaction effectuée à basse température a permis d'isoler le dihydrobenzène (dihydrobenzonorbornadiène). Celui-ci, isolé ou non, subit une réaction subséquente de "rétro-Diels–Alder" et donne le cyclopentadiène plus un benzène substitué. Les études cinétiques montrent que l'énergie d'activation de ce processus est presque suffisamment (mais pas tout à fait) basse pour satisfaire aux conditions stipulées; par conséquent, l'isolement d'un cyclopentadiène substitué en 5 avant son réarrangement n'a pas été possible dans aucun cas.

Canadian Journal of Chemistry, **50**, 3186 (1972)

In general, 5-monosubstituted cyclopentadienes (**1** where R represents an organic substituent) are less stable than their positional isomers (**2** and **3**) and constitute a small fraction of the equilibrium mixture. Equilibrium can be established through a base-catalyzed process or through a purely thermal 1,5-sigmatropic migration of a hydrogen atom, the latter process being so facile that it takes place at an appreciable rate even at room temperature, at least in the cases that have been studied (1). Our interest in studying this rearrangement in more detail, and particularly how varying the group R affects it, led us to seek a general synthesis of molecules of formula **1**. (The route used previously, requiring a nucleophilic displacement by a cyclopentadienide ion, can not be generalized to include, for example, cases where R is an aryl group.) The extremely facile rearrangement of **1** clearly imposes severe constraints on a synthetic scheme, since it can be expected that **1** will not be isolable if the step which generates it requires basic conditions or heat, with room temperature representing a probable upper limit even in favorable cases. We have, therefore, sought a route by which **1** is formed under neutral conditions in a

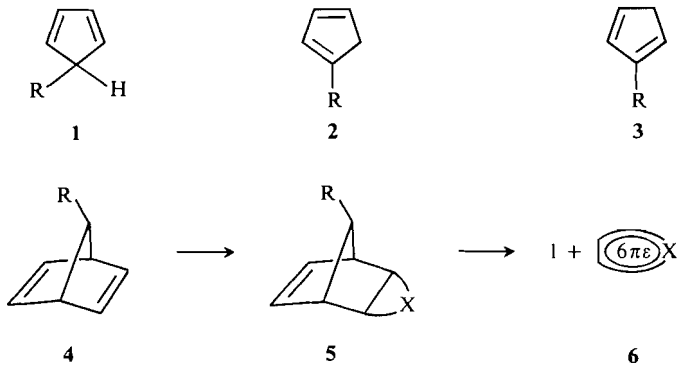
For personal use only.



thermal process of such low activation energy that the reaction takes place below room temperature. Although we have not yet succeeded in achieving this goal, we describe here the progress we have made in developing synthetic sequences which generate cyclopentadienes in reactions of low activation energy.

The synthetic plan envisaged the conversion of a 7-substituted norbornadiene (**4**), to which a general synthetic route is available (2), into a derivative (**5**) which could undergo a retro-Diels–Alder reaction to afford the cyclopentadiene and a fragment (**6**) that had aromatic character. It was hoped that the aromatic stabilization of **6** would provide a driving force for the reaction and lower its activation energy sufficiently to meet our requirements.

Since a 1,3-dipolar cycloaddition reaction of **4** to form **5** offered a reaction that could be used to develop this plan, the reaction of the model compound norbornadiene itself (**4***a*) with phenyl azide was investigated. It was found, however, that the cycloaddition reaction took place at an appreciable rate in cyclohexane solution only above 60° and that the adduct (**7**) required even higher temperatures (at least 80°) in order to undergo the required retro-Diels–Alder reaction to afford the anticipated cyclopentadiene and 1-phenyl-1,2,3-triazole. It is obvious, therefore, that these conditions are too vigorous to offer any hope of using them to isolate thermally labile cyclopentadienes.

In the course of our investigation of the conditions required to effect the reaction of norbornadiene with phenyl azide, we discovered that, in addition to the expected *exo*-adduct **7**, the *endo*-adduct (**8**) was also formed, apparently the first example of an adduct formed with this stereochemistry in such reactions. Moreover, when phenyl azide was allowed to react with a deficiency of norbornadiene or with preformed monoadduct, four (**9**, **10**, **11**, **12**) of the possible stereoisomeric bisadducts were formed, and only the *endo–endo*-bisadducts (**13**, **14**) appeared to be absent in the products. We have reported the isolation and characterization of these adducts in a preliminary communication (3) and the significance of these results with respect to the general question of the orientation of azide additions has been commented on by others (4). Structural assignments were based on an analysis of the n.m.r. spectrum and a determination of the molecular composition of each adduct. In the mass spectrum, the monoadducts showed a low intensity parent ion and readily lost N_2, while the highest mass peak observed for the bisadducts was a low intensity peak at $M - N_2$, and the loss of a further N_2 fragment was also apparent. The photochemical behavior of the adducts was also investigated briefly: both *exo–exo*-adducts (**9**, **10**) were converted cleanly to the same bisaziridine on exposure to sunlight, the *exo–endo*-adducts (**11**, **12**) also appeared to form a bisaziridine under the same conditions, but the product was not isolated or properly characterized. The *exo*-monoadduct (**7**) did not give a characterizable product under these conditions; however, it has been reported recently (5) that the latter adduct is also converted to an aziridine by photolysis under the appropriate conditions.

Since the elimination of a triazole by a retro-Diels–Alder reaction did not appear to offer a route of sufficiently low activation energy to meet our requirements, we turned to a corresponding reaction in which the fragment **6**

eliminated is a benzene. The proposed route for this required the addition of a cyclopentadienone to a norbornadiene (**4**), followed by decarbonylation of the intermediate **15** to provide the dihydrobenzene (**16**) which would be expected to undergo the retro-Diels–Alder reaction readily.

It had been reported (6) that norbornadiene does in fact react with tetraphenylcyclopentadienone (tetracyclone) in the expected manner when the components are heated together, but that the subsequent steps also take place under these conditions and the products obtained are cyclopentadiene and tetraphenylbenzene. However, when we examined the reaction by allowing norbornadiene (**4***a*) to react with tetracyclone in refluxing chloroform or benzene, the ketone **15***a* was obtained in excellent yield and was moderately stable to prolonged exposure to the reaction conditions; this Diels–Alder reaction was also markedly accelerated by aluminum chloride (7). The product was assigned structure **15***a* from its spectroscopic characteristics, which included in the i.r. spectrum a carbonyl absorption at 5.63 μ and, in the n.m.r. spectrum, two one-proton doublets with $J = 9.5$ Hz at τ 7.35 and 8.59 and a sharp peak at τ 7.14 associated with the two protons on the carbon atoms involved in the ring fusion. The lack of coupling exhibited by the latter protons indicates that the

stereochemistry of **15***a* results from the expected *exo*-addition to the norbornadiene and the considerable difference in the chemical shifts of the two protons on the one-carbon bridge of the bicycloheptene points to the stereochemistry assigned, with one of these protons in close proximity to the diphenylethylene moiety (8). Additional support for the latter assignment was provided by the observation that chemical shifts of the bridge methylene protons were not significantly changed when the ketone was reduced to the corresponding alcohol. When the Diels–Alder reaction was carried out with norbornadiene and excess tetracyclone, a small amount of an insoluble, high-melting solid was obtained which, although it was not characterized completely, is believed to be the bisadduct **17***a*, resulting from the reaction at both double bonds of norbornadiene.

The isolation of monoadduct **15***a* showed that it did not readily undergo decarbonylation at the temperature required for its formation; consequently, the application of this route to the synthesis of a thermally labile cyclopentadiene appeared unpromising. There is more quantitative support for this pessimism in the activation energies that have been determined from recent kinetic studies of the thermal decarbonylation of related molecules (8). In fact, **15***a* was even more thermally stable in our hands than we had been led to expect (6), decomposing only slowly in refluxing chloroform, and we used refluxing toluene to effect its complete decomposition to cyclopentadiene and tetraphenylbenzene. Thermal decomposition of the bisadduct **17***a*, on the other hand, appeared to stop at the decarbonylation (double) stage, and a hydrocarbon believed to be **18***a*, a bis(dihydrobenzene) not susceptible to the retro-Diels–Alder fragmentation, was isolated. The n.m.r. spectrum showed the absence of significant coupling between non-aromatic protons, providing evidence for the stereochemical assignment shown in **18***a*, and supporting the stereochemistry proposed for the precursor **17***a*.

In the hope that it was only the thermal decarbonylation reaction that had too high an activation energy and that the subsequent retro-Diels–Alder reaction might still meet our requirements, we examined the photolysis of the model adduct **15***a*, since only the decarbonylation step should be photochemically activated. (Subsequent evidence (9) suggests that this assumption may not be completely justified.) Irradiation of a solution of **15***a* at room temperature converted it to cyclopentadiene and tetraphenylbenzene in good yield, and it appeared likely, therefore, that the photochemical decarbonylation had been followed by a facile thermal retro-Diels–Alder reaction. It may be noted that if oxygen was not thoroughly removed from the reaction mixture, an oxidized photoproduct was obtained, and if oxygen was deliberately bubbled through the solution during photolysis, this material was the major product isolated. Its composition corresponds to a molecule of formula **16***a* plus O_2, and its spectroscopic characteristics indicate that it is the conjugated diene part of **16***a* that has been affected by the oxidation. The product is thermally stable and catalytic hydrogenation over palladium reduces only its isolated double bond in the norbornene system. Two structures, **19***a* and **20***a*, may be considered for the oxidized photoproduct; a decision between these can not be made on the basis of the experimental evidence available at present, but there is precedent (10) for favoring **19***a*.

Results closely paralleling those just described and leading to the corresponding products (**15***d*–**19***d*) were obtained if the sequence was carried out with 2,5-dimethyl-3,4-diphenylcyclopentadienone in place of tetracyclone in the Diels–Alder reaction with norbornadiene.

Since the Diels–Alder reaction–photodecarbonylation–retro-Diels–Alder reaction sequence described for the model series gave promising results, we examined this sequence for the case of 7-phenylnorbornadiene (**4***b*). Reaction of **4***b* with tetracyclone at 70° afforded the corresponding adduct **15***b*, but the yield was very low and was not improved by the addition of aluminum chloride. Reactions of this kind must be carried out within a strictly limited range of temperatures; at temperatures below this "window" the rate of adduct formation is impracticably low, while at temperatures above it the adduct suffers decarbonylation before it can be isolated. In the case of **15***b* this window was even narrower than in the model series; the adduct was isolated only at 70°, and even then the reaction afforded a mixture consisting mainly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of unchanged starting materials and products resulting from the subsequent decomposition of **15***b* (tetraphenylbenzene and tetracyclone adducts of phenylcyclopentadiene). However, replacing tetracyclone with 2,5-dimethyl-3,4-diphenylcyclopentadienone allowed the adduct **15***c* to be obtained in satisfactory yield. The stereochemistry shown for **15***b* and *c* is based on analogy with **15***a* and the expectation that addition to the norbornadiene had taken place on the side opposite to the phenyl substituent, and this is supported by the low field position (8) of the n.m.r. signal for the proton on the one-carbon bridge in the products; direct evidence that *exo*-addition to the norbornadiene had taken place was also given by the n.m.r. spectra of the adducts, which showed the absence of significant coupling involving non-aromatic protons.

When a dilute solution of **15***c* at between −40 and 0° was irradiated with u.v. light, the decarbonylation product **16***c* was obtained and could be trapped as its adduct **21***c* with 4-phenyl-1,2,4-triazoline-3,5-dione; the stereochemistry shown for **21***c* is that expected for adduct formation with the assumed intermediate **16***c*, but supporting evidence for the stereochemical features not present in the precursor is found only in the observation that the chemical shift of the benzylic proton corresponds closely to that assigned to the corresponding proton in **15***c*. If care was taken to keep the temperature as low as possible at all times, **16***c* itself could be observed as a product of the photolysis. The tetracyclone adduct **15***b* of norbornadiene could be converted in the same way to the analogous products **16***b* and **21***b*. At room temperature both dihydrobenzenes, (**16***b* and *c*) underwent the expected retro-Diels–Alder reactions and phenylcyclopentadiene was produced and isolated as its *N*-phenylmaleimide adduct; the adduct isolated was that of 1-phenylcyclopentadiene (**2***b*), presumably since the 5-phenylcyclopentadiene (**1***b*) originally obtained rearranged under the reaction conditions. Our failure to obtain any of the adduct of 2-phenylcyclopentadiene (**3***b*) may be significant but the scale of these reactions makes this less certain, since the latter is the less abundant isomer at equilibrium; our investigation of the distribution of isomers obtained when an equilibrium mixture of phenylcyclopentadienes was prepared (11) and allowed to react with *N*-phenylmaleimide indicated, in agreement with a recent report (12), that the diene mixture was composed of the 1-phenyl and 2-phenyl isomers in a ratio of about 7:1. Attempts to use *N*-phenylmaleimide to trap the 5-phenylcyclopentadiene as soon as it was formed in the thermolysis of the dihydrobenzenes (**16***b* and *c*) were frustrated because the dihydrobenzenes themselves formed *N*-phenylmaleimide adducts (**22***b* and *c*) too readily. The stereochemistry shown for these adducts is that expected to result from the Diels–Alder reaction, but no supporting experimental evidence was obtained for those features not present in the precursor.

It appears then that, although the thermal fragmentation of the dihydrobenzenes is a process of relatively low activation energy, it takes place at a significant rate only in a temperature range in which the rearrangement of the 5-phenylcyclopentadiene produced is too fast to allow the unrearranged 5-phenyl isomer to be trapped or observed spectroscopically. In order to obtain a slightly more precise estimate of the activation energy for the thermolysis of the dihydrobenzenes, we have used n.m.r. spectroscopy to follow their decay in the relatively limited temperature range accessible to us. The kinetic results, which are expected to be only approximate, show that both dihydrobenzenes decay according to the first order rate law and that the E_a value is 28 kcal/mol for **16***b*, and 24 kcal/mol for **16***c*. These results lead to a half-life at 33° of 130 min for **16***c*, and when this is compared with the value of 19 min reported recently (9) for the thermolysis of **16***d* at the same temperature, it appears that the phenyl substituent on the one-carbon bridge of **16***c* retards the rate of the retro-Diels–Alder reaction, but no good explanation for this effect has yet been recognized.

Although the kinetic results are only approximate, they serve to show that we have come close to, but not reached, our goal of a thermal route to cyclopentadienes that has an activation energy low enough to be of general applicability to the synthesis of thermally unstable isomers. Even if a more precise determination of the activation energy were made we would not be able to state quantitatively how close we have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

come to the goal since it is impossible to define the goal precisely in terms of energy; the kinetic parameters for the thermal rearrangement of substituted cyclopentadienes have been determined in only a few cases, 5-methylcyclopentadiene with E_a of 20 kcal/mol (1) providing a representative example, but they must be guessed at for others, including 5-phenylcyclopentadiene, the case appropriate to the present discussion.

Experimental

Melting points were determined on a calibrated Thomas–Kofler micro hot stage. Unless otherwise indicated, chloroform solutions were used to obtain i.r. spectra and the wavelengths of significant absorptions are reported in μ, solutions in 95% ethanol were used to obtain u.v. spectra and the wavelengths of maximum absorption (λ_{max}) are reported in mμ followed by the extinction coefficient (ε) in parentheses, and chloroform-*d* solutions with tetramethylsilane as an internal standard were used to obtain n.m.r. spectra and chemical shifts are reported on the τ scale followed in parentheses with an indication of the multiplicity of the signal and the number of protons associated with it. Spectrometers used were a Perkin–Elmer 237B for i.r. spectra, a Unicam SP.800A for u.v. spectra, and a Varian HA-100 for n.m.r. spectra (unless otherwise indicated). Routine mass spectra were determined at 70 eV on a CEC 21–490 or an AEI MS-902 spectrometer and the *m/e* values of significant ions are reported followed in parentheses with a figure showing the height of the peak relative to that of the base peak (100%); accurate mass measurements were made on the AEI MS-902 spectrometer.

Phenyl Azide Adducts of Norbornadiene

(1) Preparation

(a) Phenyl azide and excess norbornadiene. The solution obtained by dropwise addition of phenyl azide (1.8 g) in 0.5 ml of cyclohexane to 20 ml of norbornadiene was heated to 60–65° for 2 h. A small amount of precipitate (29 mg) formed and was collected by filtration; it proved to be the *exo–exo–trans*-bisadduct **10** (see below). The filtrate was taken to dryness, the residue was dissolved in ether, and pentane was added to the solution, which was then cooled to −20°. The crystals (2.13 g; 67%) obtained were subjected to fractional crystallization from ether and then ether–carbon tetrachloride.

The first component obtained was the *endo*-monoadduct **8** (150 mg; 5%), m.p. 123–124°.

Anal. Calcd. for $C_{13}H_{13}N_3$: C, 73.90; H, 6.20; N, 19.89. Found: C, 73.81; H, 6.10; N, 19.83.

U.v. 281 (shoulder; 6100), 289 (7900), 308 (8400); n.m.r. 2.5–3.1 (complex; 5), 4.01 (d of d, $J = 6.0$, 3.5 Hz; 1), 4.20 (d of d, $J = 6.0$, 3.5 Hz; 1), 4.67 (d of d, $J = 10.5$, 4.5 Hz; 1), 5.67 (d of d, $J = 10.5$, 3.5 Hz; 1), 6.35 (unresolved; 1), 6.53 (unresolved; 1), 8.46 (d, $J = 9.5$ Hz, further fine splitting; 1), 8.64 (d, $J = 9.5$ Hz; 1); mass spectrum 211 (2), 183 (64), 182 (67), 117 (78), 104 (87), 91 (62), 77 (100).

The second component obtained was the *exo*-monoadduct **7** (1.77 g; 56%), m.p. 54.5–55°.

Anal. Calcd. for $C_{13}H_{13}N_3$: C, 73.90; H, 6.20; N, 19.89. Found: C, 73.84; H, 6.12; N, 19.95.

(b) Norbornadiene and excess phenyl azide. The solution obtained by dropwise addition of norbornadiene (2.78 g) in 25 ml of cyclohexane to phenyl azide (8.90 g) in 10 ml of cyclohexane was heated to 60–70° for 2 h. The products obtained were separated by a series of fractional crystallizations. The first component obtained was the *exo–exo–trans*-bisadduct **10** (5.75 g; 58%) which separated from the reaction mixture and was insoluble in most common solvents. Recrystallization from pyridine afforded a pure sample, m.p. 226° (dec.) (lit. (13) 236–238° (dec.)).

Anal. Calcd. for $C_{19}H_{18}N_6$: C, 69.07; H, 5.49; N, 25.44. Found: C, 68.95; H, 5.49; N, 25.60.

U.v. (absolute EtOH) 280 (shoulder; 10 000), 288 (10 800), 305 (10 800); n.m.r. (pyridine-d_5) 2.3–2.9 (complex; 10), 4.91 (d, $J = 9.5$ Hz; 2), 5.82 (d, $J = 9.5$ Hz; 2), 6.78 (unresolved m; 2), 8.92 (unresolved m; 2); mass spectrum 302 (2), 274 (26), 273 (23), 182 (62), 156 (49), 119 (41), 104 (73), 28 (100).

The second component obtained was the *exo–exo–cis*-bisadduct **9** (2.34 g; 23%), m.p. 164–166° (dec.), which was recrystallized from ether–carbon tetrachloride.

Anal. Calcd. for $C_{19}H_{18}N_6$: C, 69.07; H, 5.49; N, 25.44. Found: C, 69.12; H, 5.65; N, 25.46.

U.v. (absolute EtOH) 280 (shoulder; 9800), 288 (10 700), 304 (10 600); n.m.r. 2.4–3.1 (complex; 10), 5.17 (d, $J = 9.5$ Hz; 2), 6.05 (d, $J = 9.5$ Hz; 2), 6.71 (broadened s; 1), 6.96 (broadened s; 1), 8.87 (broadened s; 2); mass spectrum 302 (1), 274 (2), 273 (4), 182 (17), 156 (18), 119 (100).

The remaining crystalline material (1.0 g) appeared, on the basis of its n.m.r. spectrum, to contain a further small amount of **9**, a mixture of the *exo–endo*-adducts **11** and **12** (described below), and possibly a small amount of the monoadducts 7 and **8**. Further fractional crystallization was only partially successful.

(c) endo-Monoadduct and phenyl azide. A solution of phenyl azide (500 mg) and the *endo*-monoadduct **8** (125 mg) in 10 ml of cyclohexane was heated to 50–60° for 4 h. After solvent and excess phenyl azide had been removed by vacuum distillation, the residue was dissolved in hot carbon tetrachloride–chloroform (3:1), and allowed to crystallize. The material obtained (159 mg; 81%) melted in the range 157–170° and appeared from its n.m.r. spectrum to be a 2:3 mixture of *exo–endo–cis*-bisadduct **11** and its *trans* isomer **12**. A pure sample of the *exo–endo–trans*-bisadduct **12** (34 mg), m.p. 230° (dec.), was obtained by continued recrystallization.

Anal. Calcd. for $C_{19}H_{18}N_6$: C, 69.07; H, 5.49; N, 25.44. Found: C, 69.35; H, 5.30; N, 25.21.

U.v. For personal use only.

multiplets; 2), 8.46 (d, $J = 12.0$ Hz with further fine splitting; 1), 8.62 (d, $J = 12.0$ Hz with further fine splitting; 1).

A pure sample of the *exo–endo–cis*-bisadduct **11** could not be obtained, but the n.m.r. spectrum of a sample of the mixture of isomers enriched in **11** included the following signals assigned to **11**: 4.74 (d of d, $J = 12$, 5 Hz), 5.40 (broadened d, $J = 9.5$ Hz), 5.71 (d of d, $J = 12$, 5 Hz), 6.51 (broadened d, $J = 9.5$ Hz, superimposed on m), 6.91 (m).

(2) Thermolysis and Photolysis

The *exo*-monoadduct **7** in xylene was heated in a flask fitted with a distilling head. At 120° the presence of cyclopentadiene in the distillate was demonstrated by v.p.c. and, after 2 h, phenyltriazole (79%) was recovered from the flask.

A saturated solution of the *exo–exo–trans*-bisadduct **10** in ethanol was exposed to indirect sunlight for several days (depending on the weather). The bisaziridine (corresponding to 60% conversion) was isolated from the reaction mixture and obtained, after recrystallization from cyclohexane–carbon tetrachloride, as crystals, m.p. 182–186°.

Anal. Calcd. for $C_{19}H_{18}N_2$: C, 83.15; H, 6.61; N, 10.21. Found: C, 82.95; H, 6.73; N, 10.20.

U.v. 244 (23 600), 280 (1750); n.m.r. 2.6–3.4 (complex; 10), 7.06 (broadened s; 2), 7.57 (broadened s; 4); 8.62 (broadened s; 2); mass spectrum 274 (2), 273 (2), 182 (87), 181 (69), 180 (72), 170 (81), 169 (66), 157 (69), 156 (100), 143 (76), 130 (54), 104 (71). The *exo–exo–cis*-bisadduct **9** was converted to the same product (34% yield) in the same way.

Adducts of Norbornadiene with Cyclopentadienones

(1) Preparation

(a) Tetracyclone with excess norbornadiene. A solution of tetracyclone (3.24 g) and 25 ml of norbornadiene in 65 ml of chloroform was refluxed until the red color disappeared (21 h). The ketone **15***a* (3.89 g; 91%) contaminated with a small amount of tetraphenylbenzene (isolated in 7% yield) was obtained from the reaction mixture and purified by recrystallization from acetone–benzene; crystals were obtained which melted with decomposition at 160–162° (and recrystallized to form plates, m.p. 194–195°).

Anal. Calcd. for $C_{36}H_{28}O$: C, 90.72; H, 5.92. Found: C, 90.59; H, 5.95.

U.v. 225 (shoulder; 26 100), 260 (10 500); i.r. 5.63; n.m.r. 2.5–3.2 (complex; 20), 3.46 (t, $J = 1.5$ Hz; 2), 6.56 (t, $J = 1.5$ Hz; 2), 7.14 (s; 2), 7.35 (d, $J = 9.5$ Hz, slightly broadened; 1), 8.59 (d, $J = 9.5$ Hz, slightly broadened; 1); mass spectrum 410 (4), 382 (100). The same product was obtained in less than 1 h when the reaction was carried out in benzene at room temperature in the presence of a slight excess of aluminum chloride (on a molar basis with respect to tetracyclone), but the work-up was more difficult and the yield was lower.

A sample of the ketone **15***a* was reduced with lithium aluminum hydride to the corresponding alcohol (81% yield), m.p. 200–201°.

Anal. Calcd. for $C_{36}H_{30}O$: C, 90.34; H, 6.32. Found: C, 90.34; H, 6.52.

I.r. 2.81 (sharp), 2.94 (broad); n.m.r. 2.5–3.4 (complex; 20), 3.53 (narrow unresolved m; 2), 5.41 (s; 1), 6.90 (broadened s; 2), 6.97 (broadened s; 2), 8.21 (s; 1; removed by D_2O), 7.35 (d, $J = 9.0$ Hz, slightly broadened; 1), 8.57 (d, $J = 9.0$ Hz, slightly broadened; 1); mass spectrum 478 (8), 412 (27), 386 (69), 382 (100), 233 (46), 221 (32), 191 (42).

(b) Norbornadiene with excess tetracyclone. A solution of norbornadiene (300 mg) and tetracyclone (4.22 g) in 50 ml of chloroform was refluxed for 3 days. The insoluble product appeared to be the bisadduct **17***a*, which decomposed slowly above 320°; i.r. (KBr disc), 5.63; mass spectrum 422 (21), 384 (6), 371 (9), 156 (16), 28 (100).

(c) Norbornadiene with 2,5-dimethyl-3,4-diphenylcyclopentadienone. A solution of norbornadiene (5.13 g) and the dienone (dimer (14)) (4.88 g) in 60 ml of benzene was refluxed for 45 h. The reaction mixture yielded the monoadduct **15***d* (4.66 g; 67%) m.p. 171.5–172° (lit. (15) 173°); u.v. 260 (9400); i.r. 5.65; n.m.r. 2.7–3.2 (complex; 10), 3.75 (t, $J = 1.5$ Hz; 2), 6.96 (narrow m; 2), 8.01 (s; 2), 7.50 (d, $J = 9.5$ Hz; 1), 8.74 (s; 6), 8.76 (d, $J = 9.5$ Hz; 1). The mother liquor afforded a further product which appeared to be the bisadduct **17***d* which was obtained as crystals, m.p. 219–223°, from ethanol–chloroform; i.r. 5.63; n.m.r. 2.6–3.2 (complex; 20), 7.5–8.2 (complex; 8), 8.68 (s; 12); mass spectrum 298 (22), 258 (100).

(d) 7-Phenylnorbornadiene with 2,5-dimethyl-3,4-diphenylcyclopentadienone. A solution of 7-phenylnorbornadiene (2) (4.78 g) and the dienone (4.95 g) in 60 ml of benzene was refluxed for 36 h. The reaction mixture yielded the monoadduct **15***c* (4.51 g; 55%), m.p. 170–171.5° (dec.) after recrystallization from methanol–ether.

Anal. Calcd. for $C_{32}H_{28}O$: C, 89.68; H, 6.59. Found: C, 89.71; H, 6.51.

U.v. 263 (8900); i.r. 5.65; n.m.r. 2.6–3.2 (complex; 15), 3.90 (t, $J = 2.0$ Hz; 2), 5.39 (broadened s; 1), 6.57 (narrow m; 2), 7.84 (s; 2), 8.63 (s; 6); mass spectrum 258 (100), 243 (23), 228 (8), 142 (50), 116 (16).

(e) 7-Phenylnorbornadiene with tetracyclone. The reaction between these components under conditions similar to those described above led to the formation of adducts of phenylcyclopentadienes with tetracyclone as the principal isolable products. No improvement was observed when aluminum chloride was present. When the reaction was carried out at 70° for 3 days a small yield (9%) of the desired adduct **15***b* was isolated, m.p. 162–164° (dec.); u.v. (absolute EtOH), 220 (shoulder), 260 (9600); i.r. (KBr disc) 5.62; n.m.r. 2.8–3.2 (complex; 25), 3.65 (narrow m; 2), 5.25 (broadened s; 1), 6.22 (narrow m; 2), 6.98 (s; 2).

Reference samples of the adducts of phenylcyclopentadiene (11) and tetracyclone were prepared in the usual manner. The principal product was the adduct of 1-phenylcyclopentadiene, m.p. 183–185°.

Anal. Calcd. for $C_{40}H_{30}O$: C, 91.22; H, 5.74. Found: C, 91.13; H, 5.79.

U.v. (absolute EtOH) 260 (21 900); i.r. (KBr disc) 5.62; n.m.r. 2.2–3.4 (complex; 25), 3.46 (d, $J = 2$ Hz; 1), 5.59 (d of d, J values 8, 2 Hz; 1), 6.29 (m; 1), 6.85 (complex; 2).

A very small amount of a second product, m.p. 180–181°, was considered to be the adduct of 2-phenylcyclopentadiene.

(2) Thermolyses

*(a) Norbornadiene-tetracyclone adduct **15***a*.* A solution of the adduct **15***a* (250 mg) in 70 ml of toluene was refluxed for 3 days. Removal of the solvent and recrystallization of the residue provided 1,2,3,4-tetraphenylbenzene (193 mg; 96%), m.p. 194–195° (lit. (6) 191°). The corresponding reaction in refluxing chloroform afforded tetraphenylbenzene (11%) and unchanged **15***a* (73%) after 50 h.

*(b) Norbornadiene-tetracyclone bisadduct **17***a*.* The bis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

adduct **17***a* (104 mg) was suspended in 25 ml of anisole, which was refluxed until solution was complete (about 1.5 h). About 15 ml of anisole was removed under vacuum, a brown gum which had formed was removed by filtration, ether was added to the filtrate, and the solution was cooled. The product (**18***a*) (52 mg; 53%) was collected, recrystallized from benzene–cyclohexane, and obtained as crystals, m.p. 336°.

Anal. Calcd. for $C_{63}H_{48}$: C, 93.71; H, 6.29. Found: C, 93.85; H, 6.27.

U.v. 262 (33 900), 309 (19 200); n.m.r. 2.9–3.4 (complex; 40), 6.79 (s; 4), 7.54 (broadened s; 2), 7.68 (broadened s; 2); mass spectrum 422 (100), 395 (34), 382 (37), 329 (27).

(c) Dimethyldiphenylcyclopentadienone adducts. After a solution of the norbornadiene adduct **15***d* in toluene had been refluxed for 24 h, 1,4-dimethyl-2,3-diphenylbenzene (14) (64%) was isolated. Under similar conditions the 7-phenylnorbornadiene adduct **15***c* gave the same product in 48% yield.

(3) Photolyses

Photolyses were carried out with a 450 W Hanovia high-pressure mercury lamp in a quartz immersion well.

(a) Norbornadiene-tetracyclone adduct 15a. A solution of the adduct **15***a* (356 mg) in 230 ml of 1:6 tetrahydrofuran–cyclohexane continuously purged with a stream of oxygen-free nitrogen was photolyzed at room temperature for 24 h. Solvent and volatile products were distilled on to *N*-phenylmaleimide which trapped the cyclopentadiene formed as its adduct (137 mg; 77%), m.p. 140–142°; the residue afforded 1,2,3,4-tetraphenylbenzene (229 mg; 81%), m.p. 193–195°.

Irradiation of the adduct **15***a* (138 mg) in 75 ml of 1:4 benzene–hexane agitated by a stream of oxygen at room temperature for 12 h yielded a precipitate (74 mg; 57%) which was purified by t.l.c. and recrystallization from benzene–cyclohexane, and obtained as crystals, m.p. 288–289°.

Anal. Calcd. for $C_{35}H_{28}O_2$: C, 87.47; H, 5.87. Found: C, 87.39; H, 6.26.

U.v. 260 (1200); n.m.r. 2.56–3.25 (complex; 20), 3.91 (t, $J = 2.0$ Hz; 2), 7.09 (t, $J = 2.0$ Hz; 2), 7.64 (d, $J = 2.0$ Hz; 2), 7.78 (broadened d, $J = 8.5$ Hz; 1), 8.37 (broadened d, $J = 8.5$ Hz; 1); mass spectrum 480 (5), 479 (15), 413 (29), 382 (5), 375 (21), 360 (12), 309 (100), 279 (26), 255 (10), 178 (34), 105 (53); mass measurement 479.1969 (calcd. for $C_{35}H_{27}O_2$: 479.2011), 309.1281 (calcd. for $C_{23}H_{17}O$: 309.1279).

Hydrogenation of the photo-oxidation product (94 mg) in 50 ml of ethyl acetate over 10% palladium-on-carbon converted it to a product (86 mg), m.p. 289–295°; u.v. 260 (1100); n.m.r. 2.5–3.4 (complex; 20), 7.51 (d, $J = 1.5$ Hz; 2), 7.62 (m; 2), 7.88 (broadened d, $J = 11$ Hz; 1), 8.4–9.0 (complex; 5); mass spectrum 482 (5), 377 (23), 361 (16), 309 (18), 272 (10), 231 (23), 178 (53), 105 (100).

(b) 7-Phenylnorbornadiene-dimethyldiphenylcyclopentadienone adduct **15***c*. A solution of the adduct **15***c* (228 mg) in 240 ml of 1:5 ether–hexane[1] was purged with nitrogen, cooled in an ice-salt bath, and irradiated for 3 h. The solution was transferred to a flask equipped with a septum cap and cooled in Dry Ice. A solution of freshly prepared 4-phenyl-1,2,4-triazoline-3,5-dione (17) in methylene chloride was added dropwise through a syringe until the red color of the dione persisted in the reaction mixture. Evaporation of the solution and purification of the product by t.l.c. and recrystallization from benzene–cyclohexane provided the crystalline adduct **21***c* (174 mg; 57%), m.p. 250–253° (dec.).

Anal. Calcd. for $C_{39}H_{33}N_3O_2$: C, 81.36; H, 5.78; N, 7.30. Found: C, 81.44; H, 5.69; N, 7.53.

U.v. (absolute EtOH) 250 (8700); i.r. 5.67, 5.87; n.m.r. 2.4–3.3 (complex; 20), 3.83 (narrow m; 2), 5.40 (broadened s; 1), 6.65 (broadened s; 2), 7.58 (s; 2), 8.03 (s; 6); mass spectrum 575 (2), 407 (3), 322 (3), 258 (100), 243 (35), 228 (18), 142 (50), 119 (28).

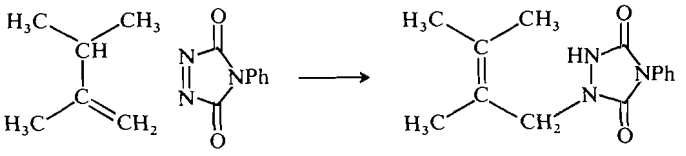
When, instead of treatment of the photolyzed solution with the triazolinedione, distillation of the solvent was carried out under vacuum while the reaction mixture was maintained at a temperature of 0° or lower, a solid was obtained (the yield varied considerably from one run to another) which, after it had been washed with cold cyclohexane, was a fairly pure sample of the cyclohexadiene **16***c*; n.m.r. (60 MHz) 2.5–3.4 (complex; ~15), 3.87 (narrow m; 2), 6.15 (broadened s; 1), 6.52 (narrow m; 2), 7.44 (s; 2), 8.33 (s; 6).

When *N*-phenylmaleimide in carbon tetrachloride was added to the product **16***c* and the solution was allowed to warm to room temperature, the adduct **22***c*, m.p. 297–299° (dec.) was isolated; i.r. 5.63, 5.85; n.m.r. 2.3–3.4 (complex; 20), 3.86 (narrow m; 2), 5.30 (broadened s; 1), 6.57 (narrow m; 2), 6.98 (s; 2), 7.81 (s; 2), 8.36 (s; 6); mass spectrum 573 (12), 431 (5), 405 (8), 400 (2), 399 (2), 320 (9), 258 (100), 243 (23), 173 (18); mass measurement 573.2667 (calcd. for $C_{41}H_{35}NO_2$, 573.2668).

When the photolysis of **15***c* was carried out in the usual manner but the reaction mixture was then left untreated at room temperature for 6 h, 1,4-dimethyl-2,3-diphenylbenzene (67%), m.p. 106–107°, was isolated, and addition of *N*-phenylmaleimide to the reaction mixture led to the isolation of its adduct with 1-phenylcyclopentadiene (39%), m.p. 176.5–177.5°.

Reference samples of the adducts of phenylcyclopentadiene (11) and *N*-phenylmaleimide were prepared in the usual way. The major product isolated (54%) was the adduct of 1-phenylcyclopentadiene, m.p. 176.5–177.5°.

[1]Hexane was treated before use with potassium permanganate–sulfuric acid to remove alkenes, and dried (16). When untreated "Certified ACS" grade hexane was used the major product at a later stage of this procedure was a solid, m.p. 119–125°, which was shown to be the product of the following reaction:



The same product was isolated when a solution of the triazolinedione in untreated hexane was left standing.

Anal. Calcd. for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44. Found: C, 79.85; H, 5.59; N, 4.48.

I.r. (KBr disc) 5.65, 5.82; n.m.r. 2.3–2.9 (complex; 10), 3.58 (m; 2), 6.45 (narrow unresolved band; 3), 8.00 (almost collapsed AB pattern, $J \sim 9$ Hz; 2).

The minor product (8%) was the adduct of 2-phenylcyclopentadiene, m.p. 160.5–162°.

Anal. Calcd. for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44. Found: C, 80.02; H, 5.79; N, 4.58.

I.r. 5.63, 5.86; n.m.r. 2.4–3.4 (complex; 10), 3.50 (narrow m; 1), 6.05 (narrow m; 1), 6.47 (narrow unresolved band; 3), 8.09 (d, $J = 8.5$ Hz; 1), 8.33 (d, $J = 8.5$ Hz; 1).

(c) 7-Phenylnorbornadiene-tetracyclone adduct **15***b*. Photolysis of the adduct **15***b* under the conditions described for **15***c* gave results paralleling those described in section *b*. The cyclohexadiene **16***b* was isolated; n.m.r. (60 MHz) 2.4–3.4 (complex; ~25), 4.07 (narrow m; 2), 5.74 (broadened s; 1), 6.70 (narrow m; 2), 6.88 (s; 2). It was also trapped as its phenyltriazolinedione adduct **21***b*, m.p. 141.5–143°.

Anal. Calcd. for $C_{49}H_{37}N_3O_2$: C, 84.09; H, 5.33; N, 6.01. Found: C, 83.52; H, 5.33; N, 6.23.

I.r. 5.67, 5.84; n.m.r. 2.4–3.2 (complex; 30), 3.72 (narrow m; 2), 5.38 (broadened s; 1), 6.44 (broadened s; 2), 6.90 (s; 2); mass spectrum 382 (87), 142 (100), 115 (25).

When **15***b* was allowed to decompose at room temperature, tetraphenylbenzene (78%) was isolated and phenylcyclopentadienes (49%) were trapped as their *N*-phenylmaleimide adducts.

(4) Kinetic Studies

Solutions of the cyclohexadienes **16***b* and *c* in chloroform-*d* were prepared and stored in Dry Ice. Samples were placed in the calibrated variable-temperature probe of a Varian A 56/60 n.m.r. spectrometer and the rate of decay of the cyclohexadiene was measured by repeated integration of the characteristic signals through at least two half lives. For **16***b* the decay of the peak at τ 6.88 was monitored and for **16***c* the decay of the methyl signal at τ 8.33 and the growth of the methyl signal at τ 7.92 of the 1,4-dimethyl-2,3-diphenylbenzene were used together. Runs were carried out with both series before instrument settings were changed; measurements were made at 33.5, 41.0, 43.5, and 48.0 °C. Data were analyzed by a standard least squares routine.

We thank the National Research Council of Canada for an operating grant supporting this work and for a Graduate Scholarship (to D.M.F., 1968–1971).

Metallation of *N*-Substituted β-Lactams. A Method for the Introduction of 3-Substituents into β-Lactams

T. DURST AND M. J. LEBELLE

Department of Chemistry, University of Ottawa, Ottawa, Canada, K1N 6N5

Received November 1, 1971[1]

N-Alkyl and *N*-aryl β-lactams yield lithio carbanions upon reaction with lithium diisopropylamide in tetrahydrofuran at −78°. These lithio salts react with a variety of electrophiles (*e.g.* ketones, esters, reactive alkyl halides) to give the 3-substituted derivatives in fair to good yield. The procedure is useful for the preparation of rather complex 3-substituted β-lactams from readily available simple derivatives.

Les β-lactames *N*-alkyle et *N*-aryle donnent des lithiocarbanions en réagissant avec le lithium diisopropylamide dans le tetrahydrofuranne à −78°. Ces sels de lithium réagissent avec divers électrophiles (par exemple cétones, esters, halogénures d'alkyles, réactifs) pour conduire aux dérivés substitués en -3, avec des rendements moyens ou bons. Cette méthode est utile pour la préparation des β-lactames complexes substitués en -3, à partir de dérivés simples, facilement accessibles. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3196 (1972)

A number of authors have recently reported that the reaction of *N*,*N*-disubstituted alkyl amides *e.g.* **1** with strong bases such as $NaNH_2$ (1, 2), *n*-BuLi (3) or lithio *s*-trithiane (3) leads to carbanions which can be alkylated with a variety of alkyl halides or condensed with carbonyl compounds. *e.g.* eq. 1.

The problems encountered in the synthesis of complex β-lactams either via cyclization of acyclic precursors or cycloaddition reactions (4), prompted us to investigate the synthesis of a variety of 3-substituted β-lactams from more readily available simple lactams via the carbanion route.

The formation of β-lactam carbanions in the penicillin and cephalosporin series has been investigated by a number of groups (5). In these examples two types of reactions have generally been observed (*a*) epimerization of the naturally occurring *cis*-β-lactam to the more stable *trans* configuration and (*b*) β-elimination of the thiolate moiety followed by further rearrangements (Scheme 1).

Several recent reports have indicated some of the synthetic potential of β-lactam carbanions. The first, by Kaiser *et al.* (6), showed that treatment of the allyldimethylammonium salt **2** with NaH in dimethylformamide–benzene resulted in the intramolecular migration of the allyl group from nitrogen to carbon thereby forming **3** (eq. 2).

More pertinent to the work discussed in this paper are the results of Böhme *et al.* (7) who were able to transform methyl *N*-benzylidene-6-aminopenicillanate (4) into a mixture of the epimeric-6-methyl derivatives **5** and **6** upon reaction with CH_3I/NaH in dimethoxyethane at 0° (eq. 3). In this case the ease of carbanion formation is undoubtedly due in large part to the additional stabilization afforded by the neighboring N=CHPh group. A similar reaction was also carried out on the analogous cephalosporin derivative.

More recently, Firestone and coworkers (8) have shown that the imine prepared from 6-aminopenicillanic acid benzyl ester and *p*-

2 3

nitrobenzaldehyde readily yielded a carbanion upon treatment with phenyllithium in tetrahydrofuran at −78°. Alkylation of this carbanion with methyl and ethyl iodide gave the 6α alkylated isomers.

We have found that simple monocyclic *N*-methyl[2] or *N*-phenyl β-lactams readily form lithio derivatives upon addition to an equimolar amount of lithium diisopropylamide in tetrahydrofuran at −78°. These species are reasonably stable at −78° and react readily with a variety of electrophiles to yield the 3-substituted derivatives in fair to good yield (eq. 4, Table 1).

Thus the lithio salt **7***a* reacted with acetone or methyl iodide to afford the products **11** and **12** in 80 and 59% yield respectively. The i.r. spectrum of each product showed a strong band in the 1730–1750 cm^{-1} region which confirmed that the β-lactam ring had been retained (9). In the n.m.r. spectrum of each product the coupling between the two remaining ring protons was <2.5 Hz, indicative of the *trans*-configuration (10). No evidence of the presence of the *cis* isomers of **11** and **12** was detected in the n.m.r. spectra of the total crude products. The other spectroscopic features were as expected and are recorded in the Experimental. The lithio salts of the β-lactams **9** and **10** also yielded only one product on reaction with the various electrophiles. These were also shown by n.m.r. to have the *trans* configuration. Not unexpectedly, diastereomeric mixtures were obtained from the lithio salt of **8**. No attempts were made to separate these diastereomers.

The 3-methyl-β-lactam **12** also yielded a lithio derivative (**12***a*) which was trapped with benzophenone to give **13** in a 30% yield. When **12***a* was quenched with H_2O, **12** was regen-

4 5 (5%) 6 (α isomer, 90%)

[2]Methylation of *N*-unsubstituted β-lactams was carried out by dissolving such lactams in excess CH_3I at 0–10° and slowly adding 1 equiv dry, powdered KOH. The yield of *N*-methylated β-lactams was generally over 80%. This alkylation procedure was also successful with other reactive halides such as benzyl or allyl bromide, but not with ethyl bromide or isopropyl iodide. In the latter experiments polymerization of the β-lactam occurred.

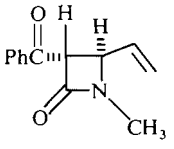
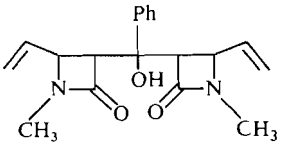
erated; no evidence of isomerization to the *cis* isomer was detected by n.m.r.

Reaction of 7*a* with methyl benzoate led to the formation of the phenacyl lactam **14** (i.r. 1750 and 1680 cm^{-1}) in 28% yield. The *trans* stereochemistry is assigned by analogy with **11** and **12** but could not be verified by n.m.r. In addition to the above material, a second product was obtained in 50% yield to which is tentatively assigned the dilactam structure **15**. The material had a broad m.p. (128–151°) and is probably a mixture of diastereomers. The i.r. spectrum of **15** showed bands at 3580 and 3400 (free and bonded OH), 1740 (C=O), 988, and 930 cm^{-1} (terminal vinyl). N.m.r. bands occurred at δ 2.4–2.8 (three sharp lines, total 6H, due to the NCH_3 group of the various diastereomers), 3.1 (s, 1H, OH), 3.5–4.0 (m, 4H, ring H), 4.8–6.0 (m, 6H, vinyl), and 7.2–7.7 (m, 5H, aromatic).



14



15

In addition to the adducts derived from the lithio salt of **10***a*, we generally observed the formation of a small amount of bi-product which was identified as **16** (see Experimental for spectroscopic data). The yield of **16** can be increased to about 27% by allowing a solution of **10***a* to warm to room temperature in the absence of a trapping agent. Its mode of formation is suggested in eq. 5. Products analogous to **16** were not observed in the reaction of the lithio salts of the *N*-alkyl-β-lactams.

solution, unless otherwise indicated, on a Beckman IR-20 spectrophotometer. Melting points and boiling points are uncorrected. For the sake of unambiguous designations, the 2-azetidinone nomenclature is used in this part of the paper.

1,4-Diphenyl-2-azetidinone

This 2-azetidinone was prepared by the method of Gilman and Speeter (11) as found in ref. 12.

4-Vinyl-2-azetidinone and 2-Methyl-4-vinyl-2-azetidinone

These 2-azetidinones were prepared by the method of Moriconi and Meyer (13) except that reduction of the 1-chlorosulfonyl-2-azetidinones was carried out with sodium sulfite (14).

4-Phenyl-2-azetidinone

This compound was obtained from the reaction of styrene and chlorosulfonyl isocyanate in methylene chloride followed by sodium sulfite reduction of the crude *N*-chlorosulfonyl β-lactam; m.p. 106–108°; lit. m.p. 108–109° (15).

N-Methylation of 2-Azetidinones. General Procedure

The 2-azetidinone was mixed with an excess of methyl iodide. The mixture was cooled to 0° and 1 equiv of freshly powdered dry potassium hydroxide was added with stirring. The mixture was then stirred at the temperatures and for the times indicated. The work-up consisted of adding methylene chloride and filtering the mixture. The methylene chloride was dried over magnesium sulfate and evaporated to give almost pure products.

1-Methyl-4-vinyl-2-azetidinone

4-Vinyl-2-azetidinone (4.01 g, 41 mmol) and 11.4 g of methyl iodide were stirred with 2.36 g of potassium hydroxide. Work-up gave 3.8 g (83%) of product, b.p. 34–35°/0.35 mm. The n.m.r. spectrum showed peaks at δ 2.75 (s, 3H), 2.45–3.39 (m, 2H), 3.78–4.09 (m, 1H), and 5.12–6.18 (m, 3H). The i.r. spectrum showed bands at 1735 (s), 1410 (m), 1390 (m), 990 (m), and 930 (m). The mass spectrum gave a molecular ion at *m/e* 111.

1,4-Dimethyl-4-vinyl-2-azetidinone

4-Methyl-4-vinyl-2-azetidinone (2.65 g, 23.8 mmol) and 6.8 g (48 mmol) of methyl iodide were stirred with 1.34 g (24 mmol) of potassium hydroxide for 10 min. Work-up gave 2.78 g of yellow oil (90%) which was pure by n.m.r. The product was distilled and gave a colorless liquid b.p. 40–50°/0.35 mm. The n.m.r. spectrum indicated peaks at δ 1.75 (s, 3H), 2.69 (s, 3H), 2.81 (s, 2H), and 5.00–6.21 (m, 3H). The i.r. spectrum showed bands at 1735 (s), 1410 (m), 1390 (m), 995 (m), and 930 (m) cm^{-1}.

1-Methyl-4-phenyl-2-azetidinone

To a solution of 4-phenyl-2-azetidinone (7.5 g, 51 mmol) in 60 ml CH_3I was added slowly 3.1 g of powdered KOH. The reaction mixture was stirred overnight at room temperature. The precipitate was filtered and washed with 50 ml of CH_2Cl_2. The solvents were evaporated and the product distilled. The yield of methylated β-lactam, b.p. 86–90°/0.2 mm, was 6.4 g (78%). The i.r. spectrum showed the β-lactam carbonyl at 1740 cm^{-1}. The n.m.r. spectrum showed the following peaks: δ 2.72 (s, 3H), 2.79 (d of d, J = 16, 2.5 Hz, 1H), 3.04 (d of d, J = 16 Hz, 4.5H), 4.47 (d of d, J = 4.5 Hz, 2.5), and 7.32 (s, 5H). The mass spectrum showed the parent peak at *m/e* = 161.

Formation of 3-Substituted-2-azetidinones. General Procedure

To a tetrahydrofuran solution of 1.1 equiv of diisopropylamine under nitrogen atmosphere at −78° was added 1.0–1.1 equiv of *n*-butyllithium (Foote Mineral Co., 1.6 *M* in hexane). After 5 min a tetrahydrofuran solution of the 2-azetidinone which had been cooled to −78° was added to the first solution and this was stirred for 0.5–1.5 min. A selected electrophile was then added, either neat if liquid, or as a tetrahydrofuran solution if solid. The reaction was stirred at −78° for the time specified. The solution was then poured into water and the aqueous phase saturated with sodium chloride. The products were extracted with methylene chloride and dried over magnesium sulfate. The products were usually purified by preparative t.l.c. or column chromatography. Yields refer to purified materials.

Formation of 3-Derivatives of 1-Methyl-4-vinyl-2-azetidinone

*(a) Acetone Derivative (**11**)*

To a solution of 3.88 mmol of the lithio salt of **7** was added 3 ml (40 mmol) of acetone. The reaction mixture was stirred for 5 min at −78°. Work-up gave 704 mg of a colorless oil from which 522 mg (80%) of **11** was isolated as a pale yellow oil by preparative t.l.c. using 5% CH_3OH in $CHCl_3$ as eluent. The i.r. spectrum showed strong bands at 3440 and 1730 cm^{-1}; n.m.r. peaks occurred at δ 1.24 (s, 3H), 1.43 (s, 3H), 2.60 (s, 1H, O—H), 2.75 (s, 3H), 2.88 (d, J=2.0 Hz, 1H), 3.90 (d of d, J=2.0 and 8.0 Hz, 1H), and 5.2–6.1 (m, 3H).

Anal. Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28. Found: C, 63.79; H, 8.97; N, 8.40.

*(b) 3-Methyl Derivative (**12**)*

A solution of 8.5 mmol of **7***a* and 3 ml (50 mmol) of methyl iodide was allowed to react for 10 min. Work-up followed by purification by preparative t.l.c. gave 630 mg (59%) of **12** as an oil. The n.m.r. spectrum showed peaks at δ 1.30 (d, J=7.5 Hz, 3H), 2.73 (s, 3H), 2.66–2.94 (m, 1H), 3.50 (d of d, J = 8.0 and 2.0 Hz, 1H), 5.10–6.10 (m, 3H).

Anal. Calcd. for $C_7H_{11}NO$: C, 67.17; H, 8.86; N, 11.19. Found: C, 66.89; H, 9.01; N, 11.02.

*(c) Benzoyl Derivatives (**14** and **15**)*

From the reaction of 4.1 mmol of **7***a* and 550 mg (4.5 mmol) of methyl benzoate was obtained 862 mg of crude product. Preparative t.l.c. gave two products on development with 5% methanol in chloroform. The upper fraction was obtained as a yellowish solid, 240 mg (28%), and was recrystallized from ether–pentane to give white needles, m.p. 66.5–67.5°. The i.r. spectrum showed strong bands at 1750 and 1680 cm^{-1}; the n.m.r. spectrum showed peaks at δ 2.80 (s, 3H), 4.50–4.70 (m, 2H), 5.24–6.00 (m, 3H), 7.24–7.29 (m, 3H), and 7.91–8.24 (m, 2H).

Anal. Calcd. for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51. Found: C, 72.48; H, 6.01; N, 6.51.

A lower fraction was extracted from the plate to yield 336 mg (50%) of white solid, m.p. 128–151° (methylene chloride–ether–pentane) to which we have assigned structure **15**. The i.r. spectrum showed bands at 3580 (w), 3400 (b), 1740 (s), 1542 (w), 988 (m), and 930 (m) cm^{-1}. The n.m.r. spectrum is described in the text.

Anal. Calcd. for $C_{19}H_{22}N_2O_3$: C, 69.92; H, 6.79; N, 8.58. Found: C, 69.95; H, 6.80; N, 8.60.

Formation of 3-Derivatives of 1,4-Dimethyl-4-vinyl-2-azetidinone

(a) Acetone Derivative

A solution of the lithio salt **8***a*, prepared from 334 mg (2.7 mmol) of **8**, was reacted with 3 ml of acetone for 5 min, at −78°. Work-up gave 538 mg of colorless oil which after purification by preparative t.l.c. gave 377 mg (77%) of white solid, m.p. 64.5–70.5° (methylene chloride–ether–pentane). The n.m.r. spectrum showed peaks at δ 1.16–1.75 (m, 9H), 2.42–3.09 (m, 5H), and 5.00–6.45 (m, 3H). The i.r. spectrum showed bands at 3580 (m), 3440 (b), 2980 (s), 1730 (s), 1375 (s), 999 (m), and 925 (m).

Anal. Calcd. for $C_{10}H_{17}NO_2$: C, 65.54; H, 9.35; N, 7.64. Found: C, 65.45; H, 9.16; N, 7.62.

(b) Benzophenone Derivative

To a solution of 3.0 mmol of the lithio salt **8***a* was added 550 mg (3.0 mmol) of benzophenone. The reaction was worked-up after 5 min to yield 850 mg of crude product. Column chromatography (silica gel, chloroform–methanol) gave 683 mg (75%) of adduct as a mixture of diastereomers, m.p. 147–152° (methylene chloride–ether). The n.m.r. spectrum showed peaks at δ 1.05 and 1.37 (two singlets, 3H), 2.66 and 2.67 (2 singlets, 3H), 2.81 and 3.03 (two singlets, 1H), 4.23 (s, 1H, exchangeable with D_2O), 4.83–5.93 (m, 3H), and 7.00–7.80 (m, 10 H). The i.r. spectrum showed bands at 3420 (b), 1730 (s), 980 (w), and 920 (w) cm^{-1}.

Anal. Calcd. for $C_{20}H_{21}NO_2$: C, 78.14; H, 6.89; N, 4.56. Found: C, 78.03; H, 6.96; N, 4.53.

Benzophenone Adduct of 1-Methyl-4-phenyl-2-azetidinone

A solution of the lithio salt **9***a* was prepared by reacting 371 mg (2.3 mmol) of **9** with 2.5 mmol of lithium diisopropylamide for 1 min. Benzophenone (420 mg, 2.6 mmol) was then added and the reaction mixture stirred for 6 min. Work-up gave 750 mg of an orange solid from which 390 mg (50%) of adduct was obtained as a white powder, m.p. 216–217° (methylene chloride–ether). The i.r. spectrum had bands at 3560 (w), 3360 (broad), and 1730 (s) cm^{-1}. The n.m.r. peaks occurred at 2.75 (s, 3H), 4.00 (broad singlet, 1H), 4.33 (d, J=2.0 Hz, 1H), and 7.00–7.66 (m, 15 H). The OH absorption could not be seen in the n.m.r.

Anal. Calcd. for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08. Found: C, 80.32; H, 6.01; N, 4.07.

Benzophenone Derivative of 1,3-Dimethyl-4-vinyl-2-azetidinone

A solution of 220 mg (1.76 mmol) of **12** was added to 1.1 equiv of lithium diisopropylamide and 320 mg (1.0 equiv) of benzophenone was added after 1.25 min. The reaction was stirred for a further 10 min. Work-up gave 558 mg of crude product which was recrystallized to give 162 mg (30%) of pure **13**, m.p. 171–172.5° (methylene chloride–ether–pentane). The i.r. spectrum showed bands at 3600 (w), 3460 (broad), 1735 (s), 1020 (w), and 925 (w) cm^{-1}. The n.m.r. showed peaks at δ 1.30 (s, 3H), 2.46 (s, 3H), 3.36 (broad singlet, 1H), 3.90 (d, J=7 Hz, 1H), 5.03–6.06 (m, 3H), and 7.12–7.69 (m, 10 H).

The mass spectrum of the compound indicated the parent peak at m/e=307, calcd for $C_{21}H_{20}NO_2$=307.

3-Derivatives of 1,4-Diphenyl-2-azetidinone

(a) 3-Iodo Derivative

A solution of 2.23 g (0.01 mol) of 2-azetidinone and 1.1 equiv of lithium diisopropylamide was stirred for 3 min. Iodide (2.54 g, 1 equiv was added; the reaction was stirred for a further 30 min. The work-up was carried out as usual except that the aqueous layer was saturated with sodium sulfite. Column chromatography (pentane–ether) of the crude product yielded 1.022 g grey solid (29%), m.p. 106.5–108° (ether–pentane). The n.m.r. spectrum indicated peaks at δ 4.72 (d, J = 2.0 Hz, 1H), 5.14 (d, J = 2.0 Hz, 1H), 7.04–7.47 (m, 10 H). The i.r. spectrum showed bands at 1755 (s), 1600 (m), and 1374 (m) cm^{-1}. The mass spectrum of the compound indicated the parent peak at m/e = 349. Since the compound tended to decompose, it was not analyzed.

(b) Cyclohexanone Derivative

To a solution of 3.14 mmol of the lithio salt of 1,4-diphenyl-2-azetidinone was added cyclohexanone (310 mg, 3.14 mmol) and the reaction stirred for 10 min. Column chromatography of the 700 mg of crude product gave 416 mg (41%) of pale yellow solid. Recrystallization from methylene chloride–ether–pentane gave white needles, m.p. 163–164°. The i.r. spectrum showed bands at 3580 (w), 3430 (b), 2940 (s), 1735 (s), 1600 (m), 1495 (m), 1380 (m), and 1145 (m) cm^{-1}. The n.m.r. spectrum showed peaks at δ 1.06–2.10 (m, 11 H), 3.16 (d, J = 2.5 Hz, 1H), 5.06 (d, J = 2.5 Hz, 1H), and 7.00–7.48 (m, 10H).

Anal. Calcd. for $C_{21}H_{23}NO_2$: C, 78.47; H, 7.21. Found C, 78.35; H, 7.21.

(c) Acetone Derivative

1,4-Diphenyl-2-azetidinone (3.97 mmol) was stirred with 1.0 equiv of lithium diisopropylamide for 30 s and 3 ml (10 equiv) of acetone was added. The reaction was stirred for 10 min. Work-up gave 1.18 g of yellow solid. Column chromatography yielded 643 mg (58%) white solid, m.p. 148–149.5° (methylene chloride–ether–pentane). The n.m.r. spectrum showed peaks at 1.32 and 1.43 (two singlets, 6H), 1.87 (s, 1H), 2.10 (d, J = 2.5 Hz, 1H), 5.00 (d, J = 2.5 Hz, 1H), and 7.00–7.45 (m, 10H). The i.r. spectrum showed bands at 3580 (w), 3460 (b), 1725 (s), 1600 (m), 1350 (m), and 1375 (m) cm^{-1}.

Anal. Calcd. for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.97. Found: C, 76.25; H, 6.77; N, 4.90.

(d) Benzoyl Derivative

1,4-Diphenyl-2-azetidinone (1.22 g, 5.49 mmol) was stirred with 1.05 equiv of lithium diisopropylamide for 30 s and 1 equiv of methyl benzoate was added. After 10 min the reaction was worked-up to give 1.85 g of yellow solid. Column chromatography yielded 1.1 g (61%) of white solid, m.p. 133–136° (methylene chloride–ether–pentane). The n.m.r. spectrum showed peaks at δ 4.80 (d, J = 2.0 Hz, 1H), 5.75 (d, J = 2.0 Hz, 1H), 6.95–7.61 (m, 13 H), 8.05–8.25 (m, 2H). The i.r. spectrum showed bands at 1740 (s), 1682 (s), and 1600 (m) cm^{-1}.

Anal. Calcd. for $C_{22}H_{17}NO_2$: C, 80.71; H, 5.24; N, 4.28. Found: C, 80.48; H, 5.47; N, 4.20.

*Decomposition of the Lithio Salt of 1,4-Diphenyl-2-azetidinone (**10***a*)

To a solution of 1.1 equiv of lithium diisopropylamide was added 2.80 mmol of 2-azetidinone and the solution allowed to warm to room temperature over 20 min. Work-up yielded 630 mg of crude material which was recrystallized from methylene chloride–ether to give 167 mg (27%)

of **17** as a white solid, m.p. 182–183°. The i.r. spectrum (KBr pellet) showed bands at 3380 (w), 1740 (s), 1710 (s), 1600 (m), 1490 (m), 1360 (m), 750 (m), and 690 (m) cm^{-1}. The n.m.r. spectrum (DMSO-d_6) showed peaks at 2.78–3.48 (m, 2H), 4.57 (d, $J = 2.5$ Hz, 1H), 4.72–5.08 (m, 1H), 5.42 (d, $J = 2.5$ Hz, 1H), 6.06 (d, $J = 7.5$ Hz, 1H), 6.48 (d, $J = 6.5$ Hz, 2H), 6.82–7.60 (m, 18 H).

Anal. Calcd. for $C_{30}H_{26}N_2O_2$: C, 80.69; H, 5.87; N, 6.27. Found: C, 80.58; H, 5.95; N, 6.25.

Ambident Ligands. I. Phenylsulfoxyacetic Acid

N. J. GOGAN, M. J. NEWLANDS, AND BECK-YU TAN (NÉE YAP)[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received October 18, 1971[2]

Phenylsulfoxyacetic acid, $C_6H_5S(O)CH_2CO_2H$, a potential ambident ligand, forms simple salts with magnesium(II), calcium(II), barium(II), manganese(II), cobalt(II), nickel(II), copper(II), zinc(II), silver(I), and mercury(I). With cadmium(II) it forms a simple salt and a complex, oxygen-bonded to the sulfoxide group. With platinum(II) it gives complexes which are sulfur-bonded to the sulfoxide group.

L'acide phénylsulfoxyacétique, $C_6H_5S(O)CH_2CO_2H$, ligand ambidentique à l'état potentiel, forme des sels simples avec le magnésium(II), calcium(II), barium(II), manganèse(II), cobalt(II), nickel(II), cuivre(II), zinc(II), argent(I), et mercure(I). Avec le cadmium(II), il forme un sel simple et un complexe, lié à l'oxygène du groupe sulfoxyde. Avec le platine(II), on obtient des complexes liés au soufre du groupe sulfoxyde.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3202 (1972)

Introduction

An interest in competition between donor sites in ligands is of relatively recent origin (1) although linkage isomerism has been known for a long time (2). Current interest stems in part from improved methods for determining the structures of complexes and in part from attempts to place observed stabilities of complexes on a more rational basis (3). The present work is part of a larger study of internal competition between donor sites in ligands which has as its long-term objective a more detailed understanding of the factors involved in such competition during complex formation.

Discussion

The ligand **1** studied in the present work has three potential donor sites, the sulfur and oxygen atoms of the SO group and the oxygen atoms of the carboxylate group. The ligand is also potentially a chelating agent, giving a five-membered chelate ring if the carboxylate group and the sulfur of the SO group are involved, and a six-membered chelate ring if the carboxylate group and the oxygen atom of the SO group are involved.

Detailed i.r. studies of sulfoxides (4), confirmed in some cases by X-ray crystallography (5–7), have shown that $\Delta\nu(S{-}O)$, $(\nu(S{-}O)_{ligand} - \nu(S{-}O)_{complex})$, is negative when coordination is via sulfur and positive when coordination is via oxygen.[3] Similar studies permit distinction between carboxylate salts and mono and bidentate carboxylate complexes (8).

1

The i.r. spectral data for the products of the reaction of phenylsulfoxyacetic acid **1** with the carbonates, basic carbonates or hydroxides of some group II metals, zinc(II), Ag(I) and some first row transition metals are given in Table 1. The data for the product of the reaction of mercurous nitrate and sodium phenylsulfoxyacetate are also given. The data for the parent acid and its sodium salt are also included for comparison. It is seen that $\Delta\nu(CO_2)$ is similar to the sodium salt for all these metal compounds indicating that the carboxylate–metal bonding is essentially ionic. The position of the SO stretching frequency is almost the same as for the parent acid and its sodium salt which indicates no bonding of the SO group to the metal. These compounds are therefore classified as simple salts. The i.r. spectra were the same before and after drying except for the presence of $\nu OH(H_2O)$ in some compounds before drying. The copper, zinc, and magnesium compounds still showed broad $\nu OH(H_2O)$ bands, at about 3010, 3250,

[1]Taken in part from the M.Sc. thesis of Beck-Yu Yap, Memorial University of Newfoundland, 1970.

[2]Revision received June 27, 1972.

[3]Recently (15) a case has been reported where bonding to SO takes place without a change in $\nu(S{-}O)$. However, in all cases so far tested a significant shift in $\nu(S{-}O)$ has indicated definite bonding.

*s = strong, ν(OH) region was examined in Nujol or HCB nulls.
†Absent in Nujol null.

and 3320 cm^{-1}, respectively, after drying for several hours under vacuum at 70°. In the case of all the other compounds these bands were absent after similar drying. This is in agreement with the elemental analyses (Table 4). When the copper salt was dried at 90° for several hours under vacuum it lost some of its water and the color changed from blue to green. The SO stretching frequency also changed. The value of $\Delta\nu$(SO), −22 cm^{-1}, for the green copper compound might indicate some interaction between the copper and the sulfur of the SO group but it is hardly large enough to be definitive for sulfur–copper bonding.

Reaction of the acid, **1**, with cadmium carbonate gave a dihydrate $Cd(C_6H_5SOCH_2CO_2)_2\cdot 2H_2O$. When crystallized from water this product has $\Delta\nu(SO) = +48$ cm^{-1} indicative of bonding through the oxygen of the SO group. The $\Delta\nu(CO_2)$ value of 210 cm^{-1} is similar to that of the sodium salt so there appears to be no covalent bonding between the $-CO_2$ groups and the cadmium. When the product was recrystallized from 95% ethanol a product with the same empirical formula but with a different i.r. spectrum was obtained. The $\Delta\nu$(SO) value is −12 cm^{-1} indicating no significant interaction between the metal and the SO group. The $\Delta\nu(CO_2)$ value, 167 cm^{-1}, is again similar to the sodium salt. The differences in the two compounds were further investigated. The X-ray powder diffraction patterns are quite different. Their melting points are also different. The properties in solution for the two compounds seem to be very similar. The molar conductance[3] is 147.28 Ω^{-1} cm^2 for the water crystallized product and 151.75 Ω^{-1} cm^2 for the product crystallized from 95% ethanol. The ^1H n.m.r. spectra in D_2O are the same for both products showing the phenyl protons and the AB system of the methylene group. It would thus appear that the two compounds are different in the solid but dissociate in solution to give the same ions. The compound recrystallized from 95% ethanol seems to be a simple salt whereas that crystallized from water seems to be a complex. The water-crystallized product shows bands below 500 cm^{-1} at 475, 380, and 300 cm^{-1}, the region where M—O stretching frequencies are expected. The ethanol crystallized product has no band in this region. The structure, therefore, of the water crystallized product would seem to be a tetra-coordinate complex with the oxygen of two phenylsulfoxyacetate ions and of two water molecules coordinated onto the metal. The carboxylate groups would presumably be outside the coordination sphere. However, ionic structures such as $[Cd(H_2O)_4]^{2+}[Cd(PhSOCH_2CO_2)_4]^{2-}$ cannot be ruled out on the above evidence.[4]

[4]We thank one of the referees for suggesting this ionic structure.

These structures are in keeping with the fact that most complexes of cadmium are tetra-coordinate complexes.

Reaction of the acid **1** with potassium tetrachloroplatinate(II) with or without the presence of an alkali metal chloride gave the compounds **2**, $M[Pt(PhSOCH_2CO_2)Cl_2]$ (M = H, K, or Cs). The i.r. spectral data given in Table 2 indicate that the ligand is attached to platinum via sulfur of the sulfoxide group. A shift of $\nu_{asym}(CO_2)$ from that of the acid (1720 cm^{-1}) indicates coordination via the carboxylate group and the large value of $\Delta\nu(CO_2)$ suggests monodentate coordination (8). All the compounds, **2**, show a medium intensity band at about 405 cm^{-1} (Table 3), which is believed to be ν(Pt—O) (*cf.* 388 and 407 cm^{-1} attributed to ν(Pt—O) in glycinate complexes of platinum(II) (9)).

The reaction of the acid, **1**, with potassium tetrachloroplatinate(II) in the presence of cesium chloride yielded, in addition to **2** (M = Cs), a compound with empirical formula $PtCl_2(C_6H_5SOCH_2CO_2H)$. This has $\Delta\nu$(SO) = −127 cm^{-1} indicating bonding of the SO group to the metal via the sulfur atom. However, the carbonyl stretching frequencies are close to that of the parent acid, indicating that the carboxylic group is not bonded to the metal. This information suggests the binuclear chlorine bridged structure shown in **3**. This structure is also supported by other evidence. The νOH(—COOH) is observed at about 2900 cm^{-1} (compared to

2920 cm^{-1} for the parent acid). The compound dissociates in water to give highly conducting solutions. The molar conductance is 755 Ω^{-1} cm^2 compared to 163–198 Ω^{-1} cm^2 for compounds **2**. The ^1H n.m.r. in acetone-d_6 shows the phenyl ring resonances as complex multiplets at 1.85 and 2.32 τ and an AB system ($J = 15$ Hz) of the methylene group at 5.38 τ. The absence of the $—CO_2H$ proton resonance indicates rapid exchange.

All compounds **2** and **3** show bands in the 310–340 cm^{-1} region which are probably assignable to ν(Pt—Cl) (10). The presence of two bands and the relatively large difference between them in **2** suggests that the Pt—Cl are *cis* to one another.

The situation with **3** is not so clear. There are three possible ν(Pt—Cl) and these could be assigned as terminal (338 cm^{-1}) and bridging (315 and 280 cm^{-1}) (11, 12) but the lowest energy band is somewhat weak. Nevertheless the general pattern of bands is very similar to that for $Pt_2(PEt_3)_2Cl_4$ discussed by Adams *et al.* (11). This evidence would suggest that **3** is a chlorine-bridged dimer.

Thus phenylsulfoxyacetic acid does behave as an ambident ligand, bonding to class "a" acceptors via oxygen and to class "b" acceptors via sulfur of the sulfoxy group. It does not appear to be as good a donor as an unsubstituted sulfoxide.

Experimental

Phenylsulfoxyacetic acid was prepared from commercial phenylthioacetic acid (Aldrich) by oxidation with hydrogen peroxide in ethanol (13). Metal salts were commercially available materials except where otherwise specified. I.r. spectra as Nujol or hexachlorobutadiene (HCB) mulls or KBr discs were recorded with a Perkin-Elmer Model 457 spectrometer (4000–250 cm^{-1}), X-ray powder diffraction patterns were recorded in the Department of Geology. Conductivity measurements were made in aqueous solution with a Beckman RC-18 conductivity bridge using standard KCl solutions as calibrant. ^1H n.m.r. spectra were recorded with a Varian A-60 spectrometer. Element analyses (C, H, S, Cl) were carried out by the Alfred Bernhardt Microanalytical Laboratory, West Germany. Metal analyses were obtained by standard methods (Ca, Mn, Co, and Cu by atomic absorption; Mg, Ni, Zn, and Cd by complexometry, Ag and Ba by gravimetry).

Salts of Phenylsulfoxyacetic Acid

(*a*) An aqueous solution of phenylsulfoxyacetic acid (3.680 g, 20.0 mmol in 100 ml) was added to heavy basic magnesium carbonate, $3MgCO_3\cdot Mg(OH)_2\cdot 3H_2O$, (0.9134 g, 2.5 mmol) and the reaction mixture was stirred until it was no longer acidic. Excess magnesium carbonate was filtered off, the solvent was removed under reduced pressure, and the residue was recrystallized from aqueous acetone and dried at 70° to give magnesium phenylsulfoxyacetate dihydrate (4.16 g, 97.5%). Salts of Ca(II), Ba(II), Mn(II), Ni(II), Cu(II), Zn(II), and Ag(I) were prepared by the same method from the corresponding carbonates, hydroxides, or basic carbonates.

(*b*) An aqueous solution of sodium phenylsulfoxyacetate (2.06 g, 10.0 mmol in 5 ml) was added to acidic aqueous mercury(I) nitrate solution (2.806 g, 10.0 mmol in 15 ml) in the dark. The white precipitate, which began to form immediately, was filtered off after 2 h and dried *in vacuo* at 70° to give mercury(I) phenylsulfoxyacetate (3.15 g, 82.0%).

Complexes of Phenylsulfoxyacetic Acid

(a) With Cadmium(II)

An aqueous solution of phenylsulfoxyacetic acid (3.680 g, 20.0 mmol in 100 ml) was added with stirring to an excess of freshly prepared cadmium carbonate (14). Stirring was continued at 50° until the solution became neutral. The

excess of cadmium carbonate was filtered off, the solvent was evaporated under reduced pressure, and the residue solidified by the addition of ethyl ether. Recrystallization from water gave the complex $[C_6H_5S(O)CH_2CO_2]_2Cd{\cdot}2H_2O$, m.p. 124–125° (4.230 g, 88.5%).

Anal. Calcd. for $C_{16}H_{18}O_8S_2Cd$: C, 37.33; H, 3.52; S, 12.46. Found: C, 37.37; H, 3.61; S, 12.26.

X-Ray powder diffraction pattern $d(I/I_{10})$; 1.77(5), 2.16(5), 2.44(5), 2.50(5), 2.68(6), 2.90(5), 3.08(4), 3.31(8), 3.47(8), 3.92(7), 4.17(6), 4.50(1), 4.91(1), 5.50(10), 7.76(3). Recrystallization from 95% ethanol gave a simple salt dihydrate with the same formula, m.p. 131–132°.

Anal. Calcd. for $C_{16}H_{18}O_8S_2Cd$: C, 37.33; H, 3.52; S, 12.46. Found: C, 37.62; H, 3.37; S, 12.23.

X-Ray powder diffraction pattern $d(I/I_{10})$; 2.32(5), 2.59(3), 2.91(7), 3.38(6), 3.62(5), 3.88(10), 4.32(8), 4.91(1), 5.37(8), 5.93(8).

(b) Hydrogen Dichloromono(phenylsulfoxyacetato)-platinate(II)

An aqueous solution of potassium tetrachloroplatinate(II) (0.4152 g, 1.00 mmol in 3 ml) was added to an aqueous solution of phenylsulfoxyacetic acid (0.1840 g, 1.00 mmol in 5 ml) to give a yellow precipitate which began to form after 5 h at 45°. The precipitate was filtered off, washed with water and dried *in vacuo* to give the title product, m.p. 230° (dec.), (0.3378 g, 75.0%).

Anal. Calcd. for $C_8H_8Cl_2O_3SPt$: C, 21.34; H, 1.79; S, 7.12; Cl, 15.75. Found: C, 21.26; H, 1.69; S, 7.04; Cl, 15.45.

(c) Potassium Dichloromono(phenylsulfoxyacetato)-platinate(II)

An aqueous solution of potassium tetrachloroplatinate(II) (0.8304 g, 2.00 mmol in 3 ml) was added to an aqueous solution of potassium phenylsulfoxyacetate prepared by neutralizing the acid (0.3680 g, 2.00 mmol in 10 ml) with the stoichiometric amount of potassium carbonate. Stirring was continued at room temperature until the initially reddish solution turned yellow. Cooling caused crystallization of a yellow material which was washed with cold water and cold 95% ethanol and then dried *in vacuo* to give the title compound, m.p. 260° (dec.) (0.2363 g, 24.2%).

Anal. Calcd. for $C_8H_7Cl_2O_3SKPt$: C, 19.68; H, 1.65; S, 6.56; Cl, 14.52. Found: C, 19.89; H, 1.56; S, 6.82; Cl, 14.17.

(d) Cesium Dichloromono(phenylsulfoxyacetato)-platinate(II) and Di-μ-chlorodichlorobis-(phenylsulfoxyacetic acid)diplatinum(II)

A mixture of potassium tetrachloroplatinate(II) (0.4152 g, 1.00 mmol), phenylsulfoxyacetic acid (0.1840 g, 1.00 mmol) and cesium chloride (0.1684 g, 1.00 mmol) was dissolved in water (10 ml) and stirred at room temperature for 14 h.

The yellow precipitate was filtered off, washed with cold water, and dried *in vacuo* to give the cesium salt, $Cs[Pt(C_6H_5SOCH_2CO_2)Cl_2]$, m.p. 230° (dec.) (0.2268 g, 39.1%).

Anal. Calcd. for $C_8H_7Cl_2O_3SCsPt$: C, 16.51; H, 1.21; S, 5.51; Cl, 14.52. Found: C, 16.34; H, 1.31; S, 5.34; Cl, 14.17.

Yellow acicular crystals of the chlorine-bridged dimer separated from the mother liquors after 3 days at 0°, m.p. 125° (0.1520 g, 33.8%).

Anal. Calcd. for $C_{16}H_{16}O_6Cl_4S_2Pt_2$: C, 21.34; H, 1.79; S, 7.12; Cl, 15.75. Found: C, 21.19; H, 1.81; S, 7.39; Cl, 15.80.

Unsuccessful Experiments

Attempts to isolate pure compounds of chromium, cobalt, iron, and molybdenum using standard methods were unsuccessful.

We thank the National Research Council of Canada for financial support and Dr. V. S. Papezik of the Department of Geology for obtaining the X-ray powder diffraction patterns.

Chaleurs de mélange du système éthyl-3 pentanol-3 tétrachlorure de carbone

H. Brusset, M. Desgranges, et J. C. Lecoq

Laboratoire de Recherches de Chimie systématique, Ecole Normale Supérieure, 24 rue Lhomond et Université Paris VI, Bâtiment F 8, rue Cuvier Paris V°

Reçu le 7 décembre, 1971

Les enthalpies de mélange du système éthyl-3 pentanol-3 tétrachlorure de carbone ont été mesurées par microcalorimétrie. La théorie classique des solutions associées conduit à une expression de l'enthalpie d'excès que nous avons simplifiée par l'introduction de la chaleur à dilution infinie de l'alcool. L'expression obtenue permet de calculer l'enthalpie de formation d'une liaison hydrogène en utilisant des résultats calorimétriques et tonométriques.

Le calcul permet de vérifier que cette enthalpie est indépendante de la concentration de la solution (jusqu'à 0.45 en fraction molaire). La valeur obtenue est en bon accord avec les résultats de la littérature.

The enthalpies of mixing in the system 3-ethyl-3 pentanol–carbon tetrachloride were measured by microcalorimetry. The classic theory of associated solutions leads to an expression for the excess enthalpy which we have simplified by introducing the heat at infinite dilution for the alcohol. The resulting expression allows the enthalpy of formation of a hydrogen bond to be calculated using calorimetric and tonometric results. The calculations show that this enthalpy is independent of the concentration of the solution (up to 0.45 in molar fraction) and is in agreement with the literature.

Introduction

La mesure des enthalpies de mélange du système éthyl-3 pentanol-3 tétrachlorure de carbone a déjà été effectuée à 3 températures (25, 40, 50 °C) en utilisant un microcalorimètre de type Calvet (1).

Dans le présent article, nous complétons l'étude de ce système à 60 °C.

Nous avons ensuite effectué le lissage des courbes expérimentales. L'utilisation de la théorie classique des mélanges associés nous permet de calculer, à partir de nos résultats calorimétriques, combinés à ceux déduits de mesures tonométriques, l'énergie d'association de l'alcool.

Etude expérimentale

Le dispositif expérimental permettant de réaliser le mélange des deux constituants du système est détaillé dans la référence 1. Rappelons simplement que l'un des constituants du mélange est contenu dans une ampoule de verre soufflé aussi mince que possible. Le second constituant du mélange occupe la partie supérieure d'un cloche de verre. L'ampoule terminée par un capillaire est maintenue dans la cloche de verre par un bouchon de liège d'où dépasse légèrement le capillaire. Tout le système ampoule–cloche est contenu dans la cellule de mesure. Les 2 constituants ne sont surmontés d'aucune atmosphère, tout le reste de l'espace étant occupé par du mercure. En faisant descendre la cloche de verre, l'extrémité inférieure du capillaire de l'ampoule vient buter au fond de la cellule; l'ampoule remonte et vient se briser sur l'extrémité pointue d'un petit agitateur en acier, les 2 liquides se mélangent. L'homogénéité du mélange est réalisée par quelques va-et-vient de l'agitateur.

Le contrôle de la température de l'enceinte est assuré par un régulateur de température RT 64 de Setaram (France).

L'utilisation de ce dispositif nous a permis de mesurer les enthalpies de mélange de l'éthyl-3 pentanol-3 dans le tétrachlorure de carbone à 4 températures. Les résultats obtenus sont donnés dans le tableau 1. Les courbes de la fig. 1 représentent l'enthalpie de mélange H^E en ordonnée en fonction de la fraction molaire d'alcool x_A.

Pour les faibles concentrations en l'un ou l'autre des constituants ($x_A < 0.15$ et $x_A > 0.85$) l'erreur expérimentale sur H^E est estimée à 2.5%. Pour les concentrations intermédiaires ($0.15 < x_A < 0.85$) cette erreur est inférieure à 2%.

L'incertitude sur la fraction molaire d'alcool varie de 0.05% aux fortes concentrations jusqu'à 1% aux faibles concentrations.

Le phénomène observé est endothermique. Ceci est normal puisque la mise en solution de l'alcool dans le solvant provoque essentiellement la désassociation partielle de

l'alcool et que cet effet est endothermique. L'enthalpie de mélange croît avec la température (2).

Lissage des courbes expérimentales

Nous avons lissé nos courbes expérimentales suivant un développement polynômial de Redlich–Kister (3) couramment utilisé (4, 5)

$$[1] \qquad H^E = x_A(1 - x_A)(a_1 + a_2x_A + a_3x_A^2 + \ldots)$$

où H^E est l'enthalpie de mélange (ou d'excès) par mole de mélange, et x_A la fraction molaire en alcool.

La méthode de lissage employée est celle des moindres carrés.

Le nombre des coefficients du développement (éq. 1) que nous utilisons n'est pas fixé *a priori*; pour le déterminer, nous employons un critère proposé par Mme Duboc (6) et que nous rappelons brièvement.

Pour une courbe donnée, nous effectuons le lissage suivant les développements successifs à 2, 3, ..., n coefficients. Pour chaque développement nous calculons la dispersion moyenne δ des points expérimentaux autour de la courbe lissée ainsi que les erreurs statistiques Δa_i sur les coefficients a_i. Nous constatons que lorsque le nombre de coefficients a_i croît, la dispersion δ décroît, passe par un minimum pour m coefficients, puis se met à croître. D'autre part, certaines erreurs statistiques Δa_i deviennent supérieures aux coefficients a_i pour un développement à $m + 1$ coefficients. Ainsi, nous sommes conduits à adopter le développement à m coefficients pour lequel la dispersion moyenne δ est minimum.

Les coefficients obtenus pour l'ensemble des courbes étudiées sont donnés dans le tableau 2. Dans ce tableau nous ne donnons que les coefficients que nous sommes conduits à adopter compte tenu du critère indiqué précédemment.

Les courbes lissées sont données sur la fig. 1.

Le premier terme a_1, des développements obtenus, représente la pente de la tangente à l'origine de la courbe considérée, ou encore la chaleur à dilution infinie $H^E_\infty = \lim (H^E/x_A)_{x_A \to 0}$ de l'alcool dans le solvant.

Application de la théorie classique des mélanges idéaux associés et résultats

Nous donnons tout d'abord la liste des symboles utilisés dans les équations qui vont suivre. H^E, enthalpie d'excès par mole de mélange; H^E_∞, enthalpie molaire à dilution infinie de l'alcool dans le solvant; x_A, fraction molaire stoechiométrique de l'alcool; x_S, fraction molaire du constituant non associé du mélange; $x^e_{A_i}$, fraction molaire effective (mélange considéré comme constitué de monomères et de polymères) du polymère d'ordre i à l'équilibre; $x^{0e}_{A_i}$, fraction molaire effective du complexe A_i dans l'alcool pur; ΔH^0, enthalpie de formation d'une liaison hydrogène; ΔH^0_p, enthalpie de formation d'une liaison hydrogène dans l'alcool pur.

La théorie classique des mélanges idéaux associés (7, 8) pose, comme hypothèse, que l'enthalpie de mélange observée n'est due qu'au phénomène de désassociation.

Les hypothèses qui permettent d'obtenir une expression de l'enthalpie d'excès H^E par mole de mélange (7, 8, 9) sont les suivantes:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*a*) Tout au moins pour des solutions suffisamment diluées d'alcool dans un solvant inerte, l'enthalpie de formation d'une liaison hydrogène a une valeur constante ΔH^0 indépendante des espèces dans lesquelles elle est engagée. Pour l'alcool pur, cette valeur peut être différente et nous l'appelons ΔH^0_p.

(*b*) L'association est linéaire, ou tout au moins les cycles sont très peu nombreux.

(*c*) L'enthalpie de mélange n'est due qu'à la désassociation de l'alcool.

Le calcul de l'enthalpie d'excès se mène alors de la façon suivante:

Par mole stoechiométrique d'alcool en solution (mole correspondant à la formule chimique R—OH de l'alcool), il y a n_{A_1} monomères, n_{A_2} dimères, ..., n_{A_i} polymères d'ordre i, et dans l'hypothèse de polymères linéaires, il y a donc $\sum_{i=2}(i-1)n_{A_i}$ liaisons hydrogène par mole stoechiométrique d'alcool pur.

L'enthalpie d'excès H^E par mole de mélange a pour expression:

$$[2]\quad H^E = \left(\sum_{i=2}(i-1)n_{A_i}\Delta H^0 - \sum_{i=2}(i-1)n^0_{A_i}\Delta H^0_p\right)x_A$$

En remplaçant dans cette expression les n_{A_i} par leurs valeurs en fonction des fractions molaires effectives $x^e_{A_i}$, puis en formant l'expression $\sum_{i=1} ix^e_{A_i}$ et tenant compte de $\sum_{i=1} in_{A_i} = 1$, l'expression 2 devient:

$$[3]\quad H^E = \left(\frac{\sum_{i=2}(i-1)\Delta H^0 x^e_{A_i}}{\sum_{i=1} ix^e_{A_i}} - \frac{\sum_{i=2}(i-1)\Delta H^0_p x^{0e}_{A_i}}{\sum_{i=1} ix^{0e}_{A_i}}\right)x_A$$

Expression dans laquelle ne figurent plus les n_{A_i} mais les fractions molaires effectives.

Cette expression 3 est plus connue sous la forme suivante (7):

$$[4]\quad H^E = \frac{\sum_{i=2}(i-1)\Delta H^0 x^e_{A_i}}{1+\sum_{i=2}(i-1)x^e_{A_i}} - \frac{\sum_{i=2}(i-1)\Delta H^0_p x^{0e}_{A_i}}{1+\sum_{i=2}(i-1)x^{0e}_{A_i}}x_A$$

Mais nous l'avons obtenue par une approche différente.

Cette forme est identique à éq. 3, car un calcul algébrique simple, mais un peu long, permet de montrer que:

$$\sum_{i=1} ix^e_{A_i} = x_A\left(1+\sum_{i=2}(i-1)x^e_{A_i}\right)$$

Ce qui donne pour l'alcool pur:

$$\sum_{i=1} ix^{0e}_{A_i} = 1+\sum_{i=2}(i-1)x^{0e}_{A_i}$$

Nous pouvons, grâce à l'introduction de la chaleur à dilution infinie H^E_∞ de l'alcool, éliminer les paramètres se rapportant à l'alcool pur (2ème partie de l'équation 3). Cette méthode a déjà été utilisée par Stokes (10). Nous avons vu que

$$H^E_\infty = \lim\left(\frac{H^E}{x_A}\right)_{x_A\to 0}$$

Formons H^E/x_A à partir de l'éq. 3.

$$[5]\quad \frac{H^E}{x_A} = \frac{\sum_{i=2}(i-1)\Delta H^0 x^e_{A_i}}{\sum_{i=1} ix^e_{A_i}} - \frac{\sum_{i=2}(i-1)\Delta H^0_p x^{0e}_{A_i}}{\sum_{i=1} ix^{0e}_{A_i}}$$

A dilution infinie ($x_A \to 0$), nous supposons qu'il ne reste plus que des monomères (11, 12). Dans ces conditions, le numérateur du 1er terme de l'éq. 5 est nul et

$$[6]\quad H^E_\infty = \frac{-\sum_{i=2}(i-1)\Delta H^0_p x^{0e}_{A_i}}{\sum_{i=1} ix^{0e}_{A_i}}$$

En formant [6] – [5] il vient:

$$[7]\quad H^E_\infty - \frac{H^E}{x_A} = \frac{-\sum_{i=2}(i-1)\Delta H^0 x^e_{A_i}}{\sum_{i=1} ix^e_{A_i}}$$

Cette équation a l'avantage de ne plus présenter de termes relatifs à l'alcool pur.

Par ailleurs, une étude tonométrique (13, 14) a permis, dans le cadre de la théorie des solutions idéales associées (8), de déterminer les constantes d'équilibre entre les polymères de l'alcool et de calculer les fractions molaires effectives $x^e_{A_i}$ des divers polymères, jusqu'à une fraction

TABLEAU 3. Répartition des polymères du système éthyl-3 pentanol-3 tétrachlorure de carbone à 25 °C (réf 14)

0.30	0.137	0.047	0.018	0.007	0.003	0.001	0.001
0.35	0.148	0.055	0.023	0.010	0.004	0.002	0.001
0.40	0.158	0.062	0.028	0.013	0.006	0.003	0.001
0.45	0.175	0.077	0.033	0.019	0.010	0.005	0.001

stoechiométrique d'alcool de 0.45 (domaine de validité de la théorie) et à 25 °C (tableau 3).

Rappelons simplement que cette étude tonométrique utilise la théorie des solutions idéales associées et un modèle à 2 constantes d'équilibre. La première constante K_1 est relative aux équilibres du type $A_1 + A_1 \rightleftarrows A_2$ où A_1 est un monomère d'alcool et A_2 un dimère.

La seconde constante K_2 est commune à tous les équilibres du type $A_i + A_1 \rightleftarrows A_{i+1}$ $(i \geqslant 2)$.

Ce modèle conduit à l'équation classique (8, 13, 14)

$$\frac{1}{P_A} = \frac{K_2}{P^0_A L} + \frac{1}{P^0_A L}\sqrt{\frac{K_1}{f_B - 1}}$$

P_A, pression partielle d'alcool; P^0_A, tension de vapeur de l'alcool pur à la température considérée; f_B, coefficient d'activité du solvant dans le mélange; L, limite du coefficient d'activité f_A de l'alcool quand $x_A \to 0$.

Le tracé de la droite $1/P_A = f(1/\sqrt{f_B - 1})$ permet de calculer sa pente $\sqrt{K_1}/P^0_A L$ et son ordonnée à l'origine $K_2/P^0_A L$.

P^0_A est connu et les mesures tonométriques permettent la détermination de L. Pour le système envisagé ici il a été trouvé à 25 °C: $K_1 = 2.5$ et $K_2 = 2.9$.

A partir de K_1 et K_2 et en appliquant la loi d'action de masse aux équilibres entre polymères indiqués précédemment, on en déduit la répartition des polymères de l'alcool en fonction de la fraction molaire stoechiométrique x_A d'alcool.

L'étude tonométrique (13, 14) a montré que, pour les mélanges d'éthyl-3 pentanol-3 dans le tétrachlorure de carbone et jusqu'à $x_A = 0.45$, la polymérisation de l'alcool est limitée pratiquement à l'ordre 6 (voir tableau 3).

TABLEAU 4. Système éthyl-3 pentanol-3 tétrachlorure de carbone: enthalpie de formation de la liaison hydrogène à 25 °C

x_A	ΔH^0 (J)
0.05	−22 978
0.10	−22 081
0.15	−21 934
0.20	−22 087
0.25	−21 610
0.30	−22 242
0.35	−21 687
0.40	−21 437
0.45	−20 687

L'utilisation de ces résultats et de ceux que nous avons obtenus par microcalorimétrie, nous permet grâce à l'éq. 7 de calculer ΔH^0 pour chaque concentration.

$$[8] \qquad \Delta H^0 = -\left(H^E_\infty - \frac{H^E}{x_A}\right)\frac{\sum_{i=1} i x^e_{A_i}}{\sum_{i=2}(i-1)x^e_{A_i}}$$

Les résultats obtenus sont donnés dans le tableau 4. (*i*) L'examen du tableau 4 nous montre que ΔH^0 est pratiquement indépendant de la concentration en alcool, dans le domaine exploré. Nous vérifions là, une hypothèse assez souvent faite (9, 10). (*ii*) La valeur moyenne de ΔH^0 est $\Delta H^0 = -21860$ J. L'écart maximum entre cette moyenne et les valeurs du tableau 4 est de 5.3%. (*iii*) Des mesures de r.m.n., exploitées à l'aide d'un modèle d'association linéaire (15), ont conduit, pour le même système, à la même température à une enthalpie de dimérisation de −24 244 J. Cette valeur diffère d'à peu près 10% de celle que nous trouvons. (*iv*) D'autres auteurs (16) utilisant un modèle un peu

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

différent du modèle classique des mélanges associés, font l'hypothèse de l'existence de 2 valeurs différentes de la chaleur de formation d'une liaison hydrogène; ils trouvent pour la première relative aux dimères $-17\,974$ J, pour la seconde, relative aux liaisons hydrogène de tous les autres polymères: $-20\,900$ J. Ces valeurs ne sont pas très éloignées de celle que nous avons calculée.

Conclusion

Les enthalpies de mélanges élevées du système éthyl-3 pentanol-3 tétrachlorure de carbone sont dues presque essentiellement à la désassociation de l'alcool.

La théorie classique des solutions associées conduit à une expression de l'enthalpie d'excès que nous avons pu notablement simplifier par l'introduction de la chaleur à dilution infinie de l'alcool. La nouvelle expression obtenue permet alors de calculer l'enthalpie de formation ΔH^0 d'une liaison hydrogène en utilisant des résultats calorimétriques et tonométriques.

Le calcul nous a permis de vérifier que ΔH^0 est pratiquement indépendant de la concentration de la solution tout au moins sur un certain domaine (jusqu'à 0.45 en fraction molaire).

Enfin, la valeur obtenue ($-21\,860$ J) est en bon accord avec les résultats donnés dans la littérature (15, 16).

Received July 29, 1971[2]

A number of both mono and bis addition compounds of dimethyl- and diphenyltin dichloride with oxygen donor molecules of the general type R_nEO (E = C, N, P, S) have been prepared and characterized by Mössbauer, infrared, and Raman spectroscopies. In the solid state the bis derivatives all have *trans* methyl or phenyl groups, and with the sole exception of $Me_2SnCl_2 \cdot 2C_5H_5NO$, all appear to have *cis*-chlorines and *cis*-donor molecules. Considerable distortions of the Ph_2Sn groups from linearity are suggested. The rather unusual $R_2SnCl_2 \cdot L$ complexes appear to have trigonal bipyramidal structures in which the R groups and one Cl atom occupy equatorial positions, with the donor molecule and second Cl atom in apical positions. Again the C_5H_5NO adduct of Me_2SnCl_2 seems to be an exception, with both apices apparently occupied by Cl atoms.

Un certain nombre de composés de mono et de bis addition du dichlorure de diméthyl- et de diphénylétain avec des donneurs d'oxygène de type général R_nEO (E = C, N, P, S) ont été préparés et caractérisés par spectroscopie Mössbauer, infrarouge et Raman. A l'état solide, les dérivés bis ont tous les groupes méthyle ou phényle en *trans* et à l'exception de $Me_2SnCl_2 \cdot 2C_5H_5NO$ seul, tous apparaissent avoir les chlores en *cis* et les molécules du donneur en *cis*. Des distorsions considérables par rapport à la linéarité des groupes Ph_2Sn sont suggérées. Les complexes peu usuels du type $R_2SnCl_2 \cdot L$ apparaissent posséder des structures trigonales bipyramidales dans lesquelles on trouve les groupes R et un atome de Cl en position équatoriale, la molécule du donneur et le second atome de Cl étant disposés au sommet. Le composé d'addition de Me_2SnCl_2 avec C_5H_5NO semble être encore une exception, les deux sommets sont occupés apparamment par des atomes de Cl.

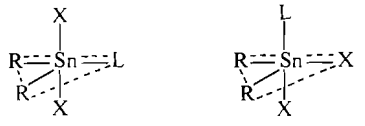
Canadian Journal of Chemistry, 50, 3212 (1972)

Introduction

Most addition compounds of diorganotin(IV) dihalides with monodentate Lewis bases reported thus far have the expected 1:2 stoichiometry (1) *i.e.*, $R_2SnX_2 \cdot 2L$ (R = alkyl, aryl; X = halogen; L = monodentate ligand), with hexacoordination about the tin atom. Scattered reports of a few complexes of the type $R_2SnX_2 \cdot L$ have appeared (2–6), but no systematic study of these latter derivatives has been made.

We felt it would be of interest to try to prepare a number of $R_2SnX_2 \cdot L$ complexes and to investigate their Mössbauer and vibrational spectroscopic properties. In a trigonal bipyramidal structure it is expected that the more electropositive organic groups should occupy equatorial positions, as observed (7) for the $Me_2SnCl_3^-$ ion. Of the remaining ligands, those of highest electronegativity will presumably occupy axial locations. There is thus the possibility of competition between the halogens and the donor molecule for one of the apical positions, with the occurrence of structure **1** or **2** presumably depending upon the nature of the Lewis base. For example, it is reported that



1 2

$Me_2SnCl_2 \cdot DMF$ shows two infrared-active Sn—Cl stretching bands (3), but only one Sn—Cl absorption is found for $Me_2SnCl_2 \cdot Me_2SeO$ (4). From these results, it was concluded (3, 4) that the DMF adduct has structure **2**, while the selenoxide derivative has structure **1**.

Addition compounds of 1:2 stoichiometry

are also of some structural interest. X-Ray data for $Me_2SnCl_2 \cdot 2Me_2SO$ (8) and $Me_2SnCl_2 \cdot 2PyO$ (9) ($PyO = C_5H_5NO$) show *cis* and *trans* arrangements, respectively, of the chlorine atoms, with the methyl groups *trans* in both complexes. The factors governing the occurrence of one or the other arrangement are by no means clear. Furthermore, recent work by Fitzsimmons *et al.* (10) on some organotin dithiocarbamates has raised the possibility that corresponding methyl- and phenyltin derivatives might not necessarily be isostructural. For compounds of the type $R_2Sn(S_2CNR'_2)_2$ *trans*-octahedral structures are observed for $R = CH_3$ and n-C_4H_9, but a *cis*-octahedral configuration is indicated for $R = C_6H_5$.

In this paper we report the preparation of a number of 1:1 adducts of Me_2SnCl_2 and Ph_2SnCl_2 with Lewis bases in which coordination to tin is via an oxygen atom. Mössbauer, infrared, and Raman spectra are used to deduce the probable structures of these derivatives, and of the corresponding 1:2 complexes. A preliminary report on some of the sulfoxide complexes of Ph_2SnCl_2 has appeared (11).

Experimental

Materials

Diethyl sulfoxide (Et_2SO) was obtained by oxidation of diethyl sulfide with nitric acid, followed by distillation under reduced pressure. The purity of the compound was checked by microanalysis and by its infrared spectrum. The other Lewis bases employed were purchased from Eastman Organic Chemicals, Aldrich Chemical Company, or Fisher Scientific Co., and were used without further purification. Diphenyltin dichloride from Alfa Inorganics was recrystallized from methanol, and dimethyltin dichloride from Columbia Organic Chemicals Co. was recrystallized from carbon tetrachloride and dried *in vacuo* prior to use. All solvents were reagent grade.

Preparation of Complexes

The 1:1 addition compounds were prepared by adding a solution of dimethyl- or diphenyltin dichloride in a suitable solvent to a stoichiometric quantity of the appropriate Lewis base dissolved in the same solvent employed for the tin compound. In the case of the $Ph_2SnCl_2 \cdot Ph_3PO$ derivative, precipitation occurred immediately on mixing the solutions, and the product was suction-filtered and dried in air. For the other 1:1 complexes, the solvent was removed under reduced pressure and the products dried *in vacuo*. Preparation of the 1:2 derivatives followed a similar route, except that 100% excess of base was used. In most cases essentially quantitative yields of the pure complexes resulted, but where necessary the products were recrystallized from chloroform or carbon tetrachloride.

With the exception of the four PyO derivatives which were obtained as buff colored powders, and $Me_2SnCl_2 \cdot (CH_2)_4SO$ which is an oil at room temperature, all the complexes precipitated as white crystalline products. Analytical data, melting points, and solvent employed are given in Table 1.

Mössbauer Spectra

The Mössbauer spectrometer has been described in detail (12). The polycrystalline powders were contained in brass cells fitted with Mylar windows. A sample thickness of ~ 1 mm was maintained by use of a Teflon spacer in the cell. All measurements were made in transmission geometry with the absorber at 80 ± 2 K and the $Ba^{119m}SnO_3$ source at 295 ± 2 K. In the case of $Me_2SnCl_2 \cdot (CH_2)_4SO$, the sample was applied dropwise from a syringe onto a Mylar window maintained at liquid nitrogen temperature. Isomer shifts are reported relative to an SnO_2 absorber at 80 ± 2 K. The data were computer-fitted to Lorentzian line shapes; no constraints were imposed. We estimate the precision of the Mössbauer measurements to be ± 0.03 mm s^{-1}.

Infrared Spectra

In the 2000–250 cm^{-1} region the infrared spectra were obtained on a Perkin–Elmer 457 grating spectrophotometer, and between 600–180 cm^{-1} on a Perkin–Elmer 180 instrument. The samples were run as Nujol mulls on CsI plates, except $Me_2SnCl_2 \cdot (CH_2)_4SO$ which was run as a thin film. Comparison spectra of the Lewis base ligands, either neat or as Nujol mulls, were also recorded.

Raman Spectra

A Cary 81 instrument, fitted with a Spectra Physics Corp. Model 125 He–Ne laser, was employed. The 6328 Å line was used as exciting light. The solid samples were contained in 5 mm o.d. flat-bottomed Pyrex tubes.

Results and Discussion

There generally seems to be little difficulty in obtaining both 1:1 and 1:2 adducts of Me_2SnCl_2 and Ph_2SnCl_2 with the oxygen donors employed here. However, we have been unable to obtain 1:1 complexes of Me_2SnCl_2 with Ph_2SO and Ph_3PO, although Ph_2SnCl_2 readily yields 1:1 adducts with these bases and $Me_2SnCl_2 \cdot (PhCH_2)_2SO$ has been reported (5). Similarly, we have not isolated $Ph_2SnCl_2 \cdot DMF$, although the existence of $Me_2SnCl_2 \cdot DMF$ has been claimed (2, 3) and confirmed here. In each case several different solvent systems were tried, but i.r. spectra always showed the presence of the bis derivative. All our attempts to prepare $Ph_2SnCl_2 \cdot 2Ph_3PO$ afforded only the mono-addition compound, despite the reported (13) preparation of the 1:2 complex. Mullins (6) has also been unable to obtain the bis-adduct.

Both 1:1 and 1:2 derivatives appear to be air stable and to offer no survival problems, except $Me_2SnCl_2 \cdot Bu_2SO$ and $Ph_2SnCl_2 \cdot PyO$.

†Semi-solid at room temperature.
‡Oil at room temperature. After freezing to 80 K and re-warming, m.p. = 51–53° and analytical data unchanged.

These slowly decompose on standing at room temperature and are best stored under refrigeration.

$Me_2SnCl_2 \cdot (CH_2)_4SO$ was originally isolated as an oil which failed to yield a solid product on trituration, on cooling in an ice bath, or after prolonged evacuation. When a sample of this compound was frozen at 80 K to record its Mössbauer spectrum and warmed again to room temperature, it reverted to an oil which then solidified over a period of several hours. The solid and liquid products show significant differences in their Mössbauer and i.r. spectra, as discussed below.

Mössbauer Spectra

^{119}Sn Mössbauer isomer shifts (δ), quadrupole splittings (Δ), and linewidths (Γ = FWHM) are given in Table 2 for all complexes prepared here. For all the 1:2 adducts of both Me_2SnCl_2 and Ph_2SnCl_2, the large Δ values clearly establish *trans*-R_2 configurations, as a *cis* arrangement of the organic groups would give a splitting no larger than *ca.* 2 mm s^{-1}

(10, 14). On the other hand, *cis* and *trans* arrangements of donor molecules are effectively degenerate as regards the electric field gradient (EFG), so that no further structural conclusions are possible on the basis of these data. There is no systematic variation of Δ with changes in Lewis base, nor is any anticipated in view of the fact that the organic ligands control the sign, and to a large extent the magnitude of the EFG at tin (15). All the 1:2 complexes have slightly lower δ values than the parent organotin halide. This may be due to shielding of the s electrons resulting from donation into the vacant 5d orbitals of tin. The somewhat smaller δ and Δ values for the phenyl- as compared to methyltin compounds are expected from electronegativity considerations and are consistent with trends observed in other systems (16).

The $Ph_2SnCl_2 \cdot L$ derivatives show Δ values lying between those for Ph_2SnCl_2 and the corresponding 1:2 adducts with no significant line broadening, thus confirming they are true addition compounds. The large difference in splittings observed for Ph_2SnCl_2 and the 1:2 complexes requires that equimolar mixtures of the two should show either four-line Mössbauer spectra or extremely broad apparent doublets. Although the 1:1 adducts of Me_2SnCl_2 generally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

have Δ values intermediate between those for the parent compound and the corresponding 1:2 complexes, the distinction is not as clear as that for the phenyltin derivatives. This is probably due to the fact that Me_2SnCl_2 has a considerably larger Δ than does Ph_2SnCl_2, so there is a relatively smaller change in Δ on forming a pentacoordinate adduct. However, these data, together with melting points and vibrational spectra, leave little doubt that all the 1:1 derivatives are formulated correctly.

When the $Me_2SnCl_2 \cdot (CH_2)_4SO$ product originally isolated as an oil was frozen at ~ 80 K, a doublet with unusually broad lines and $\Delta \simeq 3.8$ mm s^{-1} was observed. After the sample melted and resolidified at room temperature as described above, it was again cooled to 80 K and its Mössbauer spectrum redetermined. The splitting had now decreased by 0.2 mm s^{-1}, and the lines were significantly narrower. The latter spectrum is quite "clean" and cannot be interpreted in terms of an equimolar mixture of Me_2SnCl_2 and $Me_2SnCl_2 \cdot 2(CH_2)_4SO$. Because of the broad lines and the magnitude of the splitting observed in the initial spectrum, we cannot rule out the possibility that the *oil* is a mixture of neat Me_2SnCl_2 and the 1:2 adduct. However, such a suggestion does not seem to be supported by the infrared spectrum (*vide infra*). We think the oil is probably a metastable state, and that the line-broadening may arise from difficulties in controlling sample thickness when freezing the oil.

Vibrational Spectra

With the exception of the element–oxygen stretching frequencies ν(E—O) of the donor molecules, all bands of structural significance lie below 600 cm^{-1} for the methyltin complexes and below 500 cm^{-1} for the phenyltin derivatives. Thus we do not tabulate bands above these regions except for ν(E—O). It was difficult to obtain satisfactory Raman spectra in the 600–180 cm^{-1} region owing to the high background of Rayleigh scattering, and the spectra were not of particularly high quality. Our structural conclusions are therefore based primarily on the i.r. data. To facilitate discussion we consider the mono and bis adducts separately.

(i) $Ph_2SnCl_2 \cdot 2L$ Complexes

Observed vibrational frequencies and assignments are given in Table 3. Not listed are certain characteristic bands common to all the phenyltin compounds (1:1 and 1:2 adducts and neat Ph_2SnCl_2) which we mention briefly. There are two bands of weak-to-medium intensity at 1068 ± 3 and 1022 ± 1 cm^{-1} which we attribute to a phenyl in-plane C—H deformation mode, and a ring vibration at 1000 ± 3 cm^{-1}, usually of medium intensity. Strong bands assigned as out-of-plane C—H deformations (17) occur at 735 ± 6 and 695 ± 4 cm^{-1}, the former band being split in several of the compounds. There is also a strong absorption at 460 ± 5 cm^{-1} which Poller (18) attributes to the substituent-sensitive 16*b* mode of a mono-substituted benzene. This band is split in the bis-Me_2SO complex and in all the 1:1 adducts.

The general features of most of the i.r. spectra of the bis complexes can be discussed conveniently in terms of that of $Ph_2SnCl_2 \cdot 2Me_2SO$. Tanaka (19) has published i.r. data for this compound, but we disagree with several of his assignments. For example, the 1021 cm^{-1} band mentioned above is assigned as a methyl rocking mode by Tanaka (19), although this band is observed in all the phenyltin compounds reported here, and is clearly not associated with methyl rocking in Me_2SO. Both Tanaka (19) and we assign the strong, broad absorption at 420 cm^{-1} in the Me_2SO derivative as ν(Sn—O). (This is the only band involving a tin—substituent vibration which shows appreciable variation in position amongst these complexes, and we return to this point below.) The intense band at 294 cm^{-1} is not specifically assigned by Tanaka (19), and the 264 cm^{-1} band is ascribed to the asymmetric Sn—Ph stretching mode. Since all the complexes in Table 3 show strong bands in the former region but not the latter, we assign the 294 cm^{-1} absorption to ν_{as}(Sn—Ph). Further support for this assignment comes from a recent study of diphenyltin halide complexes with nitrogen donors (20), where ν_{as}(Sn—Ph) is always found in the 290–280 cm^{-1} region. However, we are unable to give a definite assignment for the 264 cm^{-1} band. Our assignments of the bands at 244 and 226 cm^{-1} (see Table 3) are just the reverse of Tanaka's (19). Our choice is based primarily on the fact that similar complexes of Ph_2SnCl_2 with N-donors show strong bands at ~ 250 and ~ 230 cm^{-1}, but the former are absent in corresponding derivatives of Ph_2SnBr_2 (20). Finally, all the

compounds in Table 3 show a fairly strong band near 200 cm^{-1} which we attribute to another Sn—Cl vibrational mode, in agreement with Tanaka (19).

The R_2SO complexes for R = Me, Et, *n*-Pr, and *n*-Bu show strong bands at ~420 cm^{-1}, which we can safely attribute to ν(Sn—O). However, for R = $(CH_2)_4SO$ this band is lowered to 377 cm^{-1}, suggesting slightly weaker Sn ← O coordination. This is born out by the somewhat smaller shift in ν(S—O) observed for this complex. Our assignment of ν(Sn—O) at 340 cm^{-1} in the bis-PyO adduct is similar to those of Clark and Wilkins (321 cm^{-1}) (21) and Kawasaki *et al.* (325 cm^{-1}) (22) for the corresponding vibration in $Me_2SnCl_2 \cdot 2PyO$. The only cases where there may be some ambiguity in assigning ν(Sn—O) are in the Ph_2SO and DMF complexes. In the former, the comparatively small shift in ν(S—O) indicates relatively weak complexation, and we feel the only reasonable assignment for ν(Sn—O) is the strong and rather complex absorption envelope centered at 268 cm^{-1}. For the bis-DMF adduct there are three fairly strong bands at 408, 380, and 346 cm^{-1} in addition to the band at 272 cm^{-1}. The 408 and 346 cm^{-1} bands probably correspond to deformation and wagging modes of the Me_2N fragment, observed in DMF itself at 405 and 350 cm^{-1} (23), but assignment of the 380 cm^{-1} absorption is in doubt. However, DMF is a weak Lewis base, and we prefer the band at 272 cm^{-1} for ν(Sn—O).

It is interesting that both asymmetric and

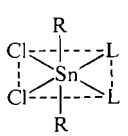
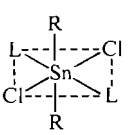
symmetric Sn—Ph vibrations appear as strong bands in the i.r., as also found for similar complexes with nitrogen donors (20). Since the Mössbauer data demand a structure with *trans*-phenyl groups, these results seem to require appreciable distortion of the C—Sn—C angle from 180°. That two Sn—Cl stretching frequencies are both infrared and Raman active leads us to assign a *cis*-chlorine arrangement in all the 1:2 adducts of Ph_2SnCl_2 reported here. We therefore conclude that these complexes have structure **3** rather than **4**:



3



4

(ii) $Me_2SnCl_2 \cdot 2L$ Complexes

Table 4 lists observed vibrational frequencies and assignments for these complexes. Tanaka (19) has also given quite a complete assignment of the i.r. spectrum of $Me_2SnCl_2 \cdot 2Me_2SO$, and except for minor details we are in excellent agreement with this author for both band positions and assignments.

In all cases ν_{as}(Sn—Me) produces a fairly strong band at $\sim 570\ cm^{-1}$ in the i.r., whereas ν_s(Sn—Me) is either absent or appears as a weak absorption at $\sim 510\ cm^{-1}$. These intensities are reversed in the Raman spectra. While consistent with the *trans*-dimethyl arrangements deduced from the Mössbauer spectra, these results are of no help in deciding the dispositions of the remaining four ligands.

Strong similarities in the positions of ν(E—O)

between corresponding methyl- and phenyltin derivatives (see Table 3) are found, suggesting similar strengths of complexation to the two organotin chlorides. Moreover, there is close agreement in ν(Sn—O) for corresponding methyl- and phenyltin adducts, and except for the DMF and Ph_3PO complexes our assignments of this band require no comment. For $Me_2SnCl_2 \cdot 2DMF$, Matsubayashi *et al.* (2) assign very strong bands at 272 and 250 cm^{-1} to ν(Sn—Cl) and attribute a medium-intensity band at 191 cm^{-1} (not observed by us) to ν(Sn—O). We prefer our assignments on the basis of (*a*) band intensities; (*b*) comparison with the spectrum for $Ph_2SnCl_2 \cdot 2DMF$; (*c*) the fact that in all other 1:2 adducts studied here ν(Sn—Cl) never lies above 256 cm^{-1}; and (*d*) the fact that we find no bands whatever in the 230–180 cm^{-1} region either in the i.r. or Raman spectra. Clark and Wilkins (21) have reported some i.r. data (600–200 cm^{-1}) for $Me_2SnCl_2 \cdot 2Ph_3PO$, and assign Sn—Cl vibrations at 261 and 246 cm^{-1}. They suggest (21) that ν(Sn—O) in this complex "probably lies close to ligand bands in the range 400–300 cm^{-1}". However, in the 440–280 cm^{-1} region we find only three weak bands at 396, 311, and 291 cm^{-1}, none of which can be reasonably assigned to ν(Sn—O). We suggest that the higher lying strong band in the 270–240 cm^{-1} region is probably ν(Sn—O), but this assignment is tentative.

All the bis derivatives have strong i.r. bands in the range 250–230 cm^{-1} which we attribute to ν(Sn—Cl). Where comparison is possible our assignments in this region are in agreement with those of other workers (2, 19, 21, 22), except as noted above.

In the Raman spectra we find bands in the Sn—O region usually of medium intensity, while lines assignable to ν(Sn—Cl) are generally weak. It is interesting to note that in all the 1:2 adducts the only strong Raman band of structural significance is ν_s(Sn—Me). Surprisingly, neither ν_s(Sn—Cl) nor ν_s(Sn—O) appears even weakly in the Raman spectrum of $Me_2SnCl_2 \cdot 2PyO$, although both modes are allowed.

We now attempt to assign structures to these complexes, it being remembered that $Me_2SnCl_2 \cdot 2Me_2SO$ is known (8) to have structure **3** and $Me_2SnCl_2 \cdot 2PyO$ to have structure **4** (9). It appears that little structural information is obtainable from i.r. spectra in the ν(Sn—Cl) region, since in all cases this band is either split or has one or more shoulders. It is possible that the 234 cm^{-1} shoulder in the PyO derivative is due to the NO out-of-plane deformation mode found at 233 cm^{-1} in the neat ligand (24). The main difference in structurally significant i.r. bands between $Me_2SnCl_2 \cdot 2PyO$ and the other 1:2 adducts is the degree of complexity of ν(Sn—O). (The *position* of this band does not distinguish between *cis* and *trans* donor molecules.) Only in the PyO complex is this mode both unsplit and without apparent shoulders. These results lead us to suggest that all the 1:2 sulfoxide derivatives of Me_2SnCl_2 have structure **3**. From i.r. results for the bis-DMF and -Ph_3PO complexes it is difficult to draw any definite conclusions, although we favor structure **3** on the basis of the Raman spectra.

(iii) $Ph_2SnCl_2 \cdot L$ Complexes

Infrared and Raman data are collected in Table 5. All these compounds show strong absorptions at ~283 and ~235 cm^{-1} in the i.r., assigned to ν_{as}(Sn—Ph) and ν_s(Sn—Ph), respectively. Both modes are also Raman-active, the latter usually having greater intensity.

The bands assigned to ν(E—O) and ν(Sn—O) are very similar in position to those in the corresponding 1:2 compounds, implying little difference in donor–acceptor interaction strengths between 1:1 and 1:2 adducts with a given base. Intense absorptions are also observed for all 1:1 derivatives at ~325 and ~270 cm^{-1}, which can be attributed to Sn—Cl vibrations. In the Raman spectra the former band is also strong while the latter is of medium-to-weak intensity. These results argue against structure **1**, in which the Cl—Sn—Cl arrangement is expected to be nearly linear, and suggest **2** is much more likely for these complexes. Mullins (6) has assigned structure **2** to $Ph_2SnCl_2 \cdot L$ (L = Ph_3PO, Ph_3AsO) in solution on the basis of dipole moment measurements.

(iv) $Me_2SnCl_2 \cdot L$ Complexes

Relevant vibrational data are given in Table 6. Both ν_s(Sn—Me) and ν_{as}(Sn—Me) appear in the i.r. with similar intensities in all the compounds. The former is also strongly active in the Raman spectra, but the latter is surprisingly weak. The positions of ν(E—O) and ν(Sn—O)

are again very similar to those in the corresponding 1:2 adducts.

With the exception of the PyO complex, all 1:1 derivatives have intense i.r. absorptions between ~340–300 cm^{-1} and in the range 255–225 cm^{-1}, which we attribute to Sn—Cl vibrations. As for the $Ph_2SnCl_2 \cdot L$ compounds, we therefore suggest structure **2** for these 1:1 adducts.

However, $Me_2SnCl_2 \cdot PyO$ is an apparent exception. By analogy with the 1:2 adduct the very strong absorption at 324 cm^{-1} (weak at 327 cm^{-1}, Raman) is assigned to ν(Sn—O). There are only three i.r. active bands lying below this, one of which (304 cm^{-1}) is in the appropriate range for ν_{as}(Sn—Cl), but is weaker than expected for this band. Morevoer, ν_{as}(Sn—Cl) is of medium-to-strong Raman intensity in the other 1:1 derivatives studied, but no Raman band is observed for $Me_2SnCl_2 \cdot PyO$ between 327 and 245 cm^{-1}. Of the two remaining bands, the one at 232 cm^{-1} (absent in Raman) may be due to the NO out-of-plane deformation in PyO, whilst that at 252 cm^{-1} (245 cm^{-1}, vw, in Raman) can reasonably be assigned to a Sn—Cl vibration. We suggest, therefore, that $Me_2SnCl_2 \cdot PyO$ may be structurally dissimilar to the other 1:1 derivatives reported here, and probably has structure **1**.

The 1:1 $(CH_2)_4SO$ derivative exhibited unusual behavior. Except for the band at 270 cm^{-1} the i.r. results for the oil originally obtained are entirely consistent with those expected from data on the other 1:1 sulfoxide adducts. After solidification was induced as described above, the spectrum underwent several interesting

changes (see Table 6). ν(S—O) decreased by 24 cm^{-1} and ν(Sn—O) rose by 11 cm^{-1}, both of which indicate strengthening of the O → Sn coordinate bond. Both Sn—Cl bands were lowered by ~13 cm^{-1}, and a weak band at 341 cm^{-1} (which may have been obscured in the oil) appeared. Most surprising was the apparent splitting of both ν_s(Sn—Me) and ν_{as}(Sn—Me), which seems difficult to explain. Neither i.r. nor Mössbauer spectrum is consistent with disproportionation according to

$$2Me_2SnCl_2 \cdot (CH_2)_4SO \rightarrow Me_2SnCl_2 \cdot 2(CH_2)_4SO + Me_2SnCl_2$$

The existence of solid-state isomers is a possibility, but there is no direct evidence at present bearing upon this point.

Conclusions

The two PyO derivatives of Me_2SnCl_2 appear to be unique amongst all the adducts of diorganotin dihalides for which structural information is available, in having structures **1** and **3**. We are aware of no other 1:2 adduct of R_2SnCl_2 to which **3** can be assigned without serious reservations, and the only other suggested example of **1** is $Me_2SnCl_2 \cdot Me_2SeO$ (4). This compound, however, was not isolated in pure form, but obtained only as a mixture with the

1:2 adduct. Since it has not been well characterized, we feel its structure is open to doubt.

It seems reasonable to expect the two ligands of greatest electronegativity to occupy the apical positions in a trigonal bipyramidal structure. In Lewis bases of the R_nEO type studied here, the effective electronegativity of the oxygen atom depends not only on the nature of E, but also on the nature of the R groups, which affects the degree of E—O multiple bonding and the stabilization of various resonance structures. If these ideas are correct, then PyO appears to be the only ligand studied here for which the effective electronegativity of oxygen may be less than that of chlorine. This could be due both to the fact that N has a higher electronegativity than C, S, or P, and that PyO is the only ligand studied in which E is part of a delocalized π-system. However, such an argument does not explain the observed difference between the PyO adducts of Me_2SnCl_2 and Ph_2SnCl_2. In this connexion a study of PyO complexes with other R_2SnCl_2 molecules might prove helpful.

We thank the National Research Council of Canada for financial support, and Mrs. A. Sallos for technical assistance.

The Chlorination of Pyrroles. Part III[1]

D. G. DURHAM, C. G. HUGHES, AND A. H. REES
Department of Chemistry, Trent University, Peterborough, Ontario

Received April 13, 1972

The chlorination and subsequent demethylation of 2-(2′-methoxybenzoyl) and 2-(2′,6′-dimethoxybenzoyl)-pyrroles are described, giving deoxypyoluteorin and pyoluteorin as main products. A number of minor products of under- and overchlorination have been characterized. Alternative syntheses of some of these antibiotics are detailed. Two routes to 2,3-dichloropyrrole are given and the Friedel–Crafts reaction of this compound utilized in synthesizing deoxypyoluteorin and pyoluteorin. A number of analogs have been made and their microbiological activities compared. The monodeoxy series is generally more active.

La chloration et la déméthylation ultérieure des (méthoxy-2′ benzoyl)-2 et (diméthoxy-2′,6′ benzoyl)-2 pyrroles sont décrites et conduisent aux déoxypyolutéorine et pyolutéorine comme produits majeurs. Un certain nombre de produits mineurs, issus de la sous-et de la surchloration, ont été caractérisés. Des synthèses possibles de quelques uns de ces antibiotiques sont données en détails. Deux voies d'accès au dichloro-2,3 pyrrole sont citées et la réaction de Friedel–Crafts sur ce composé a été utilisée dans la synthèse de la déoxypyolutéorine et de la pyolutéorine. Des composés analogues ont été synthétisés et leurs activités microbiologiques comparées. La série monodéoxy est généralement plus active.

We give practical details of our original synthesis of monodeoxypyoluteorin (**1***a*) (1) from 4,5-dichloropyrrole-1-carboxylic acid. Chlorination of 2-(2′-methoxybenzoyl) pyrrole (**2***b*) affords another route as does the Friedel–Crafts reaction of 2-anisoyl chloride on 2,3-dichloropyrrole (2). We also describe the synthesis of the bromine **3***a* and iodine **4***a* analogs and compare their activities (Table 1). The beneficial effect of a chlorine atom in the phenolic ring is seen in the activity of 5′-chlorodeoxypyoluteorin **5***a* (Table 1). No activity was found in compound **10** (X = Y = Cl), made by chlorination of 2-picolinylpyrrole (**10**) (X = Y = H).

To investigate the structure/activity relationship, we reduced the ketone **1***a* to the alcohol with borohydride. On work-up, an indicating solution was obtained which was red in acid and yellow in base. We suspect this was due to the dehydra-compound **11** as on isolation, an insoluble product was obtained, thought from its mass spectrum to be a dimer of **11**.

Chlorination of 2-(2′,6′-dimethoxybenzoyl)-pyrrole (**12***b*), followed by demethylation, gives pyoluteorin (**14***a*). Slight overchlorination gives a potentially very useful mixture containing 3′-chloropyoluteorin (**15***a*) which is more active against *Staph. aureus* than pyoluteorin itself.

[1]See ref. 8 for Part II.

The potentially insecticidal chloro-analog of pyoluteorin, 4,5-dichloro-2-(2′,6′-dichlorobenzoyl)pyrrole (**17**) was also made but found to be microbiologically inactive, indicating that under test conditions, hydrolysis via **18** was not significant.

Chlorination of pyrrole-2-carboxylic acid-3-carboxylic ester gave a good yield of the 4,5-dichloro-derivative **19** which was converted smoothly to 2,3-dichloropyrrole and hence to pyoluteorin.

Since monodeoxypyoluteorins are generally the more active (3), we prepared some pyolu-

teorin monomethyl ethers but these were less active.

The mass spectra of pyoluteorins follow from the typical pattern for aromatic ketones, showing α-cleavage, partly with hydrogen transfer from the nearby functional group.

Experimental

*Synthesis of 2-(2′-Methoxybenzoyl)pyrrole (**2b**)*

(*i*) Sodium pyrrole-2-carboxylate, 1.75 g, was heated (4) with 1 equiv 2-methoxybenzoyl chloride at 160° for 1 h. The product was extracted with ethyl acetate and this solution washed with sodium bicarbonate solution then with water, dried ($MgSO_4$), and concentrated. Preparative t.l.c. on silica, using ether/light petroleum, 1:1, gave 2-(2′-methoxybenzoyl)pyrrole (**2***b*) as a band at R_f 0.3 which was extracted with ethyl acetate, 170 mg crystallized from benzene/light petroleum, colorless plates; m.p. 130–132°; n.m.r. Table 2; i.r. ν_{max}(Nujol) 1610, 1595 cm^{-1}; u.v. max 301 mμ (ε 16 830).

Anal. Calcd. for $C_{12}H_{11}NO_2$: C, 71.6; H, 5.5; N, 7.0. Found: C, 70.6; H, 4.8; N, 7.3.

(*ii*) By the method described below for 2,6-dimethoxybenzoyl chloride, 2-methoxybenzoyl chloride and pyrrole gave **2***b* in 60% yield.

Preparation of 4,5-Dichloropyrrole-2-carboxylic Acid

(*i*) Methyl pyrrole-2-carboxylate, 6 g in 100 ml acetic acid, was treated with 2.5 mol equiv chlorine (1.5 *N* solution) in acetic acid. After 24 h, evaporation and recrystallization gave 3.7 g 4,5-dichloro-ester, shown by g.l.c. and n.m.r. to contain traces of the 3,4,5-trichloro-ester but none of the 3,5-dichloro-isomer.

The 4,5-dichloro-ester above, 4.2 g, in 200 ml of methanol, was refluxed 5 h with 110 ml 30% potassium hydroxide solution. Evaporation and careful acidification of the residue gave 3.6 g dichloro-acid, shown later to contain traces of trichloro-acid.

(*ii*) Pyrrole-2-carboxylic acid, 7.15 g, in 300 ml acetic acid, was stirred and 2 mol equiv of chlorine in acetic acid added dropwise at 20°. After 10 h, the solvent was removed and the resulting 4,5-dichloro-pyrrole-2-carboxylic acid was crystallized from benzene until it was free (n.m.r. in NaOD) from impurities, yield 2.8 g, 24%.

*Synthesis of 4,5-Dichloro-2-(2′-Methoxybenzoyl)pyrrole (**1b**)*

(*a*) 4,5-Dichloropyrrole-2-carboxylic acid, 2.2 g from synthesis (*i*) above, as the sodium salt, was reacted with *o*-methoxybenzoyl chloride (from 1.8 g acid) by the method described above. The same isolation procedure gave 85 mg 4,5-dichloro-2-(2′-methoxybenzoyl)pyrrole, m.p. 171–173°, crystallized from benzene/light petroleum, ν_{max} (Nujol) 1630, 1600, 1585 cm^{-1}; u.v. max 310 mμ; pK_a 9.8.

Anal. Calcd. for $C_{11}H_7NO_2Cl_2$: C, 51.55; H, 2.76; Cl, 27.7; N, 5.5. Found: C, 51.3; H, 2.8; Cl, 28.0; N, 5.55.

A minor band at R_f 0.5 was extracted with ethyl acetate and the compound crystallized from benzene/light petro-

(2′-methoxybenzoyl)pyrrole (**1***b*), spectroscopically identical with material from syntheses (*a*) and (*b*) above.

*Bromination of 2-(2′-Methoxybenzoyl)pyrrole (**2***b*)*

To the pyrrole, 1.5 g in chloroform, was added 0.84 g bromine in chloroform, with stirring. After 42 h the red solution was washed with sodium thiosulfate solution then with water. The dried solution was then evaporated and the residue crystallized from benzene/light petroleum giving 1.68 g 4,5-dibromo derivative, m.p. 192–193°, **3***b*.

Anal. Calcd. for $C_{11}H_7Br_2NO_2$: C, 38.3; H, 2.05; Br, 46.3; N, 4.05. Found: C, 38.6; H, 2.1; Br, 46.0; N, 3.95.

From the mother liquor, after demethylation, a compound m.p. 165–170° was separated by t.l.c. on silica using benzene/ethanol 95:5 and shown by m.s. and n.m.r. to be 2-(2′-hydroxybenzoyl)-3,4,5-tribromopyrrole (**7***a*).

*Iodination of 2-(2′-Methoxybenzoyl)pyrrole (**2***b*)*

A mixture of 0.2 g of the above pyrrole, 0.5 g iodine, and 0.4 g mercuric oxide was stirred 18 h in benzene at 20°, then filtered. The filtrate was washed with sodium thiosulfate solution, then water and dried. Evaporation of the solvent and crystallization of the residue from benzene/light petroleum gave 0.32 g 4,5-di-iodo derivative, m.p. 218–225°, **4***b*.

Anal. Calcd. for $C_{12}H_9NI_2O_2$: C, 31.8; H, 2.0; I, 56.05; N, 3.1. Found: C, 31.9; H, 1.9; I, 56.0; N, 2.95.

*Preparation and Chlorination of 2-(5′-Chloro-2′-methoxybenzoyl)pyrrole (**9***b*)*

The Friedel–Crafts method, above, of pyrrole and 5-chloro-anisoyl chloride gave 31% of the above ketone, m.p. 104–105°, crystallized from benzene/light petroleum.

Anal. Calcd. for $C_{12}H_{10}ClNO_2$: C, 61.15; H, 4.27; Cl, 15.05; N, 5.95. Found: C, 61.3; H, 4.2; Cl, 15.1; N, 5.9.

Chlorination by 2 mol equiv of *t*-butyl hypochlorite, as described above, gave the 4,5-dichloro derivative, m.p. 190–195°, crystallized from light petroleum (b.p. 100–120°).

Anal. Calcd. for $C_{12}H_8Cl_3NO_2$: C, 47.3; H, 2.65; Cl, 34.9: N, 4.6. Found: C, 47.5; H, 2.7; Cl, 34.3; N, 4.6.

*Preparation and Chlorination of 2-Picolinylpyrrole (**10**)*

In a modification of the published synthesis (5) which failed, we refluxed 5 g picolinic acid and 13 ml pure thionyl chloride in 100 ml dry benzene for 2 h. The solvent was then removed and the residue sublimed in vacuum giving 3.2 g acid chloride which was used at once.

The Friedel–Crafts reaction, as described above, of 3.2 g picolinyl chloride and 4 ml pyrrole gave 0.8 g 2-picolinylpyrrole, m.p. 69–70°, crystallized from light petroleum, m.s. *m/e* 172 (100%, M^+).

Anal. Calcd. for $C_{10}H_8N_2O$: C, 69.75; H, 4.7; N, 16.3. Found: C, 69.8; H, 4.5; N, 16.2.

Dichlorination with hypochlorite ester, as described above, gave a product, m.p. 205–209°, which from the m.s. contained some mono-chloro compound from which it was not easily separable. The crude material was found to be microbiologically inactive so it was not investigated further.

Demethylation of 2-(2′-Methoxybenzoyl)pyrroles

Table 4 lists the monodeoxypyoluteorins obtained, **1***a*–**7***a* with their m.p.'s and analyses.

*Borohydride Reduction of Monodeoxypyoluteorin (**1***a*)*

Excess aqueous sodium borohydride solution was added slowly to 80 mg 3,4-dichloro-2-(2′-hydroxybenzoyl)pyrrole in cold methanol. Within a few minutes, the yellow solution became colorless. Dilute sulfuric acid was added slowly when a red color developed which became yellow on addition of alkali. Chloroform extraction at p*H* 7 gave, after evaporation of the dried solution, an insoluble dark solid which deposited as the solution became concentrated.

Mass spectrometry showed the mol. wt. to be 486 with a pattern for four chlorine atoms, indicating that a dimer of **11** was obtained. The same result was obtained when water, not acid was used in the work-up.

*New Synthesis of 2-(2′,6′-Dimethoxybenzoyl)pyrrole (**12***b*)*

Pyrrole, 0.9 g was dissolved in 100 ml dry methylene chloride containing 2.7 g 2,6-dimethoxybenzoyl chloride

and the mixture was added to a stirred solution of 3.5 ml stannic chloride in 50 ml methylene chloride at room temperature and the system was kept at 60–70° for 2 h during which a yellow solid precipitated. After adding excess dilute sulfuric acid, the organic layer was separated, washed with water, then dried. The solution was concentrated and chromatographed on a 25 × 2 cm column of alumina, eluting with chloroform/light petroleum (4:1). The following fractions were obtained: (*i*) an oil, probably resorcinol dimethyl ether; (*ii*) a solid, m.p. 128–129°, identical with a compound obtained by Bailey and Rees (unpublished) and shown by spectroscopy to be 2,2′,4,6′-tetramethoxybenzophenone ν_{max} (Nujol) 3500 v.w., br., 1645, 1598 br., 1285, 1275, 1255, 1210, 1108, 1030, 945, 835, 790 cm^{-1}; n.m.r. ($CDCl_3$) 5.2 (3H, s, *p*-MeO), 5.33 (9H, s, 3*o*-MeO)τ; m.s. *m/e* 302 (M^+, 37%), 165 (100%); (*iii*) 1.6 g (50%) 2-(2′,6′-dimethoxybenzoyl)pyrrole, m.p. 191–193°, crystallized from benzene/light petroleum, lit. (6) m.p. 187–188° and (7) 193–196°; (*iv*) a minor product having an n.m.r. spectrum consistent with 2,4-di-(2′,6′-dimethoxybenzoyl)pyrrole contaminated with some of fraction *iii*.

Aluminum chloride could also be used for this preparation but the condition of the catalyst was important. High quality material gave 2-(2′-hydroxy-6′-methoxybenzoyl)-pyrrole, m.p. 128–130°, lit. m.p. (8) 129°. Less active catalyst did not cause monodemethylation.

Preparation of 4,5-Dichloro-2-(3′,5′-dichloro-2′-hydroxy-6′-methoxybenzoyl)pyrrole

A solution of 0.6 g chlorine in 26 ml acetic acid was added dropwise to a solution of 0.44 g 2-(2′-hydroxy-6′-methoxybenzoyl)pyrrole (**12***c*). After 4 h stirring, the solvent was removed and the residue crystallized from light petroleum giving 0.51 g tetrachloro compound, m.p. 179–181°; n.m.r., Table 5.

Anal. Calcd. for $C_{12}H_7Cl_4NO_3$: C, 40.6; H, 2.0; Cl, 40.0; N, 3.9. Found: C, 40.9; H, 2.1; Cl, 40.0; N, 3.8.

*Chlorination of 2-(2′,6′-Dimethoxybenzoyl)pyrrole (**12***b*)*

To 116 mg of the above pyrrole in 20 ml chloroform was added 2 mol equiv *t*-butyl hypochlorite in carbon tetrachloride. The mixture was stirred 3 h at 20° and the solvents removed. Preparative t.l.c. of the residue on silica HF_{254} with ether/petrol (3:1) gave the following compounds in order of decreasing R_f values: (*i*) 3′-Chloropyoluteorin dimethyl ether, (**15***b*), 51 mg, m.p. 174–176° crystallized from benzene/light petroleum; n.m.r. Table 5.

Anal. Calcd. for $C_{13}H_{10}Cl_3NO_3$: C, 46.7; H, 3.0; Cl, 32.1. Found: C, 46.8; H, 3.0; Cl, 31.6; N, 4.4.

(*ii*) 4-Chloro-2-(3′-chloro-2′,6′-dimethoxybenzoyl)pyrrole (**16***b*), n.m.r. Table 5, 55 mg, containing pyoluteorin dimethyl ether (**14***b*) from which it was not separable prior to demethylation. (*iii*) 5-Dechloropyoluteorin dimethyl ether (8), (**13***b*), 10 mg. (*iv*) Starting material, 5 mg.

Chlorination (1 equiv) at −70° gave (half scale): (*ii*) 12 mg mixture as above, 17%; (*iia*) 13 mg crude material shown by n.m.r. (Table 5) to be 2-(3′-chloro-2′,6′-dimethoxybenzoyl)pyrrole, 20%; (*iii*) 20 mg, 30%; (*iv*) 10 mg, 17%.

*3′-Chloropyoluteorin (**15***a*)*

The dimethyl ether above was treated with boron trichloride (4) giving 3′-chloropyoluteorin, m.p. 200–205° (erroneously reported (2) as its monomethyl ether); n.m.r. Table 5, m.s. Table 6.

Anal. Calcd. for $C_{11}H_6Cl_3NO_3$: C, 43.1; H, 2.0; Cl, 34.7; N, 4.6. Found: C, 43.3; H, 2.0; Cl, 35.0, N, 4.7.

*Demethylation of Mixture of Dimethylpyoluteorin (**14***b*) and 3′,4-Dichloro Isomer (**16***b*)*

The crude mixture, 220 mg, after treatment with boron trichloride (4) gave a product separated by t.l.c., benzene/ethanol (9:1) into pyoluteorin 32 mg, 15% and 130 mg, 60% of 4-chloro-2-(3′-chloro-2′-hydroxy-6′-methoxybenzoyl)-pyrrole (**16***c*), m.p. 170–172°, crystallized from benzene/light petroleum as pale yellow needles; n.m.r. Table 5.

Anal. Calcd. for $C_{12}H_9Cl_2NO_3$: C, 50.4; H, 3.1; Cl, 24.8; N, 4.9. Found: C, 50.2; H, 3.2; Cl, 24.8; N, 5.0.

2,6-Dichlorobenzoylation of Pyrrole

2,6-Dichlorobenzoyl chloride, 10 g and 3.5 g pyrrole in methylene chloride were treated with excess stannic chloride

at 50–60° for 2 h. Column chromatography on alumina gave on elution with ether/light petroleum (3:1) 1.1 g, 2-(2′,6′-dichlorobenzoyl)pyrrole, needles, m.p. 165–167°, crystallized from benzene/light petroleum; n.m.r. Table 5, m.s. *m/e* 239 (43%, M^+), 94 (100%).

Anal. Calcd. for $C_{11}H_7Cl_2NO$: C, 55.0; H, 2.95; Cl, 29.5; N, 5.8. Found: C, 55.2; H, 2.85; Cl, 29.4; N, 5.7.

Further elution gave 2,4-di-(2′,6′-dichlorobenzoyl)pyrrole, 1.5 g pale yellow cubes, m.p. 284–286°, crystallized from benzene; n.m.r. (DMSO-d_6) H3 3.34, H5 2.4, H arom. 2.52 (3H) and 2.57 (3H), NH −3.02; m.s. *m/e* 411 (45%, M^+), 266 (100%).

Anal. Calcd. for $C_{18}H_9Cl_4NO_2$: C, 52.35; H, 2.2; Cl, 34.3; N, 3.4. Found: C, 52.7; H, 2.2; Cl, 34.0; N, 3.6.

Chlorination of 2-(2′,6′-Dichlorobenzoyl)pyrrole

The above pyrrole, 0.24 g in methylene chloride was treated with 2 mol equiv *t*-butyl hypochlorite at 20°. After 2.5 h the solvent was removed and the residual 4,5-dichloro derivative **17** crystallized from light petroleum (b.p. 100–120°), 220 mg, m.p. 186–190°; n.m.r. Table 5, m.s. *m/e* 307 (80%, M^+), 309 (100%, M + 2).

Anal. Calcd. for $C_{11}H_5Cl_4NO$: Cl, 45.9; N, 4.5. Found: Cl, 45.6; N, 4.5.

Chlorination of Ethyl Pyrrole-2-carboxylic Acid-3-carboxylate

The half ester (9), 9.2 g in acetic acid, was stirred while adding a solution of 2 mol equiv chlorine in acetic acid at room temperature. After 24 h the solvent was removed and the residue crystallized from aqueous ethanol (charcoal) to give the 4,5-dichloro derivative, 9.3 g white needles, m.p. 193–195°.

Anal. Calcd. for $C_8H_7Cl_2NO_4$: C, 38.1; H, 2.8; Cl, 28.1; N, 5.55. Found: C, 38.3; H, 2.7; Cl, 28.1; N, 5.8.

Preparation of Ethyl 2,3-Dichloropyrrole-4-carboxylate

The above dichloropyrrole half ester, 1 g, was refluxed 1 h in dimethylformamide. The cold solution was poured into ice water and extracted with ether. The latter solution was extracted with sodium bicarbonate solution then washed with water and evaporated leaving the dichloroester, m.p. 141–144°, crystallized from light petroleum, needles, 550 mg; n.m.r. ($CDCl_3$) 2.95d ($J_{1,2} = 1.7$ Hz) 5H, 1.2., NH.

Anal. Calcd. for $C_7H_7Cl_2NO_2$: C, 40.4; H, 3.4; Cl, 34.1; N, 6.75. Found: C, 40.55; H, 3.4; Cl, 33.9; N. 6.9.

Preparation and 2,6-Dimethoxybenzoylation of 2,3-Dichloropyrrole

The dichloropyrrole half ester above, 2 g in 50 ml diethylene glycol was refluxed 1 h with stirring. The solution was then shown by t.l.c. to contain the dichloroester above. A solution of 2 g sodium hydroxide in 6 ml water was then added and refluxing continued 3 h when the mixture was cooled, poured into ice water, and the aqueous solution extracted with benzene, washed and dried.

To this solution of 2,3-dichloropyrrole was added 1.8 g 2,6-dimethoxybenzoyl chloride and 2.2 g stannic chloride. The mixture was kept at 50–60° for 2 h then cooled and treated with dilute sulfuric acid. Water and chloroform were added and the organic layer was separated, washed with water and dried. Evaporation of the solvent left a residue which was extracted with hot petrol (b.p. 100–120°) containing charcoal, giving 0.9 g dimethyl pyoluteorin (7), m.p. 196–198°, **14***b*.

We thank the National Research Council of Canada for financial support and the Sankyo Co. Ltd. of Tokyo for the microbiological results.

Acetate-catalyzed Bromination and Exchange Reactions of 2-Butanone

J. W. THORPE AND J. WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ontario

Received December 21, 1970[1]

Products from bromination of 2-butanone in an aqueous acetate buffer were studied in order to compare the regiochemistry of monobromination with that of deuterium exchange. The good agreement found suggests that direct reaction of Br_2 with unenolized ketone, for which there have been claims in the literature recently, is unimportant or absent under the conditions of the experiments.

Les produits issus de la bromation de la butanone-2 dans une solution aqueuse tamponnée à l'acétate, ont été étudiés en vue de comparer la régiochimie de la monobromation avec celle de l'échange au deutérium. Le bon accord trouvé laisse penser que l'action directe du brome sur la cétone non énolisée, proclamée récemment dans la littérature, n'est pas importante voire absente dans les conditions expérimentales.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3229 (1972)

Introduction

The generally-accepted mechanism of racemization, hydrogen isotope exchange, and halogenation of carbonyl compounds is rate-determining enolization followed by fast reaction of the enol or enolate ion. Evidence for that mechanism has come mainly from kinetic studies. Halogenation rates were found to be independent of both the concentration[2] and the identity of the halogen (2–4) and in several cases the rate of racemization of an optically-active ketone was shown to be identical to the rate of its halogenation or hydrogen–deuterium exchange under similar conditions (5–6).

In spite of the accumulated evidence for a common mechanism, the recent literature contains claims for additional halogenation mechanisms (7) other than that involving rate-limiting enol- or enolate-formation.[3] Rappe has claimed, for example, that bromination of 2-butanone can result in a ratio of monohalides (**3**-Br/**1**-Br = 7–7.5) quite different from that predicted on the basis of relative exchange rates (CH_2/CH_3 = 0.6–0.7) under similar conditions (*7c*). Such a result is clearly not compatible with a common rate-determining step for the two reactions and to account for the discrepancy, Rappe (*7b–e*) postulated reaction of unenolized ketone with brominating agent. If that were the case, a substantial contribution from a term in bromine concentration would have to be present in a kinetic description of the overall process but such evidence has not yet been provided to support the product studies. On the other hand there is a claim, based on kinetics, for direct reaction between acetone and bromine. Sytilin reported that initial rates of acid-catalyzed bromination of acetone depend on the concentration of bromine (8).

In view of these challenges of the long-accepted mechanisms of important reactions, we have continued to investigate reactions of ketones, including kinetic studies and product studies. This account deals with the composition of the products from acetate-catalyzed[4] bromination of 2-butanone. We refer to the bromination process in aqueous acetic acid buffer as acetate-catalyzed, although that description encompasses several mechanisms, differing in the degree to which carbonyl oxygen is protonated according to the acid (water or acetic acid) involved there. The relative contributions of various mechanisms need not be known for our purpose because bromination and exchange can be studied in virtually identical conditions.

[1]Revision received June 21, 1972.

[2]For halogen concentrations exceeding 10^{-5}–10^{-6} M (1).

[3]Although the enol and enolate mechanisms are different, they are treated together here because they have in common the zero-order dependence on halogen except at very low ($<10^{-5}$ M) halogen concentrations (1). We are not concerned here with such low concentrations, for the last part of a bromination run, from $[Br_2] \simeq 10^{-6}$ to $[Br_2] = 0$ M, must have an immeasurably small effect on product ratios if the initial bromine concentration is relatively high.

[4]Base-promoted halogenation of a ketone consumes 1 equiv of base. The reaction is therefore not really catalyzed, unlike exchange. Because we are comparing halogenation and exchange it is convenient to waive the distinction.

*Butanone (2 M) in aqueous HOAc (1 M) containing AcO^- (1 M).
†Relative yields determined by g.l.p.c. with a QF-1 column. The same relative yields were obtained using a SE30 column, suggesting that all peaks in the g.l.p.c. traces correspond to single components of the mixture.
‡The ratio X is defined in the text and in eq. 1.
§Substituted ketones are coded by kind and number of substituents. 1,1,1,3-Tetrabromo-2-butanone is coded Br_4.

Methods and Results

In principle it is a simple matter to determine whether or not the regiochemistry of halogenation of 2-butanone is the same as that of hydrogen–deuterium exchange under similar conditions. The selectivity of exchange is readily established by following the disappearance of the appropriate signals in the p.m.r. spectrum. That of bromination would follow directly from the ratio of monobromoketones formed, if these were the only products. It is not possible to keep the product mixture so simple, however. Even with a large butanone:bromine ratio (200:1), acetate-catalyzed bromination leads to at least six of the eleven bromoketones, $CH_{(3-n)}Br_nCOCH_{(2-m)}Br_mCH_3$, to bromoform, and to the acetoxyketones resulting from S_N2 reaction of monobromoketones. A rigorous determination of the regiochemistry of monobromination requires division of the haloform yield and of some polyhalo ketone yields into fractions arising from initial 1- and 3-halogenation.

We have used an approximate method for determining the ratio of monobromination rates of butanone. If butanone is used in large excess over bromine, the yields of bromoform and of highly-brominated ketones can be kept relatively low. The method consists of determining the ratio (X) of sums of relative yields of those products whose origin (either initial 1-halogenation or initial 3-halogenation) is assignable, eq. 1. If X is near unity and if the unassigned products constitute a minor fraction of the total and if the materials balance is good, then X cannot be very different from the

$$[1] \qquad X = \frac{\sum \text{yields of 3-products}}{\sum \text{yields of 1-products}}$$

$$[2] \quad 2k_3/3k_1 = \frac{\sum (\text{yields of 3-products}) + Z'}{\sum (\text{yields of 1-products}) + Z}$$

ratio $2k_3/3k_1$ of eq. 2, in which Z' and Z represent the yields of all unassigned products arising from 3-bromobutanone and 1-bromobutanone, respectively. Assignable 2-butanones were: (*a*) 3-bromo, 3-acetoxy, 3,3-dibromo-, (*b*) 1-bromo, 1-acetoxy, 1,1-dibromo, and 1,1,1-tribromo. Unassignable products were 1,1,1,3-tetrabromo-2-butanone and bromoform. The assumed initial reactions and the definitions of rate constants[5] are shown in eq. 3. Results of applying the approximate method described above are in Table 1.

Discussion

Values of X show a downward trend from about 1.0–0.69 with increases in the initial bromine:ketone ratio from 1:200–1:20. This trend is presumably largely the result of the corresponding increases in the relative amounts of

[5]Rate constants are defined on the *per hydrogen* basis, as was done previously (9). Rate constants *per group* are obtained by multiplying by the appropriate statistical factor.

unassigned products. Seven of the eight sets of data are fitted fairly well to a straight line, $X = m[Br_2] + X_0$ which extrapolates to $X_0 \simeq 1.05$ at $[Br_2]_{initial} = 0$. This is a minimum value since either weighting the other set of data in drawing the line or else nonlinear extrapolation gives a higher value. Therefore the minimum ratio of rate constants, based on the assumption that bromination proceeds exclusively by the enolization mechanism (eq. 3) and based on analysis of the product composition rather than on kinetics, is $\frac{3}{2}X = 1.58$.

The regioselectivity of deuterium exchange, in the same medium at 54.8°, was obtained by p.m.r. as described in the accompanying note (10). The ratio of observed rate constants, $k_{CH_2}^{obsd.}/k_{CH_3}^{obsd.}$, which is equal to the ratio of rate constants, k_3/k_1 (exchange), defined on the *per hydrogen* basis, was 1.69. This rate ratio for hydrogen isotope exchange of butanone can be confidently equated with the rate ratio for enolization[6] although the magnitude of the ratio, and particularly its dependence on the conditions, has been the subject of some controversy (7*c*, 11). It is very probable then that the ratio of enolization rate constants, k_3/k_1, of butanone is near 1.7 at 54.8°, in the medium used for the bromination studies. The differential effect on the two rate constants, of changing from D_2O (exchange) to H_2O (bromination), must be very small. The good agreement (1.58 *vs.* 1.69) between the two estimates of k_3/k_1 means that, contrary to recent claims (7), the product composition in bromination of butanone, like the kinetics (2–4, 12), is compatible with the enolization mechanism. Although direct reaction between bromine and butanone may occur under other conditions, it seems preferable to retain the enolization mechanism generally, unless there is compelling evidence against its applicability.

[6]The mechanism of exchange, unlike that of halogenation, appears still to be universally accepted as involving an enol or enolate intermediate. We have shown (10) that direct reaction between D_2O and butanone is extremely slow.

Experimental

Chemicals

Reagent grade acetic acid and butanone were distilled once before use. Sodium acetate was dried at 150° to obtain the anhydrous material, which was kept in a desiccator.

Products

The products obtained in this work were isolated by g.l.p.c. from preparative-scale brominations of 2-butanone and were identified through their refractive indices and their proton and mass spectra. These are: *3-bromo-2-butanone*, n_D^{22} 1.4560 (lit. (13) n_D^{20} 1.4571); n.m.r. (CCl_4) δ 4.40 (q, 1, $J = 7$ Hz, C*H*Br), 2.32 (s, 3, CH_3CO), 1.72 (d, 3, $J = 7$ Hz, CHBrCH_3); *1-bromo-2-butanone*, n_D^{22} 1.4658 (lit. (13) n_D^{20} 1.4670); n.m.r. (CCl_4) δ 3.85 (s, 2, $BrCH_2CO$), 2.68 (q, 2, $J = 7$ Hz, $COCH_2$), 1.08 (t, 3, $J = 7$ Hz, CH_2CH_3); *3-acetoxy-2-butanone*, n_D^{22} 1.4118 (lit. (14) n_D^{20} 1.4129); n.m.r. (CCl_4) δ 4.95 (q, 1, $J = 7$ Hz, C*H*(OAc)CH_3), 2.04 (s, 6, $CH_3COCH(OCOCH_3)$), 1.30 (d, 3, $J = 7$ Hz, CH(OAc)-CH_3); *1-acetoxy-2-butanone*, n_D^{22} 1.4177 (lit. (15) n_D^{19} 1.4190); n.m.r. (CCl_4) δ 4.52 (s, 2, CH_2OAc), 2.40 (q, 2, $J = 7$ Hz, $COCH_2$), 2.10 (s, 3, $OCOCH_3$), 1.07 (t, 3, $J = 7$ Hz, CH_2CH_3); *1,1-dibromo-2-butanone*, n_D^{22} 1.5126 (lit. (16) n_D^{25} 1.5112); n.m.r. (CCl_4) δ 6.15 (s, 1, C*H*Br_2), 3.15 (q, 2, $J = 8$ Hz, $COCH_2$), 1.42 (t, 3, $J = 8$ Hz, CH_2CH_3); mol. *wt. m/e* 230 (triplet); *3,3-dibromo-2-butanone*, n_D^{21} 1.5072 (lit. (17) n_D^{25} 1.5050); n.m.r. (CCl_4) δ 2.62 (s, 3, CBr_2CH_3), 2.47 (s, 3, $COCH_3$); mol. wt. *m/e* 230 (triplet); *1,1,1-tribromo-2-butanone*, n_D^{21} 1.5647 (lit. (18) n_D^{25} 1.5626); n.m.r. (CCl_4) δ 3.51 (q, 2, $J = 8$ Hz, $COCH_2$), 1.64 (t, 3, $J = 8$ Hz, CH_2CH_3); mol. wt. *m/e* 309 (quartet); *1,1,1,3-*tetrabromo-2-butanone, n_D^{22} 1.6341; n.m.r. (CCl_4) δ 5.42 (q, 1, $J = 7$ Hz, COC*H*Br), 2.18 (d, 3, $J = 7$ Hz, CHBrCH_3); mol. wt. *m/e* 388 (quintet); and *bromoform*, n_D^{22} 1.5965 (lit. (19) n_D^{20} 1.5976); n.m.r. (CCl_4) δ 7.24 (s); mol. wt. *m/e* 253 (quartet). These compounds are numbered in the above order, from **1**–**9** in the following descriptions of elution order: 20% SE-30 column (10 ft × 1/8 in.), **1**, **2**, **3**, **9**, **6**, **4**, **5**,

7, and **8**; 12% QF-1 column (10 ft × 1/8 in.), **9**, **1**, **6**, **2**, **5**, **3**, **4**, **7**, and **8**.

A rough material balance for bromination of butanone was obtained as follows. A calibration constant for a given component was obtained by injecting different known volumes of a solution of known concentration, prepared by dissolving a weighed sample of the component in carbon tetrachloride. The constant related the integral peak area observed to the known molar quantity of material injected, for the different volumes injected showed that the calibration number was independent of sample size in the size range that was used. The peaks corresponding to the monobromides, the acetoxyketones, and bromoform were calibrated in this way. Isomers gave the same detector response (same calibration constant) and the difference between the constants for acetoxyketones and bromoform was only 14%. The higher bromoketones were assigned the same factors as monobromoketones. Knowledge of the volume of the CCl_4 solution containing the products from a bromination of butanone permitted calculation of approximate concentrations and yields. The material balance was based on bromine by assuming that one mole of bromine produces Avogadro's number of C—Br bonds in the reactions. Thus, acetoxyketones were weighted as one because they arise from bromoketones, a dibromoketone was weighted two, and bromoform was given a weight of three. In a typical small scale run (Table 1, first entry) the balance on Br was about 90%. The small fraction of bromine unaccounted for is probably in the form of bromoacids from the haloform reaction.

Bromination of Butanone

2-Butanone (7.2 g, 0.100 mol), acetic acid (3.00 g, 0.0500 mol), and sodium acetate (4.10 g, 0.0500 mol) in a volumetric flask were dissolved in distilled water to make 50 ml of solution. A stirring bar was added, the flask was placed in a bath (54.8 ± 0.04°) containing a submerged stirrer and after time for equilibration, bromine (0.080 g, 5.00×10^{-4} mol) was added. As soon as decolorization occurred the solution was poured into 50 ml of ice water in a separatory funnel and the cold mixture was extracted six times with 5 ml portions of carbon tetrachloride. The combined extract was dried over anhydrous sodium sulfate before the bulk of the solvent was evaporated at the water pump. The residue was analyzed by g.l.p.c. (average of five injections), using a 10 ft × 1/8 in., 12% QF-1 column in a Varian Aerograph Model 204-B instrument equipped with flame ionization detector and with a Varian Aerograph Model 476 digital integrator.

Relative yields of products were (%): 1-Br, 16; 1-OAc, 20; 3-Br, 21; 3-OAc, 25; 1,1-dibromo-2-butanone, 2.9; 1,1,1-tribromo-2-butanone, 7.3; 3,3-dibromo-2-butanone, 1.2; 1,1,1,3-tetrabromo-2-butanone, trace; and bromoform 6.9.

Kinetics of Bromination of Acetone, Bromoacetone, and 1,1-Dibromoacetone

ROBIN A. COX AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received December 21, 1970[1]

The rate of bromine consumption in acetate-promoted bromination of acetone is not measurably dependent on bromine concentration, in confirmation of earlier work. This result casts doubt on the existence of recently-reported, nonenolic mechanisms for bromination of butanone under similar conditions. The effects of alpha bromine substituents on rates of enolization of acetone are reported.

La vitesse de disparition de brome lors de la bromation de l'acétone amorcée par l'acétate, n'est pas mesurable par rapport à la concentration en brome; ce qui confirme un travail antérieur. Ce résultat met en doute l'existence récemment rapportée d'un mécanisme non-énolique lors de la bromation de la butanone dans des conditions semblables. Les effets des substituants bromo en α sur les vitesses d'énolisation de l'acétone sont donnés. [Traduit par le journal]

Introduction

After many years of unchallenged acceptance (1) the enolization mechanism for alpha halogenation of carbonyl compounds was recently called into question by two independent investigators. Rappe (*2a–d*) claimed a large disparity between the experimental ratio of monobromides from butanone and the ratio calculated from base-catalyzed deuterium exchange rates under comparable conditions. Sytilin (3) claimed that the initial rate of bromination of acetone, catalyzed by acid, is dependent on the concentration of bromine.

In the preceding paper (4) evidence is presented for a reasonable agreement between product data pertaining to bromination of butanone and kinetic exchange data (5) for one set of conditions. This account deals with the kinetics of bromination of acetone under the same conditions. Butanone bromination proved to be too complex for analysis but a fundamental difference in mechanism between acetone and butanone reactions is so unlikely that the results for acetone can be applied directly to reactions of butanone.

Methods and Results

The concentration most easily followed in bromination of a ketone is that of bromine. In this work the potential of the Br_2, Br^- half cell, relative to that of the glass electrode, was measured with a platinum electrode in a buffered medium. Low concentrations of bromine, in the range 10^{-3}–10^{-7} *M*, were readily measured. The analysis was simplified by beginning with $[Br^-] = 0.1$, $[CH_3COCH_3] = 0.3$, and $[Br_2] = 10^{-3}$–10^{-4} *M*, so as to keep the concentrations of bromide and acetone effectively constant during the course of the reaction. Further simplification resulted from the use of a large excess (1 *M*) of acetate, which should keep the rate of enolization, if that is the mechanism, effectively constant throughout the course of bromination.

For the electrochemical reaction, $Br_2 + 2e \rightarrow 2Br^-$, the potential is given by the Nernst equation, which can be approximated as eq. 1

$$[1] \qquad E = E^0 - \frac{RT}{2F} \ln \frac{[Br^-]^2}{[Br_2]}$$

by writing concentrations instead of activities. Taking into account the constancy of $[Br^-]$, the potential of the glass electrode and any other concentrations (except $[Br_2]$) that could affect the potential but remain constant during the reaction, we can write eq. 2, in which E'

$$[2] \qquad E = E' + \frac{RT}{2F} \ln [Br_2]$$

contains all the constant terms. Its value was determined experimentally, with titrimetrically determined bromine solutions, for 5° temperature increments from 20–40°, inclusive. Initial concentrations of $[Br_2]$ in solutions used for brominating acetone could then be deter-

[1]Revision received October 8, 1971. Publication delayed at authors' request.

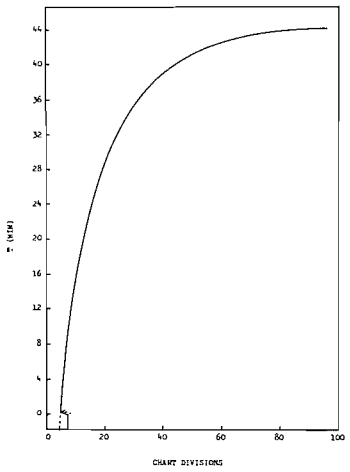

FIG. 1. Sample chart trace, acetone.

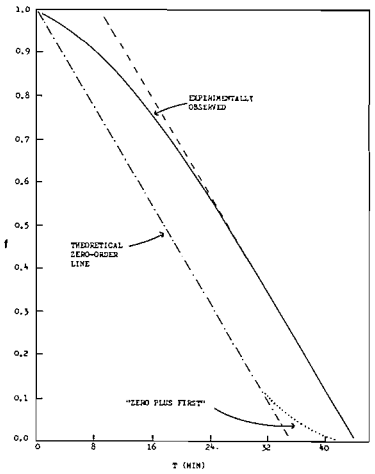

FIG. 2. Concentration/time graph for the bromination of acetone at 40°.

mined potentiometrically from the known value of E' using eq. 3.

$$[3]\quad [Br_2]_0 = \text{antilog}\left(\frac{E - E'}{C_t}\right), \text{ where}$$

$$C_t = 2.3026\,\frac{RT}{2F}$$

Potentials were read with a pH-meter and recorded with a chart recorder. The pH-meter reading (E) was linearly related to the chart paper reading (Ch) according to eq. 4.

$$[4]\quad E = -(0.760 \pm 0.001)Ch + (73.79 \pm 0.03)$$

Combining eqs. 2 and 4 gives eq. 5

$$[5]\quad [Br_2] = \exp\left(\frac{Ch' - Ch}{C_t'}\right), \text{ where}$$

$$C_t' = \frac{RT}{2(0.760F)}$$

which leads to eq. 6 if one defines an arbitrary zero such that

$$[Br_2]_0 = \exp\left(\frac{Ch' - Ch_0}{C_t'}\right)$$

Equation 6 could be used to determine f, the relative bromine concentration, at any

$$[6]\qquad f = \frac{[Br_2]}{[Br_2]_0} = \exp\left(\frac{Ch_0 - Ch}{C_t'}\right)$$

time directly from chart traces. The number f, together with $[Br_2]_0$ from eq. 3, permits calculation of $[Br_2]$ at any time from the chart trace.

The form of eq. 6 indicates that the chart trace will be a straight line of slope kC_t', if bromine consumption follows first order kinetics ($f = f_0 \exp(-kt)$). On the other hand, zero-order bromine consumption would result in a curved chart trace but a straight line plot of f against time. A typical chart trace is reproduced as Fig. 1. Figure 2 shows the expected shapes of f *vs.* t plots, as well as the actual time dependence of the relative bromine concentration. Bromine consumption does not follow the theoretical "zero-order" line,[2] Fig. 2, but it does become linear after initial acceleration of the rate and the final slope approaches that of the zero-order line. The initial increase in rate is caused by the formation of bromoacetones, which react faster than acetone but not fast enough to result in an initial stoichiometry of $3Br_2$ per molecule of ketone. The meaning of the limiting slope is discussed below.

An important feature of the f *vs.* t plot (Fig. 2) is the absence of tailing of the experimental curve toward the end of a run; a feature expected if there were a first-order (in $[Br_2]$) component superimposed on zero-order kinetics. Such tailing can be observed if the Br_2 concentration is followed to values below 10^{-5}–10^{-6} M where halogenations are known to be first order in halogen (6). They can become first order in that

[2]The zero-order line is drawn with the assumption that all brominations after the first are fast. Therefore $-d[Br_2]/dt = 3k_1[\text{ketone}][AcO^-]$.

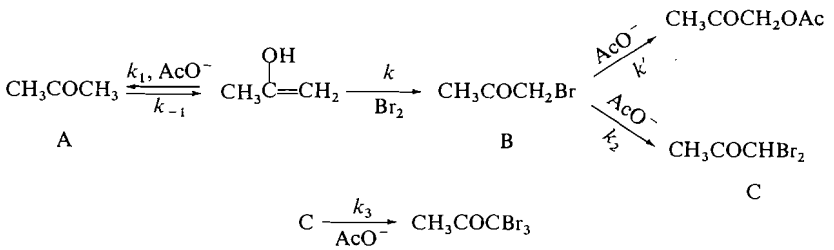

SCHEME 1

concentration range not because of direct reaction between ketone and halogen, but because k[enol][Br_2] no longer greatly exceeds k_{-1}[enol] (Scheme 1). That part of a bromination run, which was readily observed on the chart traces, was not detailed in graphs of f *vs.* t, where it would occupy the section of the f-scale between about 0.01 and 0 (Fig. 2). What is demonstrated then is that there is no detectable first-order consumption of bromine by acetone during about 99% of the reaction.

Rate constants can be extracted from f and t data by means of the equations developed below. From Scheme 1 the rate of bromine consumption is given by eq. 7, in which the rate

$$[7] \quad -\frac{d[Br_2]}{dt} = k_1[A] + k_2[B] + k_3[C]$$

constants are pseudo-first-order constants, including the constant concentration of acetate. The concentration of acetone, [A], was also held constant leaving [B] and [C], the concentration of bromoacetone and dibromoacetone, respectively, to be evaluated.

The value of [B], in terms of rate constants and known concentrations (eq. 9), is obtained by integrating differential eq. 8.

$$[8] \quad \frac{d[B]}{dt} = k_1[A] - k_2'[B], \quad \text{where} \quad k_2' = k_2 + k'$$

$$[9] \quad [B] = \frac{k_1}{k_2'}[A](1 - e^{-k_2't})$$

The value of [C] is determined as outlined below. The first-order differential equation (eq. 10) can be solved by assuming a solution, differentiating it, and equating coefficients.[3] This process leads to eq. 11.

[3]Details are not given here because the final result can be checked by differentiation. Readers interested in the particulars may obtain these by writing to the authors.

$$[10] \quad \frac{d[C]}{dt} = k_2[B] - k_3[C]$$

$$= \frac{k_1k_2}{k_2'}[A](1 - e^{-k_2't}) - k_3[C]$$

$$[11] \quad [C] = -\frac{k_1k_2[A]\,e^{-k_2't}}{k_2'(k_3 - k_2')} + \frac{k_1k_2[A]\,e^{-k_3t}}{k_3(k_3 - k_2')} + \frac{k_1k_2[A]}{k_2'k_3}$$

With [B] and [C] evaluated we can return to eq. 7 to express the measured variable, [Br_2], in terms of [A], rate constants and time. Integration between the limits $[Br_2]_0$ at $t = 0$ and $[Br_2]_t$ at $t = t$ yields eq. 12, which on division by $[Br_2]_0$ gives eq. 13.

$$[12] \quad [Br_2]_0 - [Br_2]_t = k_1[A]t + \frac{2k_1k_2[A]t}{k_2'} - \frac{k_1k_2(2k_3 - k_2')[A](1 - e^{-k_2't})}{(k_2')^2(k_3 - k_2')} + \frac{k_1k_2[A](1 - e^{-k_3t})}{k_3(k_3 - k_2')}$$

$$[13] \quad f = 1 - \frac{k_1[A]}{[Br_2]_0}\left[\left(1 + \frac{2k_2}{k_2'}\right)t + \frac{k_2(2k_3 - k_2')(1 - e^{-k_2't})}{k_2'^2(k_3 - k_2')} - \frac{k_2(1 - e^{-k_3t})}{k_3(k_3 - k_2')}\right]$$

The initial slope of the f *vs.* t plot is, therefore:

$$\left(\frac{df}{dt}\right)_{t=0} = -k_1\frac{[A]}{[Br_2]_0}$$

That is, the initial rate of change of f depends on the rate constant (pseudo-first-order) for enolization of acetone and on the initial ketone to bromine concentration ratio, as it should. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[14]\quad \left(\frac{df}{dt}\right)_{t\to\infty} = -k_1\frac{[A]}{[Br_2]_0}\left(1+\frac{2k_2}{k_2'}\right)$$

$$[15]\quad \left(\frac{df}{dt}\right)_{t\to\infty} \simeq -3k_1\frac{[A]}{[Br_2]_0}$$

$$[16]\quad f = 1-\frac{k_2[B]_0}{[Br_2]_0} \times\left\{\frac{(2k_3-k_2')}{k_2'(k_3-k_2')}(1-e^{-k_2't})+\frac{1-e^{-k_3t}}{k_3-k_2'}\right\}$$

$$[17]\quad f = 1-\frac{[C]_0}{[Br_2]_0}(1-e^{-k_3t})$$

was used to evaluate k_1.[4] The limiting slope of the f *vs.* t graph is given by eq. 14, which, because $k_2' = k_2 + k'$, reduces to eq. 15 if k' is small relative to k_2. Thus, in the absence of the S_N2 reaction, the ratio of final to initial slopes of f *vs.* t would be the stoichiometric factor (three) for bromine consumption.[5] Rate constants for enolization of acetone and of bromoacetones could, in principle, be evaluated directly by computer fitting of the f *vs.* t graph. Errors rapidly become large, however, if such fitting is used to evaluate rate constants beyond that of the first step. The rate constants k_2 and k_3 were therefore obtained from separate experiments, in which bromoacetone (B) and 1,1-dibromoacetone (C) were the starting materials. The kinetic analysis is analogous to that outlined above, except that the bromoketones can not be used in large excess because of their limited solubility. Relationships between f and t for the bromoketones are given below as eqs. 16 and 17.

Discussion

Despite the need to include the rates of "fast" reactions (8) in the overall kinetic analysis of acetone bromination, it is clear that rate-determining enolization is a satisfactory mechanism, for f *vs.* t graphs (Fig. 2) meet the time

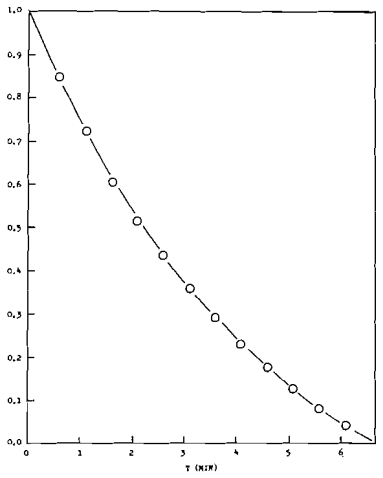

FIG. 3. Graph of f *vs.* t for the bromination of dibromoacetone at 30°.

axis without any evidence of tailing. The shape of the graph is a qualitative test for kinetic dependence on bromine concentration. Acetone is not a good system for quantitative comparison of theory with experiment because of S_N2 reaction of bromoacetone and because of bromination of 1,1,1-tribromoacetone. A reasonable fit is therefore assured, with so many adjustable (within the limits of error) rate constants available.

A quantitative comparison was possible in less complex systems. Bromination of 1,1-dibromoacetone is relatively simple, because bromination of 1,1,1-tribromoacetone is slower than that of its precursor. In Fig. 3, the solid line is that described by eq. 17, with $k_3 = 5.05 \times 10^{-3}\ M^{-1}\ s^{-1}$. The points, which are experimental values of f and t,[6] fit the theoretical curve well considering the approximations that bromination of tribromoacetone can be neglected and that enolization at the CH_3 group of dibromoacetone can be neglected.

A qualitative and a semi-quantitative fit of kinetic data to schemes based on assumed rate-determining enolization means that the mechanism is acceptable for ketones with considerably different chemical properties. It follows that 2-butanone bromination must also go by the

[4]Bell *et al.* reported $k_1 = 4.0 \times 10^{-8}\ M^{-1}\ s^{-1}$, statistically corrected at 25° (7). Our initial slope gave $k_1^{25°} = 3.96 \times 10^{-8}\ M^{-1}\ s^{-1}$.

[5]This analysis is based on the assumed Scheme 1. The one approximation in Scheme 1 is that 1,1,1-tribromoacetone does not consume an appreciable quantity of the available bromine. It turns out that the ratio of final to initial slopes is very nearly three, because bromine consumption by tribromoacetone is compensated, fortuitously, by the S_N2 reaction.

[6]The reader is reminded that f *vs.* t curves, for relatively insoluble ketones like 1,1-dibromoacetone, do not have a linear portion because the substrate concentration changes with time.

TABLE 1. Acetate-catalyzed enolization at 30°

Ketone	k^H (M^{-1} s^{-1})*	$k^H_{ketone}/k^H_{acetone}$
CH_3COCH_3	7.38×10^{-8}	1.0
CH_3COCH_2Br	3.27×10^{-4}	4.43×10^3
$CH_3COCHBr_2$	5.05×10^{-3}	6.83×10^4

*Statistically corrected rate constants. The bromoketone rate constants are not corrected for reaction at the CH_3 group.

enolization mechanism under the same conditions. The kinetics of bromine consumption by that ketone are quite complex[7] but there the ratio of monobromo ketones was shown to be in agreement with data from hydrogen isotope exchange (4); a process which can not involve reaction between unenolized ketone and D_2O (5).

It is possible, of course, that there is some direct reaction between ketones and bromine. Our results indicate that such reaction, if any, is not competitive enough to make itself manifest in either kinetics or products. The older literature contains numerous examples of ketone reaction under other conditions, which are adequately accommodated by the general enolization mechanism. Hence there appears to be no need for the extra halogenation mechanisms proposed recently (*2a–d*).

The effects of bromine substituents on acetate-promoted bromination are shown in Table 1. Bromine enhances the rate of enolization at the bromine-bearing carbon through its polar effect which overcomes an opposing steric effect. The overall effects of Br are not additive; two bromines being less than twice as effective as one in enhancing rate. The steric effect should reduce the reactivity of methylene protons of bromoacetone about two-fold, and that of the methine proton of 1,1-dibromoacetone about 40-fold, relative to that of a proton of acetone. These are rough estimates, based on the overall effects of CH_3 groups on deuterioxide-catalyzed exchange of ketones (9) and on the assumption that the steric requirements of CH_3 and Br are the same. Adjustment of the overall effects of Br substituents for the probable steric effect leaves a polar effect which is also not additive.

The effects of bromine substituents on enolization rates, at either alpha site of a ketone, are discussed in more detail in an accompanying paper.

[7]There are 13 enolization rate constants to consider in formation of pentabromobutanone as well as at least two rate constants for bimolecular substitution.

Experimental

Apparatus

The experimental setup was essentially that of Bell and Robinson (10). The reaction vessel was a cylindrical glass cell of about 120 ml capacity. It was fitted with one B-14 and two B-19 outer glass joints. The larger necks held a glass electrode (Fisher, cat. no. 13-639-1) and a platinum electrode (Johnson, Matthey and Mallory, 13 × 31 mm cylinder, type C Unimesh) each of which was sealed with epoxy resin to a B-19 inner glass joint. A 1 in., Teflon-coated bar magnet in the cell was driven by a magnetic stirrer (TRI-R Instruments, Jamaica, N.Y.) immersed in a constant temperature bath controlled to ±0.03°. Temperatures were measured with calibrated thermometers.

The lead of the platinum electrode was connected to the input terminal of a p*H*-meter (Fisher Accumet, model 310, expanded scale) and the glass electrode was hooked up to the reference terminal. Potential in millivolts could be read from the p*H*-meter which was itself connected to a chart recorder to obtain a record of potential against time. It was necessary to use shielded cable, to screen the cell with grounded copper gauze, and to use an aluminum-foil-covered, grounded shield between the apparatus and passersby in order to achieve stable, reproducible potentials. Polarization of the platinum electrode was not a problem as indicated by lack of dependence of potential on stirring speed.

Ketones and Solvents

Bromoketones had to be highly pure and especially free of more reactive higher bromoketones. Fractional distillation was unsatisfactory and all bromoketones were purified by repeated g.l.p.c. in a 10 ft × 3/8 in. QF-1 (10%) column. Pure compounds used for kinetics gave only one g.l.p.c. peak with three analytical columns: 10 ft × 1/8 in. QF-1 (12%), 5 ft × 1/8 in. FFAP (10%), and 10 ft × 1/8 in. SE-30 (20%), all on 60/80 mesh Chromosorb W. They were clear, colorless liquids with n.m.r. spectra (Varian T60) free of extraneous signals. They could be stored safely in sealed tubes at about −10° in a freezer.

Bromoacetone was prepared by the potassium chlorate method (11). A pure sample gave n_D^{25} 1.4680, lit. (12) n_D^{25} 1.4739; n.m.r. (CCl_4): δ 2.30, s, 3, CH_3CO; 3.78, s, 2, $BrCH_2CO$.

1,1-Dibromoacetone was obtained as a by-product from the preparation of bromoacetone. A pure sample had n_D^{25} 1.5232, lit. (12) n_D^{25} 1.5237; n.m.r. (CCl_4): δ 2.51, s, 3, CH_3CO; 5.67, s, 1, Br_2CHCO.

Dioxane (Fisher, Certified Grade) was purified by refluxing, first with hydrochloric acid and then with sodium, according to the procedure described by Fieser (13).

Solutions

Stock solutions were KBr (0.3333 *M*), NaOAc (2.00 *M*), HOAc (1.0 *M*), all in water and Br_2 (*ca.* 5×10^{-2} *M*) in 0.3333 *M* KBr solution. Solutions of ketones were prepared by weighing them into volumetric flasks, dissolving in dioxane, and filling with water to the mark. In the case of acetone, dioxane was omitted. Such solutions had a total

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

organic content (ketone plus dioxane) of 20% v/v and remained homogeneous on addition to the buffer solution in the cell.

Procedure

In a typical run, 50 ml of 2 *M* sodium acetate solution, 25 ml of 0.3333 *M* potassium bromide solution, and 10 ml of 1 *M* acetic acid solution were pipetted into the vessel. The electrodes were inserted and the vessel was positioned in the thermostat. After 10 or 15 min, the stock solution of bromine (5 ml) was pipetted in, the last neck was closed, and the system was left to equilibrate until the potential was absolutely steady, with the p*H*-meter in the expanded-scale mode. This generally took 0.5–1 h. During this time the ketone solution was brought to the bath temperature in another vessel.

The initial steady potential was recorded and used to calculate the bromine concentration (eq. 3, text). The recorder pen was then placed at the minimum reading by adjusting the p*H*-meter's standardizing potentiometer. Ketone solution (10 ml) was pipetted into the cell, bringing the total volume in the latter to 100 ml and the concentrations to: NaOAc, 1 *M*; HOAc, 0.1 *M*; KBr, 0.1 *M*; dioxane plus ketone, 2% v/v; acetone, 0.2–0.3 *M*; sparingly-soluble ketones, *ca.* 10^{-3} *M*; Br_2, 10^{-3}–10^{-4} *M*. Reaction was followed until the pen had traversed the 10 in. chart (end), a range of bromine concentrations of just over two powers of ten. At that point the p*H*-meter was returned to normal mode, at which setting the chart width represented some 20 powers of ten in bromine concentration. Reaction was followed a little longer, just to ensure that, at the nominal end of the run, the bromine concentration had not passed into the concentration range where ketonization of enols competes with their bromination (6).

A chart trace was treated as follows. The early, almost straight, part of the curve was extrapolated back through the irregularities (Fig. 1) caused by addition of ketone solution, to give Ch_0, eq. 6. Chart readings (Ch between 15 and 30 points), corrected for any blank reaction, and corresponding values of time were read from the trace. Values of $(Ch - Ch_0)$ and time (t) were then treated by computer, as outlined below, to obtain enolization rate constants k_1. The rate expression of the form $f = 1 + \alpha t + \beta(1 - e^{-k_2' t}) + \gamma(1 - e^{-k_3 t})$ was rewritten as a polynomial in t, $f = a_1 + a_2 t + a_3 t^2 + a_4 t^3 + \cdots$, by expanding the exponential terms as power series. The computer program solved the polynomial expression and printed out values of the coefficients. These coefficients could be expressed in terms of rate constants by substituting appropriate values of α, β, and γ from the rate expressions. The first four coefficients are: $a_1 = 1$; $a_2 = \alpha + k_2'\beta + k_3\gamma$; $a_3 = -(\beta k_2'^2 + k_3^2)/2!$; $a_4 = (\beta k_2'^3 + \gamma k_3^3)/3!$. The first coefficient is always unity, because of the treatment in terms of relative bromine concentration. The second coefficient, a_2, contains only terms in t and is the equivalent of the expression obtained by differentiating the rate expression and setting $t = 0$. Thus a_2 is always the initial slope of the f *vs.* t graph and it contains only the first enolization rate constants for the ketone under study. Details may be obtained from the authors.

Hydrogen Isotope Exchange in 2-Butanone. Further Measurements and Some Comments

R. A. Cox, J. W. Thorpe, and J. Warkentin

Department of Chemistry, McMaster University, Hamilton, Ontario

Received December 21, 1970[1]

The ratio of rate constants for exchange at the methylene and methyl positions of butanone, $k^H_{CH_2}/k^H_{CH_3}$, is shown to be near 1.69 in 1:1 acetic acid–acetate buffer; nearly twice the value (0.86) for deuterioxide catalysis at 54.8°. Methods of obtaining rate constants for acetate catalysis from composite rates (acetate and deuterioxide), or from rates in buffered media, are shown to be adequate for estimating rate ratios.

Detailed temperature dependence of the relative rate constants for either system is not yet available but the effects are known to be small. For butanone enolizations the isokinetic temperature is in the neighborhood of 35°, when reaction is catalyzed by deuterioxide in aqueous media.

Le rapport des constantes de vitesse de l'échange aux positions méthylène et méthyl de la butanone, $k^H_{CH_2}/k^H_{CH_3}$, est près de 1.69 dans un tampon 1:1 acide acétique–acétate et près de deux fois cette valeur (0.86) dans le cas de la catalyse par l'oxyde de deutérium à 54.8°. Les méthodes permettant d'obtenir les constantes de vitesse pour la catalyse par acétate à partir de vitesses combinées (acétate et oxyde de deutérium) ou de vitesses en milieu tamponné sont estimées adéquates pour la détermination des rapports de vitesse.

La dépendance de la température sur les constantes de vitesse relatives de ces systèmes n'a pas été approfondie, mais les effets sont reconnus comme étant faibles. Dans le cas des énolisations de la butanone, la température isocinétique se situe aux environs de 35° lorsque la réaction est catalysée par l'oxyde de deutérium en milieu aqueux. Discussion and Results

In order to compare the ratio of hydrogen isotope exchange rates in butanone with the ratio of bromoketones formed in comparable circumstances (1) it was desirable to redetermine the former. There is some controversy (2) with regard to the magnitude of the reactivity ratios for exchange $(k^H_{CH_2}/k^H_{CH_3})$[2] and concerning the effect of changing the catalyzing base from hydroxide to acetate.

We have made two more measurements of the relative rates of exchange in butanone at 54.8°. The media for these studies were 1:1 acetic acid–acetate buffers in D_2O and exchange was followed by n.m.r., with two different n.m.r. spectrometers. The results,

$$(k^H_{CH_2}/k^H_{CH_3})^{54.8}_{HOAc,\,AcO^-} = 1.70 \pm 0.10 \quad \text{and} \quad 1.68 \pm 0.12$$

are in good agreement with the average ratio (1.85) obtained recently (4) for butanone exchange in aqueous buffer ($HOAc/AcO^- = 0.726$) at 41.8°. The latter measurement came from mass spectrometric monitoring of the exchange process and provides support for the reliability of the n.m.r. method.

We have previously published two estimates of the reactivity ratio for acetate alone. In unbuffered, aqueous acetate the following average *observed* ratios, $k^H_{CH_2}/k^H_{CH_3}$, for exchange have been reported: 1.4 for 1 *M* acetate at 59.2° (5), 1.4 for 2.5–5.0 *M* acetate at 50° (6), and 1.05 for 0.5 *M* acetate at 30° (7). These ratios are composite values, however, because hydrolysis of acetate in unbuffered systems produces appreciable concentrations of HO^-, which has a much larger catalytic coefficient (by a factor greater than 10^5) than acetate. We used an extrapolation technique (5) to isolate the catalytic coefficients of acetate toward butanone and obtained the ratio $(k^H_{CH_2}/k^H_{CH_3})^{59.2°}_{AcO^-} = 2.16 \pm 0.36$. This number was checked by using buffer solutions (8) in which the buffer ratios ($HOAc/AcO^- = 0.0469$ and 0.0936) were low enough to leave acid-catalysis terms undetectable by n.m.r. That method gave 1.90 ± 0.17 at 54.8°.[3]

[1]Revision received October 8, 1971. Publication delayed at authors' request.

[2]All ratios cited in this paper are statistically corrected; *per hydrogen* (3).

[3]The temperature dependence of enolization rate ratios is not known quantitatively for any of the systems discussed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Although the present results are for 1:1 buffer ratios they are roughly comparable with the others since catalysis involving HOAc is unimportant compared to catalysis by AcO^-, not only in enolization of butanone (8) but also in enolization of methoxyacetone (9). It is noteworthy also that our ratios for buffer systems are not greatly different from some ratios reported for acid catalysis; 2.1 at 50° (6) and 1.9 at 40.2° (10). A small component from acetic acid catalysis would therefore not be expected to change the observed site selectivity appreciably.

Catalysis by a strong base, HO^-, does appear to involve a different selectivity. We reported (8) $(k^H_{CH_2}/k^H_{CH_3})^{54.8°}_{OD^-} = 0.86$, and somewhat larger values (1.1–1.2) for that ratio in the temperature range 0–32° (3, 5). Rappe reported 1.05 for 30° (7) and 0.91 for 40° (11) and calculated (2) the value 0.84 from our 59.2° data, in an effort to discredit the extrapolation technique (5) referred to above. The agreement between this calculated value and the measured values (above) is quite satisfactory, when the corrections for the different temperatures are made,[3] and tends to support, rather than to undermine, the extrapolation method.[4] The disagreement then, concerns the value of the rate ratio for enolization by acetate as the major basic catalyst. Although Rappe's observed ratios, 1.2–1.4 (2, 7), are a little smaller than ours, 1.4–1.9 (5, 8), or that of Bothner-By and Sun, 1.4 (6), all measurements pertaining to 50–59.2°, it is noteworthy that his own measurements indicate a still lower value for hydroxide catalysis in the same range of temperatures. As was already pointed out, the difference between *observed* rate ratios for an unbuffered acetate medium and one containing only HO^- must be a minimum value for the relative selectivities of the two bases, because data from unbuffered acetate systems are composite values of hydroxide and acetate catalysis. Rappe's data therefore are reasonably consistent with our claim that $k^H_{CH_2}/k^H_{CH_3}$ for acetate ion has nearly twice the value that it has for hydroxide in the neighborhood of 55° (5, 8).

In summary, the rate ratio reported here and used in the accompanying paper, for exchange of butanone in $HOAc/AcO^-$ buffers, is in good agreement with that obtained by a different method (4). It is also roughly the same as the rate ratio estimated for catalysis by AcO^- alone but greater than the rate ratio pertaining to catalysis by HO^-. Our findings are therefore more in harmony with those of Hine and coworkers (9), who reported that the selectivity in exchange of methoxyacetone is base dependent, than with those of Rappe (2). Exchange must involve catalyzed enolization, since a sample of pure butanone in D_2O (8), in a carefully cleaned, sealed n.m.r. tube is still not detectably exchanged after $2\frac{1}{2}$ years at room temperature.

Experimental

A buffer solution was prepared by adding anhydrous sodium acetate (0.832 g, 0.0101 mol) and acetic acid (twice distilled, 0.609 g, 0.0101 mol) to deuterium oxide (99.5 %D, 8.20 ml). To 0.82 ml of this solution in an n.m.r. tube was added 2-butanone (0.18 ml) from a calibrated pipette. Three samples in three tubes were prepared in this way, one of which was kept cold and was used for recording the initial p.m.r. spectrum. The others were sealed and were placed in a bath kept at 54.8 ± 0.04 °C. Concentrations in each tube, neglecting volume changes on mixing, were: acetic acid and sodium acetate, 0.832 *M*; 2-butanone, 2.00 *M*. The initial ratio of deuterium to exchangeable protium was about 8:1.

Exchange was followed to at least one half-life by integrating the signals from the α-protons in the p.m.r. spectrum, relative to that of the non-exchanging β-methyl group as internal standard. The CH_3 signal from the buffer components was sufficiently separated; it did not interfere with integration. Each analysis was the average of six integrations with a Varian A-60 instrument. Analyses were performed at different times by removing a tube from the bath, plunging it into ice water to reduce exchange rates to negligible levels, and transferring the cold tube to the instrument. Time outside the bath was not counted.

A second pair of samples, in which the buffer ratio was also 1:1 but the buffer concentration was 0.610 *M*, was treated in exactly the same way, except that analyses were done with a Varian T-60 instrument.

Observed rate constants were obtained from pseudo-first-order plots of $\log I_t$ against time, where I_t is the

---

here. Its small magnitude and the direction of change to be expected are illustrated for the case of hydroxide catalysis. The ratio, $(k^H_{CH_2}/k^H_{CH_3})_{OD^-}$, changes from about 0.86 at 54.8° to about 1.2 at 0°; an average increment less than 0.04 per 5°. Comparisons of data pertaining to different temperatures can therefore be drawn, as long as the difference in temperature is only 5–10°.

[4]Absolute values of rate constants from the extrapolation technique are likely to be in greater error than the ratios. A fortuitous equality of rate constants for acetate catalysis at 59.2 and 54.8° has been pointed out (2). That temperature difference should have meant rate factors near 1.6, for a given site, as estimated from activation parameters for enolization of acetone. The extrapolation method may well be at fault where actual rate constants, rather than their ratios, are concerned.

normalized integral of a given signal at time t. Straight lines were obtained, the slopes of which agreed with computer-fitted values to 3% or better. Rate constants and their standard deviations are: $k_{CH_3}^{obsd} = 6.85 \pm 0.16 \times 10^{-7}\ s^{-1}$; $k_{CH_2}^{obsd} = 11.64 \pm 0.44 \times 10^{-7}\ s^{-1}$ for buffer concentration 0.832 M; $k_{CH_3}^{obsd} = 4.10 \pm 0.13 \times 10^{-7}\ s^{-1}$; $k_{CH_2}^{obsd} = 6.89 \pm 0.28 \times 10^{-7}\ s^{-1}$ for buffer concentration 0.0610 M. Errors are indicative only of the quality of the fit to pseudo-first-order kinetics and of the probable reliability of rate ratios from a given run. Absolute values of rate constants are much less certain, being subject to errors in concentration and temperature that cancel out in the ratios. For the two runs described above, second order rate constants for a given site differ by roughly 20%.

Effects of Bromine Substituents on Rates of Acetate-promoted Enolization of Ketones

R. A. Cox and J. Warkentin

Department of Chemistry, McMaster University, Hamilton, Ontario

Received November 25, 1971[1]

Effects of bromine substituents on rates of acetate-catalyzed bromination of ketones are reported. Approximate polar contributions to the rates were obtained, based on the approximation that the steric effects of bromine and methyl are identical. Such polar substituent effects are quite large at the α′-position of an α-bromo ketone, leading to the conclusion that the carbonyl group is much better than the methylene group in transmitting polar effects.

Rate enhancements caused by α-bromine substituents are largely entropic in origin and rates correlate well with ionization constants of α-bromo acids. These results are interpreted as indicative of an enolate-like transition state for acetate-catalyzed enolization.

Les effets des substituants brome sur les vitesses de bromation des cétones, catalysée par l'acétate, sont rapportés. Les contributions polaires approximatives aux vitesses sont obtenues, fondées sur l'approximation que les effets stériques du brome et du méthyle sont identiques. De tels effets polaires de substituants sont très accentués sur la position α′ d'une α-bromo cétone permettant de conclure que le groupe carbonyle est de deux fois environ aussi bon que le groupe méthylène, dans la transmission des effets polaires. Les accroissements de vitesse dûs aux substituants α bromés sont grandement d'origine entropique et les vitesses sont en relation avec les constantes d'ionisation des α-bromoacides. L'interprétation de ces résultats révèle un état de transition du type énolate dans l'énolisation catalysée par l'acétate.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3242 (1972)

Introduction

It has been known for a long time that most α-halo ketones are enolized more rapidly than simple ketones in the presence of base (1). In acetate-catalyzed iodination at 25°, chloroacetone and bromoacetone were reported to be 45.8 and 75.0 times as fast, respectively, as acetone (2) and acetate-catalyzed α-hydrogen exchange of chloroacetone at 41.8° was found to be about 580-fold faster than exchange of acetone (3). For the alkyl, aryl ketones $C_6H_5COCH_3$, $C_6H_5COCH_2Br$, and $C_6H_5COCHBr_2$, relative acetate-catalyzed bromination rates were reported to be 1:53:104 (4), statistically corrected. The success of the iodoform reaction (5) and of haloform reactions in general, has been attributed to fast halogenation of a first-formed halo ketone at the already-halogenated α-site (6–9).

Exceptions to the general rule are found in systems with sterically-hindered α-sites. For example, α-bromobenzyl phenyl ketones are brominated more slowly than the parent ketones in the presence of acetate (10) and 2-bromo-2,4-dimethyl-3-pentanone is less reactive toward hydroxide ion than 2,4-dimethyl-3-pentanone (11).

Greater reactivity of a halo ketone, relative to that of the parent ketone, was first attributed to an enhanced rate of enolization at the substituted α-site alone rather than to greater reactivity at both α-sites. This rationale was no doubt based on the findings that unsymmetrical halogenation of acetone in basic solutions is preferred (6), that the haloform reaction yields primarily halogen-free carboxylic acid (12, 13), and on the expectation that the carbonyl group would effectively insulate the remote α-position from the polar effect of α-halogen (14). Indications that both α-positions may have their reactivity enhanced came from the finding that α-halo acids are formed in haloform reactions (7, 8), albeit in low yield, and from measurements of hydrogen isotope exchange rates (3, 15). The latter work indicates that α-chlorine enhances acetate-promoted α′-enolization rates by factors ranging from about 4.4 (methyl-α-chlorobenzyl ketone) to 19 (chloroacetone), with the effect in α-chlorocyclohexanone intermediate at 5.1. In the case of α-fluorine substituents the rate enhancement is actually larger at the unsubstituted α-position. Fluoroacetone is exchanged about 3.5 times as

fast as acetone in aqueous acetate buffer but the CH_3 group is 5.2 times as reactive as the CH_2F group, statistically corrected (3, 15).

In this article we discuss quantitative estimates of the polar effect of α-bromine substituents on rates of acetate-catalyzed enolization of ketones. A correlation between rate constants in that reaction and acidity constants of carboxylic acids is also presented.

Methods

Brominations were carried out in homogeneous media consisting of aqueous acetic acid–acetate buffer (1:10; 1 *M* in AcO^-) and dioxane (5% v/v). Reactions were pseudo-first-order; acetate being present in large excess over Br_2. All rates reported are for reactions of zero order in Br_2; that is, the bromine concentration range always exceeded the limit, *ca.* 10^{-5} -10^{-6} *M*, below which ketone bromination becomes first order in bromine (16). The overall rate of bromine consumption could therefore be equated to the overall rate of enolization. In the buffer medium employed, most of that enolization must be effected by acetate ions since catalysis by HOAc is not detectable in 1:10 (HOAc:OAc^-) buffer (17).

Enolization was followed by measuring the concentration of bromine via the redox potential of the medium, as described elsewhere (18). The method is sensitive to impurities which consume bromine and hence all ketones were checked by g.l.p.c. and were purified by preparative g.l.p.c. The shapes of graphs of relative bromine concentrations against time and the methods and equations for extracting rate constants from such data are described elsewhere (18).

Results and Discussion

To separate polar effects from steric effects, advantage was taken of the approximately equal steric requirements of methyl and bromine substituents. The steric substituent parameters (E_s) and the Van der Waals radii of Br and CH_3 are essentially the same (19). Therefore any consequence of interchanging the two substituents should be primarily the result of the difference in their inductive effects.

Table 1 contains kinetic data for the bromination of three sets of ketones. In the first set, successive substitution of bromine for methyl groups keeps the substrates sterically equivalent and rate factors therefore give a measure of the polar effect of α-bromine on α-enolization and on α′-enolization. Rate factors are of the order 780 and 92 at the α- and α′-sites, respectively, taking the corrected (bracketed) value in the second row. The value 8.0×10^{-5} M^{-1} s^{-1} for 1-bromo-2-butanone is the observed rate constant adjusted for a statistical factor of two. It is a crude value of the CH_2Br reactivity, based on the assumption that reaction at CH_3 can be neglected. The bracketed value includes a correction (see footnote to Table 1) for CH_3 reactivity.

The second set of ketones provides another measure of the α- and α′-effects. Again the effect of α-bromine is to enhance α′-reactivity by a factor near 10^3. A steric effect is introduced in going from $CH_3COC(CH_3)_3$ to $BrCH_2COC(CH_3)_3$ but that factor is known to be small compared to 10^3 (20). The second and third entries of set 2 are sterically equivalent and

TABLE 1. Rates of acetate-catalyzed enolization of ketones at 30°

Ketone	k^H (M^{-1} s^{-1})[a]	$\Delta\Delta G^*$ (kcal mol^{-1})[b]
$CH_3CH_2COCH_2CH_3$	9.4×10^{-8}	0.0
$CH_3CH_2COCH_2Br$	$8.0(7.3) \times 10^{-5}$[c]	4.1
$BrCH_2COCH_2Br$	6.7×10^{-3}	2.6
$(CH_3)_3CCOCH_3$	6.3×10^{-8}	0.0
$(CH_3)_3CCOCH_2Br$	5.8×10^{-5}	4.1
$(CH_3)_2CBrCOCH_2Br$	2.7×10^{-3}	2.3
$CH_3COC(CH_3)_3$	6.3×10^{-8}	0.0
$CH_3COCBr(CH_3)_2$	7.0×10^{-6}	2.8
$CH_3COCBr_2CH_3$	7.6×10^{-5}	1.5
CH_3COCBr_3	1.9×10^{-4}	0.5

[a]Statistically corrected. The statistical factors by which observed rate constants were divided are (starting with the top row): 4, 2, 4, 3, 2, 2, 3, 3, 3, and 3.

[b]In each set the difference between ΔG^* for that ketone and the one immediately above it, except in case of the first member of a set, which is taken as the reference compound for that set. The numbers are therefore increments in ΔG^* at 30° caused by the change in substituents. Values of ΔG^* were calculated from the equation

$$\ln k_{rate} = \ln \frac{kT}{h} - \frac{\Delta G^*}{RT}$$

[c]Based on the assumption that all enolization occurred at the CH_2Br group. The number in parentheses is the calculated CH_2Br reactivity obtained by correcting the observed rate for reaction at the other methylene group. The estimated rate for that group is 7.0×10^{-6} M^{-1}, s^{-1}, obtained by subtracting 2.6 kcal mol^{-1} from ΔG^* (observed). The equation $8.0 \times 10^{-5} = k^H_{CH_2Br} + k^H_{CH_2CH_3}$ was then applied.

again show that the effect of α-Br is also substantial (47-fold) on α′-reactivity.

In the third set of ketones the effects of one, two, and three α-bromines on α′-enolization rates of sterically-equivalent compounds are indicated. One bromine increases reactivity at the other α-site by the factor 111, compared to 92 and 47 in sets 1 and 2, respectively. A second and third bromine cause the much smaller factors 10.9 and 2.5, respectively, showing that the α-effects are far from cumulative.

The most striking result is that the polar effect of bromine is transmitted so well through the carbonyl group. The factor by which CH_2 groups attenuate inductive effects is about 2.8 per group intervening between the dipole and the carbon atom of interest (21). Therefore α′-substituents of halo ketones, which are insulated from the effect of α-halogen by two carbons, should see that effect attenuated by the factor 7.8 (*i.e.* 2.8^2). From the data of Table 1 we can calculate the actual insulating factor applicable to α′-substituents. It is given by $\log (k^{\alpha}_{Br}/k^{\alpha}_{H})/\log k^{\alpha'}_{Br}/k^{\alpha'}_{H}$, in which the ratio in the numerator is that for α-enolizations, with and without α-Br, while that in the denominator compares α′-enolizations, with and without α-Br. An equivalent expression is $\Delta\Delta G^{\ddagger}_{\alpha}/\Delta\Delta G^{\ddagger}_{\alpha'}$. The numerator is about 4.1 kcal mol^{-1} and the denominator is 2.8 or 2.3 kcal mol^{-1}, depending on the set of ketones chosen (Table 1). Thus we estimate the attenuation factor for α′-substituents to be only 1.3–1.8 compared to 7.8 calculated for two CH_2 groups. An attenuation factor below 2.8 indicates that the reactions from which that number was derived (21) are not perfect models for the systems in question here, in which the insulating group contains π-electrons.[2] Nevertheless, although we cannot assign a number to the CO component of the CH_2CO group, the small composite attenuation factor indicates that the carbonyl group is a very good transmitter of polar effects.

Although the effects of α- and α′-bromine are roughly additive (compare third, sixth, and eighth entries in $\Delta\Delta G^{\ddagger}$ column of Table 1) it is clear that the second and third halogens at a given α-site are much less effective than the first. Such lack of additivity is not new; it shows up also in the ionization constants of α-bromocarboxylic acids. In fact there is a good correlation between the pK_a values of some model acids, chosen because their pK_a values are known (22), and acetate-catalyzed enolization rate constants of corresponding bromo ketones (Fig. 1). The correlation coefficient is −0.995 and the slope of the line is -0.87 ± 0.02. This correlation suggests that the transition state for enolization is enolate-like although the extent to which negative charge is developed cannot be inferred from the slope. In a series of phenyl benzyl ketones the fractional charge developed in the ketone moiety at the transition state for acetate-catalyzed enolization was estimated to be 64% (23).

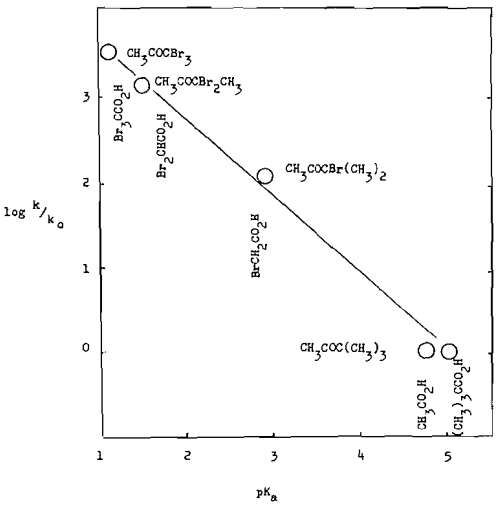

FIG. 1. Correlation of $\Delta G^{\ddagger}$ for enolization with ΔG^{0} for ionization.

Activation parameters found for acetone and bromoacetones (Table 2) are in keeping with an enolate-like transition state. For reaction at room temperature over half of the substituent effect of bromines is entropic. A likely way in which bromines increase the activation entropy is through their effect on solvation. A bromo enolate must be less solvation-dependent than an unsubstituted enolate because it can partly disperse charge internally into the polar C—Br bond. Consequently, for a given degree of charge development in an enolate-like transition state, bromine substituents should decrease the extent of solvent electrostriction.

[2]The minimum factor for the insulating unit $CH_2C{=}O$, assuming that CO transmits perfectly (attenuation of CO = 1), would be 2.8 × 1.

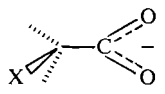
TABLE 2. Activation parameters of acetate-catalyzed enolization of acetone and bromoacetones

Ketone	CH_3COCH_3	CH_3COCH_2Br	$CH_3COCHBr_2$
k^H, [a] 20°	2.0×10^{-8}	9.1×10^{-5}	1.7×10^{-3}
25°	4.0×10^{-8}		
30°	7.4×10^{-8}	3.3×10^{-4}	5.1×10^{-3}
35°	1.3×10^{-7}		
40°	2.4×10^{-7}	8.3×10^{-4}	1.5×10^{-2}
ΔH^* (kcal mol^{-1})[b]	22.0 ± 0.3	19.6 ± 0.7	19.3 ± 0.4
ΔS^* (e.u.)[b]	-18.5 ± 0.6	-10.0 ± 2.0	-5.4 ± 1.0

[a]Statistically corrected second order rate constants (M^{-1} s^{-1}).
[b]From the equation $\ln k_{rate}/T = \ln k/h - \Delta H^*/RT + \Delta S^*/R$. Errors in the activation parameters came from root-mean-square errors in the slope and intercept of a computer-fitted line.

The charge in the ketone moiety at the transition state need not be increased by Br-substituents, for the more acidic α-bromo ketones must have more reactant-like transition states than the parent ketones (24).

A rationale for the non-cumulative effects of Br-substituents on either pK_a values or enolization rates is based on conformational preferences. An α-halo carboxylate ion (**1**)



1

probably has a preferred conformation in which the C—X dipole is perpendicular to the carboxylate plane, as drawn. Such an arrangement should lead to the minimum dipole–ion repulsions. A second halogen cannot also adopt that arrangement and consequently the net inductive withdrawing effect per halogen would be reduced through a repulsive ion–dipole interaction. The argument for an enolate-like transition state is strictly analogous.

There is one problem with regard to the enolate-like transition state for catalysis of enolization by a weak base like acetate. 2-Butanone enolizes more slowly than acetone but its reactivity per hydrogen is higher at the methylene than at the methyl group (17, 25). One way of accounting for this is to postulate predominant steric retardation with a small polar rate enhancement at CH_2 superimposed. For an enolate-like transition state that effect would have to be one of electron-withdrawal, contrary to the effect of para CH_3 on benzoic acid acidity. Because of this problem we suggested (20) that the transition state might be enol-like, at least for the more highly endothermic enolizations involving weak bases. However, this concerted mechanism, originally postulated by Swain (26) to account for a termolecular term in the kinetics of enolization of acetone (27, 28) has little support as a general mechanism, although it may be important in carboxylic acid–carboxylate anion catalyst systems (29). Moreover, Brönsted correlations (30) indicate that the transition state for enolization of acetone by weak bases is highly enolate-like ($\beta \simeq 0.8$). Our present results are more readily rationalized in terms of transition states with enolate character but do not clarify the anomalous methylene reactivity of 2-butanone toward weak bases.

It should be emphasized, in summary, that it is probably unsafe to extrapolate the reactivity trends reported here. Although the effects of I, Br, and Cl may be qualitatively the same, fluorine- (16, 31) and methoxy-substituted (32) ketones do not fit expectations based on the inductive effects of those substituents. It has been suggested (33) that polarizability of the substituent may be a controlling factor. Furthermore the quantitative relationships between α- and α′-reactivity are no doubt functions not only of the base and the substituent but also of the medium and the temperature.

Experimental

Purification of Bromoketones

The general procedure involved rapid distillation, at reduced pressure, of a CCl_4 extract of the crude bromo ketone mixture obtained from the appropriate synthesis

(see below). The fraction shown (by n.m.r.) to contain most of the desired product was stabilized by addition of magnesium oxide, which removes traces of HBr, before it was subjected to preparative g.l.p.c. 1,1,1-Tribromoacetone was partly isomerized to 1,1,3-tribromoacetone on distillation. Consequently it was isolated by g.l.p.c. of the crude CCl_4 extract directly.

Preparative g.l.p.c. was done with a 10 ft × 3/8 in. silicone QF-1 column (10%, on 60/80 mesh, non-acid-washed, Chromosorb W) in a Varian Aerograph A90-P3 instrument. The column was operated at 110–130° with helium flow rates between 50 and 100 ml/min. Compounds collected from the column were rechromatographed at least once or until they appeared to be homogeneous on three different analytical columns (10 ft × 1/8 in. QF-1, 12%; 5 ft × 1/8 in. FFAP, 10%; and 10 ft × 1/8 in. SE-30, 20%; all on 60/80 mesh Chromosorb W) and showed only the expected n.m.r. signals. Such samples were water-white and stable when stored at about −10°, without added MgO.

N.m.r. spectra were recorded on a Varian T-60 instrument.

Bromoacetone

The method of Catch and coworkers (34), in which acetone is brominated in the presence of potassium chlorate, was used. The crude product contained chloroacetone, presumably from substitution on bromoacetone by chloride generated from chlorate, and 1,1-dibromoacetone. Purification by g.l.p.c., as described above, gave bromoacetone: n_D^{25} 1.4680 (lit. (35), n_D^{25} 1.4739, (33), n_D^{15} 1.4697); n.m.r. (CCl_4) δ 2.30 (s, 3, CH_3), 3.78 (s, 2, CH_2).

1,1-Dibromoacetone

1,1-Dibromoacetone was obtained as a byproduct from the synthesis of bromoacetone (above) and from the preparation of 1,1,1-tribromoacetone (below). Pure material (g.l.p.c.) had n_D^{25} 1.5232 (lit. (35) n_D^{25} 1.5237); d_4^{23} 2.063; n.m.r. (CCl_4) δ 2.51 (s, 3, CH_3), 5.67 (s, 1, CH).

1,1,1-Tribromoacetone

1,1-Dibromoacetone (2.81 g, 0.013 mol) and *N*-bromosuccinimide (NBS) (2.32 g, 0.013 mol) were refluxed in CCl_4 (14 ml) under illumination from a 75 W tungsten spot lamp. After 12 h, the yield was 91%, estimated by n.m.r. Chromatography as described above gave pure tribromoacetone: n_D^{25} 1.5708 (lit. (35) n_D^{25} 1.5689); d_4^{20} 2.334; n.m.r. (CCl_4) δ 2.76 (s, CH_3).

1,1-Dibromoacetone was also prepared from NBS and acetone and by bromination of acetone with Br_2 in glacial acetic acid containing sodium acetate. These procedures were less satisfactory in our hands and are therefore not described in detail.

1,3-Dibromoacetone and 1,3-Dibromo-3-methyl-2-butanone

These compounds were prepared by the method of Wagner and Moore (36). The appropriate ketone (0.5 mol) in a 250 ml, three-necked flask fitted with gas inlet tube, magnetic stirrer, pressure-equalizing dropping funnel, and a reflux condenser was cooled with ice while bromine (53 ml, 1 mol) was added gradually from the funnel. Reaction was initiated with the light from a tungsten lamp when a few drops of Br_2 had been added; the rest of the Br_2 was then dropped in over a period of 2 h. When addition was complete nitrogen was bubbled through the solution overnight to sweep out HBr. The product was distilled from the flask at low pressure and chromatographed as described. From acetone was obtained 1,3-dibromoacetone: m.p. 28–28.5°; b.p. 80°, (lit. (35) m.p. 25.5–27.0°, b.p. 79.5–80.5 (9 mm)); n.m.r. (CCl_4) δ 4.10 (s, CH_2). Methyl isopropyl ketone gave 1,3-dibromo-3-methyl-2-butanone: m.p. 13–14°; b.p. 68–72° (3 mm); n_D^{25} 1.5154 (lit. (36) m.p. 10–12°, b.p. 111° (15 mm), n_D^{25} 1.5178); n.m.r. (CCl_4) δ 1.94 (s, 6, CH_3), 4.31 (s, 2, CH_2).

1-Bromo-2-butanone

1-Diazo-2-butanone was treated with HBr according to the procedure of Catch and coworkers (37) to afford the title compound: b.p. 44–45° (10 mm); n_D^{25} 1.4670 (lit. (34) b.p. 49° (10 mm), lit. (37) n_D^{20} 1.4670); n.m.r. (CCl_4) δ 1.08 (t, 3, $J = 7$ Hz, CH_3), 2.64 (q, 2, $J = 7$ Hz, CH_3CH_2), 3.76 (s, 2, $BrCH_2$).

3-Bromo-3-methyl-2-butanone

This ketone was synthesized from methyl isopropyl ketone by the method of Catch and coworkers (38) and was purified by g.l.p.c.: n_D^{25} 1.4554, (lit. (39) n_D^{25} 1.4510); d_4^{20} 1.334; n.m.r. (CCl_4) δ 1.80 (s, 6, $(CH_3)_2C$), 2.36 (s, 3, CH_3CO).

3,3-Dibromo-2-butanone

2-Butanone (7.2 g, 0.1 mol) and NBS (35.6 g, 0.2 mol) were refluxed in CCl_4 (150 ml) under illumination from a 75 W tungsten spot lamp (39). After $1\frac{1}{2}$ h the reaction was complete and the yield (n.m.r.) of the title compound was about 95%. Distillation followed by preparative g.l.p.c. gave pure 3,3-dibromo-2-butanone: n_D^{25} 1.5053 (lit. (39) n_D^{25} 1.5050); d_4^{22} 1.827; n.m.r. (CCl_4) δ 2.50 (s, CH_3CO), 2.67 (s, 3, CH_3CBr_2).

1-Bromo-3,3-dimethyl-2-butanone (Bromopinacolone)

Pinacolone (10.02 g, 0.1 mol) and NBS (17.8 g, 0.1 mol) in CCl_4 (100 ml) were heated and irradiated with the light from a 75 W tungsten spot lamp. After 24 h of refluxing, the solution contained pinacolone (70%), bromopinacolone (15%), and dibromopinacolones (15%), as estimated by n.m.r. The mixture was cooled with ice, the insoluble solids were filtered off, and the solution was concentrated on a rotary evaporator. Distillation gave a fraction boiling at 55–60° (4 mm) which contained at least 50% 1-bromo-3,3-dimethyl-2-butanone (n.m.r.) along with $(CH_3)_3CCOCHBr_2$, $BrCH_2(CH_3)_2CCOCH_3$, and $BrCH_2(CH_3)_2CCOCH_2Br$. The desired ketone was purified by g.l.p.c. as described above: n_D^{25} 1.4630 (lit. (40) n_D^{25} 1.4659, (41) n_D^{20} 1.4640); n.m.r. (CCl_4) δ 1.21 (s, 9, $(CH_3)_3C$), 4.01 (s, 2, $BrCH_2$).

Other Ketones

Acetone, butanone, and 3-pentanone were commercial, reagent-grade materials distilled in a 20 × 2 cm glass still packed with 3 mm single-turn glass helices. Center cuts showed only the expected n.m.r. signals and only a single peak on analytical g.l.p.c. columns.

Pinacolone (Aldrich, reagent grade) was purified by preparative g.l.p.c., as described above for bromo ketones. The product used was homogeneous on three analytical g.l.p.c. columns and there were no impurities detectable by n.m.r.

Procedure

The apparatus and the procedure are described elsewhere (18).

We are grateful to the National Research Council of Canada for financial support and to Mr. J. W. Thorpe for samples of some of the bromo ketones. One of us (R.A.C.) was the grateful recipient of an Ontario Graduate Fellowship.

Oxidation of Semicarbazones of Ketones. Improved Synthesis of Δ^3-1,3,4-Oxadiazolin-2-ones

P. KNITTEL, S. L. LEE, AND J. WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 31, 1972

Oxidation of readily-available semicarbazones of ketones with lead tetraacetate, followed by hydrolysis (*in situ*) of the products, makes novel Δ^3-1,3,4-oxadiazolin-2-ones easily accessible. Spectra of the compounds are discussed and some of their potential for synthesis is indicated.

L'oxydation des semicarbazones de cétones, facilement disponibles, par le tétracétate de plomb suivie de l'hydrolyse (*in situ*) des produits constitue une voie d'accès simple et nouvelle aux Δ-3 oxadiazoline-1,3,4 ones-2. Les spectres des composés sont discutés et quelques unes de leurs utilisations potentielles en synthèse sont indiquées. [Traduit par le journal]

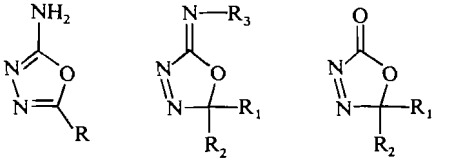
Oxidation of carbonyl derivatives of aldehydes and ketones has been studied extensively and includes, among a variety of pathways, a useful route to heterocyclic compounds (1). Aldehyde semicarbazones are cyclized to 2-amino-1,3,4-oxadiazoles (**1**) (2), possibly via 2-imino-Δ^3-1,3,4-oxadiazolines (**2***a*) which are isomerized under the reaction conditions. 4-Substituted ketone semicarbazones can be cyclized (3) to oxadiazolines **2***b*, some of which have been hydrolyzed (4) to the corresponding Δ^3-1,3,4-oxadiazolin-2-ones (**3**).



1 **2** **3**

2*a* $R_1 = R_3 = H$; R_2 = alkyl or aryl
2*b* $R_1 = R_2 = R_3$ = alkyl or aryl
2*c* $R_1 = R_2$ = alkyl or aryl; $R_3 = H$

There are no reports in the literature of oxidation of unsubstituted semicarbazones of ketones to 2-imino-Δ^3-1,3,4-oxadiazolines (**2***c*), possibly because such compounds are themselves sensitive to oxidants or because they are easily hydrolyzed. In this paper we report a convenient synthesis of oxadiazolinones **3** by oxidative cyclization of ketone semicarbazones with lead tetraacetate, followed by hydrolysis, *in situ*, of the presumed intermediates, **2***c*.

Discussion

Table 1 lists spectra and physical properties of five new oxadiazolinones. 5,5-Dimethyl-Δ^3-1,3,4-oxadiazolin-2-one, which was prepared earlier by an analogous but longer route (4), was also synthesized from its semicarbazone by the simpler method in 67% yield.

Yields of crude products were near 60% in all cases; those of analytically-pure products were typically near 40%. Considering the ease with which many semicarbazones can be prepared and the simplicity of the present procedure (see Experimental), it is evident that many oxadiazolinones **3** are now within easy reach.

Oxadiazolinones **3** are α,β-unsaturated-α,β-diaza-γ-lactones which may be compared to their carbon analogs, α,β-unsaturated-γ-lactones. A striking effect of the azo function is to raise the carbonyl stretching frequency of the lactone function. Thus, whereas α,β-unsaturated-γ-lactones absorb near 1750 cm^{-1}, oxadiazolinones **3** absorb near 1835 cm^{-1}. The azo substituent probably exerts its influence both directly at the carbonyl carbon, where sp^2 nitrogen acts inductively somewhat like a halogen atom, and indirectly at the γ-carbon, which transmits an inductive effect to the ether oxygen. An electronegative γ-substituent in a γ-lactone is known to raise ν_{CO} substantially; from about 1770 cm^{-1} in γ-valerolactone to 1797 cm^{-1} in γ-acetoxy-γ-valerolactone (5). Compounds **3**, like γ-lactones in general (5), do not change carbonyl frequency appreciably as a result of the

†Solutions in CCl_4.

‡In hexane. The $n \rightarrow \pi^*$ band shows fine structure in this solvent; individual maxima of that band are tabulated. In ethanol the first compound listed has $\lambda_{max} = 227$ (3521) and 368 nm (255), the latter band without fine structure.

§CCl_4, internal TMS. Chirality of the unsymmetrically-substituted members complicates some of the spectra. The third compound listed, for example, has magnetically non-equivalent methyls in the isopropyl substituent. Abbreviations are d = doublet, m = multiplet, s = singlet, and numbers following such symbols are relative integrals.

‖Calculated figures in the upper rows; analytical results in the lower rows.

extra rigidity imposed by spirocyclic geometry (Table 1).

A band near 1540 cm^{-1} is present in the i.r. spectra of all the oxadiazolinones (Table 1). This band is strong except in the spectrum of the benzyl-substituted member (last row), where it is of medium intensity. The most likely source of this band is the N=N stretching mode of the *cis*-azo function; high intensity being the result of the unsymmetric substitution of that group. Azo stretching bands, although weak or altogether absent in highly symmetric azo compounds, are reported to be near 1575 cm^{-1} (6) in general, and five-membered cyclic models, the 3-acetoxy-1-pyrazolines, have the N=N band at 1565 cm^{-1} (7).

U.v. spectra of oxadiazolinones **3** consist of a $\pi \rightarrow \pi^*$ band (λ_{max} near 217 nm) of medium intensity and a $n \rightarrow \pi^*$ band (λ_{max} near 370 nm) of low intensity (Table 1). The former is red-shifted if the solvent is changed from hexane to ethanol, as is common for $\pi \rightarrow \pi^*$ bands (8). The latter is also slightly red-shifted, from about 362 nm in hexane to about 368 nm in ethanol, in the case of the cyclohexanespiro compound. In contrast $n \rightarrow \pi^*$ bands of ketones are blue-shifted if solvent polarity is increased; a consequence of the decreased polarity of the excited state relative to that of the ground state (8). A red shift must therefore be indicative of greater excited state polarity and in the present case indicates that the 370 nm band arises from excitation of the n-electrons from nitrogen rather than of the n-electrons from the carbonyl oxygen.

Chemical properties of oxadiazolinones **3** indicate some potential as reagents in synthesis. Their thermal decomposition, in either polar or

For personal use only.

non-polar solvents (9), to CO_2 and disubstituted diazomethanes makes them convenient sources of the latter, which can be caused to react *in situ* with a substrate. Esters, ethers, and cyclopropanes, for example, can be prepared by heating oxadiazolinones with carboxylic acids, phenols, or olefins, respectively. Another advantage of generating diazomethanes this way, rather than by a base-catalyzed oxidation of hydrazones with mercuric oxide or silver oxide (10), is the absence of metallic impurities (Hg or Ag) which strongly catalyze decomposition (10). Hydrazones are not very convenient starting materials in any case because, although they are not particularly difficult to prepare (10–12), they are prone to disproportionation (10, 12) during storage or distillation.

The utility of oxadiazolinones **3** as reagents for synthesis is under investigation and details will be published separately.

Experimental

I.r. spectra were taken with a Perkin–Elmer Model 521 instrument, using solutions (CCl_4) in 0.1 mm cells. U.v. and p.m.r. spectra were obtained with Cary Model 14 and Varian Associates Model T60 instruments, respectively. A typical synthesis is described in detail below.

Cyclohexanespiro-5′(Δ³-1′,3′,4′-Oxadiazolin-2′-one)[1]

To cyclohexanone semicarbazone (5.0 g, 0.033 mol) in 300 ml of well-stirred, ice-cooled CH_2Cl_2, with nitrogen (L-Grade) bubbling through, was added 30 g (0.068 mol) of $Pb(OAc)_4$. After 30 min, ice water (300 ml) was added followed by 2.4 *M* HCl (20 ml). The mixture, still in the ice bath, was stirred for 20 min more. After a heavy brown sludge was removed by filtering the entire mixture through a bed of Celite, the organic layer was separated, washed twice with ice water (200 ml), and dried over magnesium sulfate. Removal of the solvent with a rotary evaporator left 2.8 g (56%) of solid, crude product. Recrystallization from petroleum ether (40–60°) followed by sublimation at ambient temperature and 10^{-2} Torr gave analytically pure material (1.86 g, 38%) melting at 59–60°.

[1]Nomenclature of this compound is according to IUPAC Rule B-11 in Nomenclature of Organic Chemistry, Sections A and B. 2nd ed. 1966.

Assessment of Free Radical Catalysis in Thermal Methyl Isocyanide Isomerization. Variation of Inert Gas Efficiency with k/k_∞ [1]

T. FUJIMOTO,[2] F. M. WANG, AND B. S. RABINOVITCH

Department of Chemistry, University of Washington, Seattle, Washington 98195

Received May 1, 1972

Experiments have been made to assess the importance of radical chain effects in thermal isomerization of methyl isocyanide. Three bath gases, propylene, propane, and hexafluoroethane were studied at 230 °C over a small region of fall-off. The relative dilution with propane was varied widely. A negative search was made for possible secondary radical products. The values of k_∞ accord with earlier results in the pure system. It is believed that radical catalysis is minor. The observed collisional efficiency of the inert gases $\bar{\beta}_\omega(\infty)$ decreases with increase of k/k_∞, in accord with previous theoretical predictions.

Nous avons effectué certains travaux dans le but de souligner l'importance des effets de chaînes radicalaires dans l'isomérisation de l'isocyanure de méthyle. Trois gaz porteurs ont été étudiées à 230 °C dans une mince région de retombée, sort le propylène, le propane et l'hexafluoroéthane. La dilution relative avec le propane variait considérablement. Les recherches dans le but de trouver des produits secondaires radicalaires possibles se sont avérées négatives. Les valeurs de k_∞ sont en accord avec les résultats précédents avec le système pur. On croit que la catalyse radicalaire est minime. L'efficacité de collision observée des gaz inertes, $\bar{\beta}_\omega(\infty)$ diminue avec l'augmentation de k/k_∞, en accord avec les prédictions théoriques précédentes.

Canadian Journal of Chemistry, **50**, 3251 (1972)

Introduction

Yip and Pritchard (1) have proposed a concurrent free-radical catalyzed process for thermal unimolecular methyl isocyanide isomerization. This proposal was based on the experimental finding of small amounts of methane and hydrogen cyanide side products, and on the observation that the rate appeared to be reduced when the system was pressurized with increasing amounts of propane, and unaffected when pressurized with carbon dioxide. This was suggested to be due to propane inhibition of a (methyl) free radical chain catalysis (2), $CH_3 + CH_3NC \rightarrow CH_3 + CH_3CN$. This implies, of course, that the transfer radical, n-C_3H_7 or i-C_3H_7, does not propagate the chain as efficiently as methyl. A steady-state treatment led to a divergently increasing rate constant with increasing concentration of methyl isocyanide. These studies were performed at 200 °C at high total pressures, from one to 100 atm of added propane "inert" gas and 1.3 atm of isocyanide.[3]

Complications may arise at higher pressures, and in any case it has appeared desirable to investigate this subject at pressures near and below 1 atm, where most of the earlier work on unimolecular behavior has been performed (3–5). Wider variation of the nature of the inert gas and of its proportion to isocyanide is also desirable.

In this note we report the studies which we have made to assess the importance of the radical chain effect in the unimolecular isomerization of methyl isocyanide. We have examined the relative rates and inhibition by three species, propylene, propane, and hexafluoroethane, whose radical trapping abilities are in decreasing order. We have searched for possible secondary radical products in the presence of propane. We have examined the effect of variation of the dilution ratio on the rate constant for isomerization at constant

[1]This work was supported by the National Science Foundation.

[2]Present address: Department of Polymer Chemistry, Kyoto University, Kyoto, Japan.

[3]Professor Pritchard informs us that the base amount of isocyanide used in (1) was 4×10^{-4} mol and not 4×10^{-5} as reported.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

total pressure, with propane as the inert gas. Finally, we have determined rate constants close to $p = \infty$ for the three inert gases used.

Experimental

The preparation and purification of methyl isocyanide, together with most of the experimental method has been described previously (3, 4). Matheson propane and hexafluoroethane were purified by repeated bulb-to-bulb distillation; the former contained a small amount of methane; Phillips propylene (research grade) was used without further purification. All runs were made at 230.5 °C.

The fall-off behavior of inert gases were studied in a 100 ml Pyrex reactor. Approximately 4.0×10^{-6} mol of methyl isocyanide was used in each run (~1.25 Torr); the pressure of inert gases ranged from 43 to 1700 Torr. Several higher-pressure dilution experiments were carried out in a 0.5 ml glass tube at a constant total pressure around 2000 Torr; the ratio of C_3H_8/CH_3NC was varied from 1:3.4 to 10:1. In all cases, propionitrile was added (10% of the methyl isocyanide used) as an internal analytical standard. Reaction was carried to around 25–35% conversion.

The search for radical products was made mainly in runs in 100 ml reactor and in several experiments in the glass tube. The quantity of methyl isocyanide varied from 4×10^{-6} to 65×10^{-6} mol in these experiments. Dilution ratios of propane varied from 130- to 170-fold excess over the parent substrate. The extent of reaction was allowed to range from 15 to 90%.

The bulk of the inert gas, trapped with run products at −196 °C, was removed while raising the temperature up to −145 °C. The products were fractionated into high and low boiling fractions by distillation at −95 °C. They were analyzed by using a 15 ft tricresylphosphate/chromosorb column for nitriles, and a tricresylphosphate/chromosorb–silver nitrate/fire-brick series column for hydrocarbons. In a few runs, a special search was made for CH_4 by trapping with silica gel at −196 °C.

Results and Discussion

Side Products

Traces of hydrogen cyanide and methane were found at higher degrees of conversion, especially at higher concentrations of isocyanide. They occurred to the extent of about 0.01 and 0.8%, respectively, of the acetonitrile produced at 80% reaction. No ethane or isomers of C_3H_7CN and C_4H_9CN were ever found within the detection limit, which was $\leqslant 0.001\%$ of the acetonitrile formed.

Nor could any hexanes, *e.g.*, *n*-hexane, 2-methylpentane, 2,3-dimethylbutane, or higher hydrocarbons be detected. In one case, a trace of *n*-butane (but *not* *i*-butane) was observed; this was evidently a line impurity. There was no evidence for the presence of C_2N_2. To this point we agree with Yip and Pritchard (1).

If isomerization were catalyzed by a concurrent free radical (CH_3) process, one would expect to find secondary radical products when the system is inhibited by a radical scavenger such as propane, even if the chain length were as large as 50 (1). Our inability to detect products of *i*-Pr or, less likely, *n*-Pr radical, whether hydrocarbons or nitriles, suggests that the radical effect does not play an important role in the isomerization of methyl isocyanide.

Rate Constants in the Fall-off and High Pressure Regions; Inert Gas Efficiency

The previous conclusion is also supported by the close coincidence of the high pressure ($> 10^3$ Torr) rate constant values for the two getter bath gases, propylene and propane, and for the inert gas C_2F_6, as well (Fig. 1).

The shapes and position of the fall-off curves below 10^3 Torr for all three collisional activation bath species are compatible with that of the parent substrate, as shown in Fig. 1. Propylene and propane fall on the same fall-off curve, within experimental error. The collisional activation efficiencies of these gases at infinite dilution in the second order, low pressure region, $\bar{\beta}_0(\infty)$, have been determined previously (5) at 280 °C to be virtually identical (0.61), which accords with their close superposition in the figure; at 230 °C, the efficiency value would be increased a little to ~0.63 (6).

Earlier, Tardy and Rabinovitch (7) have shown that $\bar{\beta}_\omega(\infty)$ decreases with increasing value of the collision rate ω, *i.e.*, with increase of k/k_∞. On referring to the universal curve, Fig. 7 (I) of ref. 6, it is seen that the value $\bar{\beta}_0(\infty) = 0.63$ corresponds to a reduced parameter $E' = 2.0$, where E' is defined as $E' = \langle \Delta E \rangle / \langle E^+ \rangle$; $\langle \Delta E \rangle$ is the average amount of energy lost per collision and $\langle E^+ \rangle$ is the average excess energy above threshold in the low pressure regime. $\langle E^+ \rangle$ has been calculated (8) for methyl isocyanide and is 425 cm^{-1}, whence $\langle \Delta E \rangle$ is found to be 850 cm^{-1} for propylene and propane. Then from the theoretical curves for the variation of $\bar{\beta}_\omega(\infty)$ with k/k_∞, given in Fig. 12*a* of ref. 6 for a range of E' values, it is found that $\bar{\beta}_\infty(\infty)$ declines monotonically to 0.47 as k/k_∞ approaches to unity. The values are summarized in Table 1, together with values for C_2F_6 which were obtained in the same way from the same sources.

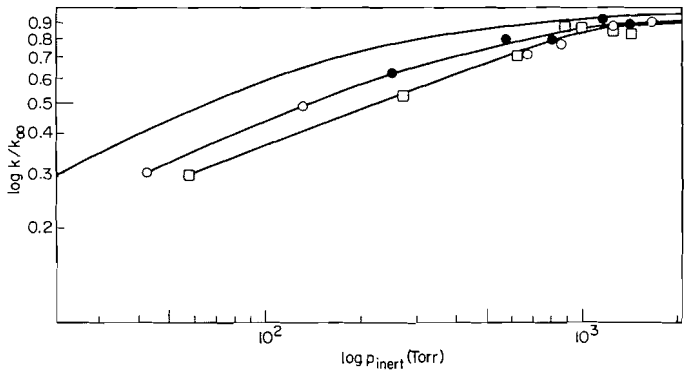

FIG. 1. Fall-off plots for CH_3NC; solid curve is plot of Schneider and Rabinovitch; ○, C_3H_8; ●, C_3H_6; □, C_2F_6.

TABLE 1. Some collisional efficiency parameters

	$\bar{\beta}_0(\infty)$* obs.†	E'	$\langle\Delta E\rangle$ (cm^{-1})	$\bar{\beta}_{0.3}(\infty)$ theor.‡	obs.	$\bar{\beta}_{0.6}(\infty)$ theor.‡	obs.	$\bar{\beta}_{1.0}(\infty)$ theor.‡
C_3H_8 / C_3H_6	0.63	2.0	850	0.56	0.49	0.50	0.43	0.47
C_2F_6	0.45	1.6	680	0.37	0.35	0.31	0.28	0.27

*The subscript on $\bar{\beta}$ refers to k/k_∞ value
†Reference 5.
‡Reference 7.

A comparison (Table 1) at several values of k/k_∞, of the pressure displacement factor (equal theoretically to $1/\bar{\beta}_\omega(\infty)$) for the C_3H_6–C_3H_8 curve, and for the C_2F_6 curve, relative to the parent strong collider curve of Schneider and Rabinovitch (3) gives reasonable numerical agreement with these predictions. But in view of the cursory nature of the comparison afforded by the present rather limited data on variation of $\bar{\beta}_\omega(\infty)$ with the region of fall-off, it is enough to claim that the agreement of the experimental results with the theoretical predictions is qualitatively correct and is quantitatively as good as may be expected for the limited data. More systematic examination of this effect is being made for the more favorable case of (inefficient) helium as the inert collider.

One may also note in Fig. 1 that not only is the relative collisional efficiency of propylene quite close to that of propane, but any difference between them at the highest pressures (the propylene rate is a little higher) is in the opposite direction to that which would be predicted for the more efficient scavenger if a radical scheme entered. At 2000 Torr, the (extrapolated) k/k_∞ values for propylene–propane and hexafluoroethane are 0.92 and 0.85, respectively. *These values agree* (as well as can be read from the curves) *with the parent molecule values* at 940 (corresponding to $\bar{\beta} = 0.47$) and 580 Torr ($\bar{\beta} \simeq 0.29$), respectively.

We believe that the data of Schneider and Rabinovitch (3) show no real indication that the values of k/k_∞ diverge from unity at still higher pressures (up to 14 atm) of isocyanide, as has been suggested (1, 2) could occur if radical catalysis enters. The reader can make up his own mind by examination of the data.

Dilution Effect at Constant Pressure

Several runs were made at a constant total pressure of 2000 Torr and variable proportions of CH_3NC–C_3H_8. The pressure chosen, 2000 Torr, was the highest practical one; it was desired to work as close to P_∞ as possible so as to minimize the effect of the differing collision efficiencies of CH_3NC and C_3H_8 on the observed k values. These experiments gave a rate constant of $83.5(\pm 1.5) \times 10^{-5}$ s^{-1}; the variation is within experimental error, although the

TABLE 2. Variation of observed rate with dilution at constant total pressure (2000 Torr)

Dilution ratio	Effective pressure (Torr)	$k \times 10^5$, s^{-1}	Parent rate at effective pressure* $k \times 10^5$ (s^{-1})
1:3.4	1881	85.1	87.1
3:1	1252	83.3	84.0
10:1	1120	82.1	83.5
1600:1	940	84.3	81.5

*From data of ref. 3.

decline with dilution may be real (Table 2). Moreover, extrapolation of the propane fall-off curve (Fig. 1) to 2000 Torr, which is at very high dilution of 1600:1, yields the concordant value, 84.3×10^{-5} s^{-1}. Although Yip and Pritchard found also that adding 1 atm of propane (at a dilution of roughly unity) did not decrease their rate, it should be noted that our dilutions extend over a range of 5×10^3 at constant pressure. It was for the purpose of increasing their dilution that they extended their propane pressures to 100 atm.

Conclusion

We conclude that (*1*) the presence of traces of methane and hydrogen cyanide does not imply an important concurrent radical process, (*2*) the rate constant of the isomerization in the region of 1 atm and below represents an elementary process, and (*3*) this system provides support for the theoretically predicted variation of the inert gas activation efficiency $\bar{\beta}(\infty)$ with fall-off region.

Our study provides no reason to doubt that the methyl isocyanide system continues as a good test for the theory of unimolecular reactions. We have no definite explanation for the very high pressure results of ref. 1. We have had some indication that some radical effect *may* enter for the thermal C_2H_5NC system, and *may* become important for n-C_3H_7NC system, but this is not definitely established.

Oriented Polycrystal Formation of Halogen-containing Organic Molecules on Alkali Halide Windows and their Usefulness in Vibrational Spectroscopic Studies

J. E. KATON, DEEPALI SINHA, M. G. GRIFFIN, AND D. A. CONDIT
Department of Chemistry, Miami University, Oxford, Ohio 45056

Received June 14, 1972

It has been found that several halogen-containing organic molecules *normally* crystallize as oriented polycrystals when in contact with alkali halide windows. This effect can lead to erroneous interpretation of crystal film spectra if it is not recognized, but can be very useful for determining molecular and/or crystal structures if the spectra are properly analyzed.

On a constaté que plusieurs molécules organiques contenant un halogène, cristallisent normalement sous forme de polycristaux orientés lorsqu'elles sont en contact avec des halogénures alcalins. Cet effet, s'il n'est pas reconnu, peut mener à une interprétation erronée des spectres de film cristallin mais peut également être très utile dans la détermination des structures moléculaires et (ou) cristallines si les spectres sont analysés correctement. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3255 (1972)

It has been known for many years that polarized infrared spectra of single crystals or oriented samples are very useful both for detailed spectroscopic assignments and for deducing the details of molecular and crystal structure (1). Sample preparation for such studies is usually very tedious at best, however. A few years ago one of the present authors reported that both cyclopropylcarbonyl chloride and cyclopropylcarbonyl bromide appeared to form oriented polycrystals on cooling, as indicated by infrared polarization effects (2). The equipment available at that time was not very suitable for such studies and the results were thought to be unusual.

We have now found that several additional halogen-containing organic compounds can be very readily induced to form polycrystals which are highly oriented when grown between alkali halide plates. This phenomenon occurs when a capillary liquid film of the material between two alkali halide windows is cooled. The cooling need not be very slow, since it normally occurs when liquid nitrogen is slowly added to a Dewar bearing the infrared cell. Compounds which have been crystallized in this fashion to date are: methyl chloroformate ($ClCO_2CH_3$) and methyl chloroformate-d_3; benzoyl chloride (C_6H_5COCl), benzoyl chloride-d_5, and benzoyl bromide; γ-chloroacetic acid (3); and methyl chloroacetate ($ClCH_2CO_2CH_3$) and methyl chloroacetate-d_3.

A striking example is furnished by methyl chloroformate, whose polarized infrared spectra are reproduced in Fig. 1. This sample was loaded into a low temperature cell as a capillary film and immediately cooled with liquid nitrogen. The spectra were recorded on a Perkin–Elmer Model 180 infrared spectrophotometer utilizing the standard accessory wire grid polarizer on a AgBr substrate. The results indicate that the molecule crystallizes with a plane of symmetry (C_s point group) and the planes are all parallel to the incident beam of the spectrometer. As a result, those absorption bands evident in the upper spectrum are due to vibrations of A' symmetry while those evident in the lower spectrum are those due to vibrations of A'' symmetry. An indication of the usefulness of such results in vibrational assignment studies is given by the band near 1449 cm^{-1} in both spectra. Upon careful observation it is noted that the frequency of this band is 1448.6 ± 0.1 cm^{-1} in the upper spectrum and 1449.2 ± 0.1 cm^{-1} in the lower. It is due to the CH_3 bending mode which is degenerate under the C_{3v} symmetry of the uncoupled CH_3 group, but splits into one A' and one A'' component under C_s symmetry. The use of polarized radiation allows

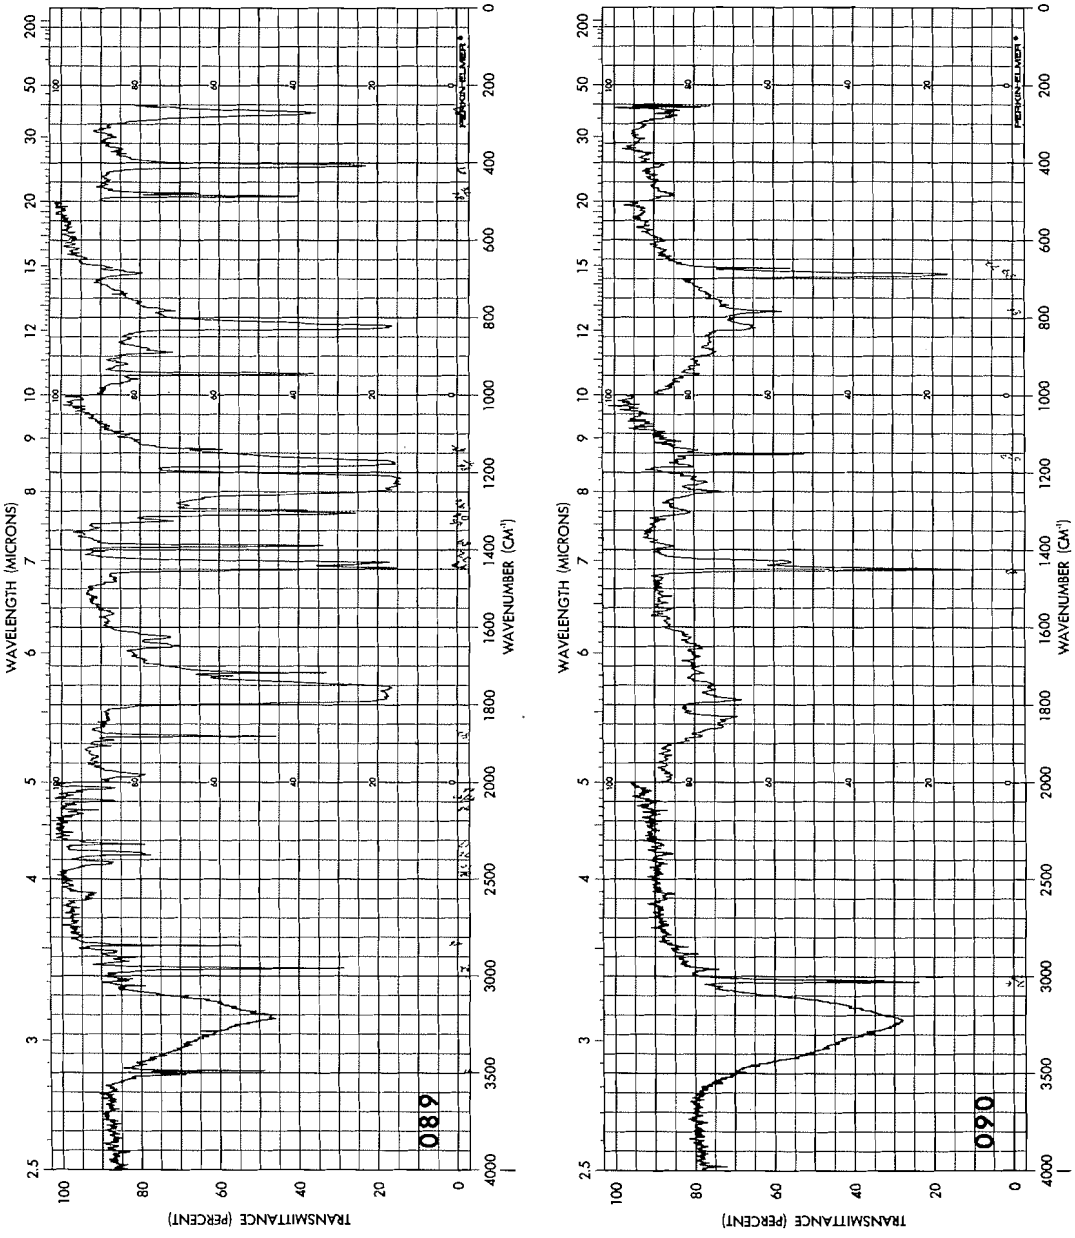

FIG. 1. Infrared Spectra of an oriented polycrystalline film of methyl chloroformate at about 100 °K. The polarizer settings differ by 90° in the two spectra.

the ready resolution of these two bands which are at best resolvable only with difficulty under other conditions. No crystal splitting is observable in the spectra. This is very unusual in our experience for such a polar material under these experimental conditions. Such data is consistent only with certain crystal structures (4).

Methyl chloroacetate when treated in the same way yields polarized infrared spectra which indicate that the molecule crystallizes with no symmetry (C_1 point group). Each fundamental appears to be crystal split into two components, however, which have transition moments perpendicular to one another. Again, such results are consistent with only a few possible crystal structures.

The results with γ-chloroacetic acid were obtained by melting the material between sodium chloride windows and allowing the sample to cool to room temperature. This indicates that such behavior can also be obtained with normally solid materials.

The generality of this behavior is not yet known, but our results indicate that it is more common than might be expected. To date, the effect has occurred with every organic halogen-containing compound which we have studied. They also indicate that one must be very careful in interpreting ordinary low temperature solid-state infrared spectra due to the inherent polarization properties of grating monochromators. Such spectra may be partially polarized unless the crystals are truly randomly oriented. On the other hand, the behavior is very valuable since it allows one to draw a good deal more information from the spectrum than can ordinarily be obtained.

Transient Response of the System Al/Al_2O_3/Electrolyte. Part I. Galvanostatic Transients

D. G. W. GOAD[1] AND M. J. DIGNAM

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 13, 1971[2]

Voltage transients under galvanostatic conditions are investigated for the system Al/Al_2O_3/electrolyte (glycol–borate) and the results, along with similar results obtained by Dewald for the system Ta/Ta_2O_5/electrolyte (0.1 N H_2SO_4), are analyzed according to the dielectric relaxation model due to Dignam. This model accounts for the general form of the transients, but systematic discrepancies are apparent. Modification of the model to include two independent ion-current-driven dielectric relaxation processes gives essentially exact agreement with the data and values for the constants in accord with those obtained earlier from potentiostatic transient measurements.

Nous étudions les transitions de voltage sous des conditions galvanostatiques pour le système Al/Al_2O_3/électrolyte (glycol–borate) et nous analysons les résultats, de même que les résultats similaires obtenus par Dewald pour le système Ta/Ta_2O_5/électrolyte (0.1 N H_2SO_4), selon le modèle de relaxation diélectrique de Dignam. Ce modèle tient compte de la forme générale des transitions, mais souffre quand même de certains défauts. Nous apportons une modification au modèle qui permet d'obtenir un excellent accord avec les données, les valeurs des constantes et les résultats précédents tirés de mesures de transition potentiostatique.

Introduction

The kinetics of anodic oxidation of the valve metals (Al, Nb, Ta, and others) has been the subject of extensive investigation in the last 20 years (1–3). Under galvanostatic conditions, a steady-state situation is fairly rapidly achieved in which the differential field strength, E, defined as the derivative of the cell overpotential with respect to film thickness, is independent of time. Under these conditions, the relation between the ion current density, i, and the differential field strength is given by (4)

$$[1] \qquad i = A \exp [-W_s(E)/kT]$$

where $W_s(E)$ can be regarded as the effective net activation energy for anodic film growth, while A is a constant. Data for the steady-state anodic oxidation of Ta, Nb, and Al are represented extremely well by eq. 1 on expanding $W_s(E)$ as a quadratic function of the field strength a point first noted by Young (1), *viz.*

$$[2] \qquad W_s(E) = \phi - \mu_s^* E(1 - \mu_s^* E/C\phi)$$

where ϕ is the effective activation energy at zero field strength, μ_s^* the effective activation dipole (or charge-activation distance product) in the low field limit, and C a dimensionless constant. The origin of the quadratic field term is discussed at length in ref. 4. For measurements made at a single temperature, the field strength need only be varied by a few percent to cover the experimentally accessible range of current densities, so that to a good approximation $\ln i$ may be represented as a linear function of E,

$$[3] \qquad i \simeq \alpha \exp (\beta_s E)$$

where

$$\beta_s = \mu_s^*(1 - 2\mu_s^* \bar{E}/C\phi)/kT$$

and

$$\alpha = A \exp\left[-(\phi - (\mu_s^* \bar{E})^2/C\phi)/kT\right]$$

$\bar{E}$ being the mean value of E over the range of experimental interest.

Under galvanostatic conditions, E is found to be independent of film thickness over the range of a few tens of Ångstroms to several thousand Ångstroms, beyond which electrical breakdown occurs (1). This result requires that any space charge within the film either be negligible, in which case ion transport must be controlled at an interface, or be confined to a region of the order of a few tens of Ångstroms near one or both of the interfaces, in which case bulk control of ion transport becomes the probable mechanism.

There is a number of models which can account satisfactorily for the form of the steady-state kinetics. In fact almost any model involving the field assisted migration of ionic species across one or more activation barriers will, under certain conditions, lead to steady-state kinetics in accord with [1] and [2]. To differentiate among the possible mechanisms, data obtained under transient conditions must be examined. The purpose of Parts I and II of these articles is to obtain and analyze such data for the system Al/Al_2O_3/electrolyte.

Potentiostatic transients for this system have been measured and analyzed by Dignam and Ryan (5). However, galvanostatic transient data and complete a.c. impedance data have not been reported for this system. In Part I, the results of galvanostatic transient measurements are presented, with a.c. impedance measurements being presented in Part II. For systems where kinetics are characterized by a set of linear equations, the various forms of transient measurements are equivalent. For the valve metal systems, however, i and E are not linearly related.

Experimental

Introduction

Galvanostatic transient measurements were performed in the manner of Dewald (6). His procedure was to form an anodic film under steady-state conditions corresponding to a current density, I_1, and field strength E_1. The current density was then switched rapidly from I_1 to a value $I_2 \neq I_1$, thus initiating the transient. The electrode potential was monitored following initiation of the transient, from which the time dependence of the "excess field", $\Delta E = E - E_2$, was calculated, E being the instantaneous value of the field strength, and E_2 its steady-state value corresponding to $I = I_2$.

In the present study, the procedure was modified slightly in order to eliminate both that part of the measured potential change arising from film growth during the transient, and that arising from possible current dependent interfacial potentials. Films were formed by increasing the aluminum/oxide electrode potential at a constant rate, corresponding to film formation at a steady-state current density I_1 (7). At a given electrode potential, V_1, the current was changed by a factor equal to I_2/I_1, and the voltage recorded as a function of time. The experiment was then repeated on the same electrode after forming the film at the same constant rate of voltage rise to a potential $V_2 > V_1$. Subtraction of the voltage data at corresponding times after initiating the transients gives ΔV from which $E/E_1 = \Delta V/(V_2 - V_1)$ may be calculated.

Film formation at a constant rate of voltage rise (which corresponds to a constant current density) rather than at constant current, eliminates the effect which any change in electrode area with film thickness would otherwise have on the measured potential differences.

The Cell and Electrodes

The cell has been described previously (7). The anodes were of aluminum sheet (99.99% Al, 0.04 in. thick), which was formed into paddle-shaped electrodes of dimensions 1 in. × 0.25 in. for the paddle, 1 in. × 0.006 in. for the tab. Following routine cleaning procedures, they were electropolished at about 0.2 A/cm^2 and 25 °C in 5 parts ethanol to 1 part 70% perchloric acid by volume (8). The electrodes were rinsed briefly in ethanol, then for 1 min in running distilled water, dried in a clean air jet, and stored in a desiccator over activated alumina. The reference electrode was a mercury/mercuric oxide electrode prepared as described by Cahan *et al.* (9). It was located in a compartment which contained a 20% aqueous solution of ammonium pentaborate. Connection to the reference electrode compartment was made by a side tube which ended in a capillary tip brought up underneath the anode and sealed by a membrane permeable to cations only (10). This configuration was chosen to minimize the impedance of the reference electrode system in order that fast response times could be achieved. The entire cell was kept in an air thermostated metal box. A 30% by weight solution of ammonium pentaborate in ethylene glycol was used as electrolyte as this gives high current efficiencies for film formation over a wide range of current density (11).

Electrical Circuit

The circuit employed (Fig. 1) operates as follows. Initially the switches S_1 and S_2 are in positions 1, and a voltage, e, applied to the input of amplifier 1 produces a linearly increasing voltage, e_1, at the output. Amplifier 3 measures the difference between e_1 and $(e_{Al} - e_{ref})$ and applies this through the integrator amplifier 5 to the resistor R_2, which causes the cell current to change until $(e_{Al} - e_{ref})$ is equal to e_1. The output of amplifier 3, e_3, is then zero and the output of amplifier 5 constant. The cell current, i', is now given by $-e_5/R_2$. Any changes in electrode area with increasing film thickness results in a change in i' until $(e_{Al} - e_{ref})$ is once again equal to e_1.

For personal use only.

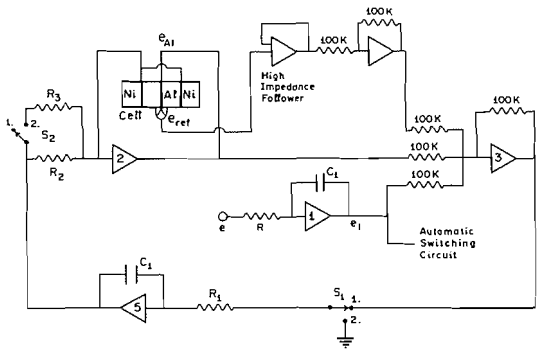

FIG. 1. Circuit used for the study of galvanostatic transients.

The transient is initiated when e_1 reaches a value determined by the input to the automatic switching circuit. The relay switches (Clair mercury wetted type) then adopt positions 2. The input to amplifier 5 is grounded and the output has a constant value of $-i'R_2$ where i' is the initial cell current. The new cell current is consequently $-e_5(R_2 + R_3)/R_2R_3$ or $(R_2 + R_3)i'/R_3$, so that $I_2/I_1 = (R_2 + R_3)/R_3$. A reversal of the initial and final switch positions in S_2 allows a decrease in cell current to be achieved on switching, *i.e.*, $I_2/I_1 = R_3/(R_2 + R_3)$.

Procedures

The automatic switching circuit, in addition to initiating the transient, triggers the oscilloscope which records the voltage $-e_3 = V_m = (e_{Al} - e_{ref}) - e_1$. Subtraction of V_m for the first transient initiated from that for the second, at corresponding times, gives $\Delta V_m = \Delta V - (V_2 - V_1) = (V_2 - V_1)\cdot(E/E_1 - 1)$. For large times, when the transient has died away, $E = E_2$ and ΔV_m takes on the constant value $\Delta V_m^\infty = (V_2 - V_1)(E_2/E_1 - 1)$. The normalized excess field can therefore be calculated from the measured potentials according to the equation

$$(E - E_2)/(E_2 - E_1) = \Delta V_m/\Delta V_m^\infty - 1$$

All of the results reported were calculated from this equation.

Although the field strengths and current densities are not required for the analysis of the data, they were nevertheless calculated as follows. The output of amplifier 1 was recorded at intervals prior to initiating the transient, from which the time derivative of the electrode potential was obtained by a linear regression analysis. From this derivative the formation current density, I_1, and field strength, E_1, were calculated using the steady-state parameters reported by Dignam, Goad, and Sole (11).

For all the runs reported, the two transients comprising a single run were initiated at times corresponding to anodic overpotentials of approximately 40 and 80 V, respectively. For one run, however, transients were initiated at 40, 60, and 80 V, allowing the ΔV_m values obtained from the 40–60 V data to be compared with those from the 60–80 V data. Within experimental error, the values were indistinguishable.

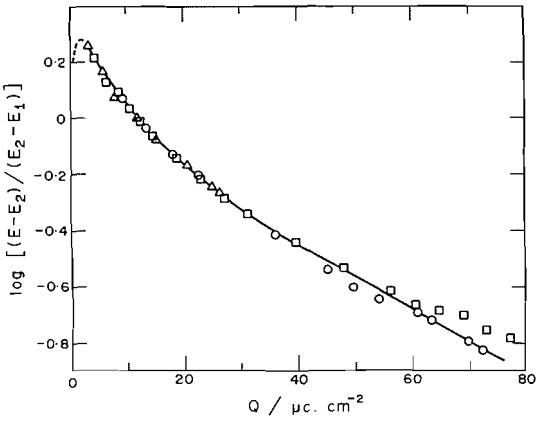

FIG. 2. Decay of the excess field, $E - E_2$, following initiation of galvanostatic transients: ○, $I_1 = 40.9\ \mu A/cm^2$, $E_1 = 8.19 \times 10^6$ V/cm, $I_2/I_1 = 11$; □, $I_1 = 208\ \mu A/cm^2$, $E_1 = 8.56 \times 10^6$ V/cm, $I_2/I_1 = 2$; △, $I_1 = 207.5\ \mu A/cm^2$, $E_1 = 8.56 \times 10^6$ V/cm, $I_2/I_1 = 0.5$; the solid line was calculated from [4] using the values for the parameters listed.

Results

Experiments were carried out for final to initial current ratios, I_2/I_1 of 0.5, 2.0, and 11.0. In Fig. 2, the results of these experiments are displayed in the form log $[(E - E_2)/(E_2 - E_1)]$ *vs.* $Q = I_2t$, the charge passed per unit area following initiation of the transient. Apart from scaling factors, the graphs represent the time decays of the "excess field", $E - E_2$. Presenting the data in this form illustrates an important feature of the kinetics of the decay process. It is characterized by the charge passed per unit area, Q, not the time elapsed. This behavior was first noted by Dewald (6) for the system Ta/Ta_2O_5/dilute aqueous H_2SO_4. In fact, the results of Fig. 2 are of the same general form as those obtained by Dewald.

The field values before the maximum in E is reached are not shown, being difficult to measure accurately because of the very rapid rate of change of E in this region. Presumably the finite rate of approach of the field to its maximum value following initiation of the transient is a consequence of having to alter the charge on the Al/Al_2O_3/electrolyte capacitor.

The solid line in Fig. 2 is the result of fitting the data to a pair of exponential functions in Q, *i.e.*

$$[4]\quad (E - E_2)/(E_2 - E_1) = M_1 \exp(m_1Q) + M_2 \exp(m_2Q)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The values of the constants which minimize the variance in E are given below:

$$M_1 = 1.32$$

$$M_2 = 1.03$$

$$m_1 = -1.44 \times 10^5 \text{ cm}^2/\text{C}$$

$$m_2 = -0.266 \times 10^5 \text{ cm}^2/\text{C}$$

A single exponential function will not represent the data well since $\log [(E - E_2)/(E_2 - E_1)]$ is not a linear function of Q.

Discussion

Four different mechanisms have been offered to account for the existence of transients in connection with the anodic oxidation of the valve metals (1, 2). The first, due to Bean, Fisher, and Vermilyea (12), and elaborated upon by Dewald (6), is based upon the assumption that ion transport is controlled within the film through a mechanism involving the field assisted generation of defect pairs. This model, frequently referred to as the high field Frenkel defect model (1), was examined recently in some detail by Dignam and Taylor (13). Using an argument based on the magnitude of the mean distance travelled by a mobile defect in the field direction following its formation. Dignam and Taylor conclude that the high field Frenkel defect model cannot apply to thin films. They further conclude that any mechanism involving both rate control within the film and the homogeneous generation of defect pairs, in which the mobile defect concentration is field or current dependent, is highly improbable for thin films. Young (14) has recently pointed out an error in their reasoning. It is the magnitude of the characteristic space charge length for the model, not the mean distance travelled by a defect (15), which should have been used in the argument advanced by Dignam and Taylor. As these two quantities are closely related (both are inversely proportional to the mobile defect concentration (15)), their original conclusions remain essentially intact. Furthermore, although the high field Frenkel defect model accounts moderately well for galvanostatic transients for the Ta system (6), it was shown first by Young for Ta (16), then by Dignam and Ryan for Al (5), that it predicts potentiostatic transients of the wrong form.

Adams, van Rysselberghe, and Willis (ref. 1 sec. 20.05) suggest a mechanism based on control at the metal/oxide interface, the number of metal ions suitably located for entry into the oxide varying with current density due, for example, to the characteristics of the screw dislocations terminating at the metal surface. This model has not been developed in a mathematical form.

Young (14, 16) has proposed a model based on rate control by ion transport within the film in which, under galvanostatic conditions, the concentration of mobile defects is assumed to approach its steady-state value at a rate proportional to i^2. The model appears to require the interaction of ionic defects in motion to create additional defects, a sort of second order avalanche mechanism. It has only been developed for the particular case of potentiostatic conditions.

The most recent models are due to one of us (M.J.D.) (4, 17, 18). In the first model (17) the oxide film was assumed to be composed of small crystallites or polymeric units, with the principal rate controlling step being ion transport between such units. It now seems unlikely that this is even approximately correct, since films only 10 to 20 Å in thickness give rise to the same transient phenomena as do much thicker films (19). Indeed, this result argues against any model involving kinetic control within the film, rather than at its boundaries. However, essentially the same set of equations as were obtained using the original model can be derived from a model involving interfacial control (4, 18). The principal features of this model are that the rate is controlled at an interface (we shall choose the oxide/electrolyte interface), with transients arising as a result of dielectric relaxation processes within the film. (Changes in the polarization of the oxide film will bring about changes in the distribution of the potential between the film and interfacial regions.) A more detailed development of the model follows. We note at this point, however, that the equations arising from this model are in accord with both steady-state data and ion current transient data obtained under potentiostatic conditions (5, 7).

Dielectric Relaxation Model

Assuming the rate to be controlled near the electrolyte/film interface, the anodic overpoten-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tial, η, may be divided into a film portion, η_x, and an electrolyte-oxide double-layer portion, η_d. Provided that the free charge at the oxide/double-layer interface, as well as that within the oxide, is negligible compared with that on the electrolyte phase, or the metal/oxide interface, the normal component of the electric displacement will be effectively constant throughout the oxide film and the double-layer, so that

$$[5] \qquad \varepsilon_0 E + P = \varepsilon_0 K_d E_d = \varepsilon_0 K_d \eta_d / d$$

where ε_0 is the permittivity of free space, E and P are the field strength and polarization in the oxide, K_d and d the effective dielectric constant and thickness of the double-layer, and E_d the field in the double-layer. Assuming the rate controlling interfacial reaction to involve the field assisted migration of ionic species of fixed boundary concentration across an activation barrier, then for E_d large (4) $i = A \exp[-W(E_d)/kT]$ where $W(E_d)$ is the net activation energy for the barrier crossing and can be expanded in the same form as was $W_s(E)$ (*cf.* [1] and [2]). Making the same approximation as was used to obtain [3], this equation can be written as

$$[6] \qquad i \simeq \alpha \exp \beta E_d$$

where for isothermal conditions, α and β can be treated as constants. Under steady-state conditions, P is assumed to take the usual form, *i.e.* $P = \varepsilon_0(K_s - 1)E$ where K_s is the static (or steady-state) dielectric constant of the film, which with [5] and [6] leads to [3] with

$$[7] \qquad \beta_s = (K_s/K_d)\beta$$

Dividing P into a component P_1 which follows the field, and a component P_2 which gives rise to the relaxation process (and hence to the transients), we may write

$$[8] \qquad P = P_1 + P_2$$

$$[9] \qquad P_1 = \varepsilon_0(K_1 - 1)E$$

where K_1 is the dynamic or high frequency dielectric constant. In this model, the form of the transients is determined almost entirely by the choice of the form of the time dependence of P_2. If dP_2/dt has the usual form for a thermally activated relaxation process, *i.e.* $dP_2/dt = (1/\Upsilon)(\varepsilon_0\chi_2 E - P_2)$ where Υ is the relaxation time and $P_2 = \varepsilon_0\chi_2 E$ under steady-state conditions, then the decay of the excess field during a galvanostatic measurement also takes this form, contrary to observation. The simplest assumption one can make which will lead to the correct form for the transients is that dP_2/dt is given by

$$[10] \qquad dP_2/dt = Bi(\varepsilon_0\chi_2 E - P_2)$$

where B is a constant. Equation 10 may be rationalized by assuming that ion transport through the vitreous oxide involves the co-operative motion of groups of atoms, and consequently leads to small irreversible displacements of the atoms close to the path of motion of the ionic defect. Such irreversible displacements will constitute, in general, polarization changes. Alternatively (or additionally), local vibrational excitation along the path of motion of a defect might induce the establishment of local equilibrium polarization, leading again to an equation of the form of [10]. In either case, the effect may be approximated by assuming that defect motion brings about equilibrium polarization within a distance r of the moving defect, in which case $B = \pi r^2/q$ where q is the charge on the mobile defect. Finally we note that [10] can only be a good approximation for conditions in which i is not too small, since conventional mechanisms involving thermal activation must contribute significantly to dP_2/dt for i sufficiently small (1).

Analysis of the Results

Equations 5 to 10 constitute a description of the dielectric relaxation model for the transients. Unfortunately, an exact analytical solution of these equations for the conditions of the experiments has not been discovered. The difficulty arises from the fact that the ion current density, i, and the total current density, I, are not in general the same, but differ by the charging current density $i^c = \varepsilon_0 dE/dt + dP/dt = I - i$. It can be shown, however, that beyond the maximum in the normalized excess field, $(E - E_2)/(E_2 - E_1)$, (*cf.* Fig. 2) the charging current may be neglected in comparison with I (see Appendix). Solving the equations in this approximation, the boundary conditions become

$$i = I_1 = \alpha \exp \beta_s E_1 = \text{constant for } t < 0$$

$$[11] \qquad i \simeq I_2 = \alpha \exp \beta_s E_2 = \text{constant for } t \geqslant 0$$

$$P_2(t = 0) \simeq P_2(t < 0)$$

The final condition arises from neglecting the change in P_2 during the charging process in

TABLE 1. Dewald's data (6) for galvanostatic transients obtained for the system $Ta/Ta_2O_5/0.1\ N\ H_2SO_4$; $I_1 \sim 10^{-4}$ A/cm^2, $I_2/I_1 = 2$

*E_r is the steady-state field required to cause oxide film growth at the rate of 1 Å/s, which Dewald took to be 6.6×10^6 V/cm.
‡For $I_2/I_1 = 2$, $(E_2 - E_1) = (1/\beta_s) \ln 2 = 0.138 \times 10^6$ V/cm (from Young's data (20) for $\bar{E} \simeq 6.6 \times 10^6$ V/cm).

which the reduced excess field reaches its maximum value. The solution of equations [5] to [10] for the conditions [11] takes the form of [4] (see Appendix) with

$$M_1 = (K_s - K_1)/K_1$$
$$M_2 = 0 \qquad [12]$$
$$m_1 = -B(K_s/K_1)$$

Thus, although the model in this form represents the general features of the transients well, it does not provide a good quantitative fit to the data, since the normalized excess field is predicted to decay according to a single, rather than a pair of exponential functions of the charge passed. The situation, however, is easily remedied by introducing a second, independent, dielectric relaxation process. Thus on replacing [8] by

$$P = P_1 + P_2 + P_3 \qquad [13]$$

and [10] by

$$dP_k/dt = B_k i(\varepsilon_0 \chi_k E - P_k) \qquad k = 2,3 \qquad [14]$$

and adding to the conditions [11] the additional condition

$$P_3(t=0) \simeq P_3(t<0) \qquad [15]$$

the equations may be solved (see Appendix) to give once again [4] with m_1 and m_2 being the roots of the equation

$$m^2 + \left[B_2 + B_3 + \frac{B_2\chi_2 + B_3\chi_3}{K_1}\right] m + \frac{B_2 B_3 K_s}{K_1} = 0 \qquad [16]$$

and M_1 and M_2 can be obtained from

$$M_1 + M_2 = (K_s - K_1)/K_1$$
$$(M_1 m_1 + M_2 m_2) = -\frac{K_s}{K_1}\frac{B_2\chi_2 + B_3\chi_3}{K_1} \qquad [17]$$

Using the values of M_1, m_1, M_2, m_2 appearing under [4], [16] and [17] have been solved numerically to give

$$\chi_2 = 1.91\ K_1$$
$$\chi_3 = 0.44\ K_1 \qquad [18]$$
$$B_2 = 1.22 \times 10^4\ \text{cm}^2/\text{C}$$
$$B_3 = 9.32 \times 10^4\ \text{cm}^2/\text{C}$$

The value of K_1 is not known very accurately; taking $K_1 = 8.5$ (7) gives $\chi_2 = 16.2$, $\chi_3 = 3.74$, and $K_s = K_1 + \chi_2 + \chi_3 = 28.5$.

In Table 1, Dewald's galvanostatic transient data for Ta (6) are presented. Fitting this data to [4], the values of the parameters which minimize the variance in E are

$$M_1 = 1.26_6$$
$$M_2 = 0.633$$
$$m_1 = -7.30_2 \times 10^4\ \text{cm}^2/\text{C}$$
$$m_2 = -1.13_2 \times 10^4\ \text{cm}^2/\text{C}$$

from which

$$\chi_2 = 1.30_4 K_1$$
$$\chi_3 = 0.594 K_1 \qquad [19]$$
$$B_2 = 0.657 \times 10^4\ \text{cm}^2/\text{C}$$
$$B_3 = 4.34 \times 10^4\ \text{cm}^2/\text{C}$$

Taking $K_1 = 27.6$ (20) gives $\chi_2 = 36.0$, $\chi_3 = 16.4$, and $K_s = 80.0$.

Comparison of the B_k and χ_k values for Al and Ta does not disclose any obvious relationships; one can say only that the larger χ value is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

associated with the smaller B value, for both systems.

Comparison with Previous Results

The above values for the parameters will be compared with those obtained previously from measurements of potentiostatic transients. Dignam and Ryan (5) fitted their data for transients obtained under potentiostatic conditions (approximately constant field conditions) for aluminum to the dielectric relaxation model, assuming only one ion-current-driven relaxation process. For Al_2O_3 films formed initially at about 2×10^{-4} A/cm^2 in a glycol–borate electrolyte, a value for B of $(1.22 \pm 0.07) \times 10^4$ cm^2/C was obtained in excellent agreement with the value of B_2 obtained in the present study. However, for films formed at about 2×10^{-6} A/cm^2 in the same electrolyte, a significantly larger value was obtained, namely $(1.46 \pm 0.04) \times 10^4$ cm^2/C. In both instances, the value of B obtained was independent of the field strength employed for the experiment, a point which was not noted in the original publication (5).

It can be shown (21) that for conditions of constant field strength, and negligible charging current, the dielectric relaxation model predicts transients of the following form:

$$[20] \quad \ln [I_{ss}/I] = \sum_k b_k \exp(-B_k Q) \qquad k = 2,3$$

where I_{ss} is the final steady-state current density and the b_k are constants determined by the initial conditions. However, over the region in which eq. 20 should be valid (*i.e.* negligible charging current), eq. 20 may be simplified to

$$[21] \quad \ln [I_{ss}/I] \propto \exp(-B_2 Q)$$

since over the entire region, $B_3 Q \gg 1$. Potentiostatic transient data yield, therefore, only the value for B_2.

As observed previously (5), the value for B_2 appears to depend somewhat on the conditions of film formation, a result expected if the film structure is dependent on formation conditions. Note that the present galvanostatic transient studies were carried out for current densities $\sim 2 \times 10^{-4}$ A/cm^2 and that the value for B_2 obtained from these studies agrees with that obtained from potentiostatic transient studies on films formed at 2×10^{-4} A/cm^2.

Analysis of Young's potentiostatic transient data for tantalum (16) by Dignam and Ryan (5) gave a value for B_2 of 8.0×10^3 cm^2/C. This value is close, but not equal, to that calculated from Dewald's data, which were for films formed in 0.1 N H_2SO_4 and at current densities $\sim 10^{-4}$ A/cm^2. Young's data, on the other hand, were for specimens formed at 100 V (constant potential) for 3.5 hn then annealed in boiling water for 5 min. As for the case of aluminum this small discrepancy is likely due to the different formation conditions employed in the two sets of measurements.

In summary, the dielectric relaxation model, with two independent ion-current-driven relaxation processes, provides a quantitative description of both galvanostatic and potentiostatic transients, a single set of constants reproducing both sets of data for the aluminum system. The same is true for the tantalum system; however, more data is required to show this (21).

Appendix

Decay of Charging Current

The charging current density, $i^c = \varepsilon_0 dE/dt + dP/dt$, on using [5] becomes $i^c = \varepsilon_0 K_d dE_d/dt$ so that the total current density $I = i + i^c$, is given by

$$[A1] \qquad I = i + I\varepsilon_0 K_d dE_d/dQ$$

where $Q = \int_0^t I\, dt$ is the charge passed per unit area of electrode. Substituting for E_d from [6] and re-arranging, [A1] becomes

$$[A2] \qquad \frac{di}{i[1 - i/I]} = \frac{\beta}{\varepsilon_0 K_d} dQ$$

Integrating [A2] for the conditions $i = I_1$ for $Q = 0$, and $I = I_2$ = a constant, gives

$$[A3] \quad \left(\frac{1 - i/I_2}{i/I_2}\right) = \left(\frac{1 - I_1/I_2}{I_1/I_2}\right) \exp\left(-\frac{\beta Q}{\varepsilon_0 K_d}\right)$$

From [7], $\beta/K_d = \beta_s/K_s \simeq 16.5$ Å/V (7) so that $\varepsilon_0 K_d/\beta = 0.54$ μC/cm^3. Thus for values of I_2/I_1 of 0.5, 2.0, and 11, we may calculate from [A3] that $|i^c| = |I_2 - i|$ falls to 1% of I_2 for values of the charge passed of 2.1, 2.5, and 3.7 μC/cm^2, respectively. The approximation $i = I_2$ is therefore a very good one over the region of data analyzed (*cf.* Fig. 2).

For personal use only.

Decay of Excess Field

The problem will be solved in the approximation $i \simeq I_2$ for $Q > 0$, and initially for the more general case of two independent dielectric relaxation processes. Accordingly, [14] may be written

$$[A4] \quad \mathrm{d}[P_k \exp(B_k Q)] = [B_k \varepsilon_0 \chi_k E \exp(B_k Q)]\,\mathrm{d}Q, \quad k = 2,3$$

which on using the boundary conditions [11] and [15] (*i.e.* $P_k(Q=0) = \varepsilon_0 \chi_k E_1$, $k = 2,3$) may be integrated to yield the following expression for P_k

$$[A5] \quad P_k = [\varepsilon_0 \chi_k E_1 + B_k \varepsilon_0 \chi_k \times \int_0^Q E \exp(B_k Q)\,\mathrm{d}Q] \exp(-B_k Q)$$

From [6] and [11], $\beta E_\mathrm{d} = \beta_\mathrm{s} E_2$ for $Q > 0$, so that [5] may be written

$$[A6] \quad \varepsilon_0 E + P = \varepsilon_0 K_\mathrm{d} (\beta_\mathrm{s}/\beta) E_2$$

Eliminating P and then P_1 using [13] and [9], and eliminating β using [7] gives

$$[A7] \quad \varepsilon_0 K_1 E + P_2 + P_3 = \varepsilon_0 K_\mathrm{s} E_2$$

Substituting for P_2 and P_3 from [A5] leads to an integral equation in E. Elimination of the two integrals by the usual method of isolation and differentiation leads to the following second order differential equation in the excess field, $\Delta E = E - E_2$.

$$[A8] \quad \frac{\mathrm{d}^2 \Delta E}{\mathrm{d}Q^2} + \left(B_2 + B_3 + \frac{B_2 \chi_2 + B_3 \chi_3}{K_1}\right) \frac{\mathrm{d}\Delta E}{\mathrm{d}Q} + \frac{B_2 B_3 K_\mathrm{s}}{K_1} \Delta E = 0$$

In deriving [A8], use has been made of the relation $K_1 + \chi_2 + \chi_3 = K_\mathrm{s}$. The solution of [A8] takes the form of [4] with m_1 and m_2 the roots of [16]. The integration constants M_1 and M_2 are evaluated from the boundary conditions that for $Q = 0$, $E = E_1 + (K_\mathrm{s}/K_1)(E_2 - E_1)$ and $\mathrm{d}E/\mathrm{d}Q = -(1/K_1)(B_2 \chi_2 + B_3 \chi_3)(E - E_1)$ (which can be derived in a straightforward manner from [A5] and [A7]) and are given in [17].

Proceeding in an identical manner for the case $B_3 = \chi_3 = P_3 = 0$, $B_2 = B$, one obtains in place of [A8]

$$[A9] \quad \mathrm{d}\Delta E/\mathrm{d}Q + B(K_\mathrm{s}/K_1)\Delta E = 0$$

Using the boundary condition $E = E_1 + (K_\mathrm{s}/K_1)(E_2 - E_1)$ for $Q = 0$, [A9] integrates to give [4] with $M_2 = 0$ and M_1 and m_1 given by [12].

Transient Response of the System Al/Al_2O_3/Electrolyte. Part II. A.c. Impedance Measurements During Steady-State Film Growth

D. G. W. GOAD[1] AND M. J. DIGNAM

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 13, 1971[2]

Experiments are described in which the a.c. impedance of the system Al/Al_2O_3/electrolyte (glycol–borate) is measured under conditions of steady-state film growth. Using an equivalent circuit of a resistive and capacitive element in parallel, the results are presented in the form of the a.c. conductance, σ_{ac}, and effective dielectric constant, K_{eff}, of the oxide film as a function of the d.c. current density, I_0, and angular frequency ω. The results show that σ_{ac}/I_0 and K_{eff} vary with (ω/I_0), but within experimental error are independent of ω and I_0 separately. The dielectric relaxation model, assuming two ion-current-driven relaxation processes and using the constants determined in Part I, reproduces the data almost within experimental scatter. A poorer fit is achieved if only one relaxation process is assumed.

Nous décrivons des expériences au cours desquelles l'impédance ac du système Al/Al_2O_3/électrolyte (glycol–borate) est mesurée dans des conditions de croissance de film à l'état stationnaire. Au moyen d'un circuit équivalent d'éléments de résistance et de capacitance en parralèle, nous présentons les résultats sous forme de conductance ac, σ_{ac} et de constante diélectrique effective, K_{eff}, du film d'oxyde en fonction de la densité du courant d.c., I_0, et de la fréquence angulaire ω. Les résultats démontrent que σ_{ac}/I_0 et K_{eff} varient avec (ω/I_0), mais ils sont indépendants, à l'intérieur de l'erreur expérimentale, de ω et I_0, séparément. Le modèle de relaxation diélectrique, qui suppose deux processus de relaxation produits par un courant d'ion, utilisant les constantes déterminées dans la partie I, reproduit les données presque à l'intérieur de l'éparpillement expérimental. Un ajustement plus grossier est obtenu lorsqu'on suppose un seul processus de relaxation.

Canadian Journal of Chemistry, **50**, 3267 (1972)

Introduction

In Part I of this paper (1) galvanostatic transient data for the system Al/Al_2O_3/electrolyte have been obtained and shown to be in accord with the dielectric relaxation model, provided that one postulates the existence of two independent ion-current-driven relaxation processes. Furthermore, the constants obtained from the analysis agree with those calculated earlier from potentiostatic transient data. The purpose of Part II of this paper is to report the results of a.c. impedance measurements made on the same system, during the course of steady-state film growth, and to test whether or not the results are in accord with the dielectric relaxation model.

The method employed is to superimpose a small constant amplitude a.c. current on a constant d.c. formation current. The components of the a.c. part of the electrode potential which are respectively in and out of phase with the a.c. cell current are then measured, from which the effective a.c. conductivity and dielectric constant of the oxide film can be calculated. Experiments of this kind have been carried out for the tantalum and aluminum systems by Winkel *et al.*, using a bridge circuit to measure the a.c. components (2). They did not, however, report data for the out-of-phase component.

In the present study, a lock-in (*i.e.* phase sensitive) amplifier, rather than an a.c. bridge, was used to measure the a.c. component, thus eliminating any problem which might otherwise arise from the presence of higher harmonics of the fundamental frequency. (Since the cell voltage and current are not linearly related, higher harmonics will be generated.)

Experimental

Apparatus

A schematic diagram of the apparatus used to maintain a constant d.c. current through the cell and superimpose a small a.c. current is shown in Fig. 1. The cell forms the feedback element of an operational amplifier (Philbrick model SP2A with 100 V booster), so that the current through the cell is the sum of the currents through the input resistors. One of the resistors is connected to a 15 V regulated, d.c. supply, the other to the output of the lock-in amplifier reference channel, which provides an a.c. signal continuously adjustable from 0 to 1 V and from 1.5 Hz to 10 kHz. Since the aluminum anode of the cell is connected to the

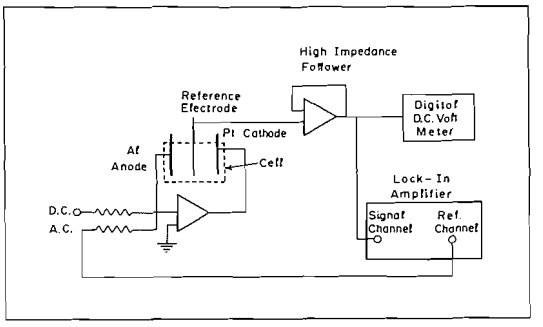

FIG. 1. Schematic diagram of the apparatus for measuring the a.c. impedance of an electrode system under galvanostatic conditions.

amplifier input, it is a virtual ground; thus the anode potential *vs.* the reference electrode is just the negative of the reference electrode potential (measured against ground). The reference electrode potential is fed through a high impedance voltage follower to both a d.c. digital voltmeter and the signal channel input of the lock-in amplifier. Thus both the d.c. and a.c. components of the electrode potential are available for recording.

The anodizing cell and electrolyte were the same in all important respects as those described in Part I (1), except that temperature control was maintained by water circulation (the cell was of double-walled construction) rather than by an air thermostat.

Results

For all the experimental runs, the d.c. electrode potential, V_0, and the two a.c. components V_{in} and V_{out}, were found to increase linearly with the time over the range of 20 to 100 V for V_0, a result expected if space charge within the film is either negligible, or confined to zones close to the oxide boundaries (*cf.* Part I). For values of V_0 less than 20 V, the time derivatives of the potentials vary by a few percent, a behavior which has been noted before in the case of dV_0/dt (3). Over the region in which steady-state conditions obtain (*i.e.* $100\text{ V} > V_0 > 20\text{ V}$), the data for a given run can therefore be represented by the values of the d.c. cell current, the amplitude and frequency of the a.c. cell current, and the time derivatives of the potentials. The derivatives were determined by linear regression analyses of the primary data. The steady-state formation current density, I_0, and corresponding field strength, E_0, were calculated from dV_0/dt as described in Part I. Having obtained I_0 and knowing the total d.c. cell current, the electrode area, and hence the

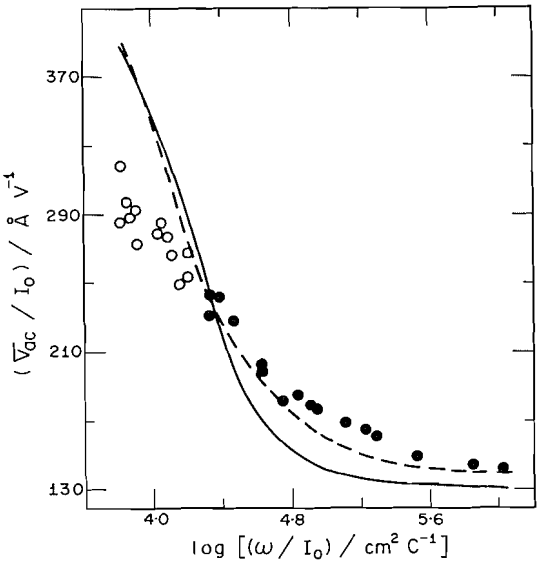

FIG. 2. Graph of $(J_{ac}/I_0) \equiv (I_{in}/E_\omega I_0)$ *vs.* log (ω/I_0). ●, $I_0 \simeq 4 \times 10^{-4}$ A/cm^2, ω varying; ○, I_0 varying, $\omega = 2\pi \times 1.5\ s^{-1}$. The solid line is calculated from [12], the broken line from [10].

amplitude of the a.c. current density, I_ω, was calculated. Finally, since for steady-state conditions there is no d.c. component to the charging current (since E_0 and I_0 are constant) then I_0 is the d.c. ion current density. Thus from Faraday's law, $E_0 = (dV_0/dt)/\Omega I_0$, $E_{in} = (dV_{in}/dt)/\Omega I_0$ and $E_{out} = (dV_{out}/dt)/\Omega I_0$ where E_{in} and E_{out} are the differential field amplitudes corresponding to V_{in} and V_{out}, and $\Omega = W_e/F\rho$, with W_e being the electrochemical equivalent weight of the oxide, ρ its density, and F the Faraday. Thus E_{in} and E_{out} may be calculated from $E_{in} = E_0(dV_{in}/dt)/(dV_0/dt)$ and $E_{out} = E_0(dV_{out}/dt)/(dV_0/dt)$. The results for a single run may therefore be represented by the values for the six quantities, I_0, E_0, I_ω, E_{in}, E_{out}, and ω for that run. A further reduction in the data can be achieved by defining a parallel equivalent a.c. conductivity, σ_{ac}, and dielectric constant, K_{eff}, according to (see Appendix)

$$[1] \qquad \sigma_{ac} = I_\omega E_{in}/(E_{in}^2 + E_{out}^2)$$

$$[2] \qquad \omega\varepsilon_0 K_{eff} = -I_\omega E_{out}/(E_{in}^2 + E_{out}^2)$$

where ε_0 is the permittivity of free space. If the anodic oxide film behaved simply as a lossy dielectric, σ_{ac} and K_{eff} would be the conductivity and dielectric constant of the film (see

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

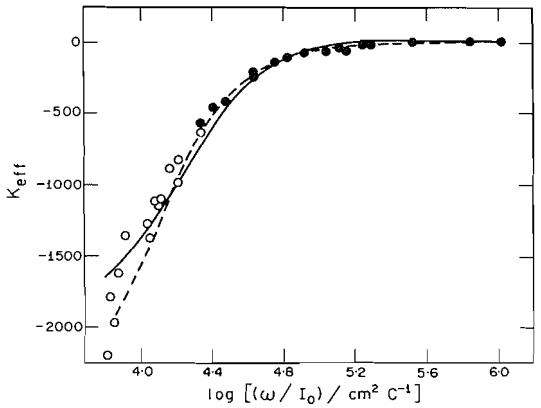

FIG. 3. Graph of $K_{eff} \equiv I_{out}/E_\omega \omega \varepsilon_0$ *vs.* log (ω/I_0). ●, $I_0 \simeq 4 \times 10^{-4}$ A/cm^2, ω varying; ○, I_0 varying, $\omega = 2\pi \times 1.5$ s^{-1}. The solid line is calculated from [13], the broken line from [11].

Appendix). It should be emphasized, however, that the calculation of σ_{ac} and K_{eff} from the primary data does not involve assumptions concerning the mechanism of anodic oxidation.

In Figs. 2 and 3 the results for all the runs are plotted in the form σ_{ac}/I_0 and K_{eff} *vs.* log (ω/I_0). A practical lower limit exists on the ratio $\omega : I_0$ which can be used, since for increasing I_0, the total time available for measurement decreases, and each measurement takes a minimum of several periods, $1/\omega$, to perform. The somewhat larger scatter in the results for small values of ω/I_0 is due to this difficulty.

Discussion

The results, plotted in the form σ_{ac}/I_0 and K_{eff} *vs.* log (ω/I_0) fall on smooth curves within experimental scatter, even though different values for I_0 have been used. Thus σ_{ac}/I_0 and K_{eff} depend on ω/I_0, but appear to be independent of ω and I_0 separately, within experimental error. Such behavior might have been anticipated from the form of the galvanostatic and potentiostatic transients (*cf.* Part I) which were shown not to involve time as a parameter. Thus all three quantities σ_{ac}/I_0, K_{eff}, and (ω/I_0), are dimensionally independent of time.

The large negative value which K_{eff} assumes when ω/I_0 is small appears at first glance to be rather surprising. However, K_{eff} cannot be interpreted simply as the dielectric constant of the oxide film since relaxation processes associated with the kinetics of ionic conduction will contribute to the current component out of phase with the field, and hence to K_{eff}. Thus the behavior of both σ_{ac} and K_{eff} provides information on the kinetics of ionic conduction.

In the following sections, expressions for K_{eff} and σ_{ac} are derived on the basis of the dielectric relaxation model, outlined in Part I, and compared with the experimental results.

Expressions for K_{eff} and σ_{ac} from Dielectric Relaxation Model

We employ at the outset the equations which involve two ion current driven dielectric relaxation processes (*cf.* Part I). Thus from [5] to [14] of Part I,

$$[3] \qquad i = \alpha \exp \beta E_d$$

$$[4] \qquad \varepsilon_0 K_d E_d = \varepsilon_0 E + P$$

$$[5] \qquad P = \varepsilon_0 \chi_1 E + P_2 + P_3$$

$$[6] \qquad dP_k/dt = B_k i(\varepsilon_0 \chi_k E - P_k), \qquad k = 2,3$$

$$[7] \qquad I = i + i^c = i + \varepsilon_0 \, dE/dt + dP/dt$$

where i, i^c, and I are the ion, charging, and total current densities, respectively; E and E_d are the fields in the oxide and oxide/electrolyte double layer, respectively; P is the polarization of the oxide film which is divided into components $\varepsilon_0 \chi_1 E$, P_2, and P_3 with corresponding electric susceptibilities χ_1, χ_2, and χ_3; ε_0 is the permittivity of free space; α, β, B_2, and B_3 are constants associated with the kinetics of ion transport (α and β) and dielectric polarization (B_2 and B_3); and t is time. Next we expand E, i, I, P, P_2, P_3, and E_d in terms of their d.c. and a.c. components, *i.e.*,

$$[8] \quad \begin{aligned} E &= E_0 + E_\omega \exp(j\omega t) + \text{harmonics} \\ i &= I_0 + (i_{in} + j i_{out}) \exp(j\omega t) + \text{harmonics} \\ I &= I_0 + (I_{in} + j I_{out}) \exp(j\omega t) + \text{harmonics} \\ P &= P_0 + (P_{in} + j P_{out}) \exp(j\omega t) + \text{harmonics} \end{aligned}$$

etc.

where $j = \sqrt{-1}$ and the subscripts in and out refer to the components which are in and out of phase, respectively, with the a.c. field of amplitude E_ω. Finally, on making the substitutions [8] into [3] to [7], and equating corresponding components, a total of 18 equations are obtained,

For personal use only.

six in each of the d.c., real, and imaginary a.c. components respectively. Elimination of the d.c. and a.c. components of i, P, P_2, P_3, and E_d leads to the following three independent equations

$$[9] \qquad I_0 = \alpha \exp(\beta_s E_0)$$

$$[10] \quad \frac{\sigma_{ac}}{I_0} = \beta_t + \left(\frac{\beta_s - \beta_t}{1+\Delta}\right)\left[1 + \left(\frac{\omega}{B_2 B_3 I_0}\right)^2 \left(\frac{B_2^2\chi_2 + B_3^2\chi_3}{K_s - K_1}\right)\right] + \frac{\varepsilon_0(\omega/I_0)^2}{B_2B_3(1+\Delta)}\left[(B_2\chi_2 + B_3\chi_3) + \left(\frac{\omega^2}{B_2B_3I_0^2}\right)(B_2\chi_2 + B_3\chi_3)\right]$$

$$[11] \quad K_{eff} = K_1 + \left(\frac{K_s - K_1}{1+\Delta}\right)\left[1 + \left(\frac{\omega}{B_2B_3I_0}\right)^2\left(\frac{B_2^2\chi_2 + B_3^2\chi_3}{K_s - K_1}\right)\right] - \left(\frac{\beta_s}{\varepsilon_0 K_s B_2 B_3 \Delta}\right)\left[(B_2\chi_3 + B_3\chi_2) + \left(\frac{\omega^2}{B_2B_3I_0^2}\right)(B_2\chi_2 + B_3\chi_3)\right]$$

where

$$\sigma_{ac} = I_{in}/E_\omega$$

$$K_{eff} = I_{out}/E_\omega \varepsilon_0 \omega$$

(they are also given by [1] and [2], see Appendix),

$$\Delta = (\omega/B_2B_3I_0)^2(B_2^2 + B_3^2 + \omega^2/I_0^2)$$

$$K_s = 1 + \chi_1 + \chi_2 + \chi_3$$

$$K_1 = 1 + \chi_1$$

$$\beta_s = (K_s/K_d)\beta$$

and

$$\beta_t = (K_1/K_d)\beta$$

Equation 9 is simply the relationship between the steady-state current density and field strength (see Part I), while [10] and [11] are the desired expressions for σ_{ac} and K_{eff} when two ion-current-driven dielectric relaxation processes are considered. The equations appropriate for a single such relaxation process are obtained from [10] and [11] on setting $\chi_3 = 0$, and $B_2 = B$, and are given by

$$[12] \quad \frac{\sigma_{ac}}{I_0} = \beta_t + \left(\frac{\beta_s - \beta_t}{1 + (\omega/BI_0)^2}\right) + \left(\frac{\varepsilon_0}{B}\right)\left(\frac{\omega}{I_0}\right)^2\left(\frac{K_s - K_1}{1 + (\omega/BI_0)^2}\right)$$

$$[13] \quad K_{eff} = K_1 - \left(\frac{(\beta_s - \beta_t)/\varepsilon_0 B}{1 + (\omega/BI_0)^2}\right) + \left(\frac{K_s - K_1}{1 + (\omega/BI_0)^2}\right)$$

In Table 1, the behavior of σ_{ac}/I_0 and K_{eff} in the high and low frequency limits is given. For both cases $K_{eff} = K_1$ in the high frequency limit, and $\sigma_{ac}/I_0 = \beta_s$ in the low frequency limit, as expected.

For both forms of the dielectric relaxation model, the experimental quantities σ_{ac}/I_0 and K_{eff} are predicted to be functions of (ω/I_0), but not of ω or I_0 independently. (This conclusion is based on the assumption that β_s and β_t are independent of E_0, which is not strictly true as noted in Part I, but is a good enough approximation for the present application.) The solid lines in Figs. 2 and 3 were computed from eqs. 12 and 13, by setting $K_1 = 8.5$, $\beta_t = 129$ Å/V, and $\beta_s/\beta_t = 3.1$ (4), then adjusting B to satisfy a weighted least squares criterion for σ_{ac}/I_0 and K_{eff}, the weighting factor being taken to be proportional to the square of the reciprocal of the standard deviation of the individual measurements of σ_{ac}/I_0 and K_{eff}. The value for B found in this way is 1.75×10^4 cm^2/C. It is evident that the fit is only fair.

The broken lines of Figs. 2 and 3 were computed from [10] and [11] using the values for K_s/K_1, χ_2/K_1, B_2, and B_3 determined in Part I of this paper, and adjusting K_1 and β_t to satisfy the same least squares criterion as above. The fit is appreciably better, being within experimental scatter except perhaps for σ_{ac}/I_0 at low (ω/I_0) where the experimental measurements are the most difficult to obtain. Furthermore, the values deduced, $K_1 = 10$ and $\beta_t = 134$ Å/V, agree within experimental error with independent measurements of these parameters (4). Thus from Fig.

TABLE 1. Expressions for σ_{ac}/I_0 and K_{eff} in the high and low frequency limits

	Single relaxation process	Two independent relaxation processes
$\underset{(\omega/I_0)\to 0}{\text{Limit}}\left(\frac{\sigma_{ac}}{I_0}\right)$	β_s	β_s
$\underset{(\omega/I_0)\to 0}{\text{Limit}}\ (K_{eff})$	$\frac{(\beta_s-\beta_t)}{\varepsilon_0 B}+\{K_s\}^*$	$\frac{(\beta_s-\beta_t)}{\varepsilon_0 B_2}+\frac{\chi_3\beta_t}{\varepsilon_0 K_1}\left(\frac{1}{B_2}-\frac{1}{B_3}\right)+\{K_s\}^*$
$\underset{(\omega/I_0)\to \infty}{\text{Limit}}\left(\frac{\sigma_{ac}}{I_0}\right)$	$\beta_t+\{\varepsilon_0\chi_2 B\}^*$	$\beta_t+\{\varepsilon_0(\chi_2 B_2+\chi_3 B_3)\}^*$
$\underset{(\omega/I_0)\to \infty}{\text{Limit}}\ K_{eff}$	K_1	K_1

*The terms in parentheses make a negligible contribution for the Al/Al_2O_3/electrolyte system.

10, ref. 4, β_t has a value of 134 Å/V for $I_0 \sim 10^{-3}$ A/cm^2, which lies approximately mid way within the range of I_0 values covered in Figs. 2 and 3 (4×10^{-4} to 1.5×10^{-3} A/cm^2). The value of K_1, as distinct from the ratios K_s/K_1 and χ_2/K_1, affects the fit significantly only in the case of K_{eff}, which approaches K_1 for large values of (ω/I_0) (*cf.* Table 1). It is apparent from Fig. 3 that a value for K_1 of 10 is, within experimental accuracy, indistinguishable from the value 8.5 (4).

In summary, the dielectric relaxation model, employing two independent relaxation processes, accounts quantitatively for a.c. impedance measurements, as well as for potentiostatic and galvanostatic transient measurements, performed on the system Al/Al_2O_3/electrolyte, a single set of constants reproducing the data from all three experiments.

Appendix

Defining I_{in} and I_{out} for any circuit element as the components of the a.c. current density, of amplitude I_ω, which are respectively in and out of phase with the a.c. field of amplitude E_ω; and E_{in} and E_{out} as the components of a.c. field which are respectively in and out of phase with the a.c. current density, then

[A1] $E_{in} = E_\omega \cos\delta, \qquad E_{out} = E_\omega \sin\delta$

[A2] $I_{in} = I_\omega \cos\delta, \qquad I_{out} = -I_\omega \sin\delta$

where δ is the phase angle between the a.c. current and field. Solving for I_{in}/E_ω and I_{out}/E_ω gives

[A3] $I_{in}/E_\omega = \sigma_{ac} = I_\omega E_{in}/(E_{in}^2 + E_{out}^2)$

[A4] $I_{out}/E_\omega = \omega\varepsilon_0 K_{eff} = -I_\omega E_{out}/(E_{in}^2 + E_{out}^2)$

where σ_{ac} and K_{eff} are the parallel equivalent conductivity and dielectric constant for the circuit element. Equations A3 and A4 have been used in writing down [1], [2], [10], and [11].

A Total Synthesis of Cadin-4, 10(15)-dien-3α-ol: Structure of Khusinol

R. B. KELLY AND J. EBER

Department of Chemistry, University of New Brunswick, Saint John, New Brunswick

Received May 23, 1972

A total synthesis of cadin-4,10(15)diene-3α-ol, one of the structures proposed for khusinol, is described. Neither this compound nor its C_3-epimer was identical with khusinol.

La synthèse totale du cadindiène-4,10(15)ol-3α, une des structures proposées pour le khusinol est décrite. Ce composé et son épimère au niveau du C_3 ne sont pas identifiés au khusinol.

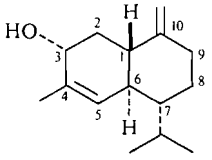
[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3272 (1972)

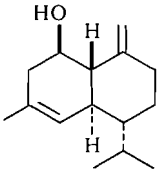
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The isolation of khusinol from the oil of *Vitiveria zizanioides* (L). Nash was first reported in 1963 and at that time structure **1** (title compound) was assigned to this sesquiterpene alcohol (1). It was also shown, by conversion to (−) γ-cadinene, that khusinol belongs to the naturally occurring antipodal series of cadalenic compounds and is therefore of interest from the point of view of biogenesis (1).

Structure **1** for khusinol was adduced from chemical evidence and, apparently, without the benefit of n.m.r. spectroscopy. More recently, however, a revised structure **2** for khusinol has been proposed (2). The latter proposal was based on further chemical evidence and high resolution n.m.r. spectroscopy. The validity of neither of these structures has been verified by synthesis.



1

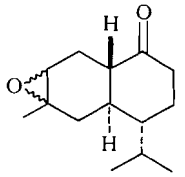


2

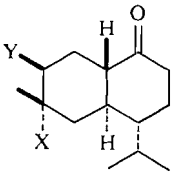
Before the proposal of structure **2** for khusinol, we were prompted by the availability in our laboratories of the convenient intermediate **3** to complete a synthesis of **1**. We now wish to give an account of the details of this synthesis (see Scheme 1) and to report that, since neither **1** nor its C_3-epimer (**12**) were identical with khusinol, these structures need no longer be considered for this sesquiterpenoid.[1]

[1]The numbering system shown in **1** is used throughout.

The totally synthetic enone **3** (3) was converted into the crystalline epoxide **4** by treatment with *m*-chloroperbenzoic acid.[2] The assignment of structure **4**, rather than the alternative structure **5**, to the epoxide is based on the following evidence. The epoxide was converted, in 92% yield, into a crystalline bromohydrin in which the bromine atom and the hydroxyl group are *trans* diaxially oriented (4). The n.m.r. signal for the methyl group at C-4 appeared at δ 1.87 in agreement with the presence of the group CH_3—C—Br. Acetylation of the bromohydrin under conditions which could not be expected to acetylate a tertiary alcohol such as **7** and which gave only a monoacetate when applied to the diol **8** (*vide supra*), did, in fact, give a crystalline acetate. Furthermore, the downfield shift (1.17 p.p.m.) of the n.m.r. signal for the C-3 proton as a result of acetylation of the bromohydrin is characteristically associated with the acetylation of a secondary alcohol such as **6** (5). The above evidence establishes structure **6** for the bromohydrin to the exclusion of **7**. Therefore, in accordance with the well established stereospecific manner in

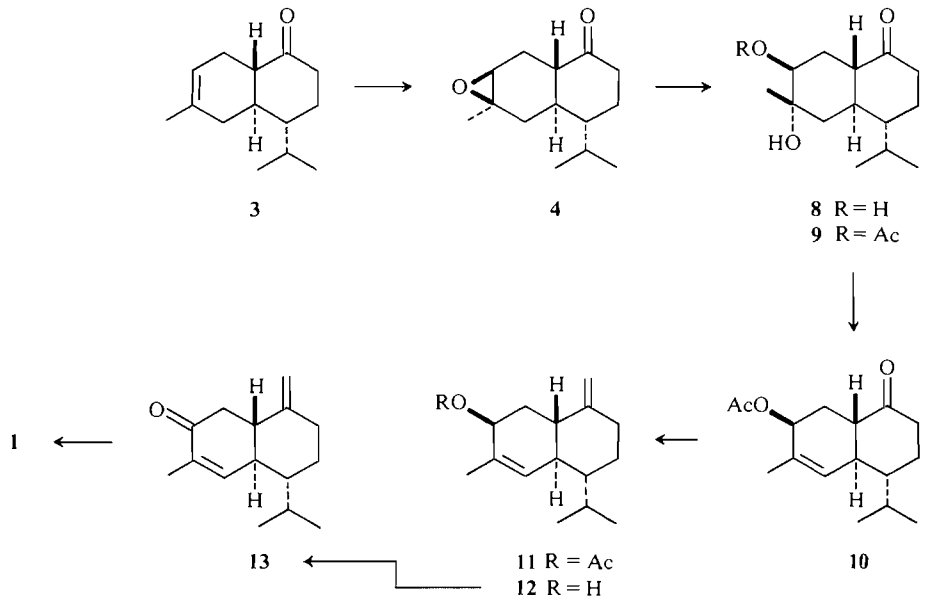


4 β-Epoxide (as in Scheme 1)
5 α-Epoxide



6 Y = OH; X = Br
7 Y = Br; X = OH

[2]The i.r. and n.m.r. spectra of all compounds were consistent with assigned structures; spectral data are given in the Experimental.



SCHEME 1

which epoxides are cleaved (4), the epoxide which is the precursor of **6** must be assigned structure **4** rather than **5**.

Hydrolysis of the epoxide **4** afforded the crystalline diaxially oriented diol **8** (4). Acetylation of the latter and treatment of the resulting monoacetate **9** with phosphorus oxychloride in pyridine gave the olefin **10**. The fact that the n.m.r. signal for the vinylic proton in **10** appeared as a singlet is proof that the double bond was introduced into the assigned position (3).

The acetate **10** was converted into the diene **11** in 79% yield via a modified Wittig reaction (6). Several cases have been reported where decalones and octalones having the keto group adjacent to a ring junction (such as in **10**), when subjected to the Wittig reaction, have yielded olefins in which the angular carbon atom originally adjacent to the ketone had undergone epimerization (7). This phenomenon has been observed only in the case of *cis*-fused systems. The possibility of this type of epimerization happening in the case of **10** to give a *cis*-fused diene is ruled out by the fact that, in the n.m.r. spectrum of the diene, the signal at δ 5.83 for the vinylic proton at C-5 appeared as a singlet. This requires that the dihedral angle between the C-5 and -6 protons be approximately 90°, a requirement satisfied by the *trans*-fused structure **11** but not by any reasonable conformation of the *cis*-fused diene corresponding to **11**.

Reduction of the acetate **11** with lithium aluminum hydride afforded the alcohol **12** which is the C_3-epimer of the desired compound (**1**).

Oxidation of **12** with activated manganese dioxide (8) gave, in 75% yield, the α,β-unsaturated ketone **13** which, on reduction with lithium aluminum hydride, afforded **1** as a crystalline compound in 98% yield. The broadening of the n.m.r. signal for the C-3 proton by 13 Hz ($w_{1/2}$) as a result of the transformation **12** → **1** is consistent with the conversion of a quasi axial hydroxyl into a quasi equatorial hydroxyl group (5). Comparison of the spectral properties and behavior on t.l.c. of the newly acquired dienol with the corresponding properties of the precursor dienol **12** showed that the two compounds were distinctly different.

Experimental

General

The n.m.r. spectra were determined in deuteriochloroform ($CDCl_3$) solutions with a Varian T-60 instrument. Chemical shifts are expressed in p.p.m. (δ values) downfield from the tetramethylsilane signal as internal standard.

Reaction products were isolated by the following procedure. The product was extracted into the specified solvent and the extract was washed two or three times with appropriate aqueous solutions as indicated. The original aqueous layer (if any) and the aqueous washings were extracted three times with the solvent and the combined extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated *in vacuo* on a rotary evaporator.

Brine refers to a saturated solution of sodium chloride.

Petroleum ether refers to the fraction with boiling point range 30–60°.

Keto Epoxide ***4***

A solution of 411 mg of the enone **3** and 454 mg of *m*-chloroperbenzoic acid in 37 ml of chloroform was stirred at room temperature for 1 h. The solution was then treated with 28 ml of 10% aqueous sodium bisulfite solution and stirred for a further 15 min. The reaction mixture was extracted with chloroform and the extract was worked-up in the usual manner by washing with 5% sodium bicarbonate solution and water. The oily residue, on crystallization from pentane afforded 245 mg (55%) of **4**, m.p. 71–73°; ν_{max} (Nujol) 1705 cm^{-1} (ketone); n.m.r. δ 0.75 and 1.00 (doublets, 3H each, $J = 7.0$ Hz, isopropyl group),[3] 1.28 (s, 3H, CH_3—C—O), 3.05 (m, 1H, H—C—O).

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.64; H, 9.97. Found: C, 75.44; H, 9.82.

Keto Bromohydrin ***6*** *and its Acetate*

A solution of 33 mg of the epoxide **4** in 2 ml of glacial acetic acid was treated, with cooling in an ice bath, with 0.5 ml of 24% hydrobromic acid in acetic acid. The reaction solution was kept at 0° for 45 min then diluted with 30 ml of methylene chloride. The resulting solution was worked-up in the usual manner by washing with water. The residue, an oil, was crystallized from pentane to give 42 mg (92%) of **6**, m.p. 123–125°; ν_{max} (Nujol) 3420 (OH) and 1685 cm^{-1} (ketone); n.m.r. δ 1.87 (s, 3H, CH_3—C—Br), 4.03 (m, $w_{1/2}$ = 6.5 Hz, 1H, H—C—OH).

The *acetate* was prepared in 72% yield in the usual manner with acetic anhydride in pyridine at room temperature. Crystallized from pentane, it melted at 143–145°, ν_{max} (Nujol) 1740 (acetate) and 1705 cm^{-1} (ketone); n.m.r. δ 1.71 (s, 3H, CH_3—C—Br), 2.00 (s, 3H, acetate), 5.20 (m, $w_{1/2} = 6.5$ Hz, 1H, H—C—OAc).

Anal. Calcd. for $C_{16}H_{25}OBr$: Br, 23.14. Found: Br, 23.02.

Keto Diol ***8***

A mixture of 445 mg of the epoxide **4**, 60 ml of acetone, and 60 ml of water was refluxed for 15 h. The acetone was evaporated *in vacuo* and the remaining aqueous solution was saturated with sodium chloride and extracted with ether. The ether extracts were worked-up in the usual manner by washing with brine. The crude product, an oil, was chromatographed on a column of 15.0 g of silica gel in benzene–ether (1:1). The eluate, on crystallization from ethyl acetate–petroleum ether afforded 237 mg of **8**, m.p. 134°; ν_{max} (Nujol) 3550 and 3350 (hydroxyls) and 1680 cm^{-1} (ketone); n.m.r. δ 1.28 (s, 3H, CH_3—C—OH), 3.63 (m, $w_{1/2} = 6.5$ Hz, 1H, H—C—OH).

Anal. Calcd. for C_{14} $H_{24}O_3$: C, 69.54; H, 10.06. Found: C, 70.20: H, 10.28.

[3]This pair of doublets appears in the n.m.r. spectra of all succeeding compounds.

Acetate ***9***

Treatment of the diol **8** in the usual manner with acetic anhydride in pyridine afforded, in 95% yield, the acetate **9**, m.p. 137°; ν_{max} (Nujol) 3410 (OH) and 1700 cm^{-1} (broad band, ketone and acetate); n.m.r. δ 1.30 (s, 3H, CH_3—C—OH), 2.06 (s, 3H, acetate). 4.82 (m, $w_{1/2} = 6.5$ Hz, 1H, H—C—OAc).

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 68.38; H, 9.40.

Enone Acetate ***10***

A solution of 2.03 g of the acetate **9** in 75 ml of pyridine was treated, with cooling on an ice-salt bath, with 16.5 ml of phosphorus oxychloride then left at room temperature for 12 h. The reaction was poured into a mixture of 500 g of ice and water and the resulting cold solution was extracted with ether. The ether extract was worked-up in the usual manner by washing, in the order mentioned, with cold 1 *N* hydrochloric acid, cold saturated sodium bicarbonate solution, and ice water. Evaporation of the ether extracts yielded 2.00 g of yellow oil which was combined with 450 mg of similar material from another run. The oil was chromatographed on a column of 120 g of silica gel impregnated with 20% of silver nitrate. Elution of the column with 25% of ether in petroleum ether, evaporation of the effluent *in vacuo* and crystallization of the residue from pentane afforded 1.40 g (61%) of **10**, m.p. 108–109°; ν_{max} (Nujol), no hydroxyl bands, 1735 (acetate) and 1710 cm^{-1} (ketone); n.m.r. δ 1.71 (s, 3H, vinylic CH_3), 2.03 (s, 3H, acetate), 5.17 (m, $w_{1/2} = 9.5$ Hz; 1H, H—C—OAc), 5.81 (s, 1H, vinylic proton).

Anal. Calcd. for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15. Found: C, 72.56; H, 8.96.

Dienol Acetate ***11***

The Wittig reaction was carried out in an atmosphere of dry, oxygen-free nitrogen as follows. A stirred suspension of 393 mg of the ketone **10** in 3 ml of dimethyl sulfoxide was treated with 3.75 ml of a 0.5 *M* solution of methylenetriphenylphosphorane (6) whereupon a mildly exothermic reaction occurred and the ketone was completely dissolved. The yellow reaction solution was stirred at room temperature for 11 h then poured into 35 ml of water. The aqueous solution was worked-up in the usual manner by extraction with ether, and washing the ether extracts with water. Evaporation of the ether extracts *in vacuo* gave 446 mg of oil which was chromatographed on a column of 15.0 g of silica gel impregnated with 20% of silver nitrate. Elution of the column with 5% of ether in pentane yielded an oil which, after crystallization from pentane, afforded 309 mg (79%) of **11**, m.p. 53–54°; ν_{max} (Nujol) 1740 (acetate), 1684 (olefin), and 890 cm^{-1} with overtone at 1780 cm^{-1} (exocyclic CH_2); n.m.r. δ 1.72 (s, 3H, vinylic CH_3), 2.03 (s, 3H, acetate), 4.47 and 4.63 (singlets, 1H each, exocyclic CH_2), 5.17 (m, $w_{1/2} = 7.0$ Hz, 1H, H—C—OAc), 5.83 (s, 1H, vinylic proton).

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.81; H, 9.99. Found: C, 78.01; H, 9.97.

Dienol ***12***

A solution of 519 mg of the dienol acetate **11** in 25 ml of ether was added dropwise to a stirred mixture of 250 mg of lithium aluminum hydride in 25 ml of ether. After stirring for 16 h at room temperature, the reaction mixture was refluxed for 2 h, cooled, and treated with 0.4 ml of brine

and stirred for a further period of 1 h. Removal of the solid material by filtration and evaporation of the filtrate *in vacuo* gave 550 mg of oil. Chromatography of the crude product on 25 g of silica gel impregnated with 20% of silver nitrate using 25% of ether in petroleum ether as solvent gave an oil which, on crystallization from petroleum ether, afforded 348 mg of **12**, m.p. 96°; ν_{max} (Nujol), no carbonyl absorption, 3225 (OH), 1648 (olefin), 880 with overtone at 1760 cm^{-1} (exocyclic CH_2); n.m.r. δ 1.78 (s, 3H, vinylic CH_3), 3.97 (m, $w_{1/2}$ = 7.0 Hz, 1H, H—C—OH), 4.50 and 4.63 (singlets, 1H each, exocyclic CH_2), 5.70 (s, 1H, vinylic proton).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.63; H, 10.71.

Dienone ***13***

A suspension of 251 mg of the dienol **12** and 5.0 g of activated manganese dioxide (8) in 75 ml of pentane was stirred at room temperature for 6 h. Removal of the solid material by filtration and evaporation of the filtrate *in vacuo* afforded an oil which crystallized from pentane to afford 186 mg (74%) of **13**, m.p. 62.5–63°; λ_{max} (EtOH) 238 nm (ε, 9700); ν_{max} (Nujol), no hydroxyl band, 1675 (ketone), 1647 (olefin), 880 with overtone at 1760 cm^{-1} (exocyclic CH_2); n.m.r. δ 1.78 (s, 3H, vinylic CH_3), 4.50 and 4.71 (singlets, 1H each, exocyclic CH_2), 6.81 (s, 1H, vinylic proton).

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.52; H, 10.16. Found: C, 82.84; H, 10.06.

Dienol ***1*** *(Cadin-4, 10(15)-diene-3α-ol)*

A solution of 130 mg of the dienone **13** in 10 ml of ether was added dropwise to a refluxing mixture of 200 mg of lithium aluminum hydride and 10 ml of ether. The reaction mixture was refluxed for 18 h then cooled and treated with 0.4 ml of brine. After stirring for 2 h, the solid material was removed by filtration and the filtrate was evaporated *in vacuo*. Crystallization of the residue from ether–petroleum ether afforded 129 mg of **1**, m.p. 115.5–116.5°; ν_{max} (Nujol) 3350(OH), 1647 (olefin), 880 with overtone at 1760 cm^{-1} (exocyclic CH_2); n.m.r. δ 1.77 (s, 3H, vinylic CH_3), 4.15 (m, $w_{1/2}$ = 20 Hz, 1H, H—C—OH), 4.50 and 4.62 (singlets, 1H each, exocyclic CH_2), 5.57 (s, 1H, vinylic proton).

This compound was separated from authentic khusinol and from the dienol **12** by t.l.c. on silica gel with chloroform as solvent.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.56; H, 11.20.

We are grateful to the National Research Council of Canada for a grant in aid of this work. Also, we thank Dr. K. K. Chakravarti, National Chemical Laboratory, Poona, India, for a sample of khusinol.

Synthesis of 8,3′-Thioanhydroguanosine[1]

KELVIN K. OGILVIE, LEWIS A. SLOTIN,[2] DENIS C. K. LIN, AND JOHN B. WESTMORE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 23, 1972

The synthesis of 8,3′-thioanhydroguanosine is described. The anhydro ring is formed by displacement of bromine from position-8 and methanesulfonate from the 3′-position using thiourea in refluxing *n*-butanol. The 8,3′-thioanhydroguanosine is converted by Raney nickel reduction to 3′-deoxyguanosine, an analogue of cordycepin.

La synthèse du 8,3′-thioanhydroguanosine est décrite. Le cycle anhydro est formé par déplacement du brome de la position-8 et du méthanesulfonate de la position-3′, en utilisant la thiourée dans le *n*-butanol à reflux. Le 8,3′-thioanhydroguanosine est transformé en 3′-déoxyguanosine, un analogue de la cordycépine, par réduction au nickel de Raney. [Traduit par le journal]

Introduction

Anhydronucleosides are important modifications of natural nucleosides. They are easily converted into either the natural ribo or sugar modified nucleosides (1, 2) and have provided an attractive synthetic route to nucleotides, particularly arabinonucleotides (3–5). Recently a thioanhydropurine nucleoside has been used in studies on enzyme specificity (6).

While several papers have recently appeared which present general methods (7–9) for the synthesis of 8,2′-anhydropurine nucleosides, there is still no simple general route to the 8,3′-anhydropurines. Indeed adenosine is the only purine nucleoside for which 8,3′-anhydroderivatives have been described (2, 10). We wish to report the synthesis of 8,3′-thioanhydroguanosine which is readily converted into 3′-deoxyguanosine, an analogue of cordycepin.

Results and Discussion

The synthesis of 8,3′-thioanhydroguanosine is outlined in Scheme 1. N^2-Dimethylaminomethylene-8-bromoguanosine (**1**, 11) was treated with excess trityl chloride at elevated temperatures (12) to produce 2′,5′-di-*O*-trityl-N^2-dimethylaminomethylene-8-bromoguanosine (**2**) in 74% yield. This product was treated with methanesulfonyl chloride in pyridine to introduce the sulfonate group on the 3′-position. Because we anticipated that the N^2- and $O^{2',5'}$-protecting groups would be at least partially hydrolyzed during the step to form the anhydrolinkage, these groups were hydrolyzed directly using hydrazine hydrate solution followed by acetic acid to yield 3′-*O*-methanesulfonyl-8-bromoguanosine (**3**).

The anhydrolinkage was formed by treating **3** with thiourea in refluxing *n*-butanol producing 8,3′-thioanhydroguanosine (**4**) in 37% yield. Compound **4** was identified by mass spectral analysis[3] including a high resolution mass spectrum, of its silylated derivative. Compound **4** was converted to 3′-deoxyguanosine (**5**, 13) using Raney nickel.

Compound **5** was further characterized by acidic hydrolysis (19) to 3-deoxyribose which showed a negative Dische test (16) but positive cysteine (17) and aniline (18) tests. 3′-Deoxyguanosine (3′-dG) has very similar properties (λ_{max} (H_2O) 254 nm 270 (sh) nm, M^+ of the tetrasilyl derivative = 555) to 2′-deoxyguanosine (2′-dG) except for paper chromatography in solvent A where 3′-dG has $R_f = 0.24$ while 2′-dG has $R_f = 0.32$.

3′-Deoxyguanosine is the guanosine analogue of cordycepin, an antibiotic first isolated by Cunningham in 1951 (20). Cordycepin is converted metabolically to the triphosphate which inhibits purine biosynthesis and RNA synthesis (21).

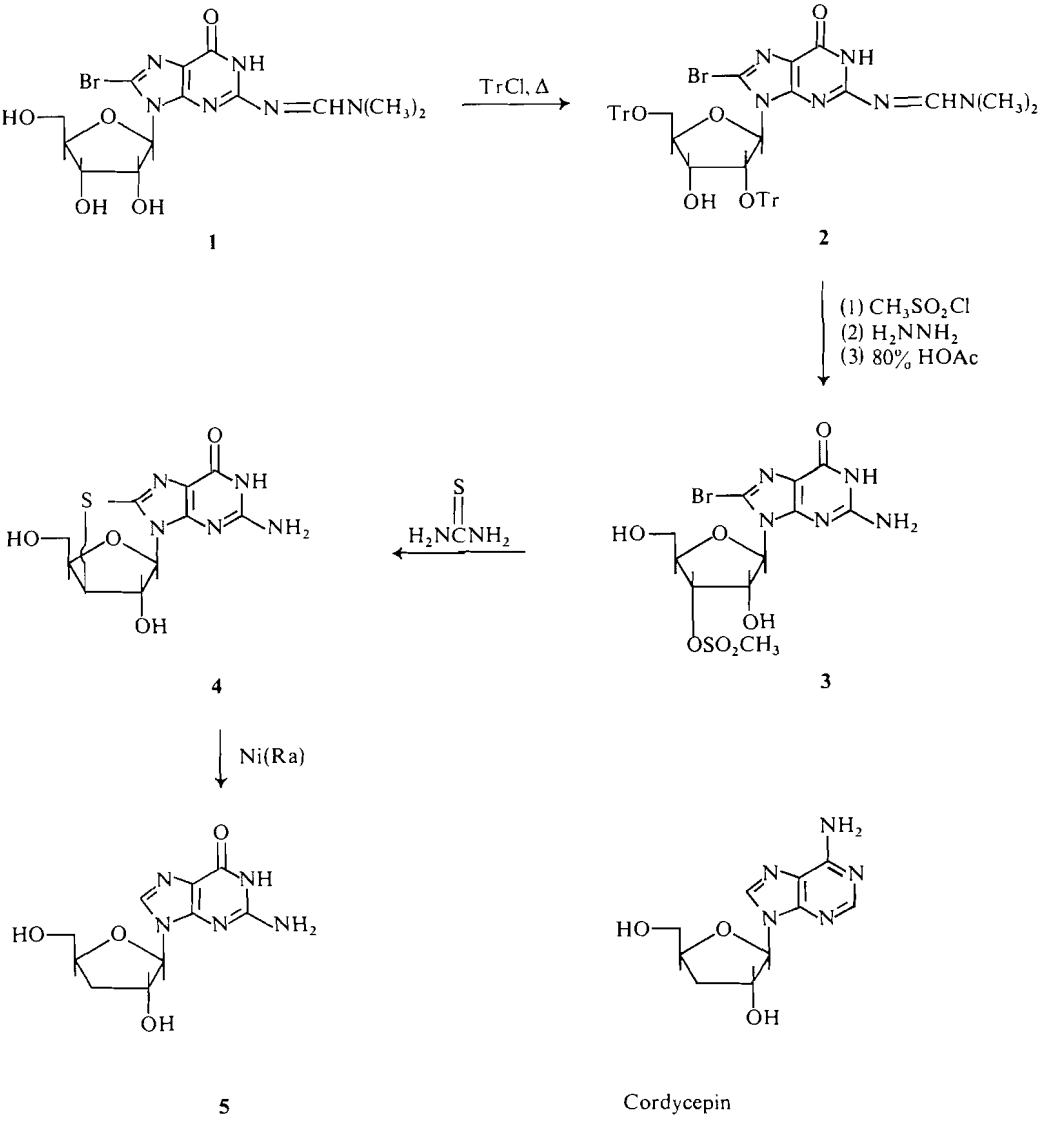
[3]A detailed mass spectral analysis of thioanhydropurines will be reported shortly (14), see also Ikehara and coworkers (15).



SCHEME 1

Experimental

General Methods

Descending paper chromatography was carried out on Whatman 3MM paper. The solvent systems employed were: solvent A, isopropyl alcohol–concentrated ammonium hydroxide–water (7:1:2); solvent B, ethanol–water (7:3). The solvents were prepared on a volume basis. Thin-layer chromatography was carried out employing the ascending technique. All thin-layer chromatography was run on Eastman Chromagram Sheets 6060 (silica gel with fluorescent indicator) on strips 10 × 2 cm. Thick-layer chromatography was carried out on glass plates (20 × 20 cm) coated with a 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd.). Nucleosides and their derivatives were detected on paper chromatograms, thin- and thick-layer plates, using a u.v. source (Mineralite output 254 nm). Compounds containing trityl groups were detected on chromatography by spraying with 10% perchloric acid solution and drying them in a stream of warm air.

I.r. spectra were obtained on a Perkin–Elmer 337 recording spectrophotometer using KBr disks for sample preparation. U.v. spectra were obtained on a Cary Model 14 recording spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6D instrument. High resolution mass spectra were obtained on an AEI MS-9 high resolution mass

spectrometer. Melting points were determined on a Fisher–Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee. Samples submitted to them were prepared by crystallization, lyophilization, or precipitation from tetrahydrofuran with hexane followed by heating in a drying apparatus over P_2O_5.

Reagent grade pyridine was distilled from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over Linde Molecular Sieve. Reagent grade *N,N*-dimethylformamide (DMF) was dried by distillation from calcium hydride and stored over Linde Molecular Sieve.

*2′,5′-Di-O-trityl-N^2-dimethylaminomethylene-8-bromoguanosine (**2**)*

N^2-Dimethylaminomethylene-8-bromoguanosine (11, 1.95 g, 4.6 mmol) and trityl chloride (3.96 g, 13.95 mmol) were stirred at room temperature in pyridine (25 ml) for 72 h followed by heating at 100 °C for 0.5 h. The solution was cooled and poured into an ice-water (1 l) mixture. The resulting precipitate was collected by filtration, dissolved in chloroform, and dried over sodium sulfate. The solution was collected by filtration and concentrated to a small volume at reduced pressure. Upon addition of hexane the product precipitated as a white solid which was collected and dried (3.5 g, 74%, m.p. 151–153 °C, R_f (THF) 0.60). The u.v. spectrum (95% ethanol) showed λ_{max} at 309 (ε 23 800) and 233 (ε 25 600) with a shoulder at 284 nm (ε 23 100). Prominent bands in the i.r. spectrum occurred at 14.2 (trityl) and 6.5 μ.

Anal. Calcd. for $C_{51}H_{45}N_6O_5Br$: C, 67.92; H, 5.03; Br, 8.86. Found: C, 67.78; H, 4.80; Br, 8.84.

2′,5′-Di-O-trityl-3′-O-methanesulfonyl-N^2-dimethylaminomethylene-8-bromoguanosine and 2′,5′-Di-O-trityl-3′-O-methanesulfonyl-8-bromoguanosine

Compound **2** (3.5 g, 3.88 mmol) was dissolved in pyridine (20 ml) and the solution was cooled to 0 °C. Methanesulfonyl chloride (4 mmol) was added and the solution was kept at 0 °C for 24 h. An additional 4 mmol of methanesulfonyl chloride was added and stirring was continued for a further 24 h at 0 °C. The solution was poured into an ice-water mixture, the precipitate was collected by filtration, dissolved in chloroform, and the resulting solution was dried over sodium sulfate. The chloroform solution was collected by filtration, concentrated to a small volume, and applied to 15 t.l.c. plates which were developed three times in ether. The band at R_f 0.30 was eluted with tetrahydrofuran (THF), the solution was concentrated, and on addition of hexane the product precipitated as a white solid (3 g, 79%), m.p. 144–145 °C. The u.v. spectrum (95% ethanol) showed λ_{max} at 312, 284.5 and 232 nm. The i.r. spectrum showed prominent peaks at 14.2 (trityl) and 8.5 μ (covalent sulfonate).

Without further purification 2 g of this product was dissolved in hydrazine hydrate – acetic acid – water (1:6:24, 10 ml) and the solution was stirred at room temperature for 48 h. The solution was poured into ice-water and the resulting precipitate was collected and dried to yield 1.55 g (85%) of 2′,5′-di-*O*-trityl-3′-*O*-methanesulfonyl-8-bromoguanosine, m.p. >169 °C (dec.); R_f (THF) 0.68. The product showed prominent peaks in the i.r. at 14.2 and 8.5 μ. The u.v. spectrum (95% ethanol) showed λ_{max} at 266 (ε 15 300) with shoulders at 233 (ε 23 600) and 274 nm (ε 13 180).

Anal. Calcd. for $C_{49}H_{42}N_5O_7BrS$: C, 63.63; H, 4.58; Br, 8.64. Found: C, 63.62; H, 4.45; Br, 8.40.

*3′-O-Methanesulfonyl-8-bromoguanosine (**3**)*

2′,5′-Di-*O*-trityl-3′-*O*-methanesulfonyl-8-bromoguanosine (1 g, 1.08 mmol) was dissolved in 80% acetic acid (7 ml) and heated on a steam bath for 15 min. The solution was poured into ice-water and the resulting precipitate was collected, dried, and crystallized from ethanol to give 390 mg (83%) of **3**, m.p. >187 °C (dec.); R_f (A) 0.47, R_f (B) 0.75. The u.v. spectrum (95% ethanol) showed λ_{max} at 261.5 (ε 14 100) and a shoulder at 270 nm (ε 12 500). A peak at 8.5 μ in the i.r. spectrum showed the presence of covalent sulfonate.

Anal. Calcd. for $C_{11}H_{14}N_5O_7BrS$: C, 30.01; H, 3.21. Found: C, 30.11; H, 3.29.

*8,3′-Thioanhydroguanosine (**4**)*

Compound **3** (51 mg, 0.116 mmol) and thiourea (18 mg, 0.23 mmol) were added to *n*-butanol (4 ml) and the solution was heated at reflux for 5 h. The solvent was removed at reduced pressure and the residue was dissolved in DMF–NH_4OH (1:1, 2 ml) and applied to Whatman 3MM paper which was developed in solvent A. The band at R_f (A) 0.32 was eluted with water and lyophilized to yield 13 mg (37%) of **4**, m.p. > 183 °C (dec.); R_f (A) 0.32, R_f (B) 0.58, R_f (EtOH) 0.45. The u.v. spectrum in water showed λ_{max} at 272 (ε 14 410) with a shoulder at 283 nm (ε 10 730).

Mol. Wt. Calcd. for $C_{10}H_7N_5O_4S \cdot 4TMS$: 585.2113. Found: 585.2122.

*3′-Deoxyguanosine (**5**)*

Compound **4** (25 mg, 0.084 mmol) was dissolved in hot water (2 ml) and after addition of a spoonful of Raney nickel the mixture was heated at reflux for 3 h. The mixture was filtered and the clear filtrate was applied to Whatman 3MM paper which was developed in solvent A. The band at R_f (A) 0.24 was eluted with water and lyophilized to yield 4 mg (18%) of 3′-deoxyguanosine (13) m.p. >198 °C (dec.). The mass spectrum of the tetrasilyl derivative showed a parent peak at *m/e* 555. On paper chromatography the product had R_f (A) 0.24 and R_f (B) 0.61 while 2′-deoxyguanosine had R_f (A) 0.32 and R_f (B) 0.61. The u.v. spectrum of compound **5** showed λ_{max} (H_2O) at 253 (ε 13 100) and 270 nm (ε 8900).

3′-Deoxyguanosine was further identified by hydrolysis (19) to 3′-deoxyribose which gave a negative Dische test (16) but positive cysteine (17) and aniline (18) tests.

We wish to acknowledge financial assistance from the National Research Council of Canada. The generous assistance of Dr. A. M. Hogg and Mr. T. Budd of the University of Alberta in obtaining the high resolution mass spectra is gratefully acknowledged.

The Triterpenes of *Lycopodium lucidulum* Michx.

K. ORITO, R. H. MANSKE, AND R. RODRIGO
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 10, 1972

Nine known serratane triterpenoids have been isolated from *Lycopodium lucidulum* Michx. mostly as their acetates. Serratenediol is the major one and is accompanied by significant amounts of serratriol. Moderate quantities of serratenediol-3-acetate, tohogenol, and episerratenediol were present together with minor amounts of 16-oxoserratriol, tohogeninol, and the phlegmanols A and E.

Neuf triterpènoides connus de la série serratane ont été isolés à partir du *Lycopodium lucidulum* Michx, la plupart sous forme d'acétates. Le serratenediol, composé majeur, est accompagné d'une quantité importante de serratriol. De quantités moyennes de serratènediolacétate-3, tohogenol, et épiserratenediol sont présentes en plus de petites quantités d'oxo-16 serratriol, tohogeninol, et phlegmanols A et E.

The elucidation of the structure of serratenediol (**1**) a pentacyclic triterpene from *Lycopodium serratum* was reported by Inubushi *et al.* (1, 14) in 1964. Subsequently intense activity in this field by various research groups has resulted in the discovery of a whole series of such triterpenes having the common structural feature—a seven-membered ring-C. These have been isolated from *Lycopodium serratum* (2–4), *L. clavatum* (2, 4–6), *L. phlegmaria* (7), *L. cernuum*, and *L. inundatum* (8). They have also been found in a fern (9) and in the bark of species of pine (10) and spruce (11). A comprehensive mass-spectrometric study of the group has also been made (13).

We now report the results of our study of the neutral triterpenes of *L. lucidulum* collected in Ontario. While this work was in progress the structure of a phenolic diterpene from the same source was determined (15).

Isolation

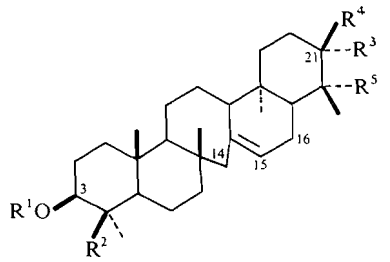
The non basic fraction of the methanolic extract of dried plant material was saponified and acetylated and the resulting crystalline mixture of acetates separated essentially by chromatographic techniques.

In another procedure the non-basic material was extracted without prior saponification and the products separated as before.

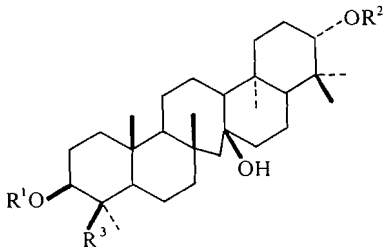
*Serratenediol (**1**), Serratenediol Diacetate (**2**), Serratenediol-3-acetate (**3**), 21-Episerratenediol Diacetate (**4**), Serratriol Triacetate (**5**), and 16-Oxoserratriol Triacetate (**6**)*

The identities of **1**, **2**, **4**, **5**, and **6** were established by direct comparison with authentic specimens (t.l.c., i.r., and mass spectra) (2, 3, 4, 6*b*, 10, 12).

Serratenediol-3-acetate (**3**) had the expected properties and its identity was confirmed by oxidation to 3β-acetoxy-14-serraten-21-one (**8**) (12) which was hydrolyzed to 3β-hydroxy-14-serraten-21-one (serrateneolone) (**7**) (10).



1 Serratenediol ($R^1 = R^4 = H$; $R^2 = R^5 = Me$; $R^3 = OH$)
2 Serratenediol diacetate ($R^1 = Ac$; $R^2 = R^5 = Me$; $R^3 = OAc$; $R^4 = H$)
3 Serratenediol-3-acetate ($R^1 = Ac$; $R^2 = R^5 = Me$; $R^3 = OH$; $R^4 = H$)
4 21-Episerratenediol diacetate ($R^1 = Ac$; $R^2 = R^5 = Me$; $R^3 = H$; $R^4 = OAc$)
5 Serratriol triacetate ($R^1 = Ac$; $R^2 = CH_2OAc$; $R^3 = OAc$; $R^4 = H$; $R^5 = Me$)
6 16-Oxoserratriol triacetate (**5** plus 16=O)
7 3β-Hydroxy-14-serraten-21-one ($R^1 = H$; $R^2 = R^5 = Me$; $R^3 + R^4 = O$=)
8 3β-Acetoxy-14-serraten-21-one ($R^1 = Ac$; $R^2 = R^5 = Me$; $R^3 + R^4 = O$=)
9 Phlegmanol E diacetate ($R^1 = Ac$; $R^2 = Me$; $R^3 = H$; $R^4 = OAc$; $R^5 = CH_2OH$)
10 Phlegmanol E triacetate ($R^1 = Ac$; $R^2 = Me$; $R^3 = H$; $R^4 = OAc$; $R^5 = CH_2OAc$)
11 Phlegmanol A triacetate ($R^1 = CO(CH_2)_2C_6H_3$-3, 4-$(OAc)_2$; $R^2 = R^5 = Me$; $R^3 = OAc$; $R^4 = H$)



12 Tohogenol ($R^1 = R^2 = H$; $R^3 = Me$)
13 Tohogenol diacetate ($R^1 = R^2 = Ac$; $R^3 = Me$)
14 Tohogeninol triacetate ($R^1 = R^2 = Ac$; $R^3 = CH_2OAc$)

Tohogenol Diacetate (13) and Tohogeninol Triacetate (14)

Tohogenol diacetate (**13**) had a p.m.r. spectrum identical with that already published (3) and showed in its i.r. spectrum the presence of hydroxyl and acetate groups. (ν_{max} (Nujol) 3600, 1730 and 1250 cm^{-1}). Contrary to the earlier report we have found that the compound does display a molecular ion (*m/e* 544, 93%), in its mass spectrum (280 °C) in addition to the fragments characteristic of serratenediol diacetate. The identity of this compound was confirmed by hydrolysis to tohogenol (**12**) and by dehydration (3) to serratenediol diacetate (**2**) identical with an authentic sample.

Tohogeninol triacetate (**14**) was isolated pure in very small quantity after several recrystallizations. However, an impure sample was dehydrated (3) to serratriol triacetate (**5**) identical with an authentic specimen.

Phlegmanol E Diacetate (9) and Phlegmanol A Triacetate (11)

Phlegmanol E diacetate (**9**) had identical spectral properties with those already published (7*b*) and upon acetylation gave phlegmanol E triacetate (**10**), again possessing the expected properties.

Phlegmanol A triacetate (**11**) had properties consistent with its structure (7) and its identity was confirmed by conversion to serratenediol (**1**) and dihydrocaffeic acid dimethyl ether by the published procedure (7).

Experimental

Melting points were determined using a Fischer Meltemp apparatus and are uncorrected. Melting points in parentheses were determined *in vacuo* and are corrected. I.r. spectra were recorded on a Beckmann I.R. 10 spectrometer, samples being dissolved in chloroform or dispersed in Nujol. P.m.r. spectra were determined in deuterochloroform using added TMS on a Varian T-60 instrument. Mass spectra were recorded on a Perkin-Elmer Hitachi RMU-6E spectrometer.

Isolation of the Triterpenoids from L. lucidulum

The dried plant material was extracted with methanol and most of the solvent removed. The residue was acidified with dilute hydrochloric acid and the remaining methanol removed in a current of steam. The water insoluble portion was separated by filtration and washed until the filtrate was colorless and neutral to test paper. The yield was approximately 5% of the dried plant material.

Separation of the Constituents

A suspension of the above material (20 g) was heated under reflux with 5% methanolic potassium hydroxide (200 ml) for 7 h and filtered. The residue was washed, dried, and acetylated with acetic anhydride–pyridine to yield a crystalline product, A (11 g). The filtrate was concentrated and diluted with water (300 ml). The resulting brown precipitate was washed, dried, and similarly acetylated to give another crystalline product, B (3.2 g).

Serratenediol diacetate (2), 21-Episerratenediol Diacetate (4), and Serratriol Triacetate (5)

Product A was dissolved in benzene and chromatographed on neutral alumina (220 g). Elution of the column with benzene gave first a fraction containing **2** (3.9 g), crystallized from chloroform–methanol, m.p. 341–343° (349–350°) (12), followed by a second fraction (**5**) (1.6 g), crystallized from benzene–hexane, m.p. 248–250° (265–266°) (2).

The filtrate from the crystallization of **2** was freed of solvents and the residue upon repeated fractional crystallization from *n*-hexane yielded **4** (92 mg), m.p. 225–228° (228–230°) (3, 6*b*, 10) and **2** (207 mg).

Tohogenol Diacetate (13)

The crystalline product, B, dissolved in benzene was chromatographed as before (neutral alumina, 65 g) to yield **2** (363 mg) and **4** (49 mg) in the first eluates, followed by **13** (443 mg) which was crystallized from benzene–hexane, m.p. 312–313° (330–331°) (3).

Phlegmanol E Diacetate (9), Tohogeninol Triacetate (14), and 16-Oxoserratriol Triacetate (6)

The slower moving fractions from the chromatography of products A and B were eluted with benzene–ether and the combined eluates examined by preparative t.l.c. on silica hexane–benzene–ether (3:3:1). A product of R_f 0.31 appeared to be a mixture of **6** and **14** in the ratio 2:3, as estimated by p.m.r. The mixture was dehydrated and reacetylated (3) to yield a product from which it was possible to isolate, by means of t.l.c. in the same system **6** (12 mg), R_f 0.31, m.p. 313–315° (320–324°) (4), and **5**, (16 mg), R_f 0.43.

Tohogeninol triacetate (**14**), (8 mg), m.p. 263–264° (3), was isolated from another preparation of the initial mixture by repeated crystallization from chloroform–methanol.

A further fraction (R_f 0.4) was also recovered from the silica plates and this, when crystallized from benzene–hexane (37 mg), m.p. 254–256° (267–268°) was identified as **9**.

Serratenediol-3-acetate (3) and Phlegmanol A Triacetate (11)

The crude neutral material (20 g) was extracted without prior saponification in a Soxhlet apparatus, successively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with ether, chloroform, and chloroform–methanol (4:1). The ether extract (2.5 g) was purified by preliminary chromatography on silica (100 g) followed by t.l.c. on silica plates as before. The faster moving fraction, crystallized from benzene–hexane (510 mg), m.p. 323–324° (335–338°), was identified as **3** (*7b*). The slower moving fraction was identified as **1**, m.p. 293–295° (302–303°) (12).

The chloroform and chloroform–methanol fractions were combined and acetylated and the product (8.7 g) chromatographed in benzene on a column of silica (200 g). The first eluates consisted of **2** (0.67 g) and **5** (0.91 g). The later fractions, with benzene–ether, were collected and purified by t.l.c. on silica plates as before and the major slow moving constituent recovered and crystallized from chloroform–methanol to yield **11** (62 mg), m.p. 297–299° (299–300°) (7).

We wish to thank Dr. D. B. MacLean of McMaster University for mass spectra of several compounds isolated in this work and Dr. Y. Tsuda of the Showa College of Pharmaceutical Sciences, Tokyo for a generous gift of sample triterpenes. Financial support from the National Research Council of Canada is gratefully acknowledged.

A General Relation Between H_0, Acid Concentration, and Water Activity for Strong Acids at Moderate Concentrations

T. T. TENG AND F. LENZI

Département de Génie chimique, École Polytechnique, Université de Montréal, Montréal, Québec

Received January 28, 1972

Values of the Hammett acidity function H_0 can be correlated for strong acid solutions up to $-H_0$ values of 3.5 via a Bascombe and Bell type equation: $-H_0 = \log (C_{H^+}/a^3_{H_2O}) + AC_{H^+}$ taking into account the degree of dissociation of the acids. This can be interpreted according to

$$H_3O^+.3H_2O \rightleftarrows H_3O^+ + 3H_2O$$

and

$$B + H_3O^+ \rightleftarrows BH_3O^+$$

Alternatively, an approach based on the treatment of equilibrium constants in terms of mole-fractions yields

$$-H_0 = 1.46 \log \frac{C^+_H}{a^3_{H_2O}} + 0.148$$

valid for the same acids (H_2SO_4, $HClO_4$, HCl, and HNO_3) and again involving a tri-dehydration of the tetra-hydrated proton. The log of the ratio $(f_{H^+hydr.} Y_{Bhydr.})/(Y_{BH^+hydr.})$ has been found to be proportional to $-H_0$ itself and to be otherwise independent of the nature of the acid anion.

On peut établir la corrélation des valeurs de la fonction d'acidité de Hammett, soit H_0, pour des solutions d'acides forts allant jusqu'à des valeurs de $-H_0$ de 3.5, au moyen d'une équation de type Bascombe et Bell: $-H_0 = \log (C_{H^+}/a^3_{H_2O}) + AC_{H^+}$, tout en tenant compte du degré de dissociation des acides. On peut interpréter ces résultats en se basant sur les équations:

$$H_3O^+.3H_2O \rightleftarrows H_3O^+ + 3H_2O$$

$$B + H_3O^+ \rightleftarrows BH_3O^+$$

D'autre part, une approche basée sur le traitement des constantes d'équilibre en termes de fractions molaires nous donne

$$-H_0 = 1.46 \log \frac{C_{H^+}}{a^3_{H_2O}} + 0.148$$

qui est valide pour les mêmes acides (H_2SO_4, $HClO_4$, HCl, et HNO_3) et qui implique une tridéshydratation du proton tétrahydraté. On découvre que le logarithme du rapport $f_{H^+hydr.} Y_{Bhydr.}/Y_{BH^+hydr.}$ est proportionnel à $-H_0$ et indépendant de la nature de l'anion de l'acide.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3283 (1972)

Introduction

Bascombe and Bell (1) suggested that the rapid rise of effective acidity with increasing concentration of stoichiometric acid in aqueous acid solutions is mainly due to proton hydration. They re-wrote Hammett and Deyrup's (2) equilibrium

$$B + H^+ \rightleftarrows BH^+$$

in the form

$$B + H^+ mH_2O \rightleftarrows BH^+ + mH_2O$$

finding that a value of $m = 4$ fitted the experimental H_0 data for HCl, HBr, $HClO_4$, and H_2SO_4 acid solutions up to 8 *M*. Bascombe and Bell assumed that the hydration of B, BH^+, and the acid anions could be ignored, and that the molar activity coefficients $f_{H^+ mH_2O}$ and f_{BH^+} or f_B and $f^m_{H_2O}$ were approximately equal.

Bascombe and Bell themselves pointed out the approximate nature of their treatment, which has also been criticized elsewhere (3, 28). Although neglect of anionic hydration is probably reasonable[1] (4), the hydration of both B and BH^+ cannot necessarily be neglected *a priori*.

[1]Wyatt (5) and Yates and Wai (13) have shown that H_0 is a common function of the water activity, a_{H_2O}, for H_2SO_4, HCl, $HClO_4$, and HNO_3; this suggests that differential anionic hydration effects would only appear as a_{H_2O} differences.

For personal use only.

The conjugate acid of the base BH^+ has been found to be mono- or di-hydrated (6); the acidity phenomenon should be more realistically attributed to the hydration difference between H^+ and B on the one hand, and BH^+ on the other (7, 8). In addition strong acids, even at moderate concentrations, cannot be considered as being necessarily completely dissociated (9).

A more general approach (10) gives

[1] $$H^+ mH_2O \overset{K_1}{\rightleftharpoons} H^+(m-n)H_2O + nH_2O$$

[2] $$BtH_2O + H^+(m-n)H_2O \overset{K_2}{\rightleftharpoons} BH^+(m-n-p)H_2O + (t+p)H_2O$$

where m is the average proton hydration.

While it is over-optimistic to assume that unique values of m and $(m-n)$ define the proton hydrates present, it may well be that there is a preponderance of a more hydrated proton species $H^+ mH_2O$ over an appreciable concentration range, and that a less or least hydrated species $H^+(m-n)H_2O$ would be much more reactive than species intermediate between $H^+ mH_2O$ and $H^+(m-n)H_2O$.

It is asserted that K_1 is sufficiently small such that up to moderate acid concentrations most of the hydrated protons will be in the m rather than the $(m-n)$ hydrated form, thus allowing the approximation $C_{H^+} \equiv C_{H^+ mH_2O} \simeq \alpha C_{\text{stoichiometric}}$ where α is the degree of dissociation, $C_{\text{stoichiometric}}$ is the experimental concentration of the acid, and C_{H^+} represents $C_{H^+ mH_2O}$.

Experimental Data Selection

H_0 values were taken from (10–15), those of a_{H_2O} from (10, 16–18, 21, 22) or calculated from density (19) and osmotic coefficient (20) data. Values of α_{HClO_4} were obtained from ref. 23, while those of α_{HNO_3} and α_{HCl} were taken from refs. 24 and 25. As advocated by Edward (26), actual hydrogen-ion concentrations (27) were used for H_2SO_4. The conversion between these and stoichiometric acid concentrations at 25 °C was that of Robertson and Dunford (18).

Modified Bascombe and Bell Treatment

Equilibria 1 and 2 can be combined to give

[3] $$BtH_2O + H^+ mH_2O \overset{K'}{\rightleftarrows} BH^+ kH_2O + hH_2O$$

where $h = t + n + p$ and $k = m - n - p$. Equilibrium 3 has previously been proposed by Edward (26). From [3],

$$K' = \frac{1}{K} = a_{BH^+ kH_2O} a^h_{H_2O} / a_{BtH_2O} a_{H^+ mH_2O}$$

and

$$pK = \log \frac{C_{BH^+ kH_2O} a^h_{H_2O}}{C_{BtH_2O} C_{H^+}} \cdot \frac{f_{BH^+ kH_2O}}{f_{BtH_2O} f_{H^+}}$$

where the a's are activities, C's are concentrations in mol/l, f's are molar activity coefficients and f_{H^+} represents $f_{H^+ mH_2O}$.

Defining H_0 in the usual way

$$H_0 \equiv pK - \log \frac{C_{BH^+ kH_2O}}{C_{BtH_2O}} = -\log \frac{C_{H^+}}{a^h_{H_2O}} \cdot \frac{f_{BtH_2O} f_{H^+}}{f_{BH^+ kH_2O}}$$

whence

[4] $$-H_0 - \log C_{H^+} + h \log a_{H_2O} = \log f_{BtH_2O} + \log f_{H^+} - \log f_{BH^+ kH_2O}$$

The terms on the right of eq. 4 represent the salt effects of the species BtH_2O, $H^+ mH_2O$ and $BH^+ kH_2O$, respectively, giving eq. 5

[5] $$-H_0 - \log C_{H^+} + h \log a_{H_2O} = AC_{H^+}$$

where A is the combined salting-in or salting-out coefficient. Equation 5 has the Bascombe and Bell form, but with h representing $(t+n+p)$ and C_{H^+} standing for the actual hydrated proton concentration. A similar equation has been developed by Dawber (29).

Calculations

Equation 5 has been applied to the actual data originally (1) used for H_2SO_4, $HClO_4$, and HCl. A value of $h \simeq 3$, as opposed to Bascombe and Bell's value of $h \simeq 4$, gives the best fit (least squares) while still leading to reasonable values of "A". H_0 values for $HClO_4$ (13) and H_2SO_4 (14) have been redetermined recently. Equation 5 has been applied to these values as well as H_0 data for HNO_3 (15) and HCl (10, 11) and similar calculations have been made for different H_0 ranges for all the sets of H_0 data of the four acids.

These calculations show that at low acidity ($-H_0 < 1.5$), optimal h values tend to increase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with decreasing acid concentration. For intermediate $-H_0$ ranges ($\simeq 1.5$ to 3.5) optimal values of h lie between 2.25 and 3.6, while for $-H_0$ values >3.5 the optimal values of h tend to decrease except for HNO_3.[2]

The results in refs. 10 and 30 confirm this general trend in the case of $HClO_4$ and HCl.

A common value of $h \simeq 3$ gives a good fit for all the data of all the acids up to $-H_0 = 3.5$.

Mole Fraction Treatment

Equilibrium 3 can be expressed in terms of mole-fractions, N_{species}, and rational activity coefficients, Y_{species}:

$$[6] \quad K_x = \frac{N_{BH^+ kH_2O} N^h_{H_2O}}{N_{BtH_2O} N_{H^+ mH_2O}} \cdot \frac{Y_{BH^+ kH_2O} Y^h_{H_2O}}{Y_{BtH_2O} Y_{H^+ mH_2O}}$$

Substituting (moles of species/total number of moles) for $N_{BH^+ kH_2O}$ and N_{BtH_2O}, a_{H_2O} for $N_{H_2O} \cdot Y_{H_2O}$, $C_{H^+ mH_2O} f_{H^+ mH_2O} / Y_{H^+ mH_2O}$ for $N_{H^+ mH_2O}$, and considering 1 liter of solution, yields

$$[7] \quad K_x = \frac{a^h_{H_2O} C_{BH^+ kH_2O}}{C_{BtH_2O} C_{H^+ mH_2O}} \cdot \frac{Y_{BH^+ kH_2O}}{Y_{BtH_2O} f_{H^+ mH_2O}}$$

where C_{species} is in mol/l of species.

Defining

$$-H_0 \equiv \text{p}\left(\frac{1}{K_x}\right) + \log \frac{C_{BH^+ kH_2O}}{C_{BtH_2O}}$$

$$[8] \quad -H_0 = -H_p + \log \frac{f_{H^+ mH_2O} Y_{BtH_2O}}{Y_{BH^+ kH_2O}},$$

where

$$H_p = -\log \frac{C_{H^+ mH_2O}}{a^h_{H_2O}}$$

Calculation

Plots of $-H_0$ against $-H_p$ have been prepared for the more recent data for $HClO_4$, H_2SO_4, as well as for HNO_3 and HCl using different values of h in the calculation of H_p. For small whole number values of h the points for the different acids lie on a common plot which is approximately linear up to moderately high acidities and passes close to the origin. Such a plot is shown in Fig. 1 for the value $h = 3$ which gives the least deviation up to an acidity of $H_0 = -3.5$.

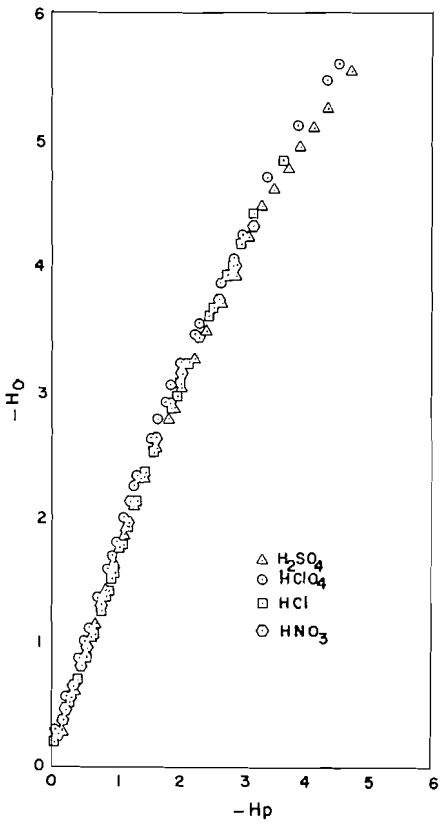

FIG. 1. Plot of $-H_0$ against $-H_p$ for $h = 3$ for the four acids. The "old" data for H_2SO_4 and $HClO_4$ (11) are not shown here to avoid over-cluttering: in fact they show no significant difference from the newer data on this plot.

The plot in Fig. 1 can be represented by

$$[8a] \quad -H_0 = -1.46H_p + 0.148.$$

Values of $-H_0$ calculated via [8*a*] compare with observed values to an average of 0.08, 0.08, 0.07, and 0.05 in H_0 units for H_2SO_4, $HClO_4$, HCl, and HNO_3 respectively. Equation 8*a* is equivalent to

$$[8b] \quad -H_0 = -H_p + (-0.46H_p + 0.148)$$

implying that the second term on the right of eq. 8 is proportional to H_p (or H_0) but is largely independent of the nature of the acid anion.

Table 1 lists the optimal h values for different $-H_0$ ranges for the four acids. Diminishing

[2]This may be due to uncertainties in the degree of dissociation which would affect eq. 5 in both the $\log C_{H^+}$ and the AC_{H^+} terms. As will be seen in Fig. 1 the behavior of HNO_3 is in accord with that of the other acids; this is possibly due to the absence of an AC_{H^+} term in eq. 8*a*.

TABLE 1. Testing of eq. 8 for optimum h for different $-H_0$ ranges for H_2SO_4, $HClO_4$, HCl, and HNO_3

Upper value of $-H_0$ range	Best fit h	Standard deviation for the straight line	Slope of the straight line	Intercept of the line	Standard deviation for $h = 3$
3.99	2.25	0.1131	1.67	0.118	0.1198
3.69	2.50	0.1078	1.59	0.131	0.1105
3.45	3.00	0.0967	1.46	0.148	0.0967
3.04	3.00	0.0930	1.48	0.134	0.0930
2.86	3.25	0.0883	1.42	0.141	0.0885
2.62	3.75	0.0809	1.35	0.138	0.0832
2.32	4.00	0.0777	1.32	0.129	0.0821
2.07	4.00	0.0757	1.32	0.128	0.0784
1.90	4.25	0.0756	1.29	0.132	0.0778
1.75	4.25	0.0731	1.30	0.123	0.0766

values of optimal h with increasing acidity is in accord with some of the results of the modified Bell and Bascombe treatment given above. The fifth column of Table 1 shows that the intercept (or additive constant of value 0.148 in [8*a*]) tends to diminish with decreasing acidity corresponding to the higher values of h. This satisfies the requirement that the additive constant should vanish for [8*a*] to hold in the limit of diminishing acidity, when $a_{H_2O} \rightarrow 1$ and $C_{H^+ mH_2O} \rightarrow 0$. Thus 0.148 can be interpreted as a term compensating for the imposed constancy in h.

The average dehydration h may indeed be higher at lower acidities; eq. 8 is, however, relatively insensitive to the value of h at low acidity when $a_{H_2O} \rightarrow 1$.

The results in Fig. 1 appear to establish an indicator-independent "acidity function", H_p, which is closely related to H_0 up to values of $-H_0 = 3.5$.

Conclusions

Both approaches lead to the result that $h \simeq 3$ gives reasonable correlation between experimental values of H_0, a_{H_2O}, and C_{H^+} up to $-H_0$ values of 3.5 (except for HNO_3 via [5]). At higher acidities a diminution in h, compatible with other data, is indicated. Equation 8*a* contains two empirical but acid-anion independent constants[3] as opposed to [5] which contains only one empirical constant, "A", which is, however, acid-anion dependent.

[3]Of which the additive constant is only important at relatively low acidities; its compensatory nature has been discussed.

Equation 3 can be rewritten as

$$BtH_2O + H^+ mH_2O \rightleftarrows BH^+ kH_2O + 3H_2O$$

Some anilines in the uncharged form have been found to be unhydrated (6), suggesting a value of $t = 0$. It has also been suggested that the conjugate acid of the indicator base may be monohydrated, indicating that $k = 1$ and thus $m = 4$, in accord with the evidence (31) pointing to the existence of the tetrahydrated proton, $H_9O_4^+$, at moderate acid concentrations.

Assuming that the reactive hydrated proton species is the monohydrate, *i.e.* $m - n = 1$, equilibria 1 and 2 can now be rewritten as

[1*a*] $$H_3O^+.3H_2O \rightleftarrows H_3O^+ + 3H_2O$$

[2*a*] $$B + H_3O^+ \rightleftarrows BH_3O^+$$

Equilibrium 1*a* is in fact a combination of hydration equilibria 2, 3, and 4 in the paper of Knewstubb and Tickner (32); [1*a*] has also been invoked in the interpretation of the kinetics of the chloride–chlorate reaction in moderately concentrated solutions of $HClO_4$ and H_2SO_4 (33).

The lower values of h at increasing acidity can be interpreted as a lowering of m, the average hydration number of the proton, while H_3O^+ would still be the reacting species, and conversely for the higher values of h at lower acidity.

The Pyrolysis of some Neopentyl Xanthates: a Competitive Formation of Olefins and Dithiolcarbonates

K. G. RUTHERFORD, B. K. TANG, L. K. M. LAM, AND D. P. C. FUNG[1]

Department of Chemistry, University of Windsor, Windsor, Ontario

Received April 28, 1972

A study of the pyrolysis of a series of neopentyl-type xanthate esters was carried out at 250 °C. The formation of olefins and dithiolcarbonates were found to be two competing processes. The olefin formation process became more important when the number of β-phenyl groups increased and when there was an electron donating group substituted at the para-position of the β-phenyl ring. Kinetics studies supported the proposal that the transition state of the olefin formation process involved a stabilized phenonium ion. However the dithiolcarbonate formation became more important when there was the least number of β-phenyl substituents and this rearrangement appeared to proceed through a concerted four-membered cyclic transition state.

Nous avons entrepris une étude de pyrolyse sur une série d'esters xanthates de type néopentyl à 250 °C. Nous trouvons que la formation d'oléfines et de dithiolcarbonates s'effectue selon deux processus compétitifs. Le processus de formation d'oléfines prend de l'importance lorsque le nombre de groupe β-phényl augmente et qu'un groupe donneur d'électrons est substitué en position para du cycle β-phényl. Les études cinétiques appuient la proposition que l'état de transition du procédé de formation d'oléfines implique un ion phénonium stabilisé. La formation de dithiolcarbonate prédomine lorsqu'il y a un nombre minimum de substituants β-phényl et ce réarrangement se produit en passant par un état de transition cyclique concerté impliquant quatre membres. Introduction

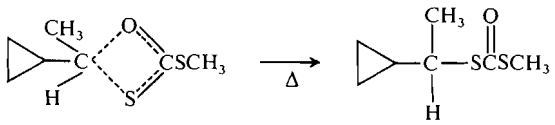
The formation of olefin(s) by the pyrolysis of xanthate esters is called the Chugaev reaction (for reviews, see ref. 1). The mechanism of this reaction has generally been agreed to involve a concerted six-membered cyclic transition state (2–5). However, other mechanisms have been proposed (6, 7).

A rather interesting side reaction observed in the pyrolysis of some *S*-methyl xanthate esters involves the formation of dithiolcarbonates. For example, in the pyrolysis of the xanthate ester of 1-cyclopropylethanol, Overberger and Borchert (8) reported yields of 45% of the olefins and 35% of the dithiolcarbonates, of which the major component was identified as 1-cyclopropylethyl dithiolcarbonate. A concerted four-membered cyclic transition state was suggested (Scheme 1).



SCHEME 1. A cyclic transition state proposed for the dithiolcarbonate formation from pyrolysis of 1-cyclopropylethyl xanthate.

Recently, this rearrangement reaction was studied by Taguchi and co-workers (9–11) who found that the pyrolysis of *trans*-2-dimethylaminocyclohexyl xanthate gave only the corresponding dithiolcarbonate while the *cis* isomer underwent the expected elimination. Participation by the neighboring amino group was suggested in an ion-pair transition state (Scheme 2).

In a study of the pyrolysis of some neopentyl xanthate esters, Laakso (12) reported no olefin formation whatsoever (Scheme 3).

The corresponding dithiolcarbonates were found in 70–80% yield. These results would appear to indicate that xanthate–dithiolcarbonate rearrangement is a true case of the classic cyclic S_Ni mechanism since one would surely expect in a neopentyl-type system at least some olefin formation would be observed from Wagner–Meerwein rearrangement (13) if an ion-pair intermediate was involved. A study was carried out to pyrolyze a series of neopentyl-type xanthates in order to investigate if Laakso's result was a general phenomenon.

Results and Discussion

Synthesis of Xanthates

A series of *S*-methyl xanthate esters of neopentyl-type alcohols were synthesized. All xanthates prepared shown in Table 1, were relatively stable. Thus these xanthates could be purified by distillation and/or recrystallization. They were synthesized according to procedures developed in this laboratory (14).

As shown in Table 1 boiling points and melting points of this series increase as the formula weight increases and as the number of β-phenyl substituents increases. It is interesting to note that neopentyl xanthate did not decompose even at reflux temperature for 24 h. Again while an electron-withdrawing group at the para-position of the β-phenyl group raises the decomposition temperature, an electron-donating group decreases it. The increasing number of β-phenyl groups also reduces the decomposition temperature of a xanthate ester.

It was decided to study the pyrolytic products in detail because the decomposition of these xanthates suggested that Wagner–Meerwein rearrangement may be occurring. The pyrolytic temperature was chosen to be 250 °C which represents a median decomposition temperature for this series.

Product Studies

Weighed amounts of xanthate were heated at 250 °C for 30 min and/or several hours when required. Olefins were separated by g.l.c. and were identified by standard procedures. The relative amounts of olefinic products were determined by the use of g.l.c. and by n.m.r. spectroscopy. The residues were analyzed by similar methods. A summary of product distributions is shown in Table 2.

To summarize the results of Table 2 the following salient points should be noted:

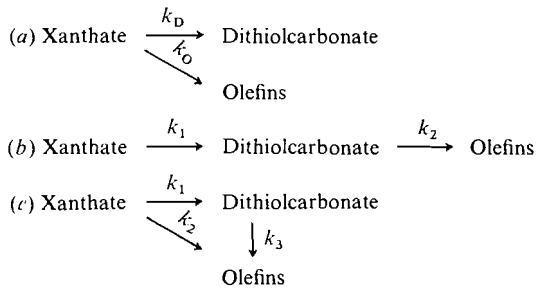
(*1*) Neopentyl xanthate undergoes only rearrangement to the dithiolcarbonate. No evidence of methyl group participation was observed.

(*2*) Increasing β-phenyl substitution leads to increasing amounts of olefin formation. The olefinic products are derived only from phenyl migration. No xanthate–dithiolcarbonate rearrangement was observed at all in the pyrolysis of 2,2,2-triphenylethyl xanthate and only a small amount (<4%) of dithiolcarbonate was observed in the diphenylpropyl system.

(*3*) There is a predominance of terminal olefins.

(*4*) No skeletally rearranged dithiolcarbonate was observed.

These observations prompted a further study into the course and nature of the pyrolysis of the xanthates under investigation.



SCHEME 4. The probable courses of reaction for the pyrolysis of neopentyl-type xanthates.

There are three probable ways to account for the products: (*a*) two competing processes to afford both olefin(s) and dithiolcarbonate; (*b*) a consecutive process, and (*c*) a competing–consecutive process (Scheme 4). A kinetic study of the pyrolysis of these xanthates was undertaken in the hope that the results would help to differentiate between the above processes.

Kinetic Studies

Small samples of the xanthates placed in loosely-corked test tubes or sealed tubes (under a nitrogen atmosphere) were suspended in a constant temperature silicone oil bath. At set intervals, reaction was quenched in ice and samples were analyzed by n.m.r. spectroscopy. Using methyl benzoate as an internal standard, the *S*-methyl groups of both the xanthate and the dithiolcarbonate were compared with the methyl group of methyl benzoate and the percent of reaction was calculated.

The rate constants of disappearance of the xanthates (k_t) were determined from the first order rate equation and are listed in Table 3.

If a given reaction occurs by two first-order

§Calculated value.

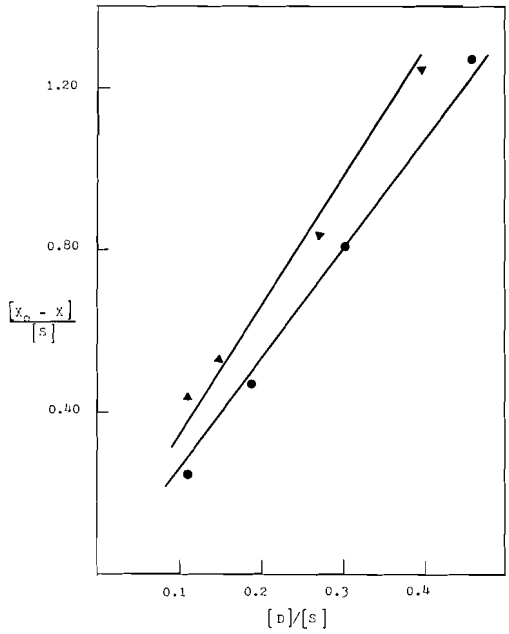

FIG. 1. The rate of disappearance of *p*-bromoneophyl (●) and neophyl (▲) xanthates against the rate of formation of the corresponding dithiolcarbonates; [S] = concentration of the internal standard.

competing processes as shown in (*a*) in Scheme 4, then

$$[1] \qquad [X] = [X_0]e^{-k_t(t)}$$

$$[2] \qquad [D] = -\frac{k_D}{k_t}[X - X_0]$$

$$[3] \qquad [O] = -\frac{k_O}{k_t}[X - X_0]$$

$$[4] \qquad k_t = k_D + k_O$$

where k_t = rate constant of disappearance of xanthate; k_D = rate constant of dithiolcarbonate formation; k_O = rate constant of olefin formation; [X] = concentration of xanthate at time t; $[X_0]$ = concentration of xanthate at time zero; [D] = concentration of dithiolcarbonate; [O] = concentration of olefin(s). Thus for two competing processes the plot of [D] *vs.* $[X - X_0]$ should be a straight line as predicted by eq. 2. If so, eq. 4 is also satisfied.

Figure 1 confirms the linear relationship between [D] and $[X_0 - X]$ for both neophyl and *p*-bromoneophyl xanthates. The rates of dithiolcarbonate formation (k_D) were calculated from the slopes of these lines and are shown in Table 3. Thus the production of olefin and dithiolcarbonate are two competitive processes in the pyrolysis of these two compounds. This result indicates that the relationship in eq. 4 is also true.

Further studies showed that there was no olefin formation from the pyrolysis of neopentyl and neophyl dithiolcarbonates under similar experimental conditions. On this basis, the consecutive process and the competing–consecutive process can be eliminated.

Wagner–Meerwein Rearrangement Leading to Olefin Formation

The rate constants of olefin formation (k_O) were calculated according to eq. 4. For 2,2-diphenylpropyl, *p*-methylneophyl and 2,2,2-triphenylethyl xanthates, it was assumed that $k_O = k_t$ because less than 5% of dithiolcarbonate was observed after 70% completion of pyrolysis.

Table 4 shows that the rate of olefin formation increases with increasing number of β-phenyl substituents. Furthermore, the rate was also increased by electron-donating groups substituted at the para-position of the benzene ring. A similar observation was obtained in the acetolysis of neopentyl-type brosylates (15).

TABLE 4. Rates of acetolysis of neopentyl-type brosylates (k_s) at 75 °C and calculated rates of olefin formation in the pyrolysis of neopentyl-type xanthates (k_O) at 250 °C

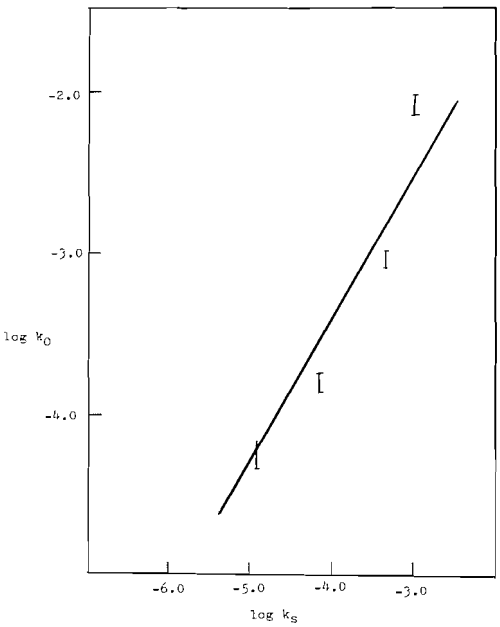

FIG. 2. The linear free energy plot of the rates of pyrolysis of neopentyl-type xanthates (k_O) and the rates of acetolysis of neopentyl-type brosylates (k_s).

Figure 2 shows a linear free energy relationship between the two reactions. The straight line relationship suggests that there is a considerable parallelism between mechanisms of the two reactions (16). It has been demonstrated that the rates of acetolysis of neophyl brosylates were moderately sensitive to substituent effects. A Hammett plot of log k_s *vs.* σ^+ values gave a ρ-value of -2.96 for the reaction. Based on these observations, it was concluded that ionization with phenyl participation was the rate determining step in the acetolysis of neophyl brosylates. This author further proposed that acetolysis of 2,2-diphenylethyl brosylate and 2,2,2-triphenylethyl brosylate should also proceed with the same mechanism (15).

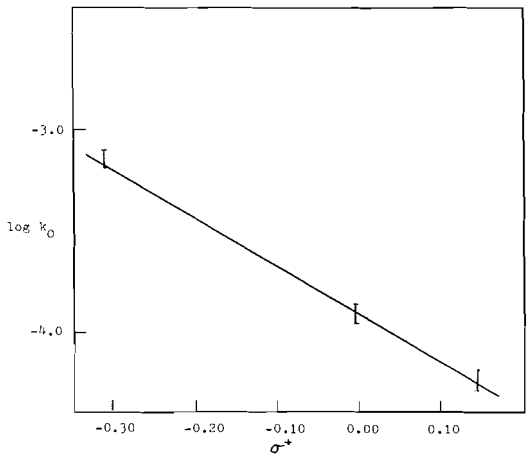

FIG. 3. Plot of log k_O for the pyrolysis of para-substituted neophyl xanthates at 250 °C against σ^+ values: -0.306 for p-CH_3; 0.00 for p-H; $+0.148$ for p-Br.

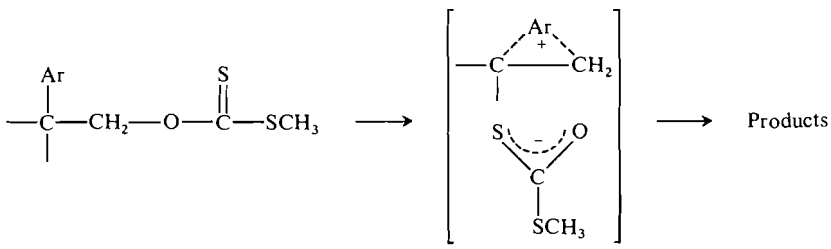
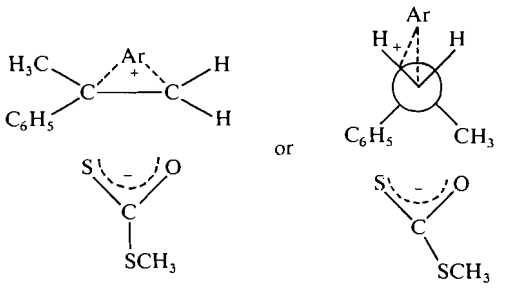
In our studies, the decomposition rates of the substituted neophyl xanthates were also found to be moderately sensitive to the nature of substituents. This observation, coupled with the apparent similarity between the two systems, suggests that a phenonium ion transition state is also involved in the olefin formation during the neophyl-type xanthate pyrolysis process as shown in Scheme 5.

Figure 3 shows a Hammett–Taft plot of calculated rate constants of olefin formation of three substituted neophyl xanthates *vs.* the corresponding σ^+ values of the substituents. A reasonably good straight line relationship was obtained. The ρ-value for the reaction was calculated to be -2.42. This further supports the proposed involvement of the phenonium ion transition state.

It is interesting to note that there is a predominance of the Hofmann-type olefins in the product. In the acetolysis of neophyl brosylate, the 2-benzylpropene to 2,2-dimethylstyrene



SCHEME 5. Proposed transition state for the olefin(s) formation process.



SCHEME 6. The proposed transition state of the pyrolysis of diphenylpropyl xanthate.

ratio was 1:1 (15). Kwart and co-workers (17, 18) reported a ratio of 2.2:1 of 2-benzylpropene to 2,2-dimethylstyrene in the pyrolysis of neophyl acetate in the gas phase at 575 °C. Statistically speaking, the ratio of the two olefins should be 3:1. Since in the pyrolysis of neophyl xanthate the observed ratio is 2:1, the larger than statistically predicted amount of conjugated olefin formed in the reaction suggests that both statistical and thermodynamic effects are important.

The 1-benzylstyrene (**1**) to methylstilbene (**2**) ratio should be 3:2 in the pyrolysis of 2,2-diphenylpropyl xanthate if statistics were the only controlling factor. Experimentally, the ratio was found to be 1:1. If isomerization of **1** to **2** was unimportant under the reaction conditions,[2] the larger than statistically predicted amount of fully conjugated olefin, **2**, again indicated that both statistic and thermodynamic effects are important during the olefin formation process. On the other hand, if all the methyl-*trans*-stilbene formed were considered to come from the isomerization of 1-benzylstyrene, the **1** to **2** ratio is 3:2, exactly as predicted by the statistical consideration. The reasons for a predominant formation of methyl-*cis*-stilbene over that of the *trans* isomer (3.5:1) is not entirely clear (Scheme 6).

Dithiolcarbonate Formation

In the dithiolcarbonate formation process, both neopentyl and neophyl xanthate gave considerable yields of dithiolcarbonates without skeletal rearrangement. The absence of skeletally rearranged dithiolcarbonates indicates that the reaction might have proceeded through a non-assisted tight ion-pair or a cyclic S_Ni mechanism as shown in Scheme 7. In case of an ion-pair, electron-donating groups at the tertiary carbon should stabilize the ion-pair while electron-withdrawing groups should destabilize it. Thus it is expected that the rate of rearrangement would be faster when $R = CH_3$ than when R = aryl. The rate of formation of neophyl dithiolcarbonate was almost nine times faster than that of the neopentyl dithiolcarbonate as shown in Table 3. Therefore a mechanism involving the formation of a non-assisted tight ion-pair intermediate during the xanthate–dithiolcarbonate rearrangement appears to be in contradiction to the observed results. On the other hand, a concerted S_Ni mechanism involves little charge development in the cyclic transition state. The presence of electron-withdrawing groups at the tertiary carbon atom will enhance the electrophilicity of the methylene carbon, and this increases the rate of dithiolcarbonate formation. This explains the observed faster rate of neophyl dithiolcarbonate formation over that of neopentyl dithiolcarbonate. Moreover, the smaller rate of formation of *p*-bromoneophyl dithiolcarbonate than that of neophyl dithiolcarbonate also supports this argument. Thus, the mechanism of the dithiolcarbonate formation may involve a concerted four-membered cyclic transition state.

Summary and Conclusions

The olefin formation and the dithiolcarbonate formation in the pyrolysis of neophyl xanthates are found to be two competing processes. The Wagner–Meerwein rearrangement becomes more important when the number of β-phenyl groups increases and when there is an electron-donating group substituted at the para-position of the β-phenyl ring. The transition state of the olefin formation process is best represented by a stabilized phenonium ion. The driving force of the rearrangement appears to be mainly electronic in nature, however, release of steric crowding at the ground state could also play an importante role. The dithiolcarbonate is thermally more stable than the corresponding xanthate and its formation becomes more important when the number of β-phenyl substituents is the least. This rearrangement

[2]Under the reaction conditions, it was found that 1-benzylstyrene isomerized up to 48% to methyl-*trans*-stilbene but gave no methyl-*cis*-stilbene. No *cis–trans* isomerization of stilbenes was observed.

appears to proceed through a concerted four-membered cyclic transition state.

Experimental

Synthesis of Xanthates

All Xanthates were synthesized according to procedures developed in this laboratory (14).[3] Elemental analyses of these xanthates are summarized in Table 5. The i.r. and n.m.r. spectral data of these compounds all supported the desired xanthate structures.

Pyrolysis of Neopentyl Xanthate

Neopentyl xanthate (5 g) was refluxed under nitrogen for 48 h. No decomposition was observed as the i.r. spectrum of the product was identical with that of neopentyl xanthate. Another attempted decomposition was carried out in sealed tube at higher temperature. The xanthate, 1 g, was sealed in a 4 ml micro test tube under nitrogen and was kept at 270 °C for 5 h. The product was analyzed by g.l.c. (8 ft Lac-728 column, 120 °C, 60 cc helium/min) and gave two peaks. The first peak (retention time, 32 min; 60%) was identified as unreacted neopentyl xanthate. The second peak (retention time, 38 min; 40%) was identified as neopentyl dithiolcarbonate: i.r. (10%, CCl_4) 2960 and 2870 (s, C—H), 1650 (s, C=O), 1365 (m, C—H), 860 (s, S—CO—S); n.m.r. (10%, $CDCl_3$) 0.97 (s, 9, $C(CH_3)_3$), 2.48 (s, 3, SCH_3), 3.07 (s, 2, SCH_2).

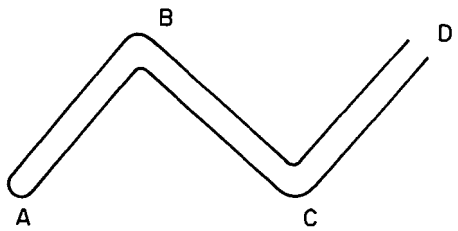

FIG. 4. An N-tube for pyrolysis.

[3]In the synthesis of para-bromoneophyl xanthate, sodium hydride was used instead of potassium metal to generate the sodium salt from the corresponding alcohol.

In an attempt to detect olefin formation, this xanthate (200 mg) was sealed in an n.m.r. tube and heated in a silicone oil bath at 250 °C. A spectrum was run every 4 h. After 40 h no olefin was observed and the corresponding dithiolcarbonate was the only product in 42% yield.

Pyrolysis of Neopentyl Dithiolcarbonate

The dithiolcarbonate (200 mg) in a sealed n.m.r. tube was kept in a silicone oil bath at 250 °C. An n.m.r. spectrum was run every 10 h. After a duration of 40 h, no decomposition was observed. The i.r. spectrum of the resultant liquid was identical to that of the starting dithiolcarbonate.

Pyrolysis of Neophyl Xanthate

Decomposition of a small amount of the xanthate (0.5 g, 2.1 mmol) was carried out in an N-tube (Fig. 4) in a silicone oil bath at 250 °C. The xanthate was pipetted into a straight tube AD 12 cm × 7 mm which was bent to an N-shape as shown in Fig. 4. Part A of the tube was immersed in an oil bath while part C was cooled. The advantage of this N-tube is to allow easy separation of olefin from the residue and also only small amounts of xanthate are required by this method. After heating for 2 h, part A was cooled and was separated from part C. The olefins in part C weighed 127 (9.5 mmol, 45%) while the residue in part A weighed 270 mg. The loss of material was due to escape of gaseous products.

Analysis of the Olefins

The olefins were separated by g.l.c. (8 ft Lac-728 column, 125 °C, 60 cc helium/min). On the chromatogram two peaks appeared with retention times of 5.5 (67%) and 7.5 min (33%). The first peak was identified as 2-benzylpropene: n_D^{25} 1.5050 (lit. (30) 1.5057); i.r. (10%, CCl_4) 3080 (s, C=CH), 3020 (s, Ar—H), 2980 and 2970 (s, C—H), 1645

(m, C=C), 1600 and 1490 (w, Ar), 884 (s, C=CH_2), 690 (s, Ar—H); n.m.r. (10%, $CDCl_3$) 1.65 (s, 3, C=C—CH_3), 3.24 (s, 2, C=C—CH_2—Ar), 4.62 (s, 2, C=CH_2), 7.00 (bs, 5, C_6H_5). The second peak was identified as 2-methyl-1-phenylpropene: n_D^{25} 1.5367 (lit. (34) n_D^{20} 1.5400); i.r. (10% CCl_4) 3060 (s, C=CH), 3020 (s, Ar—H), 2970 and 2920 (s, C—H), 1659 (m, C=C), 1600 and 1490 (w, Ar), 825 (m, C=CH), 690 (s, Ar—H); n.m.r. (10%, $CDCl_3$) 1.85 (m, 6, C=$C(CH_3)_2$), 6.10 (m, 1, C=CH), 7.07 (bs, 5, C_6H_5).

Analysis of the olefinic mixture by n.m.r. integration showed a similar product distribution.

Isomerization Study of the Olefins

A 30 mg sample of each of the two olefins was heated separately in an N-tube at 250 °C for 30 min. The n.m.r. spectrum showed that no isomerization occurred for both 2-benzylpropene and 2-methyl-1-phenylpropene.

Analysis of the Residue

The residue was separated by g.l.c. (6 ft Lac-728 column, 200 °C, 60 cc helium/min). On the chromatogram only two peaks appeared at 130 (60%) and 138 min (40%). The compound corresponding to the first peak was identical to the unreacted xanthate. The second component of the residue was identified as the neophyl dithiolcarbonate: n_D^{26} 1.5757; i.r. (10%, CCl_4) 3020 (w, Ar—H), 2950 and 2920 (s, C—H), 1640 (s, C=O), 860 (s, S—CO—S), 690 (s, Ar—H); n.m.r. (10%, $CDCl_3$) 1.34 (s, 6, $C(CH_3)_2$), 2.28 (s, 3, SCH_3), 3.20 (s, 2, SCH_2), 7.00 (bs, 5, C_6H_5).

Analysis of the residue by n.m.r. integration showed a similar product distribution.

Hydrolysis and Reduction of Neophyl Dithiolcarbonate

Neophyl dithiolcarbonate (1 g) was hydrolyzed by sodium hydroxide according to the method of Taguchi and Makao (9) followed by Ra–Ni reduction according to the method of Sondheimer and Rosenthal (19). The resultant reaction mixture was extracted with ether. The organic layer was concentrated and analyzed by g.l.c., i.r., and n.m.r. *t*-Butylbenzene was the only observed product.

Another neophyl xanthate sample (500 mg) was charged to an N-tube which was heated for 30 min. The olefins weighed 42 mg (17%). Analysis by n.m.r. integration showed that 2-benzylpropene and 2-methyl-1-phenylpropene were present in the ratio 67:33. The residue weighed 412 mg and the n.m.r. integration showed that the xanthate to the dithiolcarbonate ratio was 90:10. The loss of material was due to escape of gaseous products.

Pyrolysis of Neophyl Dithiolcarbonate

The dithiolcarbonate (22 mg) was heated in an N-tube at 250 °C for 2 h. No olefin was found. The residue was analyzed by g.l.c., i.r., and n.m.r. and was found to be the starting dithiolcarbonate.

Pyrolysis of p-Bromoneophyl Xanthate

Decomposition of this xanthate (41 mg, 0.13 mmol) was carried out in a 75 × 10 mm test tube at 250 °C for 2 h. The composition of products was analyzed by n.m.r. integration without further purification (methyl benzoate was used as internal standard). The mixture contained 50% of the unreacted xanthate and 17% of the dithiolcarbonate. The olefin portion was not analyzed.

Pyrolysis of p-Methylneophyl Xanthate

Decomposition of this xanthate (33 mg, 0.13 mmol) was carried out in a 75 × 10 mm test tube at 250 °C for 30 min. The composition of products was determined by n.m.r. integration without further purification (methyl benzoate was used as internal standard). The mixture contained 27% of the unreacted xanthate and less than 4% of the dithiolcarbonate. The olefin portion was not analyzed.

Pyrolysis of 2,2-Diphenylpropyl Xanthate

Decomposition of this xanthate (500 mg, 1.65 mmol) was carried out in an N-tube in a silicone oil bath at 250 °C for 30 min. No olefin was found in part C of the tube. The product was analyzed in the following manner.

Analysis of Olefins

The olefins were separated from the reaction mixture by liquid column chromatography (silica gel, petroleum ether (b.p. 30–60 °C)) and weighed 280 mg (88%). Olefins were further separated by g.l.c. (6 ft 10% SE-30, 170 °C, 60 cc helium/min). On the chromatogram three peaks appeared with retention times of 6.4 (39%), 7.4 (49%), and 10.8 min (12%). Analysis of the olefinic mixture by n.m.r. integration showed a similar product distribution. The first peak was identified as methyl-*cis*-stilbene: m.p. 46–47 °C (lit. (20) m.p. 48 °C); i.r. (10%, CCl_4) 3060 (s, C=CH), 3020 (s, Ar—H), 2970 and 2920 (w, C—H), 1600 and 1490 (m, Ar), 849 (m, C=CH), 690 (s, Ar—H); n.m.r. (10%, CCl_4) 2.11 (d, 3, $J = 2$ Hz, C=CCH_3), 6.21 (m, 1, C=CH), 6.70–7.10 (bd, 10, $C(C_6H_5)_2$). The second peak was identified as 1-benzylstyrene: n_D^{24} 1.5893 (lit. (21) n_D^{25} 1.5891); i.r. (10%, CCl_4) 3060 (s, C=CH), 3020 (s, Ar—H), 2910 (m, C—H), 1625 (m, C=C), 1600 and 1490 (m, Ar), 890 (s, C=CH_2), 690 (s, Ar—H); n.m.r. (10%, CCl_4) 3.65 (s, 2, C=CCH_2Ar), 4.80 (bd, 1, C=CH), 5.25 (bd, 1, C=CH), 6.90–7.10 (bs, 10, $C(C_6H_5)_2$). The third peak was identified as methyl *trans*-stilbene: m.p. 81–82 °C (lit. (20) m.p. 82 °C); i.r. (10%, CCl_4) 3060 (s, C=CH), 3020 (s, Ar—H), 2980 and 2940 (w, C—H), 1600 and 1490 (m, Ar), 849 (m, C=CH), 690 (s, Ar—H); n.m.r. (10%, CCl_4) 2.17 (d, 3, $J = 2$ Hz, C=CCH_3), 6.65 (m, 1, C—CH), 6.90–7.20 (m, 10, $C(C_6H_5)_2$).

Olefin Isomerization Study

A 30 mg sample of each of the three olefin products was heated separately in three micro test tubes at 250 °C for 30 min. The n.m.r. analysis showed that no isomerization occurred between *trans*- and *cis*-stilbenes. However, 48% of benzylstyrene was isomerized to methyl-*trans*-stilbene.

Analysis of Other Products

The remaining material on the chromatography column weighed 60 mg. The i.r. spectrum showed characteristic xanthate bands and dithiolcarbonate bands at 1645 and 860 cm^{-1}. The n.m.r. spectrum showed that the mixture contained 66% of the unreacted xanthate. Attempts to isolate the dithiolcarbonate were unsuccessful.

Pyrolysis of 2,2,2-Triphenylethyl Xanthate

Decomposition of this xanthate (1g, 2.7 mmol) was carried out in a micro test tube in a silicone oil bath at 250 °C for 30 min. The product weighed 700 mg (2.7 mmol). The t.l.c. analysis (silica gel, pentane) showed only one spot corresponding to triphenylethylene: m.p. 88–89 °C. The i.r. spectrum was identical to an authentic sample.

An Attempt to Detect Dithiolcarbonate Formation

The *S*-methyl xanthate ester of 2,2,2-triphenylethanol

(0.5 g) in an n.m.r. tube was heated in a silicone oil bath at 200 °C. An n.m.r. spectrum was run every 30 min for a period of 2 h. No dithiolcarbonate formation was observed. Another sample was heated in an oil bath at 160 °C. An n.m.r. spectrum was run every 6 h for a period of 36 h. Again, no dithiolcarbonate formation was observed.

Kinetic Studies

Kinetic studies of the pyrolysis of xanthate esters were carried out on neat samples. An accurately weighed sample (30 mg) of the solid xanthate ester to be studied was placed in a 75 × 10 mm test tube. For liquid xanthate esters, a 30 μl sample was introduced into the test tubes by means of a constant volume addition syringe and then it was weighed accurately. The test tubes were loosely corked or sealed under a nitrogen atmosphere and were suspended in a constant temperature silicone oil bath at the desired temperature. Samples were removed at set intervals and were immediately cooled in ice-water. The samples were analyzed by n.m.r. using methyl benzoate as an internal standard. The relative amounts of xanthate left unreacted and the relative amounts of products formed at each interval were estimated by n.m.r. integrations. The maximum error in integration was estimated to be about 5%.

Spectrofluorometric Studies. XI. Some Aspects of the Photochemistry of Ortho-fused Benzocycloalkenes

M. GROSSMAN, R. KUBELA, G. P. SEMELUK, AND I. UNGER

Department of Chemistry, The University of New Brunswick, Fredericton, New Brunswick

Received July 13, 1971[1]

Fluorescent yields of  $n = 2, 3, 4, 5, 6$

excited in the 2500 Å region in cyclohexane solution have been examined. There is a general trend of fluorescent yields decreasing with increasing alkene ring size. The sum of the fluorescent and triplet yields decreases with increasing ring size. Triplet energies, obtained by Evans' method and roughly confirmed by phosphorescent emission spectra at 77 °K, do not vary greatly.

Les rendements en fluorescence de $n = 2, 3, 4, 5, 6$

excité dans la région 2500 Å en solution dans le cyclohexane, ont été examinés. Les rendements en fluorescence tendent généralement à décroître lorsque la taille du cycle alcène croît. La somme des rendements triplet et fluorescence décroît avec la taille du cycle. Les énergies triplet, obtenues par la méthode d'Evans et confirmées de façon approchée par les spectres d'émission de phosphorescence à 77 °K, ne varient pas de façon prononcée. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3298 (1972)

Introduction

That benzene (1) and benzene derivatives (2–4) may on photoexcitation undergo intramolecular rearrangement has now been well established. Intermediates in such reactions can be prismane (5), fulvene (6), Dewar benzene (2), or benzvalene (7). When one of the above intermediates results from the excitation of an ortho-derivative of benzene, the meta- and para-derivatives may be produced on rearomatization. Ortho-xylene, which may be considered as an ortho-fused benzocycloalkene with an infinitely large ring, does in fact show this type of behavior in the gas phase (8) and also in liquid phase, but in much smaller yield (9). Should this also occur for other members in the ortho-fused benzocycloalkene series then one would in principle have a novel reaction for the formation of meta- and para-bridged compounds. Prior to starting a study of this type, however, it is necessary to examine the simple photochemistry of these compounds *i.e.*, to determine the singlet and triplet yields of these molecules and the effect of various parameters on these yields.

[1]Revision received June 19, 1972.

Experimental

Materials

The cyclohexane and EPA (ethyl ether, isopentane, and ethyl alcohol; 5:5:2) were Hartman–Leddon Company fluorometric grade materials and were used without further purification. The benzene was obtained from Aminco; benzocyclopentene (indane) was from Columbia Organic Chemicals. The ortho-xylene and the benzocyclohexene (1,2,3,4-tetrahydronaphthalene) were API (American Petroleum Institute) standard samples.

Benzocyclobutene (Bicyclo[4.2.0]octa-1,3,5-triene)

This cyclobutene was prepared by gas phase pyrolysis of 1,3-dihydroisothianaphthene-2,2-dioxide as described by Cava and Deana (10), except the apparatus in which the pyrolysis was carried out was slightly different. Instead of the Pyrex sleeve with the Nichrome coil, a 2 ft long Quartz glass tube (i.d. = 9 mm) was used which was heated from outside to 600 °C. Yield of the crude distilled hydrocarbon was 60%; b.p. 149–150 °C uncorrected at atmospheric pressure. It was further purified by v.p.c. using a column with 20% Carbowax 20 M on chromosorb W, and helium carrier.

Benzosuberan (1,2-Benzocyclohept-1-ene)

Benzosuberan was prepared by Clemmensen reduction of the corresponding 1-ketone (11). The obtained liquid was distilled from metallic potassium and hydrogenated over 5% palladium on charcoal in methanol at atmospheric pressure. The colorless oil, which distilled at 96–97 °C (uncorrected, 12 Torr), was purified by v.p.c. using a 15% Carbowax 20 M on chromosorb W column and helium carrier.

Benzocyclooctene (1,2-Benzo-cyclo-oct-1-ene)

This cyclooctene was prepared by Friedel–Crafts cyclization of ε-phenyl-*n*-caproyl chloride, followed by Wolff–Kishner reduction of the obtained ketone to give the crude hydrocarbon (12). The b.p. after repeated distillation was 92–100 °C (uncorrected) at 2 Torr. The material was finally purified by passing through a v.p.c. column containing 20% SE-30 on chromosorb M, using helium carrier.

Purity checks using v.p.c., absorption and fluorescence spectra indicated all the materials, with the exception of benzocyclohexene and benzocyclobutene to contain negligible impurities. The solution spectra in the first absorption region were in agreement with absorptivity measurements reported by Moore *et al.* (13, 14), as noted in a previous publication (15).

The benzocyclohexene contained <0.2 mol % of an impurity which appeared to be naphthalene, a contaminant commonly found in samples of this compound. The indirect identification and the effect of the impurity of the fluorescence measurements made in this study are ascertained by adding varying amounts of naphthalene (up to 1 mol %) to both benzocyclohexene and benzocyclopentene. Fluorescence was excited by irradiation in the wavelength regions corresponding to that for the compound under study, and to that for naphthalene. In the case of benzocyclohexene, it was found that the impurity fluorescence spectra excited in the naphthalene region did not change in appearance, but did increase in intensity for increasing amounts of added naphthalene. The quantum yield of benzocyclohexene fluorescence was not changed, however, by the presence of added naphthalene. The same was true in the case of benzocyclopentene solutions with added naphthalene, except in this case the intensity of naphthalene fluorescence, originally zero for solutions of the pure compound, increased proportionately to the quantity of added naphthalene. In the case of benzocyclohexene phosphorescence emission from EPA glass, there was some evidence of the presence of naphthalene. This occurred on the long wavelength side of benzocyclohexene phosphorescence spectra, and does not affect conclusions regarding the position of the short wavelength tail, which was used to give a rough indication of the singlet–triplet energy spacing. Although these experiments may not be conclusive, they do indicate that it is quite unlikely that the impurity in benzocyclohexene has any significant effect on the measurements made on this compound.

In addition to undergoing photodecomposition, benzocyclobutene is subject to slow thermal decomposition at room temperature, which might be due to its strained structure. The measured (low) fluorescent yield was independent of the age of sample (up to 6 months), suggesting that either the unknown decomposition products are not effective quenchers, or that they are so effective that the concentration level reached during the few days intervening between purification and measurement is sufficient to cause a saturated quenching effect. Although it is not possible at this time to choose between the alternatives, the low fluorescent yield is consistent with the expectation that the strained structure may provide a reaction pathway having a rate competitive with fluorescence.

Procedure

Room temperature fluorescent spectra of dilute solutions (~ 0.002 *M*) in cyclohexane were taken with an Aminco–Bowman spectrophotofluorometer (SPF) modified to include, (*a*) an adjustable entrance slit to the exciting monochromator, (*b*) an optical system involving mirrors and condensing lens to focus the resultant higher intensity exciting radiation on this slit, and (*c*) a phototube to monitor the transmitted radiation which allows measurements of absorbed intensity. Additional experimental details have been given previously (16, 17).

The standard phosphorescence attachment and rotating shutter were used to record phosphorescence spectra, which were observed at liquid nitrogen temperatures from EPA glassy matrix. The u.v. absorption spectra were observed in cyclohexane solution with a Hitachi Coleman Model EPS-3T recording spectrometer. Solutions used for fluorescence and phosphorescence measurements were degassed and hermetically sealed in the appropriate measuring cells. Optical quality quartz cuvette-type cells of 1 cm path length, obtained from Hellma (Canada) Limited were used for measurements involving both fluorescence and absorption. A number of fluorescence measurements were made in cylindrical quartz cells of 10 mm i.d. These were not greatly different from measurements obtained using the cuvette-type cells when care was taken to maintain a standard orientation and position in the cell holder. Aminco cylindrical quartz cells 3 mm o.d., and one constructed in this laboratory, were used for the phosphorescence experiments.

Evans' high pressure oxygen perturbation method was used to obtain singlet–triplet absorption spectra in chloroform solution of a few members of the series. Experimental details of the procedure have been given previously (18).

Triplet yields were estimated by the *cis–trans* isomerization technique (19, 20) using *cis*-butene-2. These yields are based on a value of 0.28 for the ortho-xylene triplet yield (21).

All fluorescent quantum yields are based on the ortho-xylene fluorescent yield being 0.19 (22). Since all of the fluorescent spectra cover the same spectral region, corrections for the photomultiplier tube response were unnecessary. This coincidence of spectral region was also true for the phosphorescent emission spectra.

Results and Discussion

Typical fluorescent emission spectra obtained with exciting wavelengths ranging from 230 to about 275 nm are given in Fig. 1. At wavelengths greater than ~ 275 nm no significant emission was observed, except for benzocyclohexene which had a small impurity concentration, as evidenced by the appearance of a new

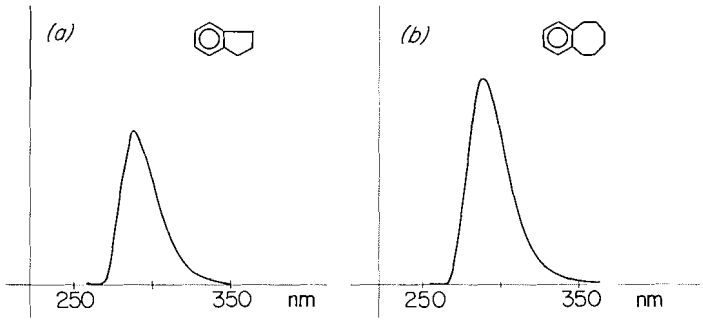

FIG. 1. (*a*) Fluorescent spectrum (uncorrected) of benzocyclopentene: 1.2×10^{-4} *M* in cyclohexane, 298 °K; $\lambda_{ex} = 250$ nm. (*b*) Fluorescent spectrum (uncorrected) of benzocyclooctene: 6.1×10^{-4} *M* in cyclohexane, 298 °K; $\lambda_{ex} = 270$ nm.

emission band covering a different spectral region. For benzocyclobutene, emission in a different spectral region was observed at the shorter wavelengths within the 230 to 275 nm absorption band, also indicating a small impurity concentration. In the case of benzocyclohexene the impurity appeared to be naphthalene, while in the other case it was not identified.

Except for the case of benzene, concentrations of sample and reference solutions were adjusted so that the absorbance (*A*) was approximately the same for both solutions at the comparison wavelengths, in order to minimize as much as possible inner filter and "around the corner" effects (23). For many pairs this adjustment at one comparison wavelength resulted in $A_{reference} \sim A_{sample}$ for all the comparison wavelengths. In these cases this was obviously a consequence of the experimental detail: (*1*) a relatively large irradiation band width (9 nm); (*2*) solution broadened absorption bands; (*3*) absorption bands covering the same wavelength range and having similar shapes.

For samples and reference having different absorbance, quantum yield measurements were corrected by a previously described procedure (23). Inner filter effects, which were self-cancelling, were found to be negligible. The results of the fluorescent quantum yield measurements are summarized in Tables 1 and 2.

The data in Table 1 represent a selection of solutions for which the absorbance match with the reference *o*-xylene solutions was very good, and for which the geometrical considerations were the most favorable. In Table 2 *all* the data obtained has been averaged; that obtained in cases of poor absorbance matches with corrections made as noted (23), that obtained in cases of good absorbance matches, and that derived from the cylindrical cells. It is to be noted that the trend in Table 1 for each excitation wavelength, is preserved in the averages summarized in Table 2.

In general there is a trend of decreasing fluorescent yield with increasing alkene ring size. Benzocyclobutene, one of the exceptions to this trend, appears to be different in other respects also, particularly with respect to its lack of stability, and so should be treated as a special case. On the other hand benzocycloheptene provides an interesting anomaly. It has previously been noted (13, 14) that the maximum molar absorbancy index of benzocycloheptene solutions in cyclohexane is an exception to a generally decreasing trend of maximum absorbancy indices with increasing ring size. However, this is *not* observed in gas phase spectra (15), suggesting some type of specific interaction with the solvent. The reasons for this are not obvious.

Several values have been reported for the fluorescent quantum yield of ortho-xylene (22, 24, 25). The value given by Berlman was chosen as our standard reference value after a careful comparison of methods and techniques used by the various authors. As a check, the fluorescent yield for benzene was determined, and found to be in good agreement with values obtained under similar conditions (26) and not too different from that reported by Berlman (22). Hence the quantum yields given in Tables 1 and 2, although not determined by an absolute method, should be fairly accurate. Triplet

†Determined as a check on the procedure. Berlman's value is 0.07.

yield results on benzocycloheptene, benzocyclohexene, and benzocyclopentene are summarized in Table 3, as are the "quantum deficits". Inspection of Table 3 shows that there is a trend of increasing quantum deficit with increasing ring size, which suggests processes other than fluorescence and intersystem crossover to triplet, become progressively more favored. The principal alternate processes are internal conversion to the ground state and intramolecular isomerization. Unfortunately it was not possible under our experimental conditions to detect with any certainty whether or not any valence isomers were present. In another series of experiments it was found that no meta and para isomers are produced photochemically until the ring size exceeds $n = 12$. The evidence so far obtained, then, leads to the conclusion that the major portion of the quantum deficit is probably accounted for by internal conversion processes.

A single experiment utilizing a high pressure of xenon with benzocyclopentene in the presence of *cis*-butene-2 showed a large increase in isomerization of the olefin. Experiments with meta-fused benzocyclodecahexene in the presence and absence of xenon showed that xenon depresses the formation of the ortho-fused isomer. It therefore appears likely that isomerization, when it can occur, proceeds through the excited singlet.

Typical phosphorescent emission spectra from EPA glassy matrix at 77 °K, obtained with exciting wavelengths corresponding to those used for exciting fluorescence, are shown in Fig. 2. The experimental arrangement is not well suited to the determination of phosphorescent yields, hence no such measurements were attempted.

The apparent coincidence of the spectral region of fluorescent emission for this series of compounds, and the corresponding and similar observation regarding the phosphorescent emission, invites comment, particularly since the behavior of benzene in these respects is very similar also. It strongly suggests that (*a*) the

Benzocyclohexene	5.88	0.41	0.35
Benzocyclopentene	6.54	0.31	0.31

*Using the *cis*-butene-2 technique, based on ortho-xylene triplet yield taken as 0.28 (21).

singlet energies of this group of compounds are nearly the same and approximately equal to that of benzene; (*b*) the triplet energies are also the same and not too different from that of benzene. As a consequence, it may be concluded that the presence of the ortho-fused ring does not greatly modify the energies involved in the benzene π–π^* system. The vibrational (and probably rotational) detail is different (15), but the energy spread and location of the first excited singlets and triplets appear to be approximately the same.

Confirmation of the above is provided by the absorption spectra previously obtained (15), and by the oxygen perturbed absorption spectra for a few members of this series. A comparison of these energies obtained from the corresponding O—O bands, is given in Table 4. Some interesting comparisons can be made between the benzocycloalkenes and the fluorinated benzenes. In both series of compounds the singlet and triplet energies, as determined from the O—O bands of the corresponding absorption spectra, are not too different from one another nor from benzene. There is, however, a tremendous difference in the observed Stokes loss. As implied above, the Stokes loss is approximately

constant in the benzocycloalkenes. In contrast, the greater the fluorine loading of the benzene ring the greater is the Stokes shift, and the further the fluorescent emission "tail" extends towards longer wavelengths.[2] Fluorine substitution appears to exert a far greater influence in benzenoid excited states than it does in the ground electronic state, whereas this is not so for hydrocarbon substituents.

The authors wish to thank the National Research Council of Canada for financial assistance, and to acknowledge the help received from Dr. Z. Valenta of this department during the course of many useful discussions.

A Kinetic and Electron Spin Resonance Study of the Polymerization of Vinyl Acetate Retarded by 2,4,6-Tri-*t*-butylphenol

H. LILLES, R. D. PARNELL, AND K. E. RUSSELL
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 27, 1972

The effect of 2,4,6-tri-*t*-butylphenol on the rate of polymerization of vinyl acetate and on the degree of polymerization of the resultant polymer has been determined. It is shown that the phenoxy radicals produced by hydrogen transfer do not reinitiate polymerization and that they disappear from solution by reaction with polyvinyl acetate radicals. The chain transfer constant is estimated to be 0.017 ± 0.004 at 45° from molecular weight studies and 0.021 ± 0.004 from rate studies. Stationary state concentrations of phenoxyl of the order of 10^{-7} *M* have been determined by e.s.r. spectroscopy. The rate constant for the reaction of polyvinyl acetate radicals with 2,4,6-tri-*t*-butylphenoxyl is $(6.6 \pm 2.3) \times 10^7$ l mol^{-1} s^{-1} at 45°.

Nous avons déterminé l'influence du 2,4,6-tri-*t*-butylphénol sur la vitesse de polymérisation de l'acétate de vinyle et sur le degré de polymérisation de ce polymère. On montre que les radicaux phénoxy produits par transfert d'hydrogène ne réinitient pas la polymérisation et ils disparaissent de la solution en réagissant avec les radicaux d'acétate de polyvinyle. La constante de transfert de chaîne est estimée à 0.017 ± 0.004 à 45° à partir d'études de poids moléculaires et à 0.021 ± 0.004 à partir d'études de vitesses. Des concentrations de radical phénoxyl à l'état stationnaire de l'ordre de 10^{-7} *M* ont été déterminées par r.p.e. La constante de vitesse de la réaction des radicaux d'acétate de polyvinyl avec le 2,4,6-tri-*t*-butylphénoxyl est $(6.6 \pm 2.3) \times 10^7$ l mol^{-1} s^{-1} à 45°. [Traduit par le journal]

Introduction

The general objective of our present work is to explore the factors which influence the rates of reaction of radical intermediates in solution and in particular to obtain such information for radical–radical processes. Whenever possible, the concentrations of radical intermediates are directly determined by means of e.s.r. spectroscopy and the results yield estimates of reaction rate constants which cannot be readily obtained by other means.

In earlier studies (1, 2) it was established that the reaction of 2,2-diphenyl-1-picrylhydrazyl (DPPH) with hindered phenols could readily be followed by e.s.r. spectroscopy. The simplest reaction examined in this way was that between DPPH and 2,4,6-tri-*t*-butylphenol in benzene; the DPPH abstracts the hydrogen atom from the OH group to give 2,2-diphenyl-1-picrylhydrazine and the tri-*t*-butylphenoxy radical. The hindered phenoxy radical has a narrow line spectrum compared with that of DPPH and its concentration can be determined in the presence of the second radical. In other work (3), the reactivities of a number of phenols towards the polyvinyl acetate radical were compared. Transfer constants, *i.e.* ratios of rate constants for attack of polyvinyl acetate radicals on phenol and on monomer, were determined, but in the absence of information concerning the relative importance of the various radical–radical termination reactions, the transfer constants could only be quoted to a low accuracy.

The present paper describes a study of the effect of 2,4,6-tri-*t*-butylphenol on the polymerization of vinyl acetate. The phenol reacts with polyvinyl acetate radicals to produce 2,4,6-tri-*t*-butylphenoxyl, a radical which has little or no reactivity towards itself (4) or towards vinyl acetate monomer. The tri-*t*-butylphenoxyl is produced in the chain transfer reaction and is lost only in the cross reaction with polyvinyl acetate radicals. It is thus possible to use measurements of the degree of polymerization to obtain an unambiguous value of the chain transfer constant and to check this value by an independent analysis of the effect of the added phenol on the rate of polymerization of the vinyl acetate (5). The transfer constant yields the rate constant for hydrogen atom abstraction from the phenol by polyvinyl acetate radicals since the propagation rate constant for vinyl acetate polymerization is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

known from independent studies. The dependence of the steady state concentration of tri-*t*-butylphenoxyl upon phenol and initiator concentrations was determined by e.s.r. spectroscopy and the rate constant for the reaction between polymer and phenoxy radicals was derived from these results.

Experimental

Materials

Azobisisobutyronitrile was recrystallized twice from diethyl ether and stored at 0°. 2,4,6-Tri-*t*-butylphenol (Aldrich Chemical Company) was recrystallized three times from methanol in an atmosphere of nitrogen and stored under nitrogen at 0°.

Vinyl acetate was fractionally distilled at atmospheric pressure and the distillate degassed on the vacuum line. The monomer was "prepolymerized" by adding 1 g azobisisobutyronitrile to 500 ml vinyl acetate and irradiating at 0° with near u.v. radiation. The prepolymerization was stopped when the magnetic stirrer indicated that the solution had become fairly viscous. The vinyl acetate was fractionally distilled from the mixture at reduced pressure (b.p. about 18°) and a middle fraction (100 ml) collected. The frozen monomer was stored on the vacuum line in the absence of light. The absorbance of the monomer was less than 0.03 at 275 nm in a 1 cm cell.

Procedure

The polymer samples were prepared as described in an earlier paper (3). Tri-*t*-butylphenol concentrations were in the range 0.002–0.07 *M*. The experiments were performed at 45 °C and the conversion of monomer to polymer was kept below 5%. Degrees of polymerization were estimated from intrinsic viscosities and from osmotic pressures of polymer solutions. The intrinsic viscosities were determined at 25° and degrees of polymerization obtained from eq. 1 (6).

$$[1] \qquad \bar{P}_n = 2.57[\eta_l]^{1.40}$$

$\bar{P}_n$ is the number average degree of polymerization and $[\eta_l]$ is the limiting viscosity number. The values of $\bar{P}_n$ obtained by this method were in good agreement (±8%) with those obtained directly by means of a Hewlett Packard Membrane Osmometer (Model 501) with toluene as solvent at 30°.

E.s.r. spectra of reaction mixtures were obtained by means of a Varian V4502 spectrometer fitted with a variable temperature control unit. The temperature of the solution for a given dial setting was regularly checked in separate calibration experiments. The steady state concentration of tri-*t*-butylphenoxyl was of the order of 10^{-7} *M* and a convenient modulation amplitude for concentration studies was 0.2 G. The microwave power was maintained at a low level in order to minimize saturation; even so, some saturation occurred and a small correction factor, determined in separate saturation studies on DPPH and phenoxy radicals, was applied. In any run the observed spectra were compared with the spectrum of a Mn^{2+} standard contained in a small capillary (7); the Mn^{2+} standard was calibrated by means of a freshly made standard solution of DPPH. All double integrations of first derivative curves were performed manually. Reaction mixtures were prepared *in vacuo* and tri-*t*-butylphenol concentrations were in the range 0.065–0.3 *M*.

Results

Polymerization Rate Studies

The purified vinyl acetate polymerized under given conditions of temperature and initiator at a reproducible rate. The ratio, $R_p/[In]^{1/2}$, where R_p is the overall rate of polymerization and [In] the initiator concentration, was found to be $(39 \pm 2) \times 10^{-4}$ $mol^{1/2}\ l^{-1/2}\ s^{-1}$ at 45°. The ratio did not vary with initiator concentration in the range 0.004–0.06 *M*; the correction for the heating effect (8) in the 5 ml reaction tube is small at 45°. The value of $(39 \pm 2) \times 10^{-4}$ $mol^{1/2}\ l^{-1/2}\ s^{-1}$ at 45° compares with an interpolated ratio of 33×10^{-4} $mol^{1/2}\ l^{-1/2}\ s^{-1}$ obtained by Matheson *et al.* (9) and 31×10^{-4} $mol^{1/2}\ l^{-1/2}\ s^{-1}$ obtained by Bird and Russell (3). Matheson *et al.* showed that a rough check on the purity of the vinyl acetate could be made by measuring the extinction coefficient of the pure monomer in the region of 275 nm since impure monomer absorbs strongly at this wavelength. The extinction coefficient of the monomer used in this work was 0.002–0.003 at 275 nm which compares with an extinction coefficient of approximately 0.0032 derived from spectra given by Matheson *et al.* (9) and Schulz and Stein (10).

The experimentally observed $R_p/[In]^{1/2}$ was used to determine the magnitude of the ratio $(2k_{tc} + 2k_{td})/k_p^2$ at 45°; in this expression $2k_{tc}$, $2k_{td}$ are the rate constants for the disappearance of polyvinyl acetate radicals by mutual combination and disproportionation respectively and k_p is the propagation rate constant. The rate of initiation of polymerization was estimated by coupling the rate constant, k_d, for the decomposition of azobisisobutyronitrile in solution (11), after correcting for solvent effect (12), with the initiator efficiency of 0.54 recently determined by Tüdös and co-workers (8). The resulting value of $(2k_{tc} + 2k_{td})/k_p^2$ is 7.6 ± 1.1 $mol\ l^{-1}\ s$ at 45°; the error limits, ± 1.1 $mol\ l^{-1}\ s$, are based on assumed uncertainties of 10% in k_d, 10% in the initiator efficiency and 5% in $R_p/[In]^{1/2}$.

The effect of tri-*t*-butylphenol on the rate of polymerization of vinyl acetate at 45° is shown

in Table 1. The reaction is strongly retarded, the addition of 0.02 M tri-t-butylphenol reducing the rate to less than one quarter of the unretarded rate. The results were analyzed by the method of Jenkins (5) on the assumption that reinitiation of polymerization by phenoxy radicals is negligible and that phenoxy radicals are lost only by a cross termination process. Jenkins defines a parameter λ equal to $R_p[M]_0/R_{p0}[M]$ where R_p, R_{p0} are the rates of the retarded and unretarded polymerization and [M], $[M]_0$ are the corresponding monomer concentrations. A plot of $1/\lambda - \lambda$ *vs.* phenol concentration should be linear and of slope $C_{tr,XOH}k_p^2[M]_0/R_{p0}(k_{tc} + k_{td})$; $C_{tr,XOH}$ is the ratio $k_{tr,XOH}/k_p$ and $k_{tr,XOH}$ is the rate constant for the hydrogen abstraction reaction 2:

[2] $$RM_n^{\cdot} + XOH \rightarrow RM_nH + XO^{\cdot}$$

The values of $1/\lambda - \lambda$ in Table 1 are plotted against phenol concentration in Fig. 1. The transfer constant $C_{tr,XOH}$ derived from these rate studies is 0.021 ± 0.004 at 45°.

Degree of Polymerization Studies

The number average degree of polymerization, $\bar{P}_n$, of the polyvinyl acetate resulting from polymerization of the pure monomer obeys relationship [3]:

[3] $$\frac{1}{\bar{P}_n} = \frac{(k_{tc} + 2k_{td})R_p}{k_p^2[M]^2} + \frac{k_{tr,M}}{k_p}$$

where $k_{tr,M}$ is the rate constant for the transfer reaction of polyvinyl acetate radicals with vinyl acetate monomer; transfer to polymer (13) can be neglected at low conversions of monomer to polymer. A plot of $1/\bar{P}_n$ *vs.* $R_p/[M]^2$

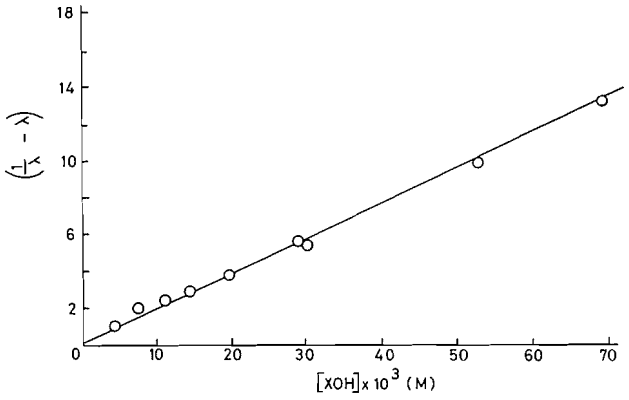

FIG. 1. Plot of $1/\lambda - \lambda$ *vs.* concentration of tri-t-butylphenol for vinyl acetate polymerization at 45°.

TABLE 2. The effect of phenol concentration on the degree of polymerization of polyvinyl acetate for two series of experiments

Series	10^4[XOH]/[M]	$10^4/\bar{P}_n$	$10^4(1/\bar{P}_n - (k_{tc} + 2k_{td})R_p/k_p^2[M]^2)$
I	0	1.832	1.66
I	0	1.957	1.77
II	0	1.888	1.69
II	0	1.919	1.72
II	7.16	2.057	1.99
I	7.19	1.969	1.90
II	13.5	2.204	2.15
II	18.7	2.439	2.40
II	27.6	2.654	2.62
II	28.5	2.758	2.72
I	31.5	2.874	2.86
I	50.8	3.369	3.35

gives a straight line of slope 7 ± 2 mol l^{-1} s and intercept $(1.72 \pm .05) \times 10^{-4}$ at 45°. The value of 7 mol l^{-1} s for $(k_{tc} + 2k_{td})/k_p^2$ is in fair agreement with the results of Schulz and Roberts-Nowakowska (14) but is much lower than the value used in an earlier study (3), based on kinetic data (9) and the assumption of disproportionation as the predominant termination mechanism (15). The monomer transfer constant, 1.72×10^{-4} at 45°, is in agreement with recent estimates; these include 1.32×10^{-4} at 40° and 1.91×10^{-4} at 60° (14), 2.0×10^{-4} at 45° (3), 1.9×10^{-4} at 60° (16), and 1.88×10^{-4} at 60° (10) (see also the summary by Lindemann (13)).

The degree of polymerization is reduced to a far less extent than the rate of polymerization on the addition of tri-*t*-butylphenol; for example, $\bar{P}_n$ is reduced to three quarters of the unretarded value at 45° by the addition of 0.02 *M* tri-*t*-butylphenol. If phenoxy radicals disappear from solution only by reaction with polyvinyl acetate radicals in a cross termination process, the dependence of $\bar{P}_n$ on phenol concentration should be given by eq. 4.

$$[4] \quad \frac{1}{\bar{P}_n} = \frac{(k_{tc} + 2k_{td})R_p}{k_p^2[M]^2} + \frac{k_{tr,M}}{k_p} + \frac{2k_{tr,XOH}[XOH]}{k_p[M]}$$

Typical results for the effect of phenol concentration on $\bar{P}_n$ at 45° are given in Table 2. A plot of $1/\bar{P}_n - (k_{tc} + 2k_{td})R_p/k_p^2[M]^2$ *vs.* [XOH]/[M] for the results at 45° is shown in Fig. 2. The transfer constant is found from degree of polymerization analysis to be 0.017 ± 0.002 at 45°.

Electron Spin Resonance Studies

A solution of tri-*t*-butylphenoxyl in pure vinyl acetate can be maintained at 45 °C for weeks with only a slight drop in radical concentration (less than 5% per week) as determined by e.s.r. spectroscopy. It is, therefore, confirmed that the phenoxy radical does not attack vinyl acetate monomer at an appreciable rate under the reaction conditions nor does it react with itself.

When tri-*t*-butylphenol (~0.1 *M*) was added to a solution of azobisisobutyronitrile in vinyl acetate at 45°, a stationary concentration of the corresponding phenoxyl was built up. A triplet

with peak to peak separation of 1.8 G (17) was readily observed at high gain. The phenoxyl concentration was independent of initiator concentration over the range 0.024–0.15 M at 45° within the limits of experimental error ($\pm 10\%$). When azobiscyclohexanenitrile was used as initiator, the same stationary concentration of phenoxyl was eventually observed. The phenoxyl concentration is thus independent of the initiator and its concentration at a given temperature.

The effect of 2,4,6-tri-*t*-butylphenol concentration on the stationary state concentration of phenoxyl was determined for the retarded polymerization at 45°. The phenoxyl concentration was 1.3×10^{-7} M when [XOH] was 0.065 M and it was proportional to the phenol concentration over the range studied. The mean value of the ratio [XO·]/[XOH] was $(1.9 \pm 0.3) \times 10^{-6}$ at 45°.

Discussion

The rate of free radical polymerization of vinyl acetate is reduced by the addition of alkyl phenols such as tri-*t*-butylphenol. The attack of polymer radicals on the phenol occurs at the OH group of the phenol because very much smaller effects are generally observed when the corresponding deuterated phenols are added at the same concentration (3, 18). The present work shows that a low stationary state concentration of tri-*t*-butylphenoxyl is built up as a result of the transfer process. The phenoxyl does not attack vinyl acetate at an appreciable rate and does not react with itself. The conclusion is therefore reached that effectively all the phenoxy radicals disappear by reaction with polyvinyl acetate radicals.

[5] $$RM_n^{\cdot} + XO^{\cdot} \rightarrow \text{products}$$

It is assumed that the products of reaction 5 are sufficiently inert not to affect the polymerization at the low concentration at which they are formed. If the rate constant of reaction 5 is k_5, the stationary state concentration of phenoxyl is given by [6].

[6] $$[XO^{\cdot}] = k_{tr,XOH}[XOH]/k_5$$

It is observed experimentally that the concentration of phenoxyl is proportional to the phenol concentration and is independent of the rate of initiation, in accord with eq. 6.

The transfer constant, $C_{tr,XOH}$ is estimated to be 0.021 ± 0.004 at 45° from rate measurements and 0.017 ± 0.002 at 45° from degree of polymerization measurements. The error limits in the value derived from rate measurements stem largely from uncertainty in the value of $(k_{tc} + k_{td})/k_p^2$. The agreement between the two estimates is satisfactory and lends further support to the proposed mechanism.

The value of $k_{tr,XOH}$ can be estimated provided that k_p is known at the polymerization temperature. The estimates of k_p in the literature vary widely but there is good agreement between the values of $k_p/(2k_{tc} + 2k_{td})$ obtained by various authors. Thus Matheson *et al.* (9) quote values of 22.6×10^{-6} at 50° and 17.2×10^{-6} at 25°, Bengough *et al.* (19) give a value of 21×10^{-6} at 45° and Bartlett *et al.* (20) a value of 17×10^{-6} at 25°. If $k_p/(2k_{tc} + 2k_{td})$ is assumed to be $(20 \pm 4) \times 10^{-6}$ at 45° and this is combined with the present estimate of $(2k_{tc} + 2k_{td})/k_p^2$, a value of $(6.6 \pm 1.7) \times 10^3$ l mol^{-1} s^{-1} is derived for k_p. The purity of the various monomer samples varied from one study to another and it is possible that larger limits of error should be assigned to k_p. However, if these limits are accepted, the rate constant for the reaction of polyvinyl acetate radicals with 2,4,6-tri-*t*-butylphenol, $k_{tr,XOH}$, is 125 ± 38 l mol^{-1} s^{-1} at 45°.

The mean value for the ratio [XO·]/[XOH] is 1.9×10^{-6} at 45°. The rate constant for the cross termination reaction 5 is given from eq. 6 as $(6.6 \pm 2.3) \times 10^7$ l mol^{-1} s^{-1} at 45°. This high value indicates that the reaction between polyvinyl acetate radicals and tri-*t*-butylphenoxyl is not subject to considerable steric hindrance. The ease of cross termination with hindered phenoxy radicals may mean that cross termination is far more important than mutual termination of phenoxy radicals even when their interaction is less subject to steric hindrance. This suggestion is being investigated by extension of these studies to other phenols, such as 4-methyl-2,6-di-*t*-butylphenol, which give phenoxyls capable of reacting with themselves at an appreciable rate.

The authors are grateful to the National Research Council of Canada for grant support, a bursary to H.L. (1967–1968) and a scholarship to R.D.P. (1969–1971).

Sequence Studies in Biosynthesis: Trichothecin

J. M. FORRESTER AND T. MONEY

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received May 8, 1972

An investigation of the precursor activity of α-bisabolol, γ-bisabolene and monocyclofarnesol indicates that these compounds are not intermediates in the biosynthesis of trichothecin.

Une étude sur l'activité du précurseur de l'α-bisabolol, γ-bisabolène et monocyclofarnésol montre que ces composés ne sont pas des intermédiaires dans la biosynthèse de la trichotécine.

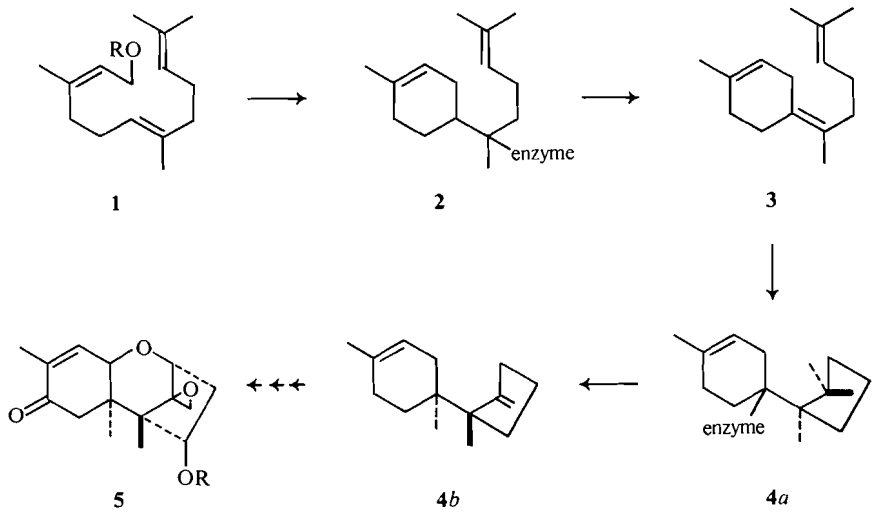
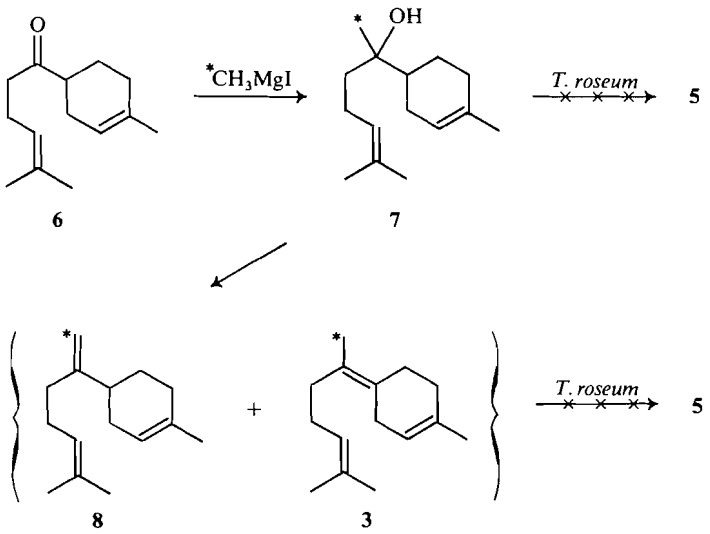
The biosynthesis of the trichothecane antibiotics has been the subject of considerable investigation. Results obtained by various research groups have shown that the complex structures (*cf.* **5**) of the group are derived from three molecules of mevalonic acid (1–4) and that farnesyl pyrophosphate (**1**) (2, 5) is an intermediate in this process (see Scheme 1). Beyond this the biosynthetic sequence has not been elucidated although the proposal has been made that cyclization of **1** could lead to γ-bisabolene (**3**) (3, 6–10) via a monocyclic intermediate **2** of undetermined structure. Subsequent cyclization of γ-bisabolene (**3**) to the trichothecane skeleton (*cf.* **4***b*) in addition to oxidation reactions of an undefined nature (3, 7, 8) could produce representative members of this group *e.g.* trichothecin (**5***a*). We have been concerned with the validity of these proposals and recent results by Adams and Hanson (4) which elegantly preclude the intermediacy of γ-bisabolene (**3**) prompt us to record our own observations in this area.

Our first investigations (1968) involved α-bisabolol (**7**) which we considered to be a possible intermediate in the process (*i.e.* equivalent to **2**) (see Scheme 2). Radioactive α-bisabolol (**7**) was obtained from ketodiene (**6**) (11) by treatment with C^{14}-methylmagnesium iodide. An aqueous solution of 9-C^{14}-α-bisabolol (0.37 mCi/mmol) was solubilized with Tween 20 and added to 5-day-old cultures of *Tricothecium roseum*.



SCHEME 1



(* = carbon – 14)

SCHEME 2

After a period of three weeks trichothecin was isolated (1) and repeatedly crystallized from petroleum ether (60–80°) until constant radioactivity (5.3×10^{-5} mCi/mmol) had been attained (incorporation 0.014%). Alkaline hydrolysis (KOH/MeOH) of tricothecin (**5***a*) yielded trichothecolone (**5***b*) (3.3×10^{-5} mCi/mmol) possessing only 60% of the original activity. Jones and Lowe have shown (1) that the isocrotonate unit in trichothecin is acetate-derived and our results indicate that extensive degradation of α-bisabolol to radioactive units (acetate?) had occurred prior to incorporation.

We then turned our attention to the precursor activity of γ-bisabolene (**3**). Dehydration of 9-C^{14}-α-bisabolol (**7**) with $POCl_3$/pyridine yielded a mixture of β-bisabolene (**8**) and γ-bisabolene (**3**). The presence of at least 50% γ-bisabolene was determined by g.l.c. and in non-radioactive runs the isomeric bisabolenes were isolated and identified by n.m.r. For the biosynthetic experiment an aqueous solution of the mixture[1] of **8** and **3** (solubilized by Tween 20) was administered to *T. roseum*. Trichothecin was isolated after three weeks and was shown to have specific activity of 1.88×10^{-5} mCi/mmol (specific incorporation 0.005%). Alkaline hydrolysis yielded trichothecolone (1.15×10^{-5} mCi/mmol), possessing only 60% of the original activity present in trichothecin.

The low and non-specific incorporation of α-bisabolol, β-bisabolene, and γ-bisabolene seemed to exclude the intermediacy of these compounds in the biosynthetic process and, as noted earlier, this has been decisively shown by Adams and Hanson (4) using specifically labelled mevalonic acid and geranyl pyrophosphate. It is of interest to note that Nozoe and co-workers (12) have come to a similar conclusion with the cuparene-type sesquiterpene helicobasidin (**13**).

An alternative biosynthetic route to the cuparene type intermediate (**4***a*) has been considered (13). This involves cyclization of monocyclofarnesol (**11**) to a spiro bicyclic intermediate (**12**) (see Scheme 3) reminiscent of the type postulated in the biosynthesis of the chamigrenes (**14**). Subsequent ring contraction could then provide **4***a*. We have evaluated the merit of this biosynthetic proposal by examining the precursor activity of monocyclofarnesol (**11**). The latter compound was synthesized in radioactive form by condensing dihydro-β-ionone (**9**) (14), in a modified Wittig reaction (15, 16), with methyl

[1]Although it would have been more meaningful to have proceeded with studies on pure β- and γ-bisabolene, the separation of small quantities of radioactive samples of these compounds would have resulted in considerable loss of valuable material. In addition we considered that if either or both isomers were on the main biosynthetic route a considerable and specific incorporation would be easily discerned.

(* = carbon – 14)

SCHEME 3

1-C^{14}-bromoacetate followed by reduction of the intermediate ester **10**. Administration of **11** to *Trichothecium roseum* in the manner described above yielded trichothecin with specific activity 0.867×10^{-5} mCi/mmol (specific incorporation 0.003%). Conversion to trichothecolone (0.237×10^{-5} mCi/mmol) with substantial decrease in radioactivity indicated that monocyclofarnesol (**11**) had been extensively degraded prior to incorporation.

These results would seem to suggest that the biosynthetic route from farnesyl pyrophosphate to trichothecin proceeds directly to intermediate **4***a* and does not involve intermediates of the type previously suggested.[2]

[2]A recent report (20) describes the incorporation of trichodiene (**4***b*) into trichothecin.

Experimental

All melting points were determined on a Kofler block and are uncorrected. I.r. spectra (ν_{max}) were recorded on a Perkin–Elmer Infracord model 137 spectrophotometer. N.m.r. spectra (τ) were determined in carbon tetrachloride or deuteriochloroform solution and recorded on a Varian Associates model T-60 spectrometer. Signal positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, coupling constants (where appropriate), and integrated peak areas are indicated in parentheses; s = singlet, br.s = broad singlet, d = doublet, t = triplet, m = multiplet. Mass spectra (M^+) were determined with an AEI model MS9 spectrometer. Microanalyses were determined by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. T.l.c. results were obtained using silica gel HF^{254} of 0.5 mm thickness. A Nuclear-Chicago Mark 1 model 6860 Liquid Scintillation counter was used for radioactivity measurements.

α-Bisabolol (7)

To a solution of methyl magnesium iodide, prepared from

methyl iodide (106.5 mg, 0.75 mmol) and magnesium powder (19.8 mg, 0.83 mmol) in ether (5 ml), was added ketodiene (**6**) (11) (51.5 mg, 0.25 mmol) in ether (2 ml). The mixture was allowed to stir at room temperature for 2 h then worked-up by adding saturated aqueous ammonium acetate solution. The ether layer was separated and the aqueous phase extracted twice with ether. The combined ether layers were washed with brine and dried (Na_2SO_4). Evaporation of the ether gave α-bisabolol (**7**) (55 mg, 100%) as a colorless oil; ν_{max}(liquid film) 3435, 2915, 1440, 1370, 1105, 830, 800 cm^{-1}; τ (CCl_4) 4.67 (s, 1H), 4.90 (t, $J = 7$ Hz, 1H), 7.60–8.23 (m, 7H), 8.37 (s, 9H), 8.50–8.87 (m, 5H), 8.93 (d, $J = 2$ Hz, 3H): M^+ *m/e* 222.

9-C^{14}-α-Bisabolol (7)

α-Bisabolol (**7**) was prepared as above using C^{14}-methyl iodide (213.0 mg, 1.5 mmol, 1 mCi, 0.667 mCi/mmol), magnesium powder (39.6 mg, 1.65 mmol) and ketodiene (**6**) (103 mg, 0.5 mmol). The yield of 9-C^{14}-α-bisabolol (**7**) was 110.0 mg (100%), and the specific activity was determined to be 0.33 mCi/mmol.

Isolation of Trichothecin (5a) from Trichothecium roseum

Trichothecium roseum was grown as described in the literature (17, 18) except that the p*H* was not adjusted. Trichothecin (**5***a*) was isolated as described in the literature (18) except that preparative t.l.c. on silica gel was used in the purification rather than column chromatography on alumina. In a typical experiment 10 flasks of *T. roseum* were allowed to grow for 3 weeks. The broth was then filtered, the mycelia washed with a little water, and the combined washings and broth extracted with carbon tetrachloride (2 × 100 ml). Evaporation of the carbon tetrachloride gave a gum (148.6 mg) which was purified by t.l.c. on silica gel, using petroleum ether–ethyl acetate (1:1). Under u.v. radiation the trichothecin (**5***a*) showed up as a dark band approximately half way up the plate. Extraction of this band with ethyl acetate and subsequent removal of solvent gave trichothecin (**5***a*) (94.3 mg). Crystallization from petroleum ether (60–80°) provided pure trichothecin (**5***a*) as white needles, m.p. 116–118 °C (lit. (17), m.p. 118 °C); ν_{max} ($CHCl_3$) 1715, 1685 cm^{-1}.

Administration of 9-C-^{14}-α-Bisabolol (7) to Trichothecium roseum

To 9-C^{14}-α-bisabolol (**7**) (52 mg, 0.087 mCi) was added water (20 ml) and Tween 20 (2 ml). This well shaken mixture was then evenly distributed among 10 flasks of 5-day-old cultures of *T. roseum* which were then left for a further 20 days. The trichothecin was isolated as before and recrystallized to constant specific activity (5.3×10^{-5} mCi/mmol) (specific incorporation, 0.014%).

Trichothecolone (5b)

Trichothecin (50 mg, 0.15 mmol) was stirred overnight at room temperature in 1 *N* methanolic potassium hydroxide solution (2 ml). Water (1.5 ml) was added and the methanol evaporated *in vacuo*. The aqueous layer was then extracted with chloroform, removal of which gave a colorless gum which slowly crystallized. This was recrystallized from benzene–petroleum ether (2:1) to give trichothecolone (39.8 mg, 100%) as white needles, m.p. 182–184 °C (lit. (19), m.p. 183–184 °C); ν_{max}($CHCl_3$) 3560, 1680 cm^{-1}.

Hydrolysis of C^{14}-Labelled Trichothecin (5a)

C^{14}-Labelled trichothecin (**5***a*) (5.3 mg) was diluted with inactive trichothecin (10.6 mg) and this was hydrolyzed as above to give C^{14}-labelled trichothecolone (**5***b*) (9.5 mg) which was recrystallized to a constant specific activity of 1.1×10^{-5} mCi/mmol, representing loss of 40% of the radioactivity.

γ-Bisabolene (3)

To a solution of α-bisabolol (**7**) (75 mg, 0.3 mmol) in pyridine (1 ml) was added a solution of phosphorus oxychloride (0.5 ml) in pyridine (2 ml). The reaction mixture was stirred overnight, added to ice-water and the aqueous mixture extracted with ether. The combined ether extracts were washed with brine, dried ($MgSO_4$), and the ether evaporated *in vacuo* to give a yellow oil (45.6 mg, 75%). Purification of this oil by preparative g.l.c. on a 30% Carbowax column at 180 °C gave two components with very similar retention times. The less volatile peak (~50%) was shown to be γ-bisabolene (**3**); ν_{max}(liquid film) 2935, 1440, 1370, 1145, 1100, 910, 825, 800 cm^{-1}; τ (CCl_4) 4.67 (br.s, 1H), 4.93 (t, $J = 7$ Hz, 1H), 7.37 (m, 2H); 8.07 (m, 8H), 8.38 (m, 12H). The more volatile peak (~50%) was shown to be β-bisabolene (**8**) plus other unidentified isomers(s), ν_{max} (liquid film) 2940, 1650, 1445, 1375, 920, 890, 830, 800 cm^{-1}; τ (CCl_4) very similar to the n.m.r. spectrum of γ-bisabolene (**3**) but showing signal at 5.3 τ attributable to C=CH_2 group in (**8**).

9-C^{14}-γ-Bisabolene (3)/9-C^{14}-β-Bisabolene (8)

C^{14}-Labelled α-bisabolol (55 mg) was dehydrated as above and the crude product purified by chromatography on alumina to yield 9-C^{14}-γ-bisabolene (**3**) and 9-C^{14}-β-bisabolene (**8**) as a colorless oil (13 mg).

Administration of 9-C^{14}-γ-Bisabolene (3)/9-C^{14}-β-Bisabolene (8) to Trichothecium roseum

A well shaken mixture of 9-C^{14}-γ-bisabolene (**3**) (13 mg, 0.024 mCi), water (5 ml), and Tween (20) (0.5 ml) was evenly distributed among five flasks of 1-week-old cultures of *T. roseum*. After 3 weeks trichothecin was isolated as before and crystallized to constant specific activity (1.88×10^{-5} mCi/mmol) (specific incorporation 0.005%). The remaining trichothecin (**5***a*) was hydrolyzed as described above to give trichothecolone (**5***b*) with specific activity of 1.15×10^{-5} mCi/mmol representing a loss of 40% of the radioactivity originally present in trichothecin.

Dihydro-β-ionone (9)

β-Ionone (19.2 g, 0.1 mol) was hydrogenated in ethanol (50 ml) using Raney nickel (~4 g) as catalyst. After uptake of the theoretical volume of hydrogen the catalyst was removed by filtration, the ethanol removed *in vacuo* and the resulting oil distilled to give dihydro-β-ionone (**9**) (14.0 g, 72%) as a colorless oil, b.p. 115–116 °C (9 mm) (lit. (14), b.p. 122–122.5 °C (12 mm)); ν_{max} 2940, 1725, 1360, 1155 cm^{-1}; τ (CCl_4) 7.68 (m, 4H), 7.94 (s, 3H), 8.43 (s, 3H), 9.00 (s, 6H); M^+ *m/e* 194.

Anal. Calcd. for $C_{13}H_{22}O$: C, 80.35; H, 11.41. Found: C, 80.59; H, 11.48.

Methyl Monocyclofarnesate (10)

Ether washed 50% sodium hydride/oil dispersion (0.48 g, 0.01 mol NaH) was added to dry benzene (50 ml), and tri-

methylphosphonoacetate (1.82 g, 0.01 mol) in benzene (5 ml), added at room temperature. After stirring at room temperature for 0.5 h, dihydro-β-ionone (**9**) (1.35 g, 0.007 mol), in benzene (5 ml) was added dropwise and the solution refluxed for 15 h. On cooling, water was added and the resulting oil extracted three times with ether, the ether was dried ($MgSO_4$) and evaporated *in vacuo*. Distillation gave methyl monocyclofarnesate (**10**) (1.0 g, 57%) as a colorless oil, b.p. 81–83 °C (0.02 mm); ν_{max} 2935, 1720, 1645, 1430, 1355, 1220, 1140 cm^{-1}; τ (CCl_4) 4.37 (br.s, 1H), 6.37 (s, 3H), 7.80 (s, 2H), 7.84 (s, 3H), 8.38 (s, 3H), 8.97 (s, 6H); M^+ *m/e* 250.

Anal. Calcd. for $C_{16}H_{26}O_2$: C, 76.76; H, 10.47. Found: C, 77.16; H, 10.59.

Monocyclofarnesol (11)

Lithium aluminum hydride (30 mg, 0.79 mmol) was added to a solution of methyl monocyclofarnesate (**10**) (300 mg, 1.2 mmol) in ether (10 ml). The resulting solution was stirred overnight and worked-up by adding ice–dilute HCl. The ether layer was separated and the aqueous layer was extracted three times with ether. The combined ether extracts were washed thoroughly with brine, dried ($MgSO_4$) and the ether evaporated *in vacuo* to give monocyclofarnesol (**11**), (252 mg, 95%) as a colorless oil, ν_{max} 3350, 2940, 1670, 1460, 1380, 1110, 1000 cm^{-1}; τ (CCl_4) 4.64 (t, $J = 7$ Hz, 1H), 5.98 (d, $J = 7$ Hz, 2H), 8.99 (s, 6H); M^+ *m/e* 222.

1-C^{14}-Monocyclofarnesol (11)

1-C^{14}-Methyl bromoacetate (306 mg, 2 mmol, 1 mCi, 0.5 mCi/mmol), trimethyl phosphite (248 mg, 2 mmol), and benzene (1 ml) were refluxed for 5 h. On cooling, benzene (4 ml) and pentane washed sodium hydride (50% oil dispersion) (240 mg, 5 mmol) were added and the solution allowed to stir at room temperature for 1.5 h. Dihydro β-ionone (**9**) (388 mg, 2 mmol) in benzene (5 ml) was then added and the solution allowed to reflux overnight. The reaction mixture was worked-up by adding water followed by ether extraction. Removal of the solvents gave a yellow oil which was purified by chromatography on silica. The fraction eluting with petroleum ether–benzene (3:1) consisted of methyl monocyclofarnesate (**10**) (171 mg). Methyl monocyclofarnesate (**10**) (171 mg, 0.68 mmol) was stirred in ether (10 ml) with lithium aluminum hydride (17.1 mg, 0.45 mmol) for 10 h. The reaction mixture was worked-up by adding dilute HCl followed by ether extraction and evaporation of the ether to give 1-C^{14}-monocyclofarnesol (**11**) (110 mg). The specific activity was determined to be 0.29 mCi/mmol.

Administration of 1-C^{14}-Monocyclofarnesol (11) to Trichothecium roseum

A well shaken mixture of 1-C^{14}-monocyclofarnesol (**11**) (55.0 mg, 0.071 mCi), water (18 ml), and Tween 20 (2 ml) was evenly distributed among 10 flasks of 7-day-old cultures of *T. roseum*. After a further 24 days the trichothecin (**5***a*) was isolated in the usual manner and recrystallized to constant specific activity (0.867×10^{-5} mCi/mmol), representing an incorporation of 0.003%. The remaining trichothecin was hydrolyzed as above to give trichothecolone (**5***b*) with specific activity of 0.237×10^{-5} mCi/mmol.

The Effect of Bridge Size on the Sigmatropic Rearrangement of 2,3-Dibenzoyl-2,3-diazabicyclo[2.2.*n*]alk-5-enes

MISS C. Y-J. CHUNG, DONALD MACKAY, AND T. D. SAUER
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received April 6, 1972

The thermal isomerization of the title compounds **3***a–d* to the bicyclic oxadiazines **4***a–d* becomes increasingly difficult with bridge size *n* and could not be detected in the case of **3***d*. The reversibility of the isomerization has been demonstrated for **3***c* ⇄ **4***c*.

Cyclooctadiene behaves both as a diene and as a dienophile in its reaction with azodibenzoyl.

L'isomérisation thermique des composés 3*a–d* en oxadiazines bicycliques 4*a–d*, devient de plus en plus difficile avec la taille *n* du pont et ne peut être détectée dans le cas de 3*d*. La réversibilité de l'isomérisation a été démontrée pour 3*c* ⇄ 4*c*. Le cyclooctadiène se comporte à la fois comme un diène et un diénophile dans sa réaction avec l'azodibenzoyle. The thermal isomerization of the [2.2.1] bicyclic adducts **1** of *cis*-hex-3-ene-2,5-dione and fulvenes to the dihydropyrans **2** has been recognized as a [3,3]-sigmatropic process (1). Two factors were implicated as driving forces, the exocyclic double bond which becomes conjugated in the product and the relief of angle strain in going from the [2.2.1] to the [3.3.0] bicyclic system (1).

We have subsequently shown (2) in the completely analogous isomerizations of the adduct, **3***a*, of azodibenzoyl with cyclopentadiene and, more recently (3), of its adduct, **3***b*, with 1,3-cyclohexadiene that neither the exocyclic double bond nor the relief of large amounts of strain are strict requirements, at least for the [2.2.1] diazabicyclo system.[1] We now wish to describe in detail the effect of variation in bridge size on the ease and reversibility of this isomerization in the homologous series **3***a–d*.

Azodibenzoyl reacted with an excess of 1,3-cycloheptadiene in refluxing benzene to give the Diels–Alder adduct **3***c*, m.p. 203–204°, in an almost quantitative yield. With 1,3-cyclooctadiene, however, it gave only a moderate yield (37%) of the adduct **3***d*, m.p. 207–208°, along with lesser amounts (10%) of the isomeric oxadiazine **4***d*, m.p. 145.5–146°, and much NH-containing material which was not examined further. Compounds **3***d* and **4***d* were separated by chromatography on alumina.

The structures of **3***c* and *d* follow from the similarity of all their spectra to those of **3***a*, (2) (Table 1), with the notable difference that the n.m.r. absorptions of their tertiary protons (and to a lesser extent the vinyl) were chemically shifted from one another, like those of **3***b* (3), and unlike those of **3***a* which are isochronous. This chemical shift difference was observable in a wide range of solvents, the values in pyridine-d_5

a, $n=1$; *b*, $n=2$; *c*, $n=3$; *d*, $n=4$;

[1]The adduct of dimethylfulvene and dimethyl azodicarboxylate has been reported (4) as very easily isomerized to a mixture of products, one of which was tentatively assigned an oxadiazine structure. Several pathways may thus be involved.

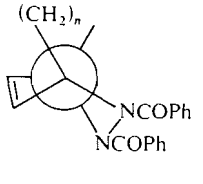
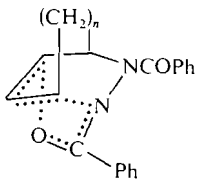
†Values and implied accuracy from the usual formulae, see *e.g.* ref. 13. The protons, while not coupled to one another, are coupled to other protons and appear as broad symmetrical peaks. The values may be approximate.
‡From ref. 3.
§Isomerization not detected.

(0.73 for 3*b*, 1.03 for 3*c* and 0.99 p.p.m. for 3*d*) being typical. Heating of the solutions of 3*b–d* in pyridine-d_5 caused coalescence of the absorptions at temperatures which increased with the bridge size (Table 2). The associated increase in the free energy of activation ($\Delta G_c^{\ddagger}$) for this exchange phenomenon parallels exactly the trend observed (5) for the related adducts of dimethyl azodicarboxylate (structures 3*b–d* with OCH_3 in place of Ph). Like these, 3*b–d* evidently exist in the twist conformation **5** in which the tertiary protons are diastereotopic. Slow interconversion of **5** with its enantiomer through a symmetric transition state exchanges the identity of these protons.

The strain-free twist forms of 3*b–d* permit a closer approach of the appropriate reacting oxygen and carbon atom pairs than does the symmetric and rigid adduct 3*a*,[2] suggesting that isomerization rates might be greater for these flexible systems than for 3*a*. Such an approach, however, would lead to a six-centered skew boat transition state, rather than to the symmetric boat form, and hence the symmetric bicyclic framework, **6**, ideally required by orbital symmetry considerations. The latter should dictate that the isomerization rates, like the exchange rates, would decrease in the order of increasing bridge size. This is indeed the case.



5



6

As reported earlier 3*a* isomerized rapidly at 100° (2) but 3*b* was stable up to 150°; at 200° the isomerization of 3*b* was complete in 1.5 h (3). By contrast 3*c* was stable indefinitely at 200°,[3] but g.l.c. analysis showed that in refluxing diphenyl ether (258°) it isomerized to 4*c*, which in turn slowly decomposed to a number of minor products. The ratio of 4*c*:3*c* rose to a maximum of 1.9:1 after 8 h and thereafter remained the same, indicating that the isomerization was reversible. The mixture, after refluxing for 6 h, was separated by conventional crystallization techniques giving unreacted 3*c* and its isomer 4*c*, m.p. 131–132°, which had all the properties expected of an oxadiazine (2, 3, 6). The reversibility was confirmed by re-heating pure 4*c* in diphenyl ether for 4 h, when the ratio of 4*c*:3*c* was about 3:1 and before much by-product had accumulated; again a mixture of 3*c* and 4*c* was obtained from which pure 3*c* was isolated by chromatography on silica gel.

The retro rearrangement of the 2-phenyl-4-benzoyl-1,3,4-oxadiazine to the *N,N'*-dibenzoylpyridazine derivative, involving in essence the synthesis of an amide group by a sigmatropic process, is thus established. It has parallels in the Claisen type rearrangement of allyloxytetrazoles, -benzoxazoles, -benzothiazoles (7), and -benzimidazoles (8). In these reactions, however, the group migrating to nitrogen is exocyclic and the reactions are irreversible.

In the non-degenerate Cope reaction with its six-carbon transition state framework the co-

[2]This is easily seen with models. The other oxygen and carbon pair are of course further apart, at their closest, than they are in 3*a*.

[3]Samples were heated in sealed evacuated tubes.

existence of both isomers in comparable amounts has been frequently noted (9, 10). In hetero-Cope reactions electronegativity differences in the atoms of the transition state must be expected to lead to significant bond energy differences between the two isomers into which it can pass. This in large measure must dictate that there should be considerable free energy differences between the isomers, especially when there is more than one hetero atom in the transition state, and hence several different bond types in the two isomers. In the large literature of Claisen rearrangements, though reversibility has been well established (9), examples in which isomerization is incomplete are rare (11, 12). The favorable equilibrium observed in **3***c* ⇄ **4***c* (a "di-hetero-Cope" system) must be considered fortuitous.

The adduct **3***d* was stable up to 320°,[3] thus ruling out the possibility that the formation of the oxadiazine **4***d*, isolated from the reaction of azodibenzoyl with an excess of 1,3-cyclooctadiene, noted earlier, could have arisen by isomerization of **3***d*. At 320° **4***d* was in fact shown to be completely degradable. Its decomposition set in about 310°, but the presence of **3***d* among the products could not be conclusively detected. Thus the thermal interconversion of **3***d* and **4***d* in either direction has not been demonstrated. Attempts to facilitate the isomerization by acid catalysis (3) also failed; **3***d* was unaffected when refluxed for 12 h in dioxan containing *p*-toluenesulfonic acid or for 1 day in pyridine containing sulfuric acid.

The free energy of activation for isomerizatio, $\Delta G^{\ddagger}_{isom}$, has already been estimated as 7 kcal mol^{-1} higher for **3***b* than for **3***a*, by comparison of their acid-catalyzed isomerizations under identical conditions (3). A direct comparison of the isomerization rates of **3***b* and *c* in refluxing diphenyl ether was obtained by g.l.c. analysis. The isomerization of **3***b* was rapid, clean, and quantitative with a first order rate constant of 2.2×10^{-2} s^{-1} ($\Delta G^{\ddagger}_{isom} = 35.6$ kcal mol^{-1}) (Table 2). The determination for **3***c* was complicated by the reversibility of the isomerization and the instability of the product **4***c* (the overall process is of the type A ⇄ B → C + D + -- and is thus kinetically complex). In the early stages (up to 3 h) of the reaction however, before by-product accumulation was significant, the concentration of **3***c* could be obtained directly from the ratio of the peak areas of **3***c* and **4***c*.[4] A plot of the concentration of **3***c* against time gave an initial slope from which the rate constant was estimated as 1.1×10^{-4} s^{-1} ($\Delta G^{\ddagger}_{isom} = 41.2$ kcal mol^{-1}).[5]

Only a lower limit can be placed on $\Delta G^{\ddagger}_{isom}$ for **3***d*. When **3***d* was refluxed for 8 h in diphenyl ether and the solution evaporated the n.m.r. spectrum of the residue was completely unchanged. If the detection limit of the isomer **4***d* is set at 5% then the rate constant is less than 1.8×10^{-6} s^{-1} representing a $\Delta G^{\ddagger}_{isom}$ value >45.5 kcal mol^{-1}.

As Table 2 shows, a direct comparison of the differences in free energy of activation for ring twisting ($\Delta\Delta G^{\ddagger}_{c}$) with the $\Delta\Delta G^{\ddagger}_{isom}$ values cannot be made[6] for successive members of the adducts **3**, but it is evident that they are perhaps half as large. This suggests that a considerable portion of the free energy of activation for isomerization can be identified with that for ring twisting as having a common origin, the requirement of a transition state with local C_s symmetry.

The increasing stability of the adducts **3** with bridge size *n* is related to an increasing twist angle. It might be expected to reach a limit when the twist angle corresponds to that of the pseudo boat form of an unbridged tetrahydropyridazine. Further increase in *n* could permit the tetrahydropyridazine to pass into the lower energy pseudo chair form, which would then resemble in stability the simple unbridged adduct **7** of butadiene. All efforts to isomerize **7** (14), alone or in the presence of acid, at temperatures up to 350° failed (above this it charred and decomposed). The thermal stability of **7** seems reasonable in the light of the known (15) high barrier to ring inversion for this ring system (~15 kcal mol^{-1}), which must be surmounted as a prerequisite to the boat form from which reaction can be initiated.

The flexibility of the [2.2.*n*]diazabicyclo

[4]The ratio of the peak areas of pure **3***c* and **4***c* was shown to be identical with the ratio of their concentrations.

[5]The early points on a plot of ln concentration of adduct against time gave a straight line fit from which the value of the rate constant could also be determined. The two values were within 10% of one another.

[6]Other activation parameters would be needed to correlate them at a common temperature. It is a safe guess that $\Delta S^{\ddagger}$ values for both processes for the adducts **3** are small and negative (13, 2). Thus $\Delta G^{\ddagger}$ values would increase slightly with temperature.

system in **3***b–d* is lost in the adducts derived from the cyclic azo compound 4-phenyl-1,2,4-triazoline-3,5-dione. Cyclohexadiene and cyclooctadiene gave quantitatively the adducts **8***a*, m.p. 172.5–174.5°, and **8***b*, m.p. 203.5–206.5°, in which the urazole ring is probably planar by analogy with related structures (16). Their room temperature n.m.r. spectra were very similar, apart from the differences expected in the methylene region. The vinyl and the tertiary protons in each were isochronous, the former as sharp multiplets (basically a triplet in **8***a* and a quartet in **8***b*) and the latter rather broadened. Ring inversional effects associated with the cycloalkene portion of the adduct **8***b*, *e.g.* **9** ⇄ **10**, are evidently fast at room temperature.

The formation of **4***d* from cyclooctadiene is of interest. Its identity follows by comparison of its spectroscopic properties in general with those of **4***a* (2), *b* (3) and *c* (Experimental), and its stereochemistry in particular from the n.m.r. absorption pattern of its tertiary protons. Its formation along with **3***d* in two competing Diels–Alder reactions represents, we believe, the first example in which a simple conjugated diene reacts as a dienophile with an azodicarbonyl compound as a heterodiene, though such a role for the latter towards other types of olefins is now well established (17–20).

Experimental

The i.r. spectra were taken on a Beckman IR10 or a Perkin–Elmer 457 spectrometer and the u.v. spectra on a Coleman EPS-3T Hitachi spectrometer. The n.m.r. spectra were run routinely on a Varian T-60, absorption values being measured against tetramethylsilane as internal standard. The coalescence temperatures for the adducts **3***b–d* were determined on a Varian HA-100 spectrometer with ethylene glycol as temperature calibration standard.

Solvents were purified by conventional means. Anhydrous magnesium sulfate was used as drying agent for solutions in organic solvents. Melting points are uncorrected.

1,3-Cycloheptadiene was made by the method of Hafner and Rellensmann (21), and 1,3-cyclooctadiene was purchased from Aldrich Chemical Co. The oxidation technique of Stickler and Pirkle (22) was used to prepare 4-phenyl-1,2,4-triazoline-3,5-dione.

6,7-Dibenzoyl-6,7-diazabicyclo[3.2.2]non-9-ene (3c)

A solution of azodibenzoyl (1.0 g, 4.2 mmol) and 1,3-cycloheptadiene (a two-fold excess) in carbon tetrachloride (25 ml) was refluxed for 16 h in the dark. The solution became almost colorless and a precipitate developed in the later stages. The solvent was removed and the residue was triturated with cold benzene (25 ml) to give the adduct (1.30 g, 94%) which had m.p. 199–201° directly. Recrystallization from carbon tetrachloride–hexane and finally from aqueous ethanol gave dense prisms, m.p. 203–204°; mass spectrum 332 (M^+, 77), 105 ($PhCO^+$, 100), 77 (Ph^+, 68); see Table 1 for other analytical data.

Isomerization of 3c to (±) cis-4-benzoyl-4,4a,5,6,9,9a-hexahydro-2-phenylcyclohepta-1,3,4-oxadiazine (4c)

Samples of the adduct **3***c* were stable indefinitely when heated at 200° in sealed evacuated tubes.

A solution of **3***c* (1.1 g, 3.2 mmol) in diphenyl ether (55 ml) was refluxed for 6 h. The solvent was distilled at 160° under reduced pressure, the final traces being removed by a stream of nitrogen at 100°. The dark residue was extracted with a large amount of hot petroleum ether (b.p. 35–60°), from which unreacted **3***c* crystallized and was removed on cooling. Evaporation of the mother liquor and crystallization of the residue from aqueous methanol gave the *oxadiazine* (17%), which was recrystallized to a constant m.p. of 131–132° from aqueous methanol; ν (CCl_4) 1643 cm^{-1} (C=O, C=N); ν (Nujol) 1630 cm^{-1} (C=O, C=N); λ_{max}(EtOH) 220, 295 nm (ε 17 600, 15 100); τ ($CDCl_3$) 2.0–2.8 (10 phenyl H), 3.5–4.3 (2 vinyl **H**, overlapping, nine lines), 4.93 (C_{4a}–H, broad, complex), 5.17 (C_{9a}–H, doublet, much further split), 7.5–8.7 p.p.m. (6 methylene H).

Anal. Calcd. for $C_{21}H_{20}N_2O_2$: C, 75.9; **H**, 6.1; N, 8.4. Found: C, 76.2; **H**, 6.3; N, 8.2.

Thin layer chromatography established the presence of at least two other minor products in the original reaction mixture.

Isomerization of 4c to 3c

The oxadiazine **4***c* (95 mg) was refluxed in diphenyl ether (5 ml) for 4 h and the solvent was removed under reduced pressure. The residue was chromatographed on silica gel from chloroform–hexane (1:1), elution with this solvent mixture giving a crystalline solid (48 mg) whose i.r. spectrum showed it to be mainly unchanged oxadiazine. Further elution with chloroform gave crystalline **3***c* (22 mg) which on recrystallization from carbon tetrachloride–hexane had m.p. 202–203°, alone or in admixture with **3***c* synthesized as described above.

Cycloaddition Reactions of Azodibenzoyl and 1,3-Cyclooctadiene

A solution of azodibenzoyl (4.0 g, 16 mmol) and 1,3-cyclooctadiene (40 ml) became almost colorless when heated at 100° for 5 h. The solution was evaporated and the residue was digested with hot benzene (40 ml) and then cooled and filtered. The small amount of insoluble material, which contained NH absorption in its i.r. spectrum, was not further examined and the benzene filtrate was chromatographed on neutral alumina. Elution first with benzene gave *(±)cis-1-benzoyl-4a,7,8,9,10,10a-hexahydro-3-phenyl-cyclo-octa-1 H-4,1,2-oxadiazine* (**4***d*) (0.59 g, 10%) and then with benzene–ether (19:1) gave *7,8-dibenzoyl-7,8-diaza-bicyclo[4.2.2]dec-9-ene* (**3***d*) (2.15 g, 37%). Further elution with benzene–ether (9:1) gave more NH-containing fractions (1.1 g).

The adduct **3***d* was twice crystallized from 90% ethanol as prisms, m.p. 207–208° (see Table 1).

The adduct **4***d* after two crystallizations from aqueous ethanol had m.p. 145.5–146°; ν (CCl_4) 1647 cm^{-1} (C=O, C=N); ν (Nujol) 1639, 1624 cm^{-1} (C=O, C=N); λ_{max}(EtOH) 220, 295 nm (ε 20 700, 17 100); τ ($CDCl_3$) 1.9–2.8 (10 phenyl H), 3.7–4.3 (2 vinyl H, overlapping, complex), 4.80 (C_{10a}—H, broad, complex), 5.08 (C_{4a}—H, multiplet), 6.7–9.1 p.p.m. (8 methylene H).

Anal. Calcd for $C_{22}H_{22}N_2O_2$: C, 76.3; H, 6.4; N, 8.1. Found: C, 76.1; H, 6.5; N, 8.2.

Attempted Thermal Isomerization of 3d and of 4d

Refluxing of either adduct for 10 h in decalin (187°) or 8 h in diphenyl ether (258°) caused no isomerization. Evaporation of the solvents at 100° in a stream of nitrogen led to the recovery of pure starting material.

Samples of each adduct (50 mg) were then heated in sealed evacuated tubes at various higher temperatures. At 305° **4***d* was unchanged after heating for 2 h, but at 320° it was converted into a dark gummy substance with a complex i.r. spectrum showing N—H absorption; evidence for the presence of **3***d* among the products, either in the spectrum or by t.l.c. analysis, was inconclusive. **3***d* was recovered with only slight discoloration and no change in its i.r. spectrum after heating for 2 h at 320°.

Attempted Acid-catalyzed Isomerization of 3d

A sample of **3***d* (50 mg) was refluxed for 12 h in dioxan (5 ml) containing *p*-toluenesulfonic acid (10 mg). Evaporation, addition of ether, and extraction of the solution with aqueous sodium hydrogen carbonate led to the recovery of pure **3***d* from the ethereal solution (n.m.r. spectrum).

Similarly **3***d* (50 mg) was refluxed for 1 day in pyridine (5 ml) containing a few drops of concentrated sulfuric acid. Evaporation and extraction of the residue with chloroform-*d* gave a solution whose n.m.r. spectrum was that of pure **3***d*.

Determination of Isomerization Rates by Gas–liquid Chromatographic Analysis

The analysis was carried out on a Varian Aerograph (series 1520) dual flame instrument using 1/8 in. columns of XE-60 on Varoport 30. A 1½ ft column with 1% stationary phase at 140° was used for the analysis of the product mixture **3***b* and **4***b* (**3***b* was unstable above 150°), and a 5 ft column with 3% stationary phase at 240° for **3***c* and **4***c*.

3*b* (20 mg) was added all at once to refluxing diphenyl ether (2 ml) and samples of the solution were withdrawn with pre-heated Pasteur pipettes at intervals over the next 2 min. The samples were diluted with acetone and chromatographed, peak areas being determined by photocopying (three times), cutting out and weighing. The first order rate constant was determined directly from the area ratios.

Similarly solutions of **3***c* and **4***c* (10 mg in each case) were refluxed in diphenyl ether (1 ml). Samples were withdrawn over a period of 30 h, diluted with acetone, and analyzed as above. Since several peaks due to by-products appeared in the later chromatograms, and since the reaction was reversible, only the early ratios of **3***c*:**4***c* were used to estimate the first order rate constant for the isomerization of **3***c*. An initial slope for the plot of concentration of **3***c* against time was used in the calculation.

Adducts of 1,3-Cyclohexadiene and 1,3-Cyclooctadiene with 4-Phenyl-1,2,4-triazoline-3,5-dione

In each case the azo compound (263 mg, 15 mmol) was added to a solution of the diene (0.5 ml) in benzene (5 ml) at room temperature. The cyclohexadiene solution became colorless instantaneously and the cyclooctadiene one within 5 min, both reactions being markedly exothermic. Evaporation gave straw-colored quantitative residues of **8***a* and *b* which crystallized. They had i.r. spectra identical with those of the adducts after recrystallization, **8***a*, m.p. 172.5–174.5° (dec.) from benzene–hexane, and **8***b*, m.p. 203.5–206.5° (dec.) from benzene–carbon tetrachloride, both as dense colorless prisms (Table 1).

Attempted Isomerization of 1,2-Dibenzoyl-1,2,3,6-tetrahydropyridazine (7)

(a) Thermal

A solution of **7** (50 mg) was refluxed in diglyme (2 ml, 222°) for 2 h. Water and ether were then added and the ether layer shaken out thoroughly with water. The residue from the ether layer was essentially pure **7** (i.r. spectrum).

A sample (50 mg) was heated in a sealed evacuated tube at 350° for 1½ h. The dark product was washed out of the tube with ether and decolorized with charcoal in the ether solution. Evaporation gave colorless, crystalline **7**, whose i.r. was that of analytically pure starting material.

(b) Acid-catalyzed

A sample (50 mg) was refluxed in heptane (50 ml) containing 2% trifluoroacetic acid for 14 h. The solution was evaporated and the residue washed with cold very dilute methanol, which induced crystallization. The product was pure **7** (i.r. spectrum).

We wish to thank Mr. R. F. Hobson of this department for the determination of the coalescence temperatures of the adducts **3***b–d*. The financial assistance of the National Research Council of Canada is acknowledged.

A Convenient Synthesis of L(+)-Muscarine

J. WHITING, Y.-K. AU-YOUNG, AND B. BELLEAU[1]

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 1, 1972

A new total synthesis of L(+)-muscarine is described. Performic acid oxidation of *N*-acetylcrotylglycine gave the corresponding 4,5-diol which was resolved at the α-carbon by stereospecific hydrolysis of the *N*-acetyl group of the L-isomer with hog kidney acylase I. The resulting α-L(+)-aminoacid diol (**3**: Chart 1) was deaminated with nitrous acid to give 4-hydroxy-5-methyl-2-tetrahydrofuran carboxylic acid with retention of configuration at position 2. Reaction of the corresponding methyl ester with dimethylamine gave two major amide constituents in 65% yield. Reduction of these two *N*,*N*-dimethylamides (**5***a* and *b*) with lithium aluminum hydride followed by quaternization with methyl iodide afforded a pure isomer of L(+)-muscarine (**6***a*) and L(+)-muscarine (**6***b*) in high yields. The biological activity of the latter was the same as that of the natural alkaloid.

Une nouvelle synthèse totale de la L(+)-muscarine est décrite. L'oxydation par l'acide performique du *N*-acétyl crotylglycine donne le diol-4,5 correspondant qui a été résolu au niveau du carbone α par hydrolyse stéréospécifique du groupe *N*-acétyle de l'isomère L par l'acylase I, provenant de rein de porc. L'α-L-(+)amino acide diol (**3**, partie I) résultant, après désamination par l'acide nitreux, conduit à l'acide hydroxy-4 méthyl-5 tétrahydrofurane-2 carboxylique avec rétention de configuration sur le carbone 2. La réaction de l'ester méthylique correspondant avec la diméthylamine donne essentiellement deux composés amides avec un rendement de 65%. La réduction de ces deux *N*,*N*-diméthylamides (**5***a* et *b*) par l'hydrure de lithium d'aluminum suivie d'une transformation en sel quaternaire par l'iodure de méthyle, a permis l'obtention d'un isomère pur de la L(+) muscarine (**6***a*) et de la L(+) muscarine (**6***b*), avec de bons rendements. L'activité biologique de cette dernière est la même que celle de l'alcaloide naturel.

Canadian Journal of Chemistry, **50**, 3322 (1972)

Introduction

As part of our research studies on the nature and function of the acetylcholine receptor protein of excitable membranes (1, 2, 3), access to the potent cholinomimetic alkaloid L(+)-muscarine (**6***b*; Chart 1) (4) and its radioactive form became essential in order to discriminate between pharmacologically specific and non-specific binding sites. Extraction of the alkaloid from natural sources (5) is impractical at best and most of the recent biological studies with this quaternary base and its stereoisomers have been carried out with totally synthetic materials (6). The synthesis, chemistry, and stereochemistry of muscarine have been reviewed by Wilkinson (7) and also by Eugster (8) who has pioneered much of the relevant work in this fundamental area of medicinal chemical research. The X-ray structure and absolute configuration of the alkaloid have been elucidated by Jellinek (9). Subsequently, Pauling (10) has drawn analogies between its conformation and that of acetylcholine in the crystalline states. We wish to report on a new synthetic approach which provides access to L(+)-muscarine more conveniently and efficaciously than before. Adaptation of the method to the preparation of the radioactive analog can be readily visualized.

The synthetic scheme illustrated in Chart 1 was adopted because of the following broad advantages that it offers: (*a*) the intermediacy of an *N*-acylated α-aminoacid provides for ready enzymatic resolution to an optically pure L(+)-aminoacid (11); (*b*) nitrous acid deamination of α-aminoacids proceeds with complete rentention of configuration (11) and, in a favorable case such as **3** (Chart 1), ring closure to a tetrahydrofuran ring should compete favorably with α-substitution by the solvent (12). In this manner, the desired natural absolute configuration about C-2 of **4** (Chart 1) would be secured without ambiguity or difficulty. From there, it should be a simple matter of adapting Eugster's techniques (8).

Performic acid oxidation of predominantly *trans*-*N*-acetyl-DL-crotylglycine (**1**) (13) followed by mild alkaline hydrolysis gave **2** in high yield as a mixture of stereoisomers. Incubation of the latter mixture at p*H* 8 with

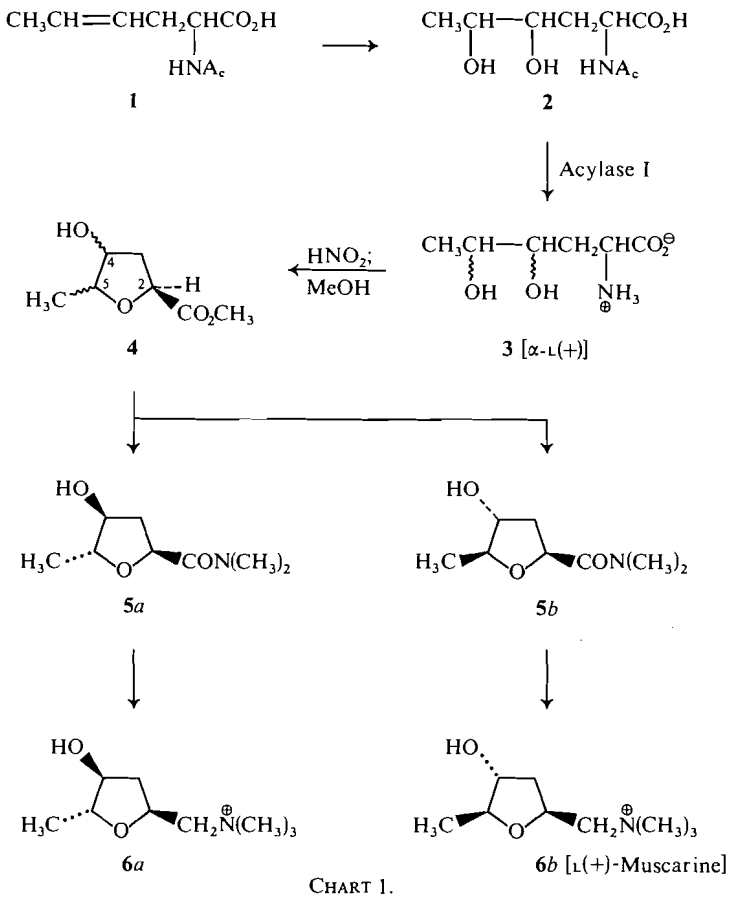

CHART 1.

hog kidney acylase I led to the isolation in 25% yield of a pure crystalline L(+)-α-aminoacid (**3**) unresolved about its hydroxyl bearing carbons. This optically active mixture of predominantly *threo*-diols was treated with nitrous acid and the resulting ring-closed acid esterified with methanolic hydrogen chloride to give optically active **4** as a clear oil in 42% yield (based on **3**). Reaction of the latter with ethanolic dimethylamine according to the literature (8 and refs. cited therein) gave a mixture of amides in good yield. Given that configurational integrity is retained at position 2, there are four possible stereoisomers about C-4 and -5 but two should predominate since *trans*-**1** should yield mostly *threo*-diols. All four were actually detected and isolated by chromatography on silicic acid but only two major crystalline fractions (**5***a* and *b*) in 1:1 ratio accounted for 65% of the total amide mixture. These two predominant isomers were reduced with lithium aluminum hydride and the resulting amines converted to their corresponding crystalline quaternary iodides. The first major isomer (from **5***a*) was shown to possess structure **6***a* by high resolution n.m.r. spectroscopy (220 MHz) (see Fig. 1). However, the relative configuration about positions 4 and 5 was not determined although we are inclined to favor the *allo*-arrangement (**6***a*) on the basis that the predominantly *trans*-configuration of the starting crotylglycine (**1**) should lead to a predominance of the DL-*threo*-diol (**2**) which in turn should ultimately give equal amounts of the two possible *trans*-enantiomers about positions 4 and 5 as the major products. In agreement with this expectation, Mr. Bruce Lippert of our laboratories established that, whereas the first major isomer **6***a* possessed very weak activity on the guinea-pig ileum (in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

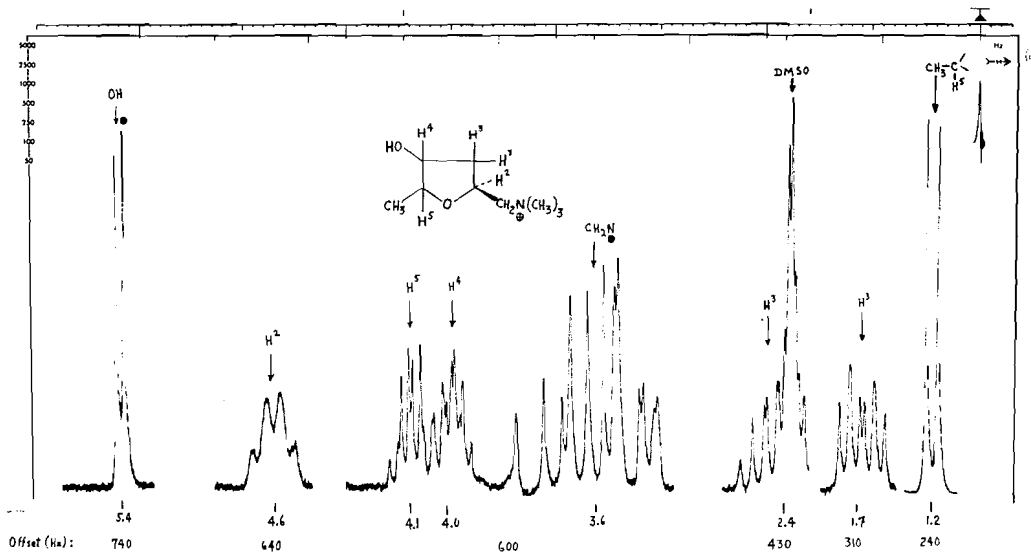

FIG. 1. The n.m.r. spectrum of **6***a* at 220 MHz in 1:1 DMSO–benzene (sweep time 100 s; sweep width 500 Hz; sweep offset variable as indicated). In the absence of benzene, H^4 and H^5 are poorly resolved. Irradiation of H^4 collapsed the OH to a singlet but irradiation of H^5 did not. Irradiation of OH caused partial collapse of H^4 but not of H^5. Only structure **6***a* is consistent with these data (supplied by Dr. A. H. Grey of the Canadian 220 MHz n.m.r. center at Sheridan Park, Ontario).

agreement with published data for DL-allomuscarine (6)), the other major isomer **6***b* surpassed acetylcholine in potency by a factor of 2. Since of all the possible stereoisomers of muscarine only the natural alkaloid displays such uniquely high activity (6), it follows that the second major isomer is L(+)-muscarine (**6***b*). Therefore, the other major isomer may be tentatively assigned the *allo*-configuration **6***a* which is enantiomeric with **6***b* at positions 4 and 5. Access to the rare L(+)-muscarine has become significantly easier than before.

Experimental

2-Acetamido-4,5-dihydroxyhexanoic Acid (2)

To a warm solution of 5.5 g of *N*-acetyl crotylglycine (13) in 22 ml of 98% formic acid was added slowly 5.5 ml of 30% hydrogen peroxide. After the addition was completed, the mixture was stirred for *5 h at 40–50° and then evaporated to dryness in vacuo*. The residue was dissolved in 25 ml of 10% aqueous sodium carbonate, the solution allowed to stand 15–17 h, followed by acidification and evaporation to dryness *in vacuo*. The residue was extracted with 2-propanol and the combined extracts treated with 25 g of Dowex 50W × 8 resin. After vigorous shaking for 30 min, the mixture was filtered and the filtrate evaporated to dryness *in vacuo* to yield a viscous yellowish oil (5 g) whose n.m.r. spectrum was consistent with structure **2** or the corresponding lactones. A substantial proportion was in the lactone form as judged from the i.r. spectrum.

Enzymatic Resolution of **2**

A solution of 4 g of the preceding material in 290 ml of pure water was treated with 2 *N* LiOH until the p*H* remained constant at 8.0 (lactone opening is gradual so that LiOH is consumed over a period of several minutes). A 5 mg portion of hog kidney acylase I (sigma) was added and the volume of the solution brought to 1600 ml and gently stirred at 38° for 20 h while adding appropriate quantities of 2 *N* LiOH so as to keep the p*H* as close to 8 as possible. The p*H* of the solution was then adjusted to 5 with acetic acid, the mixture filtered through Norit, and the filtrate concentrated *in vacuo* to a volume of about 800 ml followed by treatment with 100 g of Dowex 50W × 8 (50–100 mesh) resin in the acid form. After shaking for 30 min, the suspension was filtered, the resin washed with water, and then suspended in 200 ml of a 2 *M* solution of triethylamine in 20% aqueous methanol. The suspension was filtered, the resin washed with another 200 ml portion of the same solution and the combined filtrates evaporated to dryness *in vacuo*. The residue was first crystallized from 2-propanol and then from ethanol–water to give 1.0 g of white crystals, m.p. 185–187° (dec.), $[\alpha]_D^{25}$ 4.3° (H_2O).

Anal. Calcd. for $C_6H_{13}NO_4$: C, 44.17; H, 8.00. Found: C, 44.31; H, 7.88.

The filtrate from the Dowex resin was evaporated to dryness *in vacuo* and the residue crystallized from methanol–ether to give 1.0 g of white needles, m.p. 182–185°; $[\alpha]_D^{25}$ 43.2° (H_2O). This compound proved to be the unhydrolyzed *N*-acetyl derivative enriched in the D-isomer.

Anal. Calcd. for $C_8H_{15}NO_5$: C, 46.83; H, 7.31. Found: C, 46.61; H, 7.42.

Ring Closure to ***4***

To a solution of 7.1 g of the preceding L(+)-aminoacid in 18 ml of water containing 8.5 g of silver nitrite was added dropwise 56 ml of 1 *N* HCl while stirring vigorously at 0°. After 1 h, the mixture was allowed to warm to room temperature and continuously stirred for 15–17 h. A few drops of dilute HCl were added and the silver chloride filtered off. The filtrate was evaporated to dryness *in vacuo* and the residue dissolved in dry methanolic hydrogen chloride. After 15 h at room temperature, the solution was evaporated and the product distilled to give 2.90 g (42% yield) of a colorless oil, b.p. 94–95°/0.4 mm; i.r.: 3440 ν(OH), 1720 ν(C=O), 1190 and 1050 cm^{-1} ν(C—O); $[\alpha]_D^{25}$ −10.4° (H_2O).

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.50; H, 7.50. Found: C, 52.36; H, 7.62.

Aminolysis of ***4*** *to* ***5***

A solution of 8.5 g of the preceding ester in 125 ml of a 33% ethanolic solution of dry dimethylamine was heated at 100° in a steel bomb for 24 h. The solution was evaporated *in vacuo* and the residual oil extracted repeatedly with ether. The ether was evaporated and the light brown oil applied in a little chloroform to a column of 1800 g of Silicar CC7 (chromatographic grade). Elution with chloroform (several liters) led to separation (as continuously monitored by t.l.c.) of the crude amide into four fractions: first to be eluted was ~0.9 g of an oil followed in sequence by two major crystalline fractions of 2.2 g each and finally by an impure oily fourth fraction. The first major fraction (**5**) was recrystallized from ether to give colorless needles, m.p. 63–65°; $[\alpha]_D^{25}$ 46.4° (EtOH) (homogeneous by t.l.c. and n.m.r.).

Anal. Calcd. for $C_8H_{15}NO_3$: C, 55.47; H, 8.73; N, 8.09. Found: C, 55.36; H, 8.57; N, 7.81.

The second major fraction (**5***b*) was recrystallized from ether to give colorless needles, m.p. 57° (sublimation); $[\alpha]_D^{25}$ 4.5° (EtOH) (homogeneous by t.l.c. and n.m.r.).

Anal. Calcd. for $C_8H_{15}NO_3$: C, 55.47; H, 8.73; N, 8.09. Found: C, 55.63; H, 8.62; N, 7.91.

L(+)-*Muscarine and* L(+)-*Allomuscarine*

The preceding amides **5***a* and *b* (300 mg) were added in 15 ml of ether, after heating under reflux for 2 h, to suspensions of 1.2 g of $LiAlH_4$ in 60 ml of ether; the mixtures were hydrolyzed at 0° with 12 ml of 30% aqueous KOH. After work-up in the usual manner, the colorless oil amines were treated with excess methyl iodide in ether whereupon white crystals of **6***a* iodide and **6***b* iodide (95 and 97% yields respectively) separated. They were recrystallized from acetonitrile–acetone and dried over P_2O_5 at 100° for up to 24 h. The m.p. varied considerably (from 131–150°) depending on crystal form and drying time. For **6***a*, the m.p. was 131–132° on several occasions; $[\alpha]_D^{25}$ 29° (EtOH); its n.m.r. spectrum (220 MHz) confirmed the structural assignment (Fig. 1).

Anal. Calcd. for $C_9H_{20}INO_2$: C, 35.89; H, 6.69; N, 4.64. Found: C, 35.68; H, 6.51; N, 4.31.

For **6***b* iodide, the m.p. was 148–150° (lit. (6) 149°); $[\alpha]_D^{25}$ 3.1 (EtOH) (lit. (6) for the chloride, 6.7 (H_2O)): the n.m.r. spectrum showed the product to be homogeneous and was consistent in every detail with the structure.

Anal. Calcd. for $C_9H_{20}INO_2$: C, 35.89; H, 6.69; N, 4.64. Found: C, 35.92; H, 6.76; N, 4.47.

The cholinomimetic activity (guinea-pig ileum) of this isomer was identical to that reported for L(+)-muscarine iodide (6).

We are grateful to the National Research Council of Canada and Bristol Laboratories of Canada for the financial support of this work. The skilful assistance of A. Gauthier in the preliminary phases of this work was highly appreciated. We are also indebted to Dr. A. H. Grey of the Canadian 220 MHz n.m.r. center (Sheridan Park) and Dr. Arthur Perlin for the n.m.r. spectra and their interpretation.

The Preparation, Properties, and some Complexes of Anhydrous Manganese(III) Nitrate

D. W. JOHNSON AND D. SUTTON[1]

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 4, 1972

Manganese(III) nitrate and its dinitrogen pentoxide "adduct" have been prepared by the reaction of N_2O_5 with MnF_3. Infrared spectra and magnetic susceptibility measurements show these compounds to contain high-spin manganese(III) coordinated by nitrate groups and the "adduct" to be the nitronium salt, $[NO_2]^+[Mn(NO_3)_4]^-$. The syntheses of complexes of $Mn(NO_3)_3$ with some organic ligands, *e.g.*, 2,2′-bipyridyl, *o*-phenanthroline, acetonitrile, and triphenyl phosphine oxide are described.

Nous avons préparé le nitrate de manganèse(III) et son dérivé pentoxyde dinitré par réaction de N_2O_5 avec MnF_3. Les spectres infrarouges et les mesures de susceptibilité magnétique révèlent un manganèse(III) à spin élevé, coordonné par les groupes nitrate; de la même façon on apprend que le dérivé est un sel nitronium, $[NO_2]^+[Mn(NO_3)_4]^-$. Nous décrivons aussi la synthèse de complexes de $Mn(NO_3)_3$ avec quelques ligands organiques, c'est-à-dire 2,2′-bipyridyl, *o*-phénanthroline, acétonitrile et l'oxyde de triphényl phosphine.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3326 (1972)

Introduction

One of the most obvious features of the chemistry of manganese(III) is the small number of well established simple anhydrous compounds. These are limited to the oxide, Mn_2O_3 (1), the hydroxide, Mn(OH)O (2), and the fluoride (3). Prior to this study, manganese(III) nitrate, or its hydrate, and complexes of manganese(III) containing coordinated nitrates were all unknown. The anhydrous trivalent nitrates of the neighboring 3d elements chromium, iron, and cobalt (4–6) have all been reported in recent years. Both the chromium and iron compounds have low thermal stability and are involatile (and presumably polymeric) solids. By contrast, $Co(NO_3)_3$ is volatile and monomeric (6). Again, anhydrous iron(II) and chromium(II) nitrates and their complexes are unknown, whereas the ease of formation of the (II) oxidation state complicates the synthesis of cobalt(III) nitrato-complexes (7). We were therefore interested in determining whether the remaining member of this sequence, $Mn(NO_3)_3$, could be synthesized, bearing in mind the existence of stable manganese(II) nitrate.

We now give the details of the syntheses and properties of $Mn(NO_3)_3$, and related nitratomanganate complex anions and describe some reactions that lead to complexes with organic donor ligands.

Experimental

Preparation of Compounds

Manganese(III) Nitrate

A large excess (20 g, 0.185 mol) of dinitrogen pentoxide was condensed onto anhydrous red manganese(III) fluoride (1.0 g, 8.9 mmol) at −78 °C. The solids were mixed and allowed to warm to room temperature to liquefy the N_2O_5; liquid N_2O_4 (20 ml) was then added and the mixture was stirred at 5 °C under a dry atmosphere for 3 days, the flask being vented to the atmosphere by a phosphoric oxide guard tube. During that time a reaction took place producing a dark brown oil which was then filtered from unreacted MnF_3. Careful removal of the volatiles (mainly N_2O_4) *in vacuo* at room temperature gave a dark brown hygroscopic solid. Extreme care had to be taken to avoid excess pumping on this because the eventual product, $Mn(NO_3)_3$, has low thermal stability, and evolves N_2O_4 at room temperature also. The procedure adopted was to isolate the sample from the pump as soon as all liquid had disappeared and then to continue pumping cautiously until an infrared spectrum of the product exhibited no bands assignable to nitrogen oxides, NO^+ or NO_2^+. Samples were sealed in glass ampoules and kept at −14 °C in a refrigerator. Manipulations were carried out quickly in a dry-box, using cooled apparatus where necessary.

Anal. Calcd. for $Mn(NO_3)_3$: Mn, 22.8; N, 17.4. Found: Mn, 22.5; N, 17.4.

The same compound could be synthesized using N_2O_5 alone, but the use of N_2O_4 as a solvent enabled the reaction to proceed more quickly and minimized the evaporation of N_2O_5. Anhydrous MnF_3 was obtained from Alfa Inorganics Inc., Beverly, Mass., U.S.A. Dinitrogen pentoxide was synthesized by the action of fuming nitric acid on phosphorus(V) oxide under a stream of ozone, and dried by passage through further phosphorus(V) oxide.

Nitronium Tetranitratomanganate(III)

When the filtrate from a reaction identical to that above

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was cooled in liquid nitrogen, evacuated and the nitrogen bath removed so that the volatiles sublimed *in vacuo*, a residue of the brown hygroscopic nitronium salt $[NO_2]^+[Mn(NO_3)_4]^-$ remained.

Anal. Calcd. for $[NO_2]^+[Mn(NO_3)_4]^-$: Mn, 15.7; N, 20.1. Found: Mn, 15.8; N, 20.2.

Hydrolysis, followed by ceric sulfate titration indicated the absence of nitrite, precluding formulation as an N_2O_4 adduct or nitrosonium salt. Storage of this salt at room temperature for one week showed no observable evolution of nitrogen oxides.

The oxidation state of the metal in each compound was confirmed by the consumption of one equivalent of KI on titration in aqueous solution, and by the formation of a characteristic red solution ($\nu_{max} \sim 19.7$ kcm^{-1}) in 6 *M* H_2SO_4.

Potassium Tetranitratomanganate(II)

Stirring potassium permanganate (1.0 g, 6.4 mmol) with N_2O_4 (20 ml, 0.31 mol) in nitromethane or acetonitrile (20 ml) for 2 h produced a yellow precipitate of $K_2[Mn(NO_3)_4]$.

Anal. Calcd. for $K_2Mn(NO_3)_4$: K, 20.5; Mn, 14.4; N, 14.7. Found: K, 20.0; Mn, 14.9; N, 14.5.

Also produced was a dark "brown solution", to which we shall refer in some of the syntheses below. Carbon and hydrogen analyses and i.r. spectroscopy confirmed the absence of solvent in the precipitate. Evaporation of the brown solution produced a brown gum of indefinite composition.

Sodium Tetranitratomanganate(II)

A similar reaction using $NaMnO_4$ gave a pale yellow precipitate of $Na_2Mn(NO_3)_4$.

Anal. Calcd. for $Na_2Mn(NO_3)_4$: Na, 13.2; Mn, 15.7. Found: Na, 13.1; Mn, 15.9.

Trinitrato-2,2′-bipyridylmanganese(III)

Addition of 2,2′-bipyridyl to a nitromethane solution of $Mn(NO_3)_3$ at 5 °C in a 1:1 mole ratio gave a low yield (~20%) of dark red crystals. The same complex was also obtained by adding solid 2,2′-bipyridyl (0.32 g, 2.0 mmol) to a freshly filtered portion of the "brown solution" in nitromethane calculated to contain 2.0 mmol of manganese. Within 24 h at 5 °C large crystals of $Mn(NO_3)_3 \cdot bipy$ crystallized from the mixture in good yield (~80%). The compounds prepared by each method were shown to be identical by elemental analysis and i.r. spectroscopy.

Anal. Calcd. for $Mn(NO_3)_3 \cdot C_{10}H_8N_2$: Mn, 13.8; C, 30.2; H, 2.03; N, 17.6. Found: Mn, 13.8; C, 30.0; H, 2.08; N, 17.5.

Trinitrato-o-phenanthrolinemanganese(III)

This brick red crystalline complex was similarly prepared by both methods used for the bipyridyl complex.

Anal. Calcd. for $Mn(NO_3)_3 \cdot C_{12}H_8N_2$: Mn, 13.0; C, 34.2; H, 1.91; N, 16.6. Found: Mn, 12.8; C, 34.3; H, 1.87; N, 16.2.

Trinitratomanganese(III)·acetonitrile

Acetonitrile was used instead of nitromethane as the solvent in producing the "brown solution". Evaporation of this solution *in vacuo* gave a dark brown solid containing both $Mn(NO_3)_3$ and coordinated acetonitrile. Although reproducible analyses could not be obtained, a composition between $Mn(NO_3)_3 \cdot 1.5CH_3CN$ and $Mn(NO_3)_3 \cdot 2.0MeCN$. was indicated.

Trinitratomanganese(III)·bistriphenylphosphineoxide

Addition of triphenylphosphine oxide (1.28 g, 4.6 mmol) to the "brown solution" in nitromethane (2:1 mole ratio) yielded dark red crystals of $Mn(NO_3)_3 \cdot 2Ph_3PO$.

Anal. Calcd. for $Mn(NO_3)_3 \cdot C_{36}H_{30}P_2O_2$: Mn, 6.9; C, 54.2; H, 3.29; N, 5.3. Found: Mn, 6.9; C, 53.2; H, 3.65; N, 4.8.

Spectroscopic Measurements

Infrared spectra (4000–350 cm^{-1}) were recorded on Perkin–Elmer 457 or Beckman IR-12 spectrophotometers, using silver chloride cells. The spectra were obtained as Nujol and Fluorolube mulls. Reaction with Nujol was observed for $Mn(NO_3)_3$ and $[NO_2]^+[Mn(NO_3)_4]^-$ and the spectra are corrected. Electronic spectra were recorded on a Unicam S.P. 800 or a Cary 14 spectrophotometer.

Magnetic Measurements

Magnetic susceptibilities were measured at 22 or 0 °C by the Faraday method using $Hg[Co(NCS)_4]$ as a calibrant. Samples were manipulated, and measurements made, in a dry argon atmosphere.

Analyses

Manganese was determined by both atomic absorption spectroscopy and volumetrically following bismuthate oxidation. Sodium and potassium were determined by atomic absorption spectroscopy. Nitrogen was determined by Kjeldahl's method or in conjunction with carbon and hydrogen by the S.F.U. micro-analytical laboratory.

Results and Discussion

Manganese(III) Nitrate, $Mn(NO_3)_3$

This compound is stable indefinitely below −14 °C in a dry atmosphere, but evolves N_2O_4 rapidly at room temperature and fumes in moist air. This makes $Mn(NO_3)_3$ the least thermally stable of any of the known first row transition metal trinitrates.

Chromium(III) nitrate (4) and $Fe(NO_3)_3$ (5) decompose rapidly at 60 and 70 °C, respectively, whereas $Co(NO_3)_3$ (6) sublimes readily *in vacuo* with little decomposition at 40 °C. $Mn(NO_3)_3$ is slowly reduced to $Mn(NO_3)_2 \cdot N_2O_4$ by pure liquid dinitrogen tetroxide. Fereday (8) observed similar reduction of $Co(NO_3)_3$ in contact with N_2O_4. It is interesting to note that when a stream of dry argon is passed over the $Mn(NO_3)_3$ to remove the N_2O_4 we find that the $Mn(NO_3)_3$ decomposes with the loss of exactly 108 mol. wt. units to give a tan colored compound of formula $MnO(NO_3)$, which is stable at room temperature in a dry atmosphere ($\chi_M^{corr} = 8670 \times 10^{-6}$ c.g.s.u. at 22 °C, $\mu_{eff} = 4.52 \pm 0.1$ B.M.).

For $Mn(NO_3)_3$ the molar magnetic susceptibility at 0 °C is $\chi_M^{corr} = 8150 \times 10^{-6}$ c.g.s.u.

which gives $\mu_{eff} = 4.4 \pm 0.1$ B.M.; a value which is reduced somewhat below the theoretical "high-spin" value (*cf.*, $Fe(NO_3)_3$ (5) and $FeO(NO_3)$ (9)), and is probably due to the compound being magnetically non-dilute.

The i.r. absorption bands of $Mn(NO_3)_3$ are listed in Table 1 and are generally similar to those reported for $Cr(NO_3)_3$ (4) and $Fe(NO_3)_3$ (5). No Raman spectrum was obtained due to absorption of the He–Ne line; we have therefore made only a tentative assignment. The relative insolubility of $Mn(NO_3)_3$ in common solvents makes it seem likely that it is a polymeric compound in which some or all of the nitrates are bridging and the assignment in Table 1 is therefore arbitrarily made on C_{2v} local symmetry with two coordinated oxygen atoms. As has been noted in other nitrates (6, 10) there is apparently no observed absorption band corresponding to the out-of-plane bend.

$Mn(NO_3)_3$ is an extremely vigorous oxidizing agent. It dissolves in water rapidly evolving oxygen, to give a yellow-brown solution together with a brown precipitate, presumably representing disproportionation to Mn(II) and Mn(IV). When an ampoule of $Mn(NO_3)_3$ is broken under aqueous potassium iodide solution, the iodide is oxidized quantitatively. $Mn(NO_3)_3$ reacts violently with diethyl ether, and readily with hydrocarbons such as Nujol. This behavior is frequently displayed by complexes containing bidentate nitrate groups coordinated to a high oxidation state metal. It is sparingly soluble in nitromethane, decomposes in water, acetone, acetonitrile, and other polar solvents, and is insoluble in chloroform, carbon tetrachloride, and benzene. Reactions with a number of donor ligands have been studied and yield complexes which are discussed below.

Nitronium Tetranitratomanganate(III)

The structure of the compound obtained by reaction between N_2O_5 and MnF_3 in liquid N_2O_4 and subsequent removal of the volatile materials by sublimation is $[NO_2]^+[Mn(NO_3)_4]^-$. This formulation, rather than as a nitrosonium salt, N_2O_4 adduct, or N_2O_5 adduct, is based on the analyses and the following observations: (*a*) bands occur in the i.r. spectrum at 2380 and 2358 cm^{-1} ($\nu_3[NO_2]^+$) and 560 cm^{-1} ($\nu_2[NO_2]^+$); (*b*) no bands attributable to N_2O_4, N_2O_5, NO^+, or ionic nitrate were observed, and (*c*) the remaining i.r. bands are characteristic of coordinated nitrates (Table 1).

Tetranitrato anions are known for a wide range of metals (11–18), but this is the first instance where the tetranitrato anion exists for two oxidation states of the same metal (15, 16). The manganese(II) analog $[Mn(NO_3)_4]^{2-}$ (16) and the neighboring iron(III) complex ion $[Fe(NO_3)_4]^-$ (18) have both been shown in the compounds studied by X-ray crystallography, to be eight coordinate D_{2d} complexes containing four bidentate nitrate groups. The structure of $[Mn(NO_3)_4]^-$ is probably similar, though it might be expected to contain asymmetric bidentate nitrate groups on account of the non-spherical d-electron configuration (19).

$[NO_2]^+[Mn(NO_3)_4]^-$ is thermally more stable than $Mn(NO_3)_3$ and shows no evolution of nitrogen oxides at room temperature within one week. Thermal decomposition commences at 60 °C and does not yield $Mn(NO_3)_3$, since the decomposition temperature is above that of the nitrate itself. Similar enhanced thermal stability over that of the parent nitrate is also observed for $Cr(NO_3)_3 \cdot 2N_2O_4$ (4), $[NO]^+[Fe(NO_3)_4]^-$ and $[NO_2]^+[Fe(NO_3)_4]^-$ (12). The only point in the thermogravimetric curve where there is a sharp decrease in decomposition rate occurs at approximately 600° and at a mass loss which corresponds approximately to the composition $MnNO_6$. No analysis of this

‡Taken from ref. 15.

material was attempted. While the material may be a polymeric nitrate species it is extremely unlikely that it is the molecular oxide nitrate $MnO_3(NO_3)$. Compounds MnO_3X (*e.g.*, X = F) are molecular and unstable and few examples are known; attempts by Chapman to prepare the species $MnO_3(NO_3)$ by reaction of $KMnO_4$ or Mn_2O_7 with N_2O_5 produced a highly unstable product which eluded identification as $MnO_3(NO_3)$ with certainty (20).

The molar susceptibility of $[NO_2]^+[Mn(NO_3)_4]^-$ is $\chi_M^{corr} = 9960 \times 10^{-6}$ c.g.s.u. at 22 °C; $\mu_{eff} = 4.9 \pm 0.1$ B.M. This value is identical with the calculated spin only value of 4.90 B.M. corresponding to Mn^{3+} with four unpaired electrons. The compound is soluble in nitromethane to give a green solution, and brown solutions in acetonitrile and ethyl acetate. Decomposition occurs in water and acetone. It is insoluble in benzene and carbon tetrachloride. The molar conductivity of a saturated (2×10^{-4} *M*) nitromethane solution is exceedingly low (16.9 ohm^{-1} cm^2). A low value was also observed for $[NO_2]^+[Fe(NO_3)_4]^-$ and explained in terms of a proposed solution equilibrium with non-electrolytes such as $Fe(NO_3)_3N_2O_5$ or its dissociated and solvated components (12).

Sodium and Potassium Tetranitratomanganate(II)

Both compounds have a magnetic susceptibility of $\chi_M^{corr} = 15\,400 \times 10^{-6}$ c.g.s.u.; $\mu_{eff} = 6.0 \pm 0.1$ B.M., as is expected for high spin d^5 species. The structure of $[Ph_4As]_2[Mn(NO_3)_4]$ has been determined (16) and shows that the anion exhibits approximately D_{2d} symmetry, with all the nitrates coordinating as bidentate ligands. The infrared and Raman spectra of the sodium and potassium salts are presented in Table 2, along with that obtained by Straub *et al.* (15) for $[Ph_3CH_3As]_2[Mn(NO_3)_4]$. The assignments given in the Table refer to the C_{2v} local symmetry of the bidentate nitrate groups; splitting of the main regions of absorption observed in some cases may be due to coupling of nitrate vibrations under the full molecular symmetry (6, 10) or to crystal site-symmetry splitting. The compounds are soluble in water but are either insoluble or decompose with precipitation of some alkali metal nitrate in most organic solvents studied. Thus, where solution does occur, partial dissociation of the complex anion to give solvated $Mn(NO_3)_2$ and NO_3^- takes place, as observed by Fereday (8) for alkali metal nitrato cobaltates (II).

Trinitrato-2,2'-bipyridyl Manganese(III)

In view of the numerous possibilities for the molecular structure of this complex, bearing in mind the various coordinating modes open to the nitrate group, the crystal structure of this complex was determined, and is reported in the following paper (21). The complex is molecular and monomeric. The manganese atom has an approximate pentagonal bipyramidal coordina-

tion environment, with the four oxygen atoms of one symmetric and one asymmetric bidentate nitrate group and one bipyridyl nitrogen atom defining the equatorial plane. The remaining bipyridyl nitrogen atom, and the oxygen atom of a unidentate nitrate group are at the apices.

The infrared spectrum (Table 3) confirms the absence of nitrate ions and the presence of coordinated bipyridyl, but without the complementary Raman spectrum it is difficult to assign the i.r. spectrum with confidence in terms of discrete vibrations associated with unidentate and bidentate nitrate groups. We have attempted to observe the combination frequencies in the 1700–1900 cm^{-1} regions to aid the assignment (22) but find these to be too weak to locate with certainty. On the basis of the generalization that where a bidentate and a unidentate nitrate group are coordinated to the same or similar metal atoms in comparable oxidation states the separation of the two highest nitrate fundamental stretching frequencies will be greater for the bidentate group than for the unidentate group (19, 23), we very tentatively assign the bands at 1518 and 1265 cm^{-1} to bidentate nitrate vibrations, and those at 1500 and 1285 cm^{-1} to the unidentate nitrate group. Despite the inequivalence of the three nitrate groups in the molecule only a single band is observable in the third and lowest fundamental nitrate stretching region and is at an extremely low position, 923 cm^{-1}. This is close to the lowest value so far reported for this band, at 920 cm^{-1} in the unidentate nitrate complex $K[Au(NO_3)_4]$ (19).

$Mn(NO_3)_3$·bipy is a high spin complex having $\chi_M^{corr} = 10\,530 \times 10^{-6}$ c.g.s.u. at 22 °C, $\mu_{eff} = 5.0 \pm 0.1$ B.M. The room temperature diffuse-reflectance spectrum of a powdered sample shows a band at 19.7 kcm^{-1} assigned to a d–d transition. No complexes containing a greater proportion of bipyridyl (or *o*-phenanthroline) could be obtained even upon increasing the excess of ligand up to threefold. Thus the complexes of 1:1.5 stoichiometry formed with $Co(NO_3)_3$ (6) and InX_3 (X = Cl, Br, I, NCS) (24, 25), are apparently not formed in the case of $Mn(NO_3)_3$, under these conditions. The compound is soluble in acetonitrile sparingly in acetone to give a yellow solution, and decomposes in water to give a yellow-brown solution. It is insoluble in benzene, carbon tetrachloride, ethyl acetate, and nitromethane.

Trinitrato-o-phenanthroline Manganese(III)

The stoichiometry of this compound suggests that this complex could have a similar molecular structure to that of the bipyridyl complex. The infrared spectrum (Table 3) is similar, where bands can be discerned from *o*-phenanthroline absorption, but there are small shifts in band positions. A comparison of the X-ray powder patterns of the bipyridyl and *o*-phenanthroline complexes indicates that they are not isomorphous, although the patterns are quite similar at low angles. Thus, no definite conclusion as to the molecular structure of the *o*-phenanthroline complex can be drawn at this time. Magnetic measurements give $\chi_M^{corr} = 10\,830 \times 10^{-6}$ c.g.s.u.; $\mu_{eff} = 5.0 \pm 0.1$ B.M. at 22 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The compound shows solubility properties like those of the bipyridyl complex.

Complexes with Triphenylphosphine Oxide and Acetonitrile

Triphenyl phosphine oxide forms the high-spin complex $Mn(NO_3)_3$ $(Ph_3PO)_2$ having $\chi_M^{corr} = 10\,150 \times 10^{-6}$ c.g.s.u. and $\mu_{eff} = 4.9 \pm 0.1$ B.M. The infrared spectrum shows the nitrate bands listed in Table 3 as well as bands typical of complexed Ph_3PO (*e.g.*, ν(P=O) 1150 cm^{-1} (26)). The structure of this complex is not known. The complex dissolves in benzene and acetonitrile to give yellow solutions and is insoluble in carbon tetrachloride, nitromethane and water.

The acetonitrile complex shows infrared bands typical of coordinated nitrate groups and coordinated acetonitrile (ν(C≡N) 2291 cm^{-1}). A strong band also occurs at 415 cm^{-1} which is absent from the spectra of the other complexes and therefore is presumably not due to a Mn—O mode; it may be the Mn—N stretch of the coordinated acetonitrile though such modes have been difficult to assign with certainty (23). For this compound $\chi_M^{corr} = 11\,400 \times 10^{-6}$ c.g.s.u. $\mu_{eff} = 5.2$ B.M., assuming the formula contains two molecules of CH_3CN.

The Crystal and Molecular Structure of Trinitrato-2,2′-bipyridylmanganese(III): A Complex with Three Distinctly Different Nitrate Ligands

F. W. B. EINSTEIN, D. W. JOHNSON, AND D. SUTTON[1]

Department of Chemistry, Simon Fraser University, Burnaby, British Columbia

Received May 4, 1972

The 2,2′-bipyridyl complex of manganese trinitrate, $Mn(NO_3)_3 \cdot bipy$, forms monoclinic crystals, space group $P2_1/c$ with four molecules in a unit cell with dimensions of $a = 7.311(3)$, $b = 18.022(7)$, $c = 11.704(4)$ Å, and $\beta = 108.73(3)°$. The manganese atom is seven co-ordinate, with approximate pentagonal bipyramidal geometry. The equatorial ligand atoms consist of one nitrogen of the bipyridyl group and four oxygens from two bidentate nitrate groups; the remaining bipyridyl nitrogen and the coordinated oxygen of the unidentate nitrate group are at the apices. This is the first nitrato-complex to be shown by crystallography to possess three distinctly different coordinated nitrate groups. One nitrate group is unidentate with Mn—O = 1.896(8) Å, one is symmetrical bidentate with Mn—O = 2.236(8) and 2.201(8) Å and one asymmetric bidentate with Mn—O = 2.112(8) and 2.400(9) Å.

Le complexe de trinitrate de manganèse avec le radical 2,2′-bipyridyl, $Mn(NO_3)_3 \cdot bipy$, forme des cristaux monocliniques, dont le groupe spatial est $P2_1/c$, avec quatre molécules par maille de dimensions: $a = 7.311(3)$, $b = 18.022(7)$, $c = 11.704(4)$ Å, et $\beta = 108.73(3)°$. L'atome de manganèse, possède un nombre de coordination de sept, avec une géométrie approximative de bipyramide pentagonale. Les atomes de ligands équatoriaux consistent en un azote du groupe bipyridyl et de quatre oxygènes provenant des deux groupes nitrate bidentés; l'azote du groupe bipyridyl et l'oxygène coordonné du groupe nitrate monodenté constituent les sommets. C'est la première fois en cristallographie, qu'on étudie un complexe nitrato possédant trois groupes nitrate différemment coordonnés. En effet, un groupe nitrate est monodenté avec la liaison Mn—O = 1.896(8) Å, le second est symétriquement bidenté Mn—O = 2.236(8) et 2.201(8) Å et le troisième asymétriquement bidenté avec Mn—O = 2.112(8) et 2.400(9) Å. [Traduit par le journal]

For personal use only.

In the preceding paper (1) we reported the synthesis of 1:1 high-spin complexes of manganese(III) nitrate with bidentate nitrogen bases such as 2,2′-bipyridyl and *o*-phenanthroline. The solid state structure of such compounds is of interest in view of the diversity of possibilities which exist. There have been few structural determinations of high-spin manganese(III) compounds, some recent examples being $MnCl_5^{2-}$, $(NH_4)_2MnF_5$, and $K_2Mn(SO_4)F_3$ (2–4). Although the first of these is pentacoordinate, the other examples exhibit ligand bridging and octahedrally coordinated manganese(III). The nitrate group is capable of considerable versatility as a ligand toward metal ions (5, 6) and frequently acts as a bidentate ligand thereby inducing rather high coordination numbers. Thus eight-coordinate nitrato-complexes of 3d metals have been established for a range of oxidation states, *e.g.*, $Mn(NO_3)_4^{2-}$ (7), $Fe(NO_3)_4^-$ (8), and $Ti(NO_3)_4$ (9). If all the nitrate groups were to be bidentate in $Mn(NO_3)_3 \cdot bipy$ an eight-coordinate molecular complex could result in this case also; however, the steric requirements of the bipyridyl might hinder this arrangement. Conversely, wholly unidentate nitrate coordination could yield a pentacoordinate species. Between these extremes there exist numerous structural possibilities which might arise from a combination of unidentate, bidentate or bridging coordination. One alternative is ruled out on infrared spectral evidence (1); the structure cannot contain uncoordinated nitrate ions. Finally the possibility of octahedrally coordinated manganese(III) occurring has its own special interest regarding the possible mechanism for the removal of the degeneracy of the ground state in the d^4 configuration (Jahn–Teller effect). In tris-(acetylacetonato) manganese(III) this occurs by angular distortion (10, 11) whilst in acetylacetonato-bis(*N*-phenylamino-troponiminato) manganese(III) there are unequal bond lengths (12). For a variety of reasons, therefore, we considered the X-ray crystal structure determination of $Mn(NO_3)_3 \cdot bipy$ to be of interest.

Experimental

Trinitrato-2,2'-bipyridylmanganese(III) was prepared according to the method reported previously (1). The crystals are dichroic, appearing dark red to reflected light and dark green to transmitted light. One crystal, a parallelepiped, approximately 0.28 mm × 0.24 mm × 0.18 mm in dimension was sealed in a Lindemann glass capillary in a dry box and was used for the entire crystallographic data collection.

Weissenberg photographs of the reciprocal lattice layers $0kl$ and $1kl$, and precession photographs of the $h0l$ and $hk0$ layers were taken using Cu radiation ($\lambda = 1.5418$ Å). The systematic absences $h0l$, $l = 2n + 1$, and $0k0$, $k = 2n + 1$ together with the Laue symmetry $(2/m)$ allowed the space group to be deduced unequivocally as $P2_1/c$.

Cell dimensions were determined from accurate counter measurement of 23 of the strongest reflections having $2\theta > 30°$, using a Picker FACS-1 computer-controlled four-circle diffractometer and Mo $K\alpha_1$ radiation ($\lambda = 0.70926$ Å) with a 1.0° takeoff angle. The crystal was in a general orientation. Crystal data are as follows:

$Mn(NO_3)_3 \cdot C_{10}H_8N_2$ mol. wt. = 397.15

Monoclinic, $P2_1/c$, $a = 7.311(3)$, $b = 18.022(7)$, $c = 11.704(4)$ Å, $\beta = 108.73(3)$, $V = 1461$ Å^3, $\rho_o = 1.82(2)$ g/cc (flotation), $\rho_c = 1.81$ g/cc, $Z = 4$, $\mu = 10.6$ cm^{-1}, Mo $K\alpha$ = 0.7107 Å, $T = 20$ °C.

Reflection intensities for the unique set of data were collected by peak-top counting using niobium filtered Mo $K\alpha$ radiation, and a scintillation counter with pulse height analysis. The take-off angle was 3.5°. Each reflection with $2\theta \leqslant 45°$ was measured for 20 s with two background counts of 10 s each taken 2.0° apart plus allowance for dispersion. Every hour two standard reflections were measured; their variation was ±5% over the entire data collection. The net intensities were corrected for Lorentz and polarization effects; absorption was neglected since we estimate it would introduce a maximum error of ±1%. A reflection was considered unobserved if the net count was less than 3.0 σ, $\sigma = (\text{total count} + \text{background})^{1/2}$. 1914 reflections were measured of which 1119 were regarded as observed.

Structure Determination

An examination of the three-dimensional Patterson function based on the data in the range $2\theta \leqslant 30°$ allowed the determination of the position of the manganese atom and six other atoms. Refinement of the scale and the atomic coordinates gave $R = 38.8\%$, where $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$. A Fourier synthesis on these data revealed all the non-hydrogen atoms. Refinement of the structure, incorporating the remaining data in the range $45° \geqslant 2\theta \geqslant 30°$, and allowing anisotropic temperature parameters for only Mn, N(1), O(12), and O(13) reduced R to 6.7%. In the latter stages, all the hydrogen atoms were visible in an electron density difference map and were included at calculated positions (d(C—H) = 0.98 Å) (13).

The principal discrepancies at this stage were in the region of the unidentate nitrate group, notably the uncoordinated oxygen atoms. However, further refinement of this group (with fixed contributions from the remaining atoms) on the basis of models in which one or both of the uncoordinated oxygen atoms were described by two "fractional atom" positions with various occupancies gave no significant improvement in agreement. Instead, continued refinement of the whole structure, now incorporating anisotropic thermal parameters for all non-hydrogen atoms gave a final $R = 5.9\%$. This improvement was somewhat surprising as the major features (peaks and troughs up to $\rho = 0.7(2)$ e$^-$/Å^3) in an electron density difference map were still in the region of the unidentate nitrate group, but the high correlation coefficients (~0.3) between the x and z parameters of the uncoordinated oxygen atoms of this group may indicate indeterminacy between these parameters in the least squares procedure.[2]

Initially, constant weights were used in the refinement; in the final stages weights $w(= 1/\sigma^2)$ were given in terms of $\sigma = (A \cdot B/F_o)^{1/2}$ for $B < F_o$ and $\sigma = (A \cdot F_o/B)^{1/2}$ for $F_o \leqslant B$, where $A = 3.1$ and $B = 20$. The function minimized was $\Sigma w\{||F_o| - |F_c||\}^2$.

In the structure factor calculations, the atomic scattering factors for Mn, O, N, and C were taken from ref. 14 and that of Mn was corrected for anomalous dispersion. The final atomic coordinates and temperature factors are listed in Table 1, and the interatomic distances and angles in Table 2, along with the estimated standard deviations. Mean planes through appropriate groups of atoms are presented in Table 3. Crystallographic computer programs used in this work have been cited elsewhere (15).

Discussion

$Mn(NO_3)_3 \cdot$bipy is a monomeric, molecular, seven coordinate complex. The molecular configuration (Fig. 1) is that of an irregular pentagonal bipyramid. The manganese atom is coordinated in the equatorial plane to N(5) of the bipyridyl group and the four oxygen atoms O(21), O(22), O(31), and O(32) of two bidentate nitrate groups. The apical atoms are N(4) of the bipyridyl group and O(11), the coordinated atom of a unidentate nitrate group. The pentagon has pseudo m symmetry along Mn—N(5), and is slightly puckered. As expected, there are shorter distances between the coordinating oxygen atoms within each bidentate nitrate group compared with the non-bonded contacts between nitrate and bipyridyl groups.

The observed seven-coordinate environment of manganese(III) was rather unexpected. Whilst seven-coordinate compounds of 3d metals are not unknown, they do not occur commonly (16), and to our knowledge this is the first established instance of this geometry occurring for Mn(III). Also intriguing is the observation that the two bidentate nitrate groups are quite dissimilar,

‡Estimated standard deviations in the last significant figures are given in parentheses in this and subsequent tables.

one being symmetrically, the other asymmetrically, bonded to manganese. Thus, the structure contains three dissimilarly coordinated nitrate groups, the first time this has been reported.

An explanation for this structure probably lies in the different stereochemical requirements of nitrate and bipyridyl ligands, and for comparison we can view the complex as formally derived from $Mn(NO_3)_4^-$ by replacement of NO_3^- by bipyridyl. By comparison with $Mn(NO_3)_4^{2-}$ (7) and $Fe(NO_3)_4^-$ (8) we may assume the $Mn(NO_3)_4^-$ ion to be eight-coordinate involving four bidentate nitrate groups, each subtending an angle of about 60° at the manganese. Replacement of a nitrate group by

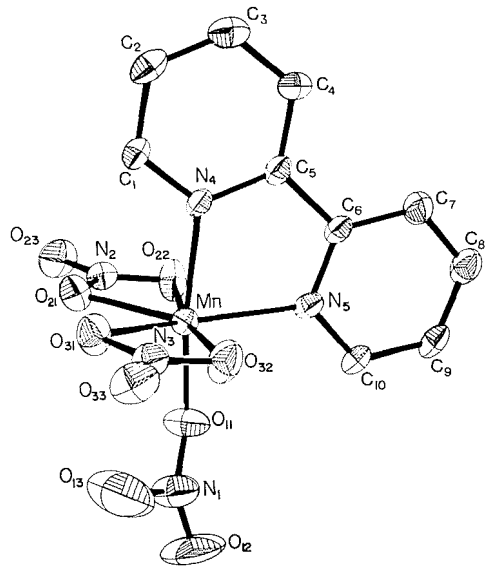

FIG. 1. The molecular configuration of $Mn(NO_3)_3 \cdot bipy$.

bipyridyl which subtends a larger interbond angle of $\sim 80°$ at manganese presumably introduces steric crowding which is relieved by one nitrate group having to adopt the unidentate configuration. It is more difficult to judge whether the coordination difference between the two remaining bidentate nitrate groups is also merely a consequence of crowding or whether it originates, at least partially, in the electronic configuration of the manganese atom, which is non-spherically symmetrical high-spin d^4. Unlike the more "regular" tetranitrato complexes for which the possibility of electronically induced distortions have been discussed (5), the inequivalence of the residual ligands in this complex may well be the main reason for the apparent differences in the bidentate nitrates. It may be noted, however, (*a*) that the long Mn—O(22) bond is *not trans* to a bipyridyl nitrogen, and (*b*) atom O(22) is one of four almost coplanar atoms in the equatorial

*As noted in the text, these atoms are statistically not coplanar.
†O(32) is 0.317 Å out of the plane.

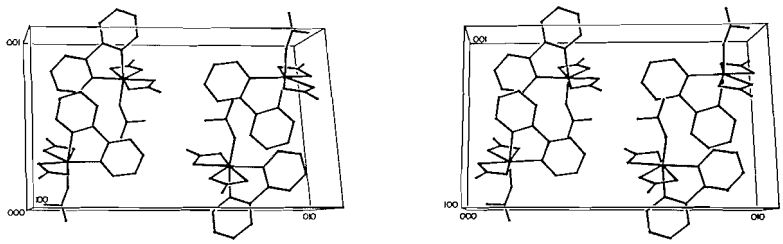

FIG. 2. A stereoscopic view showing the molecular packing.

pentagon (maximum deviation 0.03 Å), whereas the fifth atom, O(32), deviates from this "plane" by 0.32 Å (see Table 3, Plane *6*). It may well be that both nitrates are potentially symmetric but that O(22) cannot relieve crowding by a large out of plane displacement and has to do so by additional lengthening of the Mn—O(22) bond. This is consistent with the non-bonded contacts from O(22) and O(32) to the apical atoms O(11) and N(4) shown in Table 2*c*; the distances and angles to N(4) are similar but O(11) is angled towards O(22) and is closer to it than to O(32). The effect of a dissimilar ligand in a 7-coordinate complex is well illustrated in $CH_3Sn(NO_3)_3$ where all the nitrates are unsymmetrically bidentate (17), a dramatic change from four symmetric bidentate nitrates in the structure of $Sn(NO_3)_4$ (18). By contrast, the bidentate nitrate groups in the seven-coordinate molecule $VO(NO_3)_3CH_3CN$ (19) are symmetric, despite the dissimilar nature of the remaining ligands.

The latter compound offers the only other example in which the dimensions of bidentate and unidentate nitrate groups may be compared within the same molecule, and similarities with the present structure are evident. The unidentate nitrate groups are coordinated with almost identical metal–oxygen bond lengths which are significantly shorter than those to the bidentate nitrate groups.

The dimensions within the unidentate and bidentate nitrate groups are according to expectations (5). The unidentate group is the least well defined feature of the structure, due to its rather large thermal motion, but the long manganese–oxygen contact to the nearest uncoordinated oxygen atom O(13), 3.05(1) Å shows that there is no question as to the unidentate character of this nitrate group. The apparently large departure from planarity probably reflects positional inaccuracies of the uncoordinated oxygen atoms arising from both high correlation between parameters and large thermal motion. The remaining nitrate groups are each planar. The two heterocyclic rings of the bipyridyl group are planar with a dihedral angle of 5.1°.

The molecular packing illustrated in Fig. 2 is somewhat unexpected. The shortest intermolecular contact is O(13) ... O(13) = 2.88(5) Å, (see Table 2*d*) equal to the sum of Van der Waals radii. This is contrary to the anticipated "head-to-tail" packing to be expected if molecular dipolar forces dominate, and suggests that Van der Waals attraction is likely to be the main packing force.

We thank the National Research Council of Canada for support of this work through operating grants.

Charge-transfer Complexes with Nitrate Esters as Electron Acceptors

Received December 29, 1971

Nitrate esters of alcohols, containing from one to six *O*-nitro groups, react with tetramethyl-*p*-phenylenediamine (TMPD) in non-polar solvents to yield Wurster cation. The number of *O*-nitro groups necessary to produce 1 mol of Wurster cation is at least three. This is now explained in terms of the enthalpy of the reaction related to the electron affinity of nitrate esters; esters with five to six *O*-nitro groups show a relatively high enthalpy manifested by their ability to form charge-transfer complexes. Initially an unstable complex A is formed which then gives Wurster cation, both reactions being fast. A slow transformation then occurs into more stable complex B having the composition: 1 mol TMPD–2 mol of pentanitrates or 1 mol TMPD–1 mol of hexanitrate. TMPD in complex B was transformed into tetramethyl-*p*-quinonediimine dication.

That all nitrate esters with one to four *O*-nitro groups do not form complexes A and B may be due either to their relatively low enthalpy (and electron affinity), or to more favorable structures of complexes A and B of pentanitrates of D-xylitol and penta- and hexanitrates of hexitols with TMPD.

Les esters nitrates d'alcools, contenant de un à six *O*-nitro groupements, réagissent avec le tétraméthyl-*p*-phénylènediamine (TMPD) en solvants apolaires pour donner le cation de Wurster. Un minimum de trois groupes *O*-nitro est nécessaire pour produire 1 mol de cation de Wurster. On explique ceci en termes d'enthalpie de réaction reliée à l'affinité électronique des esters nitrates; les esters comprenant de cinq à six groupes *O*-nitro possèdent une enthalpie relativement élevé qui se manifeste par une certaine facilité à former des complexes de transfert de charge. Un complexe instable A est formé initialement et se transforme ensuite en cation de Wurster et ces deux réactions s'accomplissent rapidement. On observe ensuite une réaction lente en un complexe B plus stable, dont la composition est la suivante: 1 mol de TMPD–2 mol de pentanitrates ou 1 mol de TMPD–1 mol d'hexanitrate. Le TMPD du complexe B est transformé en tétraméthyl-*p*-quinonediimine (TMPQD).

Le fait que tous les esters nitrates comprenant de un à quatre groupes *O*-nitro ne forment pas les complexes A et B peut être dû, soit à leur enthalpie relativement faible (et leur électroaffinité) ou encore à des structures plus favorables des complexes A et B de pentanitrates de D-xylitol et de penta- et d'hexanitrates d'hexitols avec TMPD. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3340 (1972)

One of the authors of the present paper (1) and his co-worker (2) have shown by way of thermal analysis that some *O*-nitro compounds, such as D-mannitol hexanitrate and erythritol tetranitrate can form addition complexes with aromatic nitro compounds. Recently, preliminary reports were published (3–5) on charge-transfer complexes between nitrate esters and tetramethyl-*p*-phenylenediamine (TMPD). Further experiments carried out with pentanitrates of D-mannitol and D-xylitol confirmed our former statement that a fast reaction of nitrate esters with TMPD in the absence of daylight leads to formation of the bluish-violet colored radical-ion, known as Wurster cation (6). The short time of irradiation of the samples in the spectrophotometer did not speed up the formation of the cation.

More detailed examination of the electronic spectra of pentanitrates of D-xylitol and D-mannitol and hexanitrates of hexitols with TMPD in 1,2-dichloroethane has shown rapid formation of a low intensity, transitory band between 909 and 1030 nm, in addition to the formerly reported bands at 570 and 620 nm (curve 1, Fig. 1) known to be typical of Wurster cation. For pentanitrates of D-xylitol and D-mannitol, the long wave bands were at 909 and 980 nm respectively, for hexanitrates of D-mannitol, D-sorbitol, dulcitol, and *myo*-inositol the wavelengths were 1030, 917, 926, and 990 nm respectively. The bands are of similar wave-

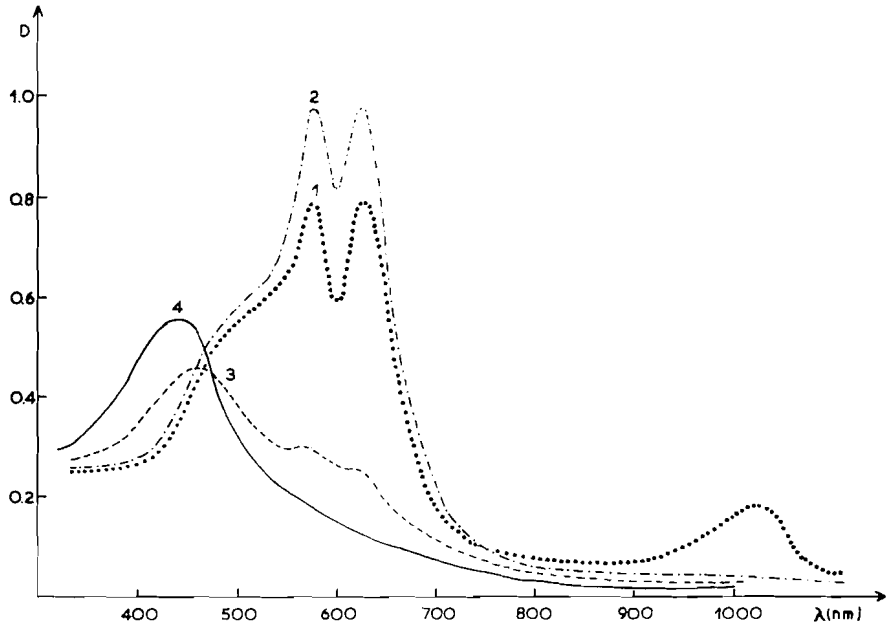

FIG. 1. General shape of electronic spectra of nitrate esters and tetramethyl-*p*-phenylenediamine (TMPD) in 1,2-dichloroethane at 23 °C.

(1) Pentanitrates of D-xylitol and D-mannitol and hexanitrates of hexitols immediately after mixing with TMPD; (2) pentanitrates of D-xylitol and D-mannitol and hexanitrates of hexitols 15 min after mixing with TMPD, and nitrate esters of alcohols with one to four *O*-nitro groups 24 h after mixing with TMPD; (3 and 4) the pentanitrates and hexanitrates (as above) 1 and 2 h, respectively, after mixing with TMPD.

lengths to the rather elusive ones described already in the literature and characteristic of some charge-transfer complexes (7).

The shape of the electronic spectra of systems with nitrate esters containing different numbers of *O*-nitro groups and carbon atoms varies considerably. All esters examined can be classified into two categories according to their behavior in 1,2-dichloroethane as a solvent:

(*a*) Substances which give curves of type 2 (Fig. 1), stable for a few days. They are obtained from nitrate esters with between one and four nitro groups (butyl nitrates, glycerol trinitrate, erythritol tetranitrate, pentaerythritol tri- and tetranitrates).

(*b*) Substances which initially give curves of type 1 but which, after 5 min, lose the band near 1000 nm; the absorption curve 1 changes into 2. The bands near 1000 nm characterize the transient charge-transfer complex A (Schemes 1 and 2) and should be considered as CT-bands. During the next 2 h, the absorption curve gradually changes into curve 4 with the maximum at 450 nm characterizing the yellow colored relatively stable complex B (Fig. 1). Nitrate esters containing five to six *O*-nitro groups and five to six carbon atoms belong to this group. They are pentanitrates of D-xylitol, D-mannitol, hexanitrates of D-mannitol, D-sorbitol, dulcitol, and *myo*-inositol.

The complexes formed from substances *b* show very strong absorption at 620 nm during the initial 30 min. The intensity of this absorption, D_{620}, is 10–60 times larger than the absorption at the same wavelength of mono-, di-, tri-, and tetranitrates, as partly reported in the preliminary communication (3).

Analysis of Curves 1 and 2

A few conclusions can be drawn from the analysis of curves 1 and 2.

By using as before (3–5) the Job method (8) of continuous changes related to absorption bands 909–1030 nm, we established that complex A was composed of 1 mol of D-xylitol or D-mannitol pentanitrate and 1 mol of TMPD, or of 1 mol of hexanitrates of hexitols combined with 2 mol of TMPD. This confirms the formerly

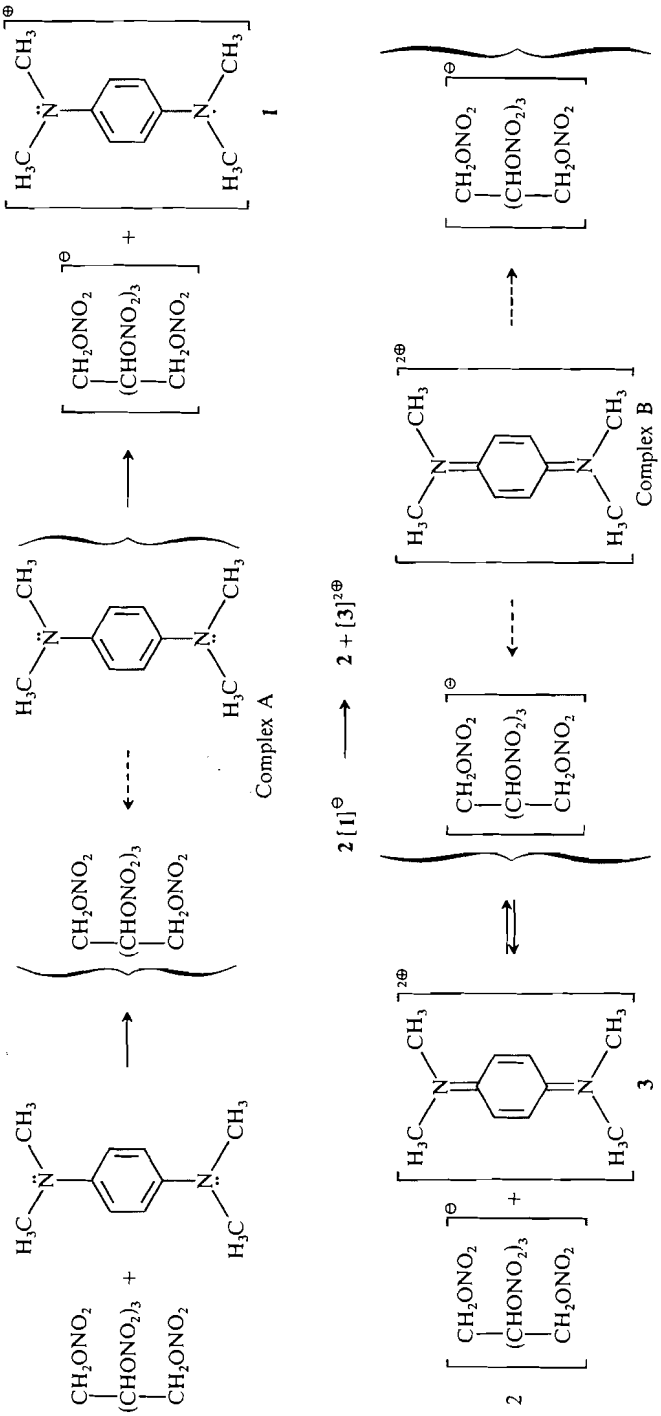

SCHEME 2

established rule that at least three ONO_2 groups are needed to withdraw one electron from TMPD (3, 4) and allows the formula of complex A to be shown as

$$\{x[R(ONO_2)_n] \leftarrow y[TMPD]\}$$

when $n = 5$; $x = y = 1$
and $n = 6$; $x = 1$; $y = 2$

The rule also holds for the formation of Wurster cation from penta-*O*-nitro compounds and TMPD: 1 mol of D-xylitol or D-mannitol pentanitrates forms 1 mol of Wurster cation.

The question arises as to why not less than three *O*-nitro groups are needed to withdraw one electron from 1 mol of TMPD in order to form complex A or Wurster cation. The answer may be found, at least in part, in the enthalpy ($-\Delta H$) of formation of Wurster cation. Since the enthalpy can serve as a measure of the electron affinity, the *comparative* values of electron affinities may be a measure of the ability to form Wurster cation.

The enthalpy was calculated from the well-known thermodynamic equation $-\Delta H = RT^2$ d ln K/dT. Assuming that the equilibrium constant K is equal to the concentration constant K_c we could use the equation

$$-\Delta H = \frac{RT_1T_2}{T_1 - T_2} \ln \frac{K_c'}{K_c''}$$

where K_c' and K_c'' are concentration constants at temperature T_1 and T_2 respectively. The concentration constants were determined from the absorbance of the band 620 nm at two temperatures, 0 and 23 °C. Since a higher temperature could not be used owing to the ease of decomposition of nitrate esters under the influence of bases, 23 °C was chosen as the upper safe limit. Temperatures lower than 0 °C were not used because we required a relatively narrow temperature range which would not necessitate taking into consideration the influence of the change of density of the solvent and the compounds with temperature, and which would guarantee that the course of the reaction was unchanged.

Obviously, examining the absorbance at only these two temperatures makes the figures less accurate so they have comparative value only. It was pointless to determine another value between 0 and 23 °C, as the absorbance would not differ sufficiently from those at these two temperatures.

Reaction of Nitrate Esters with One to Four O-Nitro Groups

The expressions describing the equilibria depend on the number of *O*-nitro groups in the molecule. Thus for *n*-, *sec*-, and *t*-butyl nitrates and ethylene glycoldinitrate where 3 mol of ester were necessary to produce 1 mol of the Wurster cation, eq. 1 was used:

$$[1] \quad 3\,RN^{I} + TMPD \underset{}{\overset{K_{c,3/1}}{\rightleftharpoons}} 3\,RN^{I\ominus} + TMPD^{\oplus}$$

where RN^{I} denotes the above mentioned nitrates. The initial concentrations of esters and TMPD are $[RN^{I}]_0 = 3a$ and $[TMPD] = a$, respectively, and the concentrations at equilibrium are $[RN^{I\ominus}]_e = [TMPD^{\oplus}]_e = x$. Hence

$$[2] \quad K_{c,3/1} = \frac{x^2}{27(a-x)^4}$$

The concentration x of the cation $TMPD^{\oplus}$ at equilibrium was calculated from the equation:

$$x = \frac{D_{620}}{E_{620} \cdot I}$$

where: D_{620} is absorption of the cation $TMPD^{\oplus}$ at $\lambda = 620$ nm; E_{620} is the molar extinction coefficient of the cation $TMPD^{\oplus}$ at $\lambda = 620$ nm, and equal to 12.5×10^3; and I is the thickness of the examined layer in cm.

When tri- and tetra-*O*-nitro compounds were examined, eq. 3 was applied:

$$[3] \quad RN^{III} + TMPD \underset{}{\overset{K_{c,1/1}}{\rightleftharpoons}} RN^{III\ominus} + TMPD^{\oplus}$$

where RN^{III} denotes glycerol trinitrate, erythritol tetranitrate, pentaerythritol tri- and tetranitrates. The initial concentrations of the esters and TMPD were $[RN^{III}]_0 = [TMPD]_0 = a$, and at equilibrium, $[RN^{III\ominus}]_e = [TMPD^{\oplus}]_e = x$.

$$[4] \quad K_{c,1/1} = \frac{x^2}{(a-x)^2}$$

The measurements of D_{620} (see Table 1 of our previous publication (3)) in 1,2-dichloroethane solution at concentrations 0.01–0.2 mol/l were taken 24 h after mixing the ester with TMPD, to ensure a constant concentration of $TMPD^{\oplus}$. A few conclusions can be drawn from the figures thus obtained:

(*a*) The values of D_{620}, K_c, and ΔH increase with the number of ONO_2 groups. The only exception is in the case of pentaerythritol tetra-

*Thickness of the layer 1 cm. The values of D_{620} were partly reported in a previous publication (3).

nitrate and can be attributed to the relatively symmetrical structure of the compound and resulting low dipole moment ($\mu = 2.5$ D in dioxane (11)) which is much lower than the 3.3 D for erythritol tetranitrate found by us, in the same solvent. One of the authors of the present paper has suggested (12) that high dipole moments favor the formation of addition complexes.

(*b*) Nitrate esters of similar polarity, *e.g.* ethylene glycol, dinitrate glycerol trinitrate, and *meso*-erythritol tetranitrate (dipole moments 3.3, 3.2 (13), and 3.3 D (14), respectively) show a very similar enthalpy calculated for one ONO_2 group.

(*c*) The enthalpies of the reactions of nitrate esters with TMPD to form $TMPD^{\oplus}$ can be used to explain the mole ratio of reactants, in most cases. Thus they explain why ethylene glycol dinitrate gives the same ratio (3/1) as butyl nitrates in spite of the presence of two *O*-nitro groups: the total value of ΔH (and also K_c) in ethylene glycol dinitrate is of the same magnitude as in butyl monoesters.

Tri-*O*-nitro compounds and *meso*-erythritol tetranitrate have much higher values of ΔH and K_c, thus explaining the ratio 1/1. Pentaerythritol tetranitrate behaves in the same way as the trinitrates and erythritol tetranitrate in spite of the relatively low figures for ΔH and K_c. Also the figures for pentaerythritol trinitrate are lower than those for glycerol trinitrate. The low figures for pentaerythritol derivatives can probably be attributed to the structure of pentaerythritol which differs considerably from the rest of the alcohols in its central carbon atom and higher symmetry.

Reaction of Nitrate Esters with Five to Six O-Nitro Groups

The equilibria take the form shown in eqs. 5 and 6

$$[5]\quad RN^{V} + TMPD \underset{}{\overset{K_{c,1/1}}{\rightleftharpoons}} RN^{V\ominus} + TMPD^{\oplus}$$

$$[6]\quad RN^{VI} + 2\,TMPD \underset{}{\overset{K_{c,1/2}}{\rightleftharpoons}} RN^{VI\ominus} + 2\,TMPD^{\oplus}$$

where RN^{V} and RN^{VI} are pentanitrate and hexanitrate esters respectively. Equation 5 is identical with [3] and the concentration constant for pentanitrates can therefore be calculated from eq. 4.

For hexanitrates the concentrations of the components initially and at equilibrium are $[RN^{VI}]_0 = a$, $[TMPD]_0 = 2a$; and $[RN^{VI\ominus}]_e = x/2$, $[TMPD^{\oplus}]_e = x$, respectively. Hence

$$K_{c,1/2} = \frac{x^3}{(2a-x)^3}$$

The results are collected in Table 2.

D-Dulcitol hexanitrate	$(1.70\pm0.01)\times10^{-4}$	$(1.08\pm0.02)\times10^{-4}$	2.75	0.46
myo-Inositol hexanitrate	$(2.92\pm0.02)\times10^{-4}$	$(1.75\pm0.01)\times10^{-4}$	3.10	0.52

*Concentrations 0.002–0.004 mol/l, thickness 0.2 cm. Measurements made 15 and 30 min after the solutions were prepared for hexanitrates and pentanitrates respectively. The values of D_{620} were partly reported before (3).

The main conclusions are as follows:

(*1*) The pentanitrates of D-xylitol and D-mannitol and hexanitrates of hexitols show a very high absorption at 620 nm, and high values of K_c and ΔH.

(*2*) Relatively high values of the enthalpy of penta- and hexanitrates explain the ratio 1:1 of the hexanitrates and TMPD. However they cannot by themselves explain the difference with the pentanitrates where the ratio is 2:1; part of the explanation may be related to conformations as discussed below.

Analysis of Curve 4, Nitrate Esters with Five or Six O-Nitro Groups

The change of intensity of absorption of curve 1, through 2 and 3, leading to curve 4 (Fig. 1), the characteristic electronic spectra arising from D-mannitol, D-sorbitol, dulcitol, and *myo*-inositol hexanitrates, and D-xylitol and D-mannitol pentanitrates, can now be discussed. The change with time of the intensity of band 620 nm, characteristic of Wurster cation, and band 450 nm, characterizing the new complex B, is depicted in Fig. 2. It has been established that this change is typical of solutions in solvents with a low dielectric constant, such as 1,2-dichloroethane, dichloromethane, and benzene. When hexanitrates of hexitols were mixed with TMPD in polar solvents such as methanol, the original bluish-violet color remained unchanged for several days and no yellow complex with band 450 nm was formed. Band 450 nm cannot be assigned to the TMPQD (tetramethyl-*p*-quinonediimine) dication since it is not found in the spectrum of TMPQD diperchlorate (15). Another feature supports the view that the band is produced by a complex and may be a CT-band, namely that the intensity of the band increases with lowering the temperature.

Also in accord with the previous finding, the conductivity of the solution of complex B in *n*-heptane considerably increased when methanol was added, indicating the dissociation of the complex into ions in a polar solvent.

As mentioned before (3, 5) the complex B, in solution in *n*-heptane, showed in the i.r. spectrum the presence of bands corresponding to the quinonoimine structure (**3**, Scheme 1) of the donor moiety of the complex. Also t.l.c. indicated that Wurster cation (**1**), formed originally with pentanitrates of D-xylitol and D-mannitol, and hexanitrates of hexitols, was subject to disproportionation as shown in Scheme 1. The quinonoimine dication (**3**) eventually formed relatively stable complexes with the penta- and hexanitrates.

By using the Job method (8) of continuous changes in the band at *ca.* 450 nm, in 1,2-dichloroethane, dichloromethane, or benzene, 24 h after mixing, the ratio between the penta- and hexanitrates as acceptors and quinonoimine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

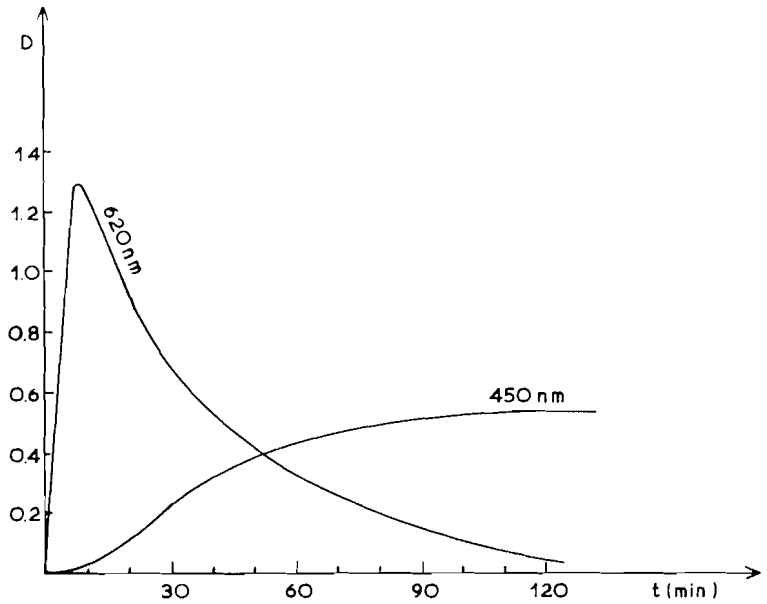

FIG. 2. Change with time of the intensity of band 620 and 450 nm of solutions of D-mannitol hexanitrate and TMPD in 1,2-dichloroethane at 23 °C.

dication was established with the results tabulated in Table 3.

Further confirmation of the ultimate formation of complex B was found in the e.s.r. spectra. Immediately after mixing pentanitrates of D-xylitol and D-mannitol or hexanitrates of hexitols with TMPD in 1,2-dichloroethane the e.s.r. spectrometer registered 13 triplets corresponding to Wurster cation, in agreement with data in the literature (16). After 2 h the signal disappeared and a broad singlet, which we assign to the complex B, was formed (Fig. 3). It was very similar to the e.s.r. signal of complexes of TMPD and chloranils in non-polar solvents (17).

The formation of complex B can be illustrated by two equations:

$$2\ R^{V}(ONO_2)_5 + TMPD \rightleftharpoons [2\ R^{V}(ONO_2)_5^{\ominus} \ldots . TMPQD^{2\oplus}]$$

$$R^{VI}(ONO_2)_6 + TMPD \rightleftharpoons [R^{VI}(ONO_2)_6^{2\ominus} \ldots . TMPQD^{2\oplus}]$$

where $TMPQD^{2\oplus}$ is the tetramethyl-*p*-quinonediimine dication.

The sequence of reactions to form complex A, Wurster cation, and complex B from hexanitrates of hexitols and TMPD is depicted by Scheme 1, those for D-xylitol pentanitrate and TMPD in Scheme 2.

TABLE 3. Ratio of nitrate ester/TMPD on the basis of band 450 nm

Nitrate ester	Ratio	λ_{max} (nm)
D-Xylitol pentanitrate	2:1	446
D-Mannitol pentanitrate	2:1	440
D-Mannitol hexanitrate	1:1	450
D-Sorbitol hexanitrate	1:1	450
Dulcitol hexanitrate	1:1	449
myo-Inositol hexanitrate	1:1	445

Unfortunately, we were unable to isolate the complexes from their solutions. Evaporating the solvent at low temperature and under reduced pressure left only a brown tarry residue showing signs of decomposition with evolution of nitrogen dioxide. This can easily be understood considering the low stability of nitrate esters in the presence of basic compounds. It is well known that even diphenylamine is too basic to be combined with nitroglycerine and similar esters.

Enthalpy of Formation of Complex B

As previously stated (3, 5), we calculated equilibrium constants K_c from the Benesi–Hildebrand equation (18), as modified by Ketelaar and his co-workers (19). From the values for K_c in 1,2-dichloroethane we calcu-

FIG. 3. E.s.r. signal of the complex B of D-mannitol hexanitrate with TMPQD dication.

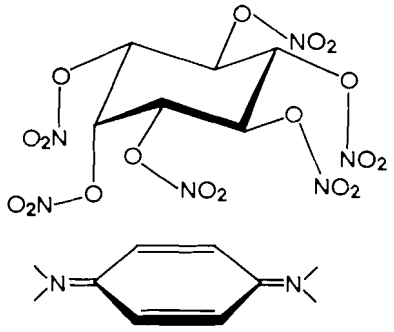

FIG. 4. Suggested structure of the complex B of *myo*-inositol with TMPQD dication.

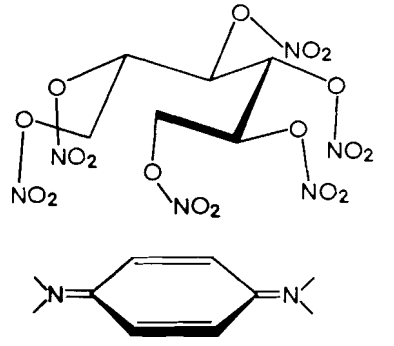

FIG. 5. Suggested structure of the complex B of chain hexitol hexanitrates with TMPQD dication.

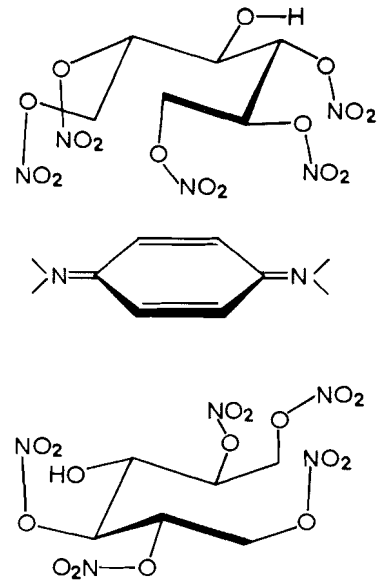

FIG. 6. Suggested structure of the complex B of D-mannitol pentanitrate with TMPQD dication.

lated the enthalpy: $-\Delta H = 5.12$ kcal/mol, a value of the same magnitude as in many $\pi-\pi$ complexes. The complex D-mannitol hexanitrate – tetramethylquinonodiimine may be considered as a $\pi-\pi$ complex. It also follows that *O*-nitro compounds with five or six *O*-nitro groups should be classified as π-electron acceptors.

Possible Structures of Complexes A and B of Nitrate Esters with Five to Six O-Nitro Groups

We attempt to explain the fact that complexes A and B can be formed only by nitrate esters with five to six *O*-nitro groups and five to six carbon atoms, in terms of conformation.

The complex with the six-membered ring of *myo*-inositol has probably the structure of parallel rings: that of the ester and of TMPD or the tetramethylquinonodiimine (Fig. 4). This is in agreement with the results of X-ray examination of classical CT-complexes (20) and in agreement with the "overlap and orientation principle" of Mulliken (21). The fact that only esters with five or six carbon atoms can form complexes A and B can probably be explained in terms of the conformation of these esters. Considering that five- and six-membered rings can readily be formed, it is now suggested that under the action of

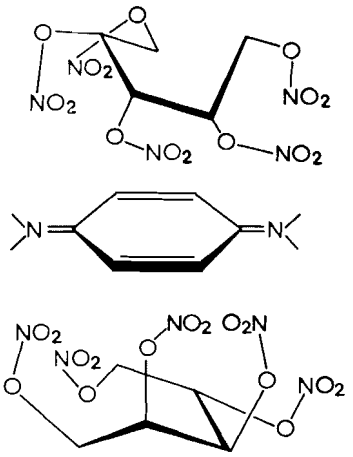

FIG. 7. Suggested structure of the complex B of D-xylitol pentanitrate with TMPQD dication.

TMPD the esters with five or six carbon atoms and five or six *O*-nitro groups are coiled into pseudo-rings. The pseudo-rings could be placed into position parallel to TMPD or the tetramethylquinonodiimine ion (Figs. 5–7).

Further experiments are being carried out with dinitrate esters of ω,ω'-diols containing five or more carbon atoms.

Experimental

Nitrate esters and tetramethyl-*p*-phenylenediamine were prepared as described earlier (4). Tetramethyl-*p*-quinonediimine diperchlorate was prepared according to Hünig and Daum (15). The solvents benzene, methanol, *n*-heptane were of spectroscopic grade. 1,2-Dichloroethane was purified as described in our previous paper (4).

The solutions of nitrate esters and TMPD were prepared away from daylight, and after mixing were kept in darkness. Electronic spectra were examined on a Unicam SP-500 spectrophotometer with thermostated cells of 0.2 and 1.0 cm thickness and concentrations of the nitrate esters varying according to the intensity of the absorbance of the solutions with TMPD, from 0.002 to 0.15 mol/l (Tables 1 and 2). I.r. spectra were measured on Unicam SP-200 and Hilger H-800 spectrophotometers, as previously described (5).

Our thanks are due to the Referees for their valuable comments and discussion.

Solvolysis of Substituted Nortricyclanes and Norbornenes at 250° [1]

NICK H. WERSTIUK AND T. KADAI

Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 4, 1972

Solvolysis of nortricyclyl bromide (**1***a*), nortricyclyl chloride (**1***b*), nortricyclanol (**1***c*), and 5- and 7-norbornenols (**2***b*, **7**) and *exo*-2,3-epoxybicyclo[2.2.1]heptane (**11**) in 10% v/v acetic acid–water at 250° yields 2-(cyclopentene)acetaldehyde (**3**), 3-(cyclopentene)acetaldehyde (**4**), 3-(cyclohexene)carboxaldehyde (**5**), norcamphor (**6**), and norbornanediols. In each case the diol concentration builds up then decreases as the conversion to **3**, **4**, **5**, and **6** occurs. When the substrates **1***a*, *b*, and *c*, **2***b*, **7**, **10***a*, and **11** are solvolyzed in deuterated medium, deuterium other than α to the carbornyl group is incorporated into the aldehydes and norcamphor.

La solvolyse du bromure de nortricyclyle (**1***a*), chlorure de nortricyclyle (**1***b*) nortricyclanol (**1***c*), norbornénols-5 et -7 (**2***b*, **7**), *exo*-époxy-2,3 bicyclo[2.2.1] heptane (**11**), dans un mélange à 10% en volume d'acide acétique–eau à 250°; conduit au cyclopentène-2 acétaldéhyde (**3**), cyclopentène-3 acétaldéhyde (**4**), cyclohexène-3 carboxaldéhyde (**5**), norcamphre (**6**), et norbonanediols. Dans tous les cas, la concentration en diol croît puis diminue au fur et à mesure que la conversion en **3**, **4**, **5**, et **6** s'effectue. Quand les substrats **1***a*, **1***b*, et *c*, **2***b*, **7**, **10***a*, et **11** sont solvolysés en milieu deutérié, un deutérium autre que celui en α du groupe carbonyle est incorporé dans les aldéhydes et le norcamphre.

Introduction

Solvolysis of 3-substituted nortricyclanes (**1***a* and *b*) and 5-substituted norbornenes in 80% ethanol–water (1), acetic acid (2*a*, *b*), or methanol (3) at 25–55° gives 3-nortricyclyl (**1***e*, *f*, and *g*) and *exo*-5-norbornenyl products (**2***c*, *d*, and *e*) via the cationic species **8** or **9**. Treatment of dehydronorbornyl acetate and nortricyclyl acetate with 50% H_2SO_4–HOAc at 95° gives norbornyl diacetates (4).

We have found that in solvolysis of the nortricyclyl substrates **1***a*, *b*, and *c*, the *endo*-5-, *exo*-5-, *anti*-7-norbornenols, and *exo*-2,3-epoxybicyclo[2.2.1]heptane at 250° in 10% v/v acetic acid–water or water only in the case of the halonortricyclanes, the aldehydes **3**, **4**, and **5** are formed in addition to norcamphor (**6**) (5*a*, *b*). When the solvolyses are carried out in deuterated medium, deuterium is incorporated into **3**, **4**, **5**, and **6**. Table 1 gives the results of our study.

Results and Discussion

Norcamphor and 3-(cyclohexene)carboxaldehyde were identified by comparison of i.r., n.m.r., m.s., and g.l.p.c. retention time data with those of authentic samples. The (cyclopentene)-acetaldehydes were identified in the following manner. That cyclopentenyl and aldehydic moieties were present was indicated by the i.r. of **3** + **4** which showed bands at 3052, 1612, and 2710 cm^{-1} (6). The n.m.r. spectrum showed absorptions at δ 9.50 and 5.68 and supported this premise. Since the 2- and 3-(cyclopentene)-acetaldehydes are not separated by g.l.p.c., the solvolysis method as described by Trahanovsky *et al.* (7) was employed for ratio determination. Reduction of **3** + **4** to the (cyclopentene)-ethanols, preparation of the nosylates of the mixture, followed by acetolysis gave the *exo*-norbornyl (84%), 2-(cyclopentene)ethyl (14%) acetates, and 1% of an unknown as was determined by g.l.p.c. A control experiment with a mixture of **3** + **4**, prepared by ceric ammonia nitrate oxidation of *exo*-norborneol (7) established a ratio 42:58 which compared favorably with the ratio of 48:52 determined for the same mixture by Trahanovsky *et al.* (7). Closer scrutiny showed that i.r. fingerprint spectroscopy is a more direct method for determining the **3**:**4** ratio. A band at 910 cm^{-1} present in the spectrum of 2-(cyclopentene)acetaldehyde (**3**) was present in the i.r. of a mixture of **3** + **4**. The relative area of the peak at 910 to that of the broad doublet at 718 (due to **3**) and 666 (due to **4**) determined for the 42:58 and 14:85 mixtures is 16 and 6%, respectively. Therefore to deter-

mine the percentage of **3** in a mixture of **3** + **4**, the percent area of the 910 peak to the 718–666 doublet is multiplied by 2.6. When the procedure is applied to pure 2-(cyclopentene)acetaldehyde, the area of the 910 peak × 2.6 is within 3% of the area of the 718 peak and thus establishes the validity of the method.

G.l.p.c. analysis of a typical run with nortricyclanol and the nortricyclyl halides showed 10–15 peaks of retention times in the region of authentic samples of *syn*- and *anti*-2,7-norbornandiol. In one run carried out in deuterated medium the diol fraction was converted to the corresponding diacetates with acetic anhydride in pyridine. N.m.r. and mass spectral studies and g.l.p.c. retention time data on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column established through the diacetates that the *syn*-7-, *anti*-7-, *exo*-5-, and *endo*-5-*exo*-2-norbornandiols are products. No attempt was made to identify all the components of higher retention time.

The data in Table 1 shows that acid (entries 10, 13–17) and a temperature >200° (entries 5

and 6) is required for the reaction. That is, nortricyclanol, *exo*-2-, *endo*-2-, and *anti*-7-norbornenols are stable in water at 250°. When the reaction is carried out in 10% v/v HOAc–H_2O at temperatures below 200° the conversion to the aldehydes and norcamphor does not occur detectably. Nortricyclyl bromide and nortricyclyl chloride are converted to **3**, **4**, **5**, and **6** in H_2O because HBr and HCl are generated during solvolysis. As shown by entries 1, 5, 10, and control experiments, the aldehydes are unstable in the presence of HCl and HBr and this accounts for the apparent formation of norcamphor only in reactions where HBr and HCl are generated. In the absence of the acids HCl and HBr the aldehydes are reasonably stable in 10% v/v HOAc–H_2O (entries 10 and 12) and are isolated from the nortricyclanol reaction in 20–25% yield. Entries 2, 8, and 9 show that 1*a*,·*b*, and *c* initially yield diols which together with norbornenols are then converted to **3**, **4**, **5**, and **6**. Scheme 1 represents various possible reaction pathways for the formation of the aldehydes and norcamphor. Further work must be done on hydroxy-cation intermediates to elucidate the exact details of the various pathways. The aldehydes and especially **6** therefore act as sinks for appropriately substituted norbornyl systems. Conceivably any appropriately substituted bicyclic system which contains seven ring-carbon atoms and which yields hydroxy-cations on solvolysis or protonation is convertible to the sink-compounds. For example, Crandall (8) has observed the conversion of *exo*-2,3-epoxybicyclo[2.2.1]heptane to 1*c*, **5**, and **6** on a g.l.p.c. column at 200°.

The conversion of 1*c* to **3** + **4** and **5** is one of a relatively small group of reactions involving the formal cleavage of bicyclo[2.2.1]heptyl system. This process provides a unique synthetic route to **3** + **4** and **5** and other unsaturated monocyclic systems (10*a–j*). For example, Jones and Jones (10*g*) have observed the conversion of *anti*-2,2,4,6-tetramethylbicyclo[2.2.1]hept-5-en-7-ol to a mixture of 1,3,5,5-tetramethyl-1-formylcyclohex-4- and -5-ene in refluxing aqueous acetic acid with a trace of H_2SO_4, and Arbusow (10*a*) has shown that treatment of pinene oxide with anhydrous $ZnBr_2$ yields the 3-(2,2,3-trimethylcyclopentene)acetaldehyde.

The solvolysis of suitably alkylated norbornenols, nortricyclanols, norbornene oxides or other bicyclic systems under the conditions described herein is an alternative synthetic method for the preparation of substituted norcamphors and aldehydes.

7	0.35	0.30	0.35	0.40	0.25	0.35	0.25	0.50
10*a*	0.20	0.15	0.20	0.25	0.25	0.20	0.15	0.20
11	0.30	0.25	0.35	0.35	0.20	0.25	0.20	0.25

*Rounded to 0.05 of one deuterium.
†C-3-*exo*- and C-3-*endo* are omitted because deuterium is incorporated via acid-catalyzed enolization (usually 1.7 D).
‡x = exo, n = endo, a = anti, s = syn.

Deuterium is incorporated in the aldehydes and norcamphor when **1***a*, *b*, and *c*, **2***b*, **7**, **10***a*, and **11** are solvolyzed in deuterated medium. Mass spectral deuterium analysis of **6** (a composite of up to d_8 species) obtained from **1***a* and *b* and the aldehydes and norcamphor (a composite in each case of up to d_6 species) obtained from **1***c* showed that the amount of deuterium incorporated depends on the acidity of the medium (entries 1, 4, 7, 11, 12). Control experiments in deuterated medium (DOAc–D_2O) show that (*a*) deuterium is not incorporated into the aldehydes **3** + **4** and **5** after they are formed, (*b*) isomerization of the double bond in **3** + **4** and **5** does not occur, and (*c*) deuterium is not incorporated into norcamphor via acid-catalyzed homoenolization (9) or some other pathway which involves HOAc–$^-$OAc. Our attempts to homoenolize camphenilone (**12**) in presence of CF_3COOD at 250° failed.

That protium–deuterium exchange occurs via protonation–deprotonation pathways (Scheme 1) is supported by the fact that deuterium is incorporated into unreacted nortricyclanol and the *syn*- and *anti*-7-*exo*- and *endo*-5-*exo*-2-norbornanediols.

In each case the deuterated norcamphor obtained from the solvolysis of **1***a*, *b*, and *c*, **2***b*, **7**, **10**, and **11** was reduced to *endo*-norborneol and the distribution of deuterium was determined by area integration analysis in the presence of $Eu(DPM)_3$(11, 12). The data are listed in Table 2. Whereas an unsubstituted norbornyl cation undergoes complete exchange under these reaction conditions (13) a hydroxy-cation fragments into the sink-compounds before complete exchange can occur.

Experimental

General

Analytical and preparative g.l.p.c. analyses were performed on Varian Model 204 B and 90 P-3 gas chromatographs with helium as the carrier gas. N.m.r. spectra were obtained in CCl_4 on Varian A-60 and HA-100 instruments with tetramethylsilane as internal standard. Mass spectra were obtained on a Hitachi–Perkin–Elmer RMU-6A spectrometer at 80 and 11 eV. Relative percent yields were obtained by tracing, cutting out, and weighing peaks. Collection losses during preparative g.l.p.c. for the aldehydes **3** and **4**, **5**, and for norcamphor (6) were determined by injecting aliquots of known concentration and determining the collection efficiency. In most experiments the isolated and corrected yields are given. Pentane was stirred over 30% fuming sulfuric acid, washed with bicarbonate solution, dried, and distilled. Pyridine was distilled from barium oxide. All solutions were dried over anhydrous $MgSO_4$ or Na_2SO_4. Nortricyclyl bromide was purchased from Frinton Laboratories, Vineland, New Jersey. Norcamphor, 3-(cyclohexene)-carboxyaldehyde, and 2-(cyclopentene)acetic acid were obtained from Aldrich Chemical Co., Milwaukee.

Acetic Acid-O-d

Acetic acid-O-*d* was prepared by heating equimolar quantities of acetic anhydride (freshly distilled) and deuterium oxide (99.8% d_2) for 12 h on the steam-bath in a flask protected from atmospheric water with a drying tube.

Nortricyclanol

Nortricyclanol, m.p. 107–110° (lit. (14) 108–110°) was prepared from norbornadiene by the procedure of Meinwald *et al.* (14).

Nortricyclyl Chloride

Nortricyclyl chloride, b.p. 48–50° (10 mm) was prepared by the chlorination of norbornene as described by Roberts *et al.* (5*b*).

Solvolysis of Nortricyclanol

Nortricyclanol (15.5 g, 0.14 mol, m.p. 107–110°) and 10% v/v CH_3COOH–H_2O (40 ml) were introduced to a thick-walled glass tube. The solution was degassed three times, the tube was sealed and then heated for 4 h at 250° in a Carius oven. The reaction mixture was neutralized with solid sodium bicarbonate, saturated with NaCl, and extracted

For personal use only.

with ether (8 × 40 ml). The ether extract was dried and the solvent was removed on the rotatory evaporator to give a viscous mass. Analytical g.l.p.c. on a 5 ft × 1/8 in. 5% SE-30 on Chromosorb W column (165°) showed that the mixture was composed of 40% diols, 50% **3** + **4**, **5**, and **6**, and 10% of products of intermediate retention time. The viscous mass was washed with pentane (4 × 20 ml). G.l.p.c. analysis showed that the aldehydes and norcamphor were extracted preferentially and the viscous material which remained solidified on standing. The aldehydes **3** + **4**, **5**, and norcamphor (**6**) were isolated by preparative g.l.p.c. on a 15 ft × 3/8 in. 15% Carbowax on Chromosorb W column (150°). After six injections, the temperature of the oven was increased to 215–220°, to clean the column of the diols which interfered with the collection of **3** + **4**, **5**, and **6**. **3** + **4**; i.r. (CCl_4), 3052 (C=C^H), 2710 (H—C^{=O}), 1612 (C=C), and 666 cm^{-1} (C=C^H); n.m.r. (CCl_4), δ 9.70 (multiplet, 1H, H—C^{=O}), 5.67 (multiplet, 2H, H_{C=C}H), 2.8–1.8 (multiplet, 7H); m.s., 80 eV, M^+ at *m/e* 110 corresponds to $C_7H_{10}O$. 2,4-DNP; m.p. 120.5–122.5° after two recrystallizations from aqueous ethanol.

Anal. Calcd. for $C_{13}H_{14}N_4O_4$: C, 53.79; H, 4.86; N, 19.30. Found: C, 53.61; H, 4.83; N, 19.29.

Compound **5**; i.r., (CCl_4), 3024 (C=C^H), 2700 (H—C^{=O}), 1730 (C=O), 1655 (C=C), 660 cm^{-1} (C=C^H); n.m.r. (CCl_4), δ 9.55 (s, 1H, H—C^{=O}), 5.68 (multiplet, 2H, H_{C=C}H), 2.2–1.8 (multiplet, 7H). The i.r. and n.m.r. were identical to those obtained for an authentic sample of 3-(cyclohexene)carboxaldehyde. M.s., 80 eV, showed M^+ at *m/e* 110 corresponding to $C_7H_{10}O$. **6**; m.p. 89–91° (lit. (8) 90–91°); m.p. of 2,4-DNP 129–131° (lit. (5*b*) 130–131.5°); n.m.r. (CCl_4), δ 2.70 (multiplet, 1H, C-1 bridgehead), 2.50 (multiplet, 1H, C-4 bridgehead), 2.1–1.5 (multiplet, 8H) was identical to that of an authentic sample; M.s., 80 eV, M^+ at *m/e* 110 corresponding to $C_7H_{10}O$.

No attempt was made to isolate the diol fractions.

Solvolysis of Nortricyclanol in Deuterated Medium

Nortricyclanol (12.1 g, 0.11 mol, m.p. 107–110°) and 10% v/v CH_3COOD–D_2O (35 ml) were introduced into a heavy walled glass tube. The solution was degassed three times, sealed under vacuum, and heated in a Carius oven for 9.5 h at 250°. The dark brown mixture was neutralized with solid sodium bicarbonate, saturated with NaCl, extracted with pentane (10 × 50 ml), and then ether (5 × 50 ml). Gas chromatography of the pentane extract on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (180°) showed that **3** + **4**, **5**, and **6** were extracted preferentially. In addition five minor components (5%) of retention time near **6** and ten components (10%) of retention time in the diol region were present. Gas chromatographic analyses of the ether extract on the same column showed ten components (90%) in the diol region, **3** + **4**, **5**, and **6** and five components in the region of **6** (total (10%). The pentane and ether extracts were decolorized with Norit, dried, and concentrated by distillation through a 12 in. Vigreux column. The concentrated pentane and ether extracts were transferred quantitatively into 10 ml and 5 ml volumetrics respectively, and made up to volume.

Injection of several aliquots (0.05 ml) of the pentane and ether extracts through the 15 ft × 3/8 in. 15% Carbowax on Chromosorb W column (180°) established the yields of the acetaldehydes (**3** + **4**), 3-(cyclohexene) carboxaldehyde (**5**), and norcamphor (**6**) as 0.6 (5%), 1.1 (9%), and 3.2 g (27%) respectively. Correction for collection losses established the actual yields as 1.1 (9%) of **3** + **4**, 1.8 (15%) of **5**, and 4.0 g (33%) of **6**. No attempt was made to isolate materials of longer retention time. However, comparison of retention time data on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column with authentic samples of *syn*- and *anti*-7-*exo*-2-norbornandiols indicated that the major components of the ether extract are the 2,7-norbornanediols.

The enolizable deuterium in **3** + **4** and **5** was washed out by three injections of each material through a 5% KOH column (150–170°) as described in the norcamphor homoenolization experiment. The deuterated norcamphor (0.16 g) isolated from the pentane extract (sodium bisulfite extraction was used to remove the aldehydes) was washed three times at 25 ± 3° for 24 h with 4–6 ml portions of a solution made up of methanol (20 ml), water (10 ml), and KOH (1.0 g). Each wash solution was worked-up by the addition of water (5 ml) and extraction with pentane (1 × 10, 4 × 5 ml). In each case the pentane extract was concentrated by distillation through a 2 ft Vigreux column and the norcamphor was isolated by preparative g.l.p.c.

Deuterium assay mass spectrometrically at 11 eV on the samples from which the enolizable deuterium was washed out, established that (*a*) **3** + **4** was composed of 2.5 d_5, 9.5 d_4, 23.5 d_3, 34.7 d_2, 24.7 d_1, and 4.2% d_0 species (2.16 atoms of deuterium); (*b*) **5** was composed of 3.0 d_5, 8.6 d_4, 18.8 d_3, 31.1 d_2, 32.7 d_1, and 4.9% d_0 species (2.00 atoms of deuterium), and (*c*) **6** was composed of 6.9 d_4, 15.6 d_3, 28.2 d_2, 39.0 d_1, and 7.6% d_0 species (1.70 atoms of deuterium).

To determine the location of the deuterium, the deuterio-*endo*-norborneol (0.020 g, 1.70×10^{-4} mol), obtained from lithium aluminum hydride in ether reduction of the norcamphor was subjected to n.m.r. area integral analysis in the presence of $Eu(DPM)_3$ (0.080 g, 1.13×10^{-4} mol) in CCl_4 (11, 12). The analysis established the following deuterium distribution; 0.20 at C-1, 0.10 at C-4, 0.30 at C-5-*exo*, 0.45 at C-5-*endo*, 0.15 at C-6-*exo*, 0.20 at C-6-*endo*, 0.20 at C-7-*syn*, and 0.15 at C-7-*anti* (1.75 atoms of deuterium).

To Check Deuterium Content in Nortricyclanol and Norbornanediols

Nortricyclanol (2.3 g, 0.021 mol, m.p. 107–110°), 10% v/v DOAc–D_2O (18 ml) were introduced into a thick walled tube and sealed under vacuum after degassing three times. The tube was heated in the Carius oven at 250° for 30 min, the reaction mixture was neutralized with solid $NaHCO_3$, and extracted with pentane (3 × 20 ml) and ether (3 × 20 ml). Analytical g.l.p.c. on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (temperature programming 165–220°) showed that the pentane extract was composed primarily (80%) of the aldehydes **3** + **4** and **5**, norcamphor, and nortricyclanol, four unidentified components (10%), and 10% of diols. Gas chromatographic analysis of the ether extract on the same column showed predominantly diols

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(90%) as well as the aldehydes **3** + **4**, and **5**, norcamphor, nortricyclanol, and three minor unidentified peaks (10%). The nortricyclanol was isolated by preparative g.l.p.c. from the concentrated pentane fraction and mass spectrometric deuterium assay showed 1.2 d_4, 2.2 d_3, 13.8 d_2, 67.8 d_1, and 15.0% d_0 species, a total of 1.02 atoms of deuterium per molecule.

The ether extract was concentrated by distillation to yield a two phase liquid and solid mixture. The liquid phase was decanted and to the remaining solid was added pyridine (5 ml) and acetic anhydride (4 ml). The solution was stirred at 25 ± 3° for 24 h and poured onto crushed ice (15 g). After the ice melted the solution was diluted to 65 ml with water and extracted with ether (4 × 15 ml). The ether extract was washed with 3% aqueous HCl (3 × 15 ml), water (2 × 15 ml), and dried. Analytical g.l.p.c. on a 10 ft × 1/8 in. 10% Carbowax column (200°) showed four components (with increasing retention time) in the ratio of 1:1:1:2. Analytical g.l.p.c. of a mixture of *syn*-7-acetoxy-, *anti*-7-acetoxy-, *exo*-5-acetoxy-, *endo*-5-acetoxy-*exo*-2-norbornyl acetates obtained from Frinton Laboratories had identical retention times to the diacetates obtained from the nortricyclanol reaction and established that the diol portion of the nortricyclanol reaction was composed primarily of norbornanediols. The diacetate mixture was separated into three fractions by preparative g.l.p.c. on a 15 ft × 3/8 in. 15% Carbowax on Chromosorb W column. Peaks 3 and 4 separated by analytical g.l.p.c. were not resolved by preparative g.l.p.c. and were collected together. Deuterium assay mass spectrometrically at 11 eV using the $M^+ - 43$ ($CH_3-\overset{\overset{O}{\|}}{C}<$) peaks because the molecular ion intensity was low gave the following data: Peak 1; 14.4 d_2, 80.9 d_1, and 4.7% d_0 species; 1.10 d per molecule; n.m.r. (CCl_4), δ 4.58 (doublet with fine structure, 1H, H—$\overset{|}{C}$—OAc), 4.20 (multiplet, 1H, H—$\overset{|}{C}$—OAc), 2.48 (multiplet, 1H, bridgehead C—H), 2.20 (multiplet, 1H, bridgehead C—H), 1.96 (singlet, 6H, $CH_3—\overset{\overset{O}{\|}}{C}—O—$), 1.90–0.90 (norbornyl envelope). Peak 2; 11.4 d_2, 85.9 d_1, and 2.7% d_0; 1.09 d per molecule; n.m.r. (CCl_4), δ 4.75 (multiplet, 1H, H—$\overset{|}{C}$—OAc). 4.40 (multiplet, 1H, H—$\overset{|}{C}$—OAc), 2.25 (multiplet, 2H, bridgehead C—H), 1.96 (singlet, 6H, $CH_3—\overset{\overset{O}{\|}}{C}—$), 1.90–0.90 (norbornyl envelope). Peak 3; 16.8 d_2, 77.4 d_1, and 5.8% d_0; 1.11 d per molecule; n.m.r., (CCl_4), δ 4.45 (multiplet, 2H, H—$\overset{|}{C}$—OAc), 2.18 (multiplet, 2H, bridgehead C—H), 1.96 (singlet, 6H, $CH_3—\overset{\overset{O}{\|}}{C}—O—$), 1.90–0.90 (norbornyl envelope).

Solvolysis of syn-7-Hydroxy-exo-2-Norborneol in Deuterated Medium

syn-7-Hydroxy-*exo*-2-norborneol (0.34 g) was heated with 10% v/v DOAc–D_2O (6 ml) in a sealed tube for 9.5 h at 250°. Work-up in the usual manner and analytical g.l.p.c. analysis of the ether extract on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (110°) showed **3** + **4** (18%), **5** (21%), and **6** (59%) as well as 2% of three other components. The deuterated norcamphor (0.040 g, 15%) (corrected yield 40%) was isolated by preparative g.l.p.c. on a 15 ft × 3/8 in. 5% KOH + 15% Carbowax on Chromosorb W column. The norcamphor was recollected by preparative g.l.p.c. and reduced with lithium aluminum hydride in ether. N.m.r.–Eu(DPM)$_3$ analysis of the deuterated *endo*-norborneol showed (rounded to 0.05 d) 0.20 d at C-1, 0.15 d at C-4, 0.20 d at C-5-*exo*, 0.25 d at C-5-*endo*, 0.25 d at C-6-*exo*, 0.20 d at C-6-*endo*, 0.15 d at C-7-*anti*, and 0.20 d at C-7-*syn*.

Solvolysis of anti-7-Norbornenol in Deuterated Medium

anti-7-Norbornenol (0.32 g) was heated at 250° with 10% v/v DOAc–D_2O (6 ml) for 9.5 h and worked-up in the usual manner. Analytical g.l.p.c. analysis showed **3** + **4** (3%), **5** (14%), and **6** (71%) as well as 12% of four other components. The deuterated norcamphor was isolated by preparative g.l.p.c. (0.072 g, 23%) (corrected yield 63%) and reduced with lithium aluminum hydride. N.m.r.–Eu(DPM)$_3$ analysis established a deuterium distribution of 0.35 at C-1, 0.30 at C-4, 0.35 at C-5-*exo*, 0.40 at C-5-*endo*, 0.25 at C-5-*exo*, 0.35 at C-6-*endo*, 0.50 at C-7-*syn*, and 0.25 at C-7-*anti*.

Solvolysis of endo-5-Norbornenol in Deuterated Medium

endo-5-Norbornenol (0.45 g) was heated in 10% v/v DOAc–D_2O (7 ml) as described previously. Work-up and g.l.p.c. analysis showed **3** + **4** (12%), **5** (15%), **6** (67%), and 6% of five other components. Preparative g.l.p.c. isolation gave 0.090 g of deuterionorcamphor (19%) (corrected yield 52%). Eu(DPM)$_3$ analysis of the *endo*-norborneol obtained by lithium aluminum hydride reduction established the deuterium distribution of 0.35 d at C-1, 0.20 at C-4, 0.20 at C-5-*exo*, 0.45 at C-5-*endo*, 0.30 at C-6-*exo*, 0.45 at C-6-*endo*, 0.25 at C-7-*anti*, and 0.25 at C-7-*syn*.

Solvolysis of exo-2,3-Epoxybicyclo[2.2.1]heptane in Deuterated Medium

exo-2,3-Epoxybicyclo[2.2.1]heptane (0.6 g, 5.5×10^{-3} mol) was heated in 10% v/v DOAc–D_2O (7 ml) as described previously. Work-up and g.l.p.c. analysis showed **3** + **4** (3%), **5** (10%), and **6** (69%) as well as 18% of three other components. Preparative g.l.p.c. analysis established an isolable yield of 0.22 g (36%) and a corrected yield of 62% for the deuterio norcamphor. The enolizable deuterium in the norcamphor was washed out with three washings of the KOH–MeOH–H_2O solution. The *endo*-norborneol obtained by lithium aluminum hydride reduction was subjected to Eu(DPM)$_3$ analysis which established a distribution of 0.30 d at C-1, 0.25 at C-4, 0.35 at C-5-*exo*, 0.35 at C-5-*endo*, 0.25 at C-6-*exo*, 0.30 at C-6-*endo*, 0.25 at C-7-*syn*, and 0.20 at C-7-*anti*.

$LiAlH_4$ Reduction of (Cyclopentene)acetaldehydes from Nortricyclanol Reaction

The mixture of aldehydes **3** + **4** (0.13 g, 1.2×10^{-3} mol) isolated by preparative g.l.p.c. as described previously was dissolved in ether (70 ml) and reduced with lithium aluminum hydride (0.023 g, 0.6×10^{-3} mol). After a 3 h reflux, 10% NaOH (0.5 ml) and water (0.2 ml) were added dropwise carefully to the cooled reaction flask. The gelatinous precipitate was filtered off and the ethereal filtrate was washed with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

saturated sodium bicarbonate (2 × 5 ml), water (1 × 5 ml), saturated aqueous sodium chloride, and dried. The mixture of (cyclopentene)ethanols (0.071 g, 57%) >99% pure as shown by analytical g.l.p.c. was isolated by preparative g.l.p.c. on a 15 ft × 3/8 in. 15% Carbowax column (170°).

Preparation of (Cyclopentene)ethanol Nosylates

The mixture of (cyclopentene)ethanols (0.071 g, 0.63×10^{-3} mol) was dissolved in dry pyridine (2.5 ml) and the solution was cooled in an ice–salt bath for 30 min. To the cold magnetically stirred solution was added freshly recrystallized (petroleum ether, b.p. 60–100°) *p*-nitro-benzenesulfonyl chloride (0.14 g, 0.64×10^{-3} mol). After stirring for 45 min at 0 to −10° the reaction mixture was poured into a solution made up of 20 ml of ice-water and 3.5 ml concentrated hydrochloric acid. The solid was collected on a sintered glass disc and washed with ice-cold 3% aqueous hydrochloric acid and several 10 ml portions of water and dried under vacuum at room temperature. The nosylate (0.13 g, 71%) had a m.p. of 64–67° (lit. (3) 65–67°).

Preparation of 2- and 3-(Cyclopentene)acetaldehydes. The CAN Oxidation of exo-Norborneol

exo-Norborneol (5.0 g, 44.6×10^{-3} mol) was oxidized with ceric ammonium nitrate (48.9 g, 89.2×10^{-3} mol) according to the procedure of Trahanovsky *et al.* (7). After 30 min at 50° the reaction mixture was cooled, water was added (150 ml) and extracted with pentane (3 × 100 ml). The pentane extract was washed with saturated aqueous sodium bicarbonate (2 × 50 ml), water (2 × 50 ml), saturated aqueous sodium chloride (2 × 50 ml), and dried. Analytical g.l.p.c. analysis on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (165°) showed that the aldehydes comprised 90% of the products. Control experiments showed that pentane extraction separated the aldehydes from the nitro-compound also produced in oxidation. The pentane was removed on the rotary evaporation to give 3.0 g of crude product which was dissolved in ether (60 ml) and added slowly to a stirred solution of lithium aluminum hydride (0.55 g) in ether (200 ml). Work-up gave 2.8 g of crude (cyclopentene)ethanols from which 0.28 g of a 2- and 3-(cyclopentene)ethanol mixture was isolated by preparative g.l.p.c. on a 15 ft × 3/8 in. 15% Carbowax column (170°).

The mixture of (cyclopentene)ethanols (0.28 g) was converted to the mixture of nosylates (0.62 g, m.p. 66–68°) as described previously.

Acetolysis of (Cyclopentene)ethanol Nosylates

The nosylate mixture (0.23 g) was dissolved in anhydrous acetic acid (13 ml) which contained anhydrous sodium acetate (0.065 g). After heating at 100 ± 2° for 13 h, work-up of the reaction mixture gave a pentane solution of acetates. Removal of the pentane gave 0.11 g of an oil. Analytical g.l.p.c. (tracing and weighing peaks) on a 10 ft × 1/8 in. 10% Carbowax column (125°) showed 58% of *exo*-norbornyl acetate and 42% of 2-(cyclopentene)ethyl acetate after comparison of retention times to those of authentic samples.

Acetolysis of Mixture of Nosylates Prepared from Aldehydes Obtained from Nortricyclanol Reaction

The mixture of nosylates (0.073 g, 0.24×10^{-3} mol) obtained previously was dissolved in anhydrous acetic acid (6 ml) containing 0.021 g of anhydrous sodium acetate and the solution was heated for 13 h at 100 ± 2°. Work-up gave a pentane solution of acetates. Removal of the pentane gave 0.034 g (89%) of an oil which when analyzed under the conditions employed previously showed 85% of norbornyl acetate, 14% of 2-(cyclopentene)ethyl acetate, and 1% of an unknown acetate.

Lithium Aluminum Hydride Reduction of 2-(Cyclopentene)acetic Acid

2-(Cyclopentene)acetic acid (8.2 g, 0.065 mol) in ether (50 ml) was added dropwise to a solution of lithium aluminum hydride (2.0 g, 0.052 mol) in ether (150 ml) and then refluxed for 12 h. Work-up as described previously, yielded 2-(cyclopentene)ethanol (7.3 g, 95%).

Silver Carbonate on Celite Oxidation of 2-(Cyclopentene)ethanol

A ten-fold excess of silver carbonate on celite (38 g, 66.2×10^{-3} mol) prepared by the method of Fetizon and coworkers (15) was suspended in benzene (250 ml) and refluxed, collecting any residual water with a Dean–Stark apparatus. After all the water was removed, 2-(cyclopentene)ethanol (0.74 g, 6.62×10^{-3} mol) in benzene (75 ml) was added dropwise. After refluxing for an additional 16 h, the hot reaction mixture was filtered through a fine porosity fritted funnel which contained a thin layer of purified celite. The filtrate was concentrated on the rotary evaporator and the 2-(cyclopentene)acetaldehyde (0.60 g, 32%) was collected by preparative g.l.p.c. on a 15 ft × 3/8 in. 15% Carbowax column (155°). 2,4-DNP; m.p. 98–99.5° after three recrystallizations from methanol (lit. (16) 98–99°; (10*d*) 100–101°).

Infrared Fingerprint Region Assay of 2- and 3-(Cyclopentene)acetaldehyde Mixtures

The i.r. fingerprint region (CS_2) of the **3** + **4** mixtures obtained from CAN oxidation of *exo*-norborneol and solvolysis of nortricyclanol showed a peak at 910 and an unresolved broad doublet with maxima at 718 and 666 cm^{-1}. The i.r. fingerprint region of **3** prepared by Ag_2CO_3 oxidation of 2-(cyclopentene)ethanol showed bands at 910 and 718. Analysis (tracing, cutting, and weighing) showed that the 910 peak was 16 and 6% of the area of the 718–666 doublet for the aldehyde mixtures obtained from the CAN oxidation and the nortricyclanol reactions, respectively. Therefore, to obtain the amount of **3** in a mixture of **3** + **4** to within ±2–3%, the 910 peak area percentage is multiplied by 2.6 (16 × 2.6 = 41.6; 6 × 2.6 = 15.6). Application of the analysis to pure **3** showed that the 910 peak area × 2.6 was within 2% of the 718 peak area, establishing the validity of the method.

Solvolysis of Nortricyclyl Halides

Nortricyclyl chloride (0.88 g, 6.8×10^{-3} mol) and water (20 ml) were introduced into a clean heavy-walled glass tube. The solution was degassed three times, sealed under vacuum, and heated in a Carius oven for 1.5 h at 250°. The dark reaction mixture was neutralized with sodium bicarbonate, saturated with sodium chloride, and extracted with ether (4 × 20 ml). The extract was decolorized with Norit, dried, and concentrated by distillation through a 12 in. Vigreux column and made up to volume in a 2 ml volumetric flask. Injection and collection of aliquots (0.1 ml) on the 15 ft × 3/8 in. 15% Carbowax on Chromosorb W column (155°) established that the isolable and corrected yields of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

norcamphor were 29 and 38% respectively. Only minor amounts <5% of the aldehydes and diols (7 components) could be detected by analytical g.l.p.c. on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (temperature programming 165–220°).

Deuterated Medium

Solvolysis of nortricyclyl chloride (2.4 g, 18.7×10^{-3} mol) in 10% v/v CH_3COOD–D_2O (15 ml) for 4 h at 250° and work-up gave 0.3 g (15%) of deuterated norcamphor. Correction for collection losses (preparative g.l.p.c.) established the actual yield at 30%. The enolizable deuterium was removed by three washings with a methanol–water–KOH solution. Mass spectrometric deuterium assay established the norcamphor as a composite of 3.9 d_8, 9.4 d_7, 12.5 d_6, 13.5 d_5, 13.9 d_4, 15.5 d_3, 15.2 d_2, 13.0 d_1, and 3.1% d_0 species (3.70 atoms of deuterium).

To determine the location of the deuterium, the deuterated *endo*-norborneol (0.020 g, 1.70×10^{-4} mol), obtained from the lithium aluminum hydride in ether reduction of deuterated norcamphor (after the enolizable deuterium was washed out), was subjected to n.m.r., integral analysis in the presence of $Eu(DPM)_3$ (0.85 g, 1.21×10^{-4} mol) in CCl_4 (11, 12). The analysis established the following deuterium distribution; 0.40 *d* C-1, 0.30 *d* C-4, 0.55 *d* C-5-*exo*, 0.55 *d* C-5-*endo*, 0.55 *d* C-6-*exo*, 0.50 *d* C-6-*endo*, 0.60 *d* C-7-*syn*, and 0.25 *d* C-7-*anti* (3.70 atoms of deuterium per molecule).

Solvolysis of nortricyclyl bromide (1.8 g, 9.8×10^{-3} mol) in 10% v/v CH_3COOD–D_2O (15 ml) for 4 h at 250° and work-up gave 0.2 g (13%) of deuterated norcamphor after preparative g.l.p.c. (corrected yield 32%). After the enolizable deuterium was washed out, mass spectrometric deuterium assay established the following distribution, 2.6 d_8, 5.6 d_7, 7.8 d_6, 10.6 d_5, 13.6 d_4, 16.6 d_3, 18.9 d_2, 18.8 d_1, and 5.6% d_0 species (3.20 atoms of deuterium).

The position of deuterium was determined via the deuterated *endo*-norborneol (0.020 g, 1.70×10^{-4} mol) using the $Eu(DPM)_3$ (0.080 g, 1.13×10^{-4} mol. CCl_4 (11, 12)) method. The analysis established the following deuterium distribution; 0.40 *d* C-1, 0.35 *d* C-4, 0.50 *d* C-5-*exo*, 0.50 *d* C-5-*endo*, 0.30 *d* C-6-*exo*, 0.40 *d* C-6-*endo*, 0.30 *d* C-7-*syn*, and 0.30 *d* C-7-*anti* (3.20 atoms of deuterium per molecule).

Treatment of 3-(Cyclohexene)carboxaldehyde Under Solvolysis Conditions

3-(Cyclohexene)carboxaldehyde (0.46 g) and 10% v/v CH_3COOD–D_2O (11 ml) were sealed under vacuum in a thick-walled tube after degassing as described previously. The solution was heated in the oven for 1.5 h at 250° and worked-up in the usual manner. Gas chromatographic analysis on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (temperature programming 170–220°) showed by comparison with authentic samples that norcamphor and the (cyclopentene)acetaldehydes were not formed. Four minor components (<10%), one of retention lower than **5** and three of longer retention time were present. After the enolizable deuterium was washed out by three injections through the 5% KOH + 20% Carbowax on Chromosorb W column (160°), mass spectrometric analysis showed that no deuterium was incorporated into **5**.

Treatment of 3-(Cyclohexene)carboxaldehyde in 18% DOAc–D_2O; 1% HCl

The aldehyde **5** (0.48 g), 18% v/v DOAc–D_2O (15 ml), and concentrated hydrochloric acid (0.4 ml) were introduced into a sealed tube, degassed three times, and sealed under vacuum. The tube was heated at 250° for 1.5 h and worked-up as described previously. Gas chromatographic analysis on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column (temperature program 180–230°) showed 12 components, and only a trace <2% of **5**. Norcamphor comprised approximately 15% of the mixture.

Treatment of 2-(Cyclopentene)acetaldehyde under Solvolysis Conditions

2-(Cyclopentene)acetaldehyde (0.58 g, 5.28×10^{-3} mol) and 10% v/v CH_3COOD–D_2O (12 ml) were sealed in a thick-walled glass tube. The tube was heated in a Carius oven for 1.5 h at 250° and worked-up in the usual manner. Gas chromatographic analysis on a 10 ft × 1/8 in. 10% Carbowax on Chromosorb W column showed that only starting material was present. After the enolizable deuterium was washed out by four injections through the 5% KOH + 20% Carbowax on Chromosorb W column (155°), mass spectrometric analysis showed that deuterium was not incorporated into **3**. I.r. analysis of the aldehyde showed that isomerization to **4** did not occur.

Check for Acid-catalyzed Homoenolization

Run 1

Norcamphor (0.5 g, 4.5×10^{-3} mol), 15% v/v DOAc–D_2O (10 ml), and concentrated HCl (0.37 ml) were introduced into a thick walled tube and sealed under vacuum after three degassings. The solution was heated at 260° for 1.5 h, worked-up in the usual manner, and made up to volume in a 4 ml volumetric flask. The norcamphor (42%) (corrected yield 73%) was isolated by preparative g.l.p.c. by injecting aliquots (0.1 ml) through the 5% KOH + 20% Carbowax column (150°). Deuterium assay mass spectrometrically after one, two, and three injections of the same sample gave the following results; one injection, 7.1 d_2, 58.4 d_1, 34.5% d_0; two injections, 1.8 d_2, 24.8 d_1, 73.4% d_0; three injections, 0.8 d_2, 4.4 d_1, 94.8% d_0 species. This established that deuterium is not incorporated into norcamphor via acid-catalyzed homoenolization and that the 5% KOH column removes at least 95% of the two enolizable deuterium from norcamphor after three injections.

Run 2

Camphenilone (0.19 g), 15% v/v DOAc–D_2O (10 ml), and concentrated HCl (0.13 ml) were introduced into a thick-walled glass tube and sealed under vacuum after degassing. The mixture was heated at 250° for 3 h and worked-up as described previously. Mass spectrometric deuterium assay on the camphenilone isolated by preparative g.l.p.c. on the 10 ft × 3/8 in. 5% KOH + 20% Carbowax column (145°) showed 98 d_0 and 2% d_1 species.

A duplicate of run 2 with camphenilone (0.18 g), 15% v/v DOAc–D_2O (10 ml), and concentrated HCl (0.11 ml) that was heated for 18 h at 275° was worked-up and analyzed by analytical g.l.p.c. (5 ft × 1/8 in. 5% SE-30 on chromosorb W column 110°). Less than 5% of the camphenilone remained. There were three major components (80%) of retention time shorter than camphenilone as well as four other minor components (20%).

Run 3

Two sealed tubes, one containing 0.21 g of camphenilone and 2 ml of 10% v/v CF_3COOD–D_2O and the other 0.28 g

in 2 ml of 10% v/v CF_3COOD–D_2O were prepared and heated at 205° for 17 and 120 h respectively. After work-up, deuterium assay on samples isolated by preparative g.l.p.c. on a 10 ft × 3/8 in. 10% Carbowax on Chromosorb W column (185°) showed that in both cases no deuterium had been incorporated into the camphenilone.

Chemistry of Aminochromes. Part XV. The Reaction of Epinochrome with Thiols[1,2]

W. S. POWELL[3,4] AND R. A. HEACOCK[5]

Chemistry Department, Dalhousie University, Halifax, Nova Scotia and Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received April 14, 1972

Epinochrome (**5**) has been shown to react with thioglycollic acid to give mainly 5,6-dihydroxy-1-methylindoline and a 4-thiosubstituted 5,6-dihydroxy-1-methylindoline. The acetyl derivatives of these compounds (*i.e.* **7***b* and **15**), along with that of the corresponding 4-thiosubstituted 5,6-dihydroxyindole (*i.e.* **11**), were isolated after acetylation of the reaction mixture. The latter compound is probably a secondary product of the reaction, having arisen from the 4-thiosubstituted 5,6-dihydroxy-1-methylindoline which is formed initially.

On a montré que l'épinochrome (**5**) réagit avec l'acide thioglycolique pour conduire principalement au dihydroxy-5,6 méthyl-1 indoline et au dihydroxy-5,6 méthyl-1 indoline thiosubstitué en position 4. Les dérivés acétylés de ces composés (c'est-à-dire **7***b* et **15**) de même que ceux qui correspondent au dihydroxy-5,6 indole thiosubstitué en position 4 (par exemple **11**) ont été isolés après acétylation du mélange réactionnel. Le dernier composé est probablement un produit secondaire de la réaction provenant du dihydroxy-5,6 méthyl-1 indoline thiosubstitué en position 4 qui s'est initialement formé.

Canadian Journal of Chemistry, **50**, 3360 (1972)

Aminochromes which are substituted in the 3-position by an alkoxyl or hydroxyl group react with thiols to give three types of products: (*i*) aminochrome/thiol addition products in which the thiol residue is attached to the 3*a*-position[6] of the indole nucleus (1, 2), (*ii*) 5,6-dihydroxyindoles (3, 4), and (*iii*) 4-thiosubstituted 5,6-dihydroxyindoles (5, 6). The aminochrome/thiol addition products were the major products formed, at least initially, when the reactions occurred in either neutral or slightly acidic solution, whereas the indolic products predominated at lower p*H*'s.

Very little work has been carried out, however, on the reactions of thiols with aminochromes which are unsubstituted in the 3-position. Bouchilloux and Kodja (7) reported that glutathione (GSH) reacted with dopachrome (**1**) (which they had eluted from a paper chromatogram of dopa oxidation products), to give three major products: 5,6-dihydroxyindole (**2***a*), 2-carboxy-5,6-dihydroxyindole (**2***b*), and a thiosubstituted 5,6-dihydroxyindole which they suggested had either the structure **3***a* or *b*. It was suggested the 5,6-dihydroxyindoles (**2***a* or *b*) were formed by the rearrangement of **1**. The thiosubstituted 5,6-dihydroxyindole was postulated to have arisen as a result of the addition of GSH to either the indolequinone **4***a* or *b* which could have been produced by the oxidation of the corresponding 5,6-dihydroxyindoles (**2***a* or *b*).

The reaction of epinochrome (**5**) with β-mercaptopropionic acid in aqueous solution at slightly acidic p*H*'s has recently been investi-

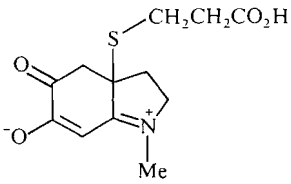
5



6

gated in these laboratories (2). It has been shown that under these conditions the major product formed initially is 3*a*-*S*-(β-carboxyethylthio)-3*a*, 4-dihydroepinochrome (**6**), which was isolated as its *p*-nitrophenylhydrazone derivative (2).

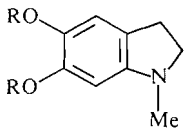
The reactions of epinochrome (**5**) with some thiols (*i.e.* thioglycollic acid and GSH) under acidic conditions have now been studied. During the course of these investigations it was found that **5** could be obtained in crystalline form more conveniently and in higher yields than by the method previously described (8) by an adaptation of the procedure employed by Heacock *et al.* (9) for the preparation of adrenochrome.

Thin-layer chromatography of the initial products of the reaction between epinochrome (**5**) and some thiols was hampered by the facile autoxidation of some of the products to indoline-5,6-quinone derivatives; this occurred when the excess thiol was separated from the reaction products during the chromatographic process. The chromatographic picture was also complicated by the ready formation of rearrangement products from the quinones described above.

The reaction between **5** and GSH in aqueous buffer at p*H* 3.3 was followed by u.v./visible spectroscopy. The absorption maximum of **5** in the visible region at 476 nm disappeared with time whilst the peak at 307 nm was replaced by a peak of lower intensity at 311 nm. An ether extract of the reaction mixture showed maximum absorption at 309 nm (in aqueous solution) whilst the aqueous phase of the reaction mixture absorbed maximally at 312 nm. It would appear from a consideration of the λ_{max} values of analogous compounds that the ether extractable product could be 5,6-dihydroxy-1-methylindoline (7*a*) and that the main product remaining in the mother liquors may be a 5,6-dihydroxy-1-methylindoline thioether.

In order to obtain more definitive information about the products of a typical interaction of this type an attempt was made to isolate the products of the reaction between epinochrome and thioglycollic acid. Since the initial reaction products were reoxidized very readily by air, they were acetylated directly after formation by acetic anhydride and pyridine.

In view of the fact that it was anticipated that 5,6-diacetoxy-1-methylindoline (7*b*) might be one of the products of this reaction, this hitherto unknown compound was synthesized by a method similar to that employed by Wyler and Chiovini (10) for the preparation of 5,6-diacetoxy-1-acetyl-2-carbomethoxyindoline (**8**).



7

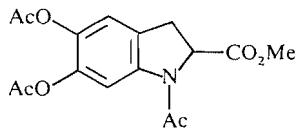
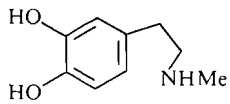
b R=Ac



8



9

Solutions of epinochrome (**5**), prepared by the oxidation of epinine (**9**) by potassium ferricyanide in phosphate buffer were immediately and rapidly reduced with sodium dithionite ($Na_2S_2O_4$) to give 5,6-dihydroxy-1-methylindoline (7*a*), which was stabilized by the addition of hydrochloric acid and isolated as 5,6-diacetoxy-1-methylindoline (7*b*) after acetylation with acetic anhydride and pyridine. It was essential to carry out all the stages in this procedure as quickly as possible to minimize losses due to either the easy reoxidation of the 5,6-dihydroxyindoline reduction product or the facile rearrangement of the aminochrome **5**. The spectroscopic data obtained for 7*b* were consistent with the 5,6-diacetoxy-1-methylindoline structure. The λ_{max} in the u.v. spectrum of this compound (*i.e.* 310 nm) was close to that previously reported for similar 5,6-dihydroxyindoline derivatives (10–14). The signals for the protons at positions 4- and 7- in the p.m.r.

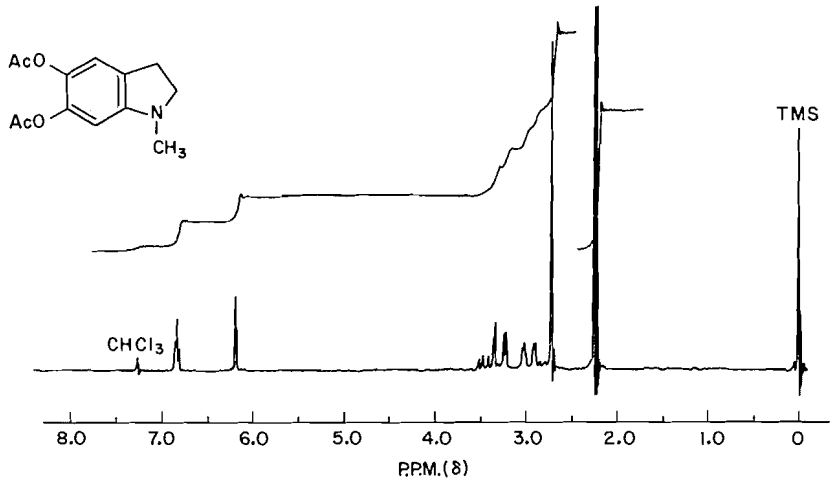

FIG. 1. P.m.r. spectrum (60 MHz) of 5,6-diacetoxy-1-methylindoline (*7b*) in $CDCl_3$ using tetramethylsilane as internal reference.

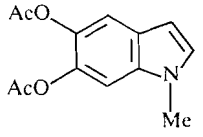
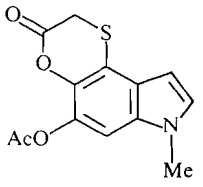
spectrum of *7b* (shown in Fig. 1) were observed at δ 6.85 and 6.21 respectively with benzylic coupling being observed between the proton in the 4-position and the C_3-methylene protons ($J = 1.1$ Hz). Similar couplings have recently been reported for analogous compounds (11, 12).

The mixture of acetylated products formed after the addition of acetic anhydride and pyridine (1:1) to the epinochrome/thioglycollic acid reaction mixture was examined by t.l.c. 5,6-diacetoxy-1-methylindole (**10**), 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone (**11**), and 5,6-diacetoxy-1-methylindoline (*7b*) were used as chromatographic standards.



10



11

The results of this chromatographic examination are given in Table 1.

It appeared that three main products were obtained, two of which were the acetylated indole thioether lactone **11** and 5,6-diacetoxy-1-methylindoline (*7b*). The indoline derivative, however, only gave a positive reaction with the indole chromogenic reagents (*i.e.* Ehrlich's reagent and cinnamaldehyde) when the chromatograms were heated for several minutes after spraying (see Table 1). This may have been due to hydrolysis of the ester linkages of *7b* by the acid present in the chromogenic reagent, upon heating the plates. The resulting 5,6-dihydroxyindoline would readily oxidize in air to the corresponding indoline-5,6-quinone, which would rearrange rapidly to the corresponding 5,6-dihydroxyindole.

The third major product, like *7b*, gave colors with Ehrlich's reagent or cinnamaldehyde only after heating, suggesting that it was also an acetylated 5,6-dihydroxyindoline derivative. In a similar manner to the 4-substituted product **11** it gave a blue-green color with aqueous sodium hydroxide usually observed for 5,6-dihydroxyindoles substituted in the 4-position. In addition to the three major products described above there were a number of minor products formed including one that appeared to be chromatographically the same as 5,6-diacetoxy-1-methylindole (**10**).

The indolic products in the reaction mixture may have been formed as a result of the loss of the protective effect of the —SH group of the excess thioglycollic acid, due to its acetylation by the acetic anhydride/pyridine mixture. Any 5,6-dihydroxyindolines (*cf.* **12**) present at this stage could be oxidized in air to the corresponding indoline-5,6-quinones (*cf.* **13**), which

12 **13** **14**

SCHEME 1

would rearrange to 5,6-dihydroxyindoles (*cf.* **14**) in the presence of pyridine (See Scheme 1).

When precautions were taken to exclude air during the course of the acetylation procedure, t.l.c. of the products indicated that, although some 5,6-dihydroxyindoles were still formed, much larger amounts of the 5,6-dihydroxyindoline compounds were obtained.

It was possible to isolate the acetylated lactonized indole thioether **11** from the reaction mixture by column chromatography on silica gel using a neutral eluting solvent system. The product obtained in this manner was identical to samples of 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone (**11**) prepared from adrenochrome by the method of Powell *et al.* (**5**).

The two basic 5,6-dihydroxyindoline derivatives were isolated from the crude reaction mixture by column chromatography on silica gel, using a basic eluting system (a hexane/pyridine mixture). They were finally obtained as pure compounds after a second separation on a silica gel column using a neutral eluting solvent system. The major product obtained in this manner was 5,6-diacetoxy-1-methylindoline (*7b*) and was identical to samples of this product obtained by acetylation of the dithionite reduction product of epinochrome (**5**). The second basic product, which was obtained as a white crystalline solid, was shown by mass spectrometry to have a molecular formula of $C_{13}H_{13}NO_4S$. The i.r. spectrum of this compound showed a strong absorption at 1761 cm^{-1}, probably due to the ester and lactone carbonyl groups. The p.m.r. spectrum of this product (Fig. 2) was similar to that of *7b* with the exception of the absence of peaks due to the H_4 proton and one of the acetyl methyl signals. In addition, a peak at δ 3.43, which can be assigned to the —*S*—CH_2— group, was also observed. The peak for the corresponding protons of **11** has been reported to occur at δ 3.50 (5).

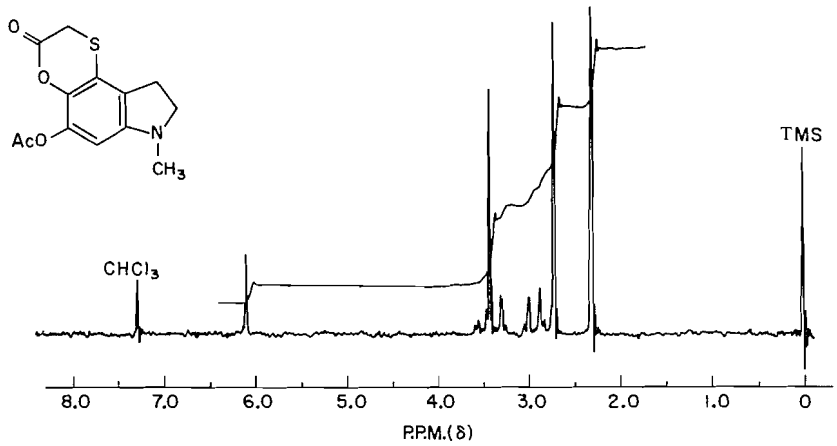

FIG. 2. P.m.r. spectrum (60 MHz) of 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindoline lactone (**15**) in $CDCl_3$ using tetramethylsilane as internal reference.

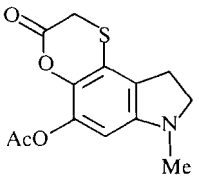
These facts show unambiguously that this product is 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindoline lactone (**15**).



15

The present investigation would suggest that aminochromes which do not have a 3-hydroxyl (or 3-alkoxyl) substituent react with thiols under acidic conditions to give the corresponding 5,6-dihydroxyindoline reduction products (*i.e.* true "leuco" derivatives) as well as 4-thiosubstituted 5,6-dihydroxyindolines. An alternative explanation can now be presented for the formation of the thiosubstituted 5,6-dihydroxyindoles reported to be formed in the reaction between dopachrome (**1**) and GSH which was investigated by Bouchilloux and Kodja (7). The indolic product may have arisen via the oxidation of an initially formed thiosubstituted 5,6-dihydroxyindoline to the thiosubstituted aminochrome. This could then rearrange to the dihydroxyindole (*cf.* Scheme 1).

Experimental

The melting points were determined on either a Leitz Hot Stage instrument or a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were obtained with the aid of a Perkin–Elmer model 237 recording spectrophotometer; the u.v./visible spectra were measured on either a Beckman DK-2 or a Bausch and Lomb "spectronic 505" recording spectrophotometer; the p.m.r. spectra were recorded on a Varian A-60A instrument and the mass spectra were obtained on a DuPont/C.E.C. 21-110B instrument.

Epinochrome (*5*)

Epinine free base[7] (2 g) was suspended in dry methanol (82 ml) and 98% formic acid added dropwise with stirring until a clear solution was obtained. Freshly prepared silver oxide (8.64 g) was added portionwise during a period of 5 min, during which time the reaction temperature was maintained between 16° and 25°. The reaction mixture was then filtered through a Dowex-1 × 8(Cl^-) (200–400 mesh) resin bed[8] (height = 3.5 cm; diameter = 4.5 cm). Dry ether (260 ml) was added to the filtrate and it was kept in a cold room at −30° for 8 h. Upon filtration epinochrome (1.17 g, 60%) was obtained as deep red needles, m.p. 80–83° with decomposition (lit. m.p. 78° (8)); λ_{max} (H_2O) nm (ε): 217 (31 400), 307 (12 600), 476 (4070); ν_{max} (Nujol): 1661, 1652, 1612, 1566 cm^{-1}.

5,6-Diacetoxy-1-methylindoline (*7b*)

A solution of potassium ferricyanide (2 g) in 50 ml of Soerensen phosphate buffer[9] (p*H* 8) was added to a stirred solution of epinine hydrochloride (250 mg) in 75 ml of the same buffer. After 4–5 s, a solution of sodium dithionite (1.36 g) in the same buffer (25 ml) was added, resulting in an almost immediate discharge of the red color of the epinochrome solution. Concentrated HCl (2.5 ml) was added to

[7]The free base of epinine was prepared by the addition of solid K_2CO_3 to a stirred aqueous solution of epinine hydrochloride. After standing in an ice bath for 1.5 h under a stream of nitrogen, the free base was filtered off, washed with water, and dried *in vacuo*.

[8]The Dowex resin was pretreated by the method previously described in the literature (9).

[9]0.5 g KH_2PO_4 and 22.6 g $Na_2HPO_4 \cdot 12H_2O$ per liter.

the solution 1–2 s after the addition of the dithionite and the reaction mixture was then concentrated to dryness *in vacuo*, benzene being added during the latter stages to enable complete removal of any water present. A 1:1 mixture of acetic anhydride and pyridine (25 ml) was added to the solid residue which had been broken up with a spatula. The acetylation mixture was left at room temperature for 4 h, filtered, and the residue washed with dichloromethane (3 × 20 ml). The washings and the acetic anhydride/pyridine solution were combined, filtered, and concentrated to dryness *in vacuo* below 50°. The residue was dissolved in a mixture of 0.5 *N* HCl (25 ml) and dichloromethane (25 ml) in a separatory funnel. The organic layer was separated and washed with saturated aqueous sodium bicarbonate solution (4 × 30 ml) and water (2 × 30 ml). The dried (Na_2SO_4) dichloromethane solution was then concentrated to dryness *in vacuo*. The crude product, which also contained a small amount of 5,6-diacetoxy-1-methylindole, was purified on a silica gel (Davison, 100–200 mesh) column (height = 18 cm; diameter = 2.2 cm) with a mixture of hexane/ethyl acetate/pyridine (15:3:2) as eluant. A series of 25 ml fractions were collected. Fractions 6–10 were combined and the solvent removed *in vacuo* below 50° to give a white crystalline solid, from which 5,6-diacetoxy-1-methylindoline (**7***b*) (200 mg) was obtained in colorless rods (m.p. 115–116°) on recrystallization from heptane; λ_{max} (EtOH) nm (ε): 206 (22 200), 257 (9710), 310 (3460); ν_{max} (Nujol): 1765, 1756 cm^{-1}. The p.m.r. δ ($CDCl_3$): 6.85 (1H, t, $J_{3A,4} = J_{3B,4}$ = 1.1 Hz, H_4); 6.20 (1H, s, H_7); 3.54–2.72(4H, m, AA'BB' system centered at 3.13, $—CH_2CH_2—$ of the five-membered ring; the C_3-methylene group, which appears as the upper field half of this system is coupled to H_4, J = 1.1 Hz); 2.72 (3H, s, *N*—CH_3); 2.25 (3H, s, *C*—CH_3); 2.22 (3H, s, *C*—CH_3). Mass spectrum: $M^{+\cdot}$ 249; calcd. for $C_{13}H_{15}NO_4$: 249.

Anal. Calcd. for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62. Found: C, 62.72; H, 6.05; N, 5.83.

The Epinochrome–Thioglycollic Acid Reaction

(a) Chromatographic Study of Reaction Products after Acetylation

Epinochrome (50 mg) was added to thioglycollic acid (1 ml) and the mixture shaken until all the solid had dissolved (*ca.* 15 min). A 1:1 mixture (7 ml) of acetic anhydride and pyridine was added and the reaction mixture kept at room temperature for 2 h. Concentration of this solution *in vacuo* gave a dark yellow oil which was dissolved in dichloromethane (25 ml). After washing with a saturated aqueous sodium bicarbonate solution (3 × 25 ml) and water (2 × 25 ml) the organic phase was dried (Na_2SO_4) and its composition investigated by t.l.c. on silica gel (see Table 1).

(b) Isolation of the Reaction Products as their Acetyl Derivatives

Epinochrome (500 mg) was added to thioglycollic acid (5 ml) and the mixture shaken until all the solid had dissolved (*ca.* 45 min). The flask containing the thioglycollic acid solution was then evacuated and nitrogen was bubbled through the reaction mixture. A 1:1 mixture (40 ml) of acetic anhydride and pyridine was added to the thioglycollic acid solution at 0°, the system being maintained under nitrogen at slightly reduced pressure throughout the addition and then for a further 2 h. Half an hour after the addition of the acetic anhydride and pyridine the reaction mixture was allowed to warm up to room temperature and after another 1.5 h it was concentrated to small bulk *in vacuo* below 50°. The residue was dissolved in dichloromethane (50 ml) and this solution was washed with a saturated aqueous solution of sodium bicarbonate (3 × 50 ml) and then with water (3 × 50 ml). A dark yellow oil was obtained upon concentration of the dried (Na_2SO_4) organic layer *in vacuo*, below 30°.

Isolation of 6-acetoxy-4-S-carboxymethylthio-5-hydroxy-1-methylindole lactone (**11**). The dark yellow oil described above (prepared from 500 mg of epinochrome) was purified chromatographically on a silica gel (Davison, 100–200 mesh) column (height = 25 cm; diameter = 2 cm) using benzene (500 ml) followed by benzene/ethyl acetate (97:3; 1000 ml) as eluting solvents. A series of fractions (fraction volume, 17 ml) were collected and these were monitored by t.l.c. on silica gel plates (using benzene/ethyl acetate (8:2) as developing solvent with Ehrlich's reagent and 1 *N* NaOH as chromogenic reagents). Fractions 65–80 were combined and concentrated to dryness *in vacuo* to give 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone (**11**) as a white crystalline solid (60 mg, 7.1%), which, after recrystallization from heptane, had a melting point of 160–163°. The identity of this product with samples of the product which had previously been prepared from the reaction of thioglycollic acid with adrenochrome (5) was established by the nondepression of m.p. and by the identity of their i.r., n.m.r., and mass spectral properties.

Isolation of 6-acetoxy-4-S-carboxymethylthio-5-hydroxy-1-methylindoline lactone (**15**) *and 5,6-diacetoxy-1-methylindoline* (**7***b*). A sample of the dark yellow oil obtained after acetylation of the epinochrome/thioglycollic acid reaction mixture (prepared from 500 mg epinochrome) and obtained in the manner described above was chromatographed on a column (height = 20 cm; diameter = 2 cm) of silica gel (Davison, 100–200 mesh) with hexane/pyridine (8:2) as eluant. Once again a series of fractions was collected (fraction volume, 20 ml). A yellow oil was obtained after concentration of fractions 8–20 to dryness *in vacuo* below 35°. This oil was rechromatographed on a column (height = 20 cm; diameter = 2 cm) of silica gel (Davison, 100–200 mesh) with the following solvents as eluants: benzene (500 ml); benzene/ethyl acetate (97:3, 1000 ml). and benzene/ethyl acetate (95:5, 2000 ml). Fractions 95–120 (fraction size, 15 ml) were combined and concentrated to dryness *in vacuo* to give 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindoline lactone (**15**) as a white crystalline solid (70 mg, 8.2%), which gave colorless needles, m.p. 137–140° after recrystallization from heptane; λ_{max} (EtOH) nm (ε): 225 (sh), 234 (19 700), 262 (9020), 319 (4010); ν_{max} (Nujol); 1761 cm^{-1}. The p.m.r. δ ($CDCl_3$): 6.10 (1H, s, H_7); 3.43 (2H, s, *S*—CH_2—); 3.63–2.71 (4H, m, AA'BB' system centered at 3.17, $—CH_2CH_2—$ of five-membered ring); 2.73 (3H, s, *N*—CH_3); 2.32 (3H, s, *C*—CH_3). Mass spectrum: $M^{+\cdot}$ 279.0561 ± 0.0008; calcd. for $C_{13}H_{13}NO_4S$: 279.0566.

In a similar fashion fractions 150–200 were combined and concentrated to dryness *in vacuo* to give 5,6-diacetoxy-1-methylindoline (**7***b*) as a white crystalline solid (115 mg, 15.1%). Recrystallization from heptane gave colorless rods, m.p. 113–115°. The fact that this product was the same as samples of 5,6-diacetoxy-1-methylindoline which had previously been prepared by the reduction of epinochrome

with sodium dithionite in the manner described above was established by the nondepression of m.p. and the identity of their i.r., p.m.r., and mass spectra.

The authors wish to thank Dr. L. M. Babineau, Directeur, Département de Biochimie, Faculté de Médecine, Université Laval, Québec 10e., Québec for the provision of space and facilities in his department, during the academic year 1969–1970, where the early stages of this work were carried out.

Thanks are accorded to Mr. D. Embree and Dr. W. D. Jamieson of A.R.L. for the mass spectral data.

Addition Reactions in the Nitration of Some Polycyclic Aromatic Compounds

A. FISCHER AND D. R. A. LEONARD
Department of Chemistry, University of Victoria, Victoria, British Columbia

Received April 28, 1972

Reaction of 3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]naphthalene with nitric acid in acetic anhydride gives two stereoisomeric 4-acetoxy-6*a*-nitro-3-oxo-1,2,3,4,6*a*,7,8,9,10,10*a*-decahydrocyclohepta[*de*]-naphthalenes as well as the expected nitro substitution products. Formation of these adducts from a substrate containing a meta-directing deactivating substituent shows that the 1,4-addition reaction of acetyl nitrate is more general than previously suspected. 1,4-Acetyl nitrate adducts are also formed from tetralin, benzsuberane, 5,6,7,8-tetrahydrocyclohepta[*fg*]acenaphthene, and 1,2,3,4,7,8,9,10-octahydrodicyclohepta-[*de*,*ij*]naphthalene. Decomposition of the last two adducts gives in each case a product with the nitro group substituted into the alicyclic ring.

La réaction de l'oxo-3 octahydro-1,2,3,7,8,9,10,10*a* cyclohepta[*de*]naphtalène avec l'acide nitrique dans l'anhydride acétique conduit aux deux acétoxy-4 nitro-6*a* oxo-3 décahydro-1,2,3,4,6*a*,7,8,9,10,10*a* cyclo-hepta[*de*]naphtalènes stéréoisomères ainsi qu'aux produits de nitration attendus. La formation de ces composés d'addition à partir d'un substrat contenant un substituant désactivant en méta montre que l'addition-1,4 de l'acétylnitrate est plus générale qu'on le pensait antérieurement. Des composés d'addition-1,4 avec l'acétyl-nitrate sont également formés à partir de la tétraline, benzsubérane, tétrahydro-5,6,7,8 cyclohepta[*fg*]acénaph-tène et octahydro-1,2,3,4,7,8,9,10 dicyclohepta[*de*,*ij*]naphtalène. La décomposition de ces deux derniers composés d'addition donne dans chaque cas un produit substitué par le groupe nitro sur le cycle alicyclique.

Nitration in acetic anhydride of *o*- and *p*-xylenes, of 1,2,3-trimethylbenzene (hemimellitene) and of indane has been reported to give diastereoisomeric 1,4-nitro-acetate addition products as well as the normal nitro substitution products (1–3). The 1,4-diene adducts arise by attack of the nitrating electrophile at the position carrying a substituent (*ipso* attack (4)) followed by combination of acetate with the resulting σ-complex, eq. 1. Adducts have only been observed when $X \neq H$. Presumably the normal σ-complex ($X = H$) loses the proton more rapidly than it adds acetate or, alternatively, the adduct once formed undergoes an extremely facile 1,4-elimination of acetic acid, leading in either case to the normal nitration product. Hence, subject only to the restriction that a substituted position must be of comparable reactivity to an unsubstituted position, adduct formation might be expected to be generally observed competing with normal nitration of aromatic compounds. The present study of the nitration of some cyclic compounds supports this hypothesis.

Nitration in acetic anhydride of 3-oxo-1,2,3,-7,8,9,10,10*a*-octahydrocyclohepta[*de*]naphthalene (**1**) gave a pair of diastereoisomeric dienes **2** (39%) and the 4-nitro (26%), 5-nitro (34%), and 6-nitro (1%) substitution products **3**. The presence of nitro and acetoxy groups in the adducts is established by the i.r. spectra and is confirmed by the mass spectra. The adducts cannot be 1,3-dienes as λ_{max} (241 and 241.5 nm) occurs at too short a wavelength. There are potentially 12 structurally isomeric 1,3-diene adducts. λ_{max} for these calculated by Woodward's rules or by analogy with known compounds containing the same chromophoric system is 268 nm or greater (5). There are potentially six (three pairs) structurally isomeric 1,4-diene adducts whose partial structures are shown as **4**, **5**, and **6**. Structure **6** has isolated olefinic and carbonyl double bonds and thus would exhibit only weak carbonyl absorption above 200 nm.

a Y = NO_2, Z = OAc
b Y = OAc, Z = NO_2

It is ruled out by the strong u.v. absorption at 241 nm ($\varepsilon \sim 800\ m^2\ mol^{-1}$). Structure **5** is not consistent with the n.m.r. spectra, which establish the presence of adjacent vinylic protons ($J \sim 10$ Hz). Moreover structure **5** requires two approximately equal ^3J couplings of magnitude (6) 2.6–4.6 Hz whereas only one such coupling was observed. The observed coupling (9.6, 4.3, −0.2 and 9.9, 3.6, −1.6 for the two isomers) are consistent only with structure **4**. The calculated λ_{max} for **4** (249 nm) is in acceptable agreement with the observed values (241 and 241.5 nm). On chemical grounds structure **4***a* is much more likely than **4***b*. Structure **4***b* has a proton which is α to a nitro group and which would allow a facile 1,4-elimination of acetic acid under the basic work-up conditions. By analogy with the previously investigated systems we assume that the acetoxy and nitro groups are *cis* in one isomer and *trans* in the other. We are unable to assign the stereochemistry of the two diene products. The dienes contain three asymmetric centers (4, 6a, and 10a) and it is probable that each of the isolated isomers consists of two pairs of enantiomers.

The structures of the nitro substitution products **3** are established by n.m.r. and mass spectra. The 4- and 6-nitro isomers have a distinctive ortho coupling (8 Hz) whereas the 5-nitro isomer exhibits a smaller meta coupling (2.5 Hz). The base peak in the mass spectrum of the 6-nitro isomer is at $m/e = 228$, corresponding to loss of OH. No significant peak at the same mass appeared in the spectrum of the 4-isomer and analogy with the behavior of the nitro-toluenes (7) establishes the position of the nitro group with respect to the methylene group in each compound. Chemical shift differences between the aromatic protons of **1** and **3***a*, *b*, and *c* support the above assignment, *e.g.* **3***b* is clearly identified as the isomer whose aromatic protons are both shifted to the lowest field since both aromatic protons are ortho to a nitro group. Similar arguments can be adduced to support the assignments of **3***a* and *c*.

The relative reactivities of the ring sites of **1** to electrophilic attack (assuming that these are reflected by the product ratios) are $6a > 5 > 4 \gg 6$. No products were observed resulting from attack at 3*a* and 10*b* positions. The preference for *ipso* attack at the 6*a* position, leading to the adducts **4***a*, rather than at the 10*b* position, leading to adducts **5***a*, is explicable in terms of the meta directing effect of the carbonyl function. It should be noticed, however, that the 4-position (ortho to carbonyl) is not much less reactive than the 5-position (meta to carbonyl). The 4-position would be expected to be more reactive than the 6 as found, both because the two methylene substituents might

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

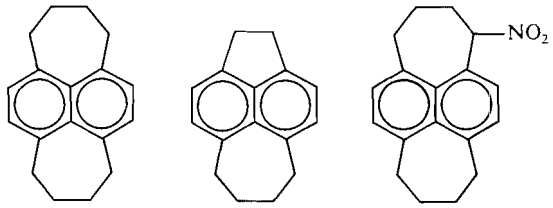
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

be expected to activate the former position to a greater extent (*cf.* *o*-xylene (8)) and because the electron-withdrawing carbonyl group should favor ortho more than para substitution (9).

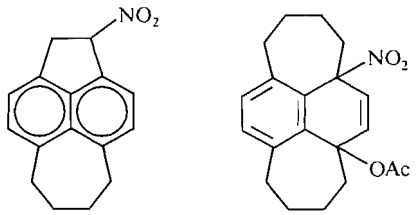
The dienes **2***a* and *b* represent the first reported examples of adducts obtained from an aromatic containing a deactivating meta directing substituent. Their formation supports the hypothesis that the addition reaction is a nitration which has been diverted in the second step. Compounds **2***a* and *b* appear to be much more stable than previously isolated dienes, probably because of the presence of the deactivating carbonyl group.

Adducts formed from the other substrates on reaction with nitric acid in acetic anhydride were much more labile and with the exception of the tetralin adduct, decomposed during work-up. However, in each case the characteristic τ 3.5–4.5 p.p.m. absorption in the spectrum of the reaction mixture prepared at low temperatures demonstrated that adducts were formed in good yield. The n.m.r. spectrum of the product mixture from tetralin indicated that two dienes were formed but only one of these was isolated. Benzsuberane likewise gave two adducts but neither was isolated. Comparable yields of diene products, as indicated by the n.m.r. spectra, showed that the fraction of *ipso* attack, leading to adduct formation, is not markedly sensitive to ring size in the series indane (3), tetralin, benzsuberane.

Formation of aryl acetate by elimination of nitrous acid is the common mode of decomposition of the dienes previously studied. However, the dienes from the octahydrodicycloheptanaphthalene **7** and the tetrahydrocycloheptaacenaphthene **8** gave the "side-chain" nitro compounds **9** and **10** as the predominant decomposition products, respectively. In the case of the acenaphthene derivative **10** the nitro group, whose presence is revealed by the i.r. absorption at 1555 cm^{-1}, is substituted into the five-membered ring and not the seven-membered ring. The parent hydrocarbon **8** exhibits a sharp singlet at τ 6.77 p.p.m., similar to the singlet at 6.68 p.p.m. in the spectrum of acenaphthene, and a broader resonance at 6.9 p.p.m., similar to that of octahydrodicycloheptanaphthalene **7** (10). In the spectrum of the product the singlet at 6.77 p.p.m. is replaced by downfield resonances which have vicinal and geminal



7 8 9



10 11

coupling constants expected for the CH_2CHNO_2 group while the broad higher field resonance attributed to the α-protons of the seven-membered ring still appears. The diene precursor to this product was extremely labile and could only be "isolated" as a minor constituent of largely unreacted starting material. The structure of the diene **11** from octahydrodicycloheptanaphthalene is established by the n.m.r. spectrum which exhibits an AB quartet centered at 4.16 p.p.m. with a coupling constant of 9.5 Hz. Thus the diene must have adjacent vinylic protons as in **11**. Formation of the nitro compounds **9** and **10** obviously parallels the reaction of 1,4-dimethylnaphthalene with nitric acid in acetic anhydride which leads to ω-nitro-1,4-dimethylnaphthalene (11). It has been shown that the dimethylnaphthalene 1,4-acetyl nitrate adducts are intermediates in this reaction (12).

For the isomeric dienes **2***a* and *b* the dihedral angle (ϕ) between the $H^4—C^4—C^5$ and $C^4—C^5—H^5$ planes can be calculated from Garbisch's equations (6), using the three and four bond coupling constants in Table 1. There is excellent agreement between the two values of ϕ (60, 60°) for the isomer (m.p. 105°) whose n.m.r. spectrum when analyzed gave a single solution. For the other isomer, m.p. 120.5°, which gave two n.m.r. solutions there is excellent agreement between the two values of ϕ (47, 48°) for one of these, that with $J_{45} = 4.42$ and $J_{46} = -0.76$ Hz, and this solution is therefore preferred. The other solution gives ϕ as 50 and 39°. The mean values of ϕ for the two isomers

TABLE 1. Computed coupling constants (Hz) and chemical shifts (τ)* for dienes **2***a* and *b*

*Two solutions were obtained for the diene **2**, m.p. 120.5°.

(60 and 47 or 44°) imply that the 1,4-hexadiene ring is planar or nearly so. If the ring were in the boat form, as Dreiding models suggest, then ϕ would be either ~93 or ~27°. 1,4-Cyclohexadiene itself is reported to have a planar ring (13).

Experimental

U.v. spectra were determined on a Unicam S.P. 800 spectrometer. I.r. spectra were determined on a Perkin–Elmer model 337 spectrometer calibrated with polystyrene. N.m.r. spectra were determined on a Varian HA-60-IL spectrometer using tetramethylsilane as internal standard. Unless specified otherwise coupling constants cited are apparent values estimated directly from the appropriate spectrum. Mass spectra were determined on an AEI MS-902 instrument. Microanalyses were by Dr. A. D. Campbell, University of Otago, Dunedin, New Zealand. Melting points are uncorrected. Nitric acid was purified by distilling fuming acid (300 cm^3) at 1 mm from urea (10 g) and sulfuric acid (500 cm^3). Alumina was neutral alumina deactivated with $7\frac{1}{2}$% (v/v) of water.

*Nitration of 3-Oxo-1,2,3,7,8,9,10,10a-octahydrocyclohepta[de]naphthalene (**1**) in Acetic Anhydride*

A solution of nitric acid (7.5 g, 0.12 mol) in acetic anhydride (25 cm^3) was added slowly to a stirred suspension of the tricyclic ketone **1** (10 g, 0.05 mol) in acetic anhydride maintained below −50° (10). The temperature of the mixture was allowed to rise to 0° and the solution stirred at this temperature for 3 h. The solution was poured into cold carbon tetrachloride (400 cm^3) and the resulting solution washed with water (3 × 400 cm^3), 0.5 *M* ammonium hydroxide (2 × 400 cm^3), and water. After drying over magnesium sulfate the solvent was evaporated at room temperature to give 18.6 g of residue: i.r. (film) 1735 ($OCOCH_3$), 1705–1675 (C=O), 1545–1520 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 1.3–3.0 (Ar*H*), 3.5–4.1 (vinyl and allylic *H*). The integrals of the aromatic and vinyl–allylic (diene) regions were the same and thus the ratio of aromatic to diene products was 3:2, on the assumption that the aromatic products had two aromatic protons and the diene products three vinyl–allylic protons. G.l.c. of the product on QF-1 and SE-30 columns showed only four peaks of relative areas, in order of retention time, 1.5, 1.5, 55, and 42%. These peaks were shown to correspond to unreacted tricyclic ketone **1** and its 6-NO_2, 5-NO_2, and 4-NO_2 derivatives **3**, respectively. No peaks corresponding to the dienes or to decomposition products, such as aryl acetates, were observed.

Recrystallization of the crude product from carbon tetrachloride followed by successive recrystallizations from methanol and ethanol gave pale yellow needles of 5-nitro-3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]naphthalene (**3***b*) which were sublimed at 145°/0.002 mm; m.p. 149.5–149.8°; i.r. (Nujol) 1695 (C=O), 1605, 1590 (aromatic ring), 1520 cm^{-1} (aromatic NO_2); u.v. max (95% C_2H_5OH) 202 (ε 2980), 274 (ε 1180), 320 nm (shoulder, ε 360 m^2 mol^{-1}); n.m.r. ($CDCl_3$) τ 1.42 and 1.93 (q, 2, J = 2.5 Hz, 4-*H* and 6-*H*), 6.7 (m, 1, C_6H_2CH), 7.0 (m, 2, $C_6H_2CH_2$), 7.3 (m, 2, $COCH_2$), 7.5–9.0 p.p.m. (m, 8, alicyclic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 245.1060 (100, M_r ($^{12}C_{14}{}^{1}H_{15}{}^{14}N^{16}O_3$) = 245.1052), 228 (20), 217 (17), 203 (34), 199 (39), 189 (10), 188 (9), 171 (16), 142 (17), 141 (26).

Anal. Calcd. for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16; N, 5.71. Found: C, 68.44; H, 6.15; N, 5.75.

Concentration of the second methanol mother liquor and five recrystallizations of the residue from ethanol gave colorless crystals of 4-nitro-3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]naphthalene (**3***a*), which were sublimed at 120°/0.002 mm; m.p. 124.5–125.1°; i.r. (Nujol) 1705 (C=O), 1595 (aromatic ring), 1535 cm^{-1} (aromatic NO_2); u.v. max (95% C_2H_5OH) 215 (ε 1900), 254 (shoulder, ε 650), 304 nm (ε 250 m^2 mol^{-1}); n.m.r. ($CDCl_3$) τ 2.62 and 2.86 (q, 2, J = 8 Hz, 5-*H* and 6-*H*), 6.8 (m, 1, C_6H_2CH), 7.1 (m, 2, $C_6H_2CH_2$), 7.4 (m, 2, $COCH_2$), 7.5–9.0 p.p.m. (m, 8, alicyclic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 245.1048 (53, M_r ($^{12}C_{14}{}^{1}H_{15}{}^{14}N^{16}O_3$) = 245.1052), 229 (3), 217 (35), 201 (28), 187 (14), 184 (14), 173 (13), 171 (13), 161 (13), 159 (19), 143 (29), 141 (37), 129 (44), 128 (100).

Concentration of the initial carbon tetrachloride mother liquor and recrystallization of the residue from carbon tetrachloride gave crude diene. Chromatography of this on alumina and elution with pentane and pentane–benzene mixtures gave, in the later fractions, an uncontaminated diene which was recrystallized three times from benzene and once from ether to give colorless crystals of 4-acetoxy-6*a*-nitro-3-oxo-1,2,3,4,6*a*,7,8,9,10,10*a*-decahydrocyclohepta-[*de*]naphthalene (**2***a* or *b*), m.p. 120.5° (dec.); i.r. (Nujol) 1735 ($OCOCH_3$), 1690 (C=C), 1675 (conjugated C=O), 1640 (C=C), 1545 cm^{-1} (NO_2); u.v. max (95% C_2H_5OH) 204.5 (ε 690), 241.5 nm (ε 810 m^2 mol^{-1}); n.m.r. 216 (4), 201 (11), 200 (65), 185 (6), 172 (13), 159 (22), 158 (100).

Anal. Calcd. for $C_{16}H_{19}NO_5$: C, 62.94; H, 6.27; N, 4.59. Found: C, 62.74; H, 6.23; N, 4.56.

A second diene fraction was obtained by concentration of the carbon tetrachloride mother liquor and recrystallization of the residue from 1:1 benzene–pentane. Chromatography on alumina, using benzene–pentane mixtures as eluant, and recrystallization of the final fractions from 1:1 benzene–pentane gave colorless prisms of a second 4-acetoxy-6*a*-nitro-3-oxo-1,2,3,4,6*a*,7,8,9,10,10*a*-decahydrocyclohepta[*de*]naphthalene (2*b* or *a*), m.p. 104–104.8° (dec.); i.r. (Nujol) 1735 ($OCOCH_3$), 1680 (C=C), 1675 (conjugated C=O), 1635 (C=C), 1545 cm^{-1} (NO_2); u.v. max (95% C_2H_5OH) 205.5 (ε 710), 241 nm (ε 830 m^2 mol^{-1}); n.m.r. Anal. Calcd. for $C_{16}H_{19}NO_5$: C, 62.94; H, 6.27; N, 4.59. Found: C, 63.11; H, 6.28; N, 4.53.

The residue obtained by concentrating the first benzene–pentane mother liquor was recrystallized from 1:3 benzene–pentane and gave a mixture of diene and nitro compounds which was discarded. The residue obtained by concentrating the new mother liquor was chromatographed on alumina and eluted with pentane and benzene–pentane mixtures. Unreacted tricyclic ketone **1** was eluted in the first 1:1 benzene–pentane fraction. The third column volume of 1:1 benzene–pentane eluted the 6-nitro ketone **3***c*. The 6-nitro-3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]-naphthalene (**3***c*) was recrystallized from chloroform–ethanol and twice from ethanol, then sublimed at 65°/0.002 mm: m.p. 68.0–69.8°; i.r. (Nujol) 1695 (C=O), 1595 (aromatic ring), 1530 cm^{-1} (NO_2); u.v. max (95% C_2H_5OH) 213 (ε 1870), 252.5 (ε 930), 307 nm (ε 240 m^2 mol^{-1}); n.m.r. Anal. Calcd. for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16; N, 5.71. Found: C, 68.64; H, 6.14; N, 5.70.

Nitration of Tetralin in Acetic Anhydride

A solution of nitric acid (9 g, 0.15 mol) in acetic anhydride (25 cm^3) was added to a mixture of tetralin (13.2 g, 0.1 mol) in acetic anhydride (25 cm^3) at −78°. The mixture was allowed to warm to 0° and stirred at this temperature for 10 h. After standing overnight at −5° the reaction mixture was worked-up as described for the tricyclic ketone. The crude product had i.r. (film) 1735 ($OCOCH_3$), 1545 (aliphatic NO_2), 1520 cm^{-1} (aromatic NO_2). Its n.m.r. indicated that approximately 50% diene was present and that all of the tetralin had reacted. The product was chromatographed on basic alumina deactivated with 5% (v/v) of water. Elution with pentane gave nitrotetralins and elution with ether–pentane mixtures gave, in the 10% ether–pentane fraction, 7-acetoxy-4*a*,7-dihydro-4*a*-nitrotetralin: i.r. 1735 (ester C=O), 1545 cm^{-1} (aliphatic NO_2); n.m.r. (CCl_4) τ 4.03 (s, 2, 5-*H* and 6-*H*), 4.16 (m, 1, 8-*H*), 4.36 (m, 1, 7-*H*), 7.2 (m, 1) 7.65 (m, 2), 7.98 (s, 3, $OCOCH_3$), 8.0–9.0 p.p.m. (m, 5).

Nitration of Benzsuberane

Benzsuberane (3 g; 0.02 mol) was nitrated at −20° for 2 h following the procedure described for tetralin. The crude product had i.r. (film) 1740 ($OCOCH_3$), 1545 (aliphatic NO_2), 1520 cm^{-1} (aromatic NO_2); n.m.r. (CCl_4) τ 1.9–3.0 (Ar*H*), 3.7–4.5 (vinylic and allylic *H*) 7.98 and 8.03 p.p.m. ($OCOCH_3$). The integral ratio of the aromatic and diene regions indicated that 40% of the product was dienes and the integral ratio of the two acetate peaks indicated that the likely stereoisomeric dienes were present in a 3:2 ratio. The dienes decomposed before separation from the product mixture.

*Nitration of 5,6,7,8-Tetrahydrocyclohepta[fg]acenaphthene (**8**)*

Preliminary study of the reaction carried out in an n.m.r. tube at −20° showed that diene was formed (200–290 Hz downfield signal from acetic anhydride) in approximately 50% yield. When the reaction was carried out on the cyclohepta-acenaphthene (prepared by the method of Fieser and Peters (14)) at −20°, following the procedure described for tetralin, a yellow solid (405 mg) was obtained whose i.r. (absence of $OCOCH_3$) and n.m.r. (absence of vinyl–allylic *H*) showed that no diene was present. Recrystallization (× 2) from carbon tetrachloride gave 1-nitro-5,6,7,8-tetrahydrocyclohepta[*fg*]acenaphthene (**10**), m.p. 123.0–123.7°; i.r. (Nujol) 1595 (aromatic ring) 1555 (aliphatic NO_2) 835, 826, 792 cm^{-1} (aromatic C—H bending); n.m.r. (CCl_4) τ 2.51 and 2.76 (q, 2, $J_{9,10} = 7$ Hz, $J_{1,10} = 1.0$ Hz, 10-*H* and 9-*H* respectively), 2.82 (s, 2, 3-*H* and 4-*H*), 3.71 (q, 1, $J_{1,2\alpha} = 7.5$ Hz, $J_{1,2\beta} = 3.0$ Hz, 1-*H*) 5.93 and 6.27 (octet, 2, $J_{2\alpha,2\beta} = 18$ Hz, $J_{1,2\alpha} = 7.5$ Hz, $J_{1,2\beta} = 3.0$ Hz, 2β-H and 2α-H respectively), 6.80 (b, 4, 5-H_2 and 8-H_2), 7.85–8.05 p.p.m. (m, 4, 6-H_2 and 7-H_2); mass spectrum (70 eV) *m/e* (relative intensity) 253 (6, M_r ($^{12}C_{16}{}^{1}H_{15}{}^{14}N^{16}O_2$) = 253), 237 (1), 221 (2), 208 (18), 207 (100), 191 (8), 189 (9), 179 (9), 178 (8), 165 (33). This compound was photosensitive and it decomposed before analysis.

When the nitration reaction was carried out at −78° and the reaction mixture quenched at this temperature by condensing gaseous ammonia into it, the product isolated contained diene as well as nitro-arenes: i.r. (film) 1735 and 1230 ($OCOCH_3$), 1550 (aliphatic NO_2), 1530 cm^{-1} (aromatic NO_2); the n.m.r. showed absorption in the vinyl–allylic region (τ 3.5–4.5). However the diene decomposed before it could be separated from the other products.

*Nitration of 1,2,3,4,7,8,9,10-Octahydrodicyclohepta-[de,ij]naphthalene (**7**)*

Preliminary study of the reaction carried out in an n.m.r. tube at −30° indicated that diene was formed and that it was still present in the reaction mixture at room temperature. The reaction was carried out on the hydrocarbon (0.25 mmol) at −35° for 30 min and the product was isolated following the procedure described for the tricyclic ketone (**1**): i.r. (film) 1745 and 1235 ($OCOCH_3$), 1550 (aliphatic NO_2), 1530 cm^{-1} (aromatic NO_2); n.m.r. (CCl_4) τ 2.60, 2.64, 2.75, 2.81, 2.97, and 3.08 (aromatic *H*), 4.07 and 4.26

(q, integral = 0.5 of aromatic region, $J_{56} = 9.5$ Hz, 5-*H* and 6-*H*), 6.5–8.8 (benzylic and alicyclic H), 8.00, 8.04, and 8.05 p.p.m. (probably two or all three from $OCOCH_3$). The diene, of likely structure **11**, could not be isolated from the other products without decomposition.

Exact Analysis of the Nuclear Magnetic Resonance Spectra of Dienes **2***a and b*

A computer program written by Dr. A. L. Wilkinson and following Castellano and Waugh's method of exact analysis of three spin systems (15) was used to evaluate coupling constants and chemical shifts for the vinyl–allylic protons of the dienes.

In the case of the first diene, two solutions were obtained which satisfied the requirements of a positive *cis* vinyl coupling and three- and four-bond vinyl–allylic couplings within the range predicted by Garbisch's equations (16). For the second diene it was necessary to irradiate in the alicyclic proton range in order to remove a coupling to the 4-proton before a solution from the three spin system could be obtained. Solutions are given in Table 1.

We thank the National Research Council of Canada and the University of Victoria for financial support and Dr. Alan L. Wilkinson for computer analysis of n.m.r. spectra.

Synthesis of 4-*O*-β-D-Glucopyranosyl-L-rhamnopyranose

G. M. BEBAULT AND G. G. S. DUTTON
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received June 1, 1972

4-*O*-(β-D-Glucopyranosyl)-L-rhamnose (scillabiose) has been synthesized in 55% yield by condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide with methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside using mercuric cyanide in acetonitrile (Helferich reaction). The disaccharide and the derived alditol are both syrups but each forms a crystalline peracetate. A convenient synthesis of 1-deoxy-D-erythritol is described.

4-*O*-(β-D-Glucopyrannosyle)-L-rhamnose (scillabiose) a été synthétisé avec un rendement de 55% par réaction du α-D-tétracétylbromoglucose avec le méthyl 2,3-*O*-isopropylidène-α-L-rhamnopyrannoside en utilisant le cyanure de mercure dans l'acétonitrile (réaction de Helferich). Le disaccharide et l'alditol correspondant sont sirops mais chacun donne un peracétate crystallin. Une nouvelle synthèse de 1-deoxy-D-erythritol est décrite.

Canadian Journal of Chemistry, **50**, 3373 (1972)

L-Rhamnose is widely distributed in nature and is commonly found as a constituent of plant gums (1), plant glycosides (2), and in bacterial polysaccharides (3). Despite this, no disaccharide having L-rhamnose as the aglycone has been synthesized (4) with the exception of 4-*O*-(3-*O*-methyl-β-D-galactopyranosyl)-L-rhamnose (5). Such disaccharides are invaluable not only for the identification of fragments obtained in structural studies but also for the determination of immunodominant groups in polysaccharides which have antigenic activity (6). The aldobiouronic acid 4-*O*-(β-D-glucopyranosyluronic acid)-L-rhamnose has been isolated from hydrolyzates of *Acrosiphonia centralis* (7), *Ulva lactuca* (8), and *Klebsiella* K9 capsular polysaccharide (9). In the first two cases this acid has been characterized after reduction to the neutral disaccharide.

The synthesis of 4-*O*-(β-D-glucopyranosyl)-L-rhamnose (scillabiose) described here was originally undertaken mainly as a model study for the subsequent synthesis of the D-manno- analog (3) but since the related aldobiouronic acid has now been identified as a component of *Klebsiella* type K9 capsular polysaccharide the preparation of this disaccharide is related to our studies on these bacteria. Scillabiose was first isolated from the glycosides scillarin A and glucoscilliphaeoside obtained from *Scilla maritima* (2, 10) and its identification as 4-*O*-(β-D-glucopyranosyl)-L-rhamnose was subsequently established (11, 12).

Methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**3**) was prepared most conveniently from methyl α-L-rhamnopyranoside (**1**) by reaction with acetone in the presence of cation exchange resin (13–16) and was purified through the crystalline 4-acetate (**2**). Condensation of this intermediate with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide using mercuric cyanide in acetonitrile (17) gave methyl 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**5**) as a crystalline product (yield 80%).

Initial attempts to prepare scillabiose heptaacetate (**7**) by direct acetolysis of **5** under several different conditions gave only very poor yields (15%) of **7**. This was eventually explained by the fact that direct acetolysis gave a product soluble in water that was thus lost during washing of the organic solvent layer. A search of the literature revealed that in a review Guthrie and McCarthy (18) do not mention any example of acetolysis where an acetal (or ketal) is formed between two secondary hydroxyl groups in a sugar ring. Subsequent to the date of this review acetolysis has been used for benzylidene acetals (19) and isopropylidene ketals (20) but in each case the rings have spanned primary and secondary hydroxyl groups. Acetolysis of isopropylidene ketals formed between two secondary hydroxyl groups has been studied by Sowa (21) in extending an earlier observation made by Jerkeman (22) but these examples involved furanose systems and

For personal use only.

epimerization. Acetolysis of methyl glycosides has been successfully achieved in several cases (18, 19, 23).

Scillabiose heptaacetate (**7**) was obtained in good yield (70%) when the isopropylidene group was removed from the intermediate **5** prior to acetolysis. This was achieved most conveniently by treatment with trifluoroacetic acid (24) and acetolysis was then carried out essentially as described by Aspinall and co-workers (19). Scillabiose heptaacetate (**7**) thus obtained had m.p. 139–140° and n.m.r. showed clearly the presence of seven acetate groups. Neither the melting point nor the optical rotation agree with that given in the literature (2, 10) for "scillabiose hexaacetate". Although satisfactory analytical data are given for a hexaacetate there is no indication why such an acetate should be formed and Bailey (4) has recognized this ambiguity by listing only scillabiose acetate. Deacetylation gave scillabiose as a syrup which was reduced and acetylated to give crystalline scillabiitol octaacetate, m.p. 132–133°. The n.m.r. spectrum of the free disaccharide and the corresponding alditol each in deuterium oxide showed $J_{1,2}$ 7.5 and 7.2 Hz, respectively, consistent with a β-D-linkage (25). Determination of the number of substituent groups in rhamnose disaccharides and intermediates is greatly facilitated by the doublet at about τ 8.70 characteristic of the 6-deoxy group.

Proof of structure of the disaccharide was obtained by periodate oxidation and methylation of the methyl glycoside of the disaccharide. The methyl glycoside (**9**) was prepared by deacetylation of **6**; removal of sodium ion with cation exchange resin was best done in the cold to prevent hydrolysis of the labile methyl glycoside of the 6-deoxy hexose. The disaccharide glycoside consumed 3.0 mol of periodate and successive borohydride reduction and methanolysis gave glycerol and 1-deoxy-D-erythritol identified by g.l.c. and mass spectrometry of their acetate derivatives. When the polyalcohol was hydrolyzed, rather than methanolyzed, one major peak and several smaller ones were obtained on g.l.c., in addition to the peaks expected for glycerol and 1-deoxy-D-erythritol. Methanolysis gave essentially only two peaks with traces of other components. This is a further example of the difficulty of obtaining quantitative hydrolysis of such polyalcohols. This and related problems have been discussed elsewhere (26). 1-Deoxy-D-erythritol was conveniently prepared by a new route involving periodate oxidation of methyl 4-*O*-acetyl-α-L-rhamnopyranoside (**13**).

Methylation (27) of the disaccharide glycoside followed by methanolysis and g.l.c. indicated the presence of methyl 2,3,4,6-tetra-*O*-methyl-D-glucopyranoside and methyl 2,3-di-*O*-methyl-L-rhamnopyranoside. Hydrolysis of the permethylated disaccharide followed by borohydride reduction gave 2,3,4,6-tetra-*O*-methyl-D-glucitol and 2,3-di-*O*-methyl-L-rhamnitol identified by g.l.c. and mass spectrometry (28) of their acetate derivatives. 2,3,4,6-Tetra-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-L-rhamnose are not separable on g.l.c. as their methyl glycosides but can be completely separated by making the trimethylsilyl derivative of the methyl glycosides. This shortens the retention time of the rhamnosides and is a method which has been used with particular success in the mannose series (29, 30). They can also be completely separated as acetate derivatives (31).

Experimental

Melting points were taken between glass slides on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter at 23 ± 1°. N.m.r. spectra were recorded on a Varian XL-100 instrument using tetramethylsilane as internal standard except as noted. Gas–liquid partition chromatography was carried out on an F and M 720 instrument at a gas flow rate of 60 ml/min using columns: (*a*) 2 ft × 1/4 in. 20% SE 30 (F and M Division, Hewlett Packard, Avondale, Pennsylvania), (*b*) 4 ft × 1/4 in. 5% butanediol succinate on 80–100 mesh Diatoport S and (*c*) 6 ft × 1/4 in. 15% OS 138 on 100–120 mesh Gas Chrom Q. T.l.c. was carried out using solvent systems A and B (see below) on silica gel G (EM Reagents). The dried plates were visualized by spraying with 35% ethanolic sulfuric acid and heating to about 150° for 3–5 min. Paper chromatographic separations were carried out on Whatman No. 1 paper using the upper layer of solvent systems C and D (see below) and were visualized using silver nitrate in acetone for non-reducing compounds (32) and *p*-anisidine spray (33) in trichloroacetic acid for reducing sugars. Solvent A, ethyl ether–toluene (2:1); B, butanone–water azeotrope; C, ethyl acetate–pyridine–water (8:2:2); D, 1-butanol–ethanol–water (4:1:5). R_G indicates with respect to 2,3,4,6-tetra-*O*-methyl-D-glucose. Solutions were concentrated below 50° *in vacuo*.

Methyl α-L-Rhamnopyranoside (1)

This compound was prepared essentially as described by Levene and Muskat (34). The glycoside crystallized from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ethyl acetate immediately upon being seeded; yield 80%. Recrystallization from ethyl acetate gave pure **1**, m.p. 108.5–109°; $[\alpha]_D$ −60.4° (*c* 9.6, water); R_f (solvent B) 0.39; (lit. (35, 36) m.p. 108–109°, $[\alpha]_D$ −62.5° (*c* 9.1, water)); n.m.r. (D_2O, external TMS): τ 5.36 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1), 6.64 (3H singlet, C-1 OMe), 8.75 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3).

Methyl 4-O-Acetyl-2,3-O-isopropylidene-α-L-rhamnopyranoside (2)

A solution of methyl α-L-rhamnopyranoside (**1**) (5 g) in dry acetone (150 ml) was magnetically stirred in an ice–water bath with 2,2-dimethoxypropane (50 ml) and Amberlite IR 120 H^+ resin (10 ml, freshly regenerated, soaked in acetone overnight) for 5 h. The solution was filtered through a layer of calcium oxide to remove traces of acid and the filtrate was concentrated. T.l.c. (solvent B) showed a major component with R_f 0.69 and a small amount of starting material. The syrupy product was acetylated with pyridine (30 ml) and acetic anhydride (30 ml). The acetate (**2**) was crystallized from ethanol (25 ml); yield 4.9 g. Recrystallization from ethanol gave pure **2**, m.p. 66–67°; $[\alpha]_D$ −16.5° (*c* 2.4, chloroform); (lit. (37) m.p. 61–63°, $[\alpha]_D$ −14.5° (*c* 2.8, chloroform)); n.m.r. ($CDCl_3$): τ 5.10 (1H singlet, H-1), 6.62 (3H singlet, C-1 OMe), 7.92 (3H singlet, C-4 OAc), 8.44, 8.66 (3H singlets, isopropylidene CH_3's), 8.83 (3H doublet, $J_{5,6}$ = 6Hz, CH_3).

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75; OMe, 11.92. Found: C, 55.73; H, 7.73; OMe, 12.11.

Methyl 2,3-O-Isopropylidene-α-L-rhamnopyranoside (3)

Methyl4-*O*-acetyl-2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**2**) (5.9 g) was dissolved in dry methanol (10 ml) and treated with sodium methoxide (0.2 *N*, 25 ml) for 30 min. Sodium ion was removed from the chilled solution with Amberlite IR 120 H^+ resin and the methanol was evaporated to give a syrupy product **3**; yield 4.9 g. T.l.c. (solvent A) showed one spot with R_f 0.54; $[\alpha]_D$ −16.4° (*c* 3.1, acetone); (lit. (34, 38) $[\alpha]_D$ −15.9° (*c* 1.6, acetone)); n.m.r. ($CDCl_3$); τ 5.14 (1H singlet, H-1), 6.62 (3H singlet, C-1 OMe), 8.70 (3H doublet, $J_{5,6}$ = 6 Hz CH_3), 8.48, 8.65 (3H singlets, *endo-*, *exo*-isopropylidene CH_3 (39)).

2,3,4,6-Tetra-O-acetyl-α-D-glucopyranosyl Bromide (4)

Compound **4** was prepared from anhydrous D-glucose either as reported by Lemieux (40) in 68% yield or more conveniently but in lower yield (55%) by the method of Dale (41). In both cases recrystallization from ether gave pure **4**, m.p. 90.5–91°; $[\alpha]_D$ +199.9° (*c* 2.2, chloroform); (lit. (40) m.p. 88–89°, $[\alpha]_D$ +197.8° (*c* 2, chloroform)).

Methyl 4-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-2,3-O-isopropylidene-α-L-rhamnopyranoside (5)

To a solution of methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside **3** (4.9 g, 22.5 mmol) and dry mercuric cyanide (5.0 g) in acetonitrile (50 ml, distilled over CaH_2) was added the bromide **4** (15 g) with stirring and the stirring was continued for 5 h. The acetonitrile was removed from the reaction mixture under reduced pressure and the remaining syrup was dissolved in chloroform (150 ml). The chloroform solution was washed with 1 *N* potassium bromide (2 × 75 ml), water (75 ml), saturated sodium bicarbonate (75 ml), and water (2 × 75 ml). The chloroform was removed and the remaining syrup, dissolved in warm ethanol (50 ml), crystallized upon cooling; yield 9.9 g, 18.0 mmol, 80%. Recrystallization from ethanol gave pure **5**, m.p. 158.5–159°; $[\alpha]_D$ −30.6° (*c* 1.7, chloroform); R_f (t.l.c. solvent A) 0.56; n.m.r. ($CDCl_3$): τ 6.66 (3H singlet, C-1 OMe), 7.96–8.03 (12H, OAc's), 8.75 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3), 8.49, 8.67 (3H singlets, isopropylidene CH_3's).

Anal. Calcd, for $C_{24}H_{36}O_{14}$: C, 52.55; H, 6.62. Found: C, 52.63; H, 6.74.

Methyl 4-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside (6)

A solution of methyl 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**5**) (2.0 g) in chloroform (90 ml) was treated at room temperature for 1 h with trifluoroacetic acid containing 1% water (10 ml). The reaction mixture was concentrated and any remaining trifluoroacetic acid was removed by distillation with toluene. The remaining syrup showed one spot on t.l.c., R_f (solvent A) 0.09 and (solvent B) 0.66; yield 1.83 g; n.m.r. ($CDCl_3$): τ 6.65 (3H singlet, C-1 OMe), 7.93–8.01 (12H, OAc's), 8.70 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3).

4-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-1,2,3-tri-O-acetyl-α-L-rhamnopyranose (Scillabiose Heptaacetate) (7)

Methyl 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside (**6**) (1.0 g) in acetic anhydride (5 ml) was shaken with concentrated sulfuric acid 2% (v/v) in acetic anhydride (10 ml) for 5 h (19). The reaction mixture was diluted with chloroform (100 ml) and the chloroform solution was washed with water (2 × 100 ml), saturated sodium bicarbonate (2 × 75 ml), and again with water (3 × 100 ml). The recovered syrup was dissolved in 2-propanol (20 ml) and the heptaacetate (**7**) crystallized immediately upon seeding with a crystal obtained from a t.l.c. plate separation (42); yield 0.85 g. T.l.c. (solvent A) showed a major component with R_f 0.34 and only a trace of cleavage products. Recrystallization from 2-propanol gave pure **7**, m.p. 139–140°; $[\alpha]_D$ −62.3° (*c* 2.6, chloroform); n.m.r. ($CDCl_3$): τ 4.04 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1), 7.86–8.04 (21H, OAc's), 8.70 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3).

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.85. Found: C, 50.07; H, 5.84.

4-O-β-D-Glucopyranosyl-L-rhamnopyranose (8)

Scillabiose heptaacetate (**7**) (500 mg) was treated with sodium methoxide (0.2 *N*, 25 ml) for 1 h at room temperature. Sodium ion was removed with Amberlite IR 120 H^+ resin and the methanol was evaporated. The remaining syrup (250 mg) showed one spot on a paper chromatogram (solvent C) with $R_{glucose}$ 1.2; $[\alpha]_D$ −24.2° (*c* 1.1, water); (lit. (10) $[\alpha]_D$ −24.8° (*c* 3.3, water)); n.m.r. (D_2O, external TMS): τ 4.88 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1 of α-L-form), 5.12 (1H doublet, $J_{1,2}$ = 0.8 Hz, H-1 of β-L-form), 5.26 (1H doublet, $J_{1',2'}$ = 7.5 Hz, H-1'), 8.65 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3).

G.l.c. of the per(trimethylsilyl) disaccharide (column *a* at 250°) gave one peak (73%) at 10.1 min and a second peak at 12.6 min (per(trimethylsilyl) sucrose 12.6 min) (43).

Methyl 4-O-β-D-Glucopyranosyl-α-L-rhamnopyranoside (9)

Methyl 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

α-L-rhamnopyranoside (**6**) (1.83 g) was deacetylated with sodium methoxide (0.2 *N*, 25 ml) for 1 h. Sodium ion was removed from the cold solution with Amberlite IR 120 H^+ resin and the methanol was removed. T.l.c. (solvent B) showed a major component with R_f 0.04 and a small amount of a faster running compound; yield 1.1 g. A portion of the syrupy product was purified by preparative t.l.c. (42) for analytical purposes $[\alpha]_D$ −57.5° (*c* 1.5, methanol); $R_{glucose}$ (solvent C) 2.9; n.m.r. (D_2O, external TMS): τ 5.30 (1H doublet, $J_{1',2'} = 7.7$ Hz, H-1'), 5.32 (1H doublet, $J_{1,2} = 1.5$ Hz, H-1), 6.61 (3H singlet, C-1 OMe), 8.65 (3H doublet, $J_{5,6} = 6$ Hz, CH_3).

Reaction of the methyl glycoside of the disaccharide **9** (0.625 g) with sodium metaperiodate (0.05 *M*, 400 ml) at 5° in the dark showed a rapid uptake of 1 mol with the consumption of periodate becoming constant (3.0 mol) in 48 h (44, 45). Iodate and excess periodate were removed by addition of barium acetate and the residual polyaldehyde was reduced with sodium borohydride (0.6 g). A portion of the polyalcohol (0.1 g), obtained by deionization, distillation with methanol, and concentration, was subjected to methanolysis (3% HCl in methanol, 10 ml, reflux, 6.5 h) and then neutralized with Duolite A 4 OH^- resin. Glycolaldehyde dimethyl acetal and solvents were removed by evaporation and the recovered syrup showed two major spots on paper chromatography (solvent D) corresponding to standard 1-deoxy-D-erythritol and glycerol. A portion was acetylated with pyridine (1 ml) and acetic anhydride (1 ml). Injection in ethyl acetate, onto column *b* at 140° gave peaks identical to authentic standards of the peracetylated derivatives of 1-deoxy-D-erythritol (12 min) and glycerol (18 min). Samples were collected and the mass spectra obtained corresponded to those of the authentic standards.

Methyl glycoside (**9**) (1.1 g) in dry methyl sulfoxide (20 ml) was methylated (46) by reaction with methyl sulfinyl anion (1.5 *M*, 20 ml) for 4 h and then shaking with methyl iodide (6 ml) overnight. The reaction mixture was diluted with water and the product was extracted with petroleum ether (b.p. 65–70°). The recovered syrup (**10**) (1 g) gave one spot on t.l.c. (solvent A) with R_f 0.28; $[\alpha]_D$ −51° (*c* 2.6, methanol); (lit. (7) $[\alpha]_D$ +7° (*c* 2.0, methanol)); n.m.r. ($CDCl_3$): τ 5.26 (1H doublet, $J_{1,2} = 1.5$ Hz, H-1), 5.37 (1H doublet, $J_{1',2'} = 7.7$ Hz, H-1'), 6.36–6.63 (21H, OMe's), 8.68 (3H doublet, $J_{5,6} = 6$ Hz, CH_3). Methanolysis of **10** (300 mg, 3% methanolic HCl, 30 ml, reflux, 8 h) and examination of the methyl glycosides as the trimethylsilyl derivatives on column *b* programmed from 110 to 205° at 2°/min, gave peaks corresponding to methyl 2,3-di-*O*-methyl-L-rhamnopyranosides (6.8, 9.8 min) and methyl 2,3,4,6-tetra-*O*-methyl-D-glucopyranosides (15.4, 20.7 min). The peak corresponding to methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucopyranoside was collected, m.p. 36° (lit. (47) m.p. 39–41°). The mixed melting point with standard was undepressed. Hydrolysis of **10** (300 mg, 2 *N* TFA, 25 ml, 5 ml methanol, reflux, 16 h) gave a 1:1 mixture of 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-L-rhamnose as shown by paper chromatography (solvent D) using authentic standards. They could also be separated by g.l.c. as their acetate derivatives on column *b* programmed from 110 to 210° at 2°/min. The glucose derivatives gave two peaks at 27.9 min (29%) and 30.2 min (21%) while the rhamnose derivatives gave two peaks at 37.0 min (38%) and 40.7 min (4%). Two unidentified peaks at 16.1 min (5%) and 18.5 min (3%) may be rhamnofuranose derivatives. A portion of the hydrolyzate was reduced with sodium borohydride and the resulting alditols acetylated with pyridine and acetic anhydride. Injection in ethyl acetate onto column *b* at any temperature gave one peak but column *c* at 225° gave two peaks identical to authentic standards of 1,4,5-tri-*O*-acetyl-2,3-di-*O*-methyl-L-rhamnitol (38.6 min) and 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol (46.3 min) (28). Samples were collected and the mass spectra obtained corresponded to those of the authentic standards.

*4-O-β-D-Glucopyranosyl-L-rhamnitol (**11**)*

The free disaccharide **8** (200 mg) was reduced with sodium borohydride (50 mg) in water (10 ml) overnight. Passage through cation exchange resin, concentration, and distillation with methanol gave **11**; $R_{glucose}$ (solvent C) 0.8; n.m.r. (D_2O, external TMS): τ 5.37 (1H doublet, $J_{1,2} = 7.2$ Hz, H-1), 8.70 (3H doublet, $J_{5,6} = 6$ Hz, CH_3).

G.l.c. of the per(trimethylsilyl) alditol (column *a* at 250°) gave one peak at 13.3 min (per(trimethylsilyl) sucrose, 16.6 min) (43).

The alditol **11** was acetylated with pyridine (3 ml) and acetic anhydride (3 ml) to give 4-*O*-β-D-glucopyranosyl-L-rhamnitol octaacetate (scillabiitol octaacetate) (**12**) (320 mg, crystallized from ethanol (20 ml)). Recrystallization from ethanol gave pure **12**, m.p. 132–133°; $[\alpha]_D$ −78.6° (*c* 2.0, chloroform); R_f (t.l.c., solvent A) 0.33; n.m.r. ($CDCl_3$): τ 7.84–7.99 (24H, OAc's), 8.66 (3H doublet, $J_{5,6} = 6$ Hz, CH_3).

Anal. Calcd. for $C_{28}H_{40}O_{18}$: C, 50.60; H, 6.07. Found: C, 50.63; H, 6.06.

*Methyl 4-O-Acetyl-α-L-rhamnopyranoside (**13**)*

A solution of methyl 4-*O*-acetyl-2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**2**) (3 g) in chloroform (135 ml) was treated for 1 h at room temperature with trifluoroacetic acid containing 1% water (15 ml). The reaction mixture was concentrated on the rotary evaporator and any remaining TFA removed by distillation with toluene. The remaining syrup crystallized neat (2.5 g). T.l.c. showed one spot with R_f (solvent B) 0.66. It was further purified by recrystallization from ethyl acetate or by sublimation, m.p. 117°; $[\alpha]_D$ −104.1° (*c* 2.2, chloroform), $[\alpha]_D$ −56.0° (*c* 2.8, water); (lit. (37) m.p. 112–116°, $[\alpha]_D$ −55° (*c* 1.8, water)); n.m.r. $CDCl_3$): τ 5.30 (1H doublet, $J_{1,2} = 1.5$ Hz, H-1), 6.64 (3H singlet, C-1 OMe), 7.90 (3H singlet, OAc), 8.80 (3H doublet, $J_{5,6} = 6$ Hz, CH_3).

Anal. Calcd. for $C_9H_{16}O_6$: C, 49.09; H, 7.32. Found: C, 49.22; H, 7.53.

*1-Deoxy-D-erythritol (**14**)*

Reaction of methyl 4-*O*-acetyl-α-L-rhamnopyranoside (**13**) (2.4 g) with sodium metaperiodate (0.05 *M*, 400 ml) at 5° in the dark reached a constant uptake of 1 mol (44, 45) in 20 h. Iodate and excess periodate were removed by addition of barium acetate and the residual polyaldehyde was deacetylated and reduced with sodium borohydride (2 g). The polyalcohol, obtained by deionization, distillation with methanol, and concentration, was subjected to methanolysis (3% HCl, 30 ml, reflux, 6.5 h) and then neutralized with Duolite A 4 OH^- resin. Glycolaldehyde dimethyl

For personal use only.

acetal and solvent were evaporated and the remaining crude syrup (1.1 g) gave $[\alpha]_D$ 0.4° (*c* 1.6, methanol); (lit. (48) $[\alpha]_D$ +7.4° (*c* 2, methanol)); R_f (solvent D) 0.57 (lit. (49) R_f (solvent D) 0.53). A portion was acetylated with pyridine and acetic anhydride and when injected onto column *b* at 140° gave a major peak at 12 min. A sample was collected and the mass spectrum obtained showed *m/e* 43, 44, 70, 71, 86, 87, 103, 115, 117, 130, 145, 159, and 189. Another portion (1 g) was converted to 1-deoxy-D-erythritol tri-(*p*-nitrobenzoate), m.p. 161–162° (acetone, 2.7 g/10 ml); $[\alpha]_D$ 81.9° (*c* 2.2, chloroform); (lit. (49) m.p. 159–160°, $[\alpha]_D$ 81.07° (*c* 2.05, chloroform)).

Anal. Calcd. for $C_{25}H_{19}O_{12}N_3$: C, 54.26; H, 3.46; N, 7.59. Found: C, 54.08; H, 3.31; N, 7.81.

*Methyl 2,3-Di-O-methyl-α-L-rhamnopyranoside (**15**)*

Methyl 4-*O*-acetyl-α-L-rhamnopyranoside (**13**) (500 mg) in dichloromethane (5 ml) was chilled in an ice–salt water bath (−5°). Boron trifluoride etherate solution (1 ml of a solution of 0.4 ml of BF_3 etherate in 10 ml of dichloromethane) was added to the reaction mixture and then diazomethane in dichloromethane (at −78°) was added dropwise while swirling the flask until a faint yellow color persisted. The reaction mixture was kept at −5° for 30 min and then allowed to warm up (50, 51). The solid polymethylene was filtered off and the filtrate was concentrated. T.l.c. (solvent A) showed a major spot at R_f 0.47 with a minor monomethyl component at R_f 0.29. The product was purified by a preparative t.l.c. separation (solvent A) (42); yield 450 mg; n.m.r. ($CDCl_3$): τ 5.25 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1), 6.49, 6.58, 6.61 (3H singlets, OMe's), 7.93 (3H singlet, OAc), 8.80 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3). Deacetylation of methyl 4-*O*-acetyl-2,3-di-*O*-methyl-α-L-rhamnopyranoside gave a syrup (t.l.c. (solvent A) R_f 0.24) (270 mg); $[\alpha]_D$ −5.6° (*c* 2.0, water); $[\alpha]_D$ −27.8° (*c* 2.0, chloroform); (lit. (52) $[\alpha]_D$ −6° (*c* 2.0, water); (53) $[\alpha]_D$ −14° (*c* 1.97); (54) $[\alpha]_D$ −26.2° (*c* 0.3, chloroform)), n.m.r. ($CDCl_3$): τ 5.24 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1), 6.52, 6.56, 6.64 (3H singlets, OMe's), 8.68 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3). A portion of **15** (200 mg) gave methyl 2,3-di-*O*-methyl-4-*O*-toluene-*p*-sulfonyl-α-L-rhamnopyranoside (300 mg), m.p. 114° (2-propanol, 100 mg/ml); $[\alpha]_D$ −36.7° (*c* 2.6, chloroform); (lit. (52) m.p. 111°, $[\alpha]_D$ −33° (*c* 2.0 chloroform)); n.m.r. ($CDCl_3$): τ 2.12–2.74 (4H, aromatic protons), 5.30 (1H doublet, $J_{1,2}$ = 1.5 Hz, H-1), 6.56, 6.68, 7.06 (3H singlets, OMe's), 7.58 (3H singlet, toluene CH_3), 8.67 (3H doublet, $J_{5,6}$ = 6 Hz, CH_3).

Anal. Calcd. for $C_{16}H_{24}O_7S$: C, 53.32; H, 6.71. Found: C, 53.11; H, 6.72.

*2,3-Di-O-methyl-L-rhamnose (**16**)*

The methyl glycoside **15** (300 mg) was hydrolyzed (2 *N* TFA, 30 ml, reflux, 5 h), the recovered syrup (260 mg) showed one spot on t.l.c. R_f (solvent B) 0.41 and on paper chromatography gave a reddish-brown spot with R_G (solvent D) 0.85 when sprayed with aniline trichloroacetate spray (lit. (53) R_G 0.83), $[\alpha]_D$ +42.2°(*c* 1.5, water) (lit. (52) $[\alpha]_D$ +40° (*c* 0.7, water)). Reduction of **16** and acetylation gave 1,4,5-tri-*O*-acetyl-2,3-di-*O*-methyl-L-rhamnitol (**17**) (280 mg). Injection of **17** in ethyl acetate onto column *b* programmed from 150 to 200° at 2°/min gave a major peak at 24.4 min and on column *c* at 225° gave a major peak at 38.6 min. A sample was collected and the mass spectrum obtained showed *m/e* 43, 44, 45, 58, 59, 69, 71, 74, 85, 87, 101, 113, 117, 143, 161, and 203 (28).

On the Mobility of Quasifree Electrons in Liquid Methane

KENJI FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received May 30, 1972

A theoretical estimate has been made of the mobility and energy of quasifree electrons in liquid methane. It is shown that the calculated mobility is in agreement with the measured mobility and that the calculated energy is also consistent with a qualitative correlation between the mobility and energy of quasifree electrons in liquid alkanes.

Une estimation théorique sur la mobilité et l'énergie des électrons quasilibres dans le méthane liquide, a été donnée. On a montré que les mobilités calculée et mesurée sont en accord et que l'énergie calculée est également compatible avec une corrélation qualitative existant entre la mobilité et l'énergie des électrons quasilibres dans les alcanes liquides. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3379 (1972)

The mobility of quasifree electrons in liquid methane has recently been measured by Fuochi and Freeman (1), who have found that it is very high as compared to the mobilities of electrons in other hydrocarbons and is about the same magnitude as that in liquid argon.

In this note we report a theoretical estimate of the electron mobility in liquid methane by use of the Cohen–Lekner theory (2), which has been successfully applied to semiempirical calculations of the electron mobilities in *n*-hexane and neopentane (3, 4). Since the electron mobility in liquid methane is considerably higher than that in neopentane where the activation energy for the mobility as expressed by the Arrhenius equation is nearly zero (5), it is very likely that the activation energy is zero for the mobility of electrons in liquid methane.

The mobility of quasifree electrons in liquid methane is then given by (2)

$$\mu_0 = \frac{2}{3}\left(\frac{2}{\pi m k T}\right)^{1/2}\left[\frac{e}{n\sigma_1 S(0)}\right]$$

where m is the mass of the electron; k, Boltzmann's constant; T, the absolute temperature; e, the electronic charge; n, the number density of molecules; σ_1, the scattering cross section; and $S(0) = nkT\kappa_T$ (κ_T is the isothermal compressibility). The physical constants used in the calculation are listed in Table 1. The electron scattering cross section is given by $\sigma_1 = 4\pi\bar{a}^2_{CH_4}$, where $\bar{a}_{CH_4}$ is the scattering length in liquid methane. $\bar{a}_{CH_4}$ is estimated to be $\bar{a}_{CH_4} = \bar{a}_{Ne} \times (\zeta_{Ne}/\zeta_{CH_4}) = 1.02$ Å, where $\bar{a}_{Ne}$ (0.556 Å) is the scattering length in liquid neon (6), and ζ_{CH_4} (1.564 a.u.) and ζ_{Ne} (2.879 a.u.) are, respectively, orbital exponents in spherically symmetric one-center wave functions of the methane molecule (7) and of the neon atom (8) which is isoelectronic to the methane molecule. It is assumed that $\bar{a}$ may be related to the orbital exponent, since the orbital exponent is a measure of the spread of the electron cloud in the atom or molecule which determines the hard core radius. The estimated scattering cross section of electrons in liquid methane is three times as great as that in gaseous methane, $\sigma_g = 4.33 \times 10^{-16}$ cm^2 (9). The same ratio between the gas and liquid phase scattering cross sections of electrons was found for *n*-pentane (3).

The calculated mobility of electrons in liquid methane is given in Table 1 together with the measured mobility. The calculated value is in agreement with the experimental value. The momentum mean free path $\Lambda = [n\sigma_1 S(0)]^{-1}$ is 122 Å for liquid methane at 120 °K and it is very close to a value of Λ, 113 Å, for liquid neopentane at 300 °K (4).

Since the methane molecule is spherically symmetric, the Wigner–Seitz model (6) for the excess electron in liquids is considered to be best applicable to liquid methane. Using the

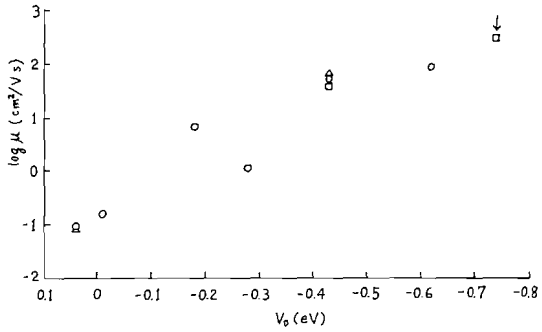

FIG. 1. Plot of V_0 *vs.* logarithm of mobility, μ, for the excess electron in liquid alkanes and tetramethylsilane: ○, mobility values from ref. 13; △, mobility values from ref. 5; □, mobility values from Ref. 1. All the V_0 values were taken from ref. 10 except for liquid methane for which V_0 was calculated in this work.

Wigner–Seitz method, the energy of the quasi-free electron state, V_0, is calculated to be -0.74 eV. This value is somewhat lower than the values of V_0 measured for the alkanes with less molecular sphericity and it is consistent with a qualitative correlation between V_0 and the electron mobilities found for the alkanes (10). Figure 1 shows a plot of V_0 *vs.* logarithm of the mobility for the excess electron in several alkanes and tetramethylsilane. It can be seen in Fig. 1 that the point for liquid methane indicated by the arrow fits with such a qualitative correlation. It should be noted, however, that the estimate of V_0 is sensitive to the choice of $\bar{a}$ for liquid methane and therefore not very accurate. Clearly the direct measurement of V_0 for liquid methane is desirable to test this prediction.

Partial Photoresolution of Some Chromium (III) Complexes of Phenanthroline and Bipyridine Using Circularly Polarized Laser Irradiation

NOEL A. P. KANE-MAGUIRE AND COOPER H. LANGFORD[1]
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received April 13, 1972

Partial photoresolution of $Cr(C_2O_4)phen_2^+$, $Cr(C_2O_4)_2phen^-$, and $Crbipy_3^{3+}$ by irradiation with circularly polarized light from an argon ion laser and 496.5 or 514.5 nm is reported. Steady states corresponding to 1–2% resolution are achieved. They are in agreement with predictions from known circular dichroism and the assumption that differential isomerization is simply a consequence of differential absorptivity of the enantiomers.

Nous rapportons la photorésolution partielle de $Cr(C_2O_4)phen_2^+$, $Cr(C_2O_4)_2phen^-$ et $Crbipy_3^{3+}$ par irradiation au moyen de lumière circulairement polarisée provenant d'un laser à ion d'argon émettant à 496.5 ou 514.5 nm. Nous obtenons les états continus correspondant à une résolution de 1–2%. Ils sont en accord avec les prédictions basées sur des résultats connus de dichroisme circulaire et sur l'hypothèse que l'isomérisation différentielle est simplement une conséquence de l'absorptivité différentielles des énantiomères.

Introduction

There has been a longstanding interest in partial resolution of racemates by irradiation with circularly polarized light. The interest has enjoyed only limited reward. The limitation is a consequence of two factors. First, the only recognized mechanism for steady state resolution is an excess of an isomerization reaction of one enantiomer over the other due to differential absorptivity of circularly polarized light (circular dichroism) and this mechanism depends on the ratio of the circular dichroism ($\Delta\varepsilon$) to the absorptivity ε. Second, it is the unusual system where photoisomerization is efficient enough to prevent competition from thermal racemization functioning as the limit to stationary state resolution. (Of course, there are a few examples of partial resolutions that do not lead to a stationary state at all. They depend on photodecomposition, not photoisomerization.)

One metal complex system, $Cr(C_2O_4)_3^{3-}$ and its aquo derivatives, has been systematically investigated (1, 2, 8). Partial photoresolution stationary states in agreement with circular dichroism and known thermal isomerization kinetics were found. We report here similar success with another family of Cr(III) complexes where we have the added advantage that thermal isomerizations are slow enough to be neglected. (This family came to attention in consequence of observation of a photochemical analog of the Pfeiffer effect where partial resolution was achieved without circular polarization (3)). The complexes are $Cr(C_2O_4)phen_2^+$, $Cr(C_2O_4)_2phen^-$, and $Cr(bipy)_3^{3+}$ – (phen = 1,10-phenanthroline; bipy = bipyridine). The $Cr(phen)_3^{3+}$ complex lacks a favorable dissymmetry factor ($\Delta\varepsilon/\varepsilon$) in the region of its first d–d absorption band.

[1]To whom correspondence should be addressed.

Experimental

The complexes were prepared according to published procedures as chloride or potassium salts (4). They were characterized by their visible spectra. Circular dichroism spectra of the oxalato species are available (5). $Cr(bipy)_3^{3+}$ has not, to our knowledge, been successfully resolved by conventional procedures.

An intense source of elliptically (nearly circularly) polarized light was provided by passing the linearly polarized beam from a Coherent Radiation argon ion laser (lines at 496.5 or 514.5 nm) through a 589 nm 1/4 wave plate. The 1/4 wave plate was adjusted to an angle minimizing the variation of intensity which would pass a linear polarizer placed beyond it. The approximately circularly polarized beam was passed through a diverging lens system (to avoid excess heating in the solution along the laser beam), and into a 10 cm cell containing the solution to be irradiated at 15 °C. The anticipated handedness of the circularly polarized light was confirmed from analogous experiments using a left-hand circular polarizer in place of the 1/4 wave plate. Light intensity was monitored by ferrioxalate actinometry (6).

Optical rotation was measured using a Perkin–Elmer 141 ($\pm 0.001°$) polarimeter.

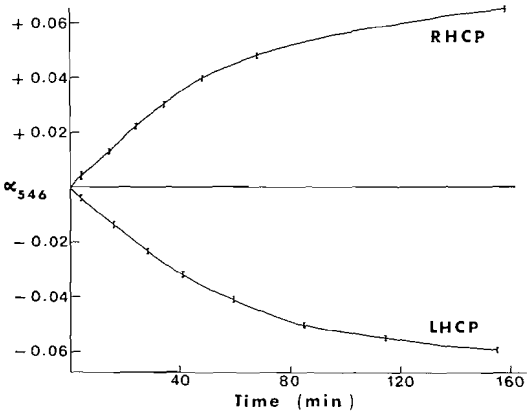

FIG. 1. Observed rotations as a function of irradiation time for $[Cr(C_2O_4)\ phen_2]Cl$ (5.06×10^{-3} *M*) in RHCP and LHCP light at 496.5 nm.

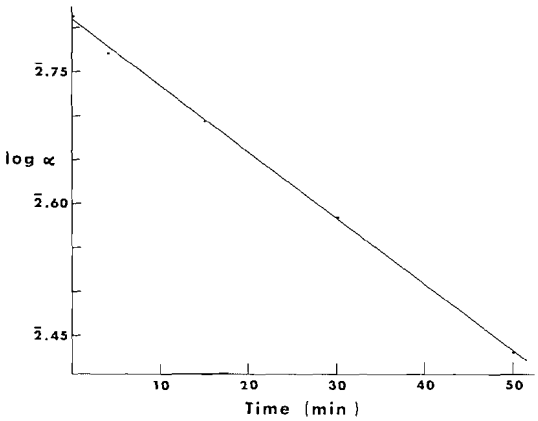

FIG. 2. Photoracemization kinetics at 496.5 nm for photoresolved (+) $Cr(C_2O_4)\ phen_2^+$ sample at 15 °C.

Results

$[Cr(C_2O_4)\ phen_2]\ Cl$

This compound has a favorable dissymmetry factor ($\Delta\varepsilon/\varepsilon$) in its first ligand field band. At 496.5 nm, $\Delta\varepsilon/\varepsilon$ is $2.4/61 = 0.039$. Under 496.5 nm irradiation, the photoreaction is isomerization. (Thermal isomerization has an insignificant rate, $t_{1/2} \simeq 23$ h at 15 °C.)

The consequences of irradiating the racemic ($\pm$) $Cr(C_2O_4)\ phen_2^+$ (5.06×10^{-3} *M* aqueous solution) with alternately right and left circularly polarized light are shown in Fig. 1. It can be seen that a steady state rotation is approached with a half life of approximately 40 min, under a light intensity of 1.8×10^{-7} einstein s^{-2} at 496.5 nm. Steady state rotations (and the corresponding specific rotations) for the three visible wavelengths available on the Perkin–Elmer polarimeter are collected in Table 1. Photoracemization kinetics at 496.5 nm for the photoresolved (+) $- Cr(C_2O_4)\ phen_2^+$ are shown in Fig. 2. These were obtained by removing the 1/4 wave plate, resulting in a 10% increase in light intensity, The half-time for racemization is 40 min and the quantum yield for the process is 0.21.

Photoresolution was also examined with irradiation at 514.5 nm. The results were essentially indistinguishable from the 496.5 nm results, as the similarity of $\Delta\varepsilon/\varepsilon$ values and the wavelength independence of this quantum yield (7) would suggest.

$K[Cr(C_2O_4)_2\ phen]$

This compound has a reasonable $\Delta\varepsilon/\varepsilon$ value of 0.039 at 514.5 nm. Kinetic behavior in a photoresolution experiment is similar to $[Cr(C_2O_4)\ phen_2]Cl$. Detailed kinetic measurements were not made although it was observed that photoinduced optical activity could be eliminated again by photoracemization in unpolarized light. The steady state resolution results are included in Table 1.

$[Cr\ bipy_3]\ (ClO_4)_3$

A value of $\Delta\varepsilon/\varepsilon$ for this complex is not available. However, it was irradiated with the "circularly" polarized light at 488.0 nm. Observed steady state rotations are recorded in Table 2.

Discussion

The kinetics shown in Figs. 1 and 2 are consistent with the nearly inevitable conclusion that isomerization rates of excited enantiomers are the same within experimental precision. The resolution results from differential absorptivity. The steady state fractional resolution should correspond to $\Delta\varepsilon/2\varepsilon$, resulting in a percent resolution of $50\,\Delta\varepsilon/\varepsilon$ (1, 2). The collected results in Table 1 are consistent with this conclusion. The percent resolutions achieved were 1.6% for $Cr(C_2O_4)\ phen_2^+$ and 2.0% for $Cr(C_2O_4)_2\ phen^-$, to be compared with the respective theoretical values of 1.9 and 2.0%. The identity of the partially resolved products is supported by the agreement of the specific rotations at the wavelengths available on the Perkin–Elmer 141 with known o.r.d. spectra. Further, in the case

of $[Cr(C_2O_4)\ phen_2]Cl$, the quantum yield at 496.5 nm for photoracemization of the photoresolved sample (0.21) is essentially identical to that of (−) $[Cr(C_2O_4)phen_2]Cl$ at 15 °C (7).

The absence of any photoinduced activity in the case of $Crphen_3^{3+}$ cannot be ascribed to kinetic factors. Under the conditions used, photoracemization is known to proceed at a rate several orders of magnitude faster than either thermal racemization or photoaquation (7). The explanation may be found in the unfavorable dissymmetry factor in the ligand field region, due to the high ε values (arising from overlap with bands of charge transfer character). Assuming a circular dichroism of similar magnitude for $Crphen_3^{3+}$ and $Crbipy_3^{3+}$, a partial photoresolution of this latter compound might be anticipated (as observed, Table 2), in view of the smaller extinction coefficients found in the d–d region.

Kinetics of Displacement of Ni(II) by Cu(II) in Bis(dithiocarbamato)nickel(II)

R. R. SCHARFE,[1] V. S. SASTRI, AND C. L. CHAKRABARTI[2]
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 12, 1972

Rates of displacement of Ni(II) in bis(dithiocarbamato)Ni(II) by Cu(II) with a variety of substituted dithiocarbamic acids in different solvents have been determined and a mechanism of the reaction and potential application of the displacement reaction to spectrophotometric titration of Cu(II) for its quantitative determination are suggested.

Nous avons déterminé les vitesses de déplacement du Ni(II) dans le bis (dithiocarbamato) Ni(II) par Cu(II) avec une variété d'acides dithiocarbamiques substitués dans différents solvants ; nous proposons un mécanisme de réaction de même que l'application possible de la réaction de déplacement au titrage spectrophotométrique de Cu(II) pour sa détermination quantitative. Introduction

For the purpose of quantitative determination of metal ions, complexation reactions of dithiocarbamic acids (DTC) are very useful (1). Recent work in this laboratory has clarified many aspects of the chemistry of dithiocarbamic acids (2–5). During the course of obtaining definitive information on the stability constants (6) and applying these data to spectrophotometric titration of metal ions such as Cu(II) and Ni(II) with dithiocarbamic acids, it was found that information on exchange rates between Cu(II) and $Ni(DTC)_2$ was necessary but lacking in the literature. Thus, the present work has been aimed at the determination of rates of displacement of Ni(II) from $Ni(DTC)_2$ by Cu(II) with respect to factors such as (*i*) effect of the substituent at the nitrogen center on the displacement rates; (*ii*) effect of the nature of solvent medium on the displacement rates.

Experimental

Reagents

Commercially obtained (Anachemia) diethyl dithiocarbamic acid as the sodium salt was used. The dimethyl, di-*n*-propyl, diisopropyl, pyrrolidine, piperidine, and hexamethylene dithiocarbamic acids were synthesized as the sodium salts by chemical reaction of stoichiometric amounts of the amine with CS_2 in a basic medium according to preparative methods described in the literature (7). All dithiocarbamic acids were recrystallized twice from hot ethanol and air-dried. Quantitative determination of the dithiocarbamate content of the reagents was done by amperometric titration with a standard Zn(II) solution at a p*H* of 6–7 by measuring the diffusion current at -1.25 V with respect to Ag/AgCl reference electrode. Spectrophotometric titration of dithiocarbamic acids with standard Cu(II) solutions gave results in agreement with those obtained by the amperometric titration. The water content of the reagents was obtained by Karl Fisher titration. Chemical analysis showed that the dithiocarbamate and water contents of the reagents add up to 100%. All the solvents and metal salts used in this study were of reagent grade purity. There were no detectable side reactions of the ligands with the solvents used in this study.

Apparatus

A modified Bausch and Lomb Spectronic 505 recording spectrophotometer was used, at a fixed wavelength, to study the slow rates of displacement of Ni(II) from $Ni(DTC)_2$ by Cu(II) with 1 cm matched quartz cells at a temperature of 25.0 ± 0.1 °C. Fast displacement rates were studied with a Durram–Gibson stopped-flow spectrophotometer fitted with an oscilloscope.

Procedure

An aliquot of 3 ml of 2.5×10^{-5} *M* $Ni(DTC)_2$ solution in the appropriate solvent was placed in a thermostatted 1 cm quartz cell, and to this was added 0.05 ml of 1.64×10^{-4} *M* Cu(II) solution by means of a Teflon device which was also used as a stirrer (4). The mixing was done with the stirrer and was complete within an average time of 6 s, and the change in absorbance due to formation of $CuDTC^+$ at a wavelength of 430–440 nm as a function of time was recorded. In the case of faster kinetics, the syringes of the stopped-flow spectrophotometer were filled with $Ni(DTC)_2$ and Cu(II) solutions and then mixed in the mixing chamber, and the change in the transmittance was recorded on the oscilloscope. The final spectrum of the product of the reaction agreed well with the spectrum of a synthetic sample of $Cu(DTC)^+$ complex. Plots of log concentration *vs.* time were linear and gave reproducible rate constants ($\pm 5\%$). Typical spectra of $Ni(DTC)_2$ and $Cu(DTC)^+$ and rate curves are given in the literature (8).

Results and Discussion

Data on the rates for the reaction

$$Ni(DTC)_2 + 2Cu^{2+} \rightarrow Ni^{2+} + 2Cu(DTC)^+$$

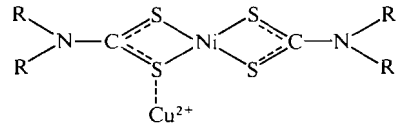
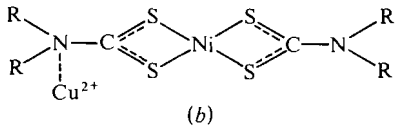
for a variety of substituted dithiocarbamic acids in different solvents are presented in Tables 1 and 2. The displacement reaction may take place in two ways, namely, (*a*) $Ni(DTC)_2$ dissociating to make one end of sulfur atom free for attachment to Cu^{2+}; (*b*) Cu^{2+} may be attacking the nitrogen center of DTC part of the nickel complex.

In case (*a*), Cu^{2+} is bonded to the sulfur atom, and in case (*b*), Cu^{2+} is bonded to the nitrogen atom. The displacement rates (Tables 1 and 2) do vary as a function of the nature of the substituent at the nitrogen atom. Steric hindrance at the nitrogen atom due to a bulky substituent results in a decrease in the displacement rate, and this makes (*b*), *i.e.*, the attack of Cu^{2+} at the nitrogen atom more likely than (*a*), *i.e.*, the attack of Cu^{2+} at the sulfur atom, since the sulfur atom is further away from the substituent group.



(*a*)



(*b*)

In methyl cellosolve, the order of reactivity is $Me_2 > Et_2 > n\text{-}pr_2 \gg i\text{-}pr_2DTC$ (Table 1). For the cyclic DTC's, the order is pyrr > pip > hexaDTC (Table 2). This trend may be due to variation of the basicity of nitrogen atom in the cyclic dithiocarbamic acids (9). On the basis of the rate data, a fast equilibrium between $Ni(DTC)_2$ and Cu^{2+} ion followed by a slow rearrangement to give $Cu(DTC)^+$, the latter being the rate determining step, is postulated, [I].

The displacement rates show a marked solvent dependence. The order of reactivity for piperidine, hexamethylene, and pyrrolidine DTC's is EtOH > MeOH > acetone > pyridine > DMSO > methyl cellosolve. The dialkyl DTC complexes do not display such a regular dependence on the solvent, and the reason for this is not known at present. The data allow one to advance the view that the solvation of the nitrogen atoms in the DTC ligands bonded to Ni(II) affects the displacement rates of Ni(II) by Cu(II).

The DTC chelates have been used in the quantitative determination of various metal ions (including Cu^{2+}) when only one of the

Remarks on the Concept of Minimum State Density in the Activated Complex Theory

W. H. WONG

Lash Miller Chemical Laboratory, University of Toronto, Toronto, Ontario

Received April 19, 1972

The concept of minimum state density in the activated complex theory and its relation to the transmission coefficient were discussed by formulating the average reaction cross-section.

Le concept de la densité de l'état minimal dans la théorie du complexe activé et ses relations avec le cöefficient de transmission sont discutés en formulant la section droite moyenne de la réaction.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3386 (1972)

In modern versions of activated-complex theory (ACT) of chemical reaction, the quasi-equilibrium hypothesis is tacitly assumed (1, 2). In these formulations, the activated complex is generally identified as the species in the vicinity of the saddle point on the relevant potential hypersurface. This conventional definition is widely adopted to interpret experimental data (3, 4) in terms of ACT. In a recent theoretical study on the behavior of reaction cross-section, Morokuma *et al.* (5) equated the rate constant from collision theory to that from the conventional ACT, *i.e.* they also assumed that the activated complex had a configuration corresponding to the most prominent topographical point on the potential surface. They found that the reaction cross-section was a diverging function of energy, contrary to the classical trajectory results (6).

For a highly exothermic reaction, this conventional definition of the transition state is even less satisfactory due to the absence of a prominent energy barrier. A suggestion has been made that the "free energy surface" rather than the potential energy surface should be used to define the transition state and that the activated complex should be located at the maximum of the free energy profile along the "reaction co-ordinate" (7). Recently the concept of minimum state density was put forward for choosing the transition state (8). This concept has been shown (8) to be related to the maximum free energy criterion (7) through a Boltzmann weighting factor. In this Note we attempt to amplify the concept in ref. 8 by deducing the average reaction cross-section in a slightly different way.

With the quasi-equilibrium hypothesis and by

equating the incident flux of the reacting pairs to the flow passing through the dividing hypersurface just outside the activated complex region, the following expression was derived by Marcus (2)

$$[1] \qquad \sum_N g(N)\frac{k^2}{\pi}\sigma_{Np} = \sum_{N^+} g(N^+)\kappa(E_{N^+})$$

where $g(N)$ and $g(N^+)$ are the degeneracy factors of the initial quantum state N and the quantum state N^+ of the activated complex, respectively. The symbol σ_{Np} is the reaction cross-section of a reacting pair in state N and with relative momentum p, κ is the transmission coefficient, and k is the wavenumber. The reaction path degeneracy factor has been omitted for brevity. The energy relation for the reactant is

$$E = E_p + E_N$$

in which E is the total energy, E_p and E_N are the relative translational and internal energies of the reactant, respectively.

Multiplying [1] by $\exp(-\beta E)$ and integrating from zero to infinity we can write

$$[2] \qquad \int_0^\infty \left[\sum_N g(N)\frac{2\mu}{\pi\hbar^2}(E-E_N)\sigma_{Np}\right] \times \exp(-\beta E)\,dE = \int_0^\infty \left[\sum_{N^+} g(N^+)\kappa(E_{N^+})\right]\exp(-\beta E)\,dE$$

One may define an average cross-section as

$$[3] \qquad \sigma(E) = \frac{\sum_N g(N)(E-E_N)\sigma_{Np}}{\sum_N g(N)(E-E_N)H(E-E_N)} = \sum_N g(N)(E-E_N)\sigma_{Np}/f(E)$$

where

$$H(x) = 1 \qquad x > 0$$
$$= 0 \qquad x \leqslant 0$$

and $f(E)$ is the energy density function (5).

Substituting [3] into [2] and making the usual assumption of the ACT,

$$[4] \qquad \kappa = 1 \qquad E - V^{\ddagger} > 0$$
$$= 0 \qquad E - V^{\ddagger} \leqslant 0$$

where $V^{\ddagger}$ is the potential energy of the activated complex, we then have

$$[5] \qquad \frac{2\mu}{\pi\hbar^2}\int_0^\infty f(E)\sigma(E)\exp(-\beta E)\,dE = \sum_{N^+} g(N^+)\int_{V^{\ddagger}}^\infty \exp(-\beta E)\,dE = \sum_{N^+} g(N^+)/\beta \exp(-\beta V^{\ddagger})$$

where μ is the reduced mass of the reactant.

Performing the inverse Laplace transform, we write

$$f(E)\sigma(E) = \frac{\pi\hbar^2}{2\mu}\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}\sum_{N^+} g(N^+)\frac{1}{\beta} \times \exp(\beta V^{\ddagger} + \beta E)\,d\beta = \frac{\pi\hbar^2}{2\mu}\sum_{N^+} g(N^+)H(E-V^{\ddagger}) = \frac{\pi\hbar^2}{2\mu}f^+(E)$$

in which f^+ is just the number of states of the activated complex with total energy equal to or less than E. Therefore

$$[6] \qquad \sigma(E) = \frac{\pi\hbar^2}{2\mu}\frac{f^+(E)}{f(E)}$$

which is the same equation obtained by Morokuma *et al.* (5) by equating directly the rate constant from collision theory to that from ACT. The characteristic frequencies of the activated complex (and hence the function $f^+(E)$) depend on the location of the transition state along the reaction coordinate. The principle of minimum state density requires that the "bottleneck" be located at S^+, given by the solution of

$$\frac{\partial}{\partial S}\left(\frac{df^+(E)}{dE}\right) = 0$$

Since in the derivation of [6], we have chosen the transmission coefficient as unity when $E - V^{\ddagger} > 0$, the boundary dividing the product region from the reactant region in the available phase space of the system should obviously be defined in such a way that the flux density passing through this boundary is a minimum. This can best be illustrated by considering the rate constant from the adiabatic transition state

theory (1, 2, 8) (see Expr. 13 of ref. 8)

$$k_r = \frac{1}{Q\beta h}\int_{E=0}^{\infty} \exp(-\beta E)\frac{df^+(E)}{dE}\,dE$$

in which Q is the partition function of the reactants. From the above expression, it is obvious that the minimization of state density is equivalent to minimizing the rate constant. This procedure is, of course, in the spirit of the variational theory of reaction rates developed by Wigner (9), by Horiuti (10), and by Keck (11), in which attempts were made to define a dividing surface that would eliminate the "recrossing" of the phase space trajectories.

I am grateful to Professor R. A. Marcus for invaluable discussions.

Phase Diagrams of Sodium Chloride and of Potassium Chloride in Water-Dioxane

A. N. Campbell and S. Y. Lam

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received June 1, 1972

The equilibrium conditions, at 25°, of the NaCl–water–dioxane and KCl–water–dioxane systems have been investigated. While water–dioxane mixtures separate into two layers in the presence of certain concentrations of sodium chloride, the system KCl–water–dioxane does not form two layers under any conditions. The LiCl–water–dioxane system has been previously investigated by Lynch (1).

Nous avons étudié les conditions d'équilibre, à 25°, des systèmes: NaCl–eau–dioxanne et KCl–eau–dioxanne. Tandis que les mélanges eau–dioxanne se séparent pour former deux couches en présence d'une certaine concentration de NaCl, le phénomène ne se produit pas lorsqu'on utilise le mélange KCl–eau–dioxanne, dans n'importe quelles conditions. Le système LiCl–eau–dioxanne avait été étudié précédemment par Lynch (1). [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3388 (1972)

In the course of calorimetric work by Bhatnagar of this Department, it was observed that in the presence of certain concentrations of sodium chloride, mixtures of dioxane and water separated into two layers. A scrutiny of the literature revealed that Lynch (1) had made a study of the LiCl–water–dioxane system. In the presence of lithium chloride, certain water–dioxane mixtures also separate into two layers. Lynch's diagram exhibits two invariant triangles. In one, the equilibrium phases are: liquid I, liquid II, and the solid ternary compound $LiCl.H_2O.(C_2H_4)_2O_2$, liquid I being almost pure dioxane. In the second invariant triangle, the equilibrium phases are the above compound, equilibrium liquid, and $LiCl.H_2O$.

Nothing appeared to be known about the systems comprising sodium and potassium chlorides, respectively, so we thought it worthwhile to spend a little time on their investigation. Little need be said about the technique, except that both liquid and equilibrium "wet"

Phase Diagrams of Sodium Chloride and of Potassium Chloride in Water-Dioxane

A. N. Campbell and S. Y. Lam

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received June 1, 1972

The equilibrium conditions, at 25°, of the NaCl–water–dioxane and KCl–water–dioxane systems have been investigated. While water–dioxane mixtures separate into two layers in the presence of certain concentrations of sodium chloride, the system KCl–water–dioxane does not form two layers under any conditions. The LiCl–water–dioxane system has been previously investigated by Lynch (1).

Nous avons étudié les conditions d'équilibre, à 25°, des systèmes: NaCl–eau–dioxanne et KCl–eau–dioxanne. Tandis que les mélanges eau–dioxanne se séparent pour former deux couches en présence d'une certaine concentration de NaCl, le phénomène ne se produit pas lorsqu'on utilise le mélange KCl–eau–dioxanne, dans n'importe quelles conditions. Le système LiCl–eau–dioxanne avait été étudié précédemment par Lynch (1). [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3388 (1972)

In the course of calorimetric work by Bhatnagar of this Department, it was observed that in the presence of certain concentrations of sodium chloride, mixtures of dioxane and water separated into two layers. A scrutiny of the literature revealed that Lynch (1) had made a study of the LiCl–water–dioxane system. In the presence of lithium chloride, certain water–dioxane mixtures also separate into two layers. Lynch's diagram exhibits two invariant triangles. In one, the equilibrium phases are: liquid I, liquid II, and the solid ternary compound $LiCl.H_2O.(C_2H_4)_2O_2$, liquid I being almost pure dioxane. In the second invariant triangle, the equilibrium phases are the above compound, equilibrium liquid, and $LiCl.H_2O$.

Nothing appeared to be known about the systems comprising sodium and potassium chlorides, respectively, so we thought it worthwhile to spend a little time on their investigation. Little need be said about the technique, except that both liquid and equilibrium "wet"

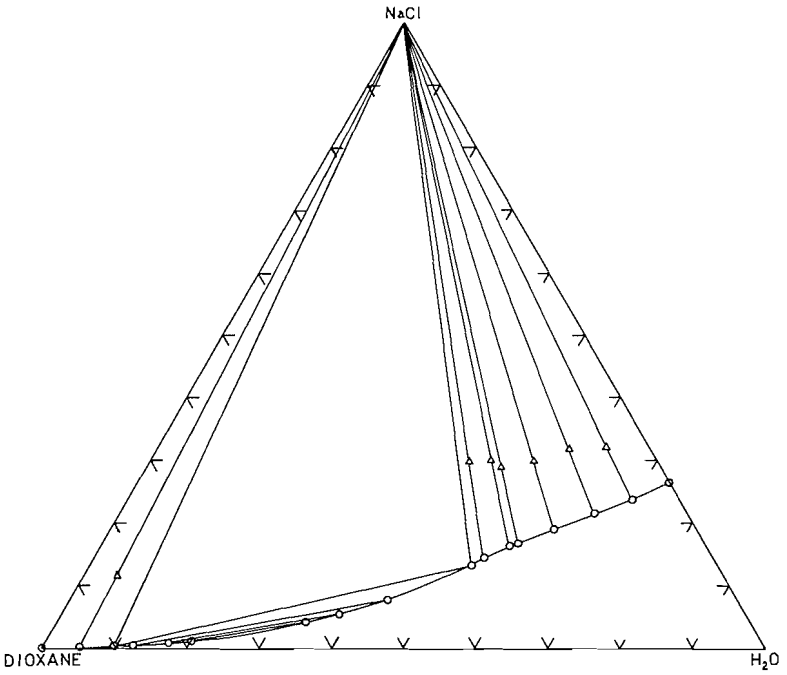

FIG. 1. Phase diagram of the NaCl–water–dioxane system.

TABLE 1. Compositions of liquids in equilibrium in NaCl–water–dioxane system

Liquid I	Liquid II
0.1% NaCl	13.3% NaCl
90.8% Dioxane	34.1% Dioxane
9.1% Water	52.0% Water

solid phases were analyzed by distillation, followed by refractive index measurement of the distillate, and weighing of the solid residue. The salt content of the solutions was also checked by volumetric determination of chloride by Mohr's method.

To summarize the results, in presence of potassium chloride at 25°, water–dioxane mixtures will not separate into two layers for any concentration of salt. The concentration of KCl in solution varies from 26.3% in pure water to zero in pure dioxane. Figure 1 shows the relations in the NaCl–water–dioxane system. For the invariant triangle, the compositions of liquids in equilibrium with pure solid NaCl are shown in Table 1. No compound is formed.

The equilibrium relations in these three systems are in agreement with the well-known facts that the affinities of the ions Li^+, Na^+, and K^+ for water are in the above order: the greater the affinity of an ion for water, the greater the probability of the formation of two layers.

Circular Dichroism of *R*-1,2-Propanediamine Complexes of Copper(II)

ROLAND A. HAINES AND E. WENDY CREWS
Department of Chemistry, University of Western Ontario, London, 72, Ontario

Received April 28, 1972

The optical activity associated with solutions containing copper(II) ions and *R*-1,2-propanediamine (*R*-pn) has been examined in detail. Circular dichroism data previously reported for $[Cu(R\text{-pn})_2]^{2+}$ have been found to be in error and new data are reported for this ion, as well as $[Cu(R\text{-pn})]^{2+}$.

L'activité optique associée aux solutions contenant les ions Cu(II) et la *R*-propanediamine-1,2 (*R*-pn) a été examinée en détail. Les données du dichroïsme circulaire citées antérieurement pour $[Cu(R\text{-pn})_2]^{2+}$ ont été trouvées être erronées et des nouvelles valeurs sont rapportées pour cet ion ainsi que pour $[Cu(R\text{-pn})]^{2+}$. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3390 (1972)

The circular dichroism (c.d.) spectrum of the bis-(*R*-1,2-propanediamine)copper(II) ion $[Cu(R\text{-pn})_2]^{2+}$ has been reported previously (1) and showed two positive c.d. maxima in the region of the d–d absorption band. Recently, we have found it necessary to examine the circular dichroism associated with this ion in detail and have obtained results which are not consistent with those reported. The results of our investigation are given in this paper.

A sample of $[Cu(R\text{-pn})_2](NO_3)_2$ prepared in our laboratory was found to have a c.d. spectrum consisting of only one positive band with a maximum at 514 nm. However, the spectrum reported had two positive maxima at 510 and 657 nm. Since no experimental details were given in that report, it was decided to examine the changes in optical activity which occur on generating the species *in situ* in an attempt to explain the discrepancy.

The species present in a solution of copper(II) ions and *R*-pn is strongly p*H* dependent. At low p*H* the 1:1 complex $[Cu(R\text{-pn})]^{2+}$ is favored while in more basic solutions the 2:1 species $[Cu(R\text{-pn})_2]^{2+}$ predominates. Detailed thermodynamic data and formation constants have been reported for both complexes (2, 3). In our studies, aqueous solutions containing copper (II) nitrate and *R*-pn·2HCl in a 1:2 molar ratio were prepared. The initial p*H* of these solutions was approximately 2.6 and under these conditions essentially no complex formation occurred. Aqueous NaOH was then added in small amounts and absorption and c.d. spectra were obtained following each addition.

The absorption spectrum initially showed a peak at 805 nm characteristic of the aquo copper(II) ion. As the p*H* was increased, this band was shifted to shorter wavelengths and above p*H* 9.9 the spectrum had a maximum at 555 nm and did not change further. For solutions of p*H* greater than 6.5, a fine white precipitate was formed in small quantities as the base was added. This precipitate is due to hydrolysis of the copper ion and has been noted previously (4). Appropriate corrections (*vide infra*) therefore had to be included in the concentrations of the species present.

For the initial solution, no measurable c.d. was observed. However, as the p*H* was increased, a positive peak was formed at 625 nm and grew in intensity until p*H* = 5.0. Above this p*H* the long tail on the low wavelength side of the c.d. maximum developed into a separate peak at 514 nm and grew at the expense of the 625 nm band. After p*H* 9.9 the c.d. spectrum became constant and consisted only of the peak at 514 nm as shown in Fig. 1(*a*).

The limiting absorption and c.d. spectra above p*H* 9.9 were considered as being characteristic of the $[Cu(R\text{-pn})_2]^{2+}$ ion and were also similar to the spectra obtained for dissolved $[Cu(R\text{-pn})_2](NO_3)_2$. Since some hydrolysis had occurred during the study, it was necessary to obtain a corrected value for the concentration of the species in solution. This was accomplished by carrying out absorption measurements at the isosbestic point (640 nm) which we observed for these solutions above p*H* 4.8. A series of standard solutions showed that at this wavelength the molar extinction coefficient $\varepsilon = 37.5$ l mol^{-1} cm^{-1}. Hence, calculations of the total

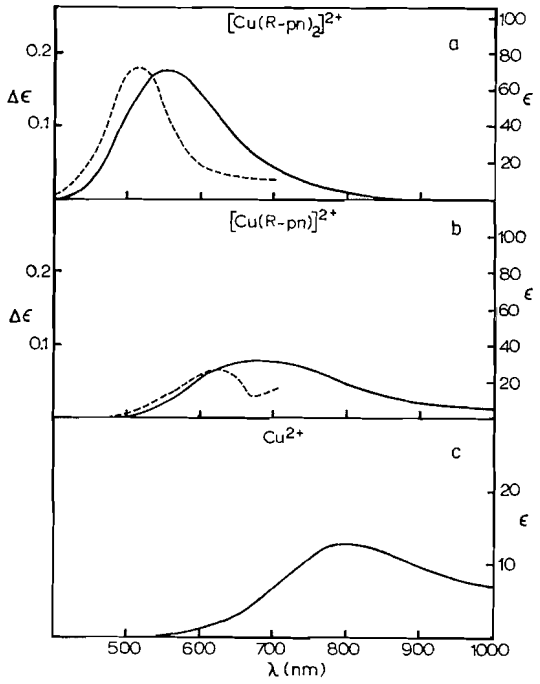

FIG. 1. Absorption (—) and circular dichroism (---) spectra of copper(II)–*R*-pn species.

copper concentration in our solution could be made and applied to both the c.d. and absorption spectra of the limiting $[Cu(R\text{-pn})_2]^{2+}$ species. The resulting values are shown in Fig. 1(*a*).

Data for the 1:1 complex were obtained by generating the species *in situ*. Copper(II) nitrate and *R*-pn·2HCl were mixed in a 20:1 molar ratio and the p*H* was adjusted to 3.6. At this acidity, formation of $[Cu(R\text{-pn})]^{2+}$ is favored and no appreciable amount of $[Cu(R\text{-pn})_2]^{2+}$ is present. The c.d. and absorption spectra determined for $[Cu(R\text{-pn})]^{2+}$ are shown in Fig. 1(*b*). The c.d. spectrum was measured directly while the absorption spectrum was derived by correcting for the absorption of uncomplexed copper(II) ion, whose absorption spectrum is shown in Fig. 1(*c*).

The 2:1 species has an absorption maximum at 555 nm with $\varepsilon = 72.1$ l mol^{-1} cm^{-1} while the c.d. spectrum has a maximum at 514 nm with $\Delta\varepsilon = 0.18$. The 1:1 species shows an absorption maximum at 675 nm with $\varepsilon = 31.5$ and a c.d. maximum at 625 nm where $\Delta\varepsilon = 0.065$. From the data calculated for these species it was possible to determine ratios for the concentrations of these two species in a given solution. Since each species makes a contribution to the total spectrum observed, it is possible to solve a series of simultaneous equations of the type

$$A_\lambda = \varepsilon_\lambda^{2:1} b c^{2:1} + \varepsilon_\lambda^{1:1} b c^{1:1} + \varepsilon_\lambda^{Cu^{2+}} b c^{Cu^{2+}}$$

where A_λ = the observed absorbance at a wavelength λ; ε_λ^x = the molar extinction coefficient of species x at λ, b = the path length in cm; and c^x is the molar concentration of species x. From measurements at three different wavelengths, the concentration of each species can be calculated. For c.d. spectra only two species contribute to the observed spectrum and two simultaneous equations of the type

$$\Delta A_\lambda = \Delta\varepsilon_\lambda^{2:1} b c^{2:1} + \Delta\varepsilon_\lambda^{1:1} b c^{1:1}$$

were solved where ΔA_λ = the observed differential absorbance at wavelength λ and $\Delta\varepsilon_\lambda^x$ is the molar c.d. value of species x at λ. (Quantities b and c^x are defined as before.) Ratios calculated from both sets of data are shown in Table 1.

TABLE 1. Calculated ratios of $[Cu(R\text{-pn})_2]^{2+}$: $[Cu(R\text{-pn})]^{2+}$

	Ratio of $[Cu(R\text{-pn})_2]^{2+}$: $[Cu(R\text{-pn})]^{2+}$	
p*H*	From c.d. spectra	From absorption spectra
4.4	0.22	0.23
4.9	0.64	0.68
5.5	1.2	1.3
6.3	1.4	1.7
6.7	2.6	2.6
7.3	14	20
9.9	$>10^6$	$>10^8$

On the basis of our studies it would appear that the spectra reported by Gillard (1) consisted of a mixture of the 2:1 and 1:1 species, possibly because of a solution which was not sufficiently basic to favor the formation of the 2:1 species. His conclusions concerning the complexity of the c.d. spectrum, however, would still appear to be valid. The tail on the long wavelength side of the c.d. peak for $[Cu(R\text{-pn})_2]^{2+}$ would suggest that more than one component band is present. For the 1:1 complex a second component actually was indicated but unfortunately was located beyond the range of our instrument. Three component transitions make up the large d–d absorption band in most square planar copper(II) complexes and in certain cases more than one com-

ponent has been observed in the c.d. spectra (5). For the *R*-pn complexes studied here, the component bands overlap quite strongly and hence assignment to individual transitions is difficult.

Experimental

R-1,2-Propanediamine dihydrochloride was obtained from Frinton Laboratories, Vineland, N.J. ($[\alpha]_{589} = -34°$ for the free base.) Solutions used in the study were approximately 3×10^{-2} *M* in copper(II) ion and were prepared as indicated in the text.

Circular dichroism spectra were obtained using a Durrum–Jasco Model ORD/UV-5 recording spectropolarimeter with c.d. attachment. Absorption spectra were determined on a Beckman-DK-1 recording spectrophotometer. Measurements of p*H* were carried out using a Sargent Model DR p*H* meter equipped with a combination glass–calomel electrode.

Reaction of *N*-Acetyl-2,3-diphenylindole with Nitric Acid

VINOD DAVE[1] AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received May 5, 1972

Based on spectroscopic and chemical evidence the 3-hydroxy-6-nitro-2,3-diphenylindolenine structure **8** is assigned to the previously reported *N*-acetyl-2,3-diphenylindole–nitric acid reaction product. The product from the acid-catalyzed rearrangement of **8** is assigned the oxindole structure **12**.

Par des preuves spectrales et chimiques, la structure **8** a été identifiée à l'hydroxy-3 nitro-6 diphényl-2,3 indolénine, produit issu de la réaction entre le *N*-acétyl diphényl-2,3 indole et l'acide nitrique. La structure oxindole **12** a été attribuée au produit issu du réarrangement acidocatalysé de **8**.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3392 (1972)

In a systematic study of the nitration of indoles, spanning a period of 35 years, Plant and his coworkers treated several indolic compounds with nitric acid (1). One such reaction between *N*-acetyl-2,3-diphenylindole (**1**) and nitric acid in acetic acid yielded a colorless compound, m.p. 262° (dec.), to which Fennell and Plant assigned the phenanthrene nitro alcohol structure **2** (2). There are two characteristic features of **2** which argue against it being the nitration product: an unusual oxidative coupling of the phenyl rings in the 2- and 3-positions, and remarkable stability of the carbinolamine moiety in **2** under the acid conditions used. In view of the doubtful structural assignment for the nitration product, the reaction was reinvestigated.

When the reaction was carried out according to the published procedure there was indeed obtained a colorless compound, m.p. 250° (dec.), whose i.r. spectrum showed the presence of N—H and/or O—H and nitro group absorption. Mass spectrometry gave the molecular ion peak at 330, confirming Fennell and Plant's molecular formula. However, the u.v. spectrum lacked the absorption due to a dihydrophenanthrene chromophore (3). Since spectroscopic information was not sufficient to establish the structure,[2] chemical means were resorted to.

On treating the nitration product with *m*-chloroperbenzoic acid (*m*-CPBA) there was obtained a lemon yellow compound, m.p.

[1]Author to whom inquiries should be addressed.

[2]Insolubility problems made it difficult to get a good integration of the n.m.r. spectrum and no exchangeable protons were apparent.

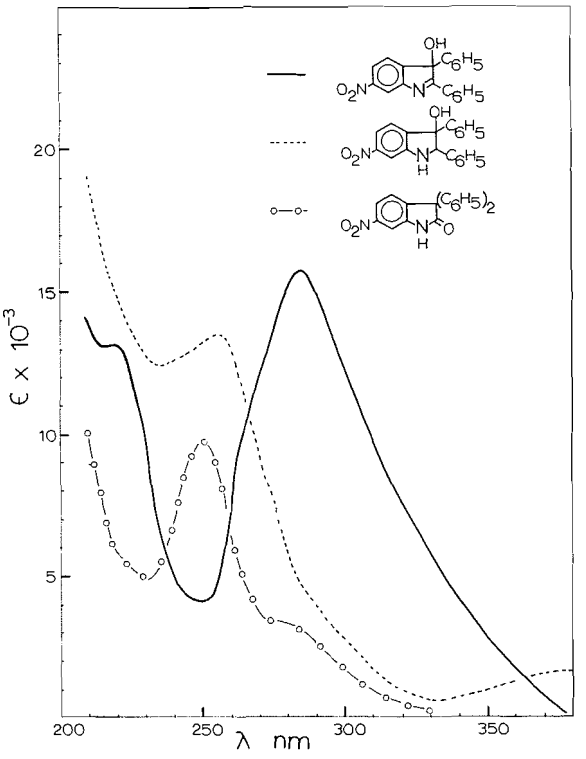

FIG. 1. The u.v. spectra of the nitro alcohol, its reduction product, and its rearrangement product.

192°, whose i.r. spectrum showed the presence of two carbonyl groups, one of which was likely due to an amide, suggesting possible cleavage of a double bond in the pyrrole ring during the peracid reaction. A literature search revealed that the two known nitro indoles **3** and **4** on oxidation gave the ring cleavage products **5** and **6** which were also yellow and had melting points close to that of the lemon yellow compound described above (4, 5).[3] Comparison of the lemon yellow compound from the peracid reaction on the nitration product with authentic samples (Scheme 1) of **5** (4) and **6** (5) showed it to be identical with **5**. The peracid reaction thus proved the presence of an indole or indolenine double bond and established that the nitro group was in the 6-position.

It was tempting to assume that the nitration product was *N*-hydroxy-6-nitro-2,3-diphenylindole (**7**). However, this possibility was discounted for the following reasons: (*a*) since 6-nitro-2,3-diphenylindole is orange in color, the *N*-hydroxy derivative would be expected to be colored, while the nitration product is colorless; (*b*) the compound did not give a positive ferric chloride test (8, 9), and (*c*) it lacked the characteristic bathochromic shift for *N*-hydroxy indoles in its u.v. spectrum in the presence of base (9).

The only structure left which could account for the available information was 3-hydroxy-6-nitro-2,3-diphenylindolenine (**8**). Support for this structure was provided by the following two observations. Firstly, sodium borohydride reduction of the carbon—nitrogen double bond in **8** gave the hydroxyindoline **9** as an orange-red solid.[4] The n.m.r. spectrum of this compound showed the presence of a methine proton at δ 5.1 and the i.r. spectrum showed absorption at 3340 and 3510 cm^{-1} due to NH and OH. The dihydro compound **9** on heating above the melting point gave 6-nitro-2,3-diphenylindole (**3**) as the only product. Secondly, reaction of the "nitro alcohol" with acetic anhydride in pyridine gave a colorless *O*-acetate. The u.v. spectrum of this compound was identical with that of the nitration product and hence the acetate was tentatively assigned the nitroacetoxyindolenine structure **11**.

Attempts to prepare the hydroperoxide **10** from the nitro indole **3** for reduction to **8** were unsuccessful. However, Taylor and his coworkers had treated several indole alkaloids with lead tetraacetate in methylene chloride to obtain 3-acetoxyindolenines (10). This reaction on 6-nitro-2,3-diphenylindole (**3**) gave a colorless compound which was identical with the *O*-acetate obtained from the nitro alcohol–acetic anhydride reaction, thus establishing the 3-acetoxyindolenine structure **11** for the latter and the 3-hydroxy-6-nitro-2,3-diphenylindolenine structure (**8**) for the nitration product.

Fennell and Plant had treated their nitration product with refluxing acetic acid and obtained an isomeric red compound, m.p. 227°, to which no structure was assigned. Repetition of the reaction gave a red-orange compound, m.p. 227–229°, whose i.r. spectrum showed the presence of a carbonyl group at 1720 cm^{-1}. Mass spectrom-

[3]Compounds formed by the double bond cleavage of 4- and 5-nitro-2,3-diphenylindole are colorless (4).

[4]The orange-red color of this dihydro compound is not surprising, since *N*-methyl and *N*-ethyl-*m*-nitroaniline are reddish-yellow in color.

etry gave the molecular ion peak at 330, corresponding to Fennell and Plant's molecular formula. Treatment of 3-acetoxy-6-nitro-2,3-diphenylindolenine (**11**) with hydrochloric acid, Taylor's general method for preparation of oxindole alkaloids (10), gave the same red compound which is therefore 3,3-diphenyl-6-nitrooxindole (**12**). From the acid reaction on 3-acetoxyindolenine **11** there was also obtained, albeit in only 3% yield, Fennell and Plant's nitration product **8**, presumably by acid hydrolysis of the acetate group, confirming the 3-hydroxyindolenine structure **8** for the nitration product.

Formation of 3-hydroxy-6-nitro-2,3-diphenylindolenine (**8**) under the nitration conditions used is understandable. The initial product of the reaction probably is 3,6-dinitro-2,3-diphenylindolenine which on hydrolysis in aqueous acid would give the 3-hydroxyindolenine **8**.[5] One possible mechanism (13) for the peracid reaction of indolenine **8** would involve formation of an oxaziridine followed by cleavage to give **5**.

In view of the present findings, the structures of products from other reactions between nitric acid and *N*-acetyl-2,3-diphenylindole under different conditions for which the basic phenanthrene skeleton have been assumed (2) should be considered suspect.

Experimental[6]

Reaction of N-Acetyl-2,3-diphenylindole with Nitric Acid

The reaction was carried out by the method of Fennell and Plant (2) to give the nitro alcohol **8** as colorless needles (23%), m.p. 250° (dec., sealed capillary) (lit. (2) 262° (dec.)); ν_{max} (Nujol) 3100 (OH) and 1500 cm^{-1} (NO_2); ν_{max} (THF) 3280 (OH) and 1520 cm^{-1} (NO_2); λ_{max} 220 (12 900) and 285 nm (15 600); *m/e* 330 (molecular ion).

Anal. Calcd. for $C_{20}H_{14}N_2O_3$ (330.3): C, 72.72; H, 4.27; N, 8.48. Found: C, 72.62; H, 4.42; N, 8.05.

Reaction of Nitro Alcohol 8 with Peracid

To a stirred solution of nitro alcohol **8** (100 mg) in chloroform (40 ml) was added a solution of *m*-chloroperbenzoic acid (200 mg) in chloroform (2.0 ml). After the pale yellow solution was stirred for 1 h at room temperature, it was first washed with 10% aqueous Na_2SO_3 and then with 5% $NaHCO_3$ solution. The organic layer was washed to neutrality, dried, and concentrated giving a yellow solid. Three recrystallizations from chloroform–petroleum ether gave lemon-yellow needles of **5** (70 mg), m.p. 190–192°; ν_{max} 3310 (NH), 1680, 1640 (—C=O), and 1530 cm^{-1} (NO_2); λ_{max} 255 (10 100) and 272 nm (8900); *m/e* 346 (molecular ion).

Anal. Calcd. for $C_{20}H_{14}N_2O_4$ (346.3); C, 69.36; H, 4.07; N, 8.09. Found: C, 69.35; H, 4.03; N, 7.44.

The compound was identical in all respects with the authentic sample of the keto amide **5** (see below).

Reaction of 6-Nitro-2,3-diphenylindole (3) with Peracid

To a stirred solution of 6-nitro-2,3-diphenylindole (5) (50 mg) in chloroform (4.0 ml) was added a solution of *m*-chloroperbenzoic acid (100 mg) in chloroform (0.5 ml). After the pale yellow solution was stirred at room temperature for 0.5 h, it was worked-up as above to give a yellow solid (52 mg). Two recrystallizations from chloroform–petroleum ether gave the keto amide **5** as lemon-yellow needles (42 mg), m.p. 190–192° (lit. (4) 192–193°).

Reaction of 2-Phenyl-3-(4'-nitrophenyl)indole (4) with Peracid

A solution of the nitroindole **4** (5, 6) (30 mg), *m*-chloroperbenzoic acid (60 mg), and chloroform (5.0 ml) was refluxed for 0.5 h. After cooling, the solution was worked-up as above giving a yellow solid. Three recrystallizations from chloroform–petroleum ether gave the keto amide **6** as yellow needles (26 mg), m.p. 185–188° (lit. (5) 187–189°). The mixed m.p. of this compound with the nitro alcohol–peracid product **5** was depressed to 163–185° and the two compounds had different R_f on t.l.c.; ν_{max} 3280 (NH), 1670, 1630 (—C=O), and 1500 cm^{-1} (NO_2); λ_{max} 257 (5500) and 272 nm (4500); *m/e* 346 (molecular ion).

Reaction of the Nitro Alcohol 8 with Sodium Borohydride

To a stirred colorless solution of the nitro alcohol (100 mg) in methanol (2.5 ml) and tetrahydrofuran (2.5 ml) was added sodium borohydride (200 mg) over a period of 5 min. The solution which immediately became yellow–orange was stirred at room temperature for 20 min, diluted with ether, washed with water, dried, and concentrated to give an orange colored solid (98 mg). The crude material was put on a silica gel preparative layer plate and developed with benzene–ether (90:10). The orange band at R_f 0.48 gave an orange–red solid (86 mg). Two recrystallizations from chloroform–petroleum ether gave the hydroxyindoline **9** as reddish-orange plates (64 mg), m.p. 158–204° (dec.)

[5]Precedent for such ready hydrolysis of a *C*-nitro group is known from the work of Plant (11) and Taylor (12) who treated *N*-acetyl and *N*-benzoyl-2,3-dimethylindole with nitric acid and isolated what was presumably the nitro alcohol **i** which on hydrolysis gave the diol **ii**.

(see below); ν_{max} 3510 and 3340 cm^{-1} (NH and OH); λ_{max} 255 (13 570) and 385 nm (1590); δ 5.1 (1H, N—CHPh); highest peak in the mass spectrum was at 314 corresponding to 6-nitro-2,3-diphenylindole.

Anal. Calcd. for $C_{20}H_{16}N_2O_3$ (332.4): C, 72.28; H, 4.85; N, 8.43. Found: C, 72.48; H, 4.71; N, 7.78.

The sodium borohydride product (15 mg) was sealed in a glass tube and heated at 180° for 2 h. After cooling, the material was recrystallized twice from chloroform–methanol–petroleum ether giving orange crystals (9 mg), m.p. 229–231°, identical in all respects with the authentic sample of 6-nitro-2,3-diphenylindole (**3**).

Reaction of 6-Nitro-2,3-diphenylindole with Lead Tetraacetate

The method of Taylor *et al.* (10) was slightly modified. To a refluxing solution of 6-nitro-2,3-diphenylindole (106 mg) in methylene chloride (10 ml) was added lead tetraacetate (270 mg). After the solution was refluxed for 3.5 h, it was cooled, filtered, and concentrated to give an oily solid. The material was put on two alumina preparative layer plates and developed with benzene–ether (87:13). The band at R_f 0.41 gave a colorless solid (83 mg). Three recrystallizations from chloroform–petroleum ether gave the nitro acetoxyindolenine **11** as a colorless solid (60 mg), m.p. 210° (dec.); ν_{max} 1770 (sh), 1755 (—CO), and 1520 cm^{-1} (NO_2); λ_{max} 285 nm (20 100); *m/e* 372 (molecular ion).

Anal. Calcd. for $C_{22}H_{16}N_2O_4$ (372.4): C, 70.96; H, 4.33, N, 7.52. Found: C, 70.39; H, 4.18; N, 6.87.

The faintly yellow band from the above plates at R_f 0.70 gave a pale yellow oil (18 mg) which failed to crystallize and was not further investigated.

Reaction of Nitro Alcohol 8 with Acetic Anhydride

A solution of nitro alcohol **8** (40 mg), pyridine (1.0 ml), and acetic anhydride (0.5 ml) was stirred at room temperature for 12 days. After the addition of chloroform, the reaction mixture was washed first with water and then with 5% $NaHCO_3$ solution. The organic layer was washed, dried, and concentrated giving a faintly yellow solid. Two recrystallizations from chloroform–petroleum ether gave the acetoxy compound **11** as colorless crystals (29 mg), identical in all respects with the authentic sample of 6-nitro-3-acetoxy-2,3-diphenylindolenine (**11**).

Reaction of the Nitro Alcohol 8 with Acetic Acid

The reaction was carried out in essentially the same way as reported by Fennell and Plant (2). The crude product was recrystallized from methanol–petroleum ether to give orange-red needles, m.p. 227–230° (lit. (2) 227°); ν_{max} 3410 (NH), 1720, 1700 (sh) (—C=O), and 1510 cm^{-1} (NO_2); λ_{max} 250 (9700), 280 (3200), and 460 nm (860); *m/e* 330 (molecular ion). This compound was identical in all respects with the authentic sample of 3,3-diphenyl-6-nitrooxindole (see below).

Reaction of 3-Acetoxy-6-nitro-2,3-diphenylindolenine (11) with Hydrochloric Acid

The method of Taylor and his coworkers (10) was used. To the refluxing solution of 6-nitro-3-acetoxy-2,3-diphenylindolenine (**11**) (50 mg) in methanol (10 ml) and chloroform (5 ml) was added concentrated HCl (0.5 ml). After the solution was refluxed for 13 h, the solvents were evaporated on the rotary evaporator. The residual orange solid was dissolved in chloroform and washed with water. The organic layer was dried and concentrated to give an orange solid (51 mg). The material was put on a silica gel preparative plate and developed with benzene–ether (95:5). The band at R_f 0.77 gave an orange solid (27 mg). Two recrystallizations from chloroform–petroleum ether gave 3,3-diphenyl-6-nitrooxindole (**12**) as orange–red needles (12 mg), m.p. 228–230°.

The band at R_f 0.42 gave a colorless compound (8 mg). Two recrystallizations from acetone–petroleum ether gave colorless needles (1.5 mg) identical in all respects with the nitro alcohol **8**.

Reaction of 2,3-Diphenylindole with Permanganate. Rearrangements of *N,N'*-Dimers

VINOD DAVE
Department of Chemistry, University of Western Ontario, London, Ontario
Received May 5, 1972

Based on spectroscopic and chemical evidence dimeric structure **1** is assigned to the major product from reaction of 2,3-diphenylindole and potassium permanganate. Thermal and acid-catalyzed rearrangements of *N,N'*-dimers **1** and **6** were studied.

Sur des bases spectrales et chimiques, la structure du dimère **1** a été attribuée au produit majeur de la réaction entre le diphényl-2,3 indole et le permanganate de potassium. Les réarrangements thermiques et acido-catalysés des *N,N'*-dimères **1** et **6** ont été étudiés. [Traduit par le journal]

Over a quarter of a century ago Koelsch (1) reacted 2,3-diphenylindole with potassium permanganate and reported the formation of a compound, $C_{40}H_{28}N_2O + C_6H_6$ (from benzene–ethanol), m.p. 199–200°, to which no structure was assigned. Because of our interest in the chemistry of indole oxidations and rearrangements (2), we have reinvestigated the reaction. When the reaction was carried out according to the procedure of Koelsch,[1] there were obtained three crystalline compounds and a glassy material. The least polar (t.l.c.), major product (30%), dimer A, $C_{40}H_{28}N_2$, had m.p. 204–206° (from chloroform–petroleum ether) and was identical in all respects with a sample recrystallized from benzene–ethanol. Though no direct comparison with Koelsch's sample was made, our compound is probably the same as his sample of m.p. 199–200°. Based on the analytical data and the following spectroscopic and chemical evidence the *N,N'*-dimeric structure **1** is assigned to dimer A.

The compound (molecular ion *m/e* 536) contained the diphenylindole chromophore (u.v.) but only aromatic hydrogen atoms (n.m.r.) and no NH group (i.r.). The above spectroscopic data suggested the probable linking of two diphenylindole molecules by the nitrogen atoms. That this was indeed the case was shown by the reductive cleavage of the nitrogen–nitrogen single bond by lithium aluminum hydride to give 2,3-diphenylindole as the only product. The dimeric indole structure **1** was further supported by the reaction with *m*-chloroperbenzoic acid (4) which gave the *N*-benzoyl-*o*-aminobenzophenone derivative **2**.

The second more polar compound, dimer B, (7%) from the permanganate reaction was a crystalline solid of m.p. 219–221°, isomeric with the *N,N'*-dimer. The third more polar compound from the reaction was a glassy material whose purity was uncertain and which was not further investigated. The most polar compound from the reaction (<1%) was a solid, m.p. 246–248°, whose trimeric nature was proved by molecular weight determination.

The acid-catalyzed and thermal rearrangements of dimer A were examined. Reaction with concentrated hydrochloric acid in refluxing acetone under benzidine rearrangement conditions (5) gave an isomeric dimer (dimer C), m.p. 235° (dec.). Heating the dimer A alone at 240° for 1 h in a sealed tube followed by column chromatography gave four crystalline products, one of which was proved to be 2,3-diphenylindole and the other three were isomeric with dimers A, B, and C. The four compounds in increasing order of polarity on alumina had melting points as follows: 270–271° (dimer D); 113–115° (2,3-diphenylindole); 298° (dec.) (dimer E); and 296° (dimer F).

Though no definite structural assignments for dimers B–F and the trimer are possible, the possibilities can be limited.[2] All the dimers B–F showed i.r. absorption due to the N–H,

[1]It is necessary to add solid permanganate, since as in case of carbazole (3), diphenylindole is recovered largely unchanged if a solution of permanganate in acetone is used (heterogenous reaction?).

[2]Throughout the discussion it has been assumed that the phenyl rings in the 2- and 3-positions remain unreactive; however, the data at hand do not necessarily prove that.

while the trimer lacked this absorption. All of the compounds showed the presence of the indole chromophore in their u.v. spectra. Dimer C, the benzidine rearrangement product, failed to react with acetic anhydride but readily gave an *N*-methyl derivative in the presence of sodium hydride – methyl iodide. This *N*-methyl compound lacked N—H i.r. absorption, and hence it must be either the 1,5′- or, more likely in view of the hindrance to acetylation, the 1,7′-linkage product (see **3**). Dimers B and E reacted with acetic anhydride to give monoacetates which lacked i.r. N—H absorption. In view of the fact that radical aromatic substitution takes place in *o*-, *m*-, and *p*-positions (6), combined with the finding that the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the benzyl radical with indole gave the 4-substituted indole derivative as one of the products (7), the dimers B and E must be two of the remaining three carbon–nitrogen coupling products (see **3**). Because of the low yields of dimers D and F no derivative preparation was attempted, but in view of the above discussion one or both of them could be the carbon–carbon coupling products (see **4**). The only trimer in the series must have structure **5** because it lacks i.r. N—H absorption.

Reaction of the related compound carbazole with potassium permanganate was reported half a century ago by Perkin and Tucker (8) who isolated two pure compounds from the reaction. The compound of m.p. 220° was proved to be 9,9′-dicarbazolyl (**6**). The compound having m.p. 265° which was reported to be isomeric with 9,9′-dicarbazolyl, but to which no structural assignment was possible, has recently been proved to be the trimer **7** (9, 10). Like *N,N′*-dimer **1**, 9,9′-dicarbazolyl (**6**) underwent thermal rearrangement at 250° to give three products, one of which sublimed during the reaction and was proved to be carbazole. The other two compounds were found to be 1,9′- and 3,9′-dicarbazolyl (**8** and **9**), by comparison with the authentic samples. Unlike dimer **1**, 9,9′-dicarbazolyl (**6**), did not undergo the benzidine rearrangement under the conditions used for rearrangement of **1**.

Reaction of potassium permanganate with indole, 2-methylindole, 3-methylindole, and 2-phenylindole gave largely unreacted starting material or, on longer reaction time gave double bond cleavage product **10**. 3-Phenylindole gave a product which lacked i.r. N—H absorption, but no homogeneous compound could be isolated. 2,3-Dimethylindole, however, reacted with potassium permanganate to give *o*-acetamidoacetophenone (**10**, R=CH_3) and the dimer of 3-hydroxy-2,3-dimethylindolenine (**11**) (2).

Experimental

General

Molecular weight determinations using a Hewlett-Packard model 301A osmometer were carried out with chloroform as solvent. Aluminum oxide PF-254, Type E (Merck, Germany) was used for analytical and preparative layer (20 g, 20 × 20 cm plate) chromatography. For other general experimental methods see ref. 2. Unless otherwise stated i.r. spectra were taken with chloroform solution, u.v. spectra with methanol, and n.m.r. spectra with deuteriochloroform solution containing tetramethylsilane as internal standard.

2,3-Diphenylindole

This starting material was either purchased from the Koch-Light Laboratories Ltd. or was made by Fischer indole synthesis, m.p. 113–115° (lit. (11) 123°).

Reaction of 2,3-Diphenylindole with Potassium Permanganate

To a solution of 2,3-diphenylindole (2.0 g) in acetone (10 ml) was added with stirring potassium permanganate (800 mg) over a period of 15 min. After the mixture was stirred at room temperature for 0.5 h, it was filtered and concentrated giving an amber colored highly viscous mass. This was put on eight silica gel preparative layer plates and developed with petroleum ether–ethyl acetate (75:25). The band at R_f 0.60 gave a pale yellow solid (1.2 g, 60%). Two recrystallizations from chloroform–petroleum ether gave *N,N′*-dimer **1** (dimer A) as a faintly yellow solid (618 mg), m.p. 204–206°; ν_{max} 1600 and 1440 cm^{-1}; λ_{max} 230 (16 650), 252 (10 410), and 300 nm (7910); *m/e* 536 (molecular ion); osmometric molecular weight 511.

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 89.38; H, 5.69; N, 5.09.

The more polar material from the above plates was put on four silica gel preparative layer plates and developed twice with benzene. A band at R_f 0.43 gave a pale yellow oil (265 mg, 13%) which gave pale yellow crystals on trituration with petroleum ether (b.p. 30–60°). One recrystallization from ether–petroleum ether (b.p. 30–60°) and two recrystallizations from chloroform–petroleum ether gave dimer B as a very faintly yellow solid (133 mg), m.p. 219–221° (dec.); ν_{max} 3460 (NH) and 1600 cm^{-1}; λ_{max} 227 (18 350), 257 (21 030), and 315 nm (14 320); *m/e* 536 (molecular ion); osmometric molecular weight 560.

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 89.26; H, 5.94; N, 5.18.

The more polar material from the above plates was put on two silica gel preparative layer plates, and developed twice using benzene–ether (97.5:2.5). Band at R_f 0.39 gave an almost colorless glassy oil (94 mg, 4.7%). I.r. showed absorption due to trace of —C=O (1690 cm^{-1}) and absence of N—H. The material failed to crystallize and was not further investigated. The band at R_f 0.29 gave an oily solid (74 mg, 3.7%). It was washed twice using ether and then recrystallized once from chloroform–petroleum ether and once from methanol–petroleum ether to give the trimer as an almost colorless solid (15 mg), m.p. 246–248°; ν_{max} 1590 cm^{-1}; λ_{max} (saturated solution) 250, 257, and 300 nm; molecular weight by osmometer 806, *m/e* 803 (molecular ion).

Anal. Calcd. for $C_{60}H_{41}N_3$ (803.9): C, 89.64; H, 5.14; N, 5.23. Found: C, 89.21; H, 5.94; N, 4.83.

Reaction of the N,N′-Dimer A (1) with Lithium Aluminum Hydride

To a stirred solution of dimer A (50 mg) in tetrahydrofuran (2.5 ml) was added lithium aluminum hydride (150 mg). After stirring the mixture at room temperature for 4 h, water was added and the mixture was extracted with ether. The organic layer was dried and concentrated giving an oily solid (50 mg). The crude mixture was put on a silica gel preparative layer plate and developed using petroleum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ether–ethyl acetate (75:25). The band at R_f 0.44 gave an oily solid (48 mg). Two recrystallizations from chloroform–petroleum ether gave an almost colorless solid (35 mg), identical in all respects with 2,3-diphenylindole.

Reaction of the N,N′-Dimer A (1) with Peracid

To a stirred solution of the dimer A (100 mg) in chloroform (1.0 ml) was added a solution of *m*-chloroperbenzoic acid (120 mg) in chloroform (1.0 ml). After stirring the solution at room temperature for 0.5 h, it was extracted first with 10% sodium sulfite and then with 5% sodium bicarbonate. The organic layer was washed and dried giving an oily solid. This material was put on a silica gel preparative layer plate and developed using petroleum ether–ethyl acetate (70:30). The band at R_f 0.29 gave an oily solid (70 mg). It was recrystallized four times from chloroform–petroleum ether giving amide **2** as a colorless solid (43 mg), m.p. 217–219°; ν_{max} 1640 cm^{-1} (amide C=O); λ_{max} 245 (9481) and 290 nm (3793); *m/e* 568 (molecular ion).

Anal. Calcd. for $C_{40}H_{28}N_2O_2$ (568.7): C, 84.48; H, 4.96; N, 4.93. Found: C, 84.79; H, 5.20; N, 4.74.

Acetate of Dimer B

A mixture of dimer B (150 mg), sodium acetate (300 mg), pyridine (2.0 ml), and acetic anhydride (0.5 ml) was refluxed for 36 h. After cooling, it was taken in chloroform, washed first with water and then with 5% sodium bicarbonate solution. The organic layer was washed with water, dried, and concentrated giving an oil which was put on two silica gel preparative layer plates and developed using benzene–ether (95:5). The band at R_f 0.38 gave a solid (110 mg), which after two recrystallizations from ether gave colorless crystals (63 mg), m.p. 177–181° (dec.); ν_{max} 1700 cm^{-1} (amide C=O); λ_{max} 250 (11 940) and 300 nm (7961); δ 1.95 (N—$COCH_3$); *m/e* 578 (molecular ion).

Anal. Calcd. for $C_{42}H_{30}N_2O$ (578.7): C, 87.17; H, 5.23; N, 4.84. Found: C, 86.78; H, 5.26; N, 5.04.

The above acetate was saponified with NaOH in refluxing methanol to give back dimer B (m.p., t.l.c.).

Reaction of the N,N′-Dimer 1 with HCl

To a refluxing solution of dimer A (250 mg) in acetone (10 ml) was added concentrated HCl (1.0 ml). After refluxing the cherry-red solution for 5.5 h, acetone was distilled on a rotary evaporator. The cooled residue was taken in chloroform, washed with water, dried, and concentrated giving dark brown oil. The crude mixture was put on two silica gel preparative layer plates and developed with benzene–petroleum ether (50:50). The band at R_f 0.49 gave an amber colored oil. This material was put on two alumina preparative layer plates and developed once using petroleum ether–benzene (75:25) and once using petroleum ether–benzene (50:50). The band at R_f 0.76 gave an almost colorless oil. This was boiled with petroleum ether, solvent pipetted out, and the material was dried giving a colorless solid (42 mg), m.p. 231–235° (dec.). Recrystallization from ether–petroleum ether (30–60°) gave dimer C as a colorless crystalline solid (28 mg), m.p. 232–235° (dec.); ν_{max} 3400 (NH) and 1600 cm^{-1}; λ_{max} 247 (18 880), 252 (17 620), and 330 nm (11 740); *m/e* 536 (molecular ion).

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 88.86; H, 5.34; N, 5.06.

N-Methyl Derivative of Dimer C

The procedure of Coggins and Benoiton (12) was used. To a hot (70°) solution of dimer C (100 mg), tetrahydrofuran (1.0 ml), and dimethylformamide (1.0 ml) was added sodium hydride (*ca.* 300 mg) and the mixture was heated at 70° for 5 min. To this hot solution was added methyl iodide (1.0 ml) and the mixture was refluxed (bath 70°). Within 15 min most of the mass had solidified. To this was added tetrahydrofuran (1.0 ml) and dimethyl formamide (1.0 ml) and reflux continued. At the end of 1 h, the mixture was cooled and water added. The mass was extracted with ether, washed with water, dried, and concentrated giving a brown oil (93 mg). This was put on a silica gel plate and developed using benzene–petroleum ether (50:50). The band at R_f 0.56 gave a colorless oil (65 mg). T.l.c. of this in above solvent system showed a single spot slightly less polar than dimer C. The compound failed to crystallize; however, adding methanol to an ether solution of the compound gave a solid, which was boiled thoroughly with methanol giving a colorless solid, which lacked any definite crystal structure and changed to glassy material at 172°, ν_{max} 1600 cm^{-1}; λ_{max} (saturated solution) 250 and 330 nm; *m/e* 550 (molecular ion).

Anal. Calcd. for $C_{41}H_{30}N_2$ (550.7): C, 89.51; H, 5.49; N, 5.09. Found: C, 89.49; H, 5.48; N, 4.62.

Thermal Reaction on Diphenylindole N,N′-Dimer 1

Dimer **1** (3.3 g) was sealed in a glass tube and heated at 240° for 1 h. The brown-black mass was allowed to stand at room temperature in acetone over a period of 3 days and the precipitated solid was removed every few hours using centrifugation. This solid was recrystallized twice from acetone giving dimer E as a colorless crystalline solid (543 mg), m.p. 298° (dec.); ν_{max} (Nujol) 3340 (N—H) and 1570 cm^{-1}; λ_{max} 253 (15 570) and 315 nm (9662); *m/e* 536 (molecular ion).

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 89.09; H, 5.72; N, 5.26.

The residue left after removal of dimer E was chromatographed on alumina. Fractions in petroleum ether–benzene (92:8) gave a crystalline solid (75 mg). Three recrystallizations from chloroform–petroleum ether gave dimer D as a colorless solid (50 mg), m.p. 270–271°; ν_{max} 3440 (N—H) and 1585 cm^{-1}; λ_{max} (saturated solution) 250, 257, and 310 nm; *m/e* 536 (molecular ion).

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 88.98, H, 5.76; N, 5.11.

Fractions in petroleum ether–benzene (86:14) to petroleum ether–benzene (80:20) gave 575 mg of crystalline 2,3-diphenylindole.

Fractions in petroleum ether–benzene (72:28) gave a solid (47 mg). Two recrystallizations from acetone gave colorless crystals (28 mg), identical in all respects with dimer E described above.

Later fractions in petroleum ether–benzene (72:28) gave a solid which was recrystallized five times from acetone–petroleum ether giving dimer F as a colorless crystalline solid (18 mg), m.p. 296° (dec.); ν_{max} 3380 (N—H) and 1590 cm^{-1}; λ_{max} (saturated solution) 245 and 315 nm; *m/e* 536 (molecular ion).

Anal. Calcd. for $C_{40}H_{28}N_2$ (536.7): C, 89.52; H, 5.26; N, 5.22. Found: C, 89.66; H, 5.51; N, 5.04.

T.l.c. of dimers E and F using petroleum ether–benzene (50:50) showed dimer F to be more polar than E, and mixed m.p. was 272–305°.

More polar fractions gave greenish-brown oil which was not investigated further.

Acetate of Dimer E

A mixture of dimer E (100 mg), sodium acetate (200 mg), pyridine (1.0 ml), and acetic anhydride (0.5 ml) was refluxed for 30 h. The cooled mixture was taken in chloroform, washed with 5% sodium bicarbonate, washed with water, dried, and concentrated giving amber colored oily solid. Three recrystallizations from chloroform–petroleum ether gave a colorless crystalline solid (54 mg), m.p. 280–283°; ν_{max} 1705 cm^{-1} (amide C=O); λ_{max} (saturated solution) 257 and 300 nm; δ 1.95 (—N(—$COCH_3$)—); *m/e* 578 (molecular ion).

Anal. Calcd. for $C_{42}H_{30}N_2O$ (578.7): C, 87.17; H, 5.23. Found: C, 87.15; H, 5.23.

The above acetate was saponified to dimer E with NaOH in refluxing methanol.

Thermal Reaction of Carbazole 9,9′-Dimer **6**

Carbazole 9,9′-dimer (8) (2.3 g) was sealed in a glass tube and heated at 250° for 3 h. A colorless crystalline solid (50 mg) had sublimed onto the cooler part of the tube and was proved to be carbazole. The brown–black residue was chromatographed on alumina. Fractions in petroleum ether–benzene (92:8) gave a solid (103 mg). Four recrystallizations from chloroform–petroleum ether gave a colorless crystalline solid (66 mg), m.p. 191–194°; ν_{max} 3440 (NH) and 1575 cm^{-1}; λ_{max} 236 (34 850), 257 (20 770), 287 (11 330), 293 (15 100), 337 (3777), and 349 nm (4155); *m/e* 332 (molecular ion). The compound was identical (m.p., mixed m.p., t.l.c.) with an authentic sample of 1,9′-dicarbazolyl (**8**) supplied by Tomlinson (13).

Fractions in petroleum ether–benzene (84:16) to petroleum ether–benzene (78:22) gave carbazole as a colorless crystalline solid (1.3 g).

Later fractions in petroleum ether–benzene (78:22) gave an oily solid (250 mg). This was put on four silica gel preparative layer plates and developed twice using petroleum ether–benzene (50:50). The band at R_f 0.50 gave a crystalline solid. Three recrystallizations from chloroform–petroleum ether gave a colorless solid (69 mg), m.p. 204–207°; ν_{max} 3480 (NH) and 1590 cm^{-1}; λ_{max} (saturated solution) 236, 257, 287, 293, 337, and 349 nm; *m/e* 332 (molecular ion). This material was identical with authentic sample of 3,9′-dicarbazolyl (**9**).

Preparation of 3,9′-Dicarbazolyl (9)

Modified procedure of Sugita (9) was used. A mixture of trimer **7** (100 mg), HI (1.5 ml, 47.6%), and few drops of 95% ethanol was heated with stirring at 160°. Within a few hours a solid had started subliming into the condenser. After heating the mixture for 50 h, the contents of the flask were cooled, taken in chloroform, and washed with 5% sodium bicarbonate. The organic layer was washed, dried, and concentrated giving a green viscous mass. This was put on a silica gel preparative layer plate and developed twice using benzene–petroleum ether (50:50). The band at R_f 0.52 gave an oily solid. Three recrystallizations from chloroform–petroleum ether gave 3,9′-dicarbazolyl (**9**) as a colorless crystalline solid (19 mg), m.p. 204–206°, (lit. (9) 212–215°). The solid that had sublimed into the condenser was proved to be carbazole.

The author would like to thank Professor E. W. Warnhoff for encouragement and constructive criticism throughout the work. He would also like to thank Professor C. F. Koelsch for details of permanganate experiment, Dr. Muriel L. Tomlinson for an authentic sample of **8**, and the National Research Council of Canada for financial support.

The Importance of Conformation in the Ozonolysis of Acetals[1]

PIERRE DESLONGCHAMPS,[2] CLAUDE MOREAU, DANIEL FRÉHEL, AND PAUL ATLANI[3]
Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

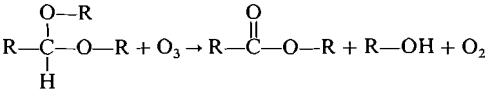
Received July 10, 1972

Six gauche conformations are theoretically possible for an acetal function and only three of them are reactive toward ozone. Each oxygen of the acetal function must have an electron pair orbital oreitned antiperiplanar to the C—H bond in order to be reactive toward ozone.

Il y a six conformations gauches pour une fonction acétal dont trois seulement sont réactives avec l'ozone. Chaque atome d'oxygène de la fonction acétal doit posséder une orbitale d'électrons libres orientée de manière antipériplanaire par rapport au lien C—H pour qu'elle soit réactive avec l'ozone.

Canadian Journal of Chemistry, **50**, 3402 (1972)

We have recently reported (1) that acetals are smoothly oxidized by ozone yielding the corresponding ester and alcohol in high yield.



We have also described that conformationally rigid β-glycosides (methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside and methyl 2-deoxy-3,4,6-tri-*O*-acetyl-β-D-glucopyranoside) are oxidized (O_3, Ac_2O–AcONa) to their corresponding aldonic acid methyl ester whereas the α-glycosides (methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside and methyl 2-deoxy-3,4,6-tri-*O*-acetyl-α-D-glucopyranoside) are inert toward ozone. Cyclic acetals (1,3-dioxolane and 1,3-dioxane) are also very readily oxidized. These results led us to postulate that an acetal would react with ozone only if it can take a conformation in which each oxygen of the acetal function can have an electron pair orbital oriented antiperiplanar to the C—H bond (1).

Scheme 1 shows the nine gauche conformers that are theoretically possible for an acetal function. However, conformers **A′**, **B′**, and **D′** are respectively mirror image of conformer **A**, **B** and **D**. Consequently, there are only six different gauche conformers (**A**, **B**, **C**, **D**, **E** and **F**) for an acetal function and of those, only the conformer having an orbital on each oxygen oriented antiperiplanar to the C—H bond should be reactive. Thus, **A**, **C** and **F** should be reactive, whereas **B**, **D** and **E** should be inert toward ozone. We wish to report experimental results which support this hypothesis.

Scheme 2 shows the conformers of Scheme 1 in which a six-membered ring has been incorporated. In this manner, conformers **A**, **B** and **C** represent the three conformers of a conformationally rigid β-glycoside while conformers **D**, **E** and **B′** correspond to the three conformers of a rigid α-glycoside (2).

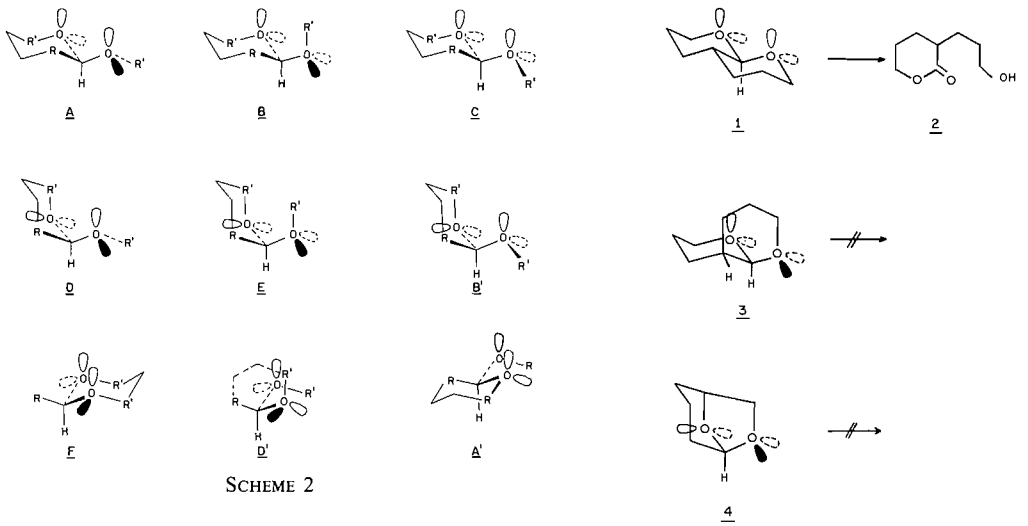
[3]Holder of a "bourse postdoctorale France-Québec", 1971–1972.

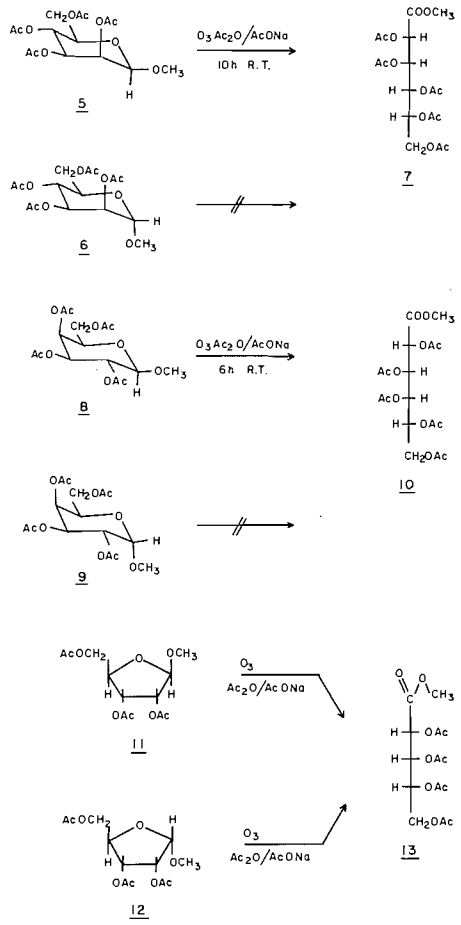


SCHEME 2

Conformationally rigid α-glycosides are inert toward ozone, conformers **D**, **E** and **B′** are therefore not reactive. Conformer **B′** is an equivalent of **B** (mirror image in Scheme 1), **B** is therefore not reactive and the same conclusion is also valid for **D′**. 1,3-Dioxane acetals represent a good model for conformer **F** and since they react with ozone, **F** is a reactive conformer. Compound **1** (*trans*-1,8-dioxaoctahydronaphthalene, (3)), a rigid model for conformer **C**, is readily oxidized into hydroxylactone[4] **2** (EtOAc, −78°, 1.5 h, 100%). Compound **3** (*cis*-1,8-dioxaoctahydronaphthalene, (3)) and compound **4** (6,8-dioxabicyclo [3.2.1] octane, (4)) are respectively rigid models for conformers **B** and **E** and they were unchanged by ozone treatment. Consequently, oxidation studies have been carried out on rigid models for conformers **B**, **C**, **E**, and **F**.

Conformer **D** represents the most stable conformation for an α-glycoside (2); since they are not reactive, **D** can be eliminated as a reactive conformer. Conformer **A** or its mirror image **A′** represents the more stable conformation for a β-glycoside; since they react with ozone, it is very likely that **A** is a reactive conformer.[5]

The preceding findings are confirmed by the observations that methyl tetra-*O*-acetyl-β-D-mannopyranoside (**5**) and β-D-galactopyrano-



[4]This compound gave satisfactory analytical data.

[5]Work is now in progress towards the synthesis of a rigid model for conformer **A**.

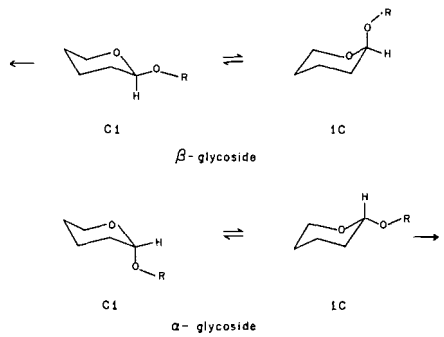

SCHEME 3

side (**8**) are converted in high yield into their corresponding penta-*O*-acetyl aldonic acid methyl ester **7**[4] and **10**[4] whereas the corresponding α-anomers **6** and **9** are inert. Those sugars represent further examples of conformationally rigid β- and α-glycosides.

There are some α- and β-methyl glycosides which are known to be conformationally labile and in such cases, both anomers should be reactive. Their respective rate of reaction should depend mainly on the population of the C1 conformation for the β anomer and the 1C conformation for the α anomer (Scheme 3). Methyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside (81% in conformation C1, (5)) is converted into methyl 2,3,4,5-tetra-*O*-acetyl-β-D-xylonate[4] in 8 h whereas only 92% conversion was observed after 71 h of reaction with methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (<2% in conformation 1C, (5)). Only 76% of methyl 2,3,4-tri-*O*-acetyl-β-D-arabinopyranoside (3% in conformation C1, (5)) is converted into methyl 2,3,4,5-tetra-*O*-acetyl-D-arabinonate[4] after 75 h of reaction whereas methyl 2,3,4-tri-*O*-acetyl-α-D-arabinopyranoside (83% in conformation 1C, (5)) is completely transformed after 7 h. The last two examples represent the first case of an α-glycoside being more reactive than the corresponding β-glycoside. Since no conformational rigidity exists in α- and β-glycofuranoside, both anomers should be reactive with ozone. Methyl 2,3,5-tri-*O*-acetyl-β- and -D-ribofuranoside (**11**, **12**) are both converted into methyl 2,3,4,5-tetra-*O*-acetyl-D-ribonate[4] (**13**) at approximately the same rate (16 h, r.t., 85%).

The Importance of Conformation of the Tetrahedral Intermediate in the Hydrolysis of Esters. Selective Cleavage of the Tetrahedral Intermediate Controlled by Orbital Orientation[1]

PIERRE DESLONGCHAMPS,[2] PAUL ATLANI,[3] DANIEL FRÉHEL, AND ALAIN MALAVAL

Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received July 10, 1972

The hydrolysis or the transesterification of esters proceeds via a hemi-orthoester tetrahedral intermediate. There are nine different gauche conformers possible for such a tetrahedral intermediate and it is proposed that each of them should decompose in a highly selective manner. It is further proposed that the lone pair orbitals of the oxygen atoms control this selective decomposition.

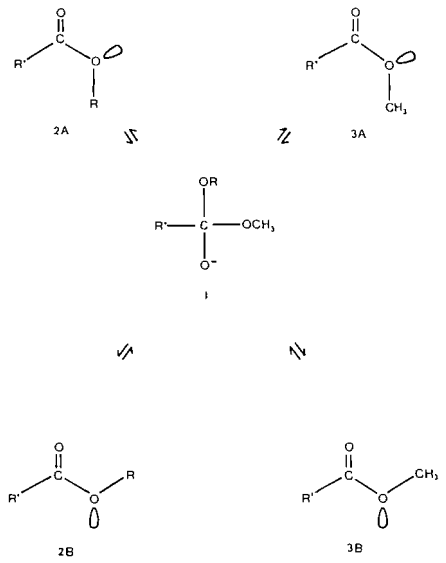
L'hydrolyse ou la transestérification d'un ester procède par un intermédiaire tétrahédrique du type hemi-orthoester. Il y a 9 conformères gauches possibles pour un hemi-orthoester et il est proposé que chaque conformère se décompose d'une manière très sélective. Il est de plus avancé que les orbitales d'électrons non-liés des atomes d'oxygène contrôlent cette décomposition sélective.

Canadian Journal of Chemistry, **50**, 3405 (1972)

The hydrolysis or the transesterification of esters proceeds normally via a hemi-orthoester tetrahedral intermediate. In principle, in a transesterification reaction, such intermediate **1** (Scheme 1) can lead to the *cisoïde* ester **2A**, the *transoïde* ester **2B**, the *cisoïde* ester **3A**, or the *transoïde* ester **3B**.

Theoretically, there are nine different gauche conformers[4] for a tetrahedral intermediate such as **1** (Scheme 2). We want to disclose experimental evidence which permits us to propose that each conformer should cleave in a specific manner to yield either one or two of the four possible esters **2A**, **2B**, **3A**, or **3B**. We would like further to propose that the lone pair orbitals on the oxygen atoms in the nine different conformers of **1** govern this remarkable selective decomposition; specific cleavage of a C—O alkyl bond in a tetrahedral conformer being allowed only if the other two oxygens of this tetrahedral conformer have each an orbital oriented antiperiplanar to the C—O alkyl bond to be broken.

For example, conformer **A** can give only the *transoïde* ester **2B** since the C—OCH_3 bond can be easily cleaved because the negative oxygen and the OR oxygen have each an orbital oriented antiperiplanar to the C—OCH_3 bond, yielding specifically the *transoïde* ester **2B**, the OR group being antiperiplanar to the C—R′ bond (Scheme 3). Cleavage of the C—OR bond



SCHEME 1

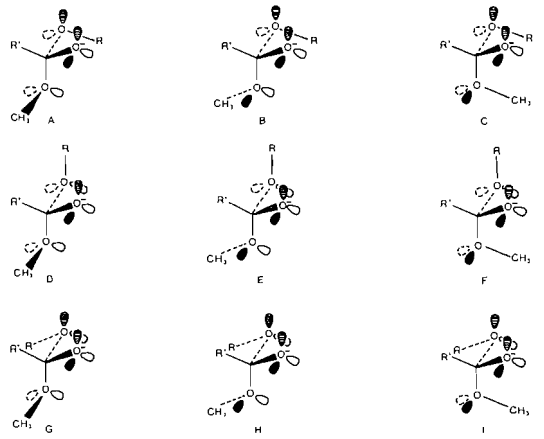
[2]A. P. Sloan Fellow, 1970–1972. To whom all correspondence should be addressed.

[3]Holder of a "bourse postdoctorale France-Québec", 1971–1972.

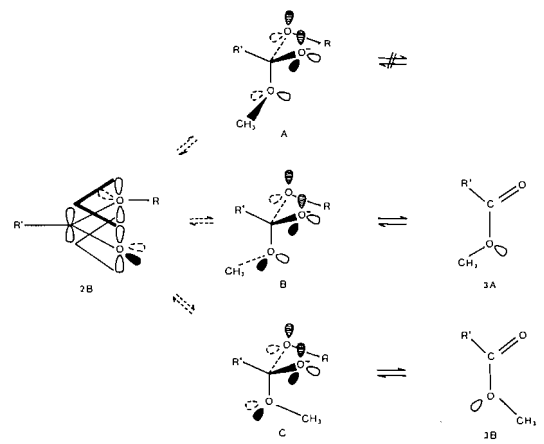
[4]When R = CH_3, **A**, **B**, and **E** are respectively mirror images of **F**, **I**, and **G**, thus in such a case only six conformers are possible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 2

in conformer **A** would be a much higher energy process and therefore should not be observed because the departure of the OR group can be assisted by only one electron pair orbital (negative oxygen), the oxygen of the OCH_3 group having no lone pair orbital oriented antiperiplanar to the C—OR bond. Conformer **B** can give either the *transoïde* ester **2B** or the *cisoïde* ester **3A**. The *transoïde* ester **2B** can be obtained since the negative oxygen and the OR oxygen have each an orbital antiperiplanar to the C—OCH_3 bond. The *cisoïde* ester **3A** can also be produced from B since the negative oxygen and the OCH_3 oxygen have each an orbital antiperiplanar to the C—OR bond. In this case, the *cisoïde* ester **3A** is obtained because the C—R′ bond is antiperiplanar to the second orbital of the OCH_3 oxygen, the O—CH_3 bond being in a gauche orientation to the C—R′ bond.



SCHEME 3

TABLE 1. Specific cleavages that should be observed

Ester **2**		Conformer **1**		Ester **3**
Transoïde	⇌	**A**	≠	
Transoïde	⇌	**B**	⇌	*cisoïde*
Transoïde	⇌	**C**	⇌	*transoïde*
	≠	**D***	≠	
	≠	**E**	⇌	*cisoïde*
	≠	**F**	⇌	*transoïde*
Cisoïde	⇌	**G**	≠	
Cisoïde	⇌	**H**	⇌	*cisoïde*
Cisoïde	⇌	**I**	⇌	*transoïde*

*If the rigid conformer such as **D** is produced, it should cleave but the transition state will be of higher energy. Ozonolysis of *trans*-1,8-dioxaoctahydronaphthalene gives an intermediate equivalent to **D** (2).

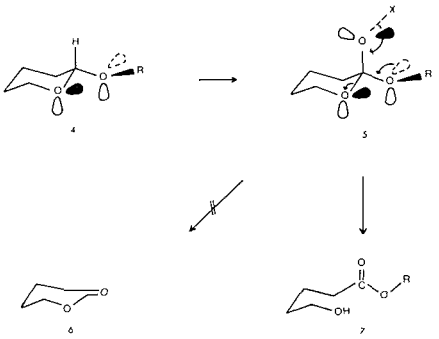
Conformer **C** can give either the *transoïde* ester **2B** or **3B**. Table 1 describes the specific cleavages that should be observed with all the nine different conformers.

In the reverse reaction, attack of methoxide ion on the *transoïde* ester **2B**, only three tetrahedral conformers (**A**, **B** and **C**) can first be formed (Scheme 3). The energy level of the transition states for reaction of each conformer resembles the energy level of each conformer. Thus, a study of the relative stability of all nine conformers should give information for a more precise knowledge on the general mechanism of ester hydrolysis.

During our study on the ozonolysis of acetals (1, 2) we have observed that the reaction of ozone with simple tetrahydropyranyl ethers (**4**) and with conformationally rigid methyl β-glycopyranosides yielded only the corresponding alkyl 4-hydroxypentanoate derivatives **7** (Scheme 4); lactone formation (**6**) was never observed. Identical results have been obtained with tetrahydrofuranyl ethers. Ozonolysis of 2-methoxy tetrahydrofuran (Ac_2O–AcONa) gave only methyl 4-*O*-acetylbutanoate, the corresponding γ-lactone was not detected.[5] This reaction is apparently therefore kinetically controlled, the transition state leading to the less stable hydroxy-ester **7** being energetically favored over the transition state leading to the

[5]Analogous results have been obtained with 2-ethoxy tetrahydrofuran and with both anomers of methyl 2,3,5-tri-*O*-acetyl-ribofuranoside (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



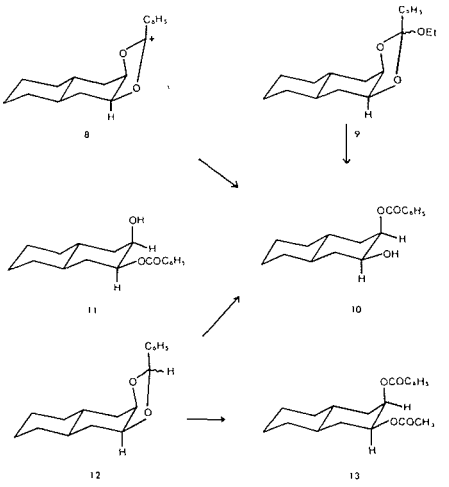
SCHEME 4

lactone **6**. We have postulated (1) that the ozonolysis of acetals proceeds via a hydrotrioxide intermediate such as **5** (X = OOH). This intermediate could also be an analog such as the hemi-orthoester **5** (X = H). By utilizing the preceding stereoelectronic theory, it is easy to understand the preferred specific decomposition of the tetrahedral intermediate **5** into the less stable product, the hydroxy-ester **7**.

We have previously established (2) that in order to react with ozone the acetal function must have a conformation in which each oxygen has an orbital oriented antiperiplanar to the C—H bond. Thus, the most stable conformation (3) for an alkyl β-glycopyranoside which corresponds to **4** should specifically give the tetrahedral conformer **5**, which can give **7** since both oxygens of the OX[6] and the OEt groups have each an orbital oriented antiperiplanar to the ring oxygen–C_2 bond. The conversion of **5** into the lactone **6** is a higher energy process because the ring oxygen atom does not have an orbital antiperiplanar to the C—OR bond in order to assist in its departure. In fact, intermediate **5** is a model for conformer **A** in Scheme 2.

King and Allbutt (4) have recently described the stereoselective hydrolysis of dioxolenium ions and orthoesters fused to anchored six-membered rings. For example, mild acid hydrolysis of the dioxolenium salt **8** or the orthoesters **9** afforded the axial ester – equatorial alcohol **10** with only a very small amount of the isomer **11**

[6]The O—X bond in **5** can also take two other gauche orientations but this is irrelevant. This O—X bond can be considered as a potential lone pair orbital by loss of a proton when X = H or by decomposition of the hydrotrioxide function when X = OOH.



SCHEME 5

(Scheme 5). We have found that the ozonolysis in ethyl acetate of the benzylidenes **12** gave mainly the axial ester – equatorial alcohol **10** (>94%). Ozonolysis of **12** in acetic anhydride – sodium acetate (1) gave only the axial benzoate – equatorial acetate **13**,[7] thus establishing that the ozonolysis of acetals doubtless proceeds via the formation of an intermediate analogous to a hemi-orthoester.

Further evidence that a hemi-orthoester such as **5** (X = H) gives only the hydroxy-ester **7** is apparent from the observation that mild basic hydrolysis (NaOH 0.1 *N*, 10 min, r.t.) of 2-ethoxy-2-dihydropyran (**15**)[8] gave only ethyl 5-hydroxypentanoate (**17**)[9] (Scheme 6). This selective reaction can be explained by the intermediate formation of hemi-orthoester **16**[10] (**5**, X = H) and its subsequent orbital-assisted decomposition to **17**. Formation of ethyl 4-hydroxypentanoate (**17**) was also observed using mild acid hydrolysis (~2 min, r.t., trace of *p*-toluenesulfonic acid in water) from 2,2-diethoxytetrahydropyran (**14**),[8] no δ-valerolac-

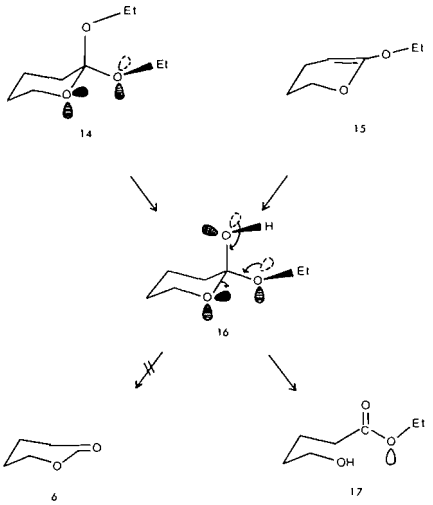
[7]The structure of **13** has been confirmed by an alternative synthesis.

[8]This product was synthesized by following the procedure described by McElvain and McKay (5) using ketene diethylacetal (6).

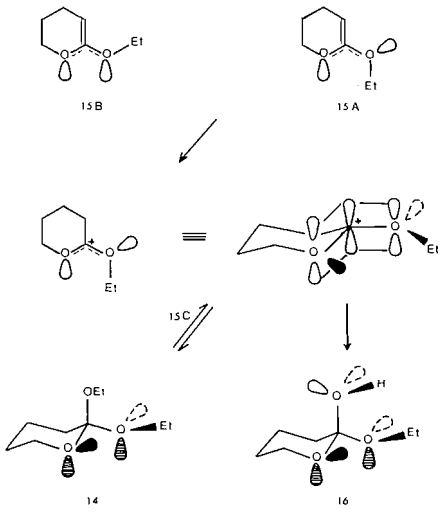
[9]The corresponding acetate gave expected analytical and spectroscopic data.

[10]The O—H bond in **16** can also take two other gauche orientations, but an O—H bond can be considered as a potential lone pair orbital by the loss of the proton.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 6



SCHEME 7

tone (**6**) being produced. Acid hydrolysis of **15** gave only **17**.[11]

Keteneketal **15** can have a *transoïde* (**15A**) or a *cisoïde* (**15B**) conformation (Scheme 7). As in an ester, the *transoïde* conformer **15A** must be highly favored (7). Proton capture at C_3 from water leads to the dioxolenium ion **15C**. Attack by hydroxide ion on **15C** should give specifically the conformer **16** in which the ring oxygen and the OEt oxygen have each an orbital antiperiplanar to the C—OH bond which has just been formed. Intermediate **15C** can also be obtained in acidic medium by loss of ethanol from **14**. In **14**, the O—Et bond of the equatorial ethyl group is in the most favored gauche conformation relative to the ring oxygen as in methyl β-glycoside (3). Furthermore, the ring oxygen and the equatorial OEt oxygen have each an orbital antiperiplanar to the axial OEt group which permits the cleavage of this axial OEt group. A good example for such a requirement in orthoester has been reported by Eliel (8).[12]

[11]Analogously, 2,2-diethoxy-4-methyl-tetrahydropyran[8] and 2-ethoxy-4-methyl-dihydropyran[8] gave only ethyl 5-hydroxy-3-methyl pentanoate.[9]

[12]King and Allbutt have considered a combination of steric and stereoelectronic effects to explain their results on the hydrolysis of dioxolenium ions; the stereoelectronic argument proposed being similar to ours (4).

Thus we suggest that the conformation of the tetrahedral intermediate is extremely important in the general mechanism of ester hydrolysis. We believe that it is specially important with regard to the hydrolysis of esters by enzymes, since it is very likely that the tetrahedral intermediate formed in such case possesses a specific conformation. We think that the above results have an attractive new chemical basis and should be given serious consideration (9). Work is now in progress to obtain more rigid chemical models in order to test further this stereoelectronic theory.

^{19}F N.M.R. Study of the Difluorochlorine(III) Cation, ClF_2^+

MORLEY BROWNSTEIN[1] AND JACOB SHAMIR

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Received July 25, 1972

The ^{19}F n.m.r. spectrum of ClF_2^+ has been observed for the first time. Solvolysis of the ClF_2^+ cation in neutral anhydrous hydrogen fluoride to give ClF_3 is extremely slight.

On a observé pour la première fois le spectre ^{19}F n.m.r. du ClF_2^+. La solvolyse du cation du ClF_2^+ dans du fluorure d'hydrogène anhydre neutre produisant du ClF_3 est extrêmement faible.

Halogen fluorocations have been a subject of continuing interest (1). 1:1 complexes of ClF_3 with AsF_5 and SbF_5 were first reported by Seel and Detmer (2) who formulated them as ionic compounds (*e.g.* $ClF_2^+.SbF_6^-$) on the basis of the conductivity of $ClF_3.SbF_5$ in ClF_3. Although the vibrational spectra of the solid complexes were initially interpreted on the basis of a purely ionic structure, it has since been conclusively shown by Raman spectroscopy (3) and X-ray crystallography (4, 5) that there is a significant degree of fluorine bridging in the solid between the ions.

Attempts have been made to obtain the ^{19}F n.m.r. spectrum of ClF_2^+ in molten ClF_2BF_4 (6) as well as for the complexes dissolved in BrF_5, SO_3 (7) or excess ClF_3 (6, 7). However, because of rapid fluorine exchange no meaningful results were reported for temperatures down to -80 °C.

We have successfully observed the ^{19}F n.m.r. signal of the ClF_2^+ cation for solutions of ClF_2SbF_6 and ClF_2AsF_6 in anhydrous HF. The complexes were prepared directly in Kel-F n.m.r. tubes with the more volatile component in excess, followed by pumping off the excess starting material. Material handling procedures were similar to those previously described (8). ^{19}F n.m.r. spectra were obtained on a Varian HA-100 n.m.r. spectrometer operating at 94.1 MHz.

At room temperature, the ^{19}F n.m.r. spectrum of ClF_2SbF_6 in HF is a single broad line because of rapid fluorine exchange. On lowering the temperature a broad ClF_2^+ peak at +25 p.p.m. from $CFCl_3$ becomes visible in addition to the solvent peak, and narrows on further cooling of the sample (Table 1). Exchange of fluorine between ClF_2^+ and the solvent can occur via ClF_3 by the reactions

$$[1] \qquad ClF_2^+ + HF_2^- \rightleftharpoons ClF_3 + HF$$

$$[2] \qquad ClF_2^+ + 2HF \rightleftharpoons ClF_3 + H_2F^+$$

With the addition of excess SbF_5, any traces of fluoride are mopped up and the solution is made strongly acidic (9).

$$[3] \qquad SbF_5 + 2HF \rightarrow H_2F^+ + SbF_6^-$$

It is now possible to observe the ClF_2^+ peak even at room temperature (Table 1). N.m.r. signals from fluorine on antimony were observed only with excess SbF_5 present, in agreement with earlier observations of fluorocation SbF_6^- salts in HF (10).

Since merely cooling the solution of ClF_2SbF_6 in HF is enough to allow observation of the ClF_2^+ peak, we conclude that solvolysis of ClF_2^+ in HF must be extremely slight and that the equilibrium position of reaction 2 lies far to the left. This conclusion is reinforced by the

TABLE 1. ^{19}F n.m.r. of ClF_2SbF_6 in HF

		ClF_2^+

knowledge that ClF_3 was present in excess during the preparation of ClF_2SbF_6. Thus traces of SbF_5 can not be present to acidify the solution.

ClF_2AsF_6 in HF also has a ClF_2^+ peak at +24 p.p.m. whose behavior as a function of temperature and solvent acidity (*i.e.* addition of excess AsF_5) is the same as that found for ClF_2^+ from ClF_2SbF_6.

VOLUME 50 NOVEMBER 1, 1972 NUMBER 21

Étude par spectromètrie i.r. des effets de solvant sur les fréquences fondamentale et harmoniques de l'acide iodhydrique

NGUYEN-VAN-THANH ET INGA ROSSI

Laboratoire d'Infrarouge, Equipe de Recherche Associée au C.N.R.S., Université de Paris VI, 91, Campus d'Orsay, Essonne, France

Reçu le 1 mai 1972

Les fréquences des transitions $(0 \rightarrow 1)$, $(0 \rightarrow 2)$, et $(0 \rightarrow 3)$ de la molécule HI en solution CCl_4 ont été déterminées par spectrométrie i.r. Les calculs des déplacements de fréquence basés sur un modèle cellulaire Lennard–Jones–Devonshire de l'état liquide sont en bon accord avec les résultats expérimentaux.

The wavenumbers of the fundamental, first and second overtones have been measured for HI in liquid CCl_4. The solvent shifts calculated, assuming a Lennard–Jones–Devonshire cell model of the solution, are in good agreement with the experimental data.

Canadian Journal of Chemistry, **50**, 3411 (1972)

Introduction

Dans l'étude des effets de solvant sur les fréquences de vibration des molécules diatomiques Buckingham (1–3) a prévu que le déplacement $\Delta\nu_{0\rightarrow v}$ de fréquence, dû au solvant, est proportionnel au nombre quantique v de vibration du niveau excité, si la constante d'anharmonicité mécanique du soluté est la même pour les états gazeux et dissous. Mais récemment, plusieurs auteurs (4–6) ont montré que pour certains vibrateurs XH, la constante d'anharmonicité dépend de la nature du solvant.

D'autre part, Monson et coll. (7), en utilisant un potentiel intermoléculaire de type Lennard–Jones–Devonshire (LJD), ont pu rendre compte de l'effet de solvant sur les déplacements de fréquence de H_2 et D_2 en solution.

Nous nous proposons de comparer les valeurs théoriques et expérimentales des déplacements de fréquences de vibration des transitions $(0 \rightarrow 1)$, $(0 \rightarrow 2)$, et $(0 \rightarrow 3)$ de la molécule HI en solution CCl_4. L'effet de solvant est interprété à l'aide du potentiel d'interaction LJD (6–12) pour l'état liquide (8, 9).

Conditions expérimentales

L'étude expérimentale a été réalisée à l'aide d'un spectromètre de type Pfund à réseau échelette de 240 traits/mm fonctionnant dans les ordres 1, 2, et 3 correspondant respectivement à 4.50 μ, 2.25 μ, et 1.5 μ. L'étalonnage du domaine spectral est obtenu par la méthode de Poggendorff en utilisant comme repères de nombre d'onde ceux des raies de vibration–rotation des transitions $(0 \rightarrow 1)$, $(0 \rightarrow 2)$, et $(0 \rightarrow 3)$ de la molécule HI à l'état gazeux (10, 11). La fonction d'appareil est une fonction triangle dont la largeur à mi-hauteur est de 0.5 cm^{-1} à 2200 cm^{-1}, de 1.0 cm^{-1} à 4400 cm^{-1} et de 1.5 cm^{-1} à 6500 cm^{-1}.

Les cuves circulaires utilisées pour les trois domaines spectraux ont respectivement les épaisseurs suivantes: 2 mm, 10 mm, et 200 mm. Les solutions saturées de HI s'obtiennent par un simple barbotage du gaz durant une quinzaine de minutes.

Afin d'éviter la formation de couples moléculaires de type $HI–H_2O$, le solvant CCl_4 a été déssèché sur un tamis moléculaire (4 Å). La concentration de HI en solution CCl_4 a été déterminée par acidimétrie. Elle est de l'ordre de 10^{-4} mol/cm^3. Avec une si faible concentration la formation de paires HI–HI semble très peu probable.

Rappels théoriques

Les expressions donnant le terme spectral de vibration pour une molécule diatomique à l'état

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

gazeux et à l'état dissous sont données par (6, 12):

$$[1]\quad G_v^{gaz} = \frac{E_v^{gaz}}{hc} = (\omega_e - W)(v+\tfrac{1}{2}) - X(v+\tfrac{1}{2})^2 + Y(v+\tfrac{1}{2})^3 + c$$

et

$$[2]\quad G_v^{sol} = \frac{E_v^{sol}}{hc} = (\omega_e - W - \bar{W})(v+\tfrac{1}{2}) - (X+\bar{X})(v+\tfrac{1}{2})^2 + (Y+\bar{Y})(v+\tfrac{1}{2})^3 + c + \bar{c}$$

D'après ces deux dernières relations, on déduit les relations donnant les nombres d'onde relatifs au déplacement de fréquence $\Delta v_{0\to v}$ des bandes du soluté lors du passage de l'état gazeux à l'état dissous:

$$[3a]\quad \Delta v_{0\to 1} = v_{0\to 1}^{gaz} - v_{0\to 1}^{sol} = \bar{W} + 2\bar{X} - \tfrac{13}{4}\bar{Y}$$

$$[3b]\quad \Delta v_{0\to 2} = v_{0\to 2}^{gaz} - v_{0\to 2}^{sol} = 2\bar{W} + 6\bar{X} - \tfrac{31}{2}\bar{Y}$$

$$[3c]\quad \Delta v_{0\to 3} = v_{0\to 3}^{gaz} - v_{0\to 3}^{sol} = 3\bar{W} + 12\bar{X} - \tfrac{171}{4}\bar{Y}$$

Les quantités $\bar{W}$, $\bar{X}$ et $\bar{Y}$ dépendent du potentiel intermoléculaire U.

Rappelons que l'hamiltonien de vibration de la molécule diatomique à l'état dissous s'écrit

$$[4]\quad H_v = H_v^0 + H_v^a + U$$

où H_v^0 est l'hamiltonien relatif à l'oscillateur harmonique. $(H_v^a + U)$ désigne l'hamiltonien perturbateur avec

$$[5]\quad H_v^a = K_3 q^3 + K_4 q^4 + \ldots$$

et tel que l'on ait $K_3 q^3 \gg K_4 q^4 \ldots$

Le potentiel intermoléculaire U peut être exprimé en fonction de deux variables τ et q

$$[6]\quad U(\tau,q) = U_e(\tau) + \frac{1}{1!}\left(\frac{\partial U(\tau)}{\partial q}\right)_e q + \frac{1}{2!}\left(\frac{\partial^2 U(\tau)}{\partial q^2}\right)_e q^2 + \ldots$$

où τ représente l'ensemble des variables qui permettent de fixer la position et l'orientation de la molécule de soluté par rapport aux molécules environnantes de solvant. La coordonnée normale sans dimension q est définie par

$$[7]\quad q = \left(\frac{\omega_e}{2B_e}\right)^{1/2}\xi$$

avec $\xi = (x - x_e)/x_e$ et x_e étant la distance internucléaire à l'équilibre de la molécule diatomique. Le calcul rigoureux de $U(\tau,q)$ est très laborieux; on peut alors expliciter U seulement en fonction de q, ce qui revient à raisonner sur une valeur moyenne de τ. L'expression du déplacement relatif de fréquence harmonique $\Delta\omega/\omega_e$ est donnée en première approximation par (6, 12):

$$[8]\quad \frac{\Delta\omega}{\omega_e} = \frac{\bar{W}}{\omega_e} \simeq -\frac{1}{2\omega_e}\left(\frac{\partial^2 u}{\partial q^2}\right)_e + \frac{3k_3}{\omega_e^2}\left(\frac{\partial u}{\partial q}\right)_e$$

en posant $(U/hc) = u$ et $K_3/hc = k_3$

Les constantes k_3 et α_e sont reliées par (13):

$$[9]\quad \alpha_e = -\frac{12}{\sqrt{2}}\left(\frac{B_e}{\omega_e}\right)^{3/2} k_3 - \frac{6B_e^2}{\omega_e}$$

Les quantités u, $(\partial u/\partial q)_e$, $(\partial^2 u/\partial q^2)_e$, k_3, α_e, B_e, et ω_e sont exprimées en cm^{-1}. On peut donc calculer la valeur théorique de $\Delta\omega$ si l'on connaît $(\partial u/\partial q)_e$, $(\partial^2 u/\partial q^2)_e$ et k_3.

Expression du potentiel intermoleculaire U

L'énergie d'interaction entre une molécule de soluté polaire 1 et une molécule de solvant 2 non polaire est la somme des énergies de répulsion, de dispersion et d'induction (14):

$$[10]\quad U_{1,2}(r) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right] - \frac{\alpha_2\mu_1^2}{\varepsilon_2 r^6}$$

où ε et σ sont les paramètres du potentiel de Lennard–Jones, et r est la distance intermoléculaire. ε_2 et α_2 sont respectivement la constante diélectrique et la polarisabilité du solvant; μ_1 désigne le moment dipolaire de la molécule de soluté. En introduisant le paramètre r^* défini par $r^* = 2^{1/6}\sigma$, la relation précédente devient

$$[11]\quad U_{1,2}(r) = \varepsilon\left[\left(\frac{r^*}{r}\right)^{12} - 2\left(\frac{r^*}{r}\right)^{6}\right] - \frac{\alpha_2\mu_1^2}{\varepsilon_2 r^6}$$

Pour décrire la distribution moléculaire au sein du liquide, nous pouvons adopter un modèle cellulaire dans lequel la molécule de soluté prend la place d'une molécule de solvant et se trouve ainsi placée dans une enceinte constituée par des molécules de solvant. Les positions moyennes des molécules sont celles des nœuds d'un réseau c.f.c. dans lequel cristallise le solvant CCl_4. Comme l'énergie d'induction est négligeable, l'énergie d'interaction entre la

TABLEAU 1. Fréquences d'absorption $\nu_{0\to1}$, $\nu_{0\to2}$, $\nu_{0\to3}$ et déplacements de fréquence $\Delta\nu_{0\to1}$, $\Delta\nu_{0\to2}$, et $\Delta\nu_{0\to3}$ de HI

For personal use only.

molécule de soluté et les Z molécules voisines de solvant s'écrit (15)

$$[12]\quad U(a) = Z\varepsilon\left[C\left(\frac{r^*}{a}\right)^{12} - D\left(\frac{r^*}{a}\right)^{6}\right]$$

où a est la distance intermoléculaire obtenue à l'aide de la relation

$$[13]\quad a = \left(\frac{M\sqrt{2}}{Nd}\right)^{1/3}$$

M désigne la masse moléculaire du solvant, d sa densité; N est le nombre d'Avogadro. Pour la molécule CCl_4, la distance intermoléculaire a est égale à 6.09 Å.

C et D sont deux facteurs numériques qui dépendent de la configuration géométrique de la maille considérée. Afin d'introduire l'effet de vibration de la molécule de soluté, nous supposons que la distance r^* (et non ε) seulement dépend de ξ. En posant

$$[14]\quad r^* = r_e^* + \Delta r$$

avec $\Delta r = (x_e\xi/2)$, où r_e^* est le paramètre de Lennard–Jones pour $\xi = 0$.

D'après la relation (8), le calcul du déplacement relatif de fréquence harmonique $\Delta\omega/\omega_e$ nécessite la connaissance des dérivées $(du/dq)_e$ et $(d^2u/dq^2)_e$. En faisant le changement de variables $q = (\omega_e/2B_e)^{1/2}$. ξ nous obtenons les expressions des dérivées de u

$$[15]\quad \left(\frac{du}{dq}\right)_e = \left(\frac{2B_e}{\omega_e}\right)^{1/2} 3Z\varepsilon\left(\frac{x_e}{r_e^*}\right) \times\left[2C\left(\frac{r_e^*}{a}\right)^{12} - D\left(\frac{r_e^*}{a}\right)^{6}\right]$$

$$[16]\quad \left(\frac{d^2\mu}{dq^2}\right)_e = \left(\frac{2B_e}{\omega_e}\right) 3Z\varepsilon\left(\frac{x_e}{r_e^*}\right)^2 \times\left[11C\left(\frac{r_e^*}{a}\right)^{12} - \frac{5}{2}D\left(\frac{r_e^*}{a}\right)^{6}\right]$$

Le déplacement relatif de fréquence harmonique est alors donné par la relation suivante

$$[17]\quad \frac{\Delta\omega}{\omega_e} \simeq -\frac{1}{2\omega_e}\left(\frac{2B_e}{\omega_e}\right) 3Z\varepsilon\left(\frac{x_e}{r_e^*}\right)^2 \times\left[11C\left(\frac{r_e^*}{a}\right)^{12} - \frac{5}{2}D\left(\frac{r_e^*}{a}\right)^{6}\right] + \frac{3k_3}{\omega_e^2}\left(\frac{2B_e}{\omega_e}\right)^{1/2} 3Z\varepsilon\left(\frac{x_e}{r_e^*}\right) \times\left[2C\left(\frac{r_e^*}{a}\right)^{12} - D\left(\frac{r_e^*}{a}\right)^{6}\right]$$

Ainsi, nous trouvons une expression analogue à celle donnée par Monson et coll. (7).

Résultats expérimentaux

Dans le tableau 1 figurent les fréquences d'absorption $\nu_{0\to v}$ et les déplacements de fréquence $\Delta\nu_{0\to v}$ de l'acide iodhydrique.

Etant donné la grande étendue spectrale des bandes ν, 2ν, et 3ν de la molécule HI en solution CCl_4, la détermination des centres de bande est beaucoup moins précise pour l'état dissous que pour l'état gazeux. Les erreurs des déplacements de fréquence $\Delta\nu_{0\to v}$ sont les suivantes

$$\delta(\Delta\nu_{0\to1}) \simeq \delta(\nu_{0\to1}^{sol}) = \pm 0.5\ cm^{-1}$$

$$\delta(\Delta\nu_{0\to2}) \simeq \delta(\nu_{0\to2}^{sol}) = \pm 1.0\ cm^{-1}$$

$$\delta(\Delta\nu_{0\to3}) \simeq \delta(\nu_{0\to3}^{sol}) = \pm 1.5\ cm^{-1}$$

Les valeurs de $\bar{W}$, $\bar{X}$, et $\bar{Y}$ s'obtiennent par résolution du système de trois équations, données par les relations 3*a*, 3*b*, et 3*c*:

$$\bar{W} = 20 \pm 8\ cm^{-1}$$

$$\bar{X} = 3.7 \pm 5.5\ cm^{-1}$$

$$\bar{Y} = 0.6 \pm 1\ cm^{-1}$$

D'après ces résultats les valeurs de $\bar{X}$ et $\bar{Y}$ n'ont

TABLEAU 2. Constantes moléculaires de HI gazeux et dissous*

HI	ω_e (cm^{-1})	$\bar{W}$ (cm^{-1})	X (cm^{-1})	$\bar{X}$ (cm^{-1})	Y (cm^{-1})	$\bar{Y}$ (cm^{-1})
Gazeux	2308.091 (10)		+38.9810 (10)		−0.1980 (10)	
Dissous (CCl_4)		25.5		—		—

*Les valeurs obtenues par Pugh et Rao (10) et Josien et coll. (16) sont également indiquées dans les tableaux 1 et 2.

TABLEAU 3. Constantes du potentiel Lennard–Jones (6–12) (14)

Molécules	σ (Å)	ε/k (°K)
HI	4.123	324
CCl_4	5.881	327

pas de signification. Seule la valeur de $\bar{W}$ peut être obtenue à partir des relations suivantes.

$$\left.\begin{aligned} 25.1 &= \bar{W} \quad (a)\\ 51.8 &= 2\bar{W} \quad (b)\\ 76.2 &= 3\bar{W} \quad (c) \end{aligned}\right\} \quad (3 \text{ bis})$$

d'où

$$\bar{W} = 25.5 \pm 0.5 \text{ cm}^{-1}$$

Dans le tableau 2, nous donnons les constantes moléculaires ω_e, X, et Y (10) et la valeur expérimentale la plus probable de $\bar{W}$. Les quantités $\bar{X}$ et $\bar{Y}$, étant entachées d'erreurs trop élevées, ne peuvent y figurer.

Calcul du deplacement de frequence

En utilisant les constantes suivantes relatives à la molécule HI: $\alpha_e = 0.16886 \text{ cm}^{-1}$ (10) et $B_e = 6.5111 \text{ cm}^{-1}$ (10), nous avons obtenu à partir de la relation (9): $k_3 = -219.544 \text{ cm}^{-1}$. Les constantes caractéristiques du potentiel de Lennard–Jones (6–12) sont données dans le tableau 3.

Avec ces constantes nous pouvons calculer les valeurs théoriques de $(\Delta\omega/\omega_e)^{\text{répulsion}}$ et $(\Delta\omega/\omega_e)^{\text{dispersion}}$ données par la relation (17) (voir tableau 4).

Discussion

D'après le tableau 2, il apparaît que si la valeur expérimentale du terme d'ordre zéro $\bar{W}$ peut être obtenue avec une précision raisonnable, celles des termes d'ordre un $\bar{X}$ et d'ordre deux $\bar{Y}$ sont très imprécises. Ceci s'explique comme nous l'avons vu précedemment par le fait que les bandes v, $2v$, et $3v$ des solutions de HI sont très larges; ce qui entraîne une certaine imprécision dans le pointé des centres de bande.

Le potentiel intermoléculaire (LJD) (6–12) dépend du premier nombre de coordination Z et des deux paramètres C et D. Pour l'état liquide, si nous ne considérons que la couche de molécules de solvant la plus proche de la molécule de soluté, les facteurs C et D prennent les valeurs suivantes: $C = 1$, $D = 2$ (15); le nombre Z peut être réduit de $Z = 12$ (état solide) à $Z = 10$ (état liquide). La "théorie des lacunes" (Hole Theory) permet de rendre compte de la décroissance de Z avec la densité du solvant (17). Par ailleurs, il semble raisonnable d'adopter le modèle de cage pour le solvant CCl_4. Bonamy et coll. (18) ont montré que l'amplitude moyenne $\bar{\rho}$ des oscillations des molécules de solvant CCl_4 reste faible devant la distance a entre deux nœuds du réseau c.f.c.

TABLEAU 4. Valeurs calculées et observées de $\Delta\omega/\omega_e$

Paramètres du potentiel (LJD)			$\frac{\Delta\omega}{\omega_e} \times 10^3$				$\frac{\Delta\omega^{\text{théor}}}{\Delta\omega^{\text{obs}}}$
Z	C	D	Répulsion	Dispersion	Théorique	Observé	
12	1.01	2.41	−19.9	+35.1	15.2	11.0	138%
10	1	2	−16.4	+24.3	7.8	11.0	71%

En effet, pour $T = 300\ ^{\circ}K$, ils ont obtenu $\bar{\rho} = 0.049$ a.

Ainsi, ayant choisi un potentiel intermoléculaire de type (LJD), nous pouvons déterminer la quantité $\bar{W} = \Delta\omega$ par la relation (8) et ensuite comparer les valeurs théoriques et expérimentales du déplacement relatif $\Delta\omega/\omega_e$. Le tableau 4 montre que la contribution des forces de dispersion est plus importante que celle des forces de répulsion, les forces d'induction étant négligeables. En adoptant les valeurs numériques suivantes: $Z = 12$, $C = 1.01$ et $D = 2.41$ (15), nous observons un écart important entre valeurs théorique et expérimentale de $\Delta\omega/\omega_e$. Cet écart n'est pas surprenant, car la valeur de $Z = 12$, valable pour l'état solide, est probablement trop élevée pour décrire l'état liquide. Par contre, avec les valeurs $Z = 10$, $C = 1$, et $D = 2$, l'accord est très raisonnable.

En conclusion, le choix d'un potentiel intermoléculaire de type LJD (6–12) permet de rendre compte de manière satisfaisante de l'effet d'un solvant non polaire CCl_4 sur les déplacements de fréquence d'une molécule diatomique polaire HI.

Nous tenons à remercier Monsieur le Professeur P. Barchewitz pour l'intérêt qu'il a porté à cette étude.

Infrared Investigation of H_2S Adsorption and Decomposition on Alumina and on Alumina Supported Molybdenum Sulfide[1]

T. L. SLAGER[2] AND C. H. AMBERG

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 1, 1972

Adsorption and subsequent reaction of H_2S on alumina gave major i.r. bands at 1341, 1568, 1625, and 3400 cm^{-1}. Relative band intensities were used to follow the first order decomposition of adsorbed H_2S and formation of H_2O. Rate constants of the surface reaction at 23, 55, and 80 °C were 0.70, 1.48, and 3.42×10^{-3} s^{-1}, respectively. A mechanism consistent with the observed spectral and kinetic data involved adsorption to an exposed Al ion forming an Al—S surface bond, and hydrogen bonding to neighboring O and OH species. It was assumed that the sulfur remained on the surface as a sulfide. The 1568 cm^{-1} band was discussed in terms of an Al—O species.

With adsorption on MoS_2–Al_2O_3, bands appeared at 1330 and 1575 cm^{-1}. Behavior in all respects was similar to that observed on the alumina support alone.

L'adsorption suivie d'une réaction ultérieure de H_2S sur l'alumine conduisent à des bandes infrarouge majeures à 1341, 1568, 1625, et 3400 cm^{-1}. Les intensités relatives des bandes ont été utilisées pour suivre la décomposition du 1er ordre de H_2S adsorbé et la formation de H_2O. Les constantes de vitesse de la réaction superficielle à 23, 55, et 80 °C sont respectivement de 0.70, 1.48, et 3.42×10^{-3} s^{-1}. Un mécanisme compatible avec les données spectrales et cinétiques observées fait intervenir une adsorption sur un ion Al exposé conduisant à une liaison superficielle Al—S et une liaison hydrogène avec les espèces voisines O et OH— on admet que le soufre reste sur la surface sous forme de sulfure. La bande à 1568 cm^{-1} a été discutée en rapport avec les espèces Al–O. Avec l'adsorption sur MoS_2–Al_2O_3 des bandes apparaissent à 1330 et 1575 cm^{-1}. Le comportement est semblable à tous égards à celui observé pour le support alumina seule.

Introduction

Hydrogen sulfide, a product of the hydrodesulfurization reaction, plays a significant role in the catalytic process in a number of ways. Although activation of hydrodesulfurization catalysts can be accomplished by reduction in hydrogen alone (1), presulfidation is generally preferred (2–5) for obvious practical reasons, and this is generally carried out with H_2S/H_2, thiophene/H_2, or similar mixtures. It might further be cited that H_2S strongly poisons butene hydrogenation on a commercial cobalt molybdate catalyst (6), as well as on unsupported MoS_2 (3), while having a much smaller effect on thiophene desulfurization. Similar behavior was noted in comparing a presulfided with a purely oxidic chromia catalyst (7). A recent critical review of the literature on hydrodesulfurization by Schuman and Shalit (8) should be consulted for further details.

In the following we report an i.r. spectroscopic study of the adsorption of H_2S on a supported MoS_2 catalyst, and on alumina, the support alone. Although it would have been most desirable to examine the adsorption on unsupported MoS_2, this proved to be intractable, as no sample could be made that would transmit sufficient radiation for reliable spectroscopic analysis. Few efforts to examine the adsorption of H_2S by means of i.r. spectroscopy have so far been reported. Blyholder and Bowen (9) saw no evidence of bands arising from adsorbed H_2S on a silica-supported nickel sample. On the other hand, Blyholder and Richardson (9) did note that H_2S adsorption on Fe_2O_3 gave rise to an OH stretching band, and suggested that this might have come about by a surface decomposition of H_2S not unlike that proposed in the present paper. Deo, Dalla Lana, and Habgood (10) were successful in finding i.r. evidence for its adsorption on alumina and on a number of other catalysts active in the Claus reaction, at pressures higher than those used in the present study. Their results and interpretation differed from ours

in a number of aspects, but are consistent with them in general. Ratnasamy and Fripiat reported the absence of noticeable effects with unsupported MoS_2 (11).

Experimental

(i) Apparatus

A Beckman IR-7 grating spectrophotometer was used to record all spectra presented. A slit program of two times normal, ranging between 0.85 and 0.24 mm, gave a spectral resolution of 1–2 cm^{-1} in the region 4000 to 900 cm^{-1}. All other instrument parameters were adjusted so that the noise level was less than 1% at 50%T.

The sample and reference cells were similar to those previously described (12). A Cahn RG electro-balance has been substituted for the null-reading quartz spring microbalance. A catalyst sample approximately 19.5 × 35 × 0.1 mm^3 was pressed at 7.0 kg mm^{-2} and mounted in a quartz sample holder. Other modifications to the system were designed to eliminate adsorbate contact with high-vacuum grease. Sodium chloride windows were attached to the flat flange surface of the cell with brass couplings and Viton O-rings. A Teflon retaining ring served to prevent distortion of the O-ring. Another Teflon ring was used to prevent scoring of the sodium chloride disks by the brass couplings.[3] A stainless steel Viton O-ring flange replaced the upper cell opening and the thermocouple joint was replaced by a tungsten-through-glass seal. The balance compartment and sample cell were isolated from the rest of the vacuum system by Teflon stopcocks. The O-rings and Teflon stopcocks were treated at temperatures up to 100 °C prior to mounting the high-area samples in the system. It was possible to maintain a static vacuum in the system of better than 10^{-5} Torr for several days.

(ii) Reagents

Hydrogen sulfide and deuterium sulfide (Matheson Corp.) were purified by bulb-to-bulb distillation and freeze–pump–thaw cycles. The middle third of the resulting liquid H_2S or D_2S was distilled into a 2 l bulb which was equipped with Teflon stopcocks. The purity was checked by mass spectrometry and found to be >99%.

Two alumina samples were used: η-Al_2O_3 as prepared by MacIver *et al.* (13) and γ-Al_2O_3 (Alon C was supplied through the courtesy of Cabot Corp. Boston, Mass.). Three alumina supported molybdenum "disulfide" catalysts were prepared by dissolving molybdenum oxide (Baker Reagent Grade) in 30% hydrogen peroxide. Alon C was added slowly with stirring.[4] The wet mass was dried in a 110 °C oven overnight. It was sulfided *in situ* with a 10:1 hydrogen: hydrogen sulfide mixture for 24 h at 300 °C.

Table 1 shows the surface areas and observed concentrations of molybdenum and sulfur for the various adsorbents. Sulfur was determined gravimetrically by oxidation to a soluble sulfate, and precipitation with barium chloride (14), and molybdenum was determined colorimetrically. Hydrogen peroxide oxidation of the sample was necessary when the sulfur occurred as a sulfide. Whenever possible, the molybdenum content was determined prior to sulfidation. The MoO_3 was dissolved in an ammonia solution buffered with tartaric acid and colored by forming an EDTA complex. The absorbance was measured at 450 mμ and the amount of molybdenum read from a calibration curve.

TABLE 1. Data for the various adsorbates used

Catalyst	Surface area* (m^2g^{-1})	Molybdenum† (wt %)	Sulfur† (wt %)	S/Mo atom ratio‡
η-Al_2O_3	235	—	—	—
γ-Al_2O_3	105	—	—	—
MoS_2–Al_2O_3 (A)	102	7.0	3.5	1.5
MoS_2–Al_2O_3 (B)	103	4.8	2.29	1.4

‡±10% absolute.

(iii) Experimental Procedure

All samples were outgassed at 300 °C and 10^{-6} Torr for 16 h. They were cooled to experimental temperature, the background spectrum determined and the adsorbate admitted. Spectra were recorded at various time intervals. When the system had reached equilibrium, the adsorbed gases were desorbed by condensation into a liquid nitrogen trap, and examined by mass spectrometry (MS-10; Associated Electrical Industries Ltd.).

Results and Discussion

Fifteen minutes after H_2S had been adsorbed onto an alumina sample at various temperatures, a spectrum was determined (*e.g.* Fig. 1*B*). This consisted of five additional i.r. bands whose frequencies are listed in Table 2. No significant differences between η-alumina and Alon C were observed. The two bands at 2568 and 1341 cm^{-1} correspond to the known stretching and bending modes of H_2S (15), within the range expected for adsorbed molecules. The very broad band appearing at about 3400 cm^{-1} can be assigned to an OH-stretching mode formed by hydrogen bonding of hydrogen atoms in H_2S to oxygen atoms in the alumina surface. Assignment to hydrogen bonding was supported by band frequency and shape, as well as by the absence of fine-structure. As the 3400 cm^{-1} band grew on standing, the band at about 3720 cm^{-1} initially present, and arising from alumina surface OH-groups lost its definition, indicating either overlap with the new band, or growth of

[3]Further detail is shown in a scale diagram in the Ph.D. thesis of T. L. Slager.

[4]Care should be taken when adding the alumina to the hydrogen peroxide, because of a tendency of the mixture to spatter.

TABLE 2. Infrared band frequencies for H_2S and D_2S adsorbed on alumina at room temperature*

Compound	Pressure (Torr)	Observed frequencies (cm^{-1})	Gas phase frequencies (cm^{-1})	Assignment

		1420vw		
		1568		
		2568vw	2684	S—H (stretch)
		3400vb		O—H (hyd.bonded)
(H_2O)		1625		H—O—H (bend)
D_2S	10.6	1860vw	1999	S—D (stretch)
		2700vb		O—D (hyd.bonded)
(D_2O)		1215		D—O—D (bend)

*vw = very weak, vb = very broad.

yet a third type of OH-band at a similar frequency. There was also a shift to somewhat higher frequency of this band during H_2S adsorption, not noted by Deo *et al.* (10), although these authors were able to induce a similar shift by doping their sample with NaOH. The remaining two bands at 1420 and 1568 cm^{-1} will be discussed below.

Hydrogen bonding is presumably the reason for the shifts of -166 cm^{-1} from the gas phase asymmetric stretch of H_2S, and of $+51$ cm^{-1} from the bending mode. This is reasonable in view of the fact that the unperturbed S—H bond will become weakened and the HSH deformation restricted through hydrogen bonding.

In order to determine whether the 1341 cm^{-1} adsorption was, in fact, the bending mode of H_2S or arose from an S—O species of some type, D_2S was used as the adsorbate. If the 1341 cm^{-1} band were due to an S—O stretching mode, as argued by Deo *at al.* (10) in the case of their intense band at 1330 cm^{-1}, then little or no difference in frequency should be expected between adsorbed H_2S and D_2S. In D_2S, the gas phase bending occurs at 934 cm^{-1} (15). Unfortunately, even the estimated positive shift of 50 cm^{-1} due to adsorption is insufficient to place this band outside the region of the very intense Al—O vibrational frequencies occurring between 1050 and 600 cm^{-1}. Thus no bending mode could be observed for D_2S. However, since no other bands occurred with D_2S adsorption near 1341 cm^{-1} which could then have been attributed to an S—O bond, the frequency in question was assumed to be the bending mode of H_2S.

Other bands in the initial spectrum of hydrogen sulfide were observed at 1568 and 1420 cm^{-1}. That at 1420 cm^{-1} was very weak. It was not observed at a pressure of 0.8 Torr, but appeared at pressures of 2 Torr or above (Fig. 1). The absorption at 1568 cm^{-1} was much stronger and its growth was proportional to the intensity of the bending mode of hydrogen sulfide at 1341 cm^{-1}. The ratio between the band areas of the 1341 and 1568 cm^{-1} bands was 1.6 ± 0.1. No sulfur compound containing aluminum, oxygen, and/or hydrogen has been reported with an i.r. absorption at or near 1568 cm^{-1}. This band could be completely removed by placing a liquid nitrogen trap in the closed system. When the surface had been repeatedly exposed to species containing carbon and hydrogen, bands appeared at 1568 and 1460 cm^{-1}. They became more intense with every adsorption–desorption cycle. Parkyns (16) observed very broad intensity bands at 1570 and 1440 cm^{-1} after several adsorption–desorption cycles using CO as the adsorbate and alumina as the adsorbent. Oxygen treatment up to 400 °C did not reduce their intensity, and deuteration did not alter their absorption frequency. He associated these with surface vibrational modes of the alumina. Similarly, Scholten *et al.* (17) found peaks at 1552 and 1473 cm^{-1} after an adsorption–desorption cycle using formic acid as the adsorbate. Evacuation at 450 °C for 20 h did not remove them. Addition of a monolayer of H_2O caused their frequency to shift to 1570 and 1452 cm^{-1}. Mathieu and Bozon (18) also reported seeing peaks at 1580 and 1480 cm^{-1} with the adsorption of ethylene and ethane on alumina. Both Mathieu and Bozon and Scholten *et al.* found

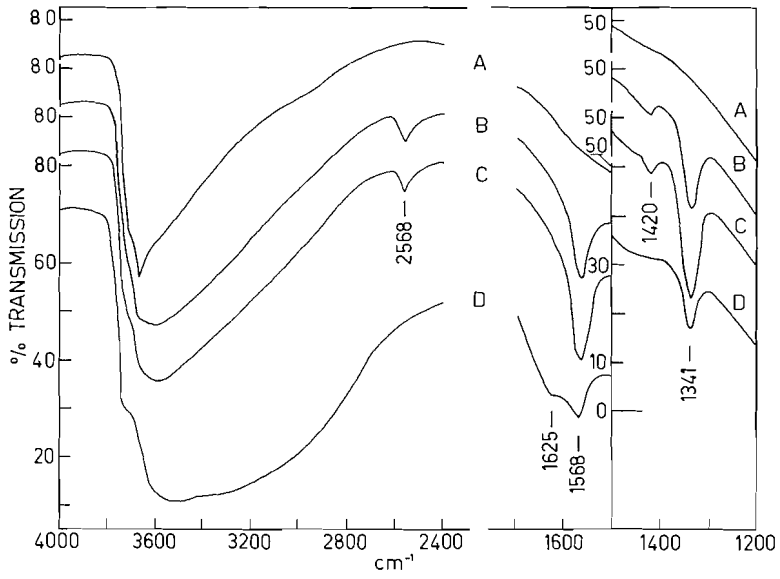

FIG. 1. Infrared bands of H_2S adsorption on Al_2O_3. *A*: background; *B*: 1/2 h; *C*: 2 h; *D*: 24 h; (pressure = 1.9 Torr; temperature = 23 °C).

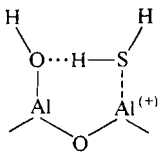
that the bands in question could be removed by oxygen treatment at 450 °C. All three sets of workers seem to agree that they arise from a surface vibrational mode. No one has hypothesized as to their origin.

In the following we propose an assignment for the 1570 cm^{-1} band, which is consistent with the large variety of compounds producing it. Since it appears with H_2S adsorption, while the one at 1460 cm^{-1} does not, it is assumed that these two arise from different vibrating species. Dorsey (19) found similar bands with alumina films, their exact frequency depending on the conditions under which they were formed. He assigned them to an Al=O vibration and estimated their range to lie between 1345 and 1696 cm^{-1}. It is plausible to interpret the 1570 cm^{-1} band as arising from adsorbates imparting double bond character to aluminum–oxygen bonds; this would also explain both the frequency variation of the band and the broad range of adsorbates which cause it to appear. One could envisage H_2S adsorption through the sulfur atom to the surface, as shown below,



acting in this manner. For the reasons cited we favor this model over that proposed by Deo *et al.* (10), in which the sulfur forms an Al—O—H···SH_2 hydrogen bond with surface hydroxyls. It is also in better accord with the mechanism of surface sulfide formation discussed below.

The absorption in the range 1440–1480 cm^{-1} might arise from some reaction of carbon with the alumina surface, since it appears with CO, H_2COOH, C_2H_4, and C_6H_6 but not with H_2S. More data are necessary to attempt an assignment of this band.

Relatively little work has been done on the adsorption and subsequent decomposition of hydrogen sulfide on alumina. Bayley (20) noted that H_2S could not be quantitatively desorbed during adsorption-desorption cycles. deRosset *et al.* (21) have investigated the same system at low coverages and high temperatures and reached the conclusion, that the formation of Al—S and Al—O bonds on oxygen vacancies following the adsorption of H_2S and H_2O was consistent with bulk thermodynamics.

The decomposition of hydrogen sulfide is readily confirmed using i.r. and gravimetric techniques as outlined below. Extended contact time with alumina (curves *C* and *D* in Fig. 1) resulted in further increase of intensity in the O—H region, and an absorption at 1625 cm^{-1} arising from the H_2O bending mode. This

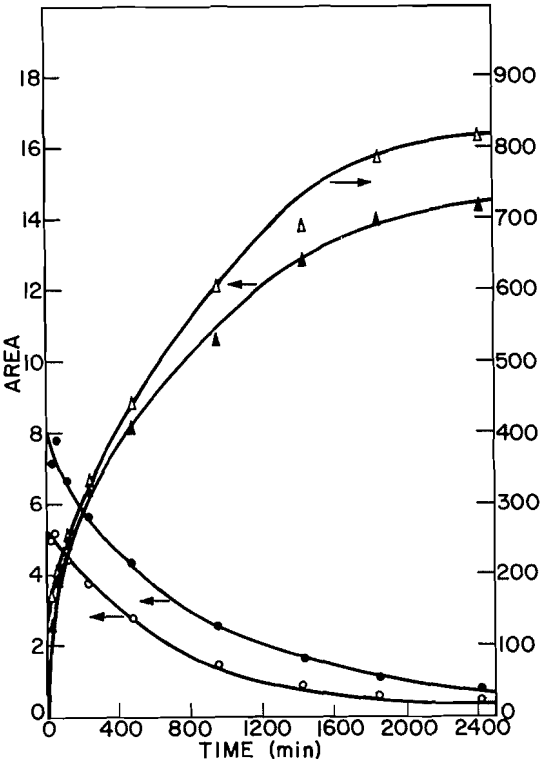

FIG. 2. Time dependence of the area of the i.r. bands appearing during the decomposition of H_2S on Al_2O_3: ●, 1341; ○, 1568; ▲, 1625; △, 3400; (pressure = 0.82 Torr; temperature = 55 °C).

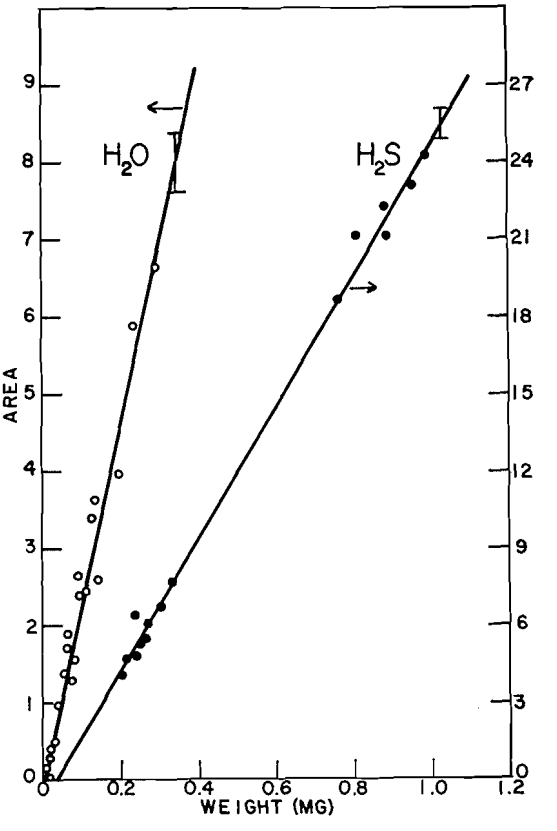

FIG. 3. Relation between the band areas of H_2S and H_2O and the weight of adsorbed material (weight of Al_2O_3 = 100 mg).

establishes that water is one of the decomposition products.

Band areas were determined using a Simpson's rule approximation, and then plotted as a function of time. The graphs of the four major bands at 1341, 1568, 1625, and 3400 cm^{-1} are given in Fig. 2. It was interesting to note that increases in the hydrogen-bonded OH stretching band at 3400 cm^{-1} paralleled the total weight increase with time of the sample. Assuming that weight changes originate exclusively from the addition or removal of H_2O or H_2S molecules, we have attempted further to define the nature of the hydrogen bonding. If one regards the bond (or set of different bonds) as being made up of weighted contributions from each species, the weighting factors remaining constant over the range of surface coverages, then the empirical relation

$$xA_{H_2S} + yA_{H_2O} = A_{O-H}$$

should hold, where the A_i's are the respective band areas of the 1341, 1625, and 3400 cm^{-1} bands, and x and y are the weighting coefficients. By solving for x and y for appropriate sets of values at various time intervals, this relationship was confirmed semiquantitatively (± 20%), as were the assumptions underlying it.

Since we are dealing with reacting species, and since absolute intensities of the deformation bands of neither adsorbed H_2O nor adsorbed H_2S are available from the literature, the following procedure had to be adopted (for a similar case, see Amberg and Seanor (22)). When the area of the 1341 cm^{-1} band is plotted against the weight of adsorbed material, an initial steep rise, essentially due to H_2S alone, is followed by a more gradual decrease as H_2S becomes converted to H_2O. The ascending branch of this curve, shown in Fig. 3, was used

TABLE 4. Rate constants for the reaction of H_2S with Al_2O_3

Experiment number	Catalyst	Temperature (°C)	Rate constant ($s^{-1} \times 10^3$) At 1341 cm^{-1}	At 1568 cm^{-1}	At 1625 cm^{-1}	Pressure (Torr)	Sample weight (mg)
28	η-Al_2O_3	23	0.948	1.55	—	0.82	68.2
29	Alon C	23	0.702	1.08	0.876	0.82*	78.6
31	Alon C	23	0.694	1.13	0.756	0.80	84.8
40	Alon C	23	—	—	1.17	27.40	84.8
60	Alon C	55	1.48	1.57	1.34	0.82	139.6
61	Alon C	23	0.749	0.846	0.597	1.90	139.6
62	Alon C	23	0.720	0.671	0.640	0.21	139.6
63	Alon C	80	3.42	3.52	2.68	0.82	139.6

*A pressure of 0.8 Torr H_2S gives monolayer coverage as calculated from the B.E.T.(N_2) isotherm.

to calculate the weight of H_2O generated on the surface. This in turn was plotted against the band area of the 1625 cm^{-1} band, as seen in the left-hand line of Fig. 3. The molar integrated intensity and the molar extinction coefficient for the bending modes of adsorbed H_2S and H_2O, calculated from the least-squares lines of these plots, are listed in Table 3, together with recent literature values for H_2O and HDO (23–25). From this it appears that the ν_2 mode for H_2O on the alumina surface is slightly less intense than it is in the unperturbed vapor state, and only marginally more so than in liquid HDO.

A logarithmic plot of D against time (Fig. 4), where D = either $A - A_\infty$ or $A_\infty - A$ for decomposition or formation, respectively (A being the area of the i.r. band under consideration), showed that hydrogen sulfide decomposition on alumina followed first order kinetics. The rate constants for the reaction under various experimental conditions are given in Table 4. The following points of interest may be noted: comparison of experiments 29 and 31 will give an indication of the reproducibility of the rate constants; 29, 31, 61, and 62 of the effect of pressure; 29, 60, and 63 of variation with temperature; 28 and 29 of similarity between the two types of aluminas. Estimates of the enthalpy and entropy of activation made on the basis of the usual assumptions gave values of $\Delta H^{\ddagger} = 5.4$ kcal/mol and $\Delta S^{\ddagger} = -58$ e.u.

Examination of Fig. 4 and Table 4 shows that the decomposition rate of hydrogen sulfide and the rate of formation of water were essentially the same. This indicates that no stable entity such as O—H^- or Al—O—H existed as a separate reaction intermediate.

A mechanism in agreement with the preceding data is shown below. Retention of the

For personal use only.

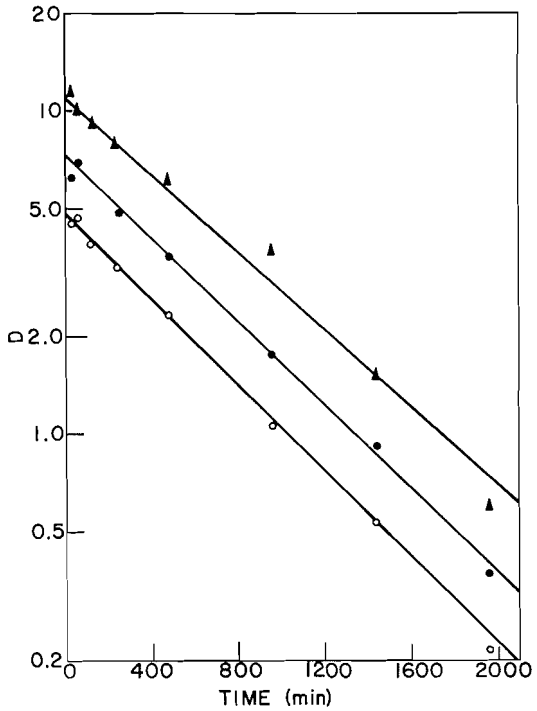

FIG. 4. First order plot of the i.r. band areas of Fig. 2 *vs.* time: ●, 1341; ○, 1568; ▲, 1625; D = either $A - A_\infty$ or $A_\infty - A$.

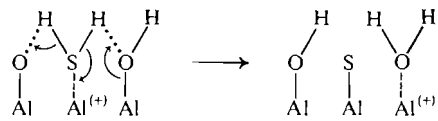
H_2S bending mode at a frequency of 1341 cm^{-1}, formation of the hydrogen bonded species absorbing at 3400 cm^{-1}, and the formation of the Al—O bond at 1568 cm^{-1} are all consistent with the formation of the adsorbed state as shown in step 1. Examination of Fig. 2 shows that hydrogen sulfide adsorbed fairly rapidly reaching a maximum in 1 to 3 h in contrast to the much slower formation of H_2O. Therefore step 1 must be a fast step in this reaction. Step 2 is consistent with the thermodynamics, and equality of the rate of decomposition and formation reactions. The adsorbed state of hydrogen sulfide was sufficiently perturbed, as shown in the shift of $+51$ cm^{-1} to 1341 cm^{-1}, so as to lower the energy requirements, causing a low value for $\Delta H^{\ddagger}$. The large negative value of $\Delta S^{\ddagger}$ indicated that a large degree of ordering occurred in going from the adsorbed state to the transition state. According to this mechanism, bond breaking in hydrogen sulfide can be thought of as being coincident with the formation of the O—H bond. Rationalization for the O—H lying next to the adsorbed hydrogen sulfide can be made following Peri's work (26) in which a plot of the percent of O—H retained, against evacuation temperature showed that at least 50% of the surface would still be covered by hydroxyl groups after evacuation at 325 °C. Thus it would be improbable that H_2S could adsorb on exposed aluminum ions without having an O—H species as a neighbor.

It is possible to consider the reaction of hydrogen sulfide with an alumina surface in terms of a redox system. Flockhart *et al.* (27) proposed the existence of two alumina sites acting as a redox system. If in the present case the decomposition of hydrogen sulfide were a redox reaction, hydrogen sulfide would have to be the reductant while a surface oxygen or hydroxyl group would have to be the oxidant. This is shown below. Bulk alumina would have to act



as the charge carrier between the two sites. It is possible that the alumina surface could act in such a fashion; however, there is insufficient evidence to argue conclusively that a redox reaction was operative in the case under discussion. The only evidence comes from the fact that the hydroxyl group has been reduced to water and the hydrogen sulfide oxidized to "aluminum sulfide", no evidence existing as to the final nature of the sulfur atom.

Other conceivable reaction paths could involve the breaking of the hydrogen–sulfur bonds to form H^+, H^0, or H^-, and S^{2-}, S^0, or S^{2+}. Decomposition forming $2\,H^+$ and S^{2-} is a possibility that cannot be discounted, as H^+ would readily react with the O^{2-} on the surface to form OH^- or H_2O. No evidence was found that would eliminate S^{2-} as a product. The formation of $2\,H^0$ and S^0 can also be thought feasible, if it is assumed that H^0 reacts much faster with oxygen species than with itself. This assumption would be necessary, because only H_2O was detected as a product in the decomposition. It is unlikely that H^- would be formed, as subsequent reaction with an OH^- or O^{2-} to form water would be inhibited by like charges. The formation of S^{2+} is also unlikely, but if formed it would probably react with the surface

For personal use only.

O^{2-} to form SO_x. Infrared bands for SO_x or S_x species were not observed, and no pertinent peaks were detected in the mass spectrum. Thus the decomposition to 2 H^- and S^{2+} is improbable. Any of the three other reaction possibilities discussed above (concerted reaction, H^+ ion formation, or hydrogen atom formation) are equally probable.

The adsorption of hydrogen sulfide on supported molybdenum sulfide produced two bands (1330 and 1575 cm^{-1}), as did adsorption on alumina. Note, however, that both frequencies were lower by about 5 to 10 cm^{-1} than those observed on alumina, and thus closer to the gaseous state, indicating that the H_2S molecule was less perturbed by adsorption on the MoS_2–Al_2O_3 catalyst than on Al_2O_3. This was possibly due to the substantial decrease in the concentration of oxygen atoms exposed on the surface. Hydrogen bonding is very much weaker to a sulfide atom than to an oxygen atom, and will not therefore affect the adsorbed H_2S as greatly on a sulfide surface. The decrease in the number of molecules hydrogen bonded to oxygen atoms was evident from the difference between the intensity of the 3400 cm^{-1} band adsorbed on supported molybdenum sulfide and on alumina, at equivalent pressures.

The two hydrogen sulfide bands disappeared upon raising the temperature higher than 110 °C at 0.8 Torr, reproducing the behavior of H_2S adsorbed on alumina. Upon decomposition, water bands again appeared, presumably by reaction with the alumina support. A separate rate study of the decomposition of hydrogen sulfide was not undertaken but, from other experiments, it appears to be of the same order of magnitude as on the alumina surface.

The financial support of the National Research Council of Canada is gratefully acknowledged. The authors are also grateful to Dr. H. W. Habgood and colleagues for making available their manuscript prior to publication, and to Dr. A. W. Ashbrook and J. Arnason for assistance with the molybdenum analysis.

Received May 1, 1972

Anodic methoxylation at a platinum electrode of α,α′-dimethoxystilbene yielded benzil tetramethylketal (**2**) which upon further electrolysis in methanol gave a 62% yield of trimethyl orthobenzoate. The mechanism of this new anodic fission reaction is briefly discussed.

La méthoxylation anodique, sur une électrode de platine, de l'α,α-diméthoxystilbène conduit au benzile tétraméthylcétal (**2**) qui par électrolyse ultérieure dans le méthanol donne le triméthylorthobenzoate, avec un rendement de 62%. Le mécanisme de cette nouvelle réaction anodique de fission est discuté brièvement.

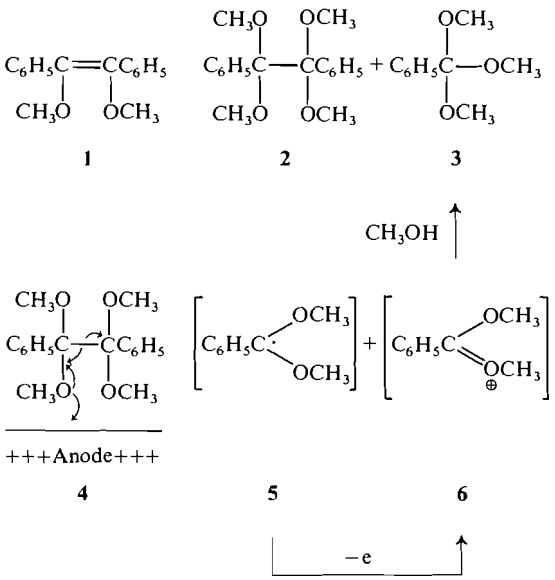
Canadian Journal of Chemistry, **50**, 3424 (1972)

During the course of our studies on the electrochemical synthesis of benzoquinone ketals, it was observed that *o*-benzoquinone tetramethyl ketal possessed the remarkable ability to suffer anodic cleavage in alkaline methanol to the corresponding hexamethyl *cis,cis*-orthomuconate (1). Because of the unprecedented nature of the reaction, the question arose as to whether this anodic cleavage is substrate specific or applicable to other types of vicinal diketals. Accordingly, we chose to test the behavior of an open-chain analog such as benzil tetramethyl ketal (**2**) which may be expected to yield methyl orthobenzoate (**3**) upon electrochemical oxidation in alkaline methanol. Unfortunately, the benzil diketal **2** is unknown and could not be prepared by the general methods familiar to the organic chemist. However, by taking advantage of our recent finding that vinyl ethers can be not only dimerized but 1,2-dimethoxylated directly at a platinum anode in methanol (2), an electrochemical synthesis of **2** from α,α′-dimethoxy stilbene (**1**) could be envisaged. The starting stilbene **1** can be prepared by first reacting benzil with sodium followed by reaction of the diketyl anion intermediate with dimethyl sulfate (3). The pure product is obtained in low yield and should have the *cis*-configuration according to Bauld (4).



1 **2** **3** **4** **5** **6**

Oxidation of **1** in 1% methanolic potassium hydroxide at a platinum anode following our previously described techniques (1, 2) gave after 1 h (3 A, 12 V) the *bis*-ketal **2** (45% yield) and trimethyl orthobenzoate (**3**) (18% yield). Under the same conditions, the *bis*-ketal **2** underwent electrolytic cleavage to **3** in 62% yield after a reaction time of 1.5–2 h. Optimum conditions for the production of **2** from **1** or **3** from **2** were not determined. The anodic fission of *o*-benzoquinone ketals (1) can thus be

extended to other vicinal diketals. The question of mechanism is of considerable interest as it bears analogy to the periodate and lead tetraacetate cleavage of vicinal diols and related structures. We have previously shown that adsorbed species at the anode provide the substrate for the solvent methanol (2). In the case of vinyl ethers, the adsorbed species were deduced to consist of radical cations on the basis that dimerization to succindialdehyde acetals is a major reaction pathway. Indeed, radical cations were shown to be generated from methoxybenzenes upon anodic oxidation to quinone ketals (5). However, anodic discharge of **2** cannot yield a resonance stabilized radical cation as is the case with vinyl ethers which benefit from π-conjugation (2). Moreover, we have also eliminated the involvement of methoxy radicals in the production of quinone ketals from methoxybenzenes (5). A mechanism involving initial discharge of a benzene ring to a radical cation subsequently allowing C—C fission through intramolecular electron shifts may also be ruled out since in the absence of methoxy or hydroxy substituents, benzene rings do not suffer anodic oxidation under the experimental conditions (6). A mechanism which might account for the results would consist in an electron discharge from an ether oxygen (as in **4**) to give a stabilized cation **6** readily captured by methanol and a stabilized radical **5** readily oxidized to cation **6**. One factor which may supply part of the driving force for the fission would be the strong steric repulsion between the four ether oxygens of the α-diketal. Of considerable interest is the formal analogy of this new C—C fission reaction to the well-known periodate or lead tetraacetate cleavage of vicinally oxygenated C—C bonds. This new reaction is potentially useful for the synthesis of mixed orthoesters, a class of compounds not accessible by conventional methods.

Experimental

Benzil Tetramethyl Diketal (2) and Trimethyl Orthobenzoate (3)

A solution of 4.8 g of α,α'-dimethoxystilbene (**1**) (3) in 250 ml of methanol containing 2.5 g of potassium hydroxide was electrolyzed for 1 h by passing a 3 A current at 12 V while stirring and cooling to 10–15°. A platinum anode (total surface area of 160 cm^2) and nickel cathode (total surface area of 240 cm^2) were used as previously described (1, 2). The anodic current density was of the order of 0.03 A/cm^2. The solvent was evaporated, the residue taken up in ether, and the extract washed with water. Evaporation of the ether yielded an oil which was distilled *in vacuo* to give 1.20 g (18% yield) of trimethyl orthobenzoate (**3**), b.p. 46–8°/0.25 nm (n.m.r. absorption at 6.99 τ for OCH_3 and 2.68 τ for aromatic protons in a ratio of 9:5) followed by 2.70 g (45% yield) of benzil tetramethyl diketal (**2**), b.p. 112°/0.25 mm (n.m.r. absorption at 6.70 τ for OCH_3 and 3.00 τ for aromatics in a ratio of 12:10; TMS as internal reference; CCl_4 as solvent). The overall current efficiency was approximately 45%. Treatment of **2** in aqueous methanol with a little dilute hydrochloric acid gave a quantitative yield of methyl benzoate (identified by i.r. and n.m.r. spectroscopy).

Further electrolysis of 1 g of **2** under the same conditions for 1.5–2 h gave after work-up and distillation a 62% yield (about 5% current efficiency) of trimethyl orthobenzoate identified as above.

Rate constants for quenching of triplet excited acetone by primary and tertiary amines in solution have been measured directly by flash and pulsed laser techniques. The rate constants were found to be independent of solvent dielectric constant over the range ε 1.9 to ε 80, but were influenced by amine ionization potential. The results are interpreted as supporting a charge-transfer model for the quenching of triplet ketones by tertiary amines. The intervention of free ions in the quenching process is discussed. Free energy calculations indicate that electron transfer from *N,N*-dimethylaniline to triplet ketones is exothermic but is slightly more favorable for triplet aromatic ketones than for triplet acetone. Evidence for direct hydrogen atom transfer was obtained for quenching of triplet acetone by *n*-hexylamine.

Les constantes de vitesse d'extinction de l'acétone excitée triplet par les amines primaires et tertiaires en solution ont été mesurées directement par les techniques Laser flash et pulsé. On a trouvé que ces constantes de vitesse étaient indépendantes de la constante diélectrique du solvant dans toute l'intervalle ε de 1.9 à 80 mais dépendaient du potentiel d'ionisation de l'amine. L'interprétation de ces résultats vient à l'appui du modèle de transfert de charge dans l'extinction des cétones triplets par les amines tertiaires. L'intervention des ions libres dans le processus d'extinction est discutée. Les calculs d'énergie libre montrent que le transfert d'électron de la *N,N*-diméthylaniline aux cétones triplets est exothermique et légèrement plus favorable pour les cétones aromatiques triplet que pour l'acétone triplet. La preuve du transfert direct de l'atome d'hydrogène a été obtenue dans l'extinction de l'acétone triplet par la *n*-hexylamine.

The recently reported detection and assignment of the triplet state of acetone in liquids (1) enable us to obtain directly quantitative data on its reactivity towards amines and other molecules in solution. Although it is assumed, usually implicitly, that triplet aliphatic ketones and $n\pi^*$ triplet aromatic ketones behave identically, such a comparison has not yet been possible owing to the lack of reliable rate data on the $n\pi^*$ triplet state of acetone and other aliphatic ketones. In this paper, we present results on the triplet state of acetone which bear on the more general quations of $n\pi^*$ triplet ketone reactivity.

Before considering the experimental results on triplet acetone, attention should be drawn to some of the data and their interpretations on the photoreduction of aromatic ketones by amines. Cohen and co-workers (2) and Davidson and co-workers (3) have proposed that the photoreduction process takes place by a step-wise mechanism. It was suggested that the initial step involved the transfer of an electron from the nitrogen atom of the amine to the electron deficient oxygen atom of the excited carbonyl group to form an ion pair. This was then followed by a proton transfer step and electron redistribution. The detailed description of the electron transfer step has undergone some revision since it was first postulated by Cohen. Initially, the species formed by electron transfer were written as separate species (2*a*), which implied the direct formation of free ions. Later, Cohen *et al.* (2*c*–2*i*) favored the formation of a charge-transfer complex or an ion-pair.

Supporting evidence for the postulate of an electron transfer process has come from flash photolysis of benzophenone with tri-*p*-tolylamine in acetonitrile, where a transient which is believed to be the amine radical cation absorbing at 670 nm was observed (4).

*Measured using a flash emission apparatus (ref. 1) except in *n*-hexane, where a Q-switched neodymium glass laser was used. Acetone concentration 0.05 *M*. Experiments carried out at 23°.

†The numbers in parentheses after the amines are first ionization potentials of the amines (ref. 17).

A number of differences between the photoreduction of benzophenone by aliphatic and alkyl aromatic amines have been observed (*3b*), mainly, that reduction with *N*,*N*-dimethylaniline is insensitive to the addition of naphthalene as quencher while the reduction with 2-butylamine is quenched. On the basis of these observations, the authors suggested that an ion-pair intermediate was not involved in the photoreduction of amines with high ionization potential.

In one instance, it was reported that quenching of a triplet aromatic ketone by tertiary amine did not occur by electron transfer. By indirect quenching method, Wagner and Kemppainen (5) studied the quenching of valerophenone triplet by triethylamine and dimethyl-*t*-butylamine in benzene, acetonitrile, and methanol. The rate constants reported for quenching by the amines were $\sim3\times10^9$ M^{-1} s^{-1} in benzene and in acetonitrile. The values obtained in methanol, however, were roughly a factor of 5 lower. The results were interpreted by these authors as indicating the absence of electron transfer in the quenching step.

In our experiments, we have measured the rate constants for quenching of triplet acetone by the tertiary amines *N*,*N*-dimethylaniline (E_I 7.14 eV) and triethylamine (E_I 7.50 eV) in solvents ranging in dielectric constants from aqueous solution (ε 80) to *n*-hexane (ε 1.9). For comparison, quenching data were also obtained for the primary amines, *n*-hexylamine (E_I 8.71 eV) and *t*-butylamine (E_I 8.64 eV). Evidence for the occurrence of hydrogen atom transfer in these reactions has been obtained by flash absorption studies (6). From our results, we will draw some general conclusions regarding (*1*) the plausibility of forming free ions, charge-transfer complex, or ion-pair from direct electron transfer, (*2*) the validity of using solvent dielectric constant as a criterion for electron transfer reaction, and (*3*) the role of amine ionization potential on quenching rate.

Results and Discussion

The results recorded in Table 1 show that the rate constants for quenching of acetone triplet by a given amine are, within experimental errors, identical in all of the solvents studied. However, the rate constants are dependent on the ionization potential, E_I, of the amine. With the exception of *n*-hexylamines, a linear correlation was obtained (Fig. 1) on plotting log k_q against E_I.

Apart from direct hydrogen atom transfer to the excited carbonyl group (8), quenching by amines can be described by the following sequence of steps

$$\underset{\text{I}}{\mathrm{A^* + B}} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} \underset{\text{complex}}{[\mathrm{A^*B \leftrightarrow AB^* \leftrightarrow A^-B^+}]} \xrightarrow[\text{II}]{k_2} \mathrm{A^- + B^+}$$

$$\mathrm{A^*} \xrightarrow{k_d} \qquad \underset{k_{d'}}{\downarrow}$$

A* is the triplet ketone, and B, the amine.

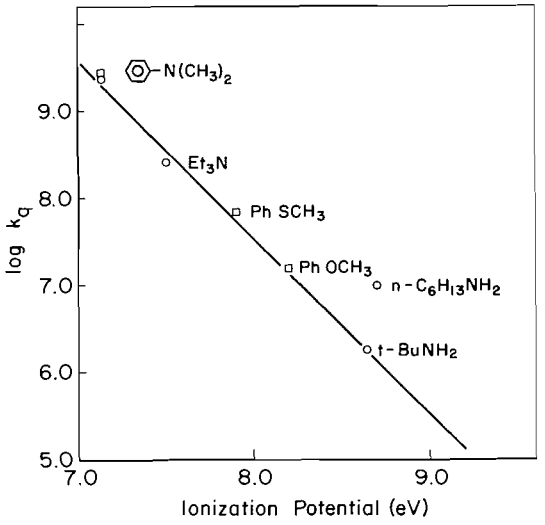

FIG. 1. Correlation between the ionization potential of the quencher and the rate constant for quenching of triplet acetone. ●, this work; □, ref. 3*d*.

A^-B^+ represents the charge-transfer (CT) states of the complex. A*B and AB* are locally excited states of A and B. In step I, A* and B are brought together with an encounter rate constant k_1, and may reversibly dissociate with a value k_{-1}. The rate constants k_d and $k_{d'}$ represent deactivation by all processes of A*, and the complex, respectively. One of these processes would be dissociation of the complex to form A + B*. This is a distinct possibility, but would appear to be excluded from the independence of k_q on solvent viscosity (water, $\eta = 1$ cP; *n*-hexane, $\eta = 0.34$ cP) and from the yield of radical (6). In step II, charge separation to form the free ions (*i.e.*, ions free from the Coulomb field of the countercharge) occurs. The reverse process, k_{-2}, will in general, not occur because of unfavorable energetics.

We do not consider the direct formation of free ions by electron transfer probable except in aqueous solution for reasons which we will describe. If we make the reasonable assumption that electron transfer occurs by an exchange mechanism such as that operative for triplet–triplet transfer, and for the annihilation of two triplet states, then we can expect relatively short-ranged interaction. For instance, the distance of interaction in the latter case is of the order of 9 Å for two phenanthrene triplets (9), while Weller finds 7 Å to be the distance separating the amine and aromatic molecules in the CT complex formed by electron transfer from amine to the singlet excited aromatic molecules (10*a*). However, to form free ions requires that the counter-charges be separated by a distance equal to $R_c > e^2/\varepsilon RT$. For instance in *n*-hexane (ε 1.9), acetonitrile (ε 37), and water (ε 80), $R_c \sim 300$, 15, 7 Å, respectively. It is abundantly clear that for encounter distances of the order of molecular diameter involved in the exchange mechanism, charges formed are still well within the Coulombic field of their countercharge, except in solvents with the highest dielectric constants such as water. We therefore feel that the earlier suggestion by Cohen and Cohen (2*a*) and Davidson and co-workers (3) of ion formation as the process responsible for quenching of the triplet carbonyl excited state unlikely. On the other hand, the formation of a CT complex which has been suggested by Cohen and co-workers (2*c*–2*i*) and Wagner and Kemppainen (5) appears to be reasonable providing certain energetic requirements, which we will discuss later, are met. It should be stressed that to the extent that A^-B^+ contributes to the complex, the encounter process (I) can be legitimately described as an electron transfer process. From this point of view, differences between the interpretations of Wagner and Kemppainen (5) and Cohen and co-workers' later works (2*c*–2*i*) would appear to be more semantic then real.

It would be most useful to estimate if the formation of A^-B^+ in the equilibrium reaction I is favored on thermodynamic grounds or not. Nernst's equation relates the free energy ΔF to the e.m.f. E^0 generated for two coupled half cells according to $\Delta F = -zFE^0$, where F is Faraday's constant, and z, the charge, which is equal to one in our case. If ΔF is expressed in eV and the e.m.f. in V, then F is unity ($F = 1$ eV/V). If for reaction I, we add to E^0 a coulomb energy term $e^2/\varepsilon a$ (where a = the distance between A^- and B^+ in the complex) and the triplet energy E_T, then we obtain an equation which is essentially identical to that previously derived by Weller and co-workers (10).

$$[1] \qquad -\Delta F = E^0 + E_T + \frac{e^2}{\varepsilon a}$$

*In acetonitrile. $E(B/B^+)$ for dimethylaniline is equal 0.78 V *vs.* s.c.e. (ref. 4). We assume $e^2/\varepsilon a = 0.07$ eV. ΔF calculated using eq. 1.
†Reference 16, *vs.* s.c.e. in acetonitrile.
‡Reference 11. We have assumed the lower value (11*b*) of the two references.
§Reference 18.

where

$$E^0 = E(A^-/A) - E(B/B^+)$$

The calculated values of $-\Delta F$ recorded in Table 2 indicate that the electron transfer process involving the tertiary amine *N,N*-dimethylaniline is thermodynamically favorable for acetone, and for the aromatic ketones listed. Differences in the calculated ΔF values between acetone and the aromatic ketones are of the order of the uncertainty in the triplet energy of acetone (78–80 kcal mol^{-1} (11)), and is therefore not necessarily significant in the absence of further supporting data. However, the significantly lower rate constant (by an order of magnitude) for quenching of triplet acetone by triethylamine than those reported for triplet benzophenone (2*h*) and valerophenone (5) is consistent with a lower $-\Delta F$ for electron transfer to triplet acetone than for the aromatic ketones.

We now enquire into the role of solvent dielectric constant and amine ionization potential on the quenching rate constant. In terms of the mechanism which we have described, the rate constant for quenching depends on a competition of rate processes.

$$k_q = k_1(1 - \alpha) \quad \text{where} \quad \alpha = \frac{k_{-1}}{k_{-1} + k_2 + k_{d'}}$$

The lower the energy of the CT complex with respect to A* and B, the higher the activation energy for k_{-1}, and therefore k_q will tend to approach the encounter rate constant k_1 ($= 2 \times 10^{10}\ M^{-1}\ s^{-1}$ for acetonitrile solution). Those amines with small $E(B/B^+)$ or low ionization potential (*i.e.*, tertiary amines) can therefore be expected to quench more efficiently than primary amines. Our results (Table 1) are in agreement with this expectation. Despite the large $-\Delta F$ for electron transfer from *N,N*-dimethylaniline to triplet acetone, the value for k_q which we have obtained is less than k_1 by an order of magnitude. This suggests that k_{-1} is not negligible compared to $k_{d'}$ and k_2. Thus far in our discussion of k_q, solvent dielectric constant plays no explicit role. There is, however, one case where ε could affect k_q in an obvious way. If formation of the free ions $A^- + B^+$ were energetically favorable in water, for instance, then we could expect k_2 to be sufficiently large ($6 \times 10^9\ s^{-1}$ (10*b*)) to result in an α being small compared to unity. Under these circumstances, k_q assumes a maximum value of k_1, the diffusion-controlled encounter rate constant. In a solvent with a low ε, the formation of free ions will not be energetically possible. In this case, k_q will be reduced by the factor $(1 - \alpha)$ over the diffusion-controlled rate. But *the absence of a dielectric constant effect on k_q cannot be considered sufficient proof for ruling out the occurrence of electron transfer in a reaction.*

The plausibility of free ion formation in aqueous solution implies that aqueous solution photolysis could differ from those in other solvents. Cohen *et al.* (2*c*) has reported that the photoreduction of aryl ketones by tertiary amines is clean in aqueous but not in non-aqueous solution. The observations could be interpreted that step I and step II are very fast and that there are no side reactions corresponding to k_d and $k_{d'}$. In other words, the complex is a very short-lived species in water.

In the preceding discussion, we have discussed the relationship between k_q and ΔF and had implicitly assumed in our qualitative dis-

cussion that the ionization potential of the amine E_I is related to the oxidation potential $E^{ox}_{1/2}$. It can be shown that E_I and $E^{ox}_{1/2}$ are in fact related (12) according to

$$[2] \qquad E^{ox}_{1/2} = E_I + \Delta E_{solv} - C$$

where C is a constant and ΔE_{solv} is the difference in the solvation energies between the ion and neutral molecule. Hence, in order to correlate E_I with $E^{ox}_{1/2}$, we must either know ΔE_{solv} or that it is constant in a given series of compounds. However, the experimental fact that a reasonably good correlation between k_q and E_I was obtained (Fig. 1), independent of the structure of B, suggests the difference in the solvation energy term is small in comparison with differences in ionization potentials in affecting the free energy of the reaction. It should also be pointed out, that as the reaction becomes progressively more endothermic (*i.e.*, as the ionization potential of the amine becomes larger), charge transfer becomes less probable and the possibility of other competing processes intervening in the overall quenching process becomes more likely. We should therefore not be surprised to find that the correlation between $-\Delta F$ (or E_I) and k_q is less than perfect for grossly endothermic CT reactions such as those involving the primary amines.[3]

The deviation in the correlation between k_q and E_I observed for the primary amines (Fig. 1) can either be interpreted in terms of an enhanced k_q for *n*-hexylamine or a reduced rate for *t*-butylamine possibly for steric reasons. If we examine the question more carefully, it can be seen that triethylamine is even more sterically hindered than *t*-butylamine and yet the former amine shows a much larger k_q than *t*-butylamine. Furthermore, the E_I values of both compounds do not deviate from the correlation between E_I *vs.* σ_I or σ^*, indicating the absence of abnormality such as steric effects (14). We therefore believe that k_q for *t*-butylamine is not low but that k_q for *n*-hexylamine is high. The increased reactivity of *n*-hexylamine can be attributed to direct hydrogen atom transfer in addition to complex formation. This supposition was supported by measuring the rate of formation of the $CH_3\dot{C}OHCH_3$ radical (6). Due to scattered light, the measurements were not as accurate as might be desired. However, the value which we obtained for *n*-hexylamine, $(2 \pm 1) \times 10^7\ M^{-1}\ s^{-1}$ was identical with the quenching rate of triplet acetone. It should be noted that because of the stronger C—H bond energies possessed by the primary hydrogens in *t*-butylamine, hydrogen abstraction does not play a significant role in the overall quenching of the triplet ketone. Quenching rate constants which we have obtained for *t*-butyl alcohol and hexamethylethane (both containing primary C—H) (15) are in complete accord with these arguments.

[3]An approximate calculation for *n*-hexylamine shows that ΔF is positive by ~ 0.4 eV ($E^{ox}_{1/2} \simeq +1.5$V *vs.* s.c.f. in acetonitrile as estimated from a correlation between $E^{ox}_{1/2}$ and E_I (13)).

Experimental

Materials

The acetone (spectroscopic grade) used was obtained from Baker Chemicals. Acetonitrile was obtained from Matheson, Coleman and Bell (spectroscopic grade) and was used as received.

n-Hexylamine was obtained from Eastman and was fractionally distilled under reduced pressure. *t*-Butylamine (Eastman Organic Chemicals) was dried over anhydrous calcium chloride and then distilled (under nitrogen atmosphere) from sodium metal. The fraction that boiled at 43 °C was collected. Triethylamine (Aldrich) was distilled under nitrogen from acetic anhydride. The distillate was dried over activated alumina and redistilled three times (b.p. 89 °C). Freshly purified sample has to be prepared just before use since triethylamine oxidized rapidly with the color of the solution changing red. *N,N*-dimethylaniline (B.D.H., AR) was distilled under reduced pressure before use. *n*-Hexane Fisher (spectroscopic grade) was passed through activated silica gel and dried over molecular sieves.

Sample Preparation

Acetone–amine samples were prepared by weighing the appropriate amount of amine with 0.05 *M* acetone in 50 ml volumetric flask. From that solution 30 ml was pipetted into the cells (10 cm path length, cylindrical quartz cells). The quartz cell was joined through graded seal glass to a degassing vessel. The solutions were degassed by the freeze–pump–thaw cycles for four successive cycles. The solution was then transferred to the cell and the sample cell was sealed.

Apparatus

Two apparatus were used to measure the rate constants for quenching of triplet acetone by amines. In relatively inert solvents (water, acetonitrile, and *t*-butanol), a capacitor discharge flash emission apparatus was used as previously described (1). In *n*-hexane solutions, quenching of triplet acetone by hydrogen abstraction from solvent required an apparatus with shorter time resolution than that used for the other solvents. For these studies, a 30 ns pulse at 265 nm from a Q-switched, amplified neodymium-doped glass

laser was used. The amplified laser system consisted of a 1/2 in. × 6 in. oscillator rod, a beam expanding telescope and a 3/4 in. × 14 in. amplifier rod. The laser was operated so as to produce 6 J of energies at 1.06 μ. Second and fourth harmonic frequencies were generated using a KDP and an ADP crystal, respectively. The flash absorption apparatus was essentially the same as previously described (7).

We wish to thank Dr. Willem Siebrand for useful discussion, Dr. Raouf O. Loutfy for generously making available to us reduction potentials for the ketones, and Mr. S. E. Sugamori for his continuing and invaluable assistance in laser instrumentation.

Oxidations with Potassium *trans*-1,2-Diaminocyclohexanetetraacetatomanganate-(III). I. Composition of the Complex and the Reaction with Methanol[1]

BO LONG POH AND ROSS STEWART

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received May 17, 1972

The complex of manganese(III) with *trans*-1,2-diaminocyclohexanetetraacetic acid has been shown to exist as the crystalline monohydrate, $KMn^{III}CyDTA(H_2O)$, where CyDTA represents the ligand *trans*-1,2-diaminocyclohexanetetraacetate.

In aqueous methanol (2.5% water v/v) three forms of the complex exist: $Mn^{III}CyDTA(H_2O)^-$ in neutral solution, $Mn^{III}CyDTA(OH)^{2-}$ in base, and $HMnCyDTA(H_2O)$ in acid. In basic methanol the complex decomposes by disproportionation following first-order kinetics. When the same solvent system contains acid the disappearance of Mn^{III} is first-order in complex and first-order in acid but in this case methanol is oxidized to formaldehyde.

The isotope effects observed in the oxidation of CH_3OD, CD_3OH, and CD_3OD are all small (1.25 or less). This together with the acid dependence indicates that the oxidation proceeds by rate-controlling electron abstraction from methanol by the protonated form of the complex, possibly via an intermediate in which one of the coordinating ligands is replaced by methanol.

Nous démontrons que le complexe de manganèse(III) avec l'acide *trans*-1,2-diaminocyclohexanetétraacétique existe sous forme cristalline monohydratée, $KMn^{III}CyDTA(H_2)$, où CyDTA représente le ligand *trans*-1,2-diaminocyclohexanetétraacétate.

En milieu méthanol aqueux (2.5% H_2O v/v), il existe trois formes du complexe: $Mn^{III}CyDTA(H_2O)^-$ en solution neutre, $Mn^{III}CyDTA(OH)^{2-}$ en solution basique et $HMnCyDTA(H_2O)$ en solution acide. Le complexe se décompose dans le méthanol basique par disproportionnation, selon une cinétique de premier ordre. Lorsque le même système de solvant contient de l'acide Mn^{III} disparaît selon un premier ordre en complexe et un premier ordre en acide, mais dans ce cas, le méthanol est oxydé en formaldéhyde.

Tous les effets isotopiques observés au cours de l'oxydation de CH_3OD, CD_3OH et CD_3OD sont petits (1.25 ou moins). Ceci, combiné avec la dépendance de l'acide, indique que l'oxydation se déroule au moyen d'une abstraction d'électron du méthanol par la forme protonée du complexe, procédé qui contrôle la vitesse, possiblement au moyen d'un intermédiaire dans lequel un des ligands coordonnés serait remplacé par le méthanol. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3432 (1972)

Introduction

In 1967 Hamm and Suwyn (1) prepared a complex of manganese(III) with *trans*-1,2-diaminocyclohexanetetraacetic acid to which they assigned the formula $KMn^{III}CyDTA\text{-}(2.5H_2O)$ on the basis of elemental analysis (CyDTA is used as an abbreviation for the *trans*-1,2-diaminocyclohexanetetraacetic acid anion ligand). They found that this complex was stable at room temperature when it was stored in the dark, and that it existed in two forms in solution. In acidic solution, a pink species with a formula believed to be $Mn^{III}CyDTA(H_2O)^-$ predominated, and under basic conditions, the predominant species was yellow in color with a formula believed to be $Mn^{III}CyDTA(OH)^{2-}$.

Manganese(III) is an exclusively one-equivalent oxidant of considerable strength but the value of the uncomplexed ion is impaired by its instability in any but the most acidic systems (2,3). The stability of $Mn^{III}CyDTA$ over a wide p*H* range induced us to use this ion in our study of the factors affecting the oxidation of hindered phenols. The latter is the subject of the accompanying paper; herein we report the results of our study of the composition of the oxidant and its reaction with aqueous methanol, the latter being the medium used in the phenol oxidation studies.

[1]Taken in part from the Ph.D. Thesis of Bo Long Poh, 1972.

Results and Discussion

Composition of Crystalline $KMn^{III}CyDTA$

Hamm and Suwyn (1) assigned the formula $KMn^{III}CyDTA(2.5H_2O)$ to the complex they prepared, on the basis of elemental analysis. We prepared our complex in the same way as Hamm

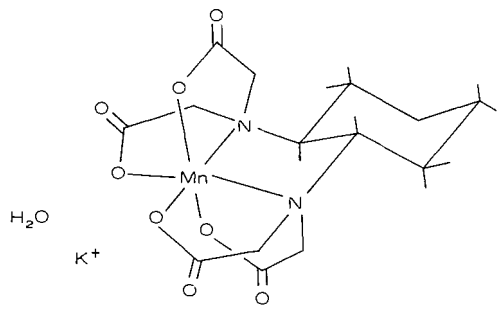

FIG. 1. Structure of potassium *trans*-1,2-diaminocyclohexanetetraacetatomanganate(III).

and Suwyn and recrystallized the crude sample (melting or decomposition point about 170°) from hot methanol–water to a m.p. of 201–203°. Karl Fischer titrations were conducted on crude and recrystallized samples of the complex. When the titrations were carried out as soon as possible after introduction of the samples the percentage of water in the two cases was found to be 6.6 and 0.6%, corresponding to 1.7 and 0.15 mol of water, respectively. It is clear that in the pure complex there is very little, if any, water that is loosely bound. After a sample of the recrystallized complex was kept in anhydrous methanol in the titration vessel for 30 min water was released corresponding to 4.0% of the weight of the complex, that is 1.0 mol of water per mole of complex. It is not certain whether a methanol molecule replaces the water molecule in the Mn^{III} complex or whether the water is released as a result of the slow decomposition of the Mn^{III} complex in the Karl Fischer reagent mixture.

Elemental analysis of the pure complex is in good agreement with the mono-aquo formula (see Experimental section) as are the results of an X-ray crystallographic study conducted by Rettig and Trotter of this department. Their structure indicates a slightly distorted octahedron of Mn^{III}; the cyclohexane ring is in a chair conformation with the two nitrogen atoms attached to the cyclohexane ring in a *trans*-diequatorial conformation (Fig. 1).

The position of the water molecule seems to vary. The major position is at a distance of 3.68 ± 0.02 Å from the Mn^{III} ion and the other position is 4.55 ± 0.02 Å from the Mn^{III} ion. These two values are much longer than a normal metal–water bond (about 2.1 Å), suggesting that the Mn^{III} ion is six-coordinated. However, the results of the Karl Fischer titrations indicate that this water molecule is bound sufficiently tightly to the manganese to remain coordinated even in solution.

The fact that the mono-aquo complex is obtained pure by recrystallization from 60% methanol and 40% water mixed solvent suggests that water is the preferred ligand. Attempts to determine the equilibrium concentration of water and methanol in the complex in the presence of 97% methanol – 3% water (the mixture used in the kinetic studies) failed. Flash evaporation of such solutions produced a solid residue which was partly decomposed and gave variable amounts of water. Throughout this article the complex will be shown containing water as the ligand.

Spectrum of the Mn^{III} Complex in Methanol (2.5% Water v/v)

The pK_a value for the equilibrium in water between the pink and yellow species of the complex was determined by Hamm and Suwyn to be 8.1.

$$\underset{\text{(pink)}}{Mn^{III}CyDTA(H_2O)^-} \overset{K_a}{\rightleftharpoons} H^+ + \underset{\text{(yellow)}}{Mn^{III}CyDTA(OH)^{2-}}$$

In methanol a similar equilibrium exists. In the absence of base, the pink species $Mn^{III}CyDTA(H_2O)^-$ predominates (absorption maximum at 510 nm). When base is added the pink color immediately changes to yellow owing to the formation of $Mn^{III}CyDTA(OH)^{2-}$ (absorption maximum at 466 nm). When acid is added to the yellow solution the color reverts back to pink immediately. We find that another form of the complex exists in methanol in the presence of an excess of acid (Fig. 2). This third species is also pink in color but its visible spectrum shows it to be different from the other two species. Its absorption maximum in the visible is at 520 nm. Addition of excess base immediately changes this species to the yellow species, and when acid is added to the resulting yellow solution, the pink color appears immediately. This third species is probably a protonated form of the Mn^{III} complex with formula $HMn^{III}CyDTA(H_2O)$. (Kinetic evidence presented in this and the accompanying paper (4) indicates the presence of such a protonated form.) Protonation probably occurs

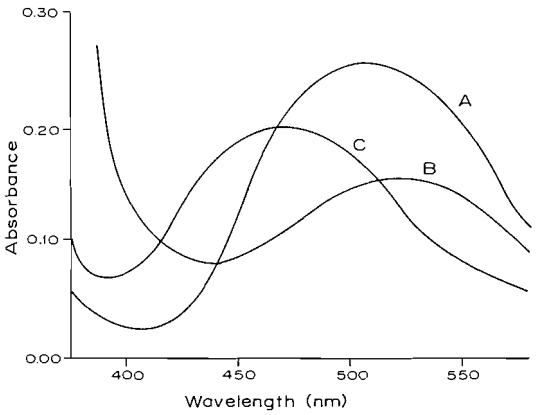

FIG. 2. Visible spectrum of a 6×10^{-4} *M* solution of $KMn^{III}CyDTA(H_2O)$ in methanol containing 2.5% water (v/v); cell width 1 cm. *A*, no acid or base added; *B*, 6.1×10^{-2} *M* in hydrochloric acid; *C*, 1.8×10^{-2} *M* in tetramethylammonium hydroxide.

at a carboxylate arm of the ligand which becomes free from coordination with the Mn^{III} ion. (The following compounds all have a free, protonated, carboxylate arm: $Cr^{III}YH(H_2O)$; $Fe^{III}YH(H_2O)$; $Ga^{III}YH(H_2O)$; $Ni^{III}YH(H_2O)$; where Y is ethylenediaminetetraacetic acid anion (5–8); in the unprotonated form, all these complexes have all the four carboxylate arms coordinated to the central metal ion.)

An attempt to measure the ionization constant of the protonated form of the Mn^{III} complex by spectrophotometry failed because of its rapid reaction with methanol.

No spectral change can be observed when acid is added to an *aqueous* solution of the Mn^{III} complex.

Decomposition of the Mn^{III} Complex in Methanol in the Presence of Base

Hamm and Suwyn reported that the Mn^{III} complex decomposes into manganese dioxide in water above p*H* 11. Similarly, in alkaline methanol the disappearance of the complex with time is due to decomposition, rather than to oxidation of methanol since only a trace of formaldehyde could be detected as a reaction product. Furthermore, when the reaction mixture at the completion of a reaction was oxidized by lead dioxide no spectrum due to the Mn^{III} complex could be obtained, thus indicating the Mn^{II} formed in the reaction mixture was not complexed to CyDTA ligands, unlike the situation in acid solution.

TABLE 1. Effect of base on the rate of decomposition of the manganese(III) complex in methanol at 25°*

Molarity of tetramethylammonium hydroxide	First-order decomposition rate (s^{-1})
0.71×10^{-2}	0.96×10^{-4}
0.90×10^{-2}	1.04×10^{-4}
1.43×10^{-2}	1.49×10^{-4}
1.78×10^{-2}	1.80×10^{-4}
2.65×10^{-2}	2.77×10^{-4}

*$[Mn^{III}]_0 = 5.4 \times 10^{-4}$ *M*.

The reaction has the following stoichiometry.

$$2Mn^{III} + 4OH^- \rightarrow Mn^{II} + MnO_2 + 2H_2O$$

The decomposition of the complex in methanolic base gave excellent first-order kinetics up to about 50% reaction. The reaction is also approximately first-order in base (Table 1). The activation parameters for the decomposition reaction are $\Delta H^* = 16.1 \pm 0.14$ kcal mol^{-1} and $\Delta S^* = -15.0 \pm 1.4$ e.u.

Reduction of the Mn^{III} Complex by Acidic Methanol

In neutral methanol the reduction of the complex is extremely slow. Addition of acid, however, results in reduction of the complex and oxidation of methanol. Three products, Mn^{II} complex, formaldehyde, and carbon dioxide, were identified, one mole of formaldehyde being produced for every 2 moles of the Mn^{III} complex used. Reaction of the Mn^{III} complex with methanol (solvent) was carried out with excess hydrochloric acid present. Plots of logarithm of the Mn^{III} absorbance *vs.* time are linear up to greater than 80% of the reaction, showing the reaction to be first order in Mn^{III}. An increase in the concentration of hydrochloric acid causes the rate to rise and then level off suggesting that the oxidant involved in the rate-determining step is the protonated species $HMn^{III}_{p^0}$. (The subscript p (for pink) identifies the color of the species and its superscript 0 (for zero) identifies the species' charge.)

The following reaction scheme is proposed to explain the kinetic results.

$$Mn^{III}_{p^-} + H^+ \underset{}{\overset{K_b}{\rightleftharpoons}} HMn^{III}_{p^0}$$

$$HMn^{III}_{p^0} + CH_3OH \xrightarrow{k} Mn^{II} + CH_3O\cdot$$

$$Mn^{III} + CH_3O\cdot \xrightarrow{\text{fast}} Mn^{II} + CH_2O$$

where $Mn_p^{III-} = Mn^{III}CyDTA(H_2O)^-$, $HMn_p^{III} = HMn^{III}CyDTA(H_2O)$.

The rate of disappearance of the Mn^{III} complex is given by eq. 1

$$[1] \quad -d[Mn^{III}]_{tot}/dt = 2k[HMn_{p0}^{III}][CH_3OH]$$

where

$$[Mn^{III}]_{tot} = [HMn_{p0}^{III}] + [Mn_p^{III-}]$$

and

$$[HMn_{p0}^{III}] + [Mn_p^{III-}] = K_b[H^+]$$

This leads to

$$[2] \quad -d[Mn^{III}]_{tot}/dt = k'[Mn^{III}]_{tot}$$

where

$$k' = 2kK_b[H^+][CH_3OH]/(1 + K_b[H^+])$$

Integration of eq. 2 gives the expression $\log [Mn^{III}]_{tot} = -k't/2.303$. The value of k' was obtained from the slopes of plots of the logarithms of the absorption of the complex at 520 nm against time. (Although both Mn_p^{III-} and HMn_{p0}^{III} absorb at this wavelength only the latter makes a significant contribution to the rate.)

Reactions of the Mn^{III} complex with methanol-d_4 (CD_3OD), methan-d_3-ol (CD_3OH), and methanol-O-*d* (CH_3OD) in the presence of deuterium chloride (hydrogen chloride was used for reaction with methan-d_3-ol) were carried out to obtain some information about the mechanism of the reaction between the Mn^{III} complex and methanol.

The values of the rate constant k' for the four isotopically distinct methanols are given in Table 2. It can be seen that the effect of deuterium substitution is small. Comparison of experiments A and D gives an isotope effect k_H/k_D of 1.25 whereas the analogous system (Experiments B and C) gives the somewhat smaller value of 1.08. Evidently a primary isotope effect is absent and the carbon–hydrogen bond in methanol is not being cleaved in the rate-controlling step. The effect of deuteration of the hydroxyl group and of the hydrochloric acid is somewhat harder to assess. A comparison of experiments A and B, and D and C, shows that the observed rate is raised somewhat by deuterium substitution of this sort. Although analysis of these data is complicated by, among other things, the uncertain effect of deuterium substitution on K_b, it is unlikely that such effects are sufficiently large to transform this small negative isotope effect into a positive effect of sufficient magnitude to correspond to rupture of the oxygen–hydrogen bond in the rate-controlling step.

TABLE 3. Effect of anion on rate of oxidation of methanol by Mn^{III} complex in acid solution at 25°*

0.82	0.81	1.52
0.33	1.30	1.49
0	1.63	1.54

*$[Mn^{III}]_0 = 5.9 \times 10^{-4}$ *M*.

The mechanism suggested for the reaction in the presence of acid involves as the rate-controlling step the transfer of an electron from methanol to manganese(III) to produce, after proton loss, a radical $CH_3O\cdot$ (or $\cdot CH_2OH$), which undergoes further, rapid, oxidation by a second mole of oxidant to give formaldehyde. Analysis of the product mixture showed that 1 mol of formaldehyde was indeed produced for every 2 mol of the Mn^{III} complex consumed. This path is further substantiated by the kinetic results obtained for the oxidation of 2,4,6-tri-*t*-butylphenol with the Mn^{III} complex in methanol in the presence of acid (4). (Recently, Wells and Barnes (9) reported the results of a study of the oxidation of methanol by Mn^{III} ion in aqueous perchloric acid. They found that 1 mol of formaldehyde was produced for every 2 mol of Mn^{III} consumed.)

Carbon dioxide was also observed as one of the reaction products. It is probably formed by oxidation of the CyDTA ligands. This is a minor reaction compared with the oxidation of methanol by the Mn^{III} complex since at the conclusion of the reaction the Mn^{II} could be

oxidized back to more than half the original concentration of the Mn^{III} complex with lead dioxide, as shown by the mixture's visible spectrum.

A convenient path for the reaction might be ligand substitution (methanol for either water or carboxylate) with the electron transfer taking place within the complex, thus accounting for the small isotope effects observed. (Indeed, ligand substitution could even be rate-controlling.) The radical that is subsequently formed by proton loss could be either the methoxy radical $CH_3O\cdot$ of the hydroxymethyl radical $\cdot CH_2OH$. The latter is the more easily formed when hydrogen-atom abstraction from methanol occurs directly. However, proton loss from the hydroxyl group of a radical-cation such as CH_3OH^+ should occur with extreme ease and we accordingly write the intermediate radical as $CH_3O\cdot$ rather than as $\cdot CH_2OH$. The results in this and the accompanying paper, however, can equally well be accommodated by the latter species.

The effect of chloride ion on the reaction is rather small, as shown by two pieces of evidence. First, the spectrum of the Mn^{III} complex in methanol containing hydrochloric acid is identical to that in methanol containing an equivalent amount of perchloric acid. Secondly, the rate of oxidation of methanol by the Mn^{III} complex is not greatly affected by the replacement of hydrochloric acid by perchloric acid (Table 3).

The protonated form of the Mn^{III} complex, $HMn^{III}CyDTA(H_2O)$, is a much more powerful oxidant than $Mn^{III}CyDTA(H_2O)^-$. It is not certain whether the slow disappearance of the latter in methanol is due to oxidation of methanol or simply to decomposition of the complex. In the absence of acid the pseudo first-order rate constant in methanol is $2.24 \times 10^{-6}\ s^{-1}$ at 25°, close to the reported rate of decomposition of $Mn^{III}CyDTA(H_2O)^-$ in water, $6.8 \times 10^{-6}\ s^{-1}$ at 25° (1).

Experimental

Potassium *trans*-1,2-diaminocyclohexanetetraacetatomanganate(III) was prepared by the method of Hamm and Suwyn (1) and was purified by recrystallization from methanol–water; m.p. 201–203°. Elemental analysis indicates that this compound has one molecule of water per molecule of compound.

Anal. Calcd. for $KMnC_{14}H_{18}N_2O_8(H_2O)$: C, 37.00; H, 4.40; N, 6.17. Found: C, 36.98; H, 4.46; N, 6.0. (Anal. Calcd. for $KMnC_{14}H_{18}N_2O_8(2.5H_2O)$: C, 34.92; H, 4.78; N, 5.82.)

Spectrophotometry was used to monitor the disappearance of the Mn^{III} complex by following the disappearance of the visible absorption near 500 nm. A $6.92 \times 10^{-2}\ M$ stock solution of $KMn^{III}CyDTA(H_2O)$ in distilled water was prepared and stored under nitrogen in a wrapped vial equipped with a rubber seal. Transfers were made using syringes and all reactions conducted in a nitrogen atmosphere.

Carbon dioxide was detected using the sodium carbonate–phenolphthalein test (10). Formaldehyde was analyzed by the chromotropic acid method (11).

All rate constants and activation parameters were obtained by the method of least squares using a Hewlett–Packard calculator and plotter, model 9125 A. The listed errors in the activation parameters are standard variance estimates (12).

The financial support of the National Research Council of Canada is gratefully acknowledged. B.L.P. is grateful to the Canadian International Development Agency for a scholarship.

Oxidations with Potassium *trans*-1,2-Diaminocyclohexanetetraacetatomanganate(III). II. Reaction of the Complex with Hindered Phenols[1]

ROSS STEWART AND BO LONG POH

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received May 17, 1972

A series of 4-substituted-2,6-di-*t*-butylphenols has been oxidized with potassium *trans*-1,2-diaminocyclohexanetetraacetatomanganate(III) $KMn^{III}CyDTA(H_2O)$, in methanol containing 2.5% water by volume. Addition of either acid or base greatly accelerates the reaction, acid because it produces $HMn^{III}CyDTA(H_2O)$, and base because it produces both $Mn^{III}CyDTA(OH)^{2-}$ and the phenolate ion.

In acidic methanol $HMn^{III}CyDTA(H_2O)$ reacts with both methanol and the phenol leading to formation of both methoxy and aryloxy radicals. The latter are stable in some instances and in others undergo further reaction. The methoxy radicals produced by the concomitant oxidation of methanol are competed for by Mn^{III} and by phenol; formaldehyde and Mn^{II} being the products in the former case and methanol and aryloxy radicals in the latter case.

In basic methanol $Mn^{III}CyDTA(OH)^{2-}$ converts the hindered phenols to aryloxy radicals, some of which are stable and others of which undergo further reaction.

Isotope effects, k_H/k_D, between 5 and 6 are observed for the oxidation of the phenols in acidic or neutral CH_3OD. Smaller effects (less than 2) are observed in basic solution. Substituents have a large effect on the reaction only in basic solution. The ρ of 2.69 in base probably reflects the effect of substituents on the ionization of the phenol.

Une série de 2,6-di-*t*-butylphénols substitués en position 4 ont été oxydés au moyen du *trans*-1,2-diaminocyclohexanetétraacétatomanganate(III) de potassium, soit $KMn^{III}CyDTA(H_2O)$, dans du méthanol contenant 2.5% d'eau par volume. L'addition d'un acide ou d'une base accélère fortement la réaction: l'acide produit $HMn^{III}CyDTA(H_2O)$ et la base, $Mn^{III}CyDTA(OH)^{2-}$ et l'ion phénolate.

En milieu méthanol acide, $HMn^{III}CyDTA(H_2O)$ réagit à la fois avec le méthanol et le phénol pour former les radicaux méthoxy et aryloxy. Dans certains cas, ces derniers réagissent et dans d'autres cas ils sont stables. Mn^{III} et le phénol entrent en compétition pour réagir avec les radicaux méthoxy produits par l'oxydation du méthanol; la formaldéhyde et Mn^{II} sont les résultats de la première possibilité, le méthanol et les radicaux aryloxy, de la seconde.

En milieu méthanol basique, $Mn^{III}CyDTA(OH)^{2-}$ réagit sur les radicaux phénols gênés pour les transformer en radicaux aryloxy, dont quelques-uns sont stables et d'autres continuent à réagir.

On observe des effets isotopiques, k_H/k_D, entre 5 et 6 pour l'oxydation des phénols en milieu CH_3OD acide ou neutre. Des effets moins importants (moins de 2) apparaissent en milieu basique. Les substituants ont un effet important sur la réaction en solution basique seulement. Le ρ de 2.69 en milieu basique reflète probablement l'effet des substituants sur l'ionisation du phénol. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3437 (1972)

Introduction

In the previous paper we reported the results of our studies on the composition and structure of potassium *trans*-1,2-diaminocyclohexanetetraacetatomanganate(III), $KMn^{III}CyDTA(H_2O)$, and its reaction with aqueous methanol (1). This paper reports the results of a study of the reaction of this complex with a series of hindered phenols in methanol containing 2.5% water by volume. Hindered phenols such as 2,4,6-tri-*t*-butylphenol (**1**) are useful substrates for oxidation studies because of their tendency to undergo clean one-equivalent oxidations to give stable aryloxy radicals (2–6).

The oxidants usually used to convert phenols to aryloxy radicals are alkaline ferricyanide (7) and lead dioxide (6). High yields are obtained with the former oxidant only when a large excess of reagent is used, and with the latter only when the reagent is high in active oxygen and when the solution is dilute in phenol. A further drawback to the use of lead dioxide in a kinetic study is its extremely low solubility.

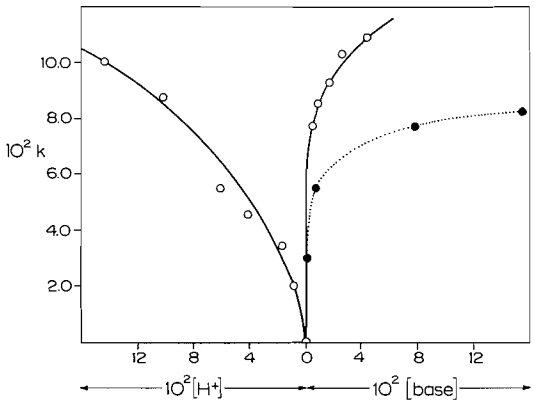

FIG. 1. Effect of added acid or base on the second-order rate of the reaction of $KMn^{III}CyDTA(H_2O)$ with 2,4,6-tri-*t*-butylphenol in methanol containing 2.5% water by volume, $T = 25°$; $[H^+]$ = molarity of hydrochloric acid, [base] = molarity of tetramethylammonium hydroxide (open circles) or *t*-butylamine (closed circles). The values of the rate plotted on the ordinate are the observed pseudo first-order rate constants divided by the concentration of phenol; $[Mn^{III}]_0 = 5.6 \times 10^{-4}$ *M*, $[ArOH]_0 = 2.5\text{–}5.1 \times 10^{-2}$ *M*.

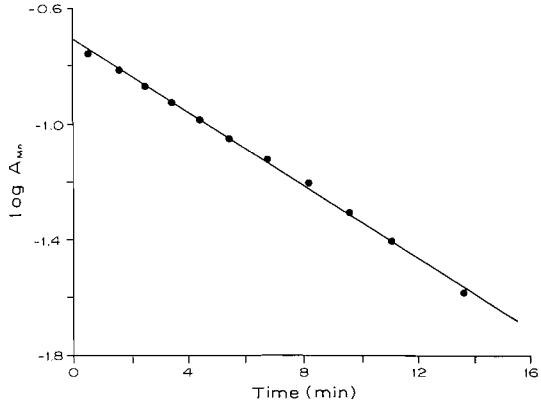

FIG. 2. Rate plot for disappearance of Mn^{III} complex in aqueous methanol containing an excess of 2,4,6-tri-*t*-butylphenol and base. $T = 25°$; $[Mn^{III}]_0 = 5.6 \times 10^{-4}$ *M*, $[ArOH]_0 = 2.52 \times 10^{-2}$ *M*, $[(CH_3)_4N^+OH^-]_0 = 1.78 \times 10^{-2}$ *M*.

We have used the one-equivalent reagent $KMn^{III}CyDTA(H_2O)$ as an oxidant for hindered phenols because this system enables us to follow the rate of the reaction in a homogeneous medium whose acidity can be easily varied. Among other things we hoped to learn was the effect of charge type of the oxidant and reductant on the rate of a reaction that takes place exclusively by one-equivalent paths. Charge type is known to be of importance in other oxidation–reduction systems (8).

Results and Discussion

The effect of acid or base on the rate of conversion of 2,4,6-tri-*t*-butylphenol (**1**) to 2,4,6-tri-*t*-butylphenoxyl (**2**) by the Mn^{III} complex is shown in Fig. 1. The addition of either acid or base causes drastic increases in the rate of the reaction. A quantitative conversion of phenol **1** to radical **2** was observed under all conditions as shown from the visible and e.s.r. spectra of the product.

In both acidic and basic systems the rate of disappearance of the Mn^{III} complex in the presence of excess phenol is first-order in Mn^{III} over several half-lives (Fig. 2). The other reactants, methanol, the phenol, and acid or base were always present in considerable excess and the rate of disappearance of Mn^{III} could be expressed as $-d[Mn^{III}]_{tot}/dt = k'[Mn^{III}]_{tot}$. When no acid or base is added the reaction is very slow and is first-order in Mn^{III} only after the first 7% or so of reaction has taken place, the initial reaction being the more rapid. Presumably this effect is due to the unbuffered nature of the system and the presence of a small amount of the more reactive oxidant Mn^{III}-$CyDTA(OH)^{2-}$. As the reaction proceeds acid is produced and eventually the equilibrium shown in eq. 1 lies far to the left.

$$[1] \qquad Mn_p^{III} \overset{K_a}{\rightleftharpoons} Mn_{y^2}^{III} + H^+$$

where $Mn_p^{III} = Mn^{III}CyDTA(H_2O)^-$, $Mn_{y^2}^{III} = Mn^{III}CyDTA(OH)^{2-}$, $HMn_{p^0}^{III} = HMn^{III}CyDTA(H_2O)$, ArOH = 2,4,6-tri-*t*-butylphenol (**1**).

The Reaction in Acidic Solution

Although doubling the concentration of Mn^{III} doubles the rate of reaction, doubling the concentration of phenol can either speed up or slow down the disappearance of Mn^{III}, depending on the concentrations of phenol that are used. These observations together with the observed activation by acid (Fig. 1) can be accounted for in the following way, where the protonated complex reacts initially with both methanol and the phenol.

$$[2] \qquad Mn_p^{III} + H^+ \overset{K_b}{\rightleftharpoons} HMn_{p^0}^{III}$$

[3] $HMn_{p^0}^{III} + CH_3OH \longrightarrow CH_3O\cdot + Mn^{II}$

[4] $HMn_{p^0}^{III} + ArOH \longrightarrow ArO\cdot + Mn^{II}$

[5] $CH_3O\cdot + Mn^{III} \xrightarrow{fast} CH_2O + Mn^{II}$

[6] $CH_3O\cdot + ArOH \xrightarrow{fast} CH_3OH + ArO\cdot$

Since the concentration of the Mn^{III} complex was much smaller than that of either methanol or the phenol, Mn^{III} should disappear at a first-order rate regardless of the relative rates of the steps in the competitive reactions 3 and 4, and 5 and 6. This was found to be so and the pseudo first-order rate constants, k', used to calculate the second-order rate constants shown in Fig. 1 were obtained experimentally from the relation $\log [Mn^{III}]_{tot} = -k't/2.303$ (see Fig. 2).

In the proposed mechanism 2,4,6-tri-*t*-butylphenol and the Mn^{III} complex compete for the methoxy radicals (or hydroxymethyl radicals (1)). If this is true, a plot of k' *vs.* the concentration of 2,4,6-tri-*t*-butylphenol should show a minimum at a certain concentration of the phenol. When the latter's concentration is at or near zero the methoxy radicals are essentially all oxidized to formaldehyde, eq. 5, thus reducing a second mole of manganese(III). Small amounts of added phenol intercept the methoxy radicals giving methanol and inert aryloxy radicals, eq. 6, and the reduction of manganese(III) is slowed. When the concentration of added phenol passes a certain value reaction 4 becomes dominant and the reaction rate then rises as a function of the phenol concentration. Figure 3 is a plot of observed rate against phenol concentration and it, indeed, has the expected shape.

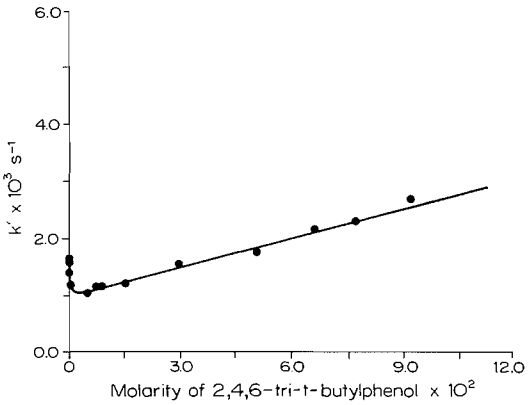

FIG. 3. Effect of changing the concentration of 2,4,6-tri-*t*-butylphenol on the rate of reduction of Mn^{III} complex in aqueous methanol containing acid. $T = 25°$; $[Mn^{III}]_0 = 5.6 \times 10^{-4}$ *M*, $[HCl] = 1.63 \times 10^{-2}$ *M*.

The Reaction in Basic Solution

The activation by base shown in Fig. 1 appears to have two causes: conversion of $Mn_{p^-}^{III}$ to the more active oxidant, $Mn_{y^{2-}}^{III}$, and conversion of the neutral phenol to the more active reductant, the phenoxide ion. The hindered phenol **1** is approximately four p*K* units weaker as an acid than is $Mn_{p^-}^{III}$ and it is possible to study the effect of the change in identity of the oxidant alone by conducting the reaction in the presence of a weak base. *t*-Butylamine was used for this purpose. Addition of small amounts of the amine greatly catalyze the oxidation reaction but the curve of rate *vs.* concentration begins to flatten out at concentrations of amine greater than about 10^{-2} *M* (Fig. 1), when the $Mn_{p^-}^{III}$ to $Mn_{y^{2-}}^{III}$ conversion is more than half complete. (The conversion of the phenol to phenoxide ion has occurred to the extent of less than 0.1% when the amine concentration is 10^{-2} *M*.) A similar effect occurs with added hydroxide ion but there is a much greater conversion of phenol to phenoxide ion and the observed reaction is correspondingly faster (Fig. 1).

In basic solution the reaction could be monitored by following the increase in absorption due to **2** at 400 nm, in addition to following the decrease in absorbance of the manganese(III) complex. Fair agreement was obtained between the two methods, considering that in basic solution some decomposition of the complex accompanies the oxidation.

Kinetic Isotope Effect

In both neutral and acidic solution a substantial isotope effect is obtained when the oxidation of **1** is conducted in methanol-*d*. The values of k_H/k_D at 25° are 4.8 in acid solution (DCl used as acid) and 5.9 in neutral solution. In basic solution the isotope effects are much smaller; less than 2.0 in all cases. An exhaustive analysis of the results in basic solution does not seem worthwhile because of the difficulties encountered in making a meaningful partition of the small effect observed between several processes, *viz.*, decomposition of the complex, oxidation of the neutral phenol, oxidation of

the phenoxide ion, and dissociation of the phenol. The small size of the isotope effects is, however, consistent with electron abstraction from the phenoxide ion being the predominant reaction.

A reasonable route for the reaction of the manganese(III) complex with methanol was considered to be substitution of methanol for the water ligand in the complex followed by electron transfer to manganese and liberation of a methoxy (or hydroxymethyl) radical (1). We do not favor this route for the hindered phenols since their bulk is such as to make substitution difficult. Furthermore, the substantial isotope effect observed in acid solution with **1** (but not with methanol) suggests that abstraction of a hydrogen atom from neutral phenol by the neutral manganese(III) complex may be taking place. In basic solution this appears to be replaced by electron transfer from the phenoxide ion to the dianionic form of the complex as the principal reaction path.

Substituent Effects

The effect of different substituents in the 4-position of 2,6-di-*t*-butylphenols was examined under various conditions (Table 1). In neutral and acidic solution the effect of substituents is slight ($\rho = -0.07$ in neutral solution and $+0.39$ in acidic solution), a condition that is consistent with the transition state having radical character as a result of hydrogen-atom abstraction from the phenolic hydroxyl group. Two groups, —OH and —CHO, cause large deviations from the Hammett plots and in the case of hydroxyl this is due to its being oxidized directly. The formyl case is more difficult to understand. Benzaldehyde is oxidized only one-tenth as fast as is 2,6-di-*t*-butylphenol under the reaction conditions and a very large reaction constant (ρ) for aromatic aldehyde oxidation would be needed to account for direct oxidation of the formyl group in the case of the substituted compound. Furthermore, a substantial kinetic isotope effect ($k_H/k_D = 4.9$) was observed when the formyl compound was oxidized in CH_3OD containing DCl, indicating that attack takes place at the phenolic group.

In basic solution there is a large effect of substituents, consistent with the phenolate

anion being the principal reactive entity. A value of 2.7 was found for the reaction constant ρ for four substituted phenols under conditions where **1** is only slightly ionized. With most electron-withdrawing substituents the reactions were too fast to measure. The high ρ is probably a reflection, principally, of the effect of substituents on the ionization step, which produces the more reactive reductants, the phenolate anions.

Reaction Products

The initial product of the reaction between the 4-substituted-2,6-di-*t*-butylphenols and Mn^{III} is believed to be the aryloxy radical **3**, and, indeed, in the case of five of the phenols the radicals are sufficiently stable for their e.s.r. spectra to be determined. In other cases further reaction takes place (see Table 2).

Experimental

Preparation of Compounds

The identity of each phenol was checked by examination of its n.m.r. spectrum and by the correspondence of its melting point with that reported in the literature. The following compounds were prepared by standard procedures (literature references in parentheses): 3,3′,5,5′-tetra-*t*-butyl-*p*-diphenoquinone, (**8**), m.p. 246–247°; bis-(1,3,5-tri-*t*-butyl-2,5-cyclohexadiene-4-one)peroxide (**9**), m.p. 148–149 (9); 3,5-di-*t*-butyl-4-hydroxybenzaldehyde[2] m.p. 189–190° (10); 2,6-di-*t*-butyl-4-bromophenol, m.p. 83–83.5° (11); 2,6-di-*t*-butyl-4-chlorophenol, m.p. 74–76° (11, 12); 2,6-di-*t*-butyl-4-iodophenol, m.p. 77–79° (11); 2,6-di-*t*-butyl-4-acetylphenol, m.p. 150–151° (13); 2,6-di-*t*-butyl-4-benzoylphenol, m.p. 124–124.5° (13); 2,6-di-*t*-butyl-4-hydroxyphenol, m.p. 103–104° (2); 2,6-di-*t*-butyl-4-cyanophenol, m.p. 145–146° (14). The other phenols were obtained from commercial sources.

[2]Since this compound reacted at an anomalously high rate it was subjected to a number of rigorous identity checks including elemental analysis.

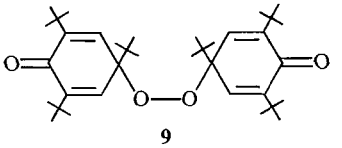
Product Analysis and Rate Measurements

Radicals were identified by e.s.r. spectrometry using a Varian E-248-1 instrument. The ultraviolet and visible spectrum of non-radical products were compared with those obtained using authentic samples. The extinction coefficient of 3,3′,5,5′-tetra-*t*-butyl-*p*-diphenoquinone (**8**) in methanol was determined at various concentrations of solute and found to obey Beer's law very closely. The slope of the plot of absorbance at 419 nm against concentration gave a slope of 79 000 for the extinction coefficient. In a similar way the extinction coefficient of bis-(1,3,5-tri-*t*-butyl-2,5-cyclohexadiene-4-one)peroxide (**9**) was shown to be 22 010 at 240 nm in methanol, compared to the literature value of 25 800 at 240 nm in benzene (9).



9

It is difficult to prepare a pure sample of 2,4,6-tri-*t*-butylphenoxyl (3) because of its reactivity towards oxygen. The method used here to determine its extinction coefficient avoids the difficult step of isolating a pure solid sample. It involves the generation of **2** from its phenol using lead dioxide as the oxidant, and determining its concentration from the amount of **9** that is formed. A 9.8 mg sample of **1** was mixed with 0.1 g of lead dioxide in a 2 ml centrifuge tube, which was sealed with a rubber cap and the contents flushed with nitrogen. A 1.5 ml aliquot of methanol (which had been flushed with nitrogen) was syringed into the tube through the rubber cap and the contents of the tube were shaken for 1 min. Then, the tube was centrifuged for 2 min, whereupon a clear blue solution of **2** appeared above the lead dioxide layer. A 0.025 ml aliquot of this clear blue solution was syringed into each of: (*a*) two 1 cm cells each containing 3 ml of oxygen-free methanol and capped with a silicon rubber disc, and (*b*) two test-tubes each containing 3 ml of methanol saturated with oxygen. Absorbance readings at 400 nm for **2** in the two oxygen-free cells were recorded. The solutions in the two test-tubes containing oxygen were left to stand for a few hours to ensure that all of **2** was converted to **9** and then the absorbance at 240 nm was recorded for each sample. Since the absorbance of 2,4,6-tri-*t*-butylphenol is at its minimum in this region any unreacted 2,4,6-tri-*t*-butylphenol would make a negligible contribution to the absorbance at 240 nm. Knowing the extinction coefficient of **9**, its concentration could be calculated, and doubling this concentration gives the concentration of **2** and hence the extinction coefficient, assuming that the same quantity of **2** was formed in the two sets of experiments. It was found that all duplicate samples gave results in good agreement with one another. This procedure was followed for three other quantities of 2,4,6-tri-*t*-butylphenol (up to 23.8 mg) with the weight of lead dioxide used being kept at 0.1 g. An average value of 1955 ± 66[3] was obtained for the extinction coefficient of **2** at 400 nm in methanol compared with the value of 2050 at 400 nm reported in benzene (15).

[3]The values calculated for the extinction coefficient of **2** at various initial concentrations of **1** are as follows: 1943 (2.07×10^{-4} *M*), 2049 (3.09×10^{-4} *M*), 1896 (4.03×10^{-4} *M*), 1933 (5.00×10^{-4} *M*). The extinction coefficient, thus, does not appear to be a function of concentration, indicating that Beer's law is obeyed for **2** and that no significant amount of dimerization occurs.

Reaction rates were determined by monitoring the disappearance of Mn^{III}, as previously described (1), and in the case of 2,4,6-tri-*t*-butylphenoxyl the appearance of the spectrum of the radical at 400 nm. All rate constants were obtained using least square calculations.

Effect of Specific Cations on the Oxidation Rate

It was observed that the rate of the oxidation reaction in basic solution varied with the identity of the cation that was used. Taking the rate for the reaction in the presence of tetramethylammonium hydroxide to be unity gives the following values for the relative rates in the presence of other bases: $(C_3H_7)_4NOH$ (1.5), $(n\text{-}C_4H_9)_4NOH$ (1.5), LiOH (1.7), NaOH (2.3), KOH (3.4). The effect of specific cations on oxidation rates has also been noted by other workers (16).

Reversibility of the Reaction

Although there was no indication that the radical-forming reaction studied herein was reversible we have observed that the corresponding reaction with ferricyanide is clearly so. Mixtures of **2** and acidic ferrocyanide produce considerable amounts of ferricyanide ion, which can be identified by its ultraviolet spectrum.

The Infrared Spectrum of Ethylene Oxide Clathrate Hydrate between 360 and 20 cm^{-1}, at 100 °K

J. E. BERTIE AND D. A. OTHEN[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received January 11, 1972[2]

The infrared spectra of authenticated samples of ethylene oxide hydrate and deuterate at 100 °K have been measured between 360 and 20 cm^{-1}. The spectra confirm that the water molecules are orientationally-disordered and reorient slowly compared to far-infrared frequencies. An empirical correlation is suggested between the frequencies of strong absorption and the number of non-equivalent hydrogen bonds, their length and distribution. The contribution to the spectrum by the ethylene oxide intermolecular vibrations is discussed.

Les spectres infrarouges d'échantillons authentiques d'hydrate et de deutérate d'oxyde d'éthylène à 100 °K ont été mesurés entre 360 et 20 cm^{-1}. Les spectres confirment une orientation désordonnée des molécules d'eau se réorientant lentement lorsqu'on les compare aux fréquences de l'infrarouge lointain. Une corrélation empirique a été suggérée entre les fréquences de forte absorption et le nombre de liaisons hydrogène non-équivalentes, leur longueur et leur distribution. La contribution au spectre, de vibrations intermoléculaires de l'oxyde d'éthylène, est discutée. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3443 (1972)

Introduction

Ethylene oxide hydrate (1, 2) has been studied by X-ray diffraction (2, 3), dielectric relaxation (4–7), and proton magnetic resonance (7–9) techniques. The variation of its stoichiometry with the parent-solution composition (10) and of its lattice dimensions with stoichiometry (11) have also been studied.

X-Ray studies (2, 3) have shown that the hydrate has the 12 Å cubic, Type I clathrate hydrate structure. The 46 water molecules per unit cell form six tetrakaidecahedral and two pentagonal dodecahedral cages, called large and small cages, respectively, hereafter. When the hydrate is formed under equilibrium conditions the large cages each contain one ethylene oxide molecule while the small cages have shown occupancies of 19 to 40%, corresponding to stoichiometries from $6.38\,C_2H_4O{\cdot}46H_2O$ to $6.80\,C_2H_4O{\cdot}46H_2O$ (3, 10). Flash frozen samples have formed (11) with the stoichiometry $1.1\,C_2H_4O{\cdot}46H_2O$ and a lattice parameter 0.4% smaller than for $6.8C_2H_4O{\cdot}46H_2O$. The ethylene oxide (guest) molecules are not hydrogen-bonded to the host, and the X-ray diffraction results showed that the guests in the large holes reorient between two preferred orientations (3). The specific orientations reported (3) have been questioned (12) as a result of calculations of the energy distribution in the cages. The water molecules are hydrogen-bonded with distorted-tetrahedral co-ordination and are orientationally-disordered (3).

Dielectric relaxation studies have shown that the water molecules reorient at about 1 Mc/s at 240 °K, but freeze into disordered orientations below about 140 °K (4). The guest molecules reorient at 6.6 Gc/s at 88 °K (5, 6) and 1 Kc/s at 28 °K (7). The mean activation energy for guest molecule reorientation between 28 and 88 °K is about 1.26 kcal/mol (7). The p.m.r. results (7–9) are consistent with those from the dielectric studies, and suggest that the molecules rotate isotropically above about 230 °K (7). These results do not appear to be consistent with the conclusions drawn from the X-ray analysis (3) concerning the number of preferred positions of the guest molecule in the large cages and the mode of reorientation between these positions, but suggest, as do the energy calculations (12), the existence of several preferred orientations with low energy barriers between them. No evidence exists for preferred positions of the guests in the small cages (3) and no evidence specifically indicates different reorientation behavior of guest molecules in the two types of cages (5–9), although a wide range of behavior does appear to occur (7).

The present work has two aims. First, to observe the spectrum of the water molecules, to give further evidence on the factors influencing the far-infrared spectrum of condensed water. Second, to try to locate absorption due to the intermolecular vibrations of the guest molecules.

This guest-molecule absorption is predicted from theoretical considerations and its presence has been inferred from the dielectric constant studies (7). At 4 °K the dielectric constant at 1 Kc/s is 4.1 ± 0.3 (7), compared to 2.85 ± 0.1 for the isostructural hydrates of the non-dipolar guests argon (13), nitrogen (13), and cyclopropane (14). The orientation relaxation for both guest and host molecules occurs below 1 Kc/s at 4 °K, and does not contribute to the value of 4.1. Therefore the difference of 1.25 must arise from lattice vibrations of the ethylene oxide molecules, probably mainly rotational vibrations. At 100 °K the situation is less clear. The dielectric constant at 1 Kc/s is about 14 (7) and includes the contribution from the orientation polarization of the guest. Part of the orientation relaxation occurs at about 10 Gc/s at 100 °K (6) but the high-frequency limit is not known. It is reasonable to assume that this limit is about 10 cm^{-1}, in which case the absorption above 10 cm^{-1} must account for a low-frequency dielectric constant of about 4.1. Quite strong absorption by the guest molecules must occur in the far-infrared spectrum to account for this value, when the corresponding value for the same water structure but with a non-dipolar guest is about 2.85.

Experimental

Two techniques, based on the work of Wurtz (15), were used to prepare the hydrate. (*i*) Ethylene oxide (Matheson 99.7%, unpurified) was bubbled through 5 ml of distilled water at room temperature for 30 min. The solution was then left in a 5 ± 2 °C cold room in a stoppered flask. When crystallization was complete the crystals were quickly blotted free from mother liquor, in the cold room, and were cooled in liquid nitrogen. The samples were kept at about 100 °K from this point on, using techniques described previously (16). (*ii*) Distilled water (5 ml), in a pre-weighed flask, was outgassed in vacuum and re-weighed. Ethylene oxide, triply-distilled in vacuum from −80 °C and checked for purity by infrared spectroscopy, was condensed into the flask from a vacuum line, and the flask was closed and re-weighed. The procedure then followed that of method (*i*).

The hydrate was ground using a SPEX freezer mill, cooled with liquid nitrogen. The sample does not contact the coolant in this grinder and must be ground in short bursts with re-cooling time between bursts, to avoid excessive heating. One minute of grinding was followed by 5 min cooling times in this work. The ground powder was stored under liquid nitrogen in the inner of two glass bottles.

The ground samples were characterized by powder X-ray methods using techniques previously described (16). The sample temperature on the camera was 130 °K.

Infrared spectra were measured between 360 and 20 cm^{-1} using a Beckman-RIIC model FS 720 interferometer. Interferograms were run from $+x$ to $-x$ cm path difference and were transformed using sine and cosine Fourier transformation, the intensity being obtained from the square root of the sum of the squares of the two transforms. Step and Moiré (continuous) driving mechanisms for the moving mirror were used, the step drive being slightly superior to the Moiré drive below 50 cm^{-1}. High-frequency cut-off filters were purchased from Beckman Instruments Inc. The electronics of the interferometer are non-standard in that the d.c. output is fed into a Hewlett–Packard model 2401C digital voltmeter and the voltage is punched onto cards using an IBM model 026 card punch driven by the voltmeter via a Hewlett–Packard model 2540B coupler. The digitized interferograms were Fourier-transformed on the IBM model 360/67 computer at the University of Alberta using BOBS IV, a program written in Fortran IV in this laboratory, and the spectra were plotted on an off-line Calcomp plotter. The program uses the subroutine RHARM from the IBM scientific sub-routine package, and permits the ratioing of two spectra to eliminate the background and obtain the absorbance of the samples. It also permits the averaging of several spectra to reduce the random noise level. Triangular apodization was used in all transforms. The calibration of the interferometer was checked several times using water vapor (17), hydrogen chloride (18), and methyl chloride (19), and the literature values were reproduced to at least ± 0.2 cm^{-1}. The only exception to this statement occurs above 250 cm^{-1}, where the step-drive gives very large errors, and is not used.

The infrared samples were prepared by mulling the powdered hydrate with liquid propane or Freon-13 using methods described previously (16). For the reference spectra the same procedure was followed except that no hydrate was used. The absence of ice absorption in these reference spectra served as a check on the technique and therefore they were recorded regularly. Two cells were used to maintain the samples at about 100 °K in the interferometer. The first was a stainless steel cell of conventional design with a copper sample holder, in vacuum, soldered to the bottom of the liquid nitrogen reservoir. We did not succeed in determining the actual sample temperature in this cell, and to reduce the doubt on this point, spectra below 120 cm^{-1} were also recorded with the sample held in a Janis model 8 DT variable temperature Dewar, using liquid nitrogen as the coolant. In this cell the sample is surrounded by gas at atmospheric pressure, and the temperature could be well-controlled at 90 ± 1 °K. Polyethylene windows, tapered to reduce interference fringes, were used throughout, except for the cold sample chamber of the Janis cell where crystal quartz windows were used.

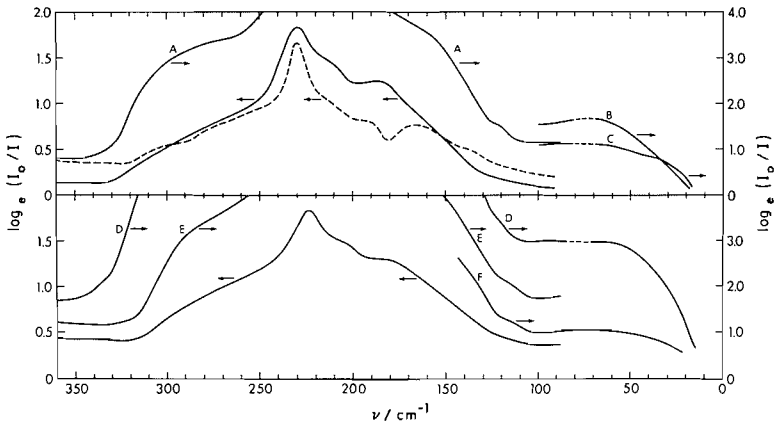

FIG. 1. The far-infrared spectrum of ethylene oxide hydrate (upper box) and deuterate (lower box) at 100 °K. Curves carrying different letters were obtained from different mulls. The arrows indicate the appropriate absorption scale. The dashed curve is the spectrum of H_2O ice I*h*, obtained in the same way as those of the hydrate.

Results

The *d*-spacings and qualitative intensities obtained from the X-ray photographs of the hydrate agreed with those calculated from the single-crystal study (3) and confirmed that the samples were ethylene oxide hydrate. The *d*-spacings differed slightly, of course, because of our lower temperature and different stoichiometry. Photographs of the two samples of ethylene oxide deuterate and one of the three hydrate samples showed very weakly the strongest ice I*h* lines, but no differences were seen between the spectra of the pure and impure hydrate samples, and the spectra of the deuterate were consistent with those of the hydrate.

The stoichiometry of our samples was not measured. One of the hydrate samples was prepared by method (*ii*) from a solution containing 13 mol% of ethylene oxide, and should have the stoichiometry $6.8C_2H_4O{\cdot}46H_2O$ (10). The other samples, prepared by method (*i*) were probably not of uniform stoichiometry. At least 85% of the solution crystallized when these samples were formed, so the solutions must have contained at least 11 mol% ethylene oxide. Using Glew and Rath's results (10), it therefore seems probable that their stoichiometries varied within a sample from about 6.3 to 6.6 or $6.8C_2H_4O$ per $46H_2O$. Unless the spectrum contained absorption specific to guest molecules in the small cages, no clear differences would be expected between the spectra of different samples with such small differences in stoichiometry, and none were observed.

The spectra of ethylene oxide hydrate and deuterate at 100 °K are presented in Fig. 1 at 2 cm^{-1} resolution. The curves shown were obtained by averaging the individual absorbance spectra in groups of about six, and smoothing a few small features that were not reproducible even after averaging. Below 100 cm^{-1} the curves shown are composites of curves, obtained as just described, which covered different frequency regions and which matched well in the overlap regions. A spectrum of ice I*h* between 360 and 100 cm^{-1} obtained in the same way as those of the hydrate is included in Fig. 1 for comparison. In all cases the reference spectrum, I_0, was obtained as discussed in the previous section. The frequencies of the various features of the hydrate spectrum are listed in Table 1. For all features other than the peak the choice of frequency is subjective and it is not useful to assign error limits. The most difficult feature to characterize by a frequency is the low-frequency edge of the plateau below 100 cm^{-1}. This feature is not sharp and its exact shape was found to be very difficult to determine. The curves in Fig. 1 show typical variations. We believe that the variation arises from the difficulty of making good mulls of the 50 to 150 μ thickness required for this region. The existence of the plateau between 100 and about 60 cm^{-1} and of the drop-off below about

110	Inflection	105
~60	Low-frequency edge of plateau	~60

60 cm^{-1} are not in doubt and no justification exists at present for further work to pin-point the frequency at which the plateau ends.

Discussion

The absorption below 360 cm^{-1} is expected to arise from the translational vibrations of the water molecules and the intermolecular vibrations of the ethylene oxide molecules. Above 100 cm^{-1} the spectrum shifts to low-frequency by about 3% when the water is deuterated, indicating clearly that the dominant absorption arises from the translational vibrations of the water molecules. Below 100 cm^{-1} the spectrum does not permit an isotope shift to be observed and therefore can not be assigned from experimental evidence.

The spectra consist of a broad absorption with well-defined features upon it, but no particularly sharp features occur. Because of theoretical considerations (20) and a knowledge of the spectra of several phases of ice (21–23), the spectra confirm the conclusion drawn from X-ray (3) and dielectric (4) studies that the water molecules are orientationally disordered, and reorient at 100 °K extremely slowly compared to far-infrared frequencies. Theory (20) predicts that the spectrum is a superposition of broad absorption, which approximates the density of states weighted by frequency-squared, and sharp absorption due to transitions allowed under the factor group of the diffraction space group, $Pm3n$, O_h^3. Nine F_{1u} water translational modes are infrared allowed by the diffraction symmetry, but because no sharp-features are

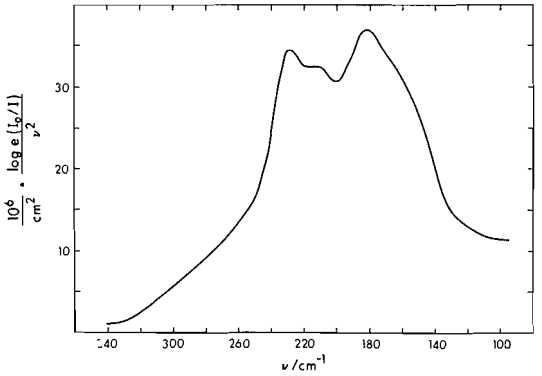

FIG. 2. $(\log_e I_0/I)/\nu^2$ plotted against ν for ethylene oxide hydrate at 100 °K. Calculated from the unlabelled curve in the upper box of Fig. 1.

seen they do not appear to influence the spectrum. The spectrum arises, then, from the disorder-allowed absorption and the curve shown in Fig. 2, representing absorbance-divided-by-frequency-squared, approximates the density of states for the translational modes of the water. Figure 2 does not extend below 100 cm^{-1} because of the possible contribution by the guest molecules in this region.

The spectrum of the hydrate, and its relationship to the spectra of ice Ih and other ice phases, can only be understood in terms of the crystal structures and intermolecular forces through calculations of the dispersion curves and density of state curves. These are not available at present, and the spectrum can therefore not be assigned or understood from a theoretical viewpoint. However, a comparison of the structures and far-infrared spectra of five phases formed by orientationally-disordered water molecules suggests an empirical correlation between the frequencies at which strong absorption occurs and the number, length, and distribution of hydrogen bonds in these phases.

Table 2 presents structural data for ices Ic (24), Ih (25 and references therein), V (26), and VI (27), and ethylene oxide hydrate, at 100 °K. For the hydrate the data of McMullan and Jeffrey (3) was corrected for a 0.8% contraction in unit cell parameter between −30 °C and −173 °C (11), assuming a proportional shortening of each hydrogen bond.

The spectra of ice Ih and ice Ic both contain a strong, rather sharp, peak centered at 229.2

	2.82	12

cm^{-1} (21). This can be related to one type of hydrogen bond, 2.75 Å long. Both spectra also contain other, weaker features, and it is a weakness of this proposal that we must neglect them. The spectrum of ice V contains a broad peak, centered at 200 cm^{-1}, with a half-width of approximately 50 cm^{-1} (22). The breadth of this peak can be taken to reflect the relatively equal distribution of a wide-range of hydrogen-bond lengths in ice V. The frequency of the maximum, 200 cm^{-1}, can be related to the weighted-mean hydrogen bond length of 2.797 Å. The spectrum of ice VI contains a broad peak centered at 187 cm^{-1}, and a shoulder at 160 cm^{-1} (23). The overall half-width of the peak plus shoulder is about 50 cm^{-1} and, again, a relatively equal distribution of a wide range of bond-lengths exists in ice VI. The peak frequency can be roughly correlated with the weighted mean hydrogen bond length of 2.813 Å. For the hydrate the strongest feature in the spectrum is the peak at 229.6 cm^{-1}. By comparison with the data on ice I this can be related to the 2.75 Å bonds, which constitute 52% of the bonds in the unit cell. This peak is broader than the corresponding peak in ice I, and the broadening on the high-frequency side can be related to the 9% of 2.74 Å bonds in the structure. The hydrate absorbs more strongly relative to the 229 cm^{-1} peak than does ice I between about 185 and 210 cm^{-1}, with definite features at these two frequencies. By comparison with the data on ices V and VI this can be related to the 26% of 2.79 Å bonds and the 13% of 2.82 Å bonds in the structure. This correlation is clearly rather approximate, but the experimental data strongly suggest that a useful correlation does exist.

We wish to emphasize that the above presents an empirical correlation, not a theoretical interpretation of the spectrum. The correlation is by no means unreasonable on theoretical grounds but the detailed assignment of these features undoubtedly is much more complicated than the correlation suggests. For example, the spectrum of ice I*c* (21) contains many features, and two peaks, yet only one type of O---O hydrogen bond exists in the structure (neglecting the small variations due to the disorder). Theoretically this spectrum is quite well understood (21), and the various features arise from features in the density of states, which in turn arise from vibrational coupling (28). The influence of this vibrational coupling on the density of states curve, and hence on the spectrum, is completely unknown for ices V, VI, and for ethylene oxide hydrate, and until the appropriate calculations have been carried out to indicate this, no theoretical interpretation of the spectrum is possible.

A noteworthy difference between the spectrum of the hydrate and that of ice I is the isotope shift of the 229 cm^{-1} peak. The peaks are essentially coincident in the hydrate and in H_2O ice I, but are at 223.1 and 221.7 cm^{-1} in the deuterate and in D_2O ice I, respectively. The ratio of peak frequencies of the hydrate to the deuterate is 1.029, compared to the 1.054 expected from a simple harmonic oscillator model, and the 1.034 found in ice I. It has been argued (21) that the low ratio in ice I can not be entirely due to anharmonicity of the translational lattice vibrations, and must reflect a larger effective harmonic potential constant for D_2O than for H_2O. This effect is clearly even more pronounced in the clathrate hydrate structure, unless the smaller isotope shift in the clathrate arises from interaction between water

For personal use only.

molecule vibrations and guest molecule vibrations. In view of the probable frequency of the guest molecule vibrations (see below), this seems to be unlikely, but it cannot be dismissed.

One of the objects of this work was to seek the absorption by the intermolecular vibrations of the ethylene oxide molecules in the cages. Because of previous experimental results on the far-infrared absorption by non-polar (29) and polar (30) liquids, and considering the dipole moment of ethylene oxide (31), there can be little doubt that most of the absorption intensity will arise from the rotational vibrations, although these are not necessarily distinct from the translational vibrations in this disordered crystal. The experimental results do not dictate the assignment of these vibrations. However, there are experimental and theoretical arguments that are relevant and these will be briefly discussed.

Inelastic neutron scattering studies (32) have shown that the density of states of water translational vibrations below 100 cm^{-1} in sulfur dioxide hydrate is similar to that in ice I, except that the maximum occurs about 20 cm^{-1} higher than in ice I. In ice I at 100 °K the maximum in the density of states shows in the infrared spectrum as a shoulder at about 60 cm^{-1}; between 100 and 60 cm^{-1} the intensity of absorption decreases as the frequency decreases, and below 60 cm^{-1} the intensity decreases even more sharply (21, 33). Using this result and theory (20), the infrared absorption by the water translational modes in sulfur dioxide hydrate is expected to decrease from 100 cm^{-1} to about 80 cm^{-1} and to decrease more sharply below about 80 cm^{-1}. It is reasonable to assume that similar absorption by the water translational vibrations occurs in ethylene oxide hydrate, which is isostructural with sulfur dioxide hydrate. The difference between this expectation and the observed spectrum (Fig. 1) must, then, be due to the absorption by the ethylene oxide intermolecular vibrations. The observed spectrum can be qualitatively reproduced by superimposing on top of this expected water absorption a broad absorption band which extends from about 100 cm^{-1} to low frequency, with a maximum absorption at about 50 cm^{-1}. Thus, if these arguments are correct, the ethylene oxide intermolecular vibrations are centered at about 50 cm^{-1} and contribute to the spectrum from about 100 cm^{-1}, to low frequencies.

Morris and Davidson (34) have shown how the experimental value of $\varepsilon_{\infty 2}$ for the hydrate, and the value calculated by neglecting the atomic polarization of the guest molecules, can be used to calculate an approximate frequency for the two rotational vibrations which cause the guest molecule's dipole to rotate, assuming that they are degenerate. Using their method the frequency is given by

$$\nu = \left[\frac{1}{\Delta n} \cdot \frac{N_m \mu^2}{3\pi c^2 I}\right]^{1/2}$$

where Δn is the difference in the refractive indices corresponding to the two values of $\varepsilon_{\infty 2}$, and c is the velocity of light. For $6.8C_2H_4O \cdot 46H_2O$, the density of guest molecules, N_m, is 3.9×10^{-3} $Å^{-3}$, the dipole moment of ethylene oxide, μ, is 1.89×10^{-18} e.s.u. cm (31), and I, taken as the mean of the two moments of inertia about the axes perpendicular to the symmetry axis, is 45×10^{-40} g cm^2 (35). The value of $\varepsilon_{\infty 2}$ neglecting the atomic polarization is calculated to be 3.2, by using eq. 4 of ref. 34 and the following parameters: $\varepsilon_\infty^0 = 2.80$, $\alpha_M = 4.68$ $Å^3$ (calculated from refractive index and density in ref. 36), $a_m = 2.9$ Å (12, 34), and $\varepsilon_{02} = 13.7$ (7). This value of $\varepsilon_{\infty 2}$ along with the experimental value of 4.1 (7) yields the frequency of the rotational vibrations as 39 cm^{-1}. However, 3.2 appears to be rather high for the calculated value of $\varepsilon_{\infty 2}$, in view of the experimental value of 2.85 for cyclopropane hydrate (14). If 2.85 is taken to be a more probable value, the frequency is calculated as 33 cm^{-1}. These calculations assume that the vibrations absorb at a single frequency. In fact the absorption is expected to be broad (7), but the calculations indicate that it should be centered near to 35 cm^{-1}. It seems likely that the frequency is not significantly temperature dependent (37).

Thus the calculations suggest that the ethylene oxide vibrations are centered at a significantly lower frequency than is obtained from the arguments based on experimental data. It seems clear that they contribute to the observed absorption below 50 cm^{-1}, but the calculations do not appear to support the result, deduced above, that they contribute at frequencies as high as 100 cm^{-1}. It is clear that further

experimental evidence is required before a firm assignment can be made.

NOTE ADDED IN PROOF: Recent work in this laboratory on cyclopropane hydrate (type I) at 100 °K has confirmed that the rotational vibrations of ethylene oxide do contribute to the spectrum of ethylene oxide hydrate at 100 °K from 100 cm^{-1} to low frequency. Full details will later be published.

We thank the National Research Council of Canada for their support of this work. One of us (D.A.O.) thanks the Canadian Kodak Company and the National Research Council of Canada for the award of scholarships. We thank Drs. D. W. Davidson and W. B. Kamb for prepublication information about their work.

Enthalpies of Dissociation of Ammonia and Amine Adducts of some Tetraalkylammonium Pentafluorosilicates

I. WHARF AND M. ONYSZCHUK

Department of Chemistry, McGill University, Montreal, Quebec

Received February 23, 1971[1]

Condensed phase enthalpies of dissociation of $[R_4N][SiF_5(NH_3)]$, in which R = C_2H_5, C_3H_7, and C_5H_{11}, are in the order: $C_2H_5— < C_3H_7— < C_4H_9— > C_5H_{11}—$, and a lower limit of 16.8 ± 0.6 kcal mol^{-1} is suggested for the gas phase interaction of NH_3 with SiF_5^-. Enthalpies of dissociation of the amine adducts, $[(C_5H_{11})_4N][SiF_5L]$, in which L = CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ are in the order: $NH_3 \simeq CH_3NH_2 < (CH_3)_2NH \simeq (CH_3)_3N$.

Les enthalpies de dissociation de phase condensée de $[R_4N][SiF_5(NH_3)]$, où R = C_2H_5, C_3H_7, C_4H_9 et C_5H_{11} sont, dans l'ordre: $C_2H_5— < C_3H_7— < C_4H_9— > C_5H_{11}—$; nous proposons une limine inférieure de 16.8 ± 0.6 kcal mol^{-1} pour l'interaction en phase gazeuse de NH_3 avec SiF_5. Les enthalpies de dissociation des groups amines, $[(C_5H_{11})_4N][SiF_5L]$, où L = CH_3NH_2, $(CH_3)_2NH$, et $(CH_3)_3N$ sont, dans l'ordre: $NH_3 \simeq CH_3NH_2 < (CH_3)_2NH \simeq (CH_3)_3N$. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3450 (1972)

Introduction

Following a previous article (1 and references therein), in which the acceptor powers of SiF_5^- and GeF_5^- were compared by measuring the condensed phase enthalpies of dissociation of the ammonia adducts of their tetrapropylammonium salts, we now report the enthalpies of dissociation of the salts $[R_4N][SiF_5(NH_3)]$, in which R = C_2H_5, C_3H_7, C_4H_9, and C_5H_{11}. Our aim has been to determine the effect of changes in cation size on the stability of ammonia adducts of SiF_5^-. Enthalpies of dissociation of the amine adducts, $[(C_5H_{11})_4N][SiF_5L]$, in which L = CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ have also been measured with the object of determining the relative basicities of the methylamines toward SiF_5^-.

Experimental

The experimental methods were essentially the same as those described previously (1). The tetramethylammonium and tetraethylammonium pentafluorosilicate salts reported in Table 1 were prepared by slowly bubbling silicon tetrafluoride (Matheson) through a well-stirred, ice-cold ethanol solution (60 ml) of the tetraalkylammonium fluoride (Aldrich) for 5 min. Tetramethylammonium pentafluorosilicate precipitated immediately, whereas the addition of benzene (60 ml) was necessary to precipitate the tetraethylammonium salt. Both salts were filtered off, washed with ether and *n*-hexane, and dried in a vacuum at room temperature.

Tetrapropyl- and tetrabutylammonium pentafluorosilicates were prepared as before (1). Tetrapentylammonium pentafluorosilicate (Table 1) was prepared by dissolving silicon dioxide (1.20 g) in a solution of tetrapentylammonium fluoride obtained by stirring silver carbonate (2.8 g) with tetrapentylammonium iodide (8.5 g) (Eastman) in a mixture of methanol (25 ml) and concentrated hydrofluoric acid. The mixture was evaporated down three times, methanol (50 ml) being added each time, to give a brown oil which solidified on stirring after benzene (50 ml) and *n*-hexane (100 ml) were added. The brown solid was recrystallized from a mixture of ethyl acetate and diethyl ether to give white needles which were dried in a vacuum at room temperature, m.p. 100–101°.

The absence of water in the above compounds was confirmed by infrared spectral measurements. Absorption bands typical of the SiF_5^- ion (1) were observed at 880 and 789 cm^{-1}, 878 and 777 cm^{-1}, and 878 and 785 cm^{-1}, for $[(CH_3)_4N][SiF_5]$, $[(C_2H_5)_4N][SiF_5]$, and $[(C_5H_{11})_4N][SiF_5]$, respectively.

Dissociation pressures were measured as described previously (1). The 1:1 interaction of gaseous ligand with each $[R_4N][SiF_5]$ salt was confirmed by *P.V.T.* measurements. Infrared spectral measurements showed that the parent SiF_5^- was reformed after thermal dissociation of each adduct.

Results and Discussion

Dissociation pressure–temperature curves were obtained for the ammonia adducts of several tetraalkylammonium pentafluorosilicates, $[R_4N][SiF_5]$, R = C_2H_5, *n*-C_3H_7, *n*-C_4H_9, and *n*-C_5H_{11}. The resulting data and thermodynamic parameters given in Table 2 show that the cation effect is significant. Interaction of ammonia with tetraethylammonium pentafluorosilicate is small, increases with increasing cation size, and becomes approximately constant for $[(C_4H_9)_4N][SiF_5]$ and $[(C_5H_{11})_4N][SiF_5]$.

*Data for the reaction
$[(C_3H_7)_4N][GeF_5(NH_3)](s) \rightarrow NH_3(g) + [(C_3H_7)_4N][GeF_5](s)$.

The influence of lattice energy changes can be seen from the cycle in Scheme 1.

For compounds with cations considerably larger than the complex anions SiF_5^- and $SiF_5(NH_3)^-$, lattice geometry and dimensions will be determined principally by cation packing and lattice energies will remain unchanged on formation of the ammonia adduct anion. Thus, in the enthalpy cycle (Scheme 1), $U_1 = U_2$, and experimental dissociation enthalpies (ΔH_1) will equal the gas-phase values (ΔH_2) and be independent of the cation. The tetrabutylammonium and tetrapentylammonium systems are examples of this type and the largest value observed for the enthalpy of dissociation, 16.8 ± 0.6 kcal mol^{-1}, gives a lower limit for the desired gas phase dissociation of the ammonia adduct of the pentafluorosilicate ion. That enthalpies of dissociation of the $(C_5H_{11})_4N^+$ and $(C_4H_9)_4N^+$ salts are not identical is not unexpected since the term $(U_1 - U_2)$ is the difference between two large numbers. Alternatively, the observed difference might be due to a greater range of solid solution behavior with the tetrapentylammonium salt, as suggested by one of the referees.

With smaller cations, lattice dimensions will be determined by the complex anions, SiF_5^- and $SiF_5(NH_3)^-$. As ammonia is absorbed, the crystal lattice of the pentafluorosilicate salt will

$$\begin{array}{ccc} [R_4N][SiF_5(NH_3)](s) & \xrightarrow{\Delta H_1} & NH_3(g) + [R_4N][SiF_5](s) \\ \downarrow U_1 & & \uparrow -U_2 \\ [R_4N]^+(g) + [SiF_5(NH_3)]^-(g) & \xrightarrow{\Delta H_2} & NH_3(g) + [R_4N]^+(g) + [SiF_5]^-(g) \end{array}$$

$$\Delta H_1 = \Delta H_2 + (U_1 - U_2)$$

calculated from data in ref. 7.

expand to accommodate the larger ammonia adduct anion. Lattice energies will decrease ($U_1 < U_2$), and the measured dissociation enthalpy (ΔH_1) will be less than the gas-phase dissociation enthalpy (ΔH_2). The tetraethylammonium system exemplifies this situation, while $[(C_3H_7)_4N][SiF_5]$ and $[(C_3H_7)_4N][SiF_5(NH_3)]$ perhaps differ only to a small extent in crystal lattice energies. Similar arguments have been used (2, 3) to account for the greater stability of salts of hydrogen dihalide ions with increasing cation size.

Unfortunately it is not presently possible to give a quantitative basis to the above discussion. Tetraalkylammonium ions are too flexible to allow for simple radius ratio arguments, while crystal structure data even for the parent SiF_5^- salts are not yet available. Preliminary X-ray diffraction studies of $[(C_3H_7)_4N][SiF_5]$, $[(C_3H_7)N]_2[SiF_5]Br$, and $[(C_4H_9)_4N][SiF_5]$ have shown that all give disordered crystals (5). Although changes in lattice geometry will occur with changes in cation size, this will not affect the above discussion provided no change occurs on formation of the adduct. However, when cation and anion are of similar size, *e.g.* as in $[(C_2H_5)_4N][SiF_5]$, a change in lattice geometry may well occur on adduct formation, and the above argument becomes irrelevant.

Standard free energy changes, $\Delta G^0_{298.15}$, for the dissociations are positive but small, reflecting the low stabilities of the ammonia adducts. The standard entropy of dissociation, $\Delta S^0_{298.15}$, for both $[(C_4H_9)_4N][SiF_5(NH_3)]$ and $[(C_5H_{11})_4N][SiF_5(NH_3)]$ is ~46 cal deg^{-1} mol^{-1}. Since for ammonia, $S^0_{298.15} = 46.0$ cal deg^{-1} mol^{-1} (4), there is very little difference in entropy between $[R_4N][SiF_5]$ (R = C_4H_9, C_5H_{11}) and its ammonia adduct, supporting the idea that crystal lattices and perhaps lattice energies do not alter significantly on formation of the ammonia adduct in those two cases. The standard entropy of dissociation of the ammonia adduct of $[(C_2H_5)_4N][SiF_5]$ is about 10 cal deg^{-1} mol^{-1}, showing the entropy of the adduct to be greater than the parent SiF_5^- salt. This is consistent with some change in crystal structure on dissociation of the adduct. It is worth noting that for the reaction

$$[(C_3H_7)_4N][MF_5(NH_3)](s) \rightarrow [(C_3H_7)_4N][MF_5](s) + NH_3(g)$$

$\Delta S^0_{298.15}$ is 35 cal deg^{-1} mol^{-1} for M = Ge, and 33 cal deg^{-1} mol^{-1} for M = Si. The similarity of these values supports the idea proposed previously (1) that crystal lattice changes on adduct formation are approximately the same for corresponding silicon and germanium systems.

Results for the thermal dissociation of the adducts of $[(C_5H_{11})_4N][SiF_5]$ with NH_3, CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ are given in Table 3. This system was chosen in the hope that with the large cation $(C_5H_{11})_4N^+$, crystal lattice changes on dissociation of the adducts would be minimal. A small decrease in the enthalpy of dissociation of the adducts is noted for the ligands $(CH_3)_2NH$ and $(CH_3)_3N$ compared with NH_3 and $(CH_3)_2NH$, while entropies of dissociation at 25 °C are about 45, 40, 39, and 32 cal deg^{-1} mol^{-1}, for the NH_3, CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ adducts, respectively. Since for the ligands $S^0_{298.15}$ values are 46.0 (4),

Line No.	Temperature range (°C)	$\log_{10} P$ (mm) $= -A/T + C$		ΔH^0 (kcal mol^{-1})	$\Delta G^0_{298.15}$ (kcal mol^{-1})
		$A \times 10^{-2}$	C		
1	90–150	7.86 ± 0.47	2.82 ± 0.30	3.6 ± 0.2	3.7 ± 0.6
2	130–210	5.44 ± 0.34	2.29 ± 0.22	2.5 ± 0.2	3.3 ± 0.4

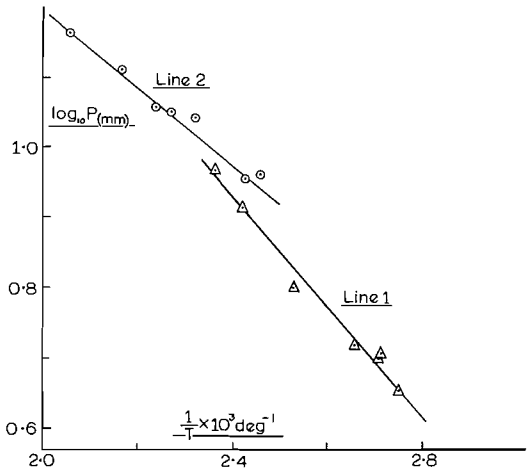

FIG. 1. Plot of $\log_{10} P$ (mm) against $1/T$ °K for the reaction
$2[(CH_3)_4N][SiF_5](s) \rightarrow SiF_4(g) + [(CH_3)_4N]_2[SiF_6](s)$.

57.7, 65.3, and 69.0 cal deg^{-1} mol^{-1} (6), in the same order, it is clear that with increasing substitution the entropies of the adducts increase by comparison with $[(C_5H_{11})_4N][SiF_5]$. Thus on adduct formation using the larger methylamine ligands, some crystal lattice change occurs, and measured dissociation enthalpies will not give approximate gas-phase values. Thermodynamic data for the hypothetical reaction

$$SiF_4 \cdot 2(CH_3)_3N(s) \rightarrow (CH_3)_3N(g) + SiF_4(CH_3)_3N(s)$$

are in Table 3. There is an evident similarity in the acceptor power toward $(CH_3)_3N$ of the five coordinate neutral, $SiF_4 \cdot (CH_3)_3N$ species and the anion, SiF_5^-.

Since the formation of either $[(CH_3)_4N][SiF_5]$ or $[(CH_3)_4N]_2[SiF_6]$ at room temperature depends on the preparative method employed, these systems may differ only slightly in stability. On drying a sample of the pentafluorosilicate at 100 °C under high vacuum, an infrared adsorption at 740 cm^{-1} in the dried material showed SiF_6^{2-} ion had been formed. This suggested that the following disproportionation had occurred.

$$2[(CH_3)_4N][SiF_5](s) \rightarrow SiF_4(g) + [(CH_3)_4N]_2[SiF_6](s)$$

Variation of SiF_4 pressure, P mm Hg, with temperature, T °K, above $[(CH_3)_4N][SiF_5]$ is shown as a plot of $\log_{10} P$ against $1/T$ in Fig. 1. Since only very low SiF_4 pressures were measured, the highest being about 14 mm at 212 °C, complete reversibility was difficult to attain. Two straight lines are identified with the transition occurring over the range 130–150 °C. The two highest points on line 1 were obtained with increasing temperature while the two lowest points on line 2 were measured with decreasing temperature. Vapor pressure equations and values for ΔH^0 and $\Delta G^0_{298.15}$ for the disproportionation reaction are given in Table 4. Small enthalpy changes for the reaction show that ΔH_f^0 for $[(CH_3)_4N][SiF_5](s)$ is close to the average of the values for $SiF_4(g)$ and $[(CH_3)_4N]_2[SiF_6]$. For SiF_4 gas at 25 °C, $\Delta H_f^0 = -373$ kcal mol^{-1} (4) while negative ion spectra (8) give $\Delta H_f^0 < -583$ kcal mol^{-1} for the gaseous SiF_5^- species. Preliminary calculations using an ionic model indicate that SiF_4 and SiF_6^{2-} have similar gas-phase enthalpies of formation. However, the lattice energy of $[(CH_3)_4N]_2[SiF_6]$ should be greater than that of $[(CH_3)_4N][SiF_5]$ and as the energetics of the disproportionation include lattice energy differences and gas-phase enthalpies, it is not possible to discuss them in greater detail at present.

We are grateful for the financial support of the National Research Council of Canada.

Total Synthesis of (±)-Ishwarane, a Tetracyclic Sesquiterpenoid

R. B. KELLY, J. ZAMECNIK, AND B. A. BECKETT
Department of Chemistry, University of New Brunswick, Saint John, New Brunswick

Received June 23, 1972

A total synthesis of (±)-ishwarane, a novel tetracyclic sesquiterpenoid possessing a tricyclo[3.2.1.$0^{2,7}$]octane system, is described. Completion of the synthesis of ishwarane firmly establishes the structure assigned to this sesquiterpenoid and provides corroboration of the structure assigned to the related sesquiterpenoid ishwarone. A total synthesis of (±)-isoishwarane, a transformation product of ishwarone, is also described.

Une synthèse totale de la (±)-ishwarane, nouveau sesquiterpène tétracyclique comportant le système tricyclo[3,2,1,$0^{2,7}$]octane, est décrite. L'aboutissement de cette synthèse établit de façon sûre la structure assignée à ce sesquiterpénoide et corrobore celle attribuée à l'ishwarone, sesquiterpène apparenté. Une synthèse totale de la (±)-isoishwarane, produit de transformation de l'ishwarone, est également donnée.

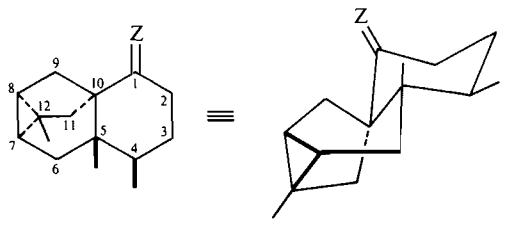
The closely related pair of sesquiterpenoids ishwarane (**1**) and ishwarone (**2**) were discovered, together with other terpenoids, in the roots of *Aristolochia indica* Linn. (1–5). The isolation of the former (**1**) from the petals of *Cymbopetalum penduliforum*, Baill., a material used for flavoring beverages, has also been reported very recently (6).

The isolation and characterization of ishwarone (**2**) was first reported in 1935 (1). It was not until 34 years later, however, that the novel and biogenetically interesting tetracyclic structure **2** was proposed for ishwarone (2, 5, see also 3). A year later, in 1970, the isolation of ishwarane was reported and, in the same communication, structure **1**, having the same carbon skeleton as ishwarone, was assigned to this sesquiterpenoid (4). The assignment of structure **1** to ishwarane was based mainly on the fact that it could be obtained from ishwarone (**2**) simply by Wolff–Kishner reduction of the keto group (4). The validity of structure **1** for ishwarane is therefore dependent on the correctness of structure **2** for ishwarone. The latter structure (**2**) was adduced from chemical evidence, including the conversion of ishwarone into (+)-nootkatane, and spectral data (2, 3, 5).



1 Z = H, H
2 Z = O

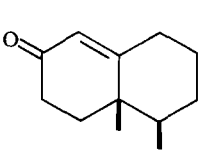
Recently we completed a total synthesis of ishwarane (**1**) (7, 8), thereby providing proof of the validity of structure **1** for ishwarane and corroboration of structure **2** for ishwarone. We now wish to describe the details of the synthesis of (±)-ishwarane.[1]

A novel structural feature of the carbon skeleton common to ishwarane (**1**) and ishwarone (**2**) is the tricyclo[3.2.1.$0^{2,7}$]octane system. Another important stereochemical aspect of this skeleton is the pair of vicinal *cis* methyl groups at C-4 and -5 and their stereorelationship to the tricyclooctane system.[2] In designing a synthesis of ishwarane these stereochemical aspects must be taken into account.

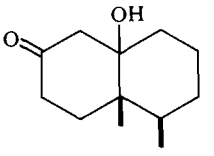
In planning the synthesis of ishwarane, it was decided that the synthetic route should, at an early stage, proceed through a bicyclic intermediate in which the vicinal *cis* methyl groups had been established. Thus, one of the stereochemical problems associated with the synthesis would be solved early in the sequence of reactions. The octalone **3** was chosen as the intermediate since it not only satisfies the requirements with regard to the *cis* methyl groups but it also possesses functionality, in the form of an α,β-unsaturated ketone, suitable for the development of the tricyclooctane system.

[1]Preliminary reports of some aspects of the work described in this article have appeared (refs. 7 and 8).

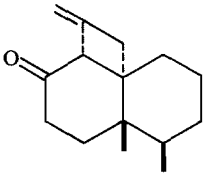
[2]The numbering system shown in **1** is adhered to throughout.



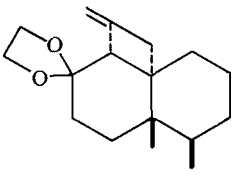
3



4



5



6

The octalone **3** was prepared either by annelation of *cis*-2,3-dimethylcyclohexanone (9) with methyl vinyl ketone and dehydration of the intermediate crystalline alcohol **4** (*cf.* 10 and 11), or by a recently published, more lengthy synthesis (10). The two methods afforded the same octalone for which the stereostructure **3** has been firmly established (10).

Having obtained the required intermediate octalone **3**, the next task was the elaboration of the tricyclooctane system. Briefly, this was accomplished by converting **3** into **5** by photo-addition of allene, skeletal rearrangement of **5**, by a series of transformations, into intermediates possessing a bicyclo[2.2.2]octane system and, finally, the transformation of the bicyclooctane system into the required tricyclooctane system (*vide infra*).

Photo-addition of allene to the octalone **3** afforded the adduct **5** in 75% yield as an oil. Consistent with the assigned structure (**5**), the i.r. spectrum of the adduct showed a keto band at 1695 cm^{-1} and bands at 1660 and 880 cm^{-1} due to the exocyclic methylene; in the n.m.r. spectrum a multiplet appeared at δ 4.96 (2H) attributable to the exocyclic methylene.[3] The stereostructure assigned to the photo-adduct follows from the established stereospecificity of the photo-addition of allene to α,β-unsaturated ketones (12, 13).

Acetalization of **5** in the usual manner converted it into the oily ethylene acetal **6** in 75% yield. In agreement with this conversion, the i.r. spectrum of the acetal was devoid of carbonyl bands and a multiplet (4H) due to the ethylene group of the acetal function appeared in the n.m.r. spectrum at δ 3.91.

Treatment of **6** with perbenzoic acid followed by chromatography on alumina furnished two epoxides **7***a* (m.p. 65°) and *b* (m.p. 30°), each in 39% yield. Both were converted individually, in two steps, to the same mixture of epimeric keto alcohols **9**, thence, in a single step to the common intermediate **10** (Scheme 1). The i.r. spectra of the two epoxides were similar and both were devoid of olefinic bands; the n.m.r. spectra, however, were distinctly different. In the case of **7***a*, the signals for the methylene protons of the oxirane ring appeared as a pair of doublets ($J = 5$ Hz) at δ 2.27 and 2.99 and the signal for the ethylene protons of the acetal function appeared as a 4-proton multiplet at δ 3.78; in contrast, the corresponding signals in the case of **7***b* were found at δ 1.95 and 2.11 (methylene protons of oxirane ring) and at δ 3.71 (ethylene of acetal function).

The stereostructures assigned to the epoxides are based on n.m.r. spectroscopy. An obvious difference in the n.m.r. spectra of the epoxides was the nature of the signal due to the ethylene group of the acetal function. In both spectra this signal appeared at *ca.* δ 3.75. However, in the case of the lower melting epimer, the signal was broader and considerably more complex than the corresponding signal in the spectrum of the other epimer. This difference was attributed to the closer proximity of the oxygen atom of the oxirane ring to the dioxolane ring in the lower melting epimer. Hence, structure **7***b* was assigned to the lower melting epimer and structure **7***a* to the other epimer (**14**). Consistently, a similar, but less pronounced effect was observed on comparison of the tertiary alcohols **8***a* and *b* which were derived from **7***a* and *b*, respectively (*vide infra*).

Corroborative evidence for the validity of the structures assigned to the epoxides (**7***a* and *b*) was found on comparison of the n.m.r. chemical shifts for the methylene protons of the oxirane rings. Models show that the oxirane ring protons in structure **7***a* are significantly closer to the dioxolane ring than in **7***b*. As a consequence of the deshielding effect of the oxygen atoms of the dioxolane ring, it could therefore be expected

[3]Only spectral data pertinent to the discussion will be given in this section; for further details see the Experimental.

SCHEME I

that the n.m.r. signals for these protons in **7***a* would appear downfield relative to the corresponding signals in the spectrum of **7***b*. In agreement with expectation and the structures assigned to the epoxides, the pertinent signals in the spectrum of **7***a* appeared at δ 2.27 and 2.99 whereas the corresponding signals in the case of **7***b* appeared at δ 1.95 and 2.11.

The epoxides **7***a* and *b* were reduced with lithium aluminum hydride in excellent yield to the corresponding crystalline tertiary alcohols **8***a* and **8***b*, respectively. Stereochemically, the structures assigned to the epimeric tertiary alcohols follow from the stereostructures previously adduced for the precursor epoxides (*vide supra*). The i.r. spectrum of **8***a* showed a hydroxyl band at 3500 cm^{-1} and the corresponding band in the case of **8***b* was observed at 3525 cm^{-1}; singlets due to the methyl group on the cyclobutane ring appeared in the n.m.r. spectra of both alcohols at *ca.* δ 1.30.

Treatment of either of the epimeric alcohols (**8***a* or *b*) with aqueous hydrochloric acid in tetrahydrofuran resulted in deacetalization followed by skeletal rearrangement to a crystalline mixture of epimeric alcohols **9** in 97% yield. Obviously, the conversion of **8***a* and *b* into the same mixture of epimeric alcohols **9** involves deacetalization to give the corresponding keto cyclobutanols, retro-aldolization to give the common intermediate diketone **11**, and, finally,

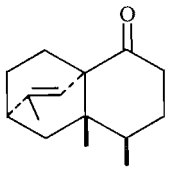
aldol condensation to give **9**. The mixture of epimeric alcohols **9** was barely separated into two components by t.l.c. but attempts to separate the mixture into two epimers by column chromatography were unsuccessful. The i.r. spectrum of the mixture (**9**) showed broad bands at 3350 (hydroxyl) and 1700 cm^{-1} (ketone); in the n.m.r. spectrum there was a singlet (3H) at δ 1.25 due to the methyl group at C-12.

The failure to resolve the mixture of keto alcohols (**9**) into two epimers had no adverse effect on the synthesis since the mixture, on dehydration with *p*-toluenesulfonic acid in boiling benzene, afforded a single enone **10** as an oil in 89% yield. Consistent with structure **10**, there were bands in the i.r. spectrum of the dehydration product at 1725 (ketone) and at 1650 cm^{-1} (olefin) and, in the n.m.r. spectrum, there was a singlet (3H) at δ 1.81 (vinylic methyl), a multiplet (1H) at 2.80 (methine adjacent to ketone), and a multiplet (1H) at 5.88 (vinylic proton).

At this point it was decided to depart briefly from the main synthetic route in order to convert **10** into the olefinic hydrocarbon **12**. The latter structure had been assigned to isoishwarane, a transformation product of ishwarone (**2**) (2, 3). In terms of structure **2** for ishwarone, the two-step transformation was envisaged as involving a rupture of the cyclopropane ring to give isoishwarone (**13**) which, on reduction of the keto group, afforded **12** (2, 3).



13

The enone **10** was successfully converted, in 74% yield, into the hydrocarbon **12** by a Huang–Minlon reduction (15). The hydrocarbon was obtained as an oil with spectral properties in agreement with structure **12**. The i.r. spectrum was devoid of carbonyl absorption but displayed a band at 1648 cm^{-1} (olefinic); in the n.m.r. spectrum there was a doublet (3H) at δ 1.73 due to the vinylic methyl, a multiplet (1H) at 2.20 due to the allylic proton, and a multiplet (1H) at 5.61 due to the vinylic proton.

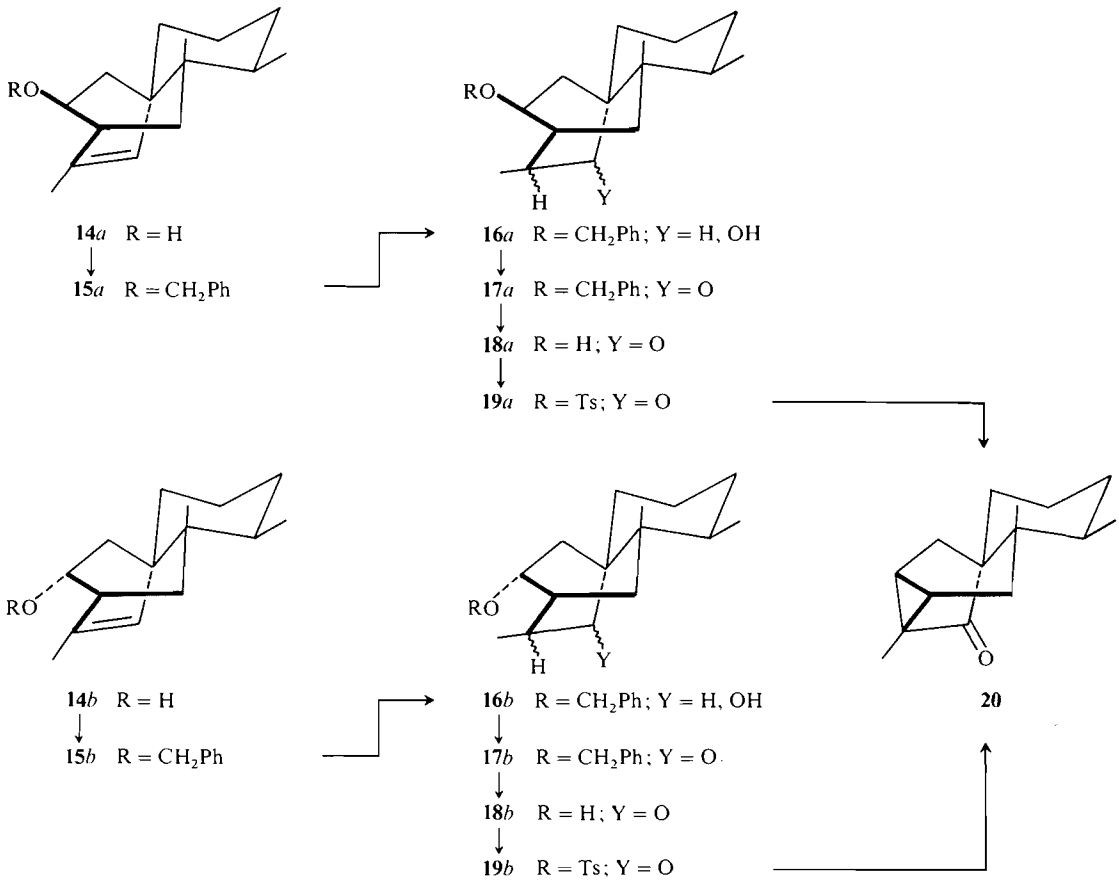
The synthetic hydrocarbon **12** was found to be identical with an authentic sample of isoishwarane prepared from ishwarone by comparison of their i.r., n.m.r., and mass spectra fragmentation patterns. Completion of the total synthesis of isoishwarane provided proof of the correctness of structure **12** for this compound and corroboration of structures **1** and **2** for ishwarane and ishwarone respectively. Furthermore, it provided assurance that the synthesis of ishwarane was proceeding along the correct stereochemical lines.

Returning to the main synthetic route, there now remained the task of converting the enone **10** into an intermediate possessing the tricyclooctane system, thence to ishwarane (**1**). This was accomplished by reduction of **10** to the pair of epimeric alcohols **14***a* and *b*, conversion of the alcohols, individually, by a parallel sequence of transformations into the common intermediate cyclopropyl ketone **20**, and reduction of the latter to ishwarane (see Scheme 2).

Reduction of the enone **10** with lithium aluminum hydride and chromatography of the product on silica gel resulted in the isolation of two epimeric alcohols **14***a* (m.p. 116°) and *b* (m.p. 110°), each in 38% yield. The i.r. spectra of the two alcohols were devoid of carbonyl absorption but each displayed an hydroxyl band and a band at 1648 cm^{-1} due to olefinic absorption. In the n.m.r. spectra, the signal for the proton associated with the secondary alcohol appeared as a multiplet at δ 3.93 in the case of **14***a* and at 3.91 in the case of **14***b*.

Stereochemically, the two alcohols could be differentiated by n.m.r. spectroscopy. In the spectrum of the higher melting epimer, the signal for the angular methyl group appeared 12 Hz downfield relative to the corresponding signal in the spectrum of the other epimer. The deshielding effect on the angular methyl group in the case of the higher melting epimer is due to the hydroxyl group (16). Therefore, the epimer melting at 116° was assigned structure **14***a* in which the hydroxyl group is within effective deshielding range of the angular methyl group leaving the alternative structure **14***b* to be assigned to the epimer melting at 110°. A similar deshielding effect, due to the oxygen function at C-8 was observed consistently in the subsequent compounds **15***a* to **18***a* inclusive.

The pair of epimeric alcohols **14***a* and *b* were converted into their respective benzyl ethers **15***a*



SCHEME 2

and *b*, both of which were obtained as oils. The i.r. spectra of both **15***a* and *b* were devoid of hydroxyl absorption but showed bands due to aromatic absorption; in the n.m.r. spectra of **15***a* and *b*, there was a singlet (2H) at *ca.* δ 4.40 due to the benzylic methylene and a multiplet (5H) due to the aromatic protons.

Hydroboration of **15***a* and *b* gave, in each case, a single crystalline alcohol. The alcohol **16***a*, derived from **15***a*, was obtained in 82% yield. The i.r. spectrum was devoid of olefinic absorption but showed hydroxyl absorption at 3475 cm^{-1}; in the n.m.r. spectrum there appeared two doublets (3H each) at δ 0.78 and 1.20 due to the secondary methyls and a multiplet (1H) at 3.88 arising from the proton at C-11. The alcohol **16***b*, obtained from **15***b* in 71% yield, exhibited spectral properties similar to those of **16***a*.

A study, with the aid of models, of the steric factors relevant to the hydroboration of **15***a* and *b* and an analysis of the spectral data for the resulting alcohols, **16***a* and *b*, revealed no reliable clues as to the precise stereochemical orientation about C-11 and -12 in the latter. This, however, was of no consequence in so far as the synthetic plan was concerned.

Jones oxidation (17) of the alcohols **16***a* and *b* gave the corresponding ketones **17***a* and *b* respectively in 80–90% yield, the former as an oil and the latter as a crystalline compound. The i.r. spectra of both **17***a* and *b* showed ketonic absorption at 1715 cm^{-1}; the n.m.r. spectrum of **17***a* showed a doublet (3H) at δ 1.13 due to the methyl group adjacent to the ketone and, in the case of **17***b*, the corresponding signal was found at δ 1.07.

Hydrogenolysis of the keto benzyl ethers **17***a* and *b* afforded the corresponding keto alcohols **18***a* and *b*, both as crystalline compounds in

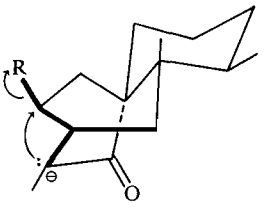
80–90% yield. The i.r. spectrum of **18***a* showed hydroxyl absorption at 3415 cm^{-1} and ketonic absorption at 1703 cm^{-1}; the n.m.r. spectrum was devoid of signals due to aromatic protons and showed a multiplet (1H) at δ 4.05 due to the proton at C-8. The spectral properties of **18***b* were similar to those of **18***a*: i.r. 3250 (hydroxyl) and 1710 cm^{-1} (ketone); n.m.r. δ 4.20 (multiplet, proton at C-8).

The tosylate **19***a*, derived from the keto alcohol **18***a*, was smoothly transformed in 70% yield, into the cyclopropyl ketone **20** by heating at 60° for 2 h in dimethyl sulfoxide containing a 45% excess of methylsulfinyl carbanion (18). The epimeric tosylate **19***b* was also converted, under identical conditions to **20**, although in somewhat lower yield (60%). The identity of the condensation product (**20**) obtained from the two sources was rigorously established (see Experimental).

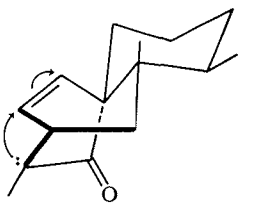
The spectral properties of the condensation product were in accord with structure **20**. Thus, there was an absorption maximum in the u.v. spectrum at 208 nm (ε 4000) due to the cyclopropyl ketone moiety; the i.r. spectrum was devoid of bands attributable to a tosyl group or a hydroxyl group but showed a band at 1715 cm^{-1} due to ketonic absorption; the n.m.r. spectrum showed a multiplet (partially obscured) at *ca.* δ 0.60 due to the protons on the cyclopropane ring and a singlet (3H) at 1.17 for the methyl group on the cyclopropane ring.

The fact that the epimeric tosylates **19***a* and *b* were both converted, under identical conditions, to the cyclopropyl ketone **20** invites speculation as to the mechanism of this conversion. The condensation **19***a* → **20** seems unexceptional since the tosylate function in **19***a* is favorably aligned for an S_N2i displacement by the carbanion at C-12. Such is not the case, however, with **19***b*. In the latter case a plausible mechanism involving a double displacement can be envisaged. Thus, the tosylate function in **19***b* could, conceivably, suffer S_N2 displacement either by methyl sulfinyl carbanion or a molecule of solvent to give the intermediates **21** or **22** which could readily undergo a classical S_N2i displacement resulting in the formation of **20**.

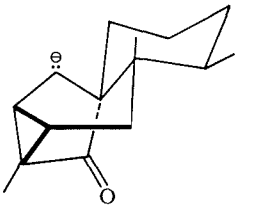
Another, less attractive mechanism, which could be envisaged for both **19***a* and *b* would involve an elimination to give the olefin **23**. Attack by the carbanion at C-12 on the double bond would result in the formation of an intermediate **24** in which the carbanion is homoconjugated with the ketone. Protonation of **24** would then give **20**.



21 R = CH_2SOCH_3
22 R = $O—\overset{\oplus}{S}(CH_3)_2$



23



24

The final step in the synthesis of ishwarane was the reduction of the cyclopropyl ketone **20** to the hydrocarbon **1**. This was achieved, in 67% yield, by the Barton modification of the Wolff–Kishner (19) reduction followed by purification of the product by preparative t.l.c. The spectral properties of the hydrocarbon were consistent with structure **1**; the i.r. spectrum showed no carbonyl absorption, and the n.m.r. spectrum showed a multiplet (2H) at δ 0.50 due to the protons on the cyclopropane ring and a singlet (3H) at 1.12 due to the methyl group on the cyclopropane ring.

The synthetic hydrocarbon **1** was identical with a sample of authentic ishwarane by the following criteria: identity of i.r. and n.m.r. spectra; identity of the fragmentation patterns of the mass spectrum; identical retention times on v.p.c.

The completion of the synthesis of ishwarane firmly establishes structure **1** for this sesquiterpenoid and provides corroboration of structure **2** for the related sesquiterpenoid ishwarone.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 237 B spectrophotometer and u.v. spectra were determined with a Perkin–Elmer

Coleman model 124 instrument. The n.m.r. spectra were recorded with a Varian T-60 instrument; chemical shifts are expressed in p.p.m. (δ-values) downfield from the signal for tetramethylsilane which is used as an internal standard.

V.p.c. was performed on a Hewlett-Packard model 5750 instrument fitted with a stainless steel column (6 ft × 1/8 in.) packed with 10% of UC-W98 (silicone gum-rubber) on diatoports (80–100 mesh). The t.l.c. was carried out on Silica Gel GF-254 procured from Brinkman Instruments (Canada) Ltd.

Reaction products were isolated by the following procedure. The product was extracted into the specified solvent and the extract was washed two or three times with appropriate aqueous solutions as indicated. The original aqueous layer (if any) and the aqueous washings were extracted three times with the solvent and the combined extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated *in vacuo* on a rotary evaporator.

Petroleum ether refers to the fraction with boiling point range 30–60°.

Brine refers to a saturated solution of sodium chloride.

*9-Hydroxy-5,10-dimethyl-2-decalone (**4**)*

A mixture of 19.2 g of *cis*-2,3-dimethylcyclohexanone (9) and 0.6 ml of an ethanolic 3 *M* solution of sodium ethoxide was cooled to −15°. The mixture was treated, with efficient mechanical stirring and in a nitrogen atmosphere, with 12.1 g of methyl vinyl ketone over a period of 6 h. The reaction mixture was then left, under nitrogen, at −16° for 15 h after which it was dissolved in 200 ml of ether. The ether solution was worked-up in the usual manner by washing with brine. The residue, obtained by evaporation of the ether extract was distilled *in vacuo*. The first fraction (b.p. 71°/20 mm, 12.0 g) was 2,3-dimethylcyclohexanone and was used for recycling as above. The fraction with b.p. 120–150°/0.2 mm, after crystallization from petroleum ether, yielded 3.07 g of **4**, m.p. 134–135°; ν_{max} (Nujol) 3350 (OH) and 1703 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.90 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.92 (s, 3H, angular methyl).

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.39; H, 10.12.

*Octalone (**3**)*

A solution of 10.0 g of the keto alcohol **4** and 1.30 g of *p*-toluenesulfonic acid in 300 ml of benzene was refluxed for 1 h while water was collected in a Dean–Stark adapter. The cooled reaction solution was worked-up in the usual manner by washing with saturated sodium bicarbonate solution followed by brine. Evaporation of the solvent *in vacuo* and distillation of the residue afforded 8.71 g (97%) of **3**, b.p. 95–97°/0.2 mm (lit. (10), 96–97°/0.2 mm); λ_{max} (EtOH) 240 nm (ε, 12 100); ν_{max} (film) 1672 (ketone) and 1605 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.91 (d, $J = 6$ Hz, 3H, secondary methyl), 1.12 (s, 3H, angular methyl), 5.70 (s, 1H, vinylic H).

The *2,4-dinitrophenyl hydrazone*, crystallized from ethanol, melted at 139–140°.

Anal. Calcd. for $C_{18}H_{22}N_4O_4$: C, 60.32; H, 6.19; N, 15.63. Found: C, 60.56; H, 6.60; N, 15.83.

*Photo-adduct **5***

Photo-addition of allene to the octalone **3** was carried out at −70° using a 450 W mercury vapor immersion lamp with a Corex sleeve. A solution of 6.20 g of **3** and 14 g of allene in 1500 ml of freshly distilled hexane was irradiated for 6 h. After irradiation, the reaction solution was left overnight in a fume hood to allow excess allene to evaporate. The solvent was evaporated *in vacuo* and the residue was chromatographed on a column of 255 g of silica gel with benzene–ether (98:2) as solvent. Distillation of the eluted material afforded 5.70 g (75%) of **5**, b.p. 105–109°/0.18 mm; ν_{max} (film) 1695 (ketone) and 1660 and 880 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.75 (s, 3H, angular methyl), 0.82 (d, $J = 6.5$ Hz, 3H, secondary methyl), 4.96 (m, 2H, vinylic protons).

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.52; H, 10.16. Found: C, 82.33; H, 10.10.

*Ethylene Acetal **6***

A solution of 10.0 g of **5**, 34.0 g of ethylene glycol, and 1.20 g of *p*-toluenesulfonic acid in 600 ml of benzene was refluxed under a nitrogen atmosphere for 18 h. During reflux, water was separated in a Dean–Stark adapter. The cooled reaction solution was worked-up in the usual manner with sodium bicarbonate solution and brine. The resulting oil was chromatographed on a column of 660 g of basic alumina (activity IV) starting with petroleum ether as solvent followed by gradually increasing proportions of benzene in petroleum ether. Thereby, 9.30 g (77%) of **6** was obtained as an oil, ν_{max} (film) 1665 and 870 cm^{-1} (olefin); n.m.r. ($CDCl_3$) δ 0.75 (poorly developed doublet, 3H, secondary methyl), 1.05 (s, 3H, angular methyl), 4.93 (m, 2H, vinylic protons).

Mol. Wt. Calcd. for $C_{17}H_{26}O_2$: 262. Found (mass spectrum): 262.

Epoxides 7a and b

A solution of 9.00 g of the acetal **6** in 300 ml of dry chloroform was treated with 3.66 g of solid sodium bicarbonate followed by 92.2 ml of a 0.43 *M* chloroform solution of perbenzoic acid. The resulting mixture was stirred at room temperature, in the dark, for 24 h. The reaction solution was shaken with 200 ml of 5% sodium bisulfite solution then worked-up in the usual manner with saturated sodium bicarbonate solution and brine. The crude product, an oil, was chromatographed on a column of 450 g of basic alumina (activity III) with gradually increasing proportions of benzene in petroleum ether as eluant. Two crystalline epoxides were separately eluted from the column.

Epoxide 7a was the first to be eluted from the column. Crystallization from pentane afforded 3.73 g (39%) of this compound, m.p. 65°; i.r. devoid of olefinic absorption; n.m.r. (CCl_4), δ 0.72 (poorly resolved doublet, 3H, secondary methyl), 1.03 (s, 3H, angular methyl), 2.27 and 2.99 (doublets, $J = 5$ Hz, 1H each, methylene of oxirane ring), 3.78 (m, 4H, ethylene of acetal group).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41. Found: C, 73.31; H, 9.42.

Epoxide 7b was the more strongly absorbed epoxide. Crystallization from pentane afforded 3.68 g (39%) of this compound, m.p. 29–30°; i.r. no olefinic absorption; n.m.r. (CCl_4), δ 0.77 (poorly resolved doublet, 3H, secondary methyl), 0.91 (s, 3H, angular methyl), 1.95 and 2.11 (doublets, $J = 5$ Hz, 1H each, methylene of oxirane ring), 3.71 (broad complex multiplet, 4H, ethylene of acetal group).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41. Found: C, 73.01; H, 9.43.

aluminum hydride, and 50 ml of dry ether was refluxed for 15 min. The reaction mixture was cooled on an ice bath and treated with a few drops of brine. The ether solution was decanted from solid material and worked-up in the usual manner with brine. Crystallization of the product from ether–pentane afforded 839 mg (83%) of **8***a*, m.p. 114°; ν_{max} (Nujol) 3500 cm^{-1} (OH); n.m.r. (CCl_4), δ 0.70 (poorly resolved multiplet, 3H, secondary methyl), 0.98 (s, 3H, angular methyl), 1.28 (s, 3H, methyl on cyclobutane ring), 3.80 (s, 4H, ethylene of acetal group).

Anal. Calcd. for $C_{17}H_{28}O_3$: C, 72.82; H, 10.07. Found: C, 73.00; H, 10.20.

Tertiary Alcohol 8b

Reduction of the epoxide **7***b* as described in the preceding experiment and crystallization of the product from pentane afforded, in 93% yield, the tertiary alcohol **8***b*, 69–70°; ν_{max} (Nujol) 3525 cm^{-1} (OH); n.m.r. (CCl_4), δ 0.73 (poorly resolved multiplet, 3H, secondary methyl), 0.93 (s, 3H, angular methyl), 1.27 (s, 3H, methyl on cyclobutane ring), 3.83 (m, 4H, ethylene of acetal group).

Anal. Calcd. for $C_{17}H_{28}O_3$: C, 72.82; H, 10.07. Found: C, 73.07; H, 9.96.

Keto Alcohols 9

(a) From Tertiary Alcohol 8a

A solution of 280 mg of **8***a* in 25 ml of tetrahydrofuran was treated with 20 ml of 1 *M* aqueous hydrochloric acid and left at room temperature under nitrogen for 20 h. Water (50 ml) was added to the reaction solution and it was extracted with chloroform. The chloroform extracts were worked-up in the usual manner by washing with water, saturated sodium bicarbonate solution, and water again. Evaporation of the chloroform extracts left an oil which, on crystallization from pentane, afforded 228 mg (97%) of **9** as a mixture of epimers, m.p. 90–114°; ν_{max} (Nujol) 3350 (OH) and *ca.* 1700 cm^{-1} (broad band, ketone); n.m.r. ($CDCl_3$), δ 0.80 (s, 3H, angular methyl), 0.85 (d, $J = 6.5$ Hz, 3H, secondary methyl), 1.25 (s, 3H, CH_3—C—OH).

The mixture was resolved by t.l.c. with benzene–ether (1:1) as solvent into two, barely separated, components (estimated ratio, 1:1).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24. Found: C, 76.41; H, 10.18.

(b) From Tertiary Alcohol 8b

The same mixture of epimeric alcohols (**9**) was obtained, in comparable yield, from **8***b* by the above procedure.

Enone 10

A solution of 250 mg of a mixture of the epimeric alcohols (**9**) and 25 mg of *p*-toluenesulfonic acid monohydrate in 100 ml of benzene was refluxed for 24 h. The cooled reaction solution was worked-up with saturated sodium bicarbonate solution and water. The product, an oil, was chromatographed on a column of 21 g of silica gel with benzene–ether (95:5) as solvent. The purified product was obtained as an oil (205 mg, 89%), ν_{max} (film) 1725 (ketone) and 1650 cm^{-1} (weak, olefin); n.m.r. ($CDCl_3$), δ 0.77 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.87 (s, 3H, angular methyl), 1.81 (m, 3H, vinylic methyl), 2.80 (m, 1H, methine adjacent to ketone), 5.88 (m, 1H, vinylic H).

Mol. Wt. Calcd. for $C_{15}H_{22}O$: 218. Found (mass spectrum): 218.

(±)-Isoishwarane (12)

The reduction of the enone **10** to isoishwarane (**12**) was carried out in a dry nitrogen atmosphere as follows (*cf.* 15). The enone **10** (150 mg) was dissolved in 6 ml of a stock solution prepared by dissolving 260 mg of dry potassium hydroxide in 26 ml of triethylene glycol. The solution was treated with 1 ml of anhydrous hydrazine (19) and allowed to reflux at 180° for 14 h. An additional 0.5 ml of hydrazine was added and reflux was continued for 1 h after which hydrazine was distilled from the reaction flask until the temperature (inside) of the reaction solution reached 210°. After keeping the reaction solution at 210° for 8 h, it was allowed to cool to room temperature then treated with 5 ml of water followed by 50 ml of ether. The ether solution was worked-up in the usual manner with dilute hydrochloric acid, saturated sodium bicarbonate solution, and brine. Chromatography of the product on a column of 10.7 g of silica gel with pentane as solvent followed by distillation in a small collar flask at 0.5 mm (bath temperature 98°) afforded 103 mg (74%) of (**12**) as an oil, ν_{max} (film) 1648 cm^{-1} (olefin); n.m.r. (CCl_4), δ 0.67 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.87 (s, 3H, angular methyl), 1.73 (d, $J = 2.0$ Hz, 3H, vinylic methyl), 2.20 (m, 1H, allylic proton), 5.61 (m, 1H, vinylic proton).

The i.r. and n.m.r. spectra and fragmentation pattern of the mass spectrum of synthetic **12** were identical with the corresponding properties of an authentic sample of isoishwarane prepared from ishwarone.

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.17; H, 11.72.

Enols 14a and b

A solution of 1.07 g of the enone **10** in 100 ml of dry ether was treated with 0.50 g of lithium aluminum hydride and the mixture was refluxed for 4 h. The cooled reaction mixture was treated dropwise with brine until the excess lithium aluminum hydride was deactivated and the ether solution was decanted from solid material. The ether solution was worked-up in the usual manner with brine. Column chromatography of the product on 107 g of silica gel, with gradually increasing portions of ether in benzene as solvent, gave two fractions.

Enol 14a. The first fraction eluted from the column afforded, after crystallization from pentane, 413 mg (38%) of **14***a*, m.p. 115–116°; ν_{max} (Nujol) 3300 (OH) and 1648 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.72 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.98 (s, 3H, angular methyl), 1.73 (d, $J = 2$ Hz, 3H, vinylic methyl), 2.26 (m, 1H, allylic methine), 3.93 (m, 1H, H—C—OH), 5.65 (m, 1H, vinylic proton).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 82.13; H, 11.16.

Enol 14b. Crystallization of the second fraction from the column from pentane afforded 412 mg (38%) of **14***b*, m.p. 110°; ν_{max} (Nujol) 3250 (OH) and 1648 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.67 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.77 (s, 3H, angular methyl), 1.77 (d, $J = 2.0$ Hz, 3H, vinylic methyl), 2.29 (m, 1H, allylic methine), 3.91 (m, 1H, H—C—OH), 5.69 (m, 1H, vinylic proton).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.62; H, 11.04.

Benzyl Ether 15a

The enol **14***a* was converted to the benzyl ether **15***a* in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dry nitrogen atmosphere by the following procedure. A mixture of 250 mg of **14***a*, 100 mg of sodium hydride, and 8 ml of dry benzene was refluxed for 5 h. After cooling to room temperature the mixture was treated dropwise with 0.5 ml of benzyl chloride and refluxing was continued for 24 h. The cooled reaction mixture was treated dropwise with 2 ml of methanol then poured into a mixture of 150 g of ice and water. The aqueous mixture was extracted with ether and the extracts were washed with water. The product was chromatographed on a column of 86 g of silica gel with increasing proportions of benzene in petroleum ether as solvent. Elution of the column afforded 307 mg (87%) of **15***a* as an oil, ν_{max} (film) 3030–3000, 2000–1600, and 800–680 (multiple bands, aromatic) and 1648 (olefin); n.m.r. ($CDCl_3$), δ 0.70 (d, $J = 6.5$ Hz, 3H, secondary methyl), 1.02 (s, 3H, angular methyl), 1.74 (d, $J = 2.0$ Hz, 3H, vinylic methyl), 2.43 (m, 1H, allylic proton), 3.57 (m, 1H, H—C—O), 4.43 (s, 2H, benzylic methylene), 5.67 (m, 1H, vinylic proton), 7.25 (m, 5H, aromatic protons).

Mol. Wt. Calcd. for $C_{22}H_{30}O$: 310. Found (mass spectrum): 310.

Benzyl Ether ***15b***

The enol **14***b* was converted into the benzyl ether **15***b* by the procedure described in the preceding experiment. The benzyl ether **15***b* was obtained in 82% yield as an oil, ν_{max} (film) 3030–3000, 2000–1600, and 800–680 (multiple bands, aromatic) and 1648 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.69 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.73 (s, 3H, angular methyl), 1.77 (d, $J = 2.0$ Hz, 3H, vinylic methyl), 2.50 (m, 1H, allylic proton), 3.70 (m, 1H, H—C—O), 4.40 (s, 2H, benzylic methylene), 7.17 (m, 5H, aromatic protons).

Mol. Wt. Calcd. for $C_{22}H_{30}O$: 310. Found (mass spectrum): 310.

Benzyl Ether Alcohol ***16a***

The following reaction was carried out in a dry nitrogen atmosphere. A solution of 220 mg of the benzyl ether **15***a* in 3 ml of dry tetrahydrofuran was treated with 0.73 ml of a 1 *M* tetrahydrofuran solution of borane and stirred at room temperature for 12 h. The reaction mixture was treated with 0.5 ml of water followed by 1 ml of 1 *M* sodium hydroxide solution. The alkaline solution was treated, with cooling on an ice bath, with 1 ml of 30% hydrogen peroxide then stirred at 45° for 45 min. The reaction mixture was worked-up with ether and brine in the usual manner. Crystallization of the product from pentane afforded 190 mg (82%) of **16***a*, m.p. 104°, ν_{max} (Nujol) 3475 (OH); n.m.r. ($CDCl_3$), δ 0.78 and 1.20 (doublets, $J = 6.5$ Hz, 3H each, secondary methyls), 1.10 (s, 3H, angular methyl), 3.60 (m, 1H, H—C—O), 3.88 (m, 1H, H—C—OH), 4.45 (s, 2H, benzylic methylene), 7.25 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{22}H_{32}O_2$: C, 80.43; H, 9.82. Found: C, 80.11; H, 10.01.

Benzyl Ether Alcohol ***16b***

The benzyl ether **15***b* (550 mg) was converted to the benzyl ether alcohol **16***b* by the procedure described in the preceding experiment. The product was purified by chromatography on a column of 33 g of silica gel in benzene–ether. Crystallization of the eluted product from pentane afforded 413 mg (71%) of **16***b*, m.p. 85–86°; ν_{max} (film) 3410 cm^{-1} (OH); n.m.r. ($CDCl_3$), δ 0.78 and 1.05 (doublets, $J = 6.5$ Hz, 3H each, secondary methyls), 0.85 (s, 3H, angular methyl), 3.73 (m, 2H, H—C—O and H—C—OH superimposed), 4.41 (s, 2H, benzylic methylene), 7.23 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{22}H_{32}O_2$: C, 80.43; H, 9.82. Found: C, 80.26; H, 9.73.

Keto Benzyl Ether ***17a***

A solution of 420 mg of the benzyl ether alcohol **16***a* in 20 ml of acetone was treated drop-wise with Jones reagent (17) until a persistent orange color was observed. The excess oxidizing reagent was then deactivated by dropwise addition of methanol until a permanent green color resulted. The reaction solution was treated with 5 ml of 1 *M* sodium bicarbonate solution and diluted with 150 ml of ether. The ethereal mixture was worked-up in the usual manner with sodium bicarbonate and brine. Purification of the oily product by preparative t.l.c. on silica gel with benzene–ether (95:5) as solvent afforded 340 mg (82%) of **17***a* as an oil, ν_{max} (film) 1715 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.83 (d, poorly resolved, 3H, secondary methyl), 1.13 (d, $J = 6.5$ Hz, 3H, secondary methyl adjacent to ketone), 1.15 (s, 3H, angular methyl), 3.68 (m, 1H, H—C—O), 4.47 (s, 2H, benzylic methylene), 7.27 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{22}H_{30}O_2$: C, 80.94; H, 9.26. Found: C, 81.03; H, 9.07.

Keto Benzyl Ether ***17b***

The benzyl ether alcohol **16***b* was oxidized to the keto benzyl ether **17***b* by the procedure described in the preceding experiment. Crystallization of the product from pentane afforded **17***b* in 91% yield, m.p. 84–85°; ν_{max} (film) 1715 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.78 (d, poorly resolved, 3H, secondary methyl), 0.92 (s, 3H, angular methyl), 1.07 (d, $J = 6.5$ Hz, 3H, secondary methyl adjacent to ketone), 3.83 (m, 1H, H—C—O), 4.45 (s, 2H, benzylic methylene), 7.17 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{22}H_{30}O_2$: C, 80.94; H, 9.26. Found: C, 80.81; H, 8.85.

Keto Alcohol ***18a***

The keto benzyl ether (**17***a*, 340 mg) in 50 ml of ethanol was hydrogenated over 180 mg of a palladium–charcoal catalyst (10% Pd) at atmospheric pressure for 1 h. Removal of the catalyst by filtration, evaporation of the solvent *in vacuo*, and crystallization of the product from ether–pentane afforded 218 mg (89%) of **18***a*, m.p. 90–91°; ν_{max} (Nujol) 3415 (OH) and 1703 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.83 (d, poorly resolved, 3H, secondary methyl), 1.15 (s, 3H, angular methyl), 1.16 (d, $J = 6.5$ Hz, 3H, secondary methyl adjacent to ketone), 4.05 (m, 1H, H—C—OH).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24. Found: C, 75.83; H, 10.20.

Keto Alcohol ***18b***

The keto benzyl ether **17***b* was converted to the keto alcohol **18***b* by the procedure described in the preceding experiment. Crystallization of the product from ether–pentane afforded **18***b* in 80% yield, m.p. 111–112°; ν_{max} (Nujol) 3250 (OH) and 1710 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.80 (d, poorly resolved, 3H, secondary methyl), 0.92 (s, 3H, angular methyl) 1.10 (d, $J = 6.5$ Hz, 3H, methyl adjacent to ketone), 4.20 (m, 3H, H—C—OH).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24. Found: C, 75.98; H, 10.54.

Cyclopropyl Ketone **20**

From Keto Alcohol **18***a*

A solution of 225 mg of **18***a* in 2 ml of dry pyridine was treated with 580 mg of *p*-toluenesulfonyl chloride and the resulting solution was kept under a nitrogen atmosphere at 3° for 3 days. The solution was then cooled on an ice bath, treated with 2 ml of ice-water, and stirred at 0° for 20 min. Ice-cold ether (60 ml) was added to the cold reaction mixture and the ethereal solution was worked-up in the usual manner with ice-cold 2 *M* hydrochloric acid and brine. The semi-crystalline product (370 mg) was used immediately for the next step.

The following reaction was carried out in a dry nitrogen atmosphere. The tosylate (370 mg) was dissolved in 5 ml of dry dimethyl sulfoxide and the solution was treated with 2.8 ml of a 0.5 *M* dimethyl sulfoxide solution of methylsulfinyl carbanion (18). The reaction solution was kept at 60° for 2 h, cooled to room temperature, and treated with 0.5 ml of water then diluted with 60 ml of ether. The ether solution was worked-up with brine in the usual manner. The product was purified by t.l.c. on silica gel with benzene–ether (95:5) as solvent. Elution of the silica gel afforded 147 mg (71%) of **20** as an oil which gave rise to a single peak on v.p.c. having a retention time of 15 min, 40 s (column temperature programmed from 50 to 250° at 10°/mm), λ_{max} (EtOH) 208 nm (ε 4000); ν_{max} (film) 1715 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ *ca.* 0.60 (m, partially obscured, protons on cyclopropane ring), 0.73 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.97 (s, 3H, angular methyl), 1.17 (s, 3H, methyl on cyclopropane ring).

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.52; H, 10.16. Found: C, 82.39; H, 9.88.

From Keto Alcohol **18***b*

The keto alcohol **18***b* was converted into the cyclopropyl ketone **20** in 60% yield by the procedure described in the preceding experiment. The product was identical with the cyclopropyl ketone obtained in the preceding experiment (i.r. and n.m.r. spectra, identical retention time on v.p.c. and inseparability on t.l.c. in various solvent systems).

*(±)-Ishwarane (***1***)*

The reduction of the cyclopropyl ketone **20** to ishwarane was carried out in a dry nitrogen atmosphere as follows (*cf.* 19). The cyclopropyl ketone **20** was dissolved in 6 ml of a stock solution prepared by dissolving 690 mg of sodium in 60 ml of ethylene glycol. The resulting solution was treated with 0.2 ml of anhydrous hydrazine (19) and heated with an oil bath until the temperature of the reaction solution reached 180°. More anhydrous hydrazine was added until the reaction solution refluxed freely at 180° and reflux at this temperature was continued for 14 h. Hydrazine was then distilled from the reaction flask until the temperature of the reaction solution reached 210°. After heating the reaction solution at 210° for 24 h, it was allowed to cool to room temperature and diluted with 60 ml of ether. The ether solution was worked-up in the usual manner with ice-cold 1 *M* hydrochloric acid, saturated sodium bicarbonate, and brine. Purification of the product by t.l.c. on silica gel with hexane as solvent afforded 64 mg (67%) of **1** as an oil which gave rise to a single peak on v.p.c. having a retention time of 17 min, 20 s (column temperature programmed from 50 to 250° at 8°/min), i.r., devoid of carbonyl absorption; n.m.r. (CCl_4), δ 0.50 (m, 2H, protons on cyclopropane ring), 0.72 (d, $J = 6.5$ Hz, 3H, secondary methyl), 0.78 (s, 3H, angular methyl), 1.12 (s, 3H, methyl on cyclopropane ring).

Anal. Calcd. for $C_{15}H_{24}$ (mol. wt. 204): C, 88.16; H, 11.84. Found (204 (mass spectrum)): C, 88.31; H, 11.65.

The synthetic hydrocarbon **1** was identical with an authentic sample of ishwarane obtained from natural sources (i.r. and n.m.r. spectra, retention times on v.p.c., fragmentation pattern of the mass spectra).

We are grateful to the National Research Council of Canada for a grant in aid of this work. We also thank Dr. T. R. Govindachari, CIBA Research Centre, Bombay, India for samples and spectra of isoishwarane and ishwarane and Dr. E. Piers, University of British Columbia, Vancouver, B.C., for his cooperation in establishing the stereochemistry of the octalone.

Primary Bond Formation in the Addition of Cyclopentenone to Chloroethylenes[1,2]

R. O. LOUTFY[3] AND P. DE MAYO

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ontario

Received June 21, 1972

The cycloaddition of cyclopentenone to all the halogenated ethylenes has been studied. There is no evidence, as has been previously suggested, that specific β addition takes place as the first step. The details of the two-step closure are discussed and it is concluded that spin relaxation is probably of no relevance for the stereochemical outcome.

La cycloaddition de la cyclopentènone sur tous les éthylènes halogénés a été étudiée. Il n'existe aucune preuve, comme cela a été suggéré antérieurement, pour que l'addition spécifique β ait lieu dans la première étape. La fermeture du cycle en deux étapes a été discutée en détail et on a conclu que la relaxation de spin n'a probablement aucun rapport avec le résultat stéréochimique.

Canadian Journal of Chemistry, **50**, 3465 (1972)

For personal use only.

In recent years there has been much activity in several laboratories on the subject of the addition of photo-excited cyclic enones to olefins (for reviews, see refs. 2, 3), regarding both mechanism and synthetic utility. The broad outlines of the reaction pathway appear to have been elucidated, but several aspects remain unclear. It appears to be generally accepted that, with or without prior complex formation, a tetramethylene intermediate is involved which may either close to the cyclobutane or revert to starting materials.[4] A similar situation is found in other reactions (*inter alia* refs. 5–8 and refs. cited therein).

Amongst the matters remaining obscure at least in part, are the stereochemical features of the reaction; that is, both the question of the orientation of the two moieties with respect to each other and that of the geometry of the resultant fusion. Concerning the first aspect, the early contribution of Corey and coworkers (9) has been remarkably effective in relating orientation with presumed electron distribution in the reactive entities. There are clear indications, however, that this interpretation is not complete (10). With regards to the second question, satisfying interpretations are still lacking to explain, for instance, the occurrence of *trans*-fusions in photo-annelation. Of these the most extraordinary example (though not in an enone) is that reported in the addition of dichloromaleic anhydride to cyclopentadiene (11). Though rationalizations both on the basis of conformational analysis (3) and on speculations as to the geometry of the excited enone (see refs. cited in (2)) have been discussed, the overall picture remains in large measure unsatisfying.

Connected with both these questions is that of which bond, that is, that α or β to the carbonyl group, is formed first in a two-step reaction. Since, in this step the orientation of one of the relevant centers is fixed (to the extent that this particular tetramethylene goes on to give product), it was thought that a complete stereochemical study of one type of addition might shed some light on the problem of the preferred bond formation and, perhaps, on certain stereochemical aspects of the problem.

The structural elucidation of a number of stereoisomers represented a massive problem, and olefins were required, therefore, in which the orientations of the substituents in the products might be elucidated by n.m.r. spectroscopy. For this reason the chloroethylenes were selected, and, in the event, the structures of all adducts were successfully resolved. The synthesis and structural elucidation of these substances will be reported separately (12).

[4]It has been suggested recently (4) that in the addition of 3-phenylcyclohex-2-enone to tetramethylethylene this may be the case whatever the multiplicity of the tetramethylene.

Whilst this study was in progress a report appeared of the results of a similar investigation (13). Whilst our results do not, in our opinion, unfortunately, allow the drawing of unequivocal positive conclusions, we believe that a number of possibilities, including that propounded in ref. (13), may be excluded, at least for the system studied.

The composition of the mixtures obtained by the addition of cyclopentenone to vinyl chloride, *cis*- and *trans*-dichloroethylenes (DCE), 1,1-dichloroethylene, and trichloroethylene are listed in Tables 1–4. Since the *cis*- and *trans*-DCE are the source of more information they will be discussed first.

A simplified possible general path for photo-annelation is shown in Scheme 1. It presents the two possible tetramethylene intermediates both of which may close or revert to starting material. We shall discuss the question of multiplicity later, but since the reaction involves the triplet manifold (2) the tetramethylene will probably initially be a triplet.[5] A number of authors have suggested that most of the products from the photo-annelation of $\alpha\beta$-unsaturated ketones derive from a process in which the first bond is formed at C-3 (Scheme 1, path β) (for example, see refs. 18–20). The evidence that this is so in general is not compelling and there are instances which indicate that α addition may occur (21). (The presence

[5]We prefer this description rather than a doublet of doublets since over the distances involved there must be overlap (14–16). For a powerful discussion of this entire problem recourse should be had to the lucid presentation of the physical chemists Salem and Rowland (17).

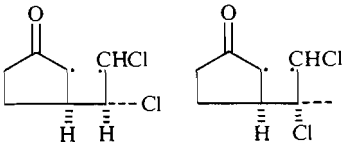
of the appropriate isobutenyl derivatives in the products of isobutene addition to cyclohexenone (9) also suggest this.)

For the DCE's it was proposed (13) that initial bond formation occurred solely at C-3 (β pathway) and that the biradical intermediates were conformationally equilibrated before ring closure. The basis for the conclusion was the analysis of the product distribution. On the assumption of C-3 bond formation, the partitioning of the two tetramethylenes, **1** and **2**,



1 **2**

can be calculated. The same tetramethylenes obtained from the isomeric DCE should, with equilibration prior to closure, partition in the same way. Although the original results suggested that this was the case (13), our present results do not confirm this.[6] A similar analysis based on α bond formation was also unsatisfactory leading therefore to the conclusion that one (or more) of the assumptions implicit in this approach was invalid. And in a certain sense, even if the analysis had been satisfactory, the results would have retained an element of ambiguity. Evidently such an analysis could only refer to bond formation leading to product. It is quite conceivable that the fastest primary bond formation (K_r) is by one pathway such as α. A fraction of these, perhaps small, go on to product and the major part reverts to starting material. A slower (K_r') primary bond formation might be by pathway β, but in this case the majority of the tetramethylenes give product. This situation would not be revealed by any product analysis.

One measure of the occurrence of this energy-wasting phenomenon, one which has been observed in thermal addition also (22), and, in fact, the method by which it was revealed (23, 24), is the value of the quantum yield of addition at infinite olefin concentration. The quantum yield has been determined for the DCE's previously (25) in neat liquid, (13 M) but have not been extrapolated to infinite concentration. Previous experience (26) suggests that the difference would not be great and so the values obtained ($\Phi_{cis\text{-DCE}} = 0.35$; $\Phi_{trans\text{-DCE}} = 0.18$)[7] incline us to believe that the *cis* addition is reversing less than the *trans* (provided that no other energy-wasting reversible intermediate lies on the reaction pathway before the tetramethylene). A similar observation has been made by Bartlett and coworkers (27) in the addition of the DCE's to triplet cyclopentadiene. But if the same two species were formed from both isomers the same reversibility would be expected. One must conclude, then, that either the tetramethylenes are not identical because equilibration has not occurred prior to closure, or both α and β bond formation occur to a different degree with the different isomer, or both. In the second and third cases the composition would depend on the rates of formation of the relevant tetramethylenes.

The present results provide another argument against the participation of the same two, and only two, tetramethylenes in DCE addition. Such species, if equilibrated, should be influenced in their partitioning between closing and reverting to starting materials, by temperature in the same way. Assuming α or β bond formation only, analysis using the product distribution obtained at $-75°$ (Table 1) leads to an even worse fit than obtained at room temperature. This would be reasonable if, at the lower temperature, the distribution were further away from equilibrium than at room temperature. Indeed the ratio of *trans* to *cis* products is closer, when approached from the isomeric DCE's, at room temperature than at low temperature. Thus, the *trans*:*cis* ratio for *cis*-DCE decreases from 1.78 at low temperature to 1.58 whilst for *trans*-DCE the ratio increases from 0.35 to 0.71. However the configuration favored at low temperature is the *opposite* of that of the starting olefin. That is, more *trans* products are formed from *cis*-DCE and more *cis* from *trans*-DCE. On the assumption that only β bond formation leads to product then this cannot be interpreted as being due to incomplete equilibration.

[6]One source of error may have been the missing of the fourth isomer (**6**) which has a longer retention time than the other three.

[7]The value given here was based on all four adducts (28, 29).

[1] 
As has been shown (28, 29) a change in temperature in enone photo-annelation leads both to change in K_r (the rate of disappearance of the quenchable species (28)) and to change in the relative partitioning of the tetramethylene. With cyclopentenone and cyclohexene for instance the value of K_r changed from 12×10^8 to 3.2×10^8 M^{-1} s^{-1} with a change of temperature from 27 to -71 °C. Over the same temperature range the fraction of molecules leading to product changed from 0.49 to 0.72. Our conclusion from these observations is that both α and β bond-formation pathways are operative. At present we have no adequate explanation for the preferred stereochemical inversion unless specific interactions between the halogen and the carbonyl group occur.

There has been much speculation as to the nature and behavior of the tetramethylenes formed in cycloaddition, particularly as regards thermally induced processes (*inter alia* 22, 27, 30–32). With photochemical reactions proceeding through the triplet, the additional complexities of spin relaxation are introduced. If in the present reactions spin correlation were the rate-determining step then much of the previous discussion would be void. However there is reason to believe that spin relaxation cannot be the slow step.

The closure of singlet tetramethylene unlike the combination of radicals, implies an activation energy reflecting part of the strain inherent in a cyclobutane. In the present cases the fusion of a cyclopentanone ring to the cyclobutane may increase this activation energy somewhat, and it should be remembered that similar photo-annelations with acetylenes to give cyclobutenes are known (33, 34) and that even additions to cyclobutenes (29) (to give the 2.2.0 bicyclohexane system) are recorded. In the latter the strain is considerably increased and must in part be reflected in the transition state. With activation energies of ~6.6 kcal/mol (35, 36) estimated for the bicyclo[3.2.0]heptane system bond closure must necessarily be slow. Further non-bonded interactions of the halogen substituents with the skeletal atoms may increase this further. With a positive activation as high as 7–8 kcal/mol (and possibly more if *trans* fusions are generated) rate constants at room temperature of the order of 10^8 s^{-1} would be admissible.

On the other hand in the presence of the halogen atoms intersystem crossing should be enhanced. Thus one chlorine atom attached to the naphthalene nucleus can decrease the lifetime of the triplet by about an order of magnitude (37). In the tetramethylenes under discussion the singlet–triplet energy splitting is necessarily small because of the near degeneracy and the tetramethylene must be subject to greater magnetic and electric perturbation than in, for instance, an aromatic hydrocarbon, quite aside from adventitious quenching by impurities such as oxygen that drastically shortens the lifetime of aromatic triplets. Since the latter may have lifetimes as short as 1 μs those for the triplet tetramethylene in solution may well be less. It is interesting that product distribution in several cycloadditions carried out in this laboratory appear to be the same under rigorous degassing (freeze–thaw cycles), nitrogen passage, and occasionally without any precaution. These experiments were not deliberately carried out, the significance at that time not being understood, and so are merely suggestive. But such observations seem to imply that the lifetime of the triplet tetramethylene is not shortened by oxygen.

But although ring closure is, it seems, slower than spin relaxation, it may not be the slowest step. The tetramethylene may well, because of electron repulsion, be formed in a conformation incapable of cyclization (30, 32) which may have to await the attaining of such an appropriate arrangement. The energy barriers to rotation have been discussed elsewhere (22, 30, 38) and if of the order of 5–8 kcal/mol, as seems likely, may well be competitive with bond closure.

We concur, therefore, with the views of Stephenson and Brauman (32) in believing (*a fortiori* in the case of the chlorinated compounds) that the original spin state in these

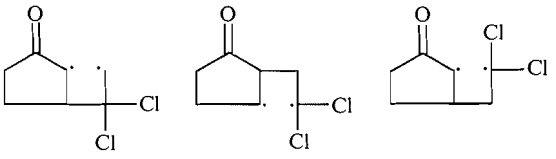
cycloadditions is irrelevant. Wagner and Zapp (8) have very recently reached similar conclusions with regards the Norrish Type II.

A limited amount of further information may be gleaned from adduct formation with the other chloroolefins.

The addition to 1,1-dichloroethylene gave the adduct which was predominantly 6,6-disubstituted. The two tetramethylenes which could give rise to this are **7** and **8**, of which **8** may be estimated to be about 8 kcal/mol more stable than **7** (40). This suggests, but does not conclusively prove, that in this case α addition is predominant. The alternative view would be that β addition is still predominant but that **9**



7 **8** **9**

has a high probability of reversal to starting material. In this case the quantum yield must of necessity be low, but the required data are not available.

On the basis of the Corey mechanism the same orientation would be expected as with ketene acetal, but to a lesser degree as is observed (though all orientation effects are contingent on the degree of reversibility). However, the overall dipole–dipole interactions would be expected to lead to the same product (10). This view makes the additional prediction that such specificity may decrease in polar media, and this is in agreement with the present results (Table 2). In acetonitrile the ratio of **10** to **11** changes by about a factor of two as against the value in diethyl ether. The small, but real changes in isomer distribution with change of temperature however imply most probably changes in reversibility and limit the conclusion which can be drawn. It should be noted that in other cases quite small orientation preferences have been observed even with polar substituents on the olefin (39–41) but unfortunately the relevant solvent studies were not made.

The case of the trichloroethylenes would be expected to be more complex. The overall dipole–dipole interaction will be less and will, furthermore, not be directed along the axis of the carbon–carbon double bond. This implies a greater solvent dependence for product distribution. Bartlett concluded that in the addition of cyclopentadiene to trichloroethylene 81.5% passed through the tetramethylene stabilized by two chlorine atoms (27). This assumed terminal addition to the diene. In the present case stabilization of an electron by an adjacent carbonyl is trivial as compared with that by a double bond (42) and it is doubtful that analogy can be made. The major product is now not the 6,6-dihalo compound, but there is little overall preference. The same appears true for the vinyl chloride adducts.

Experimental

The preparation and structure proof for these substances are described elsewhere (12, 29). Analytical gas chromatography was performed on an Aerograph (Hi Fi 600-A) hydrogen flame detector equipped with a 5% FFAP, 9 ft × 1/8 in. column using a Diatoporte S support at 100°. The areas were integrated using a Digital Readout System Model CRS-100 (Infrotronics), and the results were corrected for the differences in flame detector response.

Nitration Studies on 2-Isopropylimidazole

R. S. GLASS,[1] J. F. BLOUNT, D. BUTLER, A. PERROTTA, AND E. P. OLIVETO

Chemical Research Department, Hoffmann-La Roche Inc., Nutley, New Jersey 07110

Received March 6, 1972

The nitration of 2-isopropylimidazole has been studied under a variety of conditions involving nitration of the unprotonated imidazole, the imidazole anion, or an imidazole radical. From the reaction of nitronium tetrafluoroborate with 1-trimethylsilyl-2-isopropylimidazole there was isolated a dinitro compound the structure of which was shown by X-ray crystallography to be 1,4-dinitro-2-isopropylimidazole.

On a étudié la nitration de 2-isopropylimidazole sous des conditions diverses y comprenant la nitration de l'imidazole non protoné, l'anion de l'imidazole ou un radical de l'imidazole. De la réaction entre le tétrafluoroborate de nitronium et le 1-triméthylsilyl-2-isopropylimidazole on a isolé un composé dinitro dont la structure s'est montrée d'être le 1,4-dinitro-2-isopropylimidazole avec l'aide de la cristallographie par rayons X.

Canadian Journal of Chemistry, **50**, 3472 (1972)

In the course of preparing the potent histomonostat (1, 2) and trichomonacide (3) 1-methyl-2-isopropyl-5-nitroimidazole,[2] we found it necessary to study alternate methods of nitrating the intermediate 2-isopropylimidazole, since the standard nitration procedure (4, 5) for 2-substituted imidazoles using a mixture of nitric and sulfuric acids gave only about 50% of the desired 2-isopropyl-4(5)-nitroimidazole. Nitration in the presence of mercuric chloride (6) gave slight improvement. Addition of sulfur trioxide to the nitrating mixture gave inferior results, in contrast to the improvement reported for the nitration of imidazole (7).

To augment these studies three alternate methods of nitrating 2-isopropylimidazole were attempted: (*a*) nitration of unprotonated imidazole derivative, (*b*) nitration of an imidazole anion, and (*c*) nitration of an imidazolium radical.

Katritzky and others (8, 9) have demonstrated that basic pyridines ($pK_a > +1$) are first protonated and then slowly nitrated, while weakly basic pyridines ($pK_a < -2.5$) undergo nitration under mild conditions as free bases. Thus, the difficulty in nitrating 2-substituted imidazoles with nitric–sulfuric acid mixtures might be ascribed to the fact that the protonated species is being nitrated (7).[3]

A procedure in which unprotonated basic nitrogen heterocycles may be nitrated was reported by Olah (11) who found that nitronium tetrafluoroborate nitrates aromatic compounds in solvents such as sulfolane and acetonitrile. However, a possible complicating feature when aromatic heterocycles are nitrated could be the occurrence of C or N nitration. Indeed, Olah and co-workers (12) found that nitronium tetrafluoroborate reacts with pyridine to form the *N*-nitro salt. Other pyridines and a quinoline have shown similar behavior (13).

Nitration of 2-isopropylimidazole with nitronium tetrafluoroborate gave crude 4(5)-nitro-2-isopropylimidazole in 49% yield (31% after recrystallization). Two reasonable mechanisms for this reaction are shown in Schemes 1 and 2.

These mechanisms suggest likely reasons for the low yield of **2**. The *N*-nitro intermediate (like *N*-nitropyridine) (12) may not undergo N to C rearrangement of the nitro group (14) or at least not completely. Ring opening of the *N*-nitro salt would also lead to reduced yields of **2**. Incidentally, a stable *N*-nitro salt could not be isolated from the reaction.

Another possible cause for the low yield of **2**, namely further reaction of this compound with nitronium tetrafluoroborate, is ruled out because **2** may be recovered in good yield after exposure to the nitration conditions.

Both Schemes 1 and 2 involve the formation of fluoroboric acid (or its salt with **2**). If 2-isopropylimidazole reacts with fluoroboric acid instead of nitronium tetrafluoroborate, the

SCHEME 4

resulting salt might be stable to the reaction conditions. In this event, some 2-isopropylimidazole would be recovered on work-up, and this was indeed observed.

To avoid the formation of an unreactive 2-isopropylimidazolium salt in the nitration of 2-isopropylimidazole, a derivative which might undergo nitration without loss of a proton was investigated. 1-Trimethylsilyl-2-isopropylimidazole (**3**) might react with a NO_2^+ source according to Schemes 3 or 4. Scheme 3 is analogous to conversion of 1-trimethylsilylimidazole into 1-acetylimidazole (15), *N*,*N*′-thiocarbonyldiimidazole (16), and *N*,*N*′-imidazolesulfide (17) with acetyl chloride, thiophosgene, and sulfur dichloride, respectively. Scheme 4 is analogous to the formation of 1-acetyl-1,2,3-triazole from 2-trimethylsilyl-1,2,3-triazole and acetyl chloride (18). Unfortunately **2** was not obtained on treatment of 1-trimethylsilyl-2-isopropylimidazole with nitryl chloride.[4] The silyl compound **3**, however, afforded a mixture of **2** and a dinitro compound on reaction with nitronium tetrafluoroborate. The spectral data and elemental analysis for the dinitro compound are consistent with structure **4** (Scheme 5).

The u.v. or n.m.r. spectrum (20) of this compound does not unambiguously support one isomer (either **4***a* or **4***b*) over the other. Chemical support for the gross structure was obtained in two ways. Nitrolysis (21) of **4** in concentrated sulfuric acid gave **2**, and catalytic hydrogena-

[4]Nitryl chloride, which may be in equilibrium with nitrogen dioxide and chlorine (19*a*, *b*) has been pictured as a source of free radicals (19*a*, *c*, *d*), chloronium ions (19*d*), and nitronium ions (19*c*).

SCHEME 6

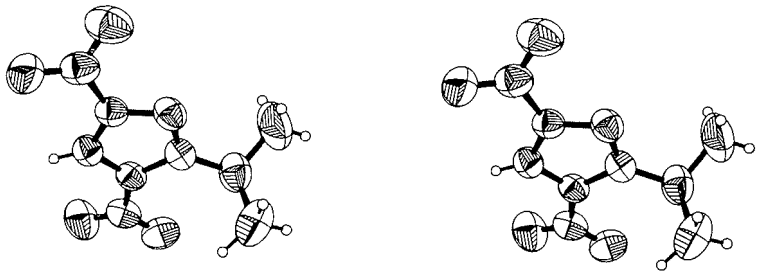

FIG. 1. Stereoscopic view of **4***a*.

tion in acetic anhydride (20*a*, 22) afforded a diacetate which was identical with that prepared by catalytic hydrogenation of **2** in acetic anhydride.

During the progress of this work a report appeared (23) which described the formation of 2-methyl-1 (4 or 5)-dinitroimidazole in high yield from the nitration of 2-methylimidazole with nitric acid in the presence of acetic anhydride. The exact position of the *C*-nitro group could not be determined. Application of these nitration conditions to **1** produced **4** in good yield. With sufficient material now easily available, crystals suitable for an X-ray analysis could be obtained, and the structure was shown to be 2-isopropyl-1,4-dinitroimidazole (**4***a*). (see Fig. 1).

Nitration of 2-isopropylimidazole anion (24) was then investigated. Sodium hydride converted 2-isopropylimidazole into the corresponding sodium salt, and the reaction of this salt with *n*-butyl nitrate in tetrahydrofuran gave only 1-*n*-butyl-2-isopropylimidazole (**5**) (Scheme 6).[5] This material was identical with the compound prepared from *n*-butyl iodide and the sodium salt of 2-isopropylimidazole.

[5]Solvolysis of nitrates has been shown to involve displacement on carbon, displacement on nitrogen, β-hydrogen elimination giving an olefin and α-hydrogen elimination giving a carbonyl compound (25).

For attempted nitration of an imidazole radical,[6] sodium 2-isopropylimidazole was reacted with tetranitromethane (28, 29), but no isolable **2** was formed. Also, decomposition of pernitrous acid (30) in the presence of 2-isopropylimidazole resulted only in the recovery of starting material.

Experimental

All melting points were taken on a Thomas–Hoover capillary melting point apparatus, and are uncorrected. All elemental analyses were performed on samples which were recrystallized an additional time.

Nitration of 2-Isopropylimidazole (1)

(A) Using Nitronium Tetrafluoroborate

To a stirred slurry of nitronium tetrafluoroborate (32) (3.03 g, 0.022 mol) and dried, distilled acetonitrile (6 ml) cooled in an ice bath, a solution of 2-isopropylimidazole (2.02 g, 0.018 mol) in dried, distilled acetonitrile (30 ml) was added dropwise. Stirring and cooling were continued for 30 min after completion of the addition. The solution was then concentrated on a rotary evaporator and added to aqueous sodium bicarbonate solution without delay. The aqueous solution was extracted with chloroform and the extract dried (anhydrous Na_2SO_4) and concentrated to dryness, giving an orange–brown solid (1.38 g, 49%). This material was dissolved in benzene–chloroform, washed through an alumina (5 g) column, and recrystallized from water to give a total of 0.86 g (31%) of **2** in two crops, m.p. 182–183.5° (lit. (3, 31) m.p. 180°).

[6]Unfortunately, very little is known about the reactivity of imidazoles towards radicals (26, 27).

(B) Using HNO_3-Ac_2O

To a solution of 4.0 g of **1** in 115 ml of glacial acetic acid was added 26.4 ml of concentrated nitric acid and then 71.2 ml of acetic anhydride was added slowly over a period of 35–40 min while maintaining the temperature at 20–22°. After being stirred at this temperature for an additional hour, the mixture was added to 200 ml of water at 17–20°, stirred for 15 min, and extracted with methylene chloride. The extracts were washed with sodium bicarbonate solution, then with saturated salt solution, and dried over sodium sulfate. Evaporation of the solvent gave 2.8 g of crude **4***a*. Crystallization from ether–hexane gave 2.2 g (44%), m.p. 79–80°, identical (i.r., u.v., n.m.r.) with material obtained by nitration of **3** (see below).

*Nitration (NO_2BF_4) of 1-Trimethylsilyl-2-isopropylimidazole (**3**)*

A solution of 1-trimethylsilyl-2-isopropylimidazole (**3**) (prepared from 2-isopropylimidazole (1.00 g, 9.1 mmol) and hexamethyldisilazane (4.00 g, 31.0 mmol) in acetonitrile (10 ml)) was added dropwise to a stirred slurry of nitronium tetrafluoroborate (1.265 g, 9.5 mmol) and acetonitrile (5 ml) cooled in an ice bath. The solution was stirred for 30 min with ice cooling and benzene (2 ml) was added. It was concentrated on a rotary evaporator, neutralized with aqueous sodium bicarbonate, and extracted with chloroform. These extracts were dried (Na_2SO_4) and concentrated to an orange oil (1.07 g). A sample (150 mg) of this material was chromatographed on a layer of silica gel and eluted with a 4:5 acetone:cyclohexane mixture. Two bands separated from material at the origin and were extracted from the silica gel. Band 1 gave 25 mg of dinitro compound **4***a* (10%). Band 2 gave 36 mg of **2** (18%). Recrystallization of band 1 material from ether–hexane gave **4***a*, m.p. 76–77°.

Anal. Calcd. for $C_6H_8N_4O_4$: C, 36.00; H, 4.03; N, 27.99. Found: C, 35.78; H, 3.99; N, 27.71.

Recrystallization of band 2 material from acetonitrile gave **2**, m.p. 181–183°, identical (i.r., t.l.c., mixed m.p.) with an authentic sample.

*Sulfuric Acid Treatment of **4a***

A sample of **4***a* (41 mg, 0.26 mmol) was dissolved in concentrated sulfuric acid (8 drops). After standing 5 h at room temperature the solution was cooled, neutralized with aqueous sodium bicarbonate solution, and the p*H* adjusted to 2 with 1 *N* hydrochloric acid. This mixture was extracted with chloroform, the aqueous phase adjusted to p*H* 5 and again extracted with chloroform. The chloroform extracts were combined, dried (Na_2SO_4) and concentrated to dryness to give a solid (28.8 mg). This material was purified by t.l.c. to give a solid (28.5 mg, 72%) which was recrystallized from water to give 14 mg (36%) m.p. 181–182.5°, identical with **2** (mixed m.p., t.l.c., i.r.).

Reaction of Sodium 2-Isopropylimidazole with n-Butyl Nitrate

Sodium hydride (2.42 g, 54.5%) mineral oil dispersion, 0.055 mol) was added in small portions to a stirring solution of 2-isopropylimidazole (5.50 g, 0.050 mol) in anhydrous tetrahydrofuran (30 ml) under a nitrogen atmosphere. After stirring the reaction mixture for 2 h a solution of *n*-butyl nitrate (33) (5.95 g, 0.050 mol) in dry tetrahydrofuran (5 ml) was added dropwise and stirring was continued overnight. The reaction mixture was poured into water and the two phases separated. The aqueous solution was extracted with three 100 ml portions of chloroform. The water-insoluble phase was dissolved in chloroform and extracted with two 50 ml portions of dilute aqueous hydrochloric acid. The acidic aqueous solution was brought to p*H* 10 with concentrated ammonia and extracted with three 100 ml portions of chloroform. These chloroform extracts and those previously obtained were combined, dried (Na_2SO_4) and concentrated to a yellow oil which was distilled. A fraction distilling at 65–80° (1 mm) was collected (2.67 g, 32%). This material formed a picrate, m.p. 130.5–132°.

Anal. Calcd. for $C_{16}H_{21}N_5O_7$: C, 48.61; H, 5.32; N, 17.72. Found: C, 48.84; H, 5.49, N, 17.91.

Reaction of Sodium 2-Isopropylimidazole with n-Butyl Iodide

Sodium hydride (4.84 g, 54.5% mineral oil dispersion, 0.110 mol) was added portionwise to a stirred solution of 2-isopropylimidazole (11.0 g, 0.10 mol) in dry tetrahydrofuran (100 ml) under a nitrogen atmosphere. After stirring the reaction mixture for 3 h at room temperature, *n*-butyl iodide (18.0 g) was added dropwise. The reaction mixture was stirred overnight and then diluted with ether and filtered through Celite. The filtrate was concentrated to an oil. A sample of this oil was converted to a picrate, m.p. 131–132°, identical with material prepared from *n*-butyl nitrate.

Anal. Calcd. for $C_{16}H_{21}N_5O_7$: C, 48.61; H, 5.32; N, 17.72. Found: C, 48.58; H, 5.48; N, 17.89.

The remaining oil was distilled to give a fraction, b.p. 47–74° (0.7 mm); 8.7 g (52%).

Crystallography

The crystal data for **4***a* are:

$C_6H_8N_4O_4$ f.w. = 200.15

Monoclinic. $P2_1/c$, $a = 15.488(5)$, $b = 6.072(3)$, $c = 10.030(5)$ Å, $\beta = 99.35(3)°$, $V = 930.7$ Å^3, $\rho_o = 1.34(3)$, $Z = 4$, $\rho_c = 1.428$ g cm^{-3} (21 °C, CuKα, $\lambda = 1.5418$ Å).

The intensity data were measured on a Hilger–Watts model Y290 four circle diffractometer by a moving crystal-moving detector method. Nickel filtered CuKα radiation and pulse height discrimination were used. Of the 1749 accessible reflections in the unique quadrant ($2\theta < 140°$), 1000 had intensities significantly greater than background. The crystal was approximately $0.05 \times 0.2 \times 0.5$ mm.

The structure was solved by straightforward application of the symbolic addition method (34). All of the heavier atoms were located from the first *E*-map except for the three isopropyl carbon atoms, which were found in the subsequent electron density map. The hydrogen atoms were located from a difference Fourier calculated after refinement of the heavier atoms. Full matrix least squares refinement was continued with isotropic temperature factors for the hydrogens and anisotropic temperature factors for the other atoms until the shifts in all parameters were less than 1/6 of their respective standard deviations. A difference Fourier based on the final parameters has no features greater than 0.1 *e* Å^{-3} in magnitude. The final $R = \Sigma||F_o|-|F_c||/\Sigma|F_o| = 0.044$ for the 1000 observed data.

The function minimized in the least squares refinement was $\Sigma w||F_o|-|F_c||^2$ where $w = 1/(3.2 + |F_o| + 0.019|F_o|^2)$ for the observed data and $w = 0$ for the unobserved data.

TABLE 1. Final parameters (e.s.d.'s) × 10^4
T.F. (iso) = $\exp[-B\sin^2\theta/\lambda^2]$
T.F. (aniso) = $\exp[-(h^2\beta 11 + k^2\beta 22 + l^2\beta 33 + \beta hk\beta 12 + 2hl\beta 13 + 2k\beta 23)]$

The refinement calculations were made with a local modification of the program ORFLS (35). Standard atomic scattering curves were used for O, C, N (36), and H (37).

The final atomic parameters and their estimated standard deviations are listed in Table 1. Tables 2 and 3 contain the bond lengths and bond angles for the non-hydrogen atoms. A table of the final F_o and F_c values has been placed in the Depository for Unpublished Data.[7]

The imidazole ring is planar to within ±0.005 Å. The 1-nitro nitrogen (N(2) is displaced 0.07 Å from the plane of the ring while N(4) and C(6) lie 0.04 and 0.06 Å, respectively, out of the plane on the opposite side from N(2). The nitro groups are both twisted slightly from the plane of the imidazole ring. The dihedral angles between the plane of the ring and the 1-nitro (N(2), O(1), O(2)) and 4-nitro (N(4), O(3), O(4)) groups are 7.3 and 10.0°, respectively.

[7]These data are available upon request from the Depository for Unpublished Data, National Science Library, National Research Council of Canada, Ottawa K1A 0S2, Canada.

The Thermal Decomposition of *N*-Arylcarbamates of *t*-Alcohols. 2. Effects of Solvent, Temperature, and Substituents

S. J. ASHCROFT[1] AND MELANIE P. THORNE
University of Keele, Keele, Staffordshire, England ST5 5BG

Received May 4, 1972

The influence of solvent, ring substituents, and tertiary carbon atom substituents on the decomposition at 423–473 K of some *N*-arylcarbamates of tertiary alcohols (p-$XC_6H_4NHCO_2C(CH_3)_2R$, where X = CH_3, H, Cl, NO_2, R = C≡CH, C_2H_5, CH=CH_2) has been investigated. In dodecane, diphenyl ether, acetophenone, nitrobenzene, and decanol, the reactions were first order yielding chiefly carbon dioxide, amine, and olefin. *t*-Pentyl carbamates yielded the olefins 2-methyl-1-butene and 2-methyl-2-butene in a 3:1 mixture. Solvent effects are reflected in variations in enthalpies and entropies of activation, but effects on the actual values of the specific rate constants are small. Substituent effects are also small, with changes in R from C≡CH to CH=CH_2 producing only a tenfold rate increase. Variations in X yield Hammett $\sigma\rho$ plots with slopes of about 0.50. These results are consistent with the charge separated cyclic transition state proposed before (1). In ethylene glycol, increased reaction rates and 1:1 yields of the olefins from the *t*-pentyl carbamates indicate a mechanism with greater carbonium ion character.

L'influence du solvant, des substituants du cycle, et des substituants sur le carbone tertiaire; sur la décomposition à 423–473 K de quelques *N*-arylcarbamates d'alcools tertiaires (p-$XC_6H_4NHCOOC(CH_3)_2R$ où X = CH_3, H, Cl, NO_2 et R = C≡CH, C_2H_5, CH=CH_2), a été étudiée. Dans le dodécane, diphényléther, acétophénone, nitrobenzène, et décanol, les réactions sont du premier ordre et conduisent principalement au gaz carbonique, amine et oléfine. Les carbamates de *t*-pentyle donnent les oléfines méthyl-2 butène-1 et méthyl-2 butène-2 dans un rapport 3:1. Les effets de solvants se reflètent sur les variations d'enthalpie et d'entropie d'activation mais ces effets sur les valeurs des constantes de vitesse spécifique sont faibles. Les effets des substituants sont également petits avec des variations lorsque R passe de C≡CH à CH=CH_2 provoquant un accroissement par 10 de la vitesse. Les variations de X conduisent aux courbes $\sigma\rho$ de Hammett avec des pentes de l'ordre de 0.50. Ces résultats sont compatibles avec un état de transition cyclique à charge séparée que l'on propose avant (1). Dans l'éthylèneglycol l'accroissement des vitesses de réactions et des rendements en mélange 1:1 d'oléfines à partir des carbamates de *t*-pentyle, montre un mécanisme à caractère plus accentué en ion carbonium. Canadian Journal of Chemistry, **50**, 3478 (1972)

Introduction

N-Phenylcarbamates and meta or para substituted *N*-phenylcarbamates of *t*-butanol have been shown previously (1) to decompose in diphenyl ether at 450 K according to eq. 1.

[1] $ArNHCOOC(CH_3)_3 \rightarrow ArNH_2 + CO_2 + CH_2{=}C(CH_3)_2$

The *N*-phenyl- and *N*-tolyl-carbamates also yielded small quantities of the corresponding diarylurea.

Reaction 1 was shown to follow a first order rate law with electron-withdrawing substituents having a small activating effect. A ρ value of 0.54 was obtained for the Hammett $\sigma\rho$ plot.

On the basis of these results it was postulated that these esters decomposed by a cyclic mechanism similar to that proposed for olefin-forming pyrolytic eliminations of esters of carboxylic acids (2–4) and xanthates (5), with the possibility that some charge separation occurred. Cyclic mechanisms have also been proposed for the liquid-phase decomposition of α-methylbenzyl *N*-phenylcarbamates (6) and for cholesteryl *N*-phenyl- and *N*-benzyl-carbamates (5, 7).

The object of the present work was to extend the investigation to include the effects of solvent, tertiary carbon atom substituents, and temperature on the decomposition reactions in order to provide additional information about the nature of the transition state, with particular reference to the amount of charge separation which occurs. Consequently rates of decomposition of *N*-phenyl- or para-substituted *N*-phenyl-carbamates in selected solvents have been measured over the temperature range 423–473 K.

TABLE 1. Product yield from decomposition of *t*-butyl *N*-phenylcarbamate*

Solvent	Temperature (K)	Amine	Urea	Total C_6H_5NH—
Dodecane	453.0	—	16.5	
	463.0	—	16.3	
	473.0		15.3	
Diphenyl ether	450.5	87.0	5.8	98.6
	453.5	88.8	4.9	98.6
	457.6	88.7	5.0	98.7
	465.5	87.9	5.5	98.9
	467.5	87.5	5.1	97.6
Acetophenone	443.0	99.5	0	99.5
Nitrobenzene	453.0	96.9	0	96.9
Decanol	443.0	50.6	0	50.6
Ethylene glycol	433.0	98.7	0	98.7
	451.0	98.5	0	98.5

*Values are given as mol % of reactant.

The results provide support for the suggestion that decomposition occurs via a charge separated cyclic transition state, although it is also evident that, in some instances, an additional mechanism is operating.

Experimental

Materials

The carbamates were prepared as before (1), recrystallized from petroleum ether (b.p. 60–80°) or from a 5:1 heptane–benzene mixture and, finally, sublimed *in vacuo*. Lower-melting *t*-pentyl carbamates, which failed to crystallize out from the solvent on cooling, were obtained as pure solids by vacuum sublimation of the oil remaining after evaporation of the solvent. The compounds were characterized by melting point, elemental analysis, and n.m.r. spectra.

Solvents, either Fisher certified reagent grade or BDH reagent grade, were used without further purification. The purity of these solvents is claimed to be at least 99%.

Kinetic Experiments

The decompositions were carried out in a system similar to that described previously, using vapor phase chromatography to follow the reactions (1). The flow-rate of the helium used to sweep the volatile products into the gas sampling loop of the chromatograph was carefully controlled by Pye gas-flow restrictors. It was shown before that, for a constant helium flow-rate, the rates of evolution of the gases are linearly related to the peak heights obtained when samples from the gas loop are injected into the chromatograph. The chromatograms were obtained on a Wilkens Aerograph with a $\frac{1}{4}$ in. × 10 ft column of 20% Quadrol on Chromosorb P at 323 K, or on a Pye (series 104) chromatograph with a $\frac{1}{4}$ in. × 10 ft column of 20% Squalene on Chromosorb P at 321 K or a $\frac{1}{4}$ in. × 3 ft Poropak Q column at 423 K. 2-Methyl-1-butene could be separated from 2-methyl-2-butene using both the Quadrol and Squalene columns.

Amine and Urea Analyses

Analyses for residual amine and urea were carried out by the methods described previously (1). The potentiometric titrations of the amine with hydrochloric acid in the 1:1 ethylene glycol–isopropanol solvent mixture were done automatically using Radiometer Automatic Titration Equipment.

Results

Reaction Products

Decomposition of the carbamates yielded carbon dioxide, an olefin (identified by comparison of retention times in the g.l.c. with those of pure samples) and a residue which could be titrated with a non-aqueous solution of hydrochloric acid and was assumed to be an amine. Aniline, positively identified by n.m.r., was obtained from decompositions of *t*-butyl *N*-phenylcarbamate in both diphenyl ether and ethylene glycol, by extracting the solvent residue with aqueous acid and ether, in the usual way.

In dodecane and, to a lesser extent in diphenyl ether, decompositions of *N*-phenyl- and *N*-tolylcarbamates also yielded small quantities of diphenyl or ditolyl urea (identified by m.p.). The values for the yields of urea, together with those for amine, for decompositions of *t*-butyl *N*-phenylcarbamate in six solvents at temperatures from 443 to 467 K are given in Table 1. Yields for ureas from *t*-pentyl carbamates were similar to those from the *t*-butyl analogs. Amine analyses were not done for the decompositions in dodecane because of immiscibility of this solvent with the titration solvent. However,

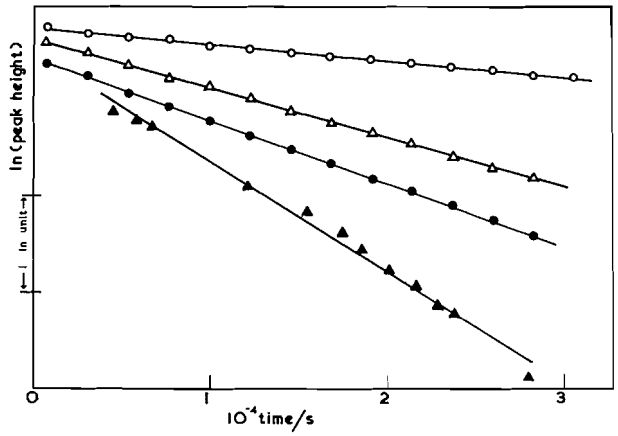

FIG. 1. First order rate plots for evolution of carbon dioxide during decomposition of *t*-butyl *N*-phenylcarbamate at 453 K in dodecane ○, acetophenone △, nitrobenzene ●, and decanol ▲. (The lines have been displaced vertically for clarity.)

decompositions of the *p*-nitro-substituted *N*-phenylcarbamates in dodecane resulted, on cooling the reaction mixture, in precipitation of a yellow solid which was identified by melting point (417–418 K) and elemental analysis as *p*-nitroaniline (lit. m.p. 419 K).

Anal. Calcd. for $C_6H_6N_2O_2$: C, 52.2; H, 4.35; N, 20.3. Found: C, 52.7; H, 4.42; N, 20.5.

Complete precipitation, to give yields of 100 mol %, of the *p*-nitroaniline could be effected by addition of low-boiling petroleum ether. *p*-Nitroaniline was not precipitated from decompositions of the appropriate carbamates in any other solvents and is not sufficiently basic to be estimated by titration.

Those reactions which yielded significant amounts of disubstituted ureas also yielded an additional volatile product. Its presence was detected from the gas chromatograms from the early stages of the reactions and its apparent rate of evolution decreased with time. The product was identified as *t*-butanol, *t*-pentanol, or 3-methyl-butyne-3-ol, depending on the carbamate from which it arose, by comparison of the retention time with that of a pure sample of the appropriate alcohol.

t-Butanol or *t*-pentanol were also produced when the respective carbamates were decomposed in decanol. In this solvent, however, all attempts to precipitate a urea failed, but the aniline determined by titration amounted to only 50% of the possible maximum (Table 1).

Actual yields of volatile products were not ascertained during this study, but it was shown previously (1) that recovery of the carbonyl group as carbon dioxide or as carbon dioxide plus urea was complete for decompositions of *t*-butyl carbamates in diphenyl ether, and that the *t*-butyl entity was not retained in the reaction mixture in any form.

Kinetic Results

The first-order rate constants were determined, as before (1), by computing the slope of the best line through the points obtained from the plot of the logarithm of the peak heights against time, using the method of least squares. The theoretical lines were generated in the computer and both the lines and points printed out using the digital incremental plotter. In all experiments except those in decanol at 453 K and above, the points obtained from measurements of the evolution of carbon dioxide or olefins were linear over at least two or three half-lives. Even in the decanol experiments the non-linearity of the points is so small that rate constants have been calculated assuming a first order rate law. Figure 1 shows the graphs for the evolution of carbon dioxide from the decomposition of *t*-butyl *N*-phenylcarbamate at 453 K in different solvents. Similar graphs were obtained for the other sets of kinetic data.

The rate constants for the decompositions of the carbamates in six different solvents at temperatures between 403 and 473 K are given in Tables 2, 3, and 4. The values quoted are usually

*Rate constant from carbon dioxide evolution.
†Rate constant from isobutene evolution.
‡Dielectric constants at temperatures given calculated from data in ref. 8.
§Rates measured by n.m.r.

the average of duplicate experiments, agreement between which was always within 7%. Rate constants have been calculated using the data for both the evolution of carbon dioxide (k_{CO_2}) and the evolution of olefin (k_{ene}). The values of k usually increase with increasing dielectric constant of the solvent, the reactions in decanol providing the exception. Decomposition of *t*-pentyl carbamates is faster than that of the corresponding *t*-butyl compounds, but the effect of the ring substituents in the *t*-pentyl series is similar to that reported for *t*-butyl carbamates (1). Log k is linearly related to the Hammett σ constants as is seen in Fig. 2, where the lines for log k_{CO_2} against the σ values are given. Similar lines were obtained for log k_{ene} *vs.* σ. The slopes (ρ values) of the lines are given in Table 5.

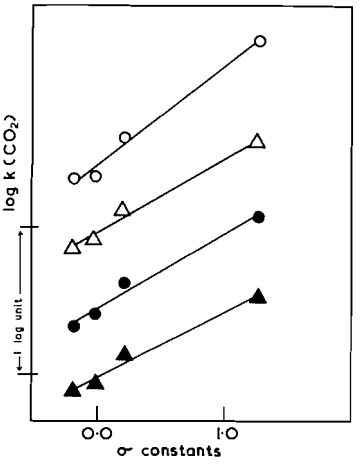

FIG. 2. Correlation between Hammett σ constants and log k_{CO_2} for evolution of carbon dioxide during decomposition at 463 K of para-substituted *N*-phenylcarbamates of *t*-pentanol in acetophenone ○, diphenyl ether △, nitrobenzene ●, and dodecane ▲. (The lines have been displaced vertically for clarity.) σ-Value of 1.27 used for p-NO_2 derivatives (1).

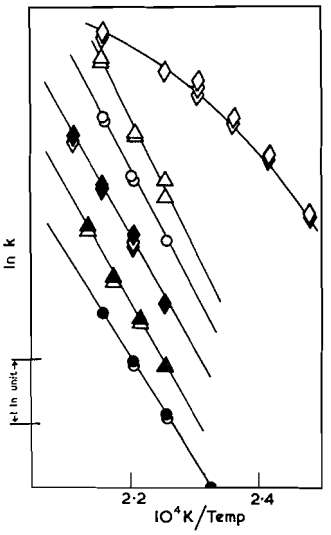

FIG. 3. Arrhenius plots (ln k_{CO_2} *vs.* T^{-1}) for carbon dioxide evolution from decomposition of *t*-butyl *N*-phenylcarbamate in decanol ●, diphenyl ether ▲, dodecane ◆, acetophenone ○, and nitrobenzene △. The non-linear plot for decompositions in ethylene glycol ◇ is also shown. (The lines have been displaced vertically for clarity.)

The values of k_{ene} and k_{CO_2} are usually the same, but in a few systems, particularly those involving ethylene glycol as solvent or *t*-pentyl *N*-(*p*-nitrophenyl)carbamate as reactant, the ratio k_{ene}/k_{CO_2} can be as low as 0.7 (Tables 2–4).

Both the possible butenes, 2-methyl-1-butene and 2-methyl-2-butene, are evolved from the *t*-pentyl compounds. An estimate of the relative proportions in which they are formed was obtained from the average value of the ratio of the two peak heights taken over all the samples in any one run (1-ene/2-ene, Table 3). In most solvents the ratio is about that which would be expected from statistical considerations, but decompositions in ethylene glycol give the two isomers in about equal proportions.

The Arrhenius and thermodynamic quantities of activation for the *t*-butyl carbamates in the different solvents and for the *t*-pentyl *N*-phenylcarbamate in diphenyl ether are listed in Table 6. These quantities were obtained from the least squares fit of the logarithmic forms of the Arrhenius equation and of the absolute rate theory equation (eq. 2), respectively. In the latter case, the transmission coefficient, κ, was taken as unity. Using either the k_{CO_2} or k_{ene} rate constants, the graphs of ln k_r *vs.* T^{-1} and of ln $(k_r \cdot T^{-1})$ *vs.* T^{-1} were linear over the temperature ranges studied, for all solvents except ethylene glycol. The Arrhenius plots for the carbon dioxide rate constants from the decomposition of *t*-butyl *N*-phenylcarbamates (ln k_{CO_2} *vs.* T^{-1}) are given in Fig. 3. Similar graphs were obtained for the other sets of data.

[2] $$k_r \cdot T^{-1} = \kappa \frac{k}{h} \cdot e^{\Delta S^*/R} \cdot e^{-\Delta H^*/RT} s^{-1}$$

Discussion

In most of the systems studied, the decomposition of the carbamate took place almost exclusively according to eq. 3.

[3] $$ArNHCOOR \rightarrow ArNH_2 + CO_2 + Olefin$$

The effects of solvent, substituents, and temperature on the reaction rates are generally consistent with the charge separated cyclic transition state suggested earlier (1) in analogy with mechanisms put forward by Maccoll (4), Smith and co-workers (9) and, more recently, Lum and Smith (10) for the gas-phase pyrolysis of acetates. The reaction scheme was envisaged as depicted in eq. 4.

The small quantities of urea and alcohol formed when *N*-phenyl- and *N*-tolyl-carbamates were decomposed in dodecane or diphenyl urea can be accounted for by the reaction sequence: eq. 3 followed by [5] and [6] as suggested previously (1).

[5] $$ArNHCOOR \rightarrow ArNCO + ROH$$

[6] $$ArNCO + ArNH_2 \rightarrow ArNHCONHAr$$

This scheme is preferred to eq. 7, also suggested previously (1), since the latter would lead one to predict the rate of alcohol evolution to rise to a maximum and then fall off as the relative concentrations of the amine and carbamate changed.

[7] $$ArNHCOOR + ArNH_2 \rightarrow ArNHCONHAr + ROH$$

Solvent Effects

The specific rate constants for the decomposition of any particular carbamate generally increase as the dielectric constant of the solvent increases. Decanol provides the exception, rates being much higher in this solvent than would be expected from considerations of dielectric constant alone. This may reflect the inadequacy of the macroscopic dielectric constant to provide a good measure of all the interactions of solvent and solute on a molecular scale (11) or it may indicate that the rates in decanol appear to be greater than is actually the case, because transesterification occurs (eq. 8).

[8] $$C_6H_5NHCOOR + C_{10}H_{21}OH \rightarrow C_6H_5NHCOOC_{10}H_{21} + ROH$$

Reports of similar reactions are sparse, but work of Gaylord and Sroog (12) indicates that such a reaction is possible and that it might be reasonably fast. Equation 8 can account for both the observed formation of alcohols and the low yields (50%) of amine, since the decyl carbamate would be unlikely to decompose at the temperatures used (6). The kinetic method used, in which the measured quantity is related to the rate of evolution of a product and not to its concentration in the reaction vessel, means that an additional reaction, such as [8], which consumes reactant, could result in an apparent rate constant which is larger than is actually the case. The degree of error would depend on the relative rates of reaction and the equilibrium constant for reaction 8.

As a measure of solvent polarity the E_T parameters determined by Dimroth *et al.* (13) from the effect of solvent on the molar transition energies of the solvatochromic band of pyridinium *N*-phenolbetaine at 298 K, have been used. The E_T values for the temperature range under consideration will be different from those at 298 K, but since the thermochromic variation of the absorption band is small compared with the solvatochromic variation,[2] the relative values will be substantially the same at the different temperature. E_T values for *n*-dodecane and *n*-decanol have not been published, but have been estimated from data given for *n*-hexane and *n*-heptane and for the C_1—C_4 primary alcohols respectively. The parameters show a reasonably good linear correlation with the free energy ($\log k$) of activation of the decompositions (Figs. 4 and 5) but the slopes are very small (Table 7), indicating that a highly charged transition species is unlikely. The slopes of log k_{CO_2} *vs.* E_T and log k_{ene} *vs.* E_T are usually the same for any one carbamate, and only lines for the effect of solvent on carbon dioxide evolution are given in Figs. 4 and 5. Table 7 shows however that, for *t*-pentyl *N*-(*p*-nitrophenyl)carbamate, where k_{ene} and k_{CO_2} are not equal, the effects of solvent on the two apparent rate constants are not the same.

The rates in ethylene glycol are, on the whole, very much greater than would be predicted

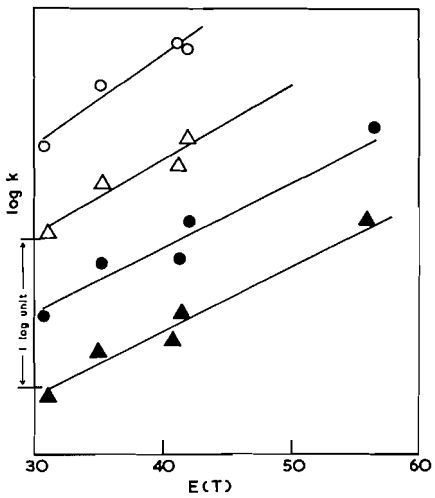

FIG. 4. Plots of log k_{CO_2} *vs.* solvent polarity parameter, E_T for carbon dioxide evolution from decomposition at 463 K of *t*-pentyl *N*-arylcarbamates. Aryl = *p*-tolyl ▲, phenyl ●, *p*-chlorophenyl △, and *p*-nitrophenyl ○. (The lines have been displaced vertically for clarity.)

[2]C. Reichardt. Private communication

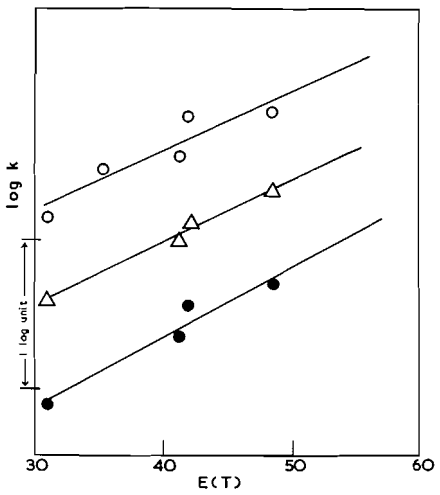

FIG. 5. Plots of $\log k$ *vs.* solvent polarity parameter, E_T for carbon dioxide evolution from decomposition of *t*-butyl *N*-phenylcarbamate at 443 K ●, 453 K △, and 463 K ○. (The lines have been displaced vertically for clarity).

from the solvent polarity plot. This could also be due to transesterification, but no tertiary alcohol was detected in the volatile products and the amine analyses indicated that aniline was formed in stoichiometric quantities. The 1:1 ratio of the two 2-methyl butenes from the *t*-pentyl carbamates instead of an approximately 3:1 ratio, indicates that the decompositions in ethylene glycol proceed in a different fashion.

The individual thermodynamic parameters of activation (Table 6) show considerable variation over the range of solvents. However, Leffler (16) has pointed out that in a series of related reactions, changes in solvent often affect both the entropy and enthalpy of activation in a compensating manner, and $\Delta H^{\ddagger}$ is frequently linearly related to $\Delta S^{\ddagger}$, by the so-called isokinetic relationship $\Delta H^{\ddagger} = \alpha + \beta\Delta S^{\ddagger}$, where α and β are constants. The existence of such a relationship is a much more significant criterion of similar mechanism than a comparison of activation enthalpies alone. Figure 6 shows that plots of $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ for the two *t*-butyl carbamates are linear, thus suggesting that the reaction mechanisms are similar in the different solvents. Schaleger and Long have pointed out (14) that $\Delta S^{\ddagger}$ values cannot be estimated to within more than ± 10.9 J mol^{-1} K^{-1} (2.6 cal mol^{-1} deg^{-1}) so that the deviations of the points from the lines in Fig. 6 probably represent no more than experimental error.

TABLE 7. Effect of solvent polarity (E_T)* on the decomposition of *t*-butyl and *t*-pentyl *N*-arylcarbamates

Aryl group	Temperature (K)	Slope of E_T *vs.* log k_{CO_2}	Slope of E_T *vs.* log k_{ene}

(The lines have been displaced vertically and horizontally for clarity.)

Substituent Effects

The effects of substituents on the tertiary carbon atom are also similar to that in acetate pyrolyses and are quite different from the effects of similar substituents in reactions involving carbonium ion mechanisms. Thus the ratio of rate constants for the decomposition of the carbamates $C_6H_5NHCO_2C(CH_3)_2R'$ at 463 K in diphenyl ether is 1.0:1.6:7.4 when R′ is CH_3,

C_2H_5, $CH{=}CH_2$ respectively. These may be compared to the relative rates of 1.0:1.5 (510 K), 2.5 (584 K) : 4.1 (570 K) for gas-phase pyrolysis of the corresponding acetates (17, 15, 10).

In contrast, the relative rates 0.72:1.0:7.4 found for the decompositions of the carbamates when R′ varies in the order $C{\equiv}CH$, CH_3, $CH{=}CH_2$ are very different from those of 2.5×10^{-2}:1.0: 2.5×10^3 estimated by Streitwieser (18) from published data for the solvolysis in 80% aqueous alcohol at 278 K of R′C-$(CH_3)_2Cl$ when R′ is also $C{\equiv}CH$, CH_3, $CH{=}CH_2$. These solvolysis reactions are known to take place via a carbonium ion mechanism, and are clearly much more influenced by β-carbon substituents than the thermal decompositions of *N*-phenylcarbamates or acetates. Furthermore, solvolysis of tertiary halides also leads to some elimination, and those *t*-carbinyl groups capable of eliminating to more than one olefin invariably yield the most substituted olefin (*i.e.* the Saytzeff product) in greatest quantities (19). Thus elimination from *t*-pentyl bromide in 80% ethanol yields 82% 2-methyl-2-butene and 18% 2-methyl-1-butene (20). Thermal decomposition of *t*-pentyl *N*-arylcarbamates, on the other hand, gives rise to an approximately 3:1 (*i.e.* statistical) ratio of 2-methyl-1-butene to 2-methyl-2-butene, in analogy with the pyrolysis of *t*-pentyl acetates (15).

The yield of 2-methyl-2-butene relative to the yield of 2-methyl-1-butene increases slightly with the electron-withdrawing power of the ring substituents, and with the polarity of the solvent. This can be accounted for if a small amount of charge separation in the transition state is assisted by the electronegative substituents and the more polar solvents, producing greater carbonium ion character. In ethylene glycol the large proportion of 2-methyl-2-butene from *t*-pentyl carbamates indicates that a mechanism involving a charged transition state is important, possibly in addition to the cyclic mechanism, in view of the non-linearity of the Arrhenius plot.

The small activating effects of electron-withdrawing substituents in the benzene ring found previously (1) for decomposition of *t*-butyl carbamates, in diphenyl ether, are also apparent in the decompositions of the *t*-pentyl carbamates, and indicate that the nitrogen atom is not directly involved in the cyclic transition state. The ρ values for the solvents dodecane, diphenyl ether, and nitrobenzene are approximately the same and compare well with a value of 0.54 found for the *t*-butyl series in diphenyl ether (Table 5). The value for the decompositions in acetophenone is slightly higher (0.68).

The reason for the low values for k_{ene}/k_{CO_2} in a few systems is not at all clear, since the measurement of the peak heights of the gases effectively measures the concentration of reactant at a given time. Only detailed product analysis will provide the necessary information to ascertain what additional reaction is occurring in these systems.

Some of the research work was done at Memorial University, St. John's, Newfoundland. One of us (M.P.T.) wishes to thank the Chemistry Department of that University for its generous hospitality and assistance for three months in 1970, and Professor J. M. W. Scott for valuable discussions.

Fortran Plotter routines were compiled by Dr. P. Borrell of this Department. We are indebted to him for his assistance and advice in their use.

Studies of the Metal–Sulfur Bond. Complexes of the Pyridine Thiols

B. P. KENNEDY AND A. B. P. LEVER

Department of Chemistry, York University, Downsview, Toronto, Ontario

Received May 8, 1972

Complexes of 2-pyridine thiol, 4-pyridine thiol, and 2-methyl-6-pyridine thiol, and some of their oxygen analogs with cobalt(II), nickel(II), zinc(II), cadmium(II), mercury(II), platinum(II), bismuth(III), and tin(IV) are characterized. On the basis of vibrational (conventional and far infrared) and electronic spectroscopy, magnetism, conductivity, and X-ray powder diffraction, the structures of these complexes are identified. In the thiol complexes, the bonding occurs, in all cases, through the sulfur, rather than the nitrogen atom. Bonding through oxygen is confirmed for the hydroxypyridine analogs. Tetrahedral MS_4^{2+} chromophores are identified for M = Co(II), Zn(II), and Cd(II), whilst square MS_4^{2+} chromophores occur with M = Ni(II) and Pt(II). The complexes exhibit sulfur-to-metal charge transfer spectra from which the optical electronegativities of the thiol ligands are shown to be near 2.4. Spectroscopic parameters for the complexes are derived and compared, together with their oxygen analogs, against phosphorus and arsenic sulfides and oxides.

Les complexes avec le pyridine-2 thiol, pyridine-4 thiol et méthyl-2 pyridine-6 thiol et quelques uns de leurs analogues oxygénés avec le cobalt(II), nickel(II), zinc(II), cadmium(II), mercure(II), platine(II), bismuth(III), et étain(IV), ont été caractérisés. Sur des bases de spectroscopic vibrationnelle (conventionnelle et infrarouge lointain) et électronique, magnétisme, conductivité et diffraction des rayons X sur les poudres; les structures de ces complexes ont été identifiées. Dans les complexes avec le thiol, la liaison se fait dans tous les cas, par l'intermédiaire du soufre plutôt que par l'atome d'azote. La liaison par l'intermédiaire de l'oxygène a été confirmée sur les analogues hydroxypyridine. Les chromophores tétraédriques MS_4^{2+} ont été identifiés pour M = Co(II), Zn(II), et Cd(II) tandis que les chromophores carrés MS_4^{2+} se font pour M = Ni(II) et Pt(II). Ces complexes donnent des spectres de transfert de charge du soufre au métal, à partir desquels les électronégativités optiques des ligands thiol ont été trouvées voisines de 2.4. Les valeurs spectroscopiques pour ces complexes ont été déduites et comparées ensembles avec leurs analogues oxygénés, avec les sulfures et oxydes de phosphore et d'arsenic. [Traduit par le journal]

There has been considerable interest in ambidentate ligands, *i.e.* ligands with more than one mode of coordination, because of the light the behavior of such molecules throws on the nature of the metal–ligand bond. In particular ligands which may, in principle, coordinate through either nitrogen or sulfur have been of especial concern (1–16). The complexity of the ligands has in some cases precluded unambiguous definition of the identity of the ligating atoms, whilst in other cases it is difficult to judge whether the coordination behavior derives from steric or electronic phenomena. Furthermore the current interest in metal–sulfur chromophores in biological molecules requires a detailed study of simple metal–sulfur systems which have not been adequately investigated in the past. For these reasons we have studied the complexation behavior of a series of closely related pyridine thiols and compared the results against data for the corresponding hydroxy derivatives. Complexes of 2- and 4-pyridine thiol and 2-methyl-6-pyridine thiol with cobalt(II), nickel(II), zinc(II), cadmium(II), mercury(II), platinum(II), tin(IV), and bismuth(III) are reported. A number of complexes of 2- and 4-hydroxypyridine are also included.

Experimental

2- and 4-pyridine thiol were purchased from Aldrich and used without further purification. Their oxygen analogs were also obtained from Aldrich as brown powders, and were each recrystallized twice from benzene (yielding colorless crystals) before use. 2-Pyridine thiol was also prepared from 2-bromopyridine (which, in turn, was made (17) from 2-aminopyridine) by the method of Thirtle (18). 2-Methyl-6-pyridine thiol was prepared from 2-amino-6-methylpyridine by a similar route (19) (m.p. = 154–6°, lit. (19) m.p. = 152–4°). The abbreviations Py2SH, Py4SH, and 2MePy6SH will be used for 2-pyridine thiol, 4-pyridine thiol, and 2-methyl-6-pyridine thiol, respectively. Similar abbreviations, using O rather than S, will be used for the corresponding hydroxy derivatives.

Co Complexes

CoX_2L_2 (X = Cl, Br; L = Py2SH, 2MePy6SH, Py4SH)

Stoichiometric quantities of $CoX_2.6H_2O$ (0.0025 mol) and L (0.005 mol) were dissolved in EtOH and the solutions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixed. A green precipitate formed immediately. It was filtered and washed with ethanol and then diethyl ether.

$CoI_2(Py2SH)_2$

This complex was prepared as above, except that CoI_2 was formed *in situ* by the double decomposition of $CoCl_2.6H_2O$ and NaI in alcohol. The precipitated NaCl was filtered and the solution of CoI_2 was used as in the preparation of CoX_2L_2.

$Co(Py2SH)_4(NO_3)_2$

Py2SH (0.01 mol) in ethanol was slowly added to an ethanolic solution of $Co(NO_3)_2.6H_2O$ (0.0025 mol), giving green, needle-like crystals. The complex was filtered and washed with ethanol and diethyl ether.

CoL_4X_2 ($L = Py2SH, Py4SH$; $X = ClO_4$)

$Co(ClO_4)_2.6H_2O$ (0.0025 mol) was dissolved in *n*-BuOH/EtOH (5:1) (~30 ml), and added to L (0.01 mol) in *n*-BuOH (~30 ml) under a N_2 atmosphere. The solution, which immediately turned green, was stirred for several hours; the green solid was filtered and washed with copious amounts of diethyl ether.

$Co(2MePy6SH)_4(BF_4)_2$

This was prepared as were the CoL_4X_2 compounds, but $Co(BF_4)_2$ was prepared *in situ* by the action of HBF_4 on $CoCO_3$.

$Co(Py2OH)_6.CoX_4$ ($X = Cl, Br$)

Ethanolic solutions of $CoX_2.6H_2O$ and Py2OH were mixed (the stoichiometric ratio being 1:3). The bromide complex started to precipitate about 10 min (at room temperature). The chloride complex came down after storing in a freezer for several days. Both complexes are blue.

$CoX_2(Py4OH)_2$ ($X = Cl, Br$)

These blue complexes were prepared in the same manner as their thio-analogs. The chloride has been reported previously (22).

Most of the above complexes (CoX_2L_2, $CoI_2(Py2SH)_2$, $CoX_2(Py4OH)_2$) were recrystallized with ethanol by soxhlet extraction. All complexes were dried under vacuum, over P_2O_5 and at 80° (excepting the perchlorates, which were dried at room temperature).

Ni Complexes

$NiCl_2(Py2SH)_2$

A green precipitate resulted immediately upon admixture of ethanolic solutions of $NiCl_2.6H_2O$ (0.0025 mol) and Py2SH (0.005 mol). It was filtered off, washed with ethanol and ether, and dried. Attempts at recrystallization gave intractable mixtures of green and yellow forms. Sometimes a yellow compound, rather than a green one, was obtained, with the formulation $NiCl_2L_x$($x = 1.2$–1.5) (based on Ni analysis). This "compound" could also be formed on heating $NiCl_2(Py2SH)_2$ in *n*-butanol.

$NiBr_2(Py2SH)_2$

$NiBr_2$ (anhydrous) (0.005 mol) was dissolved in ethanol (with a few drops of H_2O) added to an ethanolic solution of Py2SH (0.01 mol) and left in the freezer overnight. A negligible amount of fine yellow precipitate came down, and was filtered off. The filtrate was slowly evaporated on a steam bath, giving dark green crystals. As with the chloride analog, attempts at recrystallization gave only a flocculent yellow precipitate.

$NiI_2(Py2SH)_4$

NiI_2 (0.0025 mol) was prepared by metathesis between $NiCl_2$ and NaI. An ethanolic solution was treated with Py2SH (0.01 mol) and left in the freezer overnight; this yielded a thin dark film on the sides of the flask. The solution was filtered and the filtrate left in the freezer another week, giving well formed, very dark green crystals of $NiI_2(Py2SH)_4$.

$Ni(NO_3)_2(Py2SH)_4$

$Ni(NO_3)_2.6H_2O$ (0.0025 mol) and Py2SH (0.0010 mol) were each dissolved in ethanol, and mixed. The resultant green solution was placed in a freezer overnight. The well formed, dark green crystals were filtered, washed with alcohol and ether, and dried.

Zn Complexes

Zinc complexes were prepared by mixing ethanolic solutions of the appropriate Zn salt and the ligand. The resulting precipitate was recrystallized from ethanol by soxhlet extraction. (The oxo-ligand complexes were more soluble than their S counterparts, and required evaporation to a small volume and cooling in a freezer). The zinc halides required addition of the appropriate hydrohalic acid to prevent partial hydrolysis.

$Zn(NO_3)_2L_4$ ($L = Py2SH, Py4SH$)

An ethanolic solution of $Zn(NO_3)_2.4H_2O$ (0.0025 mol) was slowly added to a stirred ethanolic solution of L (0.01 mol). The complex precipitated slowly as the $Zn(NO_3)_2$ was being added.

Other Complexes

$CdX_2(Py2SH)_2$ and $HgX_2(Py2SH)_2$ ($X = Cl, Br$), and *$Cd(NO_3)_2.(Py2SH)_4$*

These were prepared in a similar fashion to the zinc complexes; they could not be recrystallized.

$Hg(Py2S)_2$

This compound could be prepared in two ways:

(*a*) Na^+Py2S^- was prepared in ethanol by addition of NaOEt to the ligand, and this solution was added to $HgCl_2$ (in ethanol). The white precipitate was recrystallized by soxhlet extraction with methanol, giving needle-like crystals.

(*b*) The same white precipitate could also be prepared by reaction of Py2SH with $Hg(OAc)_2$ in ethanol.

HgX_2L ($L = 2MePy6SH, Py4SH, Py2OH$, $X = Cl, Br$)

These were prepared in a similar fashion to the other mercury complexes.

$PtCl_2(Py2SH)_4$

$PtCl_2$ (0.0025 mol) and Py2SH (~0.0125 mol) were mixed intimately and fused together at 130° for 3 h. The resultant mixture was soxhlet extracted with methanol, giving the yellow compound.

$SnCl_4(Py2SH)_2$

On mixing ethanolic solutions of $Sn(II)Cl_2.4H_2O$ and Py2SH, a yellow-orange gum formed; probably due to aerial oxidation of the Sn(II) to Sn(IV). The gum was soxhlet extracted with chloroform to give a yellow-orange complex.

$BiCl_3(Py2SH)_2$

On mixing $Bi(III)Cl_3$ and Py2SH solutions in ethanol a yellow-orange gum formed. It was soxhlet extracted with ethanol, giving an orange solid.

Physical Measurements

Infrared spectra were obtained from Nujol mulls on a Beckman IR-12 instrument. NaCl, KBr, and polythene plates were used in the regions 4000–1000 cm^{-1}, 1000–400 cm^{-1}, and 400–190 cm^{-1}, respectively.

Electronic spectra were obtained with a Cary 14 spectrometer, from Nujol mulls in the infrared and visible regions. The higher energy region spectra (600–200 nm) were obtained from mulls in Dow-Corning fluid 200 (viscosity = 2.5×10^6 cstokes). The scattering of light was reduced considerably by crushing the compound very finely using a "Wig-L-Bug" (Crescent Dental Mfg. Co., Chicago, Ill., U.S.A.). As a check, the spectrum of naphthalene was recorded in ethanol and as the solid. They were very similar, the solution spectrum having the vibrational bands smeared out.

Conductance measurements were carried out on a Wayne–Kerr Universal Bridge, Model B221A.

Magnetic measurements (room temperature and variable temperature data) were obtained with a fully automatic Faraday balance (21).

X-Ray powder photographs were obtained on a Philips "Norelco" X-ray generator using nickel filtered copper radiation and a Debye–Scherrer type powder camera.

Analyses

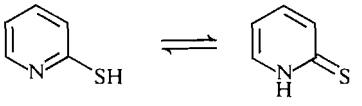
(*a*) C, H analyses were carried out by A. B. Gygli (Toronto), Galbraith (Knoxville, Tenn., U.S.A.) and Chemalytics (Tempe, Ariz., U.S.A.).

(*b*) Metals were analyzed by standard techniques (24) after destruction of the complexes with aqua regia. Some mercury determinations were carried out using a Jarrel-Ash "Dial-Atom" atomic absorption spectrophotometer.

(*c*) Halide analyses were carried out by potentiometric titration with $AgNO_3$, after destruction of the complexes by sodium fusion. The data are presented in Table 1.

Results

2- and 4-pyridine thiols, and their oxygen analogs, exist in two tautomeric forms, I and II (using 2-pyridine thiol as an example) with the thione form (II) being dominant in solution (23–25). Metal ions may be expected to coordinate through the nitrogen atom of form I (or less likely II) or through the sulfur atom of form (II) (less likely I). In the case of the four-substituted species, polymerization by bonding through both nitrogen and sulfur may occur. The possibility of the 2-substituted derivatives being involved in chelation with the generation of a four-membered ring must also be considered. Despite the simplicity and ready availability of the pyridine thiols, apart from some studies of $Ru(Py2S)_2(PPh_3)_2$ (26, 27), little definitive complexation information has appeared on these ligands.



I II

Cobalt(II) Complexes

Cobalt(II) salts react readily with the pyridine thiols in ethanolic media to yield complexes of the formula CoL_2X_2 where X is a halogen and CoL_4X_2 where X is ClO_4^-, BF_4^-, or NO_3^-. The magnetic and electronic spectroscopic data (Table 2) for these complexes leave little doubt that they are all tetrahedral. They exhibit fairly intense structured bands in the visible and near infrared regions typical of tetrahedral or pseudo-tetrahedral cobalt(II) (28) and have magnetic moments in the region 4.3–4.95 B.M. almost independent of temperature (29). The perchlorate and tetrafluoroborate complexes are readily soluble in acetonitrile, yielding solutions whose conductances (Table 3) indicate that they are 1:2 electrolytes, in agreement with the supposition that they contain CoL_4^{2+} cations. The CoL_2X_2 species, on the other hand, are essentially insoluble in common solvents with the exception of the lower alcohols, in which they are extensively solvolyzed. Consideration of the infrared spectra arising from the perchlorate and tetrafluoroborate groups implies that they retain their T_d symmetry and are therefore uncoordinated in the solid state (30–32). The far infrared spectra, considered in detail below, reveal bands in the CoL_2X_2 complexes assignable to νCo—X stretching modes (X = Cl, Br, and I) in the regions anticipated for tetrahedral molecules (33).

In contradistinction to the above, 2-hydroxypyridine reacts with cobalt perchlorate and tetrafluoroborate to yield octahedral complexes containing $Co(Py2OH)_6^{2+}$ cations (34). Attempts to prepare halogen complexes corresponding to the thiol derivatives discussed above led to complexes of empirical formula CoL_3X_2 whose magnetic and spectroscopic data, after comparison of their electronic spectra and magnetism (Table 2) with those of the CoX_4^{2-} ions (35) and the CoL_6^{2+} cations (34), leave little doubt of their formulation as $CoL_6^{2+}.CoX_4^{2-}$. As expected they are 1:1 electrolytes in nitromethane (Table 3). It has previously been reported (20) that 4-hydroxypyridine yielded the neutral chloride species $Co(Py4OH)_2Cl_2$ thereby paralleling the

thiol derivatives in behavior. This was confirmed and the corresponding bromide, $Co(Py4OH)_2Br_2$ also prepared. The electronic spectra and magnetism of these complexes are reported in Table 2; they are evidently tetrahedral. We note that our sample of $Co(Py4OH)_2Cl_2$ differs both in its magnetism and electronic spectra from that reported by Wasson *et al.* (20). Possibly two isomers exist; however, repreparation of the complex using the method reported (20) yielded a complex with the same properties as reported in Table 2.

Nickel(II) Complexes

Reaction of 2-pyridine thiol with nickel halides in alcohol yielded the dark green derivatives $Ni(Py2SH)_2X_2$, X = Cl, Br, and $Ni(Py2SH)_4I_2$. Nickel nitrate forms the dark green $Ni(Py2SH)_4(NO_3)_2$. Attempts to recrystallize these complexes led to mixtures of

*Standard ranges are (ref. 67): in CH_3CN: 1:1 electrolyte, ~140 Mho mol^{-1} cm^{-2}; 1:2 electrolyte, very wide range, 145–336 Mho mol^{-1} cm^{-2}. In CH_3NO_2: 1:1 electrolyte, ~100 Mho mol^{-1} cm^{-2}. In MeOH: 1:1 electrolyte, 90–100 Mho mol^{-1} cm^{-2}; 1:2 electrolyte, ~190 (range 160–220) Mho mol^{-1} cm^{-2}.
†Further solvolysis may be occurring in these cases.

yellow and green products from which neither pure yellow nor green products could be isolated. The bromo and chloro derivatives are paramagnetic and have electronic spectra (Table 4) typical of octahedral nickel(II) (28). They are evidently polymeric in nature. The presence of bands near or above 200 cm^{-1} in their far infrared spectra (see detailed discussion below) assignable to Ni—X stretching vibrations suggests that polymerization is through the sulfur ligand rather than the halides. Bridging halides give rise to Ni—X stretching vibrations well below 200 cm^{-1} (36). The complexes containing four pyridine thiol groups are diamagnetic and have a band in their visible absorption spectrum near 16 700 cm^{-1}, (almost independent of counter ion), characteristic of square planar nickel(II) (28). The nitrate complex exhibits a single band at 1735 cm^{-1} typical of complexes containing ionic nitrate groups (37). There seems little doubt that these complexes contain the NiL_4^{2+} cation.

The observation of an additional band (at 9340 cm^{-1}) in the spectrum of $Ni(Py2SH)_4I_2$ dissolved in pyridine, suggests that the complex becomes octahedral in this solvent (Table 4). With the remaining thiol ligands, difficulties arose in obtaining pure products with nickel salts. Mixed products were often obtained, samples analyzing with non-integral ligand-to-nickel ratios. With 2-hydroxypyridine, nickel perchlorate and tetrafluoroborate yield (34) salts of the $Ni(Py2OH)_6^{2+}$ cation.

Group IIB Complexes

All the thiols and hydroxypyridine derivatives investigated yielded zinc halide complexes of the type ZnL_2X_2 (X = Cl, Br). The hydroxypyridine derivatives exhibit bands readily attributable to Zn—X stretching vibrations within the regions expected for tetrahedral zinc (*vide infra*) suggesting that these complexes are indeed simple monomeric tetrahedral species. The zinc chloride thiol complexes all exhibit a band near 275 cm^{-1}, which is near the lower limit for zinc chloride stretching frequencies in tetrahedral zinc complexes (33).

The complex $Zn(Py2SH)_2Br_2$ exhibits a Zn—Br stretching vibration at 254 cm^{-1}, well within the appropriate range, suggesting that this complex is tetrahedral. The infrared spectra of the nitrate complexes infer the presence of ionic nitrate groups (37) and therefore the existence of tetrahedral ZnL_4^{2+} cations. Similarly CdL_4^{2+} cations occur in the isomorphic cadmium complex.

The cadmium complexes $CdX_2(Py2SH)_2$ (X = Cl, Br) appear to be tetrahedral; the chloride complex exhibits a band at 248 cm^{-1} assignable to νCd—Cl in a tetrahedral complex. In octahedral complexes the νCd—Cl frequency lies below 200 cm^{-1} (38, 39). A band at 221 cm^{-1} is tentatively assigned to the νCd—Br vibration in the tetrahedral bromide derivative, albeit it is somewhat high.

Mercury forms complexes of the type $Hg(Py2SH)_2X_2$ (X = Cl, Br) and $Hg(Py2S)_2$ with 2-pyridine thiol. The chloride and bromide complex differ in that whilst the bromide has a band at 217 cm^{-1} which may be associated with a Hg—Br stretching vibration in a mercury(II) complex (38, 39), no band which may be associated with a Hg—Cl stretching vibration is observed above 200 cm^{-1}. It is likely therefore that the chloride complex contains linear $Hg(Py2SH)_2$ units with long Hg—Cl

*Relative intensities on a given film are indicated by w = weak, m = medium, s = strong, v = very. The cobalt compounds fluoresce in the X-ray beam, thereby obscuring the weaker lines. Data for $ZnCl_2(Py2OH)_2$, $ZnCl_2(Py4SH)_2$, $ZnCl_2(Py4OH)_2$, $HgCl_2(Py2SH)_2$, and $HgBr_2(Py2SH)_2$ were also obtained (available from the authors upon request). No further isomorphism was noted.

contacts, whilst the bromide complex has a distorted octahedral structure probably similar to that exhibited by $Hg(Py)_2Cl_2$ (40). The Hg—Br vibrational frequency is at a somewhat lower energy than would be expected (39) for a tetrahedral complex. The inner complex $Hg(Py2S)_2$ is probably linear but the data thereon are not definitive in this respect.

The complexes $Hg(2MePy6SH)X_2$ (X = Cl, Br) have stoichiometries suggestive of a binuclear tetrahedral structure. The presence of two bands in the chloride complex near 300 cm^{-1}, but only one in the case of the bromide, implies an Hg—Cl terminal stretching vibration above 300 cm^{-1} consistent with this formulation. The chloride complex also has a band at 198 cm^{-1} which can be assigned to a bridging Hg—Cl stretching vibration (39). A binuclear formulation quite common with mercury halide derivatives (39, 41–45) seems highly probable. It seems likely that the corresponding $HgLX_2$ complexes with 4-pyridine thiol and 2-hydroxypyridine also have such a binuclear tetrahedral formulation.

Platinum chloride forms a complex with 2-pyridine thiol of formula $PtCl_2L_4$. This complex is unusual in that most sulfur ligands form complexes of stoichiometry $PtCl_2L_2$ with platinum chloride (46). The complex is diamagnetic and has no electronic absorption below 20 000 cm^{-1}. No absorption attributable to Pt—Cl vibrations are observed in the 300 cm^{-1} region (47) and therefore the complex is believed to contain the PtL_4^{2+}, presumably square planar, cation. The conductance data in methanol, though somewhat low (Table 3), are indicative of a 1:2 electrolyte. Thioacetamide forms a complex of similar stoichiometry (16*b*).

Bismuth trichloride reacts with 2-pyridine thiol to form orange $BiCl_3L_2$ of uncertain stereochemistry. Similarly stannic chloride forms $SnCl_4L_2$. A strong band in the far infrared spectrum of this latter complex at 295 cm^{-1}, identifiable as a Sn—Cl stretching vibration suggests a *trans* octahedral structure for this complex.

X-Ray Powder Data

Table 5 lists the *d* spacings obtained from X-ray powder photographs of some of the complexes. Comparison of the data for the series $M(NO_3)_2(Py2SH)_4$ M = Co, Zn, and Cd, suggests that all are isomorphous. The correlation between the cobalt and zinc complexes is good, but in the case of cadmium there are minor discrepancies which probably arise from the larger size of the cadmium atom. Similarly the series $MCl_2(Py2SH)_2$, M = Co, Zn, and Cd are evidently isomorphous, as are $MBr_2(Py2SH)_2$, M = Co and Zn. Comparison of the data across these series suggests that the chloro and bromo complexes of cobalt, zinc, and cadmium, of formula MX_2L_2 are all isostructural. The mercury derivatives were not found to be isomorphous with analogous cadmium derivatives. No isomorphism was noted between thiol derivatives and the corresponding hydroxypyridine derivative.

Discussion

Infrared Spectra (4000–400 cm^{-1})

Infrared spectra, in the above region, provide little informative data. Bands which may be attributed to the "thioamide I, II, III, and IV" vibrations (48, 49) do not shift in any significant fashion. In simple pyridine metal complexes a shift in the ring breathing mode is used as a guide to metal coordination (11, 50, 51). In the case of 2-pyridine thiol the band at 984 cm^{-1} tentatively assigned (52) to the ring breathing mode increases in energy by some 10–17 cm^{-1} in the various complexes. Similar increases are noted for the 977 and 989 cm^{-1} bands of 2-methyl-6-pyridine thiol and 4-pyridine thiol, respectively. Whilst these data are certainly indicative of coordination by the thiols, they do not provide information concerning the mode of coordination. Extensive coupling within the ring system, as indicated, for example, by a ^{18}O study of 2-hydroxy-pyridine (53), precludes the identification of any band definitively assigned to a C=S stretching vibration, and therefore precludes use of this vibration as a guide to metal sulfur bonding. Whilst bands have been assigned to such a vibration (25, 52), in the light of the previous argument, and the fact that the shifts in this band are small (less than 18 cm^{-1} in the complexes studied), such data cannot be used as a guide to mode of coordination.

The N—H stretching frequency in the metal complexes tends to lie at a higher energy than in the free ligand solid state spectrum (10, 34, 54, 55), but at a lower energy than the ligand

solution spectrum (10, 25). The low frequency in the free ligand spectra undoubtedly arises through extensive hydrogen bonding (55, 56) which is broken upon dissolution in a solvent. It has been suggested (10) that the comparatively sharp N—H band spectrum of some thiazolidine thione metal complexes indicated absence of hydrogen bonding, and therefore that comparison of these energies with the *solution* N—H frequency of the ligand could be used as a guide to M—N coordination. In the complexes studied here there is little difference in bandwidth between the solid state spectra of the ligands (where hydrogen bonding is undoubtedly present) and of the complexes. Thus the N—H stretching vibrations cannot be used as a guide to mode of coordination. Further proof that the perchlorate and tetrafluoroborate complexes contain uncoordinated anions is furnished by their near infrared spectra. The perchlorate complexes show no resolution of the bands near 1100 and 620 cm^{-1} which would be expected were coordination to occur (57). Similarly in the tetrafluoroborate the 1080 cm^{-1} band is unsplit, and no absorption is observed near 360 cm^{-1} (32). The nitrate complexes did not exhibit any splitting of the NO_3 ($\nu_1 + \nu_4$) combination band, indicative of uncoordinated nitrate (37).

The far infrared spectra (below 400 cm^{-1}), whilst they may substantiate a particular mode of bonding which has been deduced by other methods are not in themselves diagnostic. We therefore defer discussion of this region until after the electronic spectra, which are frequently definitive, have been discussed.

Electronic Spectra

Cobalt(II) complexes: analysis of the electronic spectra of the tetrahedral cobalt(II) derivatives described above leads to an unequivocal determination of the mode of bonding. Such analysis leads to values of Dq and B (28) which are reported for the CoL_2X_2 complexes in Table 7 and for the CoL_4^{2+} cations in Table 8. Data are also collected in Table 8 concerning the Dq and B values previously determined for model CoS_4 and CoN_4 tetrahedral chromophores. As may be seen the Dq and B ranges for the CoS_4 chromophores lie within 316–425 and 600–664 cm^{-1}, respectively, while the corresponding ranges for the CoN_4 chromophores are 467–538 and 700–757 cm^{-1}, respectively. From the data in Table 8 it is seen unequivocally that the thiol CoL_4^{2+} cations, described above, fall into the CoS_4 chromophore class. Using the "law of average environment" (28), the Dq and B values for the CoL_2X_2 derivatives may be calculated by taking averages of the Dq and B values of the appropriate CoL_4^{2+} and CoX_4^{2-} ions; Table 7 shows the more than satisfactory agreement between the observed and calculated data confirming, thereby, that the CoL_2X_2 series also contain cobalt–sulfur bonds.

The isomorphism of $ZnCl_2(Py2SH)_2$, $ZnBr_2(Py2SH)_2$, and $Zn(NO_3)_2(Py2SH)_4$ with their cobalt analogs is proof of sulfur bonding (rather than nitrogen) in the zinc derivatives. Furthermore, $CdCl_2(Py2SH)_2$ and $Cd(NO_3)_2(Py2SH)_4$ are also isomorphous with their zinc and cobalt analogs, confirming sulfur bonding in these compounds also. Whilst these com-

plexes are not isomorphous with the corresponding mercury derivatives, there seems little doubt, in view of the remarkable affinity mercury(II) has for sulfur, that the mercury complexes are also bonded through sulfur.

Comparison of the electronic spectra of the thiol derivatives with those of octahedral and square planar nickel(II) complexes involving Ni—S bonds (Table 9) also leave little doubt that the thiol complexes are sulfur bonded. Significantly higher band energies would be expected (28) if the bonding were through nitrogen. The far infrared spectrum (*vide infra*) support the contention that bonding is through sulfur in the platinum derivative, but the data are not definitive in the case of the bismuth and tin compounds. The presence of a low energy band near 20 000 cm^{-1} in the bismuth com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pound is suggestive of sulfur coordination. Bismuth(III) thiol derivatives are highly colored, red or orange, (58, 59), whilst bismuth(III) amine complexes are colorless. The charge transfer spectrum of the tin complex (*vide infra*) seems definitive of tin–sulfur bonding. Thus all the complexes discussed here involve metal–sulfur rather than metal–nitrogen coordination by the thiol ligands. Reedijk (34) had proposed that bonding was through oxygen rather than nitrogen in the hydroxy derivatives and the additional work presented here lends further support to such a conclusion.

Far Infrared Spectra (400–190 cm^{-1})

The basic procedures for analyzing far infrared spectra, by comparison of ligand and complex spectra, and by varying the counterion, have been adequately discussed in the past (60). Because of the inevitable coupling processes which occur, few if any bands in an infrared spectrum can be regarded as arising from a "pure" vibration. The title "metal–halogen" or "metal–sulfur" vibration used below should be taken to infer that a particular absorption band arises primarily, but not necessarily totally, from such a normal coordinate.

Table 6 lists the far infrared spectra of the ligands and the various complexes. 2- and 4-pyridine thiol each have a single strong band just above 300 cm^{-1} but, with the exception of a weak band near 390 cm^{-1} in the 2-thiol, are otherwise transparent in the region studied. 2-Methyl-6-pyridine thiol, on the other hand, has at least four bands in the pertinent region rendering assignment of the bands in its metal complexes rather difficult.

All the 2-pyridine thiol derivatives have a band, of varying intensity, between 380–390 cm^{-1} which corresponds to the weak band in this region in the free ligand spectrum. In addition one or two bands are found, generally between 340 and 370 cm^{-1}, which probably correspond to the 332 cm^{-1} absorption. The relatively high energy of these bands, and their lack of sensitivity towards change, either of halogen or of metal would seem to preclude their assignment as metal–ligand vibrations. In the tetrahedral cobalt(II), zinc(II), and cadmium(II) complexes of 2-pyridine thiol, the metal–halogen vibration is generally recognizable as a consequence of its sensitivity to change in halogen. The band positions are generally within the ranges expected for such tetrahedral derivatives (33, 47), though in the case of the chloro cobalt and zinc complexes they are observed to be near the lower limits of these ranges. By exclusion, bands near 230 cm^{-1} in the cobalt(II) and zinc(II) complexes, and near 200 cm^{-1} in the cadmium(II) complexes are probably metal–ligand, *i.e.* M—S in origin. Thiourea and thioacetamide complexes exhibit Co—S and Zn—S vibrations in this region (18). Cobalt–sulfur stretching vibrations have frequently been observed above 300 cm^{-1} (8, 9, 61) but the varying electronic demands of sulfur in differing bonding environments (*e.g.* thiol, thioether, thiocarbonyl, thioester, phosphine, or arsine sulfide, etc.) suggest that the metal–sulfur force constant and hence frequency, may vary considerably.

In the octahedral nickel complexes halogen sensitive bands are observed at 262 cm^{-1} for the chloride and at 198 cm^{-1} for the bromide. The band positions and their relative energies are consistent with their assignment as Ni—X stretching vibrations in an octahedral nickel complex (33, 47, 51). In particular the energies reflect the presence of terminal nickel-halogen bonds, rather than bridging bonds (36). Since these complexes are octahedral and necessarily polymeric, it follows that the bridging must be through the thiol ligand, *i.e.* through sulfur. Indeed since bridging through nitrogen would be impossible, these data provide further evidence of sulfur coordination. The possibility of mixed halogen and sulfur bridging cannot, however, be eliminated. A band at 239 cm^{-1} in both complexes may be associated with the Ni—S stretching vibration. In support of the above assignments it is pertinent that the square planar nickel complexes are transparent between 200 and 300 cm^{-1}. Additional bands observed between 300 and 400 cm^{-1} in these diamagnetic derivatives are probably associated with the νNi—S vibrations which should absorb at higher energies than in the octahedral complexes.

Comparison of the data for the 4-pyridine thiol complexes leads to the ready identification in most cases of the metal halogen stretching bands. Bands near 230 cm^{-1} in the cobalt and

zinc complexes are again assignable as metal–sulfur vibrations. The assignments in the case of the mercury complexes are tentative; they can only be rationalized in terms of a much weaker mercury–chlorine interaction than mercury–bromine as discussed above. Data for the 2-methyl-6-pyridine thiol are presented in Table 6 but are too complicated for unequivocal assignment. The 2-hydroxypyridine data reported in Table 6 are also somewhat complex.

High Energy Absorption and Optical Electronegativities

Whilst the thiols exhibit absorption above 30 000 cm^{-1} as a consequence of internal π–π^* transitions, many of the complexes exhibit absorption between 22 000 and 30 000 cm^{-1} which cannot, since they are observed in the non-transition metal complexes, be associated with crystal field transitions (Table 10). The 2-pyridine thiol complexes generally exhibit a band, usually a shoulder, near 29 000 cm^{-1} which can be associated with a weak ligand absorption (seen in solution but not in the solid state) and an additional moderately intense absorption band at lower energy. These lower energy bands (which are absent in the hydroxypyridine complexes), fall in the sequence

$$Hg(II) \geq Cd(II) \geq Zn(II) > Sn(IV) > Ni(II) \geq Co(II) > Pt(II) > Bi(III)$$

for analogous complexes (where possible). The energies are dependent upon the nature of the other coordinated ligand, but there appears to be no systematic dependence.

There is some doubt that n–π^* transitions are seen in these thiols (62) and in any event such transitions would be expected to shift up in energy, probably beyond 30 000 cm^{-1} upon coordination of the sulfur to a metal. It is therefore probable that these bands are charge transfer in origin. The sequence above does not readily indicate whether the transition is of the metal-to-ligand, or ligand-to-metal variety; the inference is that the transfer is of the metal-to-

ligand variety since the highest energy bands occur with those metals which are most difficult to oxidize (28). However, it will be shown that this is not the case. These data represent a rare example of the breakdown of the simple procedure to identify the direction of the electron transfer (28). The electron transfer process is in fact from sulfur to metal and the unusual sequence above arises because of the range of different energies of the acceptor orbitals on the metal.

The procedure for analysis of data in terms of the optical electronegativities of the metal and ligand (62, 63), has been adequately described (28, 62). It may be assumed that in the cases of mercury, cadmium, zinc, and tin, electron transfer occurs from the completed d shell, or into the empty s orbital. In the case of bismuth it is from the 6s level or into the 6p level, whilst for cobalt, platinum, and nickel the transitions will occur from or to, the d shell. Table 11 presents data which have been calculated on the basis, (*a*) that the process is metal to ligand, and (*b*) that it is ligand to metal. In the first instance data were calculated for mercury, tin, nickel, and cobalt since optical electronegativity data are available for these species. Note that the optical electronegativities are defined with respect to the spherical one-electron energy of the unsplit d orbitals (64) and not with respect to the t_{2g} subshell (62, 63) in those cases where transitions involving the d shell are concerned. We deal first with the 2-pyridine thiol complexes. On the assumption that the transition is from metal to ligand, the ligand optical electronegativities fall within the range 0.58 to 0.85 with considerable scatter. With the alternate assumption that the transition is from ligand to metal, the ligand optical electronegativities fall within the narrow range 2.35 to 2.50 with an average of 2.43. Since the data form a consistent set with the second assumption rather than the first, it is concluded that these charge transfer bands do arise through a ligand(sulfur)-to-metal transition. Using the average value of the ligand optical electronegativity, it is possible to calculate values for the optical electronegativities of the metals for which such data have not been available in the past. Thus Table 11 reports values of 1.5 for the optical electronegativities of zinc and cadmium in tetrahedral environments, and 1.7 for bismuth(III). Similar sets of consistent data are also obtained with 2-methyl-6-pyridine thiol and 4-pyridine thiol derivatives (Table 11). The 4-pyridine thiol seems to have a slightly smaller electronegativity than the α-thiols, but the difference is marginal.

The sulfide ion itself is believed (63) to have an optical electronegativity near 2.4, whilst species such as the dialkyldithiophosphates and thioethers have somewhat higher electronegativities (near 2.7 and 2.9 respectively (63)). Since amines containing only one lone pair are expected (63) to have electronegativities exceeding 3.0 these data provide further convincing evidence of the proposal that bonding is through sulfur rather than nitrogen in these derivatives. The possibility of observing sulfur-to-metal transitions in a pyridine thiol in which the nitrogen atom is coordinated to the metal is not zero, but the transition probability for such an electron jump would be quite small; it is not reasonable to ascribe the strong bands seen in these derivatives to such a transition, in an *N*-bonded complex. Finally we note that the

*Calculated from data in ref. 61.
†Assumed.

data suggest that the availability of electron density on the sulfur atom is comparable to that of the free S^{2-} ion and certainly more than that on the thiophosphates and thioethers.

Summary and Conclusions

The identity of the donor atom in these complexes has been defined unequivocally for virtually every complex discussed here, and in all cases bonding appears to be through sulfur rather than nitrogen. There is no positive evidence that in any of the complexes discussed here, the 2-pyridine thiol behaves as a bidentate ligand, as its anionic form does towards ruthenium(II) (26, 27). Such bidentate coordination may possibly occur in $Hg(PyS)_2$ and weak interaction with the nitrogen atom may be responsible for the somewhat low metal chloride stretching frequencies in the "tetrahedral" zinc and cobalt chloro derivatives.

A comparison of the crystal field and nephelauxetic effects of the pyridine thiols and hydroxy pyridines *vs.* arsenic and phosphorus oxides and sulfides is instructive. Table 12 compares the Dq and β (B(complex)/B(free ion)) values for a series of cobalt(II) tetrahedral complexes, of these various oxygen and sulfur donors.

It is noteworthy that the Dq and B values for the pyridine thiol cobalt halides are essentially independent of the thiol used. This is itself strong evidence of sulfur rather than nitrogen bonding. Had nitrogen bonding occurred we would have been dealing with a sterically unhindered ligand (Py4SH), a sterically hindered ligand (Py2SH), and a sterically highly hindered ligand (2-Me-Py6SH); in such circumstances the Dq values and the B values should have changed markedly with ligand (65). If the bonding is through sulfur, however, the steric requirements of the three ligands are essentially the same.

As far as the oxygen ligands are concerned, there is very little difference between the data for the hydroxy-pyridines and for the arsenic and phosphorus oxides. Apparently the electronic characteristics of the donor oxygen atom are little affected by the nature of the rest of the ligand. However, whilst the arsenic and phosphorus oxides yielded CoL_4^{2+} cations, only CoL_6^{2+} species may be obtained with the 2-hydroxy pyridines. In view of the fairly high electronegativity of the oxygen ligands, and the fact that tetrahedral cobalt(II) compounds tend to be covalent, a coordination number of six is probably the norm with oxygen ligands (66). The coordination number of four with the arsenic and phosphorus ligands can then be explained in terms of the bulkiness of these ligands. With sulfur, on the other hand, the much lower electronegativity, and greater polarizability, will indeed favor four coordinate tetrahedral complexes.

In the phosphorus and arsenic complexes of formula CoL_2X_2 the Dq for the oxygen complexes is greater than for the corresponding sulfur complexes as would be anticipated on the basis of the spectrochemical series. In the CoL_4^{2+} complexes of these ligands, however, there is little difference in Dq. The values of the oxide CoL_4^{2+} complexes are clearly too low. If this is a genuine phenomenon (and not an artifact of the method of calculation which may arise because of the multiplicity of the bands concerned), it may reflect the "dislike" of cobalt(II) to form tetrahedral CoO_4^{2+} complexes.

In contradistinction to the oxygen series, the pyridine thiol CoL_2X_2 complexes have markedly higher mean Dq values than the phosphorus or arsenic sulfides. In the CoL_4^{2+} series the Dq values are comparable. The lower Dq values in the P=S and As=S systems may reflect increased contribution of sulfur-to-metal bonding arising as a consequence of the softness of the atom (P or As) to which the sulfur is attached. In the thiols, or more correctly, thione compounds, the higher electronegativity of the carbon atom to which the sulfur is attached, and the electron sink character of the pyridine ring, will decrease the capability of the sulfur atom to donate electron density. Notwithstanding this effect, the optical electronegativity data suggest that the availability of electron density in these derivatives exceeds that in, for example, the thioethers and dithiophosphates. Table 13 shows previously unpublished ultraviolet data for some Me_3PS and Me_3AsS complexes originally characterized by Rodley and co-workers (61). These data reveal an optical electronegativity of 2.6–2.7 for these ligands, somewhat higher than for the thiols. Possibly these data are indicative of appreciable P=S and As=S interaction thereby decreasing the availability of the lone pair to the metal atom. Unfortunately the conclusions which may be drawn from consideration of the crystal field and optical electronegativity data for the arsenic and phosphorus sulfides seem mutually contradictory.

We are indebted to the National Research Council of Canada for financial support, and to Dr. G. A. Rodley for the supply of arsenic and phosphine sulfides.

A Positive-Ion Reaction Mechanism for the Radiation Induced Oxidation of Carbon Monoxide in the High Dose Rate Radiolysis of $CO-O_2$ Mixtures [1]

C. WILLIS,[2] A. W. BOYD, AND P. E. BINDNER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received February 17, 1972

Carbon dioxide and ozone yields have been measured in the irradiation of $CO-O_2$ mixtures with single pulses of electrons. The yields of CO_2 at 2×10^{27} eV g^{-1} s^{-1} are large $G(CO_2) = 15 \pm 1$ from 20–60% O_2. These decrease by ~50% at 10^{28} eV g^{-1} s^{-1}. Although the results are somewhat irreproducible the addition of c-C_4F_8, an electron scavenger, increases these CO_2 yields at both dose rates by up to a factor of 15. They are reduced to $G(CO_2) < 2$ by the addition of positive ion scavengers. These results are consistent with a chain reaction similar to that proposed for low dose rate studies involving O_2^+, CO_3^+, and CO_2^+ as chain carriers.

The ozone yields are consistent with a total oxygen atom yield of $G(O) = 1.4$ in pure CO from neutral processes.

Nous avons mesuré les rendements en dioxyde de carbone et en ozone obtenus par irradiation de mélanges $CO-O_2$ par pulsation simple d'électrons. A partir de 20–60% de O_2, les rendements en CO_2 sont élevés, soit $G(CO_2) = 15 \pm 1$ à 2×10^{27} eV g^{-1} s^{-1}. Ils diminuent de près de 50% à 10^{28} eV g^{-1} s^{-1}. Quoique les résultats soient assez peu reproductibles, l'addition de c-C_4F_8, un piège à électrons, augmente les rendements en CO_2 aux deux vitesses de dose par un facteur de 15. Les pièges à électrons positifs réduisent ces rendements à $G(CO_2) < 2$. Les résultats concordent avec l'hypothèse d'une réaction en chaîne semblable à celle proposée pour les études à faible vitesse de dose, impliquant O_2^+, CO_3^+, et CO_2^+ comme porteurs de chaînes.

Les rendements en ozone sont consistants avec le rendement total d'un atome d'oxygène, $G(O) = 1.4$ en CO pur à partir de procédés neutres. [Traduit par le journal]

Introduction

In a series of papers (1–7), we have proposed mechanisms and primary yields for radiolysis of CO_2, O_2, CO, and CO_2-O_2 mixtures. These have been based on product yield measurements in these systems at the high dose rates (10^{26}–10^{28} eV g^{-1} s^{-1}) obtainable with Febetron pulses. We have now looked at the high dose rate radiolysis of $CO-O_2$ mixtures.

Low dose rate studies of the $CO-O_2$ system have been reported by Lind and Bardwell (9), by Clay, Johnson, and Warman (8) and by Anderson, Best, and Willet (10). All agree that the yield of CO_2 in these systems is very high. The most detailed study is that of Clay, Johnson, and Warman who studied the γ-radiation induced oxidation of CO from 1–98% O_2 and investigated the effect of dose rate, pressure, and the presence of additives. Yields of CO_2 were highest at 50% O_2 where at 60 Torr pressure $G(CO_2) \simeq 8000$. They observed some effect of pressure but none of dose rate in the range 2×10^{14}–5×10^{15} eV g^{-1} s^{-1}. The reaction scheme they postulated is as follows:

Initiation	$CO^+ + O_2 \rightarrow CO_3^+$
	O_2^+ ($^4\pi_u$ state or higher) + $CO \rightarrow CO_3^+$
Propagation	$CO_3^+ + CO \rightarrow CO_2^+$ ($^2\pi_u$?) + CO_2
	CO_2^+ ($^2\pi_u$?) + $O_2 \rightarrow O_2^+$ ($^4\pi_u$) + CO_2
Termination	$CO_3^+ + CO + M \rightarrow CO_2^+ + CO_2 + M$

They concluded, because of the lack of effect of dose rate, that termination could not be due to charge neutralization but must be due to formation of an unexcited CO_2^+ ion thus precluding the formation of an excited O_2^+ ion which was the chain carrier in their mechanism.

Anderson, Best, and Willet (10) studying the system at higher dose rates, ~10^{23} eV g^{-1} s^{-1}, did observe an effect of dose rate indicating charge neutralization termination of the chain.

The mechanism proposed by Clay, Johnson, and Warman (8), although in agreement with their observations is not unique and is difficult to further substantiate by low dose rate studies. However, work at high dose rates could yield more information and it was for this purpose that the present study was undertaken.

Experimental

Irradiations

Two pulsed electron accelerators were used in this work, a Febetron 705[3] and a Febetron 706[3]. The 2 MeV Febetron 705 has an effective dose rate for gaseous samples of 2×10^{27} eV g^{-1} s^{-1}. The 600 keV Febetron 706 has a higher dose rate of 1×10^{28} eV g^{-1} s^{-1}.

Two types of irradiation cells were used for the determination of the CO_2 yields: cells of quartz (11) and cells of aluminum (12), both of similar dimensions. In early experiments discharges were observed from the quartz cells after they had been irradiated and it was thought that these might contribute to an "after-effect" yield in the CO–O_2 mixtures. However, the results from the aluminum cells which were well grounded during irradiation were identical to those obtained using the quartz cells, except, perhaps, for the elimination of the odd, very high yield.

The dose absorbed in these cells was determined by irradiating pure N_2O taking $G(N_2) = 12.4 \pm 0.3$ (12–14) for these dose rates.

Ozone yields were determined in a stainless steel cell containing a conventional optical system (15). The dosimetry for these measurements was achieved by irradiation of pure oxygen taking $G(O_3) = 12.8 \pm 0.5$ (5, 6, 16, 17).

Materials

NH_3, c-C_4F_8 (perfluorocyclobutane), SF_6, N_2O, and O_2, Matheson (C.P. Grade) and C_3H_6 and C_3H_8 Phillips (Research Grade) were taken directly from the cylinder. Except for O_2, the gases were subjected to freeze–pump–thaw cycles to remove impurities non-condensible at 77 °K.

The CO used was Matheson (Research Grade). This was further purified by passing through a furnace containing copper turnings at 700 °C. This pyrolyzed traces of carbonyl and also catalyzed combination of traces of O_2 with CO. The gas was then passed through a freshly conditioned column of Linde 13X molecular sieve and finally through a 1 mm i.d. spiral 2 m long immersed in liquid nitrogen. We have previously used a similar purification procedure for CO and obtained satisfactory results (4).

Analyses

CO_2

For CO_2 determinations the irradiated gas (100 ml volume) was expanded into twin cold traps (1.2 l volume) at liquid nitrogen temperatures and left for 5 min. The non-condensed gas was slowly pumped off via a U-tube immersed in liquid nitrogen. The material condensed in the traps and the U-tube was then distilled into the inlet port valve of a Loenco 15C gas chromatograph equipped with a Porapak Q column at 60 °C and thermal conductivity detectors. The scrubbing procedure used here was shown to quantitatively remove carbon dioxide by using synthetic mixtures of CO_2–CO with concentrations similar to those expected in irradiated samples.

O_3

Ozone was determined directly in the optical cell by its absorption at 254.5 nm (18). We have described this procedure previously (2, 7, 19).

[3]Manufactured by Field Emission Corporation, McMinnville, Oregon, USA.

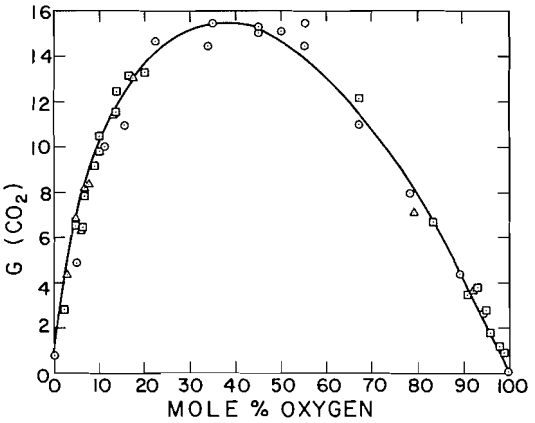

FIG. 1. CO_2 yields from single pulse irradiations of CO–O_2 mixtures at 2×10^{27} eV g^{-1} s^{-1}: ○, 450 Torr Al cell; □, 450 Torr quartz cell; △, 650 Torr quartz cell.

N_2

Nitrogen produced in the dosimetry experiments was analyzed using standard vacuum line techniques and a CEC 610 mass spectrometer.[4]

Results

CO_2 Yields

The yields of carbon dioxide from single pulse irradiations of CO–O_2 mixtures are shown in Fig. 1. As O_2 is added to CO the yield of CO_2 increases to $G(CO_2) \simeq 15 \pm 1$ between 25–55% O_2. Further increases in the O_2 concentration cause the CO_2 yield to decrease.

There is no effect of pressure for the range shown. At 1×10^{28} eV g^{-1} s^{-1} the yields were not as reproducible. In the range 25–55% O_2 they were between 6 and 9. Mixtures of 50% O_2–50% CO were irradiated at various temperatures between 373 and 77 °K. Basically identical results were obtained. There did appear to be a slight decrease in yield going from 273 to 198 °K but this was of the order of the experimental errors.

Effect of Dose

Figure 2 shows the CO_2 yield as a function of the dose for a 50% O_2–50% CO mixture. As can be seen, the yield remains constant up to at least 9×10^{20} eV g^{-1} (9 pulses).

Effect of Positive Ion Scavengers

Figure 3 shows the effect on the CO_2 yield of adding NH_3, C_3H_6, and C_3H_8 to a 45%

[4]Manufactured by Dupont Instrumental Products Division, Monrovia, California, USA.

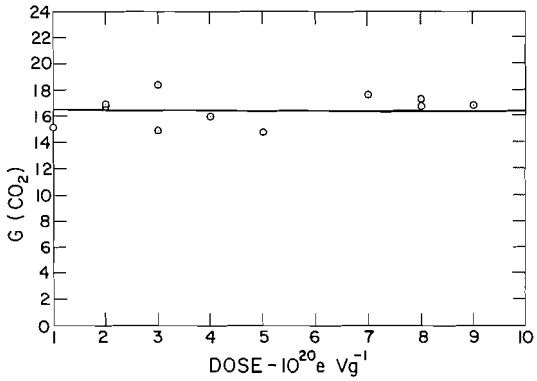

FIG. 2. $G(CO_2)$ as a function of dose at 2×10^{27} eV g^{-1} s^{-1}; 450 Torr pressure, 50%–50% CO–O_2.

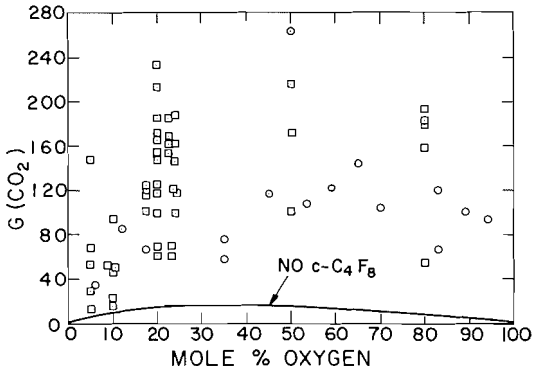

FIG. 4. Effect of c-C_4F_8 addition to CO–O_2 at 2×10^{27}–10^{28} eV g^{-1} s^{-1}: 450 Torr pressure; ○, Al cell; □, quartz cell.

O_2–55% CO mixture. NH_3 and C_3H_6 have virtually identical effects and reduce the CO_2 yield to close to zero above 5% additive. The effect of C_3H_8 is qualitatively the same but its efficiency is an order of magnitude less than that of C_3H_6 or NH_3.

In the CO–O_2–C_3H_6 and CO–O_2–C_3H_8 mixtures some CO_2 is produced from the hydrocarbon. Blank mixtures of O_2–C_3H_8 and O_2–C_3H_6 were irradiated for the experiments. Only for yields of $G(CO_2) < 1$ did the contribution from the hydrocarbon become significant.

Effect of c-C_4F_8

We could not use SF_6 as an electron scavenger where CO_2 was to be determined as we could not separate it from the CO_2 peak on the chromatographic column used. Consequently, we used c-C_4F_8 which can be separated more easily from the CO_2. We have used c-C_4F_8 in oxygen systems previously (6) and found its effect indistinguishable from that of SF_6.

The effect on the radiolytic yields of CO_2 of adding 2–5% perfluorocyclobutane to CO–O_2 mixtures is shown in Fig. 4. The effect is quite dramatic although somewhat irreproducible. For the range 25–55% O_2, the CO_2 yields increase from $G(CO_2) = 15 \pm 1$ in the absence of c-C_4F_8, to $G(CO_2) = 60$–240 in the presence of 2–5% c-C_4F_8.

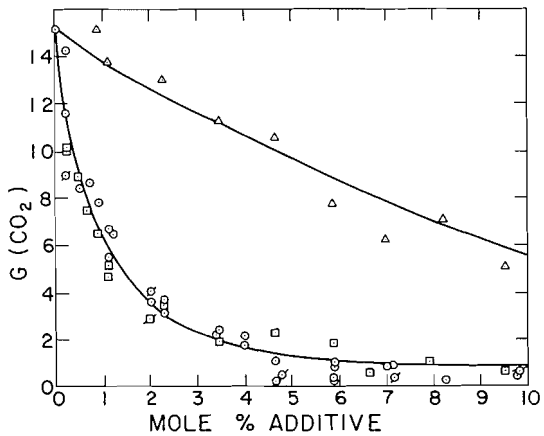

FIG. 3. Effect of adding NH_3, C_3H_6, C_3H_8 to 55% CO–45% O_2 at 2×10^{27}–10^{28} eV g^{-1} s^{-1}; 450 Torr pressure; □, C_3H_6; ○, NH_3; △, C_3H_8 in Al cell; ⊠, C_3H_6; ∅, NH_3 in quartz cell.

TABLE 1. Primary yields in CO and O_2 radiolysis

CO			O_2		
Species	Yield	Reference	Species	Yield	Reference
e	3.11	20	e	3.27	see ref. 6
CO^+	2.92		O_2^+	3.17	for
C^+	0.14	21	O^+	0.10	discussion
O^+	0.05				
$C_2O^3\Sigma$	1.40	3, 4			
O^3P	1.41	22, 23	O^3P	3.15	
O^1D	~0.0	23, 4	O^1D	2.75	7
O^1S			O^1S	0.30	

Experiments as a function of temperature for $CO-O_2-2\%$ c-C_4F_8 mixtures were difficult because of the irreproducibility of the system but it appeared that lowering the temperature in the range 273 to 198 °K significantly reduced the CO_2 yield although it should not have led to any condensation of the c-C_4F_8.

In a few isolated experiments, the effects of adding NH_3 and C_3H_6 to $CO-O_2$-c-C_4F_8 mixtures were investigated. The results were very irreproducible but a large decrease in yield was observed. Above ~3% of NH_3 or C_3H_6 the results were indistinguishable from those obtained with $CO-O_2$ mixtures with the same amount of these gases in the absence of c-C_4F_8.

O_3 Yields

The O_3 yields from $CO-O_2$ mixtures with and without SF_6 are shown in Fig. 5. In the presence of 2–5%SF_6, the O_3 yields show an almost linear dependence, decreasing from $G(O_3) = 6.2$ for 100% O_2 to an extrapolated yield of $G(O_3)_{ext} = 1.4 \pm 0.1$ for 100% CO.

The yields in the absence of SF_6 are higher and decrease from $G(O_3) = 12.8$ in 100% O_2 to an apparent intercept of $G(O_3) \sim 10$ for 100% CO. It should be noted that, in the absence of SF_6 the O_3 yield begins to diverge from linear dependence below ~45% O_2 whereas in the presence of SF_6, the yield does not begin to diverge until below ~12% O_2.

Discussion

To facilitate discussion, the primary yields of species in the radiolysis of pure CO and pure O_2 are given in Table 1.

In pure CO, oxygen atoms react to give CO_2 but in the presence of oxygen, ozone will be formed (24–29), reaction 1.

[1] $$O + O_2 (+CO, O_2) \rightarrow O_3 (+CO, O_2)$$

Thus ozone yields can be taken as a measure of the oxygen atom yield. Ozone yields from $CO-O_2$ mixtures with added SF_6, Fig. 5, then, are as would be expected.[5] They go from an extrapolated yield of $G(O_3)_{extrapolated} = 1.4 \pm 0.1$ for pure CO to $G(O_3) = 6.2$ for pure O_2. The extrapolated yield for pure CO agrees very well with earlier estimates of Briggs and Clay (22, 23). In the absence of SF_6 the ozone yields are higher, therefore oxygen atoms must be produced in the charge neutralization step.

Clearly, if oxygen atoms lead to ozone formation they cannot lead to formation of carbon dioxide. Thus charge transfer from CO^+ to O_2, [4], followed by

[4] $$CO^+ + O_2 \rightarrow CO + O_2^+$$

dissociative neutralization of O_2^+, [5],

[5] $$O_2^+ (+e) \rightarrow 2O$$

cannot explain the increase in CO_2 yield on adding O_2 to CO, Fig. 1. We must therefore suppose a mechanism not involving oxygen atoms to explain the CO_2 yield.

Consider now the effect of c-C_4F_8. The direct effect of adding this to $CO-O_2$ mixtures is to scavenge free electrons.

[6] $$e + \text{c-}C_4F_8 \rightarrow \text{c-}C_4F_8^-$$

[5] In the presence of SF_6, contributions from ion-neutralization processes are suppressed (see for example discussion in ref. 6).

[2] $$e + SF_6 \rightarrow SF_6^-$$

[3] Positive ion + $SF_6^- \rightarrow$ dissociation products.

This leads to the indirect effect of changing the neutralization step to involve c-$C_4F_8^-$ as the dominant negative species. Addition of c-C_4F_8 to CO–O_2 mixtures does not decrease the CO_2 yield but rather leads to a very significant increase in the yield, Fig. 4. This eliminates the possibility of a negative ion–molecule reaction for CO_2 production. The increase in yield, however, would be consistent with a positive ion–molecule chain reaction with chain termination by charge neutralization. Neutralization of positive ions by c-$C_4F_8^-$ may well be a much slower process than the equivalent reaction with an electron or O_2^- (30) which would allow a longer chain. The decrease in yield on going to a higher dose rate, from 2×10^{27} to 1×10^{28} eV g^{-1} s^{-1}, is consistent with this. Also, since the ionization potentials of NH_3, C_3H_6, and C_3H_8 are lower than those of CO and O_2, the marked reduction in CO_2 yield in the presence of these additives can be explained by positive charge transfer termination of the chain.

Thus we can propose a positive ion–molecule chain oxidation of CO to CO_2 with charge neutralization as chain termination, the neutralization process yielding oxygen atoms.

Initiation

[7] $$O_2 \rightsquigarrow O_2^+ + e$$

[8] $$CO \rightsquigarrow CO^+ + e$$

Propagation

[9] $$O_2^+ + O_2 + M \rightarrow O_4^+ + M$$

[10] $$O_4^+ + CO \rightarrow CO_3^+$$

[11] $$CO^+ + O_2 \rightarrow CO_3^+$$

[12] $$CO_3^+ + CO \rightarrow CO_2^+ + CO_2$$

[13] $$CO_2^+ + O_2 \rightarrow O_2^+ + CO_2$$

[14] $$e + O_2 + M \rightarrow O_2^- + M$$

Termination

[15] $$O_4^+ + e\ (\text{or } O_2^-) \rightarrow 2O\ (+O_2)$$

[16] $$CO_3^+ + e\ (\text{or } O_2^-) \rightarrow 2O + CO\ (+O_2)$$

The mechanism represented by these reactions, 7–16, is consistent with the observations. Reactions 7–13 are, of course, essentially those used by Clay, Johnson, and Warman (8), to explain the low dose rate oxidation of CO by O_2.

Reaction 9 is included because $k_9 = 2.9 \times 10^{-30}$ cm^6 $molecule^{-1}$ s^{-1} (31) and this means that neutralization of O_2^+ cannot compete with its attachment to O_2 ($\alpha_{O_2^+} = 2.2 \times 10^{-7}$ cm^3 s^{-1} (32)).

Reaction 15 is included for the sake of completeness. We are not in a position to eliminate CO_3^+ as a possible chain terminator, however, if reaction 15 does take place it must yield two oxygen atoms to come close to explaining the yield of ozone in the absence of SF_6, Fig. 5. However, the falloff in CO_2 yield ultimately requires a competition between reaction 10 and reaction 15 suggesting that O_2^+ (or O_4^+) is the more important chain terminator.

At low O_2 concentration, *i.e.* high CO concentrations, the decrease in CO_2 yield can be accounted for by formation of $C_2O_2^+$, reaction 17.

[17] $$CO^+ + CO \rightarrow C_2O_2^+$$

$$k_{17} = 1 \times 10^{-10}\ cm^3\ molecule^{-1}\ s^{-1} \quad (33)$$

Presumably $C_2O_2^+$ cannot react to give CO_3^+ and its formation will reduce the concentration of chain carriers. $C_2O_2^+$ will therefore be neutralized directly to give 2CO, reaction 18.

[18] $$C_2O_2^+ + e \rightarrow 2CO$$

As has been pointed out (34), reaction 18 is not unlikely as the ionization potentials of CO and C_2O_2 are not much higher than the bond dissociation energy of CO.[6] Formation of $C_2O_2^+$ will then explain the divergence of the ozone yields from a linear dependence below ~45% O_2 for CO–O_2 mixtures in the absence of SF_6, Fig. 5.

A check on the plausibility of this mechanism, *i.e.* reactions 1–18, has been made by computer calculations. Rate constants in the range $1–2 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} were assumed for reactions 9–12 and in the range $10^{-7}–10^{-6}$ cm^3 $molecule^{-1}$ s^{-1} for charge neutralization reactions (37–40) along with the primary ion yields in Table 1. These data and the absorbed dose and dose rate values were used with a computer program developed by Schmidt (41, 42). The use of this program in similar calculations has been described previously (43). The computed values

[6] I.P. CO^+ = 14.0 eV (35); I.P. $C_2O_2^+$ = 12.8 eV (36); D(C—O) = 11.1 eV (35).

of both $G(O_3)$ and $G(CO)$ in pure CO–O_2 mixtures agreed with the observed values within the experimental uncertainties. That is a smooth line joining the calculated CO_2 or O_3 yields fitted the experimental points as well as the lines shown in Figs. 1 and 5. Decreasing the rate constant for charge neutralization from 5×10^{-7} to 5×10^{-8} cm^3 molecule^{-1} s^{-1} (equivalent to c-C_4F_8 addition) resulted in an order of magnitude increase in the calculated yield of CO_2. Although the agreement between the calculated and experimental values supports the plausibility of the mechanism it can hardly be taken as proof as some of the rate constant values had to be assumed. A more detailed fit would not be worthwhile until rate constants are known for nearly all of the reactions.

Although it is difficult to assess the quantitative effect of NH_3, C_3H_6, and C_3H_8 as we do not know the charge transfer reaction involved one further comment is perhaps required. The rates of reactions 19 and 20.

[19] $$O_2^+ + NH_3 \rightarrow NH_3^+ + O_2$$

$$k_{19} = 2.6 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \quad (44)$$

[20] $$O_2^+ + C_3H_8 \rightarrow \text{products}$$

$$k_{20} = 1.8 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \quad (44)$$

would be expected to predict similar quantitative effects for NH_3 and C_3H_8. Clearly NH_3 is much more effective than C_3H_8, Fig. 3. This would suggest that O_2^+ (at least in its ground electronic state) is not the chain carrier. Whether the difference is due to the presence of O_4^+ rather than O_2^+ or whether the charge transfer involves other ions, may be in different electronic states, must await further kinetic data.

Conclusions

The mechanism we have derived is not significantly different to that proposed by Clay, Johnson, and Warman (8) but is based on more experimental observations. In their work (8), it was proposed that CO_3^+, CO_2^+, and O_2^+ were all in excited states. Since we clearly have chain termination by charge neutralization we can draw no firm conclusion on this point.

The major conclusions which can be made from the present work are that a positive chain oxidation of CO does occur, the primary O atom yield in pure CO is $G(\text{O atom}) = 1.4 \pm 0.1$ and that the rate of charge neutralization by c-$C_4F_8^-$ is about ten times slower than by O_2^-.

The Hydrate of Hexafluorophosphoric Acid[1]

D. W. Davidson and S. K. Garg

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received May 12, 1972

HPF_6 is said to form a hexahydrate of a unique clathrate structure in which PF_6^- ions occupy truncated-octahedral cages in a framework of hydrogen-bonded water molecules. N.m.r. studies show, however, that appreciable quantities of HF are incorporated in the lattice and that the composition is more properly $H_3O^+PF_6^-\cdot HF\cdot 4H_2O$, a result supported by chemical analysis. H_3O^+ and HF appear to be distributed over the lattice sites previously assigned to water molecules so as to involve all H atoms in the hydrogen bonding. The ^1H resonance line is narrowed by rapid proton diffusion down to 150 °K. The ^{19}F line of encaged PF_6^- is narrowed by rotation above 75 °K and reaches the rigid-lattice shape only below 25 °K.

HPF_6 est reconnu pour former une hexahydrate de structure clathrate unique dans laquelle les ions PF_6^- occupent des cages octaédriques tronquées dans une structure de molécules d'eau liées par des ponts hydrogène. Des études au RMN démontrent toutefois que des quantités appréciables de HF sont incorporées dans le réseau et que la composition serait plutôt $H_3O^+PF_6^-\cdot HF\cdot 4H_2O$, résultat supporté par analyse chimique. H_3O^+ et HF semblent distribués sur des sites du réseau attribués auparavant à des molécules d'eau, de façon à impliquer tous les atomes de H dans des ponts hydrogène. La raie de résonance ^1H est amincie par une diffusion rapide de proton au-dessus de 150 °K. La raie de ^{19}F du PF_6^- en cage est amincie par la rotation au-dessus de 75 °K et atteint la forme caractéristique du réseau rigide seulement au-dessous de 25 °K.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3515 (1972)

Hexafluorophosphoric acid appears not to be stable in isolated form (1), at least at ordinary temperatures. Commercial 65% HPF_6 is an equilibrium mixture which contains (2) about 21 wt.% H_2O, 6% HF, and 8% of the phosphoric acids HPO_2F_2, H_2PO_3F, and H_3PO_4. The PF_6^- ion itself is stable in various salts (1) and is not readily hydrolyzed in dilute solutions of the acid (3).

The solid (m.p. 31.5 °C) which crystallizes from relatively concentrated solutions is considered (4) to be a hexahydrate, apparently on the basis of determination of HPF_6 as the nitron salt. On exposure to the atmosphere at room temperature, hydrate crystals soon become liquid, reputedly because of their hygroscopic character (1). The X-ray study of the hydrate at room temperature by Bode and Teuffer (5) suggested a structure of a unique clathrate type in which each PF_6^- group occupies a truncated-octahedral cage (Fig. 1) composed of mutually hydrogen-bonded water molecules. The positions of the six F atoms were not accurately fixed, but were best represented as disordered over 48 equivalent sites within each cage (5). The position of the extra proton was not determined.

[1]NRCC No. 12786.

The truncated-octahedral structure is the only known 4-coordinated clathrate structure in which polyhedral cages of a single kind fit together to fill all the space in a 3-dimensional lattice (6). In the common clathrates of the gas hydrate type, cages of two different kinds are present (7, 8). All the water molecules of the ideal truncated-octahedral structure occupy crystallographically equivalent sites (symmetry $\bar{4}2m$) and the 24 water molecules at the vertices of the tetrakaidecahedron are equidistant from its center. These features are also unique among the known clathrate hydrates (8).

Experimental Methods

As part of a study of clathrate hydrates, we have examined the ^{19}F and ^{1}H n.m.r. derivative spectra of HPF_6 hydrate between 2 and 273 °K. Measurements were made at 17 MHz with a single coil probe which formed part of a marginal oscillator circuit. A low-power Robinson oscillator was used for a few measurements at the lowest temperatures. Other experimental details are given elsewhere (9).

Crystals of hydrate were prepared by adding sufficient water to 65% HPF_6 to bring the H_2O/HPF_6 mol ratio to about 6, cooling to nucleate hydrate formation, and storage at ~9 °C for several hours. The powdered crystals were then dried between filter paper, placed in sample tubes of polyethylene (for study of the ^{19}F resonance) and Teflon (for ^{1}H) and stored in liquid nitrogen until used. Subsequently, it was found that larger crops of crystals were obtained from samples containing less than six moles of water per mole of HPF_6.

Results and Discussion

^{1}H Magnetic Resonance

The second moments of the proton resonance lines are given in Fig. 2 and the line widths, as separations between the maximum and minimum points of the derivative curves, in Fig. 3.

Below the line-width transition centered near 135 °K the second moment has a constant value of 43 ± 2 G^2. This rigid-lattice second moment is too high to be consistent with the hexahydrate structure suggested by the X-ray study (5), a structure which cannot lead to a proton second moment much greater than that of ice Ih itself, *viz.* 32.4 ± 1.1 G^2 at 75 °K (10). Likewise, the line shape (Fig. 4) differs considerably from the shape found for the absorption by the water molecules of ice (10) and gas hydrates (9, 11). As was the case for gas hydrates of magnetic guest species (9, 11), no evidence was found at any temperature of saturation of the proton absorption signal by r.f. fields at the 5 mG level. This result is in marked contrast with the serious saturation observed (10) at low temperatures in various ice polymorphs.

Above 175 °K the second moment falls below 0.1 G^2 and the line shape becomes approximately Lorentzian. This behavior is clearly a result of rapid diffusion of the protons and differs from the behavior of ice Ih and of other clathrate hydrates where complete diffu-

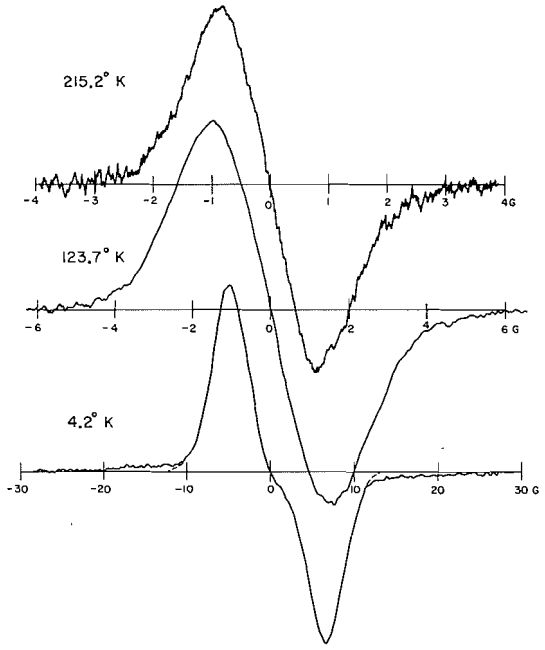

FIG. 5. Derivative line shapes of ^{19}F at three temperatures. The dashed line in the 4.2° spectrum indicates the truncation used to evaluate the second moment of the dominant narrow component.

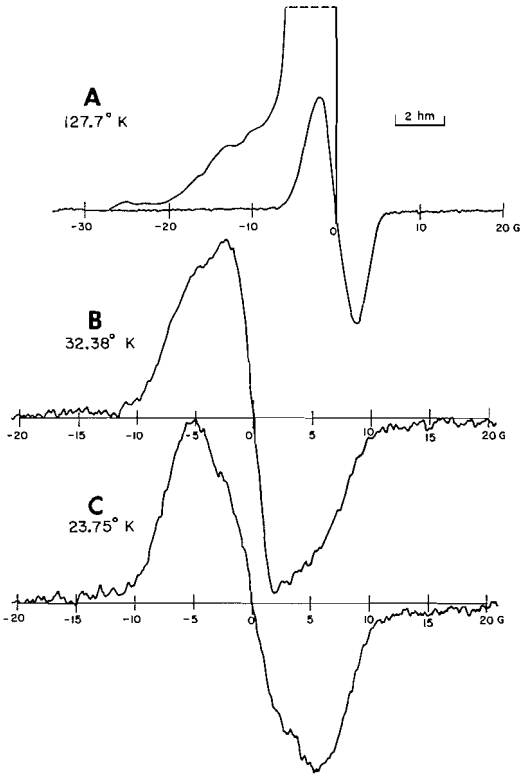

FIG. 6. ^{19}F derivative curves showing (*A*) the presence of the broad component in a half spectrum recorded at 100 times the sensitivity of the "normal" spectrum, and (*B* and *C*) the change of shape during the low-temperature line-width transition.

sional narrowing is only reached at or near the melting point. The acid protons of HPF_6 hydrate are thus very mobile and rapidly exchange with water protons.

^{19}F *Magnetic Resonance*

There are two regions of transition in the ^{19}F second moment (Fig. 2). The broad transition between 25 and 75 °K clearly marks the narrowing which results from increasingly rapid reorientation of the encaged PF_6^- ions. The second region of line narrowing coincides with the proton line-width transition and is probably again the result of proton diffusion. Line shapes in the three plateau temperature regions are shown in Fig. 5.

In the region of 170 to 250 °K the measured second moments lie between 0.7 and 0.8 G^2. These values are much too large to be attributed entirely to PF_6^- groups which are isotropically rotating but not diffusing in a water lattice in which the interactions with the protons are averaged out by proton diffusion. The sole contribution to the ^{19}F second moment in this case would be from inter-guest interactions, which, for the X-ray structure (5), is only 0.28 G^2.

Between 90 and 130 °K the observed second moment is 2.1 ± 0.1 G^2. This value agrees with the value of 2.09 G^2 calculated for isotropic reorientation of PF_6^- groups encaged in a lattice in which the protons are rigid. Under conditions of high sensitivity, however, the spectra (*e.g.* Fig. 6*A*) show additional absorption in the wings which has not been included in the evaluation of the second moment. Thus there is a broad, weak F band in addition to the relatively narrow line from rotating PF_6^- ions.

A similar broad component is also clearly present below 25 °K (see the 4.2 °K spectrum of Fig. 5), where the overlap with the now-broader PF_6^- component is more pronounced. ^{19}F spectra in this temperature region were obtained with the Robinson oscillator since measurements at the higher r.f. levels of the mar-

TABLE 1. Calculated second moments

Resonance	Conditions	Contributing species	Second moments (G^2)* $H_3O^+ \cdot PF_6^- \cdot 5H_2O$	Second moments (G^2)* $H_3O^+ \cdot PF_6^- \cdot HF \cdot 4H_2O$

		total		24.0
	Isotropic rotation of PF_6^-, diffusion of protons but not of F atoms	PF_6^-	0.28	0.49
		HF		2.02
		total		*0.71*

*Second moments in italics are to be compared with experimental values plotted in Fig. 2.

ginal oscillator showed small saturation effects. Second moments of about 15 G^2 were obtained for the narrow component by somewhat arbitrary truncation of the absorption (*cf.* Fig. 5). A value of 16.6 G^2 is calculated for PF_6^- ions (with $r_{P-F} = 1.58$ Å (12)) which are fixed in random orientations about the center of the cage in the rigid hydrate lattice.

The abrupt change in ^{19}F line width near 30 °K shown in Fig. 3 is a result of the change of line shape. As spectra *B* and *C* of Fig. 6 illustrate, the change of second moment with cooling through this transition region is the result of increasing absorption by the broader of two strongly overlapping components.

N.M.R. Evidence for the Presence of HF

The hexahydrate structure is therefore unable to account for (*a*) the large ^1H second moment and the line shape at low temperatures, (*b*) the large ^{19}F second moment above 170 °K, and (*c*) the presence of a very broad ^{19}F band at all temperatures below 130 °K. If it be assumed that the X-ray structure is correct in broad outline, these observations may be accounted for only by the presence of appreciable quantities of HF in the lattice.

Thus observation (*b*) above, which refers to temperatures at which the proton second moment is averaged almost to zero by diffusion, may be attributed to the presence in the lattice of HF molecules in which the F atoms are not rapidly diffusing. If each HF molecule present replaces a water molecule, with the F atom occupying a lattice site assigned to an O atom in the X-ray structure (5), the ^{19}F second moment is given by $[(0.28 + 1.25x) + x(1.40 + 3.7x)]/(1 + x)$, where x is the fraction of water molecules replaced by HF and the two terms are contributed by PF_6^- and HF, respectively. Solution for the observed second moment of 0.75 ± 0.05 G^2 yields the composition $HPF_6 \cdot (1.09 \pm 0.11)HF \cdot (4.91 \mp 0.11)H_2O$; that is, about one water molecule of every six present in the hexahydrate is replaced by HF.

To calculate second moments at lower temperatures we assume the composition $H_3O^+ \cdot PF_6^- \cdot HF \cdot 4H_2O$ and a random distribution of H_3O^+ and HF over the sites of the water molecules of the original unit cell (5). The calculation requires a knowledge of the HF bond length and H_3O^+ geometry in a 4-coordinated environment. For lack of a better value, we take the inter-proton distance in H_3O^+ to be 1.72 Å, the value found (13) in nitric acid monohydrate. The H—F distance may be roughly estimated from the line shape illustrated in Fig. 6*A*. The broad component is expected to have the shape characteristic of the strongly interacting pair of unlike nuclei in HF. In particular, the small peaks at the outermost edges (*e.g.* the one at −25 G in Fig. 6*A*) may be taken to approximately define the values of the field at $\pm 2\mu r^{-3}$ from the line center where the absorption of the ideal Pake doublet drops to zero for the polycrystalline case. Here μ is the proton magnetic

moment and r is the H—F bond length. A separation of 50 G gives $r_{H-F} = 1.04$ Å.

Table 1 gives the results of the calculations of the ^1H rigid lattice second moments and of ^{19}F second moments appropriate to the temperatures of the three plateaus in second moment. Values are also given for the original hexahydrate structure. The calculations make use of the methods described elsewhere (9) for the gas–hydrate type of clathrate, including assignments of the disordered positions of the water protons.

The structure in which HF is incorporated in the hydrogen-bonded lattice gives second moments which are in satisfactory agreement with those plotted in Fig. 2. Although no great accuracy can be claimed for the calculated values, a lattice stoichiometry of approximately $H_3O^+ \cdot HF \cdot 4H_2O$ is clearly indicated.

Chemical Analysis

Because of the similarity of the molecular weights of HF and H_2O, determination of HPF_6 as the nitron salt is insensitive to the presence of HF. Thus the observation (5) of 57.2 to 57.6 wt.% of HPF_6 in the hydrate is almost as consistent with the 57.0% of $HPF_6 \cdot HF \cdot 5H_2O$ as with the 57.5% of $HPF_6 \cdot 6H_2O$.

The acid content of the hydrate was determined by titration with phenolphthalein of dilute aqueous solutions of numerous samples of hydrate (including freshly-prepared samples as well as the samples which had been used for the n.m.r. studies) against $N/10$ NaOH and by back-titration against $N/10$ HCl of samples dissolved in cold excess KOH solution. The acid content was 2.13 ± 0.04 and 1.07 ± 0.02 times, respectively, as great as given by $HPF_6 \cdot 6H_2O$ and $HPF_6 \cdot HF \cdot 5H_2O$. Shapes of potentiometric titration curves with NaOH solution were almost identical with those given by equimolar mixtures of HF and HCl, that is, of HF and a strong monobasic acid.

The small but consistent excess acidity over that represented by the stoichiometry $HPF_6 \cdot HF \cdot 5H_2O$ is possibly the result of adsorption of HF by the crystals. Another possible explanation is given below.

Structural Considerations

The stoichiometry $HPF_6 \cdot HF \cdot 5H_2O$ has the structural advantage that each of the species present in the lattice H_2O, H_3O^+, and HF, can participate fully in a four-coordinated scheme of hydrogen bonding, the number of hydrogen bonds being equal to the number of hydrogen atoms. In $HPF_6 \cdot 6H_2O$, however, the H^+ contributed by HPF_6 does not fit into a fully hydrogen-bonded lattice. In the actual hydrate, the HF molecules are probably statistically distributed over all the sites previously assigned (5) to water molecules so as to preserve the original X-ray symmetry.

It is possible to account for the excess acidity noted in the last section by the incorporation into the structure during crystallization of acid "impurities" from the solution. This may be done by allowing, for example, a fraction x of the cages to be occupied by PO_3F^{2-} to give the composition $(1-x)HPF_6 \cdot xH_2PO_3F \cdot (1+x)HF \cdot (5-x)H_2O$, where the HF content is increased sufficiently to maintain full hydrogen bonding. A value of $x \simeq 0.06$ gives formal agreement with the analyses.

The n.m.r. evidence of rapid reorientation of the PF_6^- ion to temperatures below 75 °K is not readily compatible with the presence, at room temperature, of the preferred orientations suggested (5) by the X-ray results. Likewise, the estimation (5) of a P—F bond length of 1.73 Å, based on location of the sites of the F atoms, is unlikely. The magnitude of the PF_6^- contribution to the rigid lattice ^{19}F second moment is much more consistent with the bond length of 1.58 Å found (12) in KPF_6 and supported in a general way by n.m.r. studies (14) of the alkali hexafluorophosphates. If 1.40 Å is allowed for the van der Waals radius of a water molecule, the free diameter of the truncated-octahedral cage is 5.78 Å. A value of 5.86 Å for the van der Waals diameter of PF_6^- is given by $r_{P-F} = 1.58$ Å. This value is more compatible with the cage size than the value of 6.16 Å given by $r_{P-F} = 1.73$ Å.

In the clathrate hydrate of SF_6, a molecule of size and shape very similar to PF_6^- ($r_{S-F} = 1.58$ Å), the ^{19}F resonance line broadens only below 12 °K (15). Here, however, the 16-hedral cage has the relatively large mean free diameter of 6.56 Å.

We are indebted to V. G. Meadors of the Ozark-Mahoning Company, Tulsa, Oklahoma, for helpful correspondence and to A. Desaulniers of the Analytical Chemistry Section of NRCC for chemical analyses.

Infrared Spectra and Structures of Solid CH_4 and CD_4 in Phases I and II

C. CHAPADOS[1] AND A. CABANA

Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec

Received May 4, 1972

This paper reports the results of extensive infrared absorption measurements of CH_4, CD_4, and mixed isotopic crystals containing CH_4, CD_4, CHD_3, and CH_3D at low concentration in matrices of light and heavy methane in crystalline phases I and II. The interpretation of the spectra, based upon the Halford–Hornig approach, provides information on the crystal structures. The spectra indicate that the two solid phases of CH_4 are similar to the two higher temperature phases of CD_4. In phase I, there is apparently considerable motion: either the molecules undergo large angular oscillations or even rotational diffusion. In phase II, there exist two types of sites for the molecules: some molecules undergo quantized rotation similar to that found in noble gas matrices while others order with a local symmetry that is probably slightly distorted from T_d ($\bar{4}$ 3m) to D_{2d} ($\bar{4}$ 2m). Acceptable factor groups are then limited to T_d and O_h, but the former is unlikely for it could yield the f.c.c. lattice found by diffraction experiments only by a particular choice of the parameters, whereas the latter leads to the f.c.c. space group O_h^6 (Fm 3c).

On a enregistré un grand nombre de spectres d'absorption de CH_4, CD_4 et de cristaux constitués de mélanges isotopiques contenant CH_4, CD_4, CHD_3, et CH_3D à basse concentration dans des matrices de méthane et de deutérométhane en phases cristallines I et II. L'interprétation des spectres, basée sur l'approche Halford–Hornig, procure des renseignements sur la structure cristalline. Les spectres indiquent que les deux phases solides du CH_4 sont semblables aux deux phases de plus haute température du CD_4. En phase I il existe apparemment une grande liberté de mouvement: les molécules subissent soit des oscillations angulaires de grande amplitude, soit une diffusion rotationnelle. En phase II, il existe deux types de site pour les molécules: certaines subissent une rotation quantique empêchée semblable à celle qui fut trouvée dans les matrices des gaz nobles, tandis que d'autres sont ordonnées avec une symétrie locale D_{2d} ($\bar{4}$ 2m), bien que la distorsion de T_d ($\bar{4}$ 3m) soit très faible. Seuls les deux groupes facteurs T_d et O_h demeurent acceptables mais le premier est considéré peu probable puisqu'il ne peut correspondre à la structure du cube à faces centrées déterminée par des expériences de diffraction que par un choix particulier des paramètres. Le groupe facteur O_h conduit au groupe d'espace O_h^6 (Fm 3c) lequel correspond à un réseau cube à faces centrées.

Introduction

Crystalline CH_4 and CD_4 have been extensively studied both experimentally and theoretically. The main references, up to 1969, are collected in the introduction of a paper by Colwell (1). In spite of much effort directed toward the determination of the crystal structures and of the molecular energy levels in the different solid phases of the methanes our understanding of the subject has remained far from satisfactory. Heat capacity measurements (1–3) have shown that there were λ-type anomalies around 27 and 22 °K for CD_4 and one around 20 °K for CH_4. In addition there is, for CH_4, a second anomaly around 8 °K but the existence of a second λ transition for CH_4 at normal pressure has been questioned (4, 5). Measurements of nuclear magnetism (6, 7) have indicated that conversion among the three spin species occurs at low temperature in the crystal. X-Ray diffraction experiments on polycrystalline material (8) have shown that the carbon atoms lie on a face centered cubic lattice in the two phases of CH_4 and in the three phases of CD_4. Coherent neutron diffraction from a single crystal of CD_4 (9) in phase I indicates the space group O_h^5 (Fm 3m) with four molecules occupying randomly sites of C_{3v} (3m) symmetry such that the point symmetry is O_h ($m3m$) on average. After considering two possible structures for CD_4 in phase II, Press (9) selects the space group O_h^6 (Fm 3c) with eight molecules per primitive cell, of which two are orientationally disordered and six are ordered with local symmetry D_{2d} ($\bar{4}$ 2m).

Several investigations of the vibrational spectra of neat CH_4 and CD_4 crystals have been reported in the literature (10–16) with mixed isotopic crystals of these two molecules being

studied by i.r. absorption only (12, 17). The i.r. (18–20) and Raman (21) spectra of both molecules in noble gas matrices have also been extensively studied.

Unfortunately the information about the crystal structures derived from different experimental techniques is sometimes inconsistent. In the course of our experiments on the i.r. spectra of crystals, we have found that microcrystals obtained from a gaseous spray on a cold target often yield irreproducible spectra. Since this particular technique had been used in some of the previous i.r. studies it seemed worthwhile to reinvestigate the i.r. absorption of the neat crystals, especially in the light of recent theoretical models for the structure of these solids (22–25). New considerations in the analysis of the spectra of mixed isotopic solutions containing partially deuterated species (17, 26, 27) have shown that such spectra provide a new way to specify the site symmetry in the solids. Thus, such results were obtained and are analyzed in the present paper in an attempt to explain the discrepancies between the structures derived from spectral and other measurements.

Experimental

The CH_4 (stated purity 99.99%) used in our experiments was obtained from Matheson of Canada, Ltd., and used without purification. The CD_4, CHD_3, CH_2D_2, and CH_3D purchased at Merck, Sharp, and Dohme of Canada, Ltd., were analyzed by mass spectroscopy and found to contain a few % of isotopic impurities. In the present study, CD_4 was studied as a neat crystal; therefore special efforts were made to obtain a sample isotopically and chemically pure. A sample of CD_4 purified by gas chromatography was kindly given to us by Morrison. The composition of the methanes used in our experiments is given in Table 1. The medium resolution (0.3 to 0.8 cm^{-1}) spectra were recorded on a Perkin–Elmer Model 125 prism-grating spectrometer calibrated with reference to the I.U.P.A.C. tables (28); the frequency accuracy is always better than 0.5 cm^{-1} for sharp peaks. The high resolution spectra were recorded on a 2.5 m Littrow spectrometer, similar in design to that described by McCubbin *et al.* (29), built in our laboratory (30), and equipped with liquid nitrogen cooled PbS and PbSe detectors. The spectra recorded with this spectrometer were obtained with a resolution of 0.03 to 0.09 cm^{-1} and with a frequency accuracy limited by the widths of the peaks, to about 0.05 cm^{-1}. The calibration was made against accurately measured 1–0 vibration–rotation lines of CO (31).

A conventional cryostat equipped with a variable pressure gas exchanger was used to obtain any selected temperature in the range 4 to 120 °K with liquid helium or nitrogen as the coolant. The temperature stability achieved by adjusting the gas pressure in the heat exchanger was relatively good. For example, the sample temperature could be maintained within 0.5 °K by adjusting the pressure every 10 min during the first half hour. At later times the temperature stability was improved if the adjustments of the gas pressure were continued.

A small temperature gradient was created across the sample cell by using the filling tube, which entered the top of the cell as a heating element. The filling tube, 0.030 in. in diameter, was made of thin stainless steel and a current of a few mA from a 6 V a.c. source was circulated through it. This arrangement was found particularly useful in preventing clogging of the tube if it inadvertently touched the nitrogen shield. In addition this small heater has provided fine monitoring of the sample temperature. The temperature gradient thus obtained was not measured but is certainly not very large in view of the good thermal conduction of the cell body which was made of brass.

The rate of cooling at the freezing or transition points was of the order of 0.5 deg per hour. Reproducible spectra were always obtained when the samples were repeatedly cycled through the transition temperatures. The sample thickness was about 1 μ for the neat crystals and 50 μ for the isotopic mixtures.

The gaseous mixtures were prepared in a Pyrex system previously degassed and evacuated to 1×10^{-6} mm Hg. The samples were prepared by condensing the pure gas, or the appropriate isotopic mixture, to the liquid between two circular windows of 1 in. diameter sealed off to a closed

compartment by means of indium gaskets. Two window materials were used: germanium and IRTRAN-II. Because of its lower index of refraction IRTRAN-II is preferred to germanium although the spectra obtained with the two materials are very similar; slight variations in the band shapes need not be considered since they do not alter our discussion of the crystal structures.

Results and Discussion

A. The Infrared Spectra and Structure of Phase I Crystalline CH_4 and CD_4

The spectra of phase I crystals are reproduced in Figs. 1–4: Fig. 1, CH_4; Fig. 2, CD_4; Figs. 3

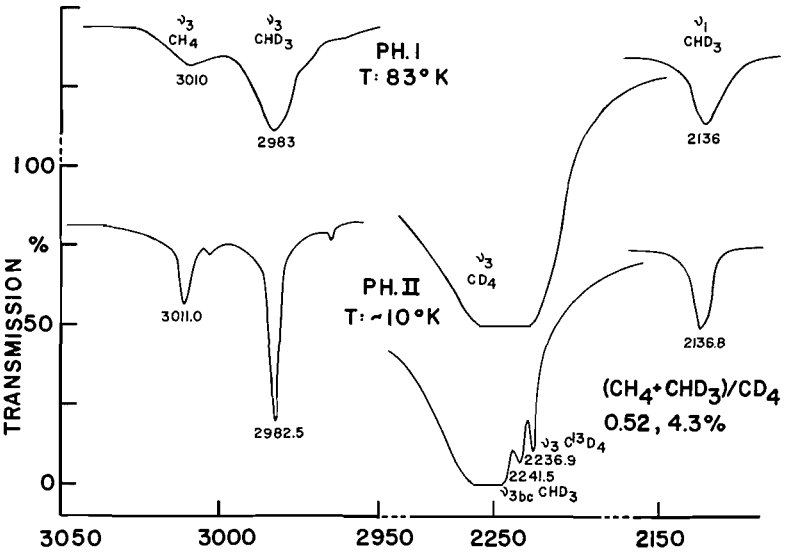

FIG. 3. Infrared absorption spectrum in the region 3050 to 2100 cm^{-1}, of 0.5% CH_4 and 4% CHD_3 in 95% CD_4: upper trace, phase I CD_4 at 83 °K; lower trace phase II CD_4 at 22 °K.

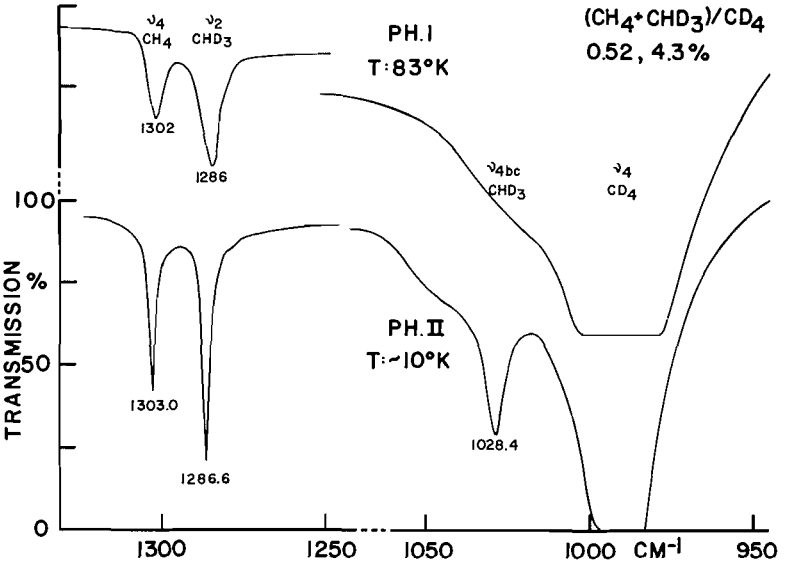

FIG. 4. Infrared absorption spectrum, in the region 1350 to 950 cm^{-1}, of 0.5% CH_4 and 4% CHD_3 in 95% CD_4: upper trace, phase I CD_4 at 83 °K; lower trace, phase II CD_4 at 22 °K.

and 4, CH_4 and CHD_3 at low concentration in CD_4. The frequencies at maximum absorption are collected in Tables 2–4. These spectra are all characterized by unusually broad bands. Although the widths decrease markedly upon lowering the temperature, the bands remain so broad over the complete range for phase I that no site or factor group components may be resolved since the splittings for such van der Waals crystals are always much smaller than the bandwidths observed for these crystals. Therefore it is impossible to carry out an analysis of the spectra, based upon group theory, that could lead to the site and factor groups. How-

ever, a qualitative discussion of the measured bandwidths and of their behavior with a variation of the temperature of the crystal is interesting.

Several factors may contribute individually or collectively to the width of the bands in these solids, but it is believed that the following are the most important: (*1*) a static orientational disorder of the molecules; (*2*) large angular oscillations of the tetrahedra around their equilibrium position; (*3*) rotational diffusion, and (*4*) large amplitude lattice vibrations. Thus the rapid narrowing of the bands occurring upon cooling the crystal would reflect either a partial ordering of the molecules, or a decrease in the amplitude of the lattice modes, or less rotational diffusion, or a combination of these phenomena. The spectra alone do not permit a choice between these alternatives but recent neutron diffraction experiments are helpful in this matter since they have indicated more ordering at 77 °K than at 35 °K (9). This information permits us to rule out partial ordering upon cooling. We may therefore conclude that the disorder in phase I results from considerable motion of the molecules but it is not possible to specify the type of motion.

B. Effects of the Crystal Site Environment on the Degenerate Vibrations of Guest Molecules in Crystalline Phase II CH_4 and CD_4

The symmetry at the site occupied by the molecules in the crystal may often be determined through the analysis of the vibrational spectrum of a guest isotopic molecule present at low concentration in a crystal of the parent host molecule. The coupling of the vibrations of

guest and host molecules is largely destroyed when the vibrational frequencies of the two molecules are different enough. Thus, the vibrations of the guest molecule are influenced almost exclusively by the site symmetry of the host crystal (32).

The spectra of several mixed isotopic solutions have been recorded with a resolution of 0.5 to 0.8 cm^{-1} and a few selected bands with high resolution (0.03–0.09 cm^{-1}). Selected examples of medium resolution spectra are reproduced in Figs. 3–5 while high resolution spectra are shown in Figs. 6 and 7. The frequencies at maximum intensities are given in Tables 5 and 6. In a previous report (17) we have already shown that CD_4 at low concentration in CH_4 phase II and vice versa yield spectra where the triple degeneracy of the infrared active modes seems completely preserved (see Figs. 3 and 4). Among the sub-groups of the free molecule point group only the local symmetries T or T_d are acceptable if the free molecule F_2 vibrational modes are true singlets in the solids. Since it appeared that the natural bandwidth is smaller than the spectral resolution, a high resolution spectrum of the ν_3 vibration of CD_4 at low concentration in CH_4 was recorded (Fig. 6). The width at half height of the band is 0.50 cm^{-1} and there is a slight asymmetry on the high frequency side revealing that the band might be an unresolved doublet. If it is a doublet, one member would be approximately 4–6 times weaker than the other with a separation of the order of 0.5 cm^{-1}. Each peak may result from molecules lying at different sites but if one

assumes that the band asymmetry results from site splitting, the true local symmetry is one of D_{2d}, S_4, C_{3v}, or C_3. However, the distortion from T or T_d symmetry should then be very small in order to produce such a small splitting. It will be shown later that, although it is unusual for such molecular crystals, two types of sites appear to be occupied in phase II solid methane. Therefore this asymmetry cannot be considered as providing strong evidence for these lower site symmetries. Moreover we hesitate to conclude the presence of a real doublet from the slight asymmetry of a line since we are not certain that lines in the solids ought to be symmetrical. Additional information might be gained from an analysis of the infrared spectra of mixed isotopic solutions of CHD_3 in phase II CH_4 and CD_4 since the E modes should split for D_{2d} and S_4 site symmetries but not for C_3 or C_{3v}. Of course T or T_d symmetry would also leave the E mode degenerate. However, for the partially deuterated methanes the site symmetry may be reflected on the spectra through a multiplicity of the lines corresponding to various orientations of the guest molecules in the host

crystal. These effects will show up for both the degenerate and nondegenerate modes and will be discussed in the next section.

C. *Effects of the Crystal Site Environment on the Vibrational Modes of Partially Deuterated Guest Molecules in Crystalline Phase II CH_4 and CD_4*

For a space-fixed tetrahedral framework there exists a number of distinguishable orientations that the individual partially deuterated methanes can assume: 6 for CH_2D_2, 4 for CHD_3 or CH_3D, and only one possible orientation for CH_4 and CD_4. The zero point entropies, which are $R \ln 6$ for CH_2D_2, $R \ln 4$ for CHD_3 or CH_3D, and zero for CH_4 and CD_4, as calculated from extrapolation of the heat capacity from 8 to 0 °K, imply that in the crystals the molecules are still randomly oriented in this respect at a temperature as low as 8 °K (1, 3). It is now postulated that partially deuterated methanes in a host crystal of CH_4 or CD_4 will also be free to orient in any of the possible different ways that obviously may or may not correspond to different energies depending upon the point symmetry of the site occupied in the crystal. For example for the trivial symmetry each orientation corresponds to a different physical situation, thus there are 6 possible energies for the CH_2D_2 molecules and 4 for either CH_3D or CHD_3. For higher site symmetries some of the

orientations are related by symmetry operations and are therefore equivalent. The case of the C_{3v} molecules will be presented in some detail.

For C_s site symmetry, only three of the four distinct orientations are energetically different since two are related by a reflection through the plane. For C_2 or C_{2v} site symmetries only two of the four space orientations are energetically different. For C_3 and C_{3v} again only two are different but their statistical weights are 1:3 whereas they are 1:1 in the cases of C_2 and C_{2v}. For S_4, D_2, D_{2d}, T, and T_d all the four orientations correspond to the same energy. The cases of D_2 and D_{2d} are not so obvious but they may be understood by observing that the three C_2 axes perpendicular to one another relate the four deuterium or hydrogen atoms. A spectrum complicated with orientational effects is a superposition of spectra each corresponding to molecules in a slightly different environment. These orientational effects were thoroughly investigated for mixed isotopic solutions of the benzenes (27) and were also shown to influence the vibrational spectra of partially deuterated methanes (17).

The medium resolution absorption spectrum of CHD_3 at low concentration (0.8%) in crystalline phase II CH_4 is reproduced in Fig. 5, where all the fundamental vibrations of CHD_3 are observed. The corresponding spectrum for a mixed crystal containing 4.3% CHD_3 in phase II CD_4 is given in Figs. 3 and 4. It shows all the bands of the guest molecule except ν_{4a} which overlaps with the strong absorption of the host molecule. With a resolution of 0.5 cm^{-1}, each vibrational band, degenerate or not, of CHD_3 in both matrices appears as a symmetrical singlet. This is entirely consistent with T or T_d site symmetries, since under these two local symmetries the doubly degenerate bands of CHD_3 should remain degenerate and there should be no orientational effects. As for D_{2d} and S_4 local symmetries, although they would not give rise to orientational effects, they should lift the degeneracy of the E modes but this may be very small as in the case of the F_2 modes of CD_4 at low concentration in CH_4. The two trigonal symmetries should not lift the degeneracy of the E modes but should give rise to orientational effects. It appeared worthwhile to record a few bands under higher resolution in an attempt to check for these two site effects. The CH_4 matrix

was used because its phase II exists at lower temperature where the lines are narrower. The ν_{3a}, ν_{3bc}, and ν_1 regions each show one slightly asymmetrical line whose widths are 0.50, 0.60, and 0.26 cm^{-1}, respectively. (The weaker lines in the ν_{3a} region may be disregarded for the moment.) Therefore, even under very high resolution, we have not obtained strong evidence for site splitting or orientational effects. We may again conclude that, although we cannot definitely rule out any of the symmetries considered in the preceding sections, if there is distortion from T or T_d site symmetry it is very small.

D. The Selection of Acceptable Factor Groups

The X-ray and neutron scattering experiments have indicated that the carbon atoms lie on a face centered cubic lattice (8–9). Therefore we will search among the super groups of the point groups previously selected for those which will necessarily place the carbon atoms on a f.c.c. lattice. Table 6 lists all the possible combinations of site and factor groups which were retained including the C_3 and C_{3v} site groups, although these are considered unlikely in view of the absence of observable orientational effects. These two trigonal groups are the only ones predicting the i.r. activity of the totally symmetric ν_1 mode of the free molecule. We have therefore checked for the infrared activity of the free molecule $\nu_1(A_1)$ mode and $\nu_2(E)$ mode with samples about 50 times thicker than those required for the gas phase allowed fundamentals. Since no absorption was found in the appropriate regions, the intensities of ν_1 and ν_2 are at least 2000 times weaker than the intensities of the gas phase allowed fundamentals. Therefore we believe that both vibrations remained symmetry forbidden in the phase II crystal. This excludes C_3 and C_{3v} local symmetries and in addition it is inconsistent with S_4 which predicts i.r. activity of the free molecule E mode. Thus we are left with T_d, T, and D_{2d} site symmetries. The total number of lines in the ν_3 and ν_4 vibration regions appears inconsistent with any of the symmetry groups that survived elimination since as is shown in Table 6 none of the combinations of site and factor groups retained would yield more than three i.r. components. Moreover the site groups T_d, T, and D_{2d} which have survived elimination are consistent with only one (with T or T_d) or two (with D_{2d}) components. Therefore none of the structures listed in Table 6 may be considered correct under the assumption that a single set of sites is occupied in the crystal. However, a visual inspection of the spectra reproduced in Figs. 1 and 2 reveals that among the lines of a given band there is a strong component which is wide and unsymmetrical and that the other lines are sharp and much weaker. This is particularly evident with CH_4 (Fig. 1) whose spectrum has been recorded at a much lower temperature than CD_4 (Fig. 2). This observation suggests that there may be two sets of sites occupied by the molecules in the crystal as was originally proposed by James and Keenan (33). Such a structure has also been recently deduced from a coherent neutron scattering study of CD_4 (9). In this structure there are eight molecules per unit cell of which six are ordered on sites of symmetry D_{2d} ($\bar{4}\,2m$) and two are free to rotate located on sites of symmetry O(432). Since D_{2d} was found an acceptable site group, our spectra will be examined for consistency with this model. For the selection of a factor group, only the main wider components will be considered; the narrower spectral features are believed attributable to quantized rotational levels of the molecules on sites of octahedral symmetry and this will be discussed later in this section. The ν_3 regions of both CH_4 and CD_4 were scanned under high resolution and although the main peaks could not be resolved it appears that they contain two wide components of appreciable intensity and one additional line of lower intensity.

If the strong highly unsymmetrical band is a doublet arising from crystal field effects, the local symmetry is D_{2d} and the factor group is T_d or O_h (see Table 6) but if on the contrary ν_3 and ν_4 are not split, the local symmetry is T or T_d and seven combinations of site and factor groups remain acceptable. Correlation diagrams have been constructed for every possible symmetry and the results of this group theoretical analysis are collected in Table 6. Unfortunately we have not succeeded in obtaining high resolution spectra of the ν_4 bands because we did not have any suitable detectors for these regions.

Further elimination might be possible by comparing the infrared and Raman frequencies,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for if they are not coincident the factor groups T and T_d are eliminated. Unfortunately the frequencies of the reported Raman bands (14) are not accurate enough ($\pm 2 cm^{-1}$) for this type of comparison to be meaningful.

Two absorption bands were found in the lattice vibration region of both molecules (15). These two bands are consistent with both symmetry combinations involving D_{2d} site symmetry but not with any combination of site and factor groups involving T or T_d site symmetry (see Table 6). It should be noted that if the site symmetry is D_{2d} the factor group T_d is not acceptable since this combination of symmetries does not yield any f.c.c. lattice (see Table 6) and that there remains only one possible factor group, O_h, which yields only the f.c.c. space group O_h^6 ($Fm\,3c$).

Within this structure there could be eight molecules per primitive cell of which six would be ordered on sites of D_{2d} ($\bar{4}\,2m$) symmetry (type A) and two free to rotate on sites of O(432) symmetry (type B). In this arrangement the eight carbon atoms form a f.c.c. lattice by symmetry. Therefore the type B molecules are in a cage surrounded by ordered type A molecules that form the f.c.c. lattice. This arrangement is exactly analogous to that existing when methane occupies a substitutional cavity in a matrix of one of the noble gases since these also crystallize with a f.c.c. structure. The resemblance with krypton is particularly striking since both crystals have cavities of very similar sizes; this was previously discussed by one of us (18, 20, 21). Since quantized molecular rotation of methane was shown to exist in the crystals of the noble gases we will try to assign the sharp lines left unexplained in the spectra of the neat crystals to vibration–rotation transitions of the type B molecules.

Essentially, for CH_4 at 10 °K there were four (and in some cases five) components with a separation somewhat smaller than the separation between the gas phase vibration–rotation lines. From the free rotor predicted intensities and from the variation with time of the intensities of the observed lines in the matrix, the strongest component was assigned to R(0). The same general pattern was found for CD_4 isolated in noble gas matrices except for the greater number of components corresponding to the Boltzmann distribution amongst the more closely spaced energy levels of CD_4 which has a greater moment of inertia. It must be remembered that although the fine structure is well resolved at 8 °K, it broadens very rapidly with temperature and that around 30 °K only the rotational envelope is preserved (20). The spectra of the neat crystals were recorded at 9 °K for CH_4 and 23 °K for CD_4; therefore from the noble gas matrices results it is obvious that the rotational features, if present, will be easier to detect in CH_4 than in CD_4.

Let us now turn our attention to the i.r. spectrum of crystalline methane in phase II and try to reconcile it with the assumption that one out of four molecules in the solid undergoes quantized molecular rotation similar to that shown to exist in noble gas matrices. According to the foregoing discussion two main bands ought to be observed: one corresponding to the R(0) line of molecules that are free to rotate (type B) and the other, about three times as intense, arising from molecules that are not free to rotate (type A). (The other vibration–rotation lines including the Q branch are much weaker since the Q(0) line is forbidden.) The infrared spectrum of phase II CH_4 (Fig. 1) shows the main features we are looking for: the most intense bands (in the ν_3 region at 3008.5 cm^{-1} and in the ν_4 region at 1301.3 cm^{-1}) arise from type A molecules, whereas the bands at 3020.1 and 1296.9 cm^{-1} would be the R(0) lines of type B molecules. The ratio of the intensities of the bands of type A molecules to those of type B molecules is about three to one. This is somewhat accidental because the two types of molecules need not have the same intensity. There are additional weak features which may be assigned to vibration–rotation lines of type B molecules: in ν_3, R(1) at 3026, Q at 3011, P(1) at 3004; in ν_4, R(1) hidden under 1301.3, R(0) at 1296.9, Q at 1292.9, and P(1) at 1289.3. Table 7 illustrates the similarity between the spectrum of neat CH_4 crystals and that of CH_4 isolated in a krypton matrix. The spacings between the various lines are very similar to the spacings found in noble gas matrices (20). The weaker features at 3000.5, 2999.4, 1294.1, 1290.1, and 1286 very likely belong to the $^{13}CH_4$ isotope. The CD_4 spectrum is also consistent with molecular rotation. In

*Reference 20.

the ν_4 region (Fig. 2) the band at 987.5 belongs to type B molecules whereas that at 992.3 arises from type A molecules; on the high frequency side, a shoulder is assigned to ν_4 of CHD_3 molecules present as an impurity whereas on the low frequency side the shoulder is due to $^{13}CD_4$ in natural abundance. In the ν_3 region the lines of type B molecules are lost under the wide band of type A molecules, although a shoulder, assigned to the R(0) line, is observed around 2260 cm^{-1}. The smaller rotational constant for CD_4 and, to a greater extent, the higher temperature of the sample are responsible for the apparent differences between the spectra of phase II CH_4 and CD_4. The Raman spectra of the neat crystals (14) may also reveal some features that could arise from molecules which are free to rotate. In the krypton matrix (21) a wide band was observed with a maximum around 3040 cm^{-1}. By comparison the band at 3037 cm^{-1} in the spectrum of neat solid CH_4 could arise frome type B molecules, whereas in the ν_2 region these molecules would be responsible for the band at 1553 cm^{-1} but this cannot be considered established until Raman spectra of higher quality are obtained. In the ν_1 region, 2901 cm^{-1} could be the band of type A whereas 2907 could be the Q(1) transition of type B molecules.

No features easily assigned to molecules free to rotate were found in the spectra of guest molecules of mixed isotopic crystals. It is not impossible that at least some of the weak lines, found close to the main bands of the guest molecules (see for example Fig. 7 of this paper and Fig. 1 of ref. 17), are vibration–rotation lines of molecules lying on sites of octahedral symmetry but it may be that the guest molecules are, in the host crystal, occupying only sites of D_{2d} ($\bar{4}\,2m$) symmetry. This problem is the subject of further studies in this laboratory.

Finally two series of experiments were carried out in an attempt to observe conversion among the various spin species of methane through a variation of the intensities of the vibration–rotation features identified in the spectrum of the neat crystal. In the first series, the spectrum was recorded at various time intervals over a period of 3 h; no time dependance was detected but unfortunately nothing may be said for the first hour where the unexplained phenomenon reported by Blanchard *et al.* (16) was observed. In the second series of experiments, oxygen was added to methane (up to 1%) since Frayer and Ewing (19) had shown that the addition of O_2 to a mixed crystal of CH_4 and noble gases increases the rate of spin equilibration. In our spectra the line width has been noticeably increased by the addition of oxygen such that it is difficult to draw a firm conclusion although it seems that features arising from the $J = 1$ level had lost some intensity but the variation of intensity was within experimental accuracy. The overlapping of the various components is such that no accurate intensity measurement is possible.

E. Conclusions

The i.r. spectra indicate that methane and methane-d_4 have the same crystal structures in phase I as well as in phase II.

In phase I the i.r. absorption bands are so wide that no information on site and factor groups may be derived. The spectra reflect considerable motion of the molecules but it not possible to specify what type of motion is involved.

In phase II the bands are much sharper, and the analysis of the observed features yields more precise information. The analysis of the vibrational bands corresponding to the internal modes of the molecule is consistent with three different site symmetries namely, T_d, T, and D_{2d} and nine different couples of site and factor groups. The diffraction experiments have fixed the carbon atoms on a face centered cubic lattice. Eight of our nine different couples are possible in a total of eleven face centered cubic

For personal use only.

space groups and one of the couples is rejected for it cannot exist in any f.c.c. space group. The D_{2d} local symmetry is the only one compatible both with our spectra and with the existence of the two lattice modes found in the far i.r. region. Therefore it is suggested that, in agreement with recent neutron diffraction experiments, the space group is O_h^6 ($Fm\,3c$). This conclusion could be checked by recording high quality Raman spectra. The lattice vibration region would be particularly useful since, amongst the eleven remaining space groups, O_h^6 ($Fm\,3c$) is the only one yielding two lattice modes. Moreover the i.r. and Raman bands would correspond to different modes and are likely to have different frequencies. It has been clearly shown that quantized rotation of the methane molecules, similar to that found in noble gas matrices, exists in this phase. The proportion of the number of molecules which are free to rotate over that of ordered molecule could be 1:3 as suggested by James and Keenan. The Raman spectra would also provide a good test for our conclusion about molecular rotation for in the A_1 mode only the Q(1) transition will be found at 9 °K since Q(0) as well as the $\Delta J = \pm 1$ transitions are forbidden. The vibrational spectra at much lower temperatures are being investigated in this laboratory. The study will be extended to the complete series of partially deuterated methanes.

The authors wish to express their gratitude to Professor J. A. Morrison for his interest and for helpful discussions concerning this work as well as for providing them with a purified sample of CD_4. Thanks are due to Nguyen Cong Thanh, L. Lambert, and C. Pépin for their assistance in recording the high resolution spectra. Technical assistance with the apparatus from Jules Rousseau is gratefully acknowledged. Financial support was provided by the "Ministère de l'Education de la Province de Québec" and by the National Research Council of Canada.

Equilibria Studies on Tetraalkylcyclopentenyl Cations. A Steric Origin for a Baker–Nathan Order?

K. Ranganayakulu and T. S. Sorensen

The Department of Chemistry, The University of Calgary, Calgary, Alberta

Received May 15, 1972

The possibilities of using observable cation equilibria to obtain evidence concerning C—H hyperconjugation are discussed. The experimental approach of this paper, using tetraalkylcyclopentenyl cation equilibria, is to vary the structure of the "normal" alkyl series in such a way that the hypothetical C—H hyperconjugative ability remains constant for a given series while the steric bulk of the groups changes. In fact, the observed equilibrium changes are minimal. Other experiments have been performed to measure both the effect of solvents on the equilibrium constants and the rate of the equilibration reaction. Still other experiments were designed to test the ability of H *vs.* CH_3 in stabilizing alkyl cations and a value of ≥ 4.6 kcal/mol favoring CH_3 has been found. Finally, the possibility of using structurally similar cation and anion equilibria to cancel out steric effects in these equilibria is discussed.

Les utilisations possibles des équilibres que l'on peut observer entre les cations pour mettre en évidence l'hyperconjugaison du C—H sont discutées. L'approche expérimentale de cette note qui utilise l'équilibre du cation tétraalkylcyclopentènyle, consiste à faire varier la structure de la série alkyle "normale" de telle manière que la propriété supposée de l'hyperconjugaison du C—H reste constante dans une série donnée tandis que l'encombrement stérique des groupes varie. En fait, les variations observées pour l'équilibre sont minimales. D'autres expériences ont été réalisées pour mesurer à la fois l'effet des solvants sur les constantes d'équilibre et la vitesse de la réaction d'équilibration. Pour vérifier la capacité de stabilisation des cations alkyles de H par rapport au CH_3, d'autres expériences ont donné une valeur ≥ 4.6 kcal/mol en faveur de CH_3. La discussion finale porte sur la possibilité d'utiliser les équilibres entre cations et anions de structures semblables pour éliminer les effets stériques dans ces équilibres.

The tetraalkylcyclopentenyl cations A and B, where R^1 and R^2 are different alkyl groups, fairly rapidly reach an equilibrium situation if the proper acid solvent system is used (eq. 1) (1). The dimethylcyclopentenyl cation substructure serves simply as a vehicle to compare the alkyl groups R^1 and R^2. Previous work (1) has shown that if R^1 = *t*-butyl and R^2 = methyl, then the equilibrium constant is 18. With R^1 = ethyl and isopropyl, respectively, the observed equilibrium constants are 1.6 and 2.6. If one restricts oneself to a comparison of the partial cation structure shown below the dashed lines in structures A and B, then one has an obvious example of the Baker–Nathan order for alkyl groups. This comparison ignores the R groups at C-4 and we have previously suggested (1) that differential inductive effects for different alkyl groups at this position are likely to be negligible. The steric consequences of the R groups at *both* C-1 and -4 are the subject of this paper.

This method for determining the ability of alkyl groups to stabilize a positive charge offers two distinct advantages over a great majority of the previous investigations (mostly solvolytic rate comparisons) (2): (*1*) the energy differences observed in comparisons between the various alkyl groups are much larger, and (*2*) one is comparing isomeric systems so that no assumptions need to be made concerning the bond energies of the extra carbon and hydrogen atoms involved in non-isomeric systems (3).

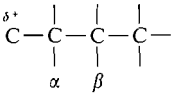
	$(CH_3)_2CH-CH_2-$		$(CH_3)_3C-\overset{CH_3}{\underset{CH_3}{C}}-$

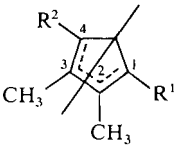
CHART 1

The objectives of the present work are: (*1*) to complete the series A ⇄ B, involving the permutation of all of the standard alkyl groups (methyl, ethyl, isopropyl, and *t*-butyl). The only permutation remaining was the ethyl *vs.* *t*-butyl comparison, *i.e.* R^1 = *t*-butyl and R^2 = ethyl in A ⇄ B.

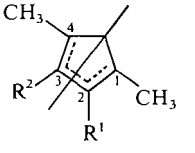
Objective (2): an unavoidable consequence of testing either the Baker–Nathan or the inductive order of alkyl groups is the problem of a changing steric situation accompanying this process. In the case of ions A and B, it is unlikely that one will have any direct R^1–R^2 interactions. Any difference observed will be due to differences in the interactions of R^1 and R^2 with two nonequivalent sites (shown by arrows) of the testing vehicle, the dimethylcyclopentenyl cation substructure. Briefly, these are (assuming a planar allyl system): at C-4, a staggered (55°) interaction with the C-3 methyl, and an eclipsed interaction with one of the C-5 protons; at C-1, an eclipsed interaction with the C-2 methyl and a staggered interaction with both C-5 protons. One approach to the problem of delineating the cause of the previously observed (1) Baker–Nathan order (hyperconjugation or steric effects?) would be to keep the hypothetical hyperconjugation portion of the alkyl group the same and to vary only the size of the alkyl group. An obvious restriction of this is that structural (steric) changes can only be made at β or higher carbon atoms since the α substitution defines the C–H hyperconjugative properties. Some restrictions on the kind of groups that one can use become apparent when one considers the possible n.m.r. spectra expected from mixtures of A and B. The R^1 groups shown in Chart 1 seemed feasible. For R^2, a methyl or an isopropyl group offered the best chances for obtaining a decipherable n.m.r. spectrum and both were used.



Objective (3): to examine other testing vehicles. In this connection, the previous work can be said to involve a 1,4-alkyl comparison in a cyclopentenyl cation ring. An alternative comparison would involve the 2- and 3-positions.



1,4-Comparison

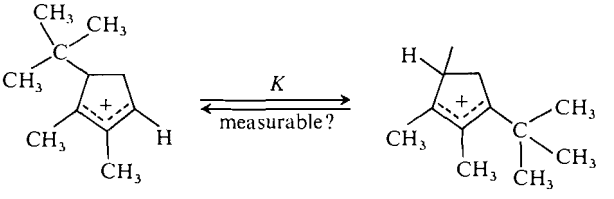


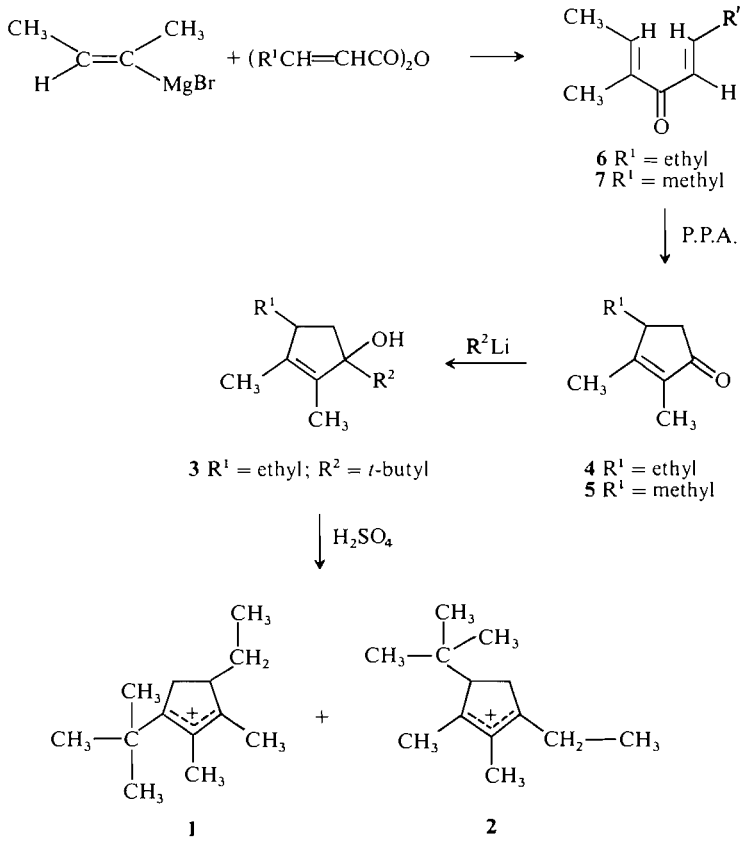
2,3-Comparison

The system where R^2 = isopropyl and R^1 = methyl was chosen.

Objective (4): to attempt to measure the equilibrium constant for a H *vs.* alkyl case. Since a *t*-butyl group appears to be the least stabilizing of the alkyl groups, the system depicted by eq. 2 was chosen.

[2]





SCHEME 1

Objective (5): the observed free energy difference, $\Delta G = -RT \ln K$, obtained for the A ⇄ B equilibria, can in general be broken down into specific contributions, $\Delta G = \Delta G$ (internal) + ΔG (differential solvation) + ΔG (differential counter ion interaction etc.). One hopes, in this study, that only the first contribution is involved but it seemed desirable to extend the previous work by investigating the position of one of the equilibria in a wider variety of acid solvents and others than was used previously (1). The ion system A ⇄ B, where R was methyl and isopropyl was chosen, since some work had already been done (1) and the n.m.r. analysis for A and B is particularly good.

Objective (6): the proposed approach to all of the above measurements involves the synthesis of only one ion of the A ⇄ B pair. In this circumstance, it became desirable to measure the rate of the equilibration process. It was hoped to measure all of the equilibria in both 93 and 96% H_2SO_4. Rate studies were therefore carried out in both of these solvents as well as in both higher and lower percentages of H_2SO_4. The two systems chosen as representative cases for investigation were the methyl *vs.* isopropyl and the methyl *vs.* *t*-butyl, the latter being particularly suited for study if one starts with the less stable of the pair.

Synthetic Approaches

The Ethyl vs. t-Butyl System

The cations **1** and **2** were prepared from the allylic alcohol **3** which was readily obtained by adding ethyl lithium to the ketone **4**. This ketone was prepared by the reactions outlined in Scheme 1, R^1 = ethyl.

The C-2 methyl groups of **1** and **2** are well separated, τ 7.71 and 7.88 respectively, and these were used, following previously described procedures (1, 4), to determine the equilibrium constant. This has been incorporated with the

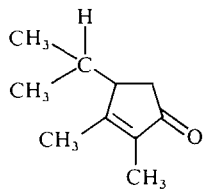
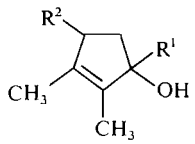
previously measured systems (1) in Table 1. The ethyl *vs.* *t*-butyl value falls intermediate between the methyl *vs.* *t*-butyl and the isopropyl *vs.* *t*-butyl cases and is, from $\Delta\Delta G$ estimations, close to what might have been calculated.

Systems Employing Other Alkyl Groups

The ketone **7** was prepared as shown in Scheme 1 using crotonic anhydride. The ketone **8** was prepared by the acid-catalyzed rearrangement of thujone, as described in the literature (5). No serious problems were encountered in adding isobutyl or neopentyl lithium to both of these ketones, giving alcohols **9**–**12**. The *sec*-butyl lithium was added only to **7** since it was expected that problems in the n.m.r. analysis would occur with the ions from **8** derived systems. In spite of many attempts using several different procedures, it proved impossible to prepare the lithium derivatives of triethylmethyl chloride or 2-chloro-2,3,3-trimethylbutane. Since these groups (from the above chlorides) represented the simplest tertiary groups which it was felt could be analyzed by n.m.r. spectroscopy, we were left with no representative of this class. In these circumstances, the perdeutero *t*-butyl group was chosen since a deuterium atom is expected to have a smaller size than a proton (6). *t*-Butyl lithium-d_9 was added to both ketones **7** and **8**, yielding the alcohols **14** and **15**.



8



9 R^2 = methyl; R^1 = isobutyl
10 R^2 = methyl; R^1 = neopentyl
11 R^2 = isopropyl; R^1 = isobutyl
12 R^2 = isopropyl; R^1 = neopentyl
13 R^2 = methyl; R^1 = *sec*-butyl
14 R^2 = methyl; R^1 = *t*-butyl-d_9
15 R^2 = isopropyl; R^1 = *t*-butyl-d_9

The pertinent n.m.r. spectral data for all of the ions are given in Table 8 in the Experimental. The actual peaks used to determine the concentrations of the two ions in the equilibrated mixture are noted there. In Table 2, we list the observed equilibrium constants together with a comparison between the ΔG values for these alkyl groups and the "normal" member of the series. The only ion system which proved difficult to analyze was the methyl *vs.* *sec*-butyl case (see below), from alcohol **13**.

Diastereomeric Cations

Each of the cations **22** and **23** exists as a pair of diastereomers and initially this so complicated the spectra that an analysis could not be made. Using 220 MHz n.m.r. spectroscopy however, it has been possible to analyze the equilibrium mixture of all four ions and to definitively assign

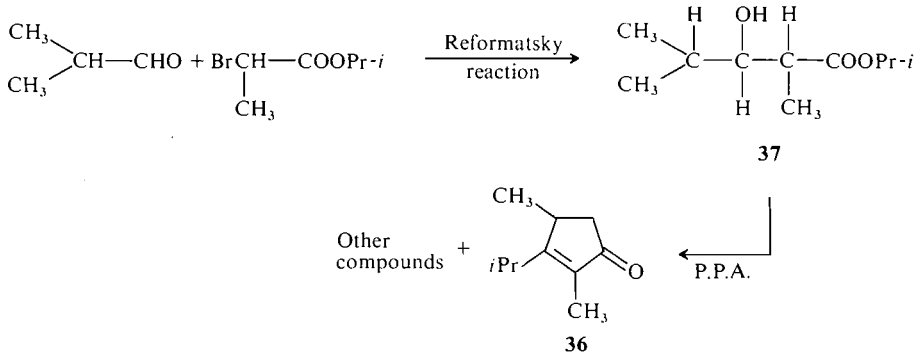
23 A		8.85 (d) $J = 7.0$ 9.14[b]
23 B		9.44 (d) $J = 6.0$ 8.98 (t) $J = 7.2$

[a]These peaks have the same chemical shift in both diastereomers.
[b]This peak appears as a singlet with shoulders on each side separated by about 6 Hz. There appear to be some lower intensity peaks buried nearby (the CH_2 protons of the isobutyl group of this diastereomer).

higher field positions expected for both the CH_3 doublet and the CH_3 triplet of the *sec*-butyl group (further from the cation center in **23**). Although two separate CH_3 doublets are observed for **22***a* and *b*, it is not possible to specifically assign the peaks.

The key n.m.r. feature of the **23** diastereomers is the large chemical shift difference in the CH_3



37

36

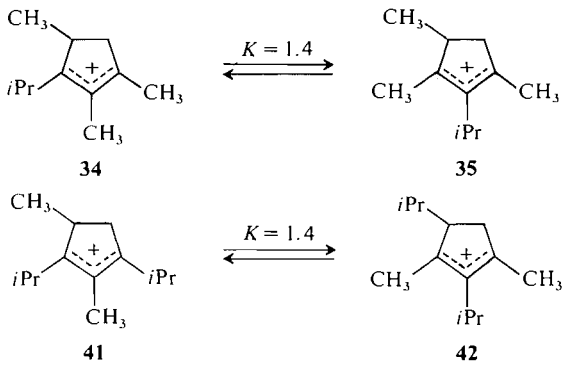
SCHEME 2

doublets of the *sec*-butyl group, τ 8.85 and 9.44, and the appearance of a methyl group (from the ethyl portion) lacking the usual triplet appearance and in fact resembling a close coupled A_2B_3 pattern. It has been previously found (7) that an isopropyl group in the C-4 position of these cations (analogous to **23**) shows an extremely large non-equivalence of the two methyl groups and this can confidently be attributed to a preferred conformation in which one of the methyl groups lies above and in the shielding region of the allyl cation portion. With the *sec*-butyl compound, the diastereomer with the very high field methyl doublet must be **23***b* and the isomer with the normal methyl doublet but with the abnormally high CH_2 chemical shift (implied from the A_2B_3 spectrum) must be **23***a*, in which the CH_2 protons are now over the allyl cation portion.

The equilibrium constants for these cations are: **22***a* ⇄ **22***b* = 1.20 or 1/1.20, **23***a* ⇄ **23***b* = 2.5 and combined **22** ⇄ combined **23** = 2.0. As will be shown later, interconversions between **22** and **23** proceed by loss of a proton at C-4 and the subsequent addition of one to C-1. This process allows for the interconversions between diastereomers if the proton goes back at C-4 on the opposite face. Interconversion of the diastereomers of **22** can also occur by proton loss from the *sec*-butyl group, destroying the asymetric center, and then reprotonation (eq. 3). The two processes in cation **22** allow inversion of different centers, for example, SR ⇄ SS and SR ⇄ RR, respectively.

Comparison of Alkyl Groups in the 2- and 3-Positions

The cation system desired was **34** ⇄ **35** and the only synthetic problem involved a preparation of the unknown ketone **36**. This was accomplished by the steps shown in Scheme 2.



34 35

41 42

In an initial attempt, the polyphosphoric acid ring closure of ethyl 3-hydroxy-2,4-dimethyl-3-isopropylpentane carboxylate (**38**) from diisopropyl ketone and ethyl α-bromopropionate) led to a complex mixture in which none of the desired product could be detected.

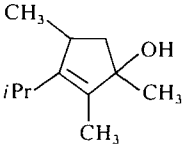
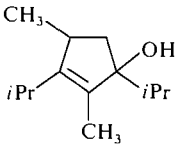
38

Addition of methyl lithium to **36** led to the alcohol **39** and since the ketone was readily available, isopropyl lithium was also added to generate the alcohol **40**. The ions were prepared in the usual way and the pertinent n.m.r. peaks are listed in Table 8. The measured equilibrium constants are shown with the structures.



39

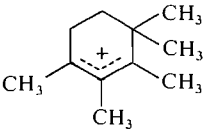


40

The H vs. t-Butyl Comparison. Results and Discussion

The cation **43** was generated from the diene mixture obtained on attempted distillation of the alcohol **45** (eq. 4), which in turn was prepared by the addition of *t*-butyl lithium to the known (8) 2,3-dimethylcyclopentenone. Care was taken in the purification of both the cyclopentenone and the diene since small extraneous n.m.r. peaks can severely limit the scope of the analysis, where in general one wants to be limited at the lower end only by the signal/noise characteristics of the instrument. The solvents used were 93 or 96% H_2SO_4 and the solution was left for a period of time sufficient to cause complete equilibration. The peak searched for was the 9H *t*-butyl peak of **44**, which by analogy to other similar systems, *e.g.*, cations **2** and **25** (Tables 2 and 8), was expected about τ 8.8–8.9. A low concentration reference peak was used to calculate the height of the *t*-butyl peak in ion **43** since this peak was well off-scale at the full amplification used.

Several n.m.r. peaks which were in approximately the correct range were located but these could not be identified unambiguously with **44**. One can however place a minimum value of 120 for the equilibrium constant $\mathbf{44} \overset{k}{\rightleftarrows} \mathbf{43}$ ($\Delta G \geq 2.8$ kcal/mol). The cation **43** is also in equilibrium with a small amount of the cyclohexenyl cation **46**, but the chemical shift positions of this ion



46

are known (9); the *gem*-dimethyl peak is, for example, at a lower field than that expected for the *t*-butyl group in cation **44**. Since a 1-*t*-butyl-substituted cyclopentenyl cation is found to be less stable than the 1-methyl analog (Table 1), it follows, assuming additivity, that the methyl *vs.* H energy difference will be a minimum of 4.6 kcal/mol. Since the energy difference between a secondary and a tertiary alkyl cation is estimated to be 11–14 kcal/mol (10), the value of $\geq$4.6 kcal/mol looks reasonable for an allyl cation case, where the change involved is likely to be less than one-half of that in an alkyl cation. Brouwer and Van Doorn (11), using completely different methods, have estimated this value to be 5.3 kcal/mol in a related cyclopentenyl cation.

Solvent Studies

The equilibrium constant for ions **20** and **21** (see Table 2) was measured in the solvent systems listed in Table 4. These two cations have previously been reported (1). The equilibration reaction is extremely slow in FSO_3H–SbF_5(4:1) and the value reported in Table 4 is possibly not yet the equilibrium one. The aprotic solvent systems were prepared by either evaporating as much FSO_3H as possible from a normal 10% cation – FSO_3H solution and then adding the other solvent or by preparing a very concentrated acid solution and diluting this with the

[c]The error is estimated as ±5% from the scatter obtained in repeated determinations.

other solvent. In the evaporation procedure, it is impossible to remove all of the calculated excess of FSO_3H, an indication of the strength of the solvation forces in these cation salts. In any event, all of the equilibrium constant values are very close to one another and quite possibly identical within the experimental error of the analysis. These results amplify and substantiate those obtained previously (1) and no evidence has yet been found to suggest that differential solvent or counter ion effects are important, although one must concede that the effects in themselves may be important. The subsequent discussion will treat ΔG values as indicative of the internal free energy differences between the cations.

Rate Studies

The rate studies were performed in a similar manner to those previously described (1) and the forward rate constants, using a reversible first order rate expression, for both ions **20** ⇄ **21** and **24** ⇄ **25**, are listed in Table 5. The accuracy of the lower percentage H_2SO_4 rate constants is poor because substantial equilibration occurs during the ion preparation. A plot of the logarithm of the forward rate constants for the *t*-butyl-substituted cations, **24** ⇄ **25** (eq. 5), against the Hammett acidity function, H_0, gives a slope of 0.96, in agreement with the value previously observed for another reaction in which a deprotonation–protonation mechanism has been definitely shown to occur (12). It is possible that other mechanisms are involved in the FSO_3H and related solvent systems.

The equilibrium rate is slightly faster for the *t*-butyl case, reflecting the less stable structure of this ion system. In all of the other ion systems, where no rate studies were made *per se*, the reactions were allowed to stand for periods of time which would have allowed complete equilibration within the practical sense of the word. In all of the *t*-butyl-substituted ions, one must not overdo this since a slow irreversible rearrangement is also occurring. This rearrangement has been described (1).

Discussion

The results may be summarized: (*1*) tetraalkyl-substituted cyclopentenyl cations equilibrate by a deprotonation–reprotonation mechanism; (*2*) the equilibrium constants appear to be a function of only the internal free energy of the two cations involved; (*3*) changes in the steric environment at the β-carbon atom of the alkyl side chain do not significantly affect the equilibrium constants observed. The first two points had previously been assumed in the earlier work (1) and the present results simply provide a sound experimental basis for these assumptions.

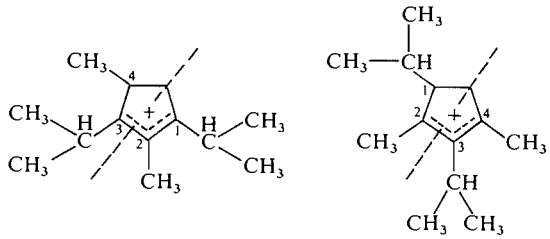
[5] 
24 **25**

[6] 
34 35

The "steric effects" experiments in this work have been cast in such a way that positive information would perhaps have proven a steric argument for our Baker–Nathan order. Since the results are basically negative (Table 2), one might examine the converse proposition, namely, that the absence of a demonstrable steric effect shows that differential C—H hyperconjugation[1] is involved. This is doubtful because it is possible by definition only to vary the β-carbon substitution and there is no guarantee that such changes will mimic changes at the α-carbon center. As pointed out previously, any important steric interactions are likely to be between the alkyl groups and the testing vehicle and one obvious extension of the present work would involve the use of other testing vehicles where the steric interactions, although unknown, could be reasonably supposed to be different.

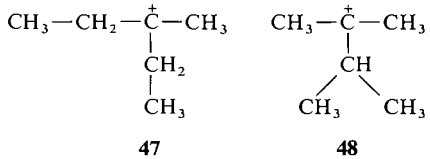
Other Comparison Vehicles

The results from the 2–3-cyclopentenyl comparison (eq. 6) are not in good agreement with the 1–4-comparison although the results are still in the same direction. One drawback in this comparison is the probable presence of some positive charge density at the C-2 position in the cyclopentenyl cations (13). The comparison thus involves two positively changed centers, C-2 and -3, and one can readily see that in the extreme, where δ^+ C-2 = δ^+ C-3, K would be 1 on pure hyperconjugative arguments. In the absence of definitive evidence on the charge density at C-2, one can only surmise that K for this comparison, on hyperconjugation grounds, should be smaller than for a 1–4-comparison. The second compound of this series involves a combined 1–4- and 2–3-comparison and in this case, the result is quite clearly much smaller than expected.

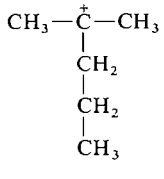


41 42

Still other comparisons of the general type discussed in this work are possible and several of these have been investigated, although not necessarily for the purposes used here. The simplest systems and the ones most likely to show differences in energy because of hyperconjugation would be alkyl cations, where the positive charge is localized. The equilibrium mixtures of the individual isomers in both the *t*-hexyl and *t*-heptyl cations are known and provide no evidence for differential C—H hyperconjugation. Thus, the C-6 system exists at equilibrium with 38% **47**, 30% **48**, and 32% **49**



47 48



49

[1]On fussy scrutiny, our use of the "big four" alkyl group series to test for C—H hyperconjugation has drawbacks. (*1*) Both the ethyl and isopropyl substituents lack local three-fold symmetry and if this allows preferred rotamers to be formed, an entropy factor could be involved in determining the size of the equilibrium constants. (*2*) ΔH and ΔG are assumed to be equal (*3*) C—C hyperconjugation is generally ignored; and (*4*) even if C—C hyperconjugation were included, the extent of delocalization C—H *vs.* C—C may not be a constant as one varies the change density at the testing position.

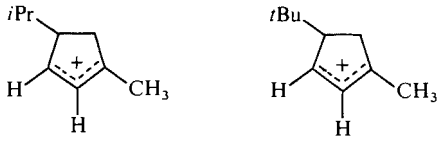
[7]

(14). A more complex procedure would involve comparisons of the type depicted by eq. 7, where for example, $R^1 = R^2 = CH_3$, R^3 = other alkyl. One practical drawback to this experiment is the ease of fragmentation of large alkyl cations (14–16) especially if a *t*-butyl group is present. It also appears likely that direct R—R steric interactions would be involved.

Other allyl cation comparisons are possible in principle. Cations analogous to those studied in this work, in which both the C-2 and -3 positions are substituted by protons, **50** and **51**, are



50 **51**

known, (17, 18) and might be thought to be superior systems. However, these ions are not stable in H_2SO_4 and other rearrangements compete with the equilibration reactions in FSO_3H solvent. The same drawback probably applies to a simple allyl cation comparison vehicle, *e.g.* **52** ⇄ **53** (eq. 8). The 1,3,4-trialkylcyclopentenyl cation system has previously been studied (4), but where R = *t*-butyl, **54** ⇄ **55** (eq. 9), only a lower limit for *K* could be obtained because of a competing rearrangement. The 9,10-dialkyl anthracenium ion system has been studied briefly (19) but this system involves too little charge density at the 9- and 10-positions to be particularly suitable. In the following paper (20), a cyclohexenyl cation system has been examined, but even here, other competing rearrangements make the experiments barely possible.

Other Approaches

Arnett and Larsen (21) have reported calorimetric heats of protonation of alkyl benzenes which correlate well with the Baker–Nathan order. The method appears to be very sensitive but suffers from the disadvantage that one is comparing non-isomeric systems; however an advantage is the fact that it directly gives ΔH values. In more recent results by Larsen (22), using substituted β-diketones, the hyperconjugative explanation for the Baker–Nathan order has been discounted and a steric explanation seems more likely.

Comparisons of Equivalent Cation and Carbanion Equilibria

In theory, perhaps the most suitable way to eliminate steric effects would be to compare isomeric cation and carbanion series, *e.g.* eq. 10. Alkyl groups stabilize a positive charge and this ensures that only two isomeric species will be involved in the cation cases. Even alkyl cations which are completely alkylated but partially

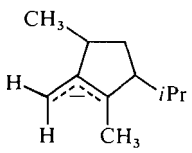
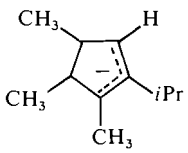
exocyclic to the rings are not observed, *e.g.* **56** (eq. 11), where R^1 = isopropyl in the above formulae. Although the requisite experiments have not been attempted, it can be predicted with some certainty (23) that carbanions of the above type would, in fact, prefer to form structures without alkyl substitution, *i.e.* **57** and **58**.



57



58

It has however been possible in this work to compare cation equilibria with very closely equivalent ketone equilibria, where the charge densities, while not negative, are at least considerably reduced. This involves the comparisons depicted by eqs. 12 and 13. The cation series has previously been reported (4), although the figure for R = *t*-butyl is only a minimum value. The ketones were equilibrated under basic conditions; in the *t*-butyl compound, both pure isomers were available and both were shown to reach the same equilibrium values. The results for the cations and ketones are in the same direction but since the critical *t*-butyl-substituted cation equilibrium constant is not known for certain, the comparisons are rather restricted.

Experimental

General

All boiling points and melting points are uncorrected. Gas chromatography analyses were made on a 6 ft × 1/4 in. 5% SE-30 on Chromosorb W column unless otherwise specified. The n.m.r. spectra of all of the neutral compounds were measured as *ca.* 10% solutions in CCl_4 or $CDCl_3$ either at 60 or 100 MHz. The 220 MHz n.m.r. spectra were recorded by the 220 MHz n.m.r. center, Ontario Research Foundation. All coupling constants are in Hz units, ±0.3 Hz.

3-Methylhepta-2,5-dien-4-one (7)

The general procedure of Normant (24) was used. The Grignard reagent (2-butenyl-2-magnesium bromide), from 136 g (1 mol) of the bromide, was added in a reverse fashion to a solution of crotonic anhydride (184 g, 1.2 mol) dissolved in 1 l of tetrahydrofuran. The tetrahydrofuran solution was cooled to −40° in a Dry-Ice bath (under nitrogen atmosphere), and the Grignard reagent was added through a heated dropping funnel. The addition was carried out over a period of about 2 h. After the addition, the contents of the reaction flask were warmed to 0° in a refrigerator and allowed to stand for 2 days, after which time the reaction mixture was decomposed by pouring it into cold saturated ammonium chloride solution. After work-up, the fraction boiling at 40–90°/8 mm was collected and subsequently refractioned using a spinning band column. Pure 3-methylhepta-2,5-dien-4-one boiled at 72–74°/8 mm, a high boiling

fraction containing crotonic anhydride and crotonic acid was discarded. The yield of the ketone was 35 g (28%); i.r.: 1665 and 1618 cm^{-1}; n.m.r.: 3.14–3.66, (m), (3H), vinyl protons; 8.03 and 8.13, (d), $J = 6.6$ Hz, the C-1 methyl group; 8.05, one-half, the other half is buried under 8.19, each of these peaks is further split into a doublet by the C-5 proton, $J = 1$ Hz, (3H), the C-7 methyl group; 8.19, (3H), the methyl group attached to C-3; refractive index, $n_D^{25} = 1.4842$.

Anal. Calcd. for $C_8H_{12}O$: C, 77.38; H, 9.74. Found: C, 77.20, H, 10.06.

*2,3,4-Trimethylcyclopent-2-en-1-one (**5**)*

This preparation follows the standard Nazarov ring closure (25). 3-Methylhepta-2,5-dien-4-one (8 g, 0.66 mol) was mixed with 4 g of polyphosphoric acid and 12 g of formic acid and placed in a 50 ml flask provided with a magnetic stirring bar and calcium chloride drying tube. The contents of the flask were heated in an oil bath with stirring at 90–100° for a period of 6 h. The reaction mixture was cooled and poured into 200 ml of cold water. After work-up, the residue, on fractional distillation, gave 5.5 g (70% yield) of 2,3,4-trimethylcyclopent-2-en-1-one, b.p. 90° (15 mm); i.r.: 1700 and 1650 cm^{-1}; n.m.r.: 7.25–7.75, (b), (3H), CH and CH_2 protons at C-4 and -5; 8.04, (3H), C-3 methyl protons; 8.38, (3H), C-2 methyl protons; 8.78 and 8.89, (d), $J = 6.6$ Hz, C-4 methyl protons.

Anal. Calcd. for $C_8H_{12}O$: C, 77.38; H, 9.74. Found: C, 77.87; H, 9.33.

The refractive index was n_D^{23} 1.4845, the reported constants are: b.p. 77–78°/11 mm, n_D^{20} 1.4836 (26).

*3-Methylocta-2,5-dien-4-one (**6**)*

2-Butenyl-2-magnesium bromide, from 136 g (1 mol) of 2-bromo-2-butene and 24.3 g (1 mol) of magnesium in tetrahydrofuran solvent, was added in reverse fashion through a heated dropping funnel under a nitrogen atmosphere to a solution of 2-pentenoic anhydride, 216 g (1.2 mol), in 1 l of tetrahydrofuran cooled to −40°. After work-up, fractional distillation of the residue gave 25 g (18% yield) of 3-methylocta-2,5-dien-4-one, b.p. 95–97°/14 mm; i.r.: 1690 and 1645 cm^{-1}; refractive index n_D^{23} 1.4835.

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.21. Found: C, 78.08; H, 10.35.

N.m.r.: 3.2–3.4, (m), the vinyl protons; 7.6–8.0, (m), (2H), the methylene protons; 8.13, one half of a doublet, the other half is buried under 8.23, and appears as a shoulder at 8.25, the peak at 8.13 is further split into a quartet, $J = 2$ Hz, the C-1 methyl protons; 8.23, (3H), the C-3 methyl protons; 8.79, 8.90, and 9.01, (t), $J = 6.6$ Hz, (3H), the C-7 methyl protons.

*4-Ethyl-2,3-dimethylcyclopent-2-en-1-one (**4**)*

3-Methylocta-2,5-dien-4-one, 9.2 g (0.067 mol), was placed in a 50 ml flask and was treated with a mixture of 4 g of polyphosphoric acid and 12 g of formic acid. The reaction mixture was stirred in a nitrogen atmosphere at 90–100° for 6 h and then worked-up. The ketone boiled at 104–105°/15 mm; yield, 5.9 g (65%). This ketone was further purified through the semicarbazide, m.p. 201–203°, after three recrystallizations from methanol.

Anal. Calcd. for $C_{10}H_{17}ON_3$: C, 61.51; H, 8.19. Found: C, 61.36; H, 8.48.

Hydrolysis with 6*N* sulfuric acid for 4 h, work-up, and distillation of the residue (spinning band column) gave the pure ketone, 10.5 g, b.p. 91–92°/8 mm; i.r.: 1715 and 1660 cm^{-1}; refractive index n_D^{23} 1.4804; 100 MHz n.m.r. in $CHCl_3$: 7.2–7.72, the CH and CH_2 protons at C-4 and -5; 7.84, (shoulder); 7.90, 8.08, one more peak is buried under 8.01, the CH_2 of the ethyl group; 8.01, (3H), the C-3 methyl group; 8.33, (3H), the C-2 methyl group; 9.06, 9.13, and 9.205, (t), $J = 7.2$ Hz, the methyl protons of the ethyl group.

*Ethyl 3-Hydroxy-2,4-dimethyl-3-isopropylpentane Carboxylate (**38**)*

The procedure followed the standard Reformatsky reaction conditions (27). From 31.8 g (0.5 g atoms) of Zn, 90 g (0.5 mol) of ethyl α-bromopropionate, and 57 g (0.5 mol) of diisopropyl ketone there was obtained, after fractionation of the crude residue, pure (by g.l.c.) ethyl 3-hydroxy-2,4-dimethyl-3-isopropylpentane carboxylate, b.p. 88–90°/8 mm; 32 g (30% yield); 60 MHz n.m.r. in CCl_4: 5.68, 5.79, 5.92, and 6.03, (q), $J = 6.6$ Hz, (2H), the CH_2 protons of the ethyl group (ester); 6.43, 6.55, 6.67, and 6.79, $J = 7.2$ Hz, (1H), the CH proton at the C-2 position; 7.24–7.74, (m), (2H), the CH protons of the isopropyl groups; 8.60, one-half of a methyl doublet, the other half is buried under 8.74, the C-2 methyl protons; 8.67, 8.74, 8.78, and 8.85, (two doublets), $J = 6.6$ Hz each, (12H), the methyl protons of the isopropyl groups; 8.87, 8.97, 9.07, (t), $J = 6$ Hz, (3H), the methyl protons of the ethyl group (ester).

*Attempted Conversion of **38** into the Cyclopentenone **36***

Cyclopentenones have been prepared (28) from the acid-catalyzed rearrangement of γ-lactones and on this basis, compound **38** was expected to yield the desired cyclopentenone **36**. Accordingly, 4 g (0.02 mol) of the ester, 1 ml of glacial acetic acid, and 30 g of polyphosphoric acid were mixed together in a 100 ml flask and heated in an oil bath at 120° for 2 h. After work-up, distillation of the residue gave an oily compound, b.p. 85–95°/8 mm. This material on g.l.c. analysis appeared to consist of at least four compounds, none corresponding to the desired ketone, as determined from the n.m.r. spectra of the individual components which were separated in small quantities by preparative g.l.c. No attempt was made to establish the structure of the individual components.

*Isopropyl 3-Hydroxy-2,4-dimethylpentane Carboxylate (**37**)*

The above ester was prepared in 70% yield using the Reformatsky reaction, starting with isobutyraldehyde, isopropyl α-bromopropionate, zinc dust, and dry benzene. The ester boiled at 90–91°/8 mm. The 60 MHz n.m.r. spectrum in CCl_4 solution showed: 4.7–5.34, (m), (1H), the CH proton of the isopropyl group (ester); 6.38–6.92, (m), (1H), the CH proton at the C-3 position; 7.15, the —OH proton; 8.14–8.64, (b), (1H), the CH proton at the C-4 position; 8.71 and 8.81, (d), $J = 6$ Hz, the isopropyl methyl protons in the ester function; one peak buried under 8.81, 8.93, 8.98, 9.06, 9.08, 9.12, 9.15, 9.17 (shoulder), the CH_3 protons at the C-4, -5, and -2 positions.

The compound has two asymetric centers so that one likely has two diastereoisomers present (thus accounting for the "extra" peaks in the methyl region).

*3,4-Dimethylcyclopent-2-en-1-one and 2,4-Dimethyl-3-isopropylcyclopent-2-en-1-one (**36**)*

The synthesis of ketone **36** follows a recent general cyclo-

TABLE 6. Fractionation of crude **36**

Weight (g)	Fraction	Boiling range (°C)	Pressure (mm)
2	I	57–60	8
1.5	II	60–61	8
2	III	61–63	8
2	IV	64–74	8
4	V	80–85	8
4	VI	85–90	8

pentenone synthesis reported by Conia and Leriverend (29). The other cyclopentenone is produced via the γ-lactone route, which curiously did not work for the preparation of **36** (see above).

The ester **37**, 30 g (0.15 mol), was mixed with 250 g of polyphosphoric acid in a 500 ml flask equipped with a magnetic stirring bar, a condenser, and a drying tube. A few drops of acetic acid were added and the mixture was initially stirred and then allowed to stand at 100–105° in an oil bath for a period of 1.5 h. The contents were cooled and worked-up by pouring into ice-cold water and then extracting the mixture with (3 × 100 ml) ether.

After washing and drying, the solvent was removed under reduced pressure and the residue was quickly distilled in a small distillation apparatus to give a pale yellow oil. Refractionation in a spinning band column resulted in the fractions shown in Table 6.

The first fraction contained mainly 3,4-dimethylcyclopent-2-en-1-one with about 20% of a low boiling impurity (g.l.c.). Fractions II and III were pure 3,4-dimethylcyclopent-2-en-1-one. Fraction IV contained mainly 3,4-dimethylcyclopent-2-en-1-one, with 10% of a high boiling impurity. Fraction V contained two products whose composition could not be established. Fraction VI contained two products which were separated using preparative g.l.c., Carbowax, 30% on Chromosorb W, column diameter 3/8 in., 12 ft. length, operating at 160°. The compounds had retention times of 13 min 12 s, and 20 min 12 s, respectively, at 100 ml/min He flow rate. The compound with retention time 20 min 12 s was the desired ketone, 2,4-dimethyl-3-isopropylcyclopent-2-en-1-one. The structure of the compound with the retention time of 13 min 12 s could not be established.

The 3,4-dimethylcyclopent-2-en-1-one had the following n.m.r. peaks (60 MHz spectrum in CCl_4 solution): 4.17, (b), (1H), the CH proton at the C-2 position; 6.98–7.83, (b), the CH and CH_2 protons of the ring at the C-4 and -5 positions; 7.90, (3H), the C-3 methyl group protons; 8.83, 8.95, (d), $J = 7.2$ Hz, (3H), the C-4 methyl protons.

The ketone **36** had the following n.m.r. peaks (60 MHz spectrum in CCl_4 solution: 6.87–8.06, a complex region comprising the CH and CH_2 protons of the isopropyl group and the C-4 and -5 protons of the ring; 8.32, 8.35, (d), $J = 1.8$ Hz, (3H), the C-2 methyl protons; 8.72, 8.74, 8.83, and 8.85, (two doublets), $J = 6.6$ Hz each, (9H), the CH_3 protons of the isopropyl group and the C-4 methyl protons.

Alkyl Lithium Reagents

Methyl, ethyl, isopropyl, *t*-butyl, and *sec*-butyl compounds were commercially available. Neopentyl, isobutyl, and *t*-butyl-d_9 compounds were prepared from the corresponding chlorides in pentane solution under an argon atmosphere, using lithium ribbon containing 1% sodium. Periods of reflux up to about 18 h were needed for complete

[a]Unless specified, centers of multiple peaks are quoted relative to internal tetramethylammonium cation = τ 6.90.
[b]The asterisk (*) refers to peaks used in the area analysis for the two ions.
[c]Peaks overlap completely.
[d]Analysis obtained by difference by subtracting the area of the C-4 methyl from the combined C-2 methyls peak.
[e]See Table 3.
[f]See ref. 1 for the undeuterated spectrum description. In both cases, the C-2 methyl groups were used in the analysis.
[g]Analysis obtained by difference. The area under the isopropyl and C-4 methyl peaks of both isomers corresponds to an area 9H. This area divided by three represents a constant 3H area and subtracting the C-2 methyl area from this gives the concentration of **35**.
[h]Buried under the isopropyl methyl protons.

reaction and after this time, the cooled solutions were filtered under argon through a glass wool plug into the storage bottle and stored in a refrigerator under an argon atmosphere. Analysis of the alkyl lithium solutions was done either by acid titration of decomposed aqueous solutions or by the Gilman procedure (30). Attempts to prepare the corresponding lithium compounds from triethylmethyl chloride and 2-chloro-2,3,3-trimethylbutane failed. The solvents tried were anhydrous ether, pentane, petroleum ether, decalin, and tetrahydrofuran. The temperatures varied from refluxing pentane to refluxing decalin. The lithium was, in several instances, converted to a very fine dispersion prior to the attempted reactions. Finally, mixed solvents like pentane-tetrahydrofuran failed. With the ether solvents, a reaction did occur, but the Gilman double titration showed no alkyl lithium formed and it seems likely that the solvent was cleaved by the lithium (with perhaps the incipient formation of the alkyl lithium).

Allylic Alcohols

The alcohols were prepared in a manner similar to previous descriptions (1, 4). The alcohols are not analyzable by g.l.c. because of a facile dehydration but the n.m.r. spectra generally indicate the presence of both the *cis* and *trans* isomers. The spectra are relatively complex in most cases and are chiefly useful to ascertain that there is no unreacted ketone present (also shown by i.r. spectroscopy) and in a general way to indicate that the chemical shift positions and integrations are reasonable. Descriptions of the n.m.r. and i.r. spectra can be found in ref. 31. The data for the alcohols

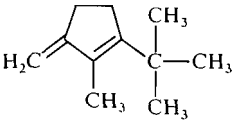
prepared are summarized in Table 7. The yields varied and no attempt was made to optimize the alcohol recovery since the primary considerations were quality not quantity.

1-t-Butyl-2,3-dimethylcyclopent-2-en-1-ol Dehydration Products

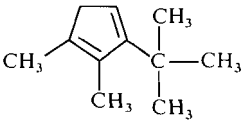
The crude alcohol was prepared by adding *t*-butyl lithium twice to 2,3-dimethylcyclopentenone (8) and working the reaction up in the usual way. An n.m.r. spectrum of the crude product indicated that the desired alcohol had been formed but on attempted distillation through a spinning band column only the dehydrated compounds were obtained, b.p. 38°/0.2 mm.

Anal. Calcd. for $C_{11}H_{18}$: C, 87.93; H, 12.07. Found: C, 87.79; H, 12.27.

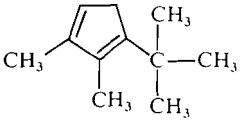
This material was however equally suitable for the desired ion preparation. The n.m.r. spectrum showed two low field broad multiplets at 4.28 and 5.46 (area ratio *ca.* 4:1), the latter being characteristic of exocyclic $=CH_2$ protons and thus giving about 12% of the diene total the structure **63**. The remaining cyclopentadiene is probably a mixture of two isomers **64** and **65** since two *t*-butyl peaks were observed at 8.83 and 9.11 with an area ratio of 2.8:1. The minor peak is therefore clearly not from the exocyclic compound **63**. Other absorptions appropriate for the assigned structures were present.



63



64



65

Preparation of the Cations

The procedures used to prepare the ions and to obtain the equilibrium constants have been described (1, 4). The n.m.r. spectrum of the cation solution immediately after preparation consists mainly of the isomer expected and it is fairly easy, in the first instance, to assign which peaks belong to which ion after equilibration. Many cyclopentenyl cations have been previously prepared and it is not difficult to specifically assign the peaks in most of the n.m.r. spectra. In Table 8, we report those peaks in the n.m.r. spectrum which are distinctive for a particular ion and also indicate which peaks were used in the area analyses. In general, C-1 and -3 methyl groups are rather broad peaks and where two isomers are present, one generally finds only one broad peak for these groups (when present) from both ions. The same considerations apply to the C-4 methine and C-5 methylene protons. In addition, the methylene and methine protons of some of the complex alkyl groups occur in the same general region. All of these peaks are not included in Table 8 but their positions can be found in ref. 31.

Rate Studies

The procedures used have been described in previous publications (1, 4). The samples were kept in a constant temperature bath at 25.0° except during the measurements, which were conducted at 25 ± 1° in the n.m.r. probe.

Base-catalyzed Equilibration of the Ketones

A 100 μl sample of the ketones **61** and **62** (the preparation of these to be reported) was added separately to two vials containing 1 ml of 30% sodium methoxide in methanol and allowed to stand at room temperature. After 2 days, 200 μl of the methanol solution from each of the vials was separately worked-up by diluting with 1 ml of water and extracting with 2 ml of ether. The ether layer was separated and dried over $CaCl_2$. The ether solution was evaporated to about 200 μl and 50 μl of this was injected onto a g.l.c. column (Carbowax, 12 ft × 3/8 in., 200°, He flow 90 ml/min.). Two peaks were observed corresponding to the ketones **61** and **62**, with retention times of 30.8 and 37.5 min, respectively. Identical results were obtained using either sample. The work-up procedure was repeated at intervals of 2 days, each time checking the concentration ratio by g.l.c. analysis. The relative amounts of the two ketones did not further change in successive work-ups. The ratio of the two ketones was found to be 1:1.8.

On the other system, only one of the ketones, *i.e.* **60**, was available (1) and the procedure adopted was similar to that used for **61–62**. The ketones **59** and **60** had retention times of 35.3 and 40.6 min, respectively, at 182°, above column conditions. The ratio of the two ketones was 1:2.8.

The authors wish to thank the National Research Council of Canada for generous financial support.

Equilibria Studies on Tetraalkylcyclohexenyl Cations

K. A. ANANTHANARAYAN AND T. S. SORENSEN

The Department of Chemistry, The University of Calgary, Calgary, Alberta

Received May 15, 1972

A cyclohexenyl cation equilibria which effectively "pits" alkyl groups against one another yields equilibrium constants in the hyperconjugative order direction; however the size of the free energy differences are only about 60% of those observed for the identical cyclopentenyl cation member. The rate of the equilibrium reaction was studied, as was the rate of several aberrant ion–ion rearrangements, one on the *t*-butyl substituted ions causing particular problems. Unfortunately, the results appear consistent with either a steric or a hyperconjugation argument.

Les équilibres entre cation cyclohexènyle qui oppose effectivement les groupes alkyles les uns aux autres, conduisent à des constantes d'équilibre de type hyperconjugaison; cependant les grandeurs des différences d'énergie libre ne sont que de 60% environ de celles observées pour le cation cyclopenténylе analogue. La vitesse de l'équilibration a été étudiée ainsi que celle de plusieurs réarrangements aberrants entre ions, l'un d'eux qui s'effectue sur des ions *t*-butyles substitués, cause des problèmes particuliers. Les résultats apparaissent malheureusement compatibles aussi bien avec l'argument stérique que celui de l'hyperconjugaison.

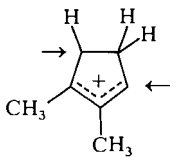
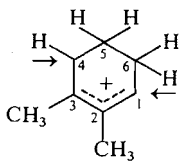
Previously it has been shown (1) that a series of equilibria involving tetraalkyl-substituted cyclopentenyl cations (eq. 1), where R^1 and R^2 are methyl, ethyl, isopropyl, and *t*-butyl groups, give an excellent correlation with the Baker–Nathan order. This result is most directly explained by either differential C—H hyperconjugation or by an unspecified steric effect or perhaps both. If steric effects are involved, then



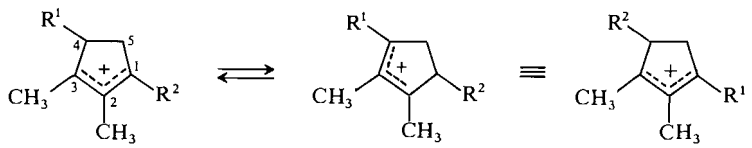


they would most certainly not be direct R^1–R^2 interactions, but in fact, differential interactions of R^1 and R^2 with two non-equivalent sites in the testing vehicle, the 2,3-dimethylcyclopentenyl cation substructure. In the cyclopentenyl system, the two sites are an sp^2 center containing an internal angle smaller than the normal 120° and an sp^3 center flanked by an sp^2 $\overset{\delta+}{C}$—CH_3 center and (assuming a planar molecule) eclipsing protons at C-5. In the corresponding cyclohexenyl ring there are slight differences. The sp^2 center can be substantially closer to 120° and the C-4 and C-5 centers probably involve pseudo axial and equatorial arrangements (2) so that the vicinal interactions are skew. The proposed experiments are not actually dependent on any assumed geometry and the essential point is simply the not unreasonable hope that the steric environment in the two cases will be different. If the various equilibrium constants are due to steric effects, then one would expect the equilibria to be rather sensitive to even small structural changes such as may be involved here. It was of interest therefore to determine whether the equilibrium constants for an analogous series of cyclohexenyl cations would match those of the cyclopentenyl series.

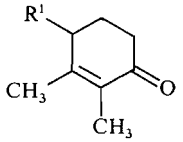
Results

Only one of the cations involved in each equilibrium "pair" was synthesized and this was then allowed to reach an equilibrium with the other isomer. The ions were prepared by the addition of the appropriate allylic alcohol to the strong acid solvents, as described previously for

[1]

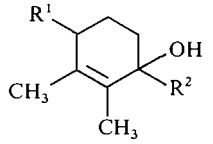


[2] 
the cyclopentenyl system (1, 3). The standard route to the allylic alcohol was as depicted by eq. 2. To prepare all of the possible combinations of R^1 and R^2 = methyl, ethyl, isopropyl, and *t*-butyl, where $R^1 \neq R^2$, requires the three ketones **1**, **2** and **3**. The trimethyl ketone **1** was known (4) and the synthesis of ketones **2** and **3**



1 $R^1 = CH_3$
2 $R^1 = CH_3CH_2$
3 $R^1 = (CH_3)_2CH$

proceeded in the same manner, starting with Hagemann's ester (see Scheme 1). The first step is well known but only methylation (4) has been tried in the second stage. For the base, the use of sodium hydride in toluene was superior to alkoxide–alcohol mixtures. More forcing conditions are required to introduce the ethyl and isopropyl groups and in all cases, the second alkylation produces mixtures of the 2,2- and the 2,4-dialkyl products. Only the 2,4 product (vinylogous β-keto acid) decarboxylates so the separation of the desired ketone is no problem. In preparing the alcohol, the usual problems were encountered with partial enolization of the ketone on R^2Li addition and with the very easy dehydration of the alcohol product (1, 2). The six alcohols **4**–**9** were prepared.



4 $R^1 = Me$; $R^2 = Et$
5 $R^1 = Me$; $R^2 = i$Pr
6 $R^1 = Me$; $R^2 = t$Bu
7 $R^1 = Et$; $R^2 = i$Pr
8 $R^1 = Et$; $R^2 = t$Bu
9 $R^1 = i$Pr; $R^2 = t$Bu

Measurement of the Ion Equilibria

For the equilibrium constant measurements the ions were initially prepared in 95% H_2SO_4 and then allowed to equilibrate at room temperature (< 1 h). As in the cyclopentenyl cation series (1), the analysis involved area measurements of peaks characteristic of each ion and the n.m.r. data for the 12 ions **10**–**21** and the peaks used in the area analyses are reported in Table 1.

Unexpected problems were encountered with all of the *t*-butyl substituted ions. It was anticipated that all of the tetraalkylcyclohexenyl cations would eventually ring-contract to a five-membered cation (2, 5, 6) but this process was

expected to be much slower than the equilibration reactions if sulfuric acid was used as the solvent. To make certain that this reaction was not responsible for the difficulties, we sought first to measure the rate of this reaction and for simplification chose the 1,2,3,4-tetramethyl system **22**, prepared from the allylic alcohol **23** (eq. 3).

At 25.0°, the first order rate constant for **22** → **24** (also prepared unambiguously from 1-isopropyl-2,3-dimethylcyclopent-2-en-1-ol) was 9×10^{-6} s^{-1} in four different sulfuric acid concentrations (91–100%). The reaction is therefore not base-catalyzed. The rate of this reaction is unlikely to be very dependent on the nature of the R^1 and R^2 alkyl groups and where $R^1 \neq R^2$, two different cyclopentenyl cations would be

[5] 
expected under conditions where the equilibration reaction is rapid. Although the rate of the six–five reaction was not measured in the other cases, it was verified that the reaction was very slow on the time scale needed for the six–six equilibration. The rate of this latter equilibration reaction should be dependent on the basicity of the solvent system used (1) and it was desirable to have a rough measure of this. For this study, the rearrangement of ion **13** to the equilibrium mixture of **12** and **13** (eq. 4) was chosen as the representative example since the area analyses are particularly good in this case. The first order rate constants for the forward reaction are reported in Table 2. The results are only approximate for the two weaker acid solvents since substantial rearrangement occurred before the first area measurements could be made. The equilibration reaction is clearly base-catalyzed, thereby implying equilibration mechanism depicted by eq. 5, and in all cases, much faster than the six–five reaction.

†Reference 1.

The fact that the equilibrations are 15–30 times faster in the cyclohexenyl series compared to the cyclopentenyl (Table 2) was expected from the prior results of Deno *et al.* (7) on the pK_a's and H–D substitution rates of both cyclohexenyl and cyclopentenyl cations.

It was clear, therefore, that the problem observed with the *t*-butyl compounds was not due to a six–five reaction. However, this aberrant reaction of the *t*-butyl ions also appeared to be solvent-independent and it proved possible to obtain some equilibrium constant measurements by working in 85% H_2SO_4 at 0°. This percentage of acid is the lowest possible if one wishes to retain relatively sharp peaks for the ion n.m.r. spectra and from extrapolation of the results in Table 2, would be predicted to result in a rapid six–six equilibration, even at 0°. Even so, the aberrant *t*-butyl ion rearrangement eventually causes enough spurious peaks in the n.m.r. spectrum so that one becomes uncertain whether a given peak is in fact a peak of the minor isomer or some other ion peak. Thus, in Table 3, the equilibrium constant figures quoted are minimum values in the case of the *t*-butyl substituted ions.

The aberrant rearrangement was eventually

shown to be as depicted in Scheme 2, using the methyl-*t*-butyl system **14**→**15** as an example. The structural assignments of ions **25** and **26** are based solely on the observed n.m.r. spectra but these are so distinctive that the assignments are unequivocal.

That it is isomer **15** which reacts was shown by dehydrating the alcohol **6** to give the three isomeric dienes **27**, **28**, and **29** (eq. 6), each separated by preparative g.l.c. When these dienes are added to the much stronger acid, FSO_3H, the allylic cations which are formed do not equilibrate with the other isomer. Dienes **28** and **29** produce only ion **15** while diene **27** gives a non-equilibrium mixture of both **15** and **14**. The ion **15** rearranges to the ion **25** with a first-order rate constant of 8.5×10^{-4} s^{-1} at 0°, while ion **14** much more slowly forms a different, unidentified, product, possibly the six–five rearrangement product analogous to ion **24**.

There appears to be an intermediate formed in the conversion of ion **15** to **25** but no definite structural assignment for this ion was possible. The rearrangement reactions in the ethyl–*t*-butyl and isopropyl–*t*-butyl ions are likely to be analogous to **15** but these were not investigated in detail. This rearrangement occurs, however, *only* in the *t*-butyl-substituted ions.

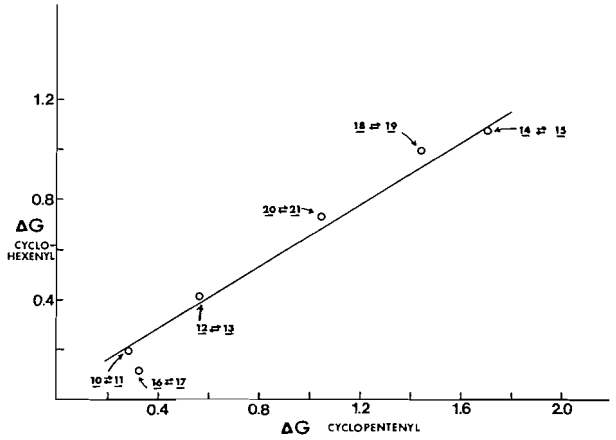

FIG. 1. Linear free energy plot of the related cyclopentenyl and cyclohexenyl cation equilibrium constants.

The aberrant ion **25** further rearranges to the cyclopentenyl cation **26** ($k = 2 \times 10^{-3}$ s^{-1} at 30°), but this process is entirely predictable, based on previous work on very similar systems (2).

Discussion

The equilibrium results for the cyclohexenyl and cyclopentenyl series are compared in Table 3. If one accepts the *t*-butyl-substituted cyclohexenyl ion equilibria as equal to the stated values, then one has an extremely close correlation between the two series and this is shown graphically in Fig. 1. The free energy difference, ΔG, between any two alkyl groups in a cyclohexenyl cation is only about 60% of the value for the corresponding cyclopentenyl series. If all of these equilibrium constants are the result of steric effects, they would have to have occurred because of slightly lower differential steric interactions of the larger alkyl group with the C-1 and -4 positions and to explain the numerical values in both series, the interaction with C-1 would, of necessity, have to be dominant. It is certainly possible that this interaction would be reduced in the cyclohexenyl cations because of the changed situation at C-6 (C-5 in the cyclopentenyl cations).

Simple cyclohexenyl cations are, however, less stable than cyclopentenyl cations for reasons which are not totally understood. One of us has suggested previously (2) that this may be the result of the cyclopentenyl cation possessing a quasi-6π-electron system *or* that direct 1,3 π-overlap stabilization, expected to be stronger in the cyclopentenyl cations, is involved. Paradoxically, if the results of this work are in fact due to differential C—H hyperconjugation, then the cyclohexenyl cations must be less stable because they are less efficient in delocalizing the charge out of the basic allyl cation system into the alkyl substituents, compared to a cyclopentenyl cation.

One has therefore two plausible explanations, admittedly of the assumed cause–expected effect type, each singly based on the effects one is trying to separate. We remain pessimistic that the problem of hyperconjugation can ever be "solved" by using the "big four" alkyl group series, even where the hyperconjugation order is observed.

Experimental

The various instruments and general procedures used in this work are described in the preceding paper (1) together with a description of the various abbreviations used in the text.

Preparation and Analysis of the Cations

The procedures were virtually identical to those used for the cyclopentenyl cations (1). The spectra are actually very similar in many ways and this has helped in assigning the n.m.r. peaks. In Table 1, we report those peaks in the n.m.r. spectrum which are distinctive for the particular cation. In general, the C-1 and -3 methyl groups, where present, absorb about τ 7.2, and since these are broad peaks, they overlap from both isomers of the equilibrium "pair". The same situation exists with the C-4 and -6 protons (*c.a.* 6.5–7.1) and the C-5 protons (*ca.* 8.0).

Kinetic Measurements

The first order cation **22**→ cation **24** rearrangement was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

followed by periodically measuring the n.m.r. spectra of thermostated (25.0°) solutions. The area analysis is not very accurate since the rather broad C_1–C_3 methyl proton peaks had to be used; the cyclohexenyl cation peak coming at τ 7.25 (6H) and the cyclopentenyl at τ 7.09 (3H). The base-catalyzed equilibration reactions (cation **12** ⇄ cation **13**) were carried out at the same temperature and the data were analyzed for reversible first order kinetics. The area analyses used the high field isopropyl methyl peaks of **13** and the C-4 methyl and C-1 isopropyl methyl peaks of **12**. The first order cation **15** → cation **25** kinetics were measured in fluorosulfuric acid at 0° using the *t*-butyl peak in **15** and either the C-4 methyl or C-4 isopropyl methyl peaks in **25**. The first order cation **25** → cation **26** kinetics were measured in fluorosulfuric acid at 25° using the C-2 methyl peaks of each ion for the area analysis.

4-Carboethoxy-2,3-dimethylcyclohex-2-en-1-one

Hagemann's ester (91.8 g, 0.504 mol) was added with stirring to sodium hydride (28 g in 56% oil dispersion, 0.65 mol) in dry toluene solvent (300 ml) at room temperature. After stirring for 2 h, hydrogen evolution ceased and iodomethane (84.5 g, 0.595 mol) was added dropwise together with 2 drops of ethanol and the reaction mixture was refluxed for 8 h. Work-up in the usual way and distillation of the residue through an 18 in. spinning band column (18:1 reflux ratio) gave 87 g (88%) of the title compound, b.p. 139–140°/8 mm, reported (8), 144–146/13 mm. Partial n.m.r. spectrum: 8.74 (t) $J = 6.9$ Hz (3H); 8.26 (3H); 8.05 (3H); 6.77 (m) (1H); 5.85 (q) $J = 7$ Hz (2H).

*2,3,4-Trimethylcyclohex-2-en-1-one (**1**)*

A second methylation, using 51.0 g, 0.256 mol, of the above ester was carried out, as above, to yield a fraction, b.p. 136–155°, containing both the 2,2- and 2,4-dimethyl adduct. This fraction was hydrolyzed with a refluxing (10 h) 10% alcoholic sodium hydroxide solution, under nitrogen. The solvent was stripped off and the solution acidified with 6 *M* HCl at 0°. This mixture was refluxed until carbon dioxide evolution ceased and then cooled and extracted with ether (3 × 30 ml). The combined ether layers were washed twice with dilute sodium carbonate and then water and finally dried over anhydrous $MgSO_4$. Distillation of the residue through a spinning band column gave 6.2 g (18%) of the title compound, b.p. 93–98°/8 mm. N.m.r.: 8.79 (d) $J = 6.9$ Hz (3H); 8.30 (3H); 8.09 (3H); i.r.: 1675 and 1645 cm^{-1}; semicarbazone 208–210°, reported (4), 210°.

*4-Ethyl-2,3-dimethylcyclohex-2-en-1-one (**2**)*

The preparation of **1** was followed (except that a 36 h reflux was used) using iodoethane. The carboethoxy compound had b.p. 141–148°/8 mm and the title ketone b.p. 98–102°/8 mm. The overall yield was 19%. N.m.r.: 9.00 (t) $J = 7$ Hz (3H); 8.32 (3H); 8.10 (3H); i.r.: 1675 and 1635 cm^{-1}; semicarbazone had m.p. 192–194°.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.9; H, 10.59. Found: C, 79.02, H, 10.48.

*4-Isopropyl-2,3-dimethylcyclohex-2-en-1-one (**3**)*

The preparation of **1** was followed (72 h reflux) using isopropyl iodide. The carboethoxy compound had b.p. 137–147°/8 mm and the title compound b.p. 48.5–51°/0.05 mm. N.m.r.: 8.98 and 9.15, two (d), $J = 6.2$ Hz each (3H each); 8.28 (3H); 8.08 (3H); i.r. 1678, 1650, 1378, and 1372 cm^{-1}. In another preparation, a very impure product was obtained which necessitated a preparative g.l.c. separation to obtain the pure title compound.

The Allylic Alcohols

These were prepared in a manner similar to previous descriptions (1–3). The n.m.r. spectra of these indicate the presence of both *cis* and *trans* isomers and the n.m.r. spectra are therefore quite complex. Descriptions of the n.m.r. and i.r. spectra can be found in ref. 9.

*1,2,3,4-Tetramethylcyclohex-2-en-1-ol (**23**)*

The compound had b.p. 75–77°/0.5 mm, yield 85%.

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.87; H, 11.76. Found: C, 78.36; H, 11.73.

*1-Isopropyl-2,3,4-trimethylcyclohex-2-en-1-ol (**5**)*

The compound had b.p. 85–92°/0.35 mm, yield 86%.

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.06; H, 12.16. Found: C, 78.79; H, 12.41.

*1-t-Butyl-2,3,4-trimethylcyclohex-2-en-1-ol (**6**)*

The compound had b.p. 75–82°/0.05 mm.

Anal. Calcd. for $C_{13}H_{24}O$: C, 79.53; H, 12.32. Found: C, 79.25; H, 12.23.

*4-Ethyl-1,2,3-trimethylcyclohex-2-en-1-ol (**4**)*

The compound had b.p. 57–59°/0.15 mm.

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98. Found: C, 76.17; H, 11.41.

*1-Isopropyl-2,3-dimethyl-4-ethylcyclohex-2-en-1-ol (**7**)*

The compound had b.p. 82–89°/0.2 mm.

Anal. Calcd. for $C_{13}H_{24}O$: C, 79.53; H, 12.32. Found: C, 79.88; H, 11.80.

*1-t-Butyl-2,3-dimethyl-4-ethylcyclohex-2-en-1-ol (**8**)*

The compound had b.p. 87–92°/0.1 mm.

Anal. Calcd. for $C_{14}H_{26}O$: C, 79.94; H, 12.46. Found: C, 80.85; H, 11.88.

*1-t-Butyl-2,3-dimethyl-4-isopropylcyclohex-2-en-1-ol (**9**)*

The compound had b.p. 124–127°/0.8 mm.

Anal. Calcd. for $C_{15}H_{28}O$: C, 80.29; H, 12.58. Found: C, 80.38; H, 12.46.

*Dehydration of Alcohol **6***

Alcohol **6** was dehydrated in the injection port (220°) of a g.l.c. column and the alkenes separated using a 6 ft × 1/4 in. column of 20% SE-30 on Chromosorb W at 124°. He flow 30 ml/min, employing sample sizes of 25 μl. The n.m.r. spectra are definitive in distinguishing the three isomers, one has =CH—, one has $=CH_2$, and the remaining one has no low field peaks.

*Low Retention Product (58 min, 37% of the total): 3-t-Butyl-1,2,6-trimethylcyclohexa-1,3-diene (**28**)*

Partial 100 MHz n.m.r.: 9.185 (d) $J = 6.5$ Hz (3H); 8.85 (9H); 8.24 (b) (3H); 8.12 (b) (3H); 4.5 (m) (1H).

*Middle Retention Product (73 min, 43% of the total): 1-t-Butyl-2,4-dimethyl-3-methylenecyclohex-1-ene (**29**)*

Partial 100 MHz n.m.r.: 8.965 (d) $J = 6.5$ Hz (3H); 8.79 (9H); 8.04–8.14 (b); 5.15 (b) and 5.35 (b) (2H).

*High Retention Product (85 min, 20% of the total): 4-t-Butyl-1,2,3-trimethylcyclohexa-1,3-diene (**27**)*

Partial 100 MHz n.m.r.: 8.81 (9H); 8.26, 8.15, 8.13 (9H).

Received May 2, 1972

The structures of transient 1,3-complexes **2** and stable 1,1-complexes **3** formed by the reaction of methoxide ion with various 4-X-2,6-dinitroanisoles in DMSO-d_6 are confirmed by n.m.r. spectroscopy. ^{13}C satellites in the proton spectra of anisoles and 1,1-complexes have been used to obtain $^1J_{^{13}C-H}$ as well as $^4J_{H-H}$ in these symmetrical compounds.

The chemical shifts of the ring protons in 1,3- and 1,1-complexes give some information concerning the influence of the substituent X on the delocalization of the negative charge. In anisoles and 1,1-complexes, $^1J_{^{13}C-H}$ of the ring protons are mainly dependent on the inductive effect of X. Furthermore, a linear relationship is observed in anisoles between the chemical shift as well as $^1J_{^{13}C-H}$ of the methoxyl protons and the Hammett σ_p constant of X, thus suggesting an identical geometry of these molecules at C-2, -1, and -6.

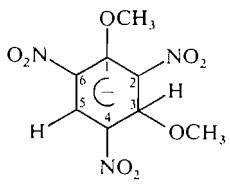
Les structures des complexes -1,3 et -1,1 de Meisenheimer **2** et **3** formés lors de l'interaction des ions CH_3O^- avec divers dinitro-2,6 anisoles X-4 substitués dans le DMSO-d_6 ont été confirmées par r.m.n. Les satellites du ^{13}C des spectres des anisoles et des complexes-1,1 ont permis de déterminer les constantes de couplage $^1J_{^{13}C-H}$ et $^4J_{H-H}$ dans ces composés symétriques.

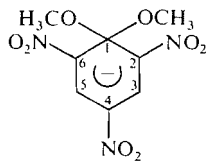
Les déplacements chimiques des protons du cycle des complexes -1,3 et -1,1 mettent en évidence l'influence du substituant X sur la délocalisation de la charge négative. Dans les anisoles et les complexes-1,1, les couplages $^1J_{^{13}C-H}$ des protons du cycle dépendent principalement de l'effet inductif du substituant X. De plus, les déplacements chimiques et les couplages $^1J_{^{13}C-H}$ des protons méthoxylés des anisoles varient linéairement avec la constante de Hammett σ_p du substituant, ce qui suggère que tous ces composés ont une géométrie identique au niveau des C-2, -1, et -6.

Canadian Journal of Chemistry, **50**, 3558 (1972)

Introduction

Servis first observed by n.m.r. spectroscopy that the reaction of methoxide ion with 2,4,6-trinitroanisole in DMSO results in the fast initial formation of the 1,3-complex followed by the slower appearance of the more stable 1,1-complex (1, 2).





Other workers observed similar results not only with 2,4,6-trinitroanisole but also with 4-cyano-2,6-dinitroanisole and 3,5-dinitro-4-methoxypyridine (3–10). More recently we obtained evidence for the formation of a number of 1,3-complexes from extensive rapid kinetic studies of this reaction with various 4-X-2,6-dinitroanisoles (11–15).

In order to substantiate the structure of the new transient 1,3-complexes thus detected, we have undertaken a thorough n.m.r. study of these reactions. Such an investigation could also be expected to yield interesting information concerning the influence of the substituent X on n.m.r. parameters of anisoles and corresponding 1,3- and 1,1-complexes.

Because of the symmetrical structures of anisoles and 1,1-complexes, the coupling constant $^4J_{H_3-H_5}$ could not be obtained from the proton spectra of these species. So we were led to examine the ^{13}C satellites which could be expected to yield $^1J_{^{13}C-H}$ as well as $^4J_{H_3-H_5}$ coupling constants.

Experimental

Materials

Anisoles

2,4,6-Trinitroanisole (Eastman Kodak) was recrystallized from aqueous methanol and dried *in vacuo*, m.p. 68°. Prepared and purified as previously described were 2,6-dinitroanisole (m.p. 118°) (16) and the following 4-X-2,6-dinitroanisoles: 4-chloro (m.p. 65°) (17), 4-cyano (m.p. 114°) (9, 18), 4-fluoro (m.p. 83°) (19), 4-trifluoromethyl (m.p. 60°) (20), 4-benzoyl (m.p. 107°) (21, 22).

4-Trifluoromethylsulfonyl-2,6-dinitroanisole was prepared by adding dropwise a mixture of 4 ml of fuming nitric acid (density 1.52) and 4 ml of concentrated sulfuric acid to a stirred and cooled (*ca.* 20°) solution of 500 mg 4-trifluoromethylsulfonyl-2-nitroanisole (23) in 4 ml concentrated sulfuric acid. The reaction mixture was heated slowly to 70° and maintained at 70–80° for 2 h. After cooling to room temperature, the solution was poured onto crushed ice (100 g) and the precipitated dinitro compound was filtered, washed with cooled water, recrystallized from carbon tetrachloride or chloroform, and dried *in vacuo*, m.p. 59°.

Anal. Calcd. for $C_8H_5F_3N_2O_7S$: C, 29.10; H, 1.52; N, 8.48; S, 9.68. Found: C, 29.54; H, 1.79; N, 8.59; S, 9.39.

The same procedure was used to prepare 4-methylsulfonyl-2,6-dinitroanisole from 4-methylsulfonyl-2-nitroanisole except that the reaction mixture was stirred at 50° for 1 h and the white crystals formed were recrystallized from methanol, m.p. 206°.

Anal. Calcd. for $C_8H_8N_2O_7S$: C, 34.79; H, 2.92; N, 10.14; S, 11.60. Found: C, 34.58; H, 3.25; N, 9.98; S, 11.67.

Isolable 1,1-Complexes

Potassium 1,1-dimethoxy-2,4,6-trinitro- or -4-cyano-2,6-dinitrocyclohexadienates were prepared as previously described by the addition of nearly 1 equiv of 5.85 *M* methanolic potassium methoxide to a solution of corresponding anisoles in a mixture of methanol and dioxane (9). The same procedure was used to prepare analogous adducts from 4-methylsulfonyl and 4-benzoyl-2,6-dinitroanisoles. Since these salts contained some dioxane of crystallization (9) the analyses were found to be rather poor, but their purity was greater than 98% by n.m.r. integration.

Because of its very high stability, we succeeded in preparing potassium 1,1-dimethoxy-4-trifluoromethylsulfonyl-2,6-dinitrocyclohexadienate by the addition of nearly 1 equiv of 1 *M* methanolic potassium methoxide to a solution of the parent molecule (100 mg) in a minimum amount of methanol. The reaction mixture turned immediately deep orange and was allowed to stand at room temperature for 15 min. Then, the solvent was removed under vacuum and the residue, collected as an orange solid, washed with dry benzene (or anhydrous ether), and dried *in vacuo* to constant weight in order to eliminate any associated solvent.

Anal. Calcd. for $C_9H_8F_3KN_2O_8S$: C, 27.00; H, 2.01; N, 7.00; S, 8.01. Found: C, 26.89; H, 2.15; N, 7.05; S, 8.22.

Nuclear Magnetic Resonance Measurements

N.m.r. spectra at 60 MHz were obtained with a Varian A-60 spectrometer at 37° (probe temperature) or between 20 and 25°, using TMS as an internal standard. Chemical shift data were taken from spectra determined at a sweep width of 500 Hz.

The transient 1,3-complexes were generated *in situ* by a dropwise addition of 5.85 *M* methanolic potassium methoxide to solutions of anisoles **1** in DMSO-d_6 (*ca.* 40 mg **1** in 0.6 ml $(CD_3)_2SO$). The spectrum of solutions was determined rapidly after each addition of methoxide ion and scanned repeatedly until no further changes were observed. After the addition of 1 equiv of base, the spectra consisted only of the signals associated with 1,1-complexes **3** and generally remained unchanged for several hours. The half-time of the transient species was often too short for an accurate determination of the $^4J_{H_3-H_5}$ coupling constant, whose order of magnitude, however, has been indicated.

In order to investigate ^{13}C satellites of anisoles and 1,1-complexes the spectra of these compounds were also recorded at 100 Hz on a Varian XL-100-12 spectrometer at the probe temperature (32°) and using TMS for field/frequency lock. ^{13}C satellites of ring protons and methoxyl protons were observed respectively from spectra at sweep widths of 250 and 500 Hz, using various sweep times.

Results and Discussion

1,3-Dimethoxy-4-X-2,6-dinitrocyclohexadienates (1,3-Complexes, 2)

Addition of a drop of 5.85 *M* methanolic potassium methoxide to solutions of 4-X-2,6-dinitroanisoles **1** (X = Cl, CO—C_6H_5, CF_3, SO_2CH_3, SO_2CF_3) in DMSO-d_6 results in an immediate decrease in the intensity of the signals due to **1** and the appearance of a transient two proton AX system with weak coupling constant ($^4J_{H_3-H_5}$ = 1.3–1.8 Hz) and two transient methoxyl singlets at higher field (Fig. 1).

Whereas the lower field doublet is consistent with the sp^2 hybrid environment for the proton H-5 of the 1,3-complexes **2**, the higher field doublet is attributed to the proton H-3 attached to the sp^3 hybridized carbon. Similar conclusions can be drawn from a comparison of the chemical shifts of the lower and the higher field

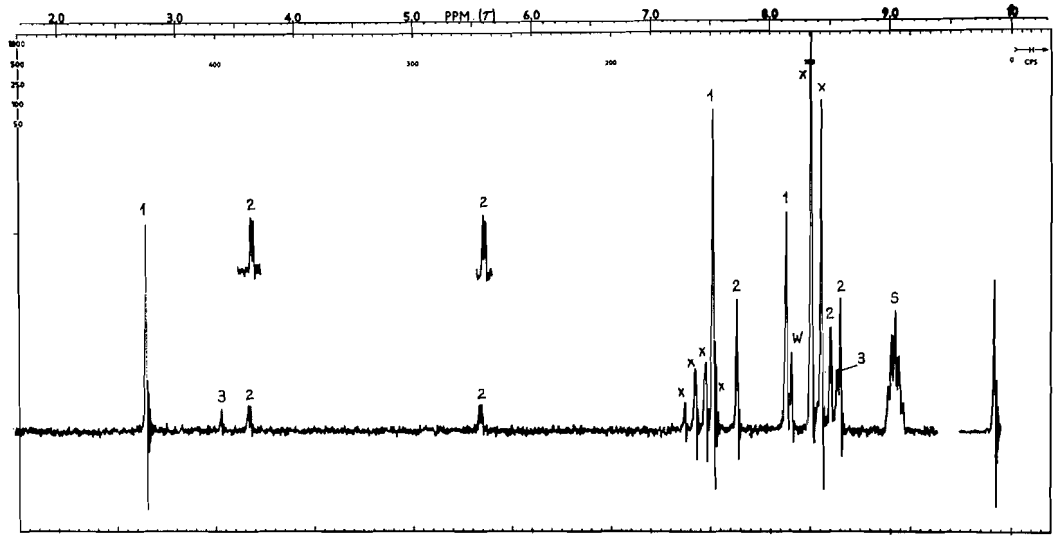

FIG. 1. The n.m.r. spectrum (60 MHz) for the reaction of methoxide ion with 4-methylsulfonyl-2,6-dinitroanisole in DMSO-d_6. Resonance of anisole, 1,3- and 1,1-complexes are identified with structure numbers **1**, **2**, **3**. Other resonances: s, solvent; x, methanol; w, H_2O.

singlets which are assigned respectively to the methoxyl protons of the sp^2 C-1 and the sp^3 C-3 carbons of **2**. Unfortunately, we were not always able to identify both of these methoxyl singlets because of resonances of methanol appearing in the same region of the spectrum.

In agreement with recent kinetic studies (11), this set of transient signals disappears more quickly with decreasing electron-withdrawing power of the substituent X and we detect concurrently the signals due to the formation of the 1,1-complexes **3**. Similar behavior is observed with the addition of a second drop of potassium methoxide, but as soon as the amount of base reaches 1 equiv, only the signals associated with 1,1-complexes **3** can be seen in the spectrum.

The results are summarized in Table 1 which also includes those previously reported for 4-cyano-2,6-dinitroanisole (9) and 2,4,6-trinitroanisole (1, 2, 5, 9, 24). The results for the

chloro derivative are in agreement with those recently published by Crampton *et al.* (24). Concerning 2,4,6-trinitroanisole, it must be noted that the literature indicated very different values for the chemical shift of the methoxyl group on the sp^2 C-1 of the 1,3-complex. As can be seen from Table 1, the values reported by Servis (1), Foster *et al.* (5) and Crampton *et al.* (24) appear consistent with the observed influence of the substituent X on this chemical shift, as opposed to the values reported by Servis (2) and Fendler *et al.* (9). Indeed, by reinvestigating the reaction of CH_3O^- ions with 2,4,6-trinitroanisole, at 100 MHz, we found a value in good agreement with the results of Crampton *et al.* (24).

We were not able to detect by n.m.r. the 1,3-complex from 4-fluoro-2,6-dinitroanisole, although we did succeed in identifying it kinetically (12). The corresponding spectrum appeared broadened, thus suggesting the presence of free radicals. A similar situation was recently encountered with 2-fluoro-4,6-dinitroanisole, and in this case, an e.p.r. signal was detected (25).

With the exception of 1,3-dimethoxy-2,4,6-trinitrocyclohexadienate, the chemical shift of the H-5 proton in 1,3-complexes **2** is found to increase roughly as a function of the Hammett σ_R constant of the substituent X, thus suggesting that the delocalization of the negative charge in **2** occurs mainly through the resonance structure **4**. Indeed, this result is not unexpected because it is in agreement with the very high capacity to resonance of a para nitro group (9, 26, 27). The abnormal behavior of the trinitro derivative with respect to this series would be due to the fact that, if $X = NO_2$, the contribution of the resonance structure **5** should not be neglected.

5

4-X-2,6-Dinitroanisoles and 1,1-Dimethoxy-4-X-2,6-dinitrocyclohexadienates

In order to observe ^{13}C satellites, the proton spectra of anisoles and isolable 1,1-complexes ($X = CO—C_6H_5$, CN, SO_2CH_3, NO_2, SO_2CF_3) were recorded at 100 MHz by using somewhat concentrated solutions in DMSO-d_6 (about 100 mg **1** or **3** in 0.6 ml $(CD_3)_2SO$). ^{13}C satellites could also be observed in the 4-trifluoromethyl-1,1-complex ($X = CF_3$) generated *in situ*, but similar attempts with fluoro and chloro derivatives were unsuccessful.

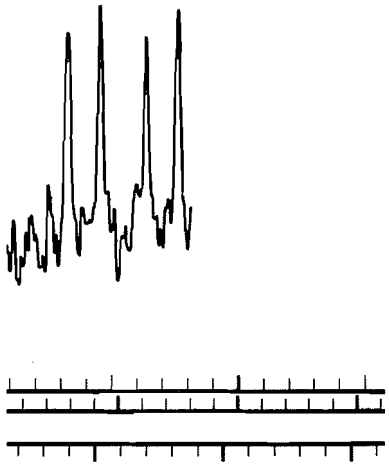

FIG. 2. The downfield ^{13}C satellite of the ring protons of 4-fluoro-2,6-dinitroanisole (100 MHz).

The ^{13}C satellites of methoxyl protons in **1** and **3** consist of a doublet, thus giving directly $^1J_{^{13}C-H}$. On the other hand, the ^{13}C satellites of the two equivalent ring protons H-3,5 in **1** and **3** consist of two doublets (and two quadruplets if X = F, Fig. 2). The two ring protons H-3,5 and the ^{13}C nucleus constitute an AA'X system, which depends on the relative values of $^1J_{^{13}C-H}$, $^3J_{^{13}C-H}$ and $^4J_{H_3-H_5}$. However, as pointed out by Schaefer and co-workers, $^3J_{^{13}C-H}$ and $^4J_{H_3-H_5}$ being much lower than $^1J_{^{13}C-H}$, a first-order analysis neglecting the long range coupling constants gives $^1J_{^{13}C-H}$ with an error of about 0.1 Hz (28).

In agreement with previous findings (29, 30), upfield and downfield positions of the ^{13}C satellites indicate a positive (upfield) ^{13}C isotope effect on the proton chemical shift, of the order of 0.1–0.3 Hz. This effect is small, but it must be noted that the $^1J_{^{13}C-H}$ values which were determined only from the downfield satellites have an additional uncertainty. This was the case for $X = CO—C_6H_5$ in **1** and **3** in which only

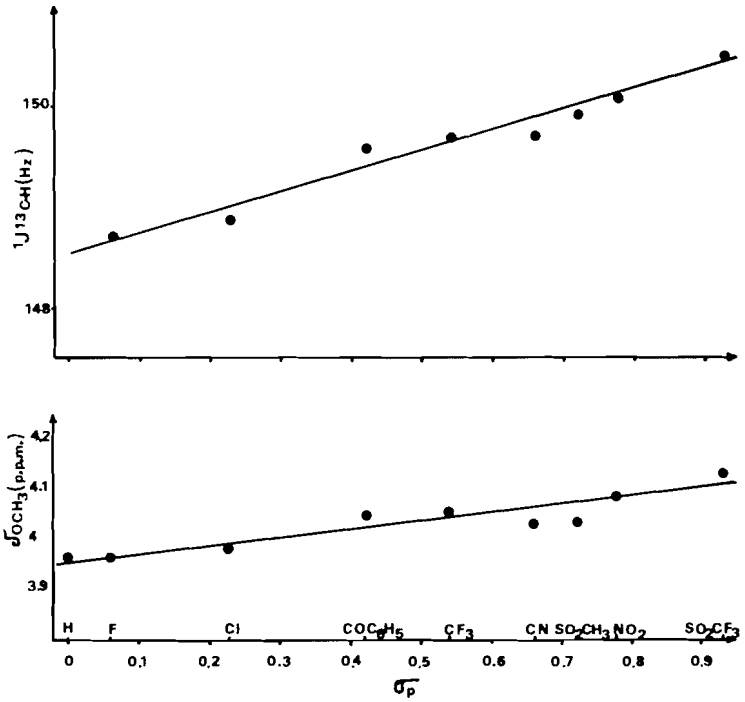

FIG. 3. Plots of δ_{OCH_3} and $^1J_{^{13}C-H}$ of methoxyl protons *vs.* σ_p for 4-X-2,6-dinitroanisoles. The δ value for X = H was taken from ref. 8.

the downfield satellite was observed, the high-field one overlapping with the absorption of the aromatic protons.

The results are listed in Table 2.

4-X-2,6-Dinitroanisoles

As previously observed for monosubstituted anisoles and other systems (35, 36) a rather good linear relationship exists between the Hammett σ_p constant of the substituent X and the chemical shift δ_{OCH_3} as well as the coupling constant $^1J_{^{13}C-H}$ of the methoxyl protons in anisoles **1** (Fig. 3).

Such relations imply that all these 4-X-2,6-dinitroanisoles exhibit a similar geometry at C-2, -1, and -6. More significantly, taking into account the X-ray study reported for 2,4,6-trinitrophenetole (37), it turns out that the methoxyl group lies in the plane of the ring while the nitro groups at the ortho positions are twisted out of this plane.

Furthermore, compared to the value reported for anisole (35) ($^1J_{^{13}C-H}$ = 143 Hz), the value of $^1J_{^{13}C-H}$ appears to be strongly increased. This result can be rationalized by considering the electron-withdrawing capacities of two nitro groups and the X substituent in **1**.

Whereas attempts to correlate the chemical shift of the protons H-3,5 in the ortho positions to X with substituent constants give poor results, the corresponding coupling constant $^1J_{^{13}C-H}$ is found to correlate fairly well with the inductive σ_I constant. This trend indicates that the hybridization of C-3,5 (38) and/or their effective nuclear charge (39) are mainly dependent on the inductive effect of the ortho substituent X.

The value of $^1J_{^{13}C-H}$ for ring protons, higher in anisoles **1** than in benzene (40) ($^1J_{^{13}C-H}$ = 157.5 Hz) appears to be normal, considering the attractive effect of four substituents attached to the ring in **1**.

The meta coupling constant $^4J_{H_3-H_5}$, which is known to be positive (47), varies with the nature of the X substituent from 2.1 Hz (X = SO_2CF_3) to 3.1 (X = F). Castellano and Kostelnik and Schaefer and co-workers have demonstrated the additivity of substituent effects on the proton–proton coupling constants in some di- and tri-substituted aromatic substrates (41, 42). If such an additivity scheme is valid

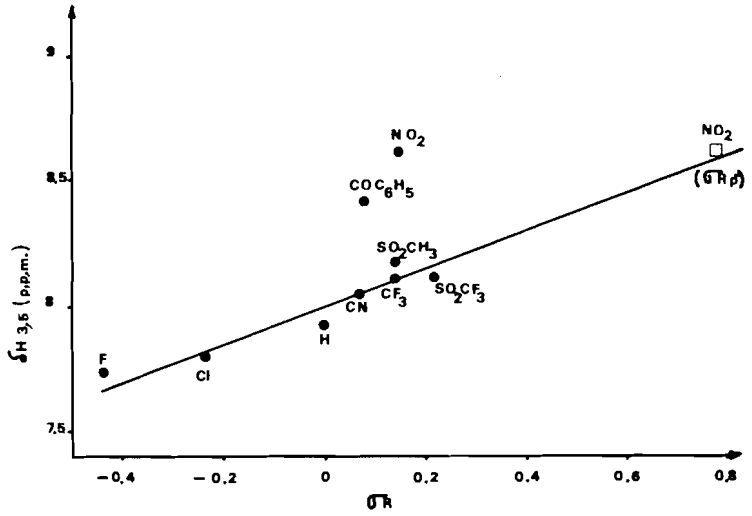

FIG. 4. Plot of $\delta_{H_{3,5}}$ *vs.* σ_R for 1,1-dimethoxy-4-X-2,6-dinitrocyclohexadienates 3. The δ value for X = H was taken from ref. 8.

TABLE 3. Predicted and observed meta coupling constants in 4-X-2,6-dinitroanisoles

X	ΔJ^X_{2-6}	J^m_{3-5} (predicted)	J^m_{3-5} (experimental)	Difference
Cl	0.88	2.20	2.6	-0.4_0
NO_2	1.03	2.35	2.8	-0.4_5
F	1.37	2.69	3.1	-0.4_1

for tetrasubstituted derivatives, such as 4-X-2,6-dinitroanisoles, J^m_{3-5} would be deduced from eq. 1 where J^B_m is the unperturbed coupling

[1] $$J_m = J_{3-5} = J^B_m + \Delta J^{OCH_3}_{3-5} + 2\Delta J^{NO_2}_{2-4} + \Delta J^X_{2-6}$$

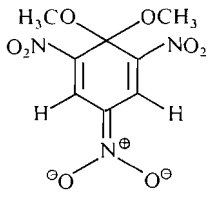
constant in benzene and ΔJ values for the substituents are derived from the corresponding monosubstituted aromatic compounds. The ΔJ values are known for Cl, F, NO_2 (42); for OCH_3, it can be deduced from J_m in anisole (43, 44).

As can be seen from Table 3, the predicted values are lower than the experimental ones, but their difference is found to be nearly constant in these three cases. However, changing the substituent X from Cl to NO_2 or F causes a similar increase in ΔJ^X_{2-6} and in the experimental values of J^m_{3-5}. Although the solvent is different, this suggests that the failure of Schaefer's additivity scheme to reproduce J^m_{3-5} in 4-X-2,6-dinitroanisoles arises from the twisting of the nitro groups at C-2 and -6 out of the plane of the ring. Such a twisting would make $\Delta J^{NO_2}_{2-4}$ less negative in eq. 1, thus increasing the value of J^m_{3-5}.

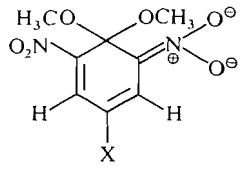
1,1-Dimethoxy-4-X-2,6-dinitrocyclohexadienates (1,1-Complexes, 3)

As could be expected from the tetragonal hybridization of C-1, the chemical shift of methoxyl protons in 1,1-complexes 3 is relatively insensitive to the nature of the X substituent.

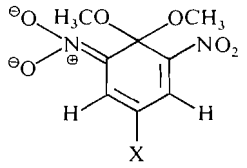
On the other hand, except for the nitro and benzoyl groups, a fairly good linear relationship is observed between chemical shift of the H-3,5 protons attached to sp^2 carbons and the Hammett σ_R constant (Fig. 4). Although these chemical shifts could be influenced by the



6



7



8

anisotropic effects of the substituent, it must be pointed out that the use of the $\sigma_{R_p^-}$ constant (0.78) for the nitro group (45) allows the corresponding value of $\delta_{H_{3,5}}$ to be placed on the linear graph. This result suggests, in agreement with LCAO calculations previously reported by Zollinger and co-workers (27), that the nitro group para to C-1 carries a very large portion of the negative charge in the 1,1-complex derived from 2,4,6-trinitroanisole (resonance structure **6**). In the other 1,1-complexes, delocalization through resonance structures **7** and **8** should not be negligible.

The coupling constant $^1J_{^{13}C-H}$ in **3** changes according to a similar sequence to that found in anisoles **1**, *i.e.* increases with increasing values of σ_I.

In addition, as already observed for 1,1-complexes of 2-X-4,6-dinitroanisoles (25), the magnitude of the coupling $^4J_{H_3-H_5}$ appears to be very close to that found in molecules **1**, thus suggesting that the geometry of the ring at C-3, -4, and -5 is similar in **3** and **1**. This result is consistent with crystallographic studies of 2,4,6-trinitrophenetole and the corresponding diethoxy-1,1-complex (37, 46).

A Nuclear Magnetic Resonance Study of Norbornadiene Partially Oriented in a Nematic Phase

E. E. BURNELL[1] AND P. DIEHL

Department of Physics, University of Basel, Basel, Switzerland

Received May 10, 1972

The n.m.r. spectrum of norbornadiene partially oriented in a nematic phase has been measured, and the geometry of the proton skeleton has been determined. The results are compared with several electron diffraction studies, and are only consistent with those in which the angle $C_1C_7C_4$ is approximately 92°.

Nous avons analysé le spectre r.m.n. du norbornadiène partiellement orienté dans une phase nématique en vue de déterminer la géométrie du squelette protoné. Les résultats ont été comparés à ceux obtenus dans plusieurs études utilisant la diffraction des électrons et concordent uniquement lorsque l'angle $C_1C_7C_4$ vaut approximativement 92°.

Canadian Journal of Chemistry, **50**, 3566 (1972)

Introduction

Small ring cyclic molecules have been of special interest to the theoretical chemist because of their strained geometries. Among this group is norbornadiene (Fig. 1). Many electron diffraction studies have been carried out to determine the molecular geometry (1–5), but this method is inaccurate in the determination of proton coordinates. In addition, Yokozeki and Kuchitsu (5) find that the angle $C_1C_7C_4$ cannot be determined with precision (see caption to Fig. 1). A further difficulty with the electron diffraction studies is that they are not consistent within themselves.

Molecules oriented in nematic solvents give accurate information about the relative proton coordinates (6). Thus, a study of norbornadiene was carried out in an attempt to determine which of the electron diffraction studies is the most plausible, and to obtain values of the angles containing protons. The various effects of nuclear motions (7) are neglected.

Experimental

A spectrum (Fig. 2) of 19 mol % norbornadiene oriented in the nematic phase of *N*-(*p*-ethoxybenzylidene)-*p'*-*n*-butylaniline was recorded on a Varian HR-220 spectrometer

[1]Permanent address: Chemistry Department, University of British Columbia, Vancouver 8, British Columbia.

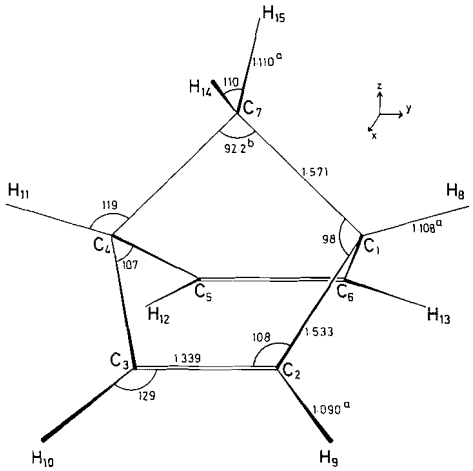

FIG. 1. Norbornadiene (bicyclo [2.2.1] hepta-2,5-diene). The angles (in degrees) and the bond lengths (in Å) are obtained from a combination of the electron diffraction data of case I of ref. 5, and the present n.m.r. study (see text). ⊖, the angle between the $C_1C_2C_3C_4$ plane and the $C_1C_6C_5C_4$ plane, is 114.7°. The angle that the $C_2C_3H_{10}H_9$ plane is bent from the $C_1C_2C_3C_4$ plane is 4°, H_9 and H_{10} moving in the negative *z* direction.

(*a*) Values recalculated from least squares fit (see text). The electron diffraction values are $r_{1,8} = r_{7,15} = 1.109$ Å; $r_{2,9} = 1.0896$ Å (assumed).

(*b*) For the angle $C_1C_7C_4$, other electron diffraction studies give: $96.7 \pm 2.3°$ (1); 96.5° (2); $92.0 \pm 0.8°$ (3); $99.5 \pm 0.6°$ (and other cases, but always >96°) (4); $96.0 \pm 0.2°$ and $94.1 \pm 3.0°$ (5).

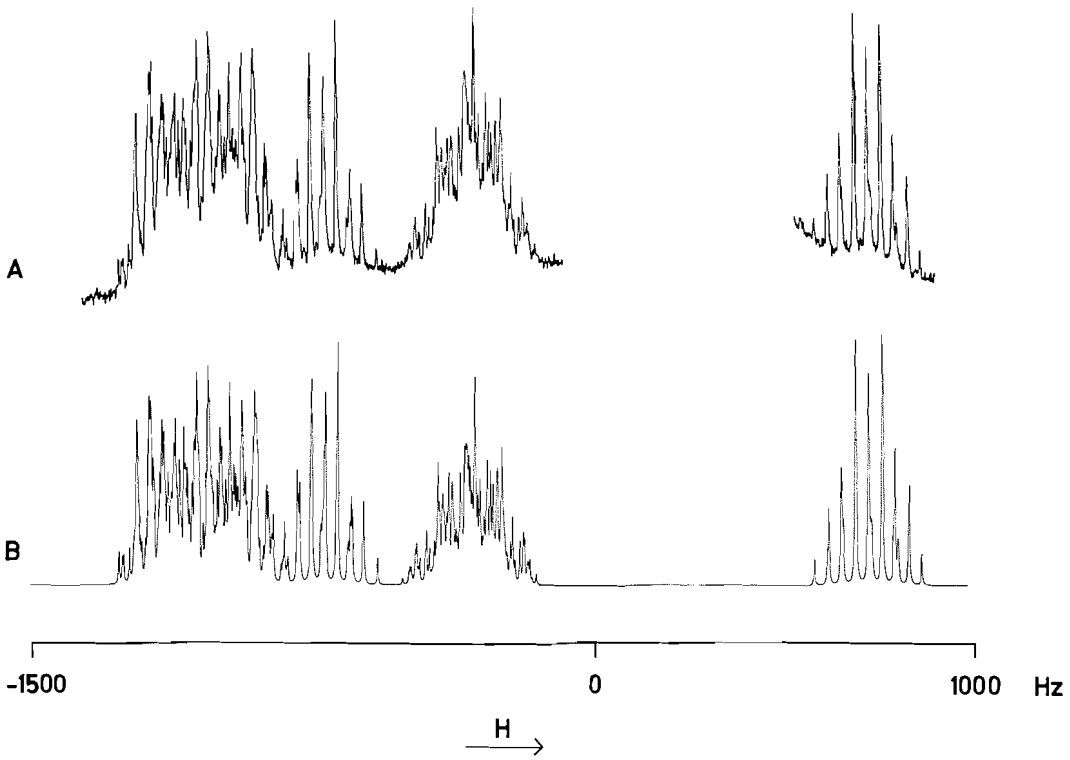

FIG. 2. Observed (A) and calculated (B) 220 MHz n.m.r. spectrum of partially oriented norbornadiene. Concentration 19 mol %; temperature ~ 25 °C; linewidth of (B) = 3 Hz.

operated in the frequency swept mode using a capillary of tetramethylsilane for field-frequency lock. The probe temperature was ~ 25 °C, and rapid spinning was used (8). The sample was left spinning in the probe for approximately 16 h to reach temperature equilibrium. The spectrum, with a linewidth of 3–4 Hz, was run at a scale of 1 Hz = 0.2 mm, and was analyzed with the iterative program LAOCOONOR (9) fitting 125 of 150 observed lines to 304 transitions with an r.m.s. error of 0.9 Hz after two iterations. The spectral parameters obtained are in Table 1.

Results and Discussion

Because of the relatively small orientation of the solute the spectrum appears as distinct groups. These groups also appear at 56.4 and 100 MHz with some overlap; however, only the 220 MHz spectrum had sufficient resolution for an analysis. Consequently, for couplings between chemically shifted nuclei, the spectrum is only sensitive to the sum of $2\,D_{ij} + J_{ij}$. The values and signs of the J_{ij} have, when possible, been taken from the literature (10, 11). The signs of the J_{ij} in Table 1 seem reasonable.

TABLE 1. 220 MHz n.m.r. parameters (in Hz) of partially oriented norbornadiene*

$D_{8,9}$	-34.8 ± 0.1	$J_{8,9}$	(2.85)†
$D_{8,10}$	2.9 ± 0.1	$J_{8,10}$	(0.99)†
$D_{8,11}$	9.5 ± 0.1	$J_{8,11}$	(1.85)†
$D_{8,14}$	33.7 ± 0.1	$J_{8,14}$	(1.65)‡
$D_{9,10}$	37.6 ± 0.1	$J_{9,10}$	(5.28)†
$D_{9,12}$	-16.4 ± 0.1	$J_{9,12}$	(0)†
$D_{9,13}$	-51.2 ± 0.1	$J_{9,13}$	(0)†
$D_{9,14}$	35.7 ± 0.2	$J_{9,14}$	(0)†
$D_{9,15}$	-0.8 ± 0.2	$J_{9,15}$	(0)†
$D_{14,15}$	-475.9 ± 0.1	$J_{14,15}$	(−12)§
$\nu_{14} - \nu_8$	334.9 ± 0.1		
$\nu_{14} - \nu_9$	1040.2 ± 0.1		

*Errors are standard deviations from LAOCOONOR (9); Values in brackets are assumed.
†From ref. 10.
‡From ref. 11.
§$J_{14,15}$ has a negligible effect on the spectrum.

In principle, the signs of the J_{ij} could be determined by studying a spectrum with a different (preferably larger) orientation.

TABLE 2. Structural parameters of norbornadiene*

	Case A †	Case B ‡
x (8) Å	(0)	(0)
y (8) Å	(2.192)	(2.157)
z (8) Å	1.613±0.003	1.645±0.011
x (9) Å	1.913±0.003	1.930±0.007
y (9) Å	1.354±0.002	1.359±0.004
z (9) Å	(0)	(0)
x (14) Å	0.910±0.0015	0.918±0.003
y (14) Å	(0)	(0)
z (14) Å	3.017±0.010	3.01 ±0.04
S_{xx}	0.0239±0.0001	0.0245±0.0003
S_{zz}	−0.0176±0.0001	−0.0182±0.0002
Weighted r.m.s. error	0.2 Hz	0.13 Hz

*Values in brackets are assumed. The scale is from the least squares fit to the electron diffraction data of case I of ref. 5.

†Case A: Results using weighting factors from the errors of Table 1.

‡Case B: The D_{ij} are given the weights from a calculation of LAOCOONOR where the J_{ij} were also varied. Consequently, $D_{8,9}$, $D_{8,10}$, $D_{8,14}$, $D_{9,14}$, and $D_{9,15}$ have much less weight than in case A.

The relative proton geometry was obtained with the iterative weighted least squares program SHAPE (12), and results are in Table 2 (case A). The weighted r.m.s. error of the experimental and recalculated D_{ij} was 0.2 Hz. However, because the signs of the J_{ij} may be incorrect, another solution is sought and found (case B, Table 2, weighted r.m.s. error = 0.13 Hz) when the D_{ij} are given weights from a calculation with LAOCOONOR where all the J_{ij} are varied. Thus, the D_{ij} between chemically shifted protons are given a much lower weight in the least squares calculation than the remaining D_{ij}. This solution is close to that found when $J_{8,14}$ is set negative.

Because of the two possible solutions, and because of the range of the diffraction data (1–5), it seemed valuable to "fit" our relative proton coordinates to the carbon coordinates of the various electron diffraction studies; this "fit" is a function of the two following parameters: (*i*) the scaling factor for the proton skeleton, and (*ii*) the height of the $C_2C_3C_5C_6$ plane above the $H_9H_{10}H_{12}H_{13}$ plane. We use an iterative least squares procedure, minimizing the difference between experimental and calculated C—H bond lengths, while keeping constant the carbon and the relative proton coordinates. With case A of Table 2, only when the angle $C_1C_7C_4$ is approximately 92° (ref. 3 and case I of ref. 5; see Fig. 1) are reasonable recalculated C—H bond lengths obtained from the least squares "fit". For the other electron diffraction studies, angle $C_1C_7C_4$ is larger than 92° (see Fig. 1), and the recalculated value of r_{18} is too short. To obtain plausible recalculated C—H bond lengths with the solution of case B, angle $C_1C_7C_4$ would have to be even smaller (~90°). Therefore we choose case A, Table 2, as the acceptable proton geometry. Consequently the acceptable electron diffraction studies are ref. 3 and case I of ref. 5. Figure 1 gives the result of combining our case A with the electron diffraction of case I of ref. 5. Errors are not quoted because of the neglect of the various effects of nuclear motions (7). A more reliable solution might be obtainable by analyzing the n.m.r. and electron diffraction spectra simultaneously.

We thank Mr. A. Frey of the E.T.H., Zürich, for the use of the Varian HR-220 spectrometer, and Dr. P. M. Henrichs for taking additional spectra at 56.4 MHz. The authors are grateful to the Swiss National Foundation for the Advancement of Science for financial support.

Two Diastereomeric Oxalatobis(*S*-butane-1,3-diamine)cobalt(III) Complexes

M. PARRIS,[1] L. J. DEHAYES, AND D. H. BUSCH
Chemistry Department, The Ohio State University, Columbus, Ohio

Received June 28, 1972

A study of the oxalatobis(*S*-butane-1,3-diamine)cobalt(III) system shows that the dissymmetric ligand imposes uniquely related geometric and configurational selectivity. The selectivity is in agreement with conformational prediction and the magnitudes of the Cotton effects lend some support to recently developed sector rules.

L'étude du système oxalatobis (*S*-butane diamine-1,3)cobalt(III) montre que le ligand dissymétrique impose une sélectivité particulière et appropriée dans la géométrie et la configuration. La sélectivité est en accord avec la conformation prévue et les amplitudes des effets Cotton viennent à l'appui des règles de secteur développées récemment. [Traduit par le journal]

During the course of an investigation into stereochemistry of the bis and tris(butane-1,3-diamine)cobalt(III) complexes, it had appeared initially that there was little stereoselectivity evidenced by this ligand in forming its *cis* complexes. The absence of stereoselectivity is more apparent than real, however, and a recent report (1) has indicated an analogous situation in the bis(*R*-propylene-diamine)cobalt(III) system which makes an interesting contrast. The following is an account of the findings which lead us to this conclusion.

The apparent circular dichroism of a solution obtained by the action of oxalate ion, under neutral or basic conditions, upon *trans* dichlorobis(*S*-butane-1,3-diamine)cobalt(III) ion is smaller, by a factor of about ten, than that of the oxalatobis(trimethylenediamine)cobalt(III) complex which has been obtained (2) as its pure enantiomer. The steric requirements of the *cis* bis(*S*-butane-1,3-diamine) system indicate that there are *two* preferred geometric isomers which are illustrated in Fig. 1. Each belongs to the C_2 point group, and, while strictly they are diastereomers, they might be described as *pseudo-enantiomers* insofar as their configurations are concerned. There are other possible geometric isomers containing chair rings but these will lead to increased ligand distortion and their contribution to an equilibrated solution may be neglected. There are additionally isomers containing skew rings, but it has been shown (3) that the chair form of trimethylenediamine is favored over the skew form to the extent of about 1.7 kcal mol^{-1}.

In the *cis* bis(*R*-propylenediamine)cobalt(III) system a diastereomeric mirror image is allowed only at the expense of an unfavorable ring conformation, that is, the favored isomer is $\Delta\lambda\lambda$ (or "lel") and the unfavored is $\Lambda\lambda\lambda$ (or "ob") regardless of which of the two possible geometric isomers with equivalent methyl groups these represent. The equilibrium constant (1) appears to be in the order of 6 which is not incompatible with the value of about 5 obtained for the equivalent ethylenediaminebis(*R*-propylenediamine)cobalt(III) system (4). For the *cis* bis(*S*-butane-1,3-diamine)cobalt(III) system, if the figure of 1.7 kcal is accepted, the same type of change is precluded, for the rings will now be in the chair form. There is no conformational

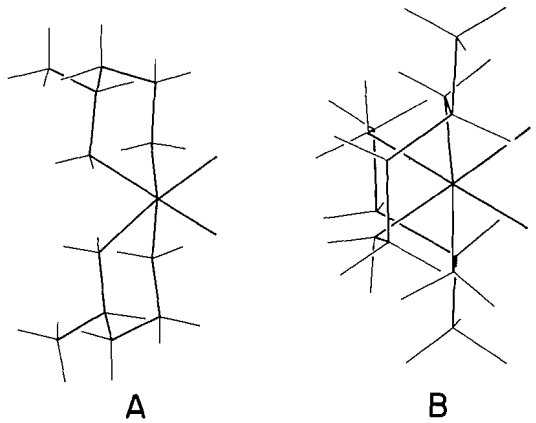

FIG. 1. Configurations of the bis(*S*-butane-1,3-diamine) cobalt(III) isomers: A, Λ; B, Δ.

[1]On sabbatical leave 1970–1971 from the Chemistry Department, Carleton University, Ottawa.

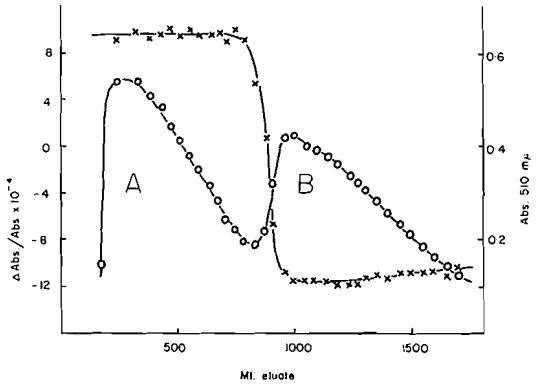

FIG. 2. Ion-exchange separation of the A, B isomers: ○, absorbance at 510 mμ; ×, dissymmetry factor at 510 mμ.

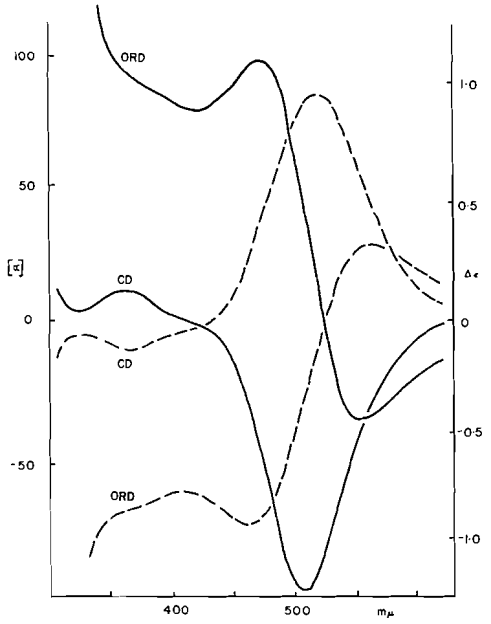

FIG. 3. C.d. and o.r.d. spectra of the A, B isomers: ---, A; —, B.

requirement to favor either Λ or Δ isomer, but it is possible to separate the two *geometric* isomers, each with a preferred absolute configuration, and here there is a marked contrast between the six- and five-membered ring complexes.

Figure 2 illustrates the progress of an ion-exchange separation of two oxalatobis(*S*-butane-1,3-diamine)cobalt(III) isomers from their equilibrium mixture and Fig. 3 shows the c.d. and o.r.d. spectra of the two isolated complexes. The faster-moving isomer, A, shows a positive c.d. in the 500 mμ region and is assigned (5) absolute configuration Λ (as in Fig. 1). Using the apparent differential extinction coefficient of the original solution, $\Delta\varepsilon_{app.} = +0.17$ (510 mμ), together with the observed values for the two separated isomers, $\Delta\varepsilon_A = +0.95$, $\Delta\varepsilon_B = -1.4$, the equilibrium constant is calculated as $K(A/B) = 1.1$, $\Delta G = 0.058$ kcal mol^{-1}.

TABLE 1. Individual contributions (kcal mol^{-1}) to excess free energy for the *cis* dichloro(*S*-butane-1,3-diamine)cobalt(III) isomers

Parameter	Value	
	Isomer A (Λ)	Isomer B (Δ)
Bond stretching	2.67	2.64
Non-bonded interactions	2.62	2.63
Bond angle distortions	6.18	6.18
Torsional distortions	0.19	0.20
Net conformational enthalpy	11.65	11.65
TS	40.35	40.18
Net free energy	−28.70	−28.53

We have carried out an assessment of ΔG using methods of conformational analysis (6–8) recently developed. Table 1 lists individual contributions to a net ΔG of 0.17 kcal mol^{-1}, wholly attributable to the small entropy difference favoring the Λ isomer (A). While the calculations have been carried out for the *cis* dichloro compounds, these results are not expected to be significantly different for the oxalato system.

An interesting feature is the difference in the differential extinction coefficients for the two isomers, +0.95 *vs.* −1.4, whereas $\Delta\varepsilon$ for (+) $[Co(tn)_2ox]^+$ is +1.21. The parent symmetry for these three complexes is C_{2v}, and in this point group the dominant pseudo-scalar function (9, 10) has the form XY, leading to a simple quadrant rule. The methyl groups in *both* isomers lie in negative sectors while the configurational contributions will be positive, for both $\Lambda(bn)_2$ and $\Lambda(tn)_2$ and negative for $\Delta(bn)_2$. Hence the magnitude of the Cotton effect for the trimethylenediamine complex should lie between the magnitudes for the two butane-1,3-diamine complexes as is observed.

Experimental

Butane-1,3-diamine was prepared and resolved by standard methods (11, 12). *Trans* (Co(*S*-butane-1,3-diamine)$_2$

Cl_2ClO_4 was prepared by an adaptation of Jonassen, Lincoln and Stranks' method (13). A mixture of 1.4 g anhydrous *S*-butane-1,3-diamine and 0.98 g anhydrous $CoCl_2$ in anhydrous ethanol was oxygenated for 4 h. The brown solution was acidified with HCl and dilute $HClO_4$. Fractional crystallization yielded the *trans* dichloro perchlorate as green octahedra, $[\alpha]_D + 8.2°$ ($C = 0.008$ M, nitromethane).

Anal. Calcd. for $C_8H_{12}N_2O_4Cl_3Co$: C, 23.7; H, 5.93; N, 13.8. Found: C, 23.5; H, 6.02; N, 13.7.

Ion-exchange separation of Λ and Δ[Co(*S*-butane-1,3-diamine)ox] oxalates. A solution of *trans*[Co(*S*-bn)$_2$Cl$_2$]-ClO_4 (0.41 g) together with sodium oxalate (1.3 g) in 4 ml H_2O was heated at 50 °C for 30 min. It rapidly developed a pink color, and, after cooling in ice and filtering off excess sodium oxalate, the pink solution was absorbed on a 60 × 1 cm column of Dowex 50W X4 ion-exchange resin (H^+ form). Oxalic acid solution (50 g/l) was used for elution. The components were separated almost completely into two bands and fractions were assessed for optical purity by comparing ratios of $\Delta\varepsilon$ to ε. The separated isomers' solutions were evaporated to small volume and then taken to dryness after filtering off oxalic acid. Extraction with absolute ethanol removed the remaining oxalic acid and the oxalato oxalates were crystallized from water/acetone.

Isomer A (Λ) was contained in the first 750 ml eluate, $[\alpha]_D + 22°$.

Anal. Calcd. for $C_{11}H_{24}N_4O_6Co$: C, 36.0; H, 6.54; N, 15.2. Found: C, 35.8; H, 7.05; N, 15.2.

Isomer B (Δ) was contained in the second 1000 ml eluate, $[\alpha]_D - 29°$.

Anal. Found: C, 36.1; H, 7.70; N, 15.3.

The Effect of Aromatic Amines on the Catalyzed Decarboxylation of 3-Oxo-glutaric Acid

K. N. LEONG AND M. W. LISTER

Department of Chemistry, University of Toronto, Toronto, Ontario

Received May 9, 1972

Equilibrium constants have been measured for the formation of MA species, where M is divalent manganese, cobalt, nickel, or zinc, and A^{2-} is the 3-oxo-glutarate ion. Equilibrium constants have also been measured for the reactions $MB^{2+} + A^{2-} \rightleftharpoons MAB$, where B is 2,2′-bipyridyl or 1,10-phenanthroline. These constants were obtained by p*H* measurements at 25 °C and an ionic strength of 0.60. The results are compared with those for similar systems, especially as regards the tendency to form ternary mixed complexes of the type MAB.

The rates of decarboxylation of the various MA and MAB species have been measured. The resulting rate constants follow the Irving–Williams order for stability constants, except that in both MAB species the cobalt compound decomposed slightly faster than the nickel compound. The aromatic base, which had been found earlier to have very little effect in copper complexes, increased the rate constants appreciably with other metals, especially with manganese and zinc. Usually 1,10-phenanthroline has a larger effect than 2,2′-bipyridyl. Some possible explanations of the results are considered.

Nous avons mesuré les constantes d'équilibre dans la formation d'espèces MA, où M est le manganèse, le cobalt, le nickel ou le zinc bivalents et A^{2-}, l'ion 3-oxo-glutarate. Nous avons également mesuré les constantes d'équilibre des réactions $MB^{2+} + A^{2-} \rightleftharpoons MAB$, où B est le 2,2′-bipyridyl ou le 1,10-phénanthroline. Ces constantes furent obtenues au moyen de mesures de p*H* à 25 °C et sous une force ionique de 0.60. Nous comparons les résultats à ceux de systèmes semblables, spécialement en ce qui concerne la tendance à former des complexes ternaires mixtes du type MAB.

Nous avons mesuré les vitesses de décarboxylation des espèces MA et MAB. Les constantes de vitesse obtenues suivent l'ordre d'Irving–Williams des constantes de stabilité, excepté que dans les deux espèces MAB, le composé de cobalt se décompose légèrement plus vite que celui de nickel. La base aromatique, chez qui on a trouvé antérieurement très peu d'effet dans les complexes de cuivre, augmente appréciablement les constantes de vitesse avec d'autres métaux, spécialement le manganèse et le zinc. La 1,10-phénanthroline possède un plus grand effet que le 2,2-bipyridyl. Nous considérons quelques explications possibles des résultats.

[Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3573 (1972)

In recent paper (1), the present authors reported experiments on the effect of two tertiary aromatic amines, 2,2′-bipyridyl and 1,10-phenanthroline, on the decarboxylation of 3-oxo-glutaric acid, catalyzed by copper ions. It was found that complexes of formula CuAB, where A^{2-} is the 3-oxo-glutarate ion and B is the aromatic amine, were responsible for the enhanced rates of decomposition. Kinetic and equilibrium measurements made it possible to compare the rate constants for decarboxylation of CuAB and CuA species. In fact the rate constants do not differ greatly, and the major enhancement of the rate arises from changes in the equilibria, and hence in the concentrations. References to related work are given in the above paper (1), but a recent paper by Hay and Leong (2) may be particularly mentioned.

The present paper extends the measurements to other transition metal ions, particularly to the divalent cations of manganese, cobalt, nickel, and zinc, which were already known to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

catalytically active species of formula MA (3). Since the catalyzed decarboxylation of ketocarboxylate ions seems to arise from the tendency of the metal to withdraw electrons from the ketocarboxylate ion (4–6), it was hoped that the rate constants could give information on the tendency of the base, B, to withdraw electrons from the metal ion. This will be considered in the discussion of the results.

Experimental

The 3-oxo-glutaric acid, 2,2′-bipyridyl, and 1,10-phenanthroline were obtained as described earlier (1).

Nickel nitrate, cobalt nitrate, zinc nitrate, and manganese nitrate were "Baker-Analyzed" reagents, and were used after recrystallization from water. Sodium nitrate, used to control ionic strength, was also "Baker-Analysed", recrystallized from water. Reagent grade nitric acid and sodium hydroxide, from the Fisher Scientific Company, were used to bring the pH within certain desired ranges. Stock solution of the transition metal nitrates, containing a small, but known, amount of nitric acid to suppress hydrolysis, were prepared, and were analyzed by EDTA titration.

Equilibrium Measurements

Equilibria were measured by means of a Beckman research pH meter, with a glass electrode and calomel reference electrode. All solutions were at 25.00 ± 0.01 °C, and had an ionic strength adjusted to 0.60 M. The pH meter was standardized, as usual, by potassium hydrogen phthalate, which was taken to have a pH of 4.008. The pH meter could be read to 0.0005 pH unit.

As it was necessary to connect pH readings to hydrogen ion concentrations, readings were taken on nitric acid solutions between 12.92 and 0.883×10^{-3} M, also containing sodium nitrate to give an ionic strength of 0.60 M. It was found that the results fitted the equation: $-\log[H^+] = pH + 0.169$, where $[H^+]$ was calculated on the assumption that all the nitric acid was ionized, and pH is the meter reading. The term 0.169 had a root mean square deviation of 0.0027 in nine measurements covering the range of concentrations given above. This gives an indication of the accuracy of the pH measurements.

Two series of measurements of equilibria were made: firstly on the formation of MA; secondly on MAB. In each series known amounts of 3-oxo-glutaric acid, metal nitrate, sodium hydroxide, and an aromatic amine if required, were mixed in solution, and the pH was measured. The equilibrium constants were calculated as described below.

The rates of decarboxylation were followed by the rate of evolution of carbon dioxide, in the apparatus already described (1). Throughout the temperature of the solutions was 25.00 ± 0.01 °C, and the ionic strength was 0.60 M. Measurements were also made on the pH of each reacting solution.

Results

Equilibrium for MA Species

It was assumed that, in solutions containing no aromatic amine, the following species were present: H_2A, HA^-, A^{2-}, M^{2+}, MA, H^+, Na^+, and NO_3^-. Here H_2A is 3-oxo-glutaric acid, and M^{2+} is the transition metal ion. Mass and charge balances and equilibrium expressions for the ionization of the acid give

$$K_{MA} = \frac{T_A - FG}{F(FG - T_A + T_M)}$$

where $K_{MA} = [MA]/[M^{2+}][A^{2-}]$, and is the desired constant, T_A = total 3-oxo-glutaric acid concentration, T_M = total transition metal concentration, T_N = total sodium hydroxide added (after allowing for its reaction with any nitric acid present), $[H^+]$ = hydrogen ion concentration, deduced from the pH reading, K_1, K_2 = successive ionization constants of 3-oxo-glutaric acid and

$$F = \frac{2T_A - T_N - [H^+]}{[H^+]/K_2 + 2[H^+]^2/K_1K_2}$$

$$G = 1 + [H^+]/K_2 + [H^+]^2/K_1K_2$$

The values of K_1 and K_2 used were 1.52×10^{-4} and 9.7×10^{-4}, taken from earlier experiments under the same conditions.

TABLE 1. Formation constant of the manganese(II) 3-oxo-glutarate complex, at 25.0 °C and $I = 0.60$ M

Run	10^2T_N	10^2T_A	10^2T_M	$10^4[H^+]$	K_{MA}
1	2.524	1.527	4.740	0.862	7.6
2	2.641	1.470	5.325	0.467	7.2
3	2.546	1.418	5.869	0.470	6.5
4	2.907	1.654	3.423	0.557	10.4

10	4.010	2.520	6.012	1.070	6.1

Table 1 gives the results for the manganese(II) complex, the last column being the calculated equilibrium constants. The average value of K_{MA} is 8.0 M^{-1}, with an average deviation of 1.7. A further estimate of the accuracy was obtained by calculating the change in the pH of the solution caused by the formation of the complex. This change for the runs in Table 1 ranged from 0.032 to 0.131, and this may be compared with the root-mean-square deviation of 0.0027 for the nitric acid calibration. It was also calculated that an error of 0.003 in the pH would alter the calculated K_{MA} by 11 to 13%

depending on the run. Tables 2, 3, and 4 give similar results for the other transition metal ions. The results can be summarized as follows:

In this table, "difference in pH" means the difference between the observed pH and the pH calculated on the assumption that no complex formation occurs; the two values are the largest and smallest differences found in different runs. "Effect of 0.003 error in pH" gives the % change in K_{MA} caused by a change of 0.003 in pH; again the two values are the extremes from various runs.

In any of these measurements, the presence of appreciable amounts of MA_2^{2-} ions would result in an increase in the calculated K_{MA} with increasing $[A^{2-}]$. This is not observed with the exception of a slight drift in K_{MA} for manganese. Hence it was assumed in later experiments that no MA_2^{2-} ions were present. In no case did K_{MA} drift appreciably with pH, so that species such as MAH^+ are not important. The K_{MA} values are decidedly lower than those reported earlier (1) from absorbance measurements. These earlier measurements depended on rather small differences in extinction coefficients, and consequently the values of K_{MA} were not very accurate. The errors involved in the present pH method can be fairly well judged from the data in Tables 1 to 4, and the calculations mentioned above. Since the measurements on MAB complexes, described below, were also done by means of pH, the K_{MA} values derived from pH were used throughout.

Equilibria for MAB Species

These measurements were similar to those already described, except that either 2,2′-bipyridyl or 1,10-phenanthroline was also added in approximately equimolar amounts as compared with the transition metal nitrate. In the calculations it was assumed that the following species were present: H_2A, HA^-, A^{2-}, M^{2+}, MA, MB^{2+}, MB_2^{2+}, MB_3^{2+}, MAB, B, BH^+, H^+, Na^+, and NO_3^-. Data on relevant equilibrium constants are available in literature (7–9) as summarized in Table 5. This table gives the logarithms of the constants, and the three

M^{2+}	Mean K_{MA} (M^{-1})	Average deviation (M^{-1})	Difference in pH	Effect of 0.003 error in pH (%)
Mn^{2+}	8.0	1.7	0.032–0.131	11–13
Co^{2+}	19.7	1.0	0.046–0.136	3–9

H^+	1	4.52	4.96

numbers for each metal are for the overall stability constants, $[MB_n^{2+}]/[M^{2+}][B]^n$, with $n = 1$, 2, or 3. The values opposite H^+ are the logarithms of $[BH^+]/[B][H^+]$. The data used in Table 5 are those of Irving and Mellor (7), who made a critical study of the information available on these stability constants, as well as their own measurements by the solvent extraction method. Their data are for 25 °C and an ionic strength of 0.1 M, but since the charge is the same on both sides of the equation in all these equilibria, their values were also used for our higher ionic strength.

In any one solution, a value of $[H^+]$ was found by pH measurement, and since $[Na^+]$ and $[NO_3^-]$ are known from the quantities added, this leaves eleven unknown concentrations and one unknown constant, $K_{MAB} = [MAB]/[MB^{2+}][A^{2-}]$. There are eight equilibrium equations and four mass or charge balance equations, so K_{MAB} can be found. In practice the algebra is difficult, and the simplest method seems to be as follows. If we define G and other symbols as above, and in addition:

$$R = \frac{T_A\left(2 + \frac{[H^+]}{K_2}\right) - G\left\{[H^+]\left(1 + \frac{[B]}{K_{HB}}\right) + T_N\right\}}{[H^+](1 + [B]/K_{HB}) + T_N - 2T_A}$$

$$K_{HB} = [BH^+]/[B][H^+]$$

it can be shown that

$$[M^{2+}] = \frac{(G + R)\left\{T_B - [B]\left(1 + \frac{[H^+]}{K_{HB}}\right) - RT_A\right\}}{(G + R)\{K_{MB}[B] + 2\beta_{MB_2}[B]^2 + 3\beta_{MB_3}[B]^3\} - K_{MA}T_A}$$

and also

$$[M^{2+}] = \frac{(G + R)T_M - RT_A}{(G + R)\{1 + K_{MB}[B] + \beta_{MB_2}[B]^2 + \beta_{MB_3}[B]^3\}}$$

where K_{MB}, β_{MB_2}, and β_{MB_3} are the stability constants given in Table 5, and T_B is the total aromatic base added. The method used was to guess a value of [B], calculate two values of $[M^{2+}]$ from the equations above, and repeat this with other values of [B] until one was found for which the two values of $[M^+]$ differed by less than 0.1%. As $[M^{2+}]$ and [B] were now known, K_{MAB} was calculated from

$$K_{MAB} = \frac{R - K_{MA}[M^{2+}]}{K_{MB}[M^{2+}][B]}$$

It was now possible to calculate the concentrations of all the species present, and to check that the equilibrium and mass balance equations were in fact obeyed.

Table 6 gives the results for manganese(II) with 2,2′-bipyridyl. The mean value of K_{MAB} is 15.1 M^{-1}, with an average deviation of 0.95 M^{-1}. As before, an estimate of the accuracy of the result was made by calculating what would have been the pH of the solution if no MAB were formed, and comparing it with the actual pH. Since this also involved a long calculation

by trial and error for the value of [B], it was only attempted for some selected runs. For run 42 in Table 6 the change of pH arising from MAB formation was 0.155, and for run 44 it was 0.096. Hence an error of 0.003 is 2 to 3% of this. However, the average deviation in K_{MAB} is 6.3%, which of course includes other errors.

Table 7 gives the results for cobalt(II) with 2,2′-bipyridyl. The mean value of K_{MAB} is 20.2 M^{-1}, with an average deviation of 1.58. In run 47, the calculated change of pH arising from MAB formation was 0.073.

Table 8 gives the results for nickel(II) with 2,2′-bipyridyl. The mean value of K_{MAB} is 19.6 M^{-1} with an average deviation of 1.1 M^{-1}. In run 57, the calculated change of pH arising from MAB formation was 0.047.

Table 9 gives the results for zinc(II) with 2,2′-bipyridyl. The mean value of K_{MAB} is 8.0 M^{-1}, with an average deviation of 0.7 M^{-1}. In run 72, the calculated change or pH arising from MAB formation was 0.076.

Table 10 gives the results for cobalt(II) with 1,10-phenanthroline. The mean value of K_{MAB}

found that a plot of $\ln (P_\infty - P_t)$ against time was linear up to about 35% of the total reaction. Here P_t is the pressure of evolved carbon dioxide at time t, and P_∞ is the pressure for complete reaction, on the assumption that one CO_2 is evolved by each 3-oxo-glutaric acid. This assumes that the decomposition of the initial product, acetoacetic acid, is relatively slow, as was already known (3, 10). Hence this plot gives a value of k_{obs}, defined by

$$d[CO_2]/dt = k_{obs}T_A$$

The concentrations of all species present were calculated from the usual mass balance and equilibrium expressions, and the observed pH.

In interpreting the results it was assumed that

$$k_{obs}T_A = k_{H_2A}[H_2A] + k_{HA^-}[HA^-] + k_{A^{2-}}[A^{2-}] + k_{MA}[MA]$$

The values of k_{H_2A}, k_{HA^-} and $k_{A^{2-}}$ were already known (3). The relatively long linear part of the plot of $\ln (P_\infty - P_t)$ against time implies that there is no very great change in the relative concentrations of the various species as the reaction proceeds. This must mean that the extent of complexing of the transition metal ion by the acetoacetic acid is not very different from that by 3-oxo-glutaric acid, but detailed information on this is not at present available.

Tables 13 to 16 give the results for various

30	2.519	5.017	1.36	1.28	9.10	10.18	4.63	3.42	8.13
31	2.594	14.99	1.15	0.719	6.07	8.02	11.13	4.82	8.33
32	2.577	9.99	0.880	0.533	5.88	10.15	9.21	4.30	8.65

transition metals. The tables include the concentrations of the reactive species present, and the values of k_{MA}, obtained by taking $k_{H_2A} = 2.08 \times 10^{-5}$, $k_{HA^-} = 4.83 \times 10^{-5}$ and $k_{A^{2-}} = 0.17 \times 10^{-5}\ s^{-1}$ (3). The mean values of k_{MA} and their average deviations are as follows:

M^{2+}	$10^5 k_{MA}$ (s^{-1})	Average deviation (s^{-1})
Mn^{2+}	2.00	0.07
Co^{2+}	6.67	0.15
Ni^{2+}	9.64	0.12
Zn^{2+}	8.53	0.27

Runs were now carried out in which either 2,2′-bipyridyl or 1,10-phenanthroline were added in an amount roughly equimolar as compared with the transition metal. In interpreting the results it was assumed that MAB species were also catalytically active, so that

$$k_{obs}T_A = k_{H_2A}[H_2A] + k_{HA} - [HA^-] + k_{A^{2-}}[A^{2-}] + k_{MA}[MA] + k_{MAB}[MAB]$$

A plot of $\ln(P_\infty - P_t)$ was linear up to about 30% of the total reaction so that k_{obs} could be obtained from these plots. In calculating the concentrations it was assumed that H^+, H_2A, HA^-, A^{2-}, M^{2+}, MA, MB^{2+}, MB_2^{2+}, MB_3^{2+}, MAB, B, BH^+, Na^+, and NO_3^- were present. The pH gave a value of $[H^+]$, and mass balance and equilibrium equations enabled all other concentrations to be calculated.

Tables 17 to 20 give the results when the base was 2,2′-bipyridyl with the various transition metal ions; Tables 21 to 23 similarly give the results when the base was 1,10-phenanthroline. The mean values of k_{MAB} obtained from these tables are collected in Table 24, which also gives the average deviation of each result.

Discussion of Results

Some comments may first be made on the results on stability constants, together with those obtained earlier for copper compounds (1). These are summarized in Table 25, which contains values of log K, as equilibrium constants are often easier to compare in this form. The results in general follow the Irving–Williams order (11), though there is a small drop at nickel in log K_{MAB} values for both aromatic bases. There is no drop in log K_{MA}, but the rise in going from cobalt to nickel is small; it is smaller than the rise for other comparable ligands, chelated

through oxygen (such as the malonate ion), where the usual rise in log K is about 0.4 (9). Possibly this irregularity arises from the fact that the metal in the MAB complexes is not in anything close to an octahedral field: the larger ligand field splitting of the base, B, will give a considerable linear component to the field. 3d electrons in a linear field are split in energy so that one orbital is considerably above the average, two are slightly above, and two well below. This would give an increasing crystal field stabilization in going from Mn^{2+} to Co^{2+}, a slight drop to Cu^{2+}, and a larger drop to

TABLE 25. Logarithms of equilibrium constants

M	log K_{MA}	log K_{MAB} B = 2,2′-bipy	log K_{MAB} B = 1,10-phen
Mn	0.90	1.18	—
Co	1.29	1.31	1.40
Ni	1.40	1.29	1.30
Cu	2.18	2.56	2.43
Zn	1.00	0.90	0.79

Zn^{2+}. Coupled with the usual Jahn–Teller distortion round Cu^{2+}, this might explain the observed trend. However, the main difficulty with this explanation is that the usual Irving–Williams trend is observed for formation constants of MB^{2+}, where such a linear field might be expected to apply.

The values of log K_{MA} in Table 25 are lower than the values reported (3) earlier, and have a wider spread in values in going from one metal to the next. Some support for this wider spread can be obtained by comparison with the stability constants (9) of similar ligands, where a spread in values at least as large as ours is generally found. The earlier values were obtained from relatively small changes in optical absorbance, or in the voltage of a cell using a zinc amalgam electrode, but the cause of the discrepancy is at present uncertain.

A comparison of the log K_{MAB} values in Table 25 shows that cobalt has a somewhat lower value of K_{MAB} if B is 2,2′-bipyridyl, nickel almost equal values, and copper and zinc lower values if B is 1,10-phenanthroline. However, the differences are so small that it is doubtful if a detailed explanation can be attempted at present. It was observed earlier (1) that for copper complexes, the 3-oxo-glutarate ion is much less strongly bound that either of the aromatic bases, though it is nearly as strong a base as they are. This was attributed, at least in part, to back-bonding by 3d electrons on M^{2+} to π^*-orbitals on the base. The same holds for the other metal ions besides copper, presumably for the same reasons. This is also true of attachment of either B or A^{2-} to MA species; in fact, MA_2^{2-} species were not observed in the present work, and were only weakly formed when M is copper.

In contrast to the slight irregularities in the equilibrium constants for the attachment of A^{2-} to MB^{2+}, the constant for the reactions

$$MA + B \rightleftharpoons MAB$$

follow the Irving–Williams order. These equilibrium constants, which are equal to $K_{MAB}K_{MB}/K_{MA}$, are larger for the stronger base 1,10-phenanthroline; this is also true for the reactions $M^{2+} + B \rightleftharpoons MB^{2+}$. A qualitative explanation of the difference between 2,2′-bipyridyl and 1,10-phenanthroline can be found in a simple Hückel molecular orbital treatment of these two molecules. If we take $\alpha_N = \alpha_C + 0.5\beta$, where α_N and α_C are the Coulomb integrals on nitrogen and carbon, and β is the exchange integral for neighboring carbons or carbon–nitrogen, and the factor 0.5 is chosen as being the difference in electronegativities, then the net charge on nitrogen is -0.199 in 2,2′-bipyridyl and -0.244 in 1,10-phenanthroline. This would presumably cause a proton to bond more strongly to 1,10-phenanthroline making it the stronger base. As regards π-backbonding in MB^{2+}, the lowest suitable m.o. in 1,10-phenanthroline is a little higher in energy (by 0.032β) than in 2,2′-bipyridyl but the coefficient of the a.o. on nitrogen is higher in 1,10-phenanthroline (0.396 compared with 0.373), giving better overlap with a 3d orbital on the metal, which would make K_{MB} larger for 1,10-phenanthroline. The Hückel m.o. method is, of course, very approximate, but it can perhaps serve to explain the relative behavior of two similar molecules.

The constants K_{MAB} provide some information on the discriminating behavior of metal ions and ligands, which has been noted in other systems (*e.g.* 12 and references therein). It was found (1) that the equilibrium constant of

$$CuA_2^{2-} + CuB_2^{2+} \rightleftharpoons 2\ CuAB$$

was about 4×10^4 if B is 2,2′-bipyridyl, and about 1.2×10^4 if B is 1,10-phenanthroline. This agrees with the previously observed behavior (13) of copper bonded to two chelating ligands, one attached by two nitrogen atoms, and the other by two oxygen atoms. Owing to the failure to observe MA_2^2 species for M = manganese, cobalt, nickel, and zinc, all that can be said is that for these metals the corresponding constants are also large. A somewhat different comparison is also often made (13) by means

TABLE 26. Logarithms of rate constants: values of log (10^5k); time in seconds

	log (10^5k)		
		MAB	
M	MA	bipy	phen
Mn	0.30	0.84	—
Co	0.82	1.19	1.32
Ni	0.98	1.12	1.27
Cu	2.29	2.42	2.23
Zn	0.83	1.42	1.71

of values of $\Delta \log K = \log K_{MAB} - \log K_{MA}$, which is the equilibrium constant for

$$M^{2+} + MAB \rightleftharpoons MA + MB^{2+}$$

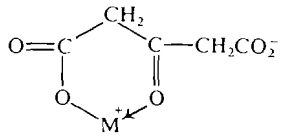
Small negative values of $\Delta \log K$ would be expected if A^{2-} and B do not affect each other's chance of bonding to a metal ion. Small positive values of $\Delta \log K$ were found for copper (0.38 if B is 2,2′-bipyridyl, and 0.25 if B is 1,10′-phenanthroline). This seems to be a common situation for copper bonded to 2,2′-bipyridyl and another chelating ligand attached through two oxygens (13–15), but negative values of $\Delta \log K$ are also found when a ligand, other than 2,2′-bipyridyl, which chelates through nitrogen is used (16–18). In the present work, the values of $\Delta \log K$ from Table 25 are

	$\Delta \log K$	
M^{2+}	bipy	phen
Mn^{2+}	0.28	—
Co^{2+}	0.02	0.11
Ni^{2+}	−0.11	−0.10
Zn^{2+}	−0.10	−0.22

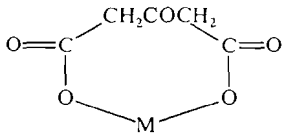
These values show a trend to more negative $\Delta \log K$ with increasing number of d electrons, but it must be remembered that a positive $\Delta \log K$ had been found for copper. The most that can be concluded at present is that the two bases give very similar trends.

If we now consider the rate constants, values of $\log k$ are collected in Table 26. Two points may be mentioned first. Firstly, as the experiments reported above were carried out without a buffer, it was not necessary to consider species in which the transition metal ion was complexed with the buffer anion. Buffered solutions would have controlled pH better, but would have greatly increased the difficulties of interpretation.

Secondly, 3-oxo-glutaric acid can, in theory, give two types of chelated complexes:

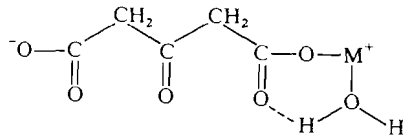


I



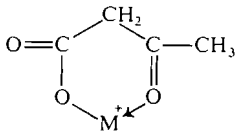
II

The first is more probable on the basis of ring size, and this type of structure has been suggested by other workers (2, 19), though not invariably (20). Recently Yerhoff and Larson (21), on the basis of infrared spectra of solid hydrates, $MA.xH_2O$, have proposed a structure with only unidentate bonding of the metal ion to the carboxylate group. They base this, in part, on the fairly small change observed in the carbonyl stretching frequency in, for instance, $CoA.xH_2O$ as compared with Na_2A. Admittedly some other possibly chelated complexes, such as those of salicylaldehyde with Co^{2+}, Ni^{2+}, and Zn^{2+} (22) or of diethyl oxaloacetate (23) also give a rather small change in frequency when the complex is formed; and it is also possible that the solid compound, even though hydrated, may have a different structure in solution. Yerhoff and Larson suggest a structure which, in solution, would presumably be

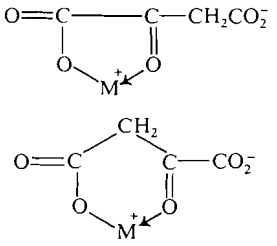


III

Since equilibrium measurements measure the total complexed 3-oxo-glutarate ions, and the rate measurements measure the total rate, it follows that k_{MA} would be an average rate con-



stant, if in fact more than one MA species is present in solution. Structure II would probably not decarboxylate readily, since the copper complex of 3-oxo-butyric acid was found not to decarboxylate (3). In structure III, it seems unlikely that the metal ion would transmit any large effect to the far end of the molecule, so that structure I is probably the most reactive species. Similar uncertainties are, of course, present in interpreting the analogous reactions of other β-ketoacids, such as oxaloacetic acid, which could give two structures analogous to I above:



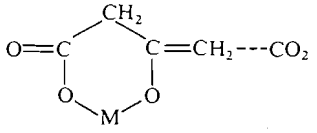
of which the first seems to be the more reactive (24).

The results in Table 26 follow the same order as the Irving–Williams order for stability constants, in the cases of the MA species, but in both MAB series the rate for nickel is slightly below that for cobalt. The similar behavior of the equilibrium constants might lead one to expect that log (rate k) plotted against log (equilibrium K) would give a straight line. No such simple relation seems to exist, the chief deviation coming from the zinc compounds, where the rate constants are relatively high. Prue (19) has noted that the gross catalytic effects, which are proportional to $k_{MA}K_{MA}$, parallel the equilibrium constants for complexing of the metal with malonate: he obtained $\log k_{cat} = 1.3 \log K_{Mal} +$ constant. We have examined the correlation of $\log k_{MA}$ with the logarithm of the stability constants of the metals complexes with various anions (referred to as $\log K_{MX}$). A straight line was drawn by least squares through the points for $\log k_{MA}$ plotted against $\log K_{MX}$, and the root mean square deviations of the points from this line were then

TABLE 27. Correlation of $\log k_{MA}$ with $\log K_{MX}$

Ligand, X	r.m.s. deviation	K_{MX}/K_{MA}: r.m.s. deviation
3-Oxo-glutarate	0.163	—
Oxalate	0.294	0.425
Malonate	0.077	0.148
Succinate	0.330	0.664
Oxaloacetate	0.088	0.273
Acetate	0.303	0.684
Glycinate	0.147	0.211
Ethylenediamine	0.192	0.224
Acetylacetonate	0.110	0.102

calculated. The results are given in Table 27, mostly from data in ref. 9. The best fit is with malonate, and this perhaps means, as Prue originally suggested, that the activated complex is close to a structure resembling a malonate complex, that is



where the CO_2 is almost separated. The slope of the best line is 0.82; *i.e.* $\log k_{MA} = 0.82 \log K_{Mal} +$ constant. However, on this interpretation it would be more precise to attempt a correlation of $\log k_{MA}$ with the ratio of the stability constants of the metal ion combined with 3-oxo-glutarate and with malonate (or other anion), as the rate is determined by the free energy change in going from the ground state to the activated complex. Unfortunately a correlation of $\log k_{MA}$ with $\log (K_{MX}/K_{MA})$ is not as good as with $\log K_{MX}$ alone: the root mean square deviations are given in the third column of Table 27. The fit with the data for malonate is still moderate, but that with the data for acetylacetonate is better. Admittedly the acetyl-acetonate chelate is not very different in structure, but some doubt is cast on conclusions about the nature of the activated complex.

If we consider the change in the rate constant in going from MA to MAB species, we can see that in general MAB species decarboxylate faster. The sole exception is CuA(1,10-phenanthroline). The increase in rate in both series is large for manganese and zinc, and least for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

copper. Thus the aromatic bases chiefly promote the effects of the catalytically least efficient metal ions. The enhanced rates of decarboxylation, which for copper arose largely from changes in equilibrium constant, are largely or completely from increases in the rate constants for cobalt, nickel, and zinc, and to a lesser extent for manganese. Similarly the rate constants for MAB species are larger when B is 1,10-phenanthroline, except when the metal is copper. As was mentioned in connection with equilibrium constants, 1,10-phenanthroline probably accepts electron density into its π-system more easily than 2,2′-bipyridyl, and this would explain the relative sizes of the rate constants except those for copper. The reason for the special position of copper is not clear, though it is possibly connected with the usually non-octahedral arrangement of ligands around it.

Intermediate Binary Carbonyls of Palladium $Pd(CO)_n$ where $n = 1-3$; Preparation, Identification, and Diffusion Kinetics by Matrix Isolation Infrared Spectroscopy

E. P. KÜNDIG, M. MOSKOVITS, AND G. A. OZIN

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario

Received April 26, 1972

The co-condensation reaction of atomic palladium with a dilute CO–argon mixture (1:1000) at 10 °K yields intermediate carbonyls of palladium $Pd(CO)_n$ where $n = 1-3$ as well as very small amounts of $Pd(CO)_4$. Isotopic substitution experiments using $^{12}C^{18}O$ were used to aid the spectral assignments. The probabilities of forming the various $Pd(CO)_n$ carbonyl species as a function of the CO concentration in Ar are analyzed and compared with the experimental observations. An analysis of the diffusion kinetics demonstrates their usefulness in assigning bands to various species in a series of compounds such as $Pd(CO)_n$. The data make possible the assignment of infrared absorptions at 2070, 2060, 2044, and 2050 cm^{-1} to tetrahedral (T_d) $Pd(CO)_4$, trigonal planar (D_{3h}) $Pd(CO)_3$, linear ($D_{\infty h}$) $Pd(CO)_2$, and linear ($C_{\infty v}$) PdCO, respectively. Cotton–Kraihanzel force constants are calculated for $Pd(CO)_n$ and are compared with those for the analogous intermediate carbonyls of nickel, $Ni(CO)_n$.

La réaction de co-condensation du palladium atomique avec un mélange dilué CO–argon (1:1000) à 10 °K permet de former des carbonyls intermédiaires de palladium, soit $Pd(CO)_n$, où $n = 1-3$ de même que de petites quantités de $Pd(CO)_4$. Nous avons utilisé la substitution isotopique, soit $^{12}C^{18}O$ pour interpréter plus facilement les bandes spectrales. Les probabilités de formation des différentes espèces carbonyl, $Pd(CO)_n$ en fonction de la concentration de CO dans l'argon sont alors analysées et comparées aux observations expérimentales. Une analyse de la cinétique de diffusion s'est avérée très utile dans l'assignation des bandes de différents groupes d'une série de composés, tels $Pd(CO)_n$. Les résultats rendent possible l'assignation des absorptions infrarouges à 2070, 2060, 2044, et 2050 cm^{-1} au $Pd(CO)_4$ tétrahédrique (T_d), au $Pd(CO)_3$ planaire trigonal (D_{3h}), au $Pd(CO)_2$ linaire ($D_{\infty h}$) et au PdCO linéaire ($C_{\infty v}$), respectivement. Nous calculons les constantes de force de Cotton-Kraihanzel pour $Pd(CO)_n$ et les comparons avec celles des carbonyls analogues intermédiaires du nickel, $Ni(CO)_n$. [Traduit par le journal]

Introduction

Vibrational spectroscopic evidence for the existence and structure of palladium tetracarbonyl has recently been independently reported by two research groups (1, 2). In both cases the experiments involved the co-condensation of atomic palladium with carbon monoxide at cryogenic temperatures (4.2–20 °K). Ozin and co-workers (1) characterized the product of this reaction by using the combined techniques of matrix infrared and Raman spectroscopy including matrix Raman polarization data. Analysis of the spectra proved that the observed lines arose from $Pd(CO)_4$ with T_d symmetry. Ogden and co-worker (2) employed $^{12}C^{18}O$ isotope substitution experiments in order to characterize the carbonyl species. In a mixed $^{12}C^{16}O/^{12}C^{18}O$ matrix infrared experiment a quintet pattern of bands was observed in the CO stretching region, with the isotopic shifts and intensities expected for $Pd(CO)_4$ with T_d symmetry.

We have extended our matrix isolation infrared experiments of the Pd–CO system to dilute CO–argon matrices to prepare and characterize the intermediate carbonyls of palladium $Pd(CO)_n$ where $n = 1-3$. The palladium carbonyls are analogous to DeKock's (3) intermediate nickel carbonyls $Ni(CO)_n$ and are of considerable interest from the point of view of their vibrational spectra, structure, and bonding.

Experimental

The argon (99.99%) and carbon monoxide (99.9%) used in this work were supplied by Matheson. The furnace and cryotip arrangement have been described previously (4). Palladium atoms were produced by evaporation from a palladium filament (99.9%) of dimensions 1.75 in. × 0.375 in. × 0.010 in. The filament was suspended between water-cooled copper electrodes and directly heated within a.c. The rate of deposition was continuously monitored during

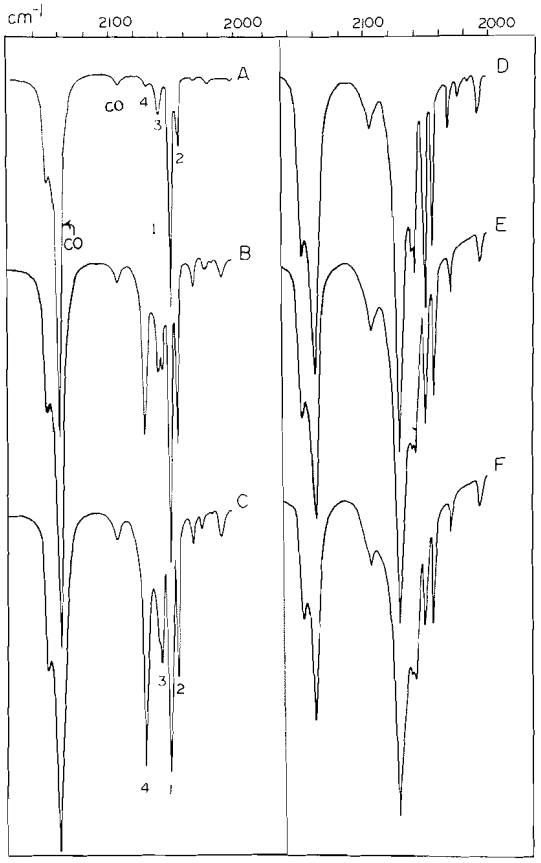

FIG. 1. The matrix isolation i.r. spectrum of the products of the co-condensation reaction between atomic palladium and CO in Ar (1:1000): (*A*), on deposition at 10 °K; (*B–F*) after successive diffusion warm up experiments at 20–30 K.

the course of the experiment using a quartz crystal microbalance with a resolution of 10^{-9} g (5). An average deposition was carried out for 4–6 h onto the cold tip of a Displex closed cycle helium refrigeration system. Infrared spectra were recorded on a Perkin–Elmer 180 spectrophotometer in the region 2400–200 cm^{-1}.

Results and Discussion

A number of experiments in which the matrix gas varied from pure CO to CO diluted in argon (M:A = 1:100–1:1000) as well as the analogous experiments using isotopically enriched carbon monoxide ($^{12}C^{18}O$ 92%, $^{12}C^{16}O$ 8%) were performed. The i.r. spectra for the Pd:CO:Ar ≅ 0.1:1.0:1000 experiments are presented in Fig. 1 and clearly show the presence of one major line (on the initial deposition, Fig. 1*A*) at 2050 cm^{-1} and three much weaker lines at 2070, 2060, and 2044 cm^{-1} (note that the band previously assigned to $Pd(CO)_4$ at 2070 cm^{-1} in pure CO matrices is, as expected, hardly visible in Fig. 1*A*). The order of band intensities at the end of the 10 °K deposition is $I_{2050} \gg I_{2044} > I_{2060} \gg I_{2070}$. Based on its intensity at 10 °K, its behavior during the warmup experiments and the isotopic shift observed with $^{12}C^{18}O$ the line at 2050 cm^{-1} was assigned to the monocarbonyl PdCO.

As can be seen in the annealing experiments, (Fig. 1*B–F*) and from a series of other runs, progressive growth and decay of the bands at 2044 and 2060 cm^{-1} occurs together with the rapid appearance of a band at 2070 cm^{-1}, assigned to the tetracarbonyl, $Pd(CO)_4$. Each of these lines has a counterpart line, with the expected frequency shifts on $^{12}C^{18}O$ substitution, calculated using the Cotton–Kraihanzel force field approximation (6), in which one assumes that the terminal CO stretching vibrations in metal carbonyls are "factored off" from the remaining vibrations of the molecule.

Observed ($^{12}C^{16}O$)	Observed ($^{12}C^{18}O$)	Calculated ($^{12}C^{18}O$)
2070 →	2022	2020
2060 →	2013	2010
2050 →	2005	2001
2044 →	1998	1995

Weak lines are observed at 2031 and 2008 cm^{-1} whose growth patterns do not correlate satisfactorily with any of the lines assigned to $Pd(CO)_n$ where $n = 1$–4 and are probably associated with aggregate carbonyl species formed in the initial diffusion processes during deposition.[1] We note that a similar effect was observed for nickel. These lines appear to be anomalous as their counterparts were not found in the $^{12}C^{18}O$ experiments and remain unaccounted for.

A *prima facie* assignment of the four bands at 2070, 2060, 2050, and 2044 cm^{-1} to the four $Pd(CO)_n$ species can be made on the basis of the

[1]Recent work in our laboratory involving the co-condensation reaction of Pd atoms with N_2/CO/Ar matrices has shown that the lines at 2031 and 2008 cm^{-1} are associated with mixed $Pd(N_2)_m(CO)_n$ species formed from trace impurities of nitrogen in the dilute matrices (E. P. Kündig and G. A. Ozin, unpublished results).

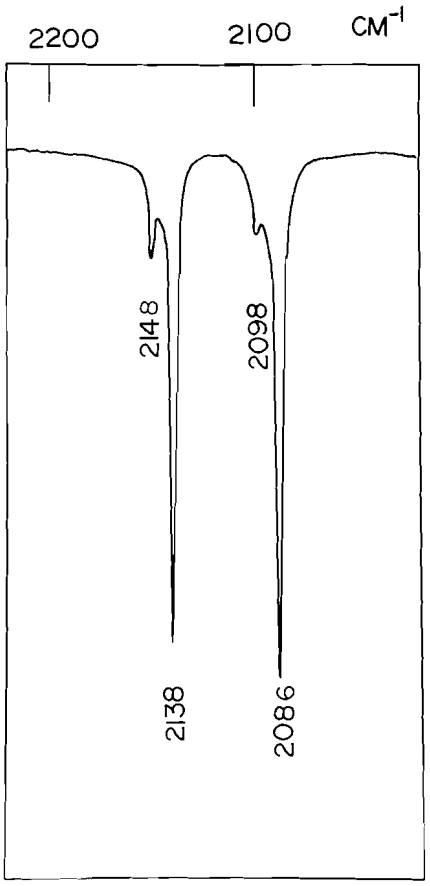

FIG. 2. The matrix i.r. spectrum of an approximately equimolar mixture of $^{12}C^{16}O$ and $^{12}C^{18}O$ in argon (1:1:500) at 10 °K.

relative intensities of the four bands assuming intuitively that at a dilution of CO:Ar = 1:1000 the relative probabilities of forming $Pd(CO)_n$ decreases monotonically with increasing n.

These assignments are strengthened further by the following analysis of the warmup data. Although these data were not obtained with rigorous quantitative analysis in mind sufficient interesting qualitative and semi-quantitative information can be obtained from them to warrant the following discussion.

Before describing the analysis of the warmup data it is necessary to briefly discuss the presently accepted nature of CO in the dilute argon matrices. It has been tacitly assumed in the literature (for example, refs. 3, 7, 8) that the 2138 cm^{-1} of matrix isolated CO belongs to monomeric CO rather than CO dimers. Moreover we have obtained new results which require that the carbon monoxide monomer–dimer problem (9, 10) be re-examined (11). A simple theory, based on a thermodynamic equilibrium between two types of CO argon lattice sites and argon vacancies provides an adequate and alternative explanation for (*a*) the CO/Ar concentration dependence, (*b*) the temperature dependent diffusion characteristics of, and (*c*) the respective matrix shifts from gaseous CO (on the basis of Buckingham's theory (12) for solvent shifts) of the i.r. absorptions at 2148 and 2138 cm^{-1}.

In carefully performed mixed isotope $^{12}C^{16}O:^{12}C^{18}O:Ar = 1:1:500$ matrix i.r. experiments both the lines at 2148 w and 2138 s cm^{-1} and their $^{12}C^{18}O$ counterpart lines were observed at 10 °K (Fig. 2). If the bands at 2138 and 2086 cm^{-1} did in fact belong to CO dimers then one would have expected to observe two additional bands associated with the mixed isotope dimer ($^{12}C^{16}O.^{12}C^{18}O$), one intermediate in frequency and one above them. One of these bands should in fact have been more intense than that of the smaller of the isotopically pure dimer bands on the basis of statistical arguments. The absence of this band makes the assignment of the 2138 cm^{-1} feature to CO dimer most unlikely.

In the present analysis the concentrations of free CO and of the four carbonyls $Pd(CO)_n$ are assumed to be proportional to their respective absorbances according to the Beer–Lambert relationship. Absorbances were calculated using peak height values. Thus

$$[1] \qquad A_n = \varepsilon_n [n] l$$

where A_n, $[n]$, and ε_n are the absorbance, concentration, and extinction coefficient respectively of $Pd(CO)_n$; and l is the matrix thickness. Similarly for the free CO, A_{co} was set equal to $\varepsilon_{co} l[CO]$. If one makes the assumption that

$$[2] \qquad \varepsilon_n = n\varepsilon_1$$

i.e. that each of the CO ligands absorbs independently of the others, and with similar strength in all the various $Pd(CO)_n$, then combining eqs. 1 and 2 one obtains

$$[3] \qquad [n] = \frac{1}{\varepsilon_1 l}(A_n/n)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

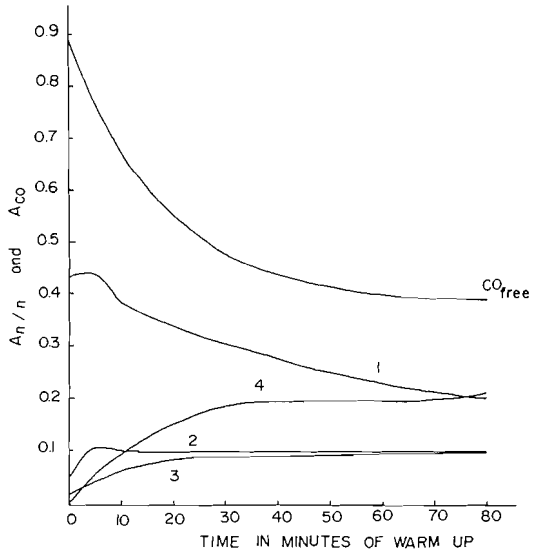

FIG. 3. A_n/n and A_{CO} as a function of warm up time, where A_n is the absorbance of $Pd(CO)_n$. The numbers 1 through 4 refer to the four $Pd(CO)_n$ species.

In the absence of suitable values for ε_1 and l we set the factor $\varepsilon_1 l$ equal to unity and use the quantity A_n/n as a direct measure of $[n]$.

Before beginning the warm ups the concentrations [1], [2], [3], and [4] were found to be in the ratio 1:0.125:0.039:0.009. To see under what circumstances this was compatible with a dilution of CO in Ar of 1:1000 we performed the following calculation.

We assume that the metal atoms are isolated from one another and that they occupy substitutional sites in the f.c.c. lattice of the solid argon. CO molecules are also assumed to occupy substitutional sites in the argon lattice and to react with the metal if it comes within one nearest neighbor distance of it. If there is no diffusion of either species before the matrix is warmed up and if the stabilities of the $Pd(CO)_n$ are in the order

$$Pd(CO)_4 \gg Pd(CO)_3 \gg Pd(CO)_2 \gg PdCO$$

then the probability P_n of finding a $Pd(CO)_n$ molecule is given by

$$[4] \qquad P_n = \binom{12}{n}\alpha^n(1-\alpha)^{12-n}$$

for $n = 1, 2, 3$ and

$$[5] \qquad P_4 = \sum_{n=4}^{12}\binom{12}{n}\alpha^n(1-\alpha)^{12-n}$$

where $\binom{12}{n}$ is the binomial coefficient and α is the CO/argon ratio.

Using formulas 4 and 5, [1], [2], [3], and [4] are found to be in the ratio $1:5.5\times10^{-3}:1.8\times10^{-5}:4.1\times10^{-8}$ for $\alpha = 10^{-3}$. The experimentally determined ratio indicates considerably more $Pd(CO)_{2\to4}$ than would be expected on the basis of this calculation. This suggests that during deposition there is considerable surface diffusion and reaction before the co-condensate is quenched. Based on this calculation alone, therefore, one cannot conclude unequivocably that one is justified in assigning the $Pd(CO)_n$ to the four bands on the basis of their intensities.

Analysis of the Warmup Kinetics

Hannay (13) gives the following equation for the rate of decrease of concentrations of two species A and B which react by diffusion in a solid

$$[6] \qquad \frac{-d[A]}{dt} = \frac{-d[B]}{dt} = 4\pi r_0[D_A + D_B] \times\left(1 + \frac{r_0}{[\pi(D_A + D_B)t]^{1/2}}\right)[A][B]$$

D_A and D_B are the diffusion coefficients of species A and B and r_0 is the radius of sphere within which A and B are assumed to react instantaneously. For typical values of diffusion coefficients in solids and for $r_0 \simeq 3$ Å the term $r_0/[\pi(D_A + D_B)t]^{1/2}$ is negligible for values of t in excess of 1. This, coupled with the assumption that one of the species B, say, diffuses much more slowly than A reduces eq. 6 to the form

$$[7] \qquad \frac{-d[A]}{dt} = 4\pi r_0 D_A[A][B]$$

which is of the form

$$\frac{d[\text{products}]}{dt} = k[A][B]$$

that is, that of second order kinetics. In our own case we assume that only CO diffuses, that trimolecular and higher encounters contribute negligibly to the formation of product and that no decomposition of the product takes place at the temperatures of the warmup experiments.

Accordingly the reactions which take place

during warmup are

$$M + CO \rightarrow \mathbf{1}$$
$$\mathbf{1} + CO \rightarrow \mathbf{2}$$
$$\mathbf{2} + CO \rightarrow \mathbf{3}$$
$$\mathbf{3} + CO \rightarrow \mathbf{4}$$

where **1**, **2**, **3**, **4** stand, respectively for the Pd mono, di, tri, tetra carbonyl and M for the free metal. The kinetics are therefore governed by the equations

$$[8] \qquad \frac{d[\mathbf{1}]}{dt} = k[CO]([M] - [\mathbf{1}])$$

$$[9] \qquad \frac{d[\mathbf{2}]}{dt} = k[CO]([\mathbf{1}] - [\mathbf{2}])$$

$$[10] \qquad \frac{d[\mathbf{3}]}{dt} = k[CO]([\mathbf{2}] - [\mathbf{3}])$$

$$[11] \qquad \frac{d[\mathbf{4}]}{dt} = k[CO][\mathbf{3}]$$

where

$$[12] \qquad k = 4\pi r_0 D_{CO}$$

and [M] stands for the free metal concentration. The free CO concentration decreases according to the equation

$$\frac{-d[CO]}{dt} = k[CO]([M] + [\mathbf{1}] + [\mathbf{2}] + [\mathbf{3}])$$

which may be written

$$[13] \qquad \frac{-d[CO]}{dt} = k[CO](N_0 - [\mathbf{4}])$$

where $N_0 = [M] + [\mathbf{1}] + [\mathbf{2}] + [\mathbf{3}] + [\mathbf{4}]$ is a constant equal to the total metal concentration in the matrix in any form. Figure 2 shows the concentration of the various species in the matrix as a function of warmup time. It indicates that with the exception of free CO the concentrations of all species at first increase with time. This indicates that initially the right hand sides of eqs. 8 through 11 are positive, thereby implying that

$$[14] \quad [M]_0 > [\mathbf{1}]_0 > [\mathbf{2}]_0 > [\mathbf{3}]_0 > [\mathbf{4}]_0$$

where the zero subscript indicates initial values.

This vindicates our assignments of the bands to the $Pd(CO)_n$ species on the basis of their relative intensities. It should be pointed out that because the concentrations of the four species are proportional to A_n/n rather than to A_n one requires a tentative assignment of the lines to the various $Pd(CO)_n$ before the concentrations can be evaluated and compared. The initial values of the A_n for the four carbonyl species were such, however, that only the assignment we stated previously is compatible with inequality (14).

Since the free metal concentration decreases monotonically with time, the concentration of the monocarbonyl is expected according to eq. 8 to come to a maximum and then decrease as indicated in Fig. 2. Although the temperature control and the time measurements were not carried out with the precision required in diffusion experiments it is instructive to see if the diffusion coefficient that one must assume for free CO in order to get the observed curves in Fig. 2 is a reasonable one. To do this we make use of the fact that initially $[\mathbf{4}] \ll N_0$ which yields the solution

$$[15] \qquad [CO] = [CO]_0 \exp(-kN_0 t)$$

for eq. 13.

A plot of $\log_e A_{CO}$ *vs.* t shows an initial straight line portion having slope of 3×10^{-4} s^{-1}. Taking N_0 to be approximately 3×10^{-8} atom cm^{-3} as determined from our deposition conditions and r_0 to be 4×10^{-8} cm, we obtain approximately 2×10^{-16} cm^2/s for D_{CO} in argon at a mean temperature of approximately 30 °K.

No literature values were found for the diffusion of CO in solid argon. One can, however, calculate the self-diffusion coefficient at 30 °K of Ar in Ar from the data of Berne *et al.* (14) to be of the order of 10^{-27} cm^2/s. It would appear that CO diffuses through solid argon much more rapidly than does argon itself. Such large differences in diffusivity of different species in the same solid are not uncommon in the solid state (15).

Our main purpose in presenting these calculations was to demonstrate their usefulness in assigning bands to various species in a series of compounds, such as $Pd(CO)_n$. The data prove that each of the observed bands at 2070, 2060, 2050, and 2044 cm^{-1} belong to a separate species since each behaves on annealing in an independent yet predictable manner.

Discussion of the Bonding, CO Stretching Frequencies and Force Constants in the Palladium Carbonyls $Pd(CO)_n$ where $n = 1$–4

Kimball (16) has employed a group theoretical approach to determine which orbitals on a metal atom are available for σ and π bonding for various symmetries $M(CO)_n$. For the palladium carbonyls $Pd(CO)_n$ we can associate four i.r. absorptions with the four species $n = 1$–4 the most probable stereochemistries of which are linear ($C_{\infty v}$) PdCO, linear ($D_{\infty h}$) $Pd(CO)_2$, trigonal planar (D_{3h}) $Pd(CO)_3$, and tetrahedral (T_d) $Pd(CO)_4$. These structural assignments for $Pd(CO)_n$ were determined independently of the corresponding $Ni(CO)_n$ data (3) and are the expected shapes which would be favored using the Gillespie–Nyholm (17) electron pair repulsion theory for a d^{10} system and Kettle's (18) overlap-integral arguments.

The assignments for $Pd(CO)_n$ and $Ni(CO)_n$ show some interesting parallelisms. Probably the most striking one is that the order of the observed CO stretching frequencies for $Pd(CO)_n$ is found to be identical to that of $Ni(CO)_n$(3). According to simple M.O. bonding theory one expects that as the coordination number increases, the metal–carbonyl π bond strength should decrease while the CO π bond strength increase, since the d_π–p_π interaction is antibonding in the CO region. This leads to the prediction that the CO π bond strength should follow the order $Pd(CO)_4 > Pd(CO)_3 > Pd(CO)_2 > PdCO$. This order should be reflected by the bond stretching force constants but not necessarily by the frequencies because the frequencies of the $Pd(CO)_{2\to4}$ depend on both stretch and stretch–stretch interaction force constants while that of PdCO depends only on stretch force constants. In fact, the experimentally determined frequencies are in the order $Pd(CO)_4 > Pd(CO)_3 > PdCO > Pd(CO)_2$ with the frequencies of the mono and dicarbonyls reversed, while the bond stretching force constants calculated from these increase monotonically with n in $Pd(CO)_n$.

A comparison of the force constants of the CO bonds in $Pd(CO)_n$ with $Ni(CO)_n$ is also desirable and the Cotton–Kraihanzel approximation is an appropriate starting point (6). In this approximation only the K_{CO} and K_{COCO} force constants are retained in the analysis. The frequencies, symmetry assignments, and secular equations are listed in Table 1 for $Pd(CO)_n$ where $n = 1$–4 together with DeKock's data for $Ni(CO)_n$. As both the i.r. and Raman frequencies of $Pd(CO)_4$ are known, K'''_{CO} and K'''_{COCO} can be determined uniquely (17.54 and 0.24 mdyn/Å respectively) and are in close agreement with Darling and Ogden's values (2) (17.55 and 0.295 mdyn/Å) estimated from their matrix infrared data for the mixed isotopic molecules $Pd(^{12}C^{16}O)_n(^{12}C^{18}O)_{4-n}$ where $n = 0$–4. In order to determine the K_{CO} and K_{COCO} force constants for the lower palladium carbonyls the K_{CO} bond stretching force constant values are assumed to be linear with the coordination number n which is in analogy with the findings of DeKock for $Ni(CO)_n$(3).

The calculations yield a set of K_{CO} force constants which as expected follow the order predicted on the basis of the simple π bonding model. The calculated K_{COCO} stretch–stretch

interaction constant for $Pd(CO)_n$ are all quite similar but smaller than the corresponding values for $Ni(CO)_n$.

It is interesting to note that the CO stretching frequencies and corresponding K_{CO} force constants for $Pd(CO)_n$ are all higher values than those for the corresponding $Ni(CO)_n$. One can attempt to rationalize this observation in the light of the following discussion.

Semi-empirical molecular orbital calculations (19) have been performed on $Ni(CO)_4$ and, on the basis of overlap populations, conclude that the nickel 4p orbitals are the major contributions to both σ and π Ni—CO bonding.

If this is also true in the palladium case one can possibly relate the lower stability of palladium carbonyls to the unfavorable energy of the palladium 5p orbitals.

Changes in the charge density in the carbon–oxygen internuclear region have also been examined (20) in a series of isoelectronic and isostructural carbonyls and correlated with infrared CO stretching frequencies. The constancy of the CO interatomic overlap populations for σ bonding orbitals confirmed the proposal that the σ-bond strengths are invarient throughout a series of related carbonyls. However, the corresponding π-overlap populations show distinct changes, implying that changes in CO bond strength which determines the variation in CO stretching frequency, is dominated by a change in the π-orbital overlap population.

Thus the higher CO stretching frequencies in $Pd(CO)_n$ compared to $Ni(CO)_n$ would appear to reflect a decreased M—CO π interaction in palladium relative to the corresponding nickel carbonyls.

It is also noteworthy that we could not detect any Pd—C stretching modes for $Pd(CO)_n$ where $n = 1$–4 in the low frequency region 500–200 cm^{-1} where the corresponding modes of $Ni(CO)_n$ are observed (3, 21). In matrix infrared studies performed independently of our own, Ogden and Darling (2) could not observe a Pd—C stretching mode for $Pd(CO)_4$.

Thus we are forced to conclude that either the vibrational modes of $Pd(CO)_n$ where $n = 1$–4 other than the CO stretching modes have low extinction coefficients and are too weak to observe or that they lie below 200 cm^{-1}.

In summary, the data appear to indicate weaker Pd—C bonds in $Pd(CO)_n$ compared to $Ni(CO)_n$ and this may be one of the contributing factors responsible for the unstable nature of $Pd(CO)_4$ relative to $Ni(CO)_4$.

We wish to thank Mr. H. Huber, Mr. B. Hughes, Mr. B. Torbet, Mr. A. Campbell, and Mr. R. Carter for technical assistance and the National Research Council of Canada and the Research Corporation for financial assistance.

A Low Temperature Infrared Study of Self-association in Thiols

R. BICCA DE ALENCASTRO[1] AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal, Québec

Received May 24, 1972

The infrared spectra of several aliphatic thiols and of benzenethiol were measured between 2400 and 2700 cm^{-1}, and 4800 and 5300 cm^{-1} in a 1:1 mixture of CCl_3F and $C_2F_4Br_2$, at temperatures ranging from 20 to −190 °C. Dimerization takes place at low temperatures and more highly associated species also appear. Free S—H groups are present in the solutions as well as in the pure liquids, even at the lowest temperatures. The association is of the S—H---S type in aliphatic thiols; both S—H---S and S—H---π bonds are found in the case of benzenethiol and α-toluenethiol. Hydrogen bonding has little effect on the anharmonicity of the S—H stretching vibration.

Les spectres infrarouges d'un certain nombre de thiols aliphatiques est du benzènethiol ont été mesurés entre 2400 et 2700 cm^{-1} et 4800 et 5300 cm^{-1} dans un mélange de CCl_3F et de $C_2F_4Br_2$ à des températures allant de 20 à −190 °C. Quand on abaisse la température, des dimères se forment suivis par des espèces plus associées. Des groupements S—H libres sont présents, toutefois, même aux plus basses températures et même dans les liquides. Les associations sont du type S—H---S dans les thiols aliphatiques alors qu'on trouve des liaisons S—H---S aussi bien que S—H---π chez le benzènethiol et le α-toluènethiol. La formation de la liaison hydrogène n'affecte guère l'anharmonicité de la vibration de valence S—H.

Introduction

S—H---S type hydrogen bonds are known to exist in dissolved and liquid thiols and thiophenols (1–6). In inert solvents, a free and an associated S—H stretching band can be distinguished at concentrations higher than 0.5–1.0 *M*. The free band is usually located at about 2580–2590 cm^{-1}, and it undergoes a low frequency shift upon hydrogen bond formation. The fundamental of the associated species shows an intrinsic intensity about 10 to 20 times greater than that of the free band (3, 4).

The associated species was usually thought to be a dimer. Infrared and n.m.r. studies of the molecular equilibria (3, 6) led to monomer–dimer equilibria highly displaced in favor of the monomer, at least at room temperature and at moderate concentrations. Some authors considered the possibility of the formation of open or cyclic dimers in both aliphatic and aromatic mercaptans (4, 5, 7). Josien, Dizabo, and Saumagne (1), and Cole, Little, and Michell (7) attributed a band found at 2564 cm^{-1} in liquid benzenethiol to a polymeric species.

We thought it might be interesting to study self-association of sulfhydryl-containing compounds over a wide temperature range and to measure the first S—H overtones as well as the fundamentals. The solvent used was a 1:1 mixture of CCl_3F (Freon 11) and $C_2Br_2F_4$ (Freon 114B2), (FR), which becomes a rigid glass at liquid nitrogen temperature. We hoped (*a*) to be able to follow the changing pattern of self-association from room to liquid nitrogen temperature; (*b*) to determine the anharmonicity constant of the S—H stretching vibration, and (*c*) to make the identification of certain free and associated species easier by exploiting the different intensity ratio of the corresponding bands at the fundamental and at the first overtone level.

Similar studies on the self-association of alcohols and amines were performed in this laboratory (8, 9) and it is hoped that the knowledge gained on the nature of hydrogen bonding of O—H, N—H, and S—H groups will be helpful in the investigation of more complex hydrogen bonded systems.

Results and Discussion

1. *Aliphatic Thiols*

We have chosen propane-1-thiol, propane-2-thiol, and 2-methyl-propane-2-thiol (tert-butylmercaptan) as representatives of primary, secondary, and tertiary aliphatic thiols with varying degrees of steric hindrance affecting

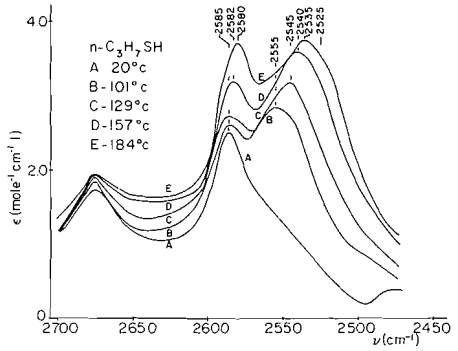

FIG. 1. The infrared spectrum (2400–2700 cm^{-1}) of a 0.69 *M* solution of propane-1-thiol in FR at different temperatures from 20 to −184 °C.

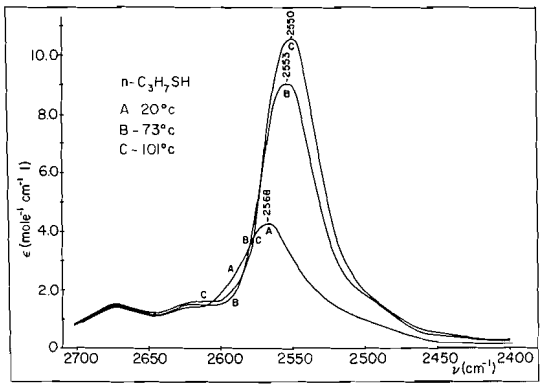

FIG. 2. The infrared spectrum (2400–2700 cm^{-1}) of liquid propane-1-thiol at 20, −73, and −101 °C.

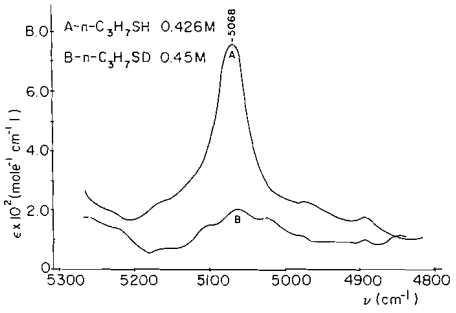

FIG. 3. The infrared spectrum (4800–5300 cm^{-1}) of solutions of propane-1-thiol and propane-1-thiol-d_1 in FR at 20 °C.

the S—H group. These compounds are sufficiently soluble in our solvent (FR). The results are very similar for these three molecules in the region of the fundamental, as well as in the region of the first overtone (Figs. 1–10).

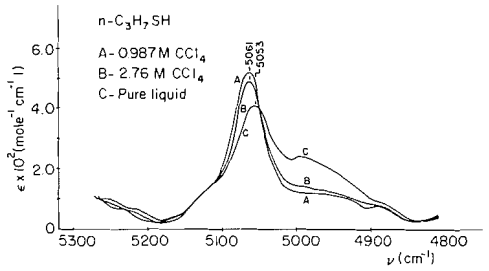

FIG. 4. The infrared spectrum (4800–5300 cm^{-1}) of solutions of propane-1-thiol in carbon tetrachloride and of the pure liquid at 20 °C.

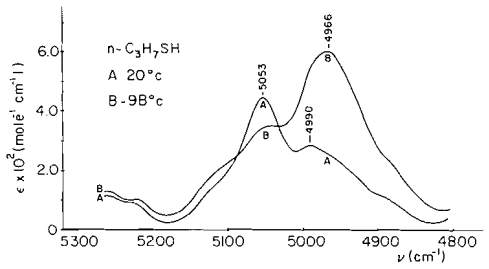

FIG. 5. The infrared spectrum (4800–5300 cm^{-1}) of liquid propane-1-thiol at 20 °C and −98 °C.

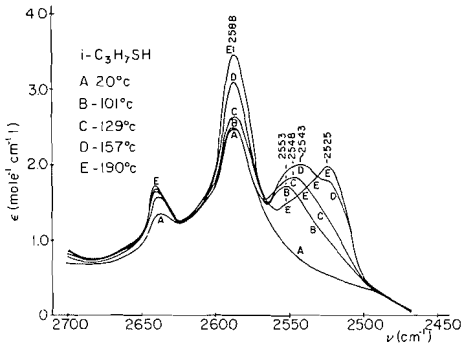

FIG. 6. The infrared spectrum (2400–2700 cm^{-1}) of a 0.47 *M* solution of propane-2-thiol in FR at different temperatures from 20 to −190 °C.

Surprisingly, in dilute solution, the fundamental of the free S—H group has its intensity increased when temperature is decreased (we shall discuss this apparent anomaly in section 2). At the same time, at lower frequencies, a broad and asymmetrical band appears which is very probably due to more than one associated species. In the case of propane-2-thiol (Fig. 6), two distinct associated bands are actually resolved. Both the free and the associated bands

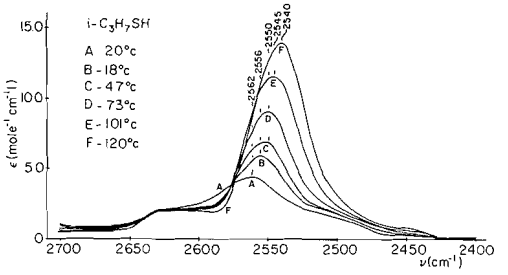

FIG. 7. The infrared spectrum (2400–2700 cm^{-1}) of liquid propane-2-thiol at different temperatures from 20 °C to −120 °C.

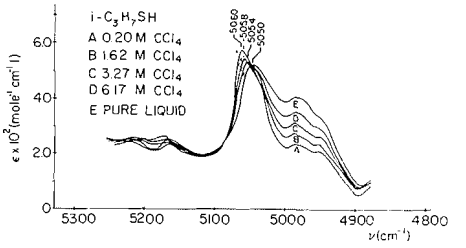

FIG. 9. The infrared spectrum (4800–5300 cm^{-1}) of solutions of propane-2-thiol in carbon tetrachloride and of the pure liquid at 20 °C.

are quite weak. Their apparent molecular extinction coefficients are of the order of $\varepsilon = 3$ l mol^{-1} cm^{-1}, and the approximate half-widths are about 30 cm^{-1} for propane-1-thiol and propane-2-thiol. In order to check our assignments, we measured the spectrum of propane-1-thiol-d_1 at room temperature as well as at low temperatures. The disappearance of both the free and the associated bands demonstrated their S—H character. (There is a weak band between 2675 and 2640 cm^{-1} in the aliphatic thiols. This band does not shift when we deuterate the —SH group, so it is not an SH band. According to Smith, Devlin, and Scott (10) it is a combination of two CH_3 deformation vibrations.)

Following suggestions by previous authors it seems natural to consider the higher frequency band located near 2540 cm^{-1} as the band due to the dimer and the lower frequency component near 2525 cm^{-1} as originating from a more associated species.

The low melting point of propane-1-thiol and propane-2-thiol enabled us to measure the spectra of the pure liquids at low temperatures (Figs. 2 and 7). At room temperature only a broad band can be seen with maximum at 2568 cm^{-1} for propane-1-thiol, and 2562 cm^{-1} for propane-2-thiol. The intensity of these bands increases upon lowering the temperature and their maxima are slightly displaced towards lower frequencies. This is a complex band due to more than one associated species.

The first overtone of the free S—H vibration is located near 5050 cm^{-1} and is split in two in dilute solutions. This splitting has been studied by several authors (10–12) and has been linked to the existence of rotamers. The splitting of the first overtone is roughly double (about 20 cm^{-1}) that of the fundamental. We have also measured the spectrum of propane-1-thiol-d_1 in this region. It contains only much weaker bands, which can be interpreted in terms of combinations involving C—H and S—D motions. This supports our assignment of the band near 5050 cm^{-1} to the free S—H stretching overtone. The corresponding anharmonicity constants can be computed from

$$\omega_e x_e = \nu_{01} - \frac{\nu_{02}}{2}$$

for the free S—H stretching vibration of the aliphatic thiols. It is of the order of 50 cm^{-1}, lower than those of the free OH and NH vibrations which are about 80 and 70 cm^{-1}, respectively (see refs. 9, 13, and references therein).

When the temperature is lowered the intensity of the free band decreases, and a band appears near 4960 cm^{-1} with a shoulder near 4930 cm^{-1}. The relative weakness of these bands is well in line with the similar behavior of the overtones of O—H and N—H associated vibrators (8, 9).

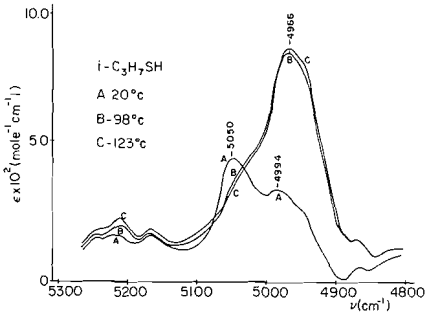

FIG. 8. The infrared spectrum (4800–5300 cm^{-1}) of liquid propane-2-thiol at different temperatures from 20 to −123 °C.

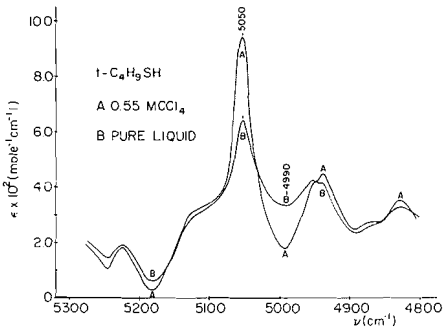

FIG. 10. The infrared spectrum (4800–5300 cm^{-1}) of a 0.55 *M* solution of methyl-2-propane-2-thiol (*t*-butylmercaptan) in carbon tetrachloride and of the pure liquid at 20 °C.

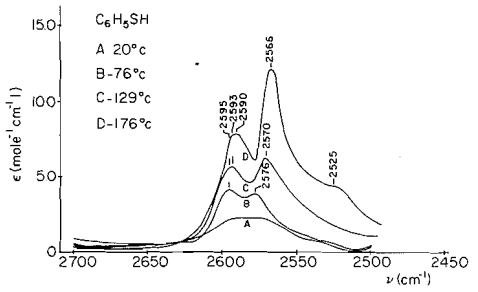

FIG. 11. The infrared spectrum (2400–2700 cm^{-1}) of a 0.29 *M* solution of benzenethiol in FR at different temperatures from 20 °C to −176 °C.

The anharmonicities computed with these overtone frequencies are about the same as that of the free band.

To ascertain the existence of these weak associated overtone bands we measured them at higher concentrations and in the pure liquid (Figs. 4, 5, 8, and 9). At −98 °C the spectrum of the pure liquid shows that the free band is still present, but its intensity is decreased and we observe a pronounced increase in the intensity of the associated bands. This implies that the pure liquid is mostly associated at this temperature, in agreement with the observations made with the fundamental. Again two strongly overlapping bands can be seen and we assign the one at higher frequencies to a dimer and the one at lower frequencies to a more associated species.

Observations made in this laboratory in the case of amines (14) showed that the bromine-containing solvent is capable of diminishing the degree of association. In order to ascertain whether the thiols behave similarly, we measured the spectrum of propane-2-thiol in CCl_3F (Freon 11) only, down to −98 °C, the lowest temperature we could reach with this solvent. The spectra were practically identical with those taken in FR at the same temperatures. It would seem then, that the bromine atoms in the solvent do not modify the association equilibria, (at least down to −98 °C).

The only new feature of the first overtone spectrum of 2-methyl-propane-2-thiol (tert-butylmercaptan) (Fig. 10) is that the free band is sharper and stronger than that of the other mercaptans. This means that in the pure liquid, the free band is less affected by overlap with neighboring bands, indicating that due to steric reasons it is associated to a lesser degree than propane-1-thiol and propane-2-thiol. The differences between the spectra of the pure liquid and dilute solutions nevertheless permit us to locate the associated band near 4990 cm^{-1} at room temperature (Fig. 10). Several weak bands can be seen in Fig. 10 at both higher and lower frequencies, but since they do not change their intensity appreciably with concentration, they must be due to combination tones not involving the S—H vibrator.

2. Benzenethiol and α-Toluenethiol

Several investigations have been carried out on the self-association of benzenethiol and substituted benzenethiols (1–7, and 15). The fundamental region shows a weak free band at 2591 cm^{-1} (for benzenethiol) and a dimer band at 2577 cm^{-1}, in dilute CCl_4 solutions. In the pure liquid the maximum is at 2569 cm^{-1} and this new maximum was attributed to a polymeric species (1).

We have measured the spectrum of a dilute solution (0.29 *M*) of benzenethiol in FR at temperatures ranging from 20 to −176 °C (Fig. 11). The free band is constantly present at about 2590 cm^{-1}, but an associated band at 2566 cm^{-1} (at −176 °C) becomes gradually stronger as the temperature is lowered. The asymmetry of this band and a weak band at 2525 cm^{-1} indicate the existence of other associated species.

As in the case of aliphatic thiols the intensity of the free band increases upon lowering the temperature. This curious fact deserves some discussion at this point. It is probably due to a

For personal use only.

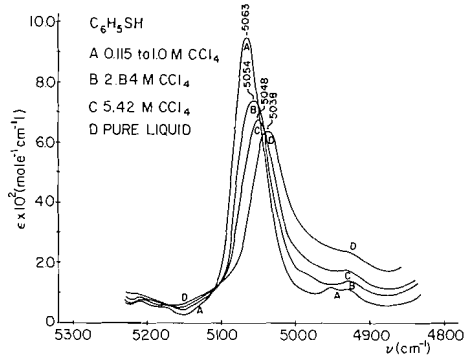

FIG. 12. The infrared spectrum (4800–5300 cm^{-1}) of solutions of benzenethiol in carbon tetrachloride and that of the pure liquid at 20 °C.

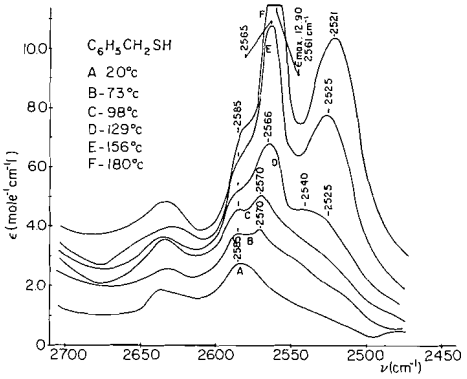

FIG. 13. The infrared spectrum (2400–2700 cm^{-1}) of a 0.37 *M* solution of α-toluenethiol in FR at different temperatures from 20 °C to −180 °C; curves displaced arbitrarily in the vertical axis.

combination of reasons. Firstly, the free and associated bands are close to each other (much more so than in the case of O—H---O or N—H---N bonds) and the apparent intensity of the free band is actually boosted by overlap with the dimer band. Secondly, if the dimer is an open dimer the free S—H endgroup should contribute to the observed intensity of the free band (actually the persistence of the free band could be used as an argument in favor of the open dimer structure). Thirdly, the equilibrium between rotamers and the different intensities of the respective bands could cause intensification of the free band in the case of aliphatic thiols if we suppose that the rotamer favored at lower temperatures has the more intense band.

In the overtone region, in dilute solutions (0.23 *M* in FR), only the free band is found with a maximum at 5076 cm^{-1}, and a half-width of about 50 cm^{-1}. It is slightly asymmetrical at its lower frequency side. At low temperature the intensity of this band decreases and a weak shoulder appears near 5020 cm^{-1}, but there is no detectable increase in intensity in the 4900–5000 cm^{-1} range. We were not able to measure the spectrum of the liquid at low temperatures (it crystallizes near −15 °C), so we studied the concentration dependence at room temperature (Fig. 12). Although only one maximum is seen in the whole range of concentrations (0.115, 1.00, 2.84, 5.42, and 9.76 *M* in CCl_4) the large half-width, the asymmetry, and the observed shifting of the frequency, together with observations made on the fundamental region, indicate that this band is actually composed of two strongly overlapping bands. They would give the usual anharmonicities of the order of 50 to 60 cm^{-1}.

Benzenethiol presents an interesting problem. The frequency of the strongest band at 2566 cm^{-1} (Fig. 11) is closer to that of the free band than the dimer band of the aliphatic thiols, and it is sharper. We are therefore justified in asking whether or not it is due to the same type of hydrogen bond (S—H---S) as in aliphatic thiols. It has been reported that the intensity of this band increases when mesitylene is added to the solution (1), and it has been suggested (5) that it could be due to S—H---π type bonds.

In order to clarify this point, we measured the spectra of α-toluenethiol which should present a spectrum similar to an aliphatic compound if there were only S—H---S type bonds present. The fundamental region of this molecule was measured from 20 to −180 °C in a 0.37 *M* solution of FR. The results are quite interesting: we find bands that correspond to both aromatic and aliphatic thiols (Fig. 13). At room temperature, the free band is at 2585 cm^{-1} which is characteristic of an aliphatic thiol. The associated bands readily appear when the temperature is lowered. At the lowest temperatures the free band is still present as a shoulder of the much more intense band centered at 2561 cm^{-1} and another broad band can be seen with maximum at 2521 cm^{-1}. This last band can be seen at intermediate temperatures to be formed by two overlapping bands (located at 2540 and 2525 cm^{-1} at −129 °C) as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

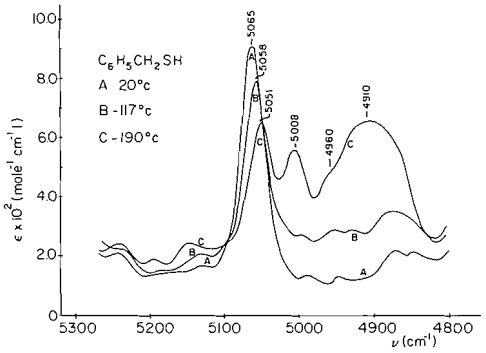

FIG. 14. The infrared spectrum (4800–5300 cm^{-1}) of a 0.37 *M* solution of α-toluenethiol in FR at different temperatures from 20 to −190 °C.

in the case of aliphatic thiols. We therefore interpret the 2561 cm^{-1} band (at −180 °C) as a dimer of the S—H---π type, and the bands found in the normal position for the aliphatic thiols (2540–2520 cm^{-1}) as due to S—H---S type association.

The free, S—H---π, and S—H---S bands (Fig. 14) are also clearly distinguished at the overtone level. It seems natural to assign the bands found at 5065 cm^{-1} (20 °C); 5008 cm^{-1} (−180 °C); and 4910 cm^{-1} (at −180 °C; with a sub-maximum near 4960 cm^{-1}) to the free, S—H---π, and S—H---S types, respectively. The latter band contains evidently several different species, however, and its intensity seems to be higher than that of the S—H---S dimer overtone for either benzenethiol or the aliphatic thiols. It must contain more highly associated species of both the S—H---S or S—H---π types, but we do not have any additional information on this. The computed anharmonicities are of the order of 50 to 60 cm^{-1} as in the previous cases.

Thus, the results obtained with α-toluenethiol help us to have a better understanding of the spectrum of benzenethiol. We interpret the 2566 cm^{-1} band as due to S—H---π type hydrogen bonding. Its overtone is likely to be in the region of 5000–5020 cm^{-1}. The other bands observed at low frequencies must be of the S—H---S type as in the case of α-toluenethiol.

Experimental

The fundamentals were measured on a Perkin–Elmer Model 621 spectrometer and the overtones on a Cary 17 instrument.

In the fundamental region, we used 0.48 and 0.9 mm cells for solutions, and 0.07 mm cells for the pure liquids. The cell windows were either silver chloride or silver bromide. In the overtone region, 1, 3, and 10 cm quartz cells were used. Their design followed conventional lines. No reactions were observed between the windows and the solutions or liquids. Temperatures were measured with a copper–constantan thermocouple.

The solvents were 1:1 mixtures of CCl_3F (Freon 11) and $C_2F_4Br_2$ (Freon 114B2) (FR) obtained from the E.I. Dupont de Nemours Co. of Canada. They were distilled and kept over phosphorus pentoxide. Spectrograde quality carbon tetrachloride from Anachemia Chems. Ltd., Montreal, was dried on molecular sieves type 4A.

The mercaptans were purchased from Aldrich Chem. Co. and were i.r., g.c. or refraction index controlled. Our benzenethiol was an Eastman Kodak Co., b.p.: 62–63/15 mm, chemical reagent quality product. The infrared spectra of all compounds we measured were practically identical with their previously published spectra. All products were handled in inert atmosphere to avoid oxidation or moisture adsorption. Deuterated propane-1-thiol was purchased from Merck, Sharp, and Dohme of Canada Ltd., with a minimum isotopic purity of about 98%, and was handled by conventional vacuum line techniques.

The solutions were prepared gravimetrically in narrow-neck volumetric flasks and the concentration was corrected for solvent contraction, admitting a linear dependence of volume with temperature. All curves were corrected for solvent absorption. Other details of the experimental technique, including calibration of the instruments were given elsewhere (13, 16).

Conclusions

The above results confirm the existence of S—H---S hydrogen bonds as postulated by previous authors. As the temperature is lowered the proportion of the dimer increases, but we find free molecules even at the lowest temperatures. At low temperatures at least one more highly associated species is present.

The S—H stretching overtones exhibit a behavior similar to that already described for alcohols and amines. The free band's relative intensity is much greater than at the fundamental level and makes it easier to identify free molecules, which are thus seen to exist even in the pure liquids, as in liquid water, alcohols, and amines (8, 9).

The anharmonicity constants are low, of the order of 50–60 cm^{-1} and they do not differ much from the free to the associated species. This is another characteristic of all *weakly* self-associated systems of the O—H---O, N—H---N, and S—H---S type.

In the case of benzenethiol and α-toluenethiol the presence of both S—H---π and S—H---S type bonds is strongly indicated.

Solvent Effects on the Phosphorescent State of Some Aromatic Carbonyls

JAMES B. GALLIVAN

American Cyanamid Company, Central Research Division, Stamford, Connecticut 06904

Received April 17, 1972

Triplet state properties of chromone, 4-chromanone, acetophenone, and several alkyl derivatives of acetophenone were studied in a variety of solvent systems. The phosphorescence excitation method was used to monitor the energies and relative intensities of singlet–triplet absorption bands in the presence and absence of heavy atom solvents. The results, combined with earlier optical and magnetic resonance studies of such systems, illustrate the importance of solvent environment in determining fundamental properties of these excited states. Observed trends are interpreted in terms of contrasting effects of changing solvent polarity on proximate n,π^* and π,π^* triplet states. To describe the relative contribution of each orbital type to the phosphorescent state, the coefficients of each wavefunction must change with solvent. Correspondingly, the solvent environment should be specified whenever orbital designations are made.

Nous avons étudié les propriétés de l'état triplet du chromone, du chromanone-4, de l'acétophénone et de plusieurs dérivés alkylés de l'acétophénone dans plusieurs systèmes de solvants. La méthode d'excitation par phosphorescence a été utilisée pour promouvoir les énergies et les intensités relatives des bandes d'absorption singulet-triplet en présence ou pas de solvants d'atomes lourds. Les résultats, combinés avec ceux provenant de la optique et magnétique résonance ultérieure de tels systèmes, illustrent l'importance de l'environnement du solvant dans la détermination des propriétés fondamentales de ces états excités. Nous interprétons les tendances observées en termes d'effets contrastants provenant du changement de polarité des solvants sur les états triplets n,π^* et π,π^* rapprochés. Afin de décrire la contribution relative de chaque type d'orbitale à l'état phosphorescent, les coefficients de chaque fonction d'onde doivent changer avec le solvant. On doit également spécifier l'environnement du solvant chaque fois qu'on fait les désignations d'orbitales. [Traduit par le journal]

Introduction

The ability to invert the relative energies of close lying n,π^* and π,π^* triplet states by altering the solvent environment has been demonstrated for certain aromatic carbonyls (1, 2). Problems associated with orbital labelling of the phosphorescent state of such compounds have been discussed (3). In a prior communication (4), zero field splitting (Z.F.S.) values determined from e.p.r. spectra of the triplet state were used to help designate orbital character. In this communication, results obtained by the phosphorescence excitation (P.E.) method are emphasized although a variety of experimental parameters are reported. The P.E. technique, as developed by Kearns and his associates (5), is considered advantageous in that it not only monitors the phosphorescent state, but also reveals the absorption spectra of the singlet–triplet transitions involved. Spectral differences in these transitions, induced by heavy atom solvents and changes in solvent polarity, provide valuable guidelines for orbital classification.

Experimental

Essential experimental details on all aspects of the work reported here, excepting the phosphorescence excitation spectra, have been given previously (3, 4, 6). The acetophenone (Fisher) and 4'-methylacetophenone (Eastman Kodak) were used as received. Eastman ethylene glycol was diluted 1:1 with distilled water to prepare the EG-W glasses. The heavy atom solvents ethyl iodide, carbon tetrabromide, and 1,5-diiodopentane (all from Eastman) and carbon tetrachloride (Baker) were used as received.

Phosphorescence excitation spectra were scanned at 77 °K on a Perkin–Elmer (Hitachi) MPF-2A luminescence spectrophotometer. High concentrations (~ 0.1 *M*) of the various solutes were examined in 3-methylpentane (3-MP), 2-methyltetrahydrofuran (MTHF), ethanol (ETOH), and ethylene glycol–water (EG–W). Spectra were also run in these same solvents containing $\sim 20\%$ ethyl iodide (ETI), or in one of the other heavy atom solvents.

Results

Phosphorescence excitation spectra for ~ 0.1 *M* solutions of acetophenone and 4'-methylacetophenone in ETOH and in ETOH–ETI are given in Figs. 1 and 2, respectively. The lowest energy band observed in each solvent system is indicated by an arrow. The results compare very

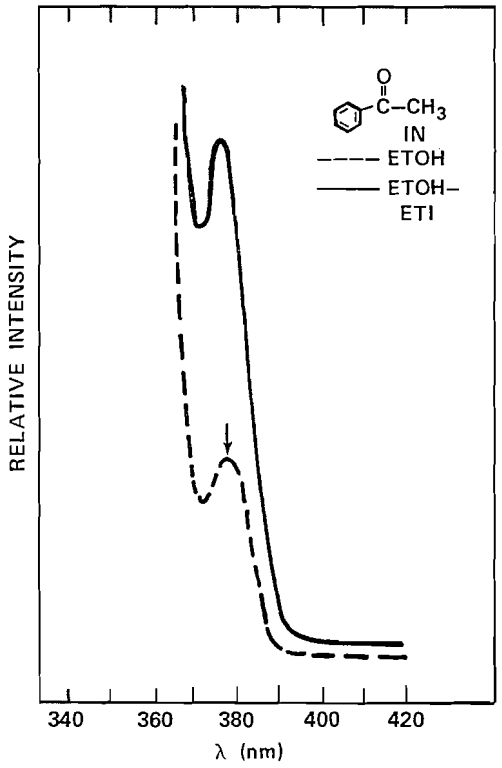

FIG. 1. Phosphorescence excitation spectra of acetophenone in ETOH and ETOH–ETI. The lowest energy band in each solvent system is indicated by an arrow.

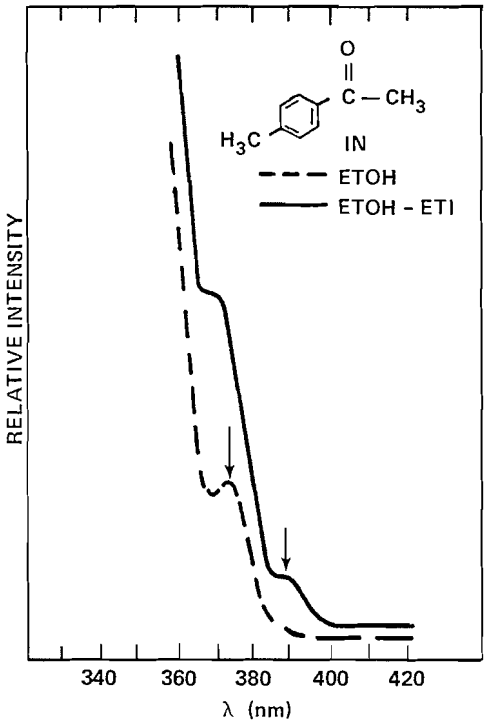

FIG. 2. Phosphorescence excitation spectra of 4′-methylacetophenone in ETOH and ETOH–ETI. The lowest energy band in each solvent system is indicated by an arrow.

favorably with those reported by Yang *et al.* (7) for these same solutes in EPA (ether, isopentane, alcohol in 5:5:2 ratios) glasses. Corresponding spectra for 3′,4′-dimethylacetophenone, chromone, and 4-chromanone are shown in Figs. 3 to 5. The weaker band observed for chromone in ETOH–ETI matches the band reported previously (3), which was observed in chloroform using the Evans oxygen perturbation technique (8). Wavelengths of the O–O bands of phosphorescence and the longest wavelength S→T absorption bands in ETOH and ETOH–ETI are given in Table 1.

In MTHF, the P.E. spectra were similar to those in ETOH, while those in 3-MP and EG–W were complicated by a number of factors. The acetophenones displayed no clearly resolved singlet–triplet absorption bands in 3-MP, although weak shoulders were indicated (*e.g.* ~372 and ~381 nm for 4′-methylacetophenone). In 3-MP–ETI and ETI itself, acetophenone exhibited a single such band, while the methyl derivatives displayed two bands (~372 and ~390 nm for 4′-methylacetophenone). As noted in prior publications (3, 4), chromone and 4-chromanone tend to associate at higher concentrations ($> 10^{-3}$ *M*) in nonpolar solvents at reduced temperatures. Thus, the observations of phosphorescence spectra from aggregates and unresolved singlet–triplet absorption bands in 3-MP were not surprising. In 3-MP–ETI the P.E. spectra of all five compounds were similar to those spectra in ETOH–ETI or in ETI itself. Neither the solutes nor ETI were miscible with EG–W at high concentrations, consequently no S→T bands were resolved in this solvent.

To minimize solvation effects due to polar heavy atom solvents, carbon tetrachloride (CCl_4), carbon tetrabromide (CBr_4), and 1,5-diiodopentane ($C_5H_{10}I_2$) were tried as substitutes for ETI in 3-MP solutions. These efforts were not successful owing to a variety of experimental problems. The CCl_4, even at very high concentrations, did not enhance spin–orbit

coupling sufficiently to permit observation of the weaker S→T bands. The CBr_4 was not sufficiently soluble to serve as a heavy atom solvent, while the $C_5H_{10}I_2$, although miscible with 3-MP, led to a snowy, non-transparent matrix on cooling with the result that no S→T bands were resolved.

In addition to the phosphorescence excitation spectra other experimental parameters were determined to supplement previously reported data. Spectral and lifetime data on the phosphorescent state of acetophenone and 4′-methylacetophenone in dilute (10^{-3}–10^{-4} *M*) solutions are given in Table 2. At these concentrations, triplet e.p.r. spectra were observed for chromone, 4′-methylacetophenone and 3′,4′-dimethylacetophenone in ETOH and EG–W. At the concentrations used for P.E. studies (~0.1 *M*), a positive e.p.r. spectrum was also observed for

Discussion

The phosphorescence excitation spectra as shown in Figs. 1 to 5 reveal weak absorption bands which represent direct population of triplet manifolds from singlet ground states. At the high solute concentrations used for these studies, the stronger of these bands is observed for each solute in both polar and non-polar solvents, without the aid of the heavy atom solvent. The weaker of these singlet–triplet (S→ T) bands is observed for all systems, except acetophenone, in the presence of high concentrations of ethyl iodide. Approximate extinction coefficients can be estimated by comparing relative phosphorescence intensities for excitation into each of these bands. In the absence of ETI, relative intensities of the stronger S→T bands and weaker S→S bands can be compared for each solute. Absolute values of ε for the S→S bands can be determined from conventional absorption spectrophotometry.

Values for ε of the stronger S→T bands in these compounds are not enhanced substantially by the addition of the heavy atom solvent. This observation, when coupled with estimated values for ε of $\sim 0.1\ l\ mol^{-1}\ cm^{-1}$, suggests that a primarily $^3n,\pi^*$ designation for these bands is appropriate. The weaker S→T bands are greatly enhanced by the presence of the heavy atom solvent. Values of ε range from $< 10^{-3}\ l\ mol^{-1}\ cm^{-1}$ in the lighter solvents to $> 10^{-2}\ l\ mol^{-1}\ cm^{-1}$ in these same solvents containing $\sim 20\%$ ETI. These observations are consistent with characteristics usually associated with transitions of primarily π,π^* character.

Acetophenone, even in polar solvents with added ETI, did not show a lower energy S→T band than that observed in 3-MP. This is consistent with the viewpoint (1, 2, 7) that the $^3n,\pi^*$ state of this compound lies lower in energy in many solvents covering a wide range of polarity.

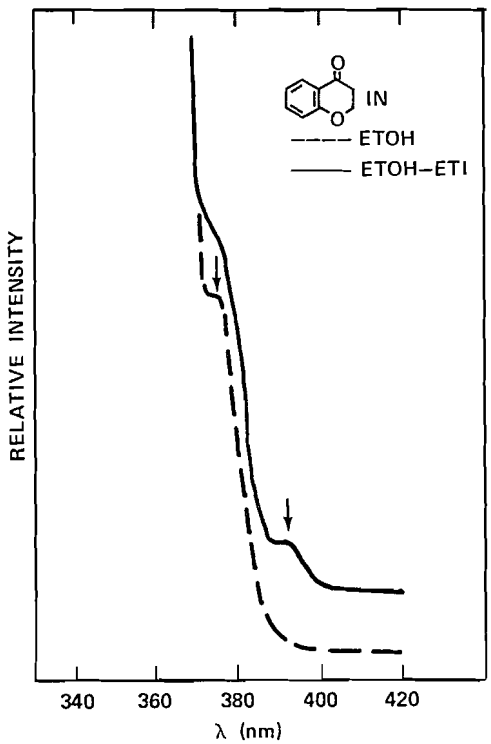

FIG. 5. Phosphorescence excitation spectra of 4-chromanone in ETOH and ETOH–ETI. The lowest energy band in each solvent system is indicated by an arrow.

The phosphorescence lifetime data (Table 2) reflect changes in radiative and/or radiationless rate processes as the solvent changes from 3-MP to MTHF to ETOH. These changes are interpreted in terms of an increasing contribution of π,π^* orbital character to the phosphorescent (n,π^*) state. On the basis of polarization data, Li and Lim (9) drew just the opposite conclusion concerning the relative energy orientation of these two states in acetophenone.

As shown in Fig. 2, 4′-methylactophenone displays one $S \rightarrow T$ absorption band ($^3n,\pi^*$) in ETOH and a second, lower energy band ($^3\pi,\pi^*$) in ETOH–ETI. These designations agree with those of Yang *et al.* (7) and are consistent with the change in relative intensities of these bands from >20:1 in ETOH to <6:1 in ETOH–ETI.

The results for 4′-methylacetophenone in 3-MP illustrate some of the problems associated with obtaining good P.E. spectra on such polar compounds in a non-polar matrix. Not only are solubilities of the samples reduced, but the increased energies of the π,π^* bands, and decreased energies of the n,π^* bands have the effect of merging the weak singlet–triplet transitions. Experimental problems resulted when alternative "non-polar" heavy atom solvents were tried, so that spin–orbit coupling enhancement was not demonstrated without the accompanying solvation effects. That such solvation effects are important is substantiated by the similarity of P.E. spectra in 3-MP–ETI, ETOH–ETI and ETI itself. The prospect of demonstrating the heavy atom role of enhancing spin–orbit coupling without the accompanying solvation effects may still be possible, *e.g.* in a heavy, rare gas matrix.

The P.E. results for 3′,4′-dimethylacetophenone, chromone, and 4-chromanone parallel those for 4′-methylacetophenone, and similar interpretations apply. The aggregation of chromone and 4-chromanone at the higher concentrations in 3-MP made all attempts to resolve $S \rightarrow T$ bands of these compounds in non-polar environments an exercise in futility. The observation of a triplet e.p.r. spectrum at 0.1 *M* 4-chromanone contrasts with our observations at 10^{-3} *M*, and points to the importance of the absolute steady state triplet concentration for e.p.r. detection. This factor must be fully assessed before drawing conclusions on negative e.p.r. results.

Radiative Lifetimes

The results given in Table 2 corroborate previously reported data (4) of generally decreasing energies and increasing lifetimes of the phosphorescent state with increasing solvent polarity. The relatively minor spectral shifts and approximately constant quantum efficiencies contrast with the order of magnitude changes in the phosphorescence lifetimes. These lifetime changes are consistent with significant increases in the radiative lifetime as the contribution of π,π^* character to the phosphorescent state increases. It is possible to estimate radiative lifetimes of these systems by employing different experimental parameters in several familiar expressions.

The first equation (10) expresses the radiative lifetime (τ_p^0) in terms of the measured phosphorescence lifetime τ_p, and measured fluorescence and phosphorescence quantum yields, ϕ_f and ϕ_p, respectively. Since the compounds

studied here show no measurable fluorescence, ϕ_f is assumed to be 0, while the ϕ_p for acetophenone, 0.65 (11), is taken as representative for these compounds; consequently τ_p^0 is simply $\sim 1.5\tau_p$. Interestingly, the compound with the longest lifetime, 3′,4′-DMA has a lowest triplet state which has been designated as n,π^* in a durene host crystal, based on the magnitude of its Z.F.S. parameter D (12*a*). However, in a more recent study of the magnetic resonance properties of the triplet states of some related aromatic carbonyls (12*b*), it is suggested that such clear cut designations may not be warranted.

Radiative lifetimes estimated from integrated intensities of the singlet–triplet absorption spectra (ref. 10, p. 49), yield values of τ_p^0 of <20 ms for the stronger bands and >1.5 s for the weaker bands in these compounds. In solvents containing $\sim 20\%$ ETI, the absorption of the weaker bands is enhanced sufficiently to give τ_p^0 values of ~ 0.1 s. The magnitudes of these τ_p^0's are consistent with n,π^* triplets (<20 ms), π,π^* triplets (>1.5 s), and π,π^* triplets (~ 0.1 s) for which spin–orbit coupling has been enhanced significantly by the presence of the heavy (iodine) atom.

Summary

The accumulated experimental evidence of these and earlier studies suggests that the phosphorescent states of these aromatic carbonyls are described best by an expression such as

$$\psi_T = \alpha\psi\ {}^3n,\pi^* + \beta\psi\ {}^3\pi,\pi^*$$

which includes the variable parameters α and β. The normalized sum $(1/\sqrt{2})(\alpha^2 + \beta^2)$ is unity with values for both α and β ranging between the limits 0 and 1, depending on the solvent environment. Although the solvent dependent luminescence properties of these and related systems have received considerable attention in recent years (1–4, 7, 13), and various interpretations of common phenomena have been offered (14, 15), additional experimental and theoretical effort will be necessary to unravel the complexities of these systems.

The author would like to thank J. S. Brinen for the e.p.r. measurements of the triplet state for the compounds studied. Thanks are also due Dr. Brinen, Dr. M. K. Orloff, and Dr. W. G. Hodsgon for valuable discussions and helpful suggestions.

The Structure and Physical Properties of μ-oxo-bis{oxotrichloro(*O*-perrhenyl chloride)rhenium(VI)}, and the Non-existence of β-$ReOCl_3$

C. CALVO, P. W. FRAIS, AND C. J. L. LOCK[1]

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received May 25, 1972

The compound previously reported as β-$ReOCl_3$ has been shown by analysis and single crystal X-ray diffraction to be μ-oxo-bis{oxotrichloro(*O*-perrhenyl chloride)rhenium(VI)}, $(Re_2O_3Cl_6)(ReO_3Cl)_2$. The crystals were triclinic, $a = 6.112(5)$, $b = 12.876(9)$, $c = 6.020(5)$ Å, $\alpha = 88.30(5)$, $\beta = 95.88(5)$, $\gamma = 105.36(5)°$, $P\bar{1}(C_i^2$, No. 2) $Z = 1$. Intensities were measured by a densitometer from photographs recorded on an integrating precession camera. The structure was refined by full matrix least squares to give a final R_2 of 0.072. The molecule is composed of a dimeric $Re_2O_3Cl_6$ unit with a bridging oxygen atom on the center of symmetry and an Re—O (bridge) distance of 1.847(1) Å. The remaining oxo-group on each rhenium is *cis* to the bridge and is strongly bonded (1.69(2) Å), and the position *trans* to the terminal oxo-group is filled by a weak bond to an oxygen atom of a perrhenyl chloride molecule. The infrared spectrum of the compound has been explained in terms of the structure.

Nous démontrons que le composé rapporté précédemment comme étant β-$ReOCl_3$ est le μ-oxo-bis{oxotrichloro(*O*-chlorure de perrhényl)rhénium(VI)}, soit $(Re_2O_3Cl_6)(ReO_3Cl)_2$, par analyse et diffraction de rayons-x d'un cristal unique. Les cristaux sont tricliniques, $a = 6.112(5)$, $b = 12.876(9)$, $c = 6.020(5)$ Å, $\alpha = 88.30(5)$, $\beta = 95.88(5)$, $\gamma = 105.36(5)°$, $P\bar{1}(C_i^2$, No. 2) $Z = 1$. Les intensités ont été mesurées au moyen d'un densitomètre à partir de photographies prises par une caméra de précession d'intégration. Nous raffinons la structure par calcul matriciel de moindres carrés pour obtenir un R_2 final de 0.072. La molécule est composée d'une unité $Re_2O_3Cl_6$ dimérique comprenant un atome d'oxygène faisant pont au centre de symétrie, avec une distance Re—O(pont) de 1.847(1) Å. Le groupe oxo-résiduel sur chaque rhénium est *cis* par rapport au pont et fortement lié (1.69(2) Å); la position *trans* par milieu fragile à l'atome d'oxygène d'une molécule de chlorure de perrhényl. Nous expliquons le spectre infrarouge de la molécule en nous basant sur la structure.

Introduction

We have described previously some products of the reaction of ReO_3 and $ReCl_5$ (1, 2). One of the products was apparently obtained by interconversion from α-$ReOCl_3$, and because of infrared data, and a superficial resemblance of the unit cell parameters of crystals of the product to those of monoclinic $MoOCl_3$, we suggested that the compound might be another form of $ReOCl_3$, which we have designated as "β-$ReOCl_3$". Further studies have shown that this conclusion was arrant nonsense and that "β-$ReOCl_3$" is an adduct of $Re_2O_3Cl_6$ and perrhenyl chloride. A single crystal X-ray diffraction study, analyses, and infrared studies have allowed us to identify the compound as μ-oxo-bis{oxotrichloro(*O*-perrhenyl chloride) rhenium(VI)}, $ClReO_3 \cdot Re_2O_3Cl_6 \cdot O_3ReCl$.

Experiments

Rhenium oxotetrachloride and perrhenyl chloride were prepared by standard methods and Nujol and solvents were purified and dried as previously outlined (3). Analyses of the rhenium to chlorine ratio as well as the oxidation state were done by neutron activation (4).

Infrared spectra were recorded on Perkin-Elmer 337 and 521 instruments. Solid samples were ground into a mull with dry Nujol and mounted between KBr, Irtran 2, or polyethylene plates with edges wrapped in Teflon tape, or crystals of $Re_2O_3Cl_6(ReO_3Cl)_2$ were squeezed between plates of Irtran 2 or polyethylene and the edges wrapped with Teflon tape to keep air and moisture out. X-Ray diffraction photographs of powdered samples were recorded on a Debye-Scherrer camera using nickel-filtered CuKα radiation. Samples were sealed inside fused silica capillary tubes.

Preparation of $Re_2O_3Cl_6(ReO_3Cl)_2$

(*a*) Equimolar amounts of ReO_3 and $ReCl_5$ were heated in a sealed, evacuated reaction vessel at ~300 °C for 24 h. Volatiles were distilled into U-traps by cooling the U-traps with liquid nitrogen. For several weeks, one of the U-traps not containing the volatiles was cooled in ice water while the volatiles were kept at room temperature. A purple frost formed on the sides of the room temperature U-traps and a green liquid formed in the cooled trap. The U-traps were sealed off and, upon standing for weeks, the purple frost decomposed and thin purple plates formed in another part of the tube. These purple plates, previously called "β-$ReOCl_3$" (1), are in fact $Re_2O_3Cl_6(ReO_3Cl)_2$. This

[1]To whom correspondence should be addressed.

method of preparation yielded only minor amounts of both purple compounds and in addition produced Re_3Cl_9, ReO_2, Re metal, $ReOCl_4$, and ReO_3Cl in varying and non-reproducible amounts.

(*b*) Rhenium oxotetrachloride was sealed in an evacuated Pyrex vessel, and irradiated with 3500 Å light for ~12 h. The yield of both purple products previously referred to as α- and β-$ReOCl_3$ (1), was very variable, and reaction only occurred about 50% of the time. After our previous publication (1), it was discovered that impurities in the $ReOCl_4$ played the major role in determining the extent and usefulness of this reaction in preparing $Re_2O_3Cl_6(ReO_3Cl)_2$.

(*c*) Once the crystal structure was solved and the existence of $ReOCl_4(OH_2)$ was confirmed (2), a reproducible method of preparation was found. One cmol of $ReOCl_4$ (estimated from the volume of the melt) and 1/2 cmol of H_2O (measured by connecting an evacuated, calibrated vessel to a source of water and varying the vapor pressure of the water by varying the temperature) were distilled into a Pyrex reaction tube (equipped with a breakseal) and sealed under vacuum. The tube was heated uniformly at ~200 °C for a few hours and then slowly cooled, taking care to avoid any temperature gradient. To the resulting mixture of $ReOCl_4$ and $ReOCl_4(OH_2)$ (2) was added (by distillation through the breakseal) 1 cmol of ReO_3Cl. The reaction vessel was then bathed in 3500 Å ultraviolet light (Rayonet Photochemical Reactor with 16 RPR 3500 Å lamps) until no further reaction occurred (~24 h) and the vessel was filled with thin purple crystals of $Re_2O_3Cl_6(ReO_3Cl)_2$. Excess $ReOCl_4$ and ReO_3Cl were separated from the product by cooling one end of the reaction tube with icewater or by hand picking the crystals of $Re_2O_3Cl_6(ReO_3Cl)_2$. The latter technique was often better since, because of the instability of $Re_2O_3Cl_6(ReO_3Cl)_2$ in a temperature gradient, it was difficult to free the crystals from impurities "purple frost" and $ReOCl_4(OH_2)$ without causing decomposition. Neutron activation analyses of the thin purple crystals gave chlorine:rhenium ratios of 2.22 and 2.15 (calcd. 2.00) and a ratio of ReO_4^-/ReO_2 in the alkaline hydrolysis of 6.3 (calcd. 5.0 for an oxidation state of $6\frac{1}{2}$). (Note: We consider this good agreement since the ratio is changing rapidly as a function of average oxidation state in this region as shown by the following oxidation states and ratios 6.4: 4:1, 6.5: 5:1, 6.6: 6.5:1, 6.7: 9:1.) Crystals prepared by all three methods were shown to be identical by X-ray powder photography.

Crystallography

Single crystal X-ray studies were done on a crystal prepared by method (*a*). The crystal was sealed in a fused silica capillary tube. All crystal data were obtained from a needle crystal of length 1.03 mm and thickness 0.05 × 0.11 mm^2.

Weissenberg and precession photographs of the crystal showed that it was triclinic. Precession photographs of the (*hk*0) and (*h*0*l*) layers, taken with CuKα radiation, were calibrated with a crystal of TiO_2 (rutile) and accurate cell parameters were obtained using the parameters for TiO_2, $a = 4.5929(5)$, $c = 2.9591(3)$ Å (5). Crystal data were

$Cl_8O_9Re_4$ Mol.wt. = 1172.4

Triclinic, $a = 6.112(5)$, $b = 12.876(9)$, $c = 6.020(5)$ Å, $\alpha = 88.30(5)$, $\beta = 95.88(5)$, $\gamma = 105.36(5)°$, $V = 454.4$ Å^3, $P\bar{1}$ (C_i^2, No. 2), ρ_0 not determined (see text), $Z = 1$, $\rho_c = 4.28$ (22 °C; CuKα, $\lambda = 1.5418$ Å).

Because of the instability of $Re_2O_3Cl_6(ReO_3Cl)_2$, it was not possible to obtain an experimental value for the density. The unit cell used in this work, which reflects the form of the crystal, is not the cell defined by International Tables for Crystallography; the I.T.C. cell is $a = 6.112(5)$; $b = 12.707(9)$; $c = 6.020(5)$ Å; $\alpha = 92.20(5)$; $\beta = 101.83(5)$; $\gamma = 93.20(5)°$ and is derived from our cell by the transformation matrix (100/110/001).

Intensity data for the (*nkl*), $n = 0$, 1, 2 layers were obtained initially from films recorded on an integrating Weissenberg camera using CuKα radiation and for the (*h*0*l*) and (*hk*0) layers on an integrating precession camera using MoKα radiation. No attempts were made to assign standard errors to each intensity measured. Using this data set, the structure was solved and an R_1 factor of 0.15[2] was obtained. Because of the shape of the crystal, considerable absorption errors existed in the CuKα data ($R_1 = 0.18$ as opposed to $R_1 = 0.12$ for MoKα data) and it was therefore decided to obtain a complete data set using MoKα radiation only.

Final intensity data used in the refinement of the structure were obtained from films recorded on an integrating precession camera using MoKα radiation, the layers recorded being (*hnl*), $n = 0$, 1, 2, 3 and (*hkm*), $m = 0$, 1, 2. All intensities were measured using a Joyce–Loebl microdensitometer and then corrected for Lorentz and polarization effects. No absorption corrections were made. This would introduce a maximum error in F_0 of 16%, but more than 90% of the data will not be in error by more than 6% as a result of absorption. Standard errors, σ, were assigned to each intensity measured and weights $w = 1/\sigma^2$ were used throughout the refinement. For each reciprocal lattice layer measured, a minimum value of σ was estimated from the accumulated relative errors of the

[2] $R_1 = \dfrac{\Sigma\| F_o| - |F_c\|}{\Sigma|F_o|}$; $\quad R_2 = \left\{\dfrac{\Sigma w(|F_o| - |F_c|)^2}{\Sigma w F_o^2}\right\}^{1/2}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

factors used to scale different films and different wedges on the densitometer. To this minimum value of σ was added an additional value which took account of the intensity and intensity profile of the spot, intensity and irregularity of the background, edges of the beam stop or layer screen shadows, and average reproducibility of each measured intensity. Smallest values of σ were therefore assigned to well defined spots of uniform integrated intensity that could be measured on three or more films. For unobserved reflections, weights calculated from $\sigma = 0.5\,F_{min}$ were used only when the calculated structure factor $|F_c| > 0.8\,F_{min}$, where F_{min} was the local minimum of the observed structure factor; otherwise they were given zero weights.

Solution of the Structure

The unit cell was triclinic with space group $P1$ or $P\bar{1}$. Patterson maps were calculated separately using zero layer Weissenberg data (CuKα) from the (100) zone, and the zero layer precession data (MoKα) from the (010) and (001) zones. The four largest peaks found in the asymmetric unit of each projection were such that two were approximately twice as large as the remaining two. This is characteristic of four rhenium atoms in the unit cell, related in pairs by a center of inversion. The choice of $P\bar{1}$ as the space group at this stage was later confirmed by the successful structure analysis.

Using the initial data set obtained chiefly with an integrating Weissenberg camera using CuKα radiation (see Experiments section), the positions of the two rhenium atoms in the asymmetric unit were easily established. The structure was found to consist of a tetramer of rhenium atoms, with distances of Re1—Re2 = 3.89(1) Å, Re2—Re′2 = 3.72(1) Å and Re1—Re″1 = 4.50(1) Å (where Re′2 indicates the atom related to Re2 by the inversion center and Re″1 indicates Re′1 translated 1 unit cell distance in the y direction). The electron density was calculated based on phases obtained from the heavy atom positions, and it became clear that the structure was not consistent with the assumption that the compound was $ReOCl_3$. Four chlorine atoms and five oxygen atoms were soon located in the asymmetric unit and the structure was found to be an adduct of $Re_2O_3Cl_6$ and two molecules of ReO_3Cl. The structure was refined using a full matrix least-squares program CUDLS written by Stephens for the CDC 6400 computer. Despite the fact that R_1 was 0.15, all bond distances, bond angles, non-bonded distances, and isotropic temperature factors were reasonable and the structure was assumed to be essentially correct. The high value of R_1 was attributed to absorption errors which were especially apparent for the Weissenberg data using CuKα radiation. A completely new set of data was obtained before refinement of the structure was continued (see Experiments section) and R_1 dropped to 0.10 by varying only the overall scale constant. Refinement was terminated when no shift of atom parameters of greater than $\frac{1}{3}\sigma$ was observed and $R_1 = 0.067$ and $R_2 = 0.072$. Of the 1768 independent reflections measured, 1576 were given non-zero weights in the last cycle of least squares refinement. Scattering curves used in the refinement process were obtained from Cromer and Waber (6) for rhenium, chlorine, and oxygen, and anomalous dispersion corrections for rhenium and chlorine were taken from Cromer (7).

A difference Fourier map calculated using the structure factors listed in Table 4 had no residual peaks greater than $+1.5\ e/Å^3$ or less than $-1.7\ e/Å^3$.[3] The final parameters of the atoms are shown in Table 1.

Discussion

$Re_2O_3Cl_6(ReO_3Cl)_2$ consists of one molecule per unit cell of a tetramer of rhenium atoms, joined by two types of bridging oxygen atoms, as illustrated in Fig. 1. One of these lies at a center of inversion. The sixth coordination site of each of the two rhenium atoms in the μ-oxo-bis{oxotrichlororhenium(VI)} portion of the molecule is filled by a weak bond to one of the oxygen atoms of perrhenyl chloride. The resulting adduct is a combination of tetrahedrally coordinated Re(VII) and octahedrally coordinated Re(VI), with an average oxidation state of 6.5, which was confirmed by analysis.

Tables 2 and 3 list bonded distances, bond angles, and non-bonded distances found in $Re_2O_3Cl_6(ReO_3Cl)_2$. An examination of the bonded distances in the $Re_2O_3Cl_6$ portion of

[3]Table 4 is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

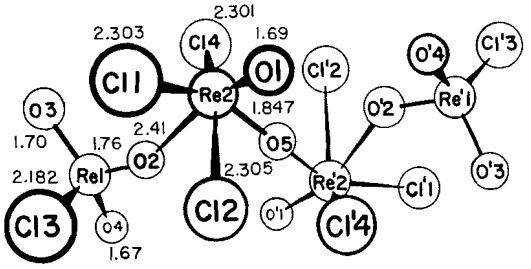

FIG. 1. Geometry of a single molecule of $Re_2O_3Cl_6(ReO_3Cl)_2$ viewed up the a^* axis. Bond distances shown in Å.

the molecule reveals several interesting, although not unexpected, features. The three chlorine–Re2 bond distances (2.303(5), 2.301(6), and 2.305(5) Å) do not differ significantly even though two chlorine atoms are *trans* to each other, whereas the third is *trans* to a bridging oxygen atom. Similar results have been observed previously (8, 9). These Re—Cl distances are shorter than most which have been measured. Typical values are 2.330(5) to 2.370(5) Å but are usually for complexes of Re(III), (IV), and (V), and the Re—Cl distances in our compound are comparable to those found in other Re(VI) (2.29(1) Å for $ReOCl_4 \cdot OH_2$(2)) and Re(VII) compounds (2.230(4) Å for ReO_3Cl(10)).

The Re2—O1 distance of 1.69(2) Å is comparable to those found in $ReOCl_4(OH_2)$ (1.63(2) Å) (2), K_2ReOCl_5 (1.66(3) Å) (11), $ReOCl_3[P(C_2H_5)_2(C_6H_5)]_2$ (1.60(5) Å) (12), $ReOCl_2(C_5H_7O_2)P(C_6H_5)_3$ (1.70(1) Å) (13), $[ReOBr_4(CH_3CN)]^-$ (1.73(6) Å) (14), and $[ReOBr_4(OH_2)]^-$ (1.71(4) Å (15), where the very strongly bonded oxo-group is postulated to be present (14).

The center of symmetry requires either the Re2—O5—Re′2 system be both symmetric and linear or that the system is asymmetric, or bent, or both, and disordered. Refinement of the isotropic temperature factors for O5 gave a value comparable to the O1 and O2 temperature factors, and the value is not abnormally large which suggests no disorder. However, the final anisotropic temperature factors for O5, while of comparable or smaller magnitude than O1 and O2, are markedly anisotropic. One can consider three reasons for this anisotropy as (*i*) absorption errors, (*ii*) disorder, (*iii*) genuine anisotropic motion. We have tested for (*i*) by refining the structure using only reflections which would not show large absorption corrections, but there was little change in the anisotropic temperature factors and no tendency for U_{22} to increase. The thermal parameters suggest the motion is in the *ac* plane and since the force constants for motion along a M—O—M bond are far higher than that for a bending motion (22), we might

*Estimated standard deviations in parentheses. Except for Re—Re, only distances less than 3.50 Å are included.

†Atoms indicated with a double prime mark are related to the atoms listed in Table 1 (x, y, z) by the symmetry relationships shown in the second column.

‡Atoms indicated with a single prime mark are related to the atoms listed in Table 1 (x, y, z) by the symmetry relations $(1-x, 1-y, 1-z)$, and belong to the same molecule (see Fig. 1).

expect that the bending motion, which will take place roughly in the *ac* plane, would be preferred. It is not possible to decide unambiguously between (*ii*) and (*iii*), but we prefer (*iii*) to (*ii*) since there is no apparent anomaly in the temperature factors of the other groups attached to Re1, which we would expect if a bent Re—O—Re bond were present, since the disorder would cause a movement of the other attached groups. In addition we see no sign of the infrared active M—O—M symmetric stretch at $\sim 500\ cm^{-1}$, which is observed for compounds of this type which have a bent M—O—M bond (22).

The apparent Re2—O5 distance of 1.847(1) Å is comparable to 1.860(5) Å reported for $K_4ReOCl_{10}\cdot H_2O$ (8) where the bridging atom lies on a four-fold axis, but not a center of symmetry. Apparently, however, the Re2—O5 distance is significantly shorter than reported for the Re—O (bridge) distance $[Pt(NH_2)_4]_2$-$Re_2O_3(CN)_4$ (1.9149(4) Å) (16) where again the oxygen atom is in a special position. The errors in the bond lengths, which are probably higher than those reported here, are so low because the atoms involved apparently lie in special positions between the two rhenium atoms, for which the interatomic distance is known with high accuracy. In all the structures reported, bending of the M—O—M system and subsequent disorder, although unlikely, might occur, but would be difficult to detect because of the position of the oxygen atom between the two heavy scatterers. Despite these reservations, the apparent difference in bond lengths is reflected in the M—O—M stretch frequencies (see later) and presumably in bond strength.

$Re_2O_3Cl_6(ReO_3Cl)_2$ is the first compound containing coordinated perrhenyl chloride whose structure has been investigated by X-ray diffraction techniques. The compound $ReOCl_4\cdot ReO_3Cl$, whose structure was postulated to be very similar to that of one of the centrosymmetrically related halves of $Re_2O_3Cl_6$-$(ReO_3Cl)_2$ (17, 18) on the basis of infrared spectroscopy, and another adduct, SO_2Cl_2-$(ReO_3Cl)_2$, whose postulated structure involved coordination through an oxygen of the sulfuryl chloride group resulting in a five coordinate rhenium atom (26) have been reported. In $Re_2O_3Cl_6(ReO_3Cl)_2$, the symmetry of the perrhenyl chloride group is C_1 compared to C_{3v} for free ReO_3Cl. This is reflected by the longer Re1—O2 bond length (1.76(1) Å) for the bridging oxygen atom as compared to the remaining Re1—O distances of 1.70(2) and 1.67(2) Å. These Re1—O distances are, on the average, shorter than those found in perrhenyl chloride (1.761(3) Å (10), and a similar shortening of the Re1—Cl3 distance from 2.230(4) Å to 2.182(7) Å is observed in going from the uncoordinated species to the adduct. The decrease in bond lengths on coordination is not unexpected for the non-bridging atoms, although one would expect a resultant lengthening in the bridging Re1—O2 distance, which is not observed.

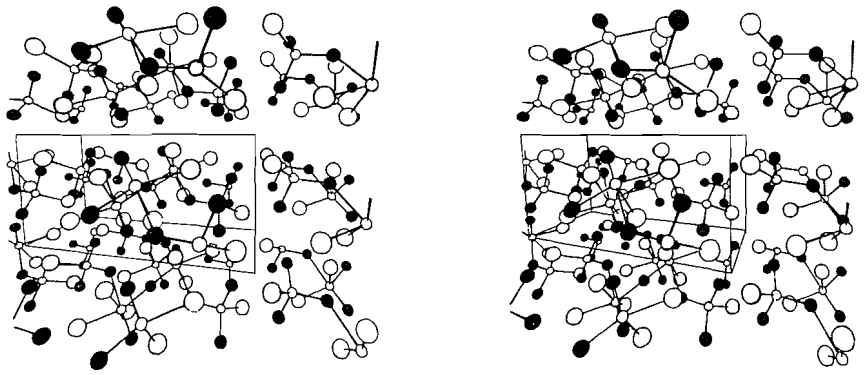

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of $Re_2O_3Cl_6(ReO_3Cl)_2$ viewed down the *a* axis. The origin of the unit cell is at the upper right and the *b* and *c* axis run approximately parallel to the planes described by *a* and the horizontal and vertical edges of the paper, respectively.

The crystal packing is shown in Fig. 2. The molecular units are packed in a layer structure with the layers running parallel to the *ab* plane. Within the layers, the molecules are stacked directly above each other in the *a* direction, and in the *b* direction the molecules are packed end to end such that the chlorine atom and two oxygen atoms of a perrhenyl chloride group in one molecule interleave with the centrosymmetrically related atoms of the next molecule. This means that the rhenium atoms (and thus the framework of the molecules) are arranged almost in a spiral along the *b* direction. The layers are also arranged such that in the *c* direction, a molecule in one layer sits almost directly above another molecule in the next layer.

The measured X-ray data for a powdered sample of $Re_2O_3Cl_6(ReO_3Cl)_2$ are reported in Table 5, with corresponding calculated values of *d* spacings and intensities calculated from the single crystal parameters determined in this work. There is fair agreement between the two sets of values although the ratio I_{calcd}/I_{obs} at low angles is consistently higher than the ratio at high angles. (This is probably caused by I_{obs} being reduced at low angles because of absorption; peaks in this region are strong and are superimposed on an appreciable background scattering caused by the glass capillary containing the sample.) We found that the X-ray powder pattern was the only easy, reliable method of checking the purity of $Re_2O_3Cl_6(ReO_3Cl)_2$. On many occasions, when we thought we had pure samples of crystals, X-ray powder photographs showed that the sample was contaminated with appreciable amounts of "purple frost" (a product which we have not yet characterized), as well as $ReOCl_4(OH_2)$ and the decomposition products noted previously (2). Because of the difficulty of purifying $Re_2O_3Cl_6(ReO_3Cl)_2$, a legitimate question arises as to whether the measured powder data are for a pure sample. The commonest, and most difficult to remove, impurity was "purple frost", and comparison of the X-ray powder photograph of this compound (1), and those of other possible impurities, with our powder photograph of $Re_2O_3Cl_6(ReO_3Cl)_2$, has convinced us that, although the agreement between observed and calculated data is only fair, the observed powder data (Table 5) is that of pure $Re_2O_3Cl_6(ReO_3Cl)_2$.

Initially it proved difficult to obtain an infrared spectrum of $Re_2O_3Cl_6(ReO_3Cl)_2$. When heated *in vacuo*, in a gas cell, the purple crystals decomposed to a yellow liquid and a nonvolatile black residue. The yellow liquid had an infrared spectrum characteristic of a mixture of $ReOCl_4$ and ReO_3Cl, whereas the residue was identified by X-ray powder diffraction as Re_3Cl_9. Similarly, in Nujol as well as $TiCl_4$ and CCl_4, $Re_2O_3Cl_6(ReO_3Cl)_2$ decomposed and infrared spectra showed peaks characteristic of a mixture of $ReOCl_4$ and ReO_3Cl (see Table 6). The Nujol mull, as well as both solutions, became emerald green, typical of solutions of $ReOCl_4$.

As reported previously (1), problems were also encountered in obtaining reproducible infrared data for solid $Re_2O_3Cl_6(ReO_3Cl)_2$ when

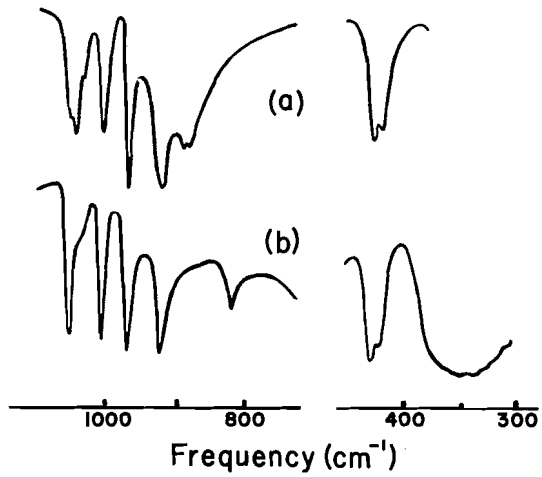

FIG. 3. The infrared spectra of (*a*) $ReOCl_4 \cdot ReO_3Cl$ (from ref. 17), and (*b*) $(Re_2O_3Cl_6)(ReO_3Cl)_2$ (this work).

$(ReO_3Cl)_2$ was β-$ReOCl_3$, but clearly the 1018 cm^{-1} peak arises from one of the impurities often observed in the X-ray powder films of apparently pure $Re_2O_3Cl_6(ReO_3Cl)_2$, possibly $ReOCl_4(OH)_2$ which has an infrared peak at $1016.5 \pm 1\ cm^{-1}$ (2).

Reproducible infrared spectra of $Re_2O_3Cl_6$-$(ReO_3Cl)_2$ were finally obtained by carefully supporting very thin, large plate crystals between Irtran 2 slabs or polyethylene discs with the disc edges wrapped in Teflon tape. The success of this technique for obtaining an infrared spectrum was very dependent on the thickness of the crystals mounted, which were as thin as possible (< 0.1 mm). The infrared spectrum is shown in Fig. 3 with that reported recently for a 1:1 adduct of $ReOCl_4$ and ReO_3Cl (17) where the postulated structure is very similar to that of one of the centrosymmetrically related halves of $Re_2O_3Cl_6(ReO_3Cl)_2$. The frequencies and assignments of these and other infrared spectra are listed in Table 6.

In the gas phase, ReO_3Cl has infrared absorptions at 1003 cm^{-1} (a_1), 971 cm^{-1} (e), and 429 cm^{-1} (a_1) (19). The lowering of symmetry on coordination in $Re_2O_3Cl_6(ReO_3Cl)_2$, results in a splitting of ν_4 (e). The two components (a' and a'') appear for $Re_2O_3Cl_6$-$(ReO_3Cl)_2$ at 970 and 930 cm^{-1} and for $ReOCl_4 \cdot ReO_3Cl$ at 973 and 931 cm^{-1} (17). The peak at 1003 cm^{-1} (a') in ReO_3Cl is unaffected by the lowering of symmetry, and is at 1003 cm^{-1} for $Re_2O_3Cl_6(ReO_3Cl)_2$ and 1005 cm^{-1} for $ReOCl_4 \cdot ReO_3Cl$. The symmetric ReO_3 deformation in ReO_3Cl at 429 cm^{-1} of a_1 symmetry is apparently split in both $Re_2O_3Cl_6(ReO_3Cl)_2$ (441 and 431 cm^{-1}) and $ReOCl_4 \cdot ReO_3Cl$ (442 and 433 cm^{-1}). The splitting cannot arise from the lowering of symmetry from C_{3v} to C_1, and in the former case, where we know the crystal structure, cannot arise from different site symmetries for the two ReO_3Cl groups. Thus the splitting must arise either from coupling between the vibrational modes of the two perrhenyl groups in the same molecule, or in reality there is no splitting, but an accidental near-coincidence between the symmetric ReO_3 deformation mode and an ReO_3Cl–(molecular residue) interaction, perhaps the Re—O stretch of the weakly bonded perrhenyl chloride oxygen atom.

The Re=O stretch in $ReOCl_4$ (gas phase) at 1040 cm^{-1} (3) is shifted to 1036 cm^{-1} for $ReOCl_4 \cdot ReO_3Cl$, and the Re=O stretch for the similar oxo group in $Re_2O_3Cl_6(ReO_3Cl)_2$ is at 1039 cm^{-1}. The very small shift in this stretching frequency implies very little change in the Re=O bond strength, and suggests a very weak bond to the group *trans* to the oxo group, consistent with the long distance to the ReO_3Cl groups in $Re_2O_3Cl_6(ReO_3Cl)_2$. There is no evidence of splitting of the 1039 cm^{-1} peak in $Re_2O_3Cl_6(ReO_3Cl)_2$, as was observed for $ReOCl_4 \cdot ReO_3Cl$ (17). Furthermore, the reported broad peak at $\sim 890\ cm^{-1}$ in the infrared spectrum of $ReOCl_4 \cdot ReO_3Cl$ (17) did not appear in the infrared spectra of pure mixtures of ReO_3Cl and $ReOCl_4$ (see Table 6), whereas evidence of the 1:1 adduct was there in all cases. A broad peak at $\sim 890\ cm^{-1}$ was observed, however, when the neat mixture of ReO_3Cl and $ReOCl_4$ between KBr plates was opened to the atmosphere for a few seconds. We therefore conclude that this absorption in the infrared spectrum of $ReOCl_4 \cdot ReO_3Cl$ is the result of a hydrolysis or oxidation product, and not the result of vibration of the weakly bonded oxygen atom of ReO_3Cl against the rhenium atom of $ReOCl_4$, as was postulated by Petrov *et al.* (17).

The infrared absorption at $\sim 830\ cm^{-1}$ observed for $Re_2O_3Cl_6(ReO_3Cl)_2$ is caused by the Re—O—Re stretching mode of the linear bridge, and is quite similar to 851 cm^{-1}

for $Cs_4[Re_2OCl_{10}]$, and 855 cm^{-1} for $K_4[Re_2OCl_{10}]$ (20, 21), which has been shown to contain a linear Re—O—Re system (8).

In passing, it should be noted that Wing and Callahan (22) have tried to relate M—O—M stretching frequencies to the M—O—M angle. It is evident that the group *trans* to the bridging oxygen atom is also important in determining this frequency. For instance, for $[(C_6H_5)_4As]_2Re_2O_3Cl_8$ and $[(C_2H_5)_4N]_2Re_2O_3Cl_8$, which are postulated to contain linear O=Re—O—Re=O systems, the bridging frequencies are at 725 and 740 cm^{-1}, respectively, with the terminal Re=O stretch frequencies at 977, 970, and 977, 955 cm^{-1}, respectively (23). A similar effect is observed for the $Re_2O_3(CN)_8^{4-}$ ion, which is also known to contain a similar linear system (16) where the Re—O—Re stretch frequency is at 720 cm^{-1} and the Re=O stretch frequency is at 1020 cm^{-1} (24). As we have seen above, however, if the oxo group is *cis* to the Re—O—Re system and a chlorine atom is *trans*, the Re—O—Re stretch frequency is at least 100 cm^{-1} higher. We have commented previously on the strong *trans* weakening effect of the Re=O system (25), which is shown clearly here in the lower M—O—M stretch frequencies and, as we have commented above, in the longer Re—O (bridging) bond length in $Re_2O_3(CN)_8^{4-}$ compared to that in $Re_2O_3Cl_6(ReO_3Cl)_2$.

The preparation of $Re_2O_3Cl_6(ReO_3Cl)_2$ is clearly dependent on the co-condensation of $ReOCl_4$, ReO_3Cl, and H_2O, as shown in preparation (*c*). The preparation probably involves a photochemical elimination of HCl from $ReOCl_4(OH_2)$ in the presence of ReO_3Cl (to complete the octahedral coordination) to give $ReOCl_3(OH)\cdot ReO_3Cl$, which quickly condenses with $ReOCl_4\cdot ReO_3Cl$ to yield $Re_2O_3Cl_6(ReO_3Cl)_2$ and another mole of HCl. This mechanism explains why preparation by methods (*a*) and (*b*) was so difficult and irreproducible, since success is obviously dependent on water being present.

The characterization of β-$ReOCl_3$ as a perrhenyl chloride complex of $Re_2O_3Cl_6$ has raised doubts about the nature of α-$ReOCl_3$ (1). Further work by us has shown that the samples prepared by Guest and Lock and used for analysis are different from the samples used by Frais and Lock for infrared and X-ray studies.

The material used by Frais and Lock and called herein "purple frost", has now been analyzed several times, and shows considerable variation in composition. Cl:Re ratios have been determined by neutron activation analysis (4) on different samples and have yielded values of 3.59, 3.19, 3.80, 2.73, 2.50, 3.66, 4.15, and 2.47. The ReO_4^-/ReO_2 ratios obtained on alkaline hydrolysis vary much less (6.0, 6.9, and 5.2) indicating an average oxidation state of ~6.5. The latter results confirm that Frais and Lock's "purple frost" is not α-$ReOCl_3$, and is different from Guest and Lock's material.

Guest and Lock's product had an average Cl:Re ratio of 3.0(1) (4 determinations) and an oxidation state of approximately 5. We were unable to test the variation in the oxidation state analysis because of lack of material, and only one analysis was made rather than the more usual 3 to 5. Clearly, the Re:Cl ratio does not distinguish between $ReOCl_3$ and $Re_2O_3Cl_6$, and the single oxidation state determination is more susceptible to error because of neutron flux variation (4). Guest and Lock's results are consistent with the existence of $ReOCl_3$, but we feel are not conclusive. Confirmation of the existence of $ReOCl_3$ must await further physical measurements.

We thank the National Research Council of Canada for financial support of this work and a scholarship to one of us (P.W.F.).

Crystal Structure of and Electron Spin Resonance of Mn^{2+} in MgV_2O_6

HOK NAM NG AND CRISPIN CALVO

Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 12, 1972

MgV_2O_6 crystallizes in the monoclinic space group $C2/m$ with lattice parameters $a = 9.279(7)$, $b = 3.502(2)$, $c = 6.731(6)$ Å and $\beta = 111.77(6)^\circ$ with $Z = 2$. The structure was refined, at room temperature, utilizing 593 symmetry independent reflections, by full matrix least squares to a final R value of 0.032. The structure consists of Mg^{2+} lying at a site of $2/m$ symmetry octahedrally coordinated to oxygen atoms with a mean separation of 2.140 Å. All the remaining atoms lie in crystallographic mirror planes with the V ion coordinated to six oxygen atoms with bond distances ranging from 1.666 to 2.671 Å. The spin Hamiltonian parameters for Mn^{2+} were determined at room temperature and again at liquid N_2 temperatures. As these values are invariant with temperature there is no indication of a phase transformation in $Mg(VO_3)_2$ to a lower symmetry space group. The spin Hamiltonian parameters are $g_x = 2.0042$, $g_y = 2.0090$, $g_z = 2.0005$; $D = -459$ G, $E = 65$ G, and $A = -78$ G with one of the principal axes, X, parallel to the b-axis and the Z-axis at an angle of 5° to the c-axis.

MgV_2O_6 cristallise sous une forme possédant le groupe spatial monoclinique $C2/m$, avec les paramètres de réseau $a = 9.279(7)$, $b = 3.502(2)$, $c = 6.731(6)$ Å et $\beta = 111.77(6)^\circ$ et $Z = 2$. La structure a été raffinée, à la température de la pièce, au moyen de 593 réflexions de symétrie indépendante, par moindres carrés de matrice complète, jusqu'à une valeur finale de R de 0.032. La structure consiste en ions Mg^{2+} se situant à des positions de symétrie $2/m$, coordonnés octaédriquement à des atomes d'oxygène à une distance moyenne de 2.140 Å. Les atomes restants se situent dans des plans-miroirs cristallographiques, l'ion V étant coordonné à six atomes d'oxygène, à des distances variant entre 1.666 et 2.671 Å. Nous avons déterminé les paramètres Hamiltoniens de spin pour Mn^{2+} à la température de la pièce et de l'azote liquide. Ces valeurs, étant indépendantes de la température, indiquent l'absence de transformation de phase dans $Mg(VO_3)_2$ en un groupe spatial de symétrie inférieure. Les paramètres Hamiltoniens de spin sont $g_x = 2.0042$; $g_y = 2.0090$, $g_z = 2.0005$; $D = -459$ G, $E = 65$ G et $A = -78$ G, un des axes principaux, X, étant parallèle à l'axe b et l'axe des Z faisant un angle de 5° avec l'axe c. Introduction

A number of divalent metal metavanadates, MV_2O_6, have been found to crystallize in the brannerite structure of $ThTi_2O_6$ (1). These include the Cd, Ca, Zn, Hg, and Co metavanadates (2–4). Most crystallize in the monoclinic system with possible space groups $C2/m$, $C2$, or Cm. Only the Cd and Hg metavanadates have been found to be dimorphous. The phase transformation in CdV_2O_6, it has been suggested, involves no change in crystal symmetry, but only a contraction of the high temperature cell dimensions (2), while β-HgV_2O_6 has the space group $Pbca$ (4). The structure of CdV_2O_6 has been refined in the centrosymmetric space group $C2/m$ (2) while that of ZnV_2O_6 in space group $C2$ (4). Except for the fact that the atoms are no longer restricted to mirror planes in the latter case the two structures are nearly identical.

Attempts to grow crystals of CdV_2O_6 large enough for an electron paramagnetic resonance study of the phase transition proved fruitless. Nevertheless Mn^{2+} in magnesium metavanadate was chosen for study since changes in the direction of the principal axes have provided a sensitive technique for detection of subtle transformations. In the system MgO–V_2O_5 compounds with oxide ratios of 3:1, 2:1, and 1:1 have been reported (5) and the crystal structure of the first two, $Mg_3(VO_4)_2$ (6) and $Mg_2V_2O_7$ (7), are now known. A recent study denies the appearance of MgV_2O_6 but claims to have obtained $Mg_3V_4O_{13}$ (8). In $Mg_3(VO_4)_2$ the vanadium ion is tetrahedrally coordinated to oxygen atoms. In one of the polymorphs of the $Mg_2V_2O_7$, half of the vanadium ions are tetrahedrally coordinated while the remainder are coordinated to five oxygen atoms. The metavanadate, MgV_2O_6, has an X-ray powder pattern similar to that of β-CdV_2O_6 (2). However, no α–β transition has been reported for this compound. In this study the structure of MgV_2O_6 has been refined from X-ray diffraction data. The e.p.r. spectra of MgV_2O_6 doped with Mn^{2+} were also examined at ambient and liquid nitrogen temperatures in an attempt to

establish whether there is a low temperature phase.

Experiments

A. X-Ray Diffraction Studies

Crystal data

MgV_2O_6 f.w. = 222.194

Space group: $C2/m$, $a = 9.279(7)$, $b = 3.502(2)$, $c = 6.731(6)$ Å, $\beta = 111.77(6)$°, $Z = 2$, $V = 203.12$ Å^3, $\rho_o = 3.66$ g/cm^3, $\rho_c = 3.64$ g/cm^3.

Crystals of MgV_2O_6 were prepared from a mixture of MgO and V_2O_5 in a molar ratio of 37:63. The mixture was melted in a Vitreosil crucible at 850 °C, cooled at 3 °C/h to 640 °C and quenched to room temperature. The yellow crystal plates of MgV_2O_6 were invariably elongated along the *b*-axis. A good quality single crystal was selected and cut to a cube of 0.3 mm in each dimension for X-ray intensity measurements.

Photographic work established the space group as $C2/m$, Cm, or $C2$ as reflections were systematically absent when $h + k = 2n + 1$, n = integer. Accurate lattice parameters were determined by a least squares fit to 15 2θ values measured with the Syntex automatic diffractometer.

Intensity data were collected on a Syntex automatic diffractometer using graphite monochromatized MoKα ($\lambda = 0.71069$ Å) radiation and θ–2θ mode of scan at a variable rate. Reflections whose intensity, corrected for background, exceeded three times the calculated standard deviation were considered observed. Reflections with intensities calculated as negative were left out of the refinement. A total of 593 symmetry-independent reflections were recorded and the data were corrected for Lorentz, polarization, and absorption effects ($\mu r = 1.36$). Symmetry-equivalent reflections differed on average by less than 2% from the mean. Within a sphere defined by $2\theta \leqslant 75°$ there were only 38 unobserved reflections in the data set.

B. Electron Paramagnetic Resonance Studies

For e.p.r. studies about 0.1% of $MnCO_3$ was added to the starting mixture of V_2O_5 and MgO before melting. The resulting MgV_2O_6 crystals were light brown in color. Several crystal plates with dimensions of the order $2 \times 1 \times 0.3$ mm were selected and aligned by X-ray techniques described previously (9). The accuracy in orientation was estimated to be ±3°. A Varian V-4503 EPR spectrometer with a 12 in. rotatable magnet was used. The microwave cavity was operated at 35 GHz in the cylindrical TE_{011} mode. The magnetic field was measured with a Varian Fieldial unit calibrated by n.m.r. techniques utilizing a Li^7 probe. The *g*-values were measured by using a DPPH standard.

Results

A. X-Ray Studies

A full matrix least squares program, written by Stephens for the CDC 6400 computer, was used to refine the structure. The final coordinates and anisotropic temperature factors of CoV_2O_6 (10) were used as initial parameters for the refinement in the centrosymmetric space group

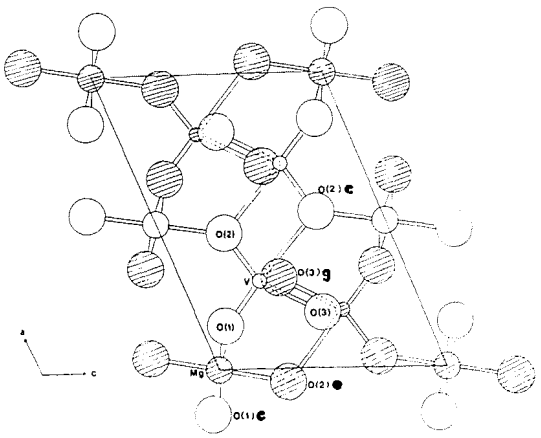

FIG. 1. Projection of the MgV_2O_6 Structure on *ac*-plane, (shaded circles for atoms at $y = 0$, unshaded circles for atoms at $y = 1/2$).

$C2/m$. Since the refinement was satisfactory, no attempt was made to refine the structure in the less symmetric space groups $C2$ or Cm. Atomic scattering curves for Mg^{2+}, V^{5+}, and O^{2-} were taken from Cromer and Waber (11) and those for magnesium and vanadium were corrected for anomalous dispersion (12). A weighting function $\omega = (2.0 + 0.25\,F_o + 0.006\,F_o^2)^{-1}$ was chosen so that $\omega(|F_o| - |F_c|)^2$, the square of the difference between the observed and calculated structure factors, would be independent of the local average of $|F_o|$. Refinement was terminated when the maximum shift in the parameters was less than 15% of the calculated standard deviation. The final R value was 0.032 and the $\omega R = \{\sum\omega|F_o - F_c|^2/\sum\omega F_o^2\}^{1/2}$ was 0.043. Table 1 contains the final atomic parameters while Table 2 compares the observed and calculated structure factors.[1]

This class of crystals can be described as composed of distorted XO_6 octahedra with $X = V^{5+}$ or Ti^{4+} (1). These octahedra share opposite corners forming chains running parallel to the *b*-axis. Octahedra in adjacent chains share edges involving O(2) and O(2)e, as shown in Fig. 1, on one side of the chain. On the other side chains interleaf such that one octahedron shares two edges with two adjacent octahedra in a neighbouring chain. These edges are O(3)a

*Oxygen atom positions are derived from those listed in Table 1 by symmetry operations designated by a...g in the same order as listed in the International tables for X-ray crystallography, vol. I.
†Estimated standard deviations include uncertainties in the unit cell lengths.

and O(3)g with one octahedron and O(3)a and O(3)g with the next one (translated by a *b* axis length).

Mg^{2+} ions lie in octahedral interstices sharing oxygen atoms with six different V^{5+} ions. MgO_6 groups form chains paralleling the *b*-axis by sharing O(1)a–O(1)c edges with two translation-equivalent MgO_6 groups. The average Mg—O bond length is 2.140 Å and the group shows an angular distortion consistent with a repulsive interaction between vanadium ions separated by a *b*-axis translation and sharing an oxygen atom with the Mg^{2+} ion. The individual bond lengths and angles are found in Table 3.

The VO_6 group has five strong bonds and one weak one. The vanadium ion is displaced by about 0.5 Å along the O(1)a–O(2)c axis towards O(1)a yielding V—O bond lengths of 1.671 and 2.671 Å. The V^{5+} ion is also displaced from the O(1)a–O(2)c axis of the octahedron away from the edges O(3)a–O(3)g shared with neighbouring vanadium ions. This displacement is primarily towards O(2)a and away from O(3)a, thus yielding bonds to these oxygen atoms of 1.666 and 2.111 Å, respectively. The remaining V—O bonds are mirror plane related, involve O(3)g and are 1.853 Å long.

B. Electron Paramagnetic Resonance Studies

The crystal symmetry of MgV_2O_6 is such that it requires one of the principal axes of the **D**-tensor to be parallel to the *b*-axis, if the paramagnetic ion substitutes directly for the magnesium, independent of whether the space group is *C*2, *Cm*, or *C*2/*m*. Furthermore, the remaining two principal axes are constrained in a plane perpendicular to the *b*-axis. One $MgV_2O_6:Mn^{2+}$ crystal was mounted along the b-axis so that the external magnetic field explored the *ac*-plane. For each orientation of the magnetic field in this plane the spectrum consists of five groups of lines corresponding to the five allowed transitions of a ^6S state ion of Mn^{2+} as shown in Figs. 2 and 3. Each group was further split into six lines due to hyperfine interaction with the Mn^{55} nucleus. This hyperfine splitting of 78 ± 5 G was found to be isotropic within experimental errors. A maximum in the fine structure splitting was found when the magnetic field was in a direction about 5° from the *c*-axis towards the *a*-axis. This direction was chosen as the *Z*-axis. As the magnetic field was rotated in the *ac*-plane, the fine structure separation was reduced, but it increased again to another maximum when the

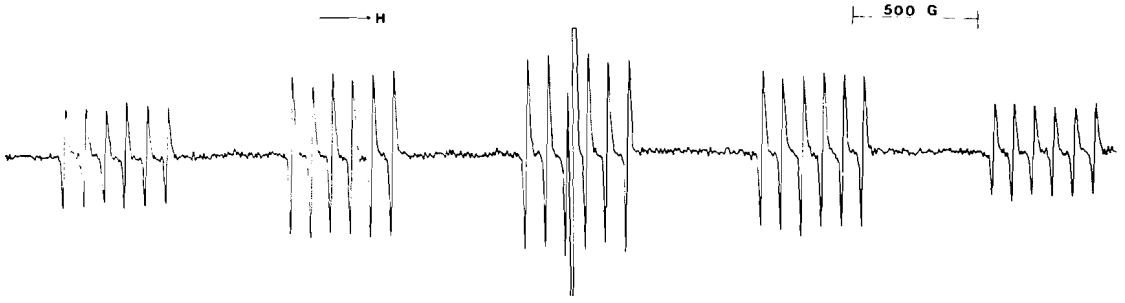

FIG. 2. Electron paramagnetic resonance spectrum of Mn^{2+} in MgV_2O_6 with $H \| Z$ (strong peak due to DPPH indicated by arrow).

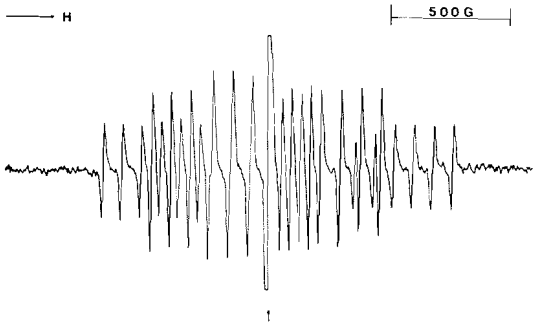

FIG. 3. Electron paramagnetic resonance spectrum of Mn^{2+} in MgV_2O_6 with $H \| Y$ (strong peak due to DPPH indicated by arrow).

magnetic field was 90° from the Z-axis in the ac-plane. This second principal axis direction was labelled the Y-axis of the **D**-tensor. That the b-axis is also a principal axis of the **D**-tensor was verified by locating the maximum in the fine structure splitting by rotating the magnetic field in a plane perpendicular to the c-axis of a second crystal. The principal axes of the **g**-tensor were assumed to coincide with those of the **D**-tensor. The principal g-values along the X, Y, and Z directions were found from the center of the hyperfine lines of the central group in the respective spectra. These parameters are tabulated in Table 4. It was observed from the spectra that D_z should have opposite sign to D_x and D_y. The relative signs of D and A were found by measuring the difference in hyperfine separations at low field and at high field (13). It was concluded that A is of the same sign as D_z but of opposite sign to D_x and D_y. The sign of the Mn^{2+} hyperfine interaction has been found in published literature to be almost always negative. It was assumed to be negative in this case also, thus giving the sign of D as negative. This sign of D was verified from the change in the relative intensity of the fine structure when the temperature was lowered to 77 °K (14).

Similar e.p.r. measurements on the same crystals were also made at 77 °K. The results showed that there was no observable change in the principal directions of the **D**-tensor at low temperature, although there was a slight but definite increase in the axial field parameter, noted in Table 4.

Discussion

The MgV_2O_6 has the brannerite structure at room temperature. The e.p.r. results are consistent with the crystallography if the Mn^{2+} substitutes for Mg^{2+} in the crystal. The crystal field around the cation reflects the same symmetry as its oxygen coordination. The Z-axis lies along the O—Mg—O bond, that is in the axial direction of the distorted octahedron. The Y-axis of the crystal field lies along the direction of projection of the Mg—O(1) bond on the ac-plane. The relatively large value of E indicates a considerable deviation from axial symmetry. This deviation is borne out by the bond angles formed between the cation and the four equatorial oxygens in the XY-plane (105.6 and 74.4°) as shown in Table 3.

The e.p.r. results show there is only one site for the Mn^{2+} ion. Since the two cations in the unit cell of MgV_2O_6 occupy sites related by lattice centering and are therefore magnetically

TABLE 4. Spin Hamiltonian parameters for Mn^{2+} in MgV_2O_4 with estimated standard deviations in parentheses; $D = \frac{3}{2}D_z$, $E = \frac{1}{2}(D_x - D_y)$, $X \| b$ axis

Component	g	A(G)		D(G)	
		300 K	77 K	300 K	77 K
X	2.0042(5)	−78(5)	−80(5)	+218(5)	+224(15)
Y	2.0090(10)	−78(5)	−80(5)	+87(5)	+98(8)
Z	2.0005(5)	−78(5)	−80(5)	−306(20)	−325(20)

equivalent, the result is consistent with a direct substitution of Mn^{2+} for Mg^{2+}. These two cation sites are all magnetically equivalent in the space groups $C2/m$, $C2$, or Cm and the ambiguity in the space group remains unresolved from the e.p.r. study.

The e.p.r. results at low temperature have to be interpreted with some caution. The cation environment apparently undergoes little change as the temperature is lowered to 77 °K. If a low temperature phase of MgV_2O_6 is the same as that in CdV_2O_6, the principal axis of the crystal field will still be constrained along the b-axis and perpendicular to it. A small change in the environment of the cation, say a rotation of the oxygen octahedron about the b-axis, will not be detected if this rotation is less than 3°, the limit of accuracy in this experiment. The changes in the crystal field parameters at 77 °K indicate a shortened distance between the cation and the axial oxygens (Mg—O(2)e) as suggested by the increased value of D, but the change is hardly significant. The results also indicate a further deviation from axial symmetry of the crystal field around the cation. Although we found no evidence for a low temperature phase of MgV_2O_6 between 77–300 °K, the possibility cannot be ignored that such a phase is present with only small changes in cell dimensions but no drastic change in crystal symmetry. However, a change as large as that indicated for CdV_2O_6, where the volume changes by about 10% (2), seems unlikely. If the structure of α-CdV_2O_6 is isotypic with that of CaV_2O_6 (3) while that of β-CdV_2O_6 is isotypic with the MgV_2O_6, then the major structural change expected is the loss of the long V–O(2) interaction. The consequence of this change in MgV_2O_6 would be stronger V–O interactions and a strengthened Mg–O(2) interaction.

Note should be taken of the enhanced distortion of the VO_6 group compared with that of the TiO_6 group in brannerite. In the latter case the bond lengths range from 1.83 to 2.20 Å. The long V—O(2)c bond length in MgV_2O_6 becomes a Ti—O bond length of 2.06 Å in the brannerite. This illustrates again the unsymmetrical nature of oxygen atom bridges between vanadate groupings.

Cycloaddition and Related Reactions of Some Unsaturated Phosphines with Dimethyl Acetylenedicarboxylate

MAUREEN DAVIES, A. N. HUGHES, AND S. W. S. JAFRY

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received December 29, 1971[1]

Diphenylvinylphosphine reacts with dimethyl acetylenedicarboxylate to give either an equilibrium mixture of two cyclic ylidic 1:1 adducts or a strained bicyclic ylidic 1:2 adduct depending upon the reaction conditions. The adducts have been characterized by trapping them as their hydrolysis or deuterolysis products or by their Wittig reactions. *trans*-1,2-Bis(diphenylphosphino)ethylene reacts with the ester to give a 1:1 zwitterionic adduct which exhibits some ylidic properties and hydrolyzes by a very unexpected mechanism. The *cis* isomer of this phosphine reacts with the ester to give the expected 1,4-diphosphorin which has been fully characterized.

La diphénylvinylphosphine réagit avec l'acétylène dicarboxylate de diméthyle pour conduire soit à un mélange à l'équilibre de deux composés d'addition 1:1 de type ylure cyclique soit à un composé d'addition 1:2 de type ylure bicyclique tendu, en fonction des conditions de la réaction. Ces composés d'addition ont été caractérisés en les piègeant en tant que produits issus de l'hydrolyse et deutériolyse ou encore par réaction de Wittig. Le bis-(diphénylphosphino)-1,2 éthylène *trans* réagit avec l'ester en donnant un composé d'addition 1:1 de type zwitterion qui possède quelques propriétés d'ylure et s'hydrolyse selon un mécanisme très inattendu. L'isomère *cis* de cette même phosphine réagit avec l'ester pour conduire à la diphosphorine-1,4 attendue qui a été complètement caractérisée. [Traduit par le journal]

Canadian Journal of Chemistry, **50**, 3625 (1972)

Until quite recently, cyclic phosphonium ylides (apart from the 1,1-disubstituted phosphorins) were relatively little known (1) and little work had been done on convenient and generally applicable syntheses of these systems. Since triphenylphosphine reacts readily with dimethyl acetylenedicarboxylate (2) and benzyne (3), it seemed likely that one possibly general route to cyclic phosphonium ylides of various ring sizes would be the cycloaddition of various unsaturated linkages such as suitable alkynes and arynes to vinylphosphines. Such additions would produce five-membered cyclic phosphonium ylides. Furthermore, by analogy with the insertions of dimethyl acetylenedicarboxylate into the P=C bonds of open-chain ylides (4), these initial products could possibly react further to give larger ylidic rings.

Such reactions would be essentially one-step processes involving relatively easily accessible starting materials. We therefore report here the results of our investigations regarding the reactions of diphenylvinylphosphine (**1**, R = H), *trans*-1,2-bis(diphenylphosphino)ethylene (**2**), *cis*-1,2-bis(diphenylphosphino)ethylene (**3**), and 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene (**4**) with dimethyl acetylenedicarboxylate. A preliminary communication regarding the reactions of **1** (R = H) with the acetylenic ester has already appeared (5). In addition, certain exploratory experiments involving the generation of benzyne in the presence of **1** and **2** are briefly mentioned. It should also be noted that, during the early stages of this work, Savage and Trippett (6) reported the cycloaddition of acrylonitrile to diphenyl(1-phenylvinyl)phosphine (**1**, R = Ph) to give the ylide **5**.

As expected, diphenylvinylphosphine reacts readily with dimethyl acetylenedicarboxylate in ether or benzene although the nature of the product depends upon the mode of addition and the proportions of the reactants. Thus, dropwise addition of a benzene solution of the ester to an equimolar amount of the phosphine in benzene at room temperature under nitrogen leads immediately to the formation of a very dark solution. Evaporation of the solution yields a tarry material in which the principal product appears to be a dark blue polymeric material. Repeated ethereal extraction of the blue material and crystallization of the residual crude product from ethanol leads to the isolation (in about 23% yield) of colorless crystals, m.p. 130–132°, which analyze well for a mole-

X = —CO_2Me

cular formula of $C_{20}H_{21}O_5P$, *i.e.* a 1:1:1 adduct of the phosphine, the ester, and water. The mass spectrum shows a molecular ion at *m/e* 372 which is consistent with the proposed molecular formula. The same product is formed regardless of whether dried or undried solvents are used (although ether containing appreciable amounts of ethanol should be avoided) and this indicates that during the reaction (or during work-up if anhydrous solvents are used), hydrolysis of an initially formed 1:1 adduct of the ester with the phosphine occurs.

The expected initial product of the reaction is the cyclic ylide **6** (a 3*H*-phosphole derivative) and, since most phosphonium ylides are very sensitive to water, this might be expected to hydrolyze to give the phosphine oxide **7** by protonation followed by ring cleavage of the resulting cyclic phosphonium hydroxide by elimination of the most stable carbanion (7). In support of this, the base peak in the mass spectrum of the 1:1:1 adduct occurs at *m/e* 201 which is typical of compounds containing the $Ph_2P(O)$— grouping (6). Furthermore, the i.r. spectrum also shows a typical (8) P=O stretching frequency at 1193 cm^{-1} and a weak substituted C=C vibration at 1664 cm^{-1}. However the ^1H n.m.r. spectrum is inconsistent with structure **7** since, although it shows the presence of two methylene groups, the coupling pattern clearly shows that these two groups are not adjacent. The spectrum shows a ten proton aromatic complex multiplet at τ 2.0–2.6, an olefinic one proton quartet at τ 2.6–3.3, two ester methyl groups at τ 6.30 and 6.37, one methylene group as a doublet of doublets centered on τ 6.69 (with the indication that $J_{HH} = 8$ and $^2J_{PH} = 16$ Hz), and one methylene group as a very closely spaced doublet ($J = ca.$ 1.5 Hz) at τ 6.65 superimposed upon the other methylene signal. One interesting feature of this spectrum is that to some extent it is concentration dependent. For example, at concentrations approaching 50%, the ester peaks are shifted a few cycles upfield while the two methylene signals are shifted very slightly downfield.

This spectrum fits the isomeric structure **9** extremely well and this structure is also consistent with the i.r. and mass spectral data. Thus, the tentatively assigned values of J_{HH} and $^2J_{PH}$ for the methylene group (τ 6.69) adjacent to the phosphorus atom are in excellent agreement with those observed for related structures in the literature (see for example, values for $^2J_{PH}$ for compounds containing the $Ph_2P(O)CH_2$— grouping quoted in ref. 6). Furthermore, the locations of the two methylene groups in the spectrum are as expected for **9**. The methylene group adjacent to the terminal ester group (τ 6.65) presumably occurs as a poorly defined doublet ($J = ca.$ 1.5 Hz) because of long-range coupling with the phosphorus atom. Such long-range couplings are known to give rise to values of $^5J_{PH}$ of the order of 1 Hz (9). On the other hand, it is possible that this methylene group is coupled to the olefinic proton which could account for the broadening of the peaks in the olefinic quartet. The fact that the olefinic signal occurs as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

quartet (in the approximate ratio 1:3:3:1) implies that J_{HH} and $^3J_{PH}$ have approximately the same value (7 Hz).

These tentative n.m.r. assignments have been confirmed by ^1H–^1H spin decoupling (field sweep) experiments. In this case, since the couplings in some instances are relatively large and the signal width is therefore considerable, selective decoupling techniques (10*a*) were found to give the best results. Irradiation of the low field doublet of the doublet of doublets of the methylene signal centered on τ 6.69 while scanning the olefinic signal causes the two high field peaks of the olefinic signal to collapse to an intense, sharp singlet centered on the more intense of the original peaks. Likewise, irradiation of the high field doublet of the methylene doublet of doublets causes the low field pair of peaks of the olefinic signal to collapse in a similar fashion. Conversely, irradiating the more intense of the two low field peaks of the olefinic signal while scanning the methylene signal at τ 6.69 causes the high field doublet of this signal to collapse to a singlet. Similar irradiation of the more intense of the two high field peaks of the olefinic signal leads to a collapse of the low field doublet of the methylene signal.

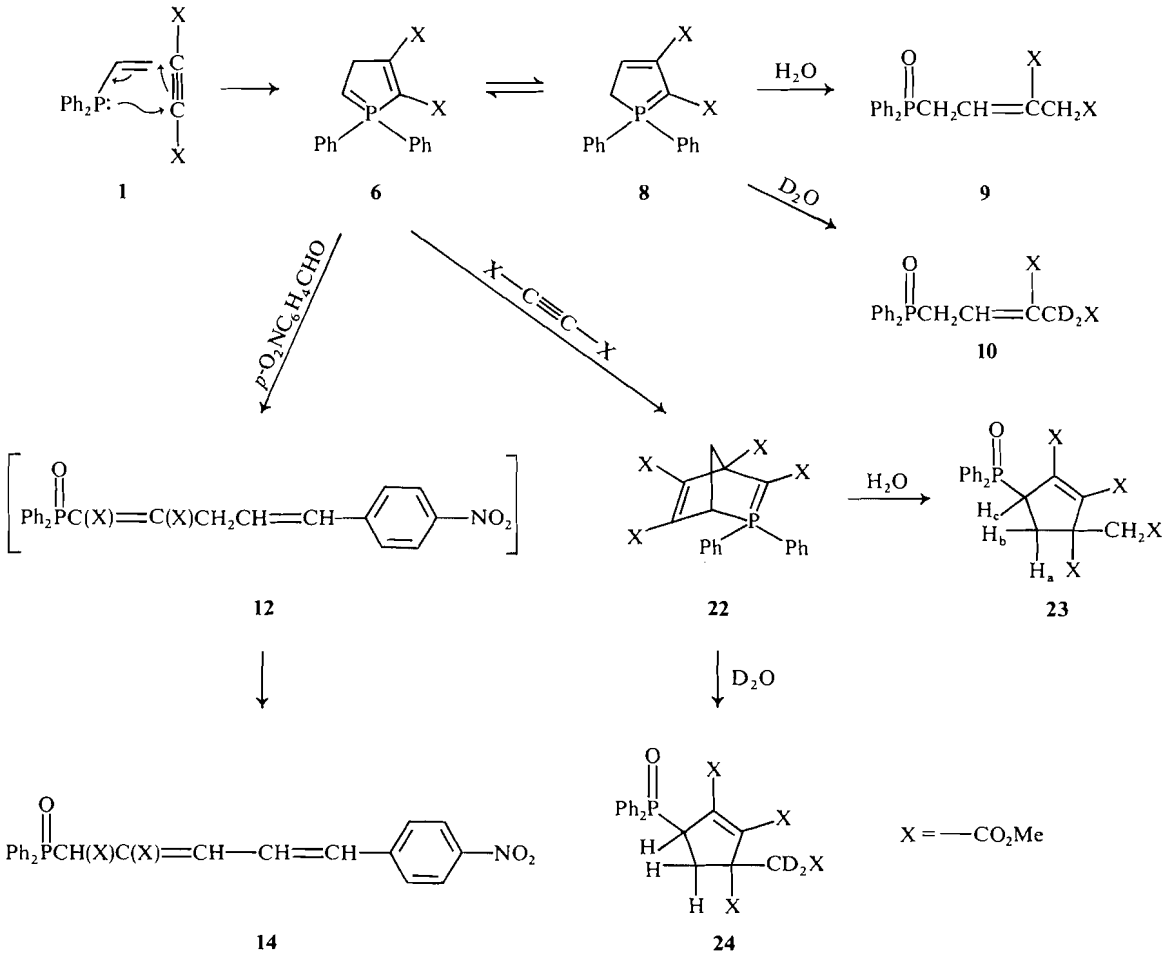
These results clearly show that the olefinic proton is coupled to the methylene protons at τ 6.69 ($J = 8$ Hz) and that the olefinic $^3J_{PH}$ coupling is 7 Hz (the small difference in these couplings accounts for the broadened peaks in the olefinic quartet). Furthermore, the $^2J_{PH}$ coupling of the methylene group adjacent to the phosphorus atom is 16 Hz and these selective decoupling experiments show (10*a*) that $^2J_{PH}$ and $^3J_{PH}$ are of opposite sign.

Very careful scanning of the spectrum in the decoupling mode shows that there is no coupling between the olefinic protons and the methylene group centered on τ 6.65 (assigned to the methylene group adjacent to the terminal ester group) and the narrow splitting of this signal (1.5 Hz) is therefore confirmed as being due to long-range P–H coupling.

Very strong support for structure **9** is also provided by the mass spectrum which shows weak peaks at *m/e* 299 (possibly $M^+ - CH_2CO_2Me$), 215 (possibly $Ph_2\overset{\overset{O}{\|}}{P}CH_2^+$) and 157 (possibly $M^+ - Ph_2\overset{\overset{O}{\|}}{P}CH_2$). These tentative assignments are confirmed by precise mass measurements (*m/e* 299: calcd., 299.0837; found, 299.0839; *m/e* 215: calcd., 215.0626; found, 215.0623; *m/e* 157: calcd., 157.0501; found, 157.0509). These peaks are very weak because cleavage would be preferred in a position allylic to the C=C link, *i.e.* adjacent to the phosphorus atom or the terminal ester group. These expected peaks are very strong in the mass spectrum of the 1:1:1 adduct. Finally, the spectrum shows a peak of medium intensity at *m/e* 340 corresponding to loss of methanol from the $-CH_2CO_2Me$ grouping. The fragmentation is confirmed by a weak metastable peak at *m** 310.7. Such eliminations are common in esters of this type (11).

The i.r. spectrum also shows two ester carbonyl stretching frequencies at 1722 (α,β-unsaturated ester) and 1749 cm^{-1} (saturated ester) and this is in agreement with structure **9**.

Structure **9** could be derived either from **7** by proton migration (a process which seems unlikely) or from hydrolysis of the cyclic ylide **8** (a 2*H*-phosphole derivative) which is a tautomer of **6**. Moreover, in such a tautomeric equilibrium, **8** should be preferred over **6** since in **8** there is more delocalization of the ylidic carbon atom negative charge over the adjacent ester group. Deuterolysis experiments support the suggestion that **9** is derived from **8** by hydrolysis. Thus, when cycloaddition of the vinylphosphine **1** (R = H) and the acetylenic ester was carried out in rigorously dried ether followed by addition of a little D_2O to the reaction mixture, it was found that mainly double deuteration (to give **10**) and some triple deuteration occurs. For example, the mass spectrum shows that the strongest molecular ion peaks occur at *m/e* 374 (double deuteration) and 375 (triple deuteration). The n.m.r. spectrum shows that the narrow doublet due to the methylene group adjacent to the terminal ester group has almost disappeared from the spectrum although there is also a reduction (from 2 to about 1.4 protons) in the intensity of the other methylene signal. The ^1H n.m.r. spectrum therefore shows that deuteration occurs mainly at the site adjacent to the terminal ester group (although some deuteration occurs at the other methylene group) and this is



SCHEME 1

consistent with the behavior expected of **8** on hydrolysis.

These observations then are fairly good evidence that the ylide **8** is formed from the initially formed ylide **6** by tautomerization. Furthermore, similar tautomeric equilibria have been observed in the case of the four-membered ylide **11** (6). Several attempts to trap **6** before tautomerization could occur were therefore made. Attempts to trap **6** in a Wittig reaction with acetone and with benzaldehyde were unsuccessful. The use of acetone gave only uncrystallizable materials and use of benzaldehyde gave the adduct **9** as the only isolable product. However, cycloaddition of the ester and phosphine in the presence of *p*-nitrobenzaldehyde leads to the formation of a 1:1:1 adduct of the ester, the phosphine, and the aldehyde for which elemental analyses are in excellent agreement with the formula $C_{27}H_{24}O_7NP$. The mass spectrum confirms the molecular weight as 505 and the base peak is again at *m/e* 201 indicating the presence

$$\begin{matrix} & O & \\ & \| & \\ Ph_2P- & & \end{matrix}$$

of the Ph_2P— grouping. Thus, a Wittig reaction has occurred and the intermediacy of a cyclic ylide is established.

The adduct expected from **6** would be **12** while that from **8** would be **13** but the ^1H n.m.r. spectrum shows that the adduct is neither of these since there are no signals due to methylene groups in the spectrum. The spectrum shows 17 aromatic/olefinic protons as a broad complex multiplet at τ 1.6–3.4, one methine proton as a

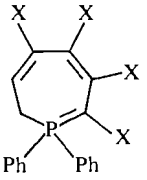
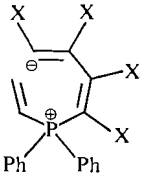
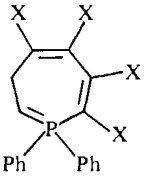
17



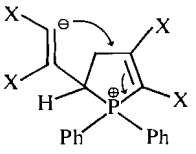
18



19



20



21

doublet ($J = 15$ Hz) centered on τ 4.38, and two ester methyl group signals at τ 6.33 and 6.38. Of the various possible isomers obtainable by addition of *p*-nitrobenzaldehyde to **6** or **8**, only **14** agrees with all the physical data since it contains no methylene groups and the low field location and the splitting of the methine proton ($J = 15$ Hz) are consistent with its position adjacent to a phosphoryl grouping and two other electron-withdrawing groups. Clearly **14** cannot be derived directly from **6** or **8** and is presumably derived from **12** by a prototropic shift. Such a shift is not surprising since it increases the conjugation in the system and the conditions of the reaction (the ylide **6** would be a strong base) would favor migration of the mildly acidic protons of the methylene group in **12**. A similar prototropic shift in **13** could produce a methine proton adjacent to an ester group (though far removed from the phosphorus atom) but this would decrease the conjugation. Some further, though not conclusive evidence for structure **14** is given by the mass spectrum which shows a peak at *m/e* 273 probably corresponding to the

$$[Ph_2\overset{\overset{O}{\|}}{P}CHCO_2Me]^+$$

fragment (precise mass found: 273.0673; calcd.: 273.0681). This could only be derived from **14** unless major rearrangements occur on electron impact. This peak is comparable in intensity with the molecular ion peak though much weaker than the base peak. In addition, the i.r. spectrum shows both saturated (1745 cm^{-1}) and α,β-unsaturated (1692 cm^{-1}) ester carbonyl stretching frequencies.

As already mentioned, the mode of reaction and proportions of the reactants in the reaction of the phosphine **1** (R = H) with the acetylenic ester can influence the nature of the product. If the phosphine (1 mol) in ether is added to an ethereal solution of the ester (2 mol) under the same reaction conditions as the 1:1 addition, a 1:2:1 adduct of the phosphine, the ester and water is obtained in about 10% yield. Analyses are in excellent agreement with a molecular formula of $C_{26}H_{27}O_9P$ and the mass spectrum shows a molecular ion at *m/e* 514 together with

$$PH_2\overset{\overset{O}{\|}}{P}—$$

the base peak at *m/e* 201 (PH_2P—). On the basis of the arguments used in the case of the 1:1:1 adduct of diphenylvinylphosphine with the ester and water, it is virtually certain that the 1:2:1 adduct is derived from hydrolysis of an ylidic 1:2 adduct of the phosphine and the ester.

There are several possible modes of reaction. For example, Michael addition of the ylide **6** to a second mole of the ester could occur to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

the ylide **15** although this type of addition is not possible for the ylide **8**. This type of mechanism was suggested by Trippett (12) for the addition of cyanomethylenetriphenylphosphorane ($Ph_3P{=}CHCN$) to dimethyl acetylenedicarboxylate and would presumably be due to the highly acidic nature of the methine proton in the initially formed zwitterion. On the other hand, Bestmann and Rothe (4) have found that addition of alkylidenephosphoranes to the ester leads (in every case studied by his group), to insertion of the ester into the $R_3P{=}CHR'$ link to give compounds of type **16**. This would suggest that **6** or **8** could react further with the ester to give the seven-membered ylides **17** or **18** respectively (or, possibly, tautomers of these). Another possible mode of reaction is the generation of the zwitterion **19** followed by cyclization to give **20**. A similar reaction path occurs in the reaction of 1,2,5-triphenylphosphole with an excess of the ester (13). Finally, the initially formed ylide **6** could react further with the ester to give **21** which could cyclize by attack at the β-position of a vinylphosphonium grouping to give the strained bicyclic ylide **22** in much the same way as **6** itself is formed.

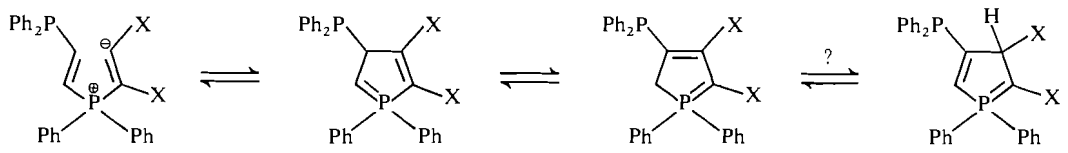
Examination of the ^1H n.m.r. spectrum of the 1:2:1 adduct shows quite conclusively that it is **23** which is derived from hydrolysis of the bicyclic ylide **22**. Thus, hydrolysis of the other possible intermediates **15**, **17**, **18**, or **20** (or possible tautomers) would lead to a product containing olefinic protons whereas careful integration of the ^1H n.m.r. spectrum of the 1:2:1 adduct shows clearly that the adduct contains no olefinic protons.

The spectrum of the 1:2:1 adduct shows ten aromatic protons as a complex multiplet at τ 1.9–2.7, one methine proton as eight unevenly spaced, poorly defined, and partly overlapping peaks of similar intensity centered on τ 5.72, four ester methyl groups at τ 6.29, 6.32, 6.38, and 6.82, two methylene protons as an *apparent* doublet at τ 6.72 and 6.81, and two other methylene protons as a poorly defined multiplet of at least 12 maxima at τ 6.80–7.70. Since the two ring methylene protons in **23** would be non-equivalent, they would have somewhat different chemical shifts and may couple with each other, the neighboring methine proton, and the phosphorus atom to give up to 16 peaks of which at least 12 are observed. Similarly, the methine proton should appear at a much lower field location as two doublets of doublets through coupling with the phosphorus atom and the non-equivalent ring methylene protons. The side-chain methylene group presumably occurs as an apparent doublet (the inner peaks of a closely spaced AB signal of which the outer peaks are buried under the ester signals and the other methylene signals) in the spectrum because its proximity to an asymmetric center renders the two protons non-equivalent as is the case with the diastereotopic protons of 1,2-dichloropropane (14*a*). The signal separation of the two inner peaks of the AB pattern in such cases normally falls in the range 2–15 Hz (*e.g.* 14*b*). It is unlikely that the splitting of this signal is due to long-range coupling with the phosphorus atom since the value of $J = 5.5$ Hz is rather high compared with other measured values of $^5J_{PH}$ (9).

Again, double resonance and mass spectral studies confirm the proposed structure **23** for the 1:2:1 adduct. Careful scanning of the n.m.r. spectrum in the decoupling mode shows that fairly strong irradiation (*i.e.* full decoupling) at τ 7.00 while scanning the region of the eight peak one-proton signal centered on τ 5.72 causes the latter signal to collapse to a doublet of doublets with one coupling constant of 7 Hz and the other of 12 Hz. Similarly, irradiation at τ 7.32 again causes the one-proton eight peak signal to collapse to a doublet of doublets in which one coupling constant is 4.5 Hz while the other is 12.5 Hz. Designating the proton at τ 7.32 as H_a, the proton at τ 7.00 as H_b, and the proton at τ 5.72 as H_c, it is clear that $J_{H_aH_c} = 4.5$, $J_{H_bH_c} = 7$, and $J_{PH_c} = 12.5$ Hz. Thus, the P–H coupling constant is of the right order of magnitude for $^2J_{PH}$ while the couplings of H_c with H_a and H_b are consistent with the proposed structure **23**.

Irradiation of the proton at τ 5.72 (H_c) while scanning the proton signals at τ 7.00 and 7.32 causes considerable changes in these regions but no clear pattern emerges because of overlap of the H_a and H_b signals. Decoupling of H_a from H_b was not feasible since instrumental limitations did not allow decoupling of two such closely spaced signals.

One fact which did emerge from these de-



25 26 27 28

SCHEME 2

coupling experiments is that the weak outer peaks of the closely spaced methylene AB signal centered on τ 6.77 appear to be at τ 6.50 and τ 7.02 since irradiations of H_c while scanning H_a or H_b show that these peaks remain unchanged while considerable changes occur in the remaining peaks. Further support for this assignment comes from the fact that the intensity ratio (5.5:1) of the two fairly clearly seen low field peaks of the AB pattern (τ 6.50 and τ 6.72) is as predicted by theory (10*b*).

Mass spectral studies offer further confirmation for the structure **23**. For example, the loss of methanol characteristic of the $-CH_2CO_2Me$ grouping (11) is shown by a peak at *m/e* 482 and the one-step fragmentation is confirmed by a metastable peak at *m** 452. Furthermore, the expected loss of the allylic $-CH_2CO_2Me$ group is shown by a weak peak (25% of the molecular ion peak and 3% of the base peak) at *m/e* 441. Again, this fragmentation is confirmed by a weak metastable peak at *m** 378.3. Unfortunately, precise mass measurements for these peaks were not possible because suitable reference peaks were not available. Similarly, a weak peak at *m/e* 240 suggests the loss of both of the

$$\begin{matrix} & O & \\ & \| & \\ \text{allylic } Ph_2P- & \text{and} & -CH_2CO_2Me \end{matrix}$$

groups and this is confirmed by precise mass studies (calcd.: 240.0634; found: 240.0636). Presumably this peak is weak because the charge would tend to

$$\begin{matrix} & O & \\ & \| & \\ \text{stay with the } Ph_2P- & \text{grouping} & \end{matrix}$$

and the fact that the base peak in the spectrum at *m/e* 201 is due to this grouping offers some support for this suggestion.

As with the 1:1:1 adduct, deuterolysis experiments on the 1:2 adduct offer further confirmation of these n.m.r. assignments since generation of this adduct in rigorously dried solvents followed by treatment of the solution with a little D_2O leads to the formation of **24**. The ^1H n.m.r. spectrum is virtually identical with that of **23** except that the AB pattern due to the side-chain methylene group has vanished from the spectrum. The only other change is a very small reduction in the signal strength of the other methylene multiplet. The heavy deuteration in the side-chain of **24** is strong evidence for the intermediacy of **22**. Reactions of **1** (R = H) with the ester are summarized in Scheme 1.

Attempts to trap the ylide **22** in a Wittig reaction with acetone, benzaldehyde, and *p*-nitrobenzaldehyde were unsuccessful. However, this is not surprising since the ylidic link in **22** would be highly hindered. Attempts to prepare perchlorate salts of **6**, **8**, and **22** were also unsuccessful but this too is not unexpected since recent work on related cyclic ylides (15) has shown that these salts are highly soluble in water and ethanol and are extremely difficult to crystallize even when the ylides themselves are available in considerable quantity.

The experiments already described for the phosphine **1** were extended to other α,β-unsaturated phosphines and, in the case of *trans*-1,2-bis(diphenylphosphino)ethylene (**2**), some quite surprising results were obtained.

When a benzene solution of dimethyl acetylenedicarboxylate is added slowly, with constant stirring under a dry nitrogen stream, to a solution (in a benzene/pentane mixture) of the *trans*-phosphine **2**, keeping the temperature around 8 °C, a light yellow precipitate is obtained. This adduct analyses well for a 1:1 adduct and is obtained in 69% yield. The mass spectrum confirms the 1:1 nature of the adduct and shows a molecular ion peak at *m/e* 538.

The most likely mode of reaction is cycloaddition of the type shown in the sequence **2** → **25** ⇌ **26** ⇌ **27** ⇌ **28** (Scheme 2). This would be very similar to the 1:1 reaction between diphenylvinylphosphine and dimethyl acetylenedicarboxylate already described where similar

tautomeric equilibria have been observed. Furthermore, Savage and Trippett (6) have suggested equilibria of this type in the reaction of **1** (R = Ph) with acrylonitrile.

The i.r. spectrum shows two distinct carbonyl frequencies. One of these is at 1712 cm^{-1} and is clearly due to a normal unsaturated ester carbonyl stretching vibration, while the other is at 1601 cm^{-1} with a smaller, though still intense, peak at 1585 cm^{-1}. These last peaks are, therefore, probably due to an ester carbonyl group adjacent to a carbon atom with appreciable carbanionic character (16). Superficially, this would suggest that the adduct is either **27** or **28** with **27** the more likely by analogy with the reaction of diphenylvinylphosphine and dimethyl acetylenedicarboxylate.

However, the ^{1}H n.m.r. spectrum of the adduct at −2 °C is definitely not consistent with **27** and probably not consistent with **26** or **28**. The spectrum shows 21 aromatic/olefinic protons as a complex multiplet at τ 2.18–3.32, one apparently olefinic proton as two poorly defined doublets of doublets centered on τ 3.60 and 4.00, respectively, and six methoxy protons as three peaks of unequal area at τ 6.13 (3 protons), 6.23, and 6.56. At −50 °C, the spectrum is much the same apart from small downfield shifts and better definition of the two doublets of doublets except that the three proton methoxy signal which occurs at τ 6.13 in the spectrum at −2 °C appears as a very closely spaced doublet with peaks of unequal intensity at τ 6.01 and 6.03. There is no evidence in the spectrum for a proton on an ylidic carbon atom which would be expected to resonate in the range τ 8–11 (9). At 42 °C, the spectrum is unstable because of sample decomposition but the spectrum of a very freshly prepared sample is much the same as the spectrum at −2 °C except that the olefinic proton signals are very poorly defined.

The ^{1}H n.m.r. spectrum in the methoxy region is consistent with the i.r. spectrum in that it indicates that one of the ester groups is adjacent to a carbanionic center and shows conformational preference as has been observed (16) for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

certain cyclic phosphonium ylides. However, this would also apply to **25** where the only non-aromatic protons are olefinic and where one ester group is adjacent to a carbanionic center. Major contributors to the resonance hybrid of **25** would be **29** and its rotational isomer **30**.

The multiplicity of the olefinic proton signal is of interest. Presumably the two fairly widely separated doublets of doublets (25 Hz) could be the result of the conformational preference of the methoxycarbonyl group as in **29** and **30** and its effect upon the proton β to the phosphonium center. One might perhaps expect this proton to appear under the aromatic signal but it has been shown that in some related structures such as **2**, *cis*-$Ph_2P(O)CH{=}CH(O)PPh_2$, and *cis*-$Ph_2P(S)CH{=}CH(S)PPh_2$, the ethylene bridge protons resonate (17) between τ 3.0 and 3.5. Further, the close proximity of the carbanion negative charge to this proton would be expected to shield it to some extent. In theory, ignoring different conformational arrangements of the ester groups in **25**, eight peaks would be expected for this proton due to coupling with the other olefinic hydrogen and the two different phosphorus atoms but it is well known (17, 18) that the protons on the bridging carbon atoms of bisphosphines show less than the normal expected multiplicity. In the opinion of the authors, the eight peaks observed are probably due to rotational isomerism of the ester groups although the difference in chemical shift of the two doublets of doublets (25 Hz) is within the normal J_{PH} coupling range for similar (17) bridged phosphines. This suggestion is reinforced by the observation that the olefinic signals become much more poorly defined as the temperature is increased. Furthermore, one ester methyl group appears as a three proton singlet at -2 °C while the other (presumably the one adjacent to the carbanion by analogy with the behavior of similar systems (16)) appears as two peaks (corresponding possibly to two conformational arrangements) at τ 6.23 and 6.56.

Thus, of the possible structures considered so far, only **25** (best represented as **29** or **30**) is fully consistent with both the ^{1}H n.m.r. and i.r. spectra, although the reasons why this tautomer should be preferred over the other possible tautomers in the equilibrium are obscure. Unfortunately, because of the extreme sensitivity of the adduct to trace amounts of water and oxygen and an apparent thermal sensitivity, it was not possible to carry out double resonance studies.

The ^{1}H n.m.r. spectrum of the adduct in trifluoroacetic acid gives further information although the spectrum itself is rather unexpected. The spectrum of a freshly prepared solution in CF_3CO_2H (with TMS added) shows, at room temperature, a ratio of approximately 20 aromatic protons at τ 1.6–2.8 to approximately one proton as a diffuse multiplet at τ 4.3–5.1 to approximately six methoxy and two methylene or methine protons as a complex multiplet between τ 5.60 and 6.65. One interesting feature of this last region is that each of the two methoxy signals (centered on τ 6.98 and 6.42 respectively) is split into two closely spaced and unequal peaks. Clearly, these methoxy signals cannot be due to rotational isomerism relative to a carbanionic center since the solution is strongly acidic. It seems likely then that the spectrum is caused by a mixture of isomers caused by protonation of two (or more) of the tautomers in the previously suggested equilibrium.

The ^{1}H n.m.r. spectrum in CF_3CO_2D is similar except that the multiplet at τ 4.3–5.1 is absent. Presumably these protons are provided by the acid or are rapidly exchanged with the acidic solvent.

Some evidence for the idea that the spectrum is caused by a mixture is given by the observation that if the acid solution is allowed to stand for several days, the spectrum is modified to show 20 aromatic protons as a multiplet at τ 1.5–2.8, one methine proton as a doublet ($J = 13$ Hz) at τ 4.49, two methoxy groups as singlets at τ 5.95 and 6.45, respectively, and two methylene protons as a multiplet partly hidden under the methoxy protons in the range τ 5.6–6.3. All of these peaks are present in the spectrum of the freshly prepared solution.

These observations are consistent with the idea that two or more of the postulated tautomers in the original ylide equilibrium are protonated by the trifluoroacetic acid but that further equilibria between ylide tautomers and protonated ylide tautomers lead to an increasing amount of the more stable protonated form.

Of the various protonated tautomers possible from the originally postulated equilibrium, only

For personal use only.

31 (derived from **27**) agrees in every respect with the ^{1}H n.m.r. spectrum of the solution of the adduct in CF_3CO_2H which has been allowed to stand for several days. Thus the methine proton at τ 4.49 is virtually identical in location and splitting with the similar protons in **32** (15) and **33** (16), while the multiplicity of the methylene protons is very like that of the similar protons in **32**.

To summarize, the i.r. and ^{1}H n.m.r. evidence indicates that the 1:1 adduct of **2** with dimethyl acetylenedicarboxylate is an equilibrium of the structures **25**, **26**, **27**, and possibly **28** in which the zwitterionic form **25** greatly predominates over the other forms. However, in the presence of acid, the ylidic contributors to the equilibrium are protonated more readily than the zwitterionic form. This may also be true in the reactions of diphenyl(1-phenylvinyl)phosphine with acrylonitrile (6) and of diphenylvinylphosphine with dimethyl acetylenedicarboxylate where the initial 1:1 adduct could not be isolated and conclusions regarding the nature of the adducts have been drawn solely on the basis of their chemical reactions.

Chemical reactions indicate that an ylidic contributor is the reactive form present in the equilibrium but, again, very unexpected results were obtained.

If the adduct has appreciable ylidic character, it should hydrolyze in the manner of an ylide to give (7) a phosphine oxide. However, when the adduct was dissolved in aqueous ethanol and warmed with stirring for several hours, the oxide **9** was formed which is identical with the hydrolysis product obtained from the 1:1 adduct of diphenylvinylphosphine with dimethyl acetylenedicarboxylate, *i.e.* one of the diphenylphosphino groups has been lost. The m.p. and the i.r., ^{1}H n.m.r., and mass spectra of this product are identical with those of an authentic sample.

This reaction is completely unexpected and is very difficult to account for. However one possible mechanism is as follows.

Presumably, the first step in the hydrolysis would be protonation of the most reactive tautomer to give a phosphonium hydroxide. In the proposed ylide/zwitterion equilibrium, the most reactive tautomer would probably be **26**, since in this case, the ylidic negative charge is stabilized only by overlap with the d-orbitals of the phosphorus atom and is not delocalized in any way. Protonation of this ylide by water would give **34**.

It would be expected that normal rearrangement of this phosphonium hydroxide would involve attack of hydroxide ion upon the phosphonium grouping followed by apical elimination of the most stable carbanion to give a phosphine oxide. On the other hand, it is well known (19) that in phosphonium compounds, nucleophilic attack may sometimes take place at the atom β to the phosphorus atom as in the sequence $R_3\overset{+}{P}\overset{\curvearrowleft}{\text{—}}X\text{—}Y\ \overset{\curvearrowleft}{\dot{N}u} \rightarrow R_3P{=}X$.

In the structure **34** the diphenylphosphino group is not β to the phosphonium group but is vinylogously β to this group and attack of hydroxide ion on **34** as shown to give **8** and then **9** by hydrolysis could conceivably occur. It is not clear why hydroxide ion should prefer, in this case, to attack by the postulated route rather than by the more conventional route of attack on the phosphonium center.

Deuterolysis experiments using hot D_2O (99.7%) for several hours give some support to this mechanism since the compound **35**, together with some trideuterated material, is produced by treatment of the 1:1 adduct of **2** with the acetylenic ester with deuterium oxide.

Accurate integrations taken by means of signal averaged ^{1}H n.m.r. spectra show clearly that the olefinic hydrogen atom in this compound is not replaced by deuterium since the aromatic/olefinic:ester methyl integration is exactly 11:6. Furthermore, the n.m.r. spectrum shows that the methylene protons adjacent to the terminal ester group have been completely replaced by deuterium whereas traces (much less than one proton on integration) of the other methylene protons remain. This is confirmed by the mass spectrum which shows a molecular ion at *m/e* 376 together with a smaller peak at *m/e* 375 corresponding to the replacement of a maximum of four hydrogen atoms by deuterium. This is consistent with the proposed mechanism since the olefinic proton in the products **9** and **35** is derived from the proton adjacent to the displaced Ph_2P group and is not particularly activated. On the other hand, the other protons in **9** are derived either from the solvent or are adjacent to a phosphonium group and, under the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

basic conditions of the reaction, these protons should be exchangeable with the deuterium oxide solvent which is present in great excess.

In the hydrolysis of the 1:1 adduct, the fate of the missing Ph_2P-group is uncertain. However, in one experiment in which the crude product of hydrolysis had been exposed to acetone, a very small amount of a colorless compound (m.p. 143°) was obtained. This compound showed no significant peaks in the mass spectrum above *m/e* 201 ($Ph_2P{=}O$) and the i.r. and ^1H n.m.r. spectra and analyses are consistent with the known (20) compound **36** (m.p. 137–139°) which can be formed by the addition of $Ph_2P(O)H$ to acetone. The compound is unstable in solution and repeated ^1H n.m.r. scans of the same sample showed that acetone is regenerated over a period of several hours. These observations tend to support attack of $\bar{O}H$ upon the exocyclic Ph_2P-group in **34** on hydrolysis of **25**.

The adduct **25** apparently does not enter into Wittig reactions.

The reactions with dimethyl acetylenedicarboxylate described for the *trans*-bisphosphine **2** were extended to the *cis*-bisphosphine **3** in order to see if addition of the type observed for **1** and **2** would occur or if the second phosphorus atom would attack on the unsaturated ester grouping in the initial zwitterionic intermediate to give the 1,1,4,4-tetraphenyl-1,4-diphosphorin **37**. Additions of this type have been observed (21) in the 1:2 addition of the ester to triphenylphosphine. During the later stages of this investigation, Tebby and co-workers (22) published a brief account of essentially the same work in which he described the cycloaddition of **3** and the acetylenic ester to give **37**.

There are only minor differences between our findings and those of Tebby. Thus, Tebby characterized the adduct mainly from the mass spectrum and the i.r. spectrum (which shows that both ester groups are attached to ylidic carbon atoms) and the behavior of the adduct **37** on hydrolysis which leads to the dioxide of **3**. No analytical data were reported although we were able to obtain reasonable analyses. Tebby was unable to carry out ^1H n.m.r. studies on the adduct because of its sensitivity to hydrolysis but, using freshly prepared samples of the adduct, we have been able to obtain reproducible ^1H n.m.r. measurements which confirm the bis-ylide nature of the adduct. The spectrum shows 22 aromatic and olefinic protons as a broad complex multiplet at τ 1.9–2.9 and six methoxy protons as a very broad unresolved hump at τ 6.2–7.1. The unresolved nature of the methoxy region is probably due to the presence of several interconvertible rotational isomers since the ester groups are adjacent to ylidic carbon atoms. Some support for this is given by the fact that the spectrum in the methoxy region at room temperature is almost identical in appearance to that of the cyclic bis-ylide **38** (23). Also, at −40° (where interconversion should be slow) the methoxy region is resolved into two reasonably sharp peaks of unequal area at τ 6.32 and 7.10 with the peak at τ 6.32 almost twice the area of the other peak. Furthermore both peaks show signs of splitting into doublets with unequal splitting of the two signals.

The adduct **37** also forms a crystalline bisperchlorate confirming its bis-ylide nature and ^1H n.m.r. studies of **37** in trifluoroacetic acid solution also confirm the proposed structure. The spectrum shows 22 aromatic/olefinic protons at τ 1.6–2.5 and six methoxy protons as a singlet at τ 6.27. The two methine protons appear as a broad hump at τ 4.6–5.0 with the broadening presumably due to exchange with the solvent.

One interesting point regarding the i.r. spectrum of **37** is that the main carbonyl absorption is at 1640 cm^{-1} with lesser peaks on either side. This is at a considerably higher location than for the apparently similar ester groups in **38** (ν = 1585 cm^{-1}). This may indicate that perhaps the carbanionic negative charges in **37** are delocalized into the ring to give something approaching an aromatic system whereas in **38** the delocalization is over the ester groups.

The cyclic phosphine **4** is a highly hindered version of **1** and reactions of **4** with dimethyl acetylenedicarboxylate were carried out in an attempt to achieve cycloadditions of the type observed for **1**. The highly strained and hindered ylides which would be produced by such cyclizations would be of considerable interest. However, attempts to carry out the cycloaddition under a wide variety of conditions using rigorously dried ethereal and non-ethereal solvents and even no solvent other than an excess of the ester, gave only the oxide of **4**. The change in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

appearance of the various reaction mixtures clearly indicates that a reaction occurs rapidly but it seems likely that the probable initially formed zwitterion **39** is too hindered to cyclize or react further and hydrolyzes on work-up in the manner observed for similar zwitterions (24) to give the corresponding phosphine oxide.

Finally, as a continuation of the work described in this paper, some preliminary experiments involving the generation of benzyne in the presence of the phosphines **1** and **2** have been carried out and, in some cases, some very unusual results have been obtained. Thus, treatment of **1** with *o*-benzenediazonium carboxylate unexpectedly gives the bisphosphine $Ph_2PCH_2CH_2PPh_2$ in moderate yield while **2** reacts with *N*-nitrosoacetanilide in the presence of potassium acetate to give the expected ylide **40** in very low yield which has been trapped as its hydrolysis product. These reactions are under further investigation and will be reported fully in a later paper.

Experimental

The i.r. spectra were recorded in Nujol mulls using a Beckman IR12 spectrophotometer while n.m.r. measurements were made with a Varian Associates model A60-A spectrometer equipped with a V-6058A spin decoupler using deuteriochloroform or trifluoroacetic acid solutions with tetramethylsilane as internal reference. Signal averaging was carried out using a Varian Data Systems model 620i unit. Mass spectra were determined using an Hitachi–Perkin–Elmer model RMU-7 double focusing mass spectrometer fitted with a direct heated inlet system. Melting points are uncorrected and were recorded using a Mel-Temp high-temperature m.p. apparatus.

Ether was dried by distillation from sodium or lithium aluminum hydride while tetrahydrofuran and benzene were dried by distillation from calcium hydride. Dimethyl acetylenedicarboxylate was freshly distilled under reduced pressure (*ca.* 1 Torr) immediately before use.

3,4,5-Triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene (**4**) was prepared by the method of Hughes and Srivanavit (25).

Addition of Dimethyl Acetylenedicarboxylate to Diphenylvinylphosphine

Dimethyl acetylenedicarboxylate (8.0 g) in benzene (50 ml) was added dropwise with magnetic stirring to diphenylvinylphosphine (12.1 g) in benzene (300 ml) under nitrogen at room temperature. The solution was heated under reflux for a few minutes during which time it turned a dark blue and a tarry precipitate appeared. One or two drops of water were then added and the mixture was again heated under reflux for a few minutes. The mixture was then evaporated under reduced pressure to about 50 ml. Ether (*ca.* 300 ml) was added to the gummy mixture and this dissolved much of the blue material. Repeated washing with small portions (*ca.* 30 ml) of ether left the crude adduct as a greyish crystalline material (7.1 g, m.p. 119–123°). The crystalline material was recrystallized from ethanol to give colorless needles (4.8 g, 23%) of the 1:1:1 adduct **9**, m.p. 130–132°.

Anal. Calcd. for $C_{20}H_{21}O_5P$: C, 64.51; H, 5.64; P, 8.33. Found: C, 64.74; H, 5.81; P, 8.78.

The i.r. spectrum shows ν_{max} at 1749, 1722, 1664, 1450, 1444, 1342, 1310, 1223, 1193, 1130, 1105, 751, 732, and 708 cm^{-1}.

Addition of Dimethyl Acetylenedicarboxylate to Diphenylvinylphosphine in the Presence of D_2O

Ether (dried by distillation from $LiAlH_4$) was shaken with D_2O and again dried with $LiAlH_4$. Dimethyl acetylenedicarboxylate (1.34 g) in ether dried as above (50 ml) was added dropwise at room temperature to diphenylvinylphosphine (2.05 g) again in ether dried as above (50 ml) under nitrogen. When the addition was complete, D_2O (5 ml) was added to the reaction mixture which was then filtered to give a dark blue solid. This solid was recrystallized twice from benzene to give colorless needles of the deuterated adduct **10** (0.07 g), m.p. 132–133°.

Addition of Dimethyl Acetylenedicarboxylate to Diphenylvinylphosphine in the Presence of p-Nitrobenzaldehyde

Dimethyl acetylenedicarboxylate (3.53 g) in dry ether (80 ml, freshly distilled from $LiAlH_4$) was added dropwise over a period of 50 min to a mixture of diphenylvinylphosphine (5.0 g) and *p*-nitrobenzaldehyde (3.21 g) in dry ether (600 ml) under nitrogen at room temperature. The solution became dark green during the addition and was allowed to stand overnight in an atmosphere of dry nitrogen. The mixture was then filtered, the filtrate was evaporated to low bulk, and the mixture was chromatographed on neutral alumina using benzene followed by acetone as eluents. The acetone fractions were collected and evaporated to low bulk to give a crude sample of the adduct **14** (1.145 g, 10%), m.p. 190–194° (dec.). Further purification was effected by dissolution of the solid in chloroform followed by reprecipitation with ether. The pure adduct **14** was obtained as fine yellow crystals, m.p. 194–199° (dec.).

Anal. Calcd. for $C_{27}H_{24}O_7NP$: C, 64.16; H, 4.79; N, 2.77; P, 6.13. Found: C, 63.69; H, 4.98; N, 2.98; P, 6.14.

The i.r. spectrum shows ν_{max} at 1745, 1692, 1630, 1600, 1515, 1440, 1345, 1275, 1249, 1159, 1110, 1020, 991, 731, and 700 cm^{-1}.

Addition of Diphenylvinylphosphine to Dimethyl Acetylenedicarboxylate

Diphenylvinylphosphine (8.8 g) in ether (50 ml) was added dropwise with stirring to freshly distilled dimethyl acetylenedicarboxylate (12.4 g) in ether (1500 ml) at room temperature under nitrogen. After the addition was complete, the dark colored mixture was filtered and the crude adduct **23** obtained as a greyish precipitate (2.3 g, 11%). This product was recrystallized from hot benzene to give the pure adduct **23** as colorless granular crystals, m.p. 198–201°.

Anal. Calcd. for $C_{26}H_{27}O_9P$: C, 60.70; H, 5.29; P, 6.02. Found: C, 60.70; H, 5.29; P, 6.63.

The i.r. spectrum (in $CHCl_3$) shows ν_{max} at 1738 (very broad), 1649, 1605, 1439, 1277, 1220 (very broad), and 1180 (shoulder) cm^{-1}.

Deuterolysis of the 1:2 adduct **22** was carried out as described for the 1:1 adduct to give **24**, m.p. 206–213°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The Reaction of trans-1,2-Bis(diphenylphosphino)ethylene (2) with Dimethyl Acetylenedicarboxylate

The *trans*-phosphine (2.4 g) was dissolved in dry benzene (25 ml) and cooled to about 10 °C. To this solution was added dry pentane (35 ml) slowly with constant stirring until the solution became slightly turbid. At this stage a few drops of benzene were added to remove the turbidity.

A mixture of dimethyl acetylenedicarboxylate (0.852 g) and benzene (10 ml) was then added slowly, under a stream of dry nitrogen with constant stirring to the *trans*-phosphine solution while keeping the temperature of the reaction mixture around 8°. When the addition was complete, a light yellow precipitate (2.10 g, 69%) of a 1:1 adduct was obtained. This was filtered under nitrogen and washed several times with dry benzene followed by pentane. The precipitate was then pumped under reduced pressure (*ca.* 2 Torr) and at 55° for several hours.

Recrystallization of the adduct could not be achieved because of its high sensitivity towards water and air.

Anal. Calcd. for $C_{32}H_{28}O_4P_2$: C, 71.4; H, 5.2; P, 11.5. Found: C, 71.1; H, 5.4; P, 11.2.

The compound decomposed over a wide temperature range on heating.

The i.r. spectrum shows ν_{max} at 1712 (normal unsaturated ester C=O stretching), 1601 (stretching of the C=O group adjacent to a carbanionic center), 1445 (P—Ph), 1350, 1240, 1170, 1130, 1120, 1104, 1060, 950, 860, 820, 810, 765, 758, 750, 740, 720, 704, 700, and 670 cm^{-1}.

Hydrolysis and Deuterolysis of the 1:1 Adduct of trans-1,2-Bis(diphenylphosphino)ethylene and Dimethyl Acetylenedicarboxylate

The 1:1 adduct (1.85 g), obtained in the above experiment, was dissolved in aqueous ethanol (30 ml, 1:1 mixture) and heated under reflux for 24 h. A white precipitate was obtained which was filtered and washed with a little benzene followed by pentane. The product was then pumped under reduced pressure (*ca.* 1 Torr) and at 60°. The crude oxide **9** (0.80 g, m.p. 132°) was obtained in 63% yield. The crude product was further recrystallized from benzene and obtained as fine cotton-like crystals.

Anal. Calcd. for $C_{20}H_{21}O_5P$: C, 64.5; H, 5.6; P, 8.3. Found: C, 64.9; H, 5.8; P, 8.8.

Deuterolysis was carried out as above except that pure D_2O was used as the deuterolyzing agent. The oxide **35** (m.p. 136°) was obtained in 70% yield. The i.r. spectrum was almost identical to that of the hydrolysis product **9**.

The ^1H n.m.r. was also found to be very similar to that of **9** except that the aliphatic protons had almost vanished from the spectrum while the mass spectrum shows a molecular ion peak at *m/e* 376 (with a small peak at *m/e* 375) which confirms that mainly tetradeuteration occurred.

The Reaction of cis-1,2-Bis(diphenylphosphino)ethylene (3) with Dimethyl Acetylenedicarboxylate

cis-1,2-Bis(diphenylphosphino)ethylene (**3**) (4.75 g) was dissolved in benzene (500 ml) and to this was added dropwise a solution of dimethyl acetylenedicarboxylate (1.744 g) in benzene (100 ml) under a dry nitrogen stream with constant stirring while maintaining the temperature of the reaction flask around 8°.

After the addition was over, a buff precipitate was formed which was filtered, washed with benzene, and then pumped under reduced pressure (*ca.* 1 Torr) at 50° for 4 h. The dry ylide **37** was obtained as a buff powder (4.76 g, 73%).

The ylide **37** is highly water sensitive and it was therefore not possible to recrystallize it since it hydrolyzed rapidly even in quite rigorously dried solvents. Furthermore, the ylide has no definite m.p. and decomposes slowly above 140°.

Anal. Calcd. for $C_{32}H_{28}O_4P_2$: C, 71.4; H, 5.2; P, 11.5. Found: C, 69.5; H, 5.4; P, 11.1.

The i.r. spectrum shows ν_{max} at 1640, 1600 (ylidic C=O stretching), 1440 (P—Ph), 1340, 1310, 1260, 1160, 1120, 740, 710, 695, and 670 cm^{-1}.

Hydrolysis of Dimethyl 1,1,4,4-Tetraphenyl-1,4-diphosphorin-2,3-dicarboxylate (37)

The ylide **37** (200 mg) was mixed with an excess of 1:1 aqueous ethanol and stirred for 5 h at room temperature. During this time, the dark brown solution became almost colorless. The solution was allowed to stand at room temperature for 2 days and a white precipitate slowly settled down. This was filtered, washed with acetone, and pumped under reduced pressure (*ca.* 1 Torr) to give the dioxide of **3** (110 mg, 68%). The dioxide was further recrystallized from a 1:1 mixture of ethanol and acetone to give colorless crystals, m.p. 244° (lit. (26) m.p. 244–245°).

The i.r. spectrum shows ν_{max} at 1440 (P—Ph) 1230, 1200, 1185, 1175, 1120, 1100, 1030, 1000, 930, 780, 765, 750, 730, 710, 700, and 670 cm^{-1}.

The mass spectrum shows the molecular ion peak at *m/e* 428.

Preparation of the Bisperchlorate of Dimethyl 1,1,4,4-Tetraphenyl-1,4-diphosphorin-2,3-dicarboxylate (37)

To the solid ylide **37** (200 mg) was added, with constant stirring and under a nitrogen stream, perchloric acid (1 ml, 74%) dropwise at room temperature. After about 10 min the solid mass, initially buff, became colorless. The mixture was stirred for another 30 min and then methanol (3 ml) was added. The mixture was warmed briefly to dissolve the solid and the solution then left for crystallization. After 2 days, fine white crystals appeared and these were filtered, washed with a little methanol, then with pentane and finally with ether. The crystals were pumped under reduced pressure (*ca.* 1 Torr) at 50° to remove residual solvent from the bisperchlorate which was obtained in 28% yield (76 mg). The salt decomposed slowly above 200°.

Anal. Calcd. for $C_{32}H_{30}Cl_2O_{12}P_2$: C, 52.0; H, 4.1; Cl, 9.7; P, 8.4. Found: C, 51.3; H, 4.0; Cl, 10.0; P, 8.0.
